There is an accessory pathway between atria and ventricles. If the impulse travels through AV node from atria to ventricles and go to atria from ventricles through accessory pathway (orthodromic conduction) the QRS complex is narrow and the tachycardia would be NCT. But if antegrade conduction is through accessory pathway and retrograde through AV node (antidromic conduction) tachycardia would be WCT. The activation of ventricle and atria take place one after another so RP interval is long and p wave is seen on ST-T wave. Orthodromic AVRT responds to vagal maneuvers and AV nodal blocking agents. But these drugs are harmful in antidromic AVRT. In such cases amiodarone is preferred drug. It is rare for a patient to become unstable with SVT but if this happens so DC shock with 25–50 J is sufficient.

Atrial Flutter

Saw tooth flutter waves are best seen in II, III, AVF at the rate of 300 bpm (250–350 bpm) with 2:1 block in the setting of structural heart disease in most of the patients. Sometimes 4:1 block is also seen. Rarely atrial flutter with 1:1 AV conduction may occur in high catecholamine states as sepsis, shock, and with the use of flecainide in the presence of fast conducting accessory pathway and becomes an emergency requiring urgent cardioversion. 50J is sufficient with the success rate of above 90%. AV nodal blocking agents and digoxin (especially in heart failure) can control ventricular rate. Flecainide is good for its prevention but should be used in combination of AV nodal blocking agent. Anticoagulant is started if atrial flutter is of more than 48 hours. Atrial flutter should always be thought if ventricular rate is 150 bpm and regular.

NCT with Irregular Rhythm

Irregular NCT is seen in AF, MAT, and sinus tachycardia with frequent atrial premature beats.

Atrial Fibrillation (Fig. 1)

The chaotic atrial activities with the rates ranging 400–600 bpm are seen as coarse or fine fibrillatory waves

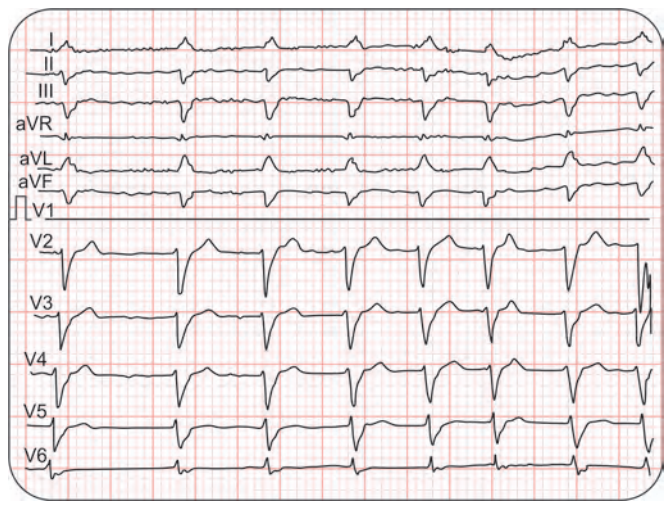

Fig. 1: Atrial fibrillation

without discernible p waves on surface ECG. It is very common in ICU. Advancing age, valvular heart diseases, thyrotoxicosis, large left atrium, sleep apnea, and chronic kidney disease are some of the important predisposing factors for AF. It is pertinent to identify and treat the cause. Management has three aspects:

- Rhythm control,
- Rate control, and
- Anticoagulation.

Urgent cardioversion is done if patient is hypotensive, there is ongoing ischemia, acute pulmonary edema, or underlying preexcitation with rapid ventricular rate. Synchronized shock of 200J is appropriate. Repeated shocks may be needed with increased energy up to 400J as success rate of cardioversion is less than 30% in ICU. If DC shock fails 300 mg amiodarone iv in 1 hour may be given and repeated as needed.

If onset of AF is within 48 hours, cardioversion is a common practice even if patient is not on anticoagulant, at risk of stroke and there is no mitral stenosis or large left atrium.

If duration of AF is not known or more than 48 hours, patient is anticoagulated for 3 weeks before cardioversion and for 4 weeks after cardioversion. The other approach is to rule out thrombus by transesophageal echocardiography start anticoagulation cardiovert the patient and continue anticoagulation for 4 weeks. In stable patient pharmacological cardioversion can be done by ibutilide, flecainide, and amiodarone.

Rate control can be achieved by AV nodal blocking agents IV diltiazem at a rate 5–15 mg/hr maintains the ventricular rate below 100 bpm in 90% cases during 24 hours infusion. Digoxin is seldom used as it takes longer time to slow the rate.

If AF persists for more than 48 hours iv heparin should be started but one should keep in mind that chances of bleeding increases with anticoagulants in sepsis without any benefit.

Wolf-Parkinson-White (WPW) Syndrome

WPW syndrome is triad of short PR interval, slurring of QRS (delta wave) and broadened QRS. Orthodromic conduction will produce NCT while antidromic conduction produces WCT. AF is very common in WPW and is life threatening as it causes rapid ventricular rate usually more than 200 bpm. QRS has a changing morphology in width and height unlike AF with fixed BBB where ventricular rate is not that fast and QRS morphology is always the same. It is the accessory path that propagates the impulses from atria to ventricles. Use of AV nodal blocking agents will be dangerous in this situation. Ibutilide, flecainide, and amiodarone are safe drugs in this condition. For unstable patient DC shock of 150–200 J is required.

Multifocal Atrial Tachycardia (MAT)

Three or more non-sinus consecutive p waves of different contours beating at a rate 100 or more per minute constitute multifocal atrial tachycardia. The P-P & P-R intervals are variable and ventricular rate is irregular. At times it is difficult to differentiate it from AF. In more than 50% cases of MAT the underlying cause is chronic obstructive lung disease. Coronary artery disease and valvular heart disease are frequently present along with chronic obstructive lung disease. Other precipitating factors may be low potassium and magnesium. Treatment should be directed toward underlying cause. DC shock is ineffective due to multiple atrial foci. AV nodal blocking agents are used to control the ventricular rate. Empirically magnesium is used with high success rate. $MgSO_4$ + 50 ccNS (2 gm) iv in 15 minutes is given followed by 6 gm $MgSO_4$ + 500 ccNS iv in 6 hours.

Wide Complex Tachycardia

When QRS duration is more than 0.12 second it is called wide complex. About 85% of wide complex tachycardia (WCT) are due to VT. About 10% are due to supraventricular tachycardia with aberrancy (SVT-A). The aberrancy could be fixed bundle branch block, functional or rate dependent block, or accessory pathway. The other causes of WCT could be pacemaker induced tachycardia where rate will never go beyond the upper limit fixed for the pacemaker, artifact where rate is very very fast but patient is hemodynamically stable and QRS complex march with regularity. Hyperkalemia where QRS is very very wide but rate is not so fast usually below 120 bpm and drugs like tricyclic antidepressants, CLASS IA and IC antiarrhythmic drugs may cause WCT.

Ventricular Tachycardia (Fig. 2)

When there are three or more consecutive ventricular premature complexes present at a rate more than 100/min it is called ventricular tachycardia (VT) and if it persists for 30 or more seconds it is termed sustained.

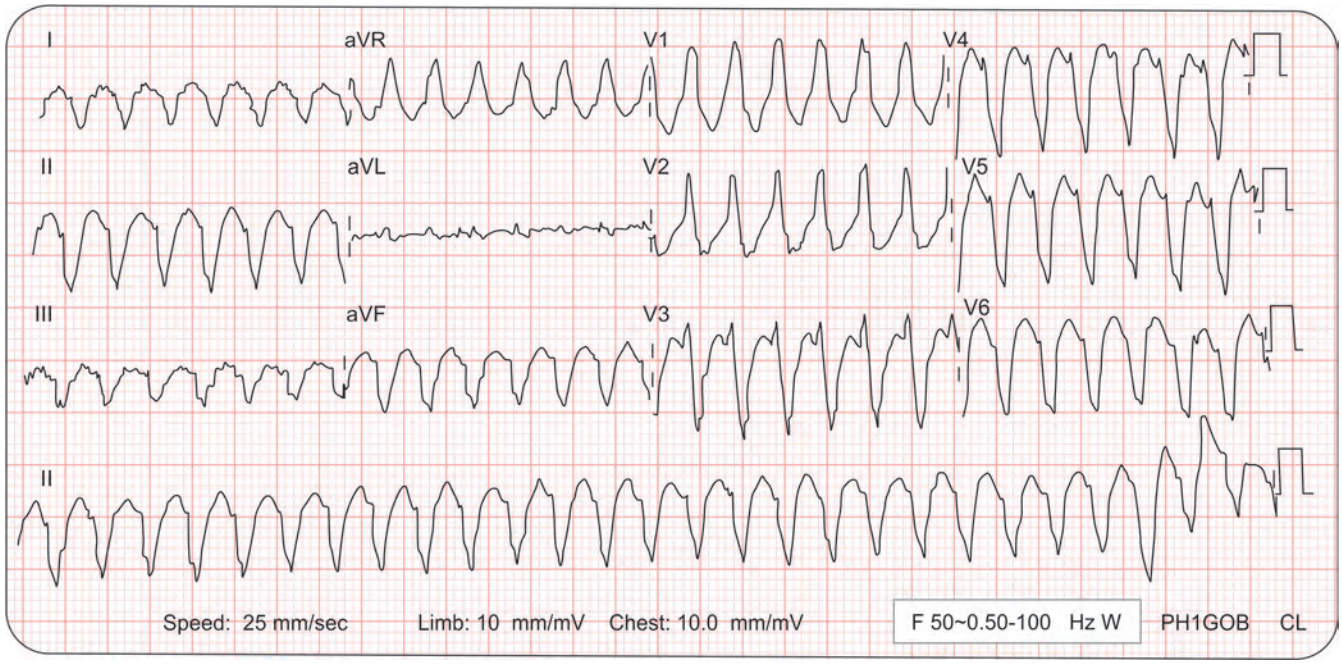

Fig. 2: Ventricular tachycardia

VT could be monomorphic where morphology of all ventricular complexes are same and polymorphic where there is continuous change in morphology of ventricular complexes.

There are certain features though not always but if present suggest VT while differentiating it from SVT-A. They are:

- H/o heart disease or previous MI.
- QRS width >0.16 second.
- AV dissociation (ventricular rate more than atrial).
- Presence of capture and fusion beats.
- RBBB with left axis and LBBB with right axis, extreme north west axis.
- Presence of concordance.
- Presence of Brugarda's sign (onset of QRS to nadir of S is >100 msec) and Josephson's sign (notch in S wave).
- All precordial leads showing QS pattern.
- Presence of RBBB like morphology (dominant R wave in V1-2 & R/S<1 in V6).
- Presence of LBBB like morphology (initial R >0.04 second RS interval>0.07second in V1-2 & any Q in V6).

Monomorphic VT

This may occur in structurally normal or diseased heart. If it is non-sustained and heart is not diseased no treatment is needed. AV nodal blocking agents are used to prevent its recurrence. But patients who have structural heart disease (coronary heart disease, dilated cardiomyopathy, valvular heart disease) need further evaluation. Hemodynamically unstable patient with monomorphic sustained VT DC shock of100–200 J is given and increment may be done up to 360 J, followed by lidocaine 1–4 mg/min iv infusion. In stable patient either shock or drugs can be given. In patients with preserved LV function procainamide, amiodarone, lidocaine, and sotalol may be given but preferred drug is amiodarone. In patients with compromised LV amiodarone or lidocaine may be used.0.5–1 mg/kg lidocaine is given iv bolus followed by iv infusion at 1–4 mg/min lidocaine is more effective if VT is due to ischemia. One should never forget to correct hypokalemia and hypomagnesemia as they are precipitating factors. When VT is unstable, recurrent, and nonresponsive to cardioversion iv amiodarone may be given.

Polymorphic VT

Polymorphic VT may occur with normal or prolonged QT interval. PMVT with normal QT is mostly due to ischemia and almost always causes significant hemodynamic instability. Therefore, patient should be shocked.

Medication that predisposes to ischemia should be withdrawn. Electrolytes should be corrected. Beta-blockers may be used to prevent recurrence. PMVT with normal QT is treated in the same way as monomorphic VT.

The prolongation of QT (QTc >460 msec) may be:

- Congenital or
- Acquired due to drugs (antibiotics, antihistamines, antiarrhythmic drugs, antidepressants, etc.), electrolyte abnormalities (hypokalemia, hypocalcemia), etc.

Torsades De Pointes

It is a form of polymorphic VT with QT prolongation seen in 12 lead baselines ECG. There is beat to beat variation and appears to be twisting around the isoelectric line of ECG. This is treated with 1–2 gm of $MgSO_4$ iv over 15–20 minute iv atropine and isoproterenol or overdrive pacing are also used for acquired form as they increase the heart rate and thus shorten the QT interval. Correction of electrolytes and removal of offending factor is a key to treatment. Congenital QTc prolongation is adrenergic mediated; hence beta-blockers are used.

Pulseless VT/Ventricular Fibrillation

Most of defibrillators in use these days are biphasic. Along with CPR and vasopressor (epinephrine) asynchronous shock of 120–200 J is given. Energy of shock is increased in stepwise manner.

Antiarrhythmic Drugs Commonly Used in ICU

- Adenosine 6 mg iv fast followed by rapid saline flush if no response repeat 12 mg iv fast.
- Esmolo 500 mcg/kg iv bolus then infusion at 50 mcg/kg/min. If needed increment of dose 25 mcg/kg/mim every 5 minute maximum up to 200 mcg/kg/min.
- Diltiazem 0.25 mg/kg iv in 2 minutes bolus if needed second bolus dose after 15 minutes at 0.35 mg/kg and maintain the infusion at 5–15 mg/min.
- Metoprolol 2.5–5 mg iv in 2 minutes. If needed may be repeated every 5–10 minutes up to three doses.
- Amiodarone 150 mg iv bolus over 10 minutes. Repeat if needed, then 1 mg/min for 6 hours followed by 0.5 mg/min for 18 hours. Total dose in 24 hours should not exceed 2.2 gm.
- Lidocaine 0.5–1 mg/kg bolus instant followed by 1–4 mg/min.
- $MgSO_4$ 1–2 gm iv in 20 minutes. A continuous infusion at the rate of 2–4 mg/min may also be administered after bolus, if needed.

DC Shock and Pacing

A critically ill patient has many precipitants of tachyarrhythmia such as infection, high catecholamine state, involvement of multiorgan so response to shock is a challenge. Moreover, critically ill patient does not tolerate shock well. Taking care of precipitants is necessary to get a successful response of shock. Serial DC shocks are not appropriate for self limiting recurrent tachyarrhythmias.

Overdrive pacing is done by pacing the heart at higher rate than its native rate. It is done to treat SVT, atrial flutter, VT, who have either failed to response or recurrent. Rhythm of sinus tachycardia, AF, and VF cannot be controlled by this.

Conclusion

Although some patients are admitted in ICU because of tachyarrhythmias majority develop them in ICU because of multiple illness and treatment. The adverse effect of tachyarrhythmia is well established and treating them in ICU is difficult also. So a very judicious approach is needed to address this problem.

POCUS in Medical ICU

Ayush Bansal, Jai Bhagwan, Himanshu Sikri

Abstract

Point-of-care ultrasound (POCUS) is a useful imaging modality in the era of modern evidence-based medicine. This article will summarize the historical development, basic physics, advantages of POCUS, and its applications in the medical intensive care unit (ICU). Based on improved accuracy and reduced time in narrowing diagnosis, it positively influences patient outcomes. Structured training programs with hands-on practice can equip the doctors acquire the necessary knowledge and skill in the field of POCUS.

Introduction

Point-of-care ultrasound (POCUS) literally refers to the point-of-care ultrasound, which is usually performed by non-radiologists in close proximity of the patient. The scope and goals are limited to specific clinical questions, which help in narrowing the diagnosis and guiding clinical therapy. It is an extremely useful imaging modality particularly for the critically ill patients. The advantages of POCUS of being quick, accurate, reproducible, radiation free, and available bedside for serial monitoring make it stand-out from other imaging modalities. In the western world, POCUS has become an integral part of the emergency medicine department and critical care. Moreover, Royal College of Emergency Medicine has made POCUS a mandatory part of the curriculum of emergency medicine training.[1] Though the use of ultrasound by emergency medicine physician and by an intensivist requires the same instrument and skill, still there are important differences in their application. POCUS is primarily used by an intensivist in the medical ICU for focusing on heart, lung, pleura, procedural guidance, and for vascular access. The intensivist does serial examinations to monitor the response to treatment, which aids in patient's management. On the other hand, the emergency medicine physician does a single extended evaluation of the whole body including heart, lungs, abdomen, testes, obstetrics, musculoskeletal, and eyes for making a provisional diagnosis.[2]

Advantage of POCUS over Routine Ultrasound

POCUS in ICU is performed by the intensivist bedside who has full knowledge of the patient's issues and there is rapid implementation of these results to patient's management. There is no time lag in decision-making, provided the intensivist has the appropriate skill at image acquisition and interpretation. On the other hand, routine ultrasound is done by a radiologist or a cardiologist who are not in constant touch with the patient and there is always a time lag due to logistic issues. Moreover, serial monitoring of the patient is difficult with routine ultrasound.[2]

History

The use of POCUS is not new and can be traced back to 1990s when the first paper supporting the use of POCUS

was published by The American College of Emergency Medicine.[3] It was followed by a series of publications highlighting POCUS to be one of the important tools in dealing critically ill patients. The use of ultrasound for central venous access was made compulsory by the National Institute for Clinical Excellence in 2002.[4] Today, there are many fellowship programs in POCUS giving training to the intensivists. In 2016, the Society for Acute Medicine published the first POCUS curriculum for the physicians in the United Kingdom.[5] Though there is no national certification course for POCUS in India, there is still a lot of potential in increasing the use of this modality. Further, the residents have an easy access of doing bedside POCUS with the advent of small portable ultrasound machines. We, therefore, need to overcome the inertia of using POCUS routinely for patient management.

Basic Physics

A clear mental picture of the three-dimensional anatomy and basic understanding of the physics of ultrasound are the prerequisites for optimal image acquisition and interpretation. The ultrasound transducers send ultrasound waves (1–15 MHz) through their piezoelectric crystals and receive reflected waves. A two-dimensional image is formed on the screen which can be optimized by using the correct transducer and adjusting its position. Higher frequency transducers produce high resolution images of superficial structures, while lower frequency transducers produce low resolution images of deeper structures. There are basically three types of transducers used in POCUS—linear, curvilinear, and phased array **(Table 1)**.

Denser media reflect most of the sonographic waves, generating a white image. On the other hand, rarer media transmit most of the waves and reflect back very few waves, generating an echogenic black image. Thus, fluid appears black, soft tissue (liver) appears gray, fibrous tissue appears white without a shadow, and bones or stones appear white with a shadow **(Figs. 1A and B)**. Air is very hyperechoic and thus prevents visualization of deeper structures.[7]

Components of POCUS

POCUS usually involves evaluation of the heart, lung, pleura, lower limb Doppler, screening abdomen and for venous access. Still, the most important aspect in medical ICU is the cardiorespiratory evaluation to identify the cause of dyspnea or hypoxia.

Heart

A quick goal directed echocardiography is the hallmark tool for evaluation of the cause of shock or acute onset dyspnea. A combination of basic two-dimensional echocardiography combined with color flow mapping and Doppler imaging of the heart and great vessels gives a basic idea of the structure and function of the heart. All the views including parasternal long and short axis views, apical views, and subcostal views must be imaged wherever possible, for addressing specific abnormalities. The intensivist can promptly look for an immediately life threatening cause of hemodynamic collapse like major valve failure, massive pulmonary embolism, cardiac tamponade, acute cor pulmonale, or regional wall motion abnormality, which needs prompt treatment. With the addition of speckle tracking, one is able to negate the subjective error in assessing regional wall motion abnormality. Serial monitoring of inferior vena cava and its collapsibility by the subcostal view helps in assessment of the fluid status of the patient.

Thoracic Ultrasonography (Lung and Pleura)

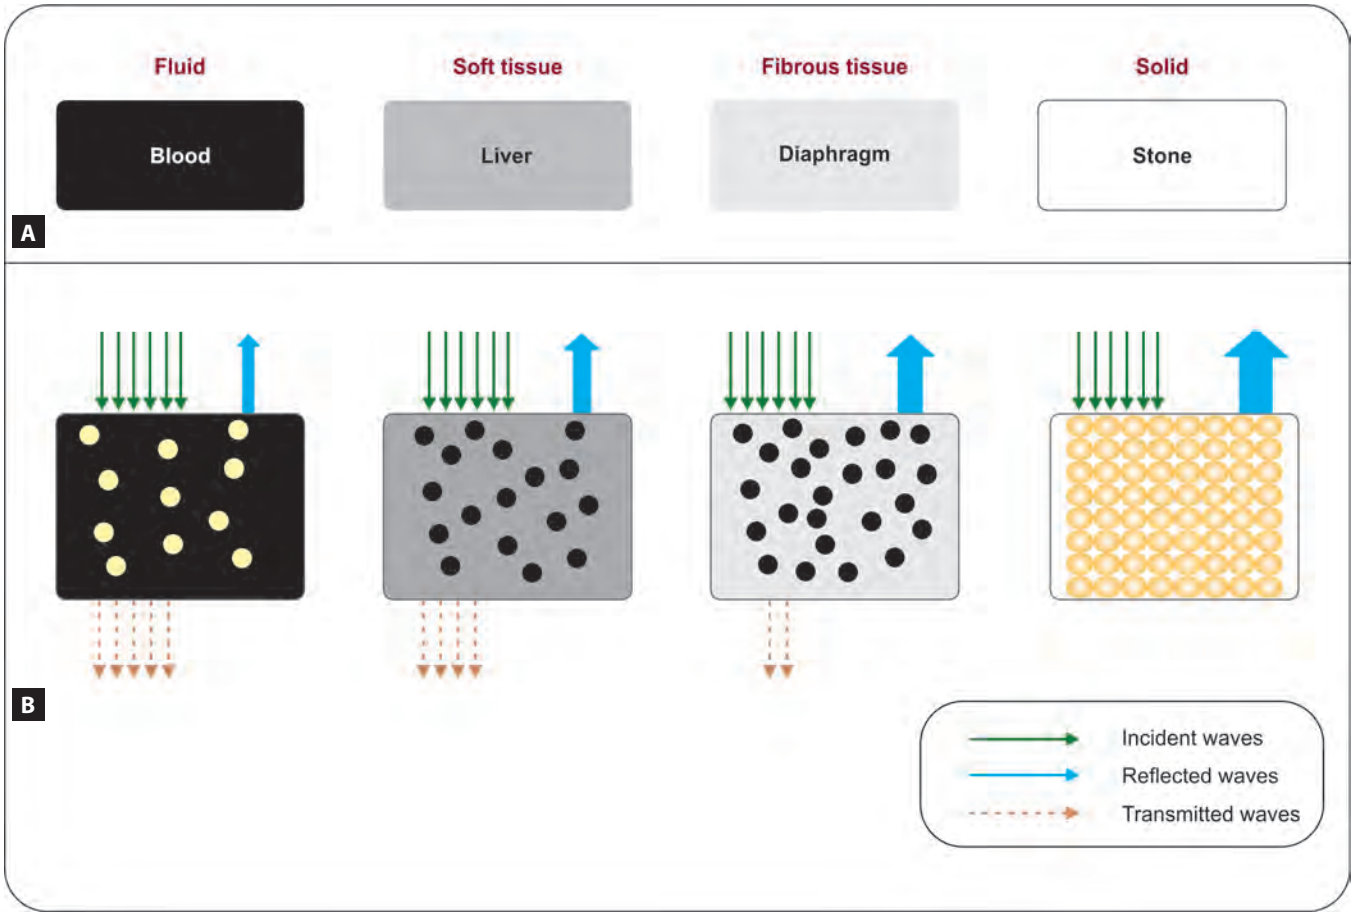
Evaluation of the cause of dyspnea can never be complete without having a look at the lungs and pleura. It is not uncommon to miss the diagnosis of a small posteriorly located consolidation in an obese patient on clinical examination.[8] Even chest X-ray in a critically ill ventilated patient does not give accurate information as there can be motion artifacts, rotation, coexisting fluid overload, and the views are usually anteroposterior.[9] However, ultrasound has a similar accuracy as compared to computed tomography and can appreciate pathologies like consolidation, pleural effusion, pneumothorax, diaphragmatic dysfunction, and one should spend time to look at both sides of the chest. Thoracic ultrasound has a sensitivity and specificity of more than 90% for diagnosing these pathologies.[10]

Some of the important findings in a thoracic POCUS are:

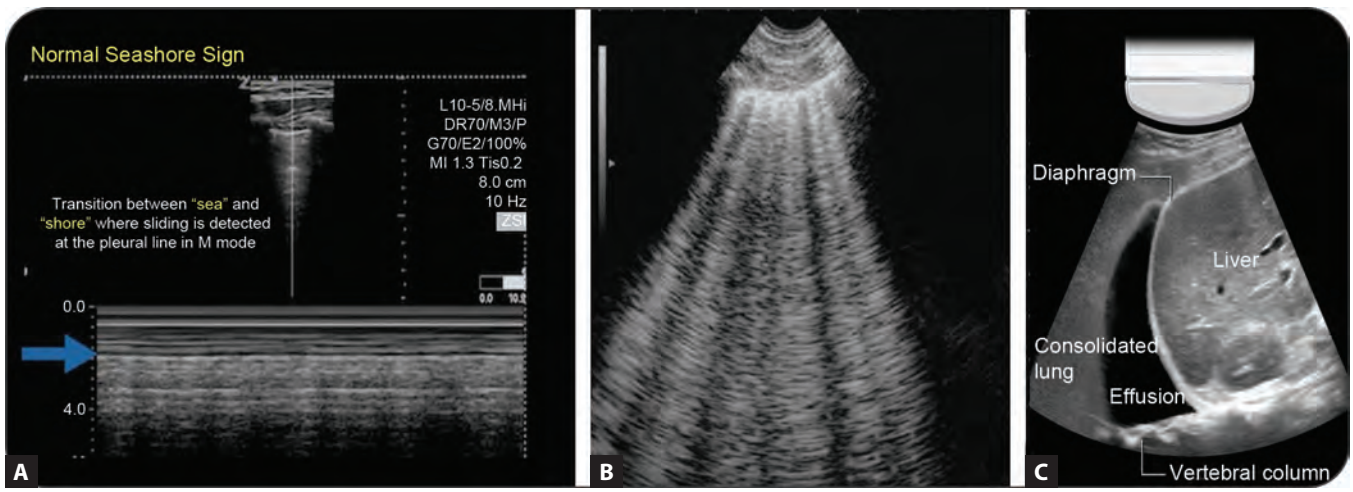
- *Seashore sign* **(Fig. 2A)** refers to the normal aeration pattern, which consists of lung sliding with A-lines.

TABLE 1 Types of transducers used in POCUS[6]

Transducer type	**Linear**	**Curvilinear (convex)**	**Phased array**
			
Frequency range (MHz)	5–10	2–5	1–5
Imaging depth (cm)	9	30	35
Applications	• Arteries/veins • Eyes • Skin/soft tissue • Pleura • Procedures – central venous catheterization, lumbar puncture	Abdominal viscera like • Liver • Gall bladder • Kidney • Urinary bladder	• Heart • Inferior vena cava • Great vessels • Pleura • Lungs



Figs. 1A and B: (A) Appearance of fluid, soft tissue, fibrous tissue, and solids on ultrasound screen. (B) Propagation of ultrasound waves through various media



Figs. 2A to C: (A) Seashore sign demonstrating lung sliding with A-lines in M-mode ultrasound. (B) Two-dimensional image of vertically oriented B-lines or lung rockets in a thoracic ultrasound. (C) Two-dimensional image showing a clear pleural effusion with lung consolidation (echogenicity similar to that of liver)

Lung sliding refers to the opposition of visceral and parietal pleura. Absence of lung sliding indicates presence of air or fluid between the visceral and parietal pleura. A-lines constitute the horizontal, hyperechoic reverberation artifacts created by repetitive reflection of ultrasound waves between the pleural line and transducer.

- *B-lines or lung rockets* **(Fig. 2B)** are the vertically oriented discrete hyperechoic lines, which extend to the sonographic window edge. They represent widened fluid-filled interlobular septa and indicate pulmonary edema, pneumonia, acute lung injury, or fibrosis, depending upon their distribution and characteristics.
- Consolidations appear with an echogenicity similar to that of liver, and thus called hepatization. Infective consolidations need to be differentiated from basal lung atelectasis **(Fig. 2C)**.
- *Pleural effusion* as small as 5 mL can be picked up.[11] Anechoic, clear fluid indicates transudate while hyperechoic, debris-filled fluid indicates exudate. Also, pleural effusion can be differentiated from pleural thickening.[12]

Abdomen

The importance of abdominal assessment cannot be undermined especially in cases of acute abdomen. Appreciation of intra-abdominal fluid, any septic foci, bladder distension, hydronephrosis can be done by the intensivist rapidly without waiting for the radiologist. Free fluid is most commonly detected in the perisplenic space and in the Morrison's pouch in the supine position.[13] Ultrasound can be used therapeutically in cases of drainage of abscesses.

Lower Limbs

Patients in ICU remain bed-ridden for prolonged periods and require regular screening of their lower limb veins. Early identification of deep vein thrombosis and subsequent prevention of pulmonary embolism is one of the important aspects in managing complications of such patients.

Ocular Ultrasound

The most important aspect of ocular ultrasound in medical ICU is to assess the intracranial pressure by the measurement of optic nerve sheath diameter. A cut-off value of 5 mm has 100% sensitivity of raised intracranial pressure which is comparable to a non-contrast CT.[14] Serial monitoring of optic nerve sheath diameter helps in optimizing therapy. Pathologies such as globe rupture, traumatic detachments, lens dislocation, and vitreous hemorrhage can also be easily picked up but these are uncommon issues encountered in medical ICU.

Ultrasound for Procedural Guidance

A variety of procedures can be performed in the ICU for routine management of patients for both diagnostic and therapeutic purposes. Ultrasound greatly increases the success rate and reduces the complication rate in cases of thoracocentesis, paracentesis, abscess drainage, regional anesthesia, lumbar puncture, and central venous catheter insertion.[15] Upper extremity deep vein thrombosis secondary to central venous catheters can also be readily picked up.

Miscellaneous

Several other uses of POCUS include looking for ectopic pregnancy, testicular torsion, epididymo-orchitis, tendon injury, etc., but these are uncommon issues encountered in the medical ICU.

Conclusion

The enthusiasm and interest in using POCUS is rising across the globe owing to its speed and accuracy in diagnosis, in an acutely unwell patient. It acts as an aide to the traditional clinical and radiological techniques in reducing the morbidity and mortality of the patients. However, there is still a huge gap in expanding the utility of this modality due to lack of training programs and trained supervisors. Therefore, this rapid and reliable diagnostic tool should be included in routine medical curriculum to make it an integral part of the patient care.

CHAPTER

99 Disease-specific Ventilation—Strategies and Evidences

RT Shriram Ganesh, S Tamilselvan, Rengarajan, Namasivayam, Sowmiya, Mukesh, Pragadeesh G

Abstract

- Normal respiration is NEGATIVE **(Table 1)** Pressure, and Ventilator driven is POSITIVE Pressure Ventilation.
- Disease-specific ventilation strategies and evidences is done in respiratory failure as evidenced by clinical symptomatology and ABG.
- Whatever mode selected, the treating physician should maintain SYNCHRONY between the ventilator and the patient. Then the mode NIV or Invasive and finally to TROUBLE SHOOT. based on the specific diseases and the ventilator alarms.

Introduction

- The topic disease specific ventilation deals in brief about the basic steps in ventilation and then disease-specific strategies in patients presenting with respiratory failure
- This could be achieved by mechanical ventilation (MV)
- There is wide variety of MV available for use in modern pulmonary care[1]
- The principles in MV are:
  - Disease-specific ventilation strategies
  - Lung protection strategy by applying safe ventilation practices

Respiratory Failure: Four Types

- The respiratory system helps to maintain adequate oxygenation.[2]
- Respiratory failure results in either inadequate oxygenation or CO_2 removal [3]or both.
- It's one of the most common medical emergencies that warrant ICU admission.[4]

TABLE 1 Negative and positive pressure ventilation

Normal respiration/negative pressure ventilation[30]	*Ventilator generated/positive pressure ventilation*
Inspiration done by respiratory muscles by sucking of air into the lungs, increasing the negative intrapleural pressure (-6 to -8 cm H_2O)	According to disease status, ventilator generates pressure in the airways to drive air into the lungs, pushing the chest wall outward

Type 1/Hypoxemic Respiratory Failure (Table 2):[5]
- Most common type
- PaO_2 <60 mm Hg **(Table 3)**
- $PaCO_2$ <45 mm Hg
- Patient presents as tachypneic, hypoxic, and hypocapnic

Type 2/Hypercapneic Respiratory Failure:[5]
- Seen in airway diseases (COPD), neuromuscular diseases, and chest wall abnormalities
- Patient presents with low-respiratory rate, hypoxia, hypercapnia, and acidotic[6]

TABLE 2 Causes of RF (respiratory failure)[9]

Acute	*Chronic*
Type 1: Acute pulmonary edema Pneumonia ARDS Pneumothorax Pulmonary embolism	**Type 1:** ILD-sarcoidosis Idiopathic pulmonary fibrosis Pulmonary artery hypertension Chronic heart failure Cyanotic congenital heart disease
Type 2: Acute exacerbation of COPD GBS Myasthenia gravis Poisoning head injury/raised ICP	**Type 2:** COPD Obesity hypoventilation syndrome Neuromuscular disorders Kyphoscoliosis Ruptured esophagus
Type 3: Upper abdominal emergencies Obesity/ascites Prolonged GA Peri-operative Smoking	**Type 4:** Cardiogenic shock Septic shock Hypovolemic shock

TABLE 3 Respiratory parameters[9]

	Normal people	*Respiratory failure*
PaO_2 (Kpa)	10.5–13.5	<7
$PaCO_2$ (Kpa)	4.7–6	>7
RR (/min)	10–25	>30
Tidal volume (mL/kg)	5–8	<3
Vital capacity (mL/kg)	30–70	<15

Type 3/Perioperative Respiratory Failure:[7] Due to atelectasis following GA

Type 4/Shock Related Respiratory Failure: Due to hypoperfusion[7]

- **Presentation of RF**

  Acute Respiratory Failure:[8]
  - Develops before compensation

  Chronic Respiratory Failure:[8]
  - Compensated to buffer respiratory acidosis

Diagnosis

Always by clinical, supported by ABG, PFT, pulse oximetry, CXR, ECHO.

Clinical Features

- **Type 1:**
  - *Mild to moderate:* Hypoxia, tachypnea, tachycardia, diaphoresis
  - *Severe hypoxia:* Bradycardia, vasodilation, hypotension, infarction, arrhythmia, cardiac failure
- **Type 2:**
- **CNS disturbances:**[10] Depression, lethargy, headache, seizure
- **ABG:**[11] To confirm and differentiate the types of RF
- **Pulse oximetry:**[10] Assessing 02 status
- **CXR and ECHO:** To differentiate between cardiogenic and noncardiogenic pulmonary edema

Treatment

- To correct arterial hypoxemia and to maintain target SpO_2 >89–90%[11] and PO_2 >55–60 mm Hg
- It is done by:
  - Oxygen supplementation[12] usually **HFNO/NIV/Invasive ventilation**

  HFNO:[13]
  - Supplies as much as 40 L/min to maintain constant O_2 flow

  NIV:
  - Nowadays useful in acute respiratory failure as an initial tool especially in COPD exacerbation,[14] weaning after extubation[15] in COPD, in immunosuppressed[17] patients in ARF, cardiogenic pulmonary edema[16]
  - NIV[18] avoids the need for intubation, nosocomial infection
  - A successful NIV depends upon properly fit interface & optimal ventilator settings
  - Full face masks[19] for ARF, nasal mask for COPD
  - Noninvasive ventilation[20] within 1–4 hours of MV, the response is observed and assessed for failed NIV trial
  - In acute severe asthma,[21] if NIV fails, requires endotracheal intubation
  - Finally NIV is beneficial in COPD and cardiogenic pulmonary edema
- *Noninvasive positive pressure ventilation:* Used in COPD, ARDS, cardiogenic pulmonary edema
- *Noninvasive negative pressure ventilation:* Used in neuromuscular disease, central hypoventilation and chest wall abnormality

TABLE 4 Parameters and goals of invasive[25] MV in different respiratory diseases

Prototype	*Restricted lung-ARDS*	*Obstructed lung-asthma*	*Neuromuscular diseases*
Mode	V-ACMV	V-ACMV	V-ACMV
VT [per KG]	4–6 mL/kg	4–6 mL/kg	6–8 mL/kg
RR [per minute]	18–35	8–12	14–18
PEEP	High PEEP based on FiO_2	5–8 cm H_2O	Up to 5 cm H_2O
I:E ratio	1:1 or 1:2	1:3–1:6	1:2–1:3
Plateau pressure	<30 cmh 20	<30 cm H_2O	
PaO_2	55–60 mm Hg	55–60 mm Hg	60–80 mm Hg
PH	7.2–7.4	7.2–7.4	-

Other uses of NIV:

- NIV weaning or postextubation
- *Facilitation technique:* For early extubation
- *Rescue or curative technique:* For avoiding reintubation who fails extubation

Invasive Mechanical Ventilation

- **Done in failed 02 therapy and NIV trial[22] and for airway protection:**
  - **Always start with a volume ACM[9] (Table 4)** (assist control mode of ventilation), then if the patient improves, shift to Pressure Support Ventilation[23] **(PSV)**
- To avoid ventilator induced lung injury (VILI), a low-tidal volume and high PEEP is always set to reduce mortality in ARDS—ARDS NETWORK STUDY[24]

Mechanical Ventilation[26] (Basics and Modes)

Mainly indicated in:

- **Depressed respiratory drive:** Sedatives, stroke, head injury
- **Excessive respiratory workload:** ALI, ARDS, pulmonary embolism
- **Ventilatory pump failure:** Flail chest, tension pneumothorax

Four Phases of Breath[28]

- **Inspiration**
- **Change from inspiration to expiration**
- **Expiration**
- **Change from expiration to inspiration:**
  - **Triggering of a breath:**
    - It describes the phase variables that changes from expiration to inspiration
    - Trigger is what initiates a breath

Time triggered—inspiration begins when a certain time has lapsed

Pressure triggered—ventilator senses the inspiratory effort reflected by drop in airway pressure and initiates inspiration

Volume triggered—when the baseline flow variable drops below the fixed flow (5–20 L/min), the machine initiates inspiration:

- **Limiting a breath**:
  - It's the set flow in pressure beyond which the variable never goes in inspiration or expiration.
- **Cycling of a breath:**

Time cycled ventilation—common cycling mechanism. Inspiratory flow is terminated once the preselected time interval has lapsed after the start of inspiration and expiratory phase is started.

Pressure cycled ventilation—useful in SIMV/IRV modes. When a preselected air pressure has been reached, expiratory valve opens and ends the inspiration.

Volume cycled ventilation-with pressure limiting valve—When a preset volume is delivered, inspiration is terminated, delivers constant VT.

Flow cycled ventilation—Here a preset flow ends the inspiratory flow useful in PSV.

Patient Ventilator Interactions

A patient interacts[31] with the ventilator based on the ventilatory drive, when inspiration starts and ventilator

requirement, to satisfy metabolic demands whereas **the ventilator interacts with the patient** based on the inspiratory trigger, delivery of gas, and cycling **(Fig. 1)**.

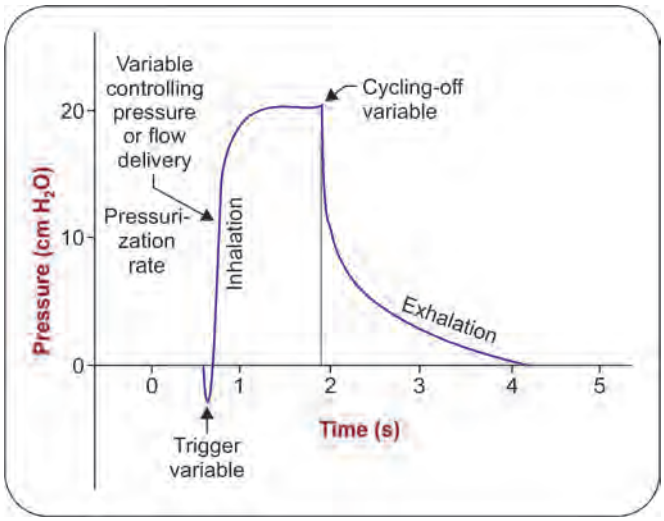

Fig. 1: Graphical representation of breath[29]

- **CMV:**
  - Patient cannot trigger the ventilator, but PCV always ensures Pplat <30–35 cm H_2O—used as a lung protective strategy in ARDS.[32]
- **ASSIST CONTROL MODE (ACM) (Fig. 2):**[33]
  - **Commonly used**. It delivers controlled breath as well as assists patient triggered breath **(Fig. 3)**; hence the patient continues to do inspiratory work even on ventilator.[34]
- **SIMV:**
  - Ideal mode for weaning providing partial ventilatory support.
- **PSV:**[23]
  - Allows breathing, providing full support making the patient fully comfortable used for weaning. **Ultimately, SIMV and PS—an ideal choice of ventilatory support facilitating quick weaning as well**.

No mode is superior one over the other. The initial settings:—FiO_2 0.5–1, tidal volume—8–12 mL/kg, RR—8–12/min, inspiratory flow rate of 40–60 L/min.

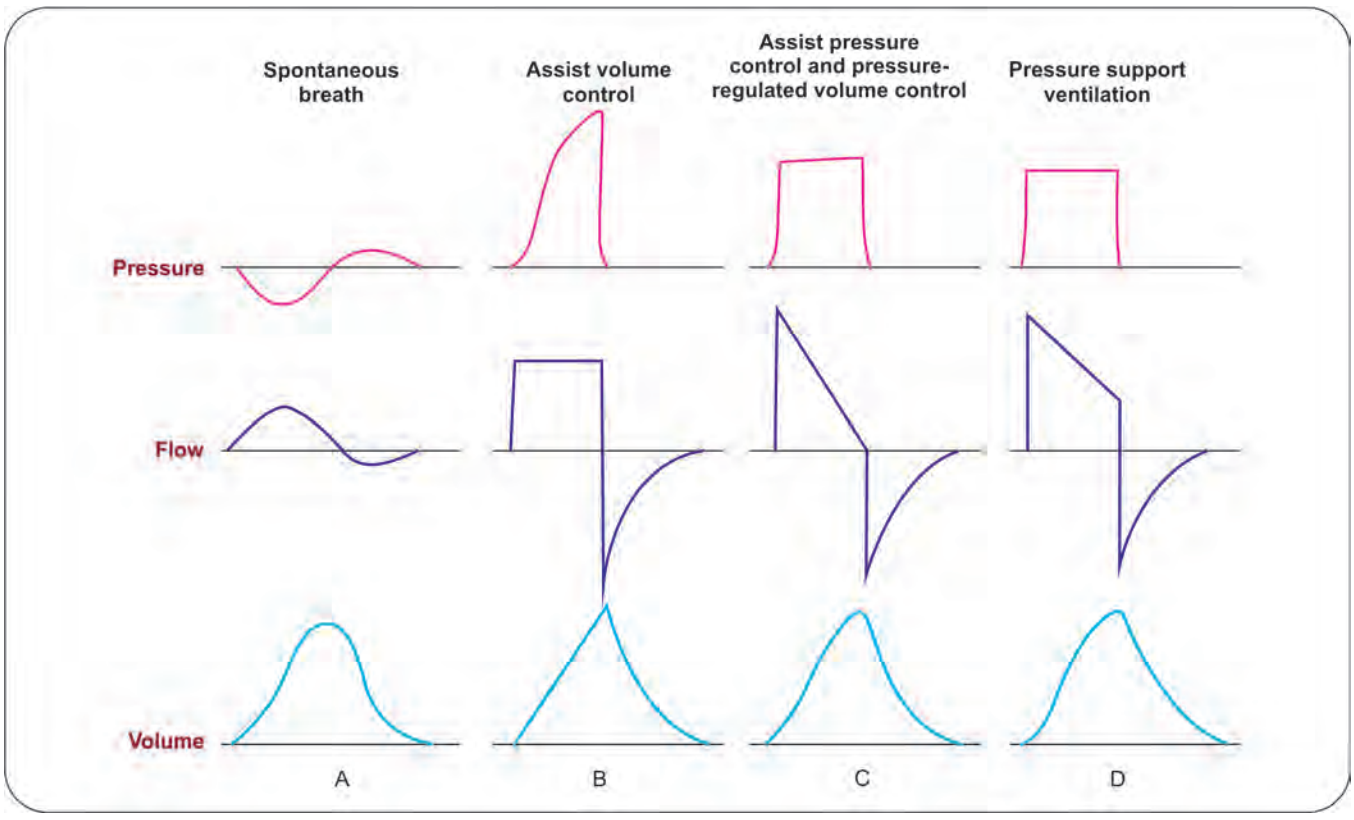

Fig. 2: Basics of mechanical ventilation[27]

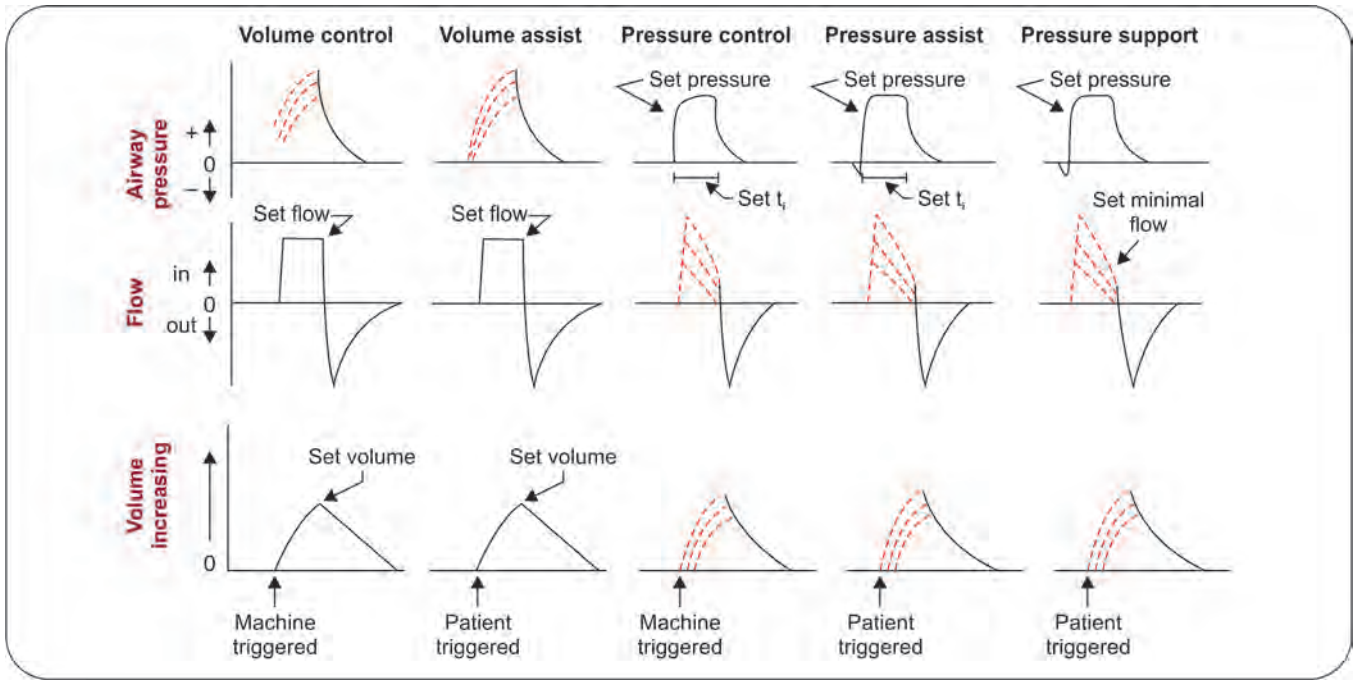

Fig. 3: Machine and patient triggering graph

Management of Patients with Severe Airflow Obstruction

- **Acute Severe Asthma**[35]
  AC mode or SIMV mode—settings:
  - Small VT: 5–7 mL/kg
  - RR: 12–15/min
  - Peak flow: 60 L/min
  - FiO_2: 0.5[35]
  - To prevent Barotrauma auto PEEP should be <10 cm H_2O
- **COPD**[36]
  SIMV or AC mode—settings:
  - VT: 5–7 mL/kg
  - RR: 24–28/min
  - FiO_2: 0.4
  - They have expiratory flow limitation, and hence auto PEEP,[36] which is balanced by setting extrinsic PEEP, which reduces patient's work of triggering

ARDS—Advances in Diagnosis and Treatment

- Berlin definition of ARDS[37]

  Based on the severity of hypoxemia:
  - **Mild:** 200–300 mm Hg with PEEP >5 cm H_2O
  - **Moderate:** 100–200 mm Hg with PEEP >5 cm H_2O
  - **Severe:** <100 mm Hg with PEEP >5 cm H_2O
- (Berlin definition has greater predictive validity for mortality)
- Timing of onset of symptoms: within 1 week of clinical insult.
- Chest X ray: bilateral opacities.
- Origin of edema: not fully explained by heart failure.

Early spontaneous breathing[38] **in mild and late ARDS**—by ACM, PSV, or APRV similar to PCM pressure control mode.

Advantages of spontaneous breathing (Fig. 4):
- to reduce ventilation induced diaphragmatic dysfunction (VIDD)[38]
- to improve tidal ventilation, O_2 exchange, delivery

THE STRATEGY OF VENTILATION IS:
- **Minimal distension strategy**—low VT <6 mL/kg[39]
- **Increased recruitment strategy**—open lung approach—high PEEP >10 cm H_2O[40]
- **Goal of plateau pressure** <30 cm H_2O to avoid shunt and improve oxygenation

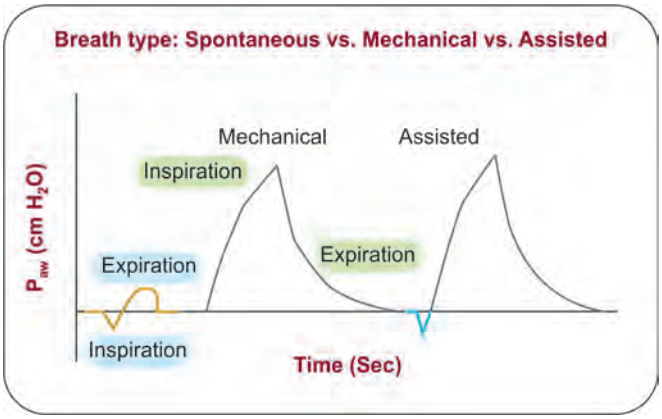

Fig. 4: Breath types graph

- This lung protective strategy ends with permissive hypercapnia[41] (treated with a higher respiratory rate of 24–28 breaths/min) and benefited by decreased mortality.[42]

Prone Positioning in ARDS

Earlier and prolonged prone positioning[42] for more than 16 hours in severe ARDS improved 28 day, 90 day mortality.

Other therapies:

- Inhaled Nitric Oxide—used in refractory ARDS
- Surfactant recombinant protein C
- Steroids[43]—methyl prednisolone 1–2 mg/kg in early severe ARDS
- ECMO[44]—useful in severe refractory ARDS

In any settings

Manipulations to Increase Oxygenation

Increase:

- FiO_2
- PEEP
- Ti

Settings to Improve Ventilation

Increase:

- RR <35/min
- VT up to 10 mL/kg
- PIP (peak inspiratory pressure)

Complications of mechanical ventilation:

- Always whatever mode is set, see to that LPS is adapted—low VT is set even in normal and diseased lungs to avoid VILI[25]

Trouble Shooting

Clinically

- **Breath stacking/dyssynchrony:**
  - Increase inspiratory flow rate
  - Sedation
- **Hypotension:**
  - Minimize PEEP/sedation
- **Altered sensorium:**
  - Especially in NIV adjust IPAP, EPAP, and increase backup RR

Based on ABG

- **Low PaO_2:**
  - Adjust flow rate or FiO_2
  - Increase:
    - EPAP/PEEP
    - Ti
- **High $PaCO_2$:**
  - Increase:
    - IPAP/PS
    - Backup RR
- **Low $PaCO_2$:**
  - Decrease:
  - IPAP
  - Backup RR

CARDS—COVID-19 with ARDS

- Management of COVID-19—Respiratory distress—Vasocenteric problem
- CARDS 2 types:
  - L-CARDS [low lung elastance—high compliance]
  - H-CARDS [high lung elastance—low compliance] [Typical ARDS lung]

Ventilatory Strategies for CARDS[45]

- **L-CARDS [mild cases]**
  Before intubation:
  NIV:
  - HFNO
  - CPAP
  - BIPAP
  - Awake prone positioning

After intubation:
  - Lower PEEP [<10 cm H_2O]
  - Liberal VT [7–9 mL/kg]
  - Prone positioning
- **H-CARDS**
  - Treated as typical ARDS lung, requiring invasive ventilation:
    - Higher PEEP [<15 cm H_2O]
    - Lower VT [5–7 mL/kg]
    - Prone positioning

Abbreviations

ACM, Assist Controlled Mode
ALI, Acute Lung Injury
ARDS, Acute Respiratory Distress Syndrome
CARDS, COVID-19 with ARDS Patients
HFNO, High Flow Nasal Cannula Oxygenation
IRV, Inverse Ratio Ventilation
MV, Mechanical Ventilation
NIV, Noninvasive Ventilation
PEEP, Positive End Expiratory Pressure
PIP, Peak Inspiratory Pressure
RF, Respiratory Failure
SIMV, Synchronized Intermittent Mandatory Ventilation
VCM, Volume Control Mode
VT, Tidal Volume

Conclusion

Ultimately one should know the basics of MV and then to decide NIV/INVASIVE VENTILATION according to specific diseases like COPD, ALI/ARDS, CCF, etc. and also see to that you always follow LPS (lung protective strategy) in ventilation.

CHAPTER

100 Prone Ventilation for Adults with ARDS

A Bhagwati

Abstract

Prone ventilation for adult respiratory distress syndrome (ARDS) patients is a resurrected concept, initially proposed in 1970s and widely used in 1990s for treatment of ARDS. However, it was not popular due to some studies and meta analysis. But the practice was reintroduced in 2015 Sepsis guidelines and currently is very popular particularly in patients with lung involvement due to COVID-19. The principle is to recruit the posterior lungs which are affected to improve oxygenation and FiO_2/PaO_2 ratio. This article briefly introduces the concept of prone position ventilation and also highlights the problems that are associated with it.

Introduction

Adult respiratory distress syndrome (ARDS) is a condition in which the lungs suffer severe widespread injury, interfering with their ability for gas exchange. Increasing pulmonary edema and alveolar collapse create a physiologic dead space, where no gas exchange can take place in the pulmonary capillaries, causing ventilation-perfusion mismatch. ARDS is a life-threatening respiratory condition characterized by hypoxemia, and stiff lungs ventilation. ARDS represents a stereotypic response to many different inciting insults and evolves through a number of different phases: Exudative phase, Fibrotic phase, and Proliferative phase. ARDS is a syndrome with multiple risk factors that trigger the acute onset of respiratory insufficiency and respiratory failure.

Causes of ARDS

Direct Lung Injury

- Aspiration of gastric contents or other causes of chemical pneumonitis
- Lung contusion, penetrating injury of the thorax affecting the lung tissues, fat emboli
- Near drowning
- Inhalation injury, pulmonary vasculitis
- Pulmonary edema due to repercussion due to transplant of lungs.

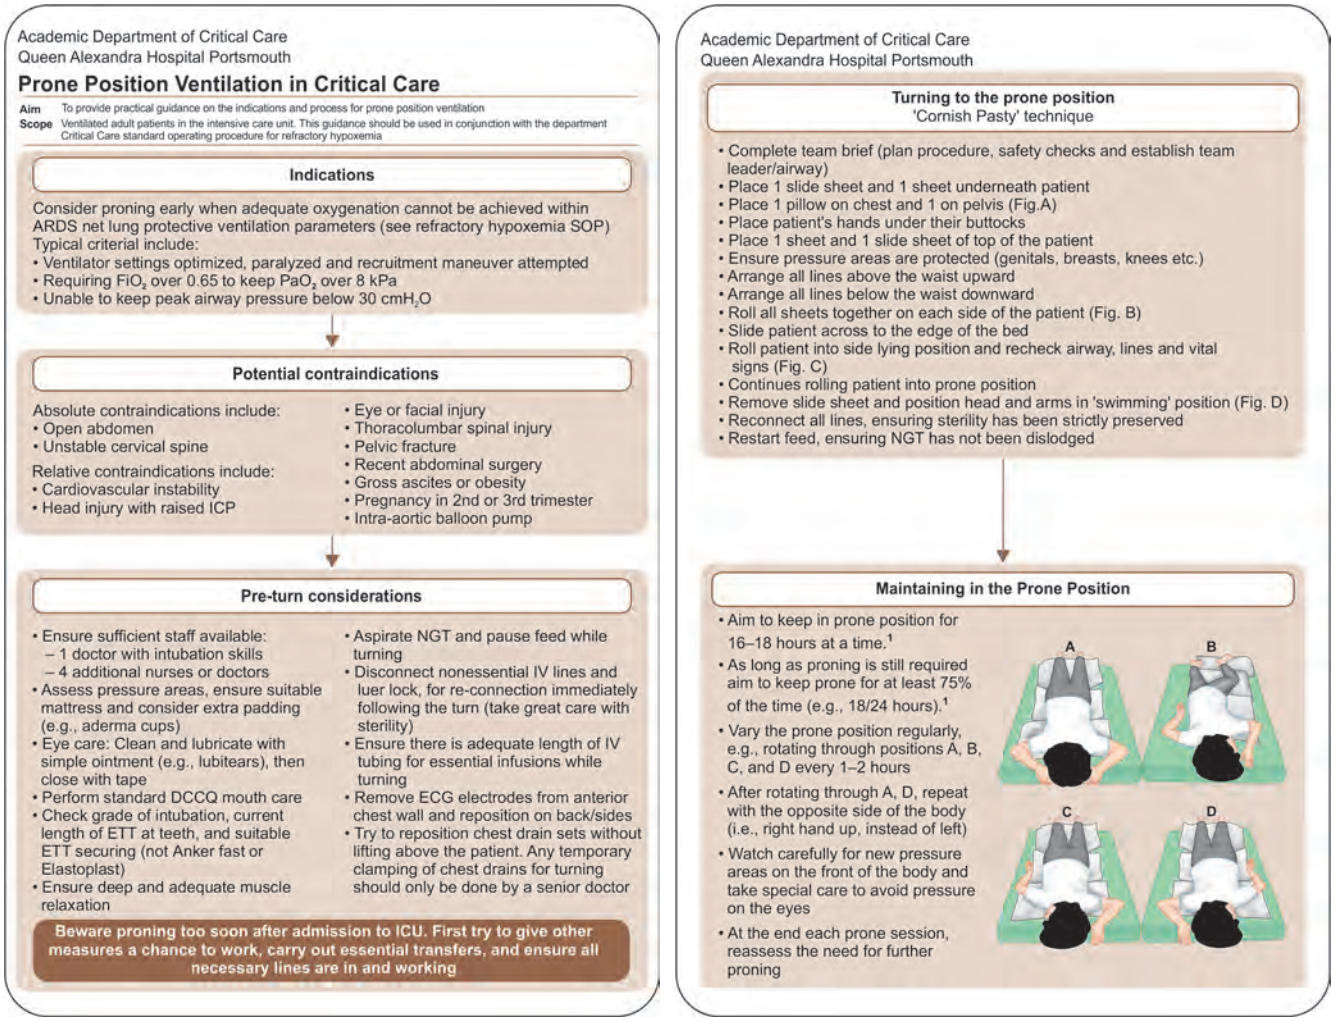
Indirect Lung Injury

- Sepsis
- Pancreatitis
- Shock with hypoperfusion
- Multiple blood transfusions (TRALI)
- Major trauma
- Burns, drug overdose
- Non-cardiogenic pulmonary edema.

Management of ARDS (Prone Ventilation)

In the intensive care unit (ICU), different types of patients requiring mechanical ventilation (MV) are admitted. It is challenging for a clinician when patient develops ARDS. Several strategies are employed, the currently

Flowchart 1: Strategies in prone ventilation



practiced and quite popular is prone positioning of a patient with ARDS on MV. Several studies and practical experience in recent times have shown improvement of oxygenation when a patient is placed in prone position. Prone ventilation was practiced in the 1995–1997 by me in Mumbai at Bhatia Hospital along with another center in Mumbai with excellent results. Unfortunately studies and meta-analysis did not evoke scientific justification for use of this protocol in MV, and fell out of use with other modalities.

However, in 2015, Surviving Sepsis guidelines revived the interest and recommended use of prone ventilation in ARDS as a part of recruitment maneuvers and thereafter it is now an accepted modality in management of ARDS patients, including finding its way in management of COVID pneumonia and COVID-induced ARDS.

Pathophysiology

In supine position, the positive pressure from the ventilator raises the anterior chest wall, but hardly has any effect on the posterior chest wall. When patient is placed in prone position, the posterior chest wall, which is less compliant, is elevated leading to more diaphragmatic excursion, which leads to increased recruitment of the posterior lung. This causes improved overall aeration of the alveoli of the posterior lungs thereby improving the lung compliance. This causes improvement of ventilation-perfusion ratio, which is compromised in ARDS patients.

Prone Position Protocol

Best Practice in Implementing Prone Position for Patients with ARDS

- Take written consent for prone ventilation, explaining to relatives in details advantages and risks involved.
- Assess the hemodynamic status and oxygenation to determine the eligibility of the patient.
- Administer sedation and muscle paralytic drugs, with sedation holiday.
- Provide care of eyes and tape eyelids, if indicated.
- Maintain adequate oral hygiene. Secure the patients tongue with oral airway to prevent tongue bite. Oral suction as and when required.
- Secure endotracheal tube and monitor to ensure that extubation or ventilatory disconnection does not occur.
- Maintain proper skin care and place hydrocolloid dressings on bony prominence, chin, and forehead.
- Position the patient's face away from the ventilator to prevent tube kinking. Reposition the patient's head hourly to prevent skin breakdown.
- Place ECG electrodes on the patient's posterior chest.
- Empty the drainage bags.
- Appoint dedicated inter-professional team to take care (airways/ventilator tubing/line) of patient in prone position.
- Monitor effectively the hemodynamic status, blood gases within 1 hour of pruning the patient and then 4 hourly intervals.

Contraindications

- Burns, open wounds on face or ventral body surface
- Spinal instability
- Facial and pelvic fractures
- Life-threatening circulatory shock
- Increased intracranial pressure
- Pregnancy
- Abdominal trauma or surgery
- Acute bleeding
- Shock

Complications

- Facial and periorbital edema
- Pressure sores
- Accidental loss or displacement of ET, thoracic or abdominal drains, and central venous catheters
- Airway obstruction
- Hypotension
- Arrhythmias
- Vomiting

Summary of Strategies in Prone Ventilation

See **Flowchart 1**.

Conclusion

Prone positioning was first proposed in the 1970s as a method to improve gas exchange in ARDS. However, translation of this application in clinical practice is challenging as discussed. Prone position ventilation has been effective in management of moderate to severe ARDS patients, begun early in the course of the disease within 36 hours of the onset, for a period ranging 12–18 hours per session. However, prone positioning is not without harm and problems as discussed earlier.

CHAPTER

101 Respiratory Emergencies: Golden Hour Rules in the First Hour

T Geetha, Ramesh Duraisamy

Abstract

Respiratory Emergencies are most common and sometimes life threatening. The Spectrum may range from Mild Respiratory Distress to Respiratory Arrest. The "Golden Hour" management is crucial to save the life. We divide the topic in to Immediate, Emergent, and Urgent management with time frame. "Every Breath is like a little rebirth" as quoted by Cristen Rodgers. So, the Emergency Team should act promptly using clues from the Brief History, Quick Physical Examination with Essential Investigations.

Introduction

"A-B-C" is the unofficial mantra of any emergency care, which describes airway, breathing, and circulation. The first two letters in this mantra relate to the patient's respiratory status. Compromise of the airway and respiration is the leading cause of death in many conditions in emergency setting. Respiratory emergencies are potentially life-threatening conditions that require immediate attention to avoid delay in treatment.

Spectrum of Respiratory Emergencies

In emergency department (ED), the patients with respiratory emergencies present with a spectrum,[1] that can range from mild respiratory distress to respiratory failure and finally respiratory arrest, which leads to death **(Fig. 1)**. Respiratory emergencies are generally identified by "Acute dyspnea" as a presentation. Dyspnea can result from respiratory, cardiac, neurological, traumatic causes, etc. **(Table 1)**.

Management of Respiratory Emergencies

For effective management of respiratory emergencies, we must have the following basic principles:[4]

- Rapid assessment of respiratory distress to arrive at the correct working diagnosis.
- With the working diagnosis, aggressive targeted treatment without delay.
- Continuous and frequent reassessment to ensure response to the appropriate treatment.

With the above principles, we can divide the Golden Hour management of respiratory emergencies into the following three parts:[5]

- Immediate management—to be done in 0–5 minutes **(Table 2)**
- Emergency management—to be done in 5–15 minutes **(Table 3)**
- Urgent management—to be done in 15–60 minutes **(Table 4)**

Indications of Noninvasive Positive Pressure Ventilation[6]

The following clinical and laboratory clues give an idea for indication of noninvasive positive pressure ventilation (NIPPV) in respiratory emergencies:

- Respiratory distress (dyspnea, tachypnea, and the use of accessory muscles of respiration)
- Acidemia (pH <7.35)

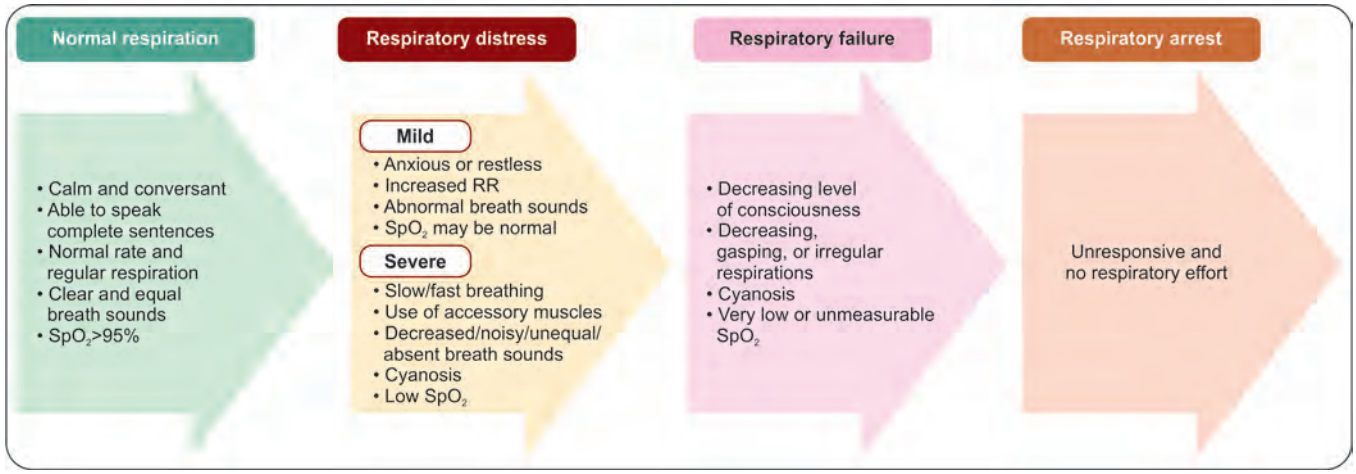

Fig. 1: Spectrum of respiratory emergencies

TABLE 1 Common causes of respiratory emergencies[2]

Respiratory:

Upper airway obstruction[3]

- Croup
- Supraglottitis
- Epiglottitis
- Neck abscess
- Ludwig's angina
- Angioedema
- Subglottic stenosis
- Tumor
- Foreign body

Other:

- A/E Asthma & COPD
- Obstructive Sleep Apnoea
- Tracheomalacia
- Tension Pneumothorax
- Trauma causing Hemothorax
- Acute Pneumonitis (Bacterial/Viral)
- Hypersensitivity pneumonitis
- Drug induced
- Pulmonary embolism

Cardiac:

- Pulmonary edema
- Arrhythmias
- Cardiac tamponade

Neurological:

- Guillain-Barré syndrome
- Myasthenia gravis
- Snake bite envenomation

Metabolic:

- Diabetic Keto Acidosis

Psychogenic:

- Anxiety
  - Panic attacks

Others:

- Anaphylaxis causing Angioedema
- SVC obstruction
- OPC poisoning

- Hypercapnia ($PaCO_2$ >45 mm Hg)
- Hypoxemia (PaO_2/FiO_2 <200)

Most frequently used types of NIPPV are CPAP and BiPAP:

- CPAP—in acute pulmonary edema, CCF, pneumonia, acute respiratory distress syndrome (ARDS), and chest wall trauma.
- BiPAP—in COPD with type 2 respiratory failure, neuromuscular disease, and sleep apnea.

Indications for Converting Noninvasive Ventilation to Invasive Ventilation[7]

- Inability to tolerate NIV
- Excessive secretions

TABLE 2 Immediate management (0–5 min)[5]

History	*Examination*	*Investigation*	*Intervention*
AMPLE H/o: (Allergies, Medications, Past H/o, Pregnancy, Last meal, Events before the presentation) **Also ask for:** • Lip/tongue/throat /Neck swelling • Stridor/Grunting • Voice change • Trauma • Chest pain • Emesis	• Ability to speak, aspiration, oropharyngeal edema, trauma • Breath sounds, Hypoxia, posturing/work of breathing/ tracheal shift • Check for shock (BP, extremities, weak pulse, sweating, tachycardia) • Disorientation/ Delirium, signs of trauma ***Look for red flag signs* (Box 1)**	• SpO_2 • Capillary glucose	**General Measures:** • Pt Positioning • IV-line placement • Airway repositioning—Jaw thirst, chin lift • Suction • O_2/bag ventilation • Urinary catheterization **Specific Measurements:** • Choking maneuvers • Airway in case of altered mental status • NIPPV—for conscious pt with Pulmonary edema, OSA, COPD. • Needle decompression for pneumothorax • Nebulized Salbutamol—for severe asthma • Adrenaline—for anaphylaxis • Call for help

TABLE 3 Emergency management (5–15 min)[5]

History	*Examination*	*Investigation*	*Intervention*
• Onset/progression • Similar episodes/Asthma/ COPD • Fever/cough • Chest pain • Unilateral leg swelling • Renal/Cardiac disease • Allergy H/O	• **Vital signs** • **Focused Respiratory Exam** ***Look:*** • Pt posture • Diaphoresis, cyanosis, pallor, ability to complete a sentence, single breath count, neck veins ***Listen:*** • Breath sounds/Wheeze/crepts • Heart sounds/murmur/rub ***Feel:*** • Pulses, pedal oedema, peripheries • Trauma • Red flag signs	• ECG • Urine Acetone • USG—for effusions, pneumothorax • ABG/VBG	**General Measures +** **Specific Measures:** • Intubation/NIPPV • Chest tube—for Pneumo/ hemothorax • Pericardiocentesis—for tamponade • Salbutamol/adrenaline—As per indication • Fluid challenge for hypotension • Antibiotics for infection • Atropine for OPC poisoning • ASV—for snake bite • Diuretics for pulmonary edema/CCF • NTG—for accelerated Hypertension/Pulmonary edema • Call for help

- Ill fitting mask/leak due to facial abnormalities
- Progressive fatigue or impending respiratory arrest
- Hypoxia despite adequate positive airway pressure and high FiO_2
- Progressive and persistent hypercapnia (>1 hour)
- High airway pressure requirement (>20 cm H_2O)

Drugs Commonly Used in Respiratory Emergencies

- Nebulized Salbutamol—Severe asthma
- Adrenaline—Anaphylaxis/Asthma (Nebulization)
- Steroids—Asthma/COPD/COVID-19 pneumonia

TABLE 4 Urgent management (15–60 min)[5]

History	*Examination*	*Investigation*	*Intervention*
• Detailed H/o including past H/o, Family H/o • CCF: orthopnea, PND, leg swelling • H/o asthma/COPD—medication H/o, past ICU admissions for the same • Cardiac ailments/ HT/Diabetes/ Dyslipidemia, etc. • Chest pain: Anginal/pleuritic • DVT: Leg pain and swelling, H/o immobilization • HIV/TB status • Smoking H/ o	• Vital Signs • Complete Systemic examination • Repeat clinical examination if there are abnormal findings in lab investigations	• CBC • RFT, Electrolytes • Ketones • RBC • ECG • Chest X-ray • HIV • Echo • Cardiac enzymes • CT Chest • D Dimer • ABG/VBG	**General Measures +** **Specific interventions:** Depending upon on the diagnosis arrived: • Needle thoracentesis in cases of pleural effusion • Steroids/NTG/Salbutamol/ Bronchodilators/Inotropes depending on the condition • NIV/Intubation: for Neuromuscular/ envenomation • Call for help

BOX 1 'Red flag signs" of acute dyspnea[2]

- Altered mental status
- Shallow breathing
- Tachypnea (RR >40/min)
- Hypotension
- Hypoxia
- Cyanosis
- Stridor
- Tracheal deviation
- Absent breath sounds (Unilateral/Bilateral)
- Unstable arrhythmia

- Antibiotics—Infective exacerbations of COPD/asthma, Sepsis, Aspirations (Foreign body/Secretions), GBS, Trauma
- Diuretics—Pulmonary edema, CCF
- Nitroglycerin—Pulmonary edema
- Atropine—Organophosphorus poisoning
- Anti-snake venom—Cobra/Krait bite

Venous Blood Gases in ED

Arterial blood gas analysis is what is generally expected to be done in emergency setting. But venous blood gas (VBG) analysis is equally valuable, and has now become routine in the initial work up of cases presenting to the ED. There are many advantages of VBG analysis: arterial puncture which causes bleeding and pain can be avoided. VBG analysis can be done with the blood drawn for other lab analysis. VBG is easy to process by modern analyzers. A venous blood gives accurate measurement of glucose, K^+, lactate, HCO_3^-, hemoglobin, and COHb. In addition, a normal venous pCO_2 will exclude hypercarbia. Venous lactate level gives early diagnosis of sepsis. Treatment response can be established by serial VBG in terms of lactate and K^+.[8]

Ultrasonogram in Respiratory Emergencies[5]

- The Bedside Lung Ultrasonography in Emergency (BLUE) protocol plays a major role in ED to diagnose various causes of respiratory failure.
- Focused Assessment with Sonography in Trauma (FAST) to diagnose pneumothorax and hemothorax.
- Bilateral increased B-line density in pulmonary edema.
- Unilateral B-lines in pneumonia with edema, or foreign body with lung collapse.
- Cardiac USG: to r/o cardiac failure, pericardial effusion and tamponade.
- Right heart strain indicates pulmonary embolism.
- A normal lung USG may be seen in bronchospasm, pulmonary embolism, anemia, or acidosis.

Conclusion

Respiratory emergencies are very common in the ED and it is imperative that all the team members be prepared to stabilize patient's oxygenation and ventilation. Using clues from the history and quick physical examination, an emergency physician can guide the work up and intervene in the golden hour. Early use of bedside testing, including USG may limit unnecessary tests and save time in determining the best treatment course.

CHAPTER

102 Basics of Mechanical Ventilation—Must Know for All Physicians

Rudrajit Paul

Abstract

Mechanical Ventilation (MV) has come to the limelight over the last 1 year due to the Covid-19 pandemic. Ventilation has saved numerous lives all over the world. Clinicians have been forced to familiarize themselves with this technology. In India, the government has supplied ventilators to many health facilities as an emergency. After the pandemic subsides, these machines will remain and there will be a huge demand for their use in different diseases. Thus, this is a good time for internists to learn about the basics of mechanical ventilation. This article describes the basic functions of the ventilator. This is not meant to be an exhaustive text on the topic. Rather, this article is meant to be a ready reckoner for the busy clinician. Essential topics like FiO_2, I:E ratio, PEEP, and plateau pressure have been discussed. Some tips for tracheal intubation have also been touched upon. Towards the end, the overall ventilator strategies for common diseases like COPD, DPLD, and, of course, COVID-19 have been discussed. The importance of arterial blood gas report in a ventilated patient has also been discussed. The various output parameters in a modern ventilator have been mentioned. So, overall, this article is meant to help the clinician during a busy shift.

Introduction

The recent Covid-19 pandemic has proved the importance of mechanical ventilation (MV) for saving lives, and every physician in the future should have some basic knowledge of this technology. This article is meant not for intensivists but mainly for physicians working regularly with critical patients. The following pages are meant to help the young medicine resident who is alone in a Critical Care Unit (CCU) with a collapsing patient. The article is written in such a way that the pages can be scanned and kept in smartphone for ready reference.

What is Mechanical Ventilation?

MV is the process of delivering inspiratory breath with predetermined parameters like target volume, target time, and target oxygen concentration.[1] This has two types: invasive and noninvasive. Among noninvasive devices, the BiPAP device is very popular and can be tried initially in many cases. Recently, the hi-flow nasal cannula has also become very popular and can reduce the need of invasive ventilation.[2] However, to honor the word limit of this publication, the following discussion will be mostly on invasive ventilation.

Historical fact: The first negative pressure "tank" ventilator was described by Dr John Dalziel in 1838. The later polio epidemic led to rapid development in this technology.

Indications

When should one consider mechanical ventilation? The *following list* will give a rough guide to the most common indications.[1,3] But it must be remembered that the initiation of MV ultimately depends on the clinical judgment of the physician. If the physician thinks that the patient cannot maintain his/her oxygen levels or

cardiopulmonary stability, then MV may be started as benefit of doubt. It must be remembered that *MV shows the greatest advantage if used early*. So, it is better to err on the side of overzealous ventilation than to wait longer when the underlying pathology has already gone into a tailspin.

- **Acute or chronic respiratory failure**
  - Central respiratory depression
    - Poisoning
    - Stroke
    - Post-neurosurgery
  - Peripheral respiratory compromise
    - Guillain-Barré (GB) syndrome
    - Myasthenia
    - Severe myositis
    - High cervical myelopathy
  - Lung pathology
    - Parenchymal pathology
  - Severe pneumonia
  - Acute respiratory distress syndrome (ARDS)
  - Severe pulmonary edema
    - Airway pathology
  - Acute chronic obstructive pulmonary disease (COPD)/Asthma
  - Airway edema in toxic gas inhalation
    - Vascular pathology
  - Pulmonary embolism
- **Severe shock**
- **Prophylactic ventilation**
  - Patient with recurrent vomiting when pharyngeal reflexes are deemed inadequate
  - After poisoning, especially if patient is anticipated to deteriorate
  - Severe cerebral edema, if hyperventilation is planned in the future
  - Severe sepsis with hyperventilation, when respiratory muscle fatigue is anticipated
  - Recurrent refractory seizures, when aspiration is a possibility or where the use of anesthetic drug is planned

This list is not exhaustive and other pertinent indications may be there. A study in the USA found that COPD, heart failure, and pneumonia were the main indications for the use of MV.[4] Another international study found that in the intensive care, acute respiratory failure was the commonest indication of MV, followed by acute chronic COPD and coma.[5] Acute respiratory failure can occur in a variety of indications from opiate poisoning to head injury.

Some Notes on Intubation

Endotracheal intubation is one skill which every physician must acquire. This is a lifesaving procedure even if ventilator is not available. For example, in a patient with poisoning and laryngeal edema, immediate intubation can prevent airway closure. The steps of intubation will not be discussed here. They may be found in great details in anesthesia texts. But only certain *relevant points* will be mentioned:[3]

- There must be a breathing circuit (Bain's circuit) in the CCU. This will help in preoxygenation of the patient before intubation. Also, if during intubation, there is sudden hypoxia, the procedure may be temporarily abandoned and breathing circuit used to improve oxygenation.
- The physician must ensure that the laryngoscope is in working condition. In personal experience of the author, the battery of the laryngoscope is not checked properly in many Indian hospitals and often, at the times of crisis, the laryngoscope light source is found defunct.
- *An IV cannula must be in situ before the procedure*. There may be sudden hypotension or hypertension during the procedure and then, IV drugs may be needed as emergency.
- Suction apparatus must be ready at the bedside.
- Do not insert the tube until you can see the vocal cords well.
- A bougie must be present in the intubation tray. This often makes the procedure easier.
- Size of tube: adult male: 7.5–8.5; adult female: 6.5–7.5.
- If the procedure gets prolonged, either call expert help or abandon the procedure temporarily; sedate the patient, oxygenate him/her; then try again.
- Do not overinflate the cuff.
- It is a good practice to perform portable X-ray after the procedure.
- If prone ventilation is planned (e.g., Covid-19), a flexometallic tube may be used.
- Please remember that laryngeal manipulation can cause sudden sympathetic surge and hypertensive emergency. Thus, if difficult intubation is anticipated,

IV fentanyl/beta-blocker may be used beforehand to prevent this surge.

Initial Settings

Often a physician is able to diagnose respiratory failure early and connect the patient to the ventilator. But then, the problem arises: how to control the settings? The touchscreen of a modern ventilator has numerous options, many of which seems daunting to a non-trained observer **(Figs. 1 and 2)**. However, the following basic steps are easy to follow and can be adequate in most cases:

- *Mode:* After intubation, it is best to put the patient in assist-control (A/C) mode, at least for some time. This is the safest mode, especially if the patient is unstable.
- *FiO_2:* This indicates the fraction of inspired oxygen. It can vary from 21 to 100. Just after intubation, especially if the intubation has been prolonged or difficult, it is best to keep the FiO_2 at 100 for a few minutes. Then, once the SpO_2 stabilizes, the FiO_2 should be quickly reduced. It must be remembered that one *should not* aim for a SpO_2 of 100%. This is unnecessary and harmful. Any SpO_2 more than 94% is considered adequate. If the SpO_2 is consistently above this level, the FiO_2 should be reduced.
- *Tidal volume:* Usually, the tidal volume is kept at 8–10 mL/kg. The body weight used for this calculation is the *Ideal Body Weight (IBW)*. But in ARDS or restrictive lung disease, the tidal volume is kept low at 5–6 mL/kg.
- *I/E ratio:* Normally, this ratio is 1:2. In COPD, this may be changed to 1:2.5 or 1:3. Conversely in ARDS or diffuse parenchymal lung disease (DPLD), this ratio may be 1:1.7 or even 1:1. The principle is that in obstructive airway disease, there is air trapping. So, the expiratory time should be increased to allow more lungs emptying and prevent auto-positive end expiratory pressure (PEEP). Some ventilators have an option, inspiratory flow rate, which is an indirect control of the inspiration:expiration time (I:E) ratio. Normal flow rate is kept around 60 L/min. If the inspiratory flow rate is higher, the time of inspiration is

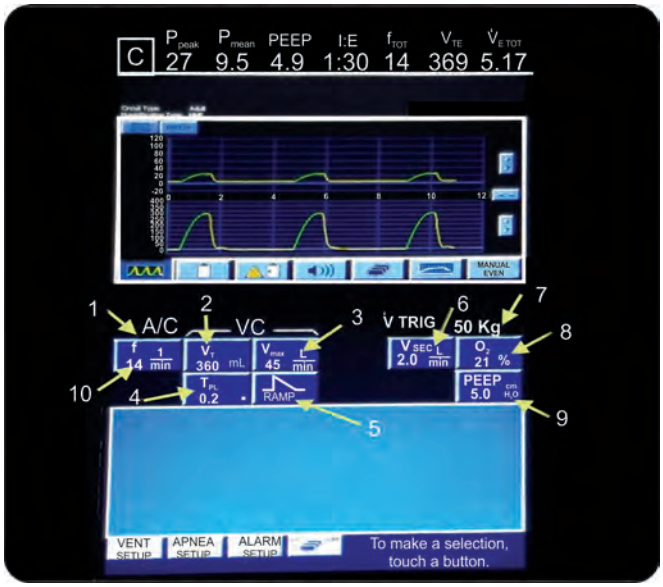

Fig. 1: Touchscreen of a typical ventilator [1—the mode (A/C: Assist Control); 2—tidal volume; 3—maximum inspiratory flow rate; 4—pause time (a short period between inspiration and expiration when there is no air flow. This pause time allows more gas exchange); 5—the shape of flow-time curve. This is usually kept decelerating to prevent barotrauma; 6—trigger for inspiratory flow; 7—IBW, based on which tidal volume is calculated; 8—FiO_2; 9—PEEP; 10—respiratory rate]. Each of these 10 parameters can be changed independently

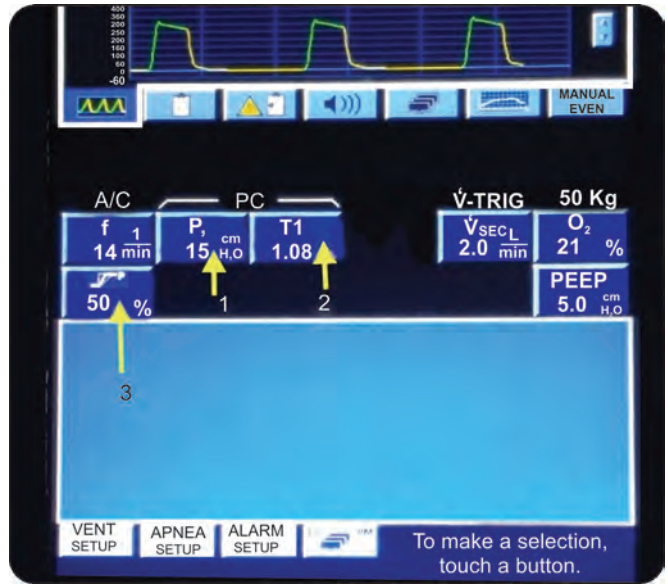

Fig. 2: Control panel of ventilator in PCV mode [1—inspiratory pressure; 2—inspiratory time (this determines the I:E ratio); 3—rise time (this means the fraction of time during inspiration after which the set inspiratory pressure is reached. Here it is set at 50%. This means after half of inspiration, the peak pressure of 15 is attained]. Rests are same as Fig. 1

decreased, thus expiration time increases. In general, in air trapping (like emphysema), expiration time is prolonged; and in decreased compliance or severe hypoxia (like ARDS), inspiration time is prolonged. Altered I:E ratio or inverse ratio ventilation is not physiological. Thus, the patient may be in distress. Hence, in these cases, sedation is needed. Sedation may be given with midazolam, fentanyl, the preceding two drugs in combination, propofol, etc.

- *Respiratory rate:* Normally, in adults, this is kept 10–14/min. Only in ARDS cases, when tidal volume is kept low, the respiratory rate may have to be increased to maintain the minute volume. If respiratory rate and inspiratory flow are controlled, the I:E ratio automatically becomes fixed. Some ventilators have "Inspiratory Time" option (for PCV mode). This is also a way to fix the I:E ratio.
- *PEEP:* The PEEP is normally kept at 3–5 cm of H_2O. However, in ARDS, the PEEP needs to be higher (discussed latter).
- *Volume cycled (VCV) or pressure controlled (PCV)?:* This is another issue where intensivists are divided into different opinionated groups. In general, the physician should remember that pressure controlled ventilation is much more difficult from maintenance point of view. Often, there is need of deep sedation with or without N/M blockade. A Spanish study, done in 2000, found that VCV versus PCV modes did not have any difference in mortality in ARDS patients.[6] So, the physician should use the ventilation mode in which he/she is comfortable.

Besides these, there are numerous other settings (like trigger sensitivity or rise time). But those intricate details are best left to the intensivists.

Recruitment Maneuvers[7]

After the Covid-19 experience, the use of recruitment maneuvers has become the buzzword in critical care. This is a specialized technique, mostly done by intensivists well versed in respiratory care. Some common procedures include:

- Airway pressure release ventilation
- Continuous positive airway pressure (CPAP) maneuver (putting the ventilator in CPAP mode and increasing the pressure to 30 cm H_2O for 30–40 seconds)
- Prone positioning

Prone positioning is a good method and if used early, it can have considerable benefit in ARDS. But the enthusiastic young medicine resident who plans to use prone positioning must remember the following:

- Prone positioning has to be maintained for 12–16 hours/day. For this to be successful, 1:1 nursing care is a must
- Usually these patients need continuous sedation
- Proper preventive care for decubitus ulcers must be given

Observation Panel

The parameters mentioned in the previous section are input variables. Once we have set these parameters, we have to observe the patient data from output section of the touchscreen **(Fig. 3)**. This will tell us whether the respiratory mechanics are appropriate. There are many output variables like respiratory rate, peak pressure, and plateau pressure (in case of VCV) and minute ventilation. Also, the curves (pressure time, volume-time, flow-time, and flow-volume) have to be observed **(Fig. 4)**.

In addition, modern ventilators have special procedures to measure certain parameters like static compliance (by inspiratory hold).

Trouble Shooting

This has been depicted in **Table 1**.

Weaning

While connecting a patient to a ventilator for lifesaving, proper weaning is equally important. Delayed weaning may cause VAP, tracheomalacia, critical care induced neuropathy, and other problems.

The most important point that must be remembered for weaning is that the underlying disease must be quelled. There should not be any significant cardiac or pulmonary dysfunction at the time of weaning. For example, if the pneumonia is controlled but still, the patient is on vasopressor support, then weaning is unlikely to be successful.

The modern technique is to put the patient on spontaneous mode of ventilator from A/C mode. In spontaneous mode, the FiO_2 is slowly brought down to 21 and the pressure support is also reduced **(Fig. 5)**. If this is sustained, that is oxygen saturation is maintained and

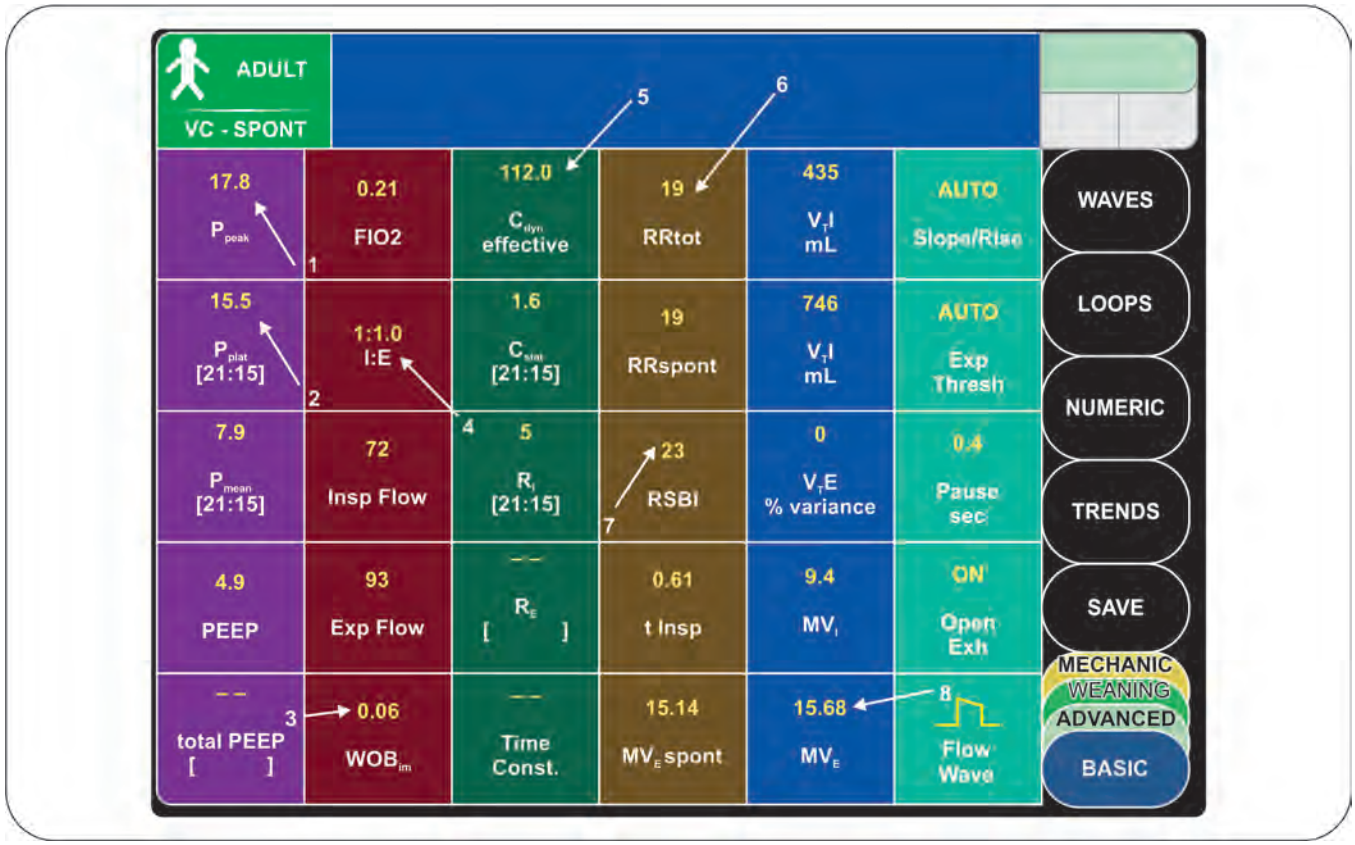

Fig. 3: The observation screen of a modern ventilator [1—peak inspiratory pressure; 2—plateau pressure; 3—work of breathing; 4—I:E ratio; 5—dynamic compliance (Normal: 50–70); 6—respiratory rate; 7—rapid shallow breathing index (this is important for weaning); 8—minute ventilation. This should be less than 10. Very high values indicate hyperventilation]. The recent ventilators may have even more parameters. Physicians should familiarize themselves with their machines

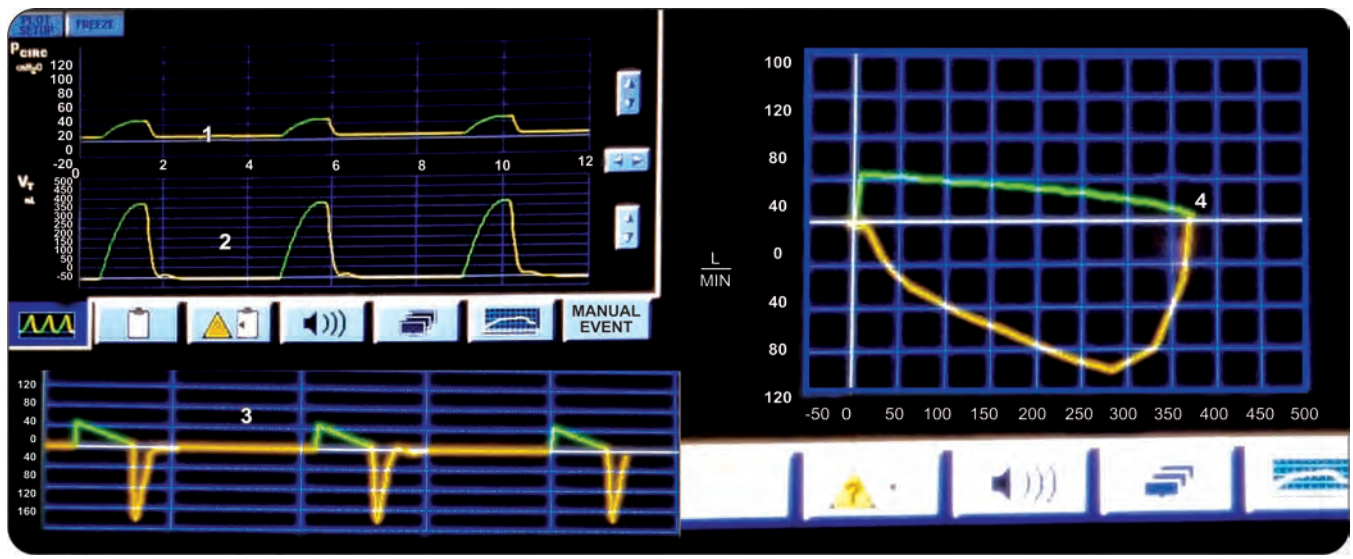

Fig. 4: The various graphs visible on ventilator screen [1—pressure-time; 2—volume-time; 3—flow-time; 4—flow-volume]

TABLE 1 Table showing some common problems faced during mechanical ventilation

Observation	*Possible causes*
Refractory hypoxia	• Oxygen source disconnected • Lung atelectasis • Airway block
Sudden hypotension	• Development of pneumothorax due to VILI • Too high PEEP • VAP with sepsis
Tachypnea	• Patient-ventilator dys-synchrony • Sepsis • Airway block

hemodynamic stability is attained, then T-piece trial can be given. The T-piece trial can be given for 30-60 minutes on the first day and then increased on subsequent days. If this is successful, extubation can be done. In some places, it is routine to put the patient on BiPAP or HFNC after extubation for some time. But this is not universal.

Difficulty in Weaning

In some cases, there is repeated weaning failure. Some common causes are: Hypokalemia, sepsis, underlying heart failure, hypothyroidism, severe anemia, massive ascites, etc. Thus, in such cases, these extra-pulmonary causes should be ruled out. Some rules of the thumb to assess suitability for weaning:

- RSBI<105 (RSBI=Respiratory rate/tidal volume in liters)
- 5<Respiratory rate<35
- Absence of significant acidosis (respiratory or metabolic)
- Good mentation
- MV<10 L. Very high minute ventilation means the patient is hyperventilating and respiratory muscles are likely to be fatigued. In such cases, extubation should be delayed.

Ventilator Strategy in COVID-19[8]

Any discussion about MV in 2020 is not complete without a few words about Covid-19. Covid-19 is associated with rapidly progressive ARDS like picture and MV is the lifesaving measure in such cases.

Although there are some data on pulmonary thrombosis in Covid-19, the gross ventilator strategies remains similar to the ARDS protocol. Thus, low tidal volume (4–8 m/kg), plateau pressure less than 30 cm of H_2O and

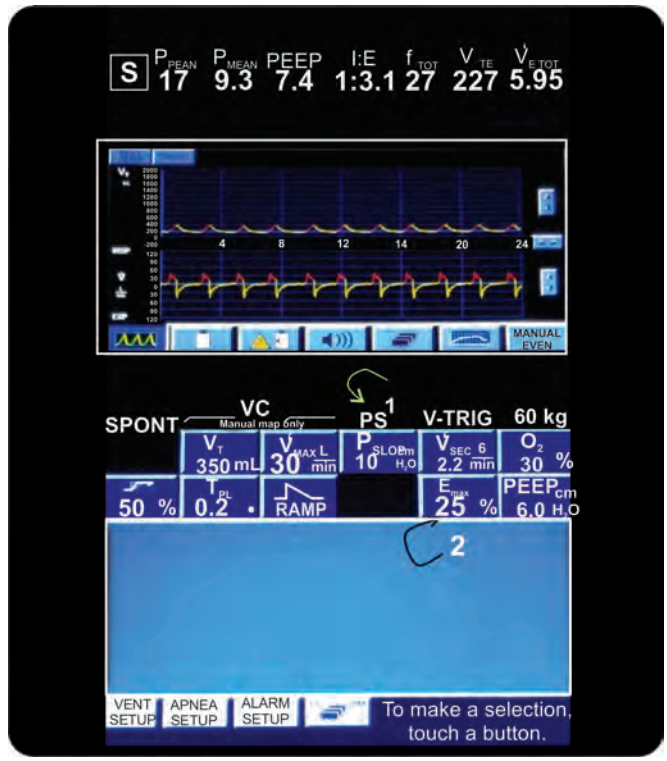

Fig. 5: Ventilator in spontaneous pressure support mode [1—the support pressure during inspiration; 2—expiratory sensitivity: this means when inspiratory flow drops to 25% of the peak value, the ventilator will switch to expiration]

conservative fluid strategy are advised. Also, a high-PEEP strategy is preferred and in severe hypoxemia, especially that which does not respond to optimum oxygenation, prone ventilation (12–16 hours/day) is recommended. A corollary of this last strategy is autoproning, which is now commonly practiced. Recruitment maneuvers can be done as needed, including staircase maneuvers (incremental PEEP).

Ventilator Strategy in COPD[1]

In COPD, there is obstructive airway disease. The patients have chronic respiratory acidosis. The ventilator strategy involves using an FiO_2 to target SpO_2 of 88–92%. The respiratory rate is kept at 10–14/min, not higher. This is because due to chronic respiratory acidosis, the HCO_3 levels are elevated as compensation. If respiratory rate is kept high, there will be quick CO_2 washout. This will precipitate metabolic alkalosis. The flow trigger is kept around 2 L/min. If this is lower, tachypnea may occur. I:E ratio is kept at 1:2.5 to 3.5. PEEP is started at 5 and then

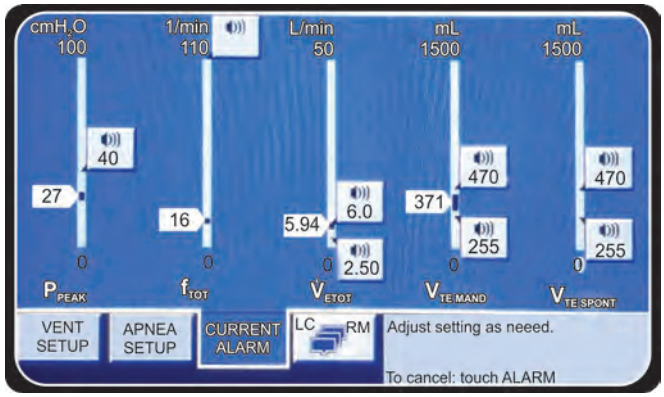

Fig. 6: The alarm settings of the ventilator. These are important because unless alarms are sounded at the right moment lives may be lost. Here, the respiratory rate alarm (f) is off. This is not correct

Fig. 7: The Apnea settings of a ventilator (top panel). This helps to save lives if there is sudden respiratory arrest in spontaneous mode

increased as needed. Expiratory sensitivity can be kept above the default setting of 25% to increase the time of expiration. Tidal volume is adjusted to maintain MV at less than 6 L. This prevents overinflation in emphysema.

Ventilator Strategy in DPLD[1]

At the outset, it must be explained to the patients' relatives that DPLD has a very poor prognosis in the CCU. The usual ventilator strategies are low tidal volume and high respiratory rate. If VCV is unable to maintain adequate minute ventilation (6–10 L/min) at acceptable plateau pressure (<30–35), then PCV mode may be used. High PEEP may be used to recruit the collapsed alveoli. I:E ratio may be kept at 1:1 or even 2:1. Prone ventilation may be used. Here, unlike COPD, high FiO_2 may be used to improve oxygenation but increasing the PEEP can also achieve that objective. Inspiratory hold technique may be used to determine lung compliance and if this is very low, recruitment may be tried (as described earlier). Failure to improve oxygenation by any means warrants the use of ECMO.

Interpretation of ABG in a Ventilated Patient

Often, the physician is asked to review the arterial blood gas (ABG) report of a ventilated patient. This is a crucial test to check the adequacy of ventilation. In an ABG report, the first parameter to check is the PaO_2. Low values indicate hypoxia and the need to increase FiO_2 or PEEP. Ideally, the PaO_2 should be around five times the FiO_2. That is, if FiO2 is 30%, the PaO_2 should be around 150. PaO_2/FiO_2<300 (where FiO_2 is expressed in decimal) is the cut-off for defining ARDS. The next parameter to be checked is $PaCO_2$. Low values indicate hyperventilation and the need to decrease minute ventilation. High $PaCO_2$ indicates inadequate ventilation. Other reasons for increased $PaCO_2$ are a high-carbohydrate diet and severe shock. ABG should be done 30–60 minutes after any change in ventilator settings.

Conclusion

- In VCV, the clinician should always look at the peak and plateau pressures during daily rounds. Persistent high pressures increases risk of barotrauma. But persistent high pressures can also mean the patient is biting the tube (thus sedation may have to be increased), or there is secretion clogging the tube (thus suction may be needed). Also, very high inspiratory flow rate may increase the peak pressure.
- A ventilated patient needs good nutrition. Otherwise, weaning will be difficult.
- If prolonged ventilation support is anticipated, early tracheostomy should be done.
- The alarm settings of a ventilator should be checked periodically to ensure that proper thresholds are set **(Fig. 6)**.
- In PCV mode, frequent suction should be avoided because it releases the alveolar pressure and can precipitate atelectasis.
- Apnea settings should always be active **(Fig. 7)**.

CHAPTER

103 ARDS in Viral Infections

Gagan Gunjan, Mohd Saif Khan, Krishna Kumar, DP Singh

Abstract

Introduction: Acute respiratory distress syndrome (ARDS) is an inflammatory lung parenchymal injury caused by various direct or indirect insults to pulmonary alveoli leading to exudative non-hydrostatic pulmonary edema. Ashbaugh and colleagues were the first to give a clinicopathological description of the ARDS in twelve adult patients. The ARDS Definition Task Force defined ARDS in 2012 (Berlin's criteria).

Pathophysiology: Pathophysiology of ARDS in patients with viral infections is not entirely clear. This is due to variable interaction between host factors and host immune response to viral antigen, which governs the severity of pneumonia or ARDS. Damage to alveolar endothelium results in increased endothelial permeability and recruitment and infiltration of leucocytes. Organ cross talk can occur through common language of pro-inflammatory cytokines and subsequently multi-organ dysfunction syndrome occur.

Management: Prognosis of ARDS in viral illness is poor with significant mortality and morbidity. Management is mainly supportive. Specific management includes anti-viral drugs, immunotherapies, and steroids. Supportive treatment has an important role to allow some time for specific treatments.

In this chapter, a focused review of ARDS caused by a variety of respiratory and non-respiratory viruses is presented along with cutting-edge developments in diagnostic and treatment modalities.

Introduction

Acute respiratory distress syndrome (ARDS) is an inflammatory lung parenchymal injury caused by various direct or indirect insults to pulmonary alveoli leading to exudative non-hydrostatic pulmonary edema. In 1967, Ashbaugh and colleagues were the first to give a clinicopathological description of the ARDS in 12 adult patients.[1] Clinically, ARDS is characterized by acute onset of dyspnea, hypoxemia, and appearance of bilateral diffuse radiological infiltrates, which are not explained by volume overload or cardiac dysfunction.[2] Severe sepsis is the most common cause leading to ARDS in about 50% of cases.[3] These infections can affect lungs directly (pulmonary ARDS) or indirectly (extrapulmonary ARDS).

Respiratory viruses that can cause ARDS can be of two types:

- Pandemic and
- Non-pandemic respiratory viruses.[4]

Influenza viruses (H5N1 and H1N1), Severe Acute Respiratory Syndrome Corona viruses (SARS-CoV), and Middle East Respiratory Syndrome (MERS) Corona viruses are notable examples of pandemic respiratory viruses, which can result in severe form of ARDS compared to non-pandemic respiratory viruses.[5-7] SARS was reported first time in 2002, originated in southern China and eventually involved more than 8,000 persons worldwide. H1N1 influenza pandemic started in 2009 from California, through Mexico, the United States spread

globally affecting mostly children and young adults. Recent addition to the list of pandemic respiratory virus is the SARS-CoV-2, which has been attributable to Corona Virus Dieases-19 (COVID-19).[8] Exact incidence of ARDS caused by viral diseases is unknown. Nevertheless, with the advent of multiplex nucleic acid amplification assays for the detection of viral pathogens, increasing numbers of viral etiologies are elucidated among the critically ill patients. In this chapter, a focused review of ARDS caused by a variety of respiratory and non-respiratory viruses is presented along with cutting-edge developments in diagnostics and treatment modalities.

Epidemiology

Incidence of ARDS varies extremely from country to country, being lowest in Brazil (10.1 per 100,000 person-years) to highest in the USA (78.9 per 100,000 person-years).[9,10] Unfortunately there is no population survey based data published from India showing incidence of ARDS. According to a multinational observational study representing a large data from 29,144 ICU patients across 50 countries, ARDS was present in 10.4% of patients admitted to ICU and 23.4% of patients on mechanical ventilator.[11]

Infections are the most common causes of ARDS, in which bacterial especially Gram negative microbial pathogens are the most common isolates from microbial cultures described in ARDS patients.[12] Exact incidence of ARDS caused by viral infections is not known. The most common viruses detected from viral pneumonia were Influenza and Rhinovirus. Respiratory syncytial virus infection is common in pediatric age group. Despite viral detection in critically ill patients, their role in pathogenesis in ARDS is debatable.

Etiology and Risk Factors of ARDS Caused by Viral Illness

Respiratory viruses can cause ARDS in those who are immunocompromised, in extreme of ages, having severe comorbidities, hematopoietic cell transplant recipients, and acquired human deficiency syndrome and in those with exaggerated host response. Most common types of viruses causing pneumonia are divided according to genetic material they contain and their pandemicity **(Table 1)**.

Pathophysiology of ARDS Due to Viral Infections

Pathophysiology of ARDS in patients with viral infections is not entirely clear. This is due to variable interaction between host factors and host immune response to viral antigen, which governs the severity of pneumonia or ARDS. Respiratory virus first invades nasal and bronchial epithelium, this invasion causes injury to respiratory airway and alveolar endothelium, cytokine release syndrome, which in worse case can take the form of cytokine storm. There is disruption in surfactant synthesis, which leads to alveolar collapse. Organ cross talk can occur through common language of proinflammatory cytokines and multi organ dysfunction syndrome occurs. In lungs, diffuse alveolar damage (DAD), a pathological hallmark of ARDS, has been observed in direct viral invasion of cells and lytic effects. Damage to alveolar endothelium results in increased endothelial permeability and recruitment and infiltration of leukocytes, which stimulate production of reactive oxygen species and nitric oxide that damage the epithelial-endothelial barrier. Few components of coagulation and fibrinolytic system are also activated in viral induced lung injury. These pathological events are translated to high incidence of both hemorrhagic and venous thromboembolic events.[20] Another unique difference in viral and bacterial etiology of ARDS is the small lymphocytes as predominant immune cells at the site of lung injury.[21] Due to cytokine-induced lymphocytic sequestration, lymphopenia ensues.

Few viruses (HSV, VZV, and CMV) remain in dormant state in ganglia or reticuloendothelial tissue and may become reactivated in the state of immunosuppression, especially in later stage of prolonged sepsis, characterized by immune-paralysis stage. Interestingly, in cases where ARDS results from inflammatory host response rather than direct cytopathic effect of virus, the antiviral therapy alone has limited value as has been observed in case of COVID-19 where SARS CoV-2 primarily injures the vascular endothelium.[22,23]

Clinical Features

Clinical features of virus induced ARDS are often nonspecific, vague, and overlapping. It is not uncommon for such patients to present with features of both ARDS as well as underlying cause. Symptoms appear within

TABLE 1 List of viruses causing pneumonia and ARDS

Name of virus	*Genetic material*	*Pandemicity of virus*	*Clinical characteristics*
Influenza A	RNA	Pandemic, H5N1 in 1997, H1N1 in 2009	Most common viral cause of pneumonia. Multiple subtypes of Influenza A Avian flu (H5N1) and swine flu (H1N1) have caused pandemics
Parainfluenza viruses 1–4	RNA	Non-pandemic	Rarely, parainfluenza virus may result in severe pneumonia and ARDS, especially in hematopoietic cell transplant recipients
Human Metapneumovirus	RNA	Non-pandemic	Sporadic cases with ARDS have been reported in severely immunocompromised, hematopoietic cell transplant recipients, and acquired human deficiency syndrome and in those living long-term care facilities
Human Rhinovirus	RNA	Non-pandemic	Main risk factors of ARDS are elderly age and immunosuppression
Ebola virus (EBOV)	RNA	Outbreak 2013–2016	22% patients infected with EBOV developed ARDS. High levels of EBOV RNA in bronchoalveolar lavage (BAL) is suggestive of EBOV induced ARDS[13]
SARS-CoV-1	RNA	Pandemic in 2002	The prevalence of ARDS in SARS can be high 20%
MERS-CoV	RNA	Pandemic in 2012	Despite virological similarity, MERS-CoV showed highest case fatality rate (34.4%) among coronaviridae
SARS-CoV-2	RNA	Pandemic in 2019-20	About 20% of hospitalized patients may develop ARDS within 8 days of symptom onset[14]
Respiratory Syncytial virus (RSV)	RNA	Non-pandemic	Common in infants and young children. Severe illness may develop in immunocompromised patients, bone marrow transplant recipients, underlying cardiopulmonary disease, and age more than 65 years[15]
Adenoviruses	RNA	Non-pandemic	Important cause of ARDS in immunocompromised adults and infants[16]
Hantavirus	RNA	Non-pandemic	Unexplained reason of ARDS linked to known exposure to special variety of rodents (deer mouse) residing in recently opened old building
Cytomegalovirus (CMV)	DNA	Non-pandemic	CMV pneumonia has been detected in 6–30% ICU patients. Immunosuppression, hematological malignancies, and prolonged mechanical ventilation are recognized risk factor for development of CMV pneumonia and viremia[17]
Herpes Simplex virus (HSV)-1	DNA	Non-pandemic	Rare cause of severe pneumonia and ARDS. However, HSV-1 has been detected in 5–64% cases of ARDS in ICU[18]
Varicella-zoster virus (VZV)	DNA	Non-pandemic	Pneumonia is the most common complication. Characteristic skin rashes help in diagnosis[19]

few days after the exposure to inciting factor and is often characterized by fever, cough, sore throat, myalgia, chills, or rigors. Watery diarrhea is also common along with abdominal pain, nausea, and vomiting, especially in illness caused by enterovirus and corona viruses.

Progressive symptoms of breathlessness, escalating requirement of oxygen, increased work of breathing, and alveolar infiltrates on chest imaging within 6–72 hours of an inciting event, ARDS should be highly suspected. On examination, patients may have tachypnea, tachycardia, and diffuse crackles, wheeze. In severe case, confusion, respiratory distress, cyanosis, and diaphoresis may be evident.

Differential Diagnosis and ARDS Mimics

There are a number of conditions that may present as acute hypoxemic respiratory failure with bilateral alveolar opacities and mimic ARDS. Some of the important mimics are being mentioned here.

- *Acute cardiogenic pulmonary edema:* It usually involves left ventricular systolic or diastolic dysfunction, but it may also occur due to fluid overload, hypertension, or severe renal disease. It can be distinguished from ARDS by evidence of cardiac dysfunction, elevated right-sided filling pressures, or related radiographic abnormalities. BNP or NT-proBNP is usually elevated.

In doubtful cardiac involvement, bedside transthoracic echocardiography may be performed to seek evidence of cardiac dysfunction.

- *Diffuse alveolar hemorrhage (DAH):* Almost two-thirds patients with DAH will present with hemoptysis. On fiber optic bronchoscopy (FOB), frothy hemorrhagic secretions are visible throughout the airways. Bronchoalveolar lavage (BAL) cytology, though nonspecific, may show hemosiderin-laden macrophages.
- *Inflammatory or autoimmune conditions:* Several specific acute inflammatory conditions may mimic ARDS, which mainly include acute eosinophilic pneumonia, pulmonary vasculitis, acute interstitial pneumonitis, acute fibrinous organizing pneumonia, cryptogenic organizing pneumonia. These conditions can be ruled out by serology, BAL specimens, ANA, C-ANCA, P-ANCA, or lung biopsy.
- *Malignancy:* Hematological malignancies, such as leukemia, lymphoma, and pulmonary secondaries of solid tumors may be mistaken for ARDS.
- *Others:* Few embolic syndromes (fat embolism syndrome and amniotic fluid embolism syndrome) may present with hypoxemia and bilateral opacities. BAL examination may reveal fat or amniotic fluid debris. Air embolism can be suspected when patients experiencing sudden-onset respiratory distress in the setting of a known risk factor, intravenous catheter insertion, or trauma.[24]

Diagnostic Criteria

The ARDS Definition Task Force has defined ARDS in 2012 known as Berlin's criteria,[25] which consist of rapid onset (within 7 days) of ARDS, impaired oxygenation status (PaO_2/FiO_2 ratio <300 mm Hg with positive end expiratory pressure, PEEP ≥5 cm H_2O), characteristic radiological opacities (diffuse, bilateral, and fluffy), and non-cardiac origin of pulmonary edema (not explained by cardiac dysfunction or fluid overload). Out of these four criteria, oxygenation status defines grading of severity of ARDS. Mild ARDS is said when PaO_2/FiO_2 ratio is in between 200 and 300 mm Hg, moderate ARDS is signified by a PaO_2/FiO_2 ratio between 200 and 100 mm Hg. Value of PaO_2/FiO_2 ratio ≤100 mm Hg corresponds to severe ARDS, which is associated with highest mortality rate.

Microbiological Tests

In the past, viral infections were purely clinical and the diagnosis of exclusion. Association of ARDS to viral etiology is confirmed by isolation of intact virus particles from cell culture or viral antigen detection by immunofluorescence, or multiplex RT-PCR. Among all these, most commonly performed and most rapid test is the multiplex RT-PCR, which gives comparable diagnostic accuracy compared to cell line culture (gold standard) and immunofluorescence techniques.[26] The best sample for highest diagnostic yield is BAL collected during FOB, which is not always possible due to highly infectious nature. Bacterial and fungal culture, lung histopathology should also be performed to find coexisting infections leading to ARDS.

Laboratory Tests

Hematological profile may reveal leukopenia, lymphopenia and thrombocytopenia, which are markers of severity of viral illness. Arterial blood gas (ABG) analysis shows hypoxemia, which is often initially accompanied by acute respiratory alkalosis (due to compensatory hyperventilation), which later is replaced by hypercapnic respiratory acidosis (due to contraction of baby lung of ARDS). Metabolic acidosis (HCO_3 <15 mEq/L) with hyperlactatemia may also develop due to the precipitating sepsis or associated organ injury.

Routine biochemical examination may manifest the evidence of organ injury (acute kidney injury or liver dysfunction) reflective of severe hypoxemia or associated shock and systemic inflammation (hypoalbuminemia and raised C-reactive protein). The prothrombin time (PT) and activated partial thromboplastin time (aPTT) may be prolonged, and D-dimer is elevated in severe viral illness and ARDS, suggesting prognostic importance of coagulation parameters.[27]

Imaging Studies

Radiological findings in viral ARDS are variable and nonspecific and graded according to the severity of ARDS. The initial chest radiograph may be normal or may reveal typically bilateral diffuse alveolar opacities with dependent atelectasis. Computed tomography (CT) of the chest may show widespread patchy and/or coalescent airspace opacities that are usually more apparent in the dependent lung zones. The opacities can be subtle (e.g.,

patchy ground glass), particularly in early ARDS, but can become consolidative in appearance as severity worsens. Lung ultrasound has emerged as noninvasive, radiation free, reproducible and promising tool with reportedly higher sensitivity (83–92%) for the diagnosis of ARDS compared with CT chest.[28]

Management

Management of ARDS in viral illness is mainly supportive. Specific management includes antiviral drugs, immunotherapies, and steroids. Supportive treatment has an important role to allow some time for specific treatments.

Respiratory Support

Main issue in ARDS is worsening gas exchange and hypoxemia due to development of intrapulmonary shunt. Therefore, reversal of hypoxemia is the key principle in the management, which can be accomplished by respiratory support in the form of various oxygen delivery devices.

Role of NIV and HFNOT: Both NIV and HFNOT are noninvasive oxygen delivery devices, which are associated with improved outcomes in acute hypoxemic respiratory failure (AHRF) patients compared to invasive mechanical ventilation. Before intubating an ARDS patient who has moderate hypoxemia, a trial of NIV or HFNOT may be warranted.

Ventilatory settings for ARDS lung include low tidal volume (TV) protective lung ventilation (TV, 4–8 mL/kg of predicted body weight) and frequently monitoring and maintaining plateau pressure (Pplat) below 30 cm H_2O to ensure safety to baby lung. Severe hypoxemia in ARDS (<150) should trigger institution of more aggressive approach such as prone position ventilation, extracorporeal membrane oxygenation (ECMO), and use of lung recruitment maneuver. Proning improves PaO_2 and decreases CO_2 retention in patients with severe ARDS. A multicentric trial (PROSEVA) has shown significant mortality improvement with proning when performed for the duration of 16 hours a day.[29-31]

Fluid Management in ARDS

The Society of Critical Care Medicine, 2020, guidelines recommend to use restricted fluid and to use dynamic tests of fluid responsiveness to determine the need of fluid.

Role of Corticosteroid

In H5N1 and H1N1 influenza ARDS, routine use of steroid was discouraged citing higher rate of nosocomial infections. Similarly, corticosteroids did not show any benefit but led to delayed viral clearance in a multicenter study performed in patients (n=309) with the MERS. Recently Oxford University released findings of RECOVERY (Randomized Evaluation of COVid-19 thERapY) trial in which dexamethasone reduced the mortality by one-third in the patients on mechanical ventilator.[32]

Antiviral Treatment

Antiviral treatment can reduce the viral load, viral shedding, and reduce the disease transmission to close contacts. It has also shown proven benefit in radiologic clearance in ARDS. However, the efficacy of antiviral is maximized if administered within 48 hours of symptom onset. Specific antiviral drugs have been listed in **Table 2**.

Following respiratory virus is detected in respiratory or blood sample, antiviral treatment may be started. In pandemic times, empirical antiviral without waiting for result is warranted to improve outcome.

Antimicrobial Treatment

In critically ill patients, due to presence of various indwelling catheters, prevention and treatment of nosocomial infection is of equally importance while managing virus induced ARDS. Therefore, considering local antibiogram and host risk factors, empirical antibacterials may be indicated.[34]

Other Pharmacological Treatment in ARDS Patients

Anti-cytokine Drug

Two drugs, Aviptadil (concentrated in the lung 40%) and Remestemcel-L are being repurposed and investigated as therapeutics in COVID-19 ARDS (CARDS). Both down-regulate the synthesis of proinflammatory cytokines in the lung.

Immunotherapies

Palivizumab (monoclonal antibody) with intravenous immunoglobulin (IVIG) has been recommended in preventing Respiratory Syncytial virus (RSV) induced

TABLE 2 Antiviral drugs in viral induced ARDS

Antiviral drug	*Indication*	*Further information*
Ganciclovir	CMV induced ARDS	Combination therapy with immunoglobulins can reduce the mortality in ARDS
Acyclovir or Valacyclovir	HSV or VZV induced ARDS	Dose of acyclovir is 10 mg/kg IV q8h for 7 days. Combination with varicella-zoster immune globulin (VZIG) therapy may be considered
Oseltamivir	H1N1 ARDS	Oral dose of 150 mg twice daily for 10 days is recommended
Zanamivir	Oseltamivir resistant H1N1 ARDS	Compassionate use of intravenous Zanamivir or add Ribavirin for Oseltamivir resistant cases
Peramivir	Investigational use in H1N1 ARDS	Compared to Oseltamivir, it has higher affinity for the influenza virus, and only single dose intravenous infusion is enough.[33] Evidence is limited in critically ill
Favipiravir	H1N1 resistant to Neuraminidase inhibitors (NAIs) and SARS CoV-2	Favipiravir is an oral antiviral, approved in Japan for the treatment of influenza. Trials are ongoing for its use in COVID-19
Ribavirin	Respiratory Syncytial virus (RSV), Metapneumovirus, Parainfluenza virus, Measles, and Hantavirus	Intravenous formulation is available for use in critically ill patients. Ribavirin nebulization may be used in ARDS
Remdesivir	SARS CoV-2	It inhibits viral RNA polymerases broad-spectrum antiviral activity, emergency use authorization (EUA)
Cidofovir	Adenovirus induced ARDS	Dose of Cidofovir is 5 mg/kg/wk for 2 weeks, then every 2 weeks. Another dosing schedule is 1 mg/kg IV thrice a week
Lopinavir–Ritonavir	SARS CoV-1	400 mg and 100 mg, respectively twice a day for 14 days. No impact on SARS CoV-2

severe pneumonia in high-risk infants and young children. Interferons-alpha-2a with ribavirin has been shown to improve survival in severe MERS-CoV infection. Convalescent plasma, due to its immunotherapeutic potential, has been successfully used in SARS, MERS, Ebola virus disease, and COVID-19.

Conclusion

Prognosis of ARDS in viral illness is poor with significant mortality and morbidity. Mortality increases with poor oxygenation status (46% with severe ARDS), late presentation, requirement of mechanical ventilation, presence of comorbidity, and higher age. However, survival has improved with advances in critical care management and early supportive measures.[35] Patients, who survive ARDS, suffer long-term consequences, which include significant weight loss, poor functional status, and poor quality of life.

Recent viral pandemics have deepened our understanding of pathophysiology and management of ARDS. Clinical features are nonspecific and overlapping with viral illness as well as ARDS, but helpful in diagnosis. Multiplex RT-PCR of respiratory sample is confirmatory for viral ARDS. Supportive management include NIV or HFNOT initially and invasive lung protective ventilation in later more severe stage of ARDS.

Specific management includes antiviral and corticosteroid, which should be started early in the course of viral illness for the maximum therapeutic benefit. Other therapies are adjunctive and still investigational.

CHAPTER

104 ABG Analysis: Physicians' Perspective

Ravindra Kumar Das

Abstract

Background: Analyzed report of Arterial Blood Gas is indicated in almost all patients admitted through emergency department (ED). ABG measurements are widely used in hospitals nowadays. Its use is particularly confined in ICU as monitor due to lack of test of accuracy and availability of simple method of analysis, management if started after correlating the clinical diagnosis with that of ABG diagnosis, mortality is reduced and discharge is improved.

Method: Prospective randomized controlled trial had been done over 136 patients of ED. Allocation ratio was 1:1. One group was managed in the background of analyzed ABG measurements and the control group was managed according to the traditional method. The ABG measurements were analyzed according to "rkdas Indian 2017 method of ABG interpretation". The primary and secondary outcomes were assessed statistically. Patients and outcome access were blinded.

Result: The percentage of death in the study group is significantly less than the control group (p-value 0.22) with 95% confidence interval (3.08–17.52). The percentage of discharge is significantly more in study group than control group (p-value 0.036) with 95% confidence interval (50.25–73.35).

Conclusion: Management in the background of interpreted ABG decreases the mortality and improves the number of discharge.

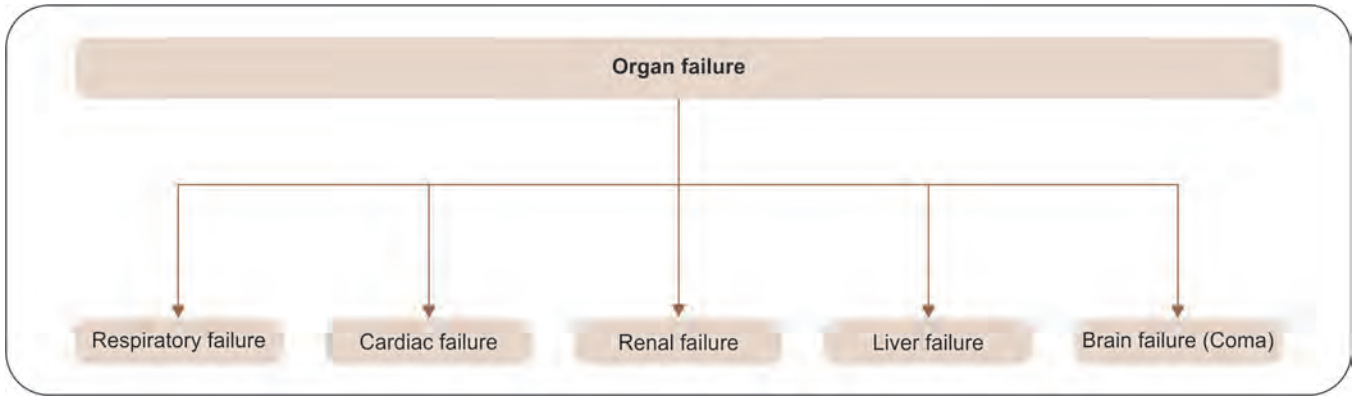
Introduction

Arterial blood gas (ABG) is the most accurate test possible without restriction. It is widely used in hospitals particularly in ICU as a monitor.[1] For physicians it is indicated in almost all patients who are admitted through emergency department (ED). Analyzed report is the ultimate representation of patients' clinical status. Correct interpretation can lead to quicker and reliable changes in the plan of care. A sensitive physician is always interested to have analyzed ABG report before planning of management.

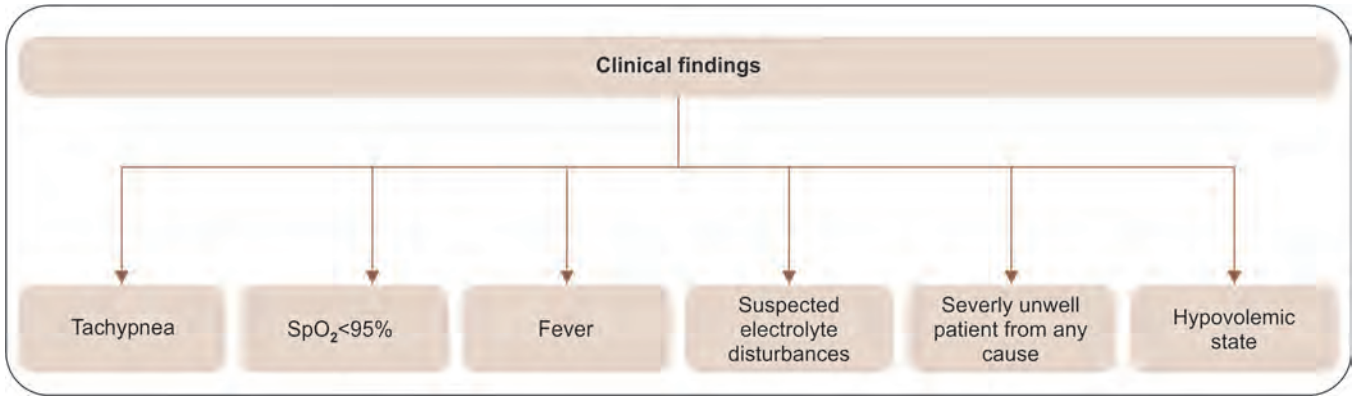
It helps the clinician in diagnosis and in some cases prognosis. Management started in the background of ABG significantly decreases the mortality. Failure to improve and deterioration of ABG parameters during management suggests early referral of the patients. In mixed disorder (multi-organ involvement) where mortality is high and complete clinical diagnosis at a glance is difficult, analyzed report of ABG helps the physicians. Wide utility of ABG is restricted in ICU as a monitor due to lack of absolute method of analysis and reliable test of its accuracy. Whenever clinical diagnosis does not match with ABG analysis, clinician often categorizes it imprecise. This difficulty has been overcome by new method of ABG interpretation.

A randomized control trial has been done and outcome is enthusiastic. Mortality is significantly decreased and

Flowchart 1: Organ failure



Flowchart 2: Clinical finding



discharge is improved when management is started after ABG correlation of clinical diagnosis.

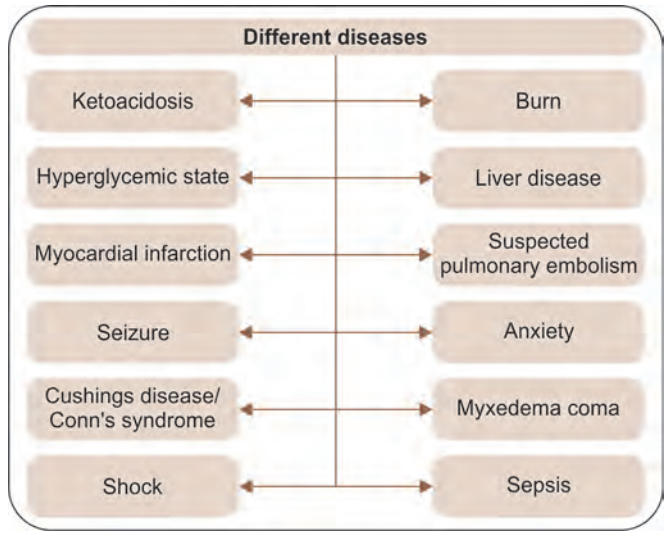
Indications

- Organ Failure **(Flowchart 1)**
- Multi Organ Failure
- Poisoning/Drug Toxicity/Alcohol Intoxication
- Clinical Findings **(Flowchart 2)**
- Different Diseases **(Flowchart 3)**
- Monitor in Ventilated Patient

Method

It was a prospective randomized control trial that was done in ED of Darbhanga Medical College, Laheriasarai. After getting ethics approval and consent form duly signed. Patients were randomized in two groups by simple

Flowchart 3: Different diseases



random allocation. Around 136 patients admitted in ED were randomized in 17 blocks and each block were allotted 8 patients with allocation ratio 1:1. Patients and outcome accesses were blinded. Arterial blood from 68 patients were taken before start of management and measurement were done by cobas b 121 machine.

Primary outcome (mortality and discharge) and secondary outcome (total days of stay in hospital) were recorded. Referral and LAMA were also considered. Statistical analysis was done by SPSS and standard method applied. Analysis of measured ABG data were done according to the method mentioned below.

"rkdas Indian 2017 Method of ABG Interpretation"[2]

- Accuracy of ABG:
  - Base excess (BE) method
  - Relation of pH to H^+ as already established[3]
  - Relation of Hb% measured through CBC and ABG
  - Relation of SpO_2% derived by machine and measured by pulse oximeter
- Gas analysis:
  - SpO_2%
  - PaO_2 mm Hg
  - Relation between PaO_2 & SpO_2 from Hb% dissociation curve
  - $PaCO_2$ mm Hg
  - Decide type of respiratory failure
  - Derivation of $PAO_2 = 150–1.25 \times PaCO_2$ mm Hg
  - P (A–a) O_2 value mm Hg
  - Cause of hypoxemia decided by algorithm[4]
  - P/F, i.e., PaO_2/FiO_2, i.e., hypoxemia index to decide ARDs and its severity
  - Oxygen content (CaO_2) in patients having anemia
  - $CaO_2 = Hb\ (gm/L) \times 1.34 \times SPO_2/100 + 0.003 \times PaO_2$
- Electrolyte analysis:
  - Osmolality = $2 \times Na\ (mEq/L) + \frac{\text{Plasma glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8}$
  - $BUN = \frac{\text{Blood urea (mg/dL)}}{2.14}$
  - Blood volume = $\frac{2L}{Hct\ (\%)}$ in cases of having no anemia or polycythemia
  - The cause of K^+ derangement is correlated with pH[5]
  - Chloride generally changes in parallel with plasma Na^+
  - Free calcium level
  - $AG = (Na^+ + K^+) – (Cl^- + HCO_3^-)$ mmol/L
  - Delta Gap (Δ gap) = anion gap – 12
  - Gap-Gap ratio = delta gap/HCO_3^- defict (24-HCO_3^-)
  - Δ gap + HCO_3^-
- Acid-Base analysis:
  - pH&H^+ value
  - HCO_3^- value
  - Direction of movement of H^+ and HCO_3^- to know about primary cause from rule of thumb[4]
  - Find out the compensatory change from knowing the primary cause
  - Movement of $PaCO_2$ and HCO_3^-
  - Calculate delta gap, gap-gap ratio, and delta gap + HCO_3^- in a patient of high anion gap metabolic acidosis to decide associated non anion gap metabolic acidosis and/or metabolic alkalosis
  - In case of primary respiratory cause decide:

    $\frac{\Delta H +}{\Delta CO_2}$, if < 0.3 – Chronic cause

    If > 0.8 – Acute cause

    If 0.3-0.8 – Acute on chronic respiratory cause
  - Decide complex disease:
    - If $PaCO_2$ and HCO_3^- moves in opposite direction
    - In a respiratory cause if there is associated metabolic cause or vice versa
    - In a respiratory cause if anion gap is >20
    - In a respiratory cause if base excess is ≥±5
    - In a high anion gap metabolic acidosis there is associated non-anion gap metabolic acidosis and/or metabolic alkalosis
  - In ABG, if pH = 7.4 ± 0.04; $PaCO_2$ = 36–45 mm of Hg; HCO_3^- = 22–26 mmol/L then no acid base disorder
  - Diagnosis of acid-base analysis.
- Complete diagnosis

Result

In the study and control group female to male were 31(45.6%) to 37(54.4%) and 36(52.9%) to 32(47%), respectively, which were not significant. Also (mean age

TABLE 1 Clinical characterization

	Case N (%)	*Control N (%)*	*p-Value*	*Significance*
Respiratory	10(14.71)	9(13.24)	0.805	Not significant
Gastrointestinal	3(4.41)	3(4.41)	1.000	Not significant
Cardiovascular	6(8.82)	5(7.35)	0.753	Not significant
Sepsis	1(1.47)	7(10.29)	0.026	Significant
Cerebrovascular accident	5(7.35)	12(17.65)	0.066	Not significant
Cardiopulmonary	4(5.88)	6(8.82)	0.510	Not significant
Multiorgan disease	9(13.24)	0(0)	0.001	Significant
End stage renal disease	1(1.47)	2(2.94)	0.559	Not significant
CKD with HF	1(1.47)	1(1.47)	1.000	Not significant
Hepatobiliary disease	2(2.94)	3(4.41)	0.648	Not significant
DM	1(1.47)	1(1.47)	1.000	Not significant
Diabetic complication	9(13.24)	4(5.88)	0.142	Not significant
Others	16(23.53)	15(22.06)	0.838	Not significant

± SD) between the two groups were (49.34±17.29) and (49.50±16.99), which were also not significant. So far as clinical characterization is concerned, in both the groups the differences in percentage of systematic involvement in all the categories were not significant except in sepsis of study group and multi-organ disease in control group **(Table 1)**.

On analysis of ABG measurement it was found that 12(17.6%) ABG were inaccurate by BE method. When the relation between pH&H^+ were matched in table, all 12 ABG were found accurate **(Table 2)**.

Moderate to severe hypoxemia were found in 10(14.72%) of patients. Type I respiratory failure were present in 5(7.35%) of patients. Type II respiratory failure were found in 9(13.2%) patients out of which 4(5.9%) were due to hypoventilation alone, 4(5.9%) with severe hypoxemia and 1(1.5%) with moderate hypoxemia.

Hyponatremia was present in 58(85.3%) patients and conspicuously one had hypernatremia. 13(19.17%) patients had hyperkalemia. Hypocalcaemia was a common finding. Hypochloremia was present in 4(6.2%) of patients.

Discussion

In my study, 17.6% of ABG were inaccurate by BE method while in general population difference between measured and derived HCO_3^- is 4.5% only.[6]

In my study, only 42.6% of patients had correct provisional diagnosis in ED. While in 80.9% of patients ABG diagnosis matched with the final clinical diagnosis. Around 19.1% of ABG were not compared to final clinical diagnosis because the patient either left or referred to higher center **(Table 3)**.

Different clinical characterizations of both groups were not significant except in sepsis and multi-organ disease group. Sepsis is a condition where there is multi-organ involvement commonly and in both the conditions mortality is high and almost equal[7] **(Table 1)**.

In 5.9% of severe hypoxemia pulse oxymeter was not useful.

The common acid-base disorders were respiratory 42(61.8%) among which the most common findings were acute or chronic respiratory alkalosis 21(50%). In the metabolic cause, acidosis was more than alkalosis **(Table 2)**. One (1.5%) of patients had no acid base disorder.

Acute exacerbation of chronic obstructive pulmonary disease (COPD) was provisionally diagnosed in 4.4% of patients, but only 1.5% had acute on chronic respiratory acidosis (acute exacerbation of COPD). Around 8.8% of patients were clinically diagnosed as COPD/cor pulmonale in which 3% had acute or chronic respiratory acidosis (acute exacerbation of COPD).

Provisional diagnosis	29	42.6
Final clinical diagnosis	55	80.9
Not available to match the clinical diagnosis	13	19.1
Total	68	100

TABLE 4 Primary outcome

	Case			*Control*				
	Frequency	*Percent*	*95% Conf. Interval*	*Frequency*	*Percent*	*95% Conf. Interval*	*p-Value*	*Significance*
Death	7	10.3	3.08–17.52	17	25	14.71–35.29	0.022	Significant
Discharged	42	61.8	50.25–73.35	30	44.1	32.3–55.9	0.036	Significant
LAMA	10	14.7	6.28–23.12	7	10.3	3.08–17.52	0.436	Not significant
Refer	9	13.2	5.15–21.25	14	20.6	10.99–30.21	0.25	Not significant

In 13(19.1%) of patients, ABG diagnosis were not matched with the final clinical diagnosis due to LAMA and referral of patients.

Death in study group were 7(10.3%), while in control group it was 17(25%), p-value 0.222, significant. Around 42(61.8%) of patients discharged in study group while 30(44.1%) were discharged in control, p-value 0.036, significant. LAMA were 10(14.75%) and 7(10.3%) in study and control group, respectively. Around 9(13.2%) and 14(20.6%) patients were referred in study and control group respectively which is not significant **(Table 4)**.

Around 10.3% patients died during therapy compared to 25% in control group **(Fig. 1)**, ABG predicted in almost all cases about the seriousness of the disease. In 5.9% patients of acute heart failure 2.9% had metabolic acidosis and died,[8] 1.5% had normal pH and 1.5% had alkalosis, they survived.[8] There was 1.5% case of AMI and pH was 7.25. In acute coronary syndrome if pH <7.3, mortality is expected to be 100%.[9]Around 2.9% had arrhythmia with acidosis, they succumbed during therapy. Acidosis contributes to the development of arrhythmia, and the patient is resistant to therapy in acidosis. One patient had CVA with altered sensorium and PaO_2 was 50 mm Hg. Commonly in such type of patients with CVA there is hyperventilation and PaO_2 should not be low but this was due to associated aspiration pneumonia. Around 1.5% of patients who died were a case of complex disease with pH 7.50, mortality is high in complex disease and pH >7.55.

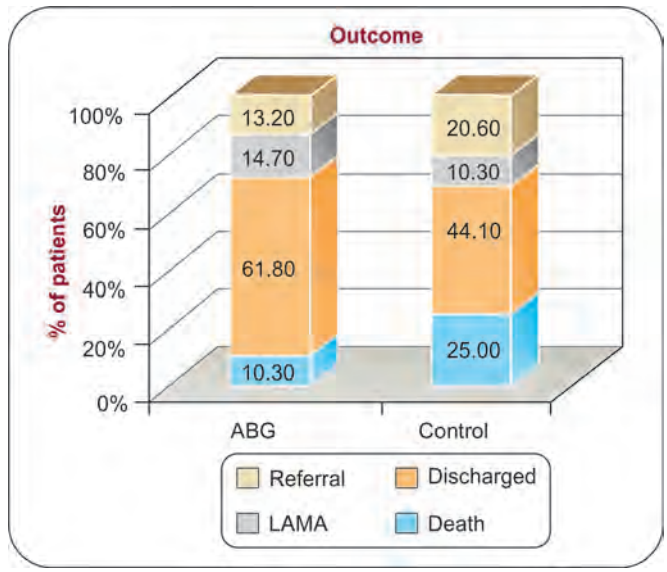

Fig. 1: Bar diagram of outcome in percentage

There were 4.4% of cases of acute exacerbation of COPD, 1.5% had pH 7.32 managed successfully with low FiO_2 and with Bi-Pap machine; 2(2.9%) patients had pH

7.12 and 7.21 in which 1 patient (1.5%) was associated with non-anion gap metabolic acidosis and treated with Bi-pap and improved; while the other needed ventilator but refused to give consent and left against medical advice.

Around 14(20.6%) patients were suffering from type I and type II respiratory failure together. Their causes were decided by algorithm and managed accordingly. ABG acted as monitor in all the 75% mixed disorder patients.[1] The outcome of the two groups shows that patients managed in the background of ABG findings had mortality less by 14.7% than control group, which is significant. The overall stay of the discharge patients were less in study group.[10]

Conclusion

Accuracy of ABG should be tested by different methods, if BE method fails. In this study, all ABG measurements were accurate. At ED in the hand of even an expert physician only about 50% of provisional diagnosis is correct. Around 81% of final clinical diagnosis matched with ABG diagnosis. From the time of admission proper management is started with ABG support in almost all cases, which may be a cause of better outcome. Almost all patients admitted through ED had ABG changes and thus indicated in all patients. In multi-organ disease (complex disease), the mortality is high. Measuring SpO_2 through pulse oxymeter become difficult in severe hypoxemia and only ABG can say about hypoxemic state of patients.

Respiratory alkalosis is common ABG finding. Around 21% patients were of respiratory failure and their cause is easily decided by algorithm and thus managed accordingly. Around 13% of patients admitted in ED are of COPD out of which 33% is diagnosed as acute exacerbation of COPD and when ABG matching is done 33% of them were wrong. ABG is accurate method to decide acute exacerbation of COPD.

ABG also acts as monitor even outside of ICU, particularly in mixed disorders. Management in the background of analyzed report of ABG reduces mortality significantly.

Analyzed report of ABG in ED is physician's necessity for management. In other word physician can proclaim ABG as "gold standard in ED."

CHAPTER

105 Hyperkalemia in ICU

SV Ramana Murty, TVSP Murthy, DJK Chakravarthy

Abstract

Hyperkalemia is a medical emergency and potentially life-threatening electrolyte disturbance. It usually presents in clinical setting of acute kidney injury, tumor lysis syndrome, major tissue damage like road traffic accidents or rhabdomyolysis. People above 60 years and those taking drugs like NSAIDs, Betablockers, and ACE inhibitors are at high risk. High index of clinical suspicion is required to diagnose hyperkalemia, since it may often be asymptomatic. All care should be taken while sending blood sample for serum potassium levels, since we may encounter pseudohyperkalemia. ECG changes usually correlate well with severity of hyperkalemia. Urgent measures are required when serum potassium is more than 7.5 mEq/L. Measures include immediate stabilization of myocardium with intravenous calcium gluconate and shift of Potassium from ECF to ICF by salbutamol nebulizations. Oral administration of ion exchange resins will reduce the serum potassium levels but slowly. We may have to go for hemodialysis in acute and severe cases. Simultaneously we have to address the original cause.

Introduction

Hyperkalemia is a medical emergency and potentially life-threatening electrolyte disorder especially in patients with renal disease, heart failure, and people using certain drugs like angiotensin converting enzyme (ACE) inhibitors, angiotensin-II receptor blockers (ARBs), beta-blockers, or non-steroidal anti-inflammatory drugs (NSAIDs). It is rare in healthy general population. Certain groups are at greater risk.

Why is It to be Addressed?

Acute severe hyperkalemia would become a life challenging and leads to dangerous cardiac arrhythmias and death if not attended to earliest.

Historical Background

- Sir Humphry Davy (1807), a British Chemist, coined the element, Potassium. It is called kalium in (Latin).
- However, Kalium is renamed as potassium. But in Periodic Table its symbol is retained as "K."
- Atomic number: 19; Element classification: Metal; Period number: 4; Molecular weight: 39.098 g/mol; and Valance: +1.

Etymology

- Derived from modern Latin word "*potassa*"
- *Potassa* + *ium*

Definition

- Hyperkalemia is defined as a plasma potassium level more than 5.5 mmol/L.
- There is no internationally accepted definition for hyperkalemia; The "European Resuscitation Council" defines hyperkalemia as a plasma level more than 5.5 mmol/L and severe hyperkalemia as more than 6.5 mmol/L.[1]

Basics

- Potassium is the principal intracellular cation 140–150mEq/L.
- The plasma (serum) potassium is 3.5–5.0 mEq/L, while the whole blood contains 50 mEq/L.
- Dietary potassium is absorbed cent percent through GIT and 90% is excreted through urine and 10% through faces.
- It maintains intracellular osmotic pressure.
- It is required for regulation of acid base balance and water balance in the cells.
- It is required for the activity of the enzyme "Pyruvate kinase."
- It is essential for transmission of nerve impulse, cardiac muscle activity, and biosynthesis of proteins by ribosomes.

Note:[2]

- The factors that enhance cell uptake of potassium from ECF compartment include: insulin, alkalosis, beta catecholamines, hyperosmolality, and cell damage.
- The factors that impair cell uptake of potassium from ECF compartment include: acidosis, chronic kidney disease, diabetes mellitus, and alpha catecholamines.

The Clinical Spectrum of Hyperkalemia Presenting in ICU, Requiring Immediate Care

Acute kidney injury, acute on chronic kidney disease, MODS **(Fig. 1)**, Acute necrotizing pancreatitis **(Fig. 2)**, septic abortion, burns, snake bite, muscle injury (rhabdomyolysis), Tumorlysis syndrome, sepsis, disseminated intravascular coagulation, metabolic acidosis, and hemolysis.

Epidemiology

- Most cases in hospitalized patients are due to chronic drug use and renal compromise.
- Risk factors include advanced age, significant prematurity and the presence of diabetes mellitus, heart failure, and sepsis.
- Hyperkalemia has been reported in 1.1–10% of all hospital admissions.[3]

Pseudohyperkalemia[4-6]

- Pseudohyperkalemia represents an artificially elevated potassium concentration in the plasma. This is due to movement of potassium (K^+) from the cells immediately prior to or following venepuncture.
- Pseudohyperkalemia is suspected when hyperkalemia is reported by laboratory in an asymptomatic individual with no obvious underlying cause and no ECG abnormalities.
- Faulty blood collection procedure, like excessive clenching of fist, prolonged tourniquet application during blood drawing, moisture in storage and delay in testing the blood sample, and gross change in room temperatures are some of the responsible factors.

Fig. 1: Male 45 years with thrombocytopenia, Hyperkalemia, MODS

Fig. 2: Male 38 years with acute pancreatitis, AKI, hyperkalemia, and MODS

Causes of Hyperkalemia

- Increased intake:
  - High potassium containing foods
  - Potassium containing drugs
  - Intravenous fluids containing potassium
- Tissue breakdown:
  - Catabolic state
  - Hemolysis
  - Rhabdomyolysis
  - Tumorlysis syndrome
  - Bleeding into soft tissues, body cavities
- Shift of potassium into extracellular fluid:
  - Metabolic acidosis
  - Tissue damage
  - Uncontrolled diabetes mellitus
  - Hyperkalemic periodic paralysis
- Impaired excretion:
  - Acute kidney injury
  - Potassium sparing diuretics
  - Reduced tubular excretion: Addison's disease
  - Reduced circulatory volume

Common Risk Factors

- Premature infants probably due to renal prematurity
- Males are more affected because of excess muscle mass
- Elderly people >60 years
- Military recruits, drug abusers, Sickle cell anemia; conditions with high risk for rhabdomyolysis
- Peripheral vascular disease

Drug use:

- Excess and chronic use of NSAIDs[7]
- Use of potassium sparing diuretics, beta-blockers, ACE inhibitors, ARBs especially with renal compromise[8]
- Direct renin inhibitors (e.g., Aliskiren)
- Cyclosporine or tacrolimus[9]
- Antibiotics (e.g., pentamidine and cotrimoxazole)
- Oral contraceptive pills
- Heparin therapy in bed ridden people

Foods Rich in Potassium (Fig. 3)

Vegetables: Potatoes, tomatoes, pumpkin, cooked spinach, Brussels sprouts

Fruits: Orange, banana, honey dew, prunes, raisins, other dried fruits

Other foods: Chocolate, nuts, seeds, peanut butter, onion, yogurt, bran products

Grading of Severity of Hyperkalemia

Hyperkalemia can be graded according to the serum concentration of potassium into:

- Mild 5.5–6.5 mmol/L
- Moderate 6.5–7.5 mmol/L
- Severe >7.5 mmol/L

Clinical Presentation

- Hyperkalemia is often asymptomatic, hence it can be called silent killer.
- Most patients are relatively asymptomatic with mild and even moderate hyperkalemia.
- Presentation may be nonspecific: with fatigue and vague muscular weakness. The patient may complain of tingling around lips or in fingers.

Physical Examination Findings

Physical signs vary as per the etiology and also serum potassium concentration:

- Pulse slow and usually irregular
- Hypertension and edema in the setting of renal disease
- Signs of hypoperfusion
- Shortness of breath, palpitations, chest pain, nausea, vomiting, and paresthesias
- Distension of abdomen and absent bowel sounds in case of acute necrotizing pancreatitis
- Muscle tenderness may be present in patients with rhabdomyolysis
- Jaundice may be seen in patients with hemolytic conditions, acute cholecystitis

Note:

- Symptoms usually develop at levels of 6.5–7 mEq /L
- But the rate of change is more important than the numerical value
- Individuals with chronic hyperkalemia may be asymptomatic relatively at higher level
- Whereas patients with a sudden rise of plasma potassium may develop severe symptoms relatively at lower values of potassium
- Neuromuscular manifestations include paresthesias and fasciculations in the arms and legs

Fig. 3: Fruits and vegetables rich in potassium

- As the serum K^+ continues to rise, an ascending paralysis with eventual flaccid quadriplegia supervenes. Classically, trunk, head, and respiratory muscles are spared. Cranial nerves least affected. However, respiratory failure can rarely occur.

ECG Manifestations of Hyperkalemia (Figs. 4A and B)[10]

Typical ECG findings in hyperkalemia include progress from tall, "peaked" T waves and a shortened QT interval to lengthening PR interval and loss of P waves, and then to widening of the QRS complex culminating in a "sine wave" morphology and death if not treated.

Diagnosis

Diagnosis of hyperkalemia depends on:

- Clinical suspicion
- Serum potassium concentration
- Characteristic ECG manifestations

Note:

- Beware of pseudohyperkalemia
- Then etiology should be recognized

Hence the investigations should envisage:

- Whether true hyperkalemia is present?
- How much severe it is?
- What is its etiology?
- Risk factors if any?

Investigations

- Serum electrolytes: Sodium, potassium, magnesium, calcium, chloride
- Blood urea, serum creatinine, bicarbonate (when Tumorlysis syndrome is suspected)
- Creatine kinase (especially when Rhabdomyolysis is suspected)
- Serum amylase, liver enzymes
- Baseline 12 lead ECG, and later repeat ECGs
- Serum cortisol levels
- Arterial blood gas report
- Ultrasound scan of abdomen
- CT scan abdomen, MRI abdomen depending on the clinical setting
- Urine complete analysis, urine electrolytes
- Complete blood counts
- Microbiological tests depending on suspected multiple organ failure or sepsis
- Blood hematology, if disseminated intravscular coagulation is suspected

Note: Clinical setting along with comorbid history, should guide the investigations required for workup of a case toward assessing the severity of hyperkalemia, and clinical background

Transtubular Potassium Gradient (TTKG)[11]

- Estimation of TTKG can reveal whether hyperkalemia is due to renal cause or extra renal cause and mineralocorticoid bioactivity in people with hyperkalemia
- TTKG value <6 suggests renal cause
- TTKG value >6 suggests extra renal cause
- Typical TTKG on normal diet is 8–9
- TTKG <5 in presence of hyperkalemia may indicate mineralocorticoid deficiency

$$\text{TTKG} = \frac{\text{Urinary } K^+}{\text{Serum } K^+} \times \frac{\text{Serum osmolality}}{\text{Urine osmolality}}$$

Emergency Management

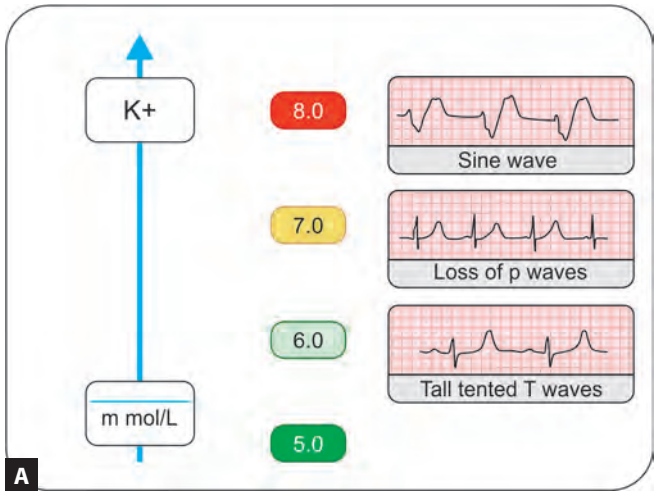
- Acute rise in serum potassium is a medical emergency
- Urgent treatment is required in cases of potentially fatal hyperkalemia, that is, serum K^+ >7.5 mEq/L

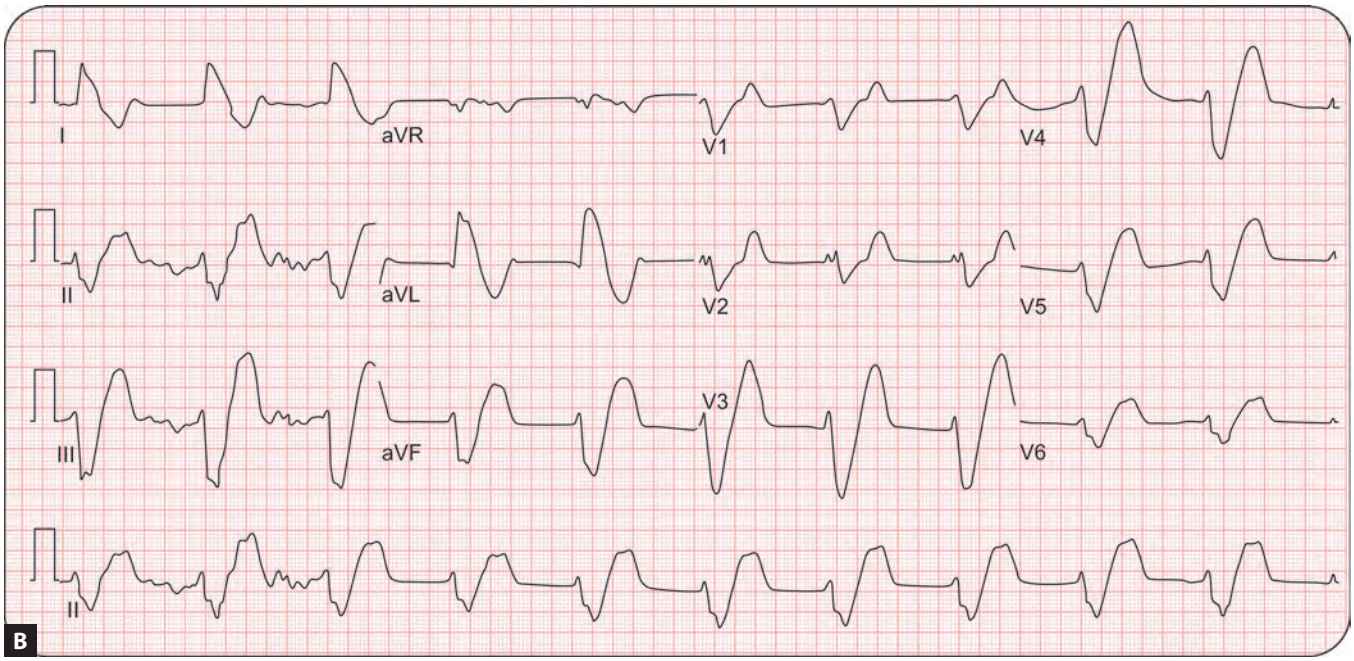
Basic principles of acute management of severe hyperkalemia in ICU:

- Stabilization of myocardium
- Shift of extracellular fluid (ECF) potassium to intracellular fluid (ICF)
- Removal of the excess potassium from the body

Stabilization of myocardium (to be done under cardiac monitoring) to prevent dangerous ventricular arrhythmias:[12]

- Inj. Calcium gluconate (10% solution) 10– 20 mL to be given iv over 5–10 minutes, or
- Inj. Calcium chloride 5 mL of 10% solution over 2 minutes
- However, calcium chloride can cause tissue necrosis if it extravasates and requires a central line
- The dose can be repeated after 5–10 minutes, if there is no change in ECG





Figs. 4A and B: (A) Typical ECG changes in Hyperkalemia (Serial changes as the serum potassium raises). (B) ECG showing changes of Hyperkalemia (Sine wave pattern) in male 45 years, DKA with serum potassium 7.9 mmol/L

- Calcium antagonizes the cardiac and neurological effects of hyperkalemia and prevents cardiac toxicity and dangerous cardiac arrhythmias
- It should be noted that calcium gluconate does not reduce plasma potassium

Shift of ECF potassium to ICF:

- Insulin and glucose infusion
- Beta 2 adrenergic agonists
- Alkalinizing agents

Insulin and glucose infusion:[13]

- Administer regular insulin 10 units as iv bolus + 50% dextrose 50 mL as iv bolus
- Onset of action is within 15–30 minutes and action lasts for 2–6 hours
- Initial bolus of glucose insulin should be followed by continuous infusion of 5% dextrose at 100 mL/hour to prevent late hypoglycemia
- Insulin—dextrose is treatment of choice in case hyperkalemia with end stage renal disease (ESRD)

- The plasma potassium concentration will fall by 0.5–1.5 mEq/L. This effect begins in 15 minutes and usually lasts for 4–6 hours
- In diabetic patients avoid extra dextrose infusion

Alkalinizing agents:

- One ampoule of sodium bicarbonate 7.5% providing 44.6 meq is given over 5 minutes or better added to 5% glucose infusion
- Onset of action is within 5–10 minutes and the effect lasts for 1–2 hours
- However, the use of alkalinizing agent is controversial and contra indicated in patients with ESRD

Note:

- When there is associated metabolic acidosis like in Tumorlysis syndrome alkali therapy can be used
- It should not be advocated in cases of ESRD

Beta 2 adrenergic agonists (Salbutamol, Ventolin, or Albuterol):[14]

- Salbutamol is given in a nebulized form
- 5 mg of salbutamol mixed with 3–4 mL of normal saline and administered through a high flow nebulizer over 10 minutes
- It generally becomes effective in 30–60 minutes and its effect persists for 2–4 hours
- It lowers serum potassium by 0.5–1.5 mEq/L

Rationale

Beta 2 agonists such as salbutamol promote cellular uptake of potassium and effectively lowers serum potassium level

Removal of the Excess Potassium from the Body

- Loop or thiazide diuretics
- Cation exchange resins
- Dialysis

Loop diuretic:

- Fruesimide 40–80 mg iv, the onset of action within 15 minutes, lower value of K^+ maintained for 2–3 hours
- Hydrochlorothiazide can be given in mild cases
- Potassium sparing diuretics contraindicated

Cation exchange resin:[15]

- Cation exchange resins, such as sodium polystyrene sulfonate (SPS) (kayexalate) promote the exchange of sodium for potassium in gastrointestinal tract
- Each gram binds 1 mEq of potassium and releases 2–3 mEq of sodium
- When given orally the usual dose is 25–30 gm mixed with 100 mL of 20% sorbitol 3–4 times daily (sorbitol prevents constipation)
- Onset of action more than 2 hours, and maintained for 4–6 hours
- It can also be given as retention enema consisting of 50 gm of resins and 50 mL of 70% sorbitol mixed in 150 mL of water every 4–6 hourly
- In general each enema can lower the plasma potassium concentration by 0.5–1.0 mEq/L within 1–2 hours and effect will last for 4–6 hours

Adverse effects of resins:

- Anorexia, nausea, vomiting, and constipation
- Intestinal necrosis typically of colon or ileum is a rare but fatal complication of SPS. Intestinal necrosis is more common in patients with reduced intestinal motility (in postoperative state)

Note: Patiromer is a non-absorbed polymer provided as a powder for suspension which binds potassium in exchange of calcium.

Dialysis[16]

- Emergency dialysis is a final measure for lethal hyperkalemia that has not responded to more conservative measures or for patients who had chronic renal failure.
- The most rapid and effective way of lowering the plasma potassium concentration is hemodialysis, which can produce a 1 mEq/L drop in serum potassium after 1 hour, and 2 mEq/L drop after 3 hours.
- Peritoneal dialysis also removes potassium but is only 15–20% as effective as hemodialysis.
- Patients with acute kidney injury require temporary but urgent venous access for hemodialysis.

Conclusion

In ICUs, we often come across electrolyte disturbances. Hyperkalemia may sometimes present silently. Hence, one should have a high index of clinical suspicion and act accordingly. Calcium gluconate, for membrane stabilization and β2-agonists, and insulin with glucose to be used in the treatment of hyperkalemia to induce a redistribution of K^+, and dialysis to be reserved for cases with severe hyperkalemia and renal compromise. The workup depends more so on the clinical background.

Respiratory Disease

CHAPTER

106 Allergic Bronchopulmonary Aspergillosis: Diagnosis and Treatment

Rajendra Prasad, Rishabh Kacker, Nikhil Gupta

Abstract

Aspergillus is ubiquitous, occurring in mycelial form and grows at 15–53°C and humid conditions. Pulmonary aspergillosis is a clinical spectrum of lung disease caused by the fungus Aspergillus. ABPA is the commonest disease among allergic bronchopulmonary mycosis. The exact prevalence of ABPA is not known but contemporary estimates suggested that ABPA complicates 1–11% of all chronic cases of bronchial asthma. The basic underlying immuno-pathophysiologic process in ABPA is a hypersensitivity reaction to fungus in the bronchial tree. Patients are usually atopic with previous history of bronchial asthma. The onset is insidious with constitutional symptoms like anorexia, fatigue, weight loss, headache, generalized aches and pains, and low-grade fever. It is characterized by repeated episodes of exacerbation with periods of remission, if untreated may progress to fibrotic lung disease. Patients with chronic fibrotic disease may present with cyanosis, cor pulmonale, and respiratory failure. Radiologically fleeting shadows are characteristic of ABPA. Bronchiectasis, centrilobular nodules and mucoid impaction are main features of ABPA seen in CT scan thorax. Oral corticosteroid remains the cornerstone for the treatment of ABPA. Optimization of baseline asthma therapy is essential. Early diagnosis and proper treatment may alter the prognosis of disease and further prevent end stage lung fibrosis.

Introduction

Aspergillus is a ubiquitous fungi, which most commonly occurs in mycelial form, is thermo tolerant and grows at 15–53°C, the optimum being 37–40°C, and favoring humid conditions. Pulmonary aspergillosis is a clinical spectrum of lung disease caused by the fungus Aspergillus. The classification of pulmonary aspergillosis includes saprophytic aspergillosis in the form of pulmonary aspergilloma, immune disease in the form of allergic bronchopulmonary aspergillosis (ABPA), IgE mediated asthma, hypersensitivity pneumonitis, allergic Aspergillus sinusitis (AAS), and infectious disease in the form of invasive and semi-invasive pulmonary aspergillosis.[1] ABPA is considered to be the commonest manifestation amongst allergic bronchopulmonary mycosis. ABPA is characterized by a hypersensitivity immunological reaction which is most commonly caused by *Aspergillus fumigatus* in about 95% of the cases and rarely by *Aspergillus flavus, Aspergillus niger, Aspergillus oryzae, Aspergillus sydowi, Aspergillus terreus, Aspergillus glaucus, Aspergillus nidulans,* and *Aspergillus clavatus*. Other fungi such as Candida, Helminthosporium, Curvularia, Drechslera, Pseudallescheria boydii, and Fusarium vasinfectum have also been found to cause an identical syndrome.[2] ABPA clinically manifests as chronic asthma, recurrent pulmonary infiltrates, and bronchiectasis.[3-11] The condition has immunologic features of immediate hypersensitivity (Type I), antigen-antibody complexes (Type III), and eosinophil-rich inflammatory cell responses (Type IVb), based on the revised Gel and Coombs classification of immunologic hypersensitivity.[12,13] ABPA was first reported in England[14] in 1952 and in India[15] in 1971. Since then, a

large number of cases have been reported from various parts of the world. Concomitant occurrence of ABPA and AAS is now being increasingly recognized which is also called as "sinobronchial allergic mycosis" syndrome.[16] ABPA is commonly associated in patients with chronic bronchial asthma and cystic fibrosis but can also occur in non-asthmatics.[17] The aim of the present write-up is to discuss the prevalence, clinical presentation, diagnosis, and treatment of ABPA.

Prevalence of Allergic Bronchopulmonary Aspergillosis

The prevalence of ABPA is highly variable complicating 1–11% of all chronic cases of bronchial asthma.[18-26] A very recent study from India, however, found a higher prevalence of Aspergillus sensitization (39.5%) and ABPA (27%) in 564 patients with asthma.[27] A study by Alok Nath et al. on 350 patients found the prevalence of Aspergillus hypersensitivity (AH) and ABPA to be 35.1% and 21.7%, respectively.[28] The condition is being increasingly recognized and the estimated prevalence rates in recent publications have been reported ranging from 5.9% to 20.5% for ABPA and 38% to 43% for AH.[29,30] A study in northern India was conducted to determine the prevalence of ABPA in patients of bronchial asthma where 244 patients were recruited consecutively over a period of 3 years and were analyzed prospectively by clinical evaluation, chest radiography, skin test, sputum culture for fungus, and serum precipitin test. Those patients with further suspicion of ABPA were further investigated by serum titers of specific IgG and IgE against *A. fumigatus*. The diagnosis of ABPA was made on predetermined major and minor criteria, where at least five major criteria had to be present. ABPA was seen in 7.4% patients with bronchial asthma.[26]

Immunopathology of Allergic Bronchopulmonary Aspergillosis

Majority of patients with ABPA are atopic with history of bronchial asthma. The pathogenesis of ABPA circles around a hypersensitivity reaction to the fungal spores and mycelial fragments of *A. fumigatus* present in the bronchial tree. Atopic individuals after inhalation of fungal spores in the bronchi result in the fungi to germinate and form vegetative elements (hyphae). Local immunologic reactions and stagnation of tenacious sputum in bronchial airways favor the trapping of fungal spores and further colonization. Antigenic substance of the fungus stimulates formation of IgE, IgG, and IgA antibodies. ABPA is immunologically classified as it gives both Type I (immediate) and Type III (Arthus, antigen-antibody immune complex) hypersensitivity reactions. Type I reaction is IgE mediated and responsible for accumulation of eosinophils, bronchospasm, edema leading to acute symptoms of diseases. Type III reaction results in polymorph aggregation, inflammation of bronchial, and peribronchial tissues and is responsible for the radiological features of ABPA. Recently, possible role of Type IVb[12,13] hypersensitivity reaction has also been observed in patients with ABPA and the presence of parenchymal granuloma and mononuclear cell infiltration seen on histopathology. Long-standing involvement of the bronchial tree leads to bronchiectasis, fibrosis, lung contraction, and lobar shrinkage.[9]

Clinical Presentation

The clinical picture of ABPA is dominated by asthma and recurrent exacerbations. The onset is insidious with constitutional symptoms like anorexia, fatigue, weight loss, headache, generalized aches and pains, and low-grade fever. Asthma is generally uncontrolled with usual anti-asthmatic therapy. It is characterized by repeated episodes of exacerbation with periods of remission in between and if untreated may progress to end stage fibrotic lung disease. It may occur at any age but is usually more prevalent in the age group of 20–40 years. Patients with chronic fibrotic disease may present with cyanosis, cor pulmonale, and respiratory failure. However, symptoms have little or no relationship to severity or chronicity of the disease, as one-third patients may be relatively asymptomatic in spite of extensive radiological shadows.[31] Expectoration of brownish mucus plugs is characteristic and has been reported in 5–54% of cases.[25] These plugs consist of fungal hyphae with eosinophils and mucous. Cough, breathlessness, and wheezing are common symptoms seen in ABPA. Hemoptysis has been reported in approximately 34–85% of cases, while pleuritic chest pain may be present in 50% of cases. In one of his study author found that hemoptysis was found in 28.6% of patients.[32] Chronic cases of ABPA may rarely present with symptoms of bronchiectasis.

On clinical examination of chest, wheezing and diffuse crepitations are the common findings but tachypnea, cyanosis, features of cor pulmonale, and sometimes hypertrophic osteoarthropathy may be seen. The disease is often misdiagnosed as tuberculosis, bronchiectasis, and bacterial pneumonia.[9] Almost half of the ABPA patients are initially misdiagnosed as pulmonary tuberculosis.[27]

Diagnostic Approach

ABPA should be suspected in any patient with asthma and parenchymal infiltrates on chest radiograph accompanied with peripheral blood eosinophilia. Not all features are required in order to diagnose ABPA. The important diagnostic criteria are the presence of recurrent pulmonary infiltrates, peripheral blood eosinophilia and positive skin test to Aspergillus antigen or positive specific IgE against *A. fumigatus*.

Radiological Features

Chest X-ray

Radiological features in patients of ABPA may be transient (acute) or permanent (chronic). Transient shadows may clear with or without steroid therapy and are mainly due to pulmonary infiltrates and stagnation of mucus in damaged bronchi.[33,34] Transient shadows are perihilar infiltrates mimicking adenopathy, air fluid levels from dilated central bronchi filled with fluid and debris. Parenchymal abnormalities are more common and present in 80–90% patients of ABPA as ill-defined homogenous shadows without evidence of loss of volume which may be of 5–15 mm in size or more as massive/lobar in extent, may be unilateral or bilateral, more in upper lobes, resolve (fleeting/migratory shadows) often after expectoration of bronchial plugs but tends to recur in same/other places. Sometimes pulmonary shadows may mimic carcinoma. Fleeting opacities are characteristic of ABPA. Author in one of his studies found that 66.7% patients had fleeting shadows. Author described "walking pneumonia" as a clue to diagnosis of ABPA.[35] Bronchial abnormalities occur in 50–70% of episodes of acute ABPA consists of tramline, parallel lines, ring shadows, and toothpaste shadows which represent normal or abnormal bronchial wall. The impacted bronchus may appear as full wine glass having an open upper end with tapering lower end,[36] gloved finger 2–3 centimeter long and 5–8 mm wide, and inverted V, Y, or toothpaste shadows. Gloved-finger shadows are due to distally occluded bronchi filled with secretions. Tram lime shadows are the thickened walls of undilated bronchi, so the distance between lines is that of a normal bronchus while parallel lines shadows represent walls of bronchiectatic bronchi, the distance between walls is greater than normal. Permanent (chronic) changes reflect histological abnormalities secondary to repeated acute episodes of ABPA, and are often associated with physiologic abnormalities. Rarely cavitations, local emphysema, pulmonary fibrosis or contracted upper lobe, honeycombing, collapse due to mucous impaction, and spontaneous pneumothorax.

Computed Tomography

High resolution computed tomography (HRCT) has been shown to be more sensitive than the plain chest radiograph and might be useful in the assessment of extent of disease. It is a sensitive noninvasive technique for the recognition of ABPA. Central bronchiectasis occurs due to the deposition of immune complex in proximal airways. Bronchiectasis, centrilobular nodules and mucoid impaction are main features of ABPA.[37] Central bronchiectasis with ABPA may be seen in 40% patients [38] and is characterized by string of pearls and signet ring appearance as described by Webb et al.[39] Central bronchiectasis (in 2nd, 3rd, 4th order large bronchi) is an important diagnostic feature of ABPA with normal small bronchi and bronchioles.[40] Because of the lack of specificity of central bronchiectasis in diagnosis of ABPA and the fact that a significant proportion of patients with ABPA have "peripheral" bronchiectasis, the term central has been suggested to be removed by the recent expert group.[38] An important HRCT finding, considered pathognomonic for ABPA, is airway plugging with high attenuation mucus (HAM).[41-45] HRCT of the chest is found to be normal in a third of the patients; in that case they are labeled as ABPA-S.[27]

Radiological Classification of Allergic Bronchopulmonary Aspergillosis

Serological ABPA (ABPA-S) (mild), ABPA-central bronchiectasis (ABPA-CB) (moderate), and ABPA-CB-other radiologic findings (ORF).[46] In ABPA-S all the diagnostic features of ABPA are present except evidence of central bronchiectasis on HRCT. It is believed that patients with ABPA-S have milder clinical course and

less severe immunological findings when compared to ABPA-CB. In ABPA-CB all findings of ABPA including central bronchiectasis on HRCT present however in ABPA-CB-ORF all findings of ABPA and CB along with other radiological features such as pulmonary fibrosis, bleb, bullae, pneumothorax, parenchymal scarring, emphysematous change, multiple cyst, fibrocavitory lesions, Aspergilloma, ground glass appearance, collapse, mediastinal lymph node, pleural effusion, and pleural thickening. Newly proposed radiological classification of ABPA based on computed tomography chest findings, categorizes ABPA as ABPA-S, ABPA with bronchiectasis, ABPA with HAM and ABPA with chronic pleuropulmonary fibrosis.

Laboratory Investigations

- A peripheral blood eosinophil count >1,000 cells/μL has been used as a threshold in the diagnosis of ABPA. However, as many as 60% of patients with ABPA present with a eosinophil count <1,000 cells/μL at diagnosis, and a quarter of ABPA patients have a count <500 cells/μL. In a recent study, the sensitivity and specificity of eosinophil count >1000 cells/μL were found to be approximately 30% and 93%, respectively, for the diagnosis of ABPA among asthmatics.[47] Due to the poor sensitivity of this cut off, an eosinophil count >500 cells/μL is proposed as the limit in the recent diagnostic criteria.[48]
- *Serological tests:* Increase in total IgE and specific IgE and IgG precipitating antibodies against *A. fumigatus*. Both total and specific IgE levels are high during development of pulmonary infiltrates and decrease after remission. The total IgE levels are >1,000 IU/mL may be as high as 20,000 IU/mL in acute cases except in cases that are in remission or on steroids therapy. Precipitating antibodies against *A. fumigatus* are present in most of cases of ABPA with pulmonary infiltrates and diminished after steroid therapy.
- *Skin test:* Positive skin tests (Type 1 and Type 3) are more reliable than precipitin tests. Immediate type 1, skin reaction is positive in most of the cases but also positive in 25% of asthmatics without ABPA. Late onset (Type 3) erythema and edema occur usually after 4–6 hours and reache at peak within 8 hours and subside by 24 hours due to deposition of IgE, IgM, IgA, and complement components.
- *Sputum smear and culture for Aspergillus:* Nearly two-thirds of patients of ABPA show positive smear and culture for Aspergillus, positive culture with Aspergillus species in sputum has been reported in 58% cases of ABPA.[9]
- *Pulmonary function test:* Is neither sensitive nor specific and does not help to define the extent of disease or exclude it, during remission patient may have normal lung function even in presence of bronchiectasis. The status depends upon the stage at which they are performed. Acute and chronic pulmonary function changes in ABPA have been described. In acute episodes obstructive changes are observed, while during irreversible stages with bronchiectasis and fibrosis restrictive changes are found. In chronic-cases diffusion capacity is reduced.

Classical Diagnostic Criteria for Allergic Bronchopulmonary Aspergillosis[4]

Major Criteria

Bronchial asthma, radiological pulmonary infiltrates, immediate skin test positivity to *A. fumigatus* antigen, elevated total serum IgE, precipitating antibodies against *A. fumigatus* antigen, peripheral blood eosinophilia, elevated serum IgE and IgG against *A. fumigates*, and central/proximal bronchiectasis with normal tapering of distal bronchi.

Minor Criteria

History of expectorating golden brown plugs in sputum, positive sputum smear and culture for Aspergillus species and Type III (Arthus) skin reactivity to *A. fumigatus*.

The presence of six of eight major criteria makes the diagnosis almost certain and latest criteria do not differentiates in major and minor, eight diagnostic criteria are laid down to detect ABPA suggested by Patterson et al. 1997[6] are: Asthma (mild or severe) or cystic fibrosis, immediate cutaneous reactivity to Aspergillus antigen, current or previous pulmonary infiltrates, elevated total IgE concentration (>l mg/L), precipitin antibodies to *A. fumigatus*, peripheral blood eosinophilia, elevated serum IgE and/or IgG-against *A. fumigatus* and central bronchiectasis.

Since, previous ABPA diagnostic criteria lacked a consistent case definition, International Society for

Human and Animal Mycology (ISHAM) criteria for ABPA diagnosis in asthmatics was published in 2013, which included:[48]

- Obligatory criteria (both should be present):
  - Total IgE >1,000IU/mL
  - Positive Aspergillus specific (Af) IgE or skin prick test
- Other criteria (2 out of 3):
  - Raised Af IgG or precipitins
  - Eosinophils >500 cells/uL
  - Radiological features consistent with ABPA

Staging of Allergic Bronchopulmonary Aspergillosis

Five stages of allergic bronchopulmonary aspergillosis have been described according to Patterson et al.:[6]

- *Acute stage:* Symptoms consistent with ABPA and fulfilling the diagnostic criteria of ABPA.
- *Remission:* Control of respiratory symptoms with radiological clearing and decline in IgE levels.
- *Exacerbation:* Clinical and/or radiological deterioration associated with an increase in IgE by >50%.
- *Steroid dependent asthma:* Patient requires oral or parenteral glucocorticoids for the control of asthma.
- *Fibrosis:* Manifestations of fibrotic lung disease.

Also, a revised classification was proposed by Agarwal et al. in 2013, which divided ABPA into seven stages:[48]

- *Stage 0 asymptomatic:* No previous diagnosis of ABPA with well controlled asthma and fulfilling the diagnostic criteria of ABPA.
- *Stage 1 acute:* Symptoms consistent with ABPA and fulfilling the diagnostic criteria of ABPA. *Stage 1a:* With mucoid impaction on thoracic imaging. *Stage 1b:* Without mucoid impaction on thoracic imaging.
- *Stage 2 response:* Clinical and/or radiological improvement with decline in total serum IgE level by ≥25%.
- *Stage 3 exacerbation:* Clinical and/or radiological deterioration associated with an increase in IgE by >50%.
- *Stage 4 remission:* Sustained clinical and radiological improvement with total serum IgE levels persisting at or below baseline for ≥6 months off treatment.
- *Stage 5a (Treatment dependent ABPA):* Two or more exacerbations within 6 months of stopping therapy or clinical and/or radiological worsening, along with increase in total serum IgE levels. *Stage 5b (Glucocorticoid dependent asthma):* Patient requires oral or parenteral glucocorticoids for the control of asthma.
- *Stage 6 advanced ABPA:* Extensive bronchiectasis on chest imaging along with either cor pulmonale and/or chronic type II respiratory failure.

Treatment of Allergic Bronchopulmonary Aspergillosis

Oral corticosteroid remains the cornerstone for the treatment of ABPA.[49] The goal of therapy is to achieve symptom resolution, clearance of radiographic infiltrates, and establishment of a stable baseline serum level of total IgE. There are two dose schedules of oral glucocorticoid therapy, low dose, and high dose. In low dose oral glucocorticoid therapy, prednisolone 0.5 mg/kg/day is given for 2 weeks, then on alternate day for 6–8 weeks and then tapered 5–10 mg every 2 weeks and then discontinued. In high dose glucocorticoid therapy, prednisolone 0.75 mg/kg is given for 6 weeks, followed by 0.5 mg/kg for 6 weeks, then taper 5 mg every 6 weeks to continue for a total of at least 6–12 months. Repeat chest X-ray in 1 month should demonstrate clearing of the infiltrates. The total serum IgE level also regresses along with the infiltrates. The failure of the total serum IgE level to decrease suggests continuation of active disease and requires additional corticosteroids. The total serum IgE level, chest X-ray, absolute eosinophil count should then be followed at 6–8 weeks of interval regularly. The goal of glucocorticoid therapy is not normalization of total serum IgE but reduction in total serum. IgE by 35–50% from baseline defines remission by 6 weeks. Serial total serum IgE levels are important for follow-up care.[48] Patients who have remission of ABPA may discontinue prednisone. The remission may last for years or may be permanent. In patients with recurrent flares of ABPA or in those with severe persistent asthma, long-term corticosteroid therapy may be necessary to control their symptoms. Patients in the fibrotic stage of ABPA may have increased sputum volume as a result of infection. Measures such as postural drainage and antibiotics may be useful, but with deterioration, exercise tolerance decreases, and oxygen therapy may be needed. Optimization of baseline asthma therapy is essential with inhaled corticosteroid and β2

agonists. In addition, prophylactic measures should be instituted when indicated to prevent the adverse effects of long-term corticosteroid treatment such as osteoporosis. Thus, patients who take prednisolone for more than 2–3 months should be considered for bone mineral density analysis to direct commencement of calcium/vitamin D supplementation with or without bisphosphonates.[50]

Alternative to Corticosteroid Treatment

Even though oral corticosteroid is the treatment of choice in ABPA, the fact that it is associated with numerous adverse effects cannot be neglected. Inhaled corticosteroids are associated with fewer side effects, and hence considering them as a viable treatment option for ABPA seems appropriate. Not a lot of studies have been conducted to evaluate the role of inhaled corticosteroids in the management of ABPA. Inhaled corticosteroids, while useful for concomitant asthma management in patients with ABPA, do not control the pathophysiology or clinical manifestations of ABPA.[51-53] In contrast to the inhaled corticosteroid therapy "pulse" therapy (10–20 mg/kg/day IV methylprednisolone infused on three consecutive days every 3–4 weeks) was found out to be generally safe and effective in two open labeled series of thirteen steroid dependent ABPA CF patients.[54,55]

Anti-fungal Drugs

The most efficacious alternative to long-term oral corticosteroids is the use of antifungal agents either in conjunction to the steroid therapy or even as a standalone therapy. Use of antifungal therapy in the treatment of ABPA is based on the assumption that allergic inflammatory responses arise in part from noninvasive airway fungal infection. Pooled analysis showed that itraconazole could significantly decrease IgE levels by >25% when compared to placebo, reduction in steroid dose by ≥50%; increase in exercise tolerance by ≥25%, improvement of ≥25% in results of spirometry, resolution of pulmonary opacities but failed to reach statistical significance, and did not cause significant improvement in lung function. Itraconazole modified the immunologic activation associated with ABPA and improve clinical outcome at least over the period of 16 weeks. The effectiveness of itraconazole in the treatment of ABPA was also demonstrated in two randomized, double-blind, placebo controlled trials in patients with asthma.[56,57] Also, a randomized trial of itraconazole versus prednisolone in acute stage ABPA found out that oral glucocorticoids were more effective than itraconazole monotherapy in producing treatment response.[58] At present, itraconazole should be limited in cases where oral steroids are contraindicated or refused by patients. The use of azoles for ABPA in asthma patients was reviewed by the Cochrane collaboration which suggested that itraconazole modifies the immunologic activation associated with ABPA and improves the clinical outcome, at least over a period of 16 weeks, though adrenal suppression with inhaled corticosteroids and itraconazole is a potential concern.[59] Newer generation triazoles such as voriconazole and posaconazole have also been reported as beneficial in the treatment of ABPA. Treatment with voriconazole as a monotherapy was shown to be associated with improvements in clinical status, lung function, and serologies.[60] A newer agent isavuconazole has been shown to be effective in a study conducted by Jacobs et al. in a patient of ABPA who was successfully treated with marked improvement and minimal adverse effects.[61]

Alternatives to Azoles

Amphotericin deoxycholate has been frequently used via inhalational route in the treatment of pulmonary fungal infection, primarily in the setting of cancer treatment and lung transplantation. Amphotericin B can be delivered via nebulization to the lower respiratory tract in doses which are capable enough to exceed the minimal inhibitory concentration of Aspergillus in the epithelial lining.[62] However, data regarding the efficacy of amphotericin B is pretty scarce as of now and thus more studies need to be conducted in order to determine its actual role in the treatment of ABPA.

Omalizumab

Omalizumab is a recombinant humanized IgG1 monoclonal antibody that binds IgE with high affinity and has been associated with improvement in symptoms, reduction in exacerbations, asthma hospitalizations, improvement in lung function, and reduction in dose of oral steroids.[48] However, a recent retrospective series conducted in France has found variable results in 32 patients of ABPA with cystic fibrosis, which though reported a reduction in the steroid need over a 21-month observation period, but there was no significant improvement in the lung function or the use of antibiotics.[63]

Conclusion

Presently ABPA is one of the important emerging immunologically mediated respiratory diseases, commonly presenting in patients of asthma. It should be highly suspected in patients presenting with history of asthma, peripheral blood eosinophilia, recurrent pneumonitis, or transient (fleeting) pulmonary infiltrates mimicking pulmonary tuberculosis. In such suspected patients, detailed evaluations are needed to prove the diagnosis. Early diagnosis and proper treatment may alter the prognosis of disease and further prevent end stage lung fibrosis.

CHAPTER

107 Obstructive Sleep Apnea

Puneet Rijhwani, Aviral Gupta

Abstract

Obstructive sleep apnea is a severe form of sleep disordered breathing, which affects over 9% of middle aged urban Indians. Male sex, obesity, age, upper airway and craniofacial anomalies, genetic, and other environmental factors, particularly ambient air pollution are risk factors for OSA. These factors result in upper airway collapse during sleep, leading to obstructive respiratory events and symptoms of OSA, such as excessive daytime sleepiness, nocturnal breathing disturbances, morning headaches, and many more. Home sleep apnea testing or polysomnography is diagnostic. A plethora of complications can result from OSA, including metabolic, cardiovascular, cerebrovascular, and neuropsychiatric complications. Obese patients with OSA should be encouraged for weight loss, and other lifestyle modifications. Positive airway pressure therapy is the cornerstone of management of the disease; with only some patients requiring surgical management.

Introduction

Sleep disordered breathing is an umbrella term, consisting of disorders characterized by an abnormal respiratory pattern during sleep, which may coexist with other respiratory, cardiovascular, nervous, or endocrine diseases. It encompasses conditions ranging from snoring at the mild end of the spectrum to obstructive sleep apnea (OSA) at the severe end.

There are three main types of sleep apnea:

- Obstructive sleep apnea (OSA), seen in more than 80% of sleep apnea patients, occurs due to blockage of air from entering and leaving the lungs.
- *Central sleep apnea (CSA)*, occurs when the brain stops responding to breathe until it senses a lack of O_2 and/or a increased level of CO_2 that needs to be exhaled.
- *Complex sleep apnea* is a combination of these two.

OSA or hypopnea syndrome is the most common sleep-related breathing disorder. It is caused by repetitive collapse of the upper airway during sleep and is characterized by obstructive apneas, hypopneas, and/or respiratory effort related arousals (RERA). It leads to daytime sleepiness, behavioral problems in children, increases cardiovascular risk in adults, and can be factor in work place or motor vehicle accidents.

Epidemiology and Risk Factors

The prevalence of OSA is high and on a rising trend due to the increasing rates of obesity in the world.[1] A literature-based analysis to estimate the global prevalence of OSA suggested that nearly 1 billion adults in the age group of 30–69 years were affected, with India standing at the fourth spot among the countries with the highest burden.[2]

Male sex is a major risk factor, with the prevalence of sleep disordered breathing estimated at 24% for men and 9% for women aged 30–60 years,[3] with 4% of men and 2% of women meeting the minimal diagnostic criteria for sleep apnea syndrome;[4] later estimates reaching up to 4%

for women and 9% for men.[3] An Indian study conducted among middle-aged urban Indians estimated an overall prevalence of OSA at 9.3% (Men—13.5%; Women—5.5%).[5] OSA is thus two to four times more common in males than females, but the risk appears to become similar to men in postmenopausal women.[6]

Obesity is the second major risk factor for development of OSA. Up to 60% of patients with OSA are overweight or obese.[7] A high body mass index (BMI) is associated with a higher risk for OSA, with BMI being more strongly associated to OSA in younger adults.[1] A substantial decrease in OSA severity following weight loss has been demonstrated, and longitudinal analysis indicate that a 10% increase in weight leads to sixfold increase in the risk of developing moderate to severe OSA, and a 32% increase in Apnea-hypopnea index (AHI).[8] Almost 90% of the patients with obesity hypoventilation syndrome have coexistent OSA.

Age is another important risk factor for the development of OSA, the prevalence increasing from young adulthood up to the sixth or seventh decade, and then it plateaus.[7,9] Age is an independent associated risk factor for OSA, with odds ratio reaching 34.5 for the 60–80 year age group as compared to 20–29 year age group.[7]

Upper airway abnormalities (such as enlarged tonsils or adenoids, small nasal cavity) and craniofacial anomalies (such as micrognathia, retrognathia, a wide craniofacial base) have also been implicated in increasing the risk of OSA.[10] Another study noted that a majority of Asian men who had severe OSA, were non-obese and differences in craniofacial anatomy was considered an important risk factor in this population (vs. White men).[11]

Genetic factors that produce the OSA phenotype usually affect body fat distribution, craniofacial morphology and neuromuscular factors. Relatives of patients with sleep apnea have two- to fourfold greater risk of sleep apnea and familial factors can explain up to 40% of the variance in AHI.[12]

Other risk factors associated with a higher risk of OSA are smoking, menopause (hormonal differences could account for the sex differences in OSA, with hormonal replacement being protective), nasal congestion,[10] and ambient air pollution (particularly nitrogen dioxide and PM 2.5).[13] A number of comorbid conditions are also associated with a higher prevalence of OSA, although whether this association is etiological or simply reflects the common risk factors of these conditions is still under evaluation. These conditions include diabetes, hypertension, congestive heart failure, stroke, coronary artery disease, atrial fibrillation, chronic lung disease, pregnancy, endocrine disorders (hypothyroidism, acromegaly), end stage renal disease, gastroesophageal reflux, and many others.[10]

Pathophysiology

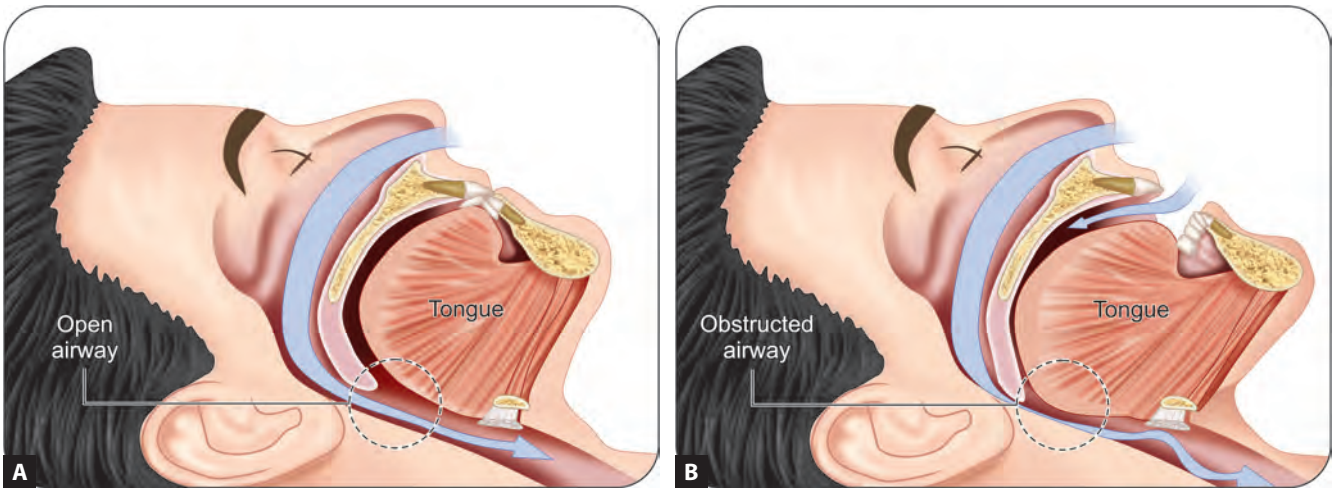
The pathogenesis of OSA is not fully understood. The upper airway collapse during sleep results from an interplay of several factors. Unfavorable upper airway anatomy (small airway due to obesity, genetics, age, craniofacial, or upper airway abnormalities) may lead to its collapse when subjected to a collapsing transmural pressure **(Figs. 1A and B)**.[14]

Decreased central respiratory output during sleep, which reduces tonic upper airway dilator muscles activity can predispose to such a collapse.[15] Upper airway caliber decreases normally during sleep and has a higher compliance. Upper airway and nervous system reflex activity is also impaired during sleep, leading to inability to maintain ventilation and increasing arterial carbon dioxide levels.[16] However, patients with OSA are observed to have a low arousal threshold, waking up frequently to increased carbon dioxide levels and hyperventilating. The resultant hypocapnia can further decrease the respiratory drive and reducing tonic muscular output, leading to airway collapse and apneic episode.[15,16] Neuromuscular incoordination and diseases that lead to it may also play a role in the pathogenesis of apnea.

Lung volume decreases with increasing age, obesity, and during sleep; which removes the caudal traction on the upper airway applied by the inflated lung, increasing airway collapsibility.[15,16] Rostral fluid shifts during sleep, particularly in conditions with extracellular volume overload, can also narrow the airway.[15]

Clinical Features

Patients with OSA often complain of daytime symptoms such as inability to remain fully awake or alert, fatigue (more common in women), tiredness, and poor focus; referred to as daytime sleepiness.[17] They do not wake up feeling refreshed (non-restorative sleep). A quantitative assessment of the sleepiness and fatigue can be done by the Epworth Sleepiness Scale.



Figs. 1A and B: Mechanism of obstructive sleep apnea

Bed partners of patients with OSA report that the patient has nocturnal breathing disturbances such as snoring, gasping, choking, snorting, or breathing pauses while sleeping. A systematic review of 42 studies noted that nocturnal gasping or choking was the single most useful clinical symptom for identifying patients with OSA (likelihood ratio 3:3); and while snoring was a frequent complaint, it had no value in suggesting OSA as a single finding (likelihood ratio 1:1).[18] For the diagnosis of OSA, snoring had a higher sensitivity (80%), but a lower specificity (50%) as compared to gasping or choking (sensitivity—52%, specificity—84%).[18]

Other symptoms found in patients with OSA are morning headaches (12–18% of patients), lasting for several hours after waking up on most days of the week.[19] There is also a high prevalence of insomnia in patients with OSA (up to 30%), and females had more insomnia symptoms as compared to males.[20] Up to 40% patients experience nocturia (even correlating with severity OSA in patients <50 years of age); treatment with continuous positive airway pressure (CPAP) significantly reduces the number of night-time urinations **(Fig. 2)**.[21]

Physical evaluation of patients with OSA reflects the comorbid conditions and etiological factors for the disorder. The most common clinical finding is obesity, particularly central obesity. Patients often have large waist circumference and neck circumference (>17 inches for men and >16 inches for women).[22] Oropharyngeal examination can indicate craniofacial abnormalities and crowded upper airway. Mallampati classification and Friedman tongue position can be used to rapidly assess the severity of airway narrowing; a meta-analysis indicating it positively correlated with predicting OSA severity.[23] Associated conditions and complications that can be found in patients with OSA are systemic hypertension, heart failure, and pulmonary hypertension.

Diagnosis

The American Academy of Sleep Medicine (AASM) has established guidelines for the diagnosis of OSA.[24] Diagnostic testing should be performed in patients with excessive daytime sleepiness and the presence of at least two of the following features—habitual loud snoring, witnessed apnea or choking or gasping during sleep, and systemic hypertension; patients fulfilling these criteria are at high risk of moderate to severe OSA.[24]

The AASM recommended against the use of clinical tools, questionnaires, and prediction algorithms to diagnose OSA in adults, in the absence of polysomnography or home sleep apnea testing.[24] Examples of such tools include the Berlin questionnaire, STOP-Bang questionnaire, the NoSAS score (which performed significantly better than the previous two[25]), the Multivariable Apnea Prediction instrument (MVAP), etc.

The use of home sleep apnea testing (HSAT, also known as out-of-center sleep testing or OCST) or polysomnography (PSG) is recommended for the diagnosis of OSA.[24] An in-laboratory PSG is considered

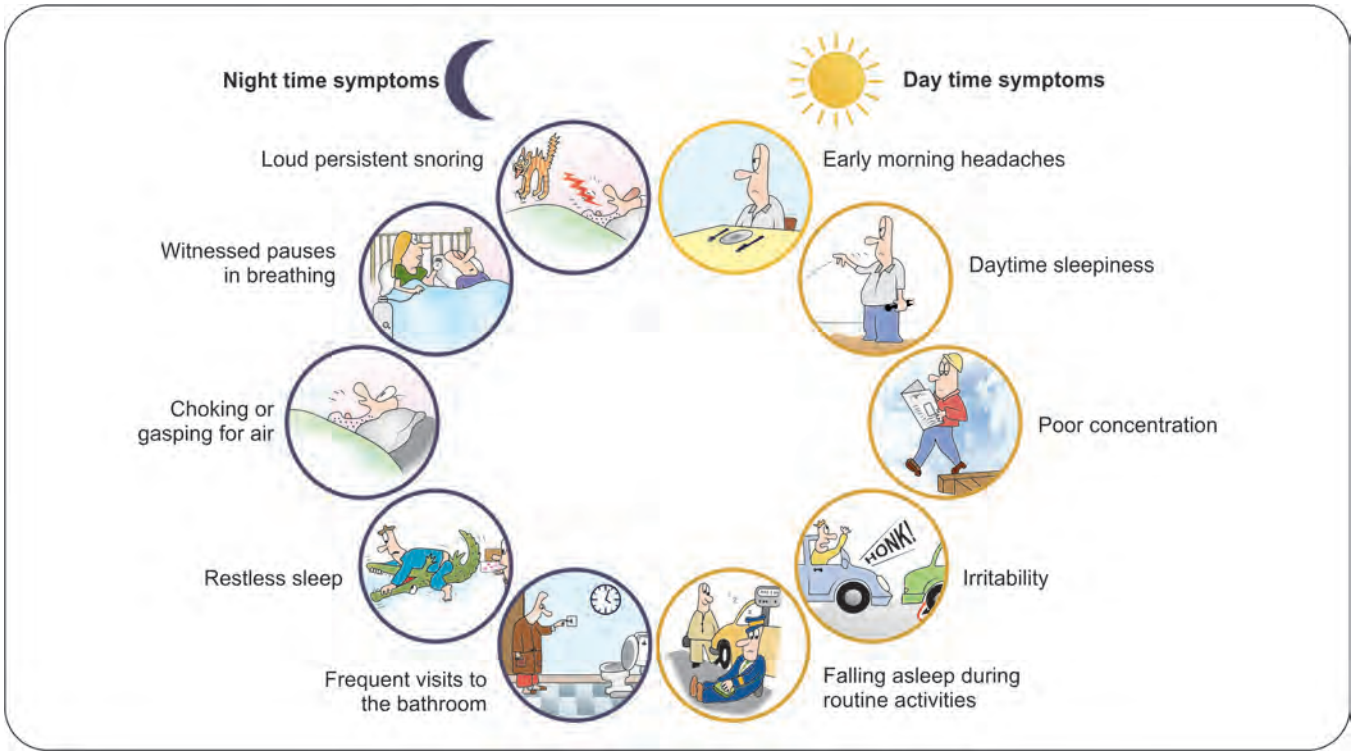


Fig. 2: Symptoms of obstructive sleep apnea

the gold standard for diagnosis, and should be performed in cases where HSAT is negative, technically inadequate, or inconclusive.[24] The diagnostic criteria for OSA, as per AASM, International Classification of Sleep Disorders (ICSD), 3rd edition are:[26]

- ≥15 predominantly obstructive respiratory events per hour of sleep during PSG or OCST, in the absence of associated symptoms or disorders
  OR
- ≥5 predominantly obstructive respiratory events per hour of sleep during PSG or OCST, with ONE or more of the following:
  - Complains of sleepiness, non-restorative sleep, fatigue, or symptoms of insomnia
  - Waking up with breath holding, choking, or gasping
  - Habitual snoring, breathing interruptions, or both noted by a bed partner or other observer
  - Comorbidities—hypertension, type 2 diabetes mellitus, coronary artery disease, atrial fibrillation, congestive heart failure, stroke, cognitive dysfunction, or mood disorder

The respiratory events include obstructive apnea (≥90% reduction in airflow for >10 seconds with continued respiratory effort), hypopnea (a ≥30% reduction in airflow for ≥10 seconds with arousal or ≥3% desaturation) and respiratory effort-related arousal, that is, RERA (arousals associated with decrease in airflow lasting at least 10 seconds, that do not meet criteria for apnea or hypopnea). The quantitative data generated from sleep study can be expressed in the form of two indices:

- Apnea-hypopnea index (AHI)—Number of apneas plus hypopneas per hour of sleep
- Respiratory disturbance index (RDI)—Number of apneas plus hypopneas plus RERAs per hour of sleep

RDI is the preferred index[24,27] and can be used to classify the severity of OSA into mild (5–14 events per hour), moderate (15–29 events per hour), and severe (≥30 events per hour).

Differential Diagnosis

Conditions that can mimic OSA and should be kept as a differential diagnosis include:

- Primary snoring—Most patients with OSA snore, but not all patients who snore have OSA
- Pulmonary disease—Asthma, chronic obstructive pulmonary disease
- Insufficient sleep
- Other sleep disorders—Central sleep apnea, narcolepsy, periodic limb movement disorder, restless legs syndrome
- Neurological disorders leading to daytime sleepiness
- Neuromuscular disorders
- Medical diseases—Hypothyroidism, end stage renal disease, hepatic encephalopathy
- Medications—Sedatives (benzodiazepines, barbiturates, non-benzodiazepines, antihistamines, antidepressants, etc.), opioids, etc.
- Psychiatric disorders (depression, anxiety) and substance abuse (alcohol, narcotics, etc.)
- Gastroesophageal reflux disease

Complications

OSA can lead to several cardiovascular, cerebrovascular, and metabolic complications, which can lead to adverse clinical outcomes and even premature death **(Fig. 3)**.

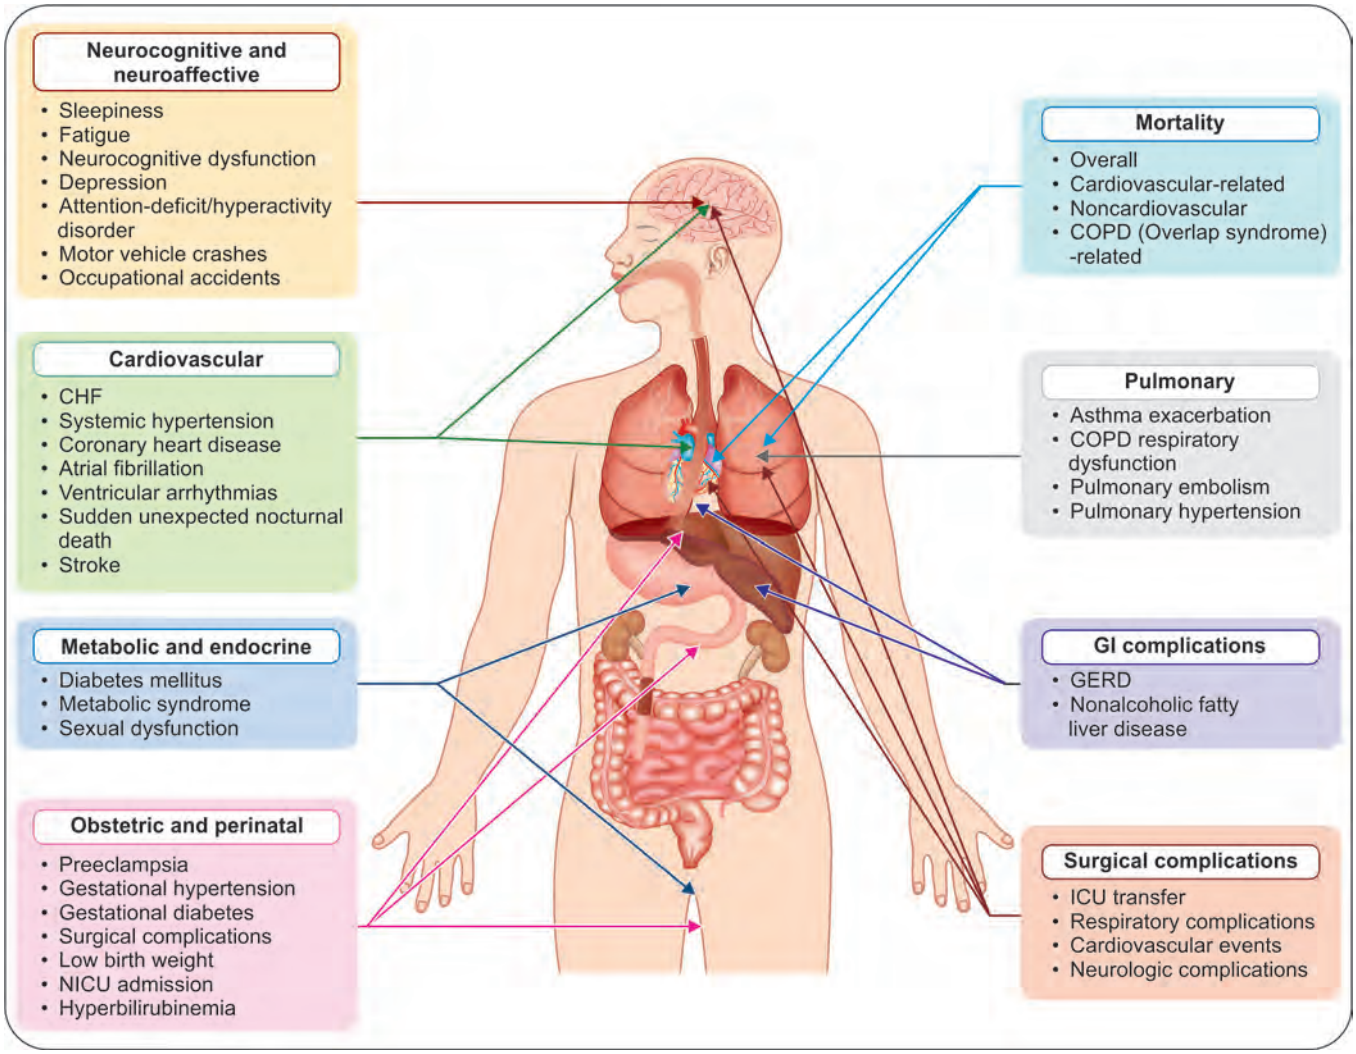

Fig. 3: Adverse outcomes of OSA

The repeated arousal events associated with intermittent hypoxia in OSA, leads to increased sympathetic activity, hemodynamic changes, inflammation, metabolic changes, and endothelial dysfunction.[28] There is increased incidence of hypertension, cardiovascular events (myocardial infarctions, heart failure, etc.), coronary artery disease, atrial fibrillation, QT prolongation, pulmonary hypertension, and even venous thromboembolism.[28]

It has been noted that patients with OSA tend to have a "non-dipping" pattern of blood pressure (lack of the typical 10% drop in blood pressure during sleep).[29] A meta-analysis of 31 articles indicated that CPAP therapy resulted in a small, but statistically significant reduction of blood pressure in patients with OSA.[30]

There was also an increased incidence of stroke in patients with OSA, particularly in men.[31] OSA has also been implicated in causing two times the increased risk of depression,[3] risk being higher in women than men.[32] Other neuropsychiatric complications include memory and cognitive defects, difficulty in maintaining attention;[33] which combined with the excessive daytime sleepiness, can lead to motor vehicle and workplace accidents.

The reported prevalence of pulmonary hypertension in OSA patients varied between 17% and 70%.[34] OSA associated pulmonary hypertension is classified under group 3 pulmonary hypertension and most of these cases are only of a mild degree.[34]

Metabolic alterations and complications are frequent in patients with OSA. Studies have demonstrated an increased prevalence of type 2 diabetes mellitus and its complications, which is independent of the shared risk factors (e.g., obesity) of both the diseases. An increased incidence of diabetes was independently and significantly associated with OSA severity (30% higher hazard with AHI >30), time spent with oxygen saturation under 90%, and the AHI in rapid eye movement (REM) sleep.[35] Sleep disordered breathing is also independently associated with metabolic dysfunction such as insulin resistance and glucose intolerance, its severity correlating with the RDI and the degree of sleep related hypoxemia.[36]

The prevalence of moderate to severe OSA in patients with metabolic syndrome is very high (60%), the combination of OSA, and metabolic syndrome (syndrome X) being called "Syndrome Z". Independent association of OSA with increased triglyceride and glucose levels, inflammatory markers, atherosclerosis, and arterial stiffness in patients with metabolic syndrome has been observed.[37] Effective treatment with CPAP reduces several components of metabolic syndrome in these patients.[37] The chronic intermittent hypoxia in OSA is also a potential candidate for leading to progression of fatty liver in obesity.[37]

Management

Patient education and behavior modification is the initial step in management of all patients with OSA. They should be educated about the natural history, risk factors, potential complications, and the increased risk of accidents due to drowsiness.[22] Overweight and obese patients should be encouraged for weight loss via dietary therapy, exercise, drug therapy, or even bariatric surgery.[8,22] Patients who suffer from OSA primarily in the supine sleep position on PSG, should be initiated on positional therapy (use of a positioning device, monitoring and sometimes the use of an objective position monitor).[22] All patients should be instructed to avoid alcohol and medications, which have an inhibitory effect on the nervous system or cause weight gain.

The mainstay of therapy for OSA in adults is positive airway pressure therapy, delivered in continuous (CPAP), bi-level (BiPAP), or autotitrating (APAP) modes. CPAP prevents upper airway collapse, which leads to respiratory events.[15] CPAP treatment is indicated in treatment of any severity of OSA.[22] It reduces AHI, excessive daytime sleepiness, lowers blood pressure, and improves quality of life,[38] but its effect on mortality remains to be demonstrated.

Other strategies include the use of oral appliances such as mandibular repositioning appliance or tongue retaining device, which enlarge the upper airway and improve its patency.[22] These devices have lower efficacy than CPAP, but have better compliance rates.[39] They are indicated for use in mild to moderate OSA, patients who fail behavioral measures, or fail or do not respond to or are not appropriate candidates for CPAP.[22]

Patients with a surgically correctable obstructive lesion of the upper airway (e.g., adenoid hypertrophy, tonsillar hypertrophy, craniofacial abnormality) can be considered for primary surgery and correction of the obstructive lesion.[22] Surgery can also be a secondary therapy if there is intolerance or failure of positive airway pressure (PAP) or oral appliance therapy.[22] Hypoglossal nerve stimulation may be considered in selected OSA patients (failed CPAP,

BMI <32 kg/m^2), a meta-analysis indicating a statistically significant reduction in AHI and daytime sleepiness at 12 months of therapy.[40] Tracheostomy eliminates OSA by bypassing the upper airway, but reduces the quality of life substantially.[15,22]

Currently no pharmacologic agent with proven long-term effectiveness is available for replacement of above therapies for OSA. A Cochrane review on drug therapy for OSA, concluded that out of the 25 drugs reviewed, only 10 drugs had some effect on the severity of OSA, but long-term outcomes of these drugs is still unknown.[41] Dronabinol (a synthetic cannabinoid) has been shown to reduce AHI in moderate to severe OSA, but it is not yet recommended in OSA, and needs further Phase III trials to support its efficacy.[42]

OSA patients continuing to have residual daytime sleepiness, despite effective PAP therapy may benefit from the addition of modafinil or armodafinil (central nervous system stimulants), after other causes of residual sleepiness are ruled out.[22]

Conclusion

Obstructive sleep apnea, the most common sleep disordered breathing, affects almost a billion people worldwide. India stands fourth among countries with the highest burden and the increasing obesity and air pollution rates worldwide will only serve to increase its prevalence. It leads to morbidity and mortality due to its cardiovascular, cerebrovascular, and metabolic complications; and impacts the patient's quality of life. Management relies upon lifestyle modification, positive airway pressure therapy, and other strategies (sometimes including surgery) for successful treatment. No pharmacotherapy is yet approved for primary therapy.

CHAPTER

108 Interstitial Lung Disease in Connective Tissue Diseases: An Update

Nirmal Garabadu

Abstract

Multiple connective tissue diseases (CTDs) manifest interstitial lung disease (ILD) and cause significant morbidity and mortality. Till date, there is no effective therapy. There are new evolving concepts of pathogenesis and rapid progress in identifying the effector cells. Serum biomarkers provide new insights for early diagnosis and disease progression. But management of patients with CTD-ILD remains sub-optimal. Multi-disciplinary clinics are now established for early diagnosis, improved management, and effective therapy.

Introduction

Connective tissue diseases (CTDs) are a group of diseases with heterogeneous systemic features and show immune-mediated multi-organ dysfunction. The respiratory tract can be affected in virtually every CTD. Interstitial lung disease (ILD) is a potential complication in many of the CTDs. In ILD a group of parenchymal lung disorders share common radiologic, pathologic, and clinical manifestations. There are six most common and important forms of ILD namely smoking related, connective tissue or autoimmune disease related, hypersensitivity pneumonitis, occupation related, medication related, and idiopathic pulmonary fibrosis (IPF). The CTDs associated with ILD are as follows:

- Systemic Sclerosis (SSc)
- Rheumatoid Arthritis (RA)
- Polymyositis/Dermatomyositis (PM/DM)
- Sjögren's Syndrome
- Systemic Lupus Erythematosus (SLE)
- Undifferentiated CTD
- Mixed CTD

Sometimes they are asymptomatic and require high-resolution computed tomography (HRCT) of lungs or pulmonary function testing (PFT) for detection. Lung involvement is a decisive contributor to mortality in CTD. The fibrosing forms are often incurable and lead to significant morbidity and mortality.

ILD associated with CTDs share a common clinical presentation such as cough (non-productive), shortness of breath to progressive dyspnea. At times ILD may be the presenting feature that predates the CTD. Prevalence of ILD in CTDs appears to be higher than previously thought. In order to initiate proper treatment early recognition of pulmonary involvement is very important.

An accurate ILD diagnosis requires thorough medical history and physical examination along with autoimmune serologic testing, high resolution chest tomography imaging, and lung biopsy (if necessary). Severity of disease and response to treatment is assessed by restrictive pattern of ventilatory defect and abnormal diffusion capacity (DLco). Frequency of ILD in different CTDs is shown in **Table 1**.

Pathogenesis of CTD-ILD

Three factors interplay in the pathogenesis. They are vascular injury, inflammation, and autoimmunity. It is characterized by a combination of

TABLE 1 Frequency of ILD in different CTDs

Connective tissue diseases	*Frequency of ILD (%)*
Rheumatoid arthritis	20–30
Systematic sclerosis	45
Sjögren's syndrome	Up to 25
Polymyositis/dermatomyositis	20–50
Systemic lupus erythematosus	2–8
Mixed connective tissue disease	20–60

- chronic inflammation within the lungs consisting of an accumulation of chronic inflammatory cells and increased levels of numerous proinflammatory cytokines, chemokines, and cell surface molecules;
- varying degrees of fibrosis.

In the pathogenic process of pulmonary fibrosis initially there is microvascular injury, which leads to endothelial or alveolar epithelial damage. Then proinflammatory and profibrotic extra cellular mediators like chemokines, cytokines, growth factors, lipids, and prostanoids come into play. The pivotal mediator of fibrosis is the Cytokine Transforming Growth Factor Beta (TGFbeta). TGFbeta along with platelet derived growth factor, endothelin-1 (ET-1) play the key role in fibroblast production **(Flowchart 1)**.

Histology

In response to lung injury in CTD associated ILD, three major histopathologic patterns occur. They are:

- Usual interstitial pneumonia (UIP),
- Non-specific interstitial pneumonia (NSIP), and
- Organizing pneumonia (OP).

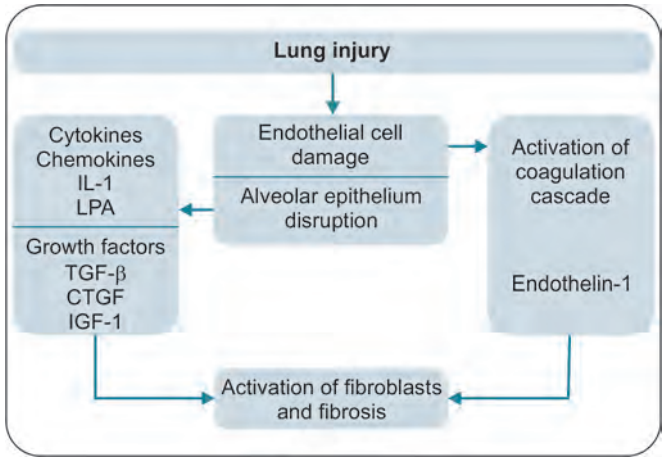
UIP is recognized by dense fibrotic areas heterogeneously distributed with areas of normal lung architecture, numerous microscopic cysts filled with mucus called honeycomb change and fibroblastic foci juxtaposed to honeycomb cysts.

NSIP shows diffuse cellular inflammation and/or fibrosis in the lung interstitium. The distribution is homogeneous pattern throughout the lungs.

OP is recognized by multiple round or oval deposits consisting of extra cellular matrix proteins and myofibroblasts.

Treatment and prognosis in ILD is determined by the etiology of ILD rather than a specific histologic pattern.

Flowchart 1: Mechanisms involved in pulmonary fibrosis. Endothelila and alveolar epithelial injury initiates activation of coagulation cascade, release of various growth factors and cytokines. This leads to activation of fibroblast and development of fibrosis



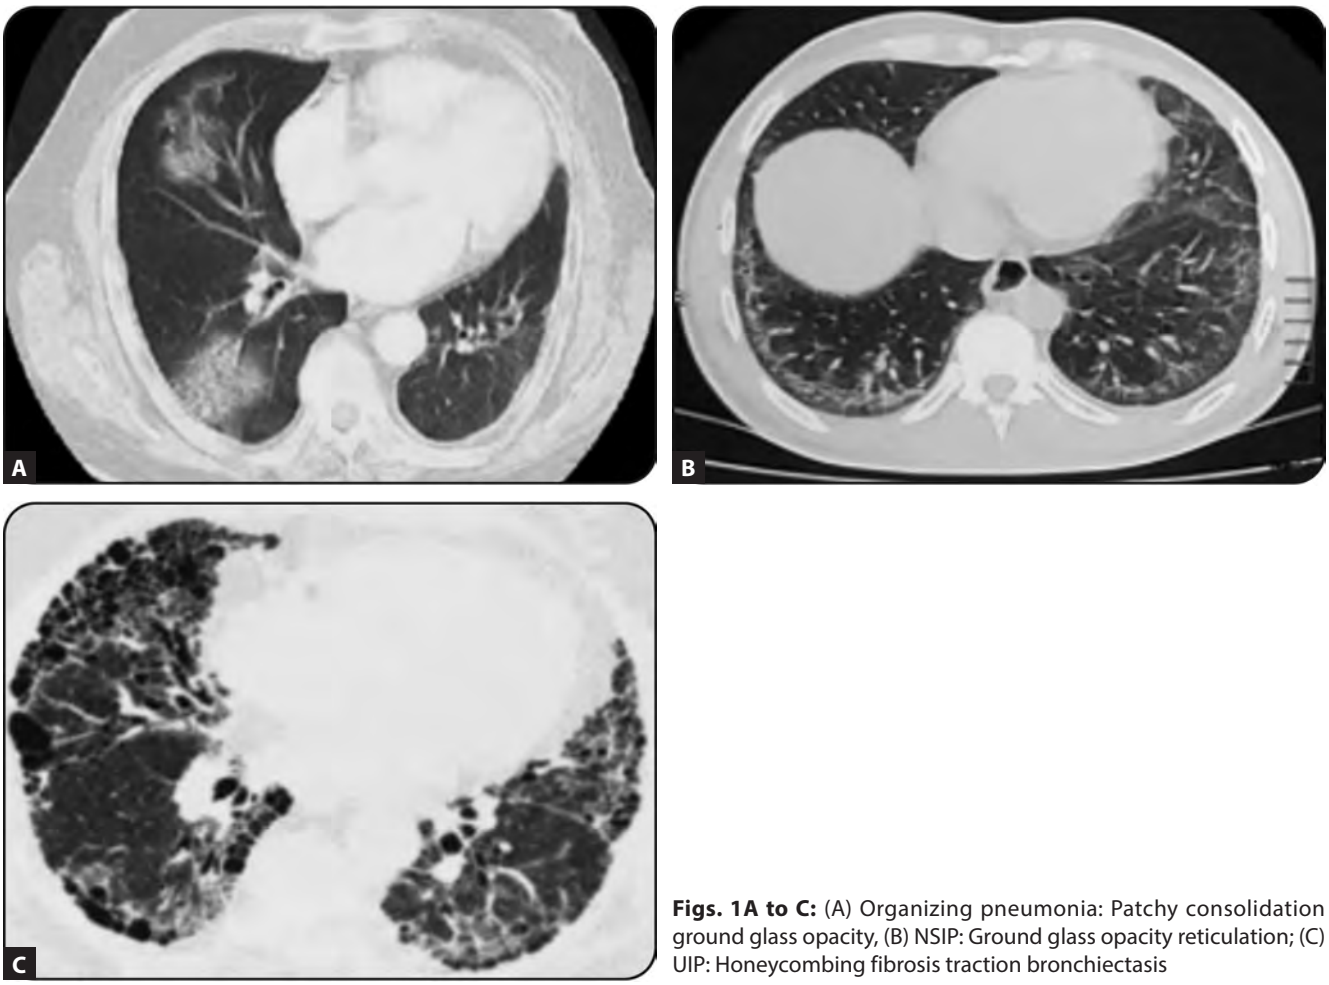
CFG, connective tissue growth factor; IGF-1, insulin like growth factor 1, LPA, lysophosphatidic acid, TGF-β, transforming growth factor β

Therefore, biopsy is not advocated unless absolutely necessary.

Radiology/HRCT Imaging

HRCT imaging of chest is essential for making accurate ILD diagnosis. Three features of chest imaging deserve specific mention.

- Distribution of opacities within the lungs—upper lobe versus lower lobe, peripheral versus central/peribronchiolar, and whether spare extreme periphery. Specific forms of ILD have characteristic distributions and no known explanation for that.
- Next, findings of fibrosis be recognized-reticular opacities often seen in periphery of the lungs, traction bronchiectasis (dilated and distorted bronchi and bronchioles due to traction by surrounding fibrosis) and honeycomb change (clusters of small cysts in extreme periphery) and volume loss. Honey combing and traction bronchiectasis occur in advanced fibrosis. These findings portend poor prognosis irrespective of etiology.
- Lastly, presence of ground glass opacities and/or consolidation—areas of hyperattenuated lung considered to be inflammatory in nature and likely to be reversible.



Figs. 1A to C: (A) Organizing pneumonia: Patchy consolidation ground glass opacity, (B) NSIP: Ground glass opacity reticulation; (C) UIP: Honeycombing fibrosis traction bronchiectasis

Imaging pattern on HRCT is characterized by reticulation associated with fibrotic features, architectural distortion, traction bronchiectasis and honeycombing.

UIP pattern on HRCT shows peripheral and basal predominant involvement. There is reticulation associated with fibrotic changes and also includes traction bronchiectasis and honeycombing.

In NSIP pattern ground-glass opacity and reticulation with traction bronchiectasis is seen predominantly, basal and bilateral OP pattern consists of patchy, subpleural, peripheral, and peribronchiolar consolidation[1] **(Figs. 1A to C)**.

Relative Frequency of Pattern of Involvement in ILD Associated with CTDS

See **Table 2**.

Autoantibodies in the Diagnosis of CTD-ILD

In specialized ILD clinics detection of autoantibodies assist diagnosing unrecognized CTD-ILD. These autoantibodies tests change the diagnosis (in about 4–19% cases) from idiopathic ILD to CTD-ILD. Distinguishing idiopathic interstitial pneumonia from CTD-ILD is absolutely important as regards prognosis and management. The major autoantibodies and their associated CTDs are given in **Table 3**.

Prognosis of CTD-ILD

High mortality and more aggressive disease is seen in male sex, a history of smoking, older age, South Asian ethnicity and UIP pattern. Another survival analysis showed disease

TABLE 2 Relative frequency of radiological and histological patterns in connective tissu disease associated ILD

CTD	UPI	NSIP	OP	LIP
Systemic sclerosis	+	+++	+	–
Rheumatoid arthritis	+++	++	++	+
Sjögren's syndrome	+	++	–	++
Polymyositis/dermatomyositis	+	+++	+++	–
Systemic lupus erythematosus	+	++	+	++
Mixed connective tissue disease	+	++	+	–

TABLE 3 Major autoantibodies and their associated CTDs

CTD	Autoantibody
Rheumatoid arthritis	High-titer RF, anti-CCP
Systematic sclerosis	Anti-centromere, anti-topoisomerase (Scl-70), anti Th/To, anti-nucleolar ANA
Systemic lupus erythematosus	ANA, anti-dsDNA, anti-ribonucleoprotein
Sjögren's syndrome	RF, anti-LA, anti-RO
Polymyositis/dermatomyositis	Anti-JO, non-JO, anti-MDA-5
Mixed connective tissue disease	Anti-ribonuleoprotein

course and intensity of ILD lesions at baseline as critical indicator for survival. In yet another study of 359 patients with median follow-up time 4 years, there were 85 deaths (23.7%).

Connective Tissue Diseases Associated with ILD

Systemic Sclerosis

Systemic sclerosis (SSc) is a rare CTD and is characterized by immune dysfunction, vasculopathy, cellular inflammation, and fibrosis of skin and multiple internal organs. Initial tissue injury is followed by excessive collagen deposition. Nearly one-half of cases develop clinically significant ILD and is a leading cause of death in these patients. Risk of ILD is greater in African-American ethnicity and in those with more extensive skin involvement (diffuse SSc).[2]

Risk factors for the development of progression of ILD are older age at disease onset, shorter disease duration and the presence of anti-Scl-70 (anti-topoisomerase antibody) and absence of anti-centromere antibody.[3] But none of these risk factors is absolute. All the patients diagnosed as systemic sclerosis should have assessment of respiratory symptoms, HRCT scan of chest and PFTs to ensure early identification of ILD. The risk of developing ILD is greatest early in the course of disease. PFTs and DLco are very useful to monitor the progression. Therefore, suggested to repeat the tests every 4–6 months for 3 years. Most patients will show a slow decline in lung function, but some have rapid progression.

Certain biomarkers serve as indicators of disease and predictors or progression. Serum levels of surfactant proteins A&D (SP-A and SP-D) and glycoprotein KL-6 were elevated when compared to healthy controls. Recently a novel biomarker chitinase-like protein YKL-40 is gaining interest.

Most of the cases show NSIP pattern in HRCT scan and histopathology. Some with advanced disease with severe fibrosis may show UIP pattern. The utility of HRCT is sufficient to make the diagnosis of UIP/IPF in about 50–60% cases.

Management/Treatment Considerations of SSC-ILD

There are no approved drugs. Current approach to treatment include routine follow-up alone in mild disease

with no signs of progression. On the other hand in patients with progressive ILD active immunosuppression is advocated along with monitoring. Based on available data, decisions for treatment is made case by case basis. All do not need treatment. Decline in lung function, progression of fibrosis on HRCT or worsening respiratory symptoms due to ILD will require active drug treatment.

In early stage of disease (requiring treatment) evidence of inflammation is commonly present, and therefore therapies target inflammatory response. Corticosteroids, cyclophosphamide, azathioprine and mycophenolate mofetil are the immunosuppressive agents used. Corticosteroid therapy is generally ineffective. Others show modest benefit.

Oral cyclophosphamide at 2 mg/kg/day was tried for 12 months in Scleroderma lung study. It showed slowing of decline in lung function, improvement in dyspnea and skin thickening. At 24 months only benefit of reduction in dyspnea remained.

Mycophenolate mofetil is a less toxic and better tolerated drug as compared to cyclophosphamide. Therefore, this drug is a better option for long term use.

Azathioprine is an alternative agent for those who do not tolerate cyclophosphamide. Data suggests Azathioprine for maintenance therapy following intravenous cyclophosphamide.

Endothelial-1 receptor antagonists (Bosentan)—BUILD-3 study did not reduce morbidity and mortality. As regards 6-minute walk test it was no better than placebo.

Tyrosine kinase inhibitors (Imatinib) blocks platelet derived growth factor receptor. A recent large multicenter randomized controlled trial showed no significant benefit in treatment of IPF.

Pirfenidone has both anti-inflammatory and anti-fibrotic effect. It inhibits collagen synthesis & TGFbeta production. It improved exercise capacity and showed no radiological progression of disease.

Nintedanib completely inhibits tyrosine kinase, fibroblast proliferation, migration & transformation. It is recommended for use in IPF where forced vital capacity (FVC) is less than 80% of predicted. Though Pirfenidone and Nintedanib are both approved for use in IPF there is no recommendation for use in SSc-ILD. Results of ongoing Scleroderma Lung Study III and SENSCIS trial may guide us regarding their use in progressive and fibrotic variety.

Lung transplantation is an option in SSc-ILD patients who fail to respond to pharmacotherapy.

Rheumatoid Arthritis (RA)

ILD is seen in 20–30% cases of RA and is second leading cause of death. Development of ILD is associated with shortened survival. Smoking, older age, severe joint affection, high rheumatoid factor, and MUC5B gene association are the risk factors. Between 3–5% of patients showed ILD prior to RA diagnosis. Although RA is more common in females, RA-ILD occurs more frequently in males.

Pathogenesis of ILD in rheumatoid arthritis patients is not clear. Both rheumatoid factor and anti-CCP antibodies in high titers are linked to development of ILD. There is growing evidence suggesting perhaps rheumatoid arthritis starts in lungs. Because some patients with high anti-CCP antibodies do not have any articular manifestation. Cigarette smoking plays a role in inducing antibody production. Smoking may promote citrullination of lung proteins particularly those having HLA-DRB1 shared epitope.

HRCT scans in RA patients show a variety of patterns. UIP pattern is most common which occurs in 40–62% cases. NSIP is second most common pattern. Patients with UIP pattern on HRCT scan have worsened survival as compared with those having NSIP pattern. Therefore, all RA patients should undergo annual screening for ILD and if ILD is suspected HRCT scan be obtained.

Optimal therapy of RA-ILD is not known. Corticosteroids and immunosuppressants though widely used show limited benefit in RA-UIP. In NSIP or organizing pneumonia corticosteroids are the mainstay of therapy. Cyclophosphamide and azathioprine have been used with varying success. Mycophenolate mofetil is another option for treatment. In fibrotic group, immunosuppressants along with Nintedanib/Pirfenidone may be used.[4]

Five-year survival in RA-UIP patients is less than 50%. Lung transplant is a reasonable option for these patients.

Polymyositis/Dermatomyositis (PM/DM)

ILD is common and found in 25–45% cases of PM/DM. In 18–20% cases ILD presents prior to myositis. ILD markedly influences the disease course of inflammatory myositis. The strongest predictive factor is the presence of specific autoantibodies. Most important are JO-1 and KL-7 (associated with anti-synthetase syndrome) and MDA5 (associated with Amyopathic dermatomyositis). ILD associated with those Myositis specific autoantibodies

is severe, rapidly progressive, and non-responsive to treatment, and therefore have very poor prognosis.[4] Pattern of radiological involvement is NSIP, UIP, Cryptogenic organizing pneumonia or diffuse alveolar damage.

There are no large controlled trials to confirm the efficacy of treatments in ILD-PM/DM. Treatment is designed differently for chronic progressive and rapidly progressive cases. In RP-ILD treatment protocol is aggressive. About 20–40% of RP-ILD with anti-MDA5 patients die within 6 months of diagnosis even if treated intensively.

Corticosteroid is the mainstay of therapy along with steroid sparing immunosuppressants. Tacrolimus, mycophenolate mofetil, rituximab, and iv immunoglobulin also show benefit in some series.

Sjögren's Syndrome

ILD is associated in about 25% cases of Sjögren's syndrome and is an important extra glandular manifestation. Subclinical lung disease is even more frequent.

Association of lymphocytic interstitial pneumonia was first described in 1973. However, NSIP in its fibrosing variant is the most common manifestation. Organizing pneumonia, usual interstitial pneumonia, and lymphocytic interstitial pneumonitis are the other types of ILD. Dyspnea and cough are the main symptoms. Presence of anti-SSA is a predisposing factor.

The course of NSIP is unpredictable. It may progress, remain stable, reverse, or can be progressive and irreversible even with treatment. UIP pattern shows irreversible lung disease and has worse prognosis than NSIP.

Corticosteroid is the mainstay of treatment along with azathioprine and cyclophosphamide in NSIP. Immunosuppressive drugs do not benefit patients with UIP. There is no standard regimen of treatment. ILD is a significant cause of death.

Systemic Lupus Erythematosus (SLE)

In SLE pleuropulmonary involvement is not uncommon. But prevalence and severity of ILD is lower. Two important pulmonary manifestations of SLE are acute lupus pneumonitis and diffuse ILD. ILD is seen in about 3–8% of cases. The presenting symptoms are dyspnea, cough, fever, and pleuritic pain. These two conditions have major impact on morbidity and mortality. Therefore, it is essential to recognize and treat them properly. HRCT scan of chest and pulmonary function tests help in diagnosis.

Predominant lung pathology determines the treatment. High dose corticosteroids are the mainstay of treatment. Other agents such as cyclophosphamide, azathioprine, iv immunoglobulin, and rituximab are used if there is no prompt improvement. In acute lupus pneumonitis, weekly rituximab shows rapid improvement in PFT and symptoms.

Mixed Connective Tissue Disease (MCTD)

Pulmonary impairment is not evident clinically in early stage of disease. In a study published in 1976, 80% cases of MCTD had pulmonary disease but 69% were asymptomatic. The most relevant autoantibody associated is U1RNP.

Although MCTD is characterized by overlap features of SSC, PM/DM, and SLE the HRCT findings appeared remarkably homogeneous. NSIP is the most common pattern in MCTD. More than 50% of patients of MCTD have abnormality in DLco.[5] Lung fibrosis is associated with increasing mortality. About 47% patients respond well to corticosteroid 2 mg/kg/day monotherapy or combination of corticosteroid and cyclophosphamide.

Undifferentiated Connective Tissue Disease (UCTD)

Undifferentiated CTD defines clinical entities with features suggestive of CTD and yet do not meet the criteria of a specific single disease.[6] Patients with established UCTD lung involvement usually appears as a complication. About 88% cases have NSIP pattern. Lung involvement is associated with worse prognosis. Treatment is same as other CTD-ILD with NSIP pattern.

Conclusion

ILD is a frequent and serious complication of CTDs. Accurate and early diagnosis is challenging, but crucial to offer appropriate treatment. Lack of international guidelines to standardize clinical, radiologic, histopathologic, and biologic parameters is a great hurdle. There is no consensus regarding drugs to be used, duration of treatment, and optimal timing. Multi-disciplinary clinics involving pulmonologists, rheumatologists, radiologists, and pathologists are necessary to design treatment modalities for optimal outcome.

CHAPTER

109 Superior Vena Cava Syndrome—Revisited

Virendra Kumar Goyal, Manoj U Mahajan

Abstract

Superior vena cava syndrome is clinically manifested by dyspnea, facial swelling and facial edema, venous engorgement of neck and chest wall due to extrinsic, and/or intrinsic obstruction of superior vena cava causing reduction in venous return from head, neck, and upper extremities. It may develop quickly or gradually depending on underlying etiology which may compress, invade, or thrombose a thin-walled vessel in superior mediastinum.

Introduction

Superior vena cava syndrome (SVCS) is clinically manifested by dyspnea, facial swelling, and facial edema, venous engorgement of neck and chest wall due to extrinsic and/or intrinsic obstruction of superior vena cava causing reduction in venous return from head, neck, and upper extremities. It may develop quickly or gradually depending on underlying etiology which may compress, invade or thrombose a thin walled vessel in superior mediastinum.

Historically, it was first described in 1757 by William Hunter in patient of syphilitic aortic aneurysm.[1] Nearly two hundred years later Schechter described more than 200 patients of SVCS, out of which 40% were due to syphilitic aortic aneurysm or tubercular mediastinitis.[2] Subsequently, advances in antibiotics decreased infectious causes considerably and currently malignancy is the leading cause of SVCS.

Anatomy

It's large, valveless and thin walled vein formed by union of right and left brachiocephalic veins at first costal cartilage in superior mediastinum; traverses through middle mediastinum behind second costal cartilage and terminates into right atrium within pericardial sac at level of third costal cartilage. Azygos vein, which is main tributary enters at T4 level and drains upper lumbar and thoracic wall. It is surrounded by relatively rigid structures of thorax including sternum, trachea, right main bronchus, aorta, pulmonary artery, and perihilar and paratracheal lymph nodes. It's easily compressible by any space occupying process in surrounding. Its diameter is around 2 cm and length around 6–8 cm. Its low pressure vessel draining venous blood from head, neck, upper extremities, and upper thorax.

Pathophysiology

Superior vena cava can be partially or completely obstructed through:

- Extrinsically by benign or malignant tumors
- Intrinsically by thrombus or aneurysm
- Combination of both processes

Gradual obstruction ensures formation of collateral/s mainly through azygous vein, internal mammary veins, lateral thoracic veins, paraspinous veins, and esophageal venous network. It is manifested as engorged superficial

subcutaneous veins with diverted blood flow direction. Despite collateral systems, venous pressure is raised up to 300 mm of saline in severe cases.[3]

Etiology

Malignant Causes (60%)

- Lung cancer, small cell (SCLC), and squamous cell (50%)
- Non-Hodgkin lymphoma (5%)
- Other malignancies (5%)
- Metastatic tumor mostly from breast cancer
- Mediastinal germ cell tumors
- Hodgkin's lymphoma
- Thymoma

Benign Causes (40%)

- Intravascular devices including central venous access devices, pacemaker/defibrillator leads, etc.
- Benign tumors including teratoma and dermoid cyst
- Cardiac causes including pericarditis and atrial myxoma
- Vascular causes including aortic aneurysm, vasculitis (Behcet's syndrome)
- Infectious causes including tuberculosis, histoplasmosis, and syphilis
- Fibrosing mediastinitis due to prior irradiation

Malignant causes predominate, especially lung cancer including SCLC and squamous cell carcinoma owing to central predisposition.[4] In young males, lymphoma especially large cell variants like diffuse large B cell lymphoma, lymphoblastic lymphoma, and primary mediastinal lymphoma may cause rapidly progressing SVCS. Rarely germ cell tumors may be found in young males. In recent years prevalence of benign causes is on rise due to expanding use of central venous catheters.

Epidemiology

Right sided tumors tend to involve superior vena cava. SVCS develops in 5–10% of right sided tumors. Exact Indian data of SVCS is lacking but considering 5% of lung cancer and lymphoma incidence gives a rough estimate of around 5,000 cases per annum. As lung cancer has preponderance in males, malignant SVCS is also common in males while benign causes are equally distributed in both sexes. Most cases of SVCS are diagnosed between 50 and 70 years of age owing to high incidence of lung cancer in that age group.

Clinical Features

Signs and symptoms depend on the following:

- Degree, site, and rapidity of obstruction of superior vena cava
- Underlying etiology
- If malignant etiology then its subtype and overall tumor burden

Partial obstruction may not manifest clinically and patient may remain asymptomatic. Few subtle signs may go unnoticed. Gradually developing obstruction allows adequate time for collateral development delaying the manifestations to appear in advanced stages. Obstruction proximal and distal to azygous vein will exhibit differently.

The most common symptom of SVCS is dyspnea followed by neck and facial swelling/fullness of head.[5] Other symptoms include cough, arm swelling, chest pain, dysphagia, hemoptysis, epistaxis, dizziness, syncope, and lethargy. Symptoms may aggravate by bending forward or lying down due to obstruction to outflow of blood from head and neck. The most common sign of SVCS is venous distention of neck and chest wall followed by facial edema, cyanosis, plethora of face, and edema of arms in descending order of frequency.

Signs may progress through four stages which may considerably overlap:

- Due to increased venous pressure, swelling of neck, face, upper extremities manifests initially, which may be demonstrated through Pemberton's sign (though classically described in retrosternal goitre). Bilateral arms elevation above head for 2 minutes manifesting as above due to decreased venous outflow aggravating obstruction is considered as positive sign.
- Involvement of cardiorespiratory system may manifest as dyspnea, cough, and hoarseness and suggest severe airway and vascular obstruction. Risk of cardiac arrest and respiratory failure is high in patients receiving sedatives or general anesthetic agents.
- As venous stasis progresses, neurological symptoms manifest, including headache, dizziness, syncope, visual disturbances due to cerebral edema, which entails poor outcome. Seizure is more likely due to brain metastases rather than cerebral edema. Small

cell lung cancer with SVCS is more likely to have brain metastases than without SVCS.

- Life threatening manifestations include stridor (due to laryngeal edema which is poor prognostic sign), syncope without aggravating maneuvers, confusion, and hemodynamic instability. All of these require emergent intervention.

"Downhill" varices where direction of blood flow is from cephalad to caudal is indicative of esophageal varices due to collateral formation. Venous obstruction proximal to azygous vein leads to varices in upper third of esophagus in contrast to distal obstruction, which causes varices in entire length of esophagus.[6]

Life expectancy is unchanged in benign causes in contrast to malignant etiology, where it is dependent on tumor histology. Lymphoma has better survival than small cell lung cancer after irradiation and disease-specific treatment.

Investigations

SVCS is a clinical diagnosis with characteristics manifestations. Current treatment is directed toward underlying etiology. Hence, work up is individualized to ascertain etiology. The most commonly employed initial modality is chest X-ray, which shows superior mediastinal widening and right sided pleural effusion in around one-fourth patients. Pleural effusions are mainly exudative in nature and exceptionally chylous, especially in lymphoma.[7]

Contrast enhanced computed tomography (CECT) scan is a modality of choice, which delineates detailed anatomical information regarding superior vena cava and its tributaries with respect to other critical structures like trachea, bronchi, esophagus, and spinal cord. CT suggests reduced or absent opacification of central venous structures and collateral venous circulation.[8] Magnetic resonance imaging (MRI) is indicated only when CECT is contraindicated in renal dysfunction.

Integrated whole body positron emission tomography-CECT is the preferred modality of choice in lymphoma and lung cancer patients as it helps in complete staging, and hence intent of treatment (definitive vs. palliative).

Histopathological evidence of malignancy is essential and it may be obtained through endobronchial fine needle aspiration, CT guided needle biopsy, mediastinoscopy, or thoracotomy (if all other modalities fail). Mediastinoscopy and thoracotomy have minimum complications and high tissue yield.[9] Thoracocentesis in pleural effusion can also establish diagnosis in two-thirds of patients.

Management

Treatment Deciding Factors

SVCS treatment entails a judicious use of available measures on a case by case basis. There are no evidence-based guidelines or recommendations available. Various factors guiding the management decision algorithm include:

- Etiology
- Treatment responsiveness of the underlying disease
- Grade of severity
- Nature of underlying disease
- Overall prognosis
- Goals of therapy

Treatment Modalities

Overall treatment is a mix and match of various available modalities in individualized sequences and combinations. Various therapeutic modalities include nursing in semi-inclined position, securing the airway, fluid restriction, avoiding upper body cannulation, diuretics, inhaled oxygen, steroids, radiotherapy, chemotherapy, removal of the foreign body (viz., catheter), endovascular thrombectomy, intravascular pharmacological or mechanical thrombolysis, stent placement, oral or parenteral anticoagulation, and surgical venous bypass.

Treatment in Various Clinical Settings

SVCS with Life-threatening Symptoms

It is not uncommon to see aggressive malignancies like acute hematological malignancies and small cell lung cancer present with stridor, respiratory failure, or altered sensorium. It is a medical emergency.

Symptomatic Management

Place the patient in semi-inclined position and access lower limbs for venous cannulation. Following securing airway and addressing issues like dyselectrolytemia and tumor lysis syndrome (TLS), emergency endovenous recanalization (e.g., mechanical or pharmacologic thrombolysis and balloon angioplasty), and SVC stenting

should be the preferred modality depending on the availability of equipment and expertise. This will be accompanied by other supportive modalities including fluid optimization, diuretics, steroids, oxygen, and anticoagulation. If the SVCS is only due to stenosis without accompanying thrombosis, the role of anticoagulants is debatable.

Definitive Management

Before commencing definite management, an adequate tissue biopsy is must.[10] Steroids should be used carefully in lymphomas as they may melt the tumor jeopardizing the biopsy findings. They may also aggravate the tumor lysis syndrome, which is again another medical emergency, needing expeditious management. It includes treating the primary pathology by surgery, radiation, or chemotherapy depending on the type and extent of disease.

SVCS without Life-threatening Symptoms

Symptomatic Management

Symptomatic management is almost same in all non-emergent cases. Upper limb, neck, or subclavian cannulation should be avoided. Depending on the severity of symptoms, diuretics may be used to reduce venous congestion in SVC drainage area including brain. Fluid intake should be optimized to avoid worsening of edema and to overcome dehydration. This is even more relevant in cases likely to have TLS. Malignancy related SVCS is frequently associated with thrombosis as well as a risk of DVT; hence, anticoagulants should be initiated in all cases unless proved otherwise. Oxygen supplementation should be reserved for cases having respiratory compromise. Steroids are important component of chemotherapy in NHL, but caution should be taken about the risk of worsening TLS and should only be started after obtaining the tumor tissue biopsy. Use in cases other than NHL is questionable.[11]

Definitive Management

Since malignancy is the most common cause of SVCS. It is pertinent to discuss treatment in two parts: malignancy related and SVCS due to other causes.

Malignant SVCS: It incorporates treating the primary malignancy with surgery, radiation, or chemoradiation. In most cases, after this, SVCS disappears; however, in case of persisting symptoms, endovascular interventions or surgical venous bypass may be used. As an example, SVCS in case of a large thymoma may be corrected by surgical venous bypass. Non-Hodgkin lymphoma is a chemosensitive tumor. The most common subtype is diffuse large B cell lymphoma, if localized then treated with radiation therapy and in advance stages treated with chemotherapy mainly anti CD20 chimeric monoclonal antibody Rituximab in combination with cyclophosphamide, adriamycin, vincristine, and prednisolone. Responses are quick within 7 days. Patient must be watched and treated for tumor lysis syndrome. SCLC is chemosensitive and radiosensitive tumor. SVCS related to SCLC is treated with chemotherapy alone or in combination with thoracic irradiation. Response rates are to the tune of 73–93%.[12] Within 1–2 weeks relief from SVCS is achieved. Chemotherapy agents of choice are etoposide and platinum. Non-small cell cancer response rates with chemotherapy (59%) and radiation therapy (63%) are comparable.[13] Nearly one-fifth patients are destined to have recurrence from SVCS.

Non-malignant SVCS: The treatment is cause dependent. Most cases are iatrogenic due to some kind of catheter. They are managed with urgent removal of the catheter followed by anticoagulation. The rare cases due to chronic inflammatory processes may be managed by endovenous stenting. Overall survival in benign causes is unchanged if timely diagnosed and treated. Recent times have shown increase in use of central venous catheters, and hence superior vena cava thrombosis. It can be treated with streptokinase, urokinase, or recombinant tissue type plasminogen activator. Heparin and oral anticoagulants reduce progression of thrombus. Removal of catheter should be considered along with anticoagulation. In case of pacemakers, electrode wires should be changed.

Complications and Care of SVCS Treatment Modalities

Bleeding risk: Thrombolytic and anticoagulants are associated with significant risk of bleeding. Patients should be regularly monitored for the same.

Stent migration: Stent migration into the heart and pulmonary vasculature may be immediately life threatening. A high index of suspicion is warranted.

Pulmonary embolism: Tumor, thrombus fragment, or rarely a stent can embolize and cause a catastrophe.

Stent occlusion: Long-term anticoagulation is a need in a patient with a stent. Hence, its long-term safety in benign causes is questionable.

Tumor lysis syndrome: As explained earlier, it may be aggravated by the use of steroids. Hence, it again requires a high index of suspicion.

Conclusion

Superior vena cava syndrome may expedite to life threatening emergency if not treated urgently. Early institution of underlying etiology has curative potential in nonmetastatic solid malignancy, advanced lymphomas, and nonmalignant causes. Tissue diagnosis and appropriate imaging is essential in management of SVCS. Palliation of symptoms can be done with diuretics, steroids, stenting, and anticoagulation as indicated.

CHAPTER

110 Asthma—COPD Overlap: Challenges in Diagnosis and Management

M Sabir

Abstract

As such overlap of asthma and COPD is not a new clinical condition but had been discussed since long in context with patients having obstructive airway disease, where it was difficult to decide whether it is asthma or COPD. Asthma-COPD overlap (ACO), previously referred as asthma-COPD overlap syndrome (ACOS), is characterized by persistent airflow limitation consistent with COPD, together with several distinguishing features of asthma.

Till date there is no universally accepted definition of ACO, but in recent past there is increasing recognition and stress on better diagnosis, management, and prevention of asthma-COPD overlap. It is difficult to define it as a single disease entity, as it is a descriptive term for clinical use that includes several different clinical phenotypes reflecting different underlying mechanisms. It has been observed that ACO patients as compared to asthma or COPD have more rapid decline in lung functions, frequent exacerbations, worsening quality of life, higher mortality rate, and are difficult to treat.

In this chapter, attempt will be made to discuss briefly salient features of ACO.

Introduction

Chronic obstructive pulmonary disease (COPD) and asthma are two obstructive airway diseases, responsible for significant morbidity and mortality; creating serious global health problem. Although asthma and COPD are clinically two distinct disease entities, having diverse etiopathogenesis, management protocols, and response to treatment, but some features at some point are overlapping and compatible with both diseases leading to a mixed picture of overlapping clinical presentation and comorbidities creating difficulties in differentiating weather it is asthma or COPD. These patients are labeled as Asthma-COPD overlap (ACO); previously referred to as asthma-COPD overlap syndrome (ACOS).[1]

Definition

As such overlap of asthma and COPD is not a new clinical condition but had been discussed since long in context with patients having obstructive airway disease, where it was difficult to decide whether it is asthma or COPD.

As early as in 1961, Prof. Orie and colleagues proposed that all obstructive airway diseases, including asthma, emphysema, and chronic bronchitis, should be considered as different manifestation of a single disease with common genetic origins. Although it generated lot of controversy but discussion at different levels on this hypothesis (Dutch hypothesis) is still continue.[2,3]

In 1995, COPD guidelines from American Thoracic Society defined asthma, chronic bronchitis, emphysema, COPD, and other clinical situations having airflow limitation **(Fig. 1)**, and identified 11 distinct clinical entities related to obstructive airway diseases dominated by COPD and asthma and overlap between two or more conditions as depicted in **Table 1**.[4-6]

Further guideline developed for asthma and COPD had placed more emphasis on recognizing them as two distinct

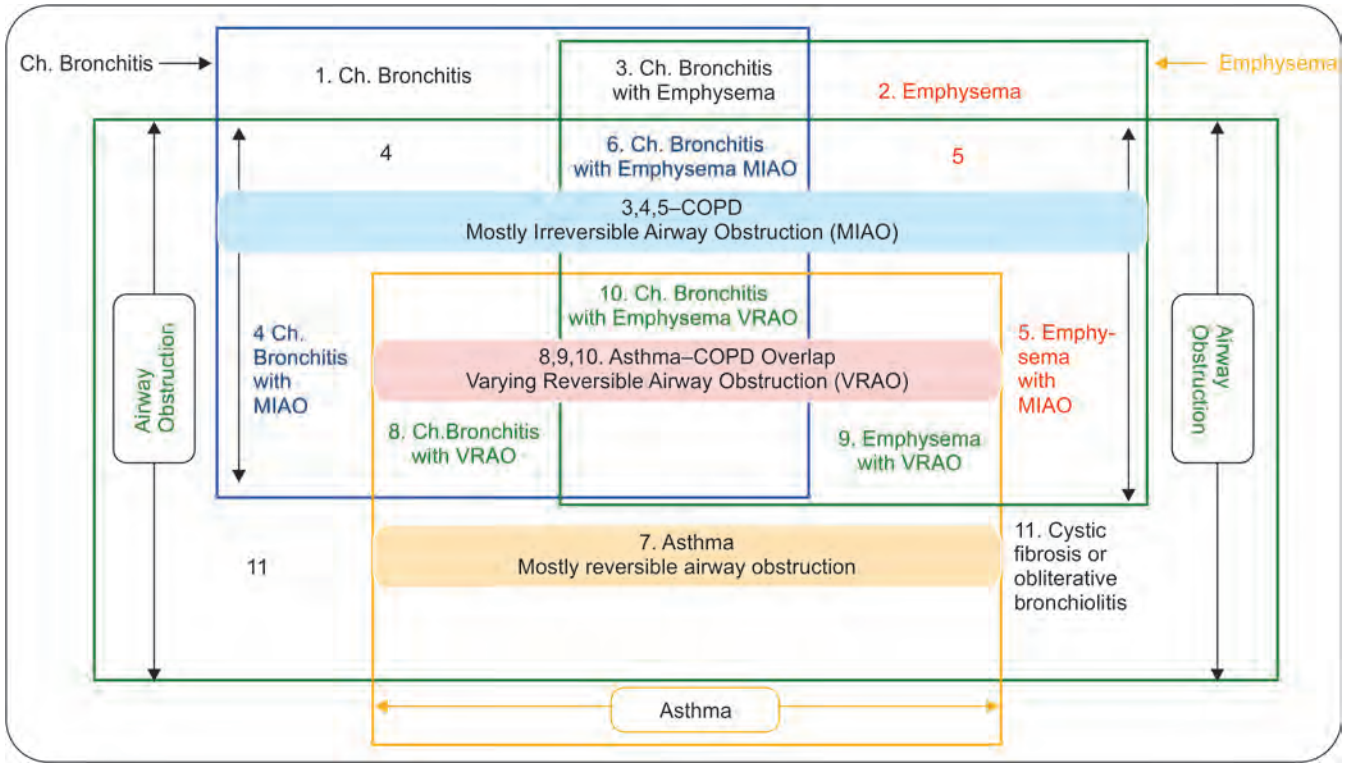

Fig. 1: Overlapping of clinical entities with obstructive airway diseases (non-proportional diagrammatic representation)
MIAO, mostly irreversible airway obstruction; VRAO, varying reversible airway obstruction

diseases where complete or incomplete reversibility of airflow obstruction is the defining characteristic. This is useful as it facilitate easier recognition of asthma and COPD, but obstructive airway diseases other than these two entities, for example, having ACO and others received less attention especially during clinical evaluation, management, and research.

In recent past there is increasing recognition and stress on better diagnosis, management, and prevention of asthma—COPD overlap.

'ACO,' also labeled as 'asthma + COPD' are terms used to collectively describe patients who have persistent airflow limitation together with clinical features that are consistent with both asthma and COPD.[1]

It is difficult to define it as a single disease entity, as it is a descriptive term for clinical use that includes several different clinical phenotypes reflecting different underlying mechanisms.

Till date there is no universally accepted definition of ACO. The description proposed by Global Initiative for Asthma (GINA) and the Global initiative for chronic Obstructive Lung Disease (GOLD) committees jointly created the term ACOS later renamed it as ACO, to much extent is of help as diagnostic tool for clinician, managing obstructive airway diseases.[1]

Others academic groups/associations, for example, Spanish Society of Pneumology and Thoracic Surgery (SEPAR), Roundtable Groups, Czech Republic guidelines, Australian Asthma management Handbook have offered different definitions of ACOS, based on persistent airflow limitation as assessed by spirometry and bronchodilator response; documented history of asthma and atopy, exposure to tobacco smoke and/or biomass burning, peripheral eosinophil count, fraction of NO in the exhaled breath (FNO) and IgE levels in different combinations.[8-13]

Salient practical features of the GINA/GOLD (2020) and other recommendations related to definitions and parameters of ACO, COPD, and Asthma are summarized in **Table 2**.

TABLE 1 Clinical entities with airway obstruction

Clinical entities ***(Prefix Nos. as per Fig. 1)***	***Definition***	***Presentation***
1. Chronic Bronchitis	Symptomatic cough and sputum daily for at least 3 months over 2 years	Persons with chronic bronchitis and/or emphysema without airflow obstruction are not classified as having COPD
2. Emphysema	Abnormal airspace enlargement	
3. Chronic Bronchitis with Emphysema	Usually occur together	
7. Asthma	Mostly reversible airway obstruction, airway hyper-responsiveness with bronchodilator responsiveness	
4, 5&6. COPD	Persistent airflow limitation	
4. Chronic Bronchitis	Usually occur together	MIAO
5. Emphysema		
6. Chronic Bronchitis with Emphysema		
8, 9&10. Asthma - COPD Overlap	Clinical features that are consistent with both asthma and COPD	Varying incompletely reversible Airway Obstruction
8. Chronic Bronchitis with (VRAO)	Some patients with asthma who have been exposed to chronic irritation, as from cigarette smoke, may develop chronic productive cough	Difficult to differentiate patients with asthma whose airflow obstruction is not completely reversible from persons with Chronic Bronchitis and/or emphysema that have partially reversible airflow obstruction with airway hyperreactivity
9. Emphysema with (VRAO)	Some patients with asthma who have developed fixed airway obstruction may have abnormal airspace enlargement	
10. Chronic Bronchitis with Emphysema with (VRAO)	Some patients with these two disorders may have clinical asthma	
11. Diseases with known etiology or specific pathology	e.g., cystic fibrosis or oblitrative bronchiolitis etc.	

MIAO, mostly irreversible airway obstruction; VRAO, varying reversible airway obstruction

Prevalence and Morbidity of Asthma-COPD Overlap

Globally more than 339 million people are living with asthma; and 65 million people have moderate to severe COPD.[1,14]

Prevalence rates for ACO have been reported to be in the range between 9% and 55% of those with either diagnosis of asthma or COPD. This variation reflects the different criteria used by different investigators at different places in the world. Concurrent doctor diagnosed asthma and COPD has been reported between 15% and 32% with one or other diagnosis.[1]

In a systematic review and meta-analysis, based on the random-effects model, the pooled prevalence of ACO was found to be 2.0% in the general population, 26.5% among patients with asthma, and 29.6% among patients with COPD, whereas the prevalence of asthma-only was 6.2% and COPD-only was 4.9%.[16] In one of the study it has been reported to be more common amongst females & young population.[15,16]

Studies suggest that patients having asthma-COPD overlap have frequent exacerbations,have poor quality of life,a more rapid decline in lung function, higher mortality,higher prevalence of comorbidities and greater use of healthcare resources as compared with patients with asthma or COPD alone.[1,7,17-19]

Risk Factors for Asthma-COPD Overlap

Cigarette smoking: Tobacco smoke may modify the small airway inflammation and remodeling associated with bronchial asthma. It is suggested that FEV1 decline in subjects with ACO is more due to air way inflammation so caused than the pulmonary emphysema.[20]

TABLE 2 Parameters in asthma, ACO, and COPD

Parameters	*Asthma*	*ACO*	*COPD*
Age in years	Any age	40 or above 40	Usually above 40
Exposure to tobacco smoke	Usually none	≥5 pack years or equivalent	≥10 pack years or equivalent
Exposure to Biomass burning	Usually none	Yes especially in women	Yes
Past medical history of "atopy" Asthma	Asthma (doctor diagnosed) allergies	Asthma (doctor diagnosed) Allergies	Usually none of these
Symptoms	Vary over time. Often triggers by exposure to dust or allergen, exercise change in weather, emotions, etc.	Usually persistent but may vary	Chronic, continuous, usually progressive
Course of disease	Often improves with treatment or spontaneously. In few patients may persists because of development of fixed airway obstruction	Partially or fully improve with treatment, slowly progressive, needs high doses of treatment	Usually progressive
Post bronchodilator response in FEV1	Almost always >12% & 200 mL increase Frequently >12% & 400 mL increase	Usually >12% and 200 mL increase Rarely >12% and 400 mL increase	Usually <12% and 200 mL increase in FEV1
X-ray chest	Usually normal	Same as COPD	Hyperinflation and other changes of COPD

Atopy: There is no direct evidence that atopy alone causes pulmonary emphysema or the chronic bronchitis typical in COPD. However, α1-anti-trypsin deficiency in airways may increase the likelihood of developing asthma. Some of the COPD patients may manifest allergic symptoms, but it is not clear whether this represents late-onset atopy or asthma.[21,22]

Age: Age is not definite risk factor for ACO. Decline in lung functions with ageing is a normal phenomenon, may create confusion while screening for ACO. Adults with asthma, especially if they are smokers, lose FEV1 more rapidly as compared to nonsmoking asthmatics. In one of the study patients with asthma tend to be younger (mean age: 51.3 years) than those with ACO (mean age: 66.7 years), and those with COPD (mean age: 72.4 years).[23]

A history of childhood or adult-onset asthma should be a major criterion for ACOS. As the prevalence of COPD increases after age 40 years, an age cutoff of 40 years is reasonable to improve the accuracy of the diagnosis.[21]

Pathogenesis/Mechanisms Underlying Asthma-COPD Overlap

Asthma and COPD are having distinct pathophysiology. ACO shares several pathological characteristics with both Asthma and COPD as it shares some of the clinical and spirometric parameters, but the mechanism underlying this overlap is not clear.

Whether ACO is simply the coexistence of asthma and COPD or a distinct phenotype related to fundamental pathogenic mechanisms of asthma and COPD remains to be determined and the mechanisms underlying the overlap between asthma and COPD remain controversial.

"Dutch hypothesis" proposes that asthma and COPD are manifestations of the same basic disease process, where asthma predisposing to COPD in due course of time in the process of aging; where ACO may be a stage of this disease process. On the contrary British hypothesis suggests that asthma and COPD are two distinct diseases generated by different pathophysiological mechanism.[2,7,24,25]

As depicted in **Figure 2**, pathogenic processes in asthma are known to include mast cell-mediated bronchoconstriction, inflammation due to local antibody production, and eosinophilic inflammation. These are mediated by complex processes involving number of different messenger molecules, including histamine, cysteinyl leukotriene, prostaglandin D2, interleukins (ILs), and chemokines ultimately producing airway obstruction.[25,26,28,29]

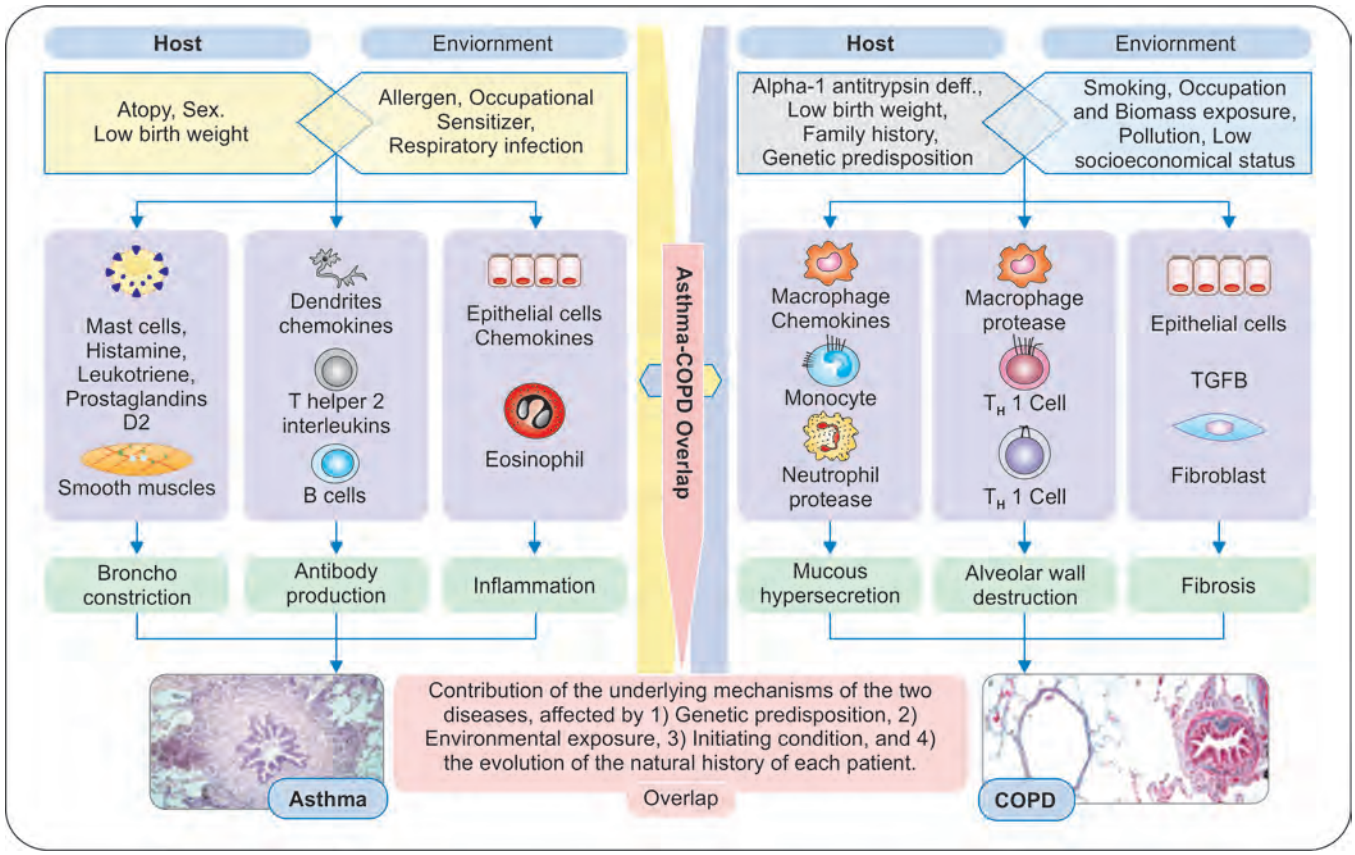

Fig. 2: Pathology of asthma, COPD, and their overlap[27]
TGFβ, tumor growth factor β; TH1, T-helper 1; TC1, type 1 cytotoxic T cells

In majority of asthmatics airflow obstruction so produced is typically reversible but in patients suffering from severe asthma it may partially or incompletely reversible (fixed airway obstruction) producing persistent airflow limitation.[30,25]

Inflammation in COPD patients is dominantly neutrophilic where involvement of inflammatory cells and messenger molecules, for example, epithelial cells, macrophages, chemokines, monocytes, neutrophils, T-helper cells, and type 1 cytotoxic cells typically producing bronchoconstriction, mucus hypersecretion, alveolar wall destruction, and fibrosis. In contrary to asthma airflow limitation in COPD is not completely reversible[30,31] **(Fig. 1)**.

In patients with overlap between asthma and COPD, the extent of the contribution of the underlying mechanisms of the two diseases may vary significantly amongst individuals, affected mainly by genetic predisposition, environmental exposure, the initiating condition, and the evolution of the natural history of each patient.

As in both asthma and COPD, the pathogenic processes are triggered by interactions between host and environmental factors; the same assumption is made in patients having ACO. In addition to the multiple risk factors as shown in **Figure 2**, evidence suggests that asthma itself is an independent risk factor for COPD especially amongst adults who had childhood asthma.[7,32] Tucson cohort study observed that asthmatic subjects were 12.5 times more likely to develop COPD than healthy individuals; and about half of the older patients with obstructive airway disease have overlapping diagnoses of both asthma and COPD.[33]

It has been observed that some asthmatic having long exposure to tobacco smoke and/or other environmental pollution, for example, biomass fuel smoke have more chances to develop COPD (asthma-COPD overlap). There

are conflicting data regarding the genetic component underlying ACO.[7,34-36]

It has been observed amongst longstanding asthmatics, that about 20% patients develops fixed airway obstruction, and by enlarge it is not reversible with bronchodilators. This group of patients with fixed airway inflammation and eosinophilic inflammation are often labeled as suffering from COPD and they are denied inhaled corticosteroids (ICS), on the contrary they may have ACO and expected to be benefited by ICS.[37,38]

Assessment

There is paucity of research data related to ACO, as these patients have been systematically excluded from clinical studies. Whatever few reports available are not exactly defining underlying mechanism, prevalence, clinical presentation, diagnosis, and management of ACO.[39]

Dyspnea, cough, expectoration, wheezing, and chest tightness are common symptoms in asthma and COPD, with some qualitative and quantitative variation; are also present in ACO on similar pattern. Patients of ACO usually experiences reduction in day-to-day activities, frequent need for reliever drugs, and recurrent acute exacerbations despite adherence to standard pharmacotherapy. Pattern of other parameters in clinical evaluation depends upon the dominance of the overlapping disease asthma or COPD **(Table 3)**.

Broad expected pattern of history and clinical evaluation of the patient suffering from obstructive airway diseases (Asthma, COPD, and ACO) have been summarize in **Table 3**.[1,21]

Investigations

Spirometry

Persistent expiratory airflow limitation with or without bronchodilator reversibility, as assessed by spirometric data are considered to be strongly suggestive of ACO[1] **(Table 4)**.

Biomarkers of asthma: Mostly used in research as there is little agreement about the most appropriate cutoff point for making a diagnosis.[11,40]

Blood or sputum eosinophil count—Measurement of blood eosinophil is well standardized and reproducible as compared to sputum eosinophil counts and are reported to be high in COPD patients with asthmatic features from 2% to 5%, or an absolute cell count 300 cells/uL^{-1}.

Fractional exhaled nitric oxide (FeNO)—Measurements of FeNO is another biomarker of asthma which is increased in asthma [50 parts per billion (ppb) in non-smokers].

Serum IgE titers—Levels are higher amongst asthmatic patients.

Carbon monoxide diffusing capacity (DLco): DLco is usually normal or low in ACO as compared to asthma (normal) and COPD (<80% predicted). DLco is a good indicator of functioning of gas exchange mechanism of lung, which is deranged in COPD.

Imaging Studies

X-ray chest—As such X-ray chest is not of much diagnostic significance for obstructive airway diseases (OAD) but of immense value in excluding other respiratory disease, for example, respiratory infections (especially tuberculosis), cystic fibrosis, obliterative bronchiectasis included in differential diagnosis of OAD.

CT scan chest—Valuable in assessing airway wall thickness and damage to peripheral lung tissues as seen in emphysema.

Blood tests—CBC, blood sugar, liver, and renal function studies to rule out systemic diseases included in differential diagnosis of OAD.

Sputum examination—For AFB and eosinophil count.

Other patho-biochemical investigations—For inflammatory cells, mediators, modulators, airway wall's smooth muscles and basement membrane studies through bronchoscopy biopsy and lavage are practically less of diagnostic value, are useful for research.

Diagnosis

Although a consensus on the exact definition and the diagnostic criteria of ACO remains elusive, the recent report of the GINA and the GOLD has highlighted a stepwise approach for the diagnosis of ACO[1] **(Table 2)**.

On the basis of detailed medical history, physical examination, and other investigations (as already described) asthma and COPD and possibility of extend of their overlap can be assessed **(Table 3)**.

Subsequently, diagnoses are confirmed through spirometric measures, including reversibility of airflow limitation. Post-bronchodilator (BD) increase in forced expiratory volume in 1 second (FEV1) ≥12% and ≥200 mL

TABLE 3 History and clinical evaluation of the patient suffering from asthma, COPD, and ACO

Parameters	***Obstructive Airway Diseases***		
	Asthma	***ACO***	***COPD***
History			
Symptoms—Dyspnea, cough, expectoration, wheezing, chest tightness			
Symptoms: • Variability • Triggers • Improvement	 • Vary over time & intensity • Allergen, seasonal, exercise, laughter • Spontaneous/quick with bronchodilator	 • Intermittent or episodic • Allergen, seasonal, exercise • Spontaneous with bronchodilator	 • Dyspnea persisted for most days. May have been preceded by cough/sputum • Nil • Limited response with bronchodilators
Age	<40 years	>40 years; 50–65 years	≥65 years if not younger
Sex	Adult women > Adult men	Slightly more amongst men	Men >women
Smoking habit and/or exposure to biomass	Nonsmoker or smokers (<5 pack years)	>10 pack-years and/or exposure to biomass or other toxic exposure	>10 pack-years and/or exposure to biomass or other toxic exposure
Obesity	More frequent	+/–	Usually not obese
Atopy/Rhinosinusitis/Asthma (Dr's. diagnosed)	Atopy/Rhinosinusitis present	Atopy/Rhinosinusitis/Asthma present	Usually no past or current diagnosis of asthma or atopy
Low birth weight	—	May have	May have
Respiratory illness specially infection, e.g., tuberculosis	Usually not	May have	May have
GERD	Present	Present	Present
Use of reliever drugs	Usually not frequent	Frequent	More frequent multiple daily doses
Limitation of exercise	Exercise not limited in between attacks	Limitation of exercise	Exercise significantly limited
Dependence	Patients with severe disease may frequently use Oral corticosteroid	Frequent use of oral corticosteroid	Oxygen
Hallmark problem	Frequent exacerbations	Very frequent exacerbations >COPD alone	Exacerbations and exercise intolerance

Based on clinical evaluation if suspected other alternative cardiorespiratory diagnosis such as heart failure, bronchiectasis and chronic bronchitis, and other forms of lung disease such as interstitial lung disease should be considered.

TABLE 4 Spirometric variables in asthma COPD overlap

Spirometric variable	***Asthma COPD overlap (ACO)***
Post-bronchodilator values	
Reduced FEV1/FVC (less than lower limit of normal, or less than 0.7 (GOLD))	Required for diagnosis of ACO
FEV1 80% predicted or more	Compatible with mild persistent airflow limitation if post-BD FEV1/FVC is reduced
Increase in FEV1 (12% or more) and 200 mL from baseline (reversible airflow limitation)	Common and more likely when FEV1 is low
Increase in FEV1 more than12% and 400 mL from baseline (marked reversibility)	Compatible with ACO

ACO: asthma COPD overlap; FEV_1: forced expiratory volume in 1 second; FVC: forced vital capacity; GOLD: global initiative for obstructive lung disease

TABLE 5 Drug treatment of aqsthma, COPD and asthma—COPD overlap

Pharmacotherapy	
Bronchodilators	
A. Beta 2 agonists	***B. Anticholinergic or Anti-muscarinic agents (AMA)***
• **Short acting (SABA)**	• **Short acting (SAMA)**
– *Salbutamol*	– *Levosalbutamol* – *Ipratropium bromide*
– *Terbutaline*	– *Fenoterol* • **Long acting (LAMA)**
– *Metaproterenol*	– *Tiotropium Bromide* – *Oxitropium Bromide*
• **Long acting-(LABA)**	– *Glycopyrronium Bromide* – *Aclidinium*
– *Formoterol*	– *Formoterol inhalation sol.* – *Darotropium* – *Dexpirronium*
– *Salmetrol*	– *Indacaterol* – *Umeclidinium* – *QAT-370*
– *Vilanterol*	– *Olodaterol* – *TD-4208*
– *Carmoterol*	– *Milveterol* ***C. Phosphodiesterase inhibitors***
– *BI-1744-CL*	– *PF-00610355* • **Methylxanthines**
– *LAS-100977*	– *Theophylline* – *Doxofylline*
	– *Acebrophylline* – *Aminophylline*
Anti-inflammatory	
A. Corticosteroids	***E. Anti-IgE Antibody***
• **Inhaled (ICS)**	– *Omalizumab*
– *Beclomethasone*	– *Budesonide* ***F. Anti-cytokine asthma therapies***
– *Flunisolide*	– *Triamcinolone* – *Pascolizumab (anti IL4)*
– *Fluticasone*	– *Ciclesonide* – *Mepolizumab, & SCH55700 (anti IL5)*
– *Mometasone*	– *Infliximab, Adalimumab and Golimumab (anti TNF-a)*
• **Systemic-Oral (OS), IV/IM**	– *IMA-638, CAT-354, and AMG 317 (anti-IL-13)*
– *Prednisolone*	– *Hydrocortisone* – *MT203 (Anti-GM-CSF)*
– *Methyl prednisolone*	– *Deflazacort* – *Anti-IL-25 (IL-17E), IL-25, IL-33, and TSLP*
B. Anti-leukotrienes	– *Anti -IFN-g, -IL-9, -IL-17, and -IL-27*
– *Zafirlukast*	– *Montelukast* ***G. Toll-like receptors (TLRs) agonists***
– *Probilukast*	– *Pranlukast* – *CpG oligodeoxynucleotide of 1018 ISS (a TLR9 agonist)*
– *Tomelukast*	– *AZD8848 (a TLR7 agonist)* – *MPL® (a TLR4 agonist)*
• **5-lipoxygenase inhibitor**	– *VTX-1463 (a TLR8 agonist)* – *CRX-675 (a TLR4 agonist)*
– *Zileuton*	– *1018 ISS & QbG10 (TLR9 agonists)*
C. Mast cell stabilizers	***H. Immunomodulators & Antimetabolites***
– *Cromolyn sodium*	– *Ketotifen* – *Methotrexate* – *Gold salt (oral auranofin)*
– *Nedocromil*	– *Troleandomycin* – *Hydroxychloroquine*
D. Monoclonal antibodies against	– *Dapsone* – *Gamma globulin (IV)*
• **IL-4 & IL-13**	– *Cyclosporine*
– *Dupilumab*	– *Lebrikizumab* ***I. Phosphodiesterase-4 inhibitors***
	– *Roflumilast*
Other	
• **Drugs for smoking cession**	• **Vaccines**
– *Nicotine replacement treatments*	– *NTHi oral immunotherapeutic (HI-164OV) against*
– *Bupropion -Varenicline*	– *Haemophilus influenzae*
– *Nicotine vaccines*	– *Pneumococcal vaccine -Influenza vaccine*
• **Antimicrobial**	• **Mucoregulators**
– *Azithromycin*	–*Carbocisteine*
– *Azole antifungal agents, itraconazole*	• **Management of comorbidities**

Reliever drugs—SABAs, SAMA, *Non selective β_2 agonist*-Adrenaline & other Catecholamines, I.V. corticosteroids & theophylline & aminophylline.
Controller drugs—all other bronchodilators & anti-inflammatory drugs.

from baseline is a common feature in ACOS patients, particularly if they had lower FEV1. Post-BD increase in FEV1 of ≥12% and ≥400 mL from baseline is also considered as a compatible factor for the diagnosis of ACOS[41] **(Table 4)**.

Treatment

Pharmacological and non-pharmacological treatment options available for asthma and COPD are used to treat ACO also depending upon the dominating disease in the overlap; asthma or COPD. Till date definite specific management protocol for treating ACO has not been evolved. Despite this, there is a common opinion among specialists that patients with characteristics of overlapping asthma and COPD should be considered and treated differently from those with COPD.

Appropriate pharmacological and non-pharmacological treatment **(Table 5)** considering most effective doses, drug delivery, compliance, affordability, availability, as far as possible free from toxic side effects and patient-friendly therapy be started after due consideration for:

- There are broad spectrum drugs, for example, bronchodilators, corticosteroids, and antibiotics and narrow spectrum drugs, for example, leukotriene receptor antagonists (LTRAs) and monoclonal antibodies, such as omalizumab, to treat inflammatory obstructive airway diseases **(Table 4)**. Depending upon the predominating overlap of asthma or COPD, they can be used in different combinations.
- ACO patients need aggressive treatment with combination of appropriate bronchodilator and optimal dose of inhaled corticosteroids (ICS).
- Monotherapy with ICS or bronchodilators should be avoided.
- ICS is essential in treatment to prevent exacerbations in future.
- Triple therapy with long-acting beta agonist (LABA) + long-acting muscarinic antagonist (LAMA) + ICS may be considered for more severe patients or patients having recurrent exacerbation.
- Additional COPD treatment as per guidelines should be given according to patient's requirement.
- Some COPD patients continue to smoke or those who smoke and have asthma have poor response with ICS; in these patients theophylline, leukotriene modifier, roflumilast (used as per clinical status of the patient) are good add on drugs.
- Avoid maintenance oral corticosteroids.
- Non-pharmacological treatment should be considered as in asthma and COPD:
  - Avoidance/exposure of allergens, asthma triggers, tobacco smoke, biomass fuel and occupational and environmental toxins
  - Rehabilitation—physiotherapy and psychotherapy
- Bronchial thermoplasty may be considered in selected cases.

Future Research

There is need for better definition, recognition, safe and effective treatment through research on better understanding of pathophysiology, biomarkers, mechanism in larger population having respiratory manifestation of airflow limitation. Most clinical trials and research are focused on asthma and COPD excluding ACO and other airway diseases. There is need to diversify this trend.

Conclusion

Asthma and COPD both are basically inflammatory obstructive airway diseases dominantly involving upper or lower airways, of course with little difference in etiopathogenesis, type of inflammation and involvement of other parts of lungs and some systemic manifestation, may possibly part of same inflammation with different phenotype/endotype. Some patients of asthma and COPD (Chronic bronchitis + airway obstruction with or without emphysema) may have some overlapping manifestation of both the diseases; and are labeled as asthma-COPD overlap-ACO.

In coming time probably management of inflammatory obstructive airway diseases will be individualized for each patient depending upon the presence of quantum of chronic bronchitis, emphysema, asthma (atopy/allergy) and resultant inflammation leading to airway obstruction and manifestation of split over of airway inflammation.

CHAPTER

111 Advanced Respiratory Failure

Arjun Khanna

Abstract

The etiology of advanced respiratory failure is varied and it is usually secondary to end stage respiratory diseases, which can stem from the lung parenchyma, chest wall, airways, and the pulmonary vasculature. Chronic respiratory failure (CRF) is defined as partial pressure of oxygen less than 60 mm Hg or partial pressure of carbon dioxide greater than 50 mm Hg, while breathing air at sea level. Respiratory failure in many respiratory diseases often starts during sleep. Thus, it is very important to evaluate the nocturnal saturation in patients with chronic respiratory diseases. Any features of SDB should raise an alarm in the physicians mind, and these patients should be subjected to nocturnal oximetry studies or full blown sleep studies. The management involves treating the underlying respiratory disease properly and offering rehabilitation and support in the form of oxygen, noninvasive ventilation, and pulmonary rehabilitation.

Introduction

Advanced or chronic respiratory failure (CRF) is a common and challenging problem faced by physicians. The etiology of advanced respiratory failure is varied and it is usually secondary to end stage respiratory diseases, which can stem from the lung parenchyma, chest wall, airways, and the pulmonary vasculature. Classically CRF is classified into hypoxemic and hypercapnic varieties. Often, patients have an overlap of both the varieties and it is not uncommon to see patients suffering from classical hypoxemic respiratory failure (e.g., interstitial lung disease—ILD), developing hypercapnia, during the course of their illness, owing to variable airway, and chest wall involvement, as the disease advances. Vice versa, also holds true as hypoxemia without hypercapnia, may be the dominant feature of chronic airways diseases such as chronic obstructive pulmonary disease (COPD) and bronchiectasis, where one usually expects to encounter hypercapnia.

Definition

The definition of this entity is based on arterial blood gas analysis. CRF is defined as partial pressure of oxygen (O_2) less than 60 mm Hg or partial pressure of carbon dioxide (CO_2) greater than 50 mm Hg while breathing air at sea level.[1] It is often, not prudent, to look for water tight compartments between hypoxemia and hypercapnia, as both often coexist in a single patient, and the erstwhile differentiation into type I and type II respiratory failure becomes more and more redundant.

Etiology

Advanced respiratory failure can arise from chronic malfunction of any of the compartments of the respiratory system. Common etiologies associated with CRF include:

- Chronic airways diseases—COPD, bronchial asthma, asthma-COPD overlap, bronchiectasis, cystic fibrosis.
- Pulmonary parenchymal disorders—Interstitial and diffuse parenchymal lung disorders, sequel

of respiratory infections such as acute respiratory distress syndrome (ARDS) and coronavirus disease (COVID-19).

- Chest wall disorders—Neuromuscular disorders including myopathies and dystrophies, kyphoscoliosis.
- Pulmonary vascular disorders—Chronic thromboembolic and other forms of pulmonary hypertension (PH), pulmonary vasculitis, pulmonary AV malformations.
- Sleep disordered breathing—SDB, which includes obstructive sleep apnea and its overlap with other chronic respiratory disorders.
- Disorders of respiratory control—Chronic hypoventilation syndromes, spinal cord and brainstem injury, some toxins and poisonings.

Clinical Features, Diagnosis, and Evaluation

The diagnosis of CRF is often delayed and patients with chronic lung disorders often present for the first time to the respiratory clinic, when they can only be offered condolences and palliation. A very important reason, why this happens is that patients with chronic respiratory diseases often decrease their activity due to increasing dyspnea. As the patient becomes more and more bed bound, the underlying disease condition often increases to an extent that the room air PO_2 falls below 60 mm Hg and pCO_2 rises above 50 mm Hg, without the patient or the caregivers realizing it.

Respiratory failure in patients with chronic respiratory disorders first sets in during sleep.[2] During sleep, there are multiple reasons of increase in hypoxia. The loss of sympathetic drive, pooling of secretions, nocturnal bronchoconstriction, and upper airway collapse, all add to nocturnal hypoxia. Patients with chronic hypoxia, function on the steep portion of their oxygen dissociation curve and tend to develop very severe hypoxia due to nocturnal changes, which take place during normal sleep. These changes have no effect on the saturation of normal people during sleep, but, in patients with long standing hypoxia, this sleep associated desaturation is often the first step in the development of CRF. These changes are often more pronounced in patients who have obstructive sleep apnea or other forms of sleep disordered breathing (SDB). The presence of SDB adds fuel to fire and pushes these patients toward frank respiratory failure.

Thus, it is very important to evaluate the nocturnal saturation in patients with chronic respiratory diseases. Any features of SDB should raise an alarm in the physicians mind, and these patients should be subjected to nocturnal oximetry studies or full blown sleep studies, as per situation. If respiratory failure is picked up during sleep and treated, the progression of these patients to frank respiratory failure can often be delayed.

Once a patient develops frank respiratory failure, he may develop frank cyanosis, fatigue, anxiety, confusion, and hypoxia. Rapid shallow breathing is often seen in patients with respiratory failure due to diseases such as ILD, wherein, patients are accustomed to breathing at very high respiratory rates. Tripod position, which implies, using limbs to support the chest wall is often seen in patients with advanced airways diseases. Cachexia and muscle wasting are ominous clinical signs in these patients, and signify advanced disease. Patients with hypercapnic predominant respiratory failure are often suffused and plethoric due to the vasodilatory effects of CO_2. Chronically elevated CO_2 levels can cause mental blunting and these patients develop subtle mental function decline, which is often overlooked.

Laboratory evaluation in these patients should be aimed at, finding the reason of CRF, if not already known. Basic evaluation should consist of a good quality HRCT Chest, 2D echo, arterial blood gas (ABG) analysis, complete pulmonary function testing including spirometry, lung volumes, and diffusion capacity. Six-minute walk test is a vital tool, which is often not done in clinical practice and provides important information regarding prognosis and response to drugs, oxygen, NIV, etc. in these patients. A very important clue in the ABG, which hints toward the development of CRF, is elevated bicarbonate levels. Bicarbonate levels more than 27 mmol/L represent a physiological response to persistently high CO_2 levels.[3] Any patient with chronic lung disease with high bicarbonate levels on ABG must be viewed with suspicion, and full CRF work-up protocol initiated.

Management

Treatment of underlying cause is not uncommon to see patients developing CRF due to suboptimal treatment of the underlying lung disease. The treatment modalities for many lungs are improving and providing hope to many such patients. A few path breaking treatment options

which are changing the face of many advanced lung diseases include:

Airway diseases: Airway diseases are among the most important and common causes of CRF in our country. One of the most important reasons why these patients reach the stage of CRF is avoidance of proper bronchodilator therapies. For COPD, excellent long acting bronchodiltaors are available. Newer anticholinergic agents such as glycopyrronium and umeclidinium, improve lung function, decrease exacerbations, and improve mortality in patients with COPD. Lung volume reduction surgery, bronchoscopic vapor ablation, etc. are newer modalities for treatment of advanced COPD, which can add years to a patient's life. For patients with advanced bronchial asthma, the key is to differentiate between Th1 and Th2 mediated inflammation. Th2 predominant patients respond to biological therapy, whereas, Th1 predominant patients may be offered bronchial thermoplasty, which is now readily available in India. For patients with advance bronchiectasis, the emphasis should be on airways hygiene and finding out the cause of bronchiectasis to personalize the therapy.

ILD: ILDs are being increasingly recognized as an important cause of CRF in our country. Owing to the more frequent usage of HRCT chest, we are picking up more ILD patients, than ever before. The first step of treating CRF in these patients is to first find out the reason of the ILD. Grossly, the ILDs may be divided into UIP (usual interstitial pneumonia) and NSIP (nonspecific interstitial pneumonia). UIP pattern on HRCT with any reason constitutes idiopathic pulmonary fibrosis. The diagnosis of IPF is associated poor outcomes. Currently approved therapies for IPF include Nintedanib and Pirfenidone, which modestly decrease lung function decline. For the NSIP, varieties of treatment would depend upon the underlying reason for ILD (sarcoidosis, hypersensitivity pneumonitis, connective tissue related), with most patients receiving a cocktail of oral steroid and immunosuppressant agents. Patients who present with frank CRF may be refractory to any kind of drug therapy and can only be offered oxygen therapy and pulmonary rehabilitation.

Pulmonary vascular disorders: PVDs are a group of challenging diseases to treat. Many of the advanced agents used to treat PH are still not available in the country, along with surgical options like pulmonary endarterectomy, which finds almost no takers in India. Riociguat is a newer agent, which is used to treat patients with chronic thromboembolic PH.[4] Most patients with group 3 PH are treated only with oxygen therapy and should not be offered any of the pharmacological agents for treatment of PH, as this might increase the VQ mismatch and worsen the respiratory failure. Like ILD, many patients with CRF due to advanced pulmonary vascular disorders, may only be candidates for pulmonary rehabilitation and lung transplantation (LT).

Oxygen therapy: Oxygen therapy may be the only treatment option left for many patients with advanced CRF. Oxygen relieves the hypoxic vasoconstriction and improves the VQ mismatch. Survival benefit in CRF has only been demonstrated in CRF in patients with advanced COPD. The indication of oxygen therapy in other reasons of CRF has been extrapolated from its use in COPD. Use of injudicious oxygen therapy in patient with underlying hypercapnia should be avoided. Uncontrolled oxygen therapy in such patients might actually be counterproductive and worsen hypercapnia. In many patients with hypercapnic respiratory failure, oxygen may have to be given with noninvasive ventilation (NIV). The classical indications for use of domiciliary oxygen therapy in patients with advanced COPD include:

- Arterial oxygen tension (PaO_2) less than or equal to 55 mm Hg, or a pulse oxygen saturation (SpO_2) less than or equal to 88%.
- PaO_2 less than or equal to 59 mm Hg, or SpO_2 less than or equal to 89%, if there is evidence of cor pulmonale, right heart failure, or erythrocytosis (hematocrit >55%).

For patients with normal awake oxygenation, oxygen may be prescribed during sleep if any of the following occurs during sleep: the PaO_2 is 55 mm Hg or less, the SpO_2 is 88% or less, the PaO_2 decreases more than 10 mm Hg, and/or the SpO_2 decreases more than 5% with signs or symptoms of nocturnal hypoxemia (e.g., impaired cognitive function, morning headaches, restlessness, or insomnia).[5]

NIV: NIV is an important tool used to treat various forms of CRF. NIV revolves around giving an inspiratory and an expiratory pressure support to the lung. The IPAP, takes care of the hypercapnia and the EPAP, opens the upper airways and recruits and opens the smaller airways and

the alveolar air sacs. NIV usage is vital in patients with CRF, due to chest wall disorders including myopathies and kyphoscoliosis. Any form of CRF, which has a component of hypercapnia, may be benefitted to some degree, by using NIV. NIV also unloads the respiratory muscles and improves oxygenation. Specific criteria are used for initiating NIV in patients with CRF due to various disorders.[6,7] However, the crux of the matter is to pick up nocturnal respiratory failure early in patients and offer them NIV early so that optimal benefits of NIV may be utilized.

Pulmonary rehabilitation (PR): PR is a broad therapeutic concept. It is defined by the American Thoracic Society and the European Respiratory Society as a "comprehensive intervention based on a thorough patient assessment followed by patient-tailored therapies that include, but are not limited to, exercise, training, education, and behavior change, designed to improve the physical and psychological condition of people with chronic respiratory disease, and to promote the long-term adherence to health-enhancing behaviors."[8]

PR can be utilized to help all kinds of patients with CRF. It is often overlooked, and we physicians tend to overlook this aspect of patient care, and focus most of our energies on pharmacotherapy only. PR programs include, exercise therapy, nutritional counseling, smoking cessation activities, psychosocial support, and an overall attempt to improve the patients quality of life. All patients with CRF should be offered the influenza and pneumococcal vaccines, as per the local guidelines and doses repeated when indicated. End of life care and advanced directives must always be taken well in time from these patients.

LT services are now available in India.[9] LT is often offered to patients with CRF, when all other options have been exhausted. The road to LT is a long drawn one, and requires considerable financial and psychosocial support. As of now, LT in India is limited primarily to the private sector. Apart from cost and logistic issues, a major problem with LT in India is the post LT care, which requires extensive immunosuppression and multiple interval lung biopsies.

Conclusion

Advanced respiratory failure can be the culmination of many respiratory disorders. It used to be classically distinguished into hypercapnic and hypoxemic varieties. However, these classifications are not watertight compartments. The aim of therapy of various chronic lung diseases should be to prevent the development of frank CRF, and treating these patients with the best possible treatment modalities available. Once frank CRF develops, the physician should look beyond pharmacotherapy and offer the patient NIV, domiciliary oxygen, pulmonary rehabilitation, vaccination, and periodically assess and counsel them regarding LT.

CHAPTER

112 Current Treatment Guidelines—Pulmonary Embolism

Akshay Kumar Chhallani, Bharat Jagiasi

Abstract

Pulmonary embolism (PE) is a major cause of morbidity and mortality among hospitalized patients. It should be promptly diagnosed and treated. All PE patients require anticoagulation. Recent advances in thrombolytics have improved the present treatment options for high risk PE who are hemodynamically unstable. If used judiciously, direct oral anticoagulation therapies are safe and convenient.

Introduction

Pulmonary embolism (PE) is a common and potentially fatal disease with a highly variable clinical presentation. PE is regarded as an extension of a deep vein thrombosis (DVT) and not a separate entity. De novo PE forming in the pulmonary arteries is rare. It is essential that therapy be administered in a timely fashion specifically in critically ill patients so that recurrent thromboembolism, post-thrombotic syndrome and death can be prevented.

Classification

Pulmonary embolism patients are stratified into high risk, intermediate risk, and low risk after carefully considering clinical variables, hemodynamic stability, biochemical and radiological parameters. The treatment of PE depends upon the risk of death.

High Risk

- This accounts for 5–10% of cases.
- Nearly half of pulmonary vasculature is affected by extensive thrombosis in those groups.
- Patients in this category are hemodynamically unstable.

PE patients are defined as hemodynamic unstable in following situations:

- Cardiac arrest or
- Obstructive shock

In spite of adequately resuscitating with fluids patient had persistent hypotension, systolic BP < 90 mm Hg or required vasopressor to achieve a systolic BP > 90 mm Hg & end organ hypoperfusion, or

- 40 mm Hg drop in systolic BP lasting for more than 15 minutes, which is not caused by sepsis, hypovolemia or new onset arrhythmia.

Reperfusion Treatment

Thrombolytic: Thrombolytic agents activate plasminogen to form plasmin, which accelerates lysis of thromboemboli.

In acute PE thrombolytic therapy will rapidly dissolve the embolic burden and improve pulmonary artery pressure (PAP); pulmonary vascular resistance (PVR).[1-3]

Successful thrombolysis will also reduce right ventricular (RV) dilation on echocardiography.

Sooner is better for administration of thrombolytic. Thrombolytic therapy should be offered as early as possible, preferably within first 2 days of symptoms onset for greater benefits.[4]

Unlike in myocardial infarction and stroke; symptomatic PE patients can be thrombolyzed up to 2 weeks after onset of symptoms.

However, thrombolytic therapy is associated with bleeding, which can be fatal and catastrophic.[5]

The overall major bleeding rate is 10%, including a 2–3% risk of intracranial hemorrhage.

Reperfusion Medication (Fibrinolytic & Thrombolytic) and Dose

Recombinant tissue plasminogen activator (rtPA)	IV Total 100 mg infusion over period of 2 hours
Streptokinase (STK)	2,50,000 IU—loading dose over ½ an hour & 1,00,000 IU/hour for next 24 hours
Urokinase	4,400 IU/kg—loading over 10 minutes and then by 4,400 IU/kg/hour for next 24 hours

Extracorporeal Membrane Oxygenation (ECMO)[6-11]

Venoarterial extracorporeal membrane oxygenation (VA-ECMO) may be helpful in patients with circulatory collapse or cardiac arrest and very high risk PE.

Specific attention needs to be given to bleeding complications particularly in patients receiving thrombolysis.

The outcome of ECMO depends upon number of factors including patient selection, expertise, and experience of center.

Till date no randomized clinical trial (RCT) done to prove statically significant improvement with ECMO in PE patients though case series showed survival in critically ill.

Intermediate Risk

Intermediate risk PE as acute PE that is associated with biochemical, echocardiographic, and/or imaging evidence of RV dilation or hypokinesis *without* systemic hypotension.

The intermediate risk group is the most heterogeneous and challenging.

In this group it is difficult to select patients who will benefit from thrombolytic treatment.

One needs to individualize the therapy and may require additional assessment.

While there is no agreed upon definition, some experts[12] distinguish between intermediate-high risk and intermediate-low risk patients using the following:

- Intermediate-low risk PE—Abnormal RV function *OR* elevated BNP or troponin.
- Intermediate-high risk PE—Abnormal RV function *AND* elevated BNP or troponin.

Intermediate high risk PE may get benefitted by thrombolytics, but there is no definitive evidence to support this.

Low Risk

Patients with low risk PE do not require thrombolytic therapy and should be treated with anticoagulation alone.

Low risk patients have excellent prognosis.

Parenteral Anticoagulation

Adequate and effective anticoagulation is the key for successful treatment of PE.

All patients with proven or suspected PE should receive anticoagulation as early as possible.

It can be done with subcutaneous, low-molecular weight heparin (LMWH) or IV unfractionated heparin (UFH) or Fondaparinux.

Fondaparinux is an anti Xa pentasaccharide synthesized in a laboratory.

LMWH has greater bioavailability and more predictable dose response and longer half-life.

Both LMWH and Fondaparinux require dose adjustments in renal failure and morbid obesity.

UFH anticoagulates by binding to and accelerating the activity of antithrombin, which prevents new thrombus formation.

Because lower risk of major bleeding and heparin-induced thrombocytopenia (HIT).

LMWH and fondaparinux are preferred over UFH for initial anticoagulation in PE.[13-16]

Oral Anticoagulant

Warfarin:

- This is Vit K antagonist.
- It requires 5 days to get full effect of warfarin.
- In acute thrombotic illness warfarin should be always overlap with UFH/LMWH/Fondaparinux for at minimum duration of 5 days.

A paradoxical exacerbation of hypercoagulability in acute thrombosis may be observed if warfarin is initiated as monotherapy.

Novel Oral Anticoagulant (NOAC)

- NOAC does not require laboratory monitoring.
- Rivaroxaban and Apixaban are direct factor X a inhibitor are approved for treatment of PE without parenteral bridging anticoagulant.
- Dabigatran is direct thrombin inhibitor, will require an initial 5 days course of parenteral anticoagulation.

Bleeding Risk

It is necessary to evaluate the risk of bleeding before starting anticoagulation.

Major risk factors for bleeding are:

- Advanced age (>75 years)
- Previous bleeding, or anemia
- Active malignancy
- Previous stroke
- Chronic kidney disease or liver disease
- Concomitant antiplatelet therapy or non-steroidal anti-inflammatory drugs
- Poor anticoagulation control

Meta-analyses done by *Kakkos SK* showed that there is 40% reduction in the risk for major bleeding with NOACs compared with VKAs.[17]

Duration of Anticoagulation

All PE patients should receive at least 3 months of anticoagulation.[18]

After 3 months of treatment, physician should plan the therapy on case-to-case basis considering benefit—risk ratio of VTE recurrence and that of bleeding.

In view of their ambiguous nature and not very clear cut defining criteria provoked or unprovoked terminologies are not taken into consideration while planning the treatment duration.

Terminology such as "provoked" versus "unprovoked" may be misleading and create confusion, hence these are no more supported by European Society of Cardiologist.[12]

Anticoagulation for Venous Thromboembolism

Unfractionated heparin	80 U/kg bolus, then infusion 18 U/kg, maintain ApTT 2–3 times the upper limit
Enoxaparin	1 mg/kg twice daily
Dalteparin	200 U/kg OD or 100 U/kg twice a day
Fondaparinux	7.5 mg once a day
Rivaroxaban	15 mg twice a day for 3 weeks and then 20 mg once a day
Apixaban	10 mg twice daily for 1 week and then 5 mg twice a day
Dabigatran	150 mg twice daily. Needs overlap with LMWH
Warfarin	Starting dose 5 mg, maintain INR 2–3 Needs overlap with UFH/LMWH

Pulmonary Embolism in Cancer[19-22]

In patients with cancer and PE, LMWH should be preferred over VKAs for first 6 months.

Edoxaban and Rivaroxaban are the two NOAC, which are tried in few cancer patients without gastrointestinal tumors.

Anticoagulation can be discontinued once cancer is cured but it is difficult to define the "cancer cure."

Pregnancy[23,24]

Pregnancy is a procoagulant state with increased risk of PE.

In pregnancy LMWH is the drug of choice to treat PE.

LMWH does not cross the placenta.

After delivery, anticoagulant treatment should be continued for more than 6 weeks and with a minimum duration of 3 months.

LMWH and warfarin can be safely administered to breastfeeding mothers.

In the event of life-threatening PE thrombolytic therapy can be attempted in pregnant patients.

VKAs and NOAC are not recommended in pregnancy possibly because of teratogenicity and fetal hemorrhagic risk.

In female patients of child bearing age, pregnancy, or breastfeeding should be excluded prior to commencing NOAC therapy.

Role of Inferior Vena Cava Filter[25-27]

The placement of inferior vena cava filter (IVC-filter) in the treatment of venous thromboembolism is controversial.

In the patients who are actively bleeding that precludes anticoagulation and who had recurrent venous thrombosis in spite of intensive anticoagulation, IVC-filter may be tried.

Early prophylactic IVC-filter after major trauma is not found to reduce symptomatic PE or death at 90 days than no placement of filter.

No convincing clinical outcome data is available to recommend prophylactic IVC filter use.

Percutaneous Catheter Directed Treatment

Pharmacomechanical catheter directed therapy involves physical fragmentation of thrombus with catheter directed low dose thrombolytic (24 mg of tPA).

As data is lacking from RCTs on clinical efficacy outcomes, this approach should be used with caution.

Chronic Thromboembolic Pulmonary Hypertension (CTEPH)[28]

Chronic thromboembolic pulmonary hypertension develops in 2–4% of acute PE patients.

Pulmonary thromboendarterectomy, lifelong oral anticoagulation, and diuretics may give relief and reduce pulmonary hypertension.

Mobilization in DVT[29,30]

Mobilization may be beneficial in reducing pain and edemas from DVTs, but large scale randomized control trials are required to validate these outcomes.

Conclusion

- Pulmonary embolism is life threatening, but potentially treatable and preventable condition.
- High risks (hemodynamically unstable) are benefitted by thrombolysis.
- All patients with PE should receive therapeutic anti-coagulation for more than 3 months.
- LMWH is preferred drug for parenteral anticoagulation.
- NOAC are promising molecule to minimize bleeding risk.
- Role of IVC filter is controversial.

Clinical Medicine

CHAPTER

113 Approach to Ascites

Veerendra Singh

Abstract

Ascites, the collection of fluid in the peritoneal cavity, can originate from hepatic, malignant, cardiac, renal, and infectious diseases. Cirrhosis, tuberculosis, and malignancy are the most common causes in Indian patients. Ultrasonography and paracentesis with ascetic fluid examination are the modalities used to establish the etiology. Sodium restriction and diuretics are mainstay of treatment of ascites due to cirrhosis. Ascites due to other causes requires specific treatment. For refractory ascites large volume paracentesis along with infusion of albumin is used. Liver transplantation is the gold standard therapy. Despite the advances in modern medicine, development of ascites is associated with poor prognosis and high mortality.

Introduction

Commonly presenting with abdominal swelling, ascites is a pathological fluid collection in the peritoneal cavity. The common causes of ascites are cirrhosis, tuberculosis, malignancy, cardiac failure, pancreatitis, and nephrotic syndrome. The management depends on the etiology of ascites from hepatic to extrahepatic causes and on the stage of ascites from uncomplicated to refractory stage.

Causes of Ascites

Various causes of ascites are shown in **Table 1**. In India, cirrhosis of liver is most common cause of ascites followed by tuberculosis versus malignancy in developed countries. Sometimes more than one condition may coexist with significant management implications. Alcoholic patients can have cirrhosis with cardiomyopathy, tuberculosis, or malignancy. For management, perspective ascites is grouped under two heads: ascites due to cirrhosis or due to causes other than cirrhosis.

Ascites Due to Cirrhosis

Portal hypertension and renal salt and water retention are the key mechanisms of ascites in cirrhosis. Ascites denotes the transition from a compensated to a decompensated stage of cirrhosis. Initially ascites is uncomplicated, not infected, and responds well to diuretics.[1] As disease progresses, ascites ceases to respond to diuretics (refractory ascites) and renal dysfunction supervenes (hepatorenal syndrome).

Uncomplicated ascites is subdivided into three grades: mild, moderate, and massive ascites. Refractory ascites has two subtypes: diuretic-resistant and diuretic-intractable.[2]

Complications of Cirrhosis

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis (SBP), a lethal complication, results from ascitic fluid infection in absence of an intra-abdominal infective focus.

TABLE 1 Causes of ascites

Portal hypertension	Infections	Miscellaneous
• Cirrhosis liver • Alcoholic hepatitis • Hepatic congestion – Congestive cardiac failure – Constrictive pericarditis – Hepatic venous outflow obstruction • Portal vein thrombosis • Non-cirrhotic portal hypertension	• Bacterial peritonitits • Tubercular peritonitis • HIV associated periotonitis **Malignancies** • Peritoneal carcinomatosis • Primary mesothelioma • Hepatocellular carcinoma • Metastatic liver disease • Pseudomyxoma peritonei	• Pancreatitis • Hypoalbuminemia • Nephrotic syndrome • Lymphatic leakage • Myxoedema • SLE

Hepatic Hydrothorax

Pleural effusion develops in approximately 5–10% of patients with cirrhosis due to transdiaphragmatic movement of fluid from peritoneal cavity to pleural space.[3] Patients usually have minimal ascites. Pleural effusion is right sided in 85%, left sided in 13%, and bilateral in 2% cases.

Ascites due to Causes other than Cirrhosis

In malignancy and tuberculosis tumor cells and tubercles lining the peritoneum produce protein rich fluid. Pancreatitis, heart failure, nephrotic syndrome, and hypothyroidism may cause ascites.

Malignant Ascites

Malignant ascites occurs secondary to:

- Peritoneal carcinomatosis: malignant infiltration of peritoneum
- Massive hepatic metastasis
- Profound desmoplastic response to infiltrating breast cancer
- Chemotherapy induced nodular regenerative hyperplasia

Two-thirds cases of malignant ascites are caused by peritoneal carcinomatosis from adenocarcinomas of pancreas, stomach, colon, ovary, uterus, lungs, or breast. The remaining are caused by hapatocellular carcinoma or hepatic metastases.

Evaluation and Diagnosis

Clinical Assessment

Ascites may be asymptomatic or may just produce an increase in abdominal girth described as tightness of cloths or belt. Massive ascites produces abdominal discomfort, umbilical eversion, hernias, and breathlessness. Physical examination is not significant in mild ascites. In moderate ascites, flank dullness and shifting dullness are sensitive findings. Massive ascites produces marked distension of abdomen. Signs of liver disease and portal hypertension should be sought. Hepatic, renal, and cardiac status should be assessed.

Pathological Assessment

Routine urine examination, complete blood counts, blood sugar, liver function tests, viral markers (HBV, HCV, and HIV), serum screatinine, NT-Pro BNP, and thyroid function tests should be obtained.

Imaging

Ultrasound is the best modality to document the presence of ascites. It can provide information about cause of ascites (fibrosis in cirrhosis, nodules in HCC, or liver metastasis). Fibroscan is a new modality to document fibrosis of liver. Doppler sonography can detect portal or hepatic vein thrombosis. Contrast enhanced CT, echocardiography, upper GI endoscopy, and colonoscopy may be ordered in select conditions. MRI using gadolinium scan can demonstrate enhancement of peritoneal lining in peritoneal carcinomatosis.[4]

TABLE 2 Tests of ascitic fluid

Routine tests	*Additional tests*
• Appearance • Total protein • Serum ascites albumin gradient (SAAG) • Cell count	• Gram stain and culture • AFB smear, culture and adenosine deaminase activity • Glucose and lactate dehydrogenase • Amylase concentration • Cytology and carcinoembryonic antigen level • Triglyceride level

Abdominal Paracentesis

Once the presence of ascites has been confirmed, the etiology of ascites is best determined by paracentesis. Between 20–50 mL of ascitic fluid should be aspirated and examined **(Table 2)**.

Appearance

In ascites due to portal hypertension the fluid is clear and straw colored. Turbid fluid can result from infection or malignancy. Milky fluid, chylous ascites results from lymphatic disruption due to malignancy, trauma, and congenital abnormalities. Bloody ascites could be due to traumatic tap or malignant ascites. Blood in traumatic fluid clots but in malignant ascites does not clot.

Total Protein

Protein levels are useful in determining etiology of ascites. Traditionally ascitic fluid is grouped into:

- Exudate with protein concentration more than 2.5 g/dL.
- Transudate with protein concentration less than 2.5 g/dL.

Exudative ascites occurs secondary to peritoneal processes (malignancy, tuberculosis) or post-hepatic sinusoidal hypertension with normal sinusoids (heart failure, hepatic vein, or inferior venacava obstruction) whereas transudative ascites results from increased sinusoidal portal hypertension (cirrhosis). Total protein levels are also useful in determining susceptibility to infection. Patients with ascitic fluid protein less than 1.0 g/dL are prone to develop SBP.

TABLE 3 Diffrentiation of ascites based on hepatic venous pressure gradient measurement

Causes of ascites	*WHVP*	*FHVP*	*HVPG*
Cirrhosis	Increased	Normal	Increased
Cardiac ascites	Increased	Increased	Normal
Malignant ascites peritoneal tuberculosis	Normal	Normal	Normal

FHVP, free hepatic venous pressure; HVPG, hepatic venous pressure gradient; WHVP, wedged hepatic venous pressure

Serum-ascites Albumin Gradient

Serum-ascites albumin gradient (SAAG) is the difference between albumin concentration in the ascitic fluid and that in the serum both collected at the same time. It is a very useful tool to establish the presence of portal hypertension. A SAAG value more than 1.1 g/dL reflects portal hypertension and indicates the ascites is due to increased pressure in the hepatic sinusoids. The SAAG has been found to be superior to the total protein concentration for the differential diagnosis of ascites.[5]

Hepatic Venous Pressure Gradient

Hepatic venous pressure gradient (HVPG) is direct measure of hepatic sinusoidal pressure measured via a catheter in right femoral or internal jugular vein. Portal hypertension is defined as HVPG value more than 6 mm Hg **(Table 3)**.

Laparoscopy

Laparoscopy offers the advantages of visual inspection of the peritoneal cavity and obtains targeted biopsies for histological studies. With the availability of new imaging techniques, the need for laparoscopy in determining the cause of ascites has decreased.

Diagnostic Developments

New novel diagnostic markers such as leukocyte esterase reagent strips for diagnosing SBP, viscosity measurement of ascitic fluid to discriminate between portal and non-portal hypertension, vascular endothelial growth factor (VEGF), bacterial DNA for documenting bacterial translocation, and markers of poor prognosis such as endotoxin and peptidoglycan/β-glucan have been proposed but still need validation.

Approach to a Patient of New Onset Ascites

See **Flowchart 1**.

Evaluation of Infection

Cell Counts

A predominance of neutrophils indicates an acute intra-abdominal inflammation. An ascites PMN count greater than 250/mm^3 establishes diagnosis of SBP.[6] Predominant mononuclear cells indicate tubercular ascites.

Smear and Bacterial Culture

Culture samples of ascetic fluid for both aerobic and anaerobic bacteria should be inoculated at the bedside into a blood culture bottle.

Ascitic Fluid Glucose and LDH Levels

Ascetic fluid LDH higher than serum LDH (ratio >1.00) and ascetic fluid glucose below 50 mg/dL suggests secondary bacterial peritonitis.

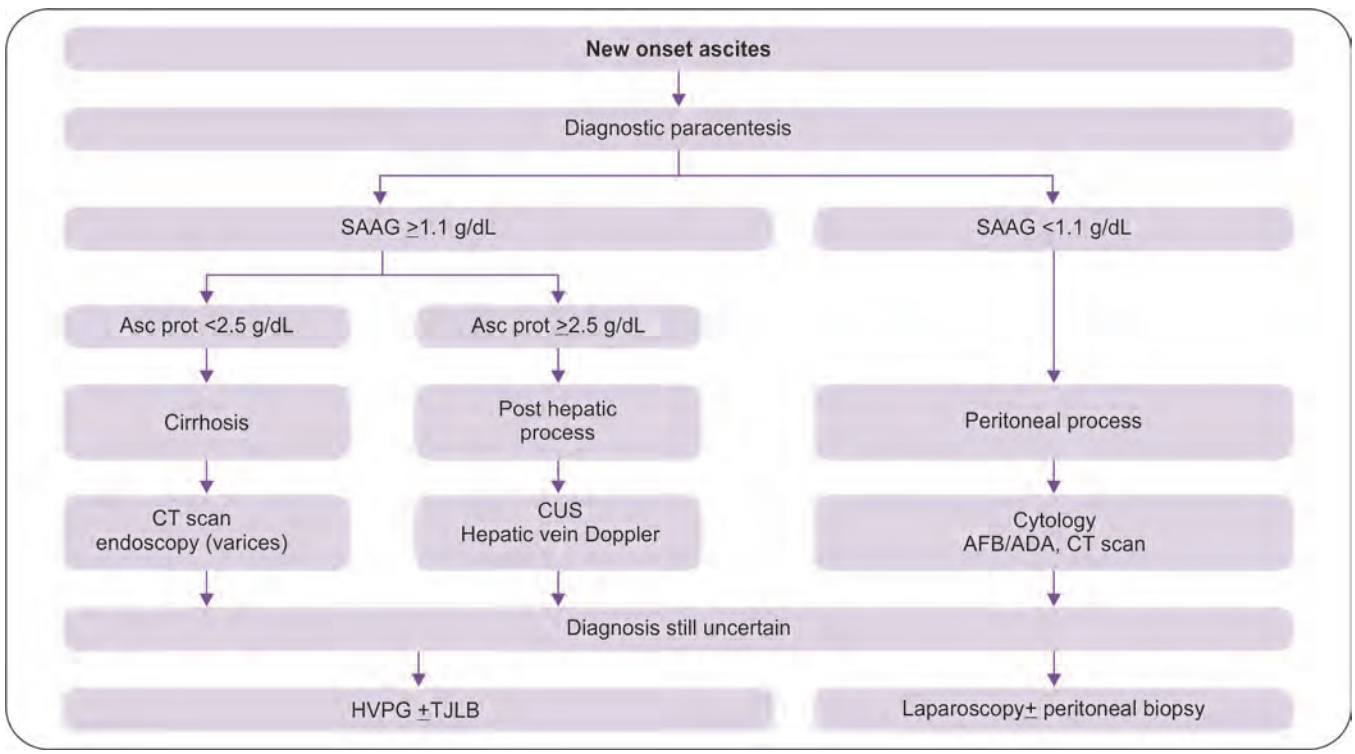
Evaluation of Tubercular Ascites

In tuberculous peritonitis, the smear for acid-fast bacilli is rarely positive and culture is positive only in about 50% of cases. Polymerase chain reaction for MTB has a high sensitivity (94%).[7] Adenosine deaminase activity (ADA) is a reliable marker of tuberculous ascites. Mononuclear cell predominant leucocytes >500/cc, total protein more than 3 g/dL, LDH >90 units/L, or ADA >36–40 IU/L has a sensitivity of 100% and a specificity of 97% for of peritoneal tuberculosis. Laparoscopy with peritoneal biopsy and histopathology is the gold standard for diagnosis of peritoneal tuberculosis.[8] Recommended stepwise approach for the diagnosis of peritoneal tuberculosis is detailed in **Flowchart 2**.

Evaluation of Malignant Ascites

Abdominal ultrasound and CT may be useful to demonstrate the primary malignancy or hepatic metastases but seldom confirms the diagnosis of peritoneal carcinomatosis. Analysis of the ascetic fluid is the most important step in

Flowchart 1: Approach to a patient of new-onset ascites



Asc prot, ascites total protein level; CUS, cardiac echosonography, HVPG, hepatic vein pressure gradient

Flowchart 2: Algorithm for diagnostic strategies in tubercular ascites

	SAAG	*Ascitic fluid protein*	*Cytology*
Peritoneal carcinomatosis	Low	High	High up to 97%
Liver metastasis	High	Low	Negative

the diagnostic work-up **(Table 4)**. Laparoscopy may be required to confirm the diagnosis.

Treatment of Ascites

Ascites due to Causes other than Cirrhosis

Treatment is to be directed at the underlying cause:

- *Infective ascites:* Appropriate antibacterial therapy
- *Tubercular ascites:* Anti-tubercular therapy along with large volume paracentesis for severe ascites
- *Pancreatic ascites:* Conservative measures like salt restriction and diuretics
- Malignant ascites: Does not respond to sodium restriction or diuretics. Large volume paracentesis (LVP), transcutaneous catheter placement, peritoneo-venous shunt, and autopumps are used

Treatment of Ascites due to Cirrhosis

Except for liver transplant, none of the therapies improves the survival. However, treatment of ascites not only improves the quality of life but prevents SBP, a lethal complication. The development of ascites in a patient of

cirrhosis denotes a poor prognosis with a median survival of 1.5 years so these patients should be considered for liver transplant.

Sodium Restriction and Diuretics

According to the European Association for the Study of the Liver, patients with cirrhosis and grade 1 ascites do not need diuretics and a low sodium diet.[9] In patients with grade 2 ascites, sodium consumption is restricted to 2 g sodium (5.2 g of dietary salt) per day along with diuretic therapy. The goal of diuretic treatment is a loss of weight up to 1.0 kg/day if both ascites and edema are present and up to 0.5 kg/day in patients with ascites alone.[10] Spironolactone, an aldosterone antagonist, is preferred as the initial diuretic. Recommended starting dose is 50–100 mg/day. Addition of a loop diuretic, furosemide or torsemide, potentiates effect of spironolactone. The maximum dose of diuretics recommended is a combination of spironolactone 400 mg/day with furosemide 160 mg/day.[11]

In patients with massive ascites, the method of choice is LVP followed by diuretic agents and a low sodium diet.[12] Approach to a patient of new ascites has been summarized in **Flowchart 3**.

Therapeutic Options for Refractory Ascites

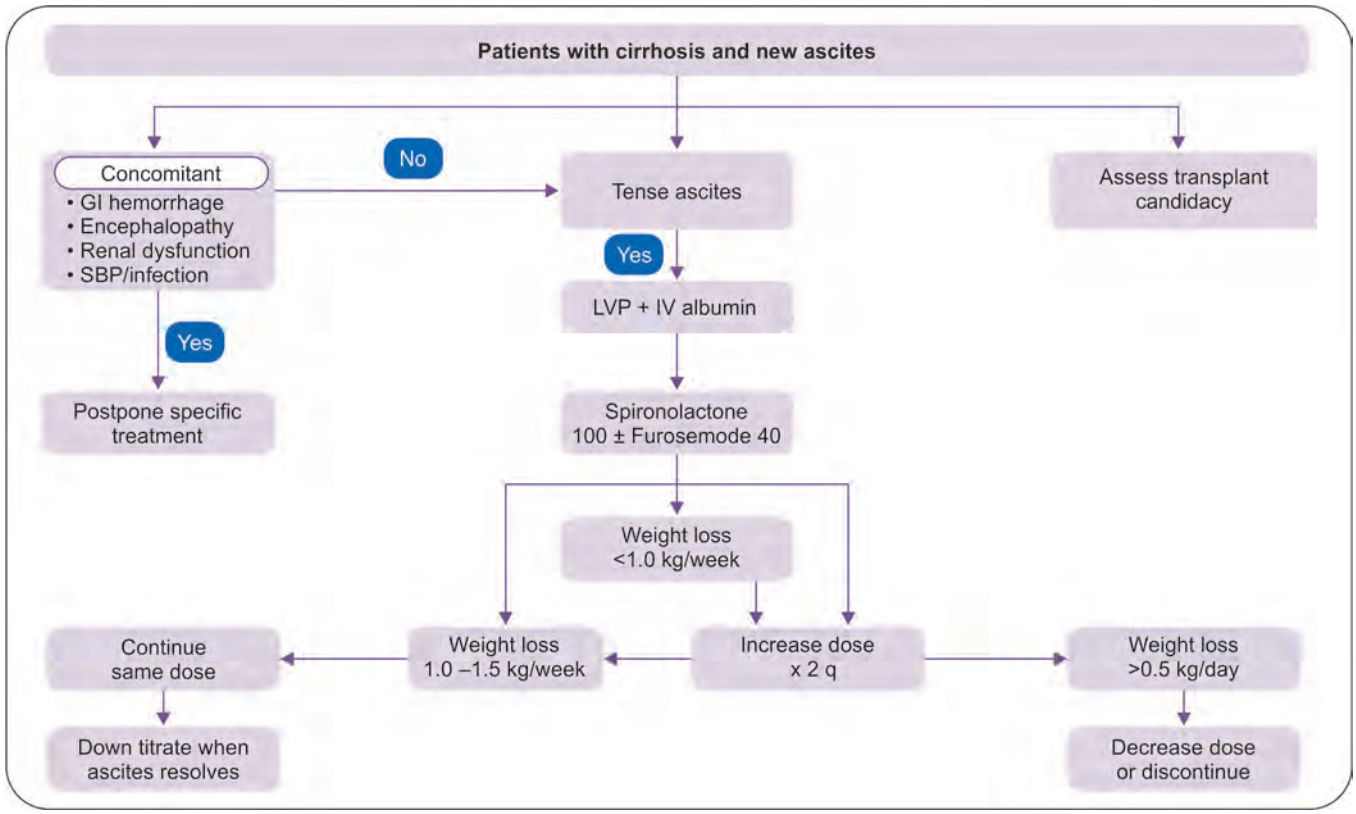
Large Volume Paracentesis

In normal clinical practice, the first-line therapeutic intervention is large volume paracentesis repeated every 2–3 week. Between 5–6 L of the ascitic fluid is removed in combination with I/V infusion of albumin (6–8 gm/L of fluid drained) to prevent paracentesis-induced circulatory dysfunction.

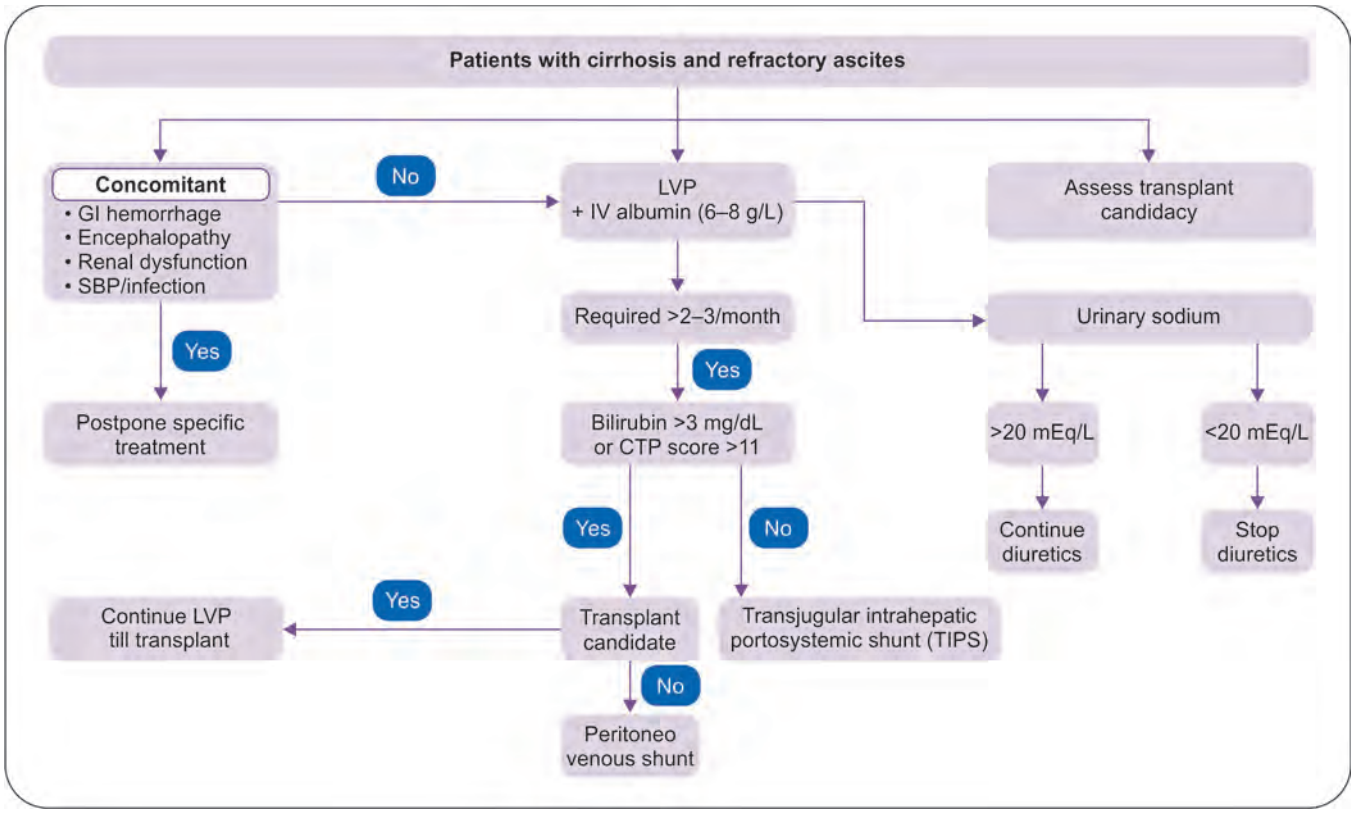
Peritoneovenous Shunt

Peritoneovenous shunt (PVS) drains ascitic fluid into the venous system. With laparascope a shunt is placed from peritoneal cavity to superior vena cava close to

Flowchart 3: Treatment strategies for patient of cirrhosis with new onset ascites



Flowchart 4: Treatment strategies for patient of cirrhosis with refractory ascites



the entrance of right atrium. A valve at the venous end prevents backflow of blood into the tubing. PVS has been reported to improve glomerular filtration rate in patients with renal insufficiency. However, long-term results were worse due to infection, shunt thrombosis, disseminated intravascular coagulation, and air embolism.

Surgical Portosystemic Shunt

In portosystemic shunt the portal vein is used as an outflow tract to relieve portal hypertension. However, because of high surgical mortality, they are seldom used nowadays.

Transjugular Intrahepatic Portosystemic Shunt

Transjugular intrahepatic portosystemic shunt (TIPS) is a non-surgical portacaval anastomosis. In this procedure, a tract is created between branches of hepatic and portal veins. Portal pressure reduction improves renal blood flow and glomerular filtration rate. Current clinical guidelines recommend using TIPS only in patients who require frequent LVP.

A Patient with Contraindications to TIPS

- In malignant ascites implantation of a permanent Pleurx® tunneled peritoneal catheter allows drainage of small amount of ascitic fluid (<2 L/day) in small portions.[13]
- An automatic low-flow pump (Alfapump®) moves ascetic fluid to the bladder in small portions (5–10 mL) every 5–10 min. It may serve as a "bridge" to liver transplantation.

Liver Transplantation

Liver transplantation is the definitive treatment for ascites, as it eliminates portal hypertension and all other accompanying complications of liver cirrhosis. Overall, 1 year survival after liver transplantation exceeds 75%.

Approach to manage refractory ascites is shown in **Flowchart 4**.[14]

Novel Therapies in Refractory Ascites

V2 Receptor Antagonists

Satavaptan, a selective V2 vasopressin receptor antagonist, acts on the distal renal tubule to increase water excretion, making it an attractive novel drug for patients who do not respond to conventional diuretics.

Vasoconstrictors

Clonidine, a centrally acting α2-agonist, when used with spironolactone decreases the need for diuretics. Midodrine, an α1-adrenoreceptor agonist, increases sodium excretion in patients with cirrhosis and refractory ascites without azotemia. In an RCT by Hanafy et al., midodrine (15 mg/day) and rifaximin (1.1 g/day) added to diuretics, increased diuresis and improved short-term survival.[15] Terlipressin, a V1 receptor agonist, improved the glomerular filtration rate and induced natriuresis in patients with cirrhosis and ascites without HRS. Despite the positive results of the aforementioned studies, the addition of clonidine or midodrine to the diuretic treatment in refractory ascites is not recommended by current guidelines.

Conclusion

Ascites, commonly presenting as abdominal swelling, is accumulation of free fluid in peritoneal cavity. Cirrhosis, tuberculosis, and malignancy are the common causes of ascites. Mild ascites is asymptomatic but large ascites causes abdominal discomfort and breathlessness. Ultrasonography detects the presence of ascites. Paracentesis with fluid examination establishes etiology of disease. Sodium restriction and diuretic therapy is the mainstay of cirrhotic ascites treatment. Ascites due to causes other than cirrhosis requires specific treatment. In refractory ascites, LVP with albumin infusions, TIPS, PVS, and automatic pumps are helpful. Liver transplantation is the gold standard therapy. Despite the advances in modern medicine, development of ascites is associated with poor prognosis and high mortality.

CHAPTER

114 Approach to Acute-on-Chronic Liver Failure

Anshuman Elhence, Abhinav Anand, Shalimar

Abstract

Acute-on-chronic liver failure (ACLF) is a clinical syndrome characterized by hepatic and/or extra-hepatic organ dysfunction in a patient with chronic liver disease. Multiple definitions exist in the literature. Irrespective of the definition, ACLF is associated with high short-term mortality. The syndrome is dynamic, and daily estimation of prognostic scores and organ dysfunction can predict the prognosis. A multidisciplinary team involving hepatologists, liver transplant surgeons, intensive care specialists, radiologists and pathologists is essential for the comprehensive management of patients with ACLF. Early identification and treatment of the acute precipitant is as essential as intensive monitoring, nutrition, antibiotics, albumin, and supportive care for extra-hepatic organ dysfunction. Liver transplantation remains the definitive treatment, albeit with its limitations. Physicians need to recognize the entity early, refer to multidisciplinary care centers, explain the prognosis, and prime the family members for the need for liver transplantation.

Introduction

Acute-on-chronic liver failure (ACLF) syndrome is characterized by abrupt hepatic decompensation secondary to an acute insult in a patient with chronic liver disease, associated with high short-term mortality. Overall, there are more than 20 definitions of ACLF available in the literature. Different definitions of ACLF provided by the European association for the study of the liver-chronic liver failure (EASL-CLIF), Asian Pacific Association for the study of the liver (APASL), and North American Consortium for the Study of End-stage Liver Disease (NACSELD) in Asia, Europe, and the USA, respectively have led to more confusion, rather than unifying the recognition of this syndrome.[1-4]

Definition

The overall concept of defining ACLF is to identify high-risk patients with high short-term mortality. The possible reasons for the different definitions of ACLF syndrome include different etiologies (acute precipitants and chronic liver disease), and different clinical presentations of hepatic and extra-hepatic insults. Comparison of the major definitions—including EASL-CLIF, APASL, and NACSELD and World Gastroenterology Organisation (WGO)—is shown in **Table 1**. An important difference is the inclusion of patients with chronic liver disease (all stages of fibrosis) in the APASL definition **(Flowchart 1)**; in contrast, the EASL-CLIF and NACSELD definitions include patients with cirrhosis only. Patients with prior decompensation are excluded in the APASL definition, while they are included in the EASL-CLIF and NACSELD definitions.

Acute Decompensation vs. ACLF

Acute decompensation (AD) refers to an event in the natural history of cirrhosis characterized by the development of jaundice, ascites, variceal bleed, or encephalopathy. AD when associated with organ failure is defined as ACLF.

TABLE 1 Comparison of various definitions of acute-on-chronic liver failure

	EASL-CLIF	*APASL*	*NACSELD*	*WGO*
Definition	Based on the presence of the three major characteristics: • Acute decompensation • Organ failure (as per SOFA-CLIF score) • High 28-day mortality rate (predefined threshold of 15%)	ACLF is an acute hepatic insult manifesting as jaundice (serum bilirubin ≥5 mg/dL and coagulopathy) (INR ≥ 1.5) complicated within 4 weeks by ascites and/or encephalopathy in a patient with previously diagnosed or undiagnosed chronic liver disease/cirrhosis, and a high 28-day mortality	Infection-related ACLF—defined as the presence of two or more organ failures—shock, grade III/IV HE, need for ventilation or renal replacement therapy	ACLF is a syndrome in patients with chronic liver disease with or without previously diagnosed cirrhosis, which is characterized by acute hepatic decompensation resulting in liver failure (jaundice and prolongation of the INR) and one or more extra-hepatic organ failures that is associated with increased mortality within a period of 28 days and up to 3 months from onset
Basis of definition	CANONIC study—1343 prospectively included AD patients	Initial arbitrary cut-off of bilirubin and INR. 2019 consensus updated based on AARC data (>3,300 cases)	Prospective, multicenter study—507 patients with infection	Expert group
Clinical presentation	OF essential Isolated renal failure or any combination (2 or more) of any 6 OFs	Liver failure essential—jaundice	Infection ≥2 OF	
Time interval since acute insult and development of ACLF	3 months	Less than 4 weeks	? 30 days	Less than 3 months
Patient inclusion	Cirrhosis only Both compensated and decompensated	Chronic liver disease (any stage of fibrosis) Compensated cirrhosis	Cirrhosis only Both compensated and decompensated	Chronic liver disease (any stage of fibrosis)
Patient exclusion	HIV HCC beyond Milan criteria	HCC Prior decompensated cirrhosis	HIV Prior organ transplant Disseminated malignancy	-
Acute precipitants	Hepatic and extrahepatic both	Hepatic	Infection	Both hepatic and extra-hepatic
Prognostic models	CLIF-C ACLF	AARC Score	MELD, CLIF-C ACLF	Not defined

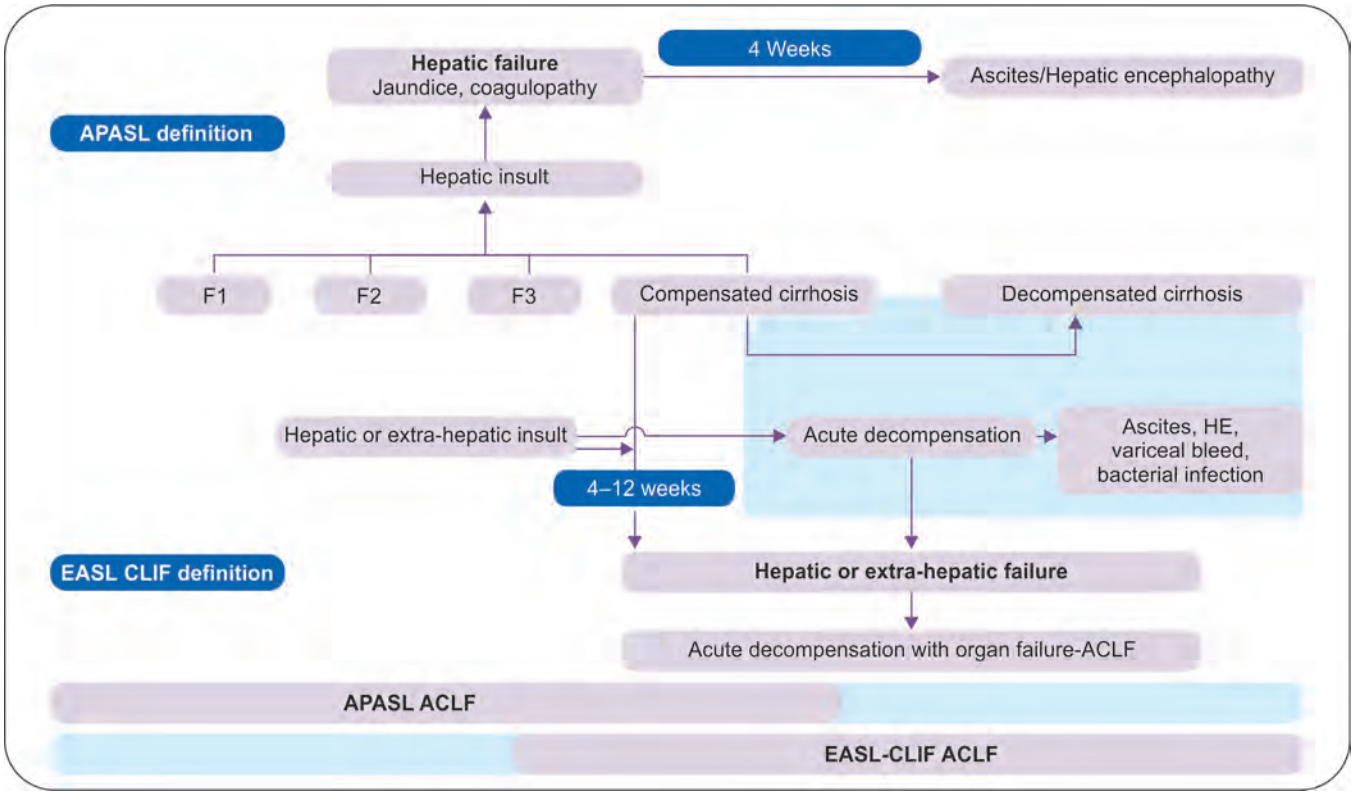
Flowchart 1: APASL and EASL-CLIF definition of acute-on-chronic liver failure



Approach to ACLF

The definition of ACLF embodies the basic constituents of the syndrome—an acute precipitant on a background of underlying chronic liver disease leading to organ failure and high short-term mortality. Each of the constituents must be addressed separately **(Flowchart 2)**.

Prognosis and Scoring Systems

The Child-Turcotte-Pugh (CTP) score and model for end-stage liver disease (MELD) do not accurately assess the risk of patients with ACLF. The EASL-CLIF and APASL divide ACLF into three grades of severity based on short-term mortality. As per the EASL-CLIF, the 28-day mortality in grade 1 ACLF [defined as single renal failure (creatinine >2.0 mg/dL) or any other single organ failure with renal dysfunction (creatinine 1.5–2 mg/dL)] is around 20–25%, grade 2 ACLF (2 organ failures) is 35–40%, and grade 3 ACLF (3 or more organ failures) is 70–80%. A linear score has been proposed CLIF-C ACLF (based on 6 organ failure scores, age, and total leukocyte count), which correlates with outcomes.

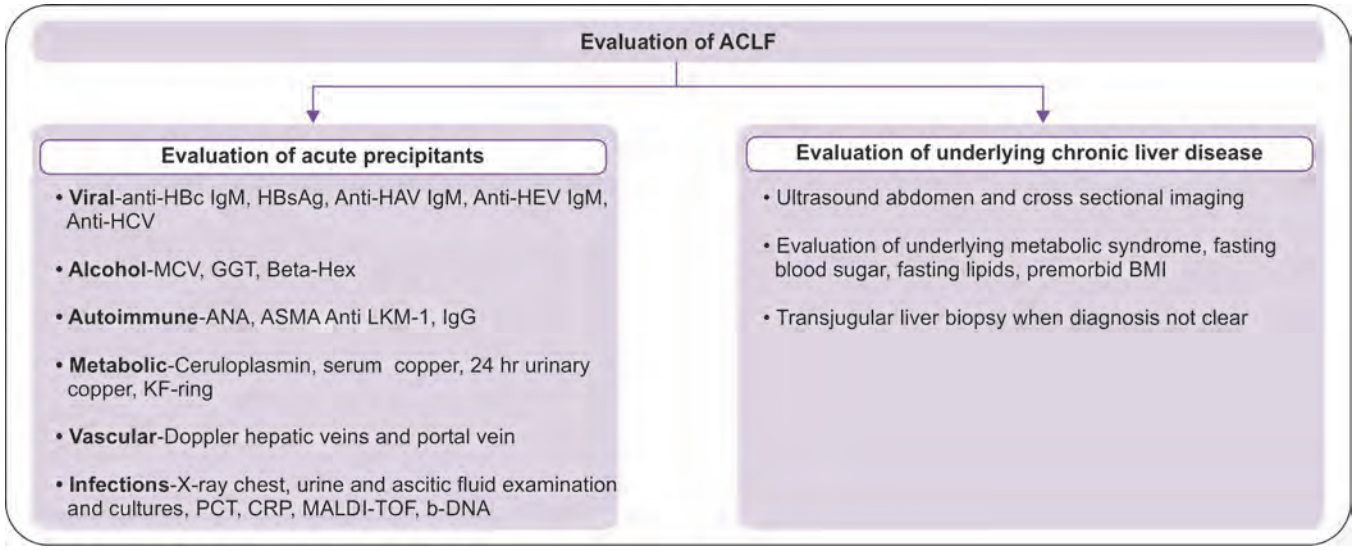
The APASL-ACLF-AARC score includes bilirubin, INR, hepatic encephalopathy (HE), lactate, and creatinine with an overall score ranging from 5 to 15. Based on the AARC score, ACLF is graded into grade 1 ACLF (score 5–7), grade 2 ACLF (8–10), and grade 3 ACLF (>10) with predicted 28-day mortality of 13%, 45%, and 86%, respectively.[1]

While assessing prognosis in patients with ACLF, it is important to use the scores as defined by definition, that is, use AARC score, if ACLF is defined by APASL definition and EASL-CLIF C ACLF in patients defined by EASL-CLIF definition.

Dynamic Assessment of the Prognostic Score

ACLF is a dynamic syndrome; therefore, it is important to assess patients daily for changes in organ failures and scores. A change in the score helps in early detection of deterioration and warrants change in the management plan. Patients showing an improvement in the grade of ACLF over the first 3 days are associated with a better outcome. The grade of ACLF between day 3 and 7 predicts outcome better than the grade at presentation.

Flowchart 2: Evaluation of patients with acute-on-chronic liver failure



ACLF, acute-on-chronic liver failure; ANA, anti-nuclear antibody; Anti-HBc, antibody to hepatitis B core antigen; ASMA, anti-smooth muscle antibody; bDNA, bacterial deoxyribonucleic acid; Beta hex, beta-hexosaminidase; BMI, body mass index; CDT, carbohydrate deficient transferrin; CRP, C-reactive protein; GGT, gamma-glutamyl transferase; HAV, hepatitis A virus; HBsAg, hepatitis B surface antigen; HCV, hepatitis C virus; HEV, hepatitis E virus; IgM, immunoglobulin M; KF, Kayser-Fleischer; LKM-1, liver-kidney microsomal-1; MALDI-TOF, matrix assisted laser desorption ionization-time of flight; MCV, mean corpuscular volume; PCT, procalcitonin.

Role of Liver Biopsy

A liver biopsy is not routinely recommended in the management of patients with ACLF. It may be indicated when the diagnosis is unclear, clinical suspicion of autoimmune hepatitis, or Wilson disease. The presence of neutrophilic infiltration, bilirubinostasis, mega-mitochondria are markers of poor prognosis in alcoholic hepatitis. Since patients with ACLF often have concomitant ascites and coagulopathy, if indicated, a transjugular route is recommended over a percutaneous one.

Management

Management of Acute Precipitants

Withdrawal of the acute insult is essential to stall the inflammatory cascade **(Fig. 1)**. Etiology specific interventions are effective. Patients with active alcoholism benefit from abstinence. It is unclear whether use of corticosteroids is associated with mortality benefit in patients with alcohol-related ACLF. Steroids are associated with increased risk of infections; their use needs to be individualized and justified in each case depending on the risk-benefit ratio. In patients with reactivation of hepatitis B presenting as ACLF, use of antiviral drugs such as tenofovir disoproxil fumarate (TDF) is associated with a better outcome. For hepatitis E virus infection, no specific therapy is recommended. Patients with autoimmune hepatitis (AIH)-ACLF without hepatorenal syndrome and sepsis can be considered for a trial of steroids.[1] In patients with Wilson disease, chelation therapy is recommended. Also, consideration should be given to early liver transplantation (LT) in those categorized as likely to have poor prognosis, as documented by new Wilson Index of more than 11. Plasmapheresis can be tried as a bridge to LT in patients with fulminant presentation of Wilson disease.

Drugs are another important precipitant of ACLF. The common drugs include anti-tuberculosis therapy and complementary and alternative medicines. A detailed history of drugs should be elicited at presentations and all drugs should be stopped.

Patients with acute variceal bleed (AVB) need to be managed with resuscitation, splanchnic vasoconstrictors and endoscopic therapy. In select cases, placement of preemptive (<72 hours of presentation) transjugular intrahepatic portosystemic shunt (TIPS) can be considered. Among patients with uncontrolled bleeding

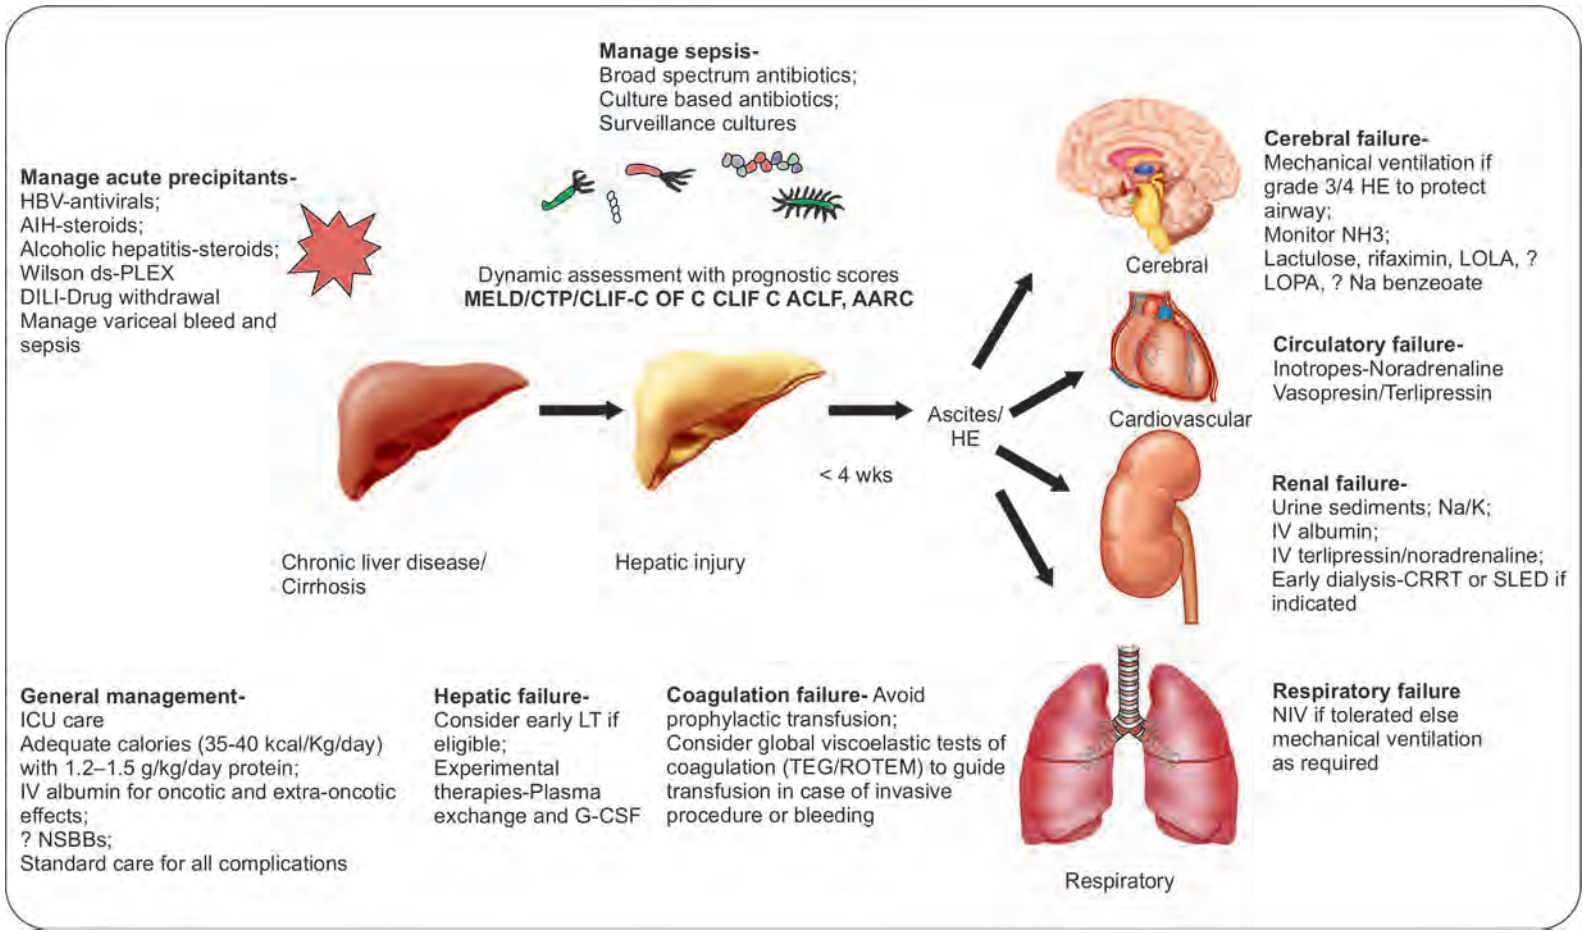


Fig. 1: The management approach to acute-on-chronic liver failure

rescue TIPS is an option, such patients usually have a poor outcome.

Bacterial infections are present in 10–30% of ACLF patients at admission, and another 30–50% may develop an infection during the hospital stay. Choice of empirical antibiotics depends on the setting. For community acquired infections a 3rd generation cephalosporin is a good choice. For nosocomial infections, piperacillin/tazobactam is preferred for areas with low-prevalence of multidrug resistance organisms (MDROs), while carbapenems are preferred in areas of high MDRO, with or without a gram positive glycopeptide for areas of high methicillin resistant *Staphylococcus aureus* (MRSA). Appropriate antibiotics according to local sensitivity patterns need to be administered at the earliest once culture reports are available.[5]

Management of Extrahepatic Organ Failures

Renal

Acute kidney injury (AKI) in ACLF can arise due to structural as well as functional causes. The withdrawal of diuretics and volume expansion with albumin is the first step. Terlipressin and noradrenaline can be considered with data suggesting that the former is more effective in the management of the hepatorenal syndrome. Renal replacement therapy (RRT) indications include symptoms of uremia, volume overload, hyperkalemia, and metabolic acidosis. Continuous RRT involves very slow blood and dialysate infusion and is preferred in patients with hemodynamic instability. Alternatively, a shorter hybrid procedure called slow-low efficiency dialysis (SLED) can offer shorter procedure times of 6–12 hours, maintaining hemodynamic stability as well.

Cerebral

Management of HE includes evaluation and management of precipitants **(Fig. 1)**. Hyperammonemia is associated with HE. Baseline hyperammonemia and persistent hyperammonemia are associated with poor outcomes in patients with ACLF. Lactulose and rifaximin are useful first-line drugs that help in reducing ammonia. The role of L-ornithine L-aspartate (LOLA), L-ornithine phenylacetate (LOPA), and sodium benzoate have not been studied in ACLF patients. Elective intubation to prevent aspiration may be considered in patients with advanced (grade 3 and 4) HE.

Coagulation

Prophylactic transfusion of plasma, based on the international normalized ratio (INR), is not recommended. Similarly, prophylactic transfusion of platelet may not be of use in the absence of active bleeding. Viscoelastic tests such as thromboelastography (TEG) and rotational thromboelastometry (ROTEM) should be used to guide transfusion in cases, which require an invasive procedure or develop bleeding complications.

Circulatory

In patients with circulatory failure, noradrenaline should be considered as a first-line agent. Vasopressin or terlipressin can be an alternative second line agent.

Respiratory

Respiratory failure should be managed with ventilatory support using either noninvasive ventilation or invasive ventilation, as tolerated, if the PaO_2/FiO_2 is less than 200. Low tidal volume lung protective ventilation should be considered, and therapeutic paracentesis done to aid in decreasing work of breathing.

General Management

ACLF patients should be managed in an intensive care unit (ICU). The higher mortality rate in ACLF should not deter physicians from providing ICU care. The overall outcomes in ACLF patients are similar to patients with other diseases, matched for the severity of the illness.

Nutrition is essential in patients with ACLF and a diet comprising of 35–40 kcal/kg/day and protein intake of 1.5 g/kg/day is recommended. Supplementation with trace elements and vitamins should be considered **(Fig. 1)**.

The use of albumin is recommended for its oncotic effects in presence of renal failure, spontaneous bacterial peritonitis, prevention of post-paracentesis circulatory dysfunction, as well as for its anti-inflammatory and antioxidant pleiotropic effects. The uses of non-selective beta-blockers and carvedilol have been shown to be safe and their discontinuation is not recommended.

Definite Management

Liver Transplantation

LT is the definite management of ACLF. There are no validated criteria for appropriate selection of candidates

for early LT. Early LT within the first week should be offered to those having poor prognosis at presentation (MELD >30 or AARC >10) without multiple organ failures and sepsis.[1] Dynamic monitoring with prognostic scores may help in early identification of patients who are at risk for poor outcome. Recent data suggests that LT is feasible, even in ACLF-3 cases who have 5–6 organ failures and is associated with a 1-year survival rate of more than 80% as compared to less than 10% among those not transplanted. Optimal timing of LT is crucial to have the best outcomes.

There are no established delisting criteria for LT in ACLF; however, transplant is not recommended in the presence of active sepsis.

Emerging Therapies

Artificial Liver Support Systems

Molecular adsorption and recirculating system (MARS) and fractionated plasma separation and adsorption (FPSA-Prometheus) have not shown any survival benefit in ACLF. Bioartificial liver support systems that substitute detoxification, biotransformation, and synthetic function as well by utilizing either human hepatoblastoma cell lines or porcine hepatocytes are promising. The recent creation of 3D liver organoids using hepatic progenitor cells or induced pluripotent stem cells might evolve as options for therapeutic use in future.

Plasma Exchange

Plasma exchange appears to be promising in small series. RCTs are needed to evaluate its role in management of ACLF.

Liver Regeneration

Since human liver has a huge regenerative potential due to the presence of progenitor cells, as evidenced by rapid regeneration after donor hepatectomy, it can also recover following acute insults. Contrasting results have been reported with granulocyte-colony stimulating factor (G-CSF), RCTs are needed before routine recommendation. Both bone marrow and umbilical cord derived mesenchymal stem cells have shown improvement in liver function when transfused via a peripheral vein.

Fecal Microbiota Transplantation

Evolving data suggests a potential role in alcohol-related ACLF not eligible for steroids or LT. Presently FMT remains an experimental therapy and should not be used outside of clinical trials.

Futility of Care

If LT is not available or contraindicated, presence of four or more organ failure and a CLIF-C ACLF score more than 64 is associated with a high mortality approaching 100%. In such situations, relatives should be explained about the poor outcomes.

Prevention of ACLF

Prevention of ACLF is of paramount importance. This can be achieved by preventing the acute triggers such as viral hepatitis—by universal vaccination (hepatitis B) and secondary prophylaxis with antivirals, abstinence from alcohol, and careful consideration before prescription of hepatotoxic drugs. However, despite active search, the trigger may not be detectable in up to 40% cases and is often attributed to pathological bacterial translocation occurring due to a combination of increased gut permeability and dysbiosis. Potential therapies targeting this aspect of pathogenesis are being evaluated.

The Role of a Physician

It is important for physicians to identify patients with poor prognostic factors early, so that they can be referred to higher centers for further treatment. Patients with ACLF should ideally be managed at a center with a multidisciplinary team comprising of hepatologists, gastroenterologists, LT surgeons, and critical care specialists. About one-third of patients reaching a referral hospital have an evidence of bacterial infection, making them poor candidates for LT. Hence, it is important to refer patients early, when they can still undergo LT. It is also the responsibility of the referring physician to explain the prognosis and prime the relatives to the need of LT.

Conclusion

It is essential to recognize ACLF as a distinct entity with high short-term mortality and potential reversibility. Prompt recognition and treatment strategy can result in a transplant-free survival of close to 50%.

CHAPTER

115 Approach to a Patient with Chronic Dyspnea of Undetermined Etiology

Manish Kumar, Krishna Kumar, DP Singh

Abstract

Dyspnea is a very common complaint encountered by medical professionals working both in general medical outpatient practice and also in emergency setup. Pulmonary and cardiac etiology are most commonly encountered; however, other causes like hematological or psychogenic causes are not very uncommon. A prompt and accurate diagnosis requires meticulous examination followed by proper use of investigative tools as per protocol.

Introduction

Dyspnea is a common presenting symptom that is encountered by clinician in everyday practice. It is said to be chronic if it is present for more than 4 weeks.[1] Dyspnea is a debilitating symptom that affects the overall quality of life, exercise tolerance, morbidity, and mortality in various disease states. It is a better predictor of mortality than angina in patients with cardiac disease and forced expiratory volume in 1 second (FEV1) in patients with chronic pulmonary disease.[2] In patients with chronic obstructive pulmonary disease (COPD) and sedentary adults, chronic dyspnea leads to low adherence to exercise training programs, decreased functional status, and poor psychological health.

The exact mechanisms of dyspnea are still not very well understood. Several recent studies have emphasized on the multidimensional nature of dyspnea. The perception of dyspnea depends on varying cortical integration of several afferent and efferent signals that involves a complex chain of events.

Chronic dyspnea is most frequently either due to respiratory or cardiac cause. However, in about one third of cases, the etiology is multifactorial.[1] COPD, cardiac failure, asthma, ischemic heart disease, interstitial lung disease (ILD), and impaired psychological condition are some of the most common causes of chronic dyspnea.

Definition

The American Thoracic Society (ATS) defines dyspnea as "subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity. The experience derives from interactions among multiple physiological, psychological, social and environmental factors, and may induce secondary physiological and behavioral responses." The ATS statement also reiterates the importance of self-reporting by patients, as dyspnea can be perceived only by the person experiencing it.[3]

Epidemiology

It is difficult to ascertain the exact prevalence of chronic dyspnea in general population as different studies incorporate both acute and chronic dyspnea. Individuals above age of 70 years have higher prevalence of chronic dyspnea. Studies have shown that almost half of the patients admitted to acute tertiary care hospitals and

one-fourth of patients in ambulatory settings present with dyspnea.[4] The prevalence of mild to moderate dyspnea ranges from 9% to 13% in adults according to some population-based studies. This figure is around 25–27% in persons older than 70 years.[5]

Clinical Assessment

A proper history and clinical examination is of utmost importance. More than two-thirds of the patients need diagnostic testing beyond clinical examination. The initial clinical assessment of a patient with chronic dyspnea is directed toward determining the underlying cause, which is fundamental for management and subsequent referral to a specialist if needed. According to a study amongst patients with chronic dyspnea who were referred to a specialist cardiologist or respiratory clinic at a tertiary center, only 51% were appropriately referred as per their final diagnosis.[1] This improper initial referral leads to significant delays in final diagnosis.

The history and findings from physical examination have low positive predictive value (PPV) individually and are more useful as negative predictive factors. However, usually the clinical findings are considered in combination, hence they are more likely to provide greater diagnostic accuracy.

History

The history given by the patient in his own words is of utmost importance. The effect of position, environmental stimuli, timing, aggravating, and relieving factors are helpful in arriving at a provisional diagnosis. For example, orthopnea indicates congestive heart failure (CHF), and nocturnal dyspnea is suggestive of CHF or Asthma. Chronic persistent dyspnea is suggestive of COPD, ILD, and chronic thromboembolic disease. A previous history of drug induced or occupational lung disease, ischemic heart disease is very vital. If the patient complains of dyspnea in the upright position with relief in supine position, that is, platypnea, it could be suggestive of left atrial myxoma or hepatopulmonary syndrome.[3]

Physical Examination

A thorough physical examination is imperative for assessment of cause, severity and proper management. It starts during history taking itself when the patient's ability to complete full sentence while talking is observed. Clinical signs of pallor, cyanosis, clubbing, and pedal edema are important. The symmetry of chest wall movements with respiration should be observed.

The hemodynamic stability of patient is confirmed by measuring the vital signs. Pulsus paradoxus (i.e., decrease in systolic blood pressure of more than 10 mm Hg during inspiration) could be due to cardiac causes such as pericardial disease, restrictive heart disease, or cardiac tamponade. Pulmonary disease such as COPD, asthma, large bilateral pleural effusion, tension pneumothorax, and pulmonary embolism may also be present with pulsus paradoxus. Increased work of breathing is evident by supraclavicular retraction, use of accessory muscles of respiration and sitting with the hands braced on knees, that is, tripod position. These signs are indicative of increased airway resistance or stiffness of lungs and chest wall.

Dullness on percussion of chest wall is indicative of pleural effusion. Likewise hyperresonance is a sign of emphysema or pneumothorax. On auscultation, wheeze, crepitations, and diminished breath sounds are vital clues to the etiological diagnosis.

On examination of cardiovascular system, signs of right heart failure like elevated jugular venous pressure (JVP), peripheral edema, accentuated pulmonary component of second heart sound, S3 gallop rhythm, and presence of murmur are important.

In a study done by Pratter et al., an algorithmic approach to diagnosis of chronic dyspnea was found to be helpful in correct diagnosis in 99% of the cases.[6] At the initial visit, the patient underwent Tier 1 testing and subsequently the clinician made a diagnosis. Patient was subjected to Tier 2 and 3 testing if needed **(Flowchart 1, Table 1)**.

There are various scales to measure dyspnea, but the two most commonly used are Medical Research Council Scale for pulmonary disease and New York Heart Association functional classification for cardiac diseases **(Table 2 and Box 1)**.

Investigations

A number of diagnostic tools may be helpful in the initial the workup of a patient with chronic dyspnea.

Flowchart 1: Algorithm for evaluation of a patient presenting with dyspnea[6]

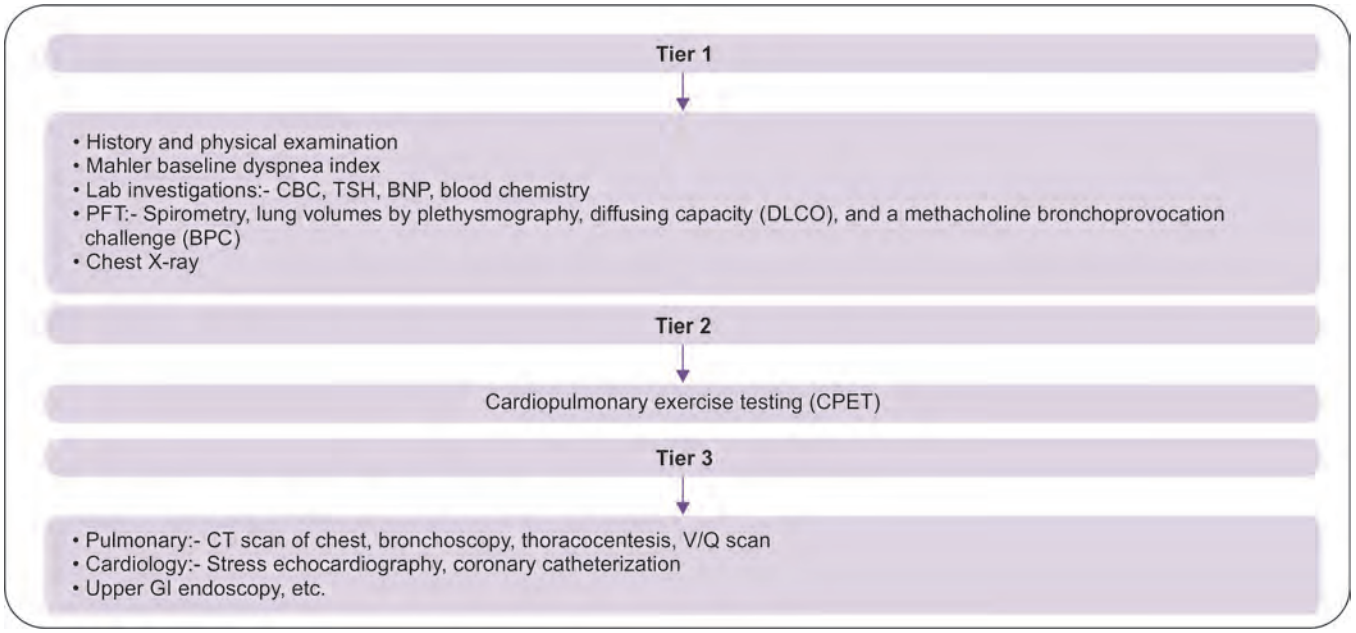

TABLE 1 Causes of dyspnea[7]

Type	*Subtype*	*Probable diagnosis*
Pulmonary	Airways	COPD, asthma, bronchiectasis, airway mass, vocal cord dysfunction
	Interstitial	ILD, passive congestion, malignancy, radiation exposure
	Alveolar	Chronic pneumonia, malignancy, emphysema
	Vascular	Pulmonary emboli, PAH
	Extrinsic	Pleural effusion, obesity, kyphoscoliosis
Cardiac	Myocardial	Ischemic heart disease, cardiomyopathy, HFrEF, HFpEF
	Arrhythmia	Atrial fibrillation, tachycardia, bradycardia
	Pericardial	Restrictive/Constrictive pericarditis, pericardial effusion
	Valvular	Aortic stenosis/Aortic regurgitation/Mitral stenosis/Mitral regurgitation
	Congenital heart disease	Intracardiac shunt, Eisenmenger syndrome
Neuromuscular	Neurogenic	Diaphragmatic paralysis, GB syndrome, myasthenia gravis, ALS
	Muscular	Muscular dystrophy, myositis, metabolic abnormalities, thyroid disease
Other causes	Anemia	Iron deficiency
	Pain	Pleural disease, postoperative period
	Psychological	Anxiety, depression, hyperventilation

ALS, amyotrophic lateral sclerosis; COPD, chronic obstructive pulmonary disease; ILD, interstitial lung disease; PAH, pulmonary arterial hypertension.

TABLE 2 Medical Research Council Dyspnea Scale[8]

MRC Dyspnea Scale
• Breathless only with strenuous exercise
• Short of breath when hurrying on the level or up a slight hill
• Slower than most people of the same age on a level surface or have to stop when walking at my own pace on the level
• Stop for breath walking 100 meters or after a walking few minutes at my own pace on the level
• Too breathless to leave the house or breathlessness while dressing or undressing

BOX 1 NYHA Classification[9]

A. Class I: Symptoms with more than ordinary activity
B. Class II: Symptoms with ordinary activity
C. Class III: Symptoms with minimal activity
   1. Class IIIa: No dyspnea at rest
   2. Class IIIb: Recent dyspnea at rest
D. Class IV: Symptoms at rest

Chest Radiography

After initial clinical assessment, chest X-ray is the most valuable tool for diagnosis. Hyperinflated lung fields are suggestive of chronic obstructive lung disease. Low lung volumes are seen in interstitial edema or fibrosis, diaphragmatic dysfunction or impaired wall motion. The evidence of interstitial disease, pulmonary infiltrates should be looked in pulmonary parenchyma. Pulmonary venous hypertension is suggested by prominent pulmonary vasculature in upper zones. Enlarged central pulmonary arteries suggest pulmonary arterial hypertension (PAH). Enlarged cardiac shadow could be due to dilated cardiomyopathy or valvular heart disease. CHF may present as bilateral pleural effusion on X-ray. Unilateral effusion may be due to carcinoma, pulmonary embolism, parapneumonic effusion, or even heart failure.[1,3]

Laboratory Investigations

A complete blood count is essential to assess the hemoglobin levels for anemia, which may cause dyspnea or polycythemia, which may indicate chronic hypoxemia. B-type natriuretic peptide detects cardiomyocyte strain. Hence, this can be used to differentiate between cardiac and respiratory causes of dyspnea. Chronic respiratory failure may cause carbon dioxide retention resulting in elevated bicarbonate levels. Here arterial blood gas (ABG) analysis may prove to be useful.[3,7]

Electrocardiography

An electrocardiogram (ECG) is a relatively cheap and readily available investigation that may suggest any underlying cardiac problem, which may be the cause for dyspnea. It may show evidence of ischemic heart disease, prior myocardial infarction resulting in systolic dysfunction, or valvular heart disease. In a study done amongst patients with chronic dyspnea, 8% were found to have atrial fibrillation on ECG. Among these patients 80% were later diagnosed as having dyspnea due to an underlying cardiac disease.[1]

Spirometry

Spirometry is a useful test for detecting obstructive and restrictive ventilatory defects. It is especially useful when airway diseases such as bronchial asthma or COPD are suspected. However, it is underused in clinical practice due to lack of time and resources. In a study of patients with chronic dyspnea in primary care setting, the diagnostic accuracy after clinical assessment was 55%, which increased to 72% after spirometry test.[1,2]

Echocardiography

Echocardiography is a vital tool to assess cardiac structure and function. In patients with chronic dyspnea, echocardiography can identify conditions such as heart failure (HFrEF), ischemic heart disease, valvular heart disease, pulmonary hypertension, and pericardial pathology. According to recommendations from International Heart Failure guidelines, echocardiography should be done at the earliest during the diagnostic workup of high-risk patients with chronic dyspnea. It is

noninvasive, can be easily performed even at the bedside in ICU or ER and has no side effects like radiation in CT scan.

Ultrasound

Chest ultrasound provides a wealth of information and it can be performed quickly and easily in critically ill patients. It has a higher diagnostic accuracy than a combination of physical examination and chest X-ray. Various patterns such as in acute interstitial syndrome, pneumothorax, pleural effusion, consolidation, etc. can be identified. It avoids ionizing radiation, and hence is quite safe. Lung ultrasound can also be used to guide fluid management and perform therapeutic procedures such as thoracocentesis.[10]

Chest Computed Tomography (CT)

CT scan of chest is most commonly used after an abnormal chest X-ray. It has a high sensitivity for diffuse parenchymal lung disease. It is also helpful in early detection of ILD or pulmonary emphysema. Although it is not the recommended modality, but still cardiomegaly and pulmonary edema can also be detected on CT chest. The only disadvantage of CT scan is the risk of radiation exposure. Hence, careful patient selection with assessment of risk and benefits should be done by the clinician prior to the CT scan. CT pulmonary angiography (CTPA) can be used to detect acute pulmonary embolism or chronic thromboembolic pulmonary hypertension (CTEPH).

Advanced Respiratory Function Tests

The advanced respiratory function tests are also valuable in detecting chronic dyspnea of respiratory etiology. The diffusing capacity of lung for carbon monoxide (DLCO) assesses the ability of lungs to transfer oxygen to blood. DLCO can be reduced both in PAH and ILD. DLCO in isolation is not sufficient to confirm or differentiate between the above two conditions. DLCO may predict mortality in a number of lung diseases, severe PAH, cancer, and various ILDs.[1]

Test for bronchial hyperresponsiveness by broncho-provocation helps in diagnosis of patients with suspected asthma having normal spirometry. A study showed hyperresponsiveness to challenge testing in 34% of patients with chronic dyspnea. Among these 69% were diagnosed with asthma or COPD.[1,3]

Tertiary Investigations

Depending upon the results of initial investigations, more specialized investigations are done if needed to determine the cause of chronic dyspnea. Imaging modalities such as cardiac MRI, CT, coronary angiography, stress echocardiography, lung ventilation/perfusion (V/Q) scan are done if required. Coronary angiography may also be done for assessment of coronary artery disease or pulmonary pressure. Bronchoscopy, muscle biopsy, or surgical lung biopsy are other tools. A FeNO test, or exhaled nitric oxide test, determines the lung inflammation and its suppression with steroids in patients with allergic or eosinophilic asthma.[11]

Cardiopulmonary Exercise Test (CPET)

In patients having dyspnea, which is out of proportion to known cardiorespiratory disease, CPET can provide valuable information. It involves incremental testing of exercise capacity while the patient is seated and continuously monitored on a stationary bicycle. CPET measures intake of oxygen, elimination of carbon dioxide, and minute ventilation, while exercising on the bicycle. It is helpful in confirming the diagnosis of psychogenic dyspnea. In a study among patients with chronic dyspnea, 90% with normal CPET results were diagnosed to be having a non-cardiorespiratory cause for dyspnea.[12]

Treatment

The optimal approach in the treatment of chronic dyspnea involves interventions that reduce the ventilatory demand, improve ventilatory capacity and respiratory mechanics and take care of the psychogenic aspect as well. Supplemental O_2 is usually given if resting O_2 saturation level is below 88% or if the saturation falls to this level with work or sleep. Supplementary oxygen has shown to improve mortality, especially in patients with COPD.[2,3]

Multiple interventions are often required and they may have additive or synergistic effects. Some of these interventions include oxygen therapy, bronchodilators, noninvasive ventilation, exercise training, lung volume reduction surgery, etc.

Opiates alter affective component of dyspnea and reduce the respiratory drive. Psychological counseling, behavioral therapy, and anxiolytics have favorable effects on affective dimension of chronic dyspnea. An important

component of dyspnea management is cardiac and pulmonary exercise training.

Conclusion

The diagnosis of patients presenting with chronic dyspnea in primary or tertiary care is challenging. Chronic dyspnea is most common due to a cardiorespiratory cause. However, one third of patients have multifactorial etiology. Common comorbidities such as obesity and deconditioning often contribute to symptomatology. This increases diagnostic difficulty and problems in management. Evidence-based algorithms are helpful to improve the diagnosis and subsequent management of patients presenting with chronic dyspnea.

CHAPTER

116 "Choice versus Chance": Mathematics behind Clinical Decision-making

Alladi Mohan, Alladi Vikramchandra

Abstract

In their everyday clinical practice, doctors are faced with decisions related to investigations, interventions, or therapeutic options. These decisions are sometimes routine and simple, but may be complicated on other occasions. Clinical decision-making is challenging because, these decisions are not only unavoidable but also must be made under uncertain conditions. Mathematics underlying decision-making includes basic mathematical language of probability and Bayes' theorem. Understanding these mathematical principles and judicious application of diagnostic reasoning can help clinicians in arriving at the appropriate course of action in a rational, scientific, and objective way.

Introduction

Clinicians have to make decisions in daily practice either regarding the choice of diagnostic testing or regarding therapeutic options or interventions. These decisions are unavoidable, and are often made intuitively under uncertain conditions and, therefore, constitute a significant challenge. In this chapter we have attempted to provide an overview regarding the mathematics behind decision-making.

Basic Mathematics

To understand the science of clinical decision-making, an understanding of the basic mathematical language of probability and Bayes' theorem is essential. Bayes' theorem is a mathematical rule that defines how existing beliefs should be revised or modified when new evidence becomes available.[1-3]

Probability

In the context of clinical decision-making, probability is defined as a measure of the belief regarding the occurrence of an event. Mathematically, probability of an event A occurring is denoted as P[A] and is read as "P of A"; this value ranges from 0.0 to 1.0.[4]

Summation Principle

If in a given clinical situation, let us assume that four possible outcomes A, B, C, and D can occur by chance. The summation principle states that the "sum of probabilities" of all these four possible chance events (outcomes) equals 1.0.[4] This is mathematically written as:

$$P[A] + P[B] + P[C] + P[D] = 1$$

Joint Probability

The concomitant occurrence of a number of events is termed as "joint probability" of occurrence of those events.[4] The joint probability of occurrence of two events A and B is expressed as P[A,B].

Conditional Probability

The probability that an event A occurs, given that the event B is known to occur is termed "conditional probability" of

event A given occurrence of event B. This is expressed in statistical notation as (P[A | B]).[4]

We can also express the relationship between joint and conditional probabilities by the following formula:

$$P[A \text{ and } B] = P[A \mid B] \times P[B]$$

Independence

In a clinical situation, if the "conditional probability" of event A, given that event B occurs, is identical to the "unconditional probability" of event A occurring, then, the events A and B are probabilistically considered to be independent.[4]

This relationship is expressed as:

$$P[A \mid B] = P[A]$$

The "joint probability" of occurrence of independent events is governed by the "product rule" which states:

$$P[A,B] = P[A] \times P[B]$$

Summation Principle for Joint Probabilities

The summation principle for joint probabilities states that if B1, B2, B3, and B4 are mutually exclusive events (i.e., only one of these can occur), and A is another event, then, probability of occurrence of event A is given by the formula:

$$P[A] = P[A,B1] + P[A,B2] + P[A,B3] + P[A,B4]$$

For computing the probability of an event from several conditional probabilities, the "averaging out" method is used.

Bayes' Theorem

In clinical practice, diagnostic tests are performed to ascertain the definitive diagnosis. The possible results that are obtained on performing such a diagnostic test are listed in **Figure 1 and Table 1**. The performance of the diagnostic test is evaluated using a "gold standard" for categorization of the subjects as "having disease" or "no disease." In this situation, Bayes' theorem can be applied to estimate the probability of the disease given a positive or a negative test result. Generally, the possibilities of two disease states (disease is present/absent) are considered. However, several disease states D1, D2, and so on (up to Dn) can also be considered. Then, by applying Bayes' theorem, the revised probability of any one disease (Di)

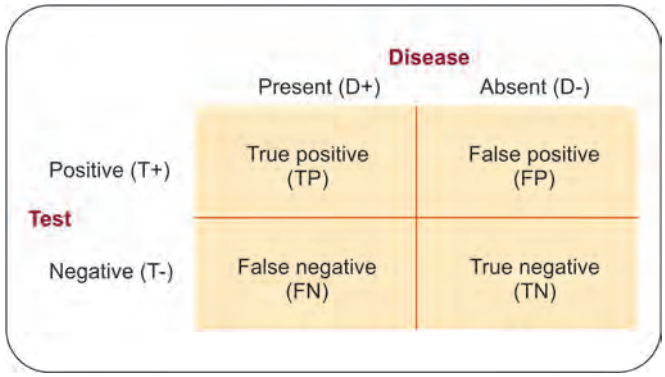

Fig. 1: Important conditional probabilities used in clinical practice

occurring given the test result R can be calculated using the formula:

$$\frac{P[R \mid Di] \times P[Di]}{P[R \mid D1] \times P[D1] + \ldots\ldots + P[R \mid Di] \times P[Di] + \ldots\ldots + P[R \mid Dn] \times P[Dn]}$$

Odds

Odds of an event are defined by the number of occurrences divided by the number of non-occurrences. For example, odds of a disease = No. of persons who develop disease during follow-up/No. of persons who do not develop disease.

If p is the probability of an event occurring, then, the probability that the event will not be occurring is denoted as (1–p). Then, the odds favoring the occurrence of the event are calculated as p/(1–p); and the odds against the event occurring are calculated as (1–p)/p.

Bayes' theorem can also be expressed in terms of odds as:

$$\underbrace{\frac{P[D+ \mid R]}{P[D- \mid R]}}_{\text{Posterior odds}} \quad \underbrace{\frac{P[D+]}{P[D-]}}_{\text{Prior odds}} \quad \underbrace{\frac{P[R \mid D+]}{P[R \mid D-]}}_{\text{Likelihood ratio}}$$

Here, D+ = disease present; D– = disease absent; R = test result; P[D+ | R] denotes the probability of the disease being present given the test result.

Likelihood Ratio

The likelihood ratio (LR) of a positive test result is the ratio of the probability of occurrence of the test result in persons with or without the disease.

LR for a positive test result = sensitivity/(1–specificity)

TABLE 1 Probabilities associated with the test results shown in **Figure 1**

Variable	*Probability notation*	*Estimate of probability*
Sensitivity True-positive rate; frequency of positive test results in persons with disease	P[T+ | D+]	TP/(TP+FN)
Specificity True-negative rate; frequency of negative test results in persons with disease	P[T- | D-]	TN/(TN+FP)
False-negative rate Frequency of negative test results in persons with disease	P[T- | D+]	FN/(TP+FN)
False-positive rate Frequency of positive test results in persons without disease	P[T+ | D-]	FP(TN+FP)
Predictive value of positive test Frequency of disease in persons with a positive test result	P[D+ | T+]	TP/(TP+FP)
Predictive value of negative test Frequency of non-disease in persons with a negative test result	P[D- | T-]	TN/(TN+FN)

FN, false negative; FP, false positive; TN, true negative; TP, true positive

Similarly, LR for a negative test result = (1–sensitivity)/specificity

Post-test odds can be computed from the "pre-test odds" and LR, using the formula:

Post-test odds = pre-test odds × LR

Some Applications of Bayes' Theorem in Clinical Medicine

Some of the applications of the aforementioned mathematical principles that are used in clinical medicine for decision-making[3,5,6] are briefly described below.

Receiver-operator Characteristic Curve

The receiver-operator characteristic (ROC) curve is plotted with 1-specificity (false positive rate) on the X-axis against sensitivity on the Y-axis. The ROC curve graphically portrays the trade-off between sensitivity and specificity for different chosen criteria (cut-off values) of positivity for the test result[4,7,8] and facilitates the identification of the optimum threshold or cut-off value **(Fig. 2, thick arrow)**. Some examples for the use of ROC curve analysis in decision-making include, defining the cut-off value of carotid intima media thickness as a surrogate marker for subclinical atherosclerosis,[9] glycosylated hemoglobin (HbA_{1c}) for the diagnosis of diabetes mellitus,[10] among others.

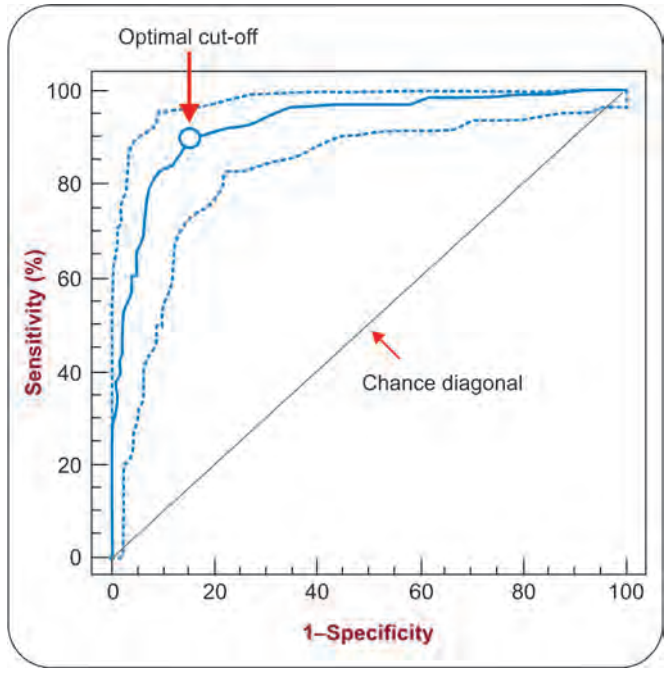

Fig. 2: Receiver-operator characteristic (ROC) curve along with 95% confidence bands (dotted lines). The ROC curve represents a graphical description of the "dynamic trade-off" between more accurate identification of subjects with disease versus those without disease. Each point on the ROC curve represents a potential cut-off value with an associated sensitivity. Area under the ROC curve (AUC) is a measure of the overall performance and ranges between 0 and 1. The line segment drawn from (0,0) to (1,1) represents the *chance diagonal* and this has an AUC = 0.5. Therefore, a diagnostic test with an AUC greater than 0.5 is better than "pure chance" in correctly categorizing a cut-off

Decision Analysis

While evaluating patients in everyday practice, a clinician takes into consideration the data obtained from the history and physical examination findings. On the basis of information thus gathered, clinicians, based on their previous experience and intuitive thinking, formulate a diagnostic work-up plan. Even though this intuitive approach has the advantage of being flexible, it is subjective and varies between various clinicians.

"Clinical decision analysis" approach has remarkably influenced decision-making in a rational way under conditions of uncertainity[4,11-14] and has facilitated choosing the best possible course of action.[4,11-14] It is an explicit, quantitative and prescriptive approach to clinical decision-making. In this approach, probabilities of arriving at a choice or chance decision, utility of the outcome from each of the options are considered and logical structure of the problem called "decision tree" is constructed. The decision tree is analyzed by considering the probability of each outcome along with its associated utility and the path with the highest expected value is chosen to arrive at a clinical decision. Clinical decision analysis has been applied in various commonly encountered clinical situations to arrive at a decision.[14-17]

Conclusion

Clear understanding of the mathematics underlying decision making and judicious application of diagnostic reasoning can help clinicians in arriving at the appropriate course of action in a rational, scientific and objective way.

CHAPTER

117 Approach to Syncope in Emergency Room

Prasanta Kumar Bhattacharya

Abstract

Syncope, characterized by transient loss of consciousness due to cerebral hypoperfusion, is a common clinical condition requiring emergency medical attention. Emergency room approach to syncope entails its diagnosis and differentiation from other causes of transient loss of consciousness such as epilepsy, vertebrobasilar insufficiency, hypoglycaemia and psychiatric illnesses; risk stratification into high- and low-risk etiologies; and management. Vasovagal syncope and syncope due to orthostatic hypotension, which carry low-risk, usually have uneventful outcomes. Syncope due to underlying cardiac causes is usually difficult to diagnose and carry a poorer prognosis, and commonly requires hospitalization for further evaluation and management. In developed countries having well-equipped syncope units, most cases of syncope can be managed and discharged from the emergency room. However, in developing countries like India, lacking such facilities, high-risk cases of syncope should ideally be hospitalized for further evaluation and management.

Introduction

Syncope is the loss of consciousness (LOC) occurring transiently due to cerebral hypoperfusion. It is characterized by a rapid onset of the LOC, which occurs for a short duration, with a spontaneous complete recovery.[1] Syncope is a common presenting problem, accounting for 1–3% of all emergency department visits with up to 50% being hospitalized.[2-5] The LOC is associated with a brief period of actual or apparent LOC, along with loss of awareness during this period of unconsciousness, associated with abnormal motor control and loss of responsiveness.[1] Transiently occurring LOC (T-LOC) can be due to either head trauma, or can be due to non-traumatic causes. Syncope falls under the latter group, but has to be differentiated from other conditions within this sub-group of non-traumatic causes, important among these are various forms of generalized seizures; psychogenic causes like psychogenic pseudosyncope, and non-epileptic seizure; vertebrobasilar insufficiency, hypoxemia, narcolepsy with cataplexy; and hypoglycemia.[4] The term presyncope is commonly used to describe a condition resembling the prodrome of syncope, but which is not followed by actual LOC,[1] probably because the hypoperfusion of the brain in presyncope does not result in LOC. Most of the times syncope presents as a medical emergency necessitating prompt management in the emergency ward. However, differentiating it from the other common causes of T-LOC, as well as identifying patients with syncope with potentially life threatening etiologies poses as a challenge in management especially in the emergency room (ER) settings. Therefore, the main focus should be in diagnosing syncope, differentiating it from other common causes of T-LOC and its risk stratification for hospitalization and optimum management.

TABLE 1 Types of syncope with underlying mechanism and causes

Type	*Mechanism*	*Causes*
Neurally mediated (*reflex* or *vasovagal*) syncope	• Transient alteration in reflexes maintaining cardiovascular homeostasis • Transient vasodilatation/loss of vasoconstrictor tone plus bradycardia with resultant loss of blood pressure control	• Vasovagal syncope • Reflex syncope, e.g.: – Post-micturition syncope – Gastrointestinal – Carotid sinus syndrome – Ocular
Syncope due to orthostatic hypotension	Sympathetic vasoconstrictor failure ± failure of compensatory tachycardia with resultant hypotension on standing	• Primary autonomic failure • Peripheral neuropathy with secondary autonomic failure, e.g.: – Diabetes mellitus • Drug-induced • Volume depletion
Cardiac syncope	Arrhythmia and/or structural heart disease leading to decreased cardiac output	• Arrhythmia: – Bradyarrhythmias (sinus node dysfunction), high grade type II AV block, complete heart block – Tachycardia-bradycardia syndrome – Ventricular tachyarrhythmias • Structural heart disease: – Valvular heart disease – Hypertrophic cardiomyopathy – Atrial myxoma

Approach to Syncope in the Emergency Room

Classification and Etiology of Syncope[1,3]

Syncope can be classified into three broad groups:

- Reflex (neurally mediated), or vasovagal syncope
- Syncope due to orthostatic hypotension
- Cardiac syncope

In about one-third of cases the etiology of syncope is unexplained,[6] while in 10–15% of patients the etiological diagnosis of syncope remains unclear even after thorough evaluation using current diagnostic guidelines.[7,8] The different types of syncope, their underlying mechanism of development and common causes are outlined in **Table 1**.

Step-by-Step Approach in the Management of Syncope in the Emergency Room[9,10]

Step-by-step approach in the management of syncope in the ER settings can be broadly sub-divided under the following headings **(Box 1)**:

BOX 1 Step-by-step approach in management of syncope in the emergency room

- Confirmation of diagnosis of syncope by differentiating from other common causes
- Determination of the cause of syncope
- Risk assessment of syncope
- Management strategy based on risk profile

Confirmation of Diagnosis of Syncope by Differentiating from Other Common Causes

Syncope occurs due to a transiently occurring global cerebral hypoperfusion. Since cerebral hypoperfusion cannot be clinically determined one has to depend on the clinical parameter of T-LOC for a diagnosis of syncope. But T-LOC can occur due to various causes other than syncope as already mentioned. Setting aside the traumatic causes of T-LOC from our current discussion, the various common non-traumatic causes of T-LOC **(Table 2)** should be brought into the differential diagnosis of syncope

TABLE 2 Common causes of transient loss of consciousness

Causes of transient loss of consciousness	*Types/Causes*
Syncope	• Reflex/vasovagal • Orthostatic hypotension • Cardiac
Epileptic seizures	• Generalized seizures • Partial seizures
Metabolic	• Hypoglycemia
Psychogenic	• Psychogenic pseudosyncope • Psychogenic non-epileptic seizures
Uncommon	• Transient ischemic attack • Sub-arachnoid hemorrhage • Subclavian steal syndrome

in any patient brought to the ER with T-LOC without any apparent cause.[1] Some of the common causes from which syncope has to be frequently differentiated include seizures, hypoglycemia, narcolepsy with cataplexy, and certain psychiatric disorders.

Syncope versus Seizures

Syncope and seizure are the two most common causes of T-LOC and differentiation between the two is not always as easy.[1,2] Both generalized and partial seizures may be confused with syncope, although there are several differentiating points between the two. Similar to the tonic-clonic movements of generalized seizures involuntary movements like myoclonus may occur in up to 90% cases of syncope, along with mild flexor and extensor posturing. Likewise, partial or partial-complex seizures with secondary generalization are commonly preceded by an aura, which should be differentiated from the premonitory features of syncope. Further, autonomic manifestations of seizures like cardiovascular, urogenital, pupillary, and cutaneous manifestations may mimic the premonitory features of syncope; the arrhythmias associated with the cardiovascular manifestations may even lead to LOC. Nevertheless, the presence of accompanying non-autonomic auras may help differentiate these episodes in seizures from syncope. Among the points of differentiation between seizures and syncope, the LOC in seizures is usually more than 5 minutes duration with prolonged postictal drowsiness and disorientation, whereas in syncope the patient regains orientation almost immediately after the event. Muscle aches may occur after both syncope and seizures, but are more severe and long lasting after a seizure. Unlike syncope, seizures are rarely provoked by emotions or pain. Further, while incontinence of urine may occur with both seizures and syncope, fecal incontinence very rarely occurs with syncope.[4]

Syncope versus Hypoglycemia

Insulin induced hypoglycemia in diabetes mellitus may cause T-LOC, which is usually preceded by features of sympathetic overactivity like tremor, palpitations, anxiety, sweating, hunger, and paresthesia. Hunger is particularly not a typical premonitory feature of syncope. Additional neuroglycopenic features in hypoglycemia include fatigue, weakness, dizziness, and cognitive and behavioral symptoms, which are not found in syncope. Diagnostic difficulties of hypoglycemia may occur in those with strict glycemic control and repeated hypoglycemic episodes leading to blunting of the characteristic warning symptoms of hypoglycemia, or hypoglycemia unawareness.

Syncope versus Cataplexy

Patients with cataplexy, which occurs in about two-thirds of patients with narcolepsy, experience an abrupt onset of partial or complete loss of muscular tone lasting for short durations of 30 seconds to 2 minutes; usually triggered by strong emotions like anger or laughter. Unlike syncope, consciousness is maintained throughout the attacks, and there are no premonitory symptoms.

Syncope versus Common Psychiatric Ailments

Various psychiatric disorders like generalized anxiety, panic disorders, major depression, and somatization disorders are associated with an apparent LOC. These should be considered in individuals who faint frequently without prodromal symptoms. In such patients there is rarely any injury in spite of repeated falls; and there are no clinically significant hemodynamic changes like hypotension and bradycardia associated with these episodes which is found typically in vasovagal syncope.

Determination of the Cause of Syncope

Once a diagnosis of syncope has been made in the ER and other likely causes of T-LOC have been clinically excluded, one should look for any serious underlying cause for the

syncope. In about 50% of cases the cause can be identified in the ER; the serious among them are usually some non-cardiovascular causes like a ruptured abdominal aortic aneurysm, an upper gastrointestinal bleeding or a subarachnoid hemorrhage.[2] Underlying cardiovascular conditions especially arrhythmias are less frequently recognized in the ER unless it is present in the ECG on admission.[11]

Risk Assessment of Syncope

When the cause of syncope cannot be ascertained in the ER, subsequent management should be guided by assessing the risk of a serious outcome in the future, especially a major cardiovascular event or sudden cardiac death. Such risk stratification includes determining the type of syncope and the patient's risk factors for a cardiac event.[1,2,9]

There are three major types of syncope as described earlier **(Table 1)**. Syncope, which is thought to be due to either reflex or postural cause, is likely to be at low risk of serious outcome. Patients with syncope of cardiac origin are usually at a higher risk of serious coucomes.[1] The 2018 European Society of Cardiology (ESC) guidelines for the diagnosis and management of syncope provide a list of high-risk and low-risk features for risk stratification of syncope in the ER.[1] These are based on certain clinical features of the syncopal attack, past history of the patient, and findings in the ECG.

Management Strategy Based on Risk Profile

Patients who have low-risk features are usually due to reflex or postural syncope. These patients usually have either some prodromal features or typical precipitating event(s). There may be a history of recurrent syncope, and the physical examination and ECG are usually normal. The outcome in patients with reflex syncope is usually very good. Syncope due to postural hypotension also has a low risk, but the prognosis is poorer than in reflex syncope due to their comorbidities.[12] These patients can be usually discharged from the ER without hospitalization. Some patients with frequent episodes of syncope or syncope-related injuries are usually referred to special clinics for further evaluation.[2]

Patients who have high-risk features usually do not have associated prodromal symptoms or typical precipitating events like in those with low-risk features. These patients also usually have history of structural heart diseases, and their physical examination and ECG findings are usually abnormal. Structural heart disease[13] and primary arrhythmias[14] are major risk factors for sudden cardiac death and overall mortality. These patients are candidates for further investigations such as echocardiography, ECG monitoring, and other sophisticated tests and referral to specialists. These patients should not be discharged from the ER and preferably hospitalized for specialist consultations and special tests mentioned.

Clinical Evaluation in the Emergency Room Setup

Some specific baseline investigations should be carried out in the ER setup. An ECG is important because a normal ECG practically rules out any cardiological cause of syncope, except for transient arrhythmia. First-degree heart block is neither associated with a cardiac nor reflex cause of syncope. An estimation of the random blood glucose should be done to exclude hypoglycemia, which may present as collapse or seizure. Estimation of hemoglobin and the hematocrit will exclude anemia, and blood loss as a cause of syncope. Blood tests for troponin and D-dimer should be done when myocardial ischemia-related syncope or pulmonary embolism is suspected.[1] A chest X-ray or a CT brain is routinely not required.[2]

Special Tests and Investigations

Carotid Sinus Massage

Carotid sinus massage (CSM) should be considered in patients over the age of 40 years with reflex syncope of unknown origin.[1] In patients with history or clinical features of reflex syncope, if CSM causes symptomatic bradycardia and/or hypotension one can diagnose carotid sinus syndrome.[2,15]

Active Standing to Measure Postural Blood Pressure

Postural hypotension is a progressive and sustained fall of more than 20 mm Hg of systolic or more than 10 mm Hg of diastolic blood pressure (BP) from baseline or a decrease in systolic BP to less than 90 mm Hg. In classic orthostatic hypotension the time from upright position to abnormal BP response is less than 3 minutes and in delayed orthostatic hypotension it is more than 3 minutes. It is important that the procedure should be done by the clinician and not delegated to other ER staff.[2,16]

ECG Recording

In addition to the standard 12-lead ECG, the patient should be put on continuous ECG monitoring if cardiac arrhythmia is suspected to be the cause of the syncope. It has been found that ambulatory ECG monitoring in unexplained syncope can identify arrhythmia to be the cause for the syncope in about 10% patients with a diagnostic yield in about 75% of such cases.[17]

Echocardiography

Patients with a heart murmur or history of structural heart disease requires an echocardiographic examination. One has to differentiate a benign flow murmur from a murmur of aortic stenosis and hypertrophic cardiomyopathy.[18]

Troponin to Rule Out Acute Coronary Syndrome

Where ECG changes are consistent with acute myocardial ischemia high sensitivity troponin test should be done to rule out acute coronary syndrome.[19]

Decision Regarding Hospitalization

Across the world the hospitalization rate of patients with syncope attending the emergency department is quite high. About one half of these patients attending the emergency department are usually hospitalized; and approximately half of the admitted patients would be discharged with no clear diagnosis, even after extensive investigations.[20] Many of the hospitalizations for syncope are unnecessary;[2] two-thirds of serious outcomes occur while the patient is in the ER and the rate of serious outcomes after the patient is shifted out of the ER is actually quite low, being as low as 3.6% at one-month follow-up.[1] Hospitalization is indicated mainly for patients requiring syncope-related treatment and those with severe comorbidities or syncope-related injury caused by the primary event. In developed countries where there are specialized syncope clinics with facilities for investigations and treatment in the ER setups patients with higher risk profiles can be managed in the ER settings and so hospitalization can be rationalized.[21,22] However, since such advanced syncope units are not commonly available in developing countries patients with high-risk should be ideally hospitalized for further evaluation and appropriate management.

Conclusion

Syncope is a common medical emergency. In the ER setting it is very important to first differentiate it from other serious causes of transient LOC like seizure or hypoglycemia. Thereafter, one should try to find out the underlying cause of syncope. A thorough history and clinical examination, and an ECG can most of the time distinguish the high-risk group of syncope due to heart diseases from those with lower risks due to orthostatic hypotension or reflex syncope. Additional tests like carotid sinus massage, echocardiography, cardiac troponin, or ECG monitoring may be required in the ER setting. Those with a high risk require urgent investigation and hospitalization.

CHAPTER

118 Nailing the Diagnosis through Nail Changes

Bidita Khandelwal, Pradeep Balasubramanian

Abstract

Nail, a cutaneous appendage, serves as an invaluable tool in unveiling the underlying systemic diseases. The nail changes can precede or coexist with the underlying systemic diseases. The presence of a particular nail change in several or all the nails is the feature of systemic disease or associated dermatologic disorder. The nail changes can involve various components of the nail such as nail matrix, nail plate, nail bed, or periungual tissue. In this chapter, we have discussed about various nail changes, specific features to identify them and its usefulness in delineating the associated systemic diseases comprehensively.

Introduction

Nail changes serves as window for diagnosis of several systemic diseases. Hippocrates in 5th century described clubbing to be associated with several systemic diseases.[1] Since then several nail changes were found to be associated with systemic diseases. The nail changes in isolation or as a complement help to diagnose underlying disease. Nail changes can precede or can occur coexist with systemic disorders. Fingernail changes are more reliable than toenail changes since toenail changes can be altered by trauma. The components of nail unit is illustrated in **Figure 1**.

In this chapter, comprehensive facts regarding identification of nail changes and the systemic diseases associated with them are discussed. An important fact that needs to be emphasized upon is that trauma to the nail matrix or nail can result in several nail changes which will be confined to the trauma inflicted nail only. Whereas the nail changes due to the systemic diseases will be seen uniformly involving all the nails. The nail disorders that will be discussed are briefed in **Table 1**.

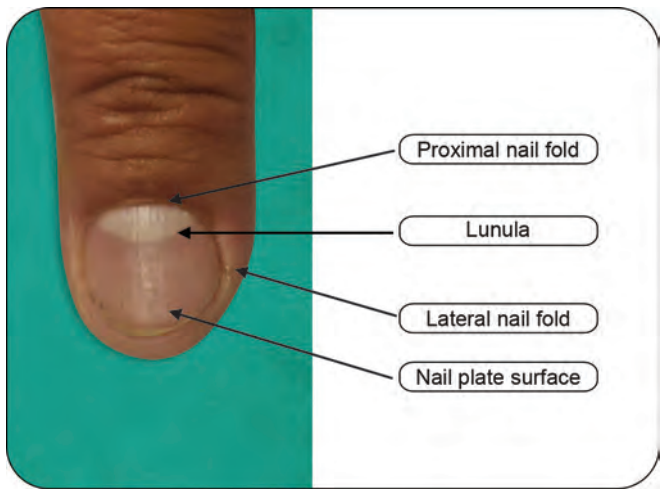

Fig. 1: Components of nail unit

Koilonychia (Spoon-shaped Nails)

It is characterized by concave dorsal surface of the nail **(Fig. 2)**. It is due to fragility of nails coupled with increased pressure exerted at the lateral and distal edges of the nails that make these edges to get reverted. The

TABLE 1 Classification of nail changes pertaining to systemic diseases

Abnormalities of nail surface	*Abnormalities of nail color*
• Koilonychia • Beau's lines • Clubbing • Pitting • Longitudinal ridging • Pterygium	• Leukonychia (total, striate, & punctate) • Terry nails • Muehrcke's lines (Apparent leukonychia*) • Lindsay nail • Splinter hemorrhages • Melanonychia • Cyanosis • Icterus • Yellow nail syndrome • Nicotine staining
Abnormalities in nail attachment	***Abnormalities in periungual region***
• Onycholysis • Pterygium	• Periungual telangiectasia • Paronychia

*Apparent leukonychia is due to the changes in the nail bed, which makes the nail look white

central aspect is depressed since it's tightly attached to nail bed.[2] Koilonychia can be congenital, acquired, or idiopathic. Iron deficiency anemia is the most common systemic cause followed by hemochromatosis, Raynaud's phenomenon, or systemic lupus erythematosus and among high altitude inhabitants.[3,4] It can also develop due to trauma to the nail matrix area, occupational exposure to petroleum-based solvents.[5]

Beau's Lines

These are transverse lines or ridges, which are parallel to lunula of the nails **(Fig. 3)**. They develop due to acute febrile illnesses, acute myocardial infarction, malnutrition, chemotherapeutic drugs, or trauma to nail matrix area. It occurs due to temporary cessation of nail growth. Nail grows at a rate of 3.5 mm per month approximately.[6] Considering this fact, the distance of these lines from the cuticle tells about the time period before when the systemic disease had resulted. The width of the line tells about the duration of illness.

Clubbing

Clubbing refers to the nail change featured by increased longitudinal and transverse curvature of nail plate combined with soft tissue hypertrophy of the digital pulp

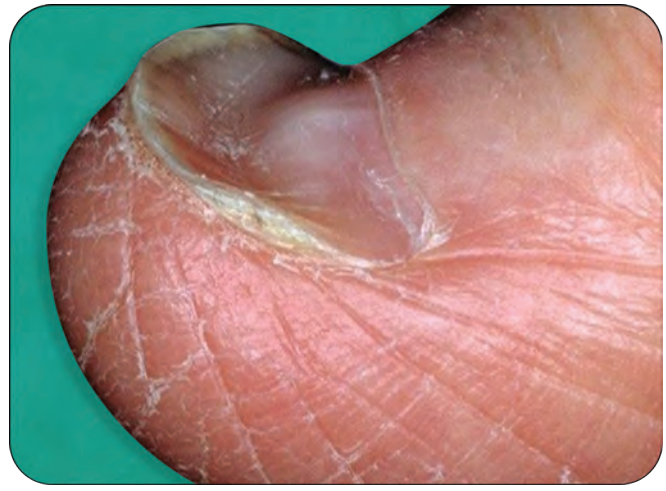

Fig. 2: Koilonychia

Fig. 3: Beau's lines

usually seen involving all the nails **(Fig. 4)**. Clubbing is extensively studied and it forms an integral component of general physical examination. Clubbing can be hereditary, acquired, or idiopathic.

The causes for clubbing can be remembered by the mnemonic CLUBBING which include:

- Cardiac diseases: congenital cyanotic heart diseases, acyanotic congenital heart diseases with reversal of shunt, infective endocarditis, atrial myxoma
- Lung diseases: lung abscess, bronchiectasis, emphysema, mesothelioma, cystic fibrosis, tuberculosis, pulmonary AV malformation, tuberculosis with cavitation

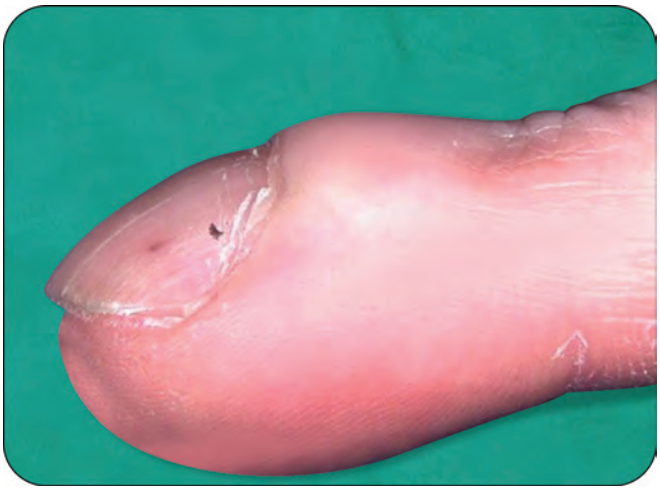

Fig. 4: Clubbing

Fig. 5: Onycholysis

- *U*lcerative colitis & Chron's disease (inflammatory bowel disease)
- *B*iliary cirrhosis (primary), cirrhosis due to other causes
- *B*ronchogenic carcinoma (most commonly small cell)
- *I*diopathic
- Co*n*genital
- *G*astrointestinal: malabsorption (celiac disease)

Miscellaneous causes: HIV, sarcoidosis, Hodgkin's disease, thyroid disorders, thymus tumor, and acromegaly.

Clubbing is caused by proliferation of connective tissue (fibroblasts, blood vessels, and bone tissue) and edema under the influence of VEGF (Vascular Endothelial Growth Factor) or PDGF (Platelet Derived Growth Factor) the levels of which get increased due to hypoxia or malignancies.[7]

Unilateral and unidigital clubbing can be caused by several factors as mentioned in the **Table 2**.

There are three famous geometric forms associated with clubbing namely:

- *Lovibond angle:* It is the angle between the nail plate and the proximal nail fold. It is usually less than 160° but increases beyond 180° in clubbing.
- *Curths angle:* It is the angle at the distal interphalangeal joint. Normally it is 180°. But in clubbing, it is reduced to less than 160°.
- *Schamroth sign:* It is featured by the obliteration of the diamond shaped space which is formed by approximation of the distal interphalangeal joint and the nail plate of the right and left identical digits.

TABLE 2 Causes of unilateral and unidigital clubbing

Causes of unilateral clubbing	*Causes of unidigital clubbing*
• Aortic or subclavian artery aneurysm • Axillary artery aneurysm • Brachial AV fistula • Recurrent dislocation of shoulder • Pancoast tumor • Erythromelalgia • Lymphangitis • Hemiplegic stroke	• Median nerve injury • Tophaceous gout • Sarcoidosis • Trauma

Following are the grades of clubbing:

- *Grade 1:* Fluctuation of nail bed
- *Grade 2:* Increased anteroposterior and transverse diameter of nails
- *Grade 3:* Increase in pulp tissue resulting in drumstick appearance of the fingers
- *Grade 4:* Hypertrophic osteoarthropathy (HOA) characterized by deep pain in the distal extremities more during night and on dependency[7]

Onycholysis

It is characterized by detachment of nail plate from nail bed resulting in whitish or yellowish coloration **(Fig. 5)**. This color change is due to the presence of air column beneath the detached portion of the nail plate. It can result due to numerous factors namely local causes (trauma, working in wet environment), cutaneous disorders (psoriasis,

Fig. 6: Pterygium of the nail

Fig. 7: Leukonychia

onychomycosis), and systemic causes (hyperthyroidism). Onycholysis in hyperthyroidism is called "Plummer's nails."[8]

Pterygium

It is the extension of the proximal nail fold over the surface of nail plate commonly seen in lichen planus **(Fig. 6)**. Pterygium inversum is a condition in which the nail bed tissue is attached to the distal under surface (ventral surface) of the nail associated with obliteration of distal groove. It is commonly seen in scleroderma.

Leukonychia

It denotes the white coloration of the nails **(Fig. 7)**. If the white color is due to abnormal keratinization it causes true leukonychia whereas the changes in nail bed lead to apparent leukonychia. Apparent leukonychia fades on application of pressure to the surface of the nails whereas true leukonychia remains unaltered. True leukonychia grows out along with the growth of the nail plate whereas apparent leukonychia persists since it is due to the changes in the nail bed.

Total Leukonychia

It is most commonly congenital or can develop secondary to renal failure, liver disorders, protein losing enteropathies, following acute illnesses.[9]

Punctate Leukonychia

It is characterized by white dot or streak seen involving nail(s). It is caused by trauma to the nail plate or nail matrix, commonly due to nail biting or habitually picking the proximal nail fold.

Mees' Lines

It is a classic example of striate true leukonychia, which is seen involving the whole width of the nails. They do not fade on application of pressure and they grow out with time.[10] Though it is characteristically known to occur in Arsenic toxicity, it is also reported in carbon monoxide poisoning, congestive cardiac failure, renal failure, due to chemotherapeutic medications, Hodgkin's disease, and pneumonia.[11]

Terry Nails

It is featured by whitish (pale) proximal portion and normal vascular band distally. It is seen associated with congestive cardiac failure, adult-onset diabetes mellitus, peripheral vascular disease, hemodialysis, and HIV.[12] Altered nail bed vascularity is a probable pathogenesis.

Muehrcke's Lines

These are apparent leukonychia featured by paired white lines, which run parallel to the lunule most commonly seen on the 2nd, 3rd, and 4th fingernails. They fade on

Fig. 8: Lindsay nails

Fig. 9: Splinter hemorrhages

application of pressure and they do not grow out with time. It is commonly caused by chronic hypoalbuminemia and chemotherapeutic medications (commonly by doxorubicin and cyclophosphamide).[13] The localized edema of nail bed that compresses the vasculature is hypothesized as the pathogenesis.

Half and Half Nail (Lindsay Nail)

It is characterized by normal proximal half and brownish discoloration of distal half of the nail **(Fig. 8)** and is seen in patients with chronic renal failure.[14] It is due to increased vascular proliferation in the distal nail bed.

Splinter Hemorrhages

These are tiny linear red or brown streak oriented linearly and longitudinally **(Fig. 9)**. It occurs due to extravasation from subungual blood vessels. Its occurrence in many or all the nails indicates systemic cause. Subacute bacterial endocarditis is the most common systemic cause followed by SLE, antiphospholipid antibody syndrome, Raynaud's disease, rheumatic heart disease, rheumatoid arthritis, internal malignancies, and medications (aspirin, warfarin, chemotherapeutic medications, tetracycline, and ganciclovir).[3,15-17] Certain dermatologic diseases like psoriasis and lichen planus can also be associated with splinter hemorrhages.

Fig. 10: Longitudinal melanonychia

Melanonychia

It is featured by black discoloration of the nail most commonly in the form of longitudinal black line (longitudinal melanonychia) **(Fig. 10)**. It occurs due to trauma, racial factors, smoking, iron deficiency anemia, hemochromatosis, thyroid disease, Addison's disease, HIV infection, and medications (antimalarials, minocycline, phenytoin, psoralens, sulfonamides, zidovudine, doxorubicin, methotrexate, and azathioprine).[18] It can be due to melanoma, which is characterized by pigmentation

of the proximal nail fold (Hutchinson sign), irregular black pigmentation of nail plate and wider band size.

Nicotine Staining of Nails

It is characterized by yellowish discoloration of the nails seen in chronic smokers.

Cyanosis

The bluish discoloration is due to the change in the color of the nail bed, which is seen through the nail plate. It is seen in the conditions causing peripheral cyanosis such as cold exposure, congestive cardiac failure, peripheral vascular disease. Transient cyanosis preceded by pallor and followed by erythema is the sequence of color change in Raynaud's phenomenon.

Icterus

In hyperbilirubinemia, the nails appear yellowish.

Yellow Nail Syndrome

It refers to the triad of yellowish color change of the nails, lymphedema and pleural effusion. It usually develops in the adults but can occasionally occur during childhood also.[19]

Red Lunula

It is seen in collagen vascular disorders, psoriasis, cardiac failure, cirrhosis, chronic obstructive pulmonary disease (COPD), and carbon monoxide poisoning.[19]

Periungual Telangiectasia

It serves as an important marker in the diagnosis of SLE, scleroderma, and dermatomyositis. It is also seen in diabetes mellitus, COPD, and rheumatoid arthritis.

Paronychia

It is the inflammation of the nail fold(s) **(Fig. 11)**. Acute paronychia is commonly caused by staphylococcus, the presence of which needs ruling out diabetes. Chronic paronychia is seen commonly among those who use detergents over a long span of time.

Psoriatic Nail Changes

Psoriasis is considered as systemic disease nowadays due to its association with metabolic disorder. Coarse pitting, longitudinal ridging, salmon patch, oil drop sign, and subungual hyperkeratosis are some of the classical nail changes in psoriasis **(Fig. 12)**. The presence of nail changes in a patient with psoriasis predicts increased chances of development of psoriatic arthritis, especially distal interphalangeal arthritis type.[20]

Onychomycosis

It is the fungal infection of the nail unit caused by dermatophytes or non-dermatophyte molds **(Fig. 13)**. It can be of various colors such as white, yellow, gray, or black. Onychomycosis is of four types based on the portion of nail it affects namely:

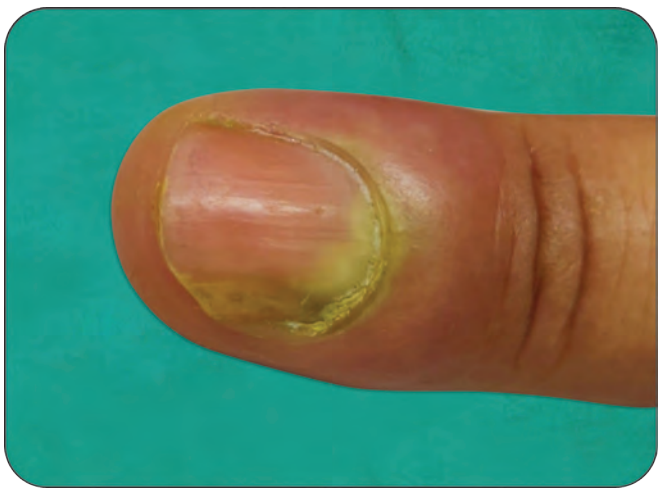

Fig. 11: Acute paronychia

Fig. 12: Coarse nail pits in psoriasis

Fig. 13: Onychomycosis

- Distal subungual onychomycosis (common type) is often seen in those whose feet or hands remain moist for prolonged duration. In diabetics and immunocompromised individuals, it is thicker and resistant to therapy,
- Proximal subungual onychomycosis is usually seen in immunocompromised individuals,
- Superficial white, and
- Total dystrophic type.

Pseudomonas Nail Infection

It causes greenish discoloration of the nails. It is seen commonly in whom the hands or feet remain wet for prolonged duration.

Acknowledgement: Journal of the American Academy of Dermatology for the figures.

Conclusion

Nails serve as an invaluable tool to diagnose the underlying systemic diseases and thus it is important to identify the nail changes. Nails can be easily examined and is a convenient diagnostic tool and thus the importance of including the nail changes as a part of general physical examination should always be emphasized.

CHAPTER

119 Anatomic Localization of Classical Neurological Symptoms

Uddalak Chakraborty, Avik Mukherjee, Jyotirmoy Pal

Abstract

Anatomical localization means the site of lesion responsible for a patient's symptoms and signs. Neurological localization requires a comprehensive understanding of anatomy and physiology of the nervous system. The process of localization shall begin during history taking, may be refined during clinical examination, and shall be reassessed after relevant diagnostic studies. Despite the advent and use of modern neuroimaging, nothing can replace a clinician's acumen to localize based on history and examination.

Introduction

"I believe a neurologist who can happily spend 3 days examining a patient for challenging anatomical localization will also be able to make a correct diagnosis within 3 minutes in acute stroke. The most important outcome of a neurological examination is anatomical localization."[1] Localization is derived from the Latin word locus which means site. The diagnostic exercise of determination of the site of nervous system affected by a disease process, from the signs and symptoms, is termed as localization in neurology.

Some authors argue that emphasis on anatomical localization over years has hindered the development of therapies in neurological diseases including epilepsy, migraine, Guillain-Barré syndrome, Parkinson's disease, multiple sclerosis and ischemic stroke, etc. However, the diagnosis of idiopathic epilepsy, migraine, and Parkinson's disease still remains clinical. Specialized neuroimaging may have complemented the clinical diagnosis, but can hardly replace it; there lies the importance of localization.

Common neurological symptoms can be localized by meticulous history taking and appropriate clinical examination, but sometimes one should be aware of false localizing signs or symptoms, which may misguide the clinician. In this chapter, we will try to localize lesions based on a few common neurological symptoms.

Weakness

Weakness is a characteristic and common motor neurodeficit, which may or may not be accompanied by other symptoms per se. First of all, true weakness should be differentiated from apparent weakness, either a vague feeling of tiredness or even malingering which may present like organic weakness. Proper clinical examination noting especially the distribution of weakness, any distractibility and a properly conducted Hoover's test may differentiate between these. After identification of true weakness, it should be categorized into an upper motor neuron type (UMN) or lower motor neuron type (LMN) weakness, differentiating features of which are given in **Table 1**.

UMN weakness predominantly affects extensors of upper limbs and flexors of lower limbs.

Hemiparesis

Weakness of upper limb, trunk, and lower limb of one side of body is usually the commonest presentation of stroke.

TABLE 1 Differentiation of UMN and LMN weakness based on symptoms

	UMN lesion	*LMN lesion*
Tone	Spastic	Flaccid
Wasting	Nil/Minimal	Significant Wasting
Fasciculation	Absent	May be present

TABLE 2 Possible localization of hemiparesis

Site of lesion	*Features*
Cerebral lesion ***Complete hemiparesis:*** Involvement of same side of face (predominantly lower half) with ipsilateral hemiparesis can be commonly localized in the internal capsule.	• **Contralateral cortex:** Distal predominant distribution of mild to moderate weakness with seizures, loss of cortical sensations, agnosia, aphasia, etc. • **Contralateral subcortical (corona radiata):** Faciobrachial weakness with aphasia, homonymous visual field defects. • **Internal capsule:** Dense hemiplegia, hemianopia, hemianesthesia.[2]
Brainstem	• Cranial nerve palsy LMN type with contralateral hemiparesis—crossed hemiparesis • Ipsilateral Horner's syndrome due to involvement of sympathetic trunk. May also be seen in ipsilateral thalamic lesions. • Ipsilateral hemiataxia due to involvement of cerebellum and its connections.
Cervical cord	• Ipsilateral hemiparesis sparing face • Ipsilateral loss of vibration and joint position sense with contralateral pain and temperature loss, usually one to two segments below the lesion (Brown-Sequard syndrome) • LMN findings at the level of lesion.

Hemiplegia means complete loss of motor function on that side.

Hemiparesis is usually due to involvement of contralateral corticospinal tract (CST) from cerebral cortex to lower medulla or ipsilateral CST in case of a high-cervical cord lesion. Localization of hemiparesis is demonstrated in **Table 2**. CST with possible sites of lesion in hemiparesis has been shown in **Figure 1**.

Cruciate hemiparesis: Weakness of ipsilateral upper limb with contralateral lower limb weakness is termed as cruciate hemiparesis. The neuroanatomical explanation involves the complex somatotopic and anatomical segregation of the CSTs in the decussation at the lower medulla oblongata or cervicomedullary junction. At this level, the ventromedially located arm fibers decussate rostral to the leg fibers, and a lesion at this specific point can lead to this entity.[3]

False Localization in Hemiparesis

Kernohan's Notch Syndrome **(Fig. 2)***:* A supratentorial lesion may lead to transtentorial herniation of the temporal lobe, with compression of the ipsilateral cerebral peduncle against the tentorial edge; since this is above the pyramidal decussation, this may lead to a contralateral hemiparesis. Occasionally, the hemiparesis may be ipsilateral to the side of lesion, and hence false-localizing; this occurs when the contralateral cerebral peduncle is compressed by the free edge of the tentorium.[4]

Monoparesis may be localized to cerebral cortex or subcortex due to selective involvement representing that particular limb.

Paraparesis

Weakness of both lower limbs may also be a common presenting symptom. We have to differentiate UMN and LMN type of lesions from history and clinical examination **(Table 3)**.

Features suggestive of myelopathy include a definite level below which sensory modalities may be impaired/absent; LMN weakness at the level of lesion and UMN weakness below the level of lesion and bladder/bowel disturbance.

Patient may complain a girdle-like sensation suggestive of the sensory level of cord involvement. *False localization:* Compressive lower cervical or upper thoracic myelopathy may produce spastic paraparesis with a mid-thoracic girdle sensation.[5]

Cerebral cause of paraparesis may be accompanied by seizure, headache, etc. Cauda equina and conus medullaris may be differentiated based on symptoms as in **Table 4**.

Quadriparesis

Weakness of all four limbs; may be again categorized into UMN and LMN **(Table 5)**.

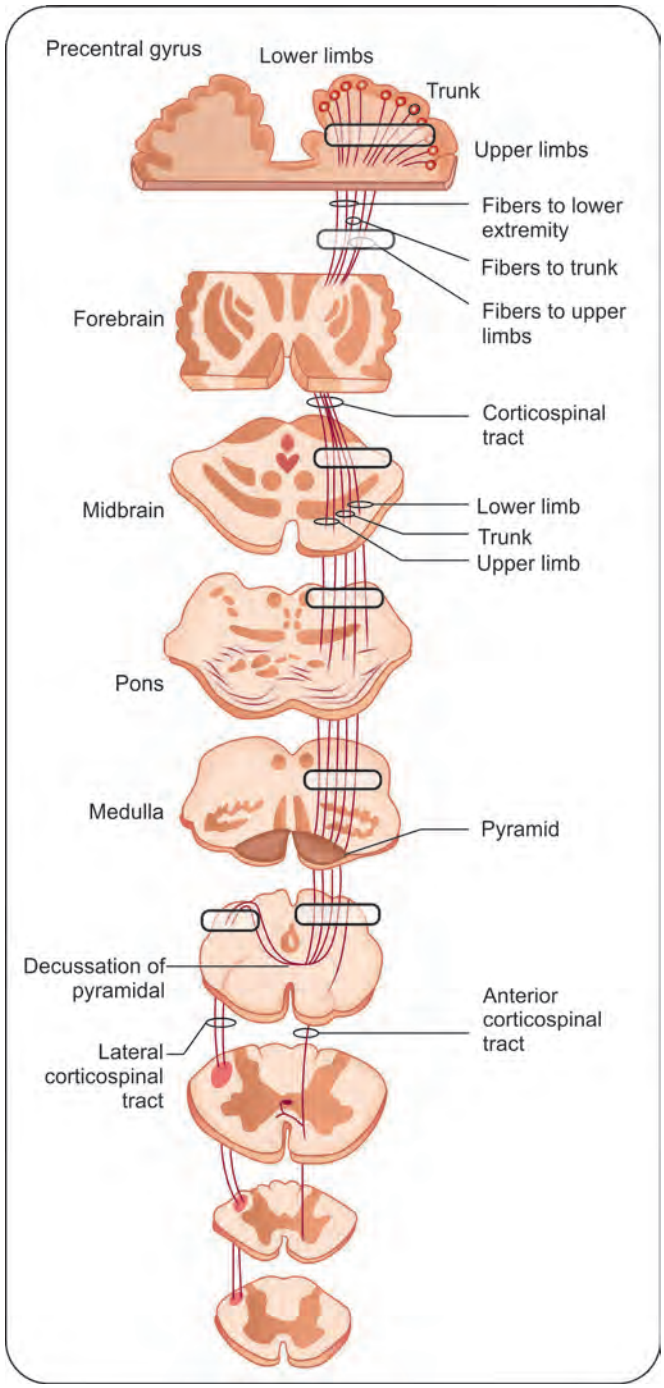

Fig. 1: Corticospinal tracts with possible levels of lesion in hemiparesis

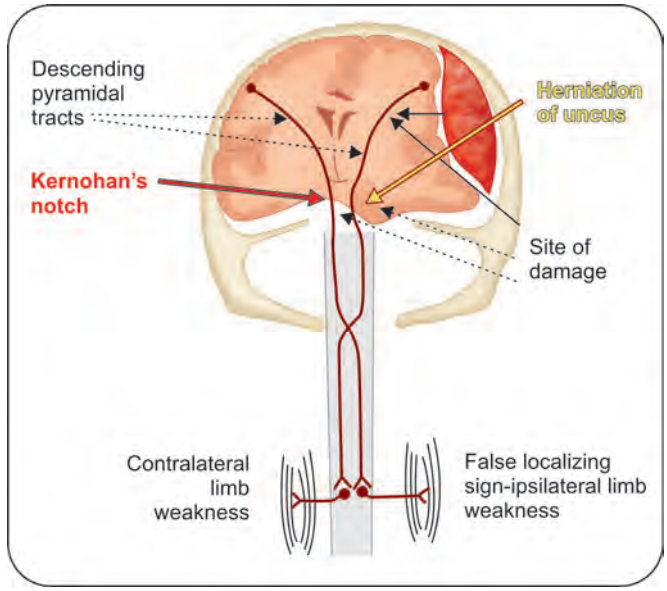

Fig. 2: Kernohan's notch syndrome

TABLE 3 Possible localization of paraparesis

Type of lesion	*Localization*
UMN	• Central nervous system above lumbosacral cord. • Commonly in thoracic cord • Rarely in cervical cord • Occasionally, midline cerebral lesion like parasagittal meningioma
LMN	• Conus medullaris • Cauda equina • Anterior horn cells in lumbar cord • Motor root of nerves of lower limb • Motor nerves of lower limb • Neuromuscular junction • Muscle

Sensory Abnormalities

Positive symptoms: Tingling (pins and needles), burning, band like, itch, aching.

Negative symptoms: Numbness, difficulty in coordination of limbs in dark places or closure of eyes **(Table 6)**.

Pattern of sensory abnormalities have been shown in **Figure 3**. Localization of sensory abnormalities are given in **Table 7**.

Incoordination

In a patient with gait imbalance, we have to rule out any nerve and muscle disorder, spinal cord or basal ganglia disorder.

Localization of ataxia has been discussed in **Table 8**.

TABLE 4 Cauda versus conus medullaris

	Cauda equina	*Conus medullaris*
Pain	Severe, asymmetric, radicular	Less common
Sensory loss	Asymmetric lower limbs, patchy	Symmetric saddle anesthesia
Motor loss	Asymmetric	Symmetric
Sphincter involvement	Less common and late	Common and early

TABLE 5 Possible localization of quadriparesis

Type of lesion	*Localization*	*Features*
UMN	**Cervical cord** **False localization**: Thoracic sensory level, paresthesia, clumsiness, and atrophy of hands.	**Cervical myelopathy**: • Weakness of all muscles below a particular level. • Sensory loss below a circumferential level. • Sphincter disturbance **High cervical cord/foramen magnum:** • Neck stiffness, suboccipital pain in C2 distribution. • Electric shock like sensation on flexion of neck. • Sequential weakness (Ehrlich's phenomenon) • Downbeat nystagmus, cerebellar ataxia (foramen magnum) • Onion skin pattern of sensory loss of face
	Brainstem	Cranial neve palsies, Horner's syndrome, Internuclear ophthalmoplegia
	Brain (bihemispheric lesion)	Pseudobulbar palsy (emotional lability/incontinence, spastic dysarthria)
LMN	**Anterior horn cells**	Pure motor weakness, prominent wasting, distal>proximal
	Polyradiculopathy **False-localizing radiculopathy** may occur in Idiopathic Intracranial Hypertension and cerebral venous sinus thrombosis and may manifest as acral paresthesias, backache and radicular pain, and less often with motor deficits	Predominant proximal weakness with sensory symptoms.
	Polyneuropathy	Distal symmetric weakness with sensory impairment in glove and stocking distribution.
	Neuromuscular junction	Predominant proximal pure motor weakness with diurnal variation, fatiguability.
	Muscle	Pure motor weakness without diurnal variation, fatiguability.

Speech Disorders

A communication disorder in the form of slurred speech, strained/effortful speech, monotonous low volume speech, word finding difficulty, comprehension difficulty, and naming problems should be recognized at first.[7,8]

Dysarthria as difficulty of articulation should be segregated from aphasia; if dysarthria present, it may be localized depending on the following types:

- *Spastic dysarthria:* Pseudobulbar/UMN involvement
- *Flaccid dysarthria:* LMN involvement

TABLE 6 Distribution of symptoms in reference to sensory and autonomic fibers

Fibers	*Symptoms*
Small fibers	Burning, painful dysesthesia, autonomic dysfunction
Large fibers	Sense of imbalance, limb incoordination, tingling
Autonomic	Postural dizziness, fainting, heat or cold intolerance, sphincter dysfunction

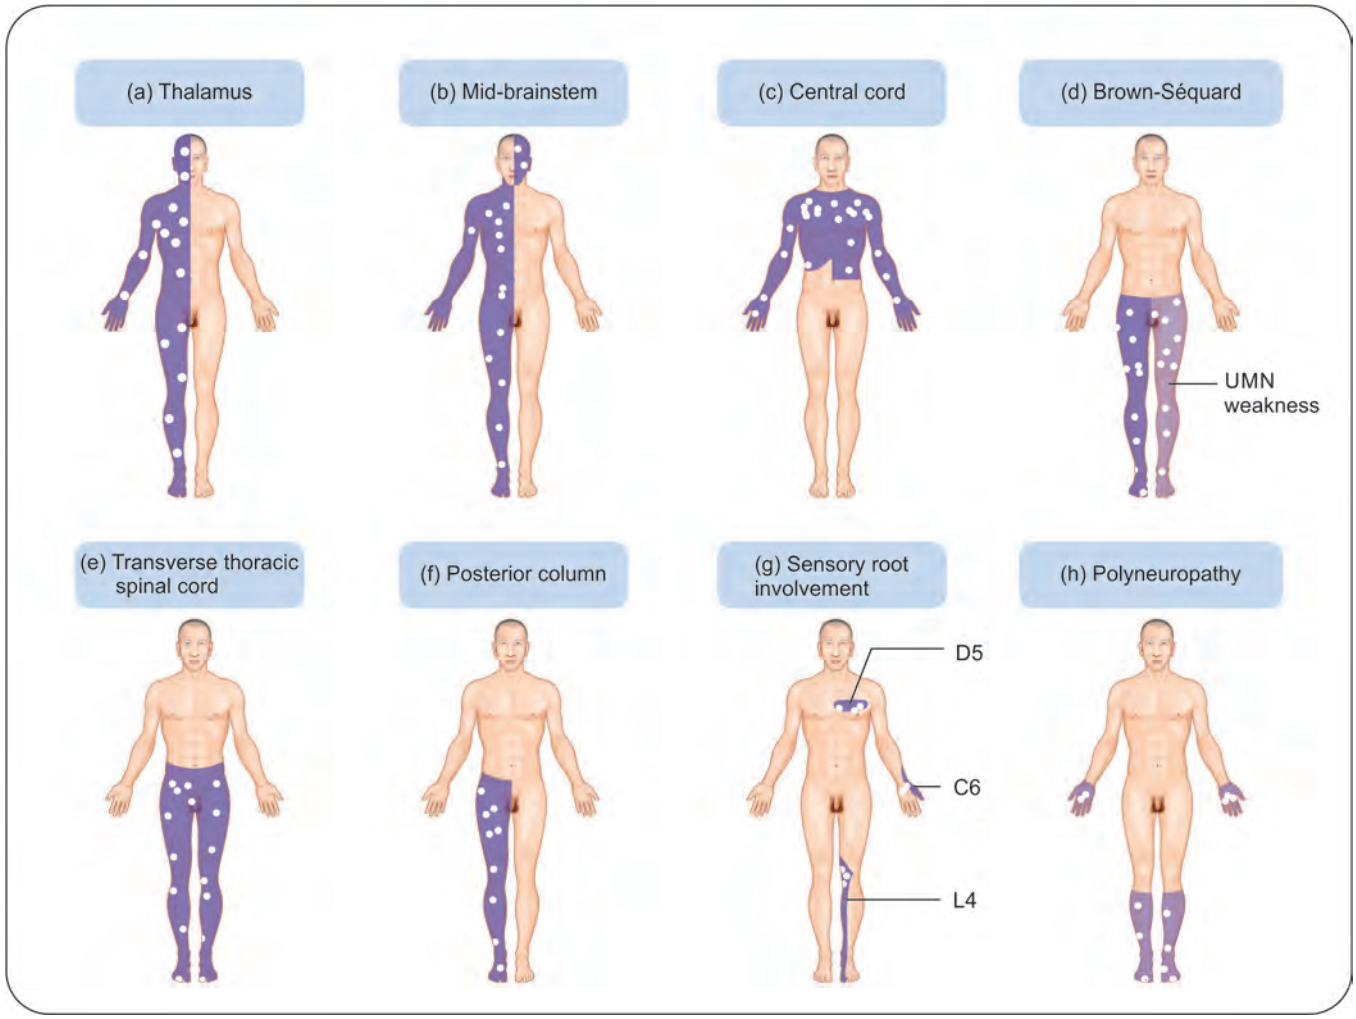

Fig. 3: Pattern of sensory abnormalities. **Principal patterns of loss of sensation. (a) Thalamic lesion:** sensory loss throughout opposite side (rare). **(b) Brainstem lesion:** contralateral sensory loss below face and ipsilateral loss on face. **(c) Central cord lesion,** e.g., syrinx: 'suspended' areas of loss, often asymmetrical and 'dissociated', i.e., pain and temperature loss but light touch intact. **(d) Hemisection of cord/unilateral cord lesion** = Brown-Séquard syndrome: contralateral spinothalamic (pain and temperature) loss with ipsilateral weakness and dorsal column loss below lesion. **(e) Transverse cord lesion:** loss of all modalitiesm, including motor, below lesion. **(f) Dorsal column lesion,** e.g., MS: loss of proprioception, vibration, and light touch. **(g) Individual sensory root lesions,** e.g., C6, D5, L4. (h) Polyneuropathy: distal sensory loss

- *Monotonous, hypophonic speech:* Extrapyramidal involvement
- *Clumping of syllables with undue separation:* Cerebellar involvement

Localization of aphasia may be done as follows:

- Reduced fluency with difficulty in word finding and impaired repetition: Broca's aphasia
- Comprehension difficulty in terms of word and sentences with impaired repetition: Wernicke's aphasia
- Expressive and comprehension difficulty: Global aphasia
- Isolated repetition difficulty: Conduction aphasia
- Preserved repetition with execution/comprehension difficulty: Isolation/transcortical aphasia.

Visual Loss

First of all, one shall be able to differentiate between decreased ability to see things, double vision or loss of pieces of visual field.

TABLE 7 Possible localization of sensory symptoms

Site of lesion	*Features*
Cerebral lesion	• **Cortex:** Cortical sensation impaired. May affect only a portion of contralateral part represented by the affected homunculus.[6] • **Internal capsule:** Uniform involvement of contralateral side with or without weakness. • **Thalamus:** Contralateral hemisensory loss; contralateral hyperalgesia and allodynia (Dejerine-Roussy syndrome).
Brainstem	• Contralateral side sensory involvement. • Ipsilateral sensory loss in face with contralateral hemisensory loss in body—usually in lateral medullary lesion.
Spinal cord	• **Complete transection**: Sensory loss below a level. • **Spinal hemisection**: Brown Sequard syndrome (ipsilateral vibration loss and proprioception loss with contralateral pain, temperature loss) • Selective dorsal (posterior column) or lateral cord (spinothalamic tract) involvement. • **Central cord:** Suspended sensory loss with sacral sparing; dissociative anesthesia.
Nerve root	Focal symptoms depending on root of involvement in a dermatomal pattern. Sensory symptoms may be minimal in case of single root involvement, due to considerable overlap by adjacent root territories.
Sensory ganglion	Pure sensory involvement in non-length dependent asymmetric fashion with sensory ataxia.[6]
Plexus	Diffuse symptoms corresponding to two or more adjacent roots usually associated with motor deficits.
Peripheral nerve	Sensory impairment in the distribution of the affected peripheral nerve; symmetric in case of polyneuropathies or asymmetric in case of mononeuropathy/mononeuritis multiplex.

TABLE 8 Possible localization of ataxia

Type of ataxia	*Features*
Frontal	Magnetic gait with out of proportion ataxia, spasticity.
Sensory	• Paresthesia, numbness with aggravation of symptoms in the dark, high steppage gait. • **Peripheral nerve (Large fiber):** Sensory symptoms in glove and stocking distribution. • **Dorsal root ganglion**: Non length dependent profound pure sensory symptoms. • **Posterior column:** Definite spinal level • **Medial lemniscus:** Brainstem symptoms
Peripheral Vestibular	Prominent vertigo with vomiting, nausea, and relative sparing of speech.
Cerebellar **False localization** Frontocerebellar pathway damage, may result in incoordination of the contralateral limbs, mimicking cerebellar dysfunction.[7]	• Dysmetria, cerebellar speech, and other symptoms, with or without brainstem symptoms may localize the lesion in cerebellum and its connections. • Usually ipsilateral lesion leads to ipsilateral symptoms. • Appendicular involvement suggestive of cerebellar hemisphere involvement, while truncal involvement may be localized to vermis; cerebellar speech due to paravermal involvement; and a combination of all may be seen in pancerebellar disease.

Monocular visual loss is suggestive of lesion in the eye itself or optic nerve anterior to the optic chiasma.

Binocular visual loss is suggestive of bilateral optic nerve lesion or a chiasmal/retrochiasmal lesion.[9]

Visual loss correctable by pin hole/glasses: Refractive error.

Visual loss not correctable by pin hole: Opacity in ocular media/neurological illness.

Color Vision

Acquired disturbance of color vision is suggestive of optic neuropathy and maculopathy; color desaturation being one of the earliest manifestations of optic neuropathy.

Localization of visual loss has been shown in **Table 9**.

Pattern of involvement of visual field and their respective localization has been shown in **Figure 4**.

Headache

Headache is one of the most common symptoms we come across in our day-to-day practice. The pain sensitive structures in the cranium which may give rise to headache are as follows:

- Scalp and aponeurosis
- Middle meningeal artery
- Dura mater and dural sinuses
- Falx cerebri

TABLE 9 Possible localization of visual loss

Site of lesion	*Features*
Ocular media	Eye pain, lacrimation, redness, no improvement in vision with pin hole
Anterior visual pathway	• Monocular vision loss • Central scotoma/altitudinal field defect in one eye • Impaired color vision • Orbit: Isolated optic neuropathy • Optic canal/intracranial site: Other cranial nerves may be involved (III, IV, VI) • Lesions close to optic chiasma: Junctional scotoma
Posterior visual pathway	• Binocular visual loss • Homonymous/heteronymous hemianopia • Color vision may be impaired
Cortical defect	• Ventral occipitotemporal defect: – Visual agnosia, prosopagnosia, topographognosia • Dorsal occipito-temporal defect: – Akinetopsia, Simultagnosia, optic ataxia, ocular motor apraxia

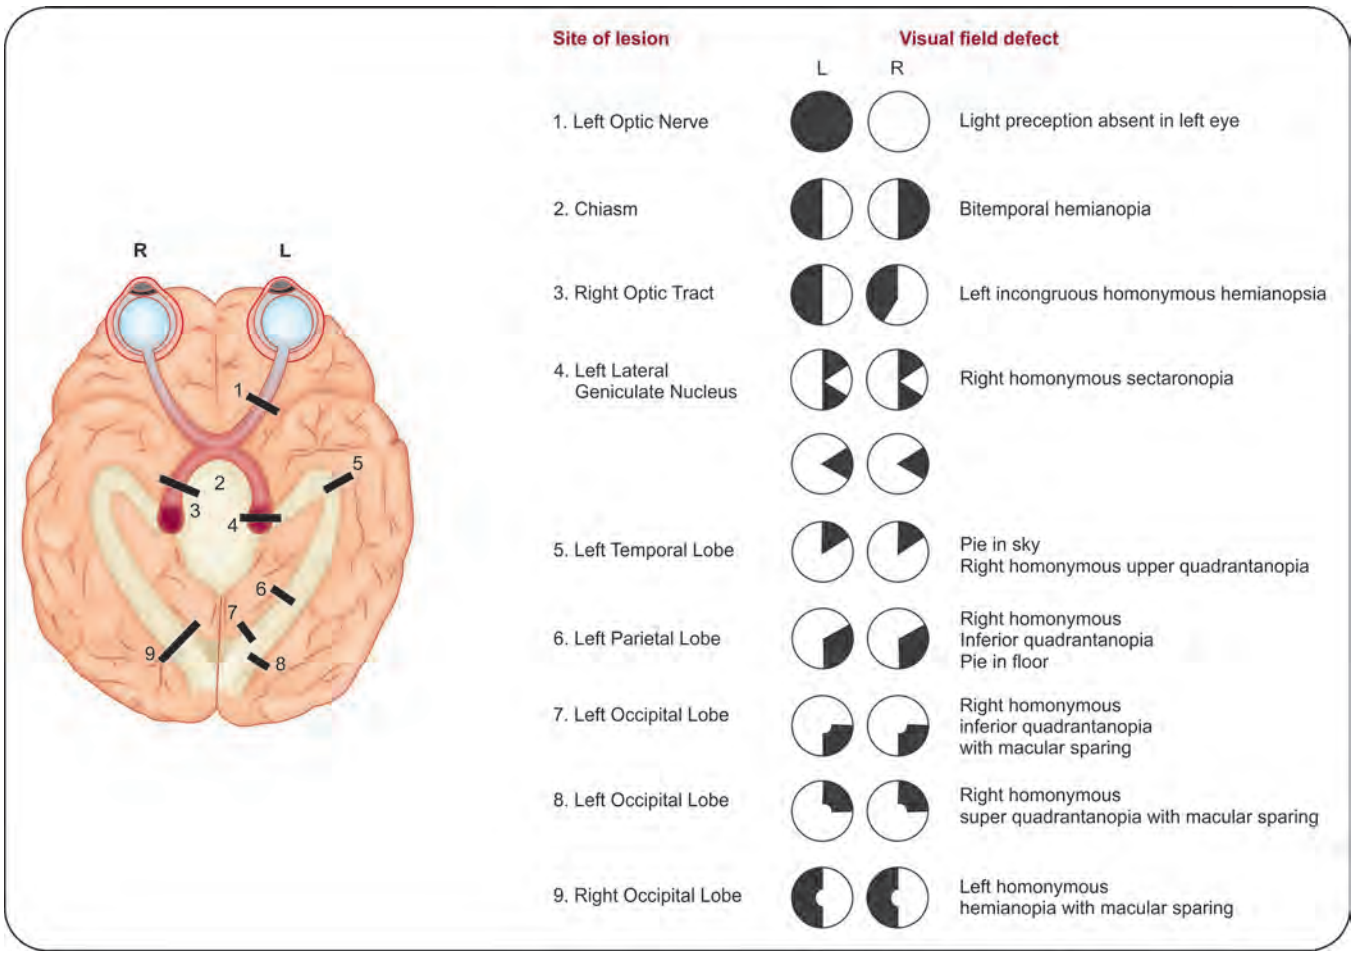

Fig. 4: Localization of visual field loss

- Proximal segments of the large pial arteries
- Cranial nerves V, VII, IX, and X
- Cervical nerves C1, C2, and C3

Headache may result due to inflammation, traction, compression, or malignant infiltration of these structures.

Primary involvement of these structures may give rise to primary headaches, which have little localizing value, while secondary involvement, for example, trauma, raised intracranial tension may give rise to secondary headaches.

In case of an extracranial structure as the source of headache, the site of pain is precise, for example, inflammation of extracranial artery in giant cell arteritis can be localized to the tender vessel.

Lesions of paranasal sinuses, teeth, eyes, upper cervical vertebrae have less sharp localization, but pain is referred in a regional distribution.

Infratentorial lesions tend to produce an occipitonuchal distribution of headache, while supratentorial lesions produce a frontotemporal headache.[10]

Among the primary headaches, cluster headache and trigeminal cephalgias have a periorbital location while migraine is usually unilateral and tension type headache is bilateral in distribution.

Conclusion

In this chapter, the authors have tried to give an overview of anatomical localization of a few classical neurological symptoms. Despite the recent advances in neuroimaging and electrodiagnostics, the importance and significance of anatomical localization is still indispensable, as it can guide the clinician to focus on a particular neuroanatomical substrate and even cut the need of unnecessary extensive investigations. We hope that this overview serves as a useful guide to the clinicians in day-to-day practice.

CHAPTER

120 Clinical Signs of Diaphragm Dysfunction

Atanu Chandra, Aritra Kumar Ray, Arkapravo Hati

Abstract

Diaphragm is a musculofibrous structure separating thorax and abdomen. While unilateral diaphragmatic weakness is mainly secondary to inflammatory, infiltrative or traumatic etiologies; bilateral weakness mainly happens in systemic neurological or myopathic disorders. Unilateral weakness is usually asymptomatic. Abdominal paradox is a characteristic clinical sign of diaphragm weakness. Sniff test is a very important diagnostic test for assessment of unilateral weakness. Thorough history, meticulous examination, and appropriate investigations are of paramount importance to evaluate and plan for management.

Introduction

The term "Diaphragmatic dysfunction" is used to describe mainly three conditions—diaphragmatic eventration, weakness, and paralysis of diaphragm.[1] Eventration can be defined as a persistent and permanent elevation of a part or all of the hemidiaphragm due to thinning.[1] Diaphragmatic weakness may be described as a partial impairment of the strength of the muscles of diaphragm to produce and maintain adequate pressure required for ventilation. On the other hand, paralysis of the diaphragm is used to denote complete impairment of this capacity.[2] Based on the etiology, this disorder can be unilateral or bilateral; permanent or temporary. Diaphragmatic flutter is another rare variety of diaphragm dysfunction which is characterized by repeated and variable cycles of regular and involuntary contractions of diaphragm. Features of diaphragmatic flutter are dyspnea, epigastric pulsations, and pain in the thoracoabdominal region.

Anatomical Considerations

Diaphragm is the musculofibrous structure, which separates the abdominal cavities from thoracic cavities. It is formed of a peripherally located muscular part and a non-contractile central fibrous portion, which is again divided into costal, sternal, and lumbar muscular groups. The muscular component of the diaphragm is composed of Type 1 (slow, fatigue resistant) and Type 2 (fast) fibers.

Phrenic nerve, which originates from the 3rd, 4th, and 5th cervical nerves (C3, C4, and C5) almost exclusively provide the afferent neurological supply to diaphragm. Both the phrenic nerves descend anterior to the scalene muscles and then travel between the subclavian arteries and veins in the neck to enter into the thorax. The right phrenic nerve travels caudally anterior to the brachiocephalic trunk along the right atrium and finally enters the abdominal cavity. The left phrenic nerve travels along the left ventricle caudally and supplies the diaphragm.

Diaphragmatic thickness is variable with gradual tapering from anterior to posterior costal areas and from the costal insertions toward central tendon. Under normal situation, the diaphragm functions as a piston to generate flow as it descends in the thoracic cavity and displaces the contents of abdominal cavity caudally thereby causing elevation of the lower portion of thorax. The negative

intrathoracic pressure thus created results in an inflow of air from mouth to lung, thereby creating tidal volume.

Etiology

Causes of unilateral diaphragm weakness:

- *Infiltrative or compressive processes:* Goiter, pathological lymph nodes, mediastinal or pulmonary malignancy, cervical arthrosis, and spondylosis.
- *Inflammatory disease:* Shingles, post-viral, mononeuritis, chronic inflammatory demyelinating polyneuropathy, parsonage—Turner syndrome.
- *Traumatic lesions:* Central venous cannulation, nerve blockade', heart/lung/liver transplant, neck/heart surgery, chiropractic manipulation.
- *Central neurological disease:* Multiple sclerosis, stroke, rhizotomy.
- *Idiopathic.*

The etiologies of diaphragmatic dysfunction are described in **Table 1**.

Causes of bilateral diaphragm weakness:

- *Neurological disease:* Multiple sclerosis, amyotrophic lateral sclerosis, medullary transection, Guillain-Barré syndrome, severe cervical spondylosis, poliomyelitis, chronic inflammatory demyelinating polyneuropathy.
- *Myopathy:* Malnutrition, dysthyroidism, muscular dystrophies, amyloidosis, corticosteroid use, post-viral critical illness/ventilator induced diaphragm dysfunction, disuse atrophy/inactivity.

TABLE 1 Etiology of diaphragmatic dysfunction

Anatomical location of the lesion	*Disease*
Cerebral cortex	• Cerebrovascular accident (CVA)
Internal capsule	• Arnold-Chiari disease • Vascular accident
Spinal cord	• Traumatic injury to the cord • Degenerative (severe spondylosis)
Central nervous system (CNS)	• Multiple sclerosis (MS)
Motor neurons	• Amyotrophic lateral sclerosis (ALS) • Post polio syndrome • Paraneoplastic neuropathy • Syringomyelia • Spinal muscular atrophy (SMA)
Brachial plexus	• Traumatic injury to the plexus • Idiopathic • Iatrogenic (Obstetric procedures, anesthetic blockade, radiotherapy)
Phrenic	• Compression/infiltration (mediastinal neoplasms) • Trauma[3] • Guillain Barre syndrome[4] infection—Pneumonias,[5] Lyme disease,[6] Herpes zoster, HIV infection[7] • Amyotrophic neuralgia (Parsonage-turner syndrome)[8] • Thoracic surgeries[9] • Others (Hypothyroidism,[10] Malnutrition,[11] Diabetes,[12] Benign thyroid hypertrophy,[13] vasculitis, porphyria, Charcot-Marie-Toot[14] disease) • Idiopathic[15]
Lung	• Obstructive airway diseases (Asthma and COPD)
Neuromuscular junction	• Lambert-Eaton syndrome[16] • Myasthenia gravis • Botulism[17]
Muscular	• Steroid myopathy[18] • Pompe disease[19] • Myositis • Muscular dystrophies • Mechanical ventilation[20]

- *Connective tissue disease:* Dermatomyositis, mixed connective tissue disease, systemic lupus erythematosus/shrinking lung syndrome.
- *Idiopathic.*
- *Sepsis.*

Clinical Features

Unilateral diaphragmatic paralysis: Patients are usually asymptomatic but may have limited ability to exercise.[21] They may also have dyspnea on exertion and in supine position. Symptoms are more severe in persons with obesity or with other comorbidities including cardiac and pulmonary pathology.[22] They may also have symptoms of gastroesophageal reflux and nocturnal hypoventilation.[23] It is often diagnosed as an incidental finding on chest skiagram as an isolated elevation of hemidiaphragm.

Clinical examination is rather nonspecific. On auscultation, decreased breath sounds are heard at the base of affected hemithorax. Reduced diaphragmatic excursion may be clinically detected by percussion of the lower rib cage at the end of expiration and inspiration respectively. Occasionally, paradoxical thoracoabdominal movement occurs during sleep.

Bilateral diaphragmatic paralysis: Patients may show dyspnea on lying down (orthopnea). Respiratory distress, which occurs sometimes during rest, may be exacerbated at the time of immersion in water.[24] Most of the patients with this disorder present with sleep disorders and features of significant hypoventilation.

On clinical examination, cyanosis, superficial, and rapid respiration, bilaterally diminished breath sounds or abdominal paradox may be noted. In bilateral diaphragmatic paralysis, inspiration occurs due to contraction of the accessory muscles of respiration such as scalene and sternocleidomastoid along with external intercostals.

Abdominal paradox: The characteristic clinical sign of diaphragmatic dysfunction is abdominal paradox.[25] During inspiration, when there is rib cage expansion, paradoxical inward motion of abdomen does occur. When accessory inspiratory muscles of the rib cage and neck contract as compensatory mechanism and lower pleural pressure, the flaccid diaphragm moves in a cephalad direction with inward movement of the abdomen. This abnormal breathing pattern is mainly seen in supine position. It is mostly seen in bilateral diaphragmatic paralysis and rarely occurs in unilateral cases. When abdominal paradox is seen in unilateral diaphragmatic paralysis, it indicates generalized respiratory muscles weakness. The mechanism of abdominal paradox has been described in **Figures 1A to D**.

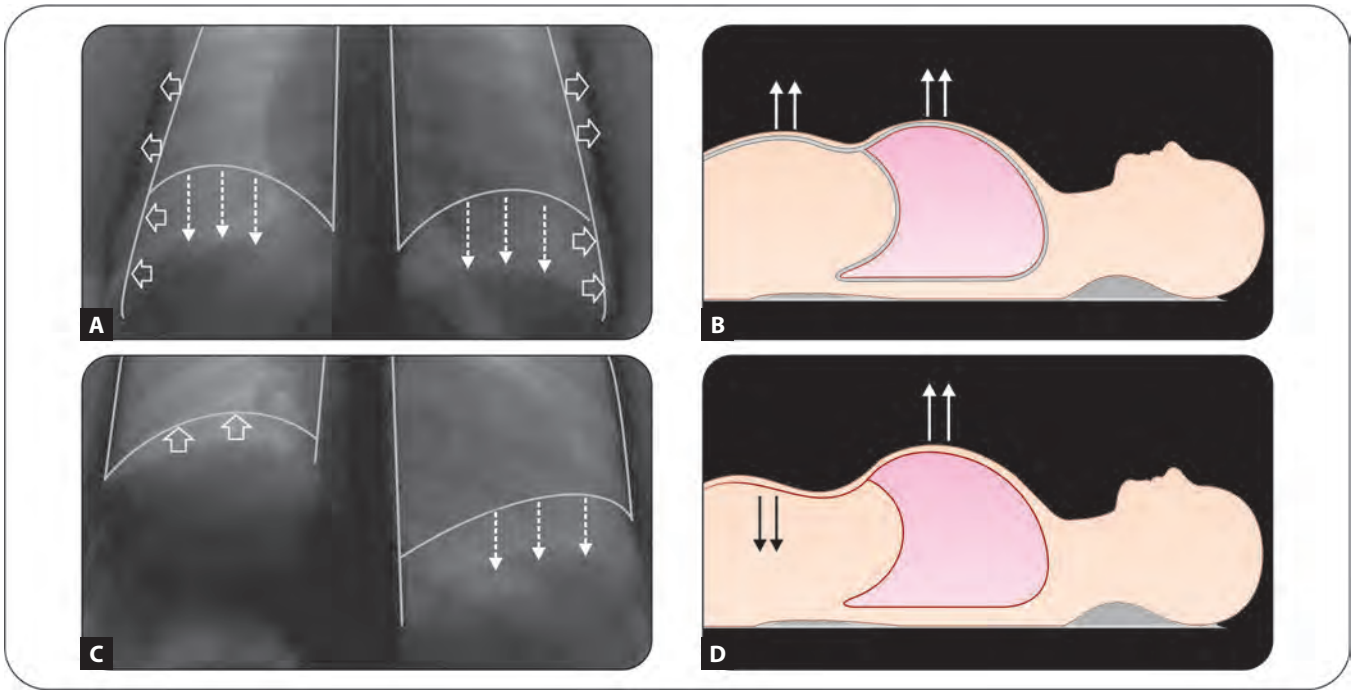
Sniff Test

Fluoroscopy of diaphragm is very important to evaluate diaphragmatic function.[25] The motion of the diaphragm is assessed by doing a rapid and short inspiratory effort through nostrils (also known as "Sniff test"). In normal persons, diaphragm will move caudally. In unilateral diaphragmatic paralysis, paradoxical (cephalad) movement is seen on the side of paralysis. There is no diagnostic value of this test in case of bilateral diaphragmatic paralysis. False negative results may be obtained due to sudden caudal motion of the paralyzed diaphragm at the onset of inspiration, which is misinterpreted as contraction. This phenomenon happens due to abrupt relaxation of abdominal muscles at the beginning of inspiration following active contraction at expiration. False positive results may be seen in about 6% cases.

Diagnosis

Diaphragmatic dysfunction is most often suspected after the incidental finding of an isolated elevation of hemidiaphragm on chest skiagram or during evaluation of unexplained dyspnea. Diagnosis is mainly based on imaging modalities including radiography, chest ultrasound, and fluoroscopy. Tests include:

- *Lung function test* is often performed as a first-line investigation to quantify and assess the physiological impact of diaphragm weakness.
  - *In unilateral diaphragmatic weakness*, functional residual volume (RV) and total lung capacity (TLC) are normally preserved. Vital capacity (VC) is mildly decreased to approximately 75% of predicted value[26] and 10–20% further decrease is noted in supine position.[27]
  - *In bilateral diaphragmatic weakness*, VC usually reaches 50% of predicted values and 30–50% further decrease is noted in supine position. RV remains elevated and TLC can even get reduced.
- *Radiologic fluoroscopy* (real time view) with sniff maneuver to depict paradoxical motion.[25,28]



Figs. 1A to D: (A) Normal contraction of the diaphragm during quiet inspiration. (B) In supine position, both the rib cage and abdomen move outward. (C) When the diaphragm is paralyzed, the negative intrathoracic pressure pulls the diaphragm and the abdominal viscera toward the thoracic cavity, thereby generating a negative abdominal pressure. (D) In supine position, it is noted how the negative abdominal pressure creates a paradoxical movement during inspiration and the abdomen moves inward

- *Ultrasound* to look at the movement of the diaphragm and changes in the muscle thickness. It is noninvasive, simple, readily available, and widely used both in the research and clinical setting. It is used to assess to assess Tdi (static measurement of diaphragm thickness) and TFdi (inspiratory diaphragm thickening fraction).
- *Sleep studies:* Polysomnography with concomitant noninvasive ventilation may be considered routinely as this approach has both a therapeutic and diagnostic value. Sleep disordered breathing (SDB) can be seen both in unilateral and bilateral diaphragmatic weakness and it becomes more prominent with the progression of the disease. Early consideration of polysomnography is very important in such patients.
- Cardiopulmonary exercise testing.
- Chest X-ray: The common alternative causes of an elevated hemidiaphragm on imaging have been depicted in **Table 2**.
- Maximum inspiratory mouth pressures.

TABLE 2 Common alternative causes of an elevated hemidiaphragm on imaging

'False' hemidiaphragm paralysis	*Extra-diaphragmatic disease*
• Morgagni hernia	• Subphrenic abscess
• Bochdalek hernia	• Pulmonary or mediastinal mass
• Hiatal hernia	• Pulmonary embolism
• Traumatic rupture	• Ascites
• Lung resection	• Asymmetrical emphysema
• Lipomas	• Atelectasis

- *Stimulation of phrenic nerve* in the neck by magnetic or electrical stimulation.
- *Transdiaphragmatic pressure measurement* (measure of strength of diaphragm).
- *Electromyography (EMG)*, a test which records and evaluates electrical activity produced by skeletal muscles.

TABLE 3 Comparison between unilateral and bilateral diaphragmatic paralysis

Diagnostic tools and treatment	***Unilateral diaphragmatic paralysis***	***Bilateral diaphragmatic paralysis***
History	Neck or chest surgery, shoulder or neck pain, neck injury, neuromuscular disease, cervical spine manipulation	Neck or chest surgery, shoulder or neck pain, neck injury, neuromuscular disease, manipulation of the cervical spine
Presentation	Asymptomatic, exercise limitation, unexplained dyspnea, incidental radiographic finding	Exercise limitation, unexplained dyspnea, orthopnea, dyspnea at rest, dyspnea when bending, respiratory failure, prolonged mechanical ventilation, constitutional symptoms
Examination	No abdominal paradox	Abdominal paradox
Laboratory tests		
Vital capacity (% of predicted value)	>70	<50
Decline in supine vital capacity (%)	10–30	30–50
Fluoroscopy	Sniff test positive	Not helpful
Thickening of diaphragm on inspiration	No change	No change
Complications	Ocassional hypoventilation during sleep, atelectasis	Frequent hypoventilation during sleep, pneumonia, atelectasis, respiratory failure
Treatment		
Observation period for recovery (yr)	1.5–3	1.5–3
Treatment for coexisting conditions	Yes	Yes
Reversal of metabolic disturbance	Yes	Yes
Noninvasive positive pressure ventilation (NIPPV)	Usually not indicated	Often indicated
Plication of diaphragm	May be helpful	Not indicated
Phrenic pacing	No	Yes, in patients with high spinal cord injury (SCI)

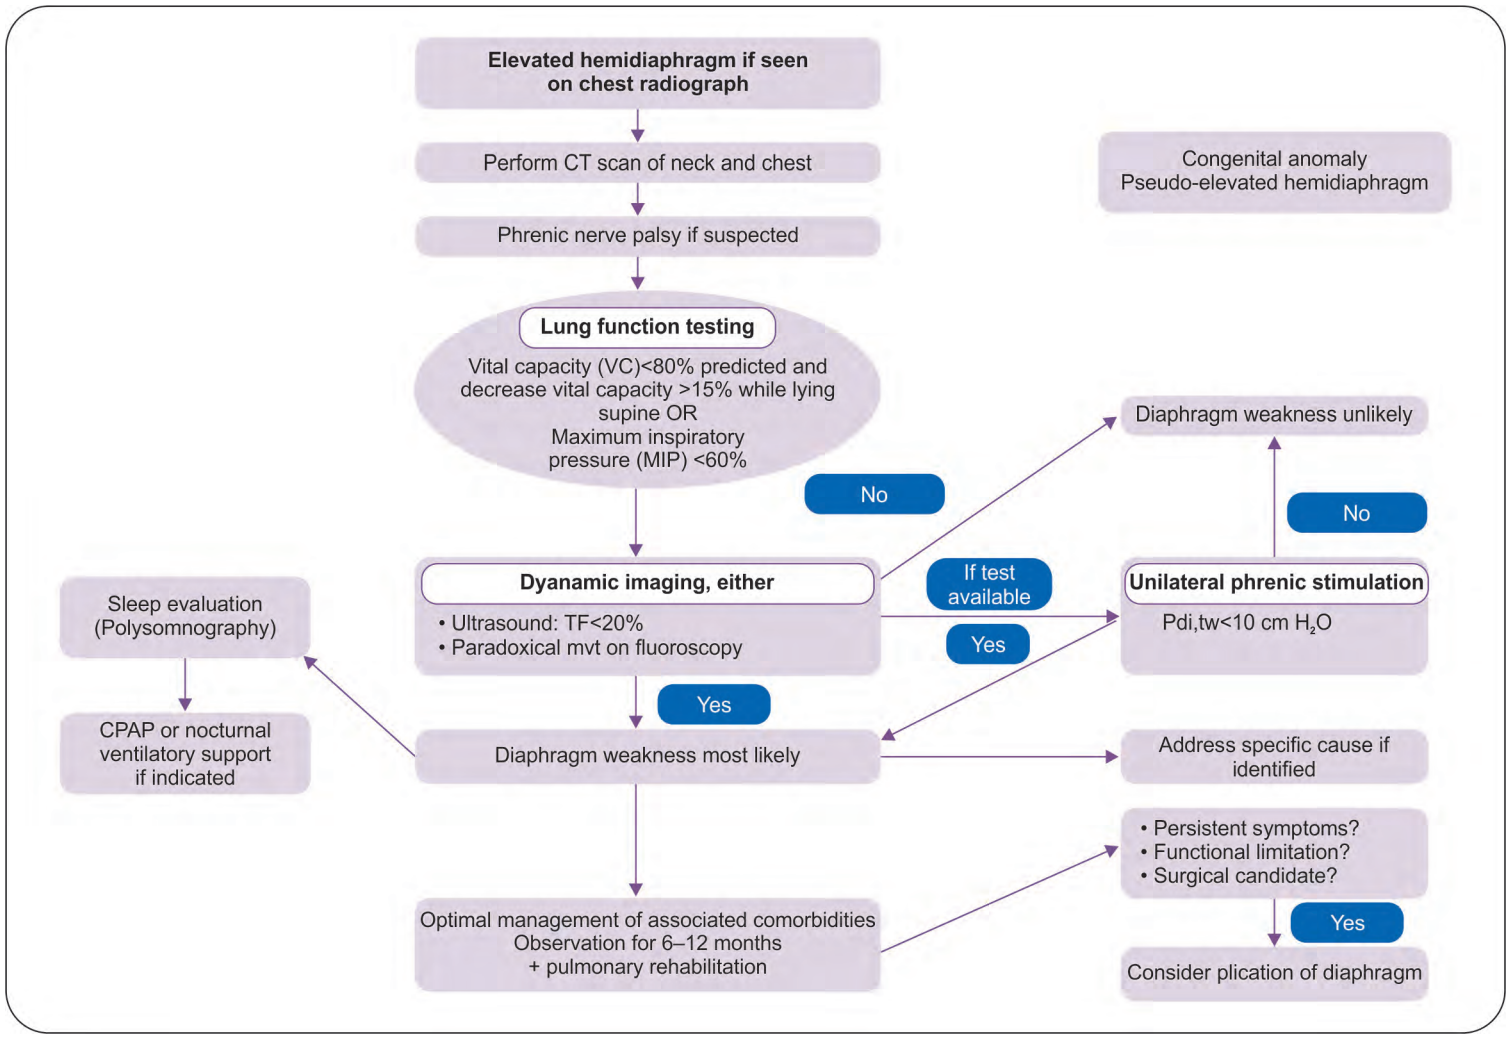
- *Arterial blood gas analysis:* Alteration of ABG is a late sign indicating severe functional impairment.
- *Computed tomography scan* of the abdomen, chest or both.
- *Magnetic resonance imaging (MRI)* to detect any pathology involving nerve roots or spinal column.

Therapeutic Management

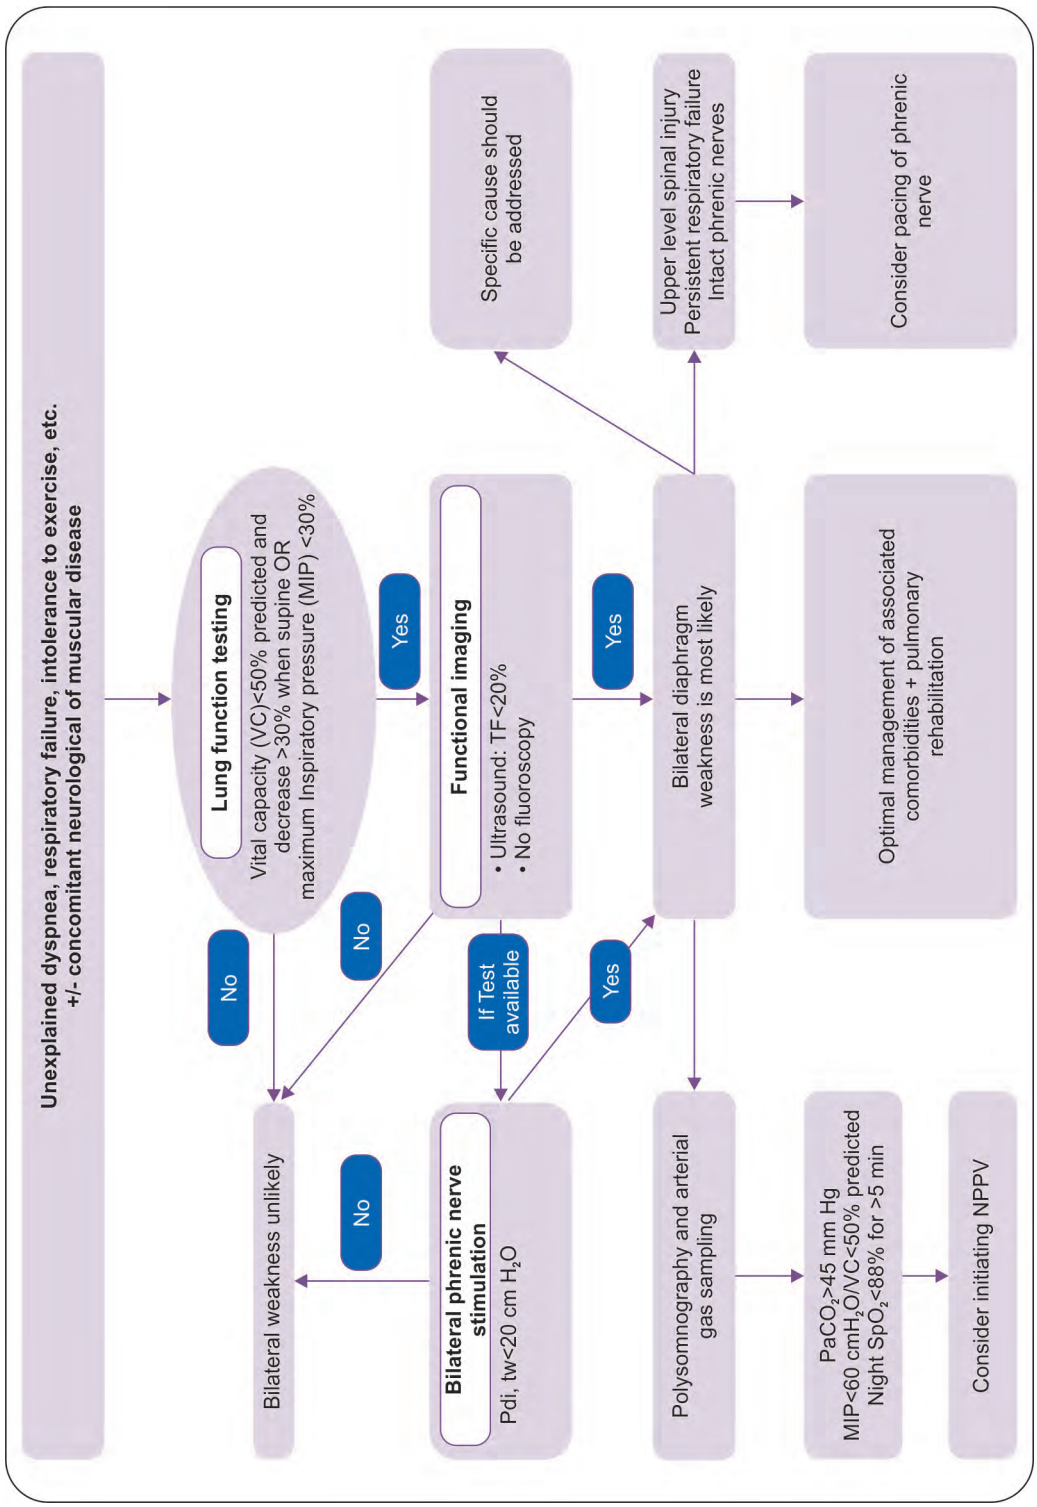
- Observation and supportive management
- Treatment of concurrent medical conditions
- Inspiratory muscle training (IMT)
- Noninvasive ventilatory support
- *Diaphragm pacemakers* can be used in case of functioning phrenic nerves such as patients with trauma to spinal cord or motor neuron disease
- Surgical procedure in the form of *diaphragmatic plication*
- *Tracheostomy* and *mechanical ventilation* in patients with a severe life threatening disease or in case of high cervical cord lesion causing quadriplegia

The comparison between unilateral and bilateral paralysis of diaphragm regarding the diagnosis and management has been described in **Table 3**. 'Diagnosis and therapeutic algorithm for unilateral and bilateral diaphragm weakness have been depicted in **Flowcharts 1 and 2**.

Flowchart 1: Diagnostic and therapeutic algorithm for unilateral diaphragm weakness



CPAP, continuous positive airway pressure; CT, computed tomography; MIP, maximal inspiratory pressure; PSG, polysomnography; TF, thickening fraction of the diaphragm; VC, vital capacity



Flowchart 2: Diagnostic and therapeutic algorithm for bilateral diaphragm weakness

MIP, maximal inspiratory pressure; NPPV, noninvasive positive pressure ventilation; TF, thickening fraction of the diaphragm; VC, vital capacity

Conclusion

Diaphragmatic weakness has been seen to be associated with poor clinical outcome in most instances. A detailed evaluation is often needed to find out the exact origin, to assess and plan to manage its impact on symptoms, exercise capacity, and sleep homeostasis. Diagnosis of bilateral or unilateral diaphragmatic dysfunction and management may be challenging for the physician as this is relatively rare, associated with subtle clinical features and difficulties faced in establishing the exact anatomical location and physiological alterations. Diaphragmatic dysfunction is often underdiagnosed but should never be neglected because it can be a very good prognostic indicator and this is often associated with a poor quality of life. Referral to a higher center with experience and expertise in this disease and access to phrenic nerve stimulation or pacing, diaphragm ultrasound and surgical expertise in diaphragm plication should be considered, where necessary.

CHAPTER

121 Approach to Chest Pain in Emergency

Partha Sarkar, Adrija Chatterjee

Abstract

Chest pain is one of the most common problems faced in the emergency room. The challenge is to develop a strategy to identify more serious pathology from non serious ones, found in majority of patients. Assessment of patient history, physical examination, 12 lead ECG, and cardiac biomarkers form the basis of assessment of chest pain. First and foremost serious life threatening causes of chest pain such as acute coronary syndrome, aortic dissection, pulmonary embolism, tension pneumothorax, and cardiac tamponade have to be ruled out. History of characteristics chest pain have to be taken as per the pneumonic SOCRATES (site, onset, character, radiation, aggravating and relieving factors and severity) helps to differentiate the different causes of chest pain, cardiac versus non cardiac. Subsequently, for acute coronary syndrome, a 12-lead ECG will help to differentiate STEMI from non STEMI. Further the cardiac biomarkers such as highly sensitive cardiac specific troponin will help to identify unstable angina from NSTEMI.

Introduction

Chest pain is one of most frequent causes of attending the emergency department. It is also one of the most difficult diagnostic challenges which presents in an emergency room.

The differential diagnosis of chest pain syndrome is broad and disparate including disease processes that range from non urgent to life threatening. Furthermore within the consideration of life threatening causes patients may be suffering from coronary causes as well as pulmonary embolism, aortic dissection, aortic rupture, pneumothorax or even esophageal rupture. There are many other diagnoses, which are much less critical but as widely as musculoskeletal pain, zoster, pleurisy, pneumonia, or gastroesophageal reflux.[1]

Goals

- Early diagnosis of acute coronary syndrome (ACS).
- Recognition of other life threatening causes.
- Minimize cost and hospitalization in patient with chest pain of benign etiology.

Diagnostic assessment and triage based on the following etiologies:

- Myocardial ischemia
- Other cardiopulmonary causes—pericardial diseases, aortic emergencies, pulmonary conditions
- Non-cardiopulmonary causes

Differential Diagnosis

- *Cardiac:* Myocaridal ischemia, pericarditis, aortic stenosis, hypertrophic obstructive cardiomyopathy (HOCM)
- *Vascular:* Acute aortic syndrome, pulmonary embolism, pulmonary hypertension
- *Pulmonary:* Pneumonia, pleuritis, pneumothorax
- *Gastrointestinal:* Esophageal reflux, esophageal spasm, esophageal rupture, peptic ulcer, gallbladder disease

- *Neuromuscular:* Costochondritis, cervical disc disease, trauma, Herpes zoster
- *Psychiatric conditions*

Rule Out Deadly Causes

ACS, pericarditis, acute aortic syndrome, pulmonary embolism, pneumothorax, esophageal rupture.

These are the serious causes of chest pain not to be missed.

How to Approach a Patient of Chest Pain?

History

Evaluating clinicians should assess the quality, location, pattern, provoking and alleviating factors, associated symptoms, past medical history.

Quality of Pain

Angina pain of myocardial ischemia is described as tightness, squeezing, or heaviness. Whereas pain of pericarditis is described as sharp stabbing in nature.

Pericarditis of an infectious etiology causes simultaneous involvement of the adjoining pleura so patients experience pleuritic chest pain characterized by a localized sharp lancinating pain, which aggravates on inhalation, coughing. Pain of infectious pericarditis felt in shoulders and neck as central diaphragm attains sensory supply from phrenic nerve. However, a more lateral diaphragmatic movement may lead upper abdominal pain.

Involvement of pleura as in pneumothorax may produce pleuritic chest pain similar to infectious pericarditis.

Massive pulmonary embolism can present as heaviness.

Acute aortic dissection leads to excruciating ripping pain or "tearing" pain.

Epigastric burning pain like sensation suggests acid reflux or peptic ulcer disease. Esophageal spasm can be severe squeezing identical to angina. Gallbladder disease produces a colicky pain.

Musculoskeletal disorders produce an aching pain whereas herpes zoster produces a sharp burning pain.

Localization of Pain

Myocardial ischemia typically produces retrosternal discomfort with radiation to neck, jaw, shoulders, or arms. Inferior wall AMI typically produces substernal or epigastric discomfort.

Chest pain of pericarditis can mimic AMI but can radiate to trapezius, which does not occur with angina.

Chest pain due to myocardial ischemia is poorly localized and diffuse while pleuritic chest pain is localized.

Ascending and descending aortic dissection differ in their location of pain with anterior aortic dissection producing midline anterior chest pain and descending aortic dissection producing back pain.

Gastrointestinal conditions usually produce abdominal or epigastric discomfort exception being esophageal pain, which is retrosternal in location.

Chest pain of Herpes zoster has dermatomal distribution.

Pattern

Chest pain of myocardial ischemia develops over minutes and is precipitated by activity and relieved by rest. Pain of stable angina lasts for 2–10 minutes and subsides on rest whereas pain of unstable angina persists even on rest. In case of myocardial infarction pain lasts for more than 30 minutes.

Chest pain in pericarditis is episodic in nature. Chest pain in aortic dissection, pneumothorax is of sudden onset.

Pain of constant intensity over a prolonged period of time is more likely to represent peptic ulcer disease than myocardial ischemia.

Aggravating and Relieving Factors

Pain of myocardial ischemia is usually relieved by rest. However, one should be aware of the phenomenon of "warm up angina" in which pain seems to get relieved by continuing at same or greater level of exertion.

Administration of nitroglycerin may relieve both myocardial ischemia pain as well as pain produced by esophageal spasm.

Pain of musculoskeletal etiology changes in intensity with positional change of upper extremities and neck.

Pain of pericarditis worsened by supine position and relieved by sitting upright and leaning forward.

Pain due to gastroesophageal reflux may be exacerbated by alcohol, some foods or reclining position.

Worsening of pain with food suggestive of peptic ulcer disease or cholecystitis, which may be relieved by acid reducing therapies. However, in setting of a

severe coronary atherosclerosis redistribution of blood flow to splanchnic vasculature after eating can trigger postprandial angina.

Associated Symptoms

Symptoms associated with myocardial ischemia may include sweating, dyspnea, nausea, vomiting, and faintness.

Pulmonary embolism and pneumothorax should be considered in the background of sudden onset respiratory distress.

Hemoptysis usually points toward pneumonia. Blood tinged frothy sputum can be found in heart failure.

Syncope should prompt consideration of hemodynamically unstable conditions in pulmonary embolism and aortic dissection.

Although nausea and vomiting suggest a gastrointestinal disorder, these symptoms may occur in the setting of myocardial infarction, especially inferior wall AMI because of activation of vagal reflex.

Oesophageal rupture usually associated with forceful vomiting.

Past Medical History

Assess for risk factors of coronary atherosclerosis and venous thromboembolism.

History of connective tissue disorder such as Marfan's syndrome should increase the suspicion of acute aortic syndrome or spontaneous pneumothorax.

Physical Examination

General

Patients with AMI often appear anxious, pale, cyanotic, or diaphoretic.

Patients with AMI may describe their pain by clenched fist against sternum termed as "levine's sign."

Often body habitus is helpful. Like patients with Marfan's syndrome have young tall thin built.

Vital Signs

Tachycardia and hypotension are suggestive of hemodynamic instability should prompt a rapid survey for AMI, massive pulmonary embolism, pericarditis with tamponade, tension pneumothorax, acute aortic dissection.

Tachypnea and tachycardia with hypoxemia point toward a pulmonary cause.

Cardiac

Search for characteristic pattern of JVP in cardiac tamponade or right ventricular dysfunction.

S4 in case of myocardial ischemia and S3 in case of infarction can be found.

Murmur of mitral regurgitation is found in case of complications of AMI. Murmur of aortic dissection indicates complications of aortic dissection.

Pericardial friction rub suggests pericarditis.

Pulmonary

Decreased breath sound, hyper-resonant percussion note in case of pneumothorax or localized crepitation in pneumonia.

Esophageal rupture or "Boerhaave syndrome" is associated with subcutaneous emphysema and on being auscultated crackling sound is heard (Hamman's crunch).

Abdominal

Localized tenderness can be found in gastrointestinal conditions such as gallbladder stone or pancreatitis.

Abdominal findings such as hepatic congestion can be found in right ventricular dysfunction.

Musculoskeletal

Localized swelling, tenderness are useful clinical sign for costochondritis (Tietze's syndrome). Vesicular rash is found in the area of discomfort suggests Herpes zoster.

Battery of Tests

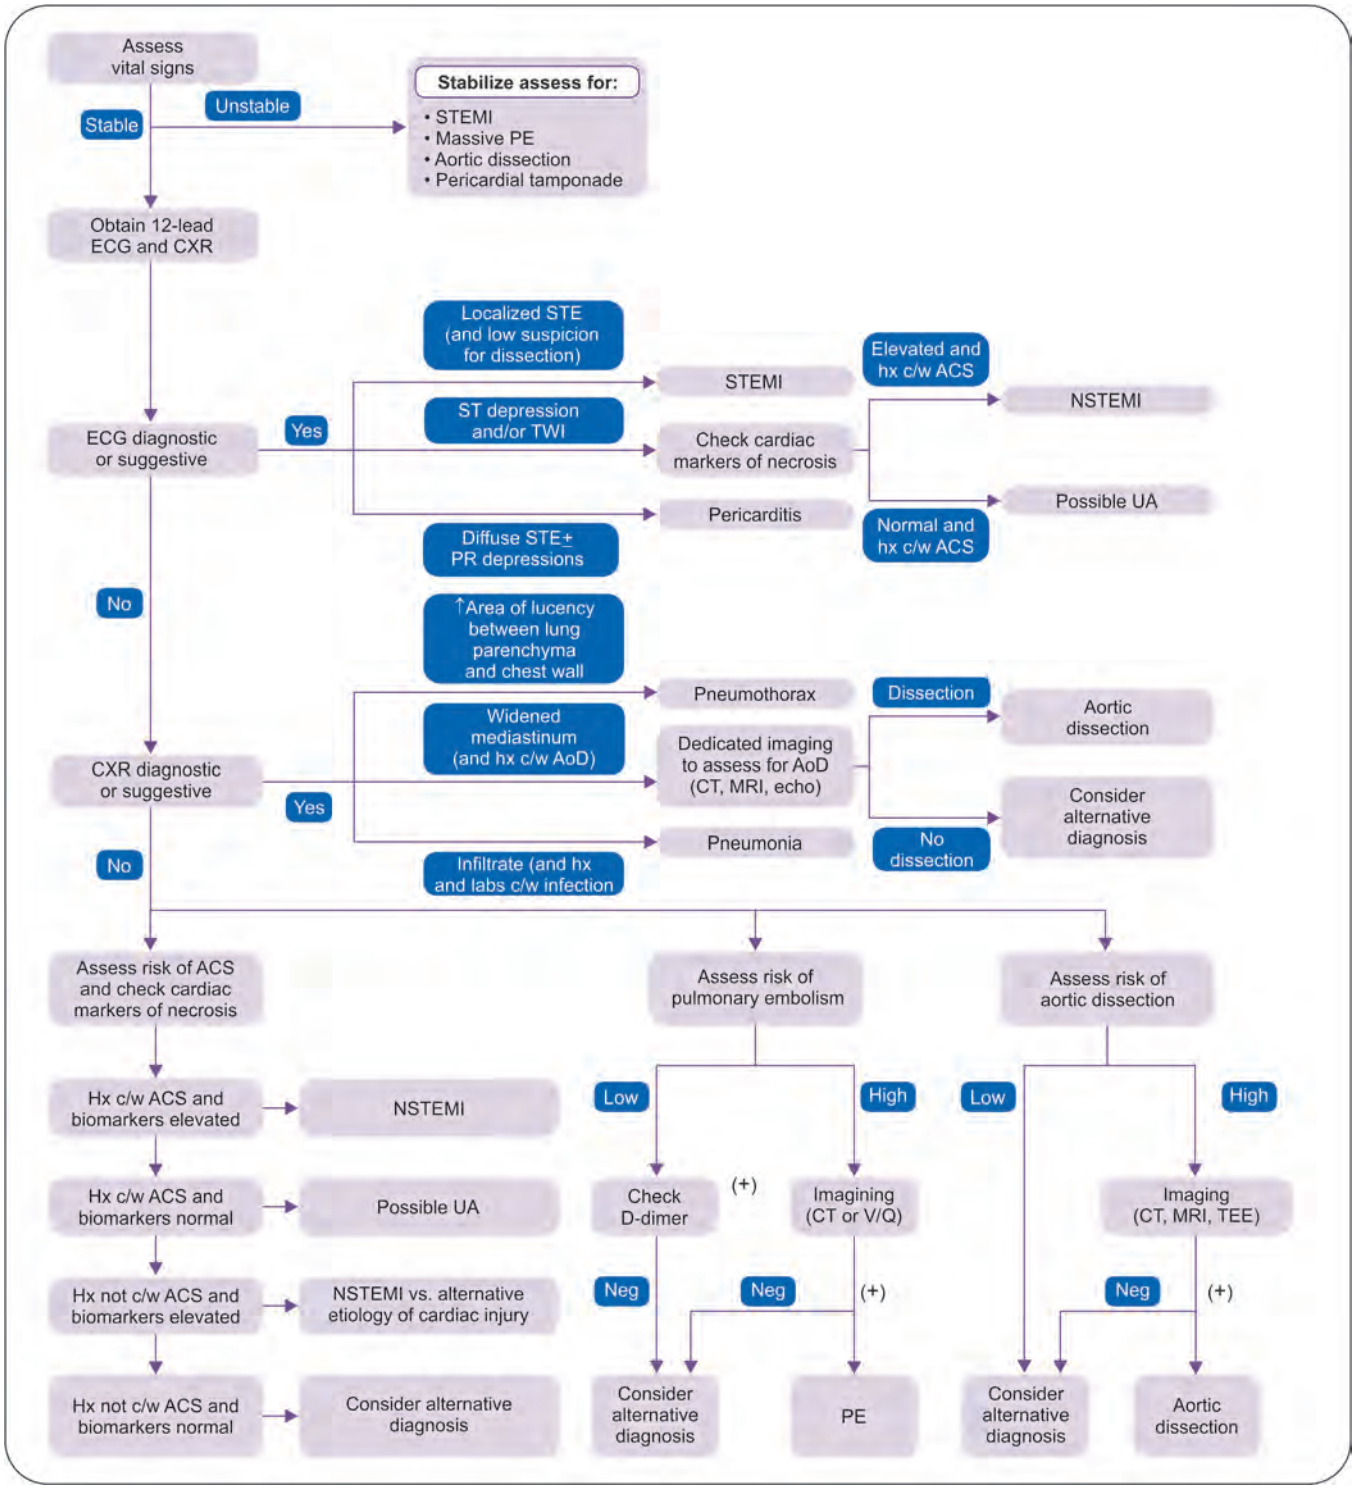
ECG

ECG is essential for identification of patients with ongoing ischemia as well as secondary cardiac complications of other disorders. ST segment elevation, ST segment depression, and symmetric T wave inversions are useful for detecting myocardial ischemia.[2] Serial evaluation of ECG every 30–60 minutes is recommended in emergency for evaluation of suspected ACS.[3]

Hyperventilation associated with panic disorder can also lead to nonspecific ST and T wave abnormalities.

Pulmonary embolism produces rightward shift of ECG axis manifesting as S wave in lead I, Q wave, and T wave in

Flowchart 1: How to approach a case of chest pain



ACS, acute coronary syndrome; STEMI, ST-elevation myocardial infarction; UA, unstable angina: CXR, chest X-ray; CT, computed tomgraphy, UA, unstable angina; ECG, electrocardiographic; TEE, transesophageal echocardiography; AoD, aortic dissection; c/w, consistent; hx, history; NSTEMI, non–ST-segment myocardial infraction; PE, pulmonary embolism; MRI, magnetic resonance imaging; V/Q, ventilation-perfusion; STE, stimulated echo.

lead III (S1Q3T3 pattern of acute cor pulmonale is classic, termed as McGinn-White sign).

ST elevation with diffuse lead involvement and PR segment depression distinguishes pericarditis from AMI.

CXR

CXR is most useful for detection of lung causes such as pneumonia, pneumothorax.

CXR findings commonly associated with pulmonary embolism include Hampton's hump or Westermark sign or Palla's sign.

CXR showing subcutaneous emphysema suggests "Boerhaave syndrome."

Cardiac Biomarkers

Circulatory proteins released from damaged myocardial cells are indicative of myocardial injury. Initially biomarkers may be normal even in patients with STEMI.

Cardiac troponin [cardiac specific troponin T (cTnT)] and cardiac specific troponin I (cTnI) are preferred biomarkers over creatine kinase MB and should be repeated in 3–6 hours in suspected ACS patients.

Serial changes in cardiac troponin are useful in discriminating acute causes of myocardial injury from chronic elevation due to underlying structural heart disease or end stage renal disease.[4]

Assessment of D-dimer test to aid in exclusion of pulmonary embolism.

Both B-type natriuretic peptide (BNP) and N terminal pro BNP (NT-probnp) is useful in diagnosis of heart failure.

Echocardiography

Patients with mechanical complications of MI or pericardial tamponade diagnosed easily with echocardiography.

Transesophageal echo is more sensitive of aortic dissection than transthoracic echo.

Provocative Tests

Exercise electrocardiography ("stress testing") is used for patients with low to intermediate risk of ACS who have not revealed a specific cause of chest discomfort on initial evaluation.[5]

Patients with ongoing chest pain should not be subjected to these stress tests.

Recent Advances

CT angiography has emerged as a sensitive technique for detection of obstructive coronary disease particularly in proximal third of major epicardial coronary arteries.[6]

CECT is useful for detection focal areas of myocardial injury.[3]

CT angiography can be used for exclusion of aortic dissection, pericardial effusion, and pulmonary embolism.

Cardiac MRI is an emerging technique for structural and functional evaluation of heart. Gadolinium enhanced MRI can provide early detection of MI and can define areas of myocardial necrosis accurately.

Early myocardial perfusion imaging can be performed for evaluating patients with low or intermediate risk of ACS.[7]

Flowchart 1 depicts the approach towards chest pain in the emergency room.

Don't Forget the Rare One

Takotsubo cardiomyopathy characterized by abrupt onset chest pain and shortness of breath, triggered by an emotionally stressful event. It mimics AMI because it is associated with ECG abnormalities and elevated cardiac biomarkers. But surprisingly coronary angiography is normal. It has predilection for women above 50 years.

Conclusion

Chest pain is one of the most common causes for admission to emergency departments. Emergency clinicians have a difficult task identifying, which patients to admit and which patients to discharge home.

Evaluation of acute chest pain in emergency is time consuming and expensive and often results in uncertain diagnosis.

A very small percentage of evaluated patients are eventually diagnosed with ACS. Most common diagnoses are gastrointestinal causes. Few of patients with chest discomfort discharged on the presumption of non-ischemic etiology from emergency are later deemed to have had a missed myocardial infarction.

So, rapid and precise identification, triage, and treatment of high-risk cardiopulmonary conditions are necessary, while low-risk patients can be safely observed with less intensive monitoring.

CHAPTER

122 Approach to a Case of Anemia

Manoj Kumar Srivastava

Abstract

Anemia is the most common symptom present in most of the clinics of tropical country and it is usually a common symptom in females and during pregnancy! Anemia, which is a symptom and not a disease, is defined as a decrease in the circulating red blood cell mass to below age specific and gender specific limit. Evaluation for anemia is one of the most common clinical problems seen in the present hospital settings. The evaluation of anemia may be straightforward in an otherwise healthy individual with a single cause of anemia, but in many cases the cause is not readily apparent and multiple conditions may be contributing. The first step in diagnosis of anemia is detection with reliable and accurate tests, so that the important clue to underlying causes are not overlooked and patients are not subjected to unwanted laboratory tests.

Introduction

Anemia, which is a symptom and not a disease, is defined as a decrease in the circulating red blood cell mass to below age specific and gender specific limit. lt is difficult to directly measure RBC mass, so the hematocrit or the hemoglobin level in the blood are usually used instead to indirectly estimate the value.[1,2]

Evaluation for anemia is one of the most common clinical problems seen in the present hospital settings. The evaluation of anemia may be straightforward in an otherwise healthy individual with a single cause of anemia, but in many cases th cause is not readily apparent and multiple conditions may be contributing.

ln clinical practice, the use of proper standard method of history taking and clinical examination supported by laboratory investigations still form the best approach.[3] There are many ways to classify anemia, but none of them is perfect. The approach to find the cause of anemia differs for different groups depending on sex, age, and race. lt is important to reach the exact diagnosis of anemia to give the proper treatment. The common traditional ways to classify the anemia depend on

- Red cell morphology and indices
- Pathogenesis
- Clinical presentation of anemia[4,5]

Classification Based on RBC Morphology and Indices

The classification of anemia based on the red cell predominantly depends on the mean corpuscular volume (MCV) of RBCs. On the basis of MCV the anemia is classified as:

- Microcytic hypochromic anemia (MCV: <80 fL)
- Normocytic normochromic anemia (MCV: 80–100 fL)
- Macrocytic anemia (MCV: >100 fL)

Classification Based on the Clinical Presentation

- Acute: Due to hemolysis or bleeding
- Chronic Anemia: Due to various chronic diseases or due to bone marrow suppression

Flowchart 1 shows different types of anemia.

Classification Based on Pathogenesis of Anemia

- **Inadequate production:** These disorders may be due to:
  - Nutritional deficiency (vitamin B 12/folic acid deficiency, iron deficiency)
  - Stem cell disorders
  - Bone marrow infiltration
  - Defective bone marrow function of ineffective erythropoisis
- Excessive destruction of RBS (hemolysis)
- Bleeding—acute or chronic

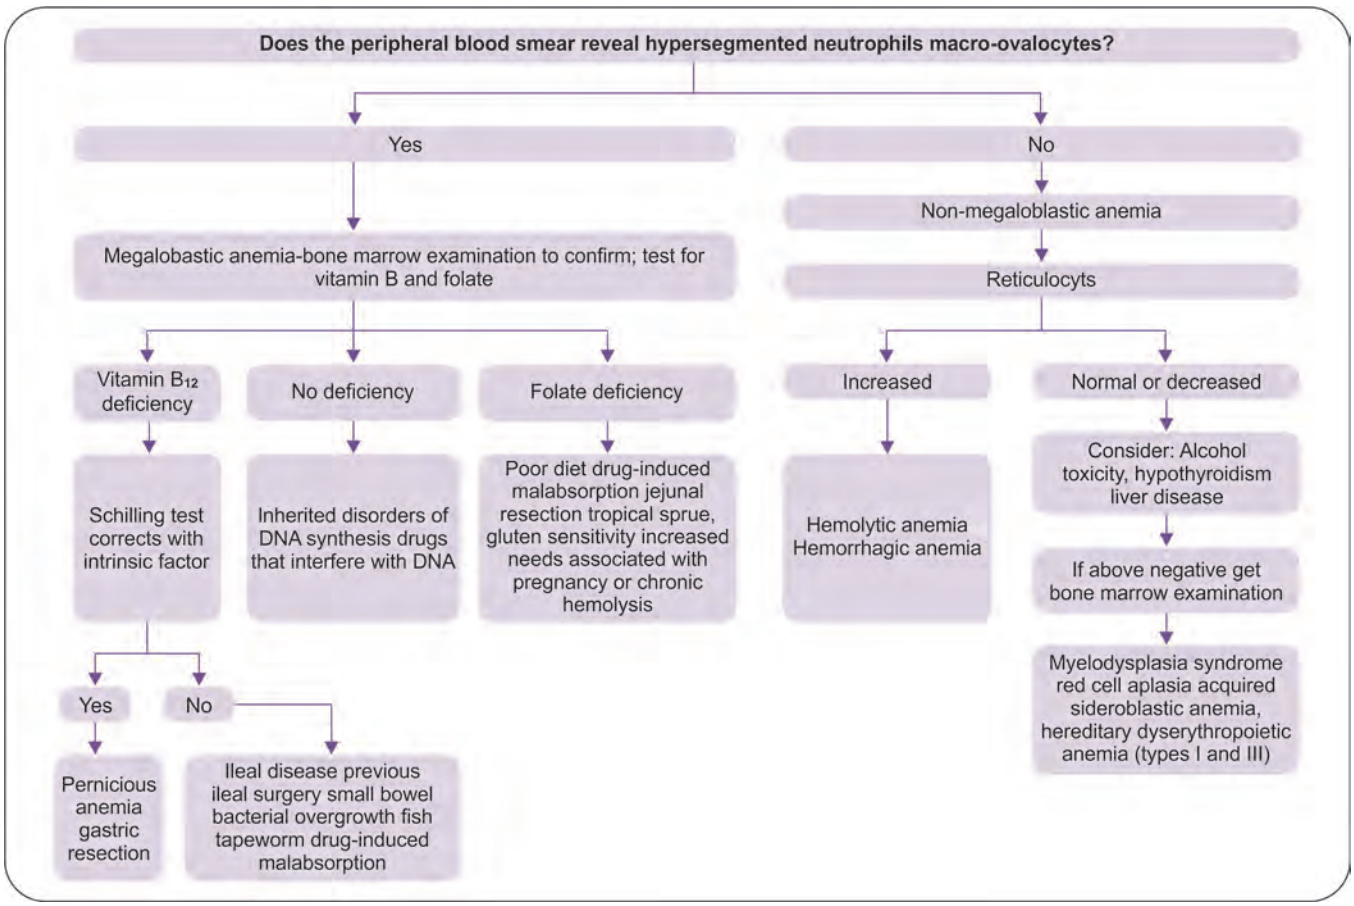
Microcytic Anemia (MCV <80 fL)

Microcytic anemia is defined as the presence of small, often hypochromic, red blood cell in a general blood picture as depicted in **Figure 1** (GBP and is characterized by a low MCV (<80 fL) **(Flowchart 2)**. Iron deficiency anemia is the most common cause of microcytosis. Overall, 50% of anemia is attributable to iron deficiency and accounts for approximately 8,41,000 deaths annually worldwide.[6,7]

Other causes of microcytic anemia are—

- Anemia of chronic disease
- Thalassemia
- Lead poisoning
- Sideroblastic anemia

Flowchart 1: Lab diagnosis cell morphology and type of anemia



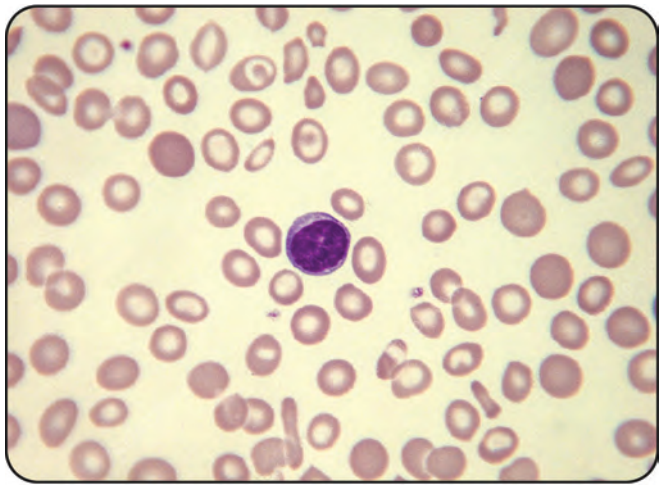


Fig. 1: Microcytic hypochromic anemia

Flowchart 2: Lab diagnosis cell morphology and bloodsmear

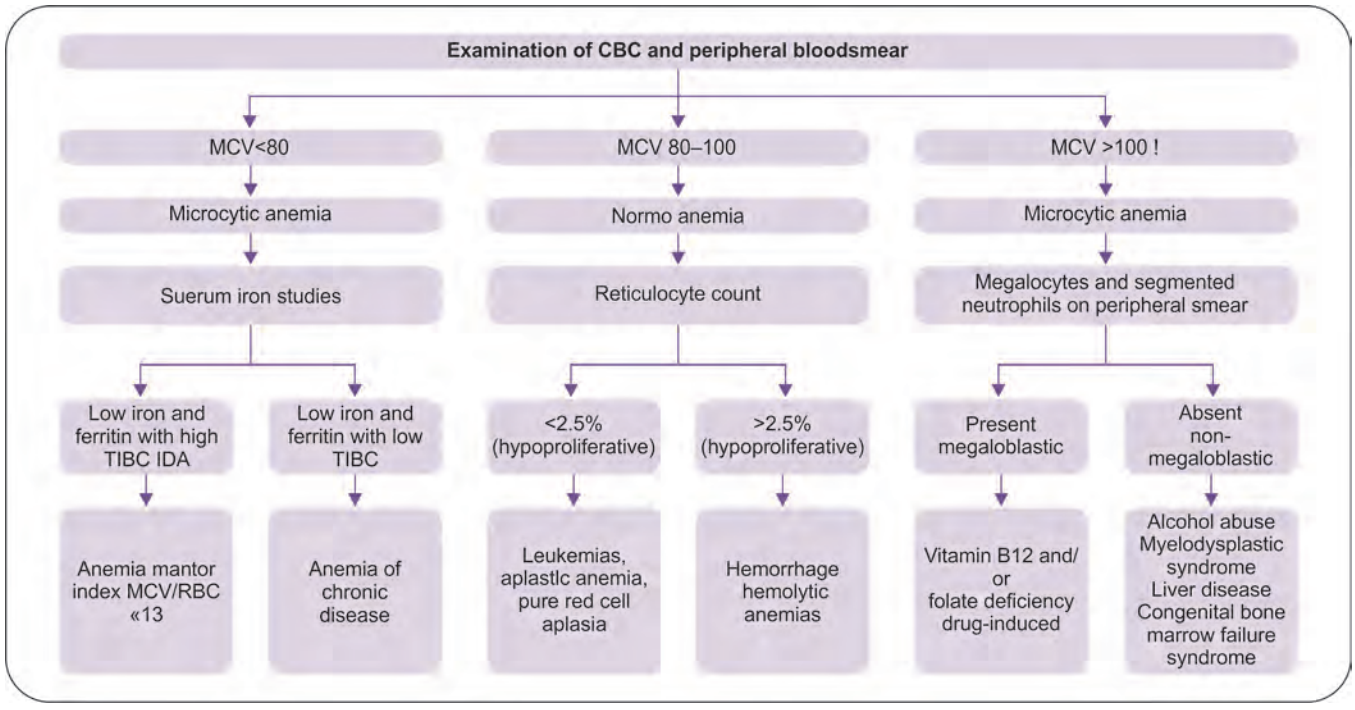

Table 1 and **Flowchart 3** show the different parameters to differentiate the discussed causes of microcytic anemia.

For megaloblastic macrocytic anemia refer **Figure 2**.

Non-megaloblastic Macrocytic Anemia

Causes of non-megaloblastic anemia are not related to defective DNA synthesis and it is characterized by the absence of megaloblasts and instead, the presence of large but mature red blood cells.

Causes of non megaloblastic macrocytosis includes—

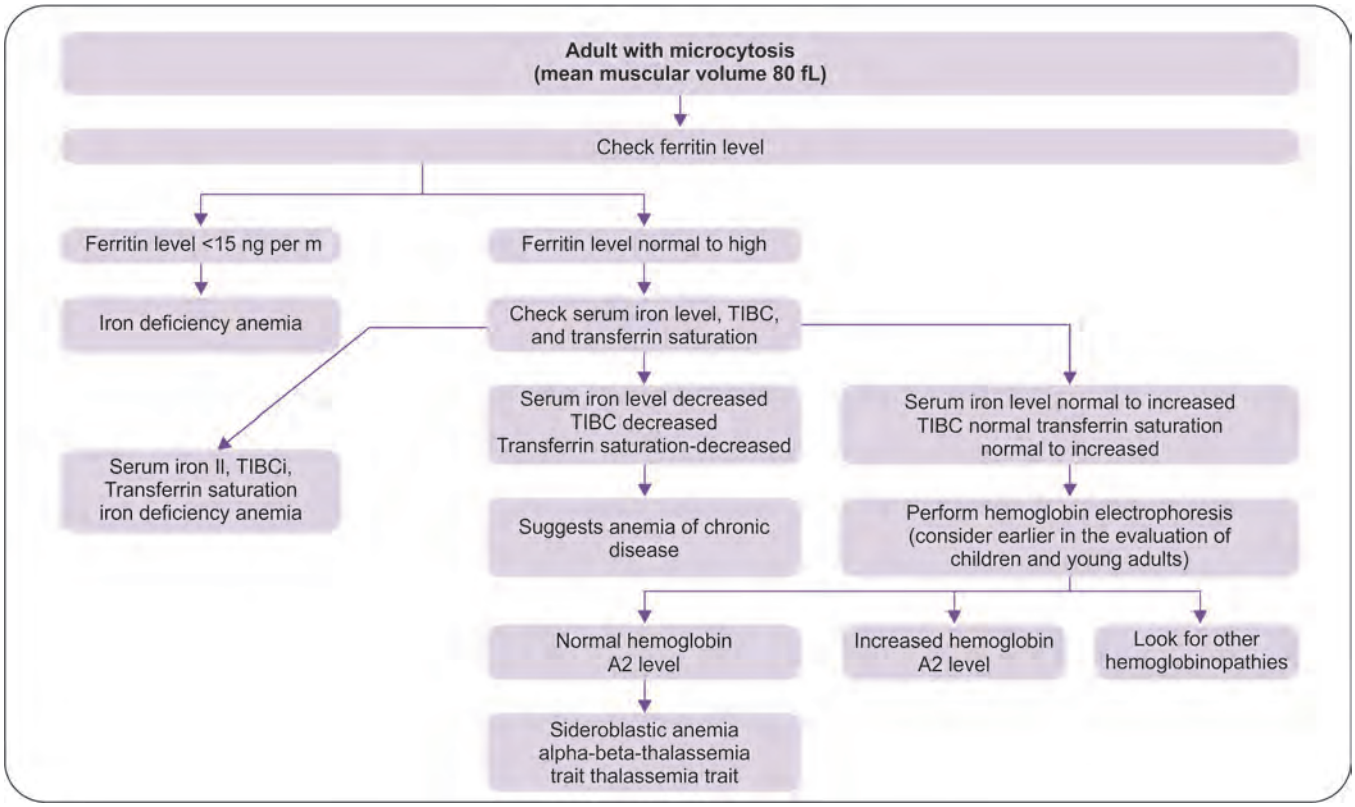
- Chronic alcoholism
- Liver disease
- Hypothyroidism
- Renal diseases

TABLE 1 Classification based on RBC morphology and indices

Parameters	*IDA*	*BT*	*Lead poisening*	*SA*	*CI*
Hgb	↓	N (or ↓)	N (or ↓)	—	↓
Se Ferritin	↓	N	N	N (or ↑)	N (or ↑)
Serum iron	↓	N	N	N (or ↑)	↓
FEP	↑	N	↑	—	↑
MCV	↓	↓	N or ↓	N	↓
RDW	↑	N	N	—	N
Reticulocyte	↓	—	—	—	N or ↓
MCV: RBC (mentzer index)	↑	↓	—	—	—
Lead	—	—	↑	—	—

BT, beta thalassemia; CI, chronic inflammation or infection; IDA, iron deficiency anemia; N, normal; SA, sideroblastic anemia

Flowchart 3: Lab diagnosis and cell morphology



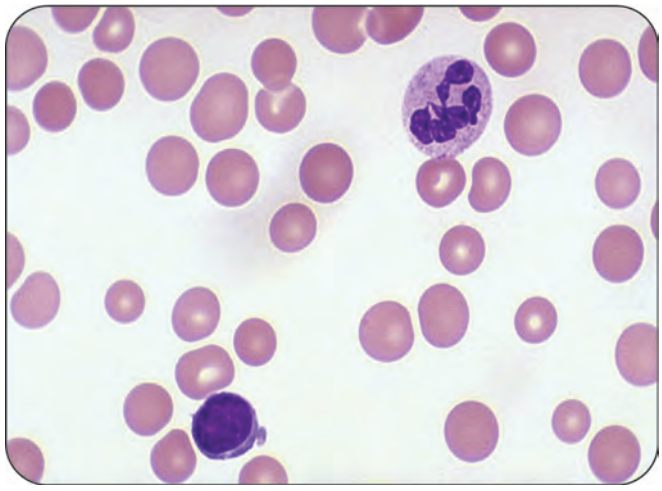


Fig. 2: Hypersegmented neutrophils and macroovulocytes (megaloblastic anemia)

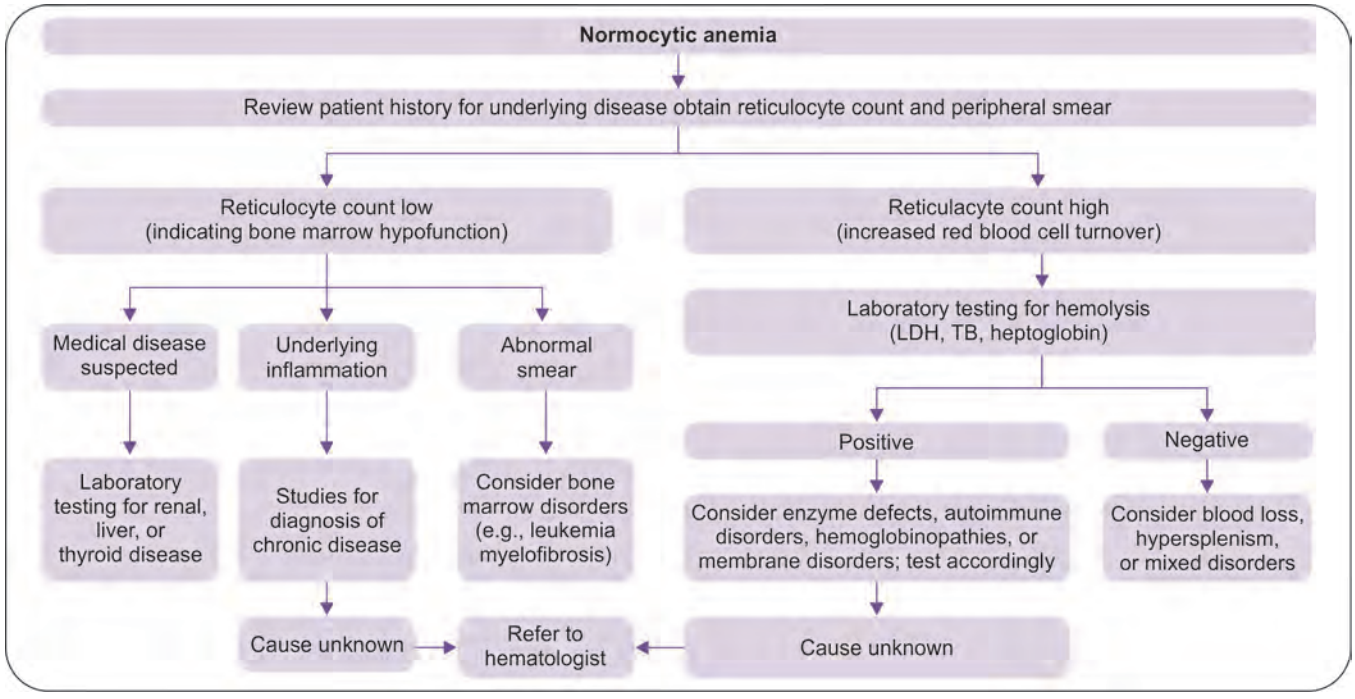
Flowchart 4: Lab diagnosis cell morphology and peripheral smear



- Reticulocytosis
- Blood disorders like red-cell aplasia, aplastic anemia myelodysplastic syndromes, and myeloid leukemia, PNH
- Drugs such as azathioprine
- Pregnancy

Normocytic Anemia (MCV 80–100 fL)

A mild normochromic, normocytic anemia is a frequent finding and mostly due to a consequence of other diseases, including:

- anemia of chronic disorders associated with chronic infection, malignant disease, all forms of inflammatory

diseases. The exact mechanism is unknown, but likely to involve multiple factors, which leads to a reduction in the serum iron concentration along with concurrent reduction in the level of transferring. That's why saturation of the iron binding capacity is usually normal or only slightly reduced.

- Other disorders including renal failure, hypothyroidism, marrow failure (aplastic anemia, pure red-cell aplasia, infiltration), acute blood loss **(Flowchart 4)**.[8,9]

Conclusion

A good clinician diagnoses the type of anemia but a excellent clinician always tries to search out the cause of the disorder. So, to manage a patient of anemia, every effort should be given in searching the etiology of anemia. The first step in diagnosis of anemia is detection with reliable and accurate tests, so that the important clue to underlying causes are not overlooked and patients are not subjected to unwanted laboratory tests.

CHAPTER

123 Approach to Aphasia

Jyotirmoy Pal, Tarun Kumar Paria, Purbasha Biswas, Manisankar Bhattarcharya

Abstract

Aphasia refers to a disorder of language processing caused by a dysfunction in specific regions of the brain. It is common after stroke and associated with relevant disability and higher mortality. Evaluation of language function (spontaneous speech, auditory comprehension, naming, repetition, reading, and writing) allows classification of aphasia. Most patients present some degree of recovery. Speech and language therapy is an effective treatment for aphasia following stroke. Other approaches, e.g., pharmacotherapy, transcranial magnetic stimulation, are being investigated.

Introduction

While assessing a patient in a neurological ward or outpatient department, one has to frequently come across cases with communication disorders. It is important to distinguish among different types of communication problems which may range from language disorder to speech production at different levels.

Broadly, communication disorders are divided into two basic groups:

- Speech defect: consisting of Dysarthia and Dysphonia
- Language dysfunction: consisting of Dysphasia/Aphasia

The fundamental difference between a speech defect and aphasia remains as follows: if one transcribes the patient's verbal expression into writing, it will read as combination of normal and grammatically correct sentences in speech defect which is not the case for aphasic participants. Thus, a language defect can simply be considered a more fundamental disturbance in communication machinery, which hinders appropriate expression of thoughts by any means, whereas in speech disorders thoughts can be properly expressed by the agency of nonverbal ways of communication, for instance writing **(Fig. 1)**.

- *Dysarthia:* It is a disorder of the motor production or articulation of speech mainly of neurologic origin.
- *Dysphonia:* It is a term that describes voice disorders, for example, involuntary tightening or constriction of vocal cords causing interruptions of speech and voice quality.
- *Aphasia/Dysphasia:* It is an acquired disorder with loss or defective language content of speech resulting from damage to speech centers of dominant hemisphere (usually left in 97%).

Language has two parts:

- Expression
- Understanding

Expression

Expression has got three components:

- Emotional component: This component of expression does not require any learning and is an expression of inner suppressed emotions

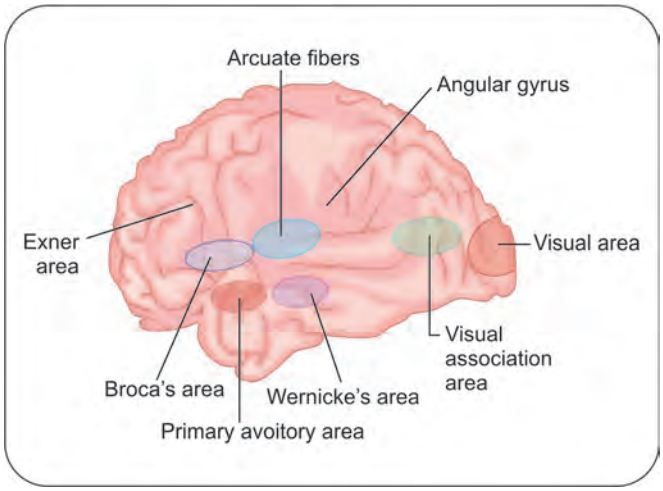

Fig. 1: Language areas of brain

- Automatic component: This component of expression occurs automatically and is generally acquired through learning
- Proposition: This is the actual speech component

Understanding

This occurs through a series of steps **(Flowchart 1)**.

Examination

Examination of speech consists of testing of the following components:

- Spontaneous speech
- Comprehension (auditory)
- Naming
- Repetition
- Writing
- Reading

Spontaneous Speech

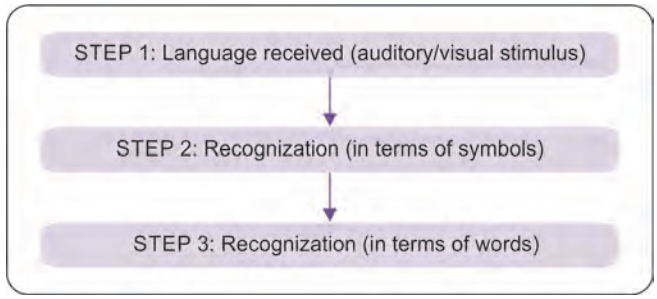
Generally motor speech defect (damage of Broca's area) manifests as loss of spontaneous speech.

- Types:
  - Complete loss : Mutism (no speech)
  - Incomplete Broca's area damage: This manifests in four forms **(Flowchart 2)**:
- *MONOPHASIA: Repetition of the same word*
- PARAPHASIA: Single letter of a word or the entire word is substituted with similar sounding words

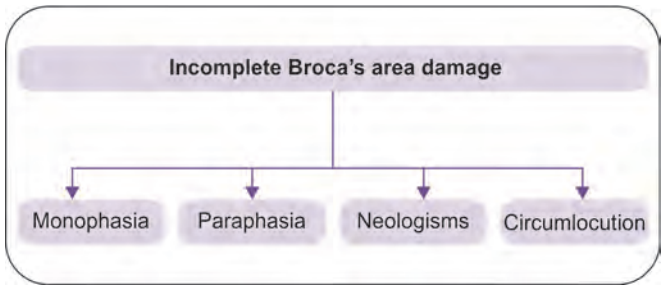
  Example 1: "Tarun" → "Arun" : single letter substitution
  Example 2: "Harry" is a bad boy. → "Tom" is a bad boy : entire word substitution
- NEOLOGISMS: New words without any meaning
- CIRCUMLOCUTION: The patient can name an object but uses different descriptions to describe a particular object

  Example: A cell phone when put infront of the patient, he can't name the object but says "this is an object used to call someone"

Flowchart 1: Pathway of understanding



Flowchart 2: Effects of incomplete Broca's area damage



Tests for Spontaneous Speech

- Fluency: Normal fluency is 100–150 words per minute or more than 7 words in a sentence, while non fluency refers to less than 10–15 words per minute
- Pronunciation
- Capability of words/sentence formation
- Speech disorder like paraphasia

Comprehension

The patient's responses to verbal requests and commands and to everyday questions and comments give information about his ability to understand speech.

Comprehension may be tested by having the patient follow verbal commands ("show me your teeth", "stick out your tongue"). Comprehension can be judged to be reasonably intact if the patient follows a complicated multistep command. However, failure to follow a command does not necessarily prove that comprehension is impaired. A patient may not comply because of apraxia. Patients with left hemisphere lesion may even have apraxia for functions of their nonparietic left hand. When the patient doesnot follow simple commands, establish whether he can say or shake his head yes or no.

Naming

Some caution is necessary while testing for naming, as there are influences of age, culture, and education.

Naming is the function of parietal lobe.

Test for Naming

While testing naming, always use common object. Naming is said to be intact when patient is given several objects to identify and can name 12 items in 1 minute.

If the patient says less than 12 items, there are three possibilities:

- Can't say name
- Can recognize the item, but can't say the function
- Can say only 4 out of 12 items

Repetition

Repetition is the function of lower parietal lobe (arcuate fibers). The ability to repeat may be selectively involved or paradoxically preserved in certain aphasic syndromes. A patient's repetition span (i.e., the number of words he can repeat) is usually two more than his digit span.

Types of repetition disorders include:

- Can't repeat
- Can repeat only a part
- Can substitute with a new syllable or word

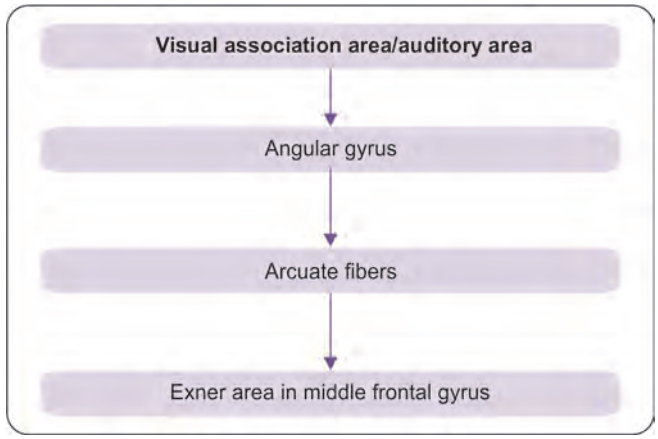
Repetition is preserved in anomic, transcortical, and some cases of subcortical aphasia.

Writing

Pathway of Writing

The patient's ability to use written language should also be assessed. It may be disturbed in conjunction with abnormalities of spoken language, or separately. Patients who are aphasic in speech are also aphasic in writing, but writing may be preserved in patients with dysarthria or verbal apraxia. The ability to write to dictation is analogous to the ability to repeat verbal material. Copying written material also assesses the ability to transfer information from visual system to language area. Having the patient copy written material may also test the connections between the receptive language areas and Exner's writing center **(Flowchart 3)**.

Flowchart 3: Pathway of writing



Reading

The patient's ability to comprehend written language symbols can be tested by having him read. Written language is perceived by the visual system and the information is conveyed to the perisylvian language centers. Dysfunctions of the language centers or interruption of the connections with visual system may cause inability to read (alexia).

Pathway of Reading

Visual association area → Angular gyrus

Alexia (Fig. 2)

- Alexia with lesion in Wernicke's area: Reading and understanding impaired, can't write dictation.
- Alexia without lesion in Wernicke's area: Reading impaired but auditory understanding preserved. This is called PURE WORD BLINDNESS.

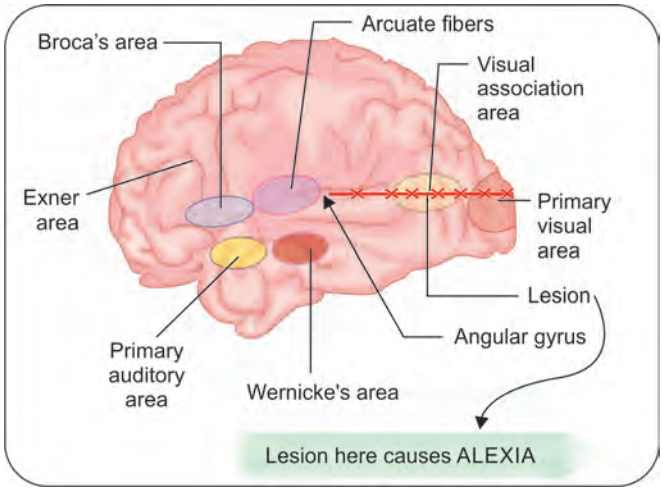


Fig. 2: Pathway of pathology of alexia

Types of Aphasia

- *Sylvian aphasia:* repetition will be lost
  - Broca's aphasia
  - Wernicke's aphasia
  - Conduction aphasia
  - Global aphasia
- *Perisylvian aphasia:* repetition is preserved
  - Anomic aphasia
  - Transcortical aphasia
  - Subcortical aphasia
  - Mixed aphasia

Sylvian Aphasia (Table 1)

Broca's Aphasia

- Fluency lost, patient will be frustrated but aware
- Communicate with small sentences with few words and with gestures
- Reading will be lost
- Writing preserved
- If there is combined damage of Broca's area and Exner's area, then both reading and writing will be lost
- *Associated* with corticospinal tract sign (Faciobrachial)

Wernicke's Aphasia

- Lesion involves:
  - Angular gyrus
  - Supramarginal gyrus
  - Wernicke's area
- Characteristics:

TABLE 1 Motor and sensory areas of brain and their connection

Wernicke's area (area 22)	*Arcuate fasciculus*	*Broca's area (area 44)*
Decoding of sounds into language information (Comprehension)	Communication between the Broca's and Wernicke's area. Needed for speech repetition	Responsible for spontaneous speech output, i.e., fluency

  - Damage to Auditory Association Area—**WORD DEAFNESS**
  - Damage to Angular Gyrus—**WORD BLINDNESS**
  - Fluency preserved
  - No appropriate response to any command (increased spoken words—**HYPERLABIA**)
  - Repetition lost

Conduction Aphasia

- Lesion involves the Arcuate fibers
- Characteristics:
  - Repetition lost
  - Fluency preserved
  - Comprehension is unaffected
  - Reading is lost
  - Writing is lost

Global Aphasia

- Features of above three aphasias
- *Associated* with hemianopia, hemisensory loss, hemiparesis

Perisylvian Aphasia

Anomic Aphasia

- Naming difficulty
- All other modalities preserved
- *Circumlocution* will be present

Subcortical Aphasia

- Repetition preserved
- Lesion involves:
  - *Caudate nucleus:* Features of Broca's aphasia with preserved repetition
  - *Thalamus:* Features like Wernicke's aphasia with preserved repetition

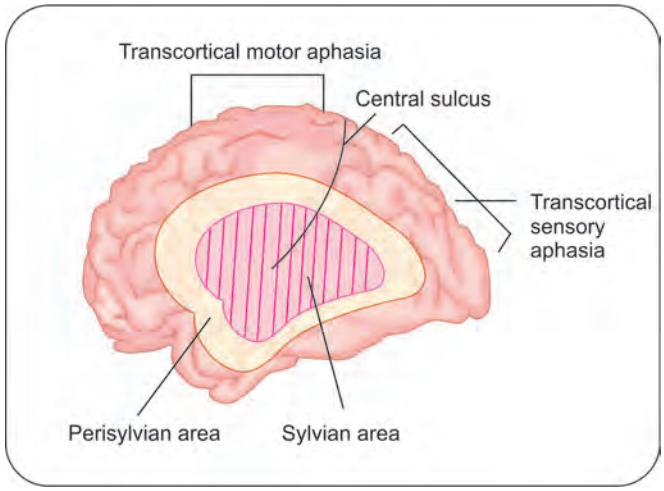

Fig. 3: Areas of transcortical aphasia

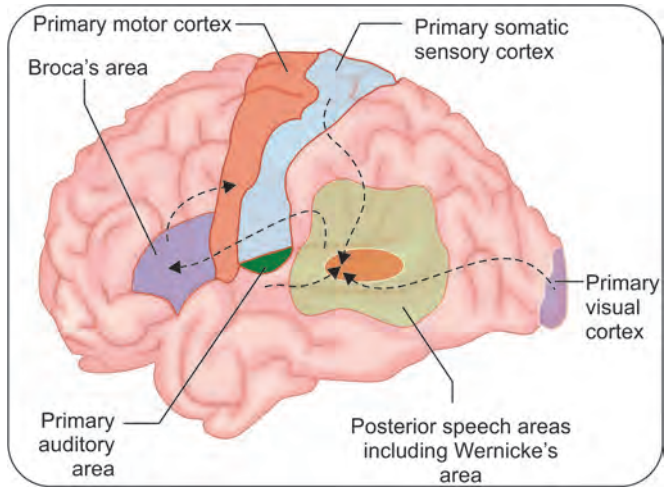

Fig. 4: Language areas of the brain

Transcortical Aphasia

This is of two types **(Fig. 3)**:

- **Transcortical sensory aphasia**:
  - Features like that of Wernicke's aphasia with preserved repetition
  - Lesion involves the area posterior to central sulcus
- **Transcortical motor aphasia:**
  - Features like that of Broca's aphasia
  - Lesion involves the area anterior to the central sulcus

Anatomy of Speech Areas

The classical model proposed by Wernicke consists of the following parts **(Fig. 4)**:

- Primary auditory area
- Secondary auditory area
- Wernicke's area (Sensory speech area)
- Broca's area (Motor speech area)
- Arcuate fasciculus
- Primary visual cortex
- Primary somatic sensory cortex
- Primary motor cortex
- Angular gyrus
- Exner's area

However, this classical model has been expanded and modified by recent reviews and are now part of *Dual Stream Model of Hickok and Poeppel.* Some of its components include:

- *Spoken speech processing:* Heschl's gyrus (bilateral superior temporal gyrus)
- *Decoding of sounds into language information:* Wernicke's area (area 22), in left superior temporal gyrus in its posterior part, as well as posterior parts of middle and inferior temporal gyri.
- *Phoneme processing:* Inferior parietal lobule, especially the supramarginal gyrus.
- *Readind comprehension:* Parieto-occipital cortex, especially the angular gyrus.
- *Spontaneous speech output:* Broca's area in the posterior inferior frontal gyrus (areas 44, 45), and the premotor cortex which program the motor cortex to produce sounds.
- *Speech repitition:* Communication between the posterior and anterior speech regions via the arcuate fasciculus and uncinate fasciculus.
- *Alerting the language network:* Anterior thalamus, basal ganglia.

Auditory Pathway and Speech

- The auditory pathway conveys the special sense of hearing. Information travels from the receptors in the Organ of Corti of the inner ear (cochlear hair cells) to the central nervous system carried by the vestibulocochlear nerve.
- This pathway ultimately reaches the primary auditory cortex for conscious perception. In addition, unconscious processing of auditory information occurs in parallel **(Figs. 5 and 6)**.

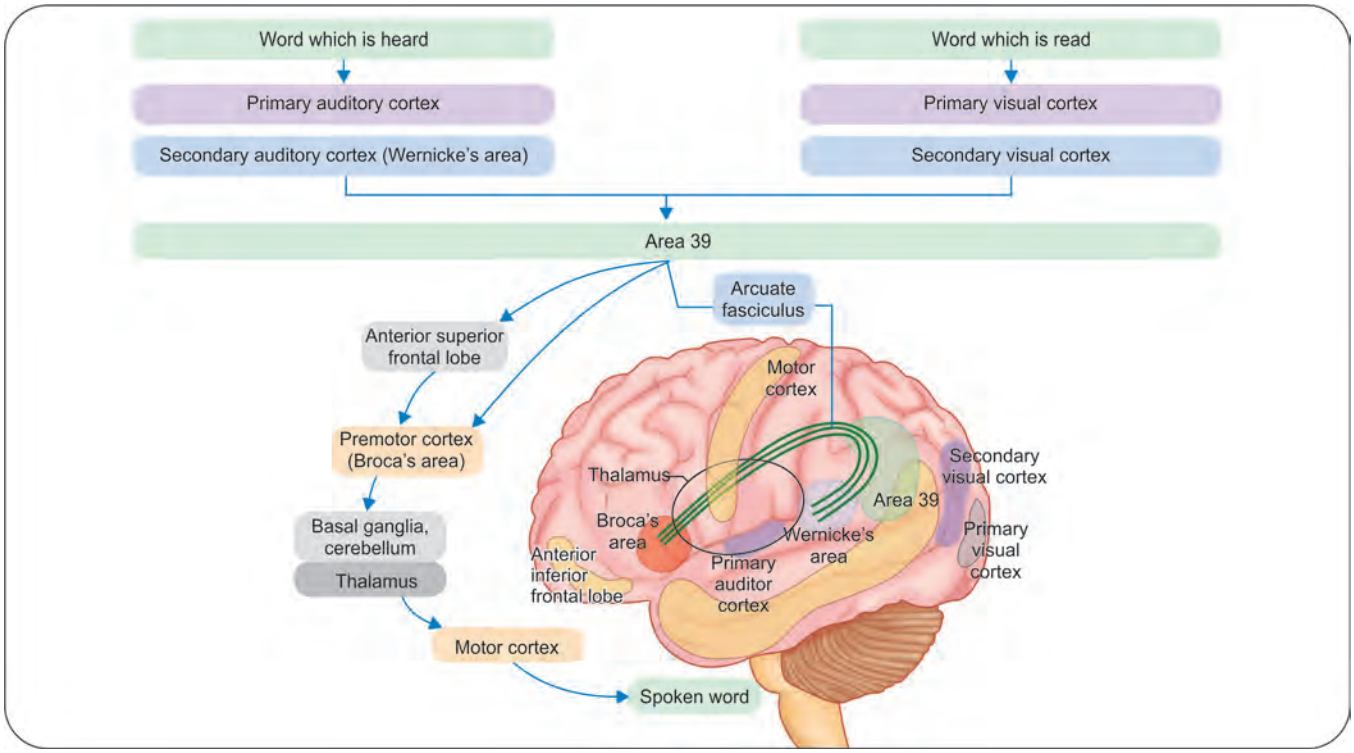

Fig. 5: Genesis of speech

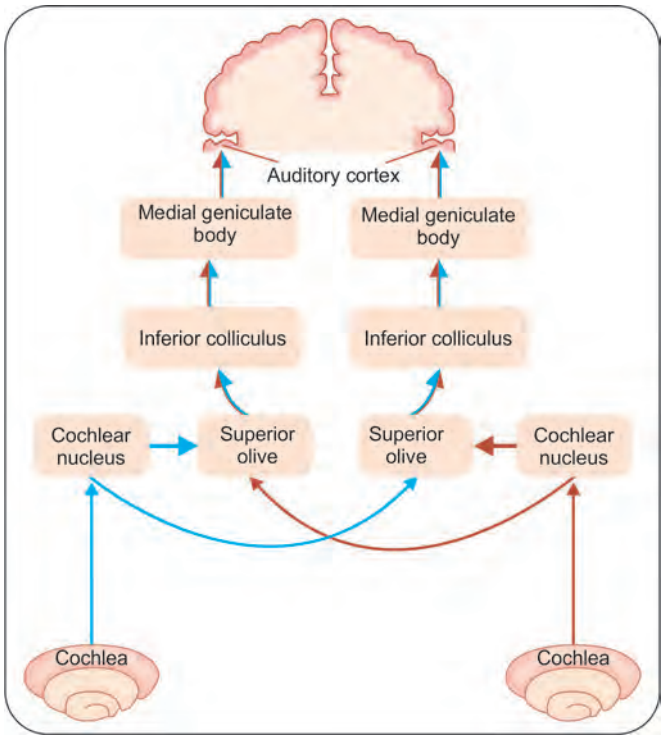

Fig. 6: Auditory pathway

Aphasia

Aphasia as mentioned earlier is a loss or impairment of language production and/or comprehension, often accompanied by a loss of ability to read and/or write resulting from damage to speech centers within the dominant (usually left in 97%) hemisphere **(Fig. 7)**.

A language disturbance occurring after a right hemisphere lesion in a right-handed person is known as *Crossed aphasia*.

Aphasia can be categorized according to whether the speech output is fluent or nonfluent:

- *Fluent aphasia (receptive aphasia):* It is the impairment mostly due to the input or reception of language with difficulties either in auditory verbal comprehension or in the repetition of words, phrases, or sentences spoken by others. For example, Wernicke's aphasia.
- *Nonfluent aphasia (receptive aphasia):* These are difficulties in articulating with relatively good auditory, verbal comprehension. For example, Broca's aphasia.

Normal fluency: Between 100–150 words/min, sentence length >7 words.

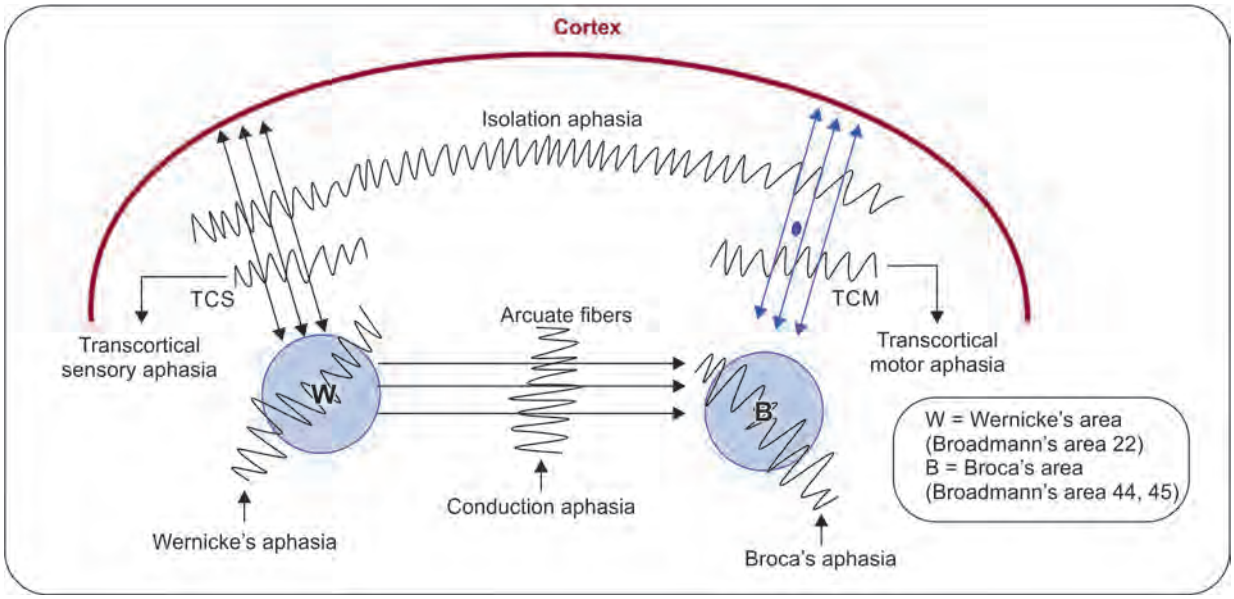

Fig. 7: Schematic representation of aphasias and associated lesions

TABLE 2 Domains of speech

Domains	*Methodology*	*Observations*
Spontaneous speech	• Observe the speech and language during routine conversation • Ask open ended questions. Example: – Why have you come to the hospital? – Describe the nature of your job • If the patient is not communicative try recitation list. Example: – List the days of a week – List the months of the year	• Initiation difficulty • Articulation • Fluency • Prosody (the melodic intonation) • Grammatical correctness (agrammatic speech sounds like telegraphic language) • Paraphasias:[1] If present, literal[2] or semantic[3]? • Neologisms[4] • Word finding pauses, circumlocution
Naming	Show different categories like objects, body parts, colors, pictures of animals Example: pen, watch, key hand, thumb, dog , cat, red/blue/ yellow colors, names of familiar people	• Impaired naming, in spite of recognition of the object or the person • Impaired naming restricted to certain category • Confabulation • Word finding difficulty, pauses, circumlocution
Auditory comprehension	• One step commands (beware of apraxias) – Stick out your tongue – Point to your nose – Open your mouth • Two steps commands (beware of body part agnosias, right left disorientation) – With your right hand, point to your left ear – Point to the ceiling and then to the floor – Raise your hand and close your eyes • Yes or no responses (inform that patient should say yes or no) – Is your name xxx? (use a wrong name) – Is your name zzz? (use correct name) – Do you live in xxx? (use wrong place) – Do you live in zzz? (use correct place) – Does Sunday come after Saturday?	• Impaired comprehension to spoken commands • If apraxia/body part agnosia interferes with body part commands, impaired "yes/no" responses

Contd...

Domains	*Methodology*	*Observations*
Repetition	• Single words: – Brown – Chair – Five hundred and fifty-five • Sentence repetition (there should be no errors of omission or commission) – It is 4 o'clock – He locked the doors – He searched for keys in his pocket – No ifs, ands, or buts – He opened the sports page of the newspaper for cricket score	• Impaired for difficult consonants in dysarthria • Impaired for complex grammatical sentences in aphasia
Reading	• Simple letters and words: – Alphabets (G, C, K, M) – Numbers (3, 8, 6, 9) – Simple words (ear, ant, car, etc.) • Obeying written commands (carry cards with these commands written) – Make a fist – Open your mouth – Point to the floor then point to the ceiling – With your right hand point to the left knee • Reading aloud with comprehension – Ask patient to read a newspaper item and ask him relevant questions	• Impaired letter formation • Spelling errors (most useful in mild Wernicke's aphasia) • Impaired grammar • Impaired reading comprehension, in spite of good speech comprehension in Broca's aphasia • Relatively preserved reading comprehension in spite of impaired auditory comprehension in Wernicke's aphasia
Writing	• Ask patient to write few sentences about why he has come to the hospital • Ask him to write about his job/business • Show him a picture and ask him to write a few sentences about it • If the patient has right sided hemiparesis, ask him to use left hand	

[1]Paraphasia: It is a phenomenon of substitutions in speech components.
[2]Literal paraphasia (Substitution of one phoneme for another; e.g., foon for spoon)
[3]Semantic paraphasia (Substitution of one word for another; e.g., pan for spoon)
[4]Neologisms: Use of non-existent words

TABLE 3 Interpretation of language assessment

C-Comprehension (requires intact Wernicke's and transcortical sensory area)
R-Repetition (requires intact Wernicke's, arcuate fibres, and Broca's areas)
F-Fluency (requires intact Broca's and transcortical motor area)

Aphasia	*Site of lesion*	*C*	*R*	*F*	*Reading*	*Writing*	*Associated signs*
Wernicke's-sensory/receptive/posterior	Involvement of inferior division of middle cerebral artery	–	–	+	**Impaired, but sometimes relatively preserved (opposite of Broca's aphasia**)	Impaired, good letter formation, spelling errors, and poor grammars	Visual field defect
Broca's-motor/expressive/anterior	Involvement of superior frontal branch of middle cerebral artery	+	–	–	Impaired with preserved speech comprehension, especially for syntax ("third alexia")	Impaired with poor letter formation and poor grammar	Right sided hemiparesis, apraxia of left limbs

Contd...

Contd...

Conduction/arcuate	Arcuate fasciculus	+	_	+	Inability to read aloud, reading comprehension usually intact	Impaired variably	Mild right hemiparesis, apraxia of left limbs, right hemisensory loss, visual field defect
Transcortical sensory	Posterior watershed zone	_	+	+	Impaired	Impaired	----------
Transcortical motor	Anterior watershed zone	+	+	_	May or may not be intact	May or may not be intact	----------
Isolation aphasia (mixed transcortical aphasia)	Both anterior and posterior watershed zone	_	+	_	Impaired	Impaired	----------
Global aphasia	Dominant frontal, parietal, and superior temporal lobe, left MCA involved	_	_	_	Impaired	Impaired	Right hemiparesis, hemisensory loss, hemianopia

Once the comprehension, repetition, and fluency are intact, we look for Reading, Writing, and Naming disorders associated with reading, writing, and naming.
R-Reading
W-Writing
N-Naming

		R	*W*	*N*
Alexia without agraphia	Occipitotemporal region	_	+	+
Alexia with agraphia	Left angular gyrus	_	_	+
Nominal/anomic/amnesic	Temporoparietal	+	+	_

TABLE 4 Lesion localization

Aphasia	*Site of lesion*
Transcortical motor aphasia	• Left frontal lobe anterior to Broca's area • Frontal deep white matter • Medial frontal region neat SMA (in the anterior cerebral artery territory)
Transcortical sensory aphasia	Left temporo-occipital region
Transcortical mixed aphasia	Large watershed infarctions in the left hemisphere, sparing the perisylvian cortex, but disconnecting them from other cortical regions
Conduction aphasia	Lesion involving either the arcuate fasciculus or the superior temporal gyrus or the inferior parietal region (supramarginal gyrus)
Wernicke's aphasia	Lesion involving Wernicke's area and adjacent temporoparietal region (inferior parietal lobule, superior temporal gyrus)
Single word comprehension defect	Lesion limited to Wernicke's area
Broca's aphasia	Lesion involving the Broca's area and adjacent cortex and subcortical white matter
Isolated speech initiation defect	Lesion limited Broca's area
Global aphasia	Large lesion involving the left frontal, temporal, and parietal lobes
Anomic aphasia	Non-localizing left hemispheric disease. Usually superior temporal gyrus, but also frontal or parietal lobe near angular gyrus
Alexia with agraphia	Left angular gyrus lesions
Alexia without agraphia	Disconnection (of language areas from right occipital cortex) by splenial lesion plus left occipital lesion. Patient has intact left hemifield, but written information presented in that hemifield is not conveyed from right occipital cortex to the language areas
Third alexia	Impaired reading comprehension in Broca's aphasia
Speech alexia	Left frontal or insular lesion

Domains of Language (Table 2)

Language has to be assessed in six domains, which are as follows:

- Spontaneous speech
- Naming
- Auditory comprehension
- Repitition
- Reading
- Writing

Interpretation of Language Assessment

See **Table 3**.

Lesion Localization

See **Table 4**.

Conclusion

A social approach of language assessment that prioritizes subjectivity is possible when we use a fourth-generation method (Campos and Furtado, 2011), which goes beyond individual evaluation and rehabilitation, providing a more effective improvement. The plasticity of the human brain and training-induced learning improve the quality-of-life due to interference in the process of cognition of individuals with dysgraphia. Although their learning tends to be specific to the trained function and not transferred to similar tasks, there are no obstacles that prevent the discussion of new training schemes. These trainings can lead to the acquisition of new knowledge and to the development of new strategies so that they are used flexibly in various tasks and contexts. These challenges are responsible for increasing learning, for progressing the task difficulty, for the motivational state of the individual, and also for reflecting on the type of feedback that the training provides.

124 Type 2 Diabetes Mellitus Originates from Fatty Liver

Rajesh Upadhyay, Ankit Gupta

Abstract

The relationship between diabetes mellitus and liver disease is bidirectional, both supporting and accelerating the development of each other. The key pathogenic mechanism is insulin resistance (IR). The main factor leading to IR is accumulation of fat in the liver. The hepatic fat predominately comes from three sources

- Dietary fat,
- De-novo lipogenesis due to high insulin level and
- Fatty acid generation from adipose tissue lipolysis.

Fat in the liver impairs insulin signaling, leading to IR. Liver is the largest metabolic organ leading to IR. The resultant IR worsens hyperinsulinemia, which affects various metabolic processes in the liver. The IR prevents glucose transport from blood to liver, thus leading to poor trapping in liver and consequent rise in blood sugar. In addition increased free fatty acids inhibit the insulin action on liver, and insulin-induced suppression of glucagon is impaired, thus leading to increased production of hepatic glucose which has a major contribution in fasting hyperglycemia. Evidence suggests that improvement in fatty liver reduces IR and prevents development and/or improvement of diabetes mellitus. There are numerous observational studies suggesting that fatty liver is an independent risk factor for development of diabetes. Chronic liver disease is associated with development of diabetes (secondary diabetes). Glucose intolerance can be seen in about 80% of patients, and diabetes in about 30% of patients with chronic liver disease. Thus, fatty liver may be considered the main organ responsible for IR and T2DM. Diabetes should be considered a reversible metabolic state due to excess intra-organ fat, especially fatty liver.

Introduction

The interest in relationship between chronic liver disease and diabetes mellitus has increased since last decade. Chronic liver disease particularly NAFLD is associated with diabetes mellitus. In the United States, NAFLD is the most common cause of chronic liver disease and affects between 80–100 million individuals.[1] According to an estimate in India, approximate 30% of the population is having NAFLD and its prevalence approaches to 64% in diabetics.[2] The association is based on insulin resistance (IR), which is the common underlying mechanism for both T2DM and NAFLD. The relationship between diabetes mellitus and liver disease is bidirectional, both supporting and accelerating the development of each other. What remains unclear is the chicken-egg conundrum—which comes first? In other words, does diabetes lead to fatty liver or fatty liver causes diabetes? An understanding of this requires a deep study of the physiology and pathogenesis of both conditions and developing clear concepts. Although IR is the common pathogenetic mechanism for both these conditions; however, it is the liver which is the key player for IR.

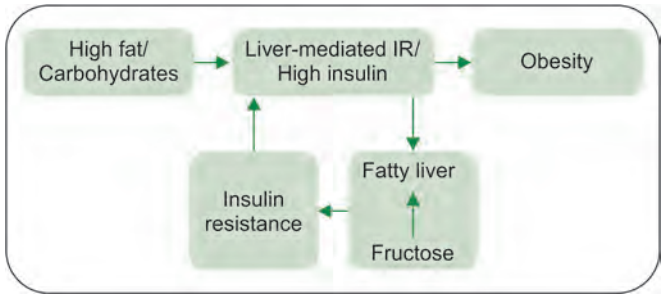
Liver is the Main Organ Producing IR

Being the largest metabolic organ of human body, it plays an important role in glucose metabolism. It is the site for glycogenesis, glycogenolysis, and gluconeogenesis. It has an immense capacity to store sugar in times of excess and push out glucose into circulation in deficient condition. Therefore, in states of fasting or hypoglycemia, liver releases glucose into the circulation by glycogenolysis and/or gluconeogenesis. On the other hand, it is also the main organ which prevents rapid rise of blood glucose after food ingestion. Whatever glucose is absorbed from the intestines it goes through the portal vein to the liver where, almost all of it is retained. The rise in prandial plasma glucose reflects only a minor component of the absorbed glucose. It is pertinent to note that the first glycemic abnormality in T2DM is postprandial hyperglycemia, which may actually indicate insufficient trapping of glucose by the liver. The insufficient trapping of glucose in the liver is due to the liver mediated IR. The main factor leading to IR is accumulation of fat in the liver. This brings us to the basic question as to what causes fatty liver **(Flowchart 1)**. High carbohydrate/high fat diet increases insulin production, which pushes sugar from blood into liver. The liver cells are filled up with stored glycogen. The hepatic fat predominately comes from three sources:

- Dietary fat,
- De-novo lipogenesis due to high insulin level, and
- Fatty acid generation from adipose tissue lipolysis.

In addition the role of absorbed fructose is also important. Fructose unlike glucose can only be metabolized by the liver and not by other tissues. In fatty liver, there is already high hepatic glucose/glycogen; hence, fructose can only be converted into fat which adds to the fatty pool. Fatty acid accumulation occurs in the liver cells which would normally be oxidized to produce energy. However, the oxidative stress and mitochondrial dysfunction in fatty liver prevents oxidation. The fatty acid is therefore esterified into triglycerides and stored in the liver cells. Fat in the liver impairs insulin signaling, leading to IR. The resultant IR worsens hyperinsulinemia, which affects various metabolic processes in the liver. First, it stimulates the enzyme hexokinase, which phosphorylates glucose. In addition, it also activates the enzymes phosphofructokinase and glycogen synthase, which are involved in glycogen synthesis. When glycogen stores are saturated, the excess glucose is then shunted to fatty acid synthesis, which further adds to liver fat.

Flowchart 1: What causes fatty liver?



The liver mediated IR is a manifestation of the inherent ability of liver to protect itself from ongoing onslaught of further sugar/fat accumulation in liver cells, which is likely to cause cell disintegration. The stored fat is therefore transported out from the cell in the form of free fatty acid and VLDL, which causes tissue IR in various organs **(Fig. 1)**. The IR prevents glucose transport from blood to liver, thus leading to poor trapping in liver and consequent rise in blood sugar.

Increased Hepatic Glucose Output in Diabetes

It is also well known that hepatic glucose output is increased in T2DM, and it has a major contribution in fasting hyperglycemia. Increased free fatty acids inhibit the insulin action on liver, and insulin-induced suppression of glucagon is impaired, thus leading to increased production of hepatic glucose excessive release of glucose from liver further increases blood sugar levels although the levels may still be maintained within the normal range due to compensatory high pancreatic beta cell production of insulin.

Phases of T2DM and the Role of Pancreatic Fat

It is well known that in diabetics, there is a prolonged period of 12–14 years of IR with compensatory hyperinsulinemia keeping the blood sugar within the normal range with gradually increasing HbA1c to prediabetic levels. Then comes the pancreatic beta cell failure resulting in reduced

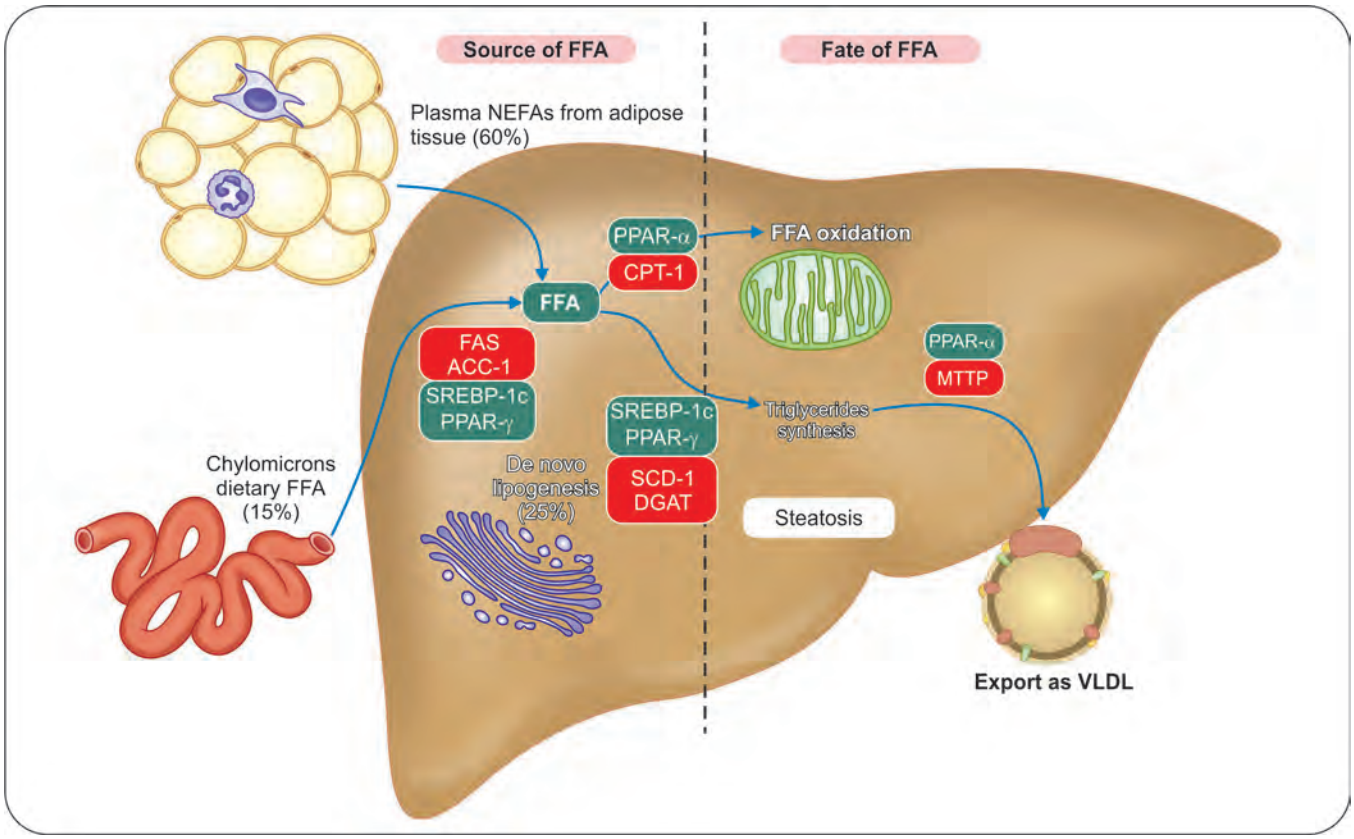


Fig. 1: Sources and fate of free fatty acids in liver

insulin production causing overt diabetes **(Fig. 2)**. The question is what causes beta cell failure? Various theories in literature have been suggested especially the burnout theory due to persistent insulin overproduction by the pancreatic beta cells leading to cell death causing reduced insulin production. If this was so then T2DM would clearly be an irreversible condition. On the contrary, there is evidence of increase in insulin secretion post-bariatric surgery or following a hypocaloric diet.[3,4] Such interventions have the ability to reverse diabetes completely. Hence, a more plausible explanation would be that the beta cells have been rendered metabolically inactive due to reversible factors. Evidence suggests that fatty acids prevent beta cell proliferation. In the genetic model, Zucker diabetic fatty rats rapid increase in pancreatic fat leads to development of diabetes. When food intake is restricted in this model, diabetes did not develop. This also suggests that a significant

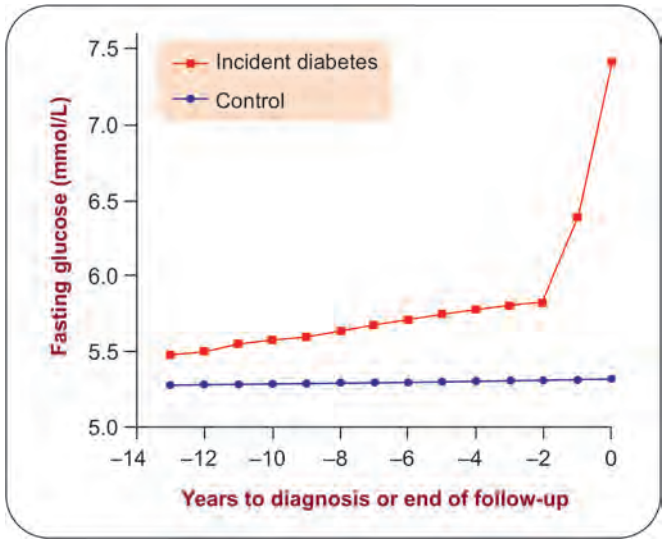

Fig. 2: Two phases of type 2 diabetes

mass of beta cells is not permanently damaged but became metabolically inactive. Thus, pancreatic fat (PF) accumulation is an important precursor for development of diabetes. The amount of PF is greater in diabetics and increases with the duration of diabetes. Patients with PF have a higher prevalence of T2DM than non-PF controls (12.6% vs. 5.2%) and T2DM was independently associated with PF.[5] A cohort of patients with biopsy proven NASH had more PF in diabetics compared to patients without diabetes.[6] The fatty liver cells are overdistended with fat which is then transported to different organs including the pancreas as free circulating fatty acids and VLDL particles which lead to tissue IR and PF accumulation. There is evidence to suggest this cross talk between the fatty liver and PF.[7] Fat in pancreas may lead to metabolic suppression of beta cells causing pancreatic failure and reduced insulin production leading to T2DM. This hypothesis appears attractive but needs to be evidence based. There are studies on post-bariatric surgery patients demonstrating lowering of pancreatic triglyceride content with simultaneous increase in insulin secretion. Bariatric surgery leads to fat mobilization from various tissues and liver/pancreas are the earliest targets of mobilization leading to reduction in liver and PF causing improvement in insulin sensitivity and insulin production. Hence, improvement in blood glucose in post-bariatric surgery patients occurs early even before body weight loss and this improvement in blood glucose has linear correlation with reduction in fat content of liver and improved sensitivity to insulin and the normalization of fasting blood glucose which occurred within 7 days.[8] PF content reduction occurred in 8 weeks and was accompanied by restoration of first phase insulin.[9]

Treatment of Fatty Liver can Ameliorate IR and Prevent Diabetes

In a rodent model, it was found that there was early development of hepatic IR without significant changes in insulin-stimulated glucose utilization or body weight in rodents fed with high fat diet.[10] In a study in T2DM patients subjected to a moderately hypocaloric and very low-fat diet, 81% reduction in intrahepatic fat content and improvement in basal and insulin-stimulated hepatic glucose metabolism was noted; however, effects on insulin-stimulated peripheral glucose uptake were not significant.[11] So dietary modification can improve hepatic insulin sensitivity. Weight loss interventions are also associated with improvement in liver histology and transaminases. Metformin an oral antidiabetic drug reduces plasma glucose via activation of AMP kinase, and reduces hepatic glucose synthesis. This enzyme also decreases lipid synthesis and enhances fat oxidation. Metformin treatment thus can improve insulin sensitivity and liver transaminases in patients with fatty liver disease. Thiazolidinediones are insulin sensitizers and can improve hepatic as well as peripheral insulin sensitivity. They can induce adipocyte differentiation, reduce free fatty acid levels, and thus decrease their delivery to liver. They also increase adiponectin levels and can increase lipid oxidation of fatty acid in liver. They also reduce TNF-alpha and C-reactive protein, which play important role in IR. Therefore, there are ample evidences to suggest[2] that targeting fatty liver can lead to improvement of IR. It is a well-known fact that persons with fatty liver have higher prevalence of T2DM (22.4%) and NASH (43.6%) as compared to 8.5% in general population.[12] This suggests that fatty liver is a risk factor for T2DM and increases the risk of development of T2DM by 2–3 folds. The risk of development of T2DM may be even higher in patients with more severe liver disease which suggests that fibrosis increases the risk. About 30% patients with cirrhosis of liver have diabetes.[13]

Evidence Suggesting Fatty Liver Leads to T2DM

Over the past 15 years there have been numerous observational studies suggesting that fatty liver is an independent risk factor for development of diabetes **(Table 1)**.

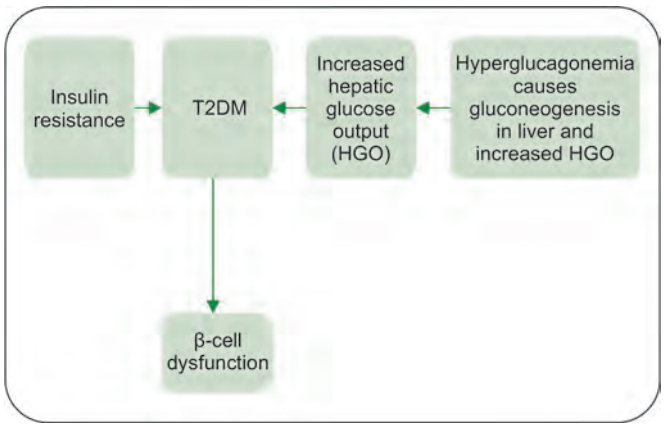
Secondary Diabetes is Related to Liver Disease

Liver is the most important organ for regulation of blood sugar. It is therefore, a simple understanding that chronic liver disease is associated with impaired glucose tolerance and development of diabetes. Glucose intolerance can be seen in about 80% of patients, and diabetes in about 30–60% of patients with chronic liver disease.[14,15] Apart from fatty liver disease, other conditions like hemochromatosis, cystic fibrosis, chronic liver disease due to alcohol abuse, chronic hepatitis C, and glycogen storage disorders are also associated with development of diabetes.

TABLE 1 Observational studies of the association between NAFLD and T2DM

Study	*Study population*	*Length of follow-up (diagnosis)*	*Main findings*
Fan et al. (2007) Chinese study	Age and sex matched 1,146 individuals with and without NAFLD	7 years, ultrasound based NAFLD diagnosis	Higher incidence of T2DM in NAFLD group (OR 4.6, 95% CI 3.0–7.1)
Shibata et al. (2007) Japanese study	3,189 male ≥ 40 years age	8 years, ultrasound based NAFLD diagnosis	NAFLD significantly increases the risk of T2DM (HR 5.5, 95% CI 3.6–8.5)
Kim et al. [2008] South Korean study	5,372 individuals	5 years, ultrasound based NAFLD diagnosis	NAFLD was independent risk factor for T2DM (HR 1.51, 95% CI 1.04–2.20).
Yamada et al. (2010) Japanese study	12,375 individuals	5 years, ultrasound based NAFLD diagnosis	Fatty liver is independent risk factor for development of T2DM (OR 1.91, 95% CI 1.56–2.34)
Sung et al. (2011) South Korean Study	11,091 individuals	5 years, ultrasound based NAFLD diagnosis	Increased risk of T2DM in NAFLD (OR 2.05, 95% CI 1.3–3.1)
Bae et al. (2011) South Korean Study	7,849 individuals	5 years, ultrasound based NAFLD diagnosis	Increased risk of T2DM in NAFLD (HR 1.33, 95% CI 1.07–1.66)
Sung et al. (2012) South Korean Study	12,853 individuals	5 years, ultrasound based NAFLD diagnosis	NAFLD was independently associated with incident T2DM (OR 2.42, 95% CI 1.7–3.36)
Ekstedt et al. (2006) Swedish study	Retrospective study, 129 individuals	13.7 years, liver biopsy based NAFLD diagnosis	At follow-up, 58% of patients developed T2DM and 20% developed impaired glucose tolerance
Alessandro Mantovani, et al. (2018) Meta-analysis	19 observational studies (296,439 individuals)	Median 5 years	NAFLD associated with two fold increase risk of diabetes
Sung et al. (2019) South Korean Study	70,303 adults	3.3 years	Diabetes risk increased with increasing insulin resistance (HR-6.6)

Flowchart 2: Triumvirate pathology of T2DM



Conclusion

The traditional triumvirate features in the pathogenesis of diabetes, viz. IR, diminished insulin release from pancreatic islet beta cells and increased hepatic glucose output **(Flowchart 2)** gave way to the ominous octet proposed by deFronzo in his Banting Lecture a decade back.[16] However, it is imperative to note that the triumvirate features had the liver contributing to categorically all the features. The octet may provide the treating physicians with different ways to tackle the treatment of diabetes, but it will be pertinent to understand that the liver-pancreas axis is involved in most of the features of the octet. Thus, liver is an important organ involved in glucose homeostasis and plays an important role in the pathogenesis of T2DM. In fact, reversal of fatty liver may help ameliorate IR, and may aid in the prevention of development of type 2 diabetes. Thus, fatty liver may be considered the main organ responsible for IR and T2DM. Diabetes should be considered a reversible metabolic state due to excess intra-organ fat especially fatty liver.

CHAPTER

125 Non-Pharmacological Management of NAFLD/NASH (Diet, Exercise, and Role of Intermittent Fasting)

Sundeep Kumar Goyal

Abstract

Nonalcoholic fatty liver disease (NAFLD) and its complications are growing with increasing prevalence of obesity. Multiple factors and pathways are involved in pathogenesis of disease. In the absence of effective pharmacotherapy that addresses all or most of the components of disease and reverses the inflammation and fibrosis, primary approach to treat NAFLD focuses on promoting weight loss through diet and lifestyle interventions. The choice of therapy is dependent on degree of overweight, comorbidities, and patient preferences. This chapter will review the dietary therapy and lifestyle changes of NAFLD.

Introduction

Nonalcoholic fatty liver disease (NAFLD) and its complications are growing with increasing prevalence of obesity worldwide. Under the umbrella of NAFLD, there are two histological phenotypes:

- Steatosis (nonalcoholic fatty liver, NAFL) and
- Steatosis with inflammation, ballooning and fibrosis (nonalcoholic steatohepatitis, NASH).

NAFLD often occurs concomitantly with other end organ diseases like diabetes, hypertension, coronary artery disease, and chronic kidney disease. These are often connected to common biology linked to metabolic stress and systemic inflammation. So term NAFLD is proposed to rename as metabolic dysfunction associated fatty liver disease (MAFLD) to give clearer concept of liver manifestations of this multisystem disease.[1] Natural history of disease is influenced by various factors like age, sex, ethnicity, diet, hormonal status, genetic, epigenetic factors, gut microbiome, alcohol, and metabolic status and leads to heterogeneous clinical phenotype.

Aim and objectives of dietary restriction and exercise: Patients with NAFLD/MAFLD are metabolically unhealthy with imbalance between calorie intake and expenditure that leads to obesity, insulin resistance, and other metabolic disorders.[2] Obesity doubles the prevalence of NASH and its progression to cirrhosis, liver failure, and hepatocellular carcinoma (HCC).[3] Prior to development of cirrhosis, clinical outcomes of disease are mostly related to cardiovascular system. With the advancement of fibrosis stage or cirrhosis development, liver-related outcomes increase exponentially.[4] The ideal goal of treatment is to subside inflammation, regression of fibrosis, and cirrhosis with simultaneously addressing concomitant metabolic disorders and cardiovascular mortality.[5] Histology based data have showed that weight loss is the only modality at present that has favorable impact on reducing hepatic as well as extrahepatic complications.[6,7] In a prospective study of 293 patients, degree of weight loss was independently associated with improvements in all NASH-related histological parameters.[8] Nevertheless, in the study just 10% of patients reached a 10% weight loss and 70% of the cohort did not lose 5% of total body weight **(Fig. 1)**.

Approximately 22 kcal/kg (±20%) is required to maintain a kilogram of body weight in a normal-weight

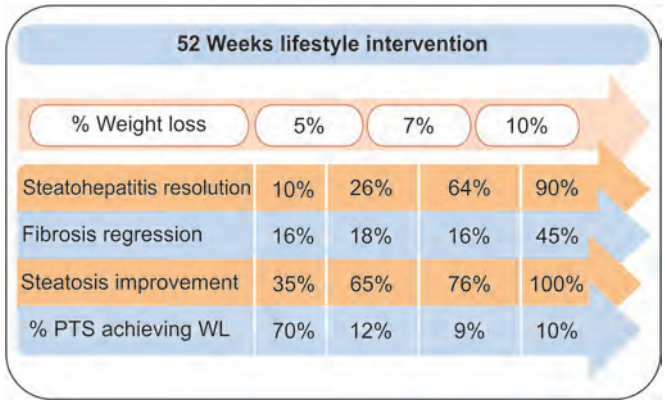

Fig. 1: Effect of weight loss on NASH[8]

adult. An average deficit of 500 kcal/day should result in an initial weight loss of about 0.5 kg/week. Both lean body mass and body fat decreases with weight loss and reach plateau after 3–6 months. Further caloric restriction and increased physical activity required to overcome this plateau effect.[9] Aim of weight loss is to preserve muscle mass and decrease visceral fat.

Types of diet: Planning a diet requires the selection of caloric intake and then choice of foods according to local culture and palatability. Replacement of food by low-calorie meals containing 250–350 kcal/package in form of nutrition bars, frozen food, and prepackaged meals resulted in early initial weight loss, which then was maintained over long term (4 year follow-up).[10] The Mediterranean diet includes consuming high level of monounsaturated fat relative to saturated fat; moderate consumption of alcohol, mainly as wine, a high consumption of vegetables, fruits, legumes, and grains, a moderate consumption of milk and dairy products, mostly in the form of cheese, and a relatively low intake of meat and meat products. Adherence to the Mediterranean dietary pattern leads to a significant decrease in liver fat and insulin resistance among overweight patients with NAFLD.[11]

Dietary Composition

Carbohydrate: Low- and very low-carbohydrate (60–130 gm and <60 gm, respectively) diets have been more effective for short-term weight loss than low-fat diets, but not for long-term weight loss, compared with a low-fat diet.[12,13] Restriction of carbohydrates less than 50 gm/day-cause rapid weight loss, due to breakdown of glycogen, ketosis development, and fluid loss. In addition, very low-carbohydrate diets are associated with a small increase in energy expenditure.[14] Side effects may be more with low-carbohydrate diet like constipation, headache, muscle cramps, diarrhea, weakness, and rash. There is some data to suggest that low-carbohydrate diet have early weight independent effect on liver steatosis and insulin resistance but after more than 7% weight loss this benefit is similar like hypocaloric low-fat diet.[15]

A low-carbohydrate diet may be planned either by reducing the total amount of carbohydrate or by consuming foods with a lower glycemic index (GI) or glycemic load. High-glycemic-load foods increase postprandial glycemia and insulinemia, particularly in patients with insulin resistance. Since the duration of post-meal satiety is related to postprandial glycemia, low-GI foods have been hypothesized to reduce hunger signals and delay the onset of the next meal. Meals with high GI were found to be associated with high-grade liver steatosis (assessed by ultrasound), particularly in insulin-resistant subjects.[16]

Fructose: Fructose mainly derived from table sugar (50% fructose) and corn syrup (55% fructose). High intake of sugar-sweetened foods in general contributes to weight gain and high liver fat due to their high-energy density, glycemic load, and palatability. Fructose role has been implicated in alteration of gut microbiome, increasing gut permeability, endotoxemia and hyperuricemia.[17,18] Soft drinks contain caramel coloring rich in advanced glycation end products, which increases insulin resistance and liver injury.[19]

Fat: The quality of fat consumed and its food sources appear to be more important for health than total fat intake. Trans fatty acids and saturated fatty acids have been associated with metabolic derangement (increase LDL, low HDL), and an elevated cardiovascular risk.[20] Saturated fat promotes visceral and liver fat deposition.[21] Assessment of dietary pattern in NASH patients showed higher saturated fat and cholesterol intake and lower polyunsaturated fatty acids (PUFA), fiber, vitamin C and E consumption.[22]

Monounsaturated fatty acids (oleic acid, palmitoleic acid in canola and olive oil) consumption favors accumulation of fat in adipose tissues rather than the liver in animal models.[23] In type 2 diabetic patients, an

isocaloric diet enriched in MUFA compared with a diet higher in carbohydrate and fiber was associated with a significant fat reduction in liver (measured by proton magnetic resonance spectroscopy) despite a stable weight in both groups.[24] Polyunsaturated fatty acids (n-6: linoleic acid, arachidonic acid and n-3: α-linolenic acid, eicosapentaenoic acid, docosahexaenoic acid) are abundant in fish oil. Low intake n-3 fatty acids and higher n-6/n-3 ratio is found in NAFLD patients than healthy controls.[25] It is associated with a proinflammatory state and increased lipogenesis leading to steatosis.[26] Conversely, n-3 PUFAs down-regulate sterol regulatory element binding protein 1c (SREBP-1c) and up-regulate peroxisome proliferator activated receptor α (PPAR-α) that would favor fatty acid oxidation and reduce steatosis.[27] PUFA Supplementation is effective in reducing total liver fat but not beneficial in histological improvement in terms of inflammation and fibrosis.[28]

High cholesterol consumption (>500 mg/day) was associated with higher risk of cirrhosis or liver cancer, instead of total fat consumption.[29]

Protein: High-protein diets have been recommended for the treatment of obesity because they are more satiating and stimulate thermogenesis. Higher-protein diets may improve weight maintenance. Total red meat and processed red meat intake are both positively associated with risk of coronary artery disease.[30]

Fiber has several beneficial metabolic effects, including increased satiety, increased incretin secretion, reduced absorption rate of CHO and proteins, modulation of gut microbiota, and increased fermentation products, such as butyrate.

Increased coffee consumption has been associated inversely with the risk of cirrhosis or progression of fibrosis but not with steatosis.[31] In epidemiological studies, coffee consumption is associated with a lower risk of metabolic syndrome.[32] Animal studies suggest, coffee exerts its effects by reducing hepatic fat accumulation, systemic and liver oxidative stress and liver inflammation.[33] Drinking coffee reduces HCC risk.[34] For the majority of healthy adults, consuming less than 400 mg of caffeine a day appears to be safe.

Intermittent Fasting

Intermittent fasting strategies, including alternate-day fasting (25% of total energy consumed on "fast" days and 125% consumed on "feast" days) and time-restricted feeding (TRF) (cessation of eating by a certain time each day) have been used as approaches to weight loss. Short-term TRF trials have shown that the alignment of the feeding period with circadian rhythms may result in weight loss and improve metabolic parameters.[35] The mechanisms by which intermittent fasting affect health may include improved insulin sensitivity and anti-inflammatory effects.

Summary of diet recommendations for NASH:[2]

- Calorie restriction (500–1000 kcal/day)
- Low-carbohydrate (<40%) diet—replace calories with PUFA, MUFA
- Low-fat diet—replace calories with low-GI foods
- Reduce trans FA (<1%), saturated fats (<7%), and cholesterol (<200 mg/day)
- Proteins from fish, poultry, nuts, and legumes & restrict unprocessed red meats (<300 g/week), processed meats (<2/week)
- Increase the intake of cereal-derived non-soluble fiber (whole grain) (25 g/day)
- Vegetables (3–5 servings/day), fruits (2–4 servings/day), nuts (4 servings/week), olive oil, and low-fat dairy products.

Physical Activity

Sedentary behavior is a component of reduced life expectancy. The energy expenditure is sum of resting metabolic rate (RMR), the thermic effect of feeding (TEF), and physical activity. Exercise (aerobic and resistance) is planned form of physical activity. While it may be difficult to lose weight with exercise alone, exercise programs added to moderate to severe caloric restriction have additional effect upon weight loss.[36] If a patient burn 100 calories during exercise each day (700 calories per week), it would take almost 5 weeks to utilize the energy (3,500 calories) in half kg of fat. Exercise alone, in the absence of any change in body weight or composition, may enhance peripheral insulin sensitivity and glucose homeostasis mediated by insulin-receptor up regulation in muscle tissue, enhancing whole-body lipid oxidation, decreased hepatic triglyceride accumulation and lower hepatic FFA uptake **(Fig. 2)**. Increased physical activity attenuates the diet-induced loss of muscle mass, which in turn increases physical functioning and insulin sensitivity.[37] Both aerobic or resistance exercise are effective in reducing liver

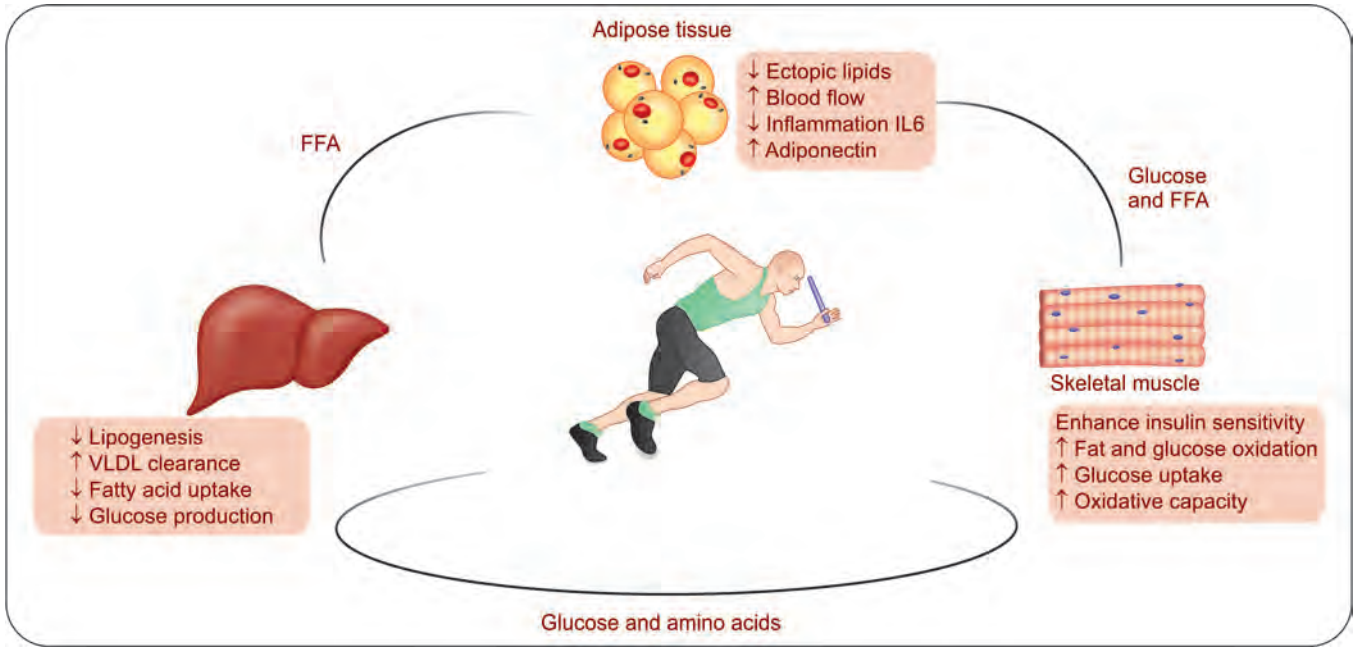

Fig. 2: Exercise effect in NAFLD and effect on liver, adipose tissue, and muscles

fat.[38] The addition of resistance exercise to weight-loss programs can help prevent the reduction in muscle and bone mass. Patients with poor cardiorespiratory reserve may better tolerate resistance exercise. Weight training results in greater increases in fat-free mass.[39]

The recommendation by American Heart Association of intense cardiorespiratory activity (aerobic & resistance) for at least 150 minutes (preferably 300 minutes) per week, or at least 75 minutes (preferably 150 minutes) is adapted by EASL for NASH patients.[40] The clinician needs to be aware for identifying high-risk patients who may require a more thorough evaluation before beginning an exercise program. The major hurdle is obtaining long-term compliance—especially in individuals who are not accustomed to regular intense exercise.

Conclusion

The primary approach to treat NAFLD focuses on the control of the underlying risk factors like diabetes, hyperlipidemia, obesity, and other comorbidities through diet and lifestyle changes. After the initial weight-loss phase, the weight-maintenance phase is key for preventing long-term complications. Strategies to enhance long-term adherence to lifestyle interventions, with a multidisciplinary approach should be included.

CHAPTER

126 Medical Management of Acute Pancreatitis

D Nageshwar Reddy, Hardik Rughwani

Abstract

Acute pancreatitis is a common disease, major etiologies being gallstones or alcohol ingestion. Diagnosis is based on clinical symptoms, elevated pancreatic enzymes, and imaging findings. Revised ATLANTA classification (2013) has defined the types, severity, organ failure, and complications of acute pancreatitis. Majority of patients have self-limiting disease while some may develop severe disease, causing organ failure and complications such as pseudocyst or wall-off necrosis (WON). Treatment involves early enteral nutrition, intravenous fluids, analgesics, with avoidance of use of antibiotics. Endoscopic and/or surgical interventions are required in case of complicated unresolving pancreatic collections.

Introduction

Acute pancreatitis (AP) is a common gastrointestinal tract (GIT) disease causing enormous physical, emotional, and socioeconomic human burden. The first clinical description of AP was given by Dutch anatomist Nicholaeus Tulp in 1652. Incidence of AP varies from 30–80/100,000 population. In India, approximately 74% of patients of AP are men with the mean age being 40 years, which is a younger age group compared to other parts of the world.

Definitions[1]

ATLANTA classification defining the severity and complications of AP was first described in 1992. Since then there has been continuing research in this field and has resulted in improvement of knowledge about the disease process, and hence management of AP. Also, there has been a major improvement in imaging modalities, which has helped to classify and define disease severity and complications in a clarified way as a part of revised ATLANTA classification proposed in 2013. This revision includes assessment of the severity clinically and provides objective terms to define the local complications of AP, which are described as follows.

Definitions and Classification: Proposed to be Used in Clinical and Research Communications

Diagnosis of AP

The diagnosis of AP requires two out of following three features:

- Pain abdomen suggestive of AP (acute onset severe, persistent, epigastric pain, aggravated with food intake, and radiating to the back);
- Pancreatic enzymes activity (serum lipase and serum amylase) more than three times elevated than normal range; and
- Imaging findings on contrast-enhanced computerized tomography (CECT), magnetic resonance imaging (MRI), or trans abdominal ultrasonography, showing characteristic changes of AP.

Routinely use of CECT in patients of AP is unjustified, as the diagnosis is apparent and most patients have a mild, non-complicated course. But if there is lack of improvement after 48–72 hours (e.g., persistent pain, nausea, fever, inability of start oral feeds), imaging using CECT or MRI is recommended for assessment of local complications such as peripancreatic fluid collection or pancreatic necrosis.

Onset of AP

The onset of AP is defined by the time when the typical abdominal pain first begins and not by the time when patient first seeks hospital care. This time of onset of pain abdomen is crucial to define the further complications of AP.

Types of AP

AP can be subdivided into two types based on presence or absence of necrosis:

- *Interstitial pancreatitis*—in the absence of pancreatic necrosis, the edematous pancreas in mild disease, is defined as interstitial pancreatitis;
- *Necrotizing pancreatitis*—in about 5–10% of patients, AP evolves to produce necrosis of pancreatic parenchyma, the peripancreatic tissue or both.

Pancreatic necrosis is defined as focal or diffuse areas of nonviable parenchyma which is 30% of the pancreas or 3 cm in size.

Complications

Organ Failure—Definition

Organ failure is defined based on the assessment of three major organ systems:

- Cardiovascular
- Respiratory, and
- Renal. Modified Marshall scoring system **(Table 1)** is used to define organ failure.

Local Complications—Definition

The concept of local complications following AP was defined by the Original ATLANTA classification (1992). Since then with the advancement of the understanding of pathophysiology and improvement of imaging has led to better characterize the local complications as acute peripancreatic fluid collection, pancreatic pseudocyst **(Fig. 1)**, acute necrotic collection, and walled-off necrosis **(Fig. 2)** based on the presence and absence of necrosis and time from the onset of pain abdomen, each of which has been defined by the revised ATLANTA classification[1] (2013) **(Table 2)**. Gastric outlet obstruction, splenic vein and portal vein thrombosis are some of the other local complications of AP.

Systemic Complications—Definition

Any exacerbation of previous comorbid conditions such as chronic lung disease, or coronary artery disease, by AP is defined as systemic complications.

TABLE 1 Modified Marshall scoring system[1]

Organ systems	*Scores*				
	0	*1*	*2*	*3*	*4*
Respiratory (FiO_2/PaO_2)	>400	301–400	201–300	101–200	≤100
Renal (creatinine mg/dL)	<1.4	1.4–1.8	1.9–3.6	3.6–4.9	>4.9
Cardiovascular (systolic BP mm Hg)	>90	<90, fluid responsive	<90, not fluid responsive	<90, pH<7.3	<90, pH<7.2

FiO_2 calculation for non-ventilated patients	
Supplemental oxygen (L/min)	*FiO_2 (%)*
Room air	21
2	25
4	30
6–8	40
9–10	50

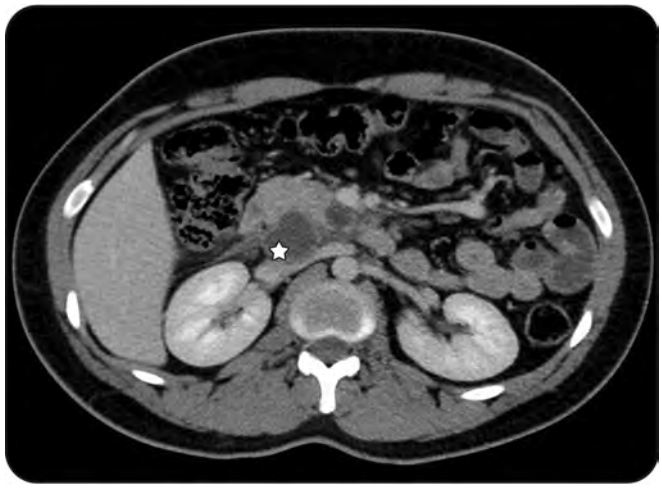

Fig. 1: Contrast enhanced CT axial images showing small pseudocysts in the uncinate process and neck of pancreas

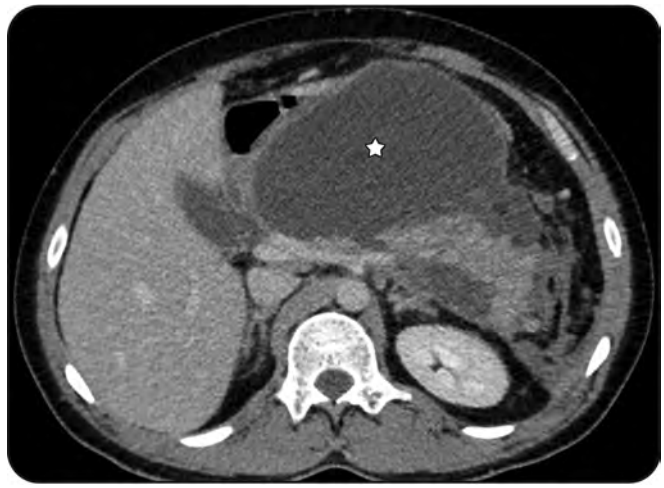

Fig. 2: Contrast enhanced CT axial images showing large peripancreatic walled off necrosis (WON) around body and tail of pancreas

TABLE 2 Terminology based on fluid collection[1] (local complications)

Type of pancreatitis	*First 4 weeks*	*After 4 weeks*
Interstitial pancreatitis	Acute peripancreatic fluid collection	Pseudocyst
Necrotizing pancreatitis	Acute necrotic collection (ANC)	Walled off necrosis (WON)

Phases[2]

The disease process of AP is not fixed and can vary from patient to patient. Arbitrarily the disease course can be divided into two overlapping phases with two peaks of mortality: Early and Late phase. These two phases are considered separately.

Early Phase

The early phase involves first week of disease presentation, but may sometimes be prolonged into the second week also. During the early phase, manifestations are due to the response to local pancreatic inflammation and injury. Pancreatic inflammation, in turn, activates cytokine cascade, which clinically manifests as systemic inflammatory response syndrome (SIRS) **(Table 3)**. There is an increased risk of developing organ failure if SIRS is persistent. The presence and duration of organ failure in the early phase determines the severity of AP. If the organ failure resolves within 48 hours, it is defined as "Transient organ failure," and if it persists for more than 48 hours, it is defined as "Persistent organ failure." Multiorgan failure (MOF) is defined when more than one organ develops failure.

Late Phase

By definition, the late phase occurs only in patients with moderately severe or severe AP. It is characterized by the persistence of local complications or systemic signs of inflammation.

Severity of AP—Definition

It is prudent to define and distinguish patients of AP based on severity. The ATLANTA classification has defined three major types of severity—mild, moderate, and severe AP **(Table 4)**.

Etiology[2]

The most common causes of AP are gallstones (40–70%) and alcohol (25–35%). Other etiologies being post ERCP (5%), post trauma, especially in children (1%), idiopathic (25%), and miscellaneous (5%). Alcohol-related

TABLE 3 SIRS[1]

Signs of systemic inflammatory response syndrome (SIRS)
SIRS—defined by presence of two or more criteria: • Heart rate >90 beats/min • Core temperature <36°C or >38°C • White blood count <4000 or >12000/mm^3 • Respirations >20/min or PCO_2 <32 mm Hg

TABLE 4 Grades of severity[1,2]

Severity	*Local/systemic complications*	*Organ failure*
Mild acute	No	No
Moderately acute	Yes	Transient (<48 hrs)
Severe acute (15–20%)	Yes	Yes (>48 hrs)

pancreatitis usually manifests as a spectrum, ranging from distinct episodes of AP to chronic pancreatitis causing irreversible changes silently.

Risk Stratification and Predicting Severe AP

For initial management and hospitalization, laboratory investigations and imaging studies can be useful but are unreliable to predict the severity of AP. Laboratory investigations like hematocrit, blood urea nitrogen (BUN), creatinine or CRP in the 1st 48 hours can be normal. Also, cross sectional imaging cannot determine severity early in disease course as necrosis is usually absent on admission and may take 2–3 days to develop. Thus, as there is an absence of any definite test to determine the severity of AP, clinical assessment of third space fluid losses, shock and signs and symptoms suggestive of organ dysfunction is of paramount importance.

Management (Flowchart 1)

Pain Management (Analgesia)

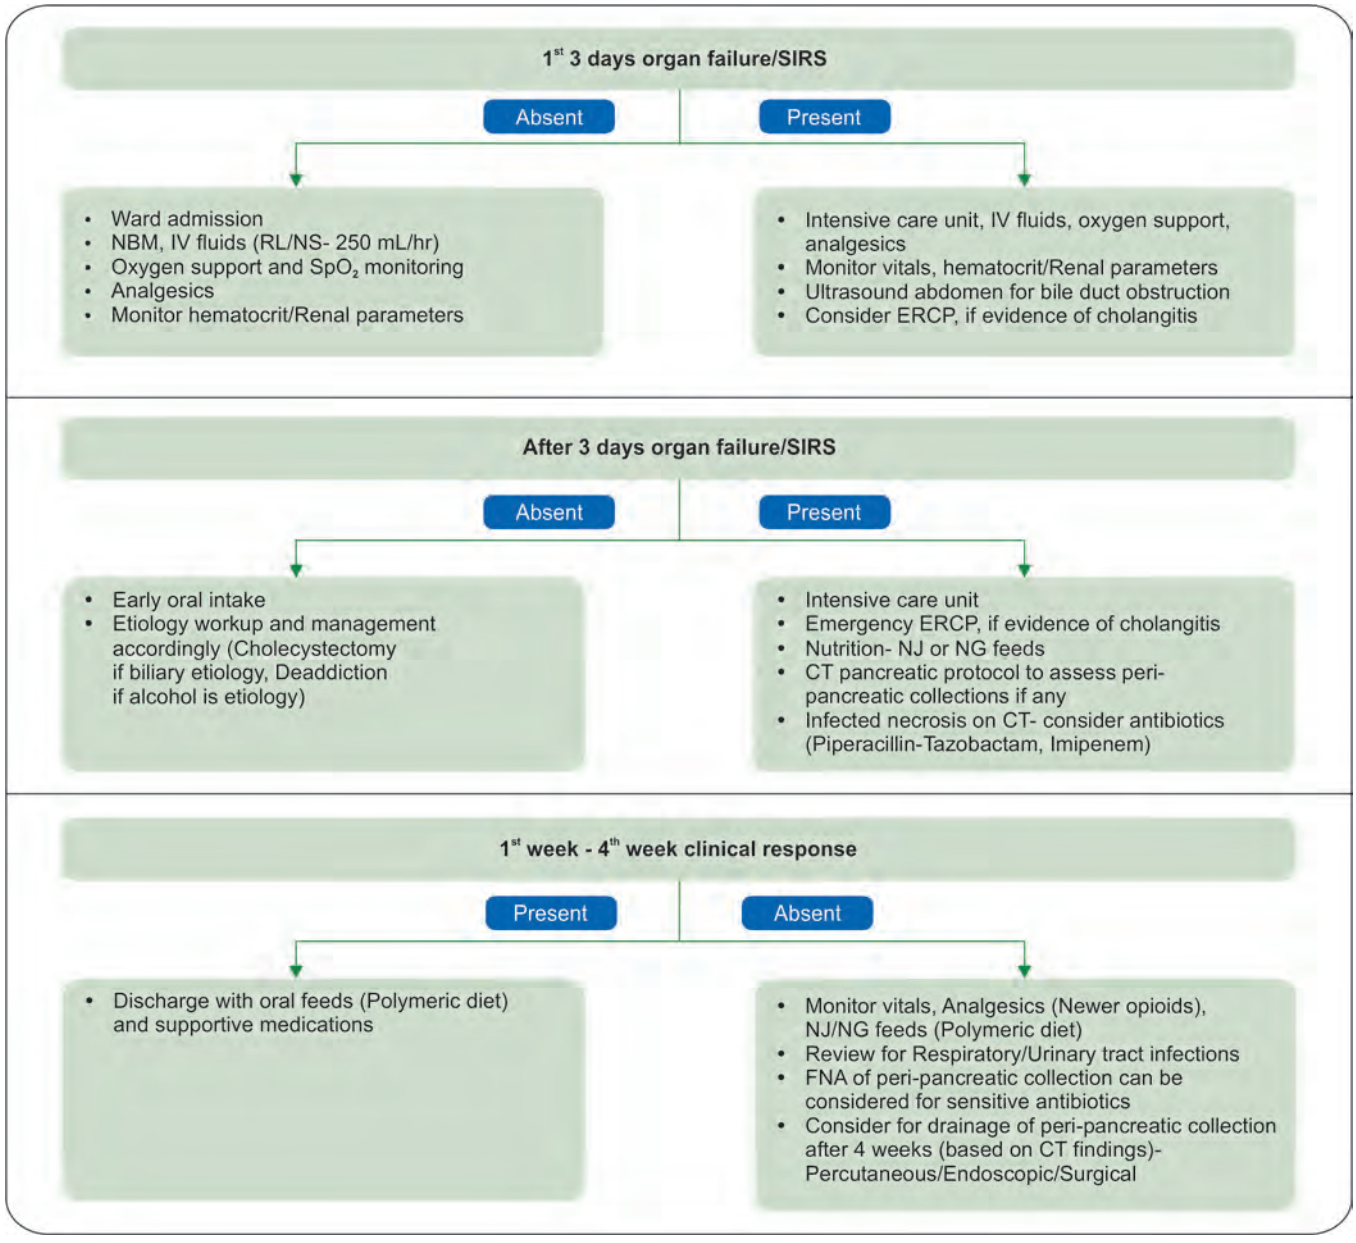
Abdominal pain is the presenting and distressing symptom in patients with AP. Effective and successful analgesia is an important component of the management of AP. An added desirable effect of the analgesic could be its impact on the underlying inflammatory process. Both opioid analgesics and nonsteroid anti-inflammatory agents (NSAIDs) have been used in patients with AP for pain relief. However, the evidence for their efficacy and safety profile is limited. The concern with NSAIDs is adverse events such as gastrointestinal bleeding and acute kidney injury. Opiates have shown by a randomized controlled trial to have better analgesic effect and safety profile compared to NSAIDs[3] for AP. Nalbuphine (an opioid with μ receptor antagonism) is a latest armamentarium useful for AP pain.

Fluid Resuscitation—Importance of Intravenous Hydration

Multiple factors are responsible for often causing hypovolemia in patients affected by AP, such as vomiting, third space loss, decreased oral intake, diaphoresis, and increased respiratory losses. Besides, inflammation of pancreas causes pancreatic edema and microcirculatory effects causing decreased blood flow, which in turn causes cell death, pancreatic tissue necrosis and pancreatic enzymes release, activating further numerous inflammatory cascades.

In AP, there is a median fluid loss of 3.2 liters.[4] The fluid should be given as 15–20 mL/kg bolus dose followed by 1.5–3 mL/kg/hour, depending on the response for the first 12–24 hours. Although the most effective approach to early fluid resuscitation has yet to be determined, studies have suggested that lactated Ringer's maybe the preferred solution for initial hydration.[5] Owing to its bicarbonate content and stable pH, this isotonic solution, when compared to normal saline, may prevent the development of metabolic acidosis, which can complicate care in patients receiving large-volume resuscitation using isotonic saline. Also, there are theoretical advantages in stabilizing the pancreas by preventing acidosis, which increases degranulation, enzyme release. The goal of fluid therapy is to achieve a mean arterial BP of minimum 70 mm Hg, hematocrit of 40–42, urine output—0.5–1 mL/min.[6] Monitoring of fluid therapy can be done using invasive methods like central venous pressure, stroke volume, arterial pressure wave-form, and noninvasive methods like IVC diameter: <1.5 cm or >50% index-deficit, lung ultrasound for fluid overload. Elderly patients and those with history of cardiac and/or renal disease should be taken carefully resuscitated.

Flowchart 1: Management of acute pancreatitis



CT, computerized tomography; ERCP, endoscopic retrograde cholangiopancreatography; FNA, fine needle aspiration; IV, intravenous; NBM, nil by mouth; NG, nasogastric; NJ, nasojejunal; SIRS, systemic inflammatory response syndrome[12]

Antibiotics—Role in AP Management

Routine use of prophylactic antibiotics in patients with mild AP and also severe AP is not recommended. Also, in patients having sterile necrosis, the use antibiotics to prevent the evolution of infection is not recommended. After 7–10 days of hospital stay, in patients with lack of improvement and having persistent fever and increasing WBC counts, infected pancreatic or peripancreatic necrosis should be suspected. Serum procalcitonin may be helpful as a useful marker. In these patients, there are two ways to manage: (a) CT-guided fine needle aspiration (FNA) with culture sensitivity can be used to start suitable

antibiotics, or (b) Empirical use of antibiotics can be done after obtaining necessary blood or urine culture sensitivity for disease causing agents, without CT-guided FNA. Infected necrosis warrants use of antibiotics which can penetrate the necrosis, such as carbapenems, quinolones, and metronidazole, as per the local pattern of sensitivity of organisms. Timely use of antibiotics in such cases can delay or sometimes avoid interventions, hence reducing morbidity and mortality. Evidence of extra-pancreatic infections like urinary tract infections, cholangitis, catheter-acquired infections, bacteremia, and pneumonia necessitates antibiotics. Routinely antifungal agents along with antibacterial agents (used for prophylaxis or treatment) are not recommended.

Nutrition in AP

Traditionally patients having AP were kept nil per mouth (NPO) to theoretically provide rest to the organ. Multiple experimental and clinical studies have subsequently shown that bowel rest causes mucosal atrophy and increases infectious complications due to bacterial translocation from the gut. Also, studies have shown that early enteral feeding in the course of AP reduces hospital stay, and hence decreased morbidity. In mild AP, if there is absence of vomiting, and if abdominal pain has improved, oral feeds should be started as soon as possible. Oral feeds in mild AP are introduced as a low-fat, low-residue, light diet as the patient improves clinically. Polymeric feeds (feeds containing all major nutrients) are preferred consisting of 25–30 kcal/kg with 1.2–2 gm/kg protein. In mild as well as severe AP, total parenteral nutrition ideally should be avoided as it increases chances of infectious complications and other peripheral or central line-related complications.

Use of nasogastric tube for enteral nutrition appears to be safe; however, the use of nasojejunal tube is typically preferred to avoid gastric phase of pancreatic stimulation. Nasogastric tube placement is far easier compared to the nasojejunal tube (requires fluoroscopic guidance for placement and is expensive), which is advantageous for patients in intensive care unit (ICU) treatment. In patients presenting as severe AP, on initial assessment, should be started on enteral tube feeding as a part of primary therapy. In the late phase of AP (2^{nd}–3^{rd} week) maintaining nutrition is critical, the target should be to provide 1500–2000 kcal diet.

Endoscopic Retrograde Cholangiopancreatography (ERCP)–Role in AP

As per the latest recommendations, patients with concurrent AP and acute cholangitis with high clinical suspicion of choledocholethiasis should undergo ERCP with biliary stenting within 24 hours of admission as a therapeutic procedure. Usually, in patients with gallstone pancreatitis who lack laboratory or clinical evidence of ongoing biliary obstruction, magnetic resonance cholangiopancreatography (MRCP) or endoscopic ultrasound (EUS) rather than ERCP should be used to screen for choledocholithiasis.

Also, ERCP on one hand, it can be a therapeutic modality for biliary pancreatitis, while on the other hand, it can be an important and preventable etiology of AP. The risk of post-ERCP pancreatitis is around 5%. Three methods to reduce the risk of post-ERCP pancreatitis, especially severe AP include:

- Pancreatic duct stents
- Use of guidewire for cannulation
- Rectal NSAIDs (diclofenac suppository) pre-procedure.

Infected Pancreatic Necrosis

The step-up approach is recommended with conservative treatment in ICU 1^{st} followed by percutaneous drainage, which is followed by minimally invasive necrosectomy.[7,8] Primarily conservative management results in mortality comparable to surgery in patients with infected pancreatic necrosis.[9] If necrosectomy is required, endoscopic step-up approach should be preferred.[10,11]

Conclusion

The diagnosis and optimal management of AP requires a systematic approach and multidisciplinary decision-making. Regardless of pancreatitis severity, recommended medical management includes goal-directed intravenous fluid resuscitation, early enteral feeding, avoidance of antibiotics as prophylaxis and urgent ERCP for patients with acute biliary pancreatitis complicated by cholangitis. Hence to conclude the first 24–48 hours are critical, and hence triaging of these patients on first presentation to hospital is an important approach to enable appropriate level of care.

CHAPTER

127 Functional Gastrointestinal Disorders

Uday C Ghoshal

Abstract

Functional gastrointestinal disorders (FGIDs), common problems in GI practice, are diagnosed by symptom-based criteria, such as the most recent iteration by the Rome Foundation, called Rome IV criteria and limited laboratory investigations. However, in presence of alarm symptoms, which may suggest presence of organic diseases, more thorough investigations may be needed. Different FGIDs may overlap in a single patient. The two common subtypes of FGIDs, such as irritable bowel syndrome (IBS) and functional dyspepsia (FD), are elaborated in this chapter. Treatment of FGIDs would depend on its subtypes, such as diarrhea- or constipation-predominant IBS or epigastric pain and postprandial distress syndrome subtypes of FD. The treatment also depends on severity of the condition, presence of psychological comorbidity, biological factors, etc.

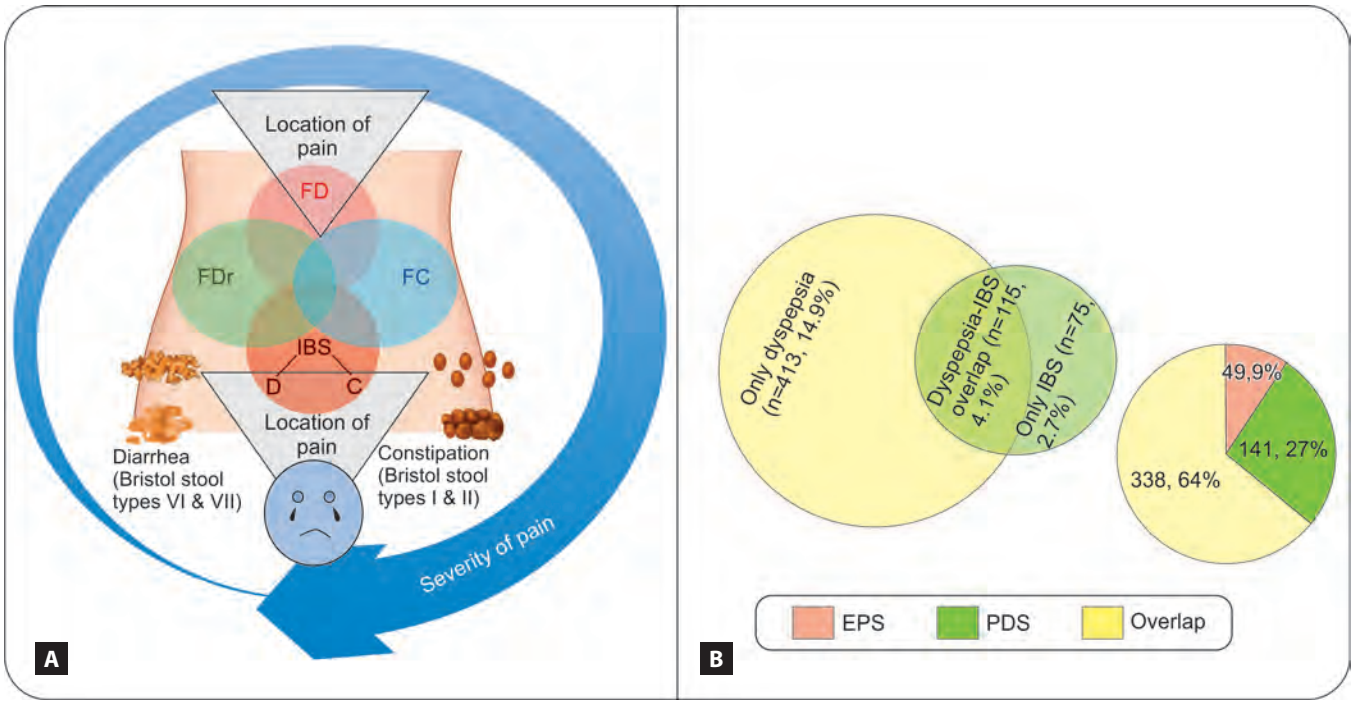
Introduction

Physicians and Gastroenterologists often encounter patients with functional gastrointestinal disorders (FGIDs) in their clinical practice. Patients with FGIDs are diagnosed based on the symptom-based criteria. FGIDs are characterized by the presence of chronic gastrointestinal (GI) symptoms (at least during the last 3 months with onset at least 6 months previously) in the absence of identifiable structural lesions explaining these symptoms on investigations including GI endoscopy.[1] It is, however, noteworthy that though the routine investigations, including GI endoscopy, do not pick-up organic lesions in patients with FGIDs, more sensitive tests may pick-up subtle structural abnormalities and molecular aberrations that may explain their symptoms. Hence, in the recent time, it has been considered that many of these disorders may be "micro-organic" in nature, challenging the concept that these disorders are entirely functional or psychogenic.[1,2] Rome Foundation, which formulates diagnostic and treatment algorithm for FGIDs, released its fourth iteration of Rome criteria in April 2016.[3] Experts of Rome Foundation correctly decided to underscore term "functional" and consider the gut to be more important than brain in the pathogenesis; hence, the new name for these disorders has been "Disorders of Gut-brain Interaction (DGBI)."[3]

FGIDs are chronic disorders that are not fatal but cause considerable impairment of quality of life, work absenteeism, burden to the society, health care, economy, and family. Considering the high frequency of these disorders in the global population, the magnitude of the problem of FGIDs cannot be underestimated. Hence, knowledge about the diagnosis and management of these disorders at primary and secondary care settings are essential issues that need to be deliberated. Accordingly, this chapter will briefly discuss the current classification of FGIDs, and the diagnostic criteria, and management of common forms of FGIDs, for example, irritable bowel syndrome (IBS) and functional dyspepsia (FD). The current classification of FGIDs (Rome IV) is presented in **Table 1**.[1,3]

TABLE 1 Different categories of functional gastrointestinal disorders according to the most recent iteration of Rome Foundation (Rome IV classification)

Esophageal disorders	
• Functional chest pain • Functional heartburn • Reflux hypersensitivity	• Globus • Functional dysphagia
Gastroduodenal disorders	
• Functional dyspepsia – Postprandial distress syndrome (PDS) – Epigastric pain syndrome • Belching disorders – Excessive supragastric belching – Excessive gastric belching	• Nausea and vomiting disorders – Chronic nausea vomiting syndrome (CNVS) – Cyclic vomiting syndrome (CVS) – Cannabinoid hyperemesis syndrome (CHS) • Rumination syndrome
Bowel disorders	
• Irritable bowel syndrome (IBS) – IBS with predominant constipation (IBS-C) – IBS with predominant diarrhea (IBS-D) – IBS with mixed bowel habits (IBS-M) – IBS unclassified (IBS-U)	• Functional constipation • Functional diarrhea • Functional abdominal bloating/distension • Unspecified functional bowel disorder • Opioid-induced constipation
• ***Centrally mediated disorders of gastrointestinal pain***	
• Centrally mediated abdominal pain syndrome (CAPS)	• Narcotic bowel syndrome (NBS)/opioid-induced GI hyperalgesia
Gallbladder and sphincter of oddi (SO) disorders	
• Biliary pain – Functional gallbladder disorder – Functional biliary SO disorder	• Functional pancreatic SO disorder
Anorectal disorders	
• Fecal incontinence • Functional anorectal pain – Levator ani syndrome – Unspecified functional anorectal pain – Proctalgia fugax	• Functional defecation disorders – Inadequate defecatory propulsion – Dyssynergic defecation
Childhood functional GI disorders: Neonate/Toddler	
• Infant regurgitation • Rumination syndrome • Cyclic vomiting syndrome (CVS) • Infant colic	• Functional diarrhea • Infant dyschezia • Functional constipation
Childhood functional GI disorders: Child/Adolescent	
• Functional nausea and vomitting disorders – Cyclic vomiting syndrome (CVS) – Functional nausea and functional vomiting ♦ Functional nausea ♦ Functional vimiting – Rumination syndrome – Aerophagia	• Functional abdominal pain disorders – Functional dyspepsia ♦ Postparandial distress syndrome ♦ Epigastic pain syndrome – Irritable bowel syndrome (IBS) – Abdominal migraine – Functional abdominal pain - NOS • Functional defecation disorders – Functional constipation – Nonretentive fecal incontinence



Figs. 1A and B: (A) Overlap between common functional gastrointestinal disorders (*Source:* Reproduced from Reference 4). (B) Summary of results from in Indian rural community study showing overlap between IBS, dyspepsia and different subtypes of dyspepsia (For the data in details, see Reference 5)
C, constipation-predominant; D, diarrhea-predominant; EPS, epigastric pain syndrome; FC, functional constipation; FD, functional dyspepsia; FDr, functional diarrhea; IBS, irritable bowel syndrome; PDS, postprandial distress syndrome

In the above classification, the different FGIDs are considered as pure disorders. However, in practice, more than two-thirds of patients present overlapping symptoms of multiple FGIDs. The various categories of bowel disorders such as IBS, functional diarrhea, and functional constipation often overlap with upper GI disorders such as FD and gastroesophageal reflux disease **(Fig. 1A)**.[4] In an earlier study on 3,426 adult population of rural northern India, overlap of FD-IBS was commoner (4.1%) than IBS alone (2.7%) though FD was the most common form of FGID (15%; **Fig. 1B**).[5] Overlap disorders often have a more severe illness, may require combination treatment, and may have a worse prognosis.[6] In this chapter, the diagnosis and treatment of two common FGIDs (FD and IBS) are briefly discussed. It is important to note that several management principles of pure FGIDs, such as those of FD and IBS, would apply to overlap disorders. For example, a patient with constipation-predominant IBS and postprandial distress syndrome subtype of FD is expected to benefit from treatment with a pan-GI prokinetic drug such as prucalopride along with fundic relaxant such as acotiamide.

Functional Dyspepsia

"Dyspepsia" is a Greek word that refers to "bad digestion." As per Rome IV criteria, FD is diagnosed using the symptom-based criteria that are listed in **Table 2**.[7] However, if a patient fulfills the symptom-based criteria, he should be considered as having uninvestigated dyspepsia. Subsequently, a few investigations, including upper GI endoscopy, are required before a diagnosis of FD is made. However, in the absence of alarm features discussed later in this chapter, even an empirical trial of drug-treatment may be instituted after due consideration by the physician on a case-to-case basis. A firm diagnosis of FD, however, requires an upper GI endoscopy. Though currently, most international recommendation warrant tests for *Helicobacter pylori* and its eradication, if present, its universal acceptability in the Indian scenario is subject to debate based on the limited available data **(Flowcharts 1A and B)**.[7]

TABLE 2 Rome IV criteria for the diagnosis of functional dyspepsia (FD)[7]

Functional dyspepsia
Diagnostic criteria 1. One or more of the following: a. Bothersome postprandial fullness b. Bothersome early satiation c. Bothersome epigastric pain d. Bothersome epigastric burning
No evidence of structural disese (including at upper endoscopy) that is likely to explain the symptoms

Must fulfill criteira for PDS and/or EPS.
Criteria fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

Epigastric pain syndrome (EPS) and postprandial distress syndrome (PDS) are the two subtypes of FD. In practice, however, patients rarely present with pure EPS or PDS, but most patients have overlapping symptoms. The criteria, as suggested by the Rome IV Committee for diagnosis of EPS and PDS, are presented in **Table 3**.[7]

Management of FD

Management of the patients with dyspepsia as per the Rome IV system is presented in **Flowcharts 1A and B**. One must not forget to look for alarm features (age >45 years, history of GI bleeding, weight loss, family history of gastric cancer, anemia, etc.). Patients with a history of alarm features must undergo thorough investigations including upper GI endoscopy and CT scan of the abdomen (in patients with a family history of gastric cancer and a high degree of clinical suspicion of gastric cancer) before considering dyspepsia to be functional.[7] It is also important to note that the age cut off of 45 years may vary depending on the local epidemiology of gastric cancer. International societies, including experts in the Rome IV committee, suggested that *H. pylori* infection, if present on appropriate testing, should preclude the diagnosis of FD. If eradication of infection improves dyspeptic symptoms, the condition should instead be called *H. pylori*-associated dyspepsia.[7] The applicability of this international guideline in India, however, may be viewed with skepticism. Though Indian literature on this issue is scanty, yet considering the high frequency of *H. pylori* infection in Indian adults, this strategy may not be practicable. Treatment of FD depends on its subtype. Whereas EPS, an uncommon subtype is treated with proton pump inhibitors and when unresponsive, antidepressants, PDS is treated with prokinetics, fundic relaxants, and psychotropic agents. Overlap syndrome is treated with combined therapeutic agents. **Table 4** lists the drugs available currently in the Indian market for the treatment of two subtypes of FD.[7]

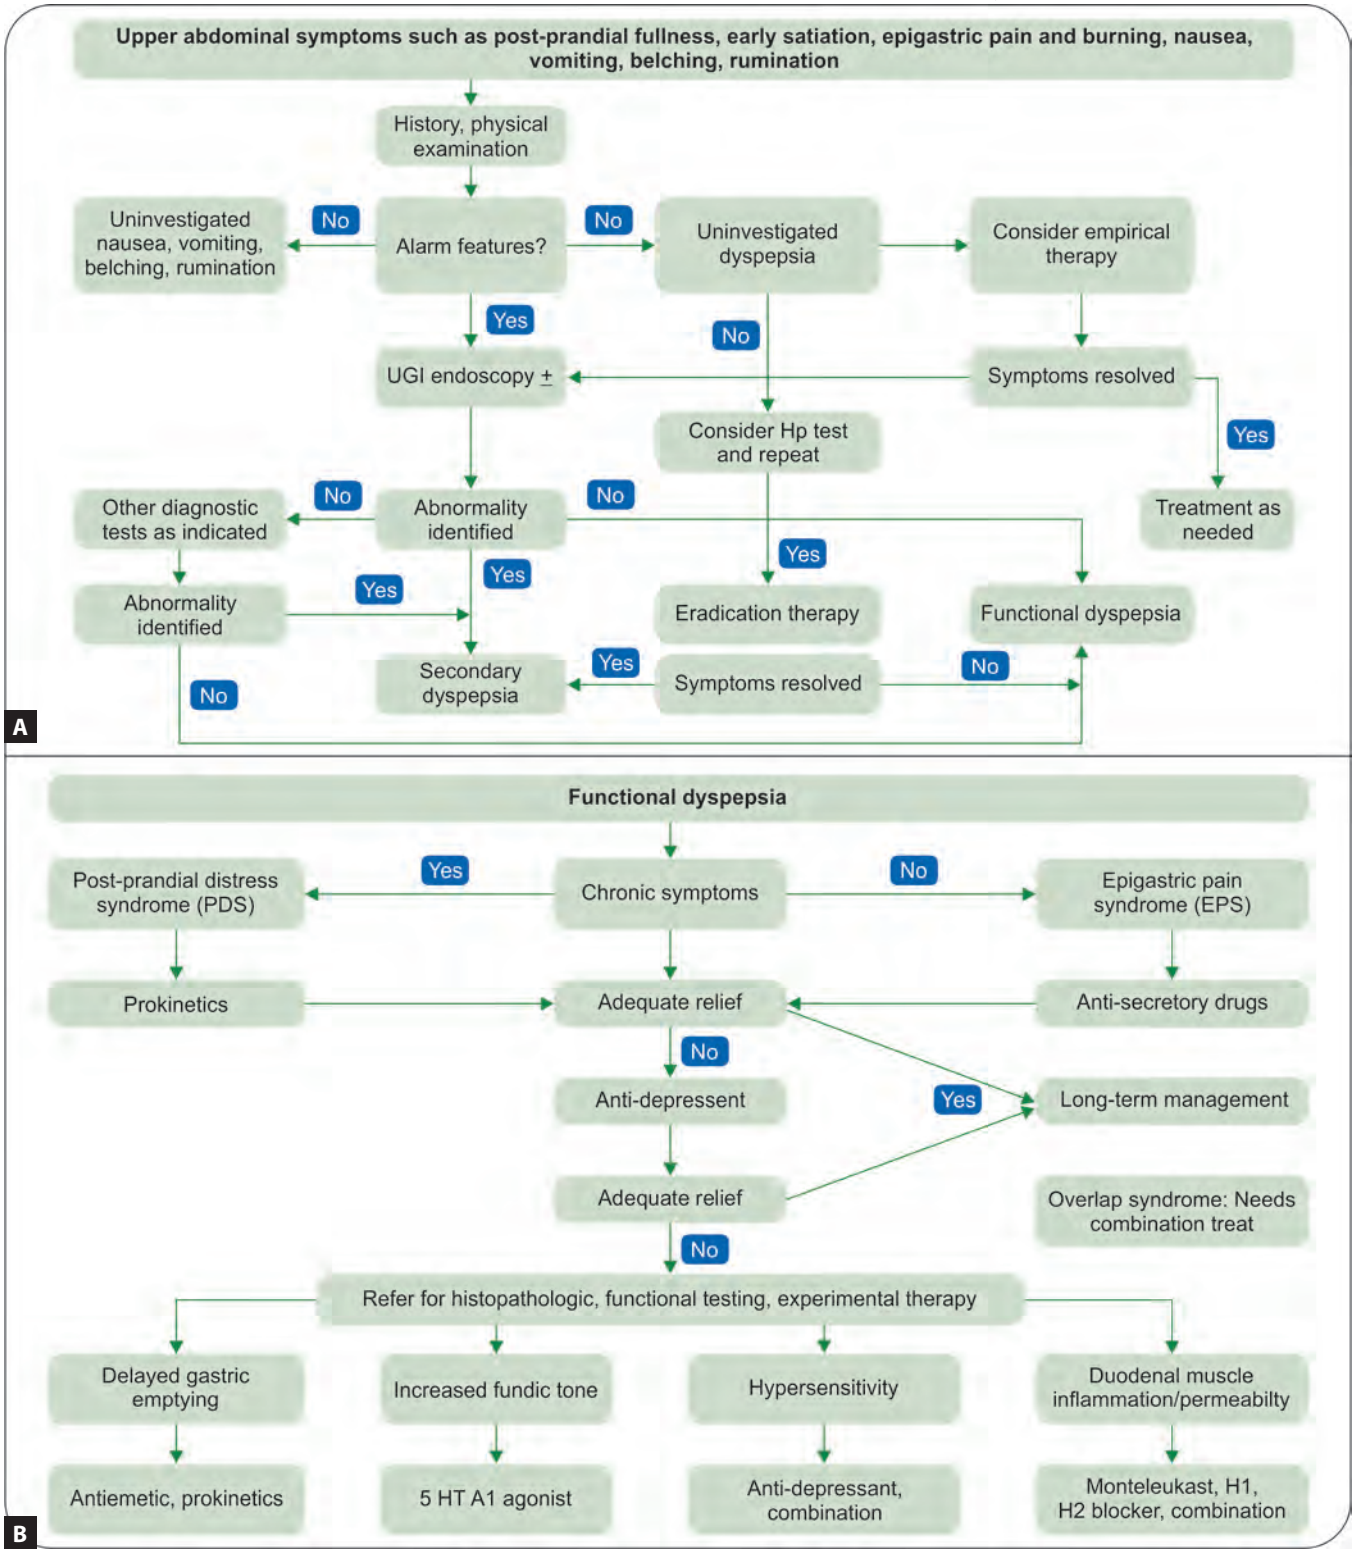
Irritable Bowel Syndrome

Diagnosis of IBS

IBS is one of the common FGIDs seen in clinical practice both by the Gastroenterologists and the Physicians. IBS was variously called earlier, albeit inappropriately, as spastic colitis, chronic amebiasis, etc. In the past, the diagnosis of IBS could only be made once extensive investigations failed to find a cause for the chronic lower GI symptoms. Manning and Thompson, for the first time, introduced the criteria-based diagnosis of IBS in 1978.[8] Since then, the Rome Foundation brought in several iterations of Rome criteria for the diagnosis of IBS. Manning's criteria **(Box 1)** encourage a positive diagnosis of IBS without the need for multiple unnecessary investigations to exclude organic diseases before diagnosing IBS.[8]

However, it is essential to note that in the study by Manning and Thompson, organic disorders excluded were peptic ulcer disease, inflammatory bowel disease, gastroesophageal reflux disease, gallstones, and carcinoma of the colon and not the conditions which closely mimic IBS such as lactose intolerance, celiac disease, microscopic colitis, small intestinal bacterial overgrowth, fecal evacuation disorder, collagenous colitis and microscopic, etc.[2,8] Hence, over-reliance on such symptom-based criteria to exclude every organic disorder (some of which are rather micro-organic) may result in overlooking such conditions. Another limitation of the Manning criteria is the lack of due consideration for the duration of symptoms. As some of the organic disorders are expected to have a short duration of symptoms, the importance of time of illness cannot be overestimated. However, despite these limitations, Manning's criteria remain quite useful and popular in practice not only among Gastroenterologists but also among Physicians. In addition to the higher sensitivity of Manning's criteria as compared to the various iteration of Rome criteria in India,[4] the simplicity of the former is a significant reason for its popularity.

Flowcharts 1A and B: Rome IV algorithm for management of functional dyspepsia



Bx, biopsy; Hp, *helicobacter pylori*; UGI, upper gastrointestinal

TABLE 3 Rome IV criteria for the diagnosis of epigastric pain and postprandial distress syndromes[7]

Postprandial distress syndrome

- *Diagnostic criteria:* Must include one or both of the following at least 3 days per week:
  - Bothersome postprandial fullness (i.e., severe enought to impact on usual activities)
  - Bothersome early satiation (i.e., severe enough to prevent finishing a regular-size meal)
- No evidence of organic, systemic, or metabolic disease that is likely to explain the symptoms on routine investigations (including at upper endoscopy)

[a]Criteria fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis

- Supportive remarks
  - Postprandial epigastic pain or burning, epigastric bloating excessive belching, and nausea can also be present
  - Vomiting warrants consideration of another diorder
  - Heartburn is not a dyspeptic symptom but may often coexist
  - Symptoms that are relieved by evacuation of feces or gas should generally not be considered as part of dyspepsia
- Other individual digestive symptoms or gourps of symptoms, e.g. from gastroesophageal reflux disease and the irritable bowel syndrome may coexist with PDS

Epigastric pain syndrome

- *Diagnositc criteria:*[a] Must include at least 1 of the following symptoms at least 1 day a week:
  - Bothersome epigastric pain (i.e., severe enough to impact on usual activities)

    AND/OR
  - Bothersome epigastic burning (i.e., severe enought to impact on usual activities)
- No evidence of organic systemic, or metabolic disease that is likely to explain the symptoms on routine investigations (including at upper endoscopy).

[a]Criteria fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis

- Supportive remarks
  - Pain may be induced by ingestion of a meal, relieved by ingestion of a meal, or may occur while fasting
  - Postprandial epigastric bloating, belching, and nausea can also be present
  - Persistent vomiting likely suggests another disorder
  - Heartburn is not a dyspeptic symptom but may often coexist
  - The pain does not fulfill biliary pain criteria
  - Symptoms that are relieved by evacuation of feces or gas generally should not be considered as part of dyspepsis
- Other digestive symptoms (such as from gastroesophageal refuls disease and the irritable bowel syndrome) may coexist with EPS

TABLE 4 Drugs available currently in Indian market for treatment of two subtypes of FD

Epigastric pain syndrome	***Postprandial distress syndrome***
• Omeprazole • Pantoprazole • Lansoprazole • Dexlansoprazole • Esomeprazole • Ilaprazole • Rabeprazole • Dexrabeprazole • Potassium competitive acid blocker	*Fundic relaxants* • Acotiamide • Buspirone • Mirtazapine *Prokinetics* • Metoclopramide • Domperidone • Mosapride • Itopride • Levosulpiride • Cinitapride • Prucalopride *Visceral neuromodulators*

TABLE 5 Rome IV criteria for IBS[9]

Recurrent abdominal pain, on average, at least 1 day per week in the last 3 months, associated with two or more of the following criteria:

- Related to defecation
- Associated with a change in frequency of stool
- Associated with a change in form (appearance) of stool

Criteria fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis

BOX 1 The Manning criteria that suggest a positive diagnosis of irritable bowel syndrome if any four of the listed six symptoms are present[8]

- Onset of pain associated with more frequent bowel movements
- Onset of pain associated with more loose bowel movements
- Relief of pain with defecation
- Abdominal distension
- Sense of incomplete evacuation
- Passage of mucus

Currently, Rome IV criteria **(Table 5)**, developed after several iterations through Rome I, II, and III criteria, are used to diagnose IBS.

Alarm Features

Alarm features also called "red flags," suggest the possible presence of an organic disease warranting investigations

before the diagnosis of IBS is made. Alarm features include the age of onset at or more than 45 years, anemia, blood in the stools, unintended weight loss, nocturnal symptoms, fever, abdominal mass, and a family history of colorectal cancer. As mentioned earlier, the age cut off of 45 years may vary depending on the local epidemiology of gastric cancer.

For clinical trials, all patients should have at least full blood counts, erythrocyte sedimentation rate, C-reactive protein, and limited colonoscopic examination, and other investigations, if indicated.[9]

BOX 2 Multidimensional clinical profile in functional gastrointestinal disorders[10]

- Categorical diagnosis (symptom-based criteria)
- Clinical modifier (e.g., IBS-C, D, M, post-infectious, FODMAP sensitive)
- Impact (mild, moderate, severe)
- Psychosocial modifier
- Physiological dysfunction and biomarker

IBS: irritable bowel syndrome, FODMAP: fermentable oligo- di-monosaccharides and polyols.

Multidimensional Clinical Profile

There has been a significant paradigm shift in the management of FGIDs after the introduction of a multidimensional clinical profile (MDCP) in the Rome IV algorithm in 2016. Currently, experts, including the author, are in the process of generating a plausibility consensus in relation to organic issues on FGIDs. According to MDCP, in addition to assigning the patients to a diagnostic category, it is essential to evaluate the patients as a whole rather than only a diagnostic label. Sir William Osler wrote that it is better to treat the patient who has the disease rather than treating the disease. MDCP necessitate the physician to assess several critical issues in addition to the categorical diagnosis of FGIDs such as IBS **(Box 2)**.[10]

A component of MDCP includes subtyping **(Fig. 2)** of FGIDs; for example, constipation-predominant or diarrhea-predominant IBS (IBS-C, and IBS-D, respectively), EPS or PDS subtypes of FDF, etc. As described in the treatment of these disorders, such subtyping is the cornerstone for the choice of appropriate drugs to treat these disorders.[9] Moreover, those with alternating (change in symptoms over weeks to months) and mixed type is more difficult to treat and may require pathophysiology modifying measures such as an attempt at manipulating gut microbiota.

Table 6 and Figure 3 list the biological factors that may contribute to two subtypes of IBS, namely diarrhea-predominant and constipation-predominant IBS.[4]

Treatment

In addition to pharmacological treatment, dietary modification (low FODMAP diet) and management of psychological issues may help in relieving symptoms and improving the quality of life. To address these issues, dieticians and psychologists are essential members of the team to manage these patients. Treatment would depend on the predominant symptoms: diarrhea, constipation, or pain/gas/bloat **(Figure 3, Table 7)**.[4]

Initial treatment for patients with IBS should include various combinations of antispasmodic, laxative, and antidiarrheal agents as they are quite safe and relatively inexpensive.[12] Antispasmodics, which reduce abdominal pain by reducing muscle spasm, include antimuscarinics, smooth-muscle relaxants, and anticholinergics.[12] Common adverse effects include dry mouth, dizziness, blurred vision, confusion, urinary retention, and constipation, which are associated with anticholinergics. Bulking agents are commonly prescribed drugs, especially for IBS-C.[12] However, bulking agents may even aggravate abdominal pain and bloating.[12] For the control of diarrhea, loperamide has the best quality of evidence but has not been shown to improve abdominal pain or distension.

Several visceral neuromodulators, which also have central nervous system effect, such as tricyclic antidepressants, serotonin reuptake inhibitors (SSRI), and serotonin-norepinephrine reuptake inhibitors (SNRI), relieve abdominal pain, diarrhea, insomnia, and depression. These drugs are useful in the treatment of IBS even in the absence of psychiatric illness.[12] Another approach to treating IBS is psychotherapy.[12] Aims of psychotherapy include reframing maladaptive beliefs, reduction of over-responsiveness to stress, reduction of maladaptive psychological responsiveness, and modification of maladaptive behaviors. Hypnotherapy is one of the essential tools in psychotherapy. The essence of hypnotherapy is to create a relaxing and calming environment and allowing the patient to refocus away

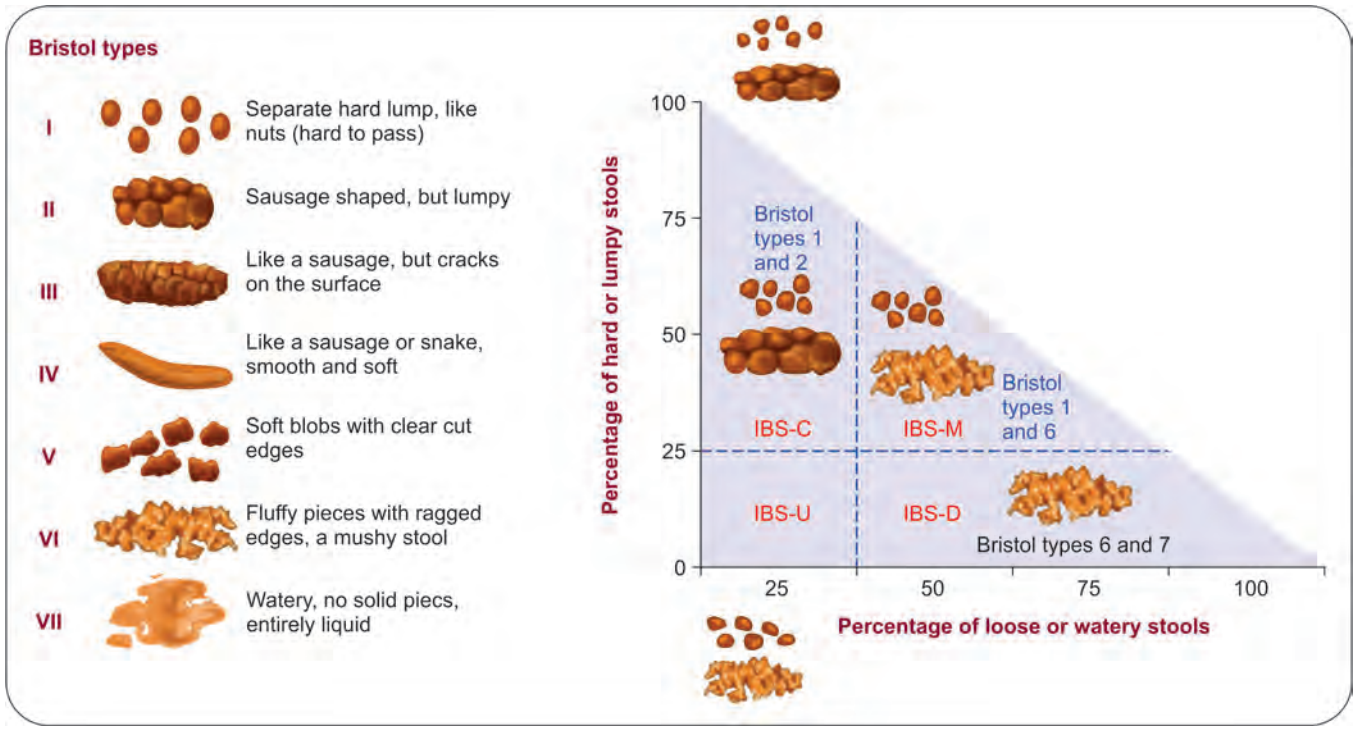


Fig. 2: Bristol stool types and method of sub-typing of IBS according to Rome IV system. IBS subtypes should be established according to stool consistency, using the Bristol stool form scale. Whether 25% of the stools are constipating types (I and II) or 25% of the stools are diarrheal types (VI or VII) determine IBS subtypes according to Rome IV criteria

TABLE 6 Different physiological factors that may cause or exacerbate symptoms of patients with two subtypes of irritable bowel syndrome[4]

Types of IBS	*Contributing physiological dysfunctions*
Constipation-predominant IBS	• Fecal evacuation disorder • Slow transit
Diarrhea-predominant IBS	• FODMAP sensitivity including lactose or fructose intolerance • Bile acid malabsorption • Non-celiac wheat sensitivity • Small intestinal bacterial overgrowth • Post-infectious

IBS: irritable bowel syndrome, FODMAP: fermentable oligo- di-monosaccharides and polyols.

from uncomfortable symptoms and toward a more pleasant perception of his or her current state. There is little evidence for the efficacy of such an approach in IBS. The major drawback of hypnotherapy is the requirement of well-trained mental health professional.

Another novel approach to the treatment of IBS is targeting the gut microbiota dysbiosis and small intestinal bacterial overgrowth (SIBO). Rifaximin, a broad-spectrum poorly absorbed antibiotic, has been found useful in the treatment of non-constipating IBS.[13] Rifaximin works against Gram-negative bacteria, Gram-positive bacteria, and anaerobes and also has anti-inflammatory activity. In the famous TARGET study, a 2-week treatment with rifaximin (550 mg thrice daily) resulted in 41% non-constipating IBS patients reporting improvement as compared to 30% placebo-treated patients.[13] However, symptoms recur in most patients within 2–3 months. This study is essential as it brings a novel concept of treating a "functional disorder," which is now believed to result from altered gut microbiota, with an antibiotic.

Dietary modification is an essential component of the treatment of patients with IBS. Symptoms exacerbation due to intolerance to different nutritional ingredients is not uncommon among patients with FGIDs, including IBS. Worsening of symptoms following intake of curry and

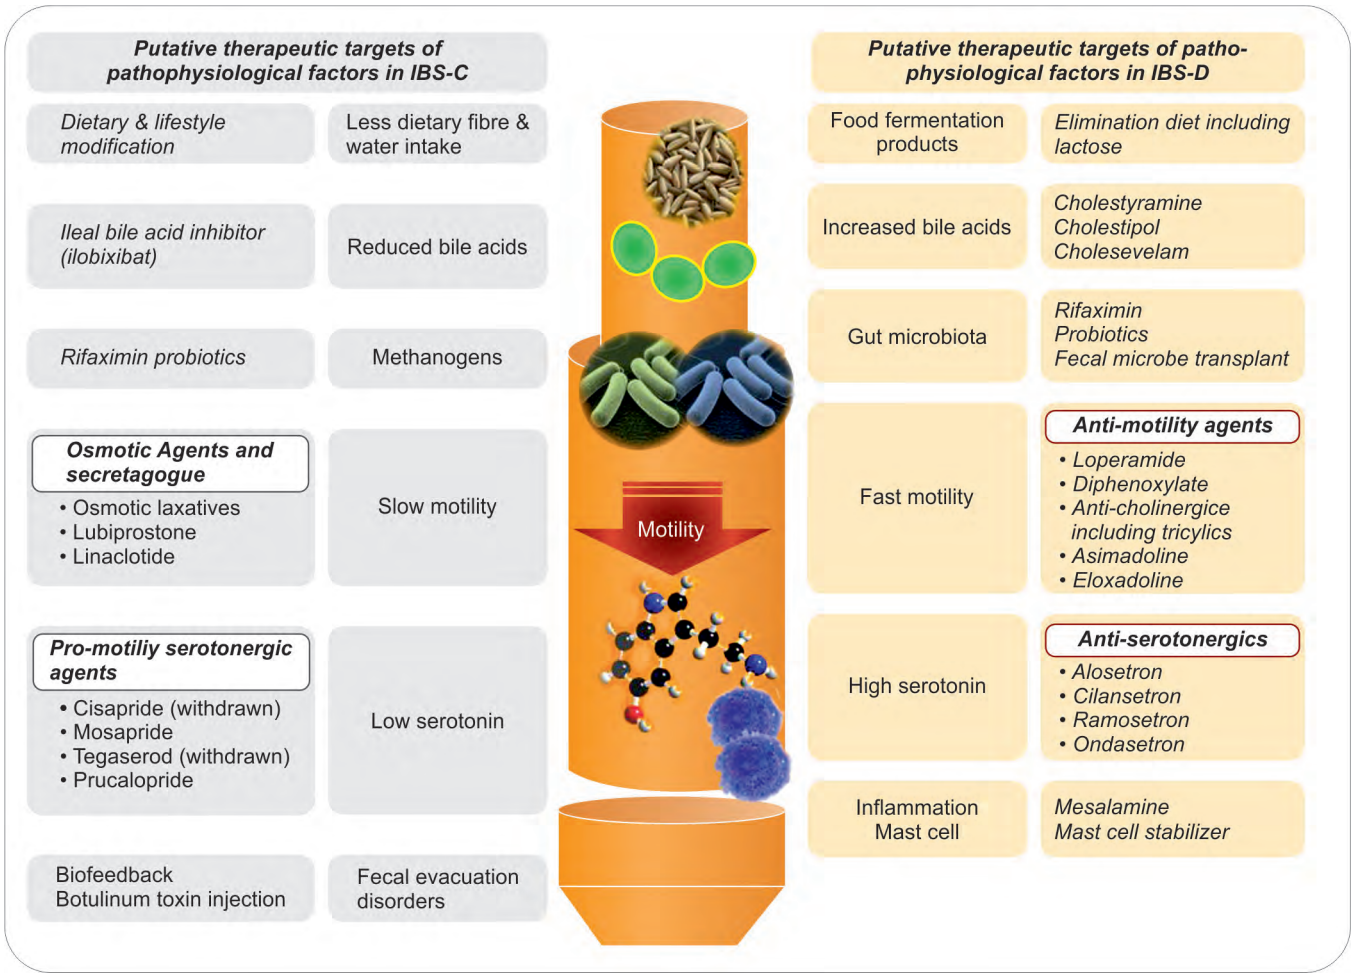

Figure 3: Pathophysiological mechanisms of constipation and diarrhea-predominant irritable bowel syndrome (IBS-C and D) and possible therapeutic agents to target these abnormalities. It is important to note that the therapeutic agents work in functional constipation and IBS-C and functional diarrhea and IBS-D comparably
(*Source:* Reproduced from Reference 4)

TABLE 7 Current symptom-based management of irritable bowel syndrome[11]

Symptom	*First line*	*Second line*	*Future*
Constipation	• Fiber • Osmotic laxative, including polyethylene glycol • Lactulose/Lactitol • Stool softener, e.g., docusate	• Bisacodyl • Sodium picosulfate • Tegaserod (withdrawn) • Lubiprostone • Linaclotide • Prucalopride (5-HT4 agonist)	Elobixibat (ileal bile acid transporter inhibitor)
Diarrhea	• Loperamide • Diphenoxylate	• Alosetron • Ramosetron • Ondansetron • Bile acid sequestrant (cholestyramine, colestipol) • Rifaximin • Clonidine	
Bloating	Treat constipation	• Probiotic • Antibiotic (rifaximin)	
Pain		• Antispasmodics • Anticholinergics • Mebeverine • Pinaverium • Otilonium bromide • Antidepressant – Tricyclic antidepressants – SSRI – RI	

SSRI: serotonin re-uptake inhibitor, RI: reuptake inhibitor

chili is not unusual in Asia.[14,15] Though malabsorption of lactose is as common among patients with IBS as healthy subjects, the patients reported symptoms following the ingestion of this disaccharide than the controls, possibly due to visceral hypersensitivity. Lactose is a component of Fermentable Oligo-, Di-, Monosaccharide, and Polyol (FODMAP) foods. All the high FODMAP foods lead to pathophysiological effects, such as production of osmotically active substances, and gas causing flatulence, distension, and pain, somewhat similar to lactose, among the patients with IBS. Hence, avoidance of high FODMAP foods improves symptoms of IBS.[16] FODMAP diet chart is available from http://spreadhealth.in/New%20Folder/High%20&%20low%20FODMAP%20foods.pdf.

Conclusion

FGIDs, including IBS and FD, are common in medical practice. These disorders have multiple pathophysiological basis. Multimodality treatment directed to the subtypes and underlying pathophysiological factors is often successful in managing these patients.

CHAPTER

128 Variceal Bleed Management

Srikanth Gopi, Deepak Gunjan

Abstract

Variceal bleed is a clinically significant event in the natural history of cirrhosis, and provides opportunity to treat and correct the underlying cause in the first decompensation. With advancement in critical care, endoscopic variceal band ligation and use of vasoactive agents had improved the management of acute variceal bleed in last few decades. However, refractory variceal bleed is difficult to manage, requires specialized care, and has poorer prognosis. Transjugular intrahepatic portosystemic shunt (TIPS) is reserved for patients with high risk for treatment failure and refractory variceal bleed. Primary and secondary prophylaxis by non-selective beta blocker is another important development in the medical management of esophageal varices and variceal bleed.

Introduction

Upper gastrointestinal bleed (UGIB), one of the common medical emergencies, can be broadly divided into variceal and non-variceal UGIB. Varices are the abnormally dilated submucosal veins in gastrointestinal tract usually developed as a complication of portal hypertension to decompress the portal system. The collaterals gradually increase in size due to various factors and the most important factor is progressive rise in portal pressure and consequent increase in flow through these collaterals.

Approximately half of the patients with cirrhosis have esophageal varices and one-third of all the patients with varices will bleed in their natural course of the disease. In India, the proportion of patients with variceal bleed among all the cases of UGIB presenting to emergency varies widely between 12% and 55% based on region of study.[1] The esophageal varices are the most common source of variceal bleed followed by gastric varices. Cirrhosis is the most common cause of the variceal bleed in >90% of the cases. The overall 6-week rebleeding rate at 6 weeks is 24–30%,[2] whereas 6-week mortality of variceal bleed in cirrhosis is 12–22%.[3] The following sections will be the overview of the management of the esophageal variceal bleed in accordance with the recent guidelines.[4-6] We will not discuss the management of gastric and ectopic varices.

Risk Stratification (Fig. 1)

Cirrhosis can be stratified according to Child-Pugh-Turcotte (CTP) stage or MELD. Higher the score, more severe is the disease. For clinical point of view, it is broadly classified into compensated and decompensated cirrhosis, and later is characterized by variceal bleed, ascites, or hepatic encephalopathy. The higher the number of the decompensation events, the worse is the prognosis.

Hepatic venous pressure gradient (HVPG) ≥10 mm Hg is associated with clinically significant portal hypertension (CSPH), where esophageal varices start to appear; and HVPG >12 mm Hg is associated with bleeding risk. HVPG responders (reduction in HVPG by ≥20% of the baseline value or absolute HVPG <12 mm Hg by NSBBs) are associated with lower risk of rebleed; however, in routine

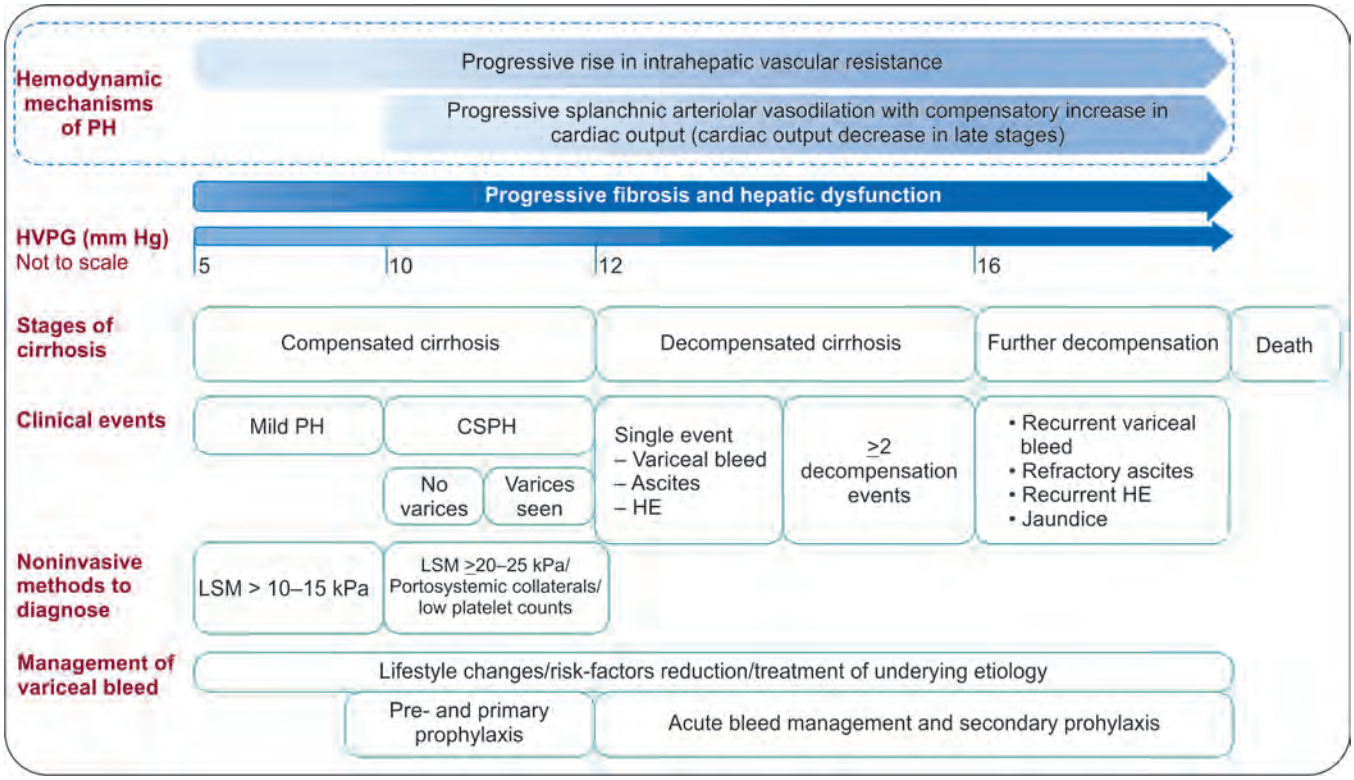

Fig. 1: Stages of cirrhosis, clinical events, and underlying hemodynamics in portal system (modified and adapted from AASLD 2016 Practice Guidance[4])
(CSPH, clinically significant portal hypertension; HE, hepatic encephalopathy; HVPG, hepatic venous pressure gradient; kPa, kilo Pascal; PH, portal hypertension)

clinical practice HVPG measurement is not feasible due to its cost and invasiveness.[4]

Management of Acute Variceal Hemorrhage (Flowchart 1)

Acute variceal hemorrhage (AVH) is to be suspected and treatment should be started immediately in all cases of UGI bleed in known cirrhotics or patient with high-risk of cirrhosis without waiting for the confirmation by endoscopy. The main cause of death in AVH is not uncontrolled bleeding, but due to additional decompensation and complications resulting from acute bleed. The management of AVH will be discussed here.

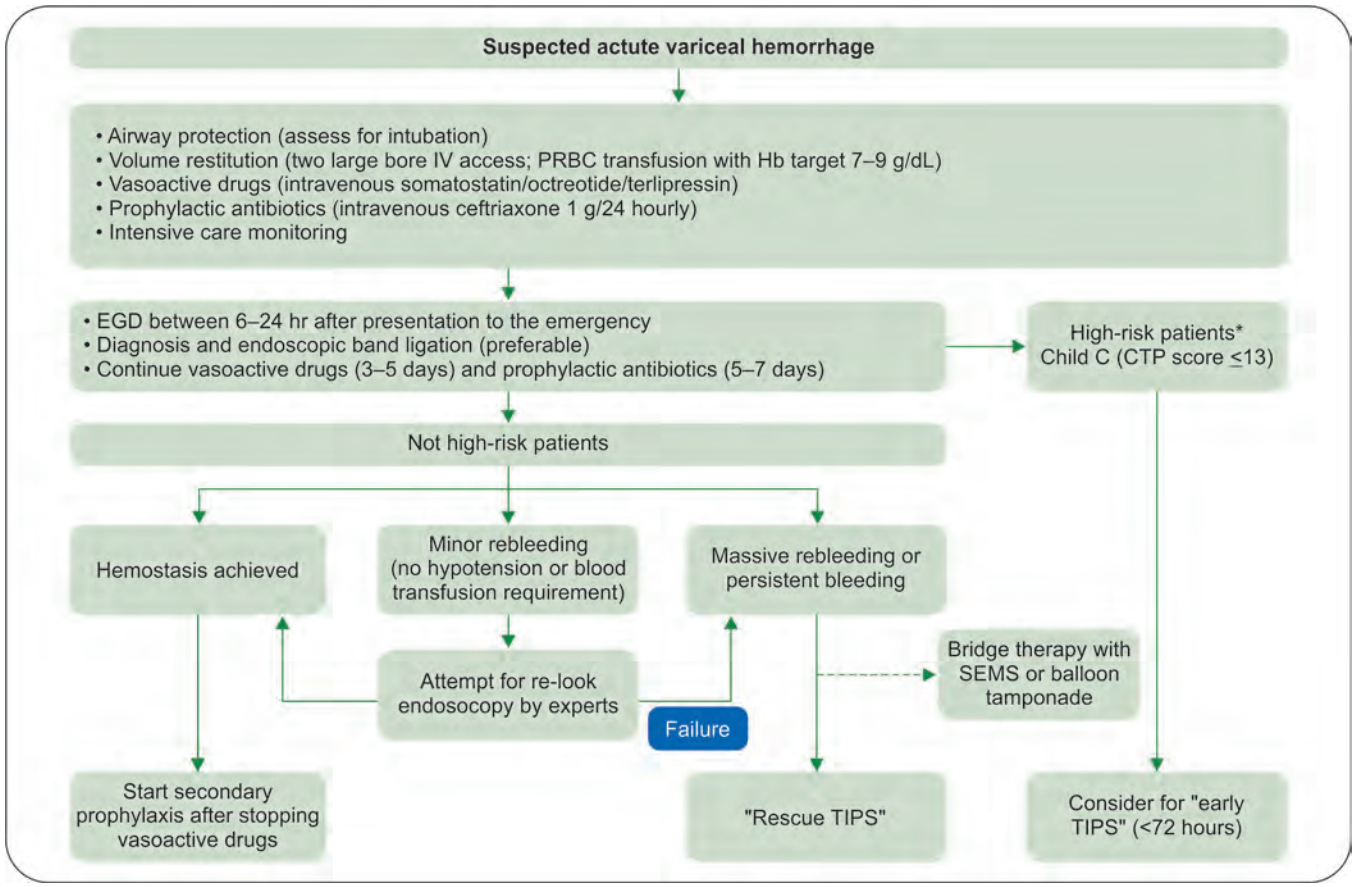
Immediate Management

Assessment of the airway and circulatory function should be done first and orotracheal intubation should be considered in any obtunded patient or in patients with massive hematemesis with high-risk of aspiration. Intravenous access with two large-bore cannula should be secured for careful volume resuscitation. Blood samples should be sent for complete blood counts, liver function test, blood urea and creatinine, and for cross-matching.

The volume resuscitation is done by the crystalloids; and a "restrictive" packed red blood cell (PRBC) transfusion strategy (i.e., target range for the post-transfusion hemoglobin level of 7–9 g/dL), which is associated with significant lower early rebleeding and mortality rates in patients with cirrhosis compared to liberal transfusion strategy.[7] However, cases with cardiovascular comorbidities, ongoing bleeding, and hemodynamic instability require higher hemoglobin target and it should be individualized considering the patient conditions.

In a recent randomized control trial, thromboelastography-guided blood-product transfusion strategy was associated with reduced blood-product transfusion to

Flowchart 1: Algorithm for acute variceal bleed management (adapted and modified from AASLD 2016 Practice Guidance[4])



(CTP, Child-Pugh-Turcotte; EGD, esophagogastroduodenoscopy; SEMS, self-expandable metallic stent; TIPS, transjugular intrahepatic portosystemic shunt)
*Baveno VI consensus and American Association for the Study of Liver Diseases guidelines also consider Child B cirrhosis with active bleed on endoscopy despite vasoactive drugs as high-risk patient.

correct coagulopathy without compromising hemostasis in cirrhotic patients.[2] There is no recommendation for use of platelet transfusion, intravenous vitamin K, or tranexamic acid to halt the acute ongoing variceal bleed. Transfusion of fresh frozen plasma or factor VIIa to correct INR is not recommended.[8]

Any one of the vasoactive drugs **(Table 1)** and antibiotic prophylaxis should be initiated at the earliest prior to esophagogastroduodenoscopy (EGD).[4] These vasoactive drugs cause splanchnic vasoconstriction and reduce the portal pressure. Even in patients on noradrenaline infusion for hypotension, one of the vasoactive drugs should be continued.[9] Intravenous antibiotic prophylaxis (ceftriaxone 1 g/24 hourly) prevent the infectious complications and reduce mortality. A nasogastric tube placement is usually not recommended and prokinetic administration can enhance the gastric mucosa visualization during endoscopy (erythromycin 250 mg IV 30–120 minutes before endoscopy, if no QT prolongation on electrocardiography).

Endoscopic Treatment

There is no need to hurry for EGD to achieve hemostasis. While the first and foremost step is hemodynamic resuscitation and stabilization before sending the patients for endoscopic hemostasis. EGD can be safely performed between 6–24 hours after presentation to the emergency, but it should be individualized if there is evidence of active ongoing bleed despite vasoactive drugs, hemodynamic instability due to blood loss despite resuscitation, actively

TABLE 1 Vasoactive drugs used in acute variceal hemorrhage (adapted from AASLD 2016 Practice Guidance[4])

Drug	*Recommended dose*	*Predominant mechanism of action*	*Significant adverse effects and contraindications*
Somatostatin	Initial IV bolus 250 µg (can be repeated in the first hour if ongoing bleeding) followed by continuous IV infusion of 250–500 µg/hr Duration: 2–5 days	Splanchnic vasoconstriction due to inhibition of vasodilatory hormones	Major adverse events are rare
Octreotide (somatostatin analogue)	Initial IV bolus of 50 µg (can be repeated in first hour if ongoing bleeding) followed by continuous IV infusion of 50 µg/hr Duration: 2–5 days	Similar to somatostatin	Major adverse events are rare. Category B drug in pregnancy
Terlipressin (vasopressin analogue)	Initial 48 hours: 2 mg IV every 4 hours until control of bleeding followed by 1 mg IV every 4 hours to prevent rebleeding Duration: 2–5 days	Mesenteric arteriolar vasoconstriction	**Common adverse events:** abdominal pain, hypertension, and hyponatremia **Contraindications:** history of ischemic disease of heart, brain, gut or peripheral limb; and in pregnancy Use with caution in elderly and hypertension

vomiting fresh blood, or persistent fresh blood from nasogastric tube.[10]

Endoscopic variceal obliterative techniques commonly used are endoscopic variceal band ligation (EVL), the preferred technique; and the endoscopic variceal sclerotherapy (EST). Once EVL is done, next session will be planned after 2–4 weeks till complete eradication of varices. Once eradicated, next screening endoscopy will be after 3–6 months and then every 6–12 months.

Role of TIPS

Monitor for rebleed (recurrence of hematemesis/drop in hemoglobin/hypotension due to bleed after endoscopic hemostasis) and assessment for high-risk factors for treatment failure should be done. In patients with high-risk of treatment failure [Child C (with CTP score ≤13) or Child B with active bleeding on endoscopy despite vasoactive drug therapy], evidence showed that the early transjugular intrahepatic portosystemic shunt (TIPS) done within 24–72 hours of presentation after first endoscopy was associated with lower treatment failure and mortality rates compared to standard therapy.[11] So, guidelines recommend "early or pre-emptive TIPS" in acute variceal bleed at high-risk of treatment failure after combined vasoactive drugs and endoscopic therapy.

Post-endoscopic Hemostasis Management

Vasoactive drugs should be continued for 3–5 days and antibiotic prophylaxis should be given for 5–7 days. Assessment for any other decompensation should be done and treated accordingly. Non-selective beta blockers (NSBBs) **(Table 2)** should be started before hospital discharge after the discontinuation of vasoactive agents unless the patient undergoes TIPS.

At our center, in hemodynamically stable patient, we keep the patient fasting for 4–6 hours after endoscopic hemostasis followed by liquid diet for 24–48 hours and then the solid food is allowed. There are some concerns for increase in splanchnic blood flow and increase in portal pressure after enteral nutrition. Some guidelines advocate withholding of enteral nutrition for at least 48–72 hours after an episode of AVH.[12] Avoid placing a nasogastric tube after EVL for first few days to avoid the risk of dislodging the newly placed bands. However, if there is indication for nasogastric tube placement, a tube can be gently placed by an experienced clinician.

Management of Refractory Bleed or Treatment Failure

Treatment failure occurs in 10–15% of the patients with AVH despite treatment and associated with high

TABLE 2 Drugs used in prophylaxis of esophageal variceal bleed (adapted from AASLD 2016 Practice Guidance[4])

Drug	*Recommended dose*	*Predominant mechanism of action*	*Significant adverse effects and contraindications*
Oral non-selective beta blockers (Propranolol or Nadolol)	**Initiation dose:** 20–40 mg BD for propranolol and 10–20 mg OD for nadolol **Dose titration:** Adjust every 2–3 days to achieve maximally tolerated dose or therapy goal achieved **Maximal daily dose:** For propranolol: 320 mg/day if no ascites and 160 mg/day if ascites present For nadolol: 160 mg/day if no ascites and 80 mg/day if ascites present **Therapy goal**: Resting heart rate of 55–60 beats/minute and systolic blood pressure should not be < 90 mm Hg	Reduce portal venous inflow by splanchnic vasoconstriction (by β2-blockade and unopposed α-adrenergic activity) and decrease cardiac output (by β1-blockade)	**Common adverse events:** fatigue, lightheadedness, and shortness of breath **Contraindications:** decompensated heart failure, advanced heart block, severe sinus bradycardia, aortic valve disease, advanced peripheral arterial disease, obstructive pulmonary disease, insulin-dependent diabetes -In spontaneous bacterial peritonitis, refractory ascites, and severe circulatory dysfunction like hyponatremia (Na^+ <130 meq/L) and hepatorenal syndrome, the dose of NSBB should be reduced or withheld temporarily till circulatory dysfunction or sepsis improves
Carvedilol	**Initiation dose:** 3.125 mg OD **Dose titration:** Adjust every 3 days to 6.25 mg BD **Maximal daily dose:** 12.5 mg/day (except in patients with persistent arterial hypertension) **Therapy goal:** Systolic blood pressure should not be <90 mm Hg	Non-selective beta-blocker (reduce portal blood flow) with additional anti-α_1-adrenergic action (reduce intrahepatic resistance)	**Common adverse events:** orthostatic hypotension, dizziness and fatigue **Contraindications:** decompensated heart failure, advanced heart block, obstructive airway disease, and severe bradycardia To be avoided in decompensated cirrhosis as it can worsen ascites and renal dysfunction

mortality.[4] Patient should be referred to higher center for adequate and prompt management. If rebleed is mild (no hemodynamic instability), a re-look endoscopy should be attempted by experienced endoscopists.

Tamponade as Bridge Therapy

If the rebleeding is persisting despite first endoscopy or the rebleed is massive (hemodynamic instability, blood transfusion or 3 g/dL drop in hemoglobin) or the second endoscopic attempt fails, balloon tamponade (Sengstaken–Blakemore tube) or self-expandable metal stent (SEMS) can be used as bridge therapy till definite portal decompressive therapies is available. The balloon tamponade can achieve hemostasis in ~80% cases and should be used for maximum of 24 hours, but it is associated with severe complications such as aspiration and esophageal rupture.[5,13] SEMS is effective and safer alternative than balloon tamponade for control of bleeding and can be left in place for up to 7 days.[14]

Rescue or Salvage TIPS

This can effectively control bleeding in more than 90% of refractory esophageal variceal bleeding cases, but the mortality rate remains high (30–50%) as well as the risk of encephalopathy.[15] So, the patients with high-risk of rebleed are to be identified and offered aggressive strategies (like early TIPS) to prevent treatment failure. Surgical shunts are rarely performed nowadays, may be done in good surgical candidate (child A cirrhosis), when TIPS is not technically feasible.

Patients who Recovered from Recent Variceal Bleed and Secondary Prophylaxis

Untreated patients who recover from first episode of bleed are at high-risk of rebleed (55–67% in first year) and mortality (25–50%).[16] So, initiation of secondary prophylaxis against rebleed is essential before hospital discharge. Patients with indication for liver transplantation should be referred for the same. The patients who underwent TIPS as a part of AVH management do not require additional therapy for rebleed prevention.

All guidelines recommend combination of NSBB (propranolol or nadolol) with EVL as first-line management for secondary prophylaxis. NSBBs **(Table 2)** form the cornerstone of combination therapy; meta-analysis showed an improvement in survival with the addition of NSBBs to EVL, while the addition of EVL to NSBBs has no survival benefit.[17] NSBBs can be used as monotherapy if patients are unable or unwilling to undergo EVL.[5] Currently neither HVPG-guided therapy nor TIPS is recommended for secondary prophylaxis. Unless contraindicated, TIPS is the recommended treatment in patients with recurrent bleed despite combination therapy and also in patients who are intolerant to NSBBs (EVL alone cannot be used as secondary prophylaxis) and especially if patient has ascites also.

Screening and Primary Prophylaxis for Varices

All cirrhotics should undergo variceal screening by endoscopy. However, EGD can be avoided in patients whose liver stiffness on transient elastography (TE) is <20 kPa with platelet count >1,50,000/μL (TE-based criteria); or serum albumin >3.6 g/dL and platelets >1,20,000/mm^3 (platelet-albumin criteria).[6,18]

There is no role of prophylaxis in cirrhosis with no varices or low-risk varices. Primary prophylaxis must be initiated in all cirrhosis with varices at high-risk of rupture. High-risk varices are small varices with red color signs, small varices in CTP C cirrhosis and medium or large varices irrespective of CTP class. The choice between NSBBs **(Table 2)** and EVL depends on variceal size, patient preference, and local resources. A recent network meta-analysis showed that NSBBs are associated with lower mortality compared to EVL.[19]

Conclusion

Acute variceal bleed is an important prognostic event in the natural history of cirrhosis. It is a medical emergency with high mortality and must be managed with resuscitation, vasoactive drugs, prophylactic antibiotics, and endoscopic treatment. Non-selective beta blocker plays a crucial role in the primary and secondary prophylaxis. TIPS has role in refractory bleed and prevention of rebleed in high-risk patients.

CHAPTER

129 Hepatorenal Syndrome: Current Diagnosis and Management

Shri Krishna Gautam

Abstract

HRS is a life threatening complication of advanced liver disease. It is considered as development of renal failure in patients with pre-existing liver disease but without any underlying renal dysfunction. The term HRS first emerged in the year 1932 in a group of postoperative patients of billiary tract surgery. The Pathophysiology of HRS is poorly understood, three essential components play vital role in Pathophysiology of HRS:

- Arterial vasodilatation in the splanchnic and systemic circulation,
- Renal vasoconstriction, and
- Cardiac dysfunction. Spontaneous bacterial peritonitis is an important risk factor for development of HRS. About one third of patient of spontaneous bacterial peritonitis develop HRS.

Most common presentation of HRS is asymptomatic followed by decrease in urine output. Due to acute kidney injury (AKI), glomerular filtration rate decreases (GFR) and the blood urea nitrogen (BUN) level increases which may result in hepatic encephalopathy as the initial clinical presentation of HRS. Based on clinical features and prognosis HRS is of two types: Type 1 HRS and Type 2 HRS.

HRS requires a very aggressive management considering its poor prognosis. There are three treatment options available for management of HRS:

- Medical therapies are the mainstay of treatment of HRS consisting of vasoconstrictor agents like: Terlipressin, Noradrenaline, and Midodrine plus Octreotide.
- Transjugular intrahepatic portosystemic shunt (TIPS) placement, and
- Liver transplantation.

Therefore, HRS is a life threatening complication of liver cirrhosis. In addition to increased knowledge regarding liver cirrhosis, portal hypertension, ascites as well as HRS, new pharmacological treatments like administration of terlipressin and albumin have proven vital role in improving the short-term outcome of HRS. The other medical treatments using different pharmacological principles such as endothelin antagonists, adenosine-receptor antagonists, and N-acetylcysteine may also help in minimizing renal vasoconstriction and improving renal function, but liver transplant remains to be the mainstay of the treatment.

Introduction

Hepatorenal syndrome (HRS) is a life-threatening complication of advanced liver disease. It is considered as development of renal failure in patients with pre-existing liver disease but without any underlying renal dysfunction.[1]

The term HRS first emerged in the year 1932 in a group of postoperative patients of biliary tract surgery.[2] International ascites club has formulated diagnostic guidelines for HRS in 1994, which were modified in 2007.[3]

Diagnostic Criteria for HRS

See **Box 1**.

BOX 1 Diagnostic criteria of HRS (EASL)

- Cirrhosis with ascites
- Serum creatinine 1.5 mg/dL (133 lmol/L)
- Absence of shock
- Absence of hypovolemia as defined by no sustained improvement of renal function (creatinine decreasing to 133 lmol/L) following at least 2 days of diuretic withdrawal (if on diuretics), and volume expansion with albumin at 1 g/kg/day up to a maximum of 100 g/day
- No current or recent treatment with nephrotoxic drugs
- Absence of parenchymal renal disease as defined by proteinuria 0.5 g/day, no micro hematuria (50 rbc/high powered field), and normal renal ultrasonography

Pathophysiology

The pathophysiology of HRS is poorly understood, three essential components are:

- Arterial vasodilatation in the splanchnic and systemic circulation,
- Renal vasoconstriction, and
- Cardiac dysfunction.

Several cytokines are involved which alter the renal blood flow and glomerular microvasculature. Important among them are cysteinyl leukotrienes, thromboxane A2, F2-isoprostanes, and endothelin-1. Knowledge about these vasoactive compounds is also important from therapeutic and preventive point of view.

Arterial Vasodilatation in the Splanchnic and Systemic Circulation

Splanchnic vasodilatation is the hallmark of portal hypertension seen in chronic liver disease. Several vasodilators like nitric oxide, glucagon, carbon mono oxide, prostacyclin are released which are responsible for these vasodilatory response.[4-7] In the initial stages, cardiac compensatory mechanism tends to counter the vasodilation.[8]

Renal Vasoconstriction

Due to splanchnic vasodilatation and renal vasoconstriction there is activation of the renin-angiotensin-aldosterone system (RAAS). The clear pathway is not known but cytokines like endothelins, prostaglandins, kallikreins, and F2 isoprostanes are considered to cause renal vasoconstriction.[9-11]

These hemodynamic changes in renal microvasculature and splanchnic vasodilation compromises renal blood flow leading to fall in glomerular filtration rate.[5]

So, HRS is initially a functional renal syndrome, which later progresses to an organic disease.

Cardiac Dysfunction

The development of cirrhotic cardiomyopathy leads to impairment of cardiac function, which may further lead to a relative impairment of the compensatory increase in cardiac output secondary to vasodilatation.

Risk Factors of HRS

Spontaneous bacterial peritonitis is an important risk factor for development of HRS.[12-14]

About one third of patient of SBP develops HRS.[12] The outcome of HRS is very poor. Median survival time of all patients with HRS is approximately 3 months only.[15] High MELD scores and type 1 HRS further worsen the prognosis. Type 1 HRS patients if not treated have very poor outcome with median survival of approximately 1 month.[16]

Clinical Features and Classification of HRS

Most common presentation of HRS is asymptomatic followed by decrease in urine output. Due to acute kidney injury (AKI), glomerular filtration rate (GFR) decreases and the blood urea nitrogen (BUN) level increases which may result in HE as the initial clinical presentation of HRS.

Based on clinical features and prognosis, HRS is of two types (type 1 and type 2).[3]

Type 1 HRS

Type 1 HRS has worse prognosis than type 2 HRS. There is very rapid deterioration in renal function in type 1 HRS. Typically, the leve[0l] of serum creatinine rises to a value higher than 2.5 mg/dL within 2 weeks or less. Most of time type 1 HRS has a triggering event. These triggers interfere with the renal blood flow.[17] Some of the common triggers are bacterial infections,18 GI bleeding, surgery, and acute hepatic injury[3,19]

Among bacterial infections, SBP is the most important trigger event to develop HRS.[20,21] There are certain predisposing factors like high levels of inflammatory markers, severe circulatory depression prior to the onset

of infection, and adrenal insufficiency, which have more chances of development of HRS.

Type 2 HRS

Type 2 HRS is more slowly progress[0i]ve than type 1 HRS, but still carries a median survival of only approximately 6 months. Typically patient presents with pre-existing resistant ascites with mild renal dysfunction (serum creatinine < 2.5 mg/dL). Type 2 HRS patient can progress into type 1 HRS after a triggering event.

Prevention of HRS

HRS has a very poor prognosis and very high mortality rate. So prevention of HRS is an important aspect in management of patients of chronic liver disease. Most important strategy is to prevent depletion of intravascular volume. Important causes of volume depletion are over diuresis, diarrhea due to lactulose, variceal bleed, and large volume paracentesis.

Use of nephrotoxic drugs should be avoided. Beside these prevention of infection and its prompt treatment is also very important for prevention of HRS.[18]

Treatment of HRS

HRS requires a very aggressive management considering its poor prognosis. There are three treatment options available for management of HRS:

- M2 4ed]ical therapies,
- Transjugular intrahep[0a] tic portosystemic shunt (TIPS) placement,
- Liver transplantation.

Aim of medical therapy is to maintain intravascular volume. Vasoconstrictors are used to counter splanchnic vasodilatation. Colloid infusion is done for volume expansion. Aim of the medical therapy is to act as a bridge until definitive treatment of liver disease is done or until the triggering event (SBP, UGI bleed) has subsided.

Medical Therapy

- Non-specific medical therapy:
  - Vitals monitoring and maintaining fluid balance is very important. Monitoring of blood pressure, central venous pressure, urine output helps in maintaining fluid balance.
  - Infection control: prophylactic antibiotic therapy should be given if indicated for prevention of SBP. Sepsis should be identified early using culture of blood, urine, and ascetic fluid. There is no role of antibiotic without proven infection.
  - Diuretic has to be stopped to prevent depletion of intravascular volume.
- *Specific therapies:*

  Vasoconstrictors: Aim is to reverse the splanchnic vasodilatation to maintain the renal blood flow vasopressin analogues are most commonly used for vasoconstriction. Terlipressin has been studied extensively in HRS patients.[15,22]

  Terlipressin improves renal function in about 40–50% patients of HRS[15,23] The dose of terlipressin is 1 mg every 4–6 hours. It can be increased up to 2 mg every 4–6 hours after 3 days if there is no improvement in renal function (fall in serum creatinine by at least 25% of baseline). Terlipressin is discontinued if serum creatinine comes below 1.5 mg/dL[22] with improvement in renal function there is increase in urine volume, blood pressure, and serum sodium concentration. Improvement is slow and can take up to 14 days for renal function to become normal. Duration is shorter with lower serum creatinine at the time of starting terlipressin.[24]

  Better response is observed in patients with baseline serum bilirubin less than 10 mg/dL.[24] Also patients who show reduction in mean arterial pressure of more than 5 mm Hg after 3 days of medical therapy have favorable response to medical therapy.[24] Reoccurrence after stopping terlipressin is rare. Terlipressin is effective in reoccurrence.

  Common side effects of terlipressin include cardiovascular and ischemic complications. So terlipressin is avoided in patients with known cardiovascular and ischemic conditions. Patients of HRS are given albumin along with terlipressin to maintain intravascular volume. Albumin is given in a dose of 1 g/kg body weight.

  Terlipressin shows improvement in renal function in patients of type 2 HRS also,[25] but there are limited studies in patients of type 2 HRS.

  There are other vasopressors that are used in type 1 HRS:

  - Midodrine plus octreotide
  - Noradrenaline

Midodrine is an alpha adrenergic receptor agonist. It is an oral drug started at a dose of 2.5 mg tds and can be increased up to 12.5 mg. Octreotide is started with a dose of 100 microgram tds and can be increased up to 200 microgram tds. There are only few studies with midodrine and octreotide.[26]

Noradrenaline (0.5–3 mg/h) is a vasopressor drug. Increased arterial pressure helps to maintain adequate blood flow to kidneys.[27] comparative studies between noradrenaline and other vasoconstrictors drugs are the area of research. Noradrenaline is given as continuous infusion with an aim to keep systolic blood pressure above 110 mm Hg.

There have been few studies on prevention of HRS. Short-term treatment (4 week) with pentoxifylline (400 mg three times a day) in a randomized double-blind st[u8]dy was shown to prevent the development of HRS in patients with severe alcoholic hepatitis. In a recent study, long-term treatment with pentoxifylline was not associated with an improved survival but with reduced frequency of some complications of cirrhosis, including renal failure, yet this 7w as not the primary endpoint of the study. Finally, norfloxacin (400 mg/day) reduced the incidence of HRS in advanced cirrhosis.

Transjugular Intrahepatic Portosystemic Shunt (TIPS)

TIPS has been used for treatment of portal hypertension associated with cirrhosis.[28] TIPS helps to control ascites along with improvement in renal function in patients of HRS.

Renal replacement therapy: Hemodialysis is used in patients of HRS. Indication of hemodialysis is similar to any cause of acute renal failure.[29,30] There are no separate studies to see results of hemodialysis in HRS patients. Comparison of renal replacement therapy and medical therapy for HRS is an area of further evaluation.

Liver Transplantation

Treatment of choice for both types of HRS is liver transplantation.[31] Liver transplantation success rate is about 65% in patients of type 1 HRS.[31] Renal failure subsides after liver transplantation. Patients who remain on renal support therapy for more than 12 weeks should be considered for combined liver kidney transplantation.

Conclusion

Therefore, HRS is a life-threatening complication of liver cirrhosis. In addition to increased knowledge regarding liver cirrhosis, portal hypertension, ascites as well as HRS, new pharmacological treatments like administration of terlipressin and albumin have proven vital role in improving the short-term outcome of HRS. The other medical treatments using different pharmacological principles such as endothelin antagonists, adenosine-receptor antagonists and N-acetylcysteine may also help in minimizing renal vasoconstriction and improving renal function,[32,33] but liver transplant remains to be the mainstay of the treatment. The multiple aspects in the pathophysiological process will likely be targeted by the future treatment of HRS.

CHAPTER

130 Hepatic Encephalopathy: Management

Sudhir Maharshi, Barjesh Chander Sharma

Abstract

Hepatic encephalopathy is defined as brain dysfunction caused by liver insufficiency and/or portosystemic shunting; its clinical manifestations include spectrum of neurological or psychiatric dysfunction ranging from subclinical alterations to deep coma. The development of hepatic encephalopathy correlates with the severity of liver disease. Hepatic encephalopathy is classified into overt hepatic encephalopathy, which is characterized by neurologic and neuropsychiatric dysfunctions detected by clinical examination and bedside tests or minimal hepatic encephalopathy, characterized by normal mental status and normal neurologic examination but abnormalities on psychometric testing. Early detection and rectification of precipitating factors is most important in the management. The first-line therapy is still lactulose which is effective in minimal, overt and recurrent hepatic encephalopathy. Rifaximin is equally effective to lactulose and is better tolerated. Branch chain amino acids have a beneficial effect on hepatic encephalopathy in protein intolerant patients. Probiotics and L-ornithine L-aspartate are also useful in the management of hepatic encephalopathy. Combinations of rifaximin and lactulose have shown promising results in the treatment of overt and recurrent hepatic encephalopathy. Embolization of large portosystemic shunts and liver transplantation are effective treatment in few and highly selected patients. Nutritional therapy and fecal microbiota transplantation are emerging treatment options but data is limited.

Introduction

Hepatic encephalopathy (HE) is identified by indiscriminate neurological and psychiatric manifestations, which adversely impacts the life of patients and their family members. The requirement of multiple hospital admissions due to HE is a matter of great concern for the health-care sector. HE has been categorized based on preexisting liver disorder, gravity of the clinical features, the trends over time, and triggering/precipitating factors **(Table 1)**.[1,2] Type A HE is a consequence of acute liver failure, type B of large portosystemic shunts (PSS), and type C of liver cirrhosis.[3] Type C is the most common. The scope of HE scales from not easily observable clinical features characterized as minimal hepatic encephalopathy (MHE), overt neuropsychiatric features characterized as overt hepatic encephalopathy (OHE) to comatose state. Overt HE is observed in 10–14% of cirrhotic patients at the time of diagnosis. Forty percent of patients with cirrhosis encounter at least one outbreak and many encounter frequent outbreaks of HE. In cirrhotic patients the prevalence of MHE is 20–80%.[3-5] In patients with cirrhosis HE is a marker of poor prognosis, with up to 85% 1-year mortality.[4] The available literature on pathogenesis suggest that an increase in ammonia concentration is implicated and a role for inhibitory neurotransmission through gamma aminobutyric acid (GABA) receptors in the central nervous system along with changes in central neurotransmitters and circulating amino acids.

TABLE 1 Classification of hepatic encephalopathy

According to WHC severity	*According to ISHEN*	*Based on underlying disease*	*Based on time course*	*Based on precipitating factors*
MHE	Covert	A	Episodic	Spontaneous
Grade I				
Grade II	Overt	B	Recurrent	Precipitated
Grade III				
Grade IV		C	Persistent	

ISHEN, International Society for Hepatic Encephalopathy and Nitrogen Metabolism; WHC, West Haven Criteria

TABLE 2 West Haven Criteria for severity of hepatic encephalopathy

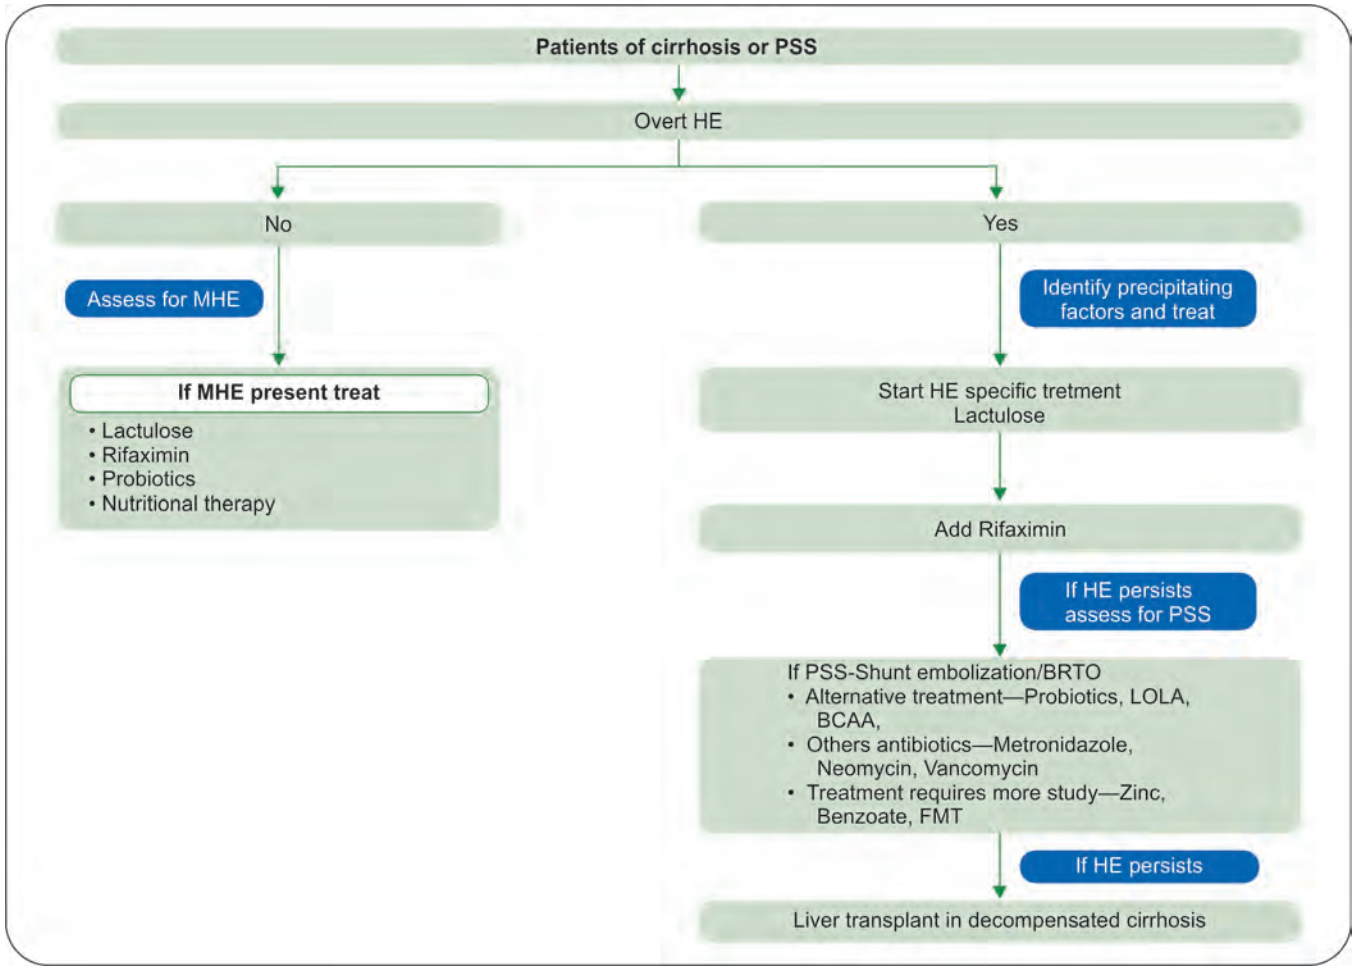
Grade of HE	*Minimal*	*Grade I*	*Grade II*	*Grade III*	*Grade IV*
Clinical features	No clinical manifestations	Short attention span, Altered sleep rhythm, Impairment of addition or subtraction, Minimal lack of awareness, Anxiety	Lethargy, Disorientation for time, Personality changes, Inappropriate behavior, Flapping tremors	Gross disorientation, Confusion, Somnolence to semi stupor, Bizarre behavior, Involuntary passage of urine and feces	Coma

HE, hepatic encephalopathy

Overt Hepatic Encephalopathy Management

Management of OHE includes finding and resolving any triggering factor, to reduce blood ammonia level with lactulose or rifaximin and the proper setup for its treatment. The severity of OHE is graded from I to IV, based on the clinical features **(Table 2)**. The treatment depends on the severity of OHE. Patients with grade I HE may be managed on outpatient basis, if caregivers are available to look for signs of worsening and to bring the patient to the hospital if required. Hospital admission of a patient with grade II HE depends on the degree of lethargy and confusion. If the patient is not able to take the treatment or if caregivers are not available for monitoring the patient, the patient needs to be admitted to the hospital. Patients with more severe HE (grades III and IV) require hospital admission for management, ideally in the intensive care unit and intubation should be considered for airway protection. All patients with HE should receive supportive care, which includes balanced nutrition, avoiding dehydration and electrolyte abnormalities, and providing a safe environment. Disoriented and agitated patients need extra care to prevent falls. Judicious use of restraints is a safe option than sedative drugs, as patients with advanced cirrhosis and HE are vulnerable to over sedation with drugs. If at all medications are required, haloperidol is a better and safe option than benzodiazepine.[6] Nutritional support includes 35–40 kcal/kg energy with 1.2–1.5 g/kg protein per day. Cirrhotic patients are usually malnourished and restriction of protein can increase mortality, so patients with HE should not restrict their protein intake.[7,8] Grades I and II HE patients can take their diet orally, but patients with severe HE are usually unable to receive oral nutrition. These patients should be fed through Ryle's tube along with necessary medications. All HE patients are advised to take small portions at regular intervals with a late-night snack of complex carbohydrates, as fasting further promotes the production of glucose from amino acids, which leads to ammonia production.[9] Vegetable proteins are preferred as they improve nitrogen balance and mental status. Addition of branched-chain amino acids (BCAA) to a low-protein diet should be considered for patients intolerant to protein. Usually patients with transjugular intrahepatic portosystemic shunt (TIPS) or surgical PSS have severe HE and use of vegetable protein or protein restriction with BCAA supplementation is beneficial in these patients. The algorithm for management of HE has been shown in **Flowchart 1**.

Flowchart 1: Algorithm for management of hepatic encephalopathy



BCCA, branch-chain amino acids; BRTO, balloon occluded retrograde transvenous obliteration; FMT, fecal microbiota transplantation; HE, hepatic encephalopathy; LOLA, L-ornithine L-aspartate; MHE, minimal hepatic encephalopathy; PSS, portosystemic shunts.

Acute Episode of Overt Hepatic Encephalopathy Management

The treatment of acute HE starts with finding and management of triggering factors and the reduction of blood ammonia level. Treatment of precipitating factors combined with standard ammonia lowering therapy is associated with a rapid reversal of HE. Common precipitating factors are constipation, gastrointestinal bleeding, infections (including spontaneous bacterial peritonitis, urinary tract infection, and respiratory tract infection), renal failure, hypokalemia, metabolic alkalosis, hypovolemia, hypoxia, hypoglycemia, and use of sedatives. Blood ammonia concentration is reduced with lactulose, lactitol, rifaximin, and other ammonia lowering agents. Lactulose is administered in the dose of 30–45 mL (20–30 gm) two to four times per day and it should be adjusted so that it results in two to three soft stools per day. Lactitol powder of 67–100 gm diluted in 100 mL of water represents an equivalent dose. It is recommended to administer lactulose or lactitol enemas (1–3 L of a 20% solution) in patients who cannot take it orally. For patients who have not improved within 48 hours or who are unable to take lactulose or lactitol, rifaximin is the next option. The recommended dose of rifaximin is 400 mg orally thrice daily or 550 mg twice daily. Both the doses are equally effective. The safety and tolerability of rifaximin has been proved for up to 2 years. As a rule, antibiotics

are added rather than substituted to nonabsorbable disaccharides. In a study, complete reversal of HE was observed more with combination of lactulose and rifaximin compared to lactulose alone (76% vs. 50.8%, p=0.004) along with decreased mortality (23.8% vs. 49.1%, P < 0.05).[10] Hence, combination therapy is recommended in the management of HE. If the precipitating factor has been resolved and there is no recurrence of HE for next 3 months, the rifaximin can be discontinued. Neomycin, vancomycin, and metronidazole are other alternatives of rifaximin but rifaximin is preferred as it has less side effects. L-ornithine L-aspartate (LOLA) and branch-chain amino acids (BCCA) are the next in consideration for patients who do not respond to conventional therapy.[11,12]

Hepatic Encephalopathy—Primary and Secondary Prophylaxis

Lactulose and rifaximin are proved to be equally effective in patients with acute variceal bleed for primary prophylaxis of HE. In a study, HE developed in a smaller number of cirrhotic patients with variceal bleed in lactulose group compared to placebo group (14% vs. 40%, p=0.03).[13] In another study, lactulose and rifaximin were equally effective.[14] Secondary prophylaxis of HE is defined as preventing another episode of HE in patients who had a previous episode of HE. In secondary prophylaxis chronic therapy with lactulose or lactitol is indicated and if HE recurs on lactulose therapy, combination therapy including lactulose and rifaximin should be considered.[10,15,16] A published study revealed the efficacy of lactulose in prevention of HE recurrence compared to placebo (19.6% vs. 46.8%, p=0.001).[16] Recurrence of HE can also be prevented with the help of probiotics, glycerol phenylbutyrate (PB), BCAA, and LOLA.[15-20] Patients with refractory HE may have large spontaneous PSS. Refractory HE in these patients can be prevented by PSS embolization and balloon occluded retrograde transvenous obliteration (BRTO) of large spontaneous splenorenal shunts.[21,22] Fecal microbiota transplantation (FMT) also prevents recurrence of HE, improve cognition and dysbiosis without major side effects in patients with cirrhosis.[23] Liver transplant is the last resort in patients with decompensated cirrhosis who present with recurrent HE despite of being on above therapy.

Management of Minimal Hepatic Encephalopathy

Patients with MHE have poor quality of life, increased risk of OHE, require frequent hospitalization, and have high mortality. The available treatment options for MHE are disaccharides (lactulose, lactitol), rifaximin, probiotics, and nutritional support.[24-28] In a study that compared a nutritional therapy of 30–35 kcal/kg and 1.0–1.5 g vegetable protein/kg with no dietary intervention in 120 cirrhotic patients with MHE, the rate of reversal of MHE was higher in those receiving nutritional therapy (71.1% vs. 28.8%, p=0.001). Prevention of OHE and improvement in quality of life was also observed with nutritional therapy.[28]

Drugs Used in Management of Hepatic Encephalopathy

Nonabsorbable Disaccharides

Lactulose and lactitol are nonabsorbable disaccharides used as first-line treatment for HE. Lactulose reduces formation and absorption of ammonia from the gut by altering the microbiota, increases nitrogen excretion in the feces and reduces production of toxic short chain fatty acids. It works as an osmotic purgative, prebiotic, and also leads to gut acidification.[29] A Cochrane data base review proved the efficacy of lactulose in HE management compared to placebo or no intervention. Efficacy of lactulose has been seen in the management of MHE, OHE, and recurrent HE. It is also effective in reducing the risk of variceal bleeding, spontaneous bacterial peritonitis, hepatorenal syndrome, liver failure, and mortality.[30] Lactulose is well tolerated, and the main side effects include abdominal cramps, diarrhea, and flatulence. About 70–80% patients of HE responds to lactulose.[31] Lactitol is as effective as lactulose, is more palatable, and have less side effects.[32,33]

Nonabsorbable Antibiotics

Ammonia lowering effect has been observed with use of antibiotics such as metronidazole, vancomycin, neomycin, paromomycin, and rifaximin as they have activity against urease-producing gut bacteria. As rifaximin has minimal systemic absorption, broad spectrum, and less adverse events, it is most commonly used. Rifaximin effectively

prevented the recurrence of HE when used as an add-on therapy for refractory HE, despite on appropriate lactulose therapy.[11] Rifaximin is effective in recovery from HE, secondary prophylaxis, and in reducing the mortality as shown in a meta-analysis.[34] It also enhances the performance and health-related quality of life in patients with MHE.[35,36] Rifaximin had similar efficacy to nonabsorbable disaccharides for acute and chronic HE, and somewhat better tolerated. Although neomycin and metronidazole have been used for the management of HE, data are very old and inadequate.[37-39] These antibiotics also have serious adverse events, like neomycin can cause nephrotoxicity, ototoxicity, malabsorption, and metronidazole can lead to peripheral neurotoxicity.

Branch Chain Amino Acids

Cirrhotic patients show reduce blood level of BCCA (leucine, isoleucine, valine). The BCCA have a role in skeletal muscle protein synthesis and detoxification of ammonia. High ammonia level decreases protein synthesis by diminishing the mTOR signaling in cirrhotic patients, this effect is prevented by BCAAs. A Cochrane data base review showed that BCAAs have a favorable effect on HE in cirrhotic patients.[40] Both oral and intravenous preparations are effective. The BCCA helps in muscle building in all cirrhotic patients with sarcopenia along with favorable effects on HE which lead to improvement in quality of life. There is no benefit of BCAA supplementation in protein-tolerant patients. A recent randomized trial on 116 patients who had an episode of HE in the past, found no benefit of BCAA on the prevention of recurrent HE, although supplementation appeared to improve MHE and muscle mass.[20] Based on these results, dietary BCAA supplementation is indicated only in severely protein-intolerant patients.

L-Ornithine L-Aspartate

LOLA promotes ammonia detoxification as it works as metabolic substrates for urea cycle in liver and glutamine synthesis in skeletal muscle thus reduces blood ammonia levels. There was improvement in HE, reduction in venous ammonia level, recovery time and duration of hospital stay with use of intravenous LOLA along with lactulose.[17] A Cochrane data base review revealed favorable effect of LOLA on HE in cirrhotic patients and reduced mortality.[41] This effect was observed with both oral and intravenous preparations.[42] Prophylactic LOLA infusion proved to be effective in decreasing venous ammonia concentration in patients who underwent TIPS placement.[43] LOLA is ineffective in patients acute liver failure.

Probiotics

Prebiotics and probiotics reduce blood ammonia concentrations by promoting colonization of acid-resistant, non-urease producing bacteria. The most efficacious species for HE appears to be Lactobacilli and Bifidobacterium. Use of probiotics improves recovery in HE, but when compared with lactulose they failed to show a benefit in significant outcomes as shown in a meta-analysis.[44] Probiotics are effective in MHE, OHE, and prevention of recurrent HE.[27]

Other Therapies

Large Spontaneous Portosystemic Shunts Embolization

Improvement in OHE and recurrence of HE has been observed with embolization of these shunts and BRTO of splenorenal shunt without deteriorating ascites, variceal bleed, and portal hypertensive gastropathy.[21,22]

Polyethylene Glycol

Polyethylene glycol (PEG) solution results in increase excretion of ammonia in the stool by its purgative action thus it helps in HE management. Although the efficacy of PEG has been proved in a study, more such studies are required for the same.[45]

Acarbose

Acarbose enhances the growth of gut saccharolytic bacterial flora and diminishes proteolytic flora that produces ammonia, mercaptans, and benzodiazepine-like substances. Improvement in HE and reduction in ammonia level has been observed with use of acarbose.[46]

Ammonia Lowering Agents

Ammonia lowering agents like PB, ornithine phenylacetate (OPA), and benzoate binds to ammonia and leads to excretion of nitrogen by urinary non-urea excretion. To date there is no definite evidence for OPA and PB for the management of HE. Sodium benzoate had similar efficacy

to lactulose in the management of HE in a small study.[47] Further studies are required to prove their efficacy.

Flumazenil

Use of flumazenil shows reduction in the GABA/benzodiazepine receptor complex activity thus reversing the neurological inhibition in HE. The short-term (minutes) favorable effect of flumazenil on HE has been proved in a meta-analysis but it does not have any effect on recovery, mortality, and quality of life.[48] Flumazenil may be useful, in patients who received benzodiazepines.

Zinc

Zinc has a role in few patients with recurrent HE, but more studies are required to prove its efficacy.

Newer Therapies

Fecal Microbiota Transplant

In cirrhotic patients there is reduced level of favorable bacterial families like Lachnospiraceae and Ruminococcaceae and rise of the pathogenic Enterobacteriaceae, Streptococcaceae. Fecal microbiota transplant prevents HE recurrence, improves cognitive function, and decreases frequent hospitalization as shown in a randomized pilot trial.[23]

Albumin

Albumin has anti-inflammatory properties; it binds and clears many toxic substances, which accumulate in liver failure. Lactulose with albumin has been proved to be more effective than lactulose alone in treatment of HE (75% vs. 53.3%, p=0.03).[49]

Other Experimental Therapy

Glutamine synthetase replacement, Liposome supported peritoneal dialysis, Melatonin, L-carnitine, Glutamatergic antagonist, serotonin antagonist, opioid antagonist, and spherical carbon (AST-120).

Conclusion

Early detection and correction of precipitating factors is utmost important in the management of HE. The most commonly used therapy is still lactulose, which is effective in MHE, OHE, and recurrent HE. Efficacy of rifaximin is similar to lactulose in the treatment of HE with less side effects. In protein intolerant patients, BCCA have a favorable effect on HE. Probiotics and LOLA also have favorable effects in the treatment of HE. Nutritional therapy and FMT are emerging therapies for HE treatment but the data are limited. Combination of rifaximin and lactulose is more effective in the management of overt and recurrent HE. Liver transplant, embolization of large PSS, and BRTO of splenorenal shunts are effective management options in highly selected patients.

CHAPTER

131 The Healthy Indian Gut Microbiota

Rupjyoti Talukdar

Abstract

This chapter discusses the current understanding of the gut microbiome in Indian population. It also highlights the differences of the Indian gut microbiome from other populations. Most of the earlier studies involved small to relative moderate sample size from specific geographic locations of India. An ideal study to evaluate the core gut microbiota of healthy Indians should involve a large homogeneous population across the country and use the same technology and data analytics tools. The LogMPIE (Landscape of gut microbiome-Pan India Exploration) is such a study. This study confirmed the most predominant organisms in the Indian gut are Prevotella copri and Faecalibacterium prausnitzii.

Introduction

The microbial ecosystem within the human body has established a symbiotic relationship that results in mutually beneficial metabolic and protective functions. Depending on the mode of delivery, the human gut gets colonized earliest from the maternal vaginal or skin flora.[1] Even though organisms had been demonstrated in amniotic fluid, studies have even raised the possibility of colonization even before birth as organisms have been demonstrated in the first meconium. However, this observation is currently under scrutiny.[2-4] Recent studies have also reported similarity between the ancient microbiome to the modern human gut microbiome, especially with modern rural population.[5] It is now known that the gut microbiome is shaped throughout life in a dynamic manner by factors such as mode of delivery, diet patterns (vegan, fiber-rich, or meat-based), use of food preservatives and emulsifiers, environmental antimicrobial peptides, lifestyle behavior, such as alcohol intake, use of antibiotics and probiotics[1,6,7] host genetics, and surrounding biodiversity.

The Indian subcontinent, which has a rich biodiversity, is undergoing a transition in the sociodemographic profile.[8] Therefore, the India gut microbiota has evolved to be an interesting area to be studied. In this chapter, we review the published data on the gut microbiota in healthy Indian individuals.

Indian Gut Microbiota and Its Determinants

Mode of Delivery and Early Diet

It was shown by Pandey et al. that the fecal microbiota of vaginally born infants was dominated by *Acinetobacter* sp., *Bifidobacterium* sp., and *Staphylococcus* sp.[9] On the contrary, the infants born by cesarean delivery conspicuously lacked *Bifidobacterium*, which is a crucial organism required for milk digestion. In a subsequent study, Kabeerdoss et al.[10] reported a dynamic evolution of organisms in the infant gut, with the most dominant being *Lactobacilli* and *Enterobacteriaceae*. This was significantly higher than in infants born by cesarean delivery on the first day of life but equaled thereafter. After 3 months

of birth, an abundance of *Bifidobacterium* was higher in stools of the vaginally born infants while there was a progressive increase in abundance of the *Bacteroides-Prevotella* group in these infants from birth to 3 months of life. Meanwhile, exclusively breast-fed infants had a higher abundance of *Enterobacteriaceae* compared to those who were additionally fed with supplemental cow's milk.[10]

Age

Balamurugan et al. reported the first Indian study on 130 children and adolescents that demonstrated a dynamic change in the gut bacterial composition.[11] The study cohort was fairly homogeneous and predominantly consumed a lactovegetarian diet with infrequent meat intake. *Bifidobacterium longum* showed predominance from the age of 2–3 years but declined rapidly after reaching adulthood. Similarly, *Lactobacillus acidophilus* was predominant in the 2–3 years age group but progressively declined as age progressed toward adulthood. On the other hand, the *Bacteroides-Prevotella-Porphyromonas* group which was low in early childhood constituted the major organisms in later childhood and adolescence. The study by Marathe et al. also suggested a change in the gut microbiota with progressing age.[12]

Habitat and Geography

A multicenter study[13] from urban and adjacent rural Delhi and Pune reported *Prevotella*, *Megasphaera*, *Faecalibacterium*, *Lactobacillus*, *Ruminococcus*, and *Roseburia* as the most dominant organisms. Interestingly, the gut microbiota in these individuals could be divided into two groups on the basis of the absolute counts of *Prevotella* and *Megasphaera*. The microbial diversity was significantly higher among the urban individuals.

Another subsequent study[14] *that evaluated the gut microbiota in rural and urban Ballabgarh (sea level) and Ladakh (11,500 ft above sea level) demonstrated region-specific differences in bacterial diversity. The genus and species level diversity were least in the rural Ladakh region while in individuals from urban Ballabgarh had* high alpha and beta diversity, while individuals from the rural region had high alpha but low beta diversity.[14] The genus *Parabacteroides*, *Blautia*, *Brevundimonas*, *Pelomonas*, and *Megamonas* were significantly higher in the Ballabgarh rural cohort. On the other hand, while *Lactobacillus* was abundant in the Ballabgarh urban cohort, *Bacteroides*, *Vibrio*, *Eggerthella*, and *Pseudomonas* were high in both the Ballabgarh cohorts.

The region-specific variation in the gut microbiota in this study was also associated with enrichment of xenobiotic metabolizing pathways in the Ballabgarh rural and urban cohorts compared to the Ladakh population, implying higher exposure to industrial chemical and drugs in the Ballabgarh populations.

Another recent study[15] that evaluated the gut microbiota in Bhopal (Central India) and Kerala (South India) identified two distinct clusters of organisms. Cluster 1 was enriched in organisms from the genera *Prevotella* while Cluster 2 was enriched with species from the genus *Bifidobacterium*, *Ruminococcus*, *Clostridium*, and *Faecalibacterium*. Location-wise distribution revealed *Prevotella* and *Megasphaera* to be predominant in Central Indian cohort while the others including *Bacteroides* were more abundant in the South Indian cohort. Moreover, the authors also reported three characteristics fecal metabolomic clusters among the study cohorts. The Central Indian cohort abounded in metabolites such as palmitic acid, stearic acid, and valeric acid, while in the South Indian cohort, there was a significant enrichment of BCAAs (especially isoleucine), cadaverine, propionate, and lauric acid.

Ethnicity

Since tribal populations are closely attached to nature and their lifestyle is largely determined by agriculture, fishing, hunting, tribe specific dietary patterns, culture, and traditions, they are likely to harbor an evolutionarily conserved gut microbiota. India harbors the largest tribal population in the world and thus constitutes the ideal for evaluation of the "normal" gut microbiota. In the first and so far, the largest study on the Indian tribal gut microbiota,[16] we evaluated healthy tribal volunteers belonging to 15 tribes of Mongoloid or Proto-Australoid decent dispersed over different geographic locations across Northeast and Southern India. The genus *Prevotella* contributed to 40% of the genus across all tribes. The other genera that constituted the core microbiota irrespective of geography and ethnicity included *Faecalibacterium*, *Eubacterium*, *Clostridium*, *Blautia*, *Collinsella*, *Ruminococcus*, and *Roseburia*. In addition to these genera, *Bacteroides*, *Dialster*, and *Veillonella* were found to abound the tribes from Manipur while *Bacteroides*, *Dialster*, *Bifidobacterium,* and

Lactobacillus abounded in the tribes from Sikkim. Tribes from Manipur had the least abundance of *Bifidobacterium*. Correlational analyses within the core microbiota revealed that *Prevotella* had a negative correlation with *Bacteroides, Faecalibacterium,* and *Clostridium* in the Telangana tribes, with *Faecalibacterium*, *Bacteroides,* and *Roseburia* in the Manipur tribes, and with *Bacteroides*, *Clostridium*, *Ruminococcus*, and *Blautia* in the tribes from Sikkim. Tribes from Sikkim had a significantly lower abundance of *Enterobacter* compared to tribes from Assam, Telangana, and Manipur.

Dietary Factors

Diet has been established as a major factor that shapes the human gut microbiota. In the foregoing sections of this review, even though there were variations in the gut microbiota according to geography and habitat, a closer look actually converges these variations to dietary patterns. Overall, *Prevotella,* which is responsible for complex plant-derived polysaccharide degradation, was dominant in a majority of the study populations implicating this as a signature genus in Indians.[13,15-17]

The study from Ballabgarh and Ladakh[14] also suggested that cooking oil and ghee could impact the Indian gut microbial composition. For instance, individuals from Ladakh consumed predominantly sunflower oil, which has a high concentration of linoleic acid that is known to be degraded by *Roseburia*. Similarly, *Sporobacter* was also abundant in individuals consuming sunflower oil; while *Collinsella* was specifically predominant in individuals who consumed clarified butter (ghee).

In the tribal study by Dehingya et al.,[16] the gut microbiota was similar between tribes from Assam and Telangana despite the geographic and ethnic differences. Therefore, it appears likely that the carbohydrate and dietary fiber-rich diet (including rice, whole grain, vegetables, fruits, legumes, tubers) determines the core microbiota, which is predominant in *Prevotellaceae*, *Ruminococcaceae*, *Lachnospiraceae,* and *Eubacteriaceae*, which are enriched in carbohydrate metabolizing enzymes. In the Lepcha, Nepali, and Bhutia tribes from Sikkim the abundance of *Bifidobacterium* and *Lactobacillus* can be explained by the higher consumption of milk products and fermented food. Among the Malayali tribes from Tamil Nadu, the higher abundance of *Bacteroidetes* and *Clostridium* could be explained by their daily intake of a moderate amount of pork meat, and non-intake of milk, and milk products due to their religious beliefs.[17]

Comparison of Indian Gut Microbiota with Worldwide Data

It has now been consistently shown that the Indian gut microbiota differs significantly from that of other regions of the world. In our study,[16] we observed two distinct clusters, the first involving the Hadza, Italian, and Americans individuals that abounded in *Faecalibacterium*. The rest of the tribal groups, including Indians, constituted the other group with a higher abundance of *Prevotella*. Interestingly, within this group there was close similarity of the Indian tribal microbiome to the Mongolian tribal microbiota. Of note, the origins of the Nepali and Tai-Phake tribes from India can be mapped to Mongolians.

In the study by Bhute et al.,[13] comparison of gut microbiota of Western and North Indian cohorts with Americans revealed 76 OTUs, out of which six, including *Prevotella*, *Lactobacillus*, *Lachnococcus,* and *Roseburia*, specifically belonged to the Indians. In this study, it was also observed that Indians shared 25 OTUs with the Bangladeshi cohort (majority belonging to families *Lachnospiraceae*, *Ruminococcaceae,* and *Enterobacteriaceae*, and genus *Prevotella*). Other than differences at the overall genera and species level OTUs, differences were also noticed between Indian and European cohorts even within the same genus.[13]

Finally, a metagenome wide meta-analyses (MGWAS) by Dhakan et al., which included datasets from India, China, USA, and Denmark demonstrated completely separate species level clustering of the Indian gut microbiome compared to the American, Danish, and Chinese microbiome.[15] *Prevotellaceae* emerged as the most highly abundant bacterial family in the Indian individuals. In addition, the Indian gut microbiota was found to be enriched in functions that corroborate with a carbohydrate-rich diet.

Conclusion

Results of gut microbiota studies can be influenced by several technical factors such as sample size, sample collection and storage, sequencing technique, reference database, and depth of statistical and bioinformatics analyses.

Contd...

Contd...

In this review, we discussed the gut microbiota in healthy Indians based on the individual studies that involved small to medium sample size and different techniques to evaluate the microbiome. The ideal way to evaluate the true core Indian gut microbiota would be to include a large homogeneous population across the entire country and use the same methods of sample processing, sequencing, and data analyses. The LogMPIE (Landscape of gut microbiome-Pan India Exploration) is such a study that was recently published.[18] This study evaluated 1,004 individuals from 14 centers across India (4 from north, 3 from east, 4 from west, and 3 from south) and bacterial metagenomic sequencing was performed in the Ion oneTouch 2 system. There were 390 microorganisms that were common in all the geographic locations, while 36 were unique to north, 149 to south, 95 to west, and 62 to east India. The most predominant organisms emerged to be *Prevotella copri* and *Faecalibacterium prausnitzii*, thereby qualifying *Prevotella* and *Faecalibacterium*.

CHAPTER

132 Celiac Disease: Who to Screen and How to Screen?

Ashish Agarwal, Archita Makharia, Govind K Makharia

Abstract

Traditionally celiac disease (CeD) has been defined as a disease involving the proximal small intestine with a presentation with diarrhea, loose stools, malabsorption, weight loss, failure to thrive, and growth retardation in children. This presentation which has long been portrayed as "classical" for CeD, allows us to diagnose only the patients with most severe gastrointestinal involvement and thus miss out those with milder or no GI manifestations. However, it is being increasingly recognized that celiac disease is a multisystem disease with a myriad of presentation including asymptomatic. Even though studies have indicated around 1% population prevalence of celiac disease, most of these patients however remain undiagnosed and hence untreated. There is thus a need for increased awareness of these varied presentations of celiac disease so that the patients can be diagnosed and treated with gluten-free diet thus preventing complications. In this chapter we have discussed the indications for screening for celiac disease and the strategy for screening these individuals.

Introduction

Celiac disease (CeD) is a chronic immune-mediated enteropathy which is triggered on consumption of gluten protein present in cereals like wheat, barley, and rye in genetically predisposed individuals. Although initially believed to be an uncommon disease and limited to the western countries, CeD has now become a global disease and it is now reported from almost all the continents.

Global Burden of CeD

In a systematic review and meta-analysis, we have recently shown that the global pooled seroprevalence (proportion of people having a positive celiac specific serological test in a population) is 1.4% (that means, 1 in 70 people is seropositive for CeD) and the prevalence of biopsy-confirmed CeD (proportion of patients having a combination of positive serological tests and villous abnormalities on duodenal biopsies) is 0.7% (means 1 in 140 individuals globally has CeD).[1] With a global population of 7.2 billion people, approximately 40–60 million people around the world are likely to have CeD.

Burden of CeD in India

Although reported since 1960s in India, an increase in number of patients with CeD in the last 2 decades has been reported from many states, predominantly Northern and Western States of India. Two population-based studies from Northern part of India have shown that the population prevalence of CeD is 1.04% (1 in 96) and 0.33% (1 in 330), respectively.[2,3] Because of predominance of reporting of CeD from the Northern states, people believe that CeD is seen only in the Northern part of India. To explore the question "is there a regional variation in the prevalence of CeD in India," we conducted a multi-site population-based study recruiting 23,331 healthy individuals from three different regions of India including Northern (Haryana),

Southern (Vellore), and Northeastern (Guwahati) regions of India. The combined pan-India prevalence of CeD is 0.67% (1 in 140). Indeed, there is a regional variation in the prevalence of CeD at this point of time, the highest being in Northern India (1.23%), lowest in Southern India (0.1%) and in between in the Northeastern region of India (0.87%).[4] This difference is likely related to the different eating patterns, with rice being staple diet in Southern India and wheat in Northern India. However, with increase in the consumption of products made from wheat in rice eating regions, it is very likely that CeD will emerge in such populations also. With the Indian population of 120 crores, it is estimated that approximately 60–80 lakhs of Indians have CeD. Of this large estimated numbers of people having CeD, only a minority have been diagnosed and a large proportion of them (85–95%) exists in the population but currently remain undiagnosed.

Where are They?

If there are so many patients with CeD both worldwide and in India, then where are they? Why are we not able to pick them up? There are multiple reasons:

- The lack of awareness amongst physicians about changing epidemiology of this disease is the most important reason. We do not think about this diagnosis in appropriate clinical setting.
- It was believed that CeD affects only children, but now it is known that CeD can affect people of all age groups. Although not well established, it is however believed that the pathophysiological changes in CeD starts since early part of life. The clinical manifestations may appear at different ages of life depending upon the severity of the disease.
- While some patients have fully expressed disease with obvious symptoms and manifests in childhood or during adolescence, in others, the disease is expressed in milder form, and hence may not come to clinical attention till late. CeD is diagnosed nowadays more often in adulthood and even in the elderly.
- The classical manifestations, as portrayed in the older textbooks, draw our attention to mainly the more classical form of disease (emaciated child with diarrhea and anemia), which are present in those having a more advanced disease. In early stages of the disease, patients may not have any symptoms or have only mild symptoms.
- While CeD is thought to be mainly a disease of the intestine and recognized in those having gastrointestinal symptoms, only half of the patients however present with predominant gastrointestinal manifestations. The GI symptoms (*Classical CeD*) include chronic diarrhea, malabsorption, failure to thrive, abdominal distension, and weight loss **(Fig. 1)**.
- Approximately half of all the patients with CeD present to a clinician with predominant non-GI symptoms such as short stature, liver abnormalities, infertility, endocrinopathies, etc. in the absence of or with minimal GI symptoms. The diagnosis of CeD is often not suspected in such patients, since most physicians believe that patients with CeD should have GI manifestations **(Fig. 1)**.

Therefore, patients with CeD can present to an internist/gastroenterologists with symptoms of chronic diarrhea, anemia, fatigability, to a pediatrician with irritability, diarrhea, failure to thrive and anemia, to a hematologist with anemia refractory or unresponsive to iron supplementation, to an endocrinologist with type 1 diabetes, hypothyroidism, or growth failure, to a dermatologist with dermatitis herpetiformis, to a neurologist with ataxia, peripheral neuropathy, and to a gynecologist with menstrual abnormalities or infertility.

Thus, there is an increased need for increasing awareness amongst primary care physicians, internists, gastroenterologists, hematologists, endocrinologists, and neurologists about a wide and varied spectrum of manifestations of CeD so that these patients are diagnosed early. An early diagnosis and initiation of gluten-free diet in them can control and the symptoms, and prevent consequences of malabsorption and nutritional deficiencies and prevent adverse health consequences.[5]

Therefore, CeD should be suspected in the patients even in the absence of typical gastrointestinal manifestations. We have summarized below the diseases or symptoms where screening for CeD should be done.

Who should be Screened for CeD (Table 1)

Patients having Diseases and Symptoms Secondary to CeD

Chronic Diarrhea with Features of Malabsorption

Patients having intermittent or chronic diarrhea with features of malabsorption, such as anemia, growth

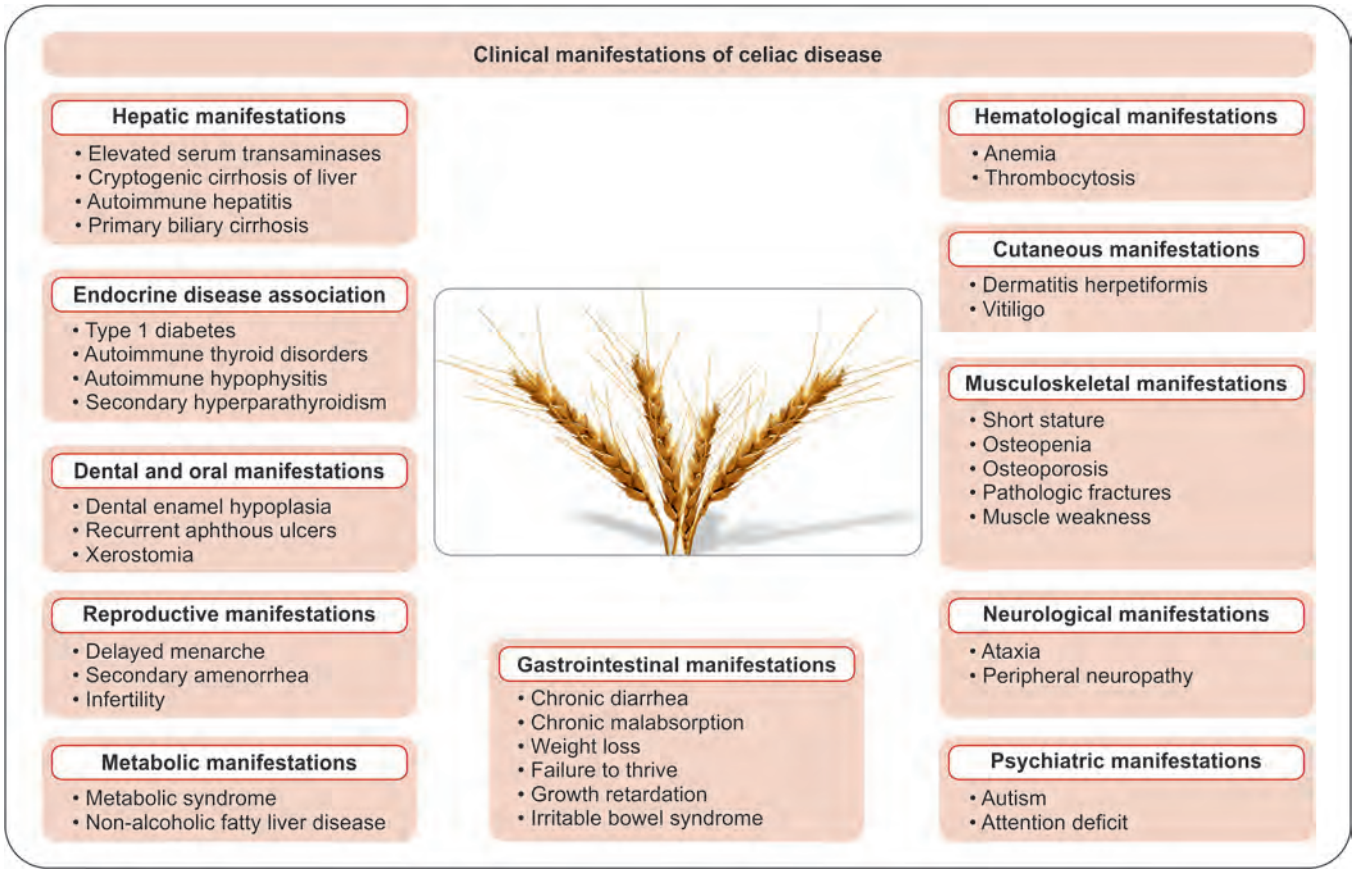

Fig. 1: Clinical manifestations of celiac disease

TABLE 1 Indications for screening for celiac disease

Gastrointestinal manifestations	*Extraintestinal manifestations*	*Associated conditions*
Chronic diarrhea	Cryptogenic hypertransaminasemia	First-degree relatives
Malabsorption	Cryptogenic cirrhosis	Type I diabetes
Growth retardation/Short stature	Infertility	Hypothyroidism
Failure to thrive	Idiopathic cerebellar ataxia	Other autoimmune diseases
Iron deficiency anemia	Dermatitis herpetiformis	Down's syndrome
IBS (IBS-D, IBS-M)		

retardation, poor weight gain, easy fatigability, should be screened for CeD. CeD is now the most common cause of malabsorption syndrome, unlike tropical sprue being the most common cause some times back.

Functional Gastrointestinal Disorders

Some of the patients with CeD may have mild GI manifestations such as altered bowel activity, abdominal pain/discomfort, and bloating. With such a symptom complex, they are likely to be diagnosed as having functional gastrointestinal diseases including irritable bowel syndrome. In fact, in a meta-analysis of 7 studies including 3,383 patients with CeD, it was shown that 38% patients with CeD had IBS-like symptoms.[6] In yet another meta-analysis of 22 eligible studies including 6,991 patients with irritable bowel syndrome, it was found that

3.3% of them had CeD more so in those having mainly IBS-diarrhea predominant and IBS-mixed subtypes.[7]

Iron Deficiency Anemia

Between 50–80% of patients with CeD have anemia and that occurs most commonly because of iron deficiency. Anemia secondary to B12 and folate deficiency in addition to iron deficiency has also been described.

On the other hand, it has been observed that 3.2% (95% CI 2.6–3.9%) of all patients with iron deficiency anemia, when screened for CeD, are found to have CeD.[8] That would mean than 1 of every 31 patients with iron deficiency anemia has CeD. In a study from India, almost 1 in 10 with iron deficiency anemia had CeD. Thus, all patients with iron deficiency anemia should be screened for CeD.

Short Stature/Growth Failure

Almost one third of the adult patients and half of the adolescent patients with CeD have short stature. Since height can increase only till 18 years of age, it is really important to make a diagnosis of CeD much before that age. A timely treatment of CeD can lead to catch up growth and attainment of a normal height.

On that other hand, of the patients presenting for the evaluation of short stature, 6.6% (approximately 1 in 15) have been found to have CeD. The proportion of patients having CeD is still higher (13.4%; 1 in 8) in those having idiopathic short stature, when all known causes have been excluded. The prediction of having CeD in these patients is higher if they also have associated GI manifestations or anemia. Nevertheless, all patients with short stature at any age, with or even without associated GI manifestations, should be screened for CeD.

Dermatitis Herpetiformis

Dermatitis herpetiformis (DH) is characterized by clusters of papules and vesicles associated with intense pruritus. The typical sites for DH lesions include extensor surfaces of upper and lower extremities, elbows, knees, scalp, and buttocks. The extent of skin lesions may vary from small area to more diffuse involving multiple sites at one time. DH shows an excellent response to GFD with complete resolution of skin lesions. Thus, all patients with DH must be screened for CeD.

Infertility

Menstrual abnormalities including delayed menarche and secondary amenorrhea are quite frequent in patients with CeD. Furthermore, patients with CeD have been found to have a low rate of fertility. Patients with CeD are at three-times higher risk for infertility than the general population. On the other hand, 2.3% of patients with infertility have been found to have CeD.[9] As CeD is one of the few treatable causes of infertility, all women patients with infertility should be screened for CeD.

Liver Abnormalities

Almost one-fourth patients with CeD have asymptomatic elevation of serum transaminases at the time of diagnosis which normalize within 1 year of GFD in majority. If this liver injury is not recognized and remains untreated, it can lead to cirrhosis of the liver. In fact, CeD has been found to be one of the causes of cryptogenic cirrhosis. Furthermore, approximately 7% of all those who have hypertransaminasemia and 5% of those having cryptogenic liver disease have been found to have CeD.[10,11] Treatment of CeD in these patients has been shown to lead to an improvement in the liver disease. Therefore, all patients with cryptogenic hypertransaminasemia and cryptogenic cirrhosis of liver should be screened for CeD. As discussed below, as anti-tissue transglutaminase antibody may be falsely positive in those with cirrhosis; therefore, a more reliable screening test in this setting is anti-endomysial antibody.

Neurological Disorders

Some of the patients with cerebellar ataxia, especially those having idiopathic ataxia, have been found to have gluten-related disorders and CeD. The treatment of CeD has also been shown to lead to some improvement in ataxia. Therefore, patients with idiopathic ataxia should be screened for gluten-related disorders. In such patients both anti-gliadin antibody and anti-tissue transglutaminase antibodies should be used for screening.

First-degree Relatives of Patients with CeD

As we know, genes play a major role in the pathogenesis of CeD. The first-degree relatives of index patients with CeD are at much higher risk of developing CeD. A recent

meta-analysis including 10,252 FDRs of patients with CeD has shown that 7.5% of first-degree relatives of CeD have CeD.[12] Furthermore, the sisters (1 in 7) and daughters (1 in 8) of the index patients with CeD are at the highest risks. Thus, all the first-degree relatives of index patients with CeD should be screened for CeD.

Type I Diabetes

CeD has been found to be strongly associated with type I diabetes and a recent meta-analysis has shown that 6% of all patients with type I diabetes have CeD.[13] It means that of 16 patients with type I diabetes, one will have associated CeD. Many of them may have symptoms because of CeD, but these symptoms are often considered to be due to diabetes, and hence they are not specifically investigated for CeD. Therefore, all patients with type I diabetes should be screened for CeD.

Autoimmune Thyroid Disease

An association has been shown between CeD and autoimmune thyroid disorders. Between 10–15% patients with CeD have coexistent clinical hypo/hyperthyroidism. In fact, a recent study showed that of 6,024 patients with autoimmune thyroid disorders screened for CeD, 1.4% patients had CeD.[14] Thus, all patients with autoimmune thyroid disorders should be screened for CeD.

Down's Syndrome

Approximately 1%–19% patients with Down's syndrome have been reported to have CeD. A recent meta-analysis of 31 studies and including 4,383 patients with Down's syndrome has reported that 5.8% of them have CeD, which is much higher than that in the general population.[15] Therefore, all patients with Down's syndrome should be screened for CeD.

Other Conditions

A higher prevalence of CeD has also been observed in certain other conditions including patients having dental enamel defects, other autoimmune disorders like systemic lupus erythematosus, juvenile rheumatoid arthritis, and autoimmune liver diseases, etc.; however, there is a lack of robust data suggesting the utility of routine screening for CeD in these patients.

How do we Screen for CeD?

Once we suspect a patient to have CeD, the first-line screening tests are the CeD specific serological tests. Immunoglobulin subclass A (IgA) anti-tissue transglutaminase, (IgA anti-tTG Ab), anti-endomysial antibody (IgA EMA), and deamidated glutamine dipeptide (IgA anti-DGP Ab) are the currently available assays for screening for CeD. Of these, IgA anti-tTG is the most commonly used test for the screening and diagnosis of CeD because of the ease of detection and a high accuracy with a sensitivity of 92.8% and specificity of 97.9%[16] (Table 2). While IgA EMA testing has a high specificity of 99%, recent systematic review has reported a lower sensitivity of 73%. Detection of anti-EMA requires indirect immunofluorescence and it is not widely available. IgA anti-DGP assay have a pooled sensitivity of 87.8% (95% CI, 85.6–89.9%), and specificity 94.1% (95% CI, 92.5–95.5%) and thus have an inferior performance than anti-tTG Ab **(Table 2)**. Since all these antibodies are IgA based, hence they may be falsely negative in patients having IgA deficiency. In such situations, IgG based tests such as IgG anti-DGP or IgG anti-tTG Ab should be done.[17]

ELISA kits for anti-tTG antibody are manufactured by many companies and their performance varies significantly. Furthermore, there are differences in the cut-off values of the anti-tTG antibody amongst ethnically different population. Hence, a clinician should be aware about these limitations.[18]

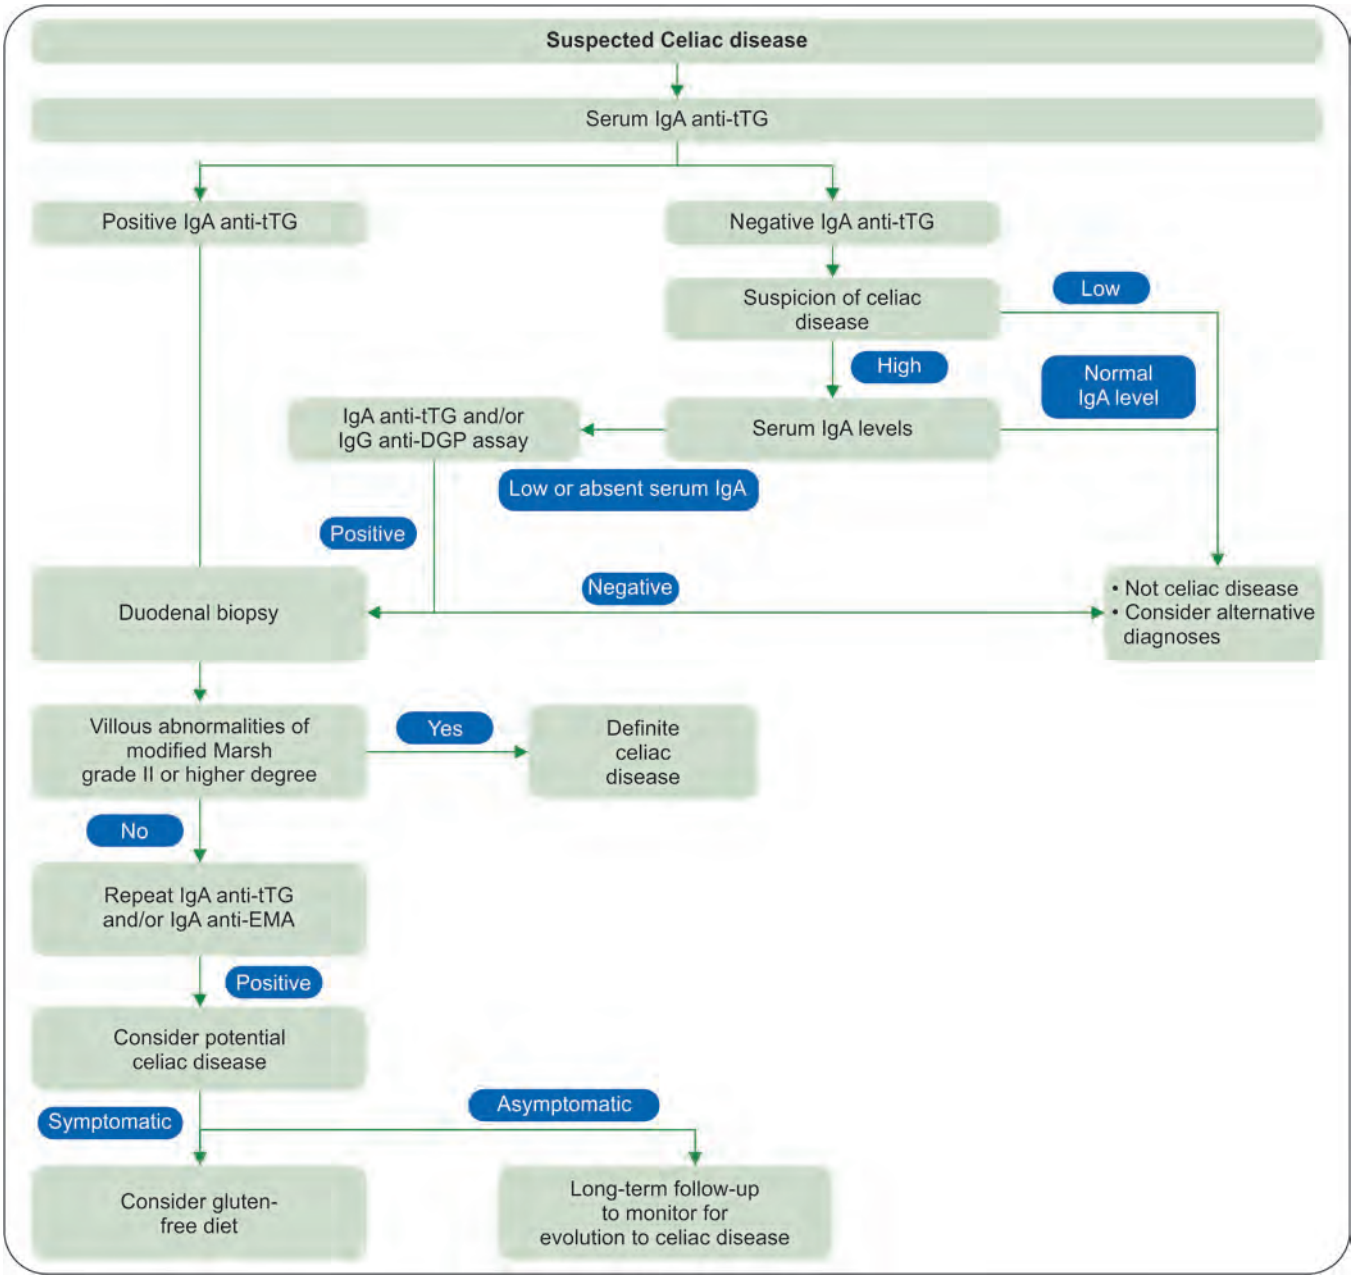
Diagnosis of Celiac Disease (Flowchart 1)

If a patient screened for CeD is detected to have a positive celiac specific serological assays, the diagnosis needs to be confirmed by demonstration of villous abnormalities in the intestinal mucosa, which is still the gold standard

TABLE 2 Diagnostic performance of various serological assays for the diagnosis of celiac disease

	Sensitivity	*Specificity*
IgA anti-tTG	92.8% (95% CI, 90.3–94.8)	97.9% (95% CI, 96.4–98.8)
EMA	73.0% (95% CI, 61.0–83.0)	99.0% (95% CI, 98.0–99.0)
IgA anti-DGP	87.8% (95% CI, 85.6–89.9)	94.1% (95% CI, 92.5–95.5)

Flowchart 1: Algorithm for the diagnosis of celiac disease



for the diagnosis of CeD. Multiple biopsy specimens from the second part of duodenum and at least one biopsy specimen from the first part of the duodenum should be taken for adequate histopathological assessment.[19-21] Modified Marsh classification system is currently used to grade the severity of villous abnormalities based on identification of increased intraepithelial lymphocytes, crypt hyperplasia, and villous atrophy. A diagnosis of CeD is made in patients with villous abnormalities of modified Marsh grade II or more.

The gold standard diagnostic criteria of CeD is based on a combination of clinical manifestations, a positive celiac specific serology and demonstration of villous abnormalities of modified Marsh grade II or more. The

European Society of Gastroenterology, Hepatology and Nutrition (ESPGHAN 2019) has suggested a *Non-Biopsy Approach* for making of a diagnosis of CeD.[20] This is based on the evidences that suggest a high degree of prediction of presence of villous abnormalities if anti-tTG Ab titers are more than tenfolds higher above the cut-off value. The ESPGHAN 2019 guidelines suggest that a non-biopsy approach may be considered in children if their anti-tTG Ab titer is more than tenfolds and there is a positive anti-endomysial antibody in a second blood samples. Otherwise, duodenal biopsies should be performed, if anti-tTG titer is less than tenfolds. For adults patients, most of the guidelines, including Indian, recommend a confirmation of diagnosis of CeD with small intestinal biopsy in patients having a positive serological test.[19,21,22]

More often around the world, the ESPGHAN guidelines are misinterpreted and the diagnosis of CeD is made even when anti-tTG Ab titer is less than tenfolds. A hurried diagnosis based on incomplete evidence leads to problems during follow-up. All efforts should be made for the confirmation of the diagnosis before advising GFD. One should realize that anti-tTG Ab, especially at low titer could be falsely positive and the enteropathic changes are not specific for CeD and they could be caused by many other conditions.

Conclusion

CeD has now become a global public health problem and it affects approximately 1% of the world's population. The spectrum of clinical manifestations of CeD is wide include both gastrointestinal and extra-intestinal manifestations. Many patients with CeD do not have GI manifestations but present solely with non-gastrointestinal manifestations. All patients with high-risk of CeD should be screened using IgA anti-tTG antibody.

CHAPTER

133 Differentiating Crohn's Disease from Intestinal Tuberculosis: A Diagnostic Challenge

Pabitra Sahu, Saurabh Kedia, Vineet Ahuja

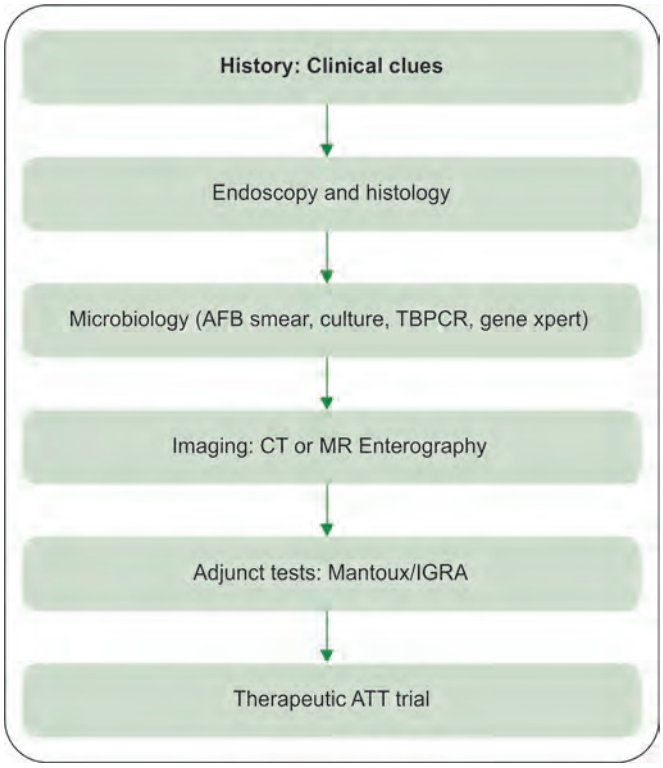
Abstract

Diagnosing intestinal tuberculosis (ITB) and Crohn's disease (CD) has always been a challenge in countries like India where TB is endemic and incidence of inflammatory bowel disease (IBD) is increasing rapidly. Definitive diagnosis of tuberculosis requires demonstrating AFB in smear or culture, caseation necrosis in biopsy or necrotic lymph node in cross sectional imaging. But all these are limited by poor sensitivity. There are certain clinical (diarrhea, hematochezia, perianal disease common in CD; fever, night sweats common in ITB), endoscopic (longitudinal, aphthous ulcers common in CD; transverse ulcers/patulous ileocecal valve common in ITB), histologic (caseating confluent large granuloma common in ITB; microgranuloma common in CD) and radiologic (long segment involvement, comb sign, skip lesions common in CD; necrotic lymph node, contiguous ileocecal involvement common in ITB) differences between CD and ITB. Despite all these differentiating features, in more than 1/3rd of cases a definitive diagnosis cannot be made without a therapeutic ATT trial. Recent advances in this field like newer biomarkers (enumeration of peripheral blood T-regulatory cells) and CT based predictive models (quantification of visceral and subcutaneous fat) can help in difficult cases. As a clinician we need to assess all these clinical and investigational parameters meticulously to solve this diagnostic conundrum.

Introduction

Intestinal tuberculosis (ITB) and Crohn's disease (CD), a sub-type of inflammatory bowel disease (IBD), are both chronic granulomatous disorders of the intestine with different etiologies, but similar presentations.[1,2] Due to globalization and industrialization Southeast Asian countries like India, which are endemic for TB, are in a state of socio-epidemiologic transition with a rising incidence of CD and other non-communicable disorders (Crohn's disease and the "white plague" hypothesis).[3,4] Despite growing number of literature, conclusive diagnosis of ITB and CD still remains a clinical conundrum. There have been reports of misdiagnosing ITB as CD for as long as 7 years before the correct diagnosis was reached.[5] Misdiagnosing these two clinical conditions can have disastrous implications like drug toxicity of anti-tubercular therapy (ATT), delay in CD-specific therapy leading to disease progression along with impaired quality-of-life, and flare up of TB on immunosuppressive therapy for CD.[6,7] For definitive diagnosis of ITB, we need to demonstrate mycobacterium tuberculosis (MTB) in smear or culture, or caseating granuloma in biopsy or a complete symptomatic and endoscopic response to ATT; but all these methods have unsatisfactorily low sensitivity.[8,9] So in clinical practice, most often we gather diagnostic clues from conglomerate of laboratory tests and investigations.[10] In this review, we will discuss the overlapping and discriminative features of both the diseases and try to elucidate a proper approach to solve the diagnostic dilemma. Evaluation of any patient suspected of ITB or CD runs through the following steps **(Flowchart 1)**:

Flowchart 1: Diagnostic algorithm



Clinical Features

Both the diseases present with some common clinical features like abdominal pain, diarrhea, partial bowel obstruction, fever, weight loss and extra intestinal manifestation (EIM) like arthralgia, skin rash, or ocular symptoms. But some of the symptoms are more frequently seen in either of two diseases. Despite some heterogeneity most studies reported diarrhea, hematochezia, perianal disease, and EIMs as being more common in CD whereas partial bowel obstruction, night sweat, and ascites predominate in ITB **(Table 1)**.[10-13] Longer disease duration also supports the diagnosis of CD over ITB, but a specific cut off for duration is not available.[12] A recent meta-analysis reported that diarrhea, hematochezia, perianal disease, and EIMs favored the diagnosis of CD, while fever, night sweats, lung involvement, and ascites favored the diagnosis of ITB.[14]

Endoscopic Appearance

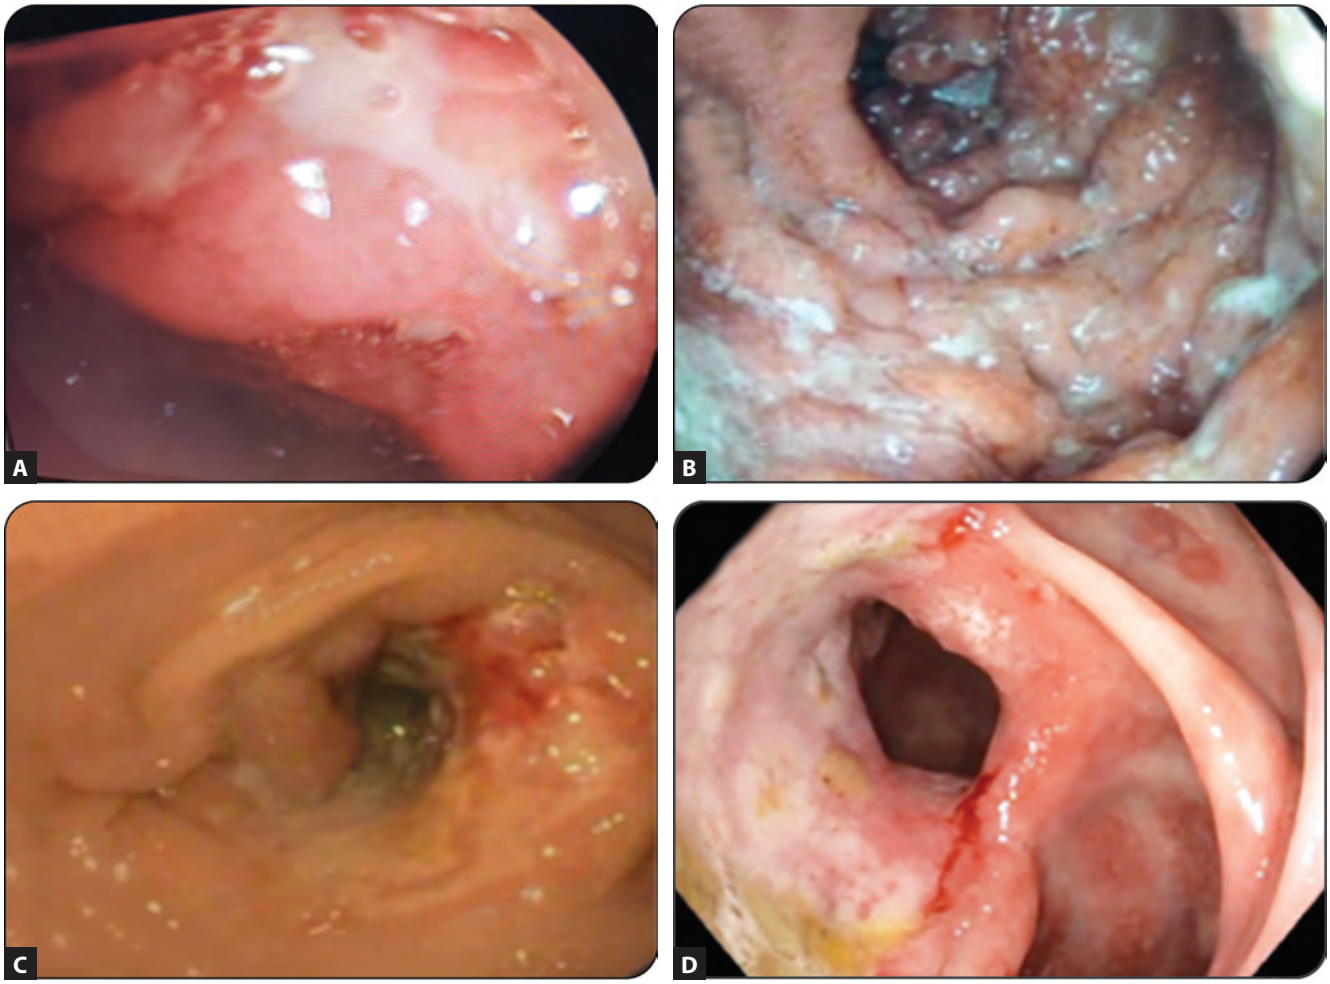
Endoscopic features in CD and ITB have been well described. Albeit some overlap, left colonic involvement, presence of longitudinal ulcers, aphthous ulcers, cobblestoning, and skip lesions are more common in CD whereas presence of transverse ulcers and patulous ileocecal valve are more common in ITB **(Table 1 and Figs. 1A to D)**.[10,11,13,14] Lee et al. described a predictive model based on four common endoscopic findings in CD (anorectal lesion, longitudinal ulcers, aphthous ulcers, and cobblestone appearance) and ITB (less than 4 segment involvement, patulous IC valve, transverse ulcers, and pseudopolyps). A score of +1 and –1 was assigned for each parameter of CD and ITB respectively. Total score >0 indicated the diagnosis of CD with a PPV of 94.9% and score <0 indicated diagnosis of ITB with a PPV of 88.9%.[15]

TABLE 1 Features differentiating CD and ITB

	Favoring Crohn's disease	*Favoring ITB*
Clinical features	• Chronic diarrhea • Hematochezia • Perianal disease • Longer duration of symptoms	• Ascites
EIM	• Peripheral arthropathy • Aphthous ulcers • Any/multiple EIMs	
Endoscopic features	• Left as well as right colonic involvement • Longitudinal ulcers • Aphthous ulcers • Cobblestoning	• Transverse ulcers • Ileocecal valve involvement
Histology (minimum 6–8 biopsies from the ulcerated and inflamed area)	• Microgranuloma	• Large caseating confluent granuloma
Radiology	• Long segment involvement • ≥3 segments involvement • Comb sign • VF/SF >0.63 • Pseudosacculation	• Ileocecal involvement • Lymph node >1 cm • Necrotic lymph node • <3 segment involvement • Short segment involvement

Histopathology

Both these diseases are chronic granulomatous disease of the GI tract and share many histopathological features



Figs. 1A to D: Endoscopic images. (A) Deep longitudinal jejunal ulcer in a patient with Crohn's disease. (B) Cobblestoning in a patient with Crohn's disease. (C) Ulcerated stricture in a patient with ITB. (D) Strictured IC valve with gaping in a patient with healed ITB

like architectural abnormalities (crypt distortion, crypt branching, or crypt loss), chronic inflammation (chronic inflammatory infiltrate, increased IEL, basal plasmacytosis) and granulomas.[10,16,17] But there are subtle differences which can be helpful to discriminate these two pathologies. As reported by Pulimood et al., granulomas are more common in tuberculosis than CD and tubercular granulomas are usually multiple (>5–10/HPF), large (>200 μm), confluent, located more in submucosa and with central caseation which is almost pathognomic for ITB while the granulomas in CD are sparse, small and poorly organized (microgranuloma).[17,18] Apart from granuloma, ulcers lined by epitheloid histiocytes and disproportionate submucosal inflammation favors the diagnosis of ITB, on the other hand focally enhanced colitis is characteristic of CD. A recent meta-analysis also echoed similar findings.[19] One of the major limitations of HPE is that more often we do not find granuloma in biopsy specimens to characterize it. Minimum 6–8 biopsies must be taken from the ulcerated and inflamed area to mitigate this problem.

Microbiology

One of the major challenges of diagnosing ITB is the poor sensitivity of microbiological tests to detect the bacilli **(Table 2)**. ITB is a paucibacillary disease, so demonstrating the organism is difficult. Acid fast bacillus (AFB) staining in a biopsy specimen has a sensitivity of 2.7–37.5% as reported in different studies.[20-22] Although culture of intestinal biopsy in Lowenstein Jensen medium is the

TABLE 2 Sensitivity of different microbiological tests for ITB

Diagnostic tests	*Sensitivity*
AFB smear[20-22]	(2.7–37.5)%
Culture (LJ/BACTEC)[21-23]	(19–50)%
TB-PCR[24]	47%
Gene-Xpert MTB/RIF[20,25]	(8.1–32)%

gold standard, it has been replaced largely by BACTEC culture which is less time consuming. Most of the studies have reported less than 50% culture positivity rate in biopsy from ITB patients.[8,21-23] Polymerase chain reaction targeted against IS6110 (TB-PCR) as a stand-alone test is not diagnostic for ITB but can help in diagnosis. Jin et al. in his meta-analysis reported a pooled sensitivity of 47% and specificity of 95% for TB-PCR in intestinal biopsy.[24] Gene-Xpert MTB/RIF in the intestinal biopsies has not been well studied in patients with ITB. In a study of 37 ITB patients it showed sensitivity of 8.1% and specificity of 100%.[20] Another study by Bellam et al. reported sensitivity of 32% and specificity of 100%.[25]

Radiology

CT/MR enterography are the preferred imaging modalities for evaluating and differentiating between patients with ITB and CD. Along with access to whole of the GI tract, cross sectional imaging has additional advantage as it can detect other significant findings like peritoneal or omental involvement and mesenteric or intra-abdominal lymphadenopathy. CT findings commonly seen in patients with CD are left colonic involvement, multifocal (>3 segments) or long-segment involvement, comb sign, and pseudosacculation. On the other hand, involvement of ileocecal area, short segment involvement (<3 cm), and presence of lymph nodes larger than 1 cm are more common in ITB.[26,27] A predictive model based on three characteristics [long segment (>3 cm) involvement, >1 cm lymph node, ileocecal involvement] had a specificity of 90% in differentiating CD from ITB.[27] A meta-analysis involving six studies concluded that necrotic lymph nodes had the highest diagnostic accuracy (sensitivity 23%, specificity 100%) for ITB diagnosis, and comb sign (sensitivity 82%, specificity 81%) followed by skip lesions (sensitivity 86%, specificity 74%) had the highest diagnostic accuracy for CD diagnosis[28] **(Figs. 2A to D)**.

Patients with ITB may also have evidence of concomitant pulmonary involvement. 3–25% of ITB patients show evidence of healed or active pulmonary TB on chest X-ray.[29] Data from our centre (not published) indicates addition of CT chest (in place of chest X-ray) with CT enterography can significantly increase the sensitivity of diagnosing ITB.

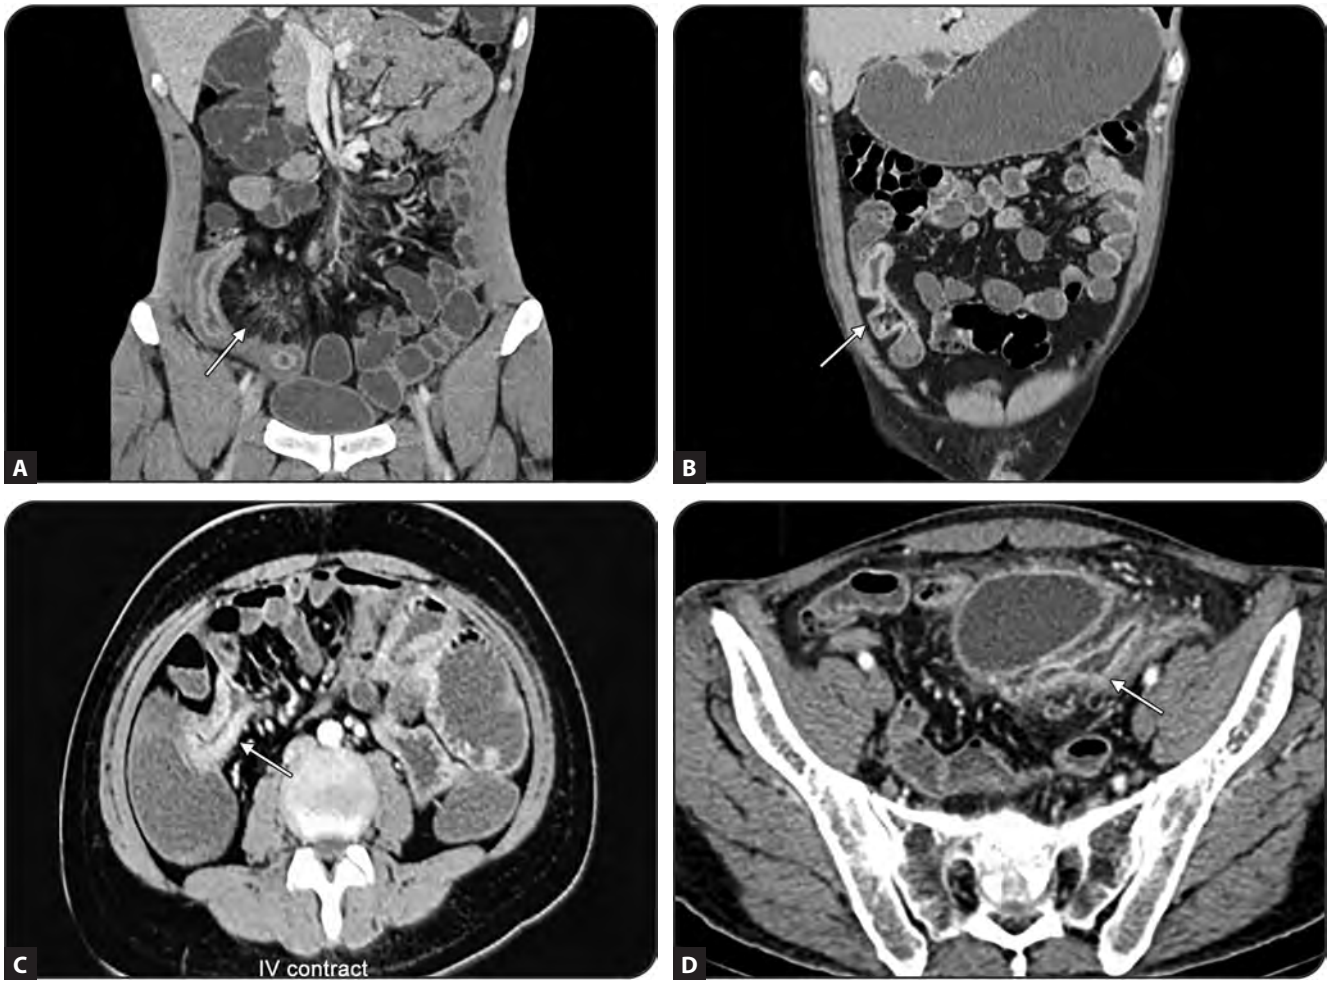
Adjunct Tests

Both interferon gamma release assays (IGRA) and Mantoux are predictive of latent TB rather than active TB; hence, a positive or a negative IGRA will neither rule in nor rule out the diagnosis of ITB. Positive Mantoux has been reported in 50–100% patients with ITB patients whereas meta-analysis on IGRA reported a pooled sensitivity of 74% and specificity of 87% in differentiating ITB from CD.[30,31] Both these tests provide supporting evidence but are not diagnostic.

Another serological test, anti-saccharomyces cerevisiae antibody (ASCA), has been investigated for this purpose but one study from India and a recent meta-analysis denied any significant role.[32,33]

Therapeutic ATT Trial

As we have discussed above, all these investigations have limited diagnostic accuracies and despite all these tests, in some cases it is nearly impossible to conclusively diagnose ITB or CD. Treating with steroid in such cases can be disastrous if the patient has underlying ITB, so trial of ATT is almost imperative for further management of such a case. A recent retrospective study from Korea reported that 17.9% CD patients were misdiagnosed as ITB and 10.8% patients of ITB were misdiagnosed as CD before the correct diagnosis being made. Forty-eight percent of ITB patients required therapeutic ATT trial for the final diagnosis.[34] Asia-Pacific consensus statements for CD have also advocated ATT trial in a patient with CD/ITB dilemma, and the diagnosis of CD should be considered in a patient who does not respond to ATT, and subsequently responds to CD-specific therapy.[35] But the big question is the timeline of ATT trial, when to say a patient as non-responder and how to assess response. A recent study from our centre compared the response between two groups (CD patients who received ATT as therapeutic trial and ITB patients). By 3 months more than 90% of patients with



Figs. 2A to D: Radiologic images (CT enterography). (A) Stricture with comb sign in a patient with CD. (B) Pseudosacculation in a patient with CD. (C) Thickening of terminal ileum with IC valve involvement in a patient with ITB. (D) Long segment stricture with enhancement and proximal dilatation in a patient with CD

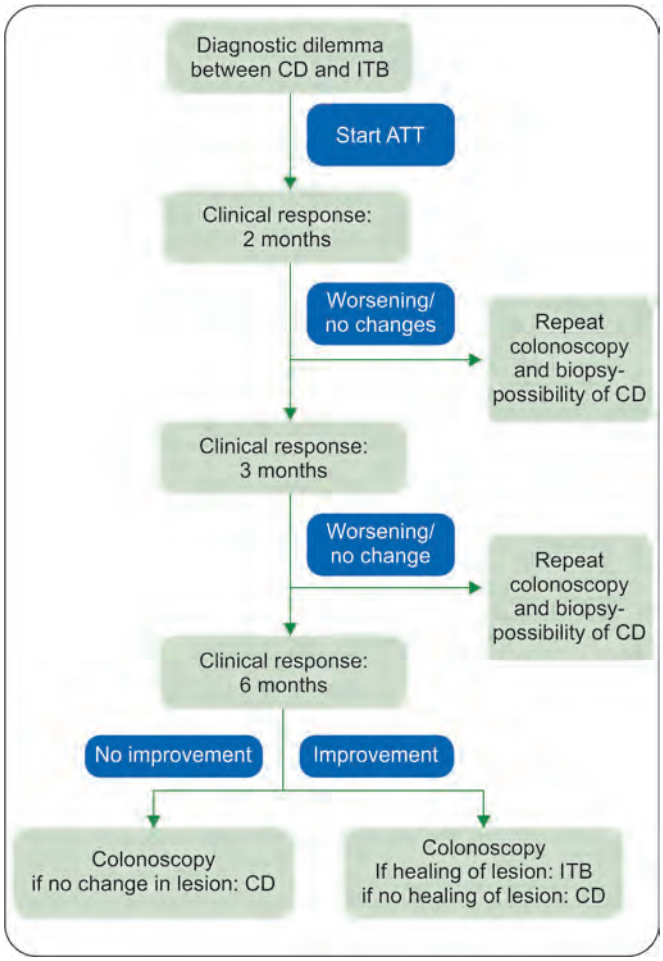
ITB, and up to 1/3rd patients with CD responded to ATT but response was ill-sustained in patients with CD, and up to 80% of them worsened on follow-up. Moreover, repeat colonoscopy at 6 months of treatment showed mucosal healing in 100% patients with ITB, whereas less than 5% of patients with CD had an endoscopic response.[36] Based on this study following algorithm has been proposed which is now a routine practice **(Flowchart 2)**.

Pitfalls of the Strategy

One of the major concerns is that should we consider possibility of MDR-TB while designating a case as CD on the basis of non response to ATT trial. There is not much data on prevalence of MDR-TB in gastrointestinal tuberculosis. Lin et al. reported MDR-TB rate of 13% among patients with lower gastrointestinal TB.[37] But an Indian study reported a prevalence of only 5.4% among patients with abdominal TB and another study from our center found no cases of MDR-TB among patients with ITB.[20,38] Moreover ITB being a paucibacillary disease is expected to have a low rate of drug resistance.

Although most ITB patients respond well to ATT, study from our centre showed that only one-fourth of patients with ITB related stricture had resolution of stricture after ATT and majority had symptoms pertaining to stricture even after ATT.[39] This observation should also be kept in mind during assessment of response to ATT.

Flowchart 2: Algorithm for follow-up of a patient with CD/ITB dilemma who has been initiated on a therapeutic ATT trial



Predictive Models

Due to limitation in accuracy and sensitivity of any single characteristic, several multiparametric predictive models incorporating more than one feature across single or multiple diagnostic modalities have been described. A multicentre study from India described hematochezia, weight loss, sigmoid colon involvement, and focal enhanced colitis as independent predictors for diagnosis of CD/ITB, and a score based on these variables had an AUC of 0.91 in differentiating CD from ITB.[10] Another Korean study included age, gender, diarrhea, transverse ulcer, longitudinal ulcer, sigmoid colon involvement, and suspicion of pulmonary TB in their predictive models. The AUC for differentiating CD and ITB was 0.98, and on validation in a separate cohort, the accuracy was similar with an AUC of 0.92.[40] But most of these predictive models have their own limitations in terms of application in clinical practice and these have not been widely validated across other population.

Recent Advances in this Field

There have been many recent advances in the field regarding newer biomarker or other investigational parameters to differentiate these two diseases.

Mesenteric fat proliferation and creeping fat have long been associated with active CD.[41,42] A Korean study described increased visceral fat (VF) in patients with CD and ratio of VF and subcutaneous fat (SF) can help in differentiating CD from ITB.[41] Yadav et al. in his study established a cut off value for VF and SF ratio. At a cut off value of 0.63, VF/SF ratio was found to have a sensitivity of 82% and specificity of 81% in differentiating CD from ITB. It showed equally good diagnostic accuracy when applied to the validation cohort.[42] Another study from our centre combined VF/SF ratio with other features on CT scan and showed that combination of VF/SF >0.63 and long segment involvement was almost exclusive for diagnosing CD.[43]

T-regulatory cells (CD4+CD25+FOXP3+) are regulators of inflammation and these are increased in peripheral blood and at the site of infection in patients with pulmonary TB. In a preliminary study, it was shown that FOXP3 mRNA expression was upregulated in the colonic mucosa of patients with ITB as compared to CD.[44] We further showed higher frequency of FOXP3+ T regulatory cells in peripheral blood of patients with ITB compared with CD. A value of more than 32.5% for FOXP3+ cells in peripheral blood could differentiate ITB and CD with 75% sensitivity and 90.6% specificity.[45] This has also been validated in a separate cohort of 73 patients.[46] VF/SF ratio and circulating FOXP3+ cells in peripheral blood are specially helpful where differentiation between CD and ITB is not possible on the basis of routine radiological, histological, and microbiological evidence.

One recent study reported that immune-histochemistry (IHC) for CD-73 in biopsies could differentiate granulomas of CD and ITB with high diagnostic specificity but it has not been replicated in other studies.[47]

He et al. developed a nomogram based on seven parameters that were significant on regression analysis including age, transverse ulcer, rectum involvement,

skipped small bowel involvement, target sign, comb sign, and IGRA (for model 1) or Mantoux test (for model 2), respectively. Nomogram 1 showed a sensitivity of 86.8% and specificity of 90.9% while nomogram 2 showed 84.2% sensitivity and 100% specificity for differentiating CD from ITB in the validation cohort.[48]

One of the most significant findings was described recently from our centre. It described that patients who received ATT before an eventual diagnosis of CD have higher chance of progressing to stricturing or fistulizing disease compared to patients who are ATT naive (OR: 11.05; 95% CI 3.17–38.56, p <0.001) and they also have higher risk of surgery than ATT naive patients (HR: 3.22; 95% CI, 1.46–7.12, p = 0.004) on long-term follow-up.[49] This finding can challenge our practice of therapeutic ATT trial in cases with diagnostic dilemma. This also highlights the importance of accurate discrimination between these two diseases right at the outset and the importance of close follow-up and early assessment in suspected cases.

TB on CD: The New Challenge

As more and more patients of CD are now being treated with anti-TNF therapy in developing countries like India, a new challenge is setting in. Agarwal et al. reported that 11.6% IBD patients on infliximab therapy developed reactivation of tuberculosis despite that all these patients were screened for latent TB before the initiation of therapy and most of them developed it within 1st year of therapy.[50] Similar findings have also been reported in other studies.[51] A recent meta-analysis compiled 128 studies (130,114 IBD patients) and reported a pooled prevalence of 0.08% for developing TB on anti-TNF therapy. The risk increased with increasing TB burden, pooled prevalence being 0.02%, 0.21%, and 1.59% for low, intermediate, and high TB burden countries, respectively. Seventy-three percent of patients who developed TB had no evidence of latent TB on screening. Apart from therapeutic challenge, this tubercular reactivation poses a new set of diagnostic dilemma, as to decide whether it was ITB to start with or it is only tubercular reactivation on immunosuppression.[52]

Conclusion

Since time long the deceptive similarities between CD and ITB has been a matter of debate among clinical practitioners. With scientific advances and availability of newer radiological tools and biomarkers, we have made significant progress in solving the clinical dilemma. But it needs careful interpretation of all diagnostic evidence and clinical judgment on case to case basis. And with newer challenges like "TB on CD" or ATT complicating disease course of CD patients, we need to be more accurate, more precise, and more vigilant in diagnosing and managing patients with ITB and CD.

CHAPTER

134 Acute Liver Failure and Acute-on-Chronic-Liver Failure in India: How They Are Different from West?

Subrat Kumar Acharya

Abstract

Acute liver failure (ALF) and acute-on-chronic-liver failure (ACLF) are severest forms of liver failure with high short-term mortality. Their definition and diagnosis depend upon the clinical phenotypic presentation and global consensus on each of these entities are lacking due to differences in regional etiologies of liver injury which is considered to be important determinants of the natural course and clinical manifestations of such liver failures. These differences have been discussed in the present chapter. While hepatitis virus(es) are the major causes of ALF and to some extent in ACLF India, etiologies of ALF in West is heterogenous with Paracetamol overdose as the major causes. Pregnant females in India are more prone to contact hepatitis virus(es), particularly hepatitis E virus and develop more severe hepatitis leading to more frequent ALF than similar patients in males and non-pregnant females. Such events in west is infrequent. Cerebral edema and infections are major complications in ALF leading to high mortality. Prognostic models in ALF are important to identify patients for liver transplant which is associated with significant improved survival in those who are likely to die with expectant therapy. The prognostic models in ALF described from west have been found to perform less efficiently than the recently described ALF-Early Dynamic model (ALF-ED) from India. The differences and controversies in definition of ACLF in Asia Pacific region including India and West (EASL-AASLD) have been discussed in the present chapter. At present Alcohol has emerged as a major cause of ACLF globally. Hepatitis virus(es), drugs, complementary alternative medicines induced acute hepatic insult over pre-existing chronic liver disease are other major causes of ACLF in India while infection, variceal bleed, and alcohol are the major causes of ACLF in west. Occurrence of sever systemic inflammatory response in such patients leading to multiorgan dysfunction results in high short-term mortality. Within 3–7 days of onset of ACLF the prognostic models described both from Asian Pacific region and west predicts mortality assisting in providing to liver transplant to such patients.

Introduction

In health, the liver has multiple functions, and liver failure usually denotes loss of these functions, often threatening life.[1] The concept of liver failure is getting clarified over time and have several phenotypes. The most frequent form of liver failure encountered in clinical practice is the chronic liver failure as in cirrhosis of the liver. In such patients, development of varices, ascites, variceal bleed, encephalopathy, renal failure, and infections gradually sets in over a long period, in many months to many year.[2] In contrast to the above sequential events in cirrhosis, some of them do present with rapid and sudden deterioration in their liver function and liver reserve resulting in features of acute decompensation (AD) (sudden and rapid development of ascites, encephalopathy, variceal bleed), often with occurrence of jaundice, prolonged International Normalized Ratio (INR) with or without kidney failure and infrequently with involvement of other extrahepatic organ dysfunction or failure over few days or weeks. Such rapid AD usually ensues subsequent to an

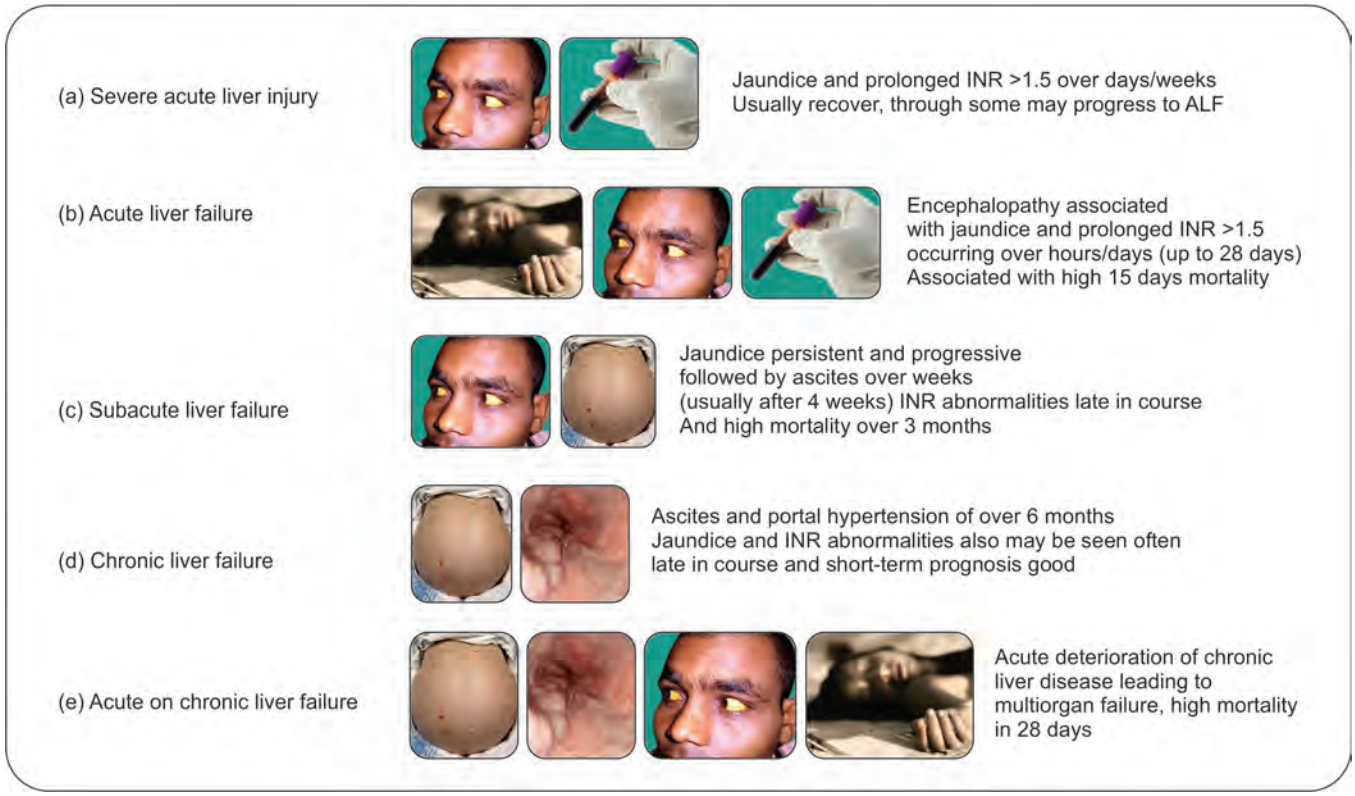

Fig. 1: Five phenotypes of liver failure. In (a), (b), and (c), there is no previous known liver disease. However, it unclear if presence of a subclinical mild liver disease will change presentation, course and outcome, e.g., in patients with non-alcoholic fatty liver, silent autoimmune hepatitis, Wilson's disease, or inactive hepatitis B carrier state. Since classification is based on clinical presentation, phenotype concept helps to classify patient for planning management

acute precipitating event like acute hepatic insult (drugs, super infection of another hepatitis virus or reactivation of underlying etiology of existing chronic liver disease), or a sequel of cirrhosis like a variceal bleed, infection thus causing, rapid loss of hepatocyte reserve in an already compromised liver.

These later patients die quickly and a 28 days mortality of around 50% (high short-term mortality) have been documented in many reports.[3-5] This is in contrast to those patients with cirrhosis who gradually decompensate over years in whom the annual mortality depending upon the decompensating event is much lower.[2] Therefore, the former patients are identified as a distinct group with liver failure and named as "Acute-on-Chronic Liver Failure (ACLF)," albeit, there is no universally accepted consensus definition of this entity.[3-5]

However, various hepatotoxic agents like drugs, hepatitis viruses, and ischemia may cause acute hepatitis in individuals with naïve liver. Patients with acute hepatitis may also have variable degree of liver injury with variable clinical manifestation and natural course such as: conventional acute hepatitis with high spontaneous recovery, severe acute liver injury (sALI), acute liver failure (ALF), or subacute hepatic failure (SHF).[6] The later two forms are associated with high short-term mortality. So the presentations of liver failure in a naïve liver could be acute or subacute. **Figure 1** depicts various forms of Liver Failure.[7]

Patients with acute hepatitis having persistent or progressive jaundice for several weeks with coagulopathy (INR >1.5), but without encephalopathy, are recognized as sALI.[6] Appearance of encephalopathy in such a patient with in few hours to days or weeks is termed as ALF **(Fig. 2)**.[7] Whereas, some with acute hepatitis, in whom the jaundice is prolonged or increases for over a month followed by appearance of ascites (as the manifestation

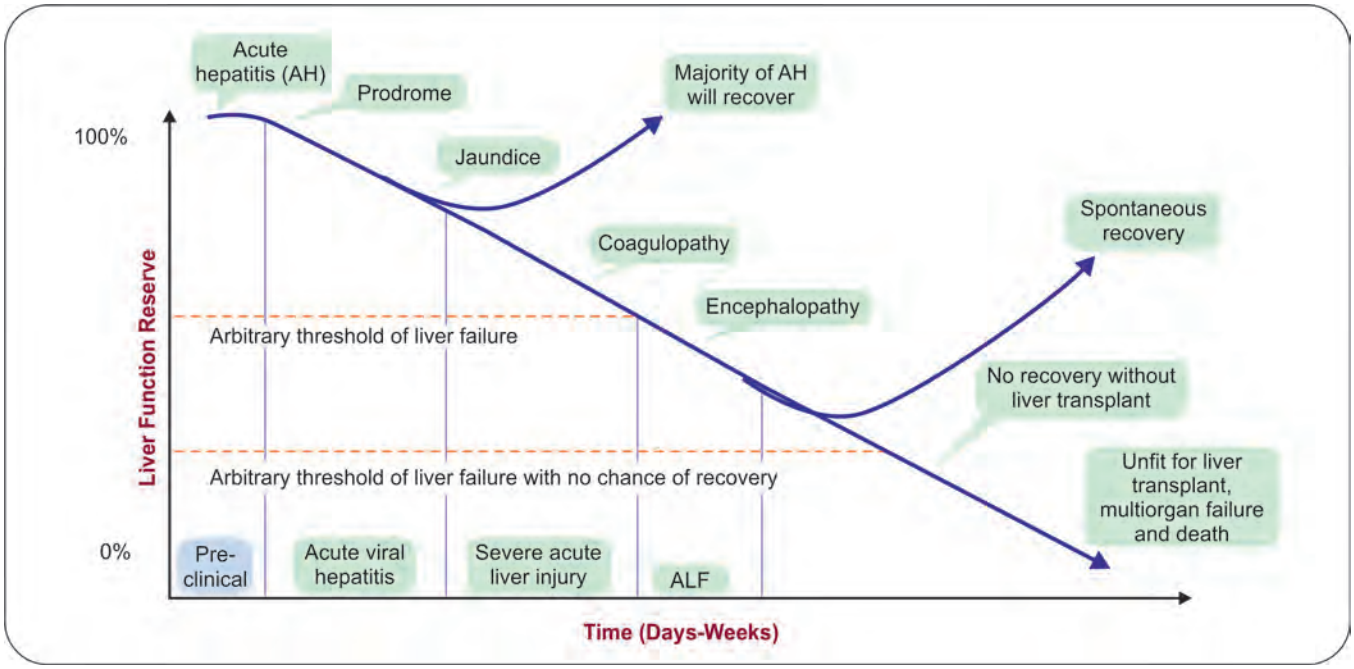

Fig. 2: Clinical course of acute liver failure as seen in Indian subcontinent after infection with a hepatitis virus or drugs or Complementary Alternative Medicine (CAM). As liver dysfunction proceeds rapidly, patient may slide from stage of acute hepatitis to severe acute liver injury and then to (or often directly to) acute liver failure. Deterioration may be seen over a few hours, days, or less often weeks

of liver failure), are identified as patients with SHF.[7] These entities of ALF, SHF, and ACLF are associated with high short-term mortality but the former two occur over a naïve liver, whereas the later ensues over a pre-existing chronic liver diseases either known or diagnosed previously or unknown carrying a silent underlying chronic liver disease[3-5,7] Their diagnosis is based on their characteristic phenotypic presentation with absence of any evidence of presence of chronic liver disease in the former two and with direct or indirect evidence of clinical/endoscopic/imaging or histologic evidence of chronic liver disease in the later. The characteristic differences between these three forms of liver failure have been depicted in **Table 1**.

The present chapter is not intended to include the management of ALF and ACLF or any other form of liver failure and they need a complete chapter by themselves.

Acute Liver Failure

Definition

Trey and Davidson in 1969 first defined ALF "as appearance of encephalopathy within 8 weeks of the onset of acute hepatitic illness, in an individual without pre-existing liver disease." However, over the ensuing time, regional difference in etiology, natural course, complication, and some demographic features in ALF were reported, resulting in variable definition of ALF.[8] Each definition included encephalopathy as an essential criteria but some centers additionally included prolonged INR (>1.5) or prothrombin time (PT) prolongation by more than 15 seconds over control or prothrombin activity (<40%) as an additional criteria to define ALF.[8] The essential difference in various definitions of ALF was "the interval between onset of acute hepatitis illness and subsequent encephalopathy and varied from 2 to 26 weeks.[9] In India, hepatitis virus(es) are the most frequent cause of ALF and encephalopathy occurred in all patients within 4 weeks of onset of jaundice.[10,11] The American Association for the Study of Liver Diseases (AASLD), however defines ALF if encephalopathy ensues within 26 weeks of onset of acute hepatitis symptoms.[9] Indian National Association for the Study of Liver (INASL) consensus statement on ALF published recently defines ALF "A clinical syndrome characterized by encephalopathy, jaundice, and prolonged PT (INR >1.5) developing in a patient without pre-existing liver disease within 4 weeks of the

TABLE 1 Clinical differentiation between acute liver failure (ALF), subacute hepatic failure (SHF), and acute on chronic liver failure (ACLF)[7]

Criteria	*ALF*	*SHF*	*ACLF*
Previous liver status	Naïve – No h/o of previous liver disease	Naïve-No history of previos liver disease	Presence of underlying liver disease either in history or by evidences accrued at presentation
Clinical			
Presentation:			
• Encephalopathy	Present (Definition)	Absent at presentation	Usually absent at presentation
• Jaundice	Usually present	Always present	Always present
• Overt features of Cerebral edema	In 50–80%	Usually absent	Usually absent—occurs as terminal event
• Ascites	Invariably absent	Always present	Always present
• Liver size	Small—not palapable—Liver span reduced markedly	Usually not small—Liver span normal or increased	Not small—may be palpable, span is not reduced in most
• Precipitting factors	Not identified—primay cause of liver damage causes liver failure	Not identified—Primary cause with impaired regeneration cause liver failure	Usally present—Sepsis, variceal bleed, super infection, Superadded DILI, alcoholic binge, flare of underlying cause of chronic liver disease, idiopathic
Laboratory Parameter			
Transaminases	Markedly raised 15–30 times ULN	Moderately raised—5–10 times ULN	Minimally or moderately raised depending upon Precipitating factors—3–5 times ULN
INR	>1.5	Usualy prolonged variably	Prolonged (>1.5 as per APASL definition)
Bilirubin	Markedly raised	Markedly raised	Moderately raised
Albumin	Usually normal—may be decreased in Pregnant females	Initially normal—reduces over time	Usually low than normal
Arterial Ammonia	Markedly raised (100 micromoles/L	Not raised or moderately raised	Mildly raised—may be raised in flares or super added liver injury (usually less than 100 micromoles)
Natural Course			
Duration of disease course	Usually 2–7 days	Months—4 week to 6 months	4 weeks to 1 year
Imaging	Naïve small liver	Regenerating nodules—resulting in humps on liver surface	Evidence of chronic liver disease with or without porto-systemic collaterals
Endoscopy	No varices (but not usually done)	In 30% small varices may present	More than half ususlly have varices
Histology	Features of acute hepatitis with sub massive necrosis of liver	Acute hepatitis with bridging necrosis	Features of Chronic liver disease with or without super added acute liver damage
Etiology	Mostly hepatitis viruses, ATT drug	Hepatitis viruses, drugs	Alcohol, hepatitis virus, NAFLD, other cause of CLD, Precipitating factors in preexisting CLD

APASL, Asian Pacific Association for the Study of Liver; CLD, chronic liver disease; INR, international normalized ratio; NAFLD, non-alcoholic fatty liver disease; ULN, upper limit of normal

onset of symptoms. A few patients presenting with sALI mostly due to DILI may develop encephalopathy later than 4 weeks up to 8 weeks."[7] Further, because the etiology of ALF is heterogenous in the West, all patients clinically do not have similar natural course and subclassification of ALF depending upon the interval between onset of acute hepatitic illness and encephalopathy has been suggested by British and French.[7-9] The French subclassification categorizes ALF in to:

- Fulminant Liver failure (encephalopathy occurring within 2 weeks of onset of jaundice) and
- Subfulminant (encephalopathy occurring between 2 and 12 weeks of jaundice).

The British subcategorizes them to three groups:

- Hyperacute liver failure (encephalopathy within 7 days of onset of jaundice
- ALF (encephalopathy between 7 days and 4 week)
- Subacute hepatic failure (SHF) (encephalopathy within 5–24 weeks of onset of jaundice).[11]

These regions noticed that those presenting with hyperacute or fulminant liver failure had better survival than the other ones and therefore subcategorized them and such events do influence on deciding high risk patients for liver transplantation. However, in India, large series have reported that rapidity of onset of encephalopathy (hyperacute) and the others had similar outcome probably due to homogeneous etiology. Therefore, in India, most patients are either hyperacute or acute without any difference in outcome and practically do not need any subcategorization.[11]

Etiology

The differences in etiology of ALF among the adults across the world are striking **(Tables 2 and 3)**.[7,9] In India, viral etiology predominates, which is responsible for

TABLE 2 Etiological profile in ALF across various centers in India[7,9,11]

90% of ALF cases. The various viral etiologies in order of frequencies those reported in published studies include, non-A to non-E in about 40%, HEV in approximately one third, whereas HBV and HAV causing ALF is less frequent.[7,10,11] Among other causes of ALF, drugs—especially antituberculosis drugs—account for 6% of the cases of ALF. Whereas in the West, where safe drinking water is available, feco-orally transmitted viruses (HEV and HAV) are not seen; drugs and toxins are major causes of ALF and acetaminophen overdose is the most common factor responsible. **Tables 2 and 3** highlight the different etiologies of ALF across the world.[7,9]

Complications of ALF

Patients with ALF may develop various life-threatening complication but their magnitude varies regionally.

- *Renal failure:* In the western reports renal failure in ALF was documented in 40–80% of ALF. NSAIDs and acetaminophen are the dominant cause of ALF in the West and these agents are well-known nephrotoxic agents. In contrast, hepatitis virus(es) being the most common cause of ALF in India do not cause direct nephrotoxicity and therefore renal failure have been reported in about 10% of the patients.[7,9,11] The other causes associated with increased incidence of renal failure include amanita poisoning and trimethoprim-sulfamethoxazole toxicity.
- *GI bleed:* Gastrointestinal bleed has been reported less frequently from all the part of the world, despite associated coagulation abnormality in these patients. The usual reported frequency of gastrointestinal bleed in most series varied between 7% and 20%.[9]
- *Cerebral edema:* Frequency of overt cerebral edema in ALF have been reported to be present in 58% of the Indian patients at hospitalization.[12] Eighty-two percent patients of these with cerebral edema died in comparison to 44% mortality in those without it.[11,12] Cerebral edema irrespective of the region was reported to be one of the main causes of death in ALF. Both from the east as well from the West, cerebral edema has been reported more frequently as the encephalopathy grade worsens.[7,9,11,12] Intracranial pressure estimation assesses the intracranial hypertension subsequent to cerebral edema. With the wide availability of such

methods, presence of intracranial hypertension due to cerebral edema has been documented in all patients with ALF irrespective of the grades of encephalopathy.[9] However, in the West, over the years, improvement in awareness about ALF, early referral to tertiary care center and improved intensive unit care, frequency of cerebral edema in the West is being reported to be less frequent than in former years.[9]

- *Sepsis:* Infection in ALF is frequent and reported from both West and India.[9] ALF is a condition associated with innate immune system compromise occurring rapidly.[7] Therefore infection in them occur very early in the course of the disease.[9,12] The incidence of infection in the authors' experience, from a single center in India is around 55%, the most common site of infection is respiratory tract and the commonest organisms are Gram-negative bacilli.[9,11] Quarter of the patient in the series reported by the author had also fungal infections.[11] From the UK, the report on ALF in early series, identified that about 90% of their patients develop infection, which included bacterial sepsis in 80% and 32% had fungal infection.[9] In more recent reports the predominant organisms reported from the West are Gram-negative but the initial reports from the UK the gram positive organisms were isolated more frequently.[13]

Key points: Complications

- Renal failure in ALF is frequent in the West, because the bulk of the patients are due to drugs (Acetaminophen is associated with direct nephrotoxicity)
- Renal failure in ALF is infrequent in India because of predominant viral etiology
- Sepsis is frequent in ALF. In the West and the bacterial species are mixed between Gram-positive and Gram-negative whereas Gram-negative organisms are common in India. In about quarter of Indian patients' fungal infection has also been documented

Gender, Pregnancy, and Acute Liver Failure

All over the globe, in ALF females predominates except in Japan where the sex distribution is even between the two genders. Despite the fact that the etiology across the region are distinct, the predilection of female sex to develop ALF remains unclear. In India as described earlier, hepatitis virus(es) are the major etiological agent particularly HEV. Various epidemiological as well as sporadic studies reveal that pregnant females are more prone than nonpregnant females and males to contact HEV infection and also develop severe liver diseases than similar male and nonpregnant females patients.[7,9] Further, it is believed that pregnant women with ALF than the ALF in nonpregnant women and males are more sick with higher complication rates and mortality. However, the later conjecture was not evidence based and a large study on pregnant ALF due to viral hepatitis from India disproved this conjecture indicating that in India pregnant females with ALF (except in Acute Fatty Liver of Pregnancy or severe pre-eclamptic toxemia induce ALF) do not benefit from the termination of pregnancy.[14] A summary of studies reporting pregnancy and ALF is shown in **Table 4**.[7,9]

The number of pregnant patients developing ALF is relatively small in the West and therefore do not constitute a major problem in management. In India, about 60% of the females with ALF in the child bearing age are pregnant whereas, the fertility rate among similar population in general is 2.9%.[9,14] It is believed that pregnancy is a immunocompromised state with predilection to contact various infections and manifest usually in more severe form. Multiple epidemics of HEV infection have been documented in India.[7] During such epidemics, pregnant females had more frequent infection (12–20%) than the men and nonpregnant women (2–4%) for unclear reasons.[9,15] The frequency of ALF among the pregnant females was also higher (10–22%) than similar men and nonpregnant women (1–2%).[7,9] This observation indicate that pregnant females are more prone as well develop more severe liver disease subsequent to HEV infection, which is the major cause of viral hepatitis as well as ALF in India. Therefore, the mortality was significantly higher among pregnant women with epidemic hepatitis (10–39%) than in the general population affected with similar hepatitis (0.06–12%).[9,11] In the sporadic setting, HEV is one of the most important etiology of ALF in India accounting for about 30–45% of patients hospitalized with ALF **(Table 2)**. However, the mortality in pregnant females has been found to be similar to that of nonpregnant females and males and is independent of the cause or trimester.[14] The reason for predilection of pregnant females to contact HEV and severe liver disease remains unclear. To elucidate this, viral and host factors in HEV-ALF were evaluated in one study.[15] The study reported more frequent progesterone receptor (PR) gene mutations (PROGINS) associated with reduced expression of PR and progesterone induced blocking factor (PIBF), a

TABLE 4 Studies reporting female predominance and role of pregnancy in ALF[7,9]

Country	No. of cases (N)	Number of females overall (%)	Pregnancy	Percentage of female patients with pregnancy associated liver failure	Etiology of ALF	Overall mortality (pregnant females)
USA	1696	1173 (69%)	16	1.5%		
UK	422	257 (61%)				
Germany	109	69 (63%)	3			33%
Australia	80	64 (80%)	-			
India	1015	590 (58%)	249	38.5%	59.4% (HEV)	54%
India	180	111 (62%)	49/83	59%	96% (HEV)	66%
France	363			2%		
Japan	856	423 (49%)	-			

higher IL-12/IL-10 ratio, and a high viral load. The author associated these changes to the poor outcome in HEV-ALF in pregnant females. Pregnancy as a predisposition to ALF in India could be due to: (1) large number of pregnant population (3%); (2) unavailability of clean drinking water; (3) predilection of pregnant females to contact HEV infection. Hepatitis E virus has been identified as a very important cause of severe liver disease in areas of world where more than 70% of the global population resides. The Global Disease Burden study by World Health Organization identified that, approximately 3.7 million people are infected by HEV annually and 70,000 of them die due to HEV induced severe liver disease of whom a large proportion are pregnant.[16]

Acute fatty liver of pregnancy (AFLP) on the other hand is more frequent in the West than in India.[7] Termination of pregnancy is required for improving prognosis in AFLP. However, termination of pregnancy may not be appropriate in pregnant females with HEV-ALF, because:

- ALF-HEV, in comparison to other causes of ALF, has lowest mortality,[17]
- the mortality in ALF-HEV with pregnancy, ALF-HEV in females without pregnancy and males with ALF-HEV are similar and not higher, indicating that in the pregnancy once ALF develops does not influence the natural course.[14]

Genotypes 1 and 2 of hepatitis E virus are prevalent in hyperendemic regions where the reservoir for HEV seems to be human, and cause outbreaks, sporadic acute hepatitis, ALF, and ACLF.[18] Genotypes 3 and 4 are more prevalent in the USA, Europe, and Japan, where the reservoir seems to be represented by pigs, and the zoonotic transmission is considered to be the cause of infection of human beings, leading to autochthonous acute HEV. Genotypes 3 and 4 have not been reported to be associated with severe liver disease and the majority of cases appear to represent subclinical infection.[19]

Key Points: ALF in Pregnancy

- West and Europe: Pregnant females account for 1–3% of cases
- India: 40–60% of females of child-bearing age with ALF are pregnant and HEV is the most frequent cause in them
- Mortality is not increased in pregnant ALF than the others
- Termination of pregnancy not indicated in such patients
- AFLP: Genetic predisposition, termination of pregnancy improves prognosis

Outcome

The etiology of ALF, which is regionally varied, influences outcome, particularly in the West where the etiology is heterogeneous. Paracetamol is the major cause of ALF in the West. Paracetamol induced ALF presents rapidly (hyperacute) with a spontaneous survival rate of 64% which is significantly higher than similar outcome due to other causes such as ALF due to idiosyncratic drug toxicity (spontaneous survival in 20% cases).[9,11] However, paracetamol induced ALF may progress very rapidly in some. The paracetamol being the frequent etiology in the West constitutes the bulk of all ALF patients in these regions and therefore the total number of deaths due to paracetamol toxicity exceeds all other diagnoses. Nearly one third of these patients who develop encephalopathy die. Paracetamol overdose whether suicidal or unintentional presenting with ALF has similar outcomes.[20]

In the India, acetaminophen overdose induced ALF is infrequent. The drug induced ALF are due to antituberculosis therapy (ATT).[21] The mortality in ATT-ALF has been reported to be 70%.[21] In India, about 90–95% of ALF are due to hepatitis viruses (homogeneous etiology).[7,9,11,12] ATT induced ALF constitutes about 6–7% of all ALFs.[21] Therefore, etiology could not be identified as an independent predictor of mortality.[9,12,21] However, when HEV as a separate group was compared with each individual other etiologies, such as ATT induced ALF and non-A non-E–ALF, etc. the survival frequency among HEV was reported to be significantly superior to other etiologies.[18,21] These survival frequencies reported are transplant-free survivals. Liver transplantation is established therapy in all end stage liver disease and with transplantation, overall survival exceeds 75%.[7,9]

Key points: Outcome
- West: Etiology affects the outcome, because etiology is heterogeneous
- India: Etiology in general does not influence the outcome, because etiology is almost due to hepatitis virus(es)
- Among hepatitis virus induced ALF, HEV has a better prognosis
- Commonest cause of drug induced ALF in India is antitubercular drugs and have high mortality

Prognostic Models[7,9,12]

Liver transplantation has been well established as a curative option in ALF.[9,11] Prognostic models are therefore necessary to identify patients who will need transplantation or should continue on medical therapy. Many prognostic models from all around the globe have been described.[7,9] Each of the prognostic models in summary have highlighted the following important facts. Age and etiology in most reports are important variables influencing survival. HAV, HEV, acetaminophen toxicity, and acute fatty liver of pregnancy induced ALF, survive more frequently.[7,9,12] Patients with drug induced, autoimmune, HBV, and cryptogenic ALF all have spontaneous survival of less than 30%.[7,9,18,21,22] Wilson's disease with ALF survive rarely.[7] Among the dynamic variables, the degree of encephalopathy was documented to influence survival—Patients with encephalopathy grade of III or more in comparison to less advanced encephalopathy (I & II) die more frequently.[7,9,21,22]

Among the prognostic models, King's College Hospital Criteria (KCC) for liver transplantation were proposed by O'Grady, and have been widely used.[22] Although these criteria are specific, they are not very sensitive in predicting cases that will need transplantation. Unfortunately, none of the currently available models have consistently demonstrated reliable accuracy in predicting outcome.[23]

Multiple prognostic models have been reported from India.[7,9,12] A report from North India, the following variables present at admission were identified as independent predictors for poor outcome:
- age 40 years or more;
- bilirubin 15 mg/dL or more;
- PT prolongation 25 seconds or more; and
- clinical features of overt cerebral edema.[21] With increasing number of above risk factors, mortality increased; with three or more factors it was 93%.[11,12,24]

In another study from India, clinical prognostic indicators (CPI) included age 50 years or more, jaundice encephalopathy interval (JEI) more than 7 days, grade 3 or 4 encephalopathy, presence of cerebral edema, PT ≥35 seconds, and creatinine ≥1.5 mg/dL. Presence of any 3 of 6 CPIs was superior to model for end stage liver disease (MELD) or King's College hospital (KCH) criteria in identifying survivors and nonsurvivors.[9]

ALF is a dynamic process in which variables determining prognosis at admission change over time, and thus the clinical course varies accordingly. A new prognostic model, ALF early dynamic (ALFED) model was reported which included four variables: arterial ammonia, serum bilirubin, INR, and hepatic encephalopathy more than grade II, which were identified as the independent predictor of outcome at admission.[7,24] This model evaluated the dynamicity of these four variables over 3 days and documented that the prediction of outcome using these variables on day 3 was markedly superior to the prediction based on admission parameters. Recently, the INASL recommended the ALFED prognostic model to be more appropriate for the Indian subcontinent because it was derived from the cohort of Indian patients who had predominantly viral etiology unlike in the West where viral etiology as a cause of ALF is infrequent.[7]

This is one of the first dynamic models to assess and stratify ALF patients dynamically over a period of 3 days rather than considering variables at baseline. ALFED model study identified four prognostically significant variables: arterial ammonia, serum bilirubin, INR, and hepatic encephalopathy more than grade II. This ALFED

TABLE 5 ALFED Score[7,24]

Variables over 3 days	*Score assigned*
Hepatic encephalopathy (Persistent or progressed to grade >2)	2
INR (Persistent or increased to ≥5)	1
Arterial ammonia (Persistent or increased to ≥123 µmol/L)	2
Serum bilirubin (Persistent or increased to ≥15 mg/dL)	1

Each of the variables above on the day 3 of hospitalization carries a score determined on the strength of the beta integer of the odd's ratio identified in multivariate analysis to predict mortality. Each of the above variables were independent predictors of mortality. On day 3 a score of 4 is associated with 90% mortality where as score 1 is associated with about 5% mortality. With increasing score mortality increases

TABLE 6 Principles in the management of ALF

Aggressive supportive therapy:
Intensive care unit, organ support system, nutrition, electrolyte correction, hypoglycemia prevention, monitoring, hydration
Identification and removal of precipitating factors:
Control of GI bleed, sepsis, hyponatremia, renal failure, constipation, psycho-active drugs.
Reduction of nitrogenous load from the Gut:
Lactulose (not used), antibiotics, enema
Manipulation of neurotransmitters:
Flumazenil, branched chain amino acids (not used)
Cerebral edema:
IV Mannitol, thiopentone, hypertonic saline, hypothermia (not used), IV phenytoin (not used)
Ammonia lowering therapy:
L-ornithine L-aspartate (LOLA- not used), L-ornithine phenyl acetate (LOPA), sodium benzoate, hypothermia (not used), CRRT, plasma exchange
Novel therapies:
Molecular adsorption various bioartificial support system, recirculating system (MARS, promethus), probiotics with increased capacity to consume ammonia (not found beneficial)
Liver
Transplantation: LDLT (living donor liver transplant), DDLT (deceased donor liver transplant), auxiliary LT, split LT

model had an AUROC of 0.91 in the derivation cohort and of 0.92 in the validation cohort. The model showed similar increase in mortality with increasing risk scores from 0 to 6 **(Table 5)**. The performance of the ALFED model was found to be superior to the KCH and the MELD score, even when their 3-day serial values were considered. An ALFED score of ≥4 had a high PPV (85%) and NPV (87%) in the validation cohort. Further, in each patient the model could stratify the risk of dying or surviving on day 3 (score 1 through 6) of hospitalization. Those with score of 1–3 had a survival frequency of about 80% or more and those with ≥4 had a mortality risk of more than 80%.[7,24] These parameters at baseline were also independent predictors of mortality, but the dynamic assessment made these parameter as also model for survival. In India ALF etiology is hepatitis virus and usually individuals without any underlying chronic liver pathology develop ALF. In ALF along with hepatic necrosis, the liver regeneration simultaneously kicks off. Therefore, with liver regeneration, these predictive parameters change, and hence dynamic assessment are important to identify the outcome more accurately. The management and pathogenesis in ALF need another chapter and particularly the therapeutic approach against specific drivers of pathogenesis need special mention **(Table 6)**.

Summary

- ALF in India and the West have different etiology and natural course, and therefore the prognostic models are different. In India, the etiology is homogenous in contrast to the West where it is heterogeneous
- In the West: Drug induced ALF and in the East: Viral etiology is the most common
- Outcome of viral (HAV, HEV) and Drug (paracetamol) are better than other etiologies, but antitubercular drug-ALF has high mortality
- In India, pregnant females are more prone for ALF but not so in the West
- Prognostic models described across the world; dynamic models have been described recently from India and are appropriate for Indian patients
- Management: conservative, organ support and liver transplantation in select group

Acute-on-Chronic-Liver Failure

Introduction

In the early sections of the present chapter the concept of liver failure in general and ALF, ACLF, and chronic liver

failure as well as SHF in particular has been highlighted. **Table 1** depicts the essential phenotypic difference between ALF, SHF, and ACLF.

Patients with decompensated cirrhosis clinically presents with heterogeneity with variable prognosis. AD in cirrhosis usually denotes appearance of ascites, encephalopathy, variceal bleeding or combination of any later three.[4,5] Since liver transplantation in such patients is probably is the only curative option, there short-term survival prediction (usually in 2 years) has been used at many centers.[2] Three states with increasing risk of death have been proposed for decompensated cirrhosis defined by the occurrence of a first variceal bleeding alone (without other decompensating events—mortality 20%), any first non-bleeding decompensating event alone (80% ascites—mortality 24%), or any second decompensating event (mortality—50–78%).[25] However, recent reports indicate that, a more advanced rapid AD state do occur with a very high short-term 28 days mortality of around 20–90% depending upon degree and extent of associated extrahepatic organ failure.[25] These are patients, who developed systemic inflammatory response through proinflammatory precipitating factors (sepsis, excessive alcohol consumption, sudden reactivation of previous chronic liver disease inducing further acute hepatic necrosis) who are usually jaundiced with prolonged INR and develop various organ failures (OF) probably because of cytokine storm effecting extrahepatic organs resulting from the proinflammatory precipitating events. These are patients with ACLF.

Definitions and Concept

The term ACLF was first introduced to identify the above mentioned often observed but not categorized entity in 2002.[26] The first consensus definition on ACLF was provided by APASL (Asian Pacific Association for the Study of Liver) as "an acute hepatic insult manifesting as jaundice (total bilirubin ≥5 mg/dL) and coagulopathy (INR ≥1.5), complicated within 4 weeks by ascites and/or encephalopathy in a patient with chronic liver disease."[3] However, it was slightly modified in 2014 in which chronic liver disease was modified to "with previously diagnosed or undiagnosed chronic liver disease/cirrhosis" and a "high 28 days mortality" was added.[27] With this APASL criteria, 28 days mortality was reported by the APASL between 25–34%.[27] However, certain patients with AD having above criteria with OF had markedly higher mortality than those without. Therefore, the EASL-AASLD (European Association for the Study of Liver-American Association for the Study of Liver) defined ACLF as "Acute deterioration of pre-existing, chronic liver disease, usually related to a precipitating event and associated with increased mortality at 28 days due to multisystem organ failure." Some report suggested and documented that severity of OF assessed by sequential organ failure assessment (SOFA) scores could differentiate patients with various prognosis (58% with OF vs. 8% without OF).[31]

The first prospective, observational, multicentric European study known as CANONIC study documented the distinction between AD without OF and AD with OF (which according to Western concept was ACLF). Among patients with known cirrhosis admitted with AD (ascites, variceal bleed, encephalopathy, infection; n=1,343), the 28 days and 90 days mortality in those with OF versus those without OF were 34% and 51% versus 5% and 14%, respectively. Thus, this study provided the documentation that patients with AD who were hospitalized with or developed OF after hospitalization were distinct and were named as—ACLF and justified their definition (EASL-CLIF—European Association for the Study of Liver-Chronic Liver Failure definition).[28] North American Consortium for the Study of End-Stage Liver Disease (NACSELD) defined ACLF by the presence of at least two very severe extrahepatic OFs (shock, grade III/IV HE, renal replacement therapy, or mechanical ventilation), which are much more stringent criteria than those of the EASL-CLIF consortium or the APASL. The NACSELD-defined ACLF is associated with a 30-day mortality rate of 41% compared to 7% for patients without ACLF. Accordingly, by definition, the main difference between traditional AD and ACLF is the short- and medium-term prognosis. To unify the definition on ACLF the WGO (World Gastroenterology Association) suggested that "ACLF is a syndrome in patients with chronic liver disease with or without previously diagnosed cirrhosis, which is characterized by acute hepatic decompensation resulting in liver failure (jaundice and prolongation of the INR) and one or more extrahepatic organ failures that is associated with increased mortality within a period of 28 days and up to 3 months from onset"**(Fig. 3)**.[4]

Components of ACLF

All the above definitions and concept irrespective in their disagreement and region of origin elucidated that there should be five components in ACLF:

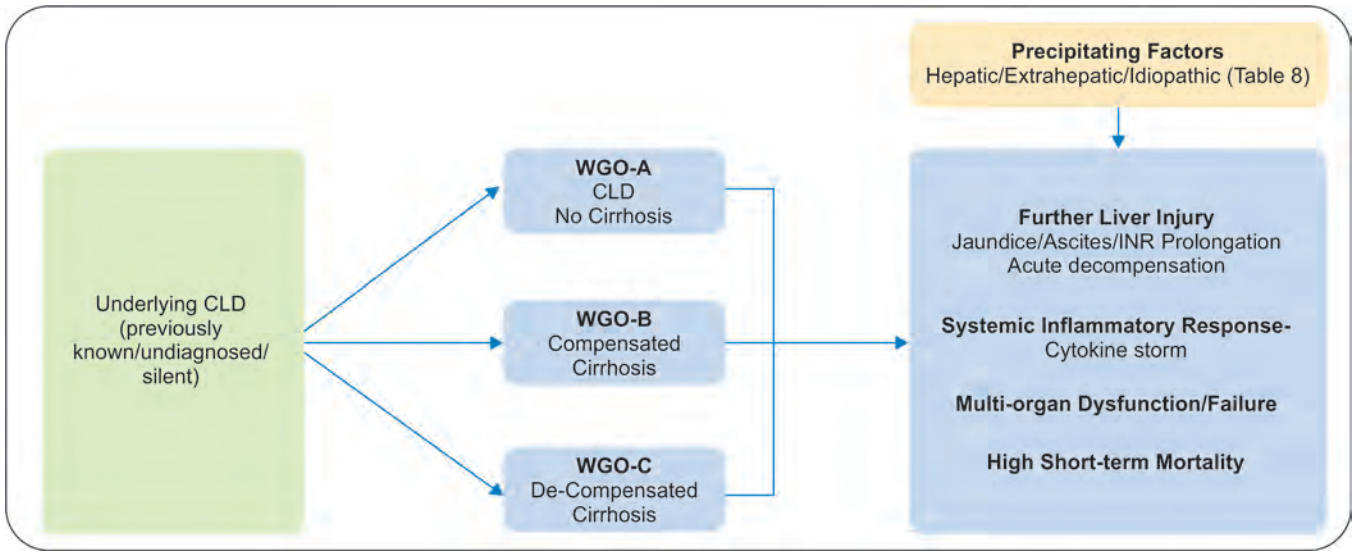

Fig. 3: World Gastroenterology Definition of ACLF[4]
AD, acute decompensation; ACLF, acute on chronic liver failure; CLD-A, chronic liver disease (non-cirrhotics) CLD-B (cirrhosis compensated), CLD-C (cirrhosis with previous history of decompensation)

- There should be pre-existing chronic liver disease (APASL excluded known decompensated liver disease and emphasized that only non-cirrhotics or compensated cirrhosis of any etiology should be included as underlying silent liver disease, which may have been diagnosed or undiagnosed previously; however, the EASL-CANONIC study as described earlier did not exclude patients with chronic liver disease with previous history of decompensation and WGO in an effort to unify these categorized underlying Chronic liver Disease to A-CLD without cirrhosis, B-compensated Cirrhosis and C-Cirrhosis with previous history of decompensation—**Fig. 3**).
- There should be a precipitating factor causing acute hepatic insult with systemic inflammatory response which were different regionally (described below) which should result in overt acute deterioration of hepatic function as well as reserve, resulting in features overt liver failure (CANONIC study defined them as AD and included both hepatic and extrahepatic insult but APASL excluded extrahepatic insults like variceal bleed and sepsis and emphasized on only acute hepatic insult to be further qualified by presence of conjugated hyperbilirubinemia of more than 5 mg/dL with INR more than 1.5 accompanied with development AD in the form of ascites and/or encephalopathy; there by quantifying the severity of the hepatic insult resulting in AD).
- The above-mentioned acute deteriorations should occur within a short period of time (APASL defined it to be within 4 weeks).
- The presence or development of hepatic failure should be associated with extrahepatic organ failure like encephalopathy, respiratory failure, renal failure, coagulation abnormality, circulatory compromise in form of hemodynamic instability as per the EASL-AASLD and NASCLED definition but APASL did not include it and suggested that only with liver failure the mortality exceeded 30% and should be enough to define ACLF and extrahepatic organ failures are the sequels of ACLF. However, the INASL consortium experiences documented that indeed occurrence of the extrahepatic organ failure imparts high short-term mortality.[29-31]
- As has been elucidated earlier, these patients with CLD are distinct from AD and should be categorized as another form of liver failure and to be termed as ACLF. By now both APASL and Western group agree that they have high 28 days mortality (various reports from different region describe it to a tune of around 50%).[1,5] The mortality, however, linearly increases with increases in number of extrahepatic OF (20% with one OF to 90% with ≥4 extrahepatic OF) **(Table 7)**.[28,31]

TABLE 7 European Association for the Study of Liver Consortium for Liver Failure Sequential Organ Failure Assessment Score (EASL-CLIF-SOFA Score- Panel A) and ACLF Grades (Panel B)[28,31]

Panel A				
Parameter for organs		***Score 1***	***Score 2***	***Score 3***
Liver—Serum Bilirubin (mg/dL)		< 6	6-11.9	≥12
Kidney—Serum Creatinine (mg/dL)		<2	2-3.4	≥3.5
Brain—Encephalopathy (West-Haven Criteria)		Grade 0	Grade 1–2	Grade 3–4
Coagulation (INR)		<2	2-2.4	≥2.5
Circulation (MAP in mm Hg)		≥70	<70	Vaso pressure requirement
Respiration	(PaO_2/Fio_2) or SPO_2/FiO_2	>300 >357	≤300–>200 ≤357–>214	≤200 ≤214
Score 1: Absence of OD or OF. Score 2: Organ Dysfunction (OD). Score 3: Organ Failure (OF) INR: International Normalized Ratio; MAP: mean arterial pressure				

Panel B		
AD group	***Mortality***	***ACLF grade***
No OF	4%	**NO ACLF**
One OF + No BD/KD	6.3%	
Single KF	18.6%	**ACLF Grade 1**
Single non kidney OF + KD/BD	27.6%	
Two OF	32%	**ACLF Grade 2**
Three OF	68%	**ACLF Grade 3**
4-6 OF	89%	

TABLE 8 Precipitating factors causing ACLF[27-32]

Acute hepatic Insult	Acute Extra hepatic Insult		Idiopathic Other non-identifiable cause of hepatic insult like Complementary and Alternative medicines (CAM)
	Environmental	Non-environmental	
• HBV Reactivation • HAV super infection • HEV Super infection • Hepatotoxic drug injury • Autoimmune hepatitis flare • Wilson's disease flare • Surgery/liver resection/Transarterial chemoembolization for liver cancer	• Bacterial infection • Alcohol excessive continuous consumption within last 3 months	Variceal bleeding	In various series on ACLF 30–50% patients with ACLF did not have identifiable precipitating factors and in India CAM may be a possibility of hepatic insult

Precipitating Factors Causing ACLF

Varieties of acute insults causing rapid deterioration in liver functions (clinical, biochemical, coagulation parameters) needing hospitalization have been documented and they vary regionally. In brief they can be categorized as follows in **Table 8**.[4,5,26,28-32]

Acute hepatic insult as mentioned in the above table are more often documented as the cause of ACLF in Asian Countries whereas they are less frequent in Europe and America. The hepatitis virus(es) are endemic in Asia as well as antitubercular therapy.[30,31] In the West the common causes were variceal bleed, infection, and idiopathic.[31] However, in recent time Asian region as well as in India the major cause of ACLF has been reported because of continuous excess alcohol consumption, which causes chronic liver disease as well as acute insult on the liver resulting in rapid AD (severe alcoholic hepatitis) and ACLF.[29,30]

Categorization/Types of ACLF and Prediction/ Prognostic Models in ACLF

Depending upon the pre-existing hepatic reserve due to underlying CLD and further loss of hepatic functional capacity due to acute hepatic insult and its regenerative capacity, severity of the systemic inflammatory response due to the cytokine storm and their effect on extrahepatic

organs, the course in ACLF is dynamic and usually unfolds over subsequent few days usually between 3–7 days.[33,34]

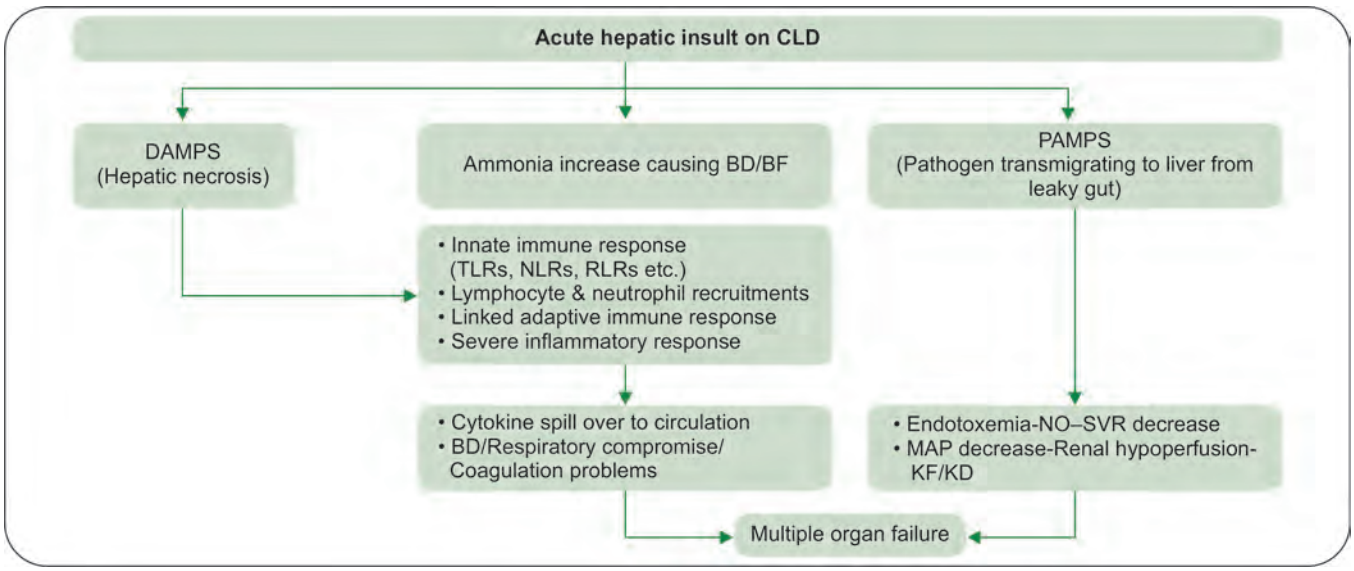
Types/Categorization of ACLF

The canonic study first tried to identify and qualify the extrahepatic organ failure by quantifying the change in the sequential organ failure assessment (SOFA).[28,31] The study included six organs to be evaluated for SOFA score (Liver, Kidney, Brain, Coagulation, Circulation, and Respiration) and graded their dysfunction based on values of serum bilirubin, creatinine, INR, mean arterial pressure (MAP), and ratio between PaO_2/FiO_2 or SpO_2/FiO_2, respectively and allocated 1–3 point scores to these values. Patients with score 2 for each parameter were considered as organ dysfunction (OD) like liver dysfunction (LD), kidney dysfunction (KD), brain dysfunction (BD), circulatory dysfunction (CD), coagulation dysfunction or respiratory dysfunction (RD) and patients with score 3 were defined as individual organ failure. This score was named as EASL, CLIF, SOFA score and depending on these scores as mentioned above. No OD and OF were defined for each of the six organs and then the ACLF in patients with AD were graded as No ACLF, ACLF grade 1–3 depending upon presence or subsequent development of number of OD/OF. With increasing grade, the 28 days mortality increased **(Table 7)**. Since OF were not included in APASL definition, the ACLF was not categorized or typed in APASL cohorts collated subsequently. However, in APASL cohort and many other reports on ACLF which included large cohorts of patients with ACLF reported that occurrence of OF was major determinant of outcome and prognosis.[32] Further the admission grading or status of organs were dynamic and the outcome prediction based on the OF on day 3–7 were more accurate predictors of outcome. Both EASL-CLIF (CLIF-C-ACLF) score and APASL groups have defined their dynamic prognostic scores, which simply reflect the dynamic changes of variable organ parameters.[3,33]

Pathogenesis (Flowchart 1)[26,31]

Pathogenesis in ACLF is unclear. However, the severe cytokine storm in ACLF has been documented to be more pronounced (documented by enhanced C-reactive protein response, neutrophilic leukocytosis, tumor necrosis α, IL18) than in patient with AD as well as in patients with compensated cirrhosis without AD.[31] The ammonia levels also have been recently identified to be markedly increased in such patients than in the other groups.[32] The Cause of Cytokine Storm has been briefly explained in the **Flowchart 1**. The DAMP (damage associated molecular pathogen) due to liver cell damage in diseases causing

Flowchart 1: Pathogenesis in ACLF



BD, brain dysfunction; BF, brain failure; DAMP, damage associated molecular pattern; KD, kidney dysfunction; KF, kidney failure; NLRs, nod like receptors; NO, nitric oxide; PAMP, pathogen associated molecular pattern; RLRs, rig like receptors; TLR, toll like receptors

TABLE 9 Principles in management of ACLF

- Intensive care unit, organ support system, nutrition, electrolyte
- Treatment of infection with appropriate antibiotics with monitoring of renal function and maintenance of serum albumin values with albumin replacement preventing volume overload
- Treatment of precipitating factors:
  - antivirals in HBV reactivation
  - steroid in alcoholic ACLF after ruling out infection
  - specific management for acute variceal bleeding if occurs, d) withdrawal of hepatotoxic drug, CAM
- Specific organ failure management:
  - For RF/RD—CRRT
  - Noradrenaline if needed to maintain MAP>70 mm Hg
  - Treatment for encephalopathy if occurs
  - Adrenal insufficiency (may occurs in some)-IV hydrocortisone
- Treating systemic inflammatory response:
  - Molecular Adsorbtion Recirculating System(MARS)—till date no evidence that it improves survival
  - plasma exchange—experimental
- Immunomodulatory/Regenerative therapy: G-CSF has been tried in small studies, but needs to be validated in large multicentric studies
- Fecal microbial transplantation: has been tried in alcoholic ACLF in small studies with promising results
- Liver transplantation if needed

super added injury to liver or sepsis or bleeding causing ischemia to liver are recognized by the innate immune systems presence in liver cells such as TLRs and other Innate immune PRR (pathogen recognizing receptors) sensors and produce various cytokines which cause neutrophilic recruitment and also attracts the immune cells of adaptive immune system resulting in release of various proinflammatory cytokines which may spill over to systemic circulation effecting various extrahepatic organs. Perpetuating the events by the transmigration of gut microbes due to a leaky gut documented in such patients further enhance such response and also induces endothelial nitric oxide by upregulating the nitric oxide synthase enzyme.[32] These events result in various organ dysfunction or OF depending upon the severity of the cytokine storm and the degree of liver injury resulting in ACLF.

Management

The management principles comprise of:

- Treating the precipitating factors
- Support to the failing organ
- Continuous assessment and by day 3–7 decision for liver transplant.

The Model for End Stage Liver Disease (MELD) score and addition of sodium value (MELD-Na) score in addition to the scores of failing organs have been the principles to prognosticate and transplant such patients to improve survival.[32-34] **Table 9** briefly provides the components of management in ACLF.

Conclusion

ACLF is a syndromic condition that occurs in patients with underlying chronic liver disease (CLD) irrespective of the cause of CLD. These patients develop intense systemic inflammation, organ failure, and high short-term mortality and ensue in close temporal relationship with a precipitating event, which is regionally variable. Whether extrahepatic organ failure is an integral part of the syndrome or consequence is the difference in defining the syndrome in the West and Asia. Bacterial infection is frequent in these patients and in the West it is considered as a precipitating event, but in Asia it is considered as a frequent association in ACLF. However, irrespective the differences between the West and Asia the syndrome is seen across the world and about half of them need liver transplant.

CHAPTER

135 Proton Pump Inhibitors—Long-term Use: Boon or Bane?

Manish Manrai, Rohit Upreti

Abstract

Proton Pump Inhibitors (PPIs) have been an important part of the physicians' arsenal in the fight against acid peptic disorders. PPIs are among the drugs which are most frequently prescribed both to outpatients and those admitted in the hospital including critically ill patients. The approved indications for PPI therapy include erosive esophagitis, peptic ulcer, NSAID-induced ulcer, Gastroesophageal Reflux Disease, *Helicobacter pylori* infection and management of pathologic hypersecretory conditions like Zollinger-Ellison syndrome. However, long-term use of PPIs has also been associated with multiple side effects including small intestinal bacterial overgrowth, pneumonia, increased bone fractures, Vit B12 deficiency among others. A sensible strategy for PPI prescription should be as per indications, avoiding broad off-label use and following deprescription strategies.

Introduction

The pharmacologic use of Proton Pump Inhibitors (PPIs) started in the late 1980s and since then they have been an important part of the armamentarium of physicians and gastroenterologists for treating acid peptic disorders.

PPIs are substituted benzimidazoles, which are similar to the H2 receptor antagonists (H2RAs) in structure but have a different mechanism of action. PPIs are given as prodrugs. Oral formulations are prepared as acid resistant delayed release enteric coated capsules or tablets so that they do not undergo destruction due to the acid in the stomach. PPIs easily diffuse across lipid membranes into acidified compartments like parietal cell canaliculus where the protonation of the prodrug takes place and gets converted to its active form, a thiophilic sulfenamide cation.[1] This cation irreversibly inactivates the H/K-ATPase **(Figure 1)** by forming a covalent disulfide bond with it.[1,2]

PPIs should be taken empty stomach because food decreases the bioavailability of all agents by around 50%. They are taken around 1 hour before a meal, so that the maximal activity of proton pump secretion is at the same time as the peak serum concentration of the PPI. They have a short half-life of approximately one and a half hour, but since they irreversibly inhibit the proton pump the secretion of acid remains inhibited up to 24 hours. In optimal doses PPIs inhibit around 90–98% of 24-hour acid secretion. When intravenous preparations are used, only the actively secreting pumps are inactivated. Therefore, during the first 24–48 hours of treatment, the intravenous formulations must be given as infusion or as repeated bolus injections.[1]

PPIs are the cornerstone of treatment regimens of a number of acid peptic disorders and other related conditions. The various definitions of long-term use of PPI that have been used in different studies vary from one repeated prescription over 12 months to continuous therapy for periods ranging from 4 to >12 months.[3] Prolonged use of PPI, however, is a two-edged sword and has been related with an excess of systemic adverse effects,

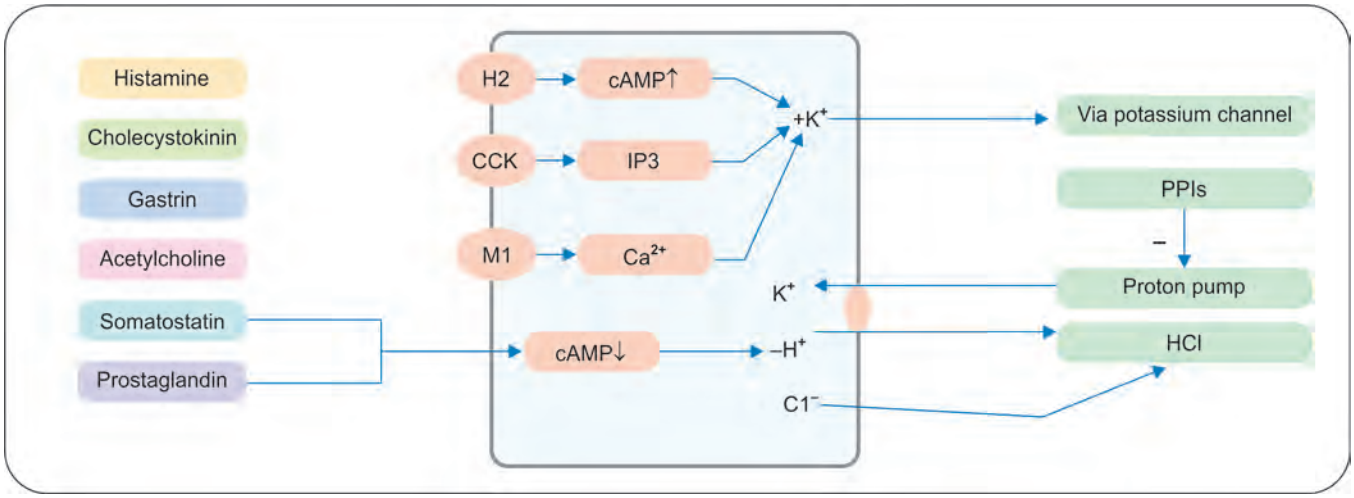

Fig. 1: Mechanism of action of proton pump inhibitor: PPIs irreversibly inactivates the H/K-ATPase by forming a covalent disulfide bond with it and thus inhibit the common pathway involved in the acid release from the cell

which lead to the subject that whether long-term use of PPI is a boon or a bane?

Long-term PPI Use: Is It a Boon?

PPIs have statistically proven benefit over placebo/H2RAs in management of diseases associated with increased acid production. The indications for PPI therapy, which are approved by FDA include Gastroesophageal Reflux Disease (GERD), erosive esophagitis, peptic ulcer, NSAID-induced ulcer (treatment and prophylaxis), *Helicobacter pylori* infection (along with antibiotics) and management of pathologic hypersecretory conditions (including Zollinger-Ellison syndrome).[4]

However apart from the above-mentioned indications, the existing evidence suggests overuse of PPIs with almost 25–70% of prescriptions lacking appropriate indication.[5] In fact, the "off-label" use of PPIs is among the highest (55% prevalence) in intensive care units.[6]

In patients of GERD, who present with reflux symptoms after meals, long-term inhibition of acid secretion is achieved by use of PPIs.[5-10] Since the effect of acid suppression remains for almost 24 hours, a single dose of PPI empty stomach in the morning is effective. There is evidence that PPIs can be used in prevention of recurrent reflux symptoms as well as esophageal erosions/ulcers.[7-9] The regular use of PPIs as maintenance therapy of GERD decreases the recurrence rates to less than 15% for 1 year compared to recurrence rates of more than 50% for patients without any maintenance therapy.[11,12] Long-term administration of PPIs may also prevent transformation of Barrett's esophagus to a neoplastic lesion.[13] Common indications of long-term PPI use along with the studies establishing their role have been summarized in **Table 1**.

TABLE 1 Indications of long-term use of PPIs

Indication	*Study*	*Inference*
NSAID ulcer prophylaxis	Sugano et al., 2012[10]	Decreased incidence
GERD	Pace et al., 2005[11]	Decreased recurrence

The other common indication of long-term PPI use is for prevention of NSAID-induced gastroduodenal ulcers recurrence by decreasing it to approximately one-tenth on comparison with patients treated with placebo.[10] Thus, they are the drug of choice for the prevention of aspirin/NSAID induced ulcers.

Long-term Use of PPI: Is It a Bane?

Increased usage of PPI for past many years now has led to the conundrum of their long-term effects. Prolonged PPI use has been implicated in adverse effect of several body functions and has been associated with increased incidence of various diseases. Common adverse effects of long-term PPI usage along with the studies establishing their role have been summarized in **Table 2**.

TABLE 2 Adverse effects of long-term use of PPIs

Side effect	*Study*	*Inference*
SIBO	Lo WK et al., 2013[22]	Increased risk
Gall bladder dysfunction	Cahan et al., 2006[26]	Increased risk
Pneumonia	Wongtrakul et al., 2020[29]	Increased risk
Acute interstitial nephritis	Xie et al., 2016[31]	Increased risk
Chronic kidney disease	Wijarnpreecha et al., 2017[32]	Increased risk
Hypomagnesemia	Park CH et al., 2014[33]	Decreased magnesium levels
Dementia	M A Khan et al., 2020[35]	No definite risk
Bone fracture	Nassar et al., 2018[37]	Increased risk of bone fracture

TABLE 3 Adverse effects of PPI based on their property of acid inhibition or unrelated to it

Due to acid inhibition	Pneumonia, GI infection, Carcinoid tumor, GI mucosal hypertrophy, Fractures, SIBO, Vit B12 deficiency, Gastric cancer, SBP
Unrelated to acid inhibition	Collagenous colitis, Acute interstitial nephritis, Dementia

These side effects can be separated either as per the mechanism or as per the involved site.

As Per the Mechanism

Adverse effects of PPIs occur either due to the fact that they cause acid inhibition or else they are unrelated to their property of acid inhibition.[14] These adverse effects have been shown in **Table 3**.

As Per the Site Involved

Gastrointestinal System

Increased risk of gastrointestinal infection—Use of PPIs has an association with increased risk of *Clostridium difficile* (*C. difficile*) infection.[15,16] Possible mechanism is that long-term PPI use alters the colonic microbiome and hampers the normal barriers against *C. difficile*, which proliferates using the available amino acids.[17,18]

Gastric neuroendocrine tumor—Prolonged PPI use leads to increased intra-gastric pH thereby causing increased plasma gastrin concentration, thus stimulating enterochromaffin like (ECL) cells proliferation.[19] There are only isolated case reports of PPI administration-related gastric neuroendocrine tumors in humans and presently to ascertain a pathogenic role, the data is scarce.[20] Therefore, at present there is insignificant clinical relevance of the risk of carcinoid tumor after long-term PPI use. Although periodic endoscopic screening may be considered during the period of use.

Gut microbiome changes and Small Intestinal Bacterial Overgrowth (SIBO)—The resultant decrease in the acid secretion and the bactericidal effect of the gastric juice due to PPIs leads to an increase in the microbial density of the gut especially with *Streptococcus* which colonize the oral cavity.[21] Lo et al. in a meta-analysis done in 2013 found that as compared to non-users, there was 7.5 times increased risk of SIBO in PPI users. Therefore, prolonged PPI administration is considered a risk factor for SIBO (Defined as presence of 100,000 bacterial colonies/mL in small intestinal contents).[22] However, the clinical importance of this altered microbiome in patients treated with PPIs is elusive at present.

Spontaneous bacterial peritonitis (SBP)—PPI administration is useful in few cases of cirrhosis as they reduce the risk of variceal rupture and ulcer occurrence.[23] Long-term PPI use leads to hypochlorhydria promoting bacterial translocation, colonic transmigration and may lead to Gram-negative organisms related SBP in cirrhotics.[24] Although, the available evidence at present does not recommend withholding PPIs whenever indicated in patients with liver disease; the evidence does suggest that PPI use is associated with augmented risk of SBP in cirrhotics.

Gastric cancer—In patients with *H. pylori* infection, long-term PPI usage increases mucosal inflammation, hastens mucosal atrophy, which might be a potential risk factor for gastric malignancy.[25] However, more data is required to establish causality between long-term PPI use and gastric malignancy in *H. pylori* patients.

Gall bladder dysfunction—Cahan et al. in 2006 found that PPI therapy reduces gallbladder motility in healthy volunteers.[26] Chronic PPI therapy may pose a risk for long-term gallbladder dysfunction and biliary complications.

Atrophic gastritis—PPIs can alter the gastric mucosal architecture and Li et al. found in a meta-analysis in 2017 that there was a higher presence of gastric atrophy in PPI group compared to the control group.[27]

Respiratory

Pneumonia—PPIs increase gastric pH by suppressing gastric acid release, promoting bacterial overgrowth which in turn leads to colonization of trachea and pneumonia. There is evidence to suggest that immune cell function may also be impaired by PPIs, thereby augmenting the risk of infectious complications.[28] Wongtrakul et al. in their recent meta-analysis concluded a significantly higher risk of development of pneumonia in cirrhotic patients with a history of PPI use than those without. Thus, prudent use of PPIs in patients with definite indication may be suggested.[29]

Renal

Acute interstitial nephritis—In patients on PPI treatment, an allergic reaction to the drug may cause interstitial nephritis.[30] As many as 70% of acute interstitial nephritis was reportedly related to drugs, of which 14% were caused by PPIs in biopsy-proven cases.[31]

Chronic kidney disease—The mechanism by which PPI use can lead to CKD is not well understood. One of the mechanisms proposed is the acute interstitial nephritis caused by PPI. Other postulated mechanisms include lysosomal acidification hydrogen/potassium adenosine triphosphatase enzyme system abnormalities, reduced renal tubular cells regeneration, altered gene expression, and elevated oxidative stress.[32] Although, there is a need of more data to ascertain this association, it is suggested that the indication of initiation as well as continuation of PPIs should be carefully assessed in patients with pre-existing risk factors for CKD development.

Nutrient Absorption

Hypomagnesemia—One of the postulated mechanism for hypomagnesemia related to PPI use is a reduction in the affinity of magnesium to its transport receptors caused by the pH change thereby decreasing the active transport of magnesium across the intestinal lumen. Park et al., in their meta-analysis, showed an increased incidence of hypomagnesemia in PPI users.[33]

Vitamin B12—The acidic environment of the stomach assists in the release of Vit. B12 bound with food and subsequently helps its binding to intrinsic factor. Lam et al. in 2013 found a 65% increased risk of B12 deficiency in PPI users more than 2 years.[34]

Neurological

Dementia—Long-term PPI use inhibits beta and gamma secretase, which may lead to an increase in the amyloid beta peptide levels in the brain. Khan et al. in their systematic review found lack of evidence pertaining to the proposed suggestion of PPI use and an increased risk of dementia.[35] They recommended that PPI use should not be curtailed because of concerns about dementia risk.

Drug Interactions

Anti-platelets—There is competitive inhibition of CYP2C19 to variable grades by PPIs, thus affecting the metabolism of clopidogrel. Omeprazole is the most noteworthy inhibitor of CYP2C19. The two meta-analyses done in this regard found an increased rate of adverse cardiovascular events in patients on simultaneous PPI-clopidogrel therapy.[36] While the pharmacological interaction between these two drugs is established beyond doubt, more data is required to ascertain the clinical significance of this interaction.

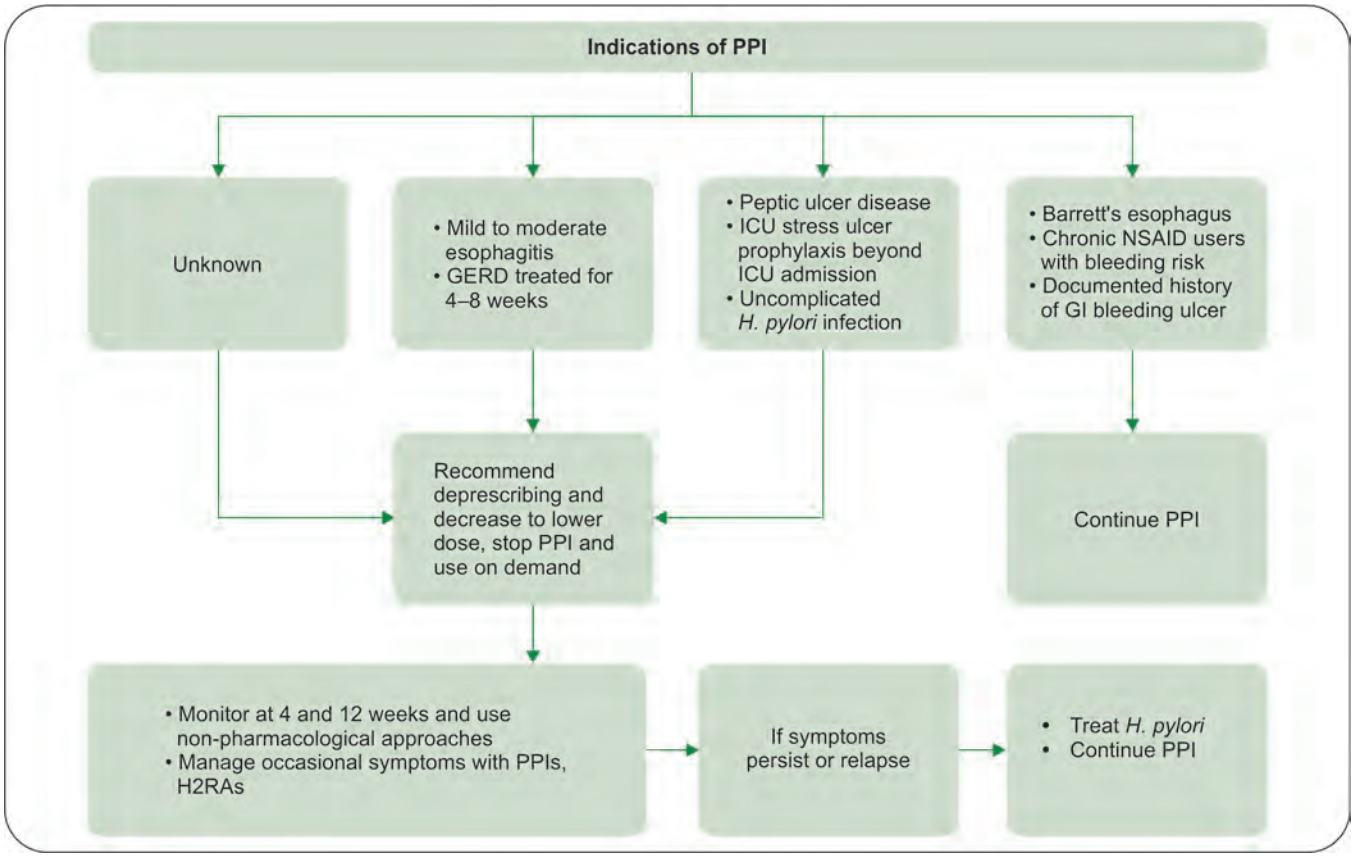
Endocrine

Alteration in bone density—The bone health and increased fracture susceptibility due to PPIs may be linked to impaired calcium absorption (acid suppression leads to decreased release of ionized calcium from insoluble calcium salts) and hypergastrinemia. In a meta-analysis conducted by Nassar et al. published in JBM in 2018 it was found that long-term PPI use might increase the fracture risk but has no significant alteration of bone mineral density (BMD).[37] Presently there is insufficient evidence to recommend regular BMD monitoring of patients on PPIs.

Hematological

PPIs have their anti-inflammatory properties as they can bind to neutrophils and can inhibit neutrophil accumulation and release of ROS. However, long-term use can also lead to neutropenia and thrombocytopenia.[38] In general, the recognized theories are the immune-

Flowchart 1: The algorithm for deprescribing PPIs



mediated and the toxic mechanism. Drug-induced antibodies against circulating hemocytes form the basis of immune mediated mechanism whereas the toxic mechanism is due to direct toxicity of the drug to hematopoietic cells.

All-cause Mortality

Xie et al., in their cohort study, demonstrated an increased risk of all-cause mortality in association with PPI use.[39] The speculated mechanism for this association was the probable role of oxidative stress, heme oxygenase-1 and accelerated senescence of human endothelial cells.

The Road Ahead

Presently, PPIs are among the most frequently prescribed class of drugs and are often continued for duration way beyond the indication. In view of this and with many recent studies suggestive of systemic adverse effects of long-term PPI use, a lot of research is going on to formulate a well-structured model to deprescribe PPIs.

Deprescribing PPIs

Patients on PPIs should be monitored for symptom recurrence and symptoms should gradually be managed with on-demand PPIs, stepping down to H2RA therapy, other over-the-counter agents (e.g., calcium carbonate) or nonpharmacologic approaches (weight loss, avoid meals 2–3 hours before bed time, head end elevation, avoid dietary triggers). Stepping down to H2RA involves discontinuation or tapering of the PPI followed by prescription of an H2RA. Any H2RA at any approved dose and dosing interval can be used.[40] Implementation of deprescription guidelines **(Flowchart 1)** will encourage clinicians to carefully evaluate the ongoing use of medications and potentially reduce the negative effects of polypharmacy.

Conclusion

PPIs have a robust helpful impact when used correctly for the standard indications. However, PPIs have also been incriminated with multiple systemic side effects. Although the evidence is limited for causality at present and this is an area of active research, there is enough evidence to indicate a tendency to develop adverse effects with long-term use of PPIs. Optimal strategy at this time for PPI prescription is to advise it to patients with clear indications, following of clear deprescription strategies and avoidance of broad off-label usage.

CHAPTER

136 Eosinophilic Esophagitis—An Underdiagnosed Entity

Goundappa Loganathan, H Leena Shree

Abstract

Eosinophilic oesophagitis (EOE) is a locally immune mediated chronic oesophageal disease occurring as a consequence of allergen exposure. It is a male predominant widely prevalent but less well recognized disease with genetic preponderance and often associated with atopy. EoE has a progressive course from mucosal disease to subepithelial disease over decades resulting in fibro stenotic esophageal disease. The diagnosis is based on the constellation of symptoms, endoscopic and histological findings with >15 eosinophils/HPF confirming the diagnosis. The new genetic, molecular, cellular, animal, and translational studies show the cascade of coordinated type 2 inflammatory response. The newer classification based on histologic, endoscopic, and molecular features defines three endotypes each with distinct genetic, clinical, endoscopic, and histological features. Treatment principles include elimination of possible food allergen, mast cell stabilizer, proton pump inhibitor which has a cause and effect relationship, steroids, and biologicals. Earlier diagnosis with newer tools and biopsy help to diagnose EoE early in disease thus preventing progression to fibro stenotic disease thereby reducing morbidity. (Eosinophilic oesophagitis; Food allergens; esophageal eosinophilia; proton pump inhibitors; Allergy)

Introduction

Eosinophilic esophagitis (EoE) is a part of spectrum of eosinophilic disorders of the gastrointestinal tract histologically characterized by eosinophilic infiltration and inflammation consequent to exposure to an allergen, often food, resulting in esophageal dysfunction and progressive serious complications, though a definite cause eludes. This diagnosis from esophageal eosinophilia (1968) has progressed from initial association with reflux disorders to EoE in 1993. A male predominant disease, is associated with various allergic disorders including atopy and seen to increase progressively over these two decades. Etiopathobiology includes genetic and IgG 4 association and as a cause with familial susceptibility. Care of these patients involves primary care providers to multi-specialty departments.

Definition

EoE is defined as locally immune mediated chronic esophageal disease with clinical symptoms of esophageal dysfunction and histological eosinophil predominant inflammation with a progressive natural course.[1-5] It is IgG 4 mediated disease associated with atopy (20–80%), urticaria and anaphylaxis; positive family history (50%), asthma (30–50%) and allergic rhinitis (50–75%) in children.[6]

Natural History

- *Epidemiology:* It is a disease with global presence including America, Europe, Australia, and Asia, male predominant [3:1], ethnically variable (more common in Caucasians) with overall pooled prevalence of 22.7/100,000, 0.5–1 per thousand, 2–7% of gastroscopy,

12–23% of gastroscopy for dysphagia, and is seen to be increasing over time.[7]

- *Course:* EoE is a chronic and progressive disease. Earlier symptoms in children are due to inflammation and later in life due to subepithelial collagen deposition resulting in fibro stenotic EoE. Presence of strictures was observed in 17% and 71% with less than 2 years and 20 years of symptoms thus emphasizing the need for early diagnosis.
- *Temporal trends:* From 9 to 12.8/100,000 over 3 years in Ohio, USA, 0.35 to 9.5/100,000 in Minnesota, USA, over 15 years, 1.2 to 7.4/100,000 in Switzerland over 20 years indicating that there is an increasing incidence. The reasons for increase will be discussed in etiopathobiology in addition to awareness and increasing mucosal biopsies.

Etiopathobiology (Fig. 1)

- *Allergen and Hygiene Hypothesis:*[8] The strength of evidence stems from increased prevalence and incidence in developed countries which have better *hygiene* and association with most of the allergic disorders in a significant proportion. *Aero-allergen* exposure gains support by the increased incidence in summer or fall. Increased prevalence is noted in arid region, cold weather lacking vegetation, rural low density populated regions. This requires further research. *Food* elimination results in improvement of EOE, and hence is considered a risk. Various reasons mentioned stay unproven. Allergen/infection in an unprimed host living in virtual hygienic environment initiate Th2 response over Th1 which is mild and protective.
- *Helicobacter pylori (H. pylori)/Proton Pump Inhibitor (PPI) Hypothesis—Harmful or protective*: Presence of *H. pylori* polarizes the immune system toward a Th1 response and the lack of it leads to Th2 response. EoE has a strong inverse relationship with *H. pylori* and atopic disorders.[9]
  - *PPI* is hypothesized to increase upper gastrointestinal tract (GIT) permeability facilitating new route of antigen entry;
  - use of PPI is associated with food specific IgE antibodies.
  - PPI has shown anti-inflammatory/anti-eosinophilic effects.

  Use of PPI has resulted in histological resolution of inflammation and eosinophils in 30–40% making use of PPI as a candidate trial drug. PPI thus can cause EoE indirectly by removing the protective barrier and eliminating *H. pylori*; paradoxically PPI heals EoE by its anti-inflammatory and anti-eosinophilic activity; conclusive evidence is required to say if PPI is causative or curative.[10-17]
- *Early Life Exposure Hypothesis/Environmental Factor:*[18-23] EoE is associated with use of antibiotics in children delivered by caesarean, less than 1 year of age, premature babies, non-exclusively breast fed babies. Establishment of esophageal microbiome would help in understanding microbial dysbiosis as the cause.

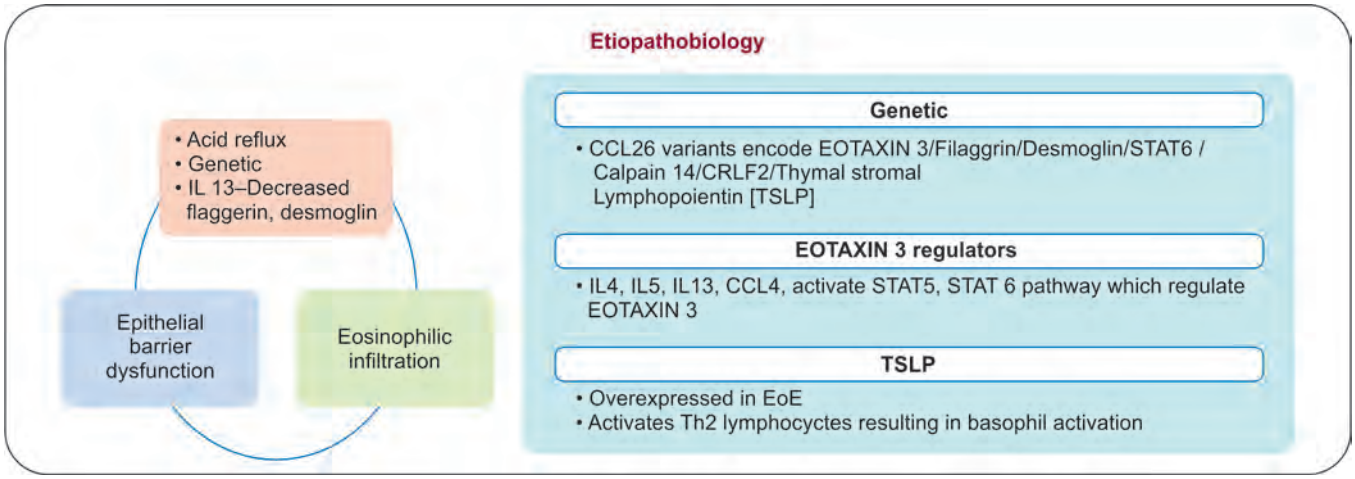

Fig. 1: Etiopathobiology shows the mechanism due to acid reflux, genetic, cytokine induced mechanisms

- *Familial/Genetic Susceptibility:* EoE is associated with connective tissue and auto-immune disorders.[24,25] EoE has racial and gender bias, predominance in white ancestry, inherited in non-Mendelian manner, a sibling risk ratio of 80%; parents had history of esophageal stricture and eosinophilic infiltrate in 10% and 8% respectively.

The new genetic, molecular, cellular, animal, and translational studies help to postulate a detailed pathway. This shows how, exposure to allergens results in a complex and coordinated type 2 inflammatory cascade. Delayed intervention can result in odynophagia, esophageal strictures, and food impaction.[26]

The genetics, epigenetics, and transcriptional analysis, the role of cytokines, chemokines, and other molecules, pathological and protective cells including commensal bacteria are vividly described.[26-28]

Diagnosis

The diagnosis of EoE is made on the constellation of clinical manifestations, endoscopic and histological findings.

- *Clinical:* There is a distinct phenotypic variability in symptomatology amongst people in early and advanced disease. Esophageal dysfunction symptoms include esophageal dysphagia in 60–100%, food impaction in 25%, heart burn in 30–60%, atypical chest pain in 8–44% and 1–8% of those with refractory reflux symptoms.[29] Dysphagia, refractory heart burn, and mucosal disruption on intubation are the predominant symptom/sign in advanced disease. Vomiting, food rejection and growth retardation are also observed.[30] Association of symptoms of atopy adds to the diagnosis.
- *Endoscopic:* Endoscopic Reference Scoring (EREFS) **(Table 1)** classification as given by Hirano et al. has scoring for visually observed endoscopy findings like edema, rings, exudates, furrows, and strictures graded separately at upper, middle, and lower third of esophagus. The inflammatory signs edema, exudates, and furrows had a sensitivity of 89%, 96%, 89%, and specificity of 88%, 76%. and 90%, respectively and correlated with eosinophilia. Composite inflammatory score, the sum of maximum of inflammatory variables namely edema, rings, and exudate excluding furrows and stricture showed a superior correlation amongst the diagnostic and post-treatment cohorts.[31,32] Schatzki's ring is one of the endoscopic manifestations of EoE.
- *Histologic:* Biopsy is mandatory in patients clinically suspected to have EoE even if the esophageal mucosa looks normal. Endosonography guided deeper biopsies would provide more information. A meta-analysis of EoE endoscopic findings in isolation have poor sensitivity, specificity, and predictive value[33] and the sensitivity increases to 100% when 6–9 esophageal mucosal biopsies are taken.[34,35] Presence of ≥15 eosinophils/hpf confirms the diagnosis of EoE.

Newer principles[36] **(Fig. 2)**:

- Removal of age cut-off
- Removing PPI from list of diagnostic criteria
- Evaluate for condition causing esophageal eosinophilia rather than excluding them
- Criteria should be clinically operational
- Should be utilizable in patients in whom diagnosis was made using earlier criteria, applicable clinically widely and for future research

Newer tools:

- Tetsuo Shoda et al.[37] using EoE diagnostic panel (EDP) and Consortium of Eosinophilic Disease Researchers (CEGIR), Endoscopic Reference Scoring (EREFS) and histologic scoring system (HSS) analyzed the

TABLE 1 Endoscopic reference scoring

Variable	*Grade 0*	*Grade 1*	*Grade 2*	*Grade 3*
Edema	Distinct Vascularity	Decreased Vascularity	Absent Vascularity	
Rings	None	Mild ridges	Moderate/Distinct rings	Severe—Cannot pass scope
Exudate	None	Mild ≤10% of surface area	Severe > 10% of surface area	
Furrows	None	Mild	Severe	
Stricture	Absent	Present		

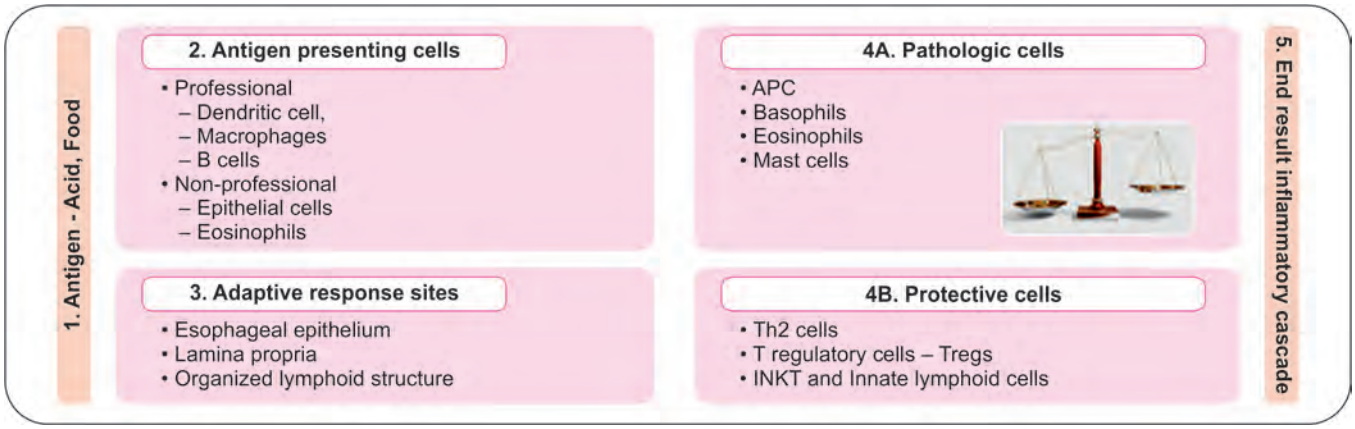

Fig. 2: Antigens presenting cells (APC) present the antigen to the adaptive response sites. Imbalance between pathological and protective cells result in inflammatory cascade

association of histologic, endoscopic, and molecular features. This study characterized three endotypes namely EoEe1, EoEe2, and EoEe3 each with distinct genetic, clinical, endoscopic and histological features providing effective therapeutic intervention **(Table 2)**.

Diagnostic criteria:

- Symptoms suggestive of esophageal dysfunction
- Presence of eosinophilic infiltrate (≥15 e/hpf) on esophageal biopsy
- Exclusion of other disease like Gastro Esophageal Reflux Disease (GERD) and Proton Pump Inhibitor Responsive Esophageal Eosinophilia (PPI-REE) after 8 weeks PPI trial.

AGREE Conference[36] 2018 includes the following:

- Symptoms of esophageal dysfunction.
- Esophageal mucosal biopsies with eosinophils ≥15/hpf (60 eosinophils/smm).
- Presence of exudates, grooves, rings, stenosis, luminal narrowing, and crepe' mucosa.
- Concomitant atopic conditions.
- Esophageal eosinophilic infiltration in isolation.
- Evaluation of potential contributors of esophageal eosinophilia.

- *Updated diagnostic algorithm*[36] **(Fig. 3)**
- *Emerging diagnostic tools:* Transnasal endoscopy, Endoscopic functional lumen imaging probe (FLIP), Cytosponge to obtain biopsy have sensitivity and specificity of 75% and 86%, respectively, esophageal string test and real time mucosal impedance measurements.[38] Absolute eosinophil count (AEC) is the single biomarker of relevance as on this date.[27]

Treatment

Treatment principles include elimination of potential antigen, attenuation or elimination of antigen induced allergic/immunogenic pathway induced inflammation early in the disease using PPI and steroids and to treat fibrostenotic complications of like strictures endoscopically in advanced disease. 3D acronym for Diet, Drugs, and Dilatation forms the basis of treatment of EoE.

Diet: Elimination diet: Elemental diet still is the most effective strategy but associated with poor compliance. A meta-analysis by Arias et al. observed efficacy of elemental diet in 90.8%, six food elimination diet (SFED—cow milk, wheat, egg, soy, peanut, and seafood) in 72.1% and allergy testing directed elimination diet in 45.5% of cases.[39] A novel 2-4-6 step up elimination diet strategy with each elimination diet step lasting for 6 weeks observed 43% remission in Two Food Elimination Diet (TFED Milk and gluten containing diet), 60% in those receiving TFED and four food elimination with addition of eggs and legumes (FFED) and 79% with six food elimination diet by additionally excluding nuts and seafood. This method helped to identify possible food antigen and avoided unnecessary food elimination.[40]

Drugs:

- *Steroids:* Dampening of EoE associated inflammation, improving mucosal barrier function and histologic

TABLE 2 EoE Endotypes

Variable	*EoEe1*	*EoEe2*	*EoEe3*
% of subjects	35%	29%	36%
Inflammation	Pauci -Inflammatory Near normal esophagus	High type 2 immune mechanism with steroid refractoriness Inflammatory	Higher frequency of narrow caliber esophagus Fibrostenotic
Epithelial differentiation genes	Small changes		Low expression
Onset	Pediatric	Adult	Adult
Allergy	Atopic	Atopic	Non-Atopic
Steroid sensitivity	Sensitive	Refractory	Refractory
Genetic	Low expression of ALOX 15 Mild phenotype	Inflammatory cytokines IL-4, TSLP are expressed Expression in ACTG2 gene	Enriched for epithelial genes that lose expression, of ACPP, CITED2, CTNNAL1, EML1, FLG, GRPEL2, MT1MPNLIPPR3, TSPAN12
Treatment response		Anti-Type 2 immune therapy (anti IL-4 Ralpha) Anti TSLP Biologicals	
Learning	• Adult and pediatric EoE have comparable pathogenesis • Adult and pediatric EoE are amenable to similar therapeutic interventions • Eosinophils levels may not indicate severity or help to subtype EoE • Endotyping offers useful subtyping of EoE • Biomarkers need to be developed • EoE exists in three disease endotypes with characteristic/unique clinical, endoscopic and molecular features • Endotyping could transcend eosinophil levels as gold standard		

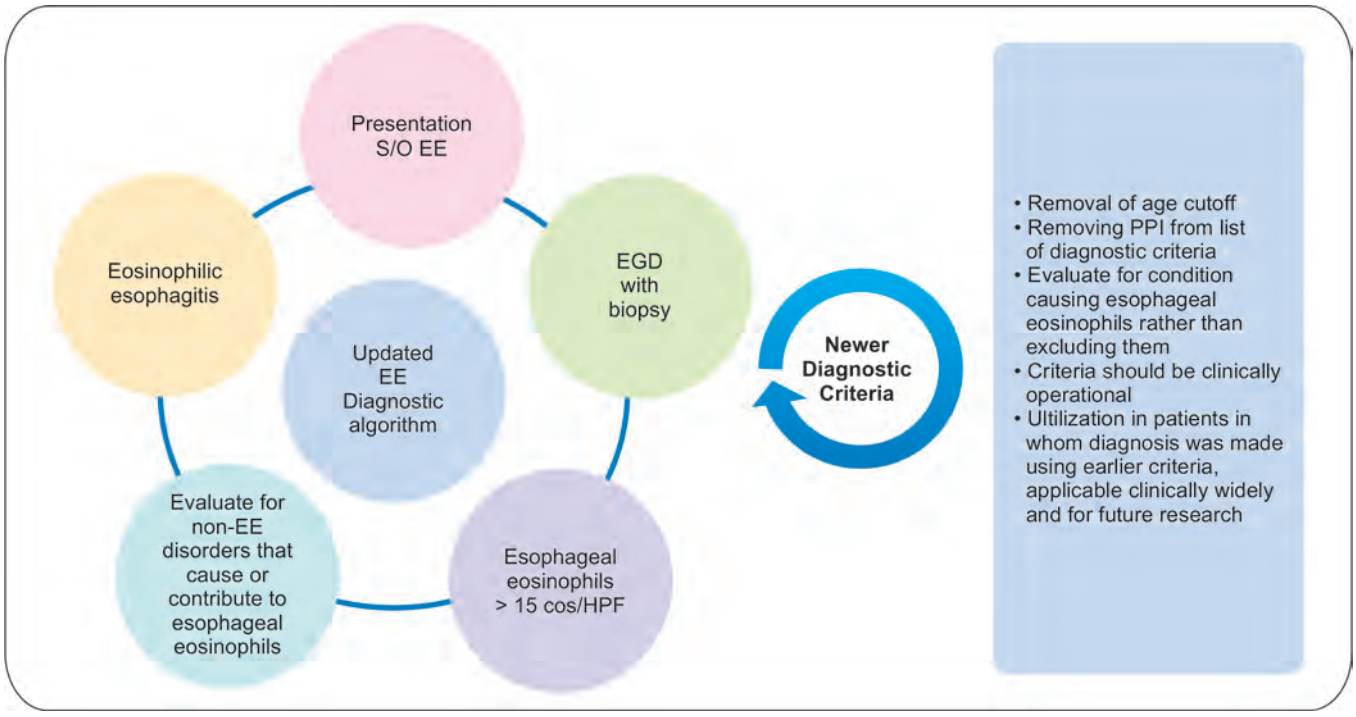

Fig. 3: Showing the updated EoE algorithm and the principles in newer diagnostic criteria

TABLE 3 Follow up and monitoring response

Variable	*Non-response*	*Response*	*Complete remission*
Symptom	Less than 30% symptom persistence in a symptom metric	90% decrease in symptom metric. Eosinophilia decrease by 30%	Greater than 90 % response in symptom metric EEsAI score < 20
Endoscopy	Persistent endoscopic finding < 30% decrease in EREFS	Improved endoscopic findings EREFS ≥ 2 but less than baseline	Normal esophagus EREFS < 2
Histology	Persistent eosinophilia ≥15 eos/HPF	Reduced eosinophilia 7–14 eos/HPF to 1–6 eos/HPF	Normal biopsy < 1 eos/HPF

EEsAI, eosinophilic esophagitis symptom activity index; eos/hpf, eosinophils/high power field; EREFS, eosinophilic esophagitis endoscopic reference score

remodeling; improved esophageal diameter and dispensability.[41-44] Induction regimen of oral 1 mg budesonide twice daily for 2–4 weeks to reach clinical response followed by maintenance regimen of 0.25 mg twice daily for not less than 6 months after which steroid can be discontinued if remission is maintained. Deep remission was achieved at 89 weeks in 9.4% of adult EoE patients with corticosteroid discontinuation at 104.7 weeks and relapse at 22.4 weeks. Relapse is managed with induction regimen for 1–2 weeks. Esophageal candidiasis in 20% and herpetic infection, adrenal insufficiency were reported following steroid use. Oral and aerosolized fluticasone is also used.

- *PPI:* The ability of PPI to reduce inflammation—PPI responsive esophageal eosinophilia (PPI-REE) has made it a first-line therapeutic modality. Use of PPI (8 weeks) by a meta-analysis showed clinical response in 60.8%, histological remission in 50.5%, sustained remission in 73–86%.[45,46]
- *Leukotriene B4 inhibitor:* Use of Montelukast a leukotriene B4 inhibitor results in mast cell inhibition thereby reducing cytokine release retarding or preventing inflammatory cascade.
- *Biologicals:* These include monoclonal antibodies against IL-13, IL-5, IL-4, anti-tumor necrosis factor alpha (TNF alpha) and antibodies against immunoglobin E. Studies indicate a promise for dupilumab, monoclonal antibody acting on IL-4 receptor by a negative regulation of Th2 response causing inhibition of IL-4/IL-13 signaling.[47]

Dilatation therapy: Advanced disease with fibro-stenotic manifestation need endoscopic dilatation, incising of Schatzki's ring.

Reduction in esophageal subepithelial activity (ESEA) could evolve as a relevant objective endpoint of treatment. ESEA can be known by deeper biopsies guided by endosonography. Presently available instruments—biomarkers and clinical techniques—are limited or not fully utilized. This remains as a need to meet.[48,49]

Treatment Response and Monitoring: spectrum includes non-response, response, and complete remission **(Table 3)**. All biomarkers now on use are investigational and include IL-3, IL-5, IL-6, IL-13, transforming growth factor alpha, and beta, TNF alpha, eotaxin 1, 2, and 3 thymic stromal lymphoprotein (TSLP) and major basic protein and neurotoxin derived from eosinophils.

Future Directions

Aimed at identifying the antigens responsible for the inflammatory cascade, early detection of EoE, noninvasive biomarkers for detection and monitoring, target directed therapies and prevention of relapse after achieving remission.

Conclusion

EoE is a chronic antigen induced immune mediated progressive disease of the esophagus characterized by eosinophilic infiltration. This progresses from inflammation to fibrostenotic disease. Earlier diagnosis by liberal biopsies in symptomatic but with normal esophageal mucosa can identify more patients. Endosonography guided deeper biopsies will give more information on subepithelial activity, which results in fibrostenotic disease. Earlier intervention improve the quality and quantity of life with less morbid and mortality indices. Increasing awareness amongst family physicians and patients with allergic disorders coupled with esophageal biopsies is desirable.

CHAPTER

137 Non-Cirrhotic Portal Hypertension in India

Srikant Mohta, Anoop Saraya

Abstract

Non-cirrhotic portal hypertension is an entity with a normal hepatic venous pressure gradient (HVPG) but significant portal hypertension. It could be due to pre-hepatic, hepatic, or post-hepatic causes. The most notable etiologies are extrahepatic portal vein obstruction (EHPVO) and non-cirrhotic portal fibrosis (NCPF) while other causes include schistosomiasis, congenital hepatic fibrosis, and regenerative nodular hyperplasia. The pathogenesis for NCPF and EHPVO is multifactorial and not very clear. However, there is evidence to suggest the role of a prothrombotic state and infection. EHPVO presents 10–20 years before NCPF and they both predominantly present with gastrointestinal bleed without other decompenstations. In severe cases, they may have ascites and encephalopathy as well. They differ in their association of portal biliopathy, associated autoimmune conditions, histology, and diagnostic modalities needed. Diagnosis is established easily for EHPVO by Doppler ultrasonography; however, NCPF requires exclusion of cirrhosis and may necessitate a liver biopsy. Treatment options include variceal ligation and beta-blocker for secondary prophylaxis of bleeding. A major complication of EHPVO is portal biliopathy which needs endoscopic therapy if cholangitis occurs. Shunt surgeries remain important in the long term; however, their role for bleeding has reduced due to better endotherapy and availability of newer modalities like TIPSS. With advent of better therapy, the prognosis of these conditions has improved and most patients live a healthy life.

Introduction

Portal hypertension (PHT) is usually defined by araised hepatic venous pressure gradient (HVPG) more than 5 mm Hg. HVPG is the difference in pressure between portal vein (PV) and inferior vena cava. The most common cause of PHT is cirrhosis in which case the HVPG is raised due to sinusoidal resistance. However, there is another group of diseases with PHT, but a normal HVPG, which are grouped under non-cirrhotic PHT (NCPH). Causes of NCPH are primarily vascular and may be prehepatic, hepatic, and posthepatic **(Table 1)**.

Non-cirrhotic portal fibrosis (NCPF) and extrahepatic portal venous obstruction (EHPVO) are two common causes of NCPH and will be discussed in detail while others will be discussed briefly in the chapter.

Non-Cirrhotic Portal Fibrosis

NCPF is a disease without a specific known cause, because of which it is also termed as idiopathic PHT. Hallmark features include massive splenomegaly, often with hypersplenism with no liver cell failure.[1] The disease is commoner in developing countries. The disease accounts for 10–30% of cases of variceal bleed in several parts of the world including India.[2] However, a recent review compiling the studies from India showed a declining prevalence in prospective studies.[3] It is seen most commonly in the age group of 30–40 and has a male preponderance.

Etiopathogenesis

The accurate etiopathogenesis is unknown; infections and prothrombotic states are the factors which have been

TABLE 1 Important causes of non-cirrhotic portal hypertension

Prehepatic	*Hepatic*	*Posthepatic*
EHPVO Splenic vein thrombosis Massive splenomegaly	• Presinusoidal—PBC, PSC, schistosomiasis, NCPF, congenital hepatic fibrosis • Sinusoidal—Alcoholic hepatitis, drug induced fibrosis • Postsinusoidal—Budd Chiari syndrome, sarcoidosis, tuberculosis, veno-occlusive disease	• Posthepatic Budd Chiari syndrome (IVC web, RA thrombosis) • Restrictive cardiomyopathy • Severe tricuspid regurgitation

EHPVO, extrahepatic portal vein obstruction; IVC, inferior vena cava; NCPF, non-cirrhotic portal fibrosis; PBC, primary biliary cholangitis; PSC, primary sclerosing cholangitis; RA, right atrium.

incriminated most commonly. Although data is limited, better obstetric hygiene and neonatal care are likely the reason behind to bring down the incidence of NCPF. This has been shown in Western countries and supports the role of hygiene in pathogenesis of disease.[1] India is more predisposed as populations have lack of clean drinking water, inadequate sewage facilities, and continuous gut inflammation due to antigenic exposure. Autopsy series from western countries showing high prevalence of PV thrombosis lend support to the role of prothrombotic factors. An imbalance of low ADAMTS13 and von Willebrand factor levels could be linked to promotion of PV radicals. This was first established from relation between therapeutic arsenic exposure (Fowler's solution) and NCPF in Europe. It has been shown to be associated with autoimmune diseases like inflammatory bowel disease (IBD) and celiac disease. Patients with HIV have shown a higher prevalence of NCPF.[4] Possible contributory factors could include opportunistic gastrointestinal (GI) infections, antiretroviral therapy or the effect of the viral by itself.

Extrahepatic Portal Venous Obstruction

EHPVO is a cause of PHT seen predominantly in children. The central pathophysiology involves a chronically blocked PV supplying blood via collaterals to a normally functional liver. EHPVO is the commonest cause of PHT (up to 80%) and uppergastrointestinal bleeding (up to 60%) in children in developing nations.[5]

In children, specific prothrombotic states are identified less commonly and methylene tetrahydrofolate reductase (MTHFR) deficiency is the commonest. Amongst adults and in western nations, primary myeloproliferative disorders (MPD) are common. Overall, prothrombotic states are found in one third to half the cases. Thrombosis may also occur due to inflammation in the local milieu or paraneoplastic thrombosis. In spite of all evaluation, up to 70% cases may remain idiopathic.

Etiopathogenesis

Perinatal history is important as sepsis and manipulation of the umbilical vein have been implicated as inciting factors.[6] At the time of diagnosis, most of the times a cavernoma is seen as the initial thrombosis is often missed as it is asymptomatic and there is formation of collaterals within 1–2 weeks followed by cavernoma in another week. These collaterals are able to compensate partially and overcome the prehepatic obstruction, but their insufficiency leads to formation of varices.

Diagnosis

The typical scenario when one should suspect NCPF and EHPVO is presentation with GI bleed with relatively well preserved liver function tests. Ultrasound of the abdomen provides a further clue since massive splenomegaly is seen in both conditions, which is larger than cirrhosis. Doppler shows a thrombosed PV with surrounding collaterals (cavernoma) in case of EHPVO and normal flow in NCPF.

Clinical Features

EHPVO presents in the first decade with peaks at 3 and 8 years of age.[7] NCPF on the other hand is seen more in young and middle aged adults median age of onset in Indian series being 30–32 years.[8] Patients often give a history of long standing dull aching pain in the left upper abdomen due to massive splenomegaly; however, it requires medical attention infrequently. Unlike cirrhosis, the episodes of variceal bleed are often not life threatening and well tolerated. Being a childhood chronic disorder affecting the

TABLE 2 Differences between NCPF and EHPVO

	NCPF	*EHPVO*
Nature of precipitating event	Mild, recurring	Severe, progressive
Affected age	Childhood and adolescence	Early childhood
Associated autoimmune diseases	Yes	No
Growth retardation	Not seen	Seen
Portal biliopathy	Not seen	Seen
Encephalopathy	Usually absent	Minimal HE usually occurs in natural history
HVPG	Normal or elevated	Normal
Investigation of choice for diagnosis	Liver biopsy	Ultrasound Doppler
Hallmark on liver biopsy	Obliterative portal venopathy	Normal liver architecture unless secondary biliary cirrhosis occurs

EHPVO, extrahepatic portal vein obstruction; HVPG, hepatic venous pressure gradient; NCPF, non-cirrhotic portal fibrosis.

liver blood supply, EHPVO is often complicated by anemia and growth retardation **(Table 2)**.

Incidences of variceal bleed are frequently precipitated by infections and recurrences tend to decrease after puberty. Hypersplenism is present in both the disorders. Although liver cell failure is rare, ascites may occur in up to one third of the patients. This usually occurs after a bleed and is related to low serum albumin levels or in cases of secondary biliary cirrhosis. The left upper abdomen pain may be exacerbated and acute at times of perisplenitis or splenic infarction.

On clinical examination, liver span is normal or slightly reduced. Peripheral clinical stigmata of cirrhosis are absent. Icterus may be seen in EHPVO in those with portal biliopathy.

Laboratory Parameters

Hypersplenism with anemia is the commonest finding. Liver function tests are usually normal; however, albumin levels in serum may be reduced at the time of bleed further creating a diagnostic dilemma with cirrhosis. Elevated conjugated bilirubin and cholestatic pattern (raised alkaline phosphatase) may be a harbinger of portal biliopathy in long standing cases.[7] Prolonged prothrombin time, reduced fibrinogen is seen in most patients. The shunted blood flow leads to impaired production of coagulation factors and lead to a low grade of disseminated intravascular coagulopathy.[9] Hyperdynamic circulation is seen in both conditions and along with raised nitric oxide has been proposed to lead to autonomic dysfunction. Cell mediated immunity may be hampered.

Findings on Esophagogastroduodenoscopy

Esophageal varices are seen in more than 80% of patients. Compared to cirrhotics, esophageal varices are larger and gastroesophageal varices are commoner.[10] Ectopic varices in the rectum and colon may lead to lower GI bleed in EHPVO.

Radiological Features

At clinical suspicion, ultrasound of the abdomen with Doppler for splenoportal axis is the initial investigation of choice. In NCPF, liver is normal in size and spleen is enlarged with a dilated and patent splenoportal axis. PV is thickened (>3 mm) and intrahepatic branches show a withered tree appearance. The etiological workup for cirrhosis is negative. NCPF may mimic early stage cirrhosis very often and only HVPG can reliably differentiate between them. The diagnosis of EHPVO in children is usually much simpler as the finding of a portal cavernoma replacing the PV has a very high sensitivity and specificity. In adults, with cirrhosis, it becomes difficult as cirrhosis may also lead to bland PV thrombosis. There is cavernomatous transformation of PV. CT and MR venography have better sensitivity and also provide a roadmap to surgery.[11]

Pathology

EHPVO can be reliably diagnosed by USG; however, a liver biopsy may be needed to differentiate early cirrhosis and NCPF. The characteristic pathological findings for NCPF by phlebosclerosis, periportal, and perisinusoidal fibrosis, aberrant vessels in portal tract, preserved lobular architecture, and "obliterative portal venopathy."[12] In cases of EHPVO, the PV is replaced by cluster of varying sized vessels more so around the hilum. Nodular arrangement and fibrosis, which are characteristic of cirrhosis are absent.

Natural History

The natural course of NCPF is usually much more predictable as compared to the complexity seen in EHPVO sometimes. A likely reason for this is the early insult in life, which leads to a long time available for the disease to progress insidiously. It may lead to short stature, parenchymal destruction, poor quality of life, hepatic encephalopathy, and portal biliopathy.

Once GI bleed is controlled after variceal eradication, long-term prognosis in NCPF is excellent. Liver cell failure and decompensation is usually absent but may occur at times of GI bleed or in nodular NCPF.[13] Uncontrolled upper GI bleeding from varices may lead to mortality.

While the general outcome of EHPVO is good, certain complications need to be monitored and treated carefully. Growth retardation occurs in up to half of the children. The postulated mechanism behind this is deprivation of hepatotropic factors and malabsorption due to portal hypertensive enteropathy.[14] They also have a poor health-related quality of life.

Portal biliopathy is defined as cholangiographic abnormalities, which occur in patients with *portal* cavernoma. This may be intrahepatic or extrahepatic. Long standing portal cavernoma in the biliary region causes compressive and ischemic changes on the biliary tree. Portal biliopathy usually remains asymptomatic may lead to jaundice, biliary colic, abdominal pain, and recurrent cholangitis. Another dreaded complication is minimal hepatic encephalopathy (MHE). It is understandably more after shunt surgery but it may occur even prior to surgery.[15] Usage of lactulose improves MHE. Prolonged portal biliopathy leads to extinction of liver parenchyma gradually and may mimic cirrhosis later. It may manifest as poor synthetic function, jaundice, and decompensation in the form of ascites.

Treatment

The event that can change the natural history of a patient with NCPH is massive upper GI bleed. Control of the index bleed and prevention of further bleed is the focus in most cases. Another aspect of the treatment is symptomatic splenomegaly and hypersplenism. Rest of the treatment revolves around complications like MHE, portal biliopathy, and growth failure.

Control and Prophylaxis of Variceal Bleed

Variceal bleed is an important complication in NCPH. In view of limited data as compared to variceal bleed, guidelines recommend the principles of management to remain same.[16] The patient should be resuscitated with fluids and be taken up for endoscopy within 24 hours. Endotherapy in the form of endovascular ligation is the mainstay of therapy in terms of intervention. Older studies used more of sclerotherapy. These techniques are successful in more than 80% patients. Vasoactive agents should be started prior to endotherapy to reduce the severity of bleed and possibly control it. The goal should be variceal eradication as role of beta blockers is not very clear although they are widely used. Non-selective beta blockers should be used for secondary prophylaxis.

Transjugular Intrahepatic Portosystemic Shunt (TIPS)

TIPS is an option for treatment for complicated NCPH, especially those with recurrent or refractory bleed. However, it is best avoided in cases of renal dysfunction, malignancy, or prothrombotic conditions.

Surgery

The most common indication for surgical management is recurrent bleed or bleed refractory to endotherapy. Other indications are symptomatic hypersplenism, hepatopulmonary syndrome, or portopulmonary hypertension.[17] Surgery has now mainly been replaced by TIPS. The types of surgeries performed are:

- *Shunt procedures:* They bypass blood from the portal system to systemic circulation removing the carvernoma from the pathway. Shunts may be

physiological or non-physiological depending on whether they preserve the hepatic portal blood flow or not (maintained in physiological). As is expected, surgery reduces complications of PHT like varix size and spleen size; however, adverse effects from portosystemic shunting include risk of MHE and shunt nephropathy.[18] Selective shunts like distal splenorenal shunt are associated with less complication than proximal, non-selective shunts. Shunt surgery is undertaken only after a particular age (generally 8 years) and with a favorable anatomy (adequate shuntable vein diameter).[19]

- *Ablative procedures:* These surgeries are very morbid and include visceral devascularization with or without splenectomy. It has gone out of vogue due to advances in endotherapy and is reserved for emergency scenarios.

Salvage Emergency Therapy

In spite of newer endoscopic modalities, in 10% of the cases endotherapy fails. Options then include ablative procedures, TIPS, or balloon occluded retrograde transvenous obliteration.[16,17]

Routine anticoagulation is not recommended in EHPVO or NCPF according to the current available data. The management for portal biliopathy is generally supportive and not curative. Biliary stenting is done using ERCP for biliary strictures.[20]

Miscellaneous Causes of NCPH

Although infrequently seen in clinical practice, a few important causes of NCPH that merit discussion have been described here.

Schistosomiasis

Schistosomiasis is one of the most common causes of NCPH in the world but rarely seen in India. *Schistosoma mansoni* and *Schistosoma japonicum* are the two main species of Schistosoma that are known to cause liver disease. *S. japonicum* is distributed throughout the world and *S. mansoni* is endemic to Africa and Middle East. Both are however not found in India. The eggs are stuck in the portal venules and lead to granulomatous inflammation. Over a period, fibrosis occurs and portal pressures increase.[21] Chronic hepatic schistosomiasis is characterized by hepatomegaly with features of PHT. Diagnosis is based on detection of eggs in stool or rectal biopsy or ELISA test for antigen. On ultrasound, PV radicles show echogenic thickening giving the appearance of a mesh of fish scales. There may be complete reversal of periportal thickening with use of antihelminthic like praziquantel.

Congenital Hepatic Fibrosis

Congenital hepatic fibrosis (CHF) is a developmental disorder of the portobiliary system characterized histologically by defective remodeling of the ductal plate and progressive fibrosis of the portal tracts.[22] It is usually autosomal recessive in inheritance and presents in the first or second decade of life. Autosomal recessive polycystic kidney disease and ciliopathies are commonly associated disorders.[23] Clinical findings include an enlarged, abnormally shaped liver and splenomegaly with preserved liver functions. Biliary complications include cholangitis and an increased predisposition to cholangiocarcinoma. Imaging reveals dilatation of biliary system and enlarged caudate lobe and splenomegaly. Since no specific therapies are available, treatment of complications and eventually liver transplant may be needed.

Nodular Regenerative Hyperplasia

Nodular regenerative hyperplasia (NRH) is a characterized by widespread benign transformation of hepatic parenchyma into small regenerative nodules. It is common in Europe and Japan with preponderance amongst octogenarians.[24] There is a limitation of population based studies on NRH. It can be caused by various drugs (commonly chemotherapeutic agents and immunosuppressants), hematological, autoimmune, inflammatory, and neoplastic disorders. Pathogenesis appears to be related to adaptive hyperplastic reaction of hepatocytes in response to mechanical or functional abnormalities of portal hepatic blood flow. Pathologically, it is differentiated from cirrhosis by absence of perinuclear collagen and fibrous septa. Most patients remain asymptomatic, but some present with NCPH. Treatment is aimed at removal of inciting factor and management of primary disease.[25]

Conclusion

NCPH are important causes of PHT in developing countries like India. The most important disorders are NCPF in adults and EHPVO in children. The complications if managed well, patients can have a good prognosis and leave a healthy life.

CHAPTER

138 Drug-induced Liver Injury

Harshad Devarbhavi

Abstract

Drug-induced liver injury is an under-diagnosed cause of liver disease. It mimics all forms of liver disease. The three patterns of DILI are hepatocellular, cholestatic, and mixed. Presence of hepatocellular jaundice in DILI is associated with a mortality of >10%; this is also known as "Hy's law". Combination anti-TB drugs, i.e., isoniazid, rifampicin, and pyrazinamide are the most common cause of DILI and drug-induced acute liver failure (ALF) in India followed by traditional and complementary medicines. Prompt recognition and cessation of the "culprit" drug is the key to managing patients with DILI followed by supportive therapy. Few antidotes include N-acetyl cysteine for paracetamol toxicity and drug-induced ALF, cholestyramine for leflunomide DILI, and steroids for drugs associated with hypersensitivity features or drugs causing autoimmune like hepatitis.

Introduction

Drug-induced liver injury (DILI) is underdiagnosed and underappreciated as a cause or contributor to liver injury. Drugs and toxins should be considered in the differential diagnosis of all types of liver injury across all ages, although the risks are higher in older individuals and in women. It is not clear why older individuals or women have an increased risk; this may be due to increased intrinsic risk or because older people take more drugs and therefore have more opportunities to experience adverse drug reactions (ADRs). This review will focus on recent concepts on DILI with particular emphasis on DILI from India.

DILI is a diagnosis of exclusion. A high degree of suspicion and consequently a careful history of prescription medication and over the counter drugs (pain killers) exposure as well as exposure to herbal and traditional medicines or dietary supplements (often overlooked by the physician) should be obtained. While most patients experience DILI within the first 2–3 months of therapy, in some instances (e.g. amoxicillin-clavulanate related DILI) symptoms can present with up to a month delay after treatment cessation or arise after months of exposure to a drug such as nitrofurantoin, minocycline, and alpha methyldopa.[1]

Causality Assessment

Since DILI is a diagnosis of exclusion there are no established diagnostic markers. Causality assessment methods are used to determine likelihood of a drug causing liver injury and the best known is the Roussel Uclaf causality assessment method (RUCAM).[2] Information on time to onset (latency), course of reaction upon medication discontinuation, time to resolution, risk factors, concomitant drugs exclusion of other causes, prior knowledge on DILI potential, and response to readministration are variables required to establish a compatible relationship with the suspected

causative agent. The degree of causality is assessed as definite (highly probable), probable, possible, and unlikely in descending order of strength.[2]

Case Definitions and Severity

Transient asymptomatic minor elevation of aspartate transaminase (AST) or alanine transaminase (ALT) is common during routine evaluation. In one study incidence of baseline liver chemistry abnormalities in a population of over 18,000 patients (without underlying liver disease), the baseline prevalence of any ALT elevation above the upper limit of normal (ULN) was 6% while the overall prevalence of ALT values of more than 3 × ULN was 0.076% (<1 in 1,000).[3]

Transient elevation of AST or ALT may occur following exposure to medication and may resolve on its own or with continuation of drugs or following decrease in dose. This phenomenon (*called adaptation*) is characteristic of antituberculosis (anti-TB) drug or statin therapy and depends on the frequency of liver biochemistry estimation. Awareness of this condition will prevent inappropriate withdrawal of medications such as in the treatment of tuberculosis where even a temporary cessation of treatment may have adverse disease outcome including risk of drug resistance.[4] Transient elevation of transaminases in patients with elevated liver enzymes while on statin therapy (e.g. in patients with coronary heart disease or diabetes)[5] is not an indication to stop therapy.

DILI is defined as an adverse hepatic reaction that is unexpected on the basis of the pharmacological action of the drug administered. International expert panel[1] recommended DILI to be considered when any one of the following thresholds are met *even in the absence of symptoms*:

- ALT or AST ≥ 5 × ULN
- ALP ≥ 2 × ULN in the absence of extrahepatic source driving the rise in ALP level
- Total bilirubin concentration exceeding 2 × ULN associated with any elevation of the aminotransferases or alkaline phosphatase.[1]

In the presence of symptoms including extrahepatic symptoms of hypersensitivity such as skin rashes or eosinophilia, ALT or AST ≥ 3 × ULN is deemed to be DILI. The symptoms related to DILI are often similar to that of acute liver injury or cholestasis due to other etiology including any of the following: fever, nausea, vomiting, jaundice, dark urine, right upper quadrant pain, skin rashes, and itching.[1]

The level of elevation of liver enzymes alone does not reflect liver function severity. Liver enzyme elevation is a reflection of liver injury not function, whereas bilirubin elevation (liver excretory function), or increased INR or decreased albumin (liver synthetic function) are more accurate indices of liver function.[6] The presence of jaundice, or development of ascites, coagulopathy, and/or encephalopathy indicates severe disease[1] and connotes poor prognosis.[7]

Hy's Law

Hyman Zimmerman observed the presence jaundice in the setting of DILI suggested severe hepatocellular functional impairment with potential for liver failure and 10–50% mortality.[6,8] Thus, "Hy's law" is used clinically and during drug evaluation to indicate highly significant and severe hepatotoxic potential of a drug when patients fulfill the following criteria, that is, AST or ALT more than 3 × ULN + bilirubin >2 × ULN (in absence of biliary tract disease).[8] Presence of jaundice during anti-TB therapy results in a mortality of 16–26% in India.[7,9] Patients with anti-TB DILI who fulfill Hy's law criteria have a mortality of 17%. Furthermore, development of acute liver failure during treatment of anti-TB drugs results in a mortality in two-thirds of patients.[10] Paradoxically in the Indian setting a substantial proportion of individuals who develop anti-TB DILI, never required the drugs in the first place, having received anti-TB drugs empirically on a presumptive basis.[10,11] Therefore, great caution should be exercised while administering anti-TB drugs empirically, especially in women, the elderly, and those with comorbidities.[12]

Patterns of Liver Injury

Most patients with DILI in clinical practice are characterized based on their liver biochemistry, these are categorized as hepatocellular, cholestatic, or mixed pattern of DILI.[1] Pattern of liver disease is based on Ratio (R value) of ALT (or AST) activity expressed as fold elevation over its ULN laboratory range to ALP activity. Pattern of DILI is hepatocellular when R is ≥5, cholestatic when R is ≤2 and mixed when R is 2–5.[1] The pattern of liver injury has implications for prioritizing immediate

investigations essential to exclude alternative causes of the event as well as prognosticate outcome.

Examples of drugs associated with above patterns and other additional patterns are listed below:[13]

- *Hepatocellular:* Isoniazid, rifampicin, pyrazinamide, diclofenac, lamotrigine, minocycline, nitrofurantoin, nevirapine, efavirenz, sulfonamides, disulfiram.
- *Cholestatic:* Chlorpromazine, erythromycin, penicillins, amoxicillin-clavulanate, sulfonamide, terbinafine, androgens, oral contraceptives.
- *Mixed pattern:* Phenytoin, carbamazepine, lamotrigine, sulfonamides.
- *Drug reaction with eosinophilia and systemic symptoms (DRESS):* Carbamazepine, phenytoin, phenobarbitone, allopurinol, lamotrigine, cephalosporins, dapsone, sulfonamide, nevirapine.
- *Autoimmune like hepatitis:* Nitrofurantoin, α-methyldopa, minocycline, diclofenac, statins, adalimumab, infliximab, herbals and complimentary medicines.
- *Nonalcoholic fatty liver disease (NAFLD):* Amiodarone, methotrexate, tamoxifen, 5-fluorouracil, amiodarone, didanosine, stavudine.
- *Vanishing bile duct (ductopenic) syndrome:* Azathioprine, amoxicillin-clavulanate, carbamazepine, chlorpromazine, erythromycin, phenytoin, terbinafine and cotrimoxazole.

Causes

Antibiotics are the most common cause of idiosyncratic DILI and drug-induced acute liver failure worldwide and also in India.[7,9,13-16] In India, first-line combination anti-TB drugs, isoniazid, rifampicin, and pyrazinamide are the commonest agents causing DILI accounting for 46% of all cases followed by complementary and alternative medicines at 14%.[9] Combination anti-TB drugs accounts for 67–72% of cases of drug-induced acute liver failure followed by anti-epileptic drugs (10%), and dapsone (5.5%) in a single center series.[9,17,18] DILI from anti-TB drugs appears disproportionately more severe than other drugs causing liver injury.[7] Almost three-fourths of anti-TB DILI occur within the first 2 months of administration of drugs although the risk of DILI persists throughout the course of treatment.[19] Paradoxically paracetamol-induced DILI and liver failure is very uncommon in India and accounts for less than 1% of DILI or drug-induced ALF.[9,18] This is in stark contrast to the high incidence of paracetamol hepatotoxicity in western countries. In a prospective India nationwide study,[9] drugs causing DILI in the descending order of frequency were as follows:

- Combination anti-TB drugs (46.4%)
- Complementary and alternative medicines (13.9%)
- Antiepileptic drugs (AED) (8.1%)
- Non-anti-TB antimicrobials (6.5%)
- Antimetabolites (3.8%)
- Antiretroviral drugs (3.5%)
- NSAIDs (2.6%)
- Hormones (2.5%)
- Statins (1.4%)
- Others (11.3%)

Although patients with pre-existing liver disease are not more likely than others to experience hepatic injury on exposure to drug, recovery from DILI in patients with chronic liver disease is generally poor.[20] Complementary and alternative medicines (73%) and anti-TB drugs (22%) are responsible for 99% of cases of drug-induced acute on chronic liver failure (ACLF) in India and Asia and is associated with 46% mortality, much more than other causes of ACLF.[21]

Mechanism of Liver Injury

Simplistically, the mechanism of DILI may be divided into two broad groups, that is, direct hepatotoxicity as exemplified by paracetamol overdose or idiosyncratic injury wherein the characteristics of the individual patient/subject plays a major role in causing DILI.[20] In idiosyncratic reaction, the dose of a drug does not play a role although most DILIs are encountered following exposure to drugs used in daily dose of 50 gm or higher.[22] **Table 1** summarizes the characteristics of mechanism of injury. A recently described third category is the indirect hepatotoxicity, wherein hepatotoxicity is secondary to the indirect action of agent on liver or immune system **(Table 1)**.[23]

Management

The first consideration in the management of DILI is to harbor a high index of suspicion regarding the role of medications in causing liver injury. The drugs implicated should be stopped immediately and alternate causes including viral hepatitis especially hepatitis E (which is common in Northern India)[24] and biliary causes

TABLE 1 Mechanism of drug-induced liver injury and associated features

Basis for injury	*Dose dependence*	*Incidence in humans*	*Latent period*	*Implicated agents*
Direct (intrinsic) hepatotoxicity	Yes	Common (1–100%)	Often short	Paracetamol, ferrous sulfate, i.v. amiodarone, IV methotrexate, aspirin, cancer chemotherapy
Idiosyncratic (unpredictable reaction)	No	Rare (1:10000)	Often long and variable	INH, rifampicin, pyrazinamide amox-clavulinate, sulfonamides, cephalosporins
Indirect hepatotoxicity	No	Intermediate	Delayed (months)	Steroids, anti-TNF, Anti-CD20, checkpoint inhibitors, protein kinase inhibitors

(by ultrasonography) should be excluded. Most episodes of DILI resolve with discontinuance of the culprit drug and with supportive treatment. There are very few antidotes for specific drugs producing DILI. These include N-acetylcysteine for paracetamol toxicity,[25] desferrioxamine for ferrous sulfate toxicity, L-carnitine for valproate DILI, and cholestyramine for leflunomide DILI. Patients who develop hypersensitivity skin rashes and eosinophilia or DRESS should be considered for steroid treatment, which should be continued for 4–8 weeks, although steroids have not been evaluated in a randomized fashion.[26]

Reintroduction of anti-TB drugs after an episode of anti-TB DILI needs special mention. The American Thoracic Society guidelines are the most up to date and elaborate.[27,28] Ethambutol has no hepatotoxic potential and needs to be continued during and after DILI. Rifampicin is the least hepatotoxic drug and needs to be considered first followed by isoniazid and pyrazinamide. These drugs may be administered sequentially with staggered doses. In case of a severe DILI at index presentation, pyrazinamide should be omitted during rechallenge.[27]

Conclusion

Anti-tuberculosis drugs are the most common cause of DILI and drug-induced acute liver failure in India. DILI is a diagnosis of exclusion. Awareness of the fact that drugs can mimic all forms of liver disease is crucial in diagnosing DILI. Occurrence of hepatocellular jaundice entails a mortality of >10%, and hence the implicated drug should be stopped immediately. There is emerging evidence of the increasing role of traditional and complimentary medicines in causing DILI all over the world including India.

CHAPTER

139 Achalasia Cardia—Diagnosis and Endoscopic Treatment

Mohan Ramchandani, Partha Pal

Abstract

Achalasia cardia is a primary esophageal motility disorder due to autoimmune neurodegeneration of esophageal myenteric plexus resulting in impaired relaxation of lower esophageal sphincter (LES) on swallowing and failure of peristalsis in distal smooth muscle segment of the esophagus. High resolution manometry (HRM) has greatly improved the sensitivity of diagnosing achalasia in the early stages of disease when endoscopy and barium esophagogram can be normal or equivocal. Manometrically achalasia cardia can be divided into three subtypes, which help in deciding treatment, and hence have prognostic significance. The primary distinction from other motility disorders (e.g., Jackhammer esophagus and distal esophageal spasm) is failure of LES relaxation in achalasia. So, most of the therapies are directed toward reduction in LES pressures. Treatment modalities in AC acts by causing either mechanical disruption of LES by per oral endoscopic myotomy (POEM), laparoscopic Heller's myotomy (LHM) and pneumatic dilatation (PD) or biochemical reduction in LES pressure (pharmacological therapy, e.g., nitrates and botulinum toxin). There is renewed interest in this motility disorder in the past few years as with the advent of third space endoscopy (i.e., POEM), the endoscopic management of achalasia has been revolutionized.

Introduction

Achalasia cardia (AC) is rare yet most common and best characterized esophageal motility disorder.[1] It is equally common in both sexes and most frequently observed in 40–60 years age.[2] AC is characterized by progressive degeneration of ganglion cells in the esophageal myenteric plexus resulting in impaired relaxation of lower esophageal sphincter (LES) on swallowing and failure of peristalsis in distal smooth muscle segment of the esophagus.[1] Presenting symptoms are dysphagia to both liquids and solids, regurgitation of undigested food, retrosternal chest pain, heartburn, weight loss, and symptoms due to aspiration pneumonia.[3] Upper GI endoscopy and timed barium esophagogram are the initial investigations and high resolution manometry (HRM) is diagnostic.[4] Therapy in AC is directed toward reduction in LES pressures either by biochemical reduction or mechanical disruption of LES. Mainstay of management of AC is by pneumatic dilatation (PD), per oral endoscopic myotomy (POEM) and laparoscopic Heller's myotomy (LHM) in surgical fit candidates. Biochemical reduction of LES by botulinum toxin (BT)/pharmacotherapy (nitrates, calcium channel blockers) are reserved for surgical unfit patients or patients with limited life expectancy due to short lasting efficacy. Esophagectomy is reserved for surgically fit patients with long standing symptoms who failed multiple therapies repeatedly.[2,5] In this chapter we shall focus on diagnosis and endoscopic treatment (BT, POEM, and PD) of AC.

Diagnosis

History and Clinical Examination

Dysphagia to both solids and liquids (85–91%), regurgitation of undigested food (75–91%), substernal chest pain and

TABLE 1 Clinical features favoring esophageal motility disorder over mechanical dysphagia

	Esophageal motility disorder	***Mechanical dysphagia***
Duration	Long standing	Short in malignant
Course	Intermittent	Progressively increasing
Relation with food and posture		
Relation with type of food	Both liquids and solids from the onset	Soilds then liquids later on
Relation with posture	Decreased with raising arms and erect position	No such
Relation with temperature of food	More in extreme temperatures (hot and cold)	None
Associated symptoms		
Regurgitation	Common	Unusual
Chest pain	Episodic pain highly suggestive	Usually painless
Weight loss	No or minimal	Profound

TABLE 2 Eckardt score

Score	***Dysphagia***	***Regurgitation***	***Retrosternal pain***	***Weight loss (kg)***
0	None	None	None	None
1	Occasional	Occasional	Occasional	<5
2	Daily	Daily	Daily	5-10
3	Each meal	Each meal	Each meal	>10

heartburn (40–60%), weight loss and aspiration pneumonia (8–10%) are the various symptoms of achalasia.[3,6,7] Appropriate history taking help to differentiate esophageal motility disorders from mechanical dysphagia **(Table 1)**. Liquids require better neuromuscular coordination than solids for esophageal emptying so dysphagia to both solids and liquids are present from the onset. Compression of the esophagus between spine and manubrium sterni in specific postures like raising arms in erect position increase the intraesophageal pressure and propel food in aperistaltic esophagus.

Achalasia is often misdiagnosed as gastroesophageal reflux disease (GERD) as retrosternal chest pain and heartburn are common. Reflux or lactate production by fermentation of undigested carbohydrates lead to heartburn. Chest pain is least responsive to treatment compared to other symptoms but can spontaneously disappear over time.[7] Weight loss is not as profound as in mechanical dysphagia. Aspiration pneumonia can occur due to regurgitation into bronchopulmonary tree can lead to cough and fever. Impaired belching due to compression of membranous trachea by dilated esophagus and inadequate relaxation of upper esophageal sphincter is a rare but noteworthy symptom in achalasia.[8] Eckardt score is a system for evaluation of achalasia symptoms and treatment efficacy which is based on degree of dysphagia, regurgitation, chest pain, and weight loss **(Table 2)**.[9] Clinical examination is usually unremarkable except emaciation and oral cavity ulcerations in some patients. Examination of the respiratory system may show diminished breath sounds, dull note on percussion, and crepitations over area of consolidation due to aspiration pneumonia.[6]

Diagnostic Tools

Primary Diagnostic Tools

Upper GI endoscopy and timed barium esophagogram are the initial investigations in any case of dysphagia. Once, mechanical obstruction is ruled out on endoscopy/barium swallow, HRM is diagnostic and helps subclassification.[10]

Upper GI Endoscopy

Normal upper GI endoscopy rules out mechanical causes of dysphagia. Upper GI endoscopy in AC shows dilated and often tortuous esophagus with food/liquid residue.

The contracted LES in AC does not open spontaneously and is usually traversed with a gentle pressure with the endoscope unlike neoplastic/fibrotic strictures.[6] The esophageal mucosa is usually normal in AC but can develop erythema and ulceration due to food stasis (stasis esophagitis). Stasis predisposes to esophageal candidiasis. Tertiary contractions may be noticed during endoscopy due to spontaneous, simultaneous contractions of esophageal smooth muscles. An esophageal epiphrenic diverticulum (EED) (pulsion type pseudodiverticulum) can be associated with AC, which makes endoscopic therapy challenging but yet feasible.[11]

Laboratory Work Up

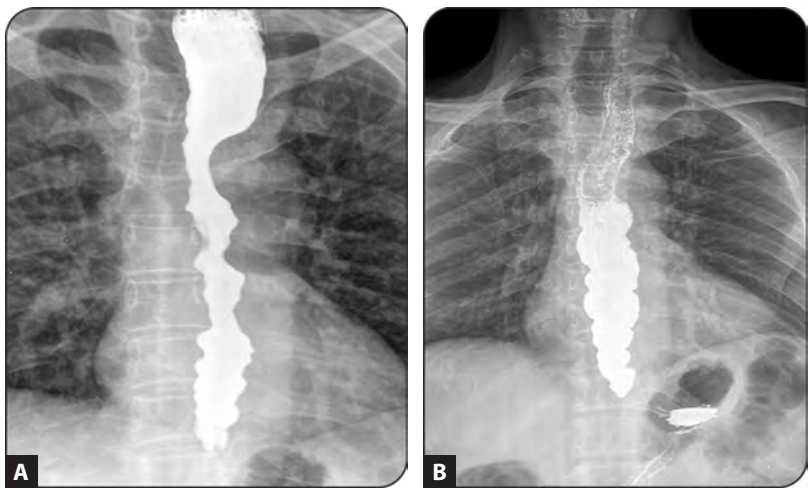
Complete blood count, serum creatinine, serum electrolytes, liver function tests, and thyroid profile can be done as a part of work up for endoscopic/surgical myotomy, which requires general anesthesia.

Imaging

Timed barium esophagogram: Timed barium esophagogram is the imaging of choice in AC. 100–250 mL of barium (45% weight/volume) is swallowed by the patient over 15–20 seconds and X-ray done at 1, 2, and 5 minutes.[12] The height and width of the barium column in esophagus is measured at 1, 2, and 5 minutes which denotes the esophageal emptying. In AC, there is delayed emptying of barium from the esophagus, tertiary contractions and bird-beak appearance **(Figs. 1A and B)**. It is done in both pre- and post-treatment states in AC to evaluate response to therapy. Hugely dilated esophagus or megaesophagus (>7 cm) can be seen in late/long standing cases of AC. Dilated, tortuous esophagus in late stage AC is termed as sigmoid esophagus. Both mega-esophagus and sigmoid esophagus denote decompensated disease, which implies poor response to therapy. Esophageal epiphanic diverticulum (EED) can rarely be found in association with AC.[12]

Other imaging: Chest X-ray may be required in AC to evaluate for aspiration pneumonia. Computed tomography (CT) of chest could be helpful to rule out pseudoachalasia. Endoscopic ultrasound (EUS) findings of marked (>10 mm)/asymmetric lower esophageal wall thickening suggest underlying malignancy.[13]

High resolution manometry (HRM) **(Table 3)***:* HRM is superior to conventional esophageal manometry for diagnosis and classification of AC with higher sensitivity and reproducibility. AC can be classified into three subtypes according to Chicago classification 3.0 **(Table 3) (Fig. 2A)**.[4] Type I AC represents later stage disease leading to dilated atonic esophagus due to minimal esophageal muscle activity. Type II AC is characterized by panesophageal pressurization indicating simultaneous contraction of esophageal muscles between upper and LES due to disorganized neuromuscular activity of esophagus



Figs. 1A and B: Timed barium esophagogram (TBE) in achalasia cardia. (A) Preprocedure TBE after 1 minute showing tertiary contractions and dilated esophagus and no esophageal emptying. (B) Preprocedure TBE after 2 minutes showing dilated esophagus with minimal esophageal emptying

(Fig. 2B). Panesophageal pressurization indicates that esophageal smooth muscle tone is still intact, and hence type II AC represents early stage of disease. Type II AC is the most common subtype of AC and most responsive to PD. Type III AC is characterized by premature, spastic contraction of the distal esophagus **(Fig. 2C)**. Type III AC is least common and least responsive to both endoscopic and surgical therapy.[2]

TABLE 3 High resolution manometry diagnostic criteria of achalasia cardia[27]

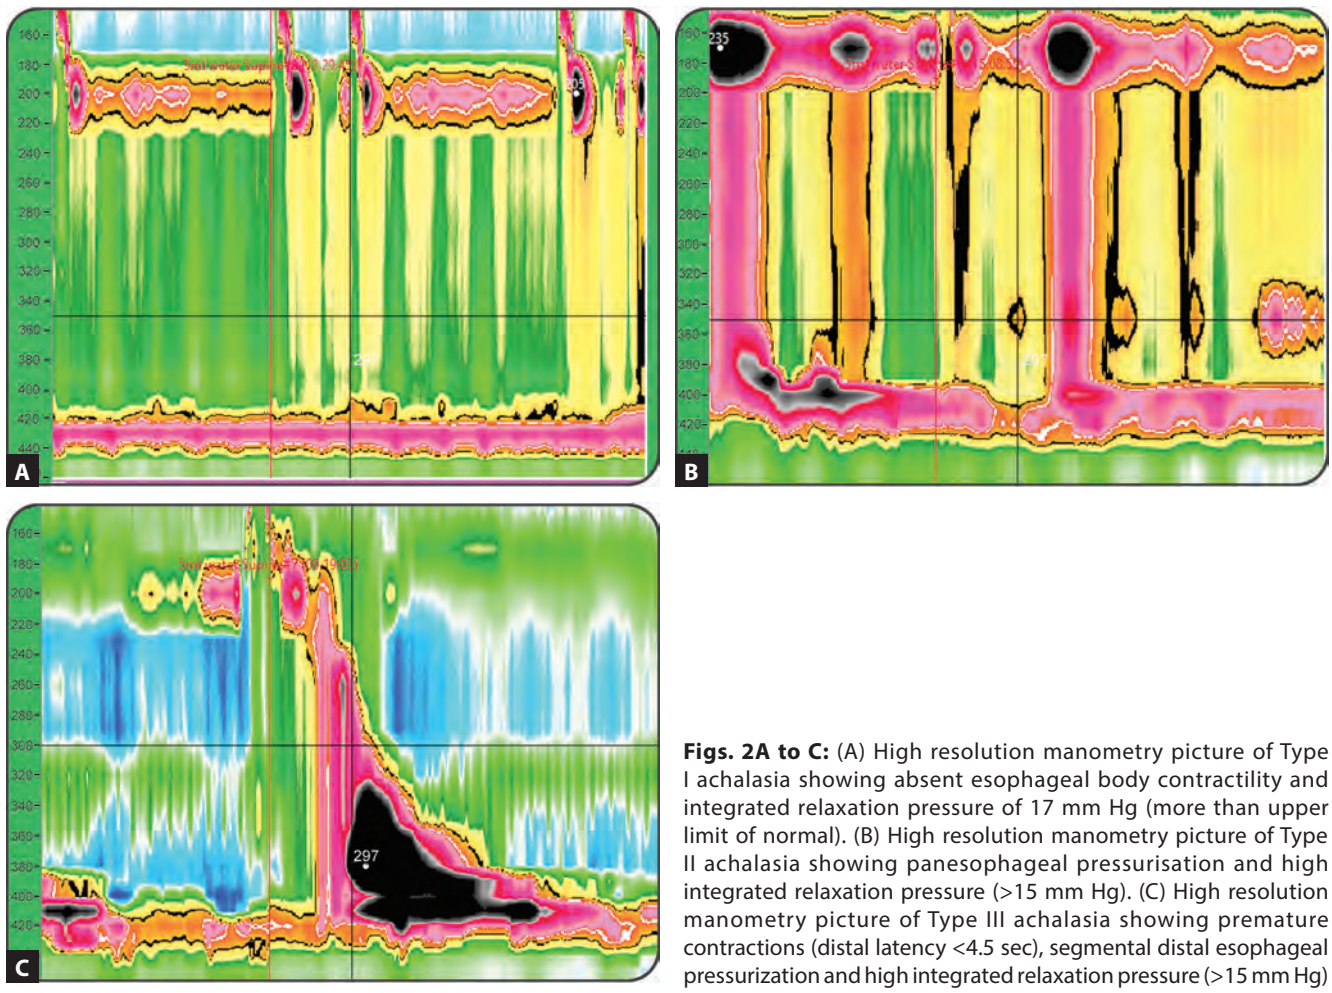
Integrated relaxation pressure (IRP) > upper limit of normal with 100% failed peristalsis
• Type I: No contractility, no esophageal pressurization, IRP >10 mm Hg
• Type II : Panesophageal pressurization in ≥20% swallows, IRP> 15 mm Hg
• Type III: Premature contractions (distal latency <4.5 s) in ≥20% swallows, Segmental esophageal pressurization, IRP>15 mm Hg

Differential Diagnosis (Table 4)

The differential diagnoses of AC are GERD, pseudo-achalasia, esophageal motility disorders, and mechanical dysphagia.

Management

The goal of management of AC is symptomatic relief of dysphagia and associated complications. Treatment directed at underlying pathology is not available as pathophysiology is poorly understood. Treatment of AC is directed by AC subtypes and surgical risk of the patient.[2] Mechanical disruptions of LES by PD, LHM, or POEM



Figs. 2A to C: (A) High resolution manometry picture of Type I achalasia showing absent esophageal body contractility and integrated relaxation pressure of 17 mm Hg (more than upper limit of normal). (B) High resolution manometry picture of Type II achalasia showing panesophageal pressurisation and high integrated relaxation pressure (>15 mm Hg). (C) High resolution manometry picture of Type III achalasia showing premature contractions (distal latency <4.5 sec), segmental distal esophageal pressurization and high integrated relaxation pressure (>15 mm Hg)

TABLE 4 Differential diagnosis of achalasia cardia

Suspected diagnosis	*Clinical clues*	*Diagnostic testing*
GERD	Normal clinical examination	• History of reflux, regurgitation and heartburn • Endoscopic findings of esophagitis, Lax LES, or hiatus hernia • 24 Hour pH monitoring
Pseudoachalasia	Hepatomegaly (may suggest liver metastasis) and supraclavicular lymph nodes	• Symptoms of dysphagia • Endoscopic finding of mechanical resistance at GE junction and may show GE junction tumor • EUS may show asymmetric, thickening of GEJ (>10 mm) • CT chest may show extrinsic compression by tumor or lung malignancy
Other motility disorders (Distal esophageal spasm, Jackhammer esophagus)	Hot and cold food sensitivity and disproportionate chest pain relative to dysphagia could be a diagnostic clue	• On high resolution manometry • Normal IRP • Distal esophageal spasm (DES) (>20% premature contractions: distal latency <4.5 sec) • Jackhammer esophagus (>20% swallows with distal contractile integral -DCI >8000 mm Hg.s.cm)
Mechanical dysphagia	Duration and course of dysphagia, relation to food/posture and associated symptoms can differentiate (*See* **Table 1**)	• Endoscopy usually shows mechanical obstruction (malignancy, web, strictures, etc.) • Biopsy can be taken if any growth is noted in endoscopy • Barium swallow findings show asymmetric, long segment strictures with shouldering

*Chicago Classification v.3.0[27]

are the mainstays of AC treatment. However, in patients with high surgical risk and/or limited life expectancy, biochemical reduction of LES pressure can be attempted (botulinum toxin ± pharmacotherapy). In this review we shall discuss endoscopic treatment of AC (botulinum toxin, PD, and POEM).

Botulinum Toxin

BT blocks release of acetylcholine (ACh) from the presynaptic cholinergic nerve terminals. Selective loss of inhibitory nitrinergic (NO producing) ganglion cells with partial preservation of cholinergic neurons is responsible for such therapeutic benefit.[14] Hundred units of vacuum dried BT powder is dissolved in sterile saline solution (4 mL) and 1 mL (25 U) each is then injected into all four quadrants via sclerotherapy needle under endoscopic guidance at 1 cm above the Z line (squamocolumnar junction). Doses >100 U do not have increased efficacy. BT decreases LES pressure in one third of patients and improves dysphagia in two-thirds of patients of AC for up to 6 months. Up to 50% patients require reinjection by 612 months.[15] The short lasting effect is due to growth of new cholinergic neurons leading to loss of efficacy. Side effects like esophageal perforation, mediastinitis, and heartburn/chest pain can occur post BT, but BT is usually safe.[16] Repeat injections can be done for patients in whom surgical risk remains high even on follow-up but it can lead to fibrosis precluding continued BT injections/other endoscopic therapy. Hence, repeated BT injections should be used in patients with high surgical risk and poor life expectancy.[17]

Pneumatic Dilatation

PD is a recommended initial treatment for AC.[2] PD is done with Rigiflex balloon dilator (Microvasive, Milliford, MA, USA) available in three sizes (outer diameter: 30 mm, 35 mm, and 40 mm). Initially 30 mm balloon is used followed by progressively larger size balloon (graded approach) except in case of young male in whom 35 mm can be used initially due to poor response rate with 30 mm.[18,19] Graded dilatation is performed for index dilatation. Repeated dilatation on follow-up when required for recurrent symptoms is known as "on demand approach." Patient is kept on overnight fast. Conventionally the procedure is done under fluoroscopic guidance with conscious sedation although a novel technique without fluoroscopy under endoscopic guidance has been described.[20] Initially a guide wire (preferably 0.038 inch diameter) is passed into the stomach under endoscopic guidance and scope is withdrawn to the GE junction (GEJ). The length between

the incisors and GEJ is noted along length of endoscope. Endoscope is then withdrawn maintaining position of the catheter. Rigiflex balloon is passed over the guide wire into the stomach marking a tape in the dilating ballon catheter corresponding to distance from incisors to GEJ (balloon catheter working length 90 cm and diameter is 14 Fr). Alternatively small amount of radiographic contrast can be injected at the GEJ prior to placing catheter to mark the GEJ. Balloon (length 10 cm) is then placed across the GEJ under fluoroscopic guidance (by help of radiopaque marks in the balloon catheter). Small volume of dilute contrast can be used for radiographic visualization of balloon. As the placement of balloon waist is confirmed across GEJ, the balloon is gradually inflated with air to 10–15 psi until the balloon waist disappears and maintained for 1 minute **(Fig. 3)**. Adequacy of dilatation confirmed by waist obliteration, blood smearing of the balloon, chest pain, and mucosal tear/widening of GEJ. Adverse events are esophageal perforation (3–5%), hematoma formation, diverticula formation.[21] Incidence of GERD post PD is around 2–4%. Tachycardia, persistent chest pain more than 4 hours should alert the endoscopist for possible perforation. Contrast esophagogram should be done if perforation is suspected based. Small perforations can be managed conservatively with antibiotics and parenteral nutrition whereas large perforations with free flow of barium into mediastinum warrant urgent thoracotomy and repair. Hence, patients with high surgical risk should not be subjected to PD.[21] Age less than 40 years, chest pain, type III achalasia, and pretreatment esophageal diameter less than 4 cm are poor predictors of treatment success with PD. Response rate for chest pain is around 50%.[22] Based on available evidence (meta-analysis of three RCTs and one large RCT), clinical efficacy of PD is comparable with LHM although long-term durability (especially in young males) was higher in LHM compared to PD as higher proportion (24%) of patients had recurrent symptoms after PD requiring redilatation compared to LHM (14%).[23,24] PD was compared with POEM in a recent RCT which showed significantly higher success rate at 2 years follow-up with POEM compared to PD (92% vs. 54%). This low response rate in PD could be due to dilatation with only 30–35 mm balloon and inclusion of 40 mm balloon would increase response rate to 76% **(Table 5)**.[25]

Fig. 3: Pneumatic dilatation in achalasia by Rigiflex balloon dilator. The waist of the balloon is seen between the two crus of diaphragm and radiopaque marks can be seen in the balloon catheter

Per Oral Endoscopic Myotomy

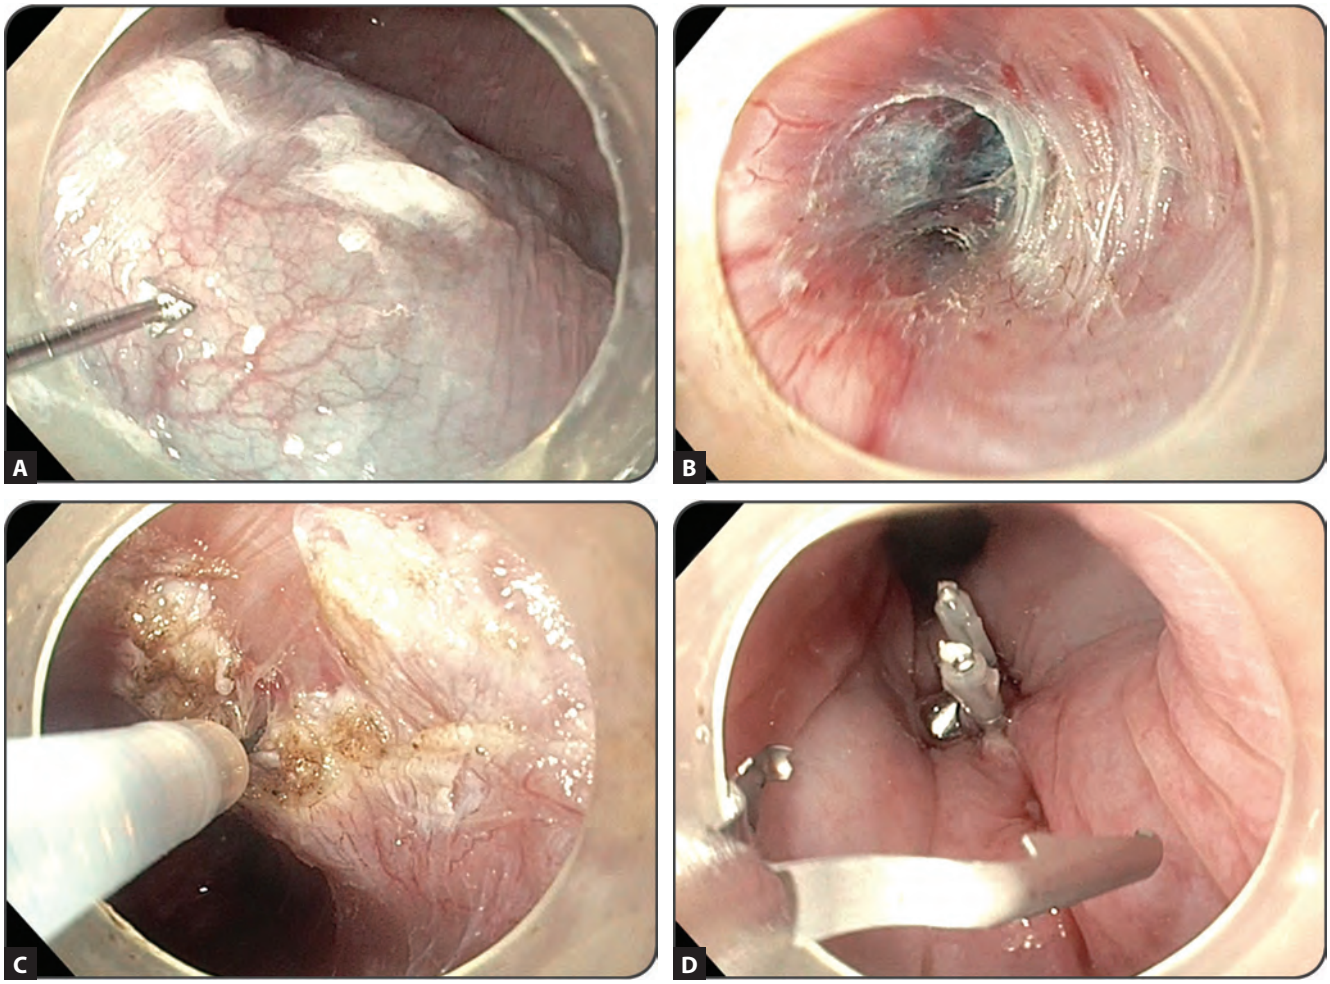
POEM is a form of natural orifice transluminal endoscopic surgery (NOTES), which uses submucosal endoscopy to perform myotomy and is efficacious for both treatment naive and treatment failure cases. The procedure is done under general anesthesia with endotracheal intubation and carbon dioxide insufflation.[26] There are four steps of POEM: mucosal incision, creation of submucosal tunnel, myotomy, and closure of mucosal incision **(Fig. 4)**. Normal saline (10 mL) mixed with 0.3% indigocarmine is injected approximately 13 cm proximal to GEJ and 2-cm longitudinal incision is made anteriorly or posteriorly with the use of triangular tip (TT knife) **(Fig. 4A)**. Endoscope with transparent cap inserted into submucosal tunnel and tunnel is extended by injection and cautery **(Fig. 4B)**. Attention should be given not to injure the mucosal layer by keeping the scope close to circular muscle layer. The tunnel should be one third of the esophageal circumference and should extend 3 cm distal to the GEJ. GEJ is identified by palisade vessel visualization/narrowing of tunnel/visualization of aberrant longitudinal muscle bundle/by transillumination of ultra-slim gastroscope in the submucosal tunnel. Myotomy should begin at 2–3 cm distal to mucosal entry and initially circular muscle is cut with TT knife until longitudinal muscles are visible **(Fig. 4C)**. Then myotomy should continue in the plane between circular and longitudinal muscle fibers. Prior to closure, 20 mL saline with 80 mg gentamicin is injected into the tunnel

TABLE 5 Landmark randomized controlled trials comparing outcome of various treatment modalities for achalasia cardia

Name/year	*Comparison*	*n*	*Success*	*Follow-up*	*Adverse events*	*GERD*	*Drawbacks*
Moonen et al., 2016[22]	PD vs. LHM + Dor Fundoplication	n-96 n-105	82% 84%	5 years	5% 11%	12% 34%	Re-dilatation required in 25% of PD patients—considered as treatment success
Boeckxstaens et al., 2016[24]	PD vs. LHM + Dor Fundoplication	n-96 n-105	86% (2 years) 90% (2 years) p=0.46	43 months	4% 12%	15% 23%	• Follow-up short as effect may decrease over time • Rigorous PD protocol over 2 years—only 3rd series of PD within 2 years of 2nd series considered as failure
Ponds et al., 2019[25]	POEM vs. PD	n-67 n-66	92% 54%	2 years	0% 3.03 %	41% 7%	• Only allowed PD up to 35 mm • Considered re-dilatation as treatment failure
Werner et al., 2019[38]	POEM vs. LHM + Dor fundoplication	n-112 n-109	83% 81.7% (p=0.007 non-inferiority)	2 years	2.7% 7.3%	44% 29%	• Length of myotomy was not standardized • POEM was not accompanied by any anti-reflux procedure where LHM was done with for fundoplication

and then mouse incision is closed by application of 5–10 clips at a distance of 5 mm applying first clip at the distal end of the longitudinal incision **(Fig. 4D)**. A water soluble contrast esophagogram is done at postoperative day 1 (POD1) to exclude leak and ascertain smooth passage of contrast into stomach. Routine CT most procedure is not warranted. Patients, who tolerate oral diet and timed barium esophagogram has shown no leak, can be started on liquid diet on POD1, pureed diet on POD2 and regular diet from POD4. Initial clinical success with POEM is 82–100% and intermediate term efficacy at 2 years is 78–91% at 2 years follow-up.[27-29] The choice of anterior (1 o'clock) or posterior myotomy (5–6 o'clock) is operator dependent and based on clinical scenario as there is equal efficacy of both the approaches with shorter procedure time in posterior approach.[30,31] Adverse events can be insufflation related (pneumoperitoneum: 16–30%, 8% require decompression, pneumomediastinum: 8.7–11%, 2.7% require decompression, mediastinal emphysema: 4.9%, and subcutaneous emphysema: 21–36%), bleeding (early or delayed) an mucosal perforation (2.6%).[32] Low/extra low flow CO_2 can reduce the incidence of pneumoperitoneum (up to 10%). Tense capnoperitoneum manifested by high end tidal CO_2 can be treated with Veress needle.[33] Minor bleeding during dissection can be controlled with coagrasper or electrocautery knife. Significant delayed bleeding is rare (0.7%) and can be tackled by reentering the tunnel and coagulating the culprit vessel.[34] Mucosal perforation can be closed with clips ± endoloops, fibrin glue, suturing by overstitch device or fully covered metal stent. The prevalence of increased esophageal acid exposure, reflux esophagitis, and GERD symptoms after POEM ranges from 13% to 58%, 18% to 65%, and 17% to 40%, respectively.[35] Novel modifications of POEM by addition of fundoplication (POEM-F) like in LHM have been shown to reduce reflux in pilot studies.[36] Anterior gastric wall is retracted at GEJ to form endoscopic fundoplication wrap. Increased procedure time, cost, and uncertain durability are the drawbacks of this novel procedure. Preservation of sling fibers by identifying two penetrating vessels at distal end of myotomy can reduce degree of esophagitis.[37] A short course of proton pump inhibitor (PPI) for 1 month is recommended for all patients and further continuation of therapy should be based on pH metry, symptoms, and endoscopic finding of esophagitis.[2]

POEM has been shown to be superior to PD and non-inferior to LHM in two recent RCTs. It is emerging as one of the first-line options to treat AC **(Table 5)**.[25,38] Results of POEM are better than LHM, especially in type III achalasia due to ability to perform long myotomy based on length of spastic distal segment of esophagus.[2] POEM is also better than LHM in case of sigmoid esophagus and other spastic motility disorders.[39]



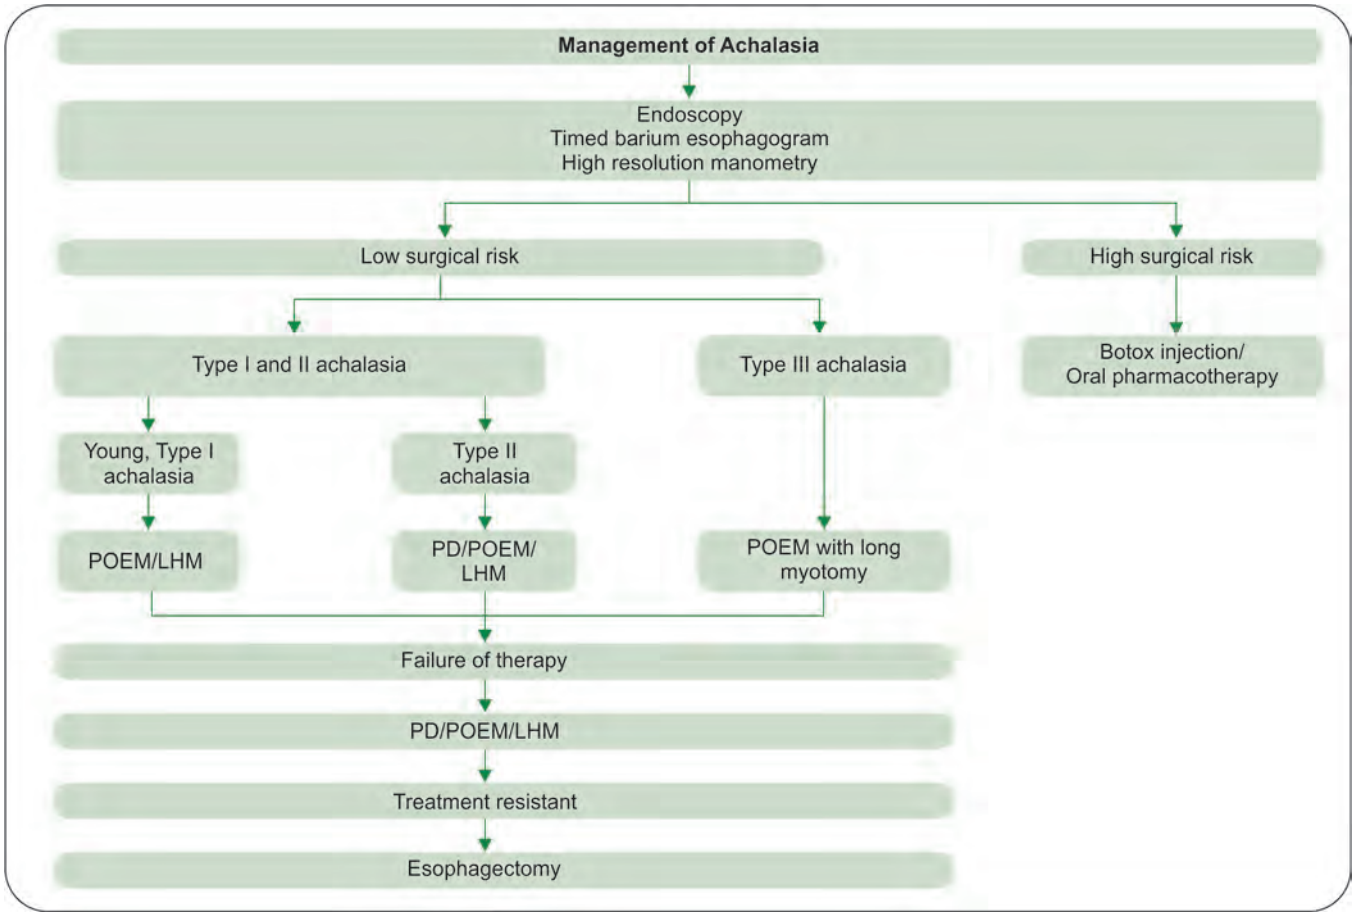
Figs. 4A to D: Steps of per oral endoscopic myotomy. (A) Mucosal incision, (B) Submucosal tunneling, (C) Myotomy, (D) Closure of mucosal incision

TABLE 6 Comparison of treatment efficacy of various treatment modalities in achalasia cardia

	PD	*LHM*	*POEM*
Type I AC	63.3–85%	81%	91.3%
Type II AC	90–93%	93–100%	96.3%
Type III AC	33.3–40%	80–86%	87.5–98%
Overall efficacy	44–84%	57–89.3%	75–97%
Follow-up (yrs)	≥5 years	≥5 years	1–3 years
GERD	2–4%	2–33%	20–54%

AC, achalasia Cardia; GERD, gastroesophageal reflux disease; LHM, laparoscopic Heller's myotomy, POEM, per oral endoscopic myotomy; PD, pneumatic dilatation

Flowchart 1: Diagnosis and management algorithm for achalasia cardia



Conclusion

Diagnosis of achalasia is based on clinical history and investigations like endoscopy, timed barium esophagogram, and HRM. Treatment of achalasia should be individualized **(Table 6) (Flowchart 1)**. Patients with high surgical risk should undergo BT/pharmacotherapy. For patients with low surgical risk options are PD, LHM with fundoplication, and POEM. In young (<40 years), type I achalasia POEM/LHM should be the first option of treatment as response rates to PD is low. In type II AC, PD can be used as initial option along with POEM/LHM as results to PD is best in type II AC. For type III AC, POEM with extended myotomy is recommended. On failure of therapy, any of the three modalities can be used as salvage therapy but POEM is preferred in both prior endoscopic failure. Esophagectomy should be reserved for end stage AC that is surgically fit with leg standing symptoms after repeated failure of different therapies.

CHAPTER

140 Non-Variceal Upper GI Bleed—Clinical Approach

Bhabadev Goswami, Preeti Sarma

Abstract

Non-variceal upper GI bleed could be caused by peptic ulcer disease, Mallory Weiss tear, erosive gastritis/duodenitis, esophagitis, and malignancy. The resuscitation and management go hand in hand. The hematocrit may be initially high due to adjustments in the vascular spaces and the physician should not be misled by it. Gastrointestinal endoscopy has revolutionized both the diagnosis and treatment of non-variceal upper GI bleed. Risk stratification tools enable physicians to assess the risks of mortality and rebleeding.

Introduction

Upper gastrointestinal (GI) bleed with source of bleeding in esophagus, stomach, or proximal duodenum comprises the major cases of non-variceal upper GI bleed of which peptic ulcer disease (related to *Helicobacter pylori* infection, use of NSAIDs, low dose aspirin) happens to be the most common cause.[1] Despite great advances in the field of medical gastroenterology, the annual incidence remains at around 50–150 per 100,000 population with a mortality of around 10–35%.[2]

The common causes of non-variceal upper GI bleed are peptic ulcer (20–50%), Mallory Weiss tear (15–20%), erosive gastritis/duodenitis (10–15%), esophagitis/esophageal ulcer (5–10%), malignancy (1–2%), angiodysplasias/vascular malformations (5%).[2] *Severe GI bleeding* is described as GI bleeding that is associated with shock or orthostatic hypotension, decrease in hematocrit by 6% or decrease in hemoglobin by 2 g/dL or transfusion requirement of at least two units of PRBCs. *Occult GI bleed* describes subacute bleeding that is not clinically visible. *Obscure GI bleed* refers to a type of bleeding wherein the site of bleed could not be determined after routine upper GI endoscopy, colonoscopy, and even a small bowel radiography.[3]

Initial Assessment

History and Physical Examination: Simultaneous to resuscitation, history taking and initial assessment of the vital signs is done. It is important to ask for history of nasopharyngeal malignancy, hemoptysis, heartburn, alcohol use, use of medicines (NSAIDs, aspirin), dysphagia, excessive vomiting, liver disease, chronic kidney disease.[3] Regarding physical examination, special attention should be paid to signs of hypovolemia like tachycardia, hypotension, orthostatic hypotension along with a close examination of the skin, lips, and buccal mucosa. The abdomen should be examined for tenderness, scar or any lump along with a rectal examination. Signs of chronic liver disease should be specifically looked for as they can help us differentiate variceal from non-variceal bleed.

Laboratory Studies

In addition to routine tests, it is important to do the blood grouping and cross matching of the patient as PRBC transfusion may be needed. The hematocrit of the patient may not reflect the actual amount of blood loss in the immediate period as the vascular space needs time to

adjust to the blood loss and administration of crystalloid intravenous fluid. Special attention should be paid to the mean corpuscular volume (MCV), serum ferritin, total iron binding capacity (TIBC), total leukocyte count (TLC), platelet count, prothrombin time (INR). The blood urea nitrogen (BUN) is usually higher than the serum creatinine in upper GI bleed cases due to intestinal bacteria acting on the blood proteins and increasing absorption of urea. Elderly patients, especially those who are known cases of cardiac ailment, need to have an ECG done.

Management

A case of upper GI bleed necessitates hospital admission, but those patients having mild bleed, being hemodynamically stable, near normal blood tests, with easy access to hospital care may be treated on outpatient basis. On the other hand, those patients who are hemodynamically unstable, have lost a large amount of blood, are having serious associated comorbidities need ICU admission.

Treatment of an upper GI bleed patient should start along with the examination and history taking. Once intravenous access has been established, crystalloids like normal saline are the fluid of choice and attempt should be made to keep the pulse below 100/min and the systolic blood pressure above 100 mm Hg. Blood transfusion with PRBC may be needed to keep Hb >7 g/dL.[4] The hematocrit level should be monitored every 4–8 hours. In cases of severe acute upper GI bleed or in patients with altered mental status, endotracheal intubation may be needed.

The advent of proton pump inhibitors (PPIs) has revolutionized the management of non-variceal upper GI bleed along with availability of endoscopic therapy. But then there are cons of PPIs like no change in blood transfusion requirements and no change in rebleeding rates (except in cases of PUD).[3]

Role of Endoscopy

GI endoscopy has brought in major advantages in the management of upper GI bleed, be it variceal or non-variceal. Important points to note are:

- Patient must be hemodynamically stable with heart rate of less than 100/min and systolic blood pressure greater than 100 mm Hg.
- There must be no respiratory difficulty, altered sensorium or ongoing hematemesis as these cases might needs endotracheal intubation first.
- Correction of coagulopathy and decreased platelet count is paramount.
- Emergency versus urgent endoscopy—those patients who have active high volume bleed need to undergo *emergency endoscopy* (within 6 hours) after medical resuscitation and preferably after having access to an ICU bed. *Urgent endoscopy* (within 12 hours) is suitable for patients who do not have ongoing hemorrhage and are hemodynamically stable.[3]
- Role of gastric lavage in upper GI bleed cases is controversial as some societies do not approve of it. However, in cases with large volume bleeding, careful gastric lavage and prokinetic agents like metoclopramide or erythromycin can help in endoscopic visualization.
- Around 1% of patients may experience complications like aspiration pneumonia, inadvertent bleeding, perforation, hypotension, hypoxia.

Endoscopic techniques of hemostasis have revolutionized the management of upper GI bleed. Amongst these techniques are the contact probes of which the multipolar electrocoagulation probe is the most commonly used. It enables to tamponade a bleeding vessel and then thermal energy is used to seal off the offending vessel. Risks include perforation, coagulation injury. Another useful technique is the use of endoscopic injection therapy mostly done with epinephrine, diluted to a concentration of 1:10,000 or 1:20,000 into or around the site of bleeding. It is easily available, cheap, safe in patients with coagulopathy, less chances of perforation or thermal burns. Then there are the endoscopic hemoclips that apply mechanical pressure to the bleeding site. Hemostatic spray is a kind of inorganic powder with clotting abilities.

Risk Stratification

There are several stratification tools to help patients with non-variceal upper GI bleed. These scores help identify patients with higher risk of mortality and rebleeding.[5,6] It enables physicians to assess patients who need higher medical care or urgent endoscopy. Amongst these scores, the pre-endoscopy scores are:

- BLATCHFORD SCORE—includes blood pressure, BUN, hemoglobin, heart rate, syncope, melena, liver disease, heart failure
- CLINICAL ROCKALL SCORE—includes patient's age, presence of shock, coexisting illnesses

- ARTIFICIAL NEURAL NETWORK SCORE- includes 21 variables to predict the presence of stigmata of recent hemorrhage and the need for endoscopic therapy.
- AIMS65—agregate of five variables like albumin <3 g/dL, INR >1.5, altered mental status, systolic BP ≤90 mm Hg, age >65 years.

Amongst the post-endoscopy scores, COMPLETE ROCKALL SCORE is most popularly used. It includes the Clinical Rockall Score and the endoscopic findings. This scoring system correlates well with mortality but not with risk of rebleeding.

Role of Surgery[3]

There are some situations where surgery plays an important role in non-variceal upper GI bleed cases:

- Cases of severe and ongoing hemorrhage wherein endoscopy and colonoscopy procedures fail to localize the bleeding site and control it.
- Cases of massive hemorrhage who are hemodynamically unstable need either an urgent angiography or urgent surgical exploration.
- Cases of severe, recurrent obscure GI bleed may benefit from surgical exploration.

Individual Etiologies

We shall now address some special issues pertaining to non-variceal upper GI bleed.

Peptic ulcer: With the advent of PPIs, it has been observed that worldwide, incidence of bleeding peptic ulcers has decreased whereas, bleeding from ulcers due to intake of NSAIDs, aspirin have gradually increased. However, in the developing countries it has been seen that the prevalence of *H. pylori* infection is nearly 80% whereas, in the developed countries it ranges between 20–50%. Amongst the patients taking NSAIDs gastric ulcers tend to be more common than duodenal ulcers. The Forrest classification[7] is used in cases of bleeding peptic ulcers to categorize the endoscopic findings:

Forrest 1A—active spurting bleed
Forrest 1B—oozing bleed
Forrest 2A—non bleeding visible vessel (NBVV)
Forrest 2B—adherent clot
Forrest2C—flat pigmented spot
Forrest 3—clean based ulcer

Patients with active arterial, NBVV, adherent clot are at high risk for rebleeding and would benefit from endoscopic therapies. Adherent clot is defined as a blood clot overlying an ulcer that is resistant to several minutes of vigorous jet water irrigation. When a clean based ulcer is found at the time of endoscopy, the chances of rebleeding are less than 5%. However, if it is a clean-based ulcer in the stomach, it is suggested that a biopsy of the ulcer edge and the gastric mucosa should be taken to rule out malignancy. In cases of gastric and duodenal ulcer suspected to be due to *H. pylori* infection, endoscopic mucosal biopsies of the normal looking antrum and greater curvature (midbody) should be taken. The role of PPIs in reducing rebleedingin peptic ulcer cases is more pronounced in people of Asian origin than others. Luminal gastric pH needs to be higher than 6.8 is needed for normal clotting function. H2 receptor antagonists can do this job but tolerance to this drug is the major hindrance. In case of PPIs this problem does not occur, thereby ensuring mortality benefit especially in Asian patients.[3]

Routine second look endoscopy in bleeding peptic ulcers is not always recommended[8] unless the first examination was inadequate due to poor visualization, technical issues with hemostasis or clinically significant rebleeding has occurred. Repeat upper GI endoscopy is advisable in cases of gastric ulcer after 6–10 weeks of acid suppression therapy. Those patients who continue bleeding despite two sessions of endoscopic hemostasis are suitable for angiographic embolization or surgery. Urgent surgery is advisable for those patients who have massive hemorrhage, who cannot be resuscitated. Also, if the endoscopic expertise is not available for treatment of a large or pulsating visible vessel and if on endoscopy, a bleeding malignant ulcerated mass is found, surgery is a more suitable option.

Following endoscopic hemostasis of patients with high-risk endoscopic stigmata (active arterial bleeding/NBVV/adherent clot), patient should be put on high dose intravenous PPI in a hospital setting. Drugs like NSAIDs, warfarin should be withheld. Those patients who need aspirin for cardiovascular illnesses may be started on the drug by day 7.

It is recommended to test all cases of bleeding due to peptic ulcer disease for *H. pylori* infection. Bleeding can however cause false negative result of *H. pylori*. Antibiotic therapy should be initiated for those found to be positive

for *H. pylori* infection. It is important to confirm the eradication of *H. pylori* once treatment is completed.[3] In cases of bleeding due to aspirin use, concomitant therapy with a PPI in future can reduce the rebleeding rates significantly. On the other hand, those patients who need to continue NSAIDs long-term, need to opt for selective COX2 inhibitors.

Esophagitis: Esophagitis may be caused due to gastroesophageal reflux disease (GERD), infections like Candida, Herpes simplex virus, Cytomegalovirus and also pill induced esophagitis,ultimately leading to upper GI bleed. GERD causing esophagitis and upper GI bleed is treated with a PPI for a period of at least 8–12 weeks along with lifestyle modifications. It is essential that these cases need to undergo a repeat endoscopy and biopsy to rule out Barrett's esophagus. For all the rest etiologies, endoscopic biopsy/brushing is taken and treatment is done according to etiology.[9]

Ulcer hemorrhage in hospitalised patients: There are two types of conditions usually seen in cases presenting with ulcer hemorrhage within the hospital—Stress Related Mucosal Injury/Stress Ulcer(SRMI) and Inpatient Ulcers. SRMI is characterized by diffuse bleeding from erosions and superficial ulcers, usually due to decreased mucosal protection and mucosal ischemia. It is most commonly seen in the stomach, and the most common risk factors are severe coagulopathy and mechanical ventilation for more than 48 hours. Prophylactic treatment with an H2 receptor antagonist or PPI can prevent bleeding in cases who are at high risk for SRMI. In those cases who present with UGI bleed, whether it is due to SRMI or inpatient ulcers, good medical treatment can help heal the lesions. Endoscopic therapy is feasible only in focal inpatient ulcer hemorrhage.[10]

Dieulafoy's lesion: This lesion comprises of a large submucosal artery that protrudes through the mucosa and can cause massive bleeding. Most commonly, such lesions occur in the gastric fundus, within 6 cm of the gastroesophageal junction. Whenever such a lesion is identified and treated endoscopically, it is suggested to mark the site with submucosal injection of ink for future need of easy identification and retreatment.[3]

Mallory-Weiss tears: This is characterized by mucosal or submucosal lacerations that start at the gastroesophageal junction and extend to a hiatus hernia sac distally. Usually the patients with Mallory-Weiss tear, present with non-bloody vomiting that is followed by hematemesis, probably due to raised intra-abdominal pressure. This lesion usually self heals but in cases with severe bleeding, endoscopic hemostasis may be attempted with hemoclips or multipolar electrocoagulation.[3]

Cameron's lesion: This lesion is described as linear erosions or ulcerations in the proximal stomach at the end of a hiatus hernia sac, near the diaphragmatic pinch due to mechanical trauma and local ischemia. It is a common cause of obscure GI bleed. Medical management is done with PPI and Iron supplements if needed.[3]

Neoplastic etiology: Tumors of the upper GI tract, mostly esophagus, stomach, or duodenum that are large, ulceroproliferative masses can present with upper GI bleed. Endoscopic hemostases is a temporary measure till the definitive management can be initiated. Those tumors that continue to bleed despite endoscopic hemostases need to undergo angiography with embolization. Wherever possible, GIST tumors should undergo resection.[3]

Gastric antral vascular ectasia (GAVE): This type of lesion is characterized by rows of ecstatic mucosal blood vessels that start from around the pylorus and extend proximally to the antrum. Also called "Watermelon Stomach", the exact cause of this lesion is not known, but may be due to mucosal trauma from contraction waves in the antrum. It has been found to be associated with cirrhosis, scleroderma, end stage renal disease. GAVE is targeted with endoscopic hemostatic methods like laser, MPEC, argon plasma coagulation. Besides these, medical management of anemia like iron supplements, blood transfusion may be needed.

Portal hypertensive gastropathy: This comprises of ectatic blood vessels in the proximal gastric body, cardia due to increased portal venous pressure and severe mucosal hyperemia. Management options are with beta-blockers, TIPS, liver transplantation. Endoscopic management does not have much role.

Hemobilia: Patients of hemobilia present with upper GI bleed and deranged liver function tests. It may occur as a complication in cases of liver biopsy, ERCP, TIPS or those who are suffering from hepatocellular carcinoma or parasitic infection of the hepatobiliary system. Side viewing endoscopy (SVE) is needed for diagnosis and

arterial embolization with arteriography may be used for treatment.

Hemosuccus pancreaticus: This kind of lesion is associated with pancreatic pathology or as a complication of ERCP or due to rupture of splenic artery aneurysm into the pancreatic duct. SVE is needed for diagnosis while angiographic embolization or surgery is needed for treatment purposes.

Aortoenteric fistula: This is a condition wherein patient presents with acute and massive hemorrhage with very high mortality rates. In some cases, there might be a herald bleed that may precede. Primary aortoenteric fistula is the communication between native abdominal aorta and third part of duodenum. Secondary aortoenteric fistula is a communication between the small intestine (most commonly, third part of duodenum) and an infected abdominal aortic surgical graft. In both the cases, surgery plays the more important role in management, and endoscopic hemostasis has no role.

Conclusion

The resuscitation and management of non-variceal upper GI bleed goes hand in hand. Prompt action on the part of the treating physicians as well as timely use of endoscopy for diagnosis and management can help save valuable lives.

CHAPTER

141 Recent Updates in Management of IBS

Nikhil Gupta, Manisha Dwivedi, SP Misra

Abstract

Irritable bowel syndrome is a symptom complex resulting from an interplay of various gastrointestinal and extraintestinal factors. Previously thought to have been resulted as a pathology in the gut brain axis, the pathophysiology and management of IBS has been reconditioned recently. The introduction of new diagnostic criteria and concept of mutidimensional clinical profile has changed the management of IBS completely. In this chapter we have concised the most updated knowledge on the diagnosis and management of IBS and its various subtypes.

Introduction and Epidemiology

Irritable bowel syndrome (IBS) is a functional gastrointestinal (GI) disorder characterized by chronic abdominal pain and altered bowel habits, which are unexplained by any organic cause during routine workup.[1] It is not a disease, but a complex of symptoms arising out of pathologies of diverse clinical significance. IBS is a global problem with prevalence ranging anywhere from 1% to 45% of the general population having symptom complex satisfying the diagnostic criteria of IBS.[2,3]

More than one third of patients in GI practice have functional GI disorders (FGID) and of all the FGIDs, IBS accounts for the most common diagnosis.[4] The documented prevalence of IBS in Asians ranges from 4% to 9% depending on the criteria used.[5-7] IBS is twice as prevalent in women as compared to men globally.[8] However, there is no sex predilection in South Asia, South America, and Africa.[9] IBS significantly affects the quality of life and imposes a large burden to the patient and the health-care system.

Rome IV Criteria for Diagnosis of IBS: Something New Something Borrowed

Manning and Thompson in 1978 introduced the concept of making positive diagnosis of IBS using a set of criteria,[10] which led to an exemplar shift in the diagnostic approach in patients with IBS.

This was followed by Rome I, Rome II, and Rome III criteria pertaining to the origin of newer scientific evidences.

The Asian consensus[11] was published in 2010 considering the differences in dietary habits and stool frequency patterns in Asians, which was different from the criteria used to define stool frequency and stool form as they were based on the Western studies.

Rome IV criteria were published in 2016,[12] a decade after Rome III was introduced. Rome IV criteria emphasized on the gut brain interaction rather than the older concept of psychogenic predominant pathogenesis of IBS.

As per the Rome IV criteria IBS is defined as—Recurrent abdominal pain on average at least 1day/week in the last

3 months, associated with two or more of the following criteria:*

- Related to defecation
- Associated with change in frequency of stool
- Associated with change in form (appearance) of stool

*Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.

Following changes are notable in Rome IV as compared to ROME III:

- Term abdominal discomfort has been deleted considering the dubious nature of the term and also that it is not present in every language.
- Abdominal pain to be present on at least 1 day/week based on scientific evidence[13]
- Bloating and distention are recognized as common symptoms
- Improvement with defecation has been replaced with related to defecation as it has been
- Found that many patients report increase in pain with defecation

ROME III Criteria: At least 3 months, with onset at least 6 months previously of recurrent (at least 3 days/month) abdominal pain or discomfort associated with two or more of the following:

- Improvement with defecation
- Onset associated with a change in frequency of stool
- Onset associated with a change in form of stool

ASIAN Consensus: Recurrent abdominal pain, bloating, or other discomfort for ≥3 months associated with one or more of the following:

- Relief with defecation
- Change in stool form (show patient the Bristol Stool Scale)
- Change in stool frequency

ROME IV Criteria: Recurrent abdominal pain on average at least 1 day/week in the last 3 months, associated with two or more of the following criteria:*

- Related to defecation
- Associated with change in frequency of stool
- Associated with change in form (appearance) of stool

*Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.

Rome IV also mentions about the location of pain, which can be present anywhere in the abdomen in contrast to the older criteria which considered lower abdominal pain as consistent with IBS.[14]

In context to Asian population, a Chinese study compared the diagnosis of IBS using the Rome III criteria as well as Rome IV criteria and showed lower sensitivity of Rome IV as compared to Rome III in Asian population and concluded that Rome IV positive patients were subgroup of Rome III with more severe manifestations of the disease.[15]

Rome IV also recognizes overlap syndrome amongst various FGIDs as observed in various studies.[16-18] This is an important step based on scientific evidence as it will help the clinicians to diagnose and manage such patients.

In 2019, Second Asian consensus on IBS[19] was published representing the current knowledge and management protocols in context to Asian population. The consensus emphasized that IBS is a disorder of Gut brain interaction rather than predominantly the psychopathological phenomenon. The consensus also encouraged the treatment based on micro-organic pathology.

Subtyping and Assessing the Severity of IBS: The Concept of Multidimensional Clinical Profile

The concept of multidimensional clinical profile was introduced to categorize patients on the basis of the severity of their symptoms along with psychological evaluation and physiological dysfunction **(Table 1)**. This helps the physicians to address other issues apart from only the categorical diagnosis.

Severity assessment helps physicians to rationally approach any patient, and necessitate the aggressive management of patients with severe symptoms. Various scales have been used to assess the severity of IBS, but none have been accepted till date.

Multidimensional clinical profile also emphasizes on the micro-organic basis of IBS such as abnormal gut transit, post-infectious IBS, low-grade inflammation, gut dysbiosis, dietary intolerance, abnormal intestinal permeability, and central as well as peripheral nervous dysregulation **(Flowchart 1)**.

Subtyping of IBS is essential as it helps in defining the targeted therapy and those with mixed type and unclassified types need modifications of the pathophysiological process such as alteration of Gut microbiota or neurohumoral regulation.

TABLE 1 Severity assessment of IBS patients on the MDCP model[20]

Clinical features	*Mild*	*Moderate*	*Severe*
Psychometric correlate	FBDSI, <36 IBS-SSS, 75–175	FBDSI, 36–109 IBS-SSS, 175–300	FBDSI, >110 IBS-SSS, >300
Physiological factors	Primarily bowel dysfunction	Bowel dysfunction and CNS pain dysregulation	Primarily CNS pain dysregulation
Psychosocial difficulties	None or mild psychosocial distress	Moderate psychosocial distress	High psychosocial distress, catastrophizing, abuse history
Sex	Men = women	Women > men	Women >>> men
Age	Older > younger	Older = younger	Younger > older
Abdominal pain	Mild/intermittent	Moderate, frequent	Severe/very frequent or constant
Number of other symptoms	Low (1–3)	Medium (4–6)	High (≥7)
Health-related quality of life	Good	Fair	Poor
Health-care use	0–1/yr	2–4/yr	≥5/yr
Activity restriction	Occasional (0–15 days)	More often (15–50 days)	Frequent/constant (>50 days)
Work disability	<5%	6–10%	≥11%

IBS, irritable bowel syndrome; IBS-C, constipation-predominant IBS; IBS-D, diarrhea-predominant IBS; IBS-M, mixed IBS; FODMAP, fermentable oligo-, di-, monosaccharides, and polyols.

Multidimensional Clinical Profile of Irritable Bowel Syndrome

- Categorical diagnosis (symptom-based criteria)
- Clinical modifier (IBS-C, IBS-D, IBS-M, post-infectious, FODMAP sensitive)
- Impact (mild, moderate, severe)
- Psychosocial modifier
- Physiological dysfunction and biomarkers

Treatment

An incorporative approach including patient education, cognitive behavioral therapy, diet, and lifestyle modification are required for the management of IBS.

This usually needs an involvement of the dietician and a clinical psychologist.

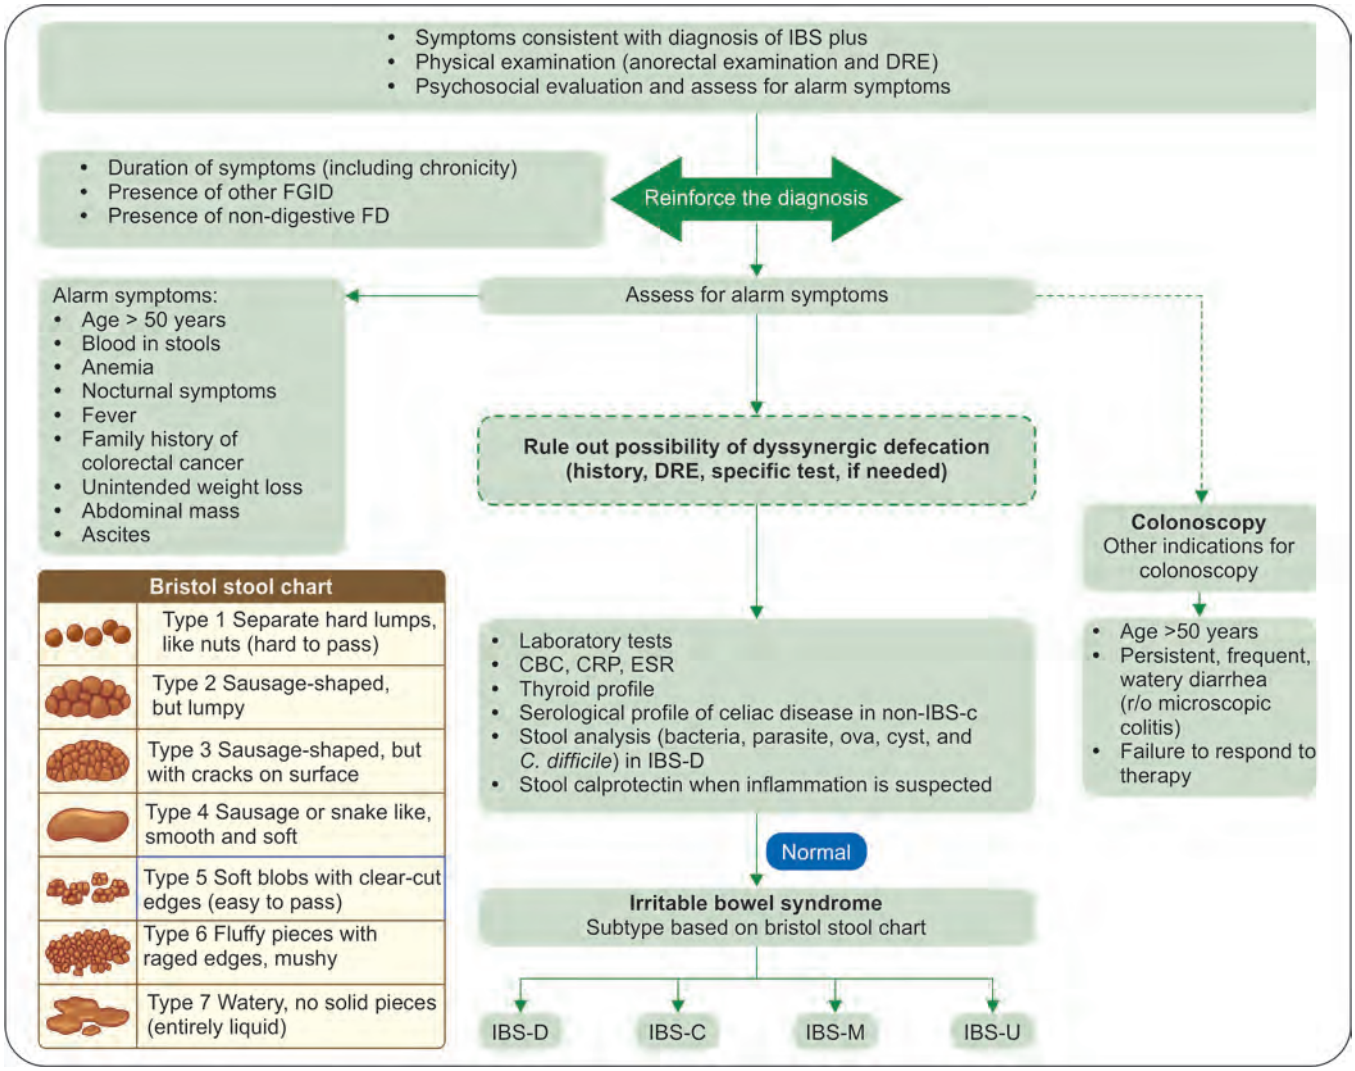
A step up approach depending on the severity of the predominant symptom and the multi-disciplinary clinical profile is helpful in guiding the treatment **(Table 2)**.

The current first-line therapies are directed toward individual symptoms; however, the newer therapies are based on altering the micro-organic pathophysiology.

TABLE 2 Current step up therapy for treatment of IBS

Predominant symptom	*First step*	*Second step*
Constipation	• Fiber supplementation • Polyethylene glycol • Lactulose/Lactitol • Stool softener	• Lubiprostone • Linaclotide • Prucalopride • Sodium picosulfate • Bisacodyl
Diarrhea	Loperamide	• 5HT3 antagonist (alosetron) • Bile acid sequestrant (cholestyramine) • Rifaximin • Clonidine
Pain	• Antispasmodic (anticholinergics) • Peppermint oil	• Tricyclic anti-depressants (TCA) • SSRI • SNRI • Psychological therapy
Bloating	• Diet modification • Treat constipation	• Probiotic • Rifaximin • TCA • SSRI

Flowchart 1: Diagnostic algorithm and management of IBS



Newer Therapies for IBS

Lumen Directed Therapy: Targeting the Low Grade Inflammation Dysbiosis and Intestinal Permeability

Nonabsorbable Antibiotics

Multiple case control studies from around the globe have inferred microbial dysbiosis in patients with IBS.[21] Thus, use of non-absorbable antibiotics for management of IBS was suggested.

Neomycin was initially used in patients with IBS; however, the use was limited due to adverse effects.

Rifaximin was tested initially in small scale trials in patients with IBS.[22,23] Subsequently, in a large randomized trial,[24] positive effects were found in 8–10% patients of IBS who did not have constipation. This effect was present during the 10 weeks of follow-up; however, the effect gradually decreased thereafter. Therefore in another retreatment trial[25] repeat administration of rifaximin was assessed and it was found that retreatment was efficacious as in naïve patients without the concern of antibiotic resistance.

Rifaximin has pleiotropic effects on the gut apart from managing the gut dysbiosis. Variable effects include anti-inflammatory effects, restoring the gut barrier function

and effects on visceral hyperalgesia through unknown mechanisms.

Pre-Probiotics and Synbiotics

Probiotics are live microorganism, which when consumed in prescribed amounts confer multiple health benefits. The available data[26] exhibit an overall positive effect of pre-probiotics on the symptoms of IBS; however, comparative analysis of the bacterial species is lacking.

Probiotics affect the luminal dysbiosis, low grade inflammation, and helps restoring the mucosal integrity in patients with IBS. Apart from the direct effects, probiotics also indirectly modulate the gut-brain interaction.[27,28]

Synbiotics are combinations of pre- and probiotics with synergistic actions. Synbiotics are hypothesized to be beneficial in IBS; however, results are inconsistent and data is sparse.

Fecal Microbiota Transplant (FMT)

Alteration in gut microbiota is one of the proposed mechanisms in the pathogenesis of IBS. Fecal microbiota has been efficacious in treating patients with pseudomembranous colitis with great success. Hence, its role in other luminal as well as non-luminal disorders has been hypothesized. So far many small case series and randomized trials have been published and have assessed IBS severity score as the outcome measure. However, the results were conflicting.

Sahly et al.[29] in 2020 published a double blind randomized controlled trial assessing the efficacy of single donor FMT in 30 gm and 60 gm doses as compared to placebo and found significant response (89.1% vs. 23.6% $p<0.0001$) in reduction in IBS symptoms. However, mild self limiting GI symptoms after FMT need a word of caution.

Mast Cell Stabilizer and Other Anti-inflammatory Drugs

Low grade inflammation in the gut as well as presence of inflammatory cells especially lymphocytes and mast cells have been found in patients with IBS and are considered as one of the microbiologic change.

Mesalazine, used as an anti-inflammatory drug in IBD was found to have no role in patients with IBS.[30,31]

Mast cells being predominant inflammatory cells are one of the targets for recent therapies of IBS. Mast cells are also involved in pathogenesis of visceral hypersensitivity in patients with IBS.[32] Mast cell stabilizer ketotifen was found to increase the discomfort threshold to rectal distension in patients with IBS and had significant effects on abdominal pain and QOL.[33] This effects was hypothesized due to H1 receptor antagonism of ketotifen, which is a secondary action. Another H1 receptor antagonist, Ebastine, was also found to significantly decrease abdominal pain over a 12-week treatment period.[34]

Dietary Modifications

Worsening of symptoms has been reported by many patients after ingestion of certain foods. It has been postulated that food acts through various mechanisms including osmotic, chemical, mechanical and neuroendocrine effects. These pathologic mechanisms can potentiate the already present microbiologic pathology present in the gut. It has also been found that food material containing incompletely digestible carbohydrates, fats, and high caloric diet are incompletely absorbed in the small intestine and are a cause of significant bloating and abdominal discomfort due to fermentation by the gut microbiota. Thus, current recommendations evaluate patients after modifying intake of such food as well as alcohol, caffeine, milk, or any lactulose containing diet.

If these recommendations are cashed on improving symptoms the FODMAP diet **(Fig. 1)**[35] eliminating foods containing fermentable oligosaccharides, disaccharides, monosachharides, and polyols are adviced.[19]

Food eliminating Gluten has also been advocated in non-celiac IBS patients on the basis of evidence of decrease in intestinal inflammation and mucosal injury on gluten free diet.

Therapeutic Updates on Constipation Predominant IBS

Guanylate Cyclase C Agonist

The stimulation of enterocyte guanylate cyclase c (GCC) receptors activates the apical CFTR that leads to water secretion by the gut mucosa.[36] *Linaclotide* is an orally administered 14 amino acid containing peptide that acts as an agonist of GCC. In a dose dependent manner linaclotide softens the stools and also improves symptoms of abdominal pain, bloating, and discomfort.

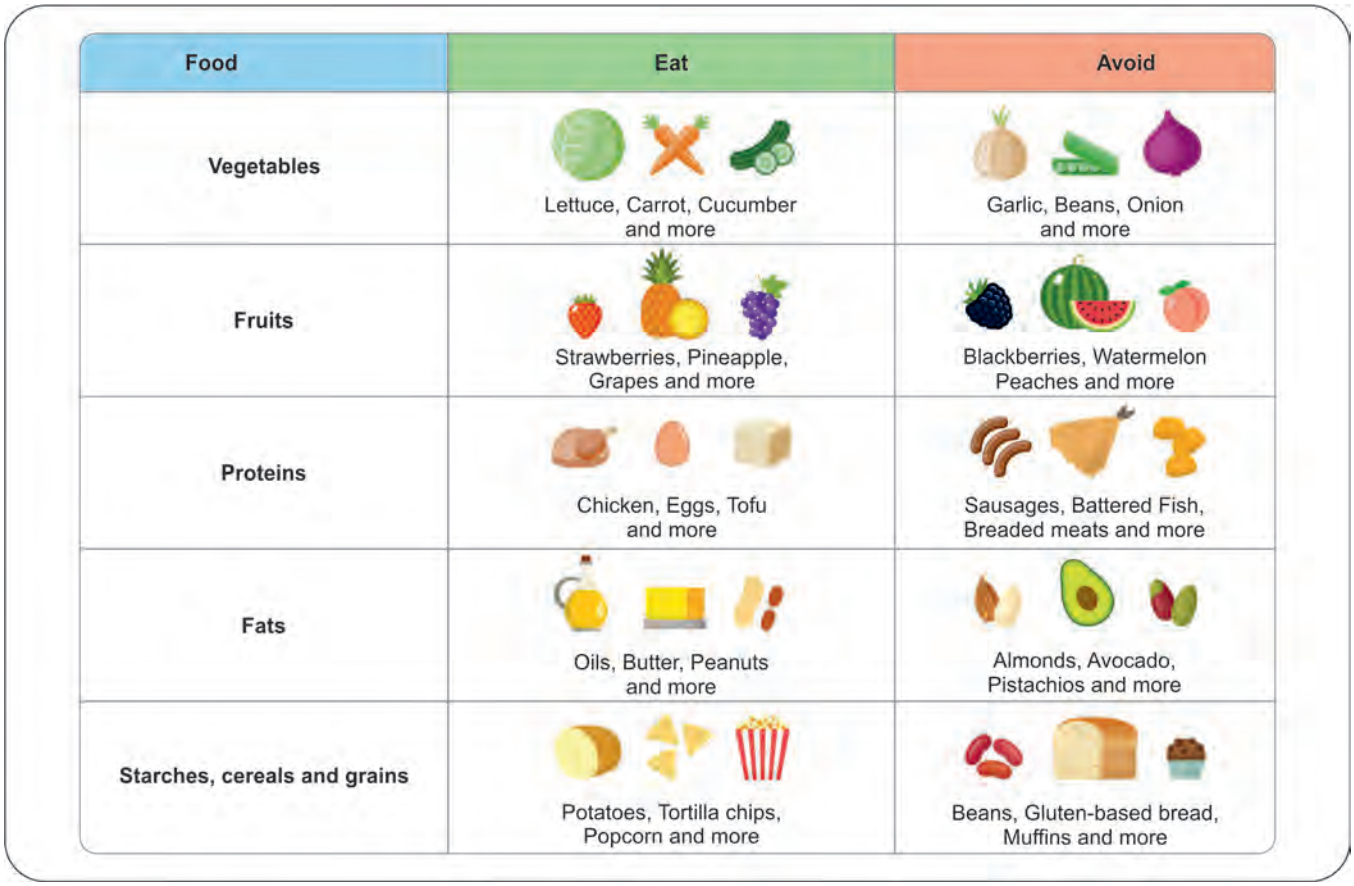


Fig. 1: Low foodmap diet

290 µg daily was shown to improve stool frequency and ease of defecation.[37,38] The most common side effect is diarrhea, which can be managed by reducing the dose.

Plecanatide is another 16 amino acid GCC agonist approved for management of chronic constipation and recently FDA approved for IBS-C.

Lubiprostone

It is a fat soluble molecule that activates type 2 chloride channels in the enterocytes releasing more water into the intestinal lumen increasing water content of the stool. At a dose of 8 µg twice daily *lubiprostone* has shown efficacy in reduction of symptoms and stool consistency.[39] Most common side effects are nausea and diarrhea.

5-HT4 Agonists

Activation of 5-HT_4 enhances the gut motility by amplifying the release of acetylcholine from nerve endings.

5-HT4 agonist *Tegaserod* was shown to be efficacious in management of IBS-c; however, it was withdrawn owing to potential cardiovascular risks.[40,41]

A novel 5-HT_4 receptor agonist *Prucalopride* has been approved for treatment of chronic constipation and has been evaluated in IBS-C considering the anecdotal reports of improvement in bloating, abdominal pain, and discomfort in the trials for constipation.[42]

Ghrelin Receptor Agonists

Ghrelin is a gut hormone involved in appetite control and gut motility in upper as well as lower GI tract. *Relamorelin* is a novel injectable ghrelin receptor agonist studied as a motility amplifier in patients with diabetic gastroparesis.[43] It has also been evaluated in women with chronic constipation and has been found to improve gastric emptying rate and stool frequency but had no effect on stool consistency. Further studies are warranted in patients with IBS-C.

Tenapanor

Small molecule inhibitor of GI N^+/H^+ exchanger isoform 3, *tenapanor* increases water secretion in the gut improving global symptoms of IBS-C. At a dose of 50 mg BD *tenapanor* offers a newer mode of treatment in this class.[44]

Therapeutic Updates on Diarrhea Predominant IBS

Eluxadoline

This is a novel mixed μ opioid receptor and κ receptor agonist and δ agonist evaluated for treatment of IBS-D. It was studied in a dose of 75 mg and 100 mg per day for 26–52 weeks.[45] Eluxadoline helps improve overall symptoms and particularly stool consistency and frequency.

However, pertaining to risk of pancreatitis due to sphincter of Oddi dysfunction it should not be used in patients with history of pancreatitis, SOD or alcohol abuse or any liver dysfunction.

5-HT3 Antagonists

Serotonin modulates the gut motility and sensitivity through a variety of receptors. Alosetron is a 5-HT_3 antagonist was found to be efficacious in treatment of IBS-D.[46] However, this drug was associated with risk of ischemic colitis and severe constipation.

Ramosteron is a novel 5-HT_3 antagonist[47] found to be effective in improving global symptoms of IBS-D including pain scores, which were not improved by Ondansetron when compared for management of IBS-D.

Drugs Acting on Bile Acids

Bile acids are known to be important in stimulating secretion in the bowel and enhance gut motility that are relevant in causing diarrhea. Several studies have revealed the increase bile acid loss as a cause of IBS-D.[48] FGF19 is produced from the ileum that acts as an important factor in regulating bile acid synthesis in the liver. In bile acid diarrhea there is reduced feedback inhibition by FGF19. Cholestyramine is most commonly used bile acid sequestrant along with newer agents like colestipol and colesevelam.[49]

Farnesoid X activated receptor is also involved in inhibition of bile acid synthesis in liver by various mechanisms. Obeticholic acid is one of the various FXR receptor agonists that has been found to reduce bile acid synthesis and improve secondary bile acid diarrhea.[50]

Fig. 2: IBStim device

On the contrary, increased bile acids in the lumen stimulate water secretion and motility and improve constipation. Chenodeoxycholic acid was found to improve bowel function and bowel motility when tested.[51]

Elobixibat or A3309, through antagonism of ileal bile acid transporter reduces reuptake, and hence increases luminal bile acid content. Elobixibat has also been found to improve colonic transit and improve symptoms in patients with IBS-C.[52]

Modulating the Central Pain Mechanism

IBStim Device: The Cranial Nerve Stimulator (Fig. 2)

Recently approved for use in patients for modulating abdominal pain in IBS patients, this device is approved for adolescents of age group 11–18 years. It modulates the pain pathways in the CNS by low frequency electrical stimulation of peripheral cranial nerves. It is single use device and works for 5 days.[53]

Conclusion

IBS is chronic relapsing remitting functional GI disorder. With enhanced understanding of the micro-organic basis of the disorder newer therapies are directed at modifying the pathology of the disease rather than the individual symptoms. It is however very necessary to clinically diagnose the patient with respect to the recent diagnostic criteria and order important battery of investigations for making a positive diagnosis of IBS.

CHAPTER

142 Evaluation of Occult GI Bleed

Sanjay Bandyopadhyay

Abstract

Occult gastrointestinal bleeding signifies bleeding from the gastrointestinal tract that often goes unrecognized by the patient. It usually manifests as positive fecal occult blood test, or if continues for a long period of time, it may progress to iron deficiency anemia. A thorough evaluation of gastrointestinal tract including esophago-gastro-duodenoscopy and colonoscopy clinches the diagnosis in most of the cases. Recently, introduction of capsule endoscopy and balloon enteroscopy have made a major impact by identifying small bowel causes of bleeding. The primary concern is to rule out malignant causes, particularly in elderly. For patients with no identifiable pathology, long-term prognosis appears favorable with oral supplement of iron.

Introduction

Gastrointestinal (GI) bleeding can have a multitude of clinical presentation. The bleeding may be mild, moderate, or severe depending on the severity or rapidity of bleeding. Patient may present with clinically obvious symptoms of hematemesis, melaena, hematochezia, or, in some cases, fresh bleeding per rectum. Furthermore, bleeding may be hidden with patient totally unaware of its existence. This review will focus on this later type of bleeding called occult GI bleeding.

Occult GI bleeding is defined as bleeding that is unknown to the patient, and includes patients with positive fecal occult blood test (FOBT) and/or iron deficiency anemia (IDA).[1] On the other hand, *obscure* GI bleeding is that which is evident to the patient but is from a source that is not readily identifiable by routine esophagogastroduodenoscopy (EGD) and/or colonoscopy.[1]

Causes

Any lesion presents anywhere in the GI tract may present with occult GI bleeding.[2] In a review of five prospective studies on patients with occult GI bleeding, majority was found to have upper GI source (29–56%) followed colorectal source (20–30%). Surprisingly, synchronous lesions were found in up to 17% cases. All these studies used only OGD and colonoscopy, and hence, no source was identified in 29–52% cases. **Table 1** shows the potential causes of Occult GI bleeding.

History and Physical Examination

A detail history and targeted physical examination should form the basis of clinical evaluation. Abdominal pain with aspirin or other non-steroidal anti-inflammatory drug use suggests ulcerative mucosal injury. Unintentional weight loss suggests a malignancy. A past history of GI bleeding or abdominal surgery may give important diagnostic clues. Initiation of anticoagulants or antiplatelet medications in the preceding weeks may precipitate bleeding in an undiagnosed lesion. A family history of GI bleeding may suggest hereditary hemorrhagic telangiectasia (associated with vascular lesions on the lips, tongue, or palms) or blue rubber bleb nevus syndrome (a syndrome with venous

TABLES 1 Causes of occult gastrointestinal bleeding

Mass lesions	• Carcinoma (common) • Adenoma (usually > 1.5 cm)
Inflammation	• Erosive esophagitis (common) • Ulcer (any site, including peptic ulcer, common) • Cameron lesions • Erosive gastritis • Celiac disease • Ulcerative colitis • Crohn's disease • Colitis (non-specific) • Idiopathic cecal ulcer
Vascular	• Vascular ectasia (common) • Varices (any site, rare) • Portal hypertensive gastropathy (PHG) (common) • Portal colopathy • Gastric antral vascular ectasia (GAVE) • Dieulafoy's ulcer (rare) • Hemosuccus pancreaticus (rare) • Hemobilia (rare)
Infection	• Hookworm • Whipworm • Strongyloidiasis • Ascariasis • Tubercular enterocolitis • Amebiasis
Other	• Long-distance running • Factitious

malformations in the GI tract, soft tissues, and skin). A history of gastric bypass surgery may suggest impaired iron absorption.[1] Examination of skin may indicate the presence of an underlying condition like dermatitis herpetiformis (in celiac disease); erythema nodosum (in Crohn disease); an atrophic tongue and brittle, spoon-shaped nails (Plummer-Vinson syndrome); and freckles on the lips and in the mouth (Peutz-Jeghers syndrome).[3] Stigmata of chronic liver disease may suggest bleeding due to portal hypertension. Anemia may be obvious on clinical examination. Palpable hard nodular liver or palpable abdominal lump may be signs of underlying advanced disease.

Diagnostic Studies

The choice of diagnostic modality should depend on clinical suspicion of potential site and probable cause of underlying disease, and any associated symptoms. Upper GI bleeding from lesions up to the second part of duodenum can be detected by EGD. Classically, small bowel bleedings are evaluated by enteroscopy. Older methods like Push enteroscopy reach only the proximal small intestine. However, bleeding sources in mid and distal small bowel need evaluation with wireless capsule endoscopy (WCE), deep enteroscopy, and computed tomography (CT) or magnetic resonance (MR) enterography.[4] Lower GI bleeding (colonic and terminal ileal source) can be detected with colonoscopy. Laparotomy with intraoperative enteroscopy remains an option for those rare patients who have recurrent bleeding from a source not yet identified with the previously mentioned methods. Small bowel barium studies have a very low diagnostic yield and been largely replaced by capsule endoscopy. EGD and colonoscopy will find the bleeding source in 48–71% of patients. In patients with recurrent bleeding, repeat EGD and colonoscopy may find missed lesions in up to 35% of those who had negative initial findings.[3] If a cause is not found after EGD and colonoscopy had been performed, capsule endoscopy has a diagnostic yield of 63–74%.[4]

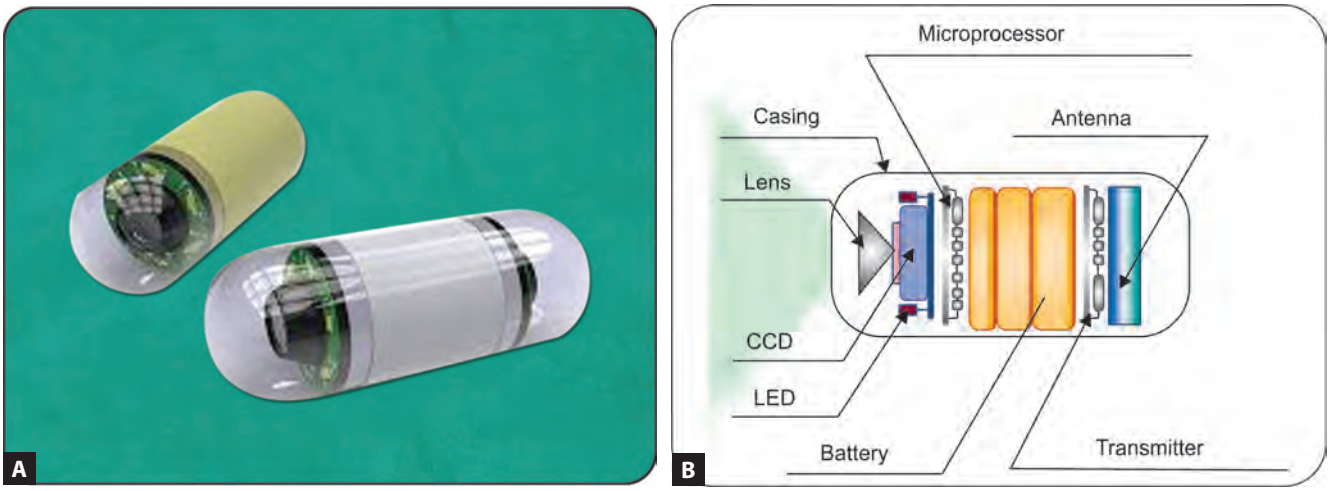
Capsule Endoscopy and Different Methods of Enteroscopy

These tools are particularly useful for establishing the source of bleeding in small intestine—a notoriously difficult site to examine with other methods.

Capsules used for endoscopy contain light-emitting diodes, a lens, a camera, batteries, and a radiofrequency transmitter **(Figs. 1A and B)**. Captured images are transmitted to a data recording device worn by the patient, downloaded to a computer workstation, where the images are analyzed.[5] The capsule is disposable and, because of its small size, readily passes through the GI tract. Capsule retention is a potential complication but, fortunately, occurs in less than 1%.[6]

Push enteroscopy consists of per oral insertion of a specialized, long, flexible tube up to 50–60 cm beyond the ligament of Treitz. This allows thorough examination of the distal duodenum and proximal jejunum, and biopsies can be taken if needed. It is rarely practiced nowadays.

Deep enteroscopy has been a major advance in the evaluation of the small bowel as it offers scope for therapy and tissue biopsy, though multiple sessions may be needed for complete examination.[7] There are several forms of deep enteroscopy, including double-balloon enteroscopy (DBE), single-balloon enteroscopy (SBE), and spiral



Figs. 1A and B: Components and designs of capsule endoscopy system: (A) Capsule; (B) Schematic diagram of components of capsule

enteroscopy (SPIRUS) **(Figs. 2A to C)**.[7-9] The principle involves the use of an endoscope and an overtube, although procedures are emerging that may not require an overtube. Initially scopes are inserted as deep as possible; careful withdrawal of the scope then allows evaluation of the entire small bowel. With DBE, balloons are used to grip the intestine while inserting the endoscope. By inflating the overtube balloon enough to grip the intestinal wall, the endoscope can be inserted further without forming redundant loops in the small intestine and then the overtube can in turn be inserted while the endoscope balloon is inflated. The single balloon technique in theory is technically simpler than DBE. Spiral enteroscopy uses a special overtube with raised helices at the distal end, and clockwise rotation of the overtube pleats the small bowel onto the overtube and prevents looping. Data to date suggest that DBE allows greater depth of insertion than the other two.[7]

Evaluation

There are two different clinical presentations of occult GI bleed:

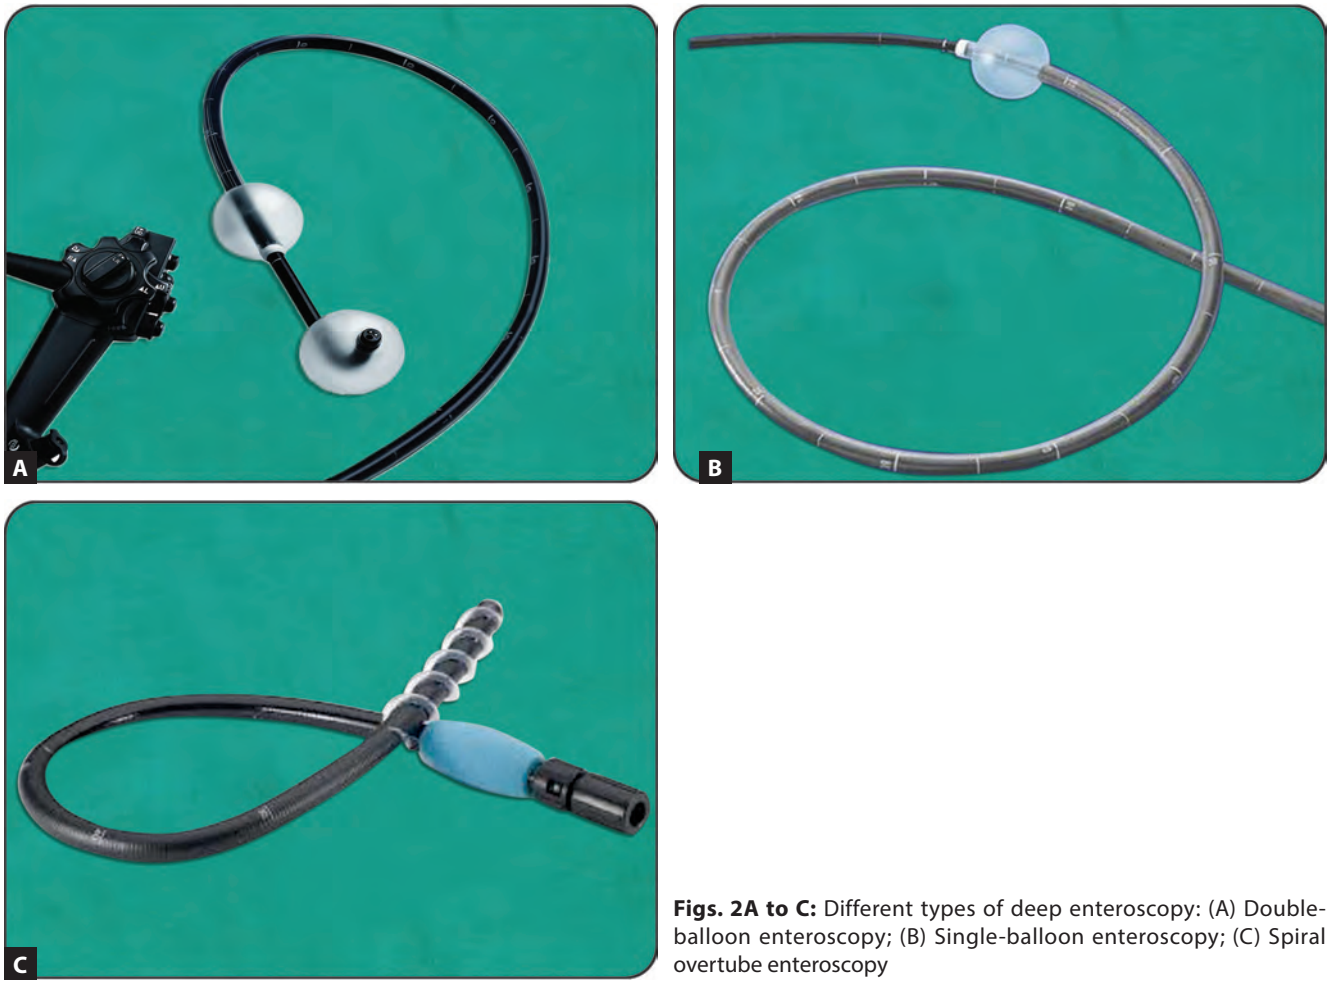
- Positive FOBT without iron deficiency anemia
- Iron deficiency anemia with or without a positive FOBT

Positive FOBT without Iron Deficiency Anemia

Normal fecal blood loss varies from 0.5 to 1.5 mL/day.[10] However, loss of up to 100 mL of blood per day may not cause any visible change in the color of the stool.[11] FOBT, usually classic guaiac-based tests, is often used in day-to-day clinical practice by physicians. Other types of FOBT like fecal immunochemical tests and the heme porphyrin test are not available in India. The likelihood of positive test depends not only on the sensitivity of a particular test but also on the frequency and rate at which the causative lesion bleeds, bowel motility, and the anatomic site of the bleed.[12] Guaiac-based tests are best at detecting blood from the lower rather than the upper GIT as the pseudoperoxidase activity of heme, detected by guaiac-based tests, is continuously degraded as it moves down the GIT.

Oral iron therapy is commonly believed to cause positive guaiac tests, but prospective studies have proven this belief to be wrong.[13] Finally, bismuth (found in certain antacids and antidiarrheal drugs) makes the stool dark and even black in appearance, but does not cause a blue guaiac reaction and should not be mistaken for blood.

Flowchart 1 illustrates the approach proposed by the American Gastroenterological Association (AGA) for patients with positive FOBT.[4] Colonoscopy is preferred because of its high sensitivity for detecting colonic mucosal lesions, and its intervention capabilities with biopsy, polypectomy, and treatment of bleeding lesions.[4] Barium studies have lower sensitivity than colonoscopy and are generally not recommended. CT colonography may be an alternative to colonoscopy, if bowel preparation is a problem.[14] However, it does not have therapeutic capabilities.



Figs. 2A to C: Different types of deep enteroscopy: (A) Double-balloon enteroscopy; (B) Single-balloon enteroscopy; (C) Spiral overtube enteroscopy

Identification of an abnormality consistent with the magnitude of bleeding makes further workup after colonoscopy unnecessary. If colonoscopy is negative, further studies are not required in the asymptomatic patient unless anemia develops.[4] Exceptions are patients with upper GI symptoms, in whom EGD should be performed along with colonoscopy.

Fecal blood content in therapeutically anticoagulated patients is usually within normal limits. Hence, a positive FOBT should not be attributed to low-dose aspirin or anticoagulation, and as such, will require at least endoscopic evaluation.[15]

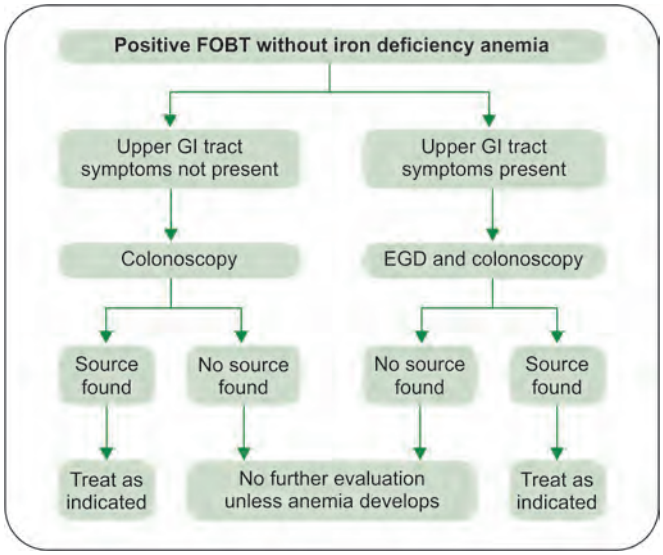
Iron Deficiency Anemia with or without a Positive FOBT

Worldwide IDA is the most common cause of anemia. Under normal circumstances, iron balance is tightly regulated at the level of intestinal mucosa. Average daily loss of iron is 1 mg coming from microscopic GI bleeding and sloughed intestinal cells.[16] In India, more than 50% of population is iron-deficient.[17]

The approach recommended by AGA for evaluation of patients who have IDA with or without a positive FOBT has been illustrated in **Flowchart 2**.[18] Men and postmenopausal women with IDA are assumed to have GI blood loss, unless proved otherwise. However, premenopausal women who have IDA that cannot be explained by heavy menses, or those who have GI symptoms, should be evaluated for a GI cause.

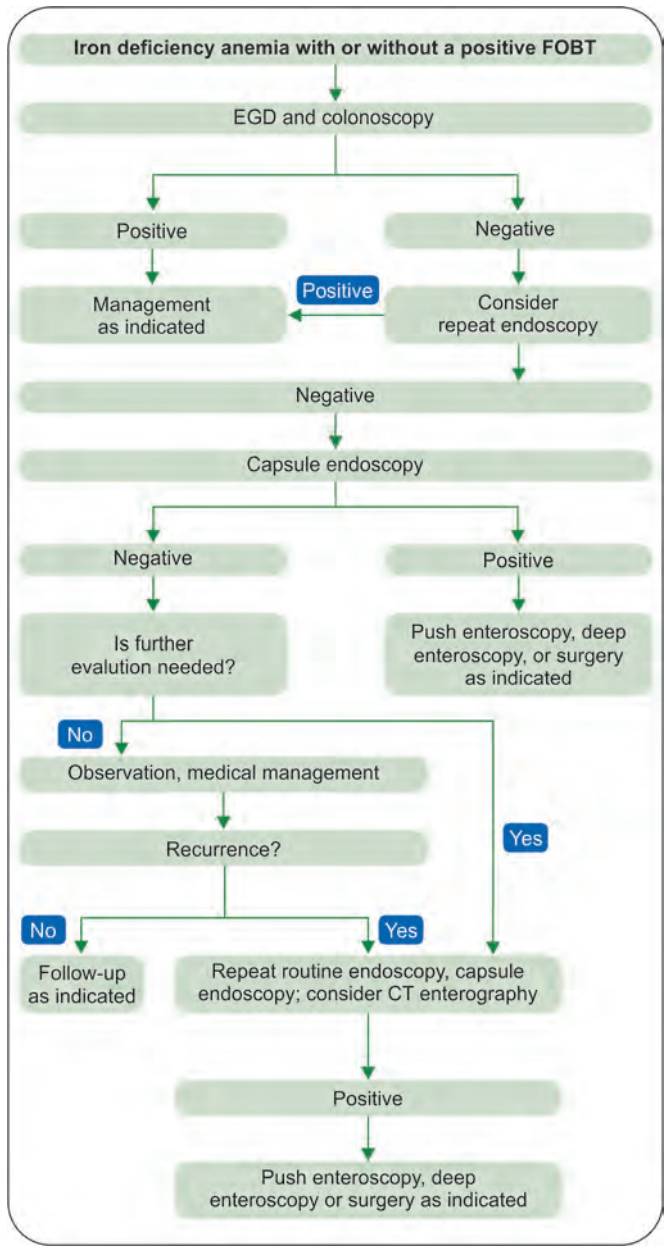
Endoscopic evaluation should start with EGD and colonoscopy. During EGD, biopsies should be taken from duodenal mucosa to look for celiac disease, an often ignored cause of IDA.[19] If EGD and colonoscopy are normal, they are called obscure occult GI bleed.

Flowchart 1: Evaluation of the patient with a positive FOBT



EGD, esophagogastroduodenoscopy; FOBT, fecal occult blood test; GI, gastrointestinal

Flowchart 2: Proposed algorithm for diagnosis of iron deficiency anemia with or without a positive FOBT



CT, computed tomographic; EGD, esophagogastroduodenoscopy; FOBT: fecal occult blood test

The prevalent expert opinion suggests that they should undergo repeat upper endoscopy and colonoscopy, at least once. If these repeat studies are negative, capsule endoscopy should be the next investigative procedure with a focus on small bowel.

Whenever capsule endoscopy identifies a lesion on small bowel, further course of action depends on the nature of the lesion.

- If the identified lesion needs a tissue diagnosis or if the lesion requires endotherapy (like endoscopic hemostasis, endoluminal ablation, resection, or dilatation), balloon enteroscopy should be performed. The choice of route of balloon enteroscope insertion (either antegrade, i.e., orally or retrograde, i.e., inserted anally) will depend on the estimated site of lesion as observed on running the capsule endoscopy video.
- If capsule endoscopy shows a lesion that can be managed medically or that requires surgery, balloon enteroscopy is not justified.

If capsule endoscopy fails to identify a lesion, it may be repeated on another occasion (second-look capsule endoscopy). Alternatively, CT or MR enterography may be considered.

Sometimes, CT or MR enterography are performed before capsule endoscopy to check for luminal patency sufficient to allow unobstructed passage of the capsule.[20]

Surprisingly, in some cases, the diagnosis may be obvious on CT or MR precluding the need for capsule endoscopy. Radioisotope scan using radioactive technetium bound red blood cells (RBCs) are not favored due to significant radiation exposure, imprecise localization, and lack of therapeutic potential.[21] Angiography and guided

intervention is reserved for acute brisk bleeding that do not fall in the category of occult GIB or IDA.[20,22]

A small percentage of cases may not have any lesion identified even after exhaustive evaluation. In them, covert non-GI blood loss should be considered. Also, the diagnosis and type of anemia need to be rechecked by a hematologist.[1]

Treatment

Essentially, the treatment should focus on the underlying cause of occult bleeding. Anemia is treated with oral ferrous sulfate in a dose of 325 mg twice or thrice daily. Ferrous fumarate or gluconate is acceptable alternative for those unable to tolerate ferrous sulfate. Parenteral iron therapy is reserved for those with malabsorption disorders or severe oral intolerance.[23] For patients with positive FOBT but no identifiable GI pathology, the long-term prognosis appears favorable. Majority of these true obscure cases respond to oral iron thrapy.[24]

Conclusion

A multitude of diseases of GIT can present as occult GI bleed, manifesting as a positive FOBT or IDA. Majority of these bleeds are caused by ulcerative diseases of the upper GIT while malignancy is rare. Routine endoscopy (UGI endoscopy and colonoscopy) is the first step in evaluation of these patients. Some patients have common lesions but with an unusual or atypical appearance; others may harbor rare/uncommon diseases. Capsule endoscopy and deep (often balloon-assisted) enteroscopy are useful to identify the diseases of small bowel. The later often offers scope for curative intervention. The outcome of therapy depends on identification of a specific bleeding lesion, severity of bleeding, and, finally, access to advanced diagnostic/therapeutic modalities.

CHAPTER

143 Endoscopic Ultrasound for the Internist

Surinder S Rana

Abstract

Endoscopic ultrasound (EUS) is a relatively new innovation in the field of gastrointestinal (GI) endoscopy that combines the endoscope and ultrasound transducer for examining the GI tract wall and structures beyond. The ability to place the ultrasound transducer very close to the structures/organs being evaluated allows use of high frequencies that provide very high resolution images. EUS is used for both diagnostic as well as therapeutic purposes. The diagnostic indications can be either for primary diagnosis where EUS is used as a primary diagnostic modality for diagnosing diseases like evaluation of idiopathic acute pancreatitis as well as diagnosis of chronic pancreatitis or as a secondary diagnostic modality for detailed evaluation of already diagnosed disease like submucosal lesions, dilated bile duct, and pancreatic cystic lesions or EUS guided FNA of GI as well as surrounding structures like lymph nodes or locoregional staging of GI cancers. Therapeutic EUS has phenomenally expanded in last one decade and a number of procedures like pseudocyst/walled off necrosis drainage, celiac plexus blockade/neurolysis, intra-abdominal abscess drainage, mediastinal abscess drainage, vascular interventions, intratumoral therapy, and biliary as well as pancreatic drainage can be safely done under EUS guidance. Development of newer technologies like EUS elastography and contrast EUS is going to further expand the role of EUS. It is important for an internist to be aware of the indications and strengths of EUS in various abdominal, thoracic as well as pelvic diseases.

Introduction

Endoscopic ultrasound (EUS) is a relatively new innovation in the field of gastrointestinal (GI) endoscopy that combines the endoscope (for visualizing the mucosa of the GI lumen) and ultrasound transducer for examining the GI tract wall and structures beyond it.[1] The desire to see the structures beyond the GI lumen led on to development of EUS. Over last three decades, EUS has evolved tremendously from a research tool to important investigational tool in routine clinical practice. The ability to place the ultrasound transducer very close to the structures/organs being evaluated allows use of high frequencies that provide very high resolution images.[2] These images are much better than those obtained by transabdominal ultrasound as well as other cross-sectional imaging techniques. Therefore, there has been gradual expansion in its clinical indications and it has evolved from a purely diagnostic modality to an important therapeutic tool. Its advent has made the locoregional staging of many GI cancers accurate and also made a number of GI therapeutic procedures safer. The advent of EUS guided fine needle aspiration (FNA) has made it the procedure of choice for tissue diagnosis of various benign as well as malignant GI lesions. It has changed the daily clinical practice of not only gastroenterologists, but also surgical gastroenterologists, oncologists, pulmonologists, radiologists, as well as internists. Therefore, it is very important for an internist to be aware of the current

indications, strengths as well as limitations of EUS. This review discusses in brief the diagnostic and therapeutic indications of EUS.

Types of EUS Scopes

Broadly, there are two types of EUS scopes (echo-endoscopes). The first developed echoendoscope was a radial echoendoscope with a 360-degree transducer that has a scanning plane of ultrasound perpendicular to the long axis of the echoendoscope. This is a purely diagnostic echoendoscope and no intervention or FNA can be done with this scope. To overcome this limitation, linear echoendoscopes were developed in which the scanning plane of transducer is parallel to the long axis of the echoendoscope so that the entire needle can be seen in real time during FNA/interventions.[3]

Apart from these two commonly echoendoscopes, a new echoendoscope has recently been developed. The forward viewing echoendoscope has a forward endoscopic view instead of oblique endoscopic view of linear echoendoscope and has a shorter and more flexible tip. Therefore, it is more easily maneuverable and can be used instead of oblique viewing echoendoscope in difficult anatomical situations. However, absence of elevator at the tip of echoendoscope makes the interventions difficult with this scope. Therefore, this scope is usually used in those situations where linear echoendoscope cannot be used because of anatomical constraints.

Indications of EUS

The clinical indications for EUS can be divided into two broad categories: diagnostic and therapeutic **(Table 1)**. The diagnostic indications can be either for primary diagnosis where EUS is used as a primary diagnostic modality for diagnosing diseases like evaluation of idiopathic acute pancreatitis as well as diagnosis of chronic pancreatitis or as a secondary diagnostic modality for detailed evaluation of already diagnosed disease like submucosal lesions (SMLs), dilated bile duct and pancreatic cystic lesions (PCL) or EUS guided FNA of GI as well as surrounding structures like lymph nodes or locoregional staging of GI cancers.

Therapeutic EUS has phenomenally expanded in last one decade and a number of procedures like pseudocyst/walled off necrosis drainage, celiac plexus blockade/neurolysis, intra-abdominal abscess drainage, mediastinal abscess drainage, vascular interventions, intratumoral therapy and biliary as well as pancreatic drainage can be safely done under EUS guidance.

EUS as a Primary Diagnostic Modality

Idiopathic Acute Pancreatitis

EUS provides high-resolution images of pancreas and biliary tract, and therefore is an important investigation for evaluation of patients with idiopathic acute pancreatitis. It is an excellent modality for diagnosis of occult cholelithiasis or choledocholithiasis, microlithiasis, or gallbladder sludge **(Fig. 1)**, pancreatic duct anomalies like pancreas divisum, occult pancreatic neoplasm and importantly, exclude chronic pancreatitis.[4] Studies have shown that EUS is a useful and minimally invasive tool for the diagnostic evaluation of idiopathic pancreatitis and in case of negative EUS examination relapses of pancreatitis are infrequent.[5,6] EUS may also help in

TABLE 1 Indications for EUS

Diagnostic EUS	*Therapeutic EUS*
Primary diagnostic modality • Idiopathic acute pancreatitis • Diagnosis of chronic pancreatitis especially early chronic pancreatitis	• Drainage of pancreatic fluid collections • Biliary and pancreatic duct drainage in cases of failed ERCP • Transmural gallbladder drainage • EUS-guided celiac plexus neurolysis/blockade • Drainage of mediastinal and intra-abdominal abscesses and collections • EUS-guided vascular interventions • EUS-guided palliative oncological interventions • EUS-guided gastrojejunostomy
Secondary diagnostic modality • Dilated common bile duct • Pancreatic cystic lesions • GI submucosal lesions • Locoregional staging of GI cancers • EUS guided fine needle aspiration or biopsy • EUS guided aspiration of minimal pleural effusion/ascites	

ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasound; GI, gastrointestinal

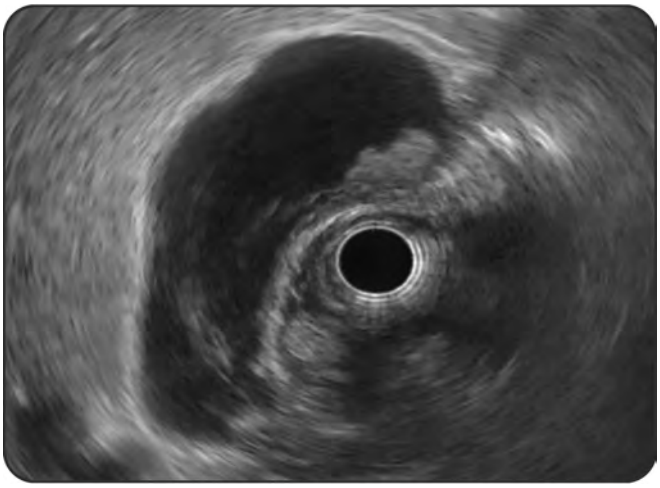

Fig. 1: EUS: gallbladder sludge in idiopathic acute pancreatitis

Fig. 2: EUS in a patient with chronic pancreatitis. Ductal calculi (arrow) noted

diagnosing uncommon causes for AP such as pancreaticobiliary ascariasis and parathyroid adenomas.

Diagnosis of Chronic Pancreatitis

EUS has unique capability of demonstrating subtle structural alterations in the pancreatic parenchyma as well as ducts even before conventional imaging modalities demonstrate any abnormality **(Fig. 2)**.[7] The conventional imaging modalities like computed tomography (CT) and magnetic resonance cholangiopancreatography (MRCP) can pick up advanced morphological changes of chronic pancreatitis (CP) only, and therefore they have very low sensitivity for diagnosis of early CP. EUS by demonstrating early parenchymal and ductal changes can help in early diagnosis of CP. In patients with presumed acute recurrent pancreatitis, EUS can help in excluding underlying CP.

However, EUS is not a panacea for diagnosis of CP. Being a highly sensitive imaging modality, there is a concern for overdiagnosis of CP. To overcome these limitations, advanced and complicated scoring systems incorporating multiple parenchymal and ductal EUS features have been used for diagnosis of CP. Despite these scoring systems, concerns about interobserver variability as well as aging, smoking, obesity, and chronic alcohol consumption causing EUS changes in pancreas mimicking CP persist. Therefore, EUS findings of CP should be interpreted in an appropriate clinical context and, if required, should be confirmed and followed up by serial EUS examinations. Newer EUS techniques like EUS elastography that evaluate the stiffness of pancreas appear to be promising techniques for confident diagnosis of early CP.[7] However, further studies are required to determine their exact role in diagnosis of early CP.

EUS as a Secondary Diagnostic Modality

EUS for Submucosal Lesions

SMLs are usually asymptomatic lesions with normal overlying mucosa detected on routine endoscopy and require further evaluation for confirmatory diagnosis. Endoscopy and biopsy have limited role in evaluation of SMLs because of normal overlying mucosa. The ability of EUS to image structures beyond GI lumen makes it ideal modality for investigations of SMLs. EUS is an excellent modality to differentiate extramural compression and SML as well as determine the type and nature of SML.[8-10] EUS can help in presumptive diagnosis of SML by accurately estimating the size, the layer of origin, the echo-pattern and the margins of the lesion. The diagnostic accuracy of EUS can further be enhanced by cytological or histological analysis of specimens obtained by EUS guided FNA/fine needle biopsy (FNB).

EUS for Unexplained Dilated Common Bile Duct

EUS transducer from duodenum closely images the CBD, and therefore has very high diagnostic accuracy for lower and mid CBD lesions.[11-13] Isolated CBD dilatation is commonly encountered in clinical practice because

Fig. 3: EUS in dilated common bile duct (CBD). A stone noted in lower CBD (arrow)

Fig. 4: EUS: mucinous cystadenoma of pancreas

of wide spread use of cross-sectional imaging modalities for patients with non-specific abdominal symptoms. In many of these patients cross-sectional imaging modalities like ultrasound, CT, and MRCP fail to identify the etiology of dilated CBD and many of these patients required endoscopic retrograde cholangiopancreatography (ERCP) for confirming the diagnosis. ERCP is an invasive procedure with inherent risks of serious adverse effects like post ERCP pancreatitis. In these clinical situations EUS has been demonstrated to be an excellent diagnostic modality for identifying underlying etiology of unexplained CBD dilatation **(Fig. 3)**. More importantly, if EUS is normal, there is extremely less likelihood of presence of any significant underlying disease and patient therefore should be reassured and no further follow-up is required.[11-13]

EUS in Pancreatic Cystic Lesions

Evaluation of patients with PCL requires a confident differentiation of malignant, potentially malignant and benign PCL. EUS is a useful modality for evaluation of PCL as it can provide information about the detailed morphology of cysts **(Fig. 4)** as well as enable guided FNA to obtain cyst fluid for cytological, biochemical as well as molecular analysis.[14-17] Cyst fluid carcinoembryonic antigen (CEA) levels more than 192 ng/mL have been shown to have highest sensitivity and specificity for differentiating mucinous from non-mucinous PCL.[14] Cyst fluid molecular markers hold considerable promise for proper evaluation of PCL. New EUS based technologies like contrast-enhanced EUS, EUS guided cystoscopy, needle-based confocal laser endomicroscopy, and through-the-needle forceps biopsy provide important information for accurate diagnosis of PCL.

EUS for Locoregional Staging of GI Cancers

EUS can accurately define the walls of the GI tract and thus is an accurate modality to assess the transverse spread of malignant lesion. It can also accurately assess the extraluminal involvement of the malignant lesion by identifying lymph nodal as well as arterial and venous involvement. Therefore, over last decade EUS has thus become an important investigation for preoperative assessment for majority of the GI cancers including esophageal, gastric, pancreaticobiliary, as well as rectal cancers.[18] EUS from esophagus can also evaluate the mediastinum, and therefore EUS is an important imaging modality for accurate staging of non-small cell lung cancer. Combining EUS with endobronchial ultrasound (EBUS) allows access to all mediastinal lymph node stations, and therefore is an important staging modality for lung cancer.[18,19]

EUS-guided Tissue Acquisition

Linear echoendoscope is used to perform EUS-guided FNA with great precision in real time as the needle is visualized in real time throughout the procedure. The advantage of EUS-guided FNA is its ability to acquire

Fig. 5: EUS-guided FNA from preaortic lymph node

Fig. 6: EUS-guided drainage of pancreatic pseudocyst

tissue from difficult to access anatomical locations in abdomen, retroperitoneum, mediastinum, and perirectal spaces.[20] EUS guided FNA is now routinely used in clinical practice to acquire tissue for histological diagnosis from pancreas, lymph nodes in mediastinum and abdomen **(Fig. 5)**, GI SMLs, perirectal lesions, left lobe of liver, left adrenal, and mediastinal masses. EUS can also be used for aspirating minimal amount of ascites and pleural effusion.[21-23] It can also be used for visualizing as well as sampling peritoneal as well as pleural deposits in patients with undiagnosed pleural effusion as well as ascites.[21,23,24] Despite being in GI endoscopy practice for more than a decade, EUS FNA has important limitations like false positivity in pancreatic masses in CP and autoimmune pancreatitis and false negativity because of technical difficulty, marked desmoplastic background, sampling error, or interpretative errors. Moreover, certain diseases like lymphoma and autoimmune pancreatitis require cote biopsy for confident diagnosis. To overcome these limitations of EUS FNA, newer FNB needles have been developed for use with EUS.[25,26] EUS guided FNB has been demonstrated to provide samples with increased cellularity along with preserved histologic architecture, and therefore seems to be an ideal tissue acquisition technique for histological as well as molecular testing.

Therapeutic EUS

EUS has the ability to visualize organs and lesions adjacent to GI tract and thus provide an opportunity to target them for various therapeutic procedures. The advantages of EUS is its ability to provide a real time imaging of the targeted area and also, importantly, avoiding adjacent vascular and other structures.[27] Various EUS guided interventional procedures that are being performed are drainage of pancreatic fluid collections, biliary and pancreatic duct drainage in cases of failed ERCP, transmural gallbladder drainage, celiac plexus neurolysis (CPN)/blockade, drainage of mediastinal and intra-abdominal abscesses and collections, various vascular interventions, endoscopic gastrojejunostomy and is useful for targeted chemotherapy and radiotherapy.

CPN is a procedure of chemical ablation of the celiac plexus using absolute alcohol or phenol for relief of intractable pain because of pancreatic cancer. It is usually done under ultrasound, or CT guidance or surgically. Advent of EUS guided CPN has made this procedure very safe with rare adverse effects. Although EUS, CPN is safe and effective, but the pain relief is usually short lasting and patient may require repeated procedures for effective pain relief.[28]

EUS guided transmural drainage of pancreatic fluid collections including pseudocysts **(Fig. 6)** as well as walled off necrosis has evolved as its treatment of choice and is preferred over surgical as well as percutaneous drainage.[29,30] Being minimally invasive, safe, effective, and absence of external percutaneous drainage catheter are important advantages of EUS guided drainage of pancreatic fluid collections. Developments of fully covered lumen apposing metal stents (LAMS) have further improved results of EUS guided drainage of pancreatic

fluid collections. Similarly, abscesses or collections in locations adjacent to GI tract like mediastinal, left lobe of liver, lesser sac, and pelvic collections can be drained under EUS guidance.[27]

EUS-guided transmural drainage of biliary tract and pancreatic duct is an effective alternative to percutaneous or surgical drainage of these ducts in patients with failed ERCP.[27] Although these procedures are effective but are technically challenging, and therefore should be performed only by experts in centers with radiological and surgical back up. Similarly, EUS can be used for draining gallbladder in cases of acute cholecystitis not responding to antibiotics and has been shown to be safer and effective alternative to percutaneous drainage of gallbladder with added advantage of absence of percutaneous drain.

Advancement in accessories for EUS has led on to exploration of unthinkable therapeutic areas. Various palliative oncological interventions like EUS-guided brachytherapy, fiducial marker placement, ethanol ablation, and EUS-guided delivery of antitumor agents can be performed and studies have shown them to be safe and effective.[27] EUS has expanded into vascular interventions field also with various EUS guided interventions like EUS guided glue or coil injections into gastric/ectopic varices as well as pseudoaneurysms being safely performed. EUS-guided intrahepatic portosystemic shunt has also been performed as an alternative to TIPS (transjugular intrahepatic portosystemic shunt) for the treatment of consequences of portal hypertension. Advancement in EUS had made it possible to perform various surgical procedures like gastrojejunostomy safely in a minimally invasive fashion under EUS guidance.[31]

Conclusion

EUS is an important investigation in the armamentarium of an endoscopist. EUS has been shown to have a significant impact in management of patients with various GI disorders with significant change in both the diagnosis as well as management.[3] The advent of EUS-guided FNA for tissue diagnosis as well as therapeutic EUS has led on to wider clinical applications of EUS. Locoregional staging of various GI cancers is one of the important clinical applications of EUS in clinical practice. Development of newer technologies like EUS elastography and contrast EUS is going to further expand the role of EUS. It is important for an internist to be aware of the indications and strengths of EUS in various abdominal, thoracic, as well as pelvic diseases.

CHAPTER

144 Gastroesophageal Reflux Disease—What's New!

Piyush Dadhich, Shraddha Sharma, Shreyans Singhvi, Gautam Bhandari, Sunil Kumar Dadhich

Abstract

Gastroesophageal reflux disease (GERD) is a frequently encountered disease in clinical practice that significantly hampers the quality of life of patients. Long-term complications of GERD are another area of concern that necessitates timely diagnosis and treatment. Both acid and non-acid reflux have been implicated into the pathophysiology of GERD. Ambulatory 24-hour pH monitoring is the gold standard test for diagnosis. Proton pump inhibitors (PPIs) along with lifestyle modifications are the mainstay of treatment. However, they have their own range of side effects, which precludes their long-term use. Moreover, 20–40% patients show persistent symptoms despite adequate PPI therapy. Management of refractory GERD requires optimization of PPI therapy, addition of a nighttime H_2 receptor antagonist, baclofen and neuromodulators. However, promising results have not been obtained with any of these so far. Newer enantiomers of PPI, potassium-competitive acid blockers, and TLESR-reducers are under trial phase. However, due to the disturbing recurrent nature of symptoms, patients' preference for surgical and endoluminal therapies is apparent. This chapter briefly outlines the pathophysiology and current treatment options for GERD with focus on recent advancements in medical, endoluminal, and surgical management strategies of the disease.

Introduction

Gastroesophageal reflux disease (GERD) is a global disease. While the prevalence in western population is 18.1–27.8%, it is believed to be lower in the East Asian population (<10%). The overall prevalence of GERD in India is 7.6%.[1,2]

GERD is associated with deleterious effects on day-to-day activities, reduced work efficiency, and sleep, ultimately affecting the quality of life. Further, long-term complications like stricture, Barrett's esophagus, and adenocarcinoma also necessitate timely diagnosis and treatment.

Definitions[3]

- **GERD**—Troublesome symptoms sufficient to impair an individual's quality of life or injury or complications that result from the retrograde flow of gastric contents into the esophagus, oropharynx, and/or respiratory tract.
- **NERD**—GERD symptoms without erosions on endoscopy in absence of recent acid-suppressive therapy.
- **Erosions on endoscopy (EE)**—EE with/without GERD symptoms.
- **Barrett's esophagus (BE)**—Endoscopic presence, confirmed histologically of columnar-lined esophagus. It is known to have malignant potential.
- **Extraesophageal GERD syndrome**—This includes:
  - Conditions with established association with GERD (cough, laryngitis, asthma, and dental erosions).
  - Conditions with only a proposed association (pharyngitis, sinusitis, idiopathic pulmonary fibrosis).

Causative and Protective Factors

- **Causative Factors**

Older age	Pregnancy
Obesity	Smoking and alcohol
Anxiety/depression	Less physical activity
Large meals just before sleep	High dietary fat intake
Certain medication like NSAIDs, calcium channel blockers	

- **Protective Factors:** *Helicobacter pylori* infection and physical activity seem to play a protective role.

Pathophysiology[4]

GERD is the disease of lower esophageal sphincter (LES). The acid reflux is most commonly caused due to transient relaxation of lower esophageal sphincter (TLESRs), which is a physiological phenomenon and increases in frequency postprandially.

Other factors that contribute to acid reflux include:

- Decreased LES pressure
- Increased intra-abdominal pressure
- Hiatal hernia
- Poor esophageal acid clearance
- Delayed gastric emptying

Non-acid Reflux[5]

- Undoubtedly, acid reflux is the chief cause of symptoms in GERD patients, making gastric acid suppressive therapy (proton pump inhibitor, PPI) the mainstay of treatment.
- In patients with symptoms despite acid suppression, the culprit in more than 80% cases is non-acid reflux (pH>4).
- Three types of refluxes have been defined based on pH:
  - Acid reflux—pH<4
  - Weakly acidic reflux—pH 4–7
  - Weakly alkaline reflux—pH>7
- The proposed mechanisms are:
  - Duodenogastric-esophageal reflux—Regurgitation of duodenal contents, containing biliary and pancreatic secretions into stomach and esophagus.
  - Large volume of refluxate triggering symptoms irrespective of its acidity by mechanical stimulation of esophagus.
  - Greater proximal esophageal extent of reflux resulting in increased likelihood of symptoms.

Clinical Features

- GERD symptoms can be classified into typical and atypical:[3]

Typical symptoms	*Atypical symptoms*	
• Heartburn • Regurgitation • Water brash	• Nausea, vomiting • Belching • Early satiety • Epigastric pain • Hoarseness • Globus sensation • Dental enamel loss	• Chest pain • Nocturnal awakening • Chronic cough • Asthma • Chronic sinusitis • Recurrent sore throat

- Atypical extraesophageal symptoms lead to difficult and delayed diagnosis.
- They have poor response to conventional therapy.

Diagnosis[3,5-8]

The initial diagnosis is usually made on the basis of cardinal symptoms and response to PPI therapy.

In presence of atypical symptoms, it is important to rule out other gastrointestinal disorders (e.g., ulcers, malignancy) and non-gastrointestinal diseases (e.g., ischemic heart disease).

PPI Diagnostic Test

- Patients with typical symptoms can be put on PPI therapy and followed up to 8 weeks.
- Almost 20–40% patients continue to be symptomatic even on adequate PPI treatment.
- The patients with inadequate response and those with alarm symptoms need further evaluation.

Alarm features	
Dysphagia	Early satiety
Odynophagia	Vomiting
Gastrointestinal bleeding	Age > 55 years
Weight loss	Family history of upper GI malignancy
Iron deficiency anemia	

Upper Gastrointestinal (UGI) Endoscopy

- UGI endoscopy should be done in all patients with
  - Alarm features
  - Suboptimal response to PPI therapy.

  - Long standing GERD, endoscopy is necessary to assess for complications.
- Erosive esophagitis should be graded on the basis of endoscopy findings as follows:

Los Angeles classification of erosive esophagitis[3]	
Grade A	One or more mucosal breaks, ≤5 mm, none of which extends between the tops of the mucosal folds
Grade B	One or more mucosal breaks, >5 mm long, none of which extends between the tops of two mucosal folds
Grade C	Mucosal breaks that extend between the tops of two or more mucosal folds, but which involve <75% of the esophageal circumference
Grade D	Mucosal breaks that involve at least 75% of the esophageal circumference

- Endoscopy guided biopsy is indicated in patients where eosinophilic esophagitis is suspected and in those with Barrett's esophagus.

Ambulatory 24-hour pH Monitoring

- It is the gold standard for diagnosis of GERD
- It is used to quantify:
  - Esophageal acid exposure time (EAT)
  - Number of reflux events (events when pH decreases to <4)
  - Nature of refluxate (acidic/neutral/alkaline)
- An EAT of more than 6% and a total of more than 80 reflux episodes in 24 hours are considered abnormal.
- Normally carried out for 24 hours, the test can be extended up to 96 hours using Bravo esophageal pH recorder capsule.
- It is done:
  - *Off PPI:*
    In patients with unproven GERD (no or LA grade A/B esophagitis)
    Before surgery
    Atypical presentations
  - *On PPI:*
    In proven GERD (LA grade C/D esophagitis) or BE > 1 cm or prior abnormal pH study
    To establish causation of refractory symptoms

Esophageal Manometry

- It does not help in diagnosis of GERD
- It is used to localize LES before placement of capsule in 24-hour pH metry.
- It helps to diagnose motor disorders like achalasia.

Barium Esophagogram

- It has no role in diagnosing GERD
- It helps in detecting achalasia, esophageal stricture, or hiatus hernia.

EndoFLIP (Endoscopic Functional Luminal Imaging Probe) System

- It assesses the distensibility of esophageal body and GE junction at various volume-controlled (usually 20–30 mL) distending pressures
- GERD patients seem to have increased GE junction distensibility
- FLIP can also identify esophageal motility disorders
- It serves as a useful tool in anti-reflux procedures

Multichannel Intraluminal Impedance Monitoring

- To diagnose non-acid reflux, pH monitoring is not quite helpful as it uses acidity as marker of reflux but not the actual reflux.
- Multichannel intraluminal impedance monitoring combined with pH monitoring can reliably identify non-acid reflux.
- The technique uses changes in resistance to electrical currents to detect the presence of intraluminal liquid.

Treatment[3,7]

Lifestyle Modifications

In patients with uncomplicated GERD, the initial step of management is lifestyle modifications which include:

- Elevation of head end of bed by 4–8 inches
- Dietary changes
  - Avoiding fatty, spicy, large meals
  - Avoiding late evening snacks
  - Avoiding chocolate, citrus foods, caffeine, carbonated drinks
- Minimizing smoking and alcohol
- Weight reduction
- Avoid NSAIDs

Medical Management

This comprises of acid-neutralizing (antacids) and acid-suppressing (H2RA, PPI) agents.

- *Antacids:*
  - Mostly used for occasional or short-term symptoms

  - Include sodium, calcium, aluminum, magnesium salts, and alginate containing agents
- *Histamine type-2 receptor antagonists (H2RA):*
  - Better efficacy and prolonged action than antacids
  - However, tachyphylaxis (usually within 2 weeks) is an issue
  - Should not be given at same time as PPI
  - Currently, there are four FDA-approved H2RAs: cimetidine, famotidine, nizatidine, and ranitidine
  - Lavoltidine and lafutidine are under trial
- *Proton pump inhibitors:*
  - Most potent and hence, the mainstay of treatment
  - PPIs have a better, faster, and long-lasting effect in both NERD and EE
  - Most effective when taken 30 minutes before meals

Acid suppression can be achieved in the following three ways:

- *Step-up therapy:*
  - Starting with less potent agent and moving up for response
  - Patient is first started on H2RA
  - If no response is seen for 2 weeks, patient is shifted to PPI followed by double dose of PPI
- *Step-down therapy:*
  - Patient is started with twice daily dose of PPI
  - When response is achieved, he is switched to once daily dose followed by on-demand dose
- *On-demand therapy:*
  - Here patient is given standard dosage of H2RA or PPI as and when needed

Side Effects of PPI

- The efficacy and ease of availability of PPI has led to its misuse
- Patients either self-treat themselves or once prescribed, continue them for prolonged periods without re-evaluation
- This leads to excessive cost of therapy as well as adverse effects
- Most of the side effects are mild and self-limiting like headache, nausea, abdominal pain, and flatulence
- Recent studies, however, reveal association of PPI with some serious adverse effects

Side effects of PPIs	
Pneumonia	Vitamin B_{12} deficiency
C. difficile diarrhea	Iron deficiency
Risk of fractures	Thrombocytopenia
Hypomagnesemia	Rhabdomyolysis
Acute interstitial nephritis	Enteric infections and neoplasms

Refractory GERD[9,10]

Refractory heartburn is defined as symptoms of reflux of gastric content that do not respond to a double dose of a PPI given for at least 8 weeks.

Functional heartburn and reflux hyper-sensitivity are the most common underlying mechanisms. Other less common mechanisms include psychological factors, functional bowel disorders, delayed gastric emptying, bile reflux, rapid PPI metabolism, PPI resistance or improper PPI timing.

Every patient with refractory GERD should also be evaluated for Eosinophilic esophagitis (EoE), achalasia and Zollinger-Ellison syndrome.

The management of refractory GERD includes:

- Optimization of PPI therapy
  - Lifestyle modifications
  - Better compliance
  - Proper dosing time
  - Splitting the dose
  - Shifting to another PPI
- Adding a night-time H2 receptor antagonist.
- Baclofen- A gamma-aminobutyric acid-B agonist (5-20 mg three times a day) reduces gastroesophageal reflux by decreasing TLESR rate.
- Neuro-modulators (like tricyclic-antidepressants, selective serotonin-reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors and trazodone) are effective in patients with functional heartburn or reflux hypersensitivity.
- Endoscopic treatment
- Antireflux surgery.

Recent Developments in Medical Management[11]

- *Extended-release PPIs:* In order to increase their potency, PPIs have been modified into enantiomers that undergo slower hepatic metabolism and maximum absorption and thus increased bioavailability.
  - Dexlansoprazole MR:

    - Dual delayed-release formulation of dexlansoprazole (R-enantiomer of lansoprazole)
    - Two peaks of drug release; at 1–2 hours and at 4–5 hours
    - Can be given irrespective of meal timings
  - Tenatoprazole and S-Tenatoprazole:
    - Contain an imidazopyridine molecule (not a benzimidazole molecule like other PPIs)
    - Offer better night-time control, due to prolonged half-life
  - Esomeprazole strontium delayed-release (Esomezol)
  - Ilaprazole
- *PPI combinations:*
  - *PPI-VB101 (Vecam):* Combination of omeprazole and succinic acid that increases activation of proton-pumps in parietal cells
  - *OX-17:* Omeprazole plus famotidine
  - *NMI-826:* Nitric-oxide-enhanced PPI
  - *Secretol:* Omeprazole plus lansoprazole
- *Potassium-competitive acid blockers (P-CABs):*
- Act by reversibly inhibiting gastric H^+/K^+-ATPase by competing with K^+
- Do not need prior proton pump activation
- Have a faster onset of action; hence, useful as on-demand therapy
- Linaprazan, Soraprazan, Revaprazan, and TAK-438 are P-CABs under trials
- Associated with side effects like hepatotoxicity.
- *TLESR reducers:*
- *Cannabinoid Receptor-agonists:* Delta-9-tetrahydrocannabinol (CB1/CB2 receptor agonist), Rimonabant (CB1 receptor antagonist)
- *Cholecystokinin/Gastrin Receptors-antagonist:* Itriglumide, Loxiglumide
- *GABA-B agonists:* Baclofen, Lesogaberan

Endoscopic Management

- Endoluminal procedures offer a less invasive means of treating GERD
- Patients suitable for endotherapy are those with:
  - Typical symptoms of GERD
  - Low-grade EE (Los Angeles Grades A and B)
  - Endoscopy negative with abnormal esophageal acid exposure
  - No or small hiatal hernia (<3 cm)
  - At least a partial response to PPI treatment
  - Preference for nonmedical, nonsurgical therapy
- Contraindications:
  - Morbid obesity
  - Esophageal motility disorder (e.g., achalasia, scleroderma)
  - Prior esophageal/gastric surgery
  - Esophageal stricture or Barrett esophagus
  - Esophageal/gastric varices
  - Pregnant/lactating women
- Basic techniques of endotherapy:
  - Constriction of LES by using thermal energy
  - Augmenting LES pressure by injecting bulking agent
  - Mechanical alteration of gastroesophageal junction (GEJ)
- Currently, three endoluminal methods are in practice:[12]
  - *Stretta procedure:*
    - Here, compliance of LES is reduced by using radiofrequency ablation
    - This decreases frequency of TLESRs and hence, reflux
  - *Transoral incisionless fundoplication (TIF):*
    - Here using the Esophyx Z device, an anterior full thickness fundoplication is done
    - This constructs a valve 3–5 cm in length and greater than 270 degrees circumferential wrap around LES
- *Ultrasonic surgical endostapler*
  - This technique makes use of a modified endoscope that incorporates a miniature camera, an ultrasound probe, and a stapler on its tip
  - With the use of this endoscope, an anterior full-thickness fundoplication is done
- Endoscopic procedures still under development are:
  - Anti-reflux mucosectomy
  - Endoscopic full thickness plication
  - Submucosal injection of a biocompatible substance

Surgical Management[3,7]

- The anti-reflux surgery is said to have only marginal long-term benefit over PPI therapy
- Patients with typical symptoms respond better to surgery than those with atypical or extra-esophageal symptoms

- Approximately half of the patients will still need anti-reflux medications, post-surgery
- Further, postoperative complications like solid food dysphagia, diarrhea, and early satiety have been reported in 7–10% patients
- Surgery does not prevent progression to adeno-carcinoma
- Patients who will be benefitted the most from surgery are those with:
  - No response, non-compliance or intolerance to medical therapy
  - Complications like refractory esophagitis, stricture, and BE
  - Large hiatus hernia (>5 cm)
  - Documented acid reflux with defective anti-reflux barrier
  - Cardiac dysfunction
  - Normal gastric emptying and esophageal motility
- *Linx™ reflux management system:*[13]
  - This device is in the form of a ring made by series of titanium beads with a magnetic core connected with titanium wires
  - This ring is placed, laparoscopically, around the lower end of distal esophagus
  - It prevents reflux by augmenting LES
  - Short-term studies are promising with more than 90% patients reporting improvement in quality of life
  - However, dysphagia was seen in 68% patients

Conclusion

GERD is a common gastrointestinal disorder with significant impact on quality of life. PPIs, though mainstay of treatment, have got serious long-term side-effects and are less promising in patients with non-acid reflux and extra-esophageal manifestations. There may be a rise in patient's interest in anti-reflux surgery and endoluminal therapy in future; thus, highlighting the need to explore beyond the conventional therapy.

CHAPTER

145 Post-Infectious Irritable Bowel Syndrome

BK Tripathi

Abstract

Post-infectious irritable bowel syndrome (PI-IBS), a subclass of IBS, where this clinical entity has been linked with occurrence of various gastrointestinal infections, bacterial, protozoal, viral, etc. Studies have clearly shown its occurrence in different ethnicity and every part of the world. As it starts after an episode of GI infection, a few studies throw some light toward its mechanism. Its pathophysiology, clinical features, prognosis, and possible treatment have been discussed here.

Introduction

Many patients of IBS, on being enquired, when did their symptom begin, will struggle to give a correct date. But some occasional patients would come out with an answer, suggest a specific date, saying I was fine until.....Such patients who connect onset of their symptoms to an episode of disorder infectious gastroenteritis, appear to be a little different from others. This subset of patients may be labeled as post-infectious irritable bowel syndrome (PI-IBS). However, most patients of PI-IBS cannot recognize their illness by the past events because either they do not remember or they do not give much importance to any such episode. The clinical syndrome, PI-IBS, denotes persistence of abdominal discomfort, bloating, and constipation diarrhea, which continue despite absence of inciting pathogens. A met analysis in the past concluded that the risk of developing PI-IBS increases sixfold after GI infection and remains elevated for next 1–3 years.[1]

Epidemiology

A link between enteric infection and IBS dates back to the Second World War when numerous cases of GI discomfort were seen in British troupes that had earlier suffered from enteric infection. Since then a number of studies in various parts of the world have reported such illnesses. The incidence or prevalence of PI-IBS, 5–32%, in such studies tell us that it is a global phenomenon and not related to a particular ethnic group or environment **(Box 1)**.[2,3] The wide variation in this reported incidence or prevalence may be because of differences in study methodology, inclusion criteria, definition of IBS, etc. **Table 1** describes the prevalence of PI-IBS in some of these countries.[4] The prevalence rate of PI-IBS (11.5%) does not vary much, if we take into account the post-infection period, that is, 3, 6, 12, 13–59, or more than 60 months.[5] But initial infective organisms matter and overall, the rate

BOX 1 Factors involved in PI-IBS

- Genetic susceptibility
- Intestinal inflammation
- Intestinal permeability
- Altered visceral sensitivity
- Severity of infection
- Psychiatric disturbances
- Pathogens involved
- Host factors

TABLE 1 Prevalence of PI-IBS in different areas

Canada	14.9%
US	17.6%
Norway	54.3%
UK	14.9%
Denmark	20.9%
Germany	45.8%
France	4.5%
Italy	4.5–24.0%
Spain	11.4%
Bangladesh	16.5%

of PI-IBS was the highest after protozoa/parasitic infective enteritis, followed by bacterial and the lowest rates were seen with viral infection.[6]

Pathophysiology

IBS is a disease where diagnosis is based on clinical criteria in absence of any organic changes. Though gut mucosa of patients of IBS are endoscopically normal, recently complex alteration in digestive mucosa has been identified in PI-IBS patients. These changes mainly alter the integrity of intestinal epithelial barrier. It results in paracellular permeability, which can encourage exposure and migration of microflora or food borne antigens. This in turn stimulates intestinal mucosal immunity, leading to persistent intestinal microinflammation. The possibility of inflammatory state of intestinal mucosa is substantiated by the occurrence of infiltration of T lymphocytes, mast cells, and enterochromaffin cells. These cells are responsible for release of cytokines and mediators of inflammation. In one study, increased intestinal permeability was associated with increased stool frequency and was proved by demonstrating increased lactulose-mannitol fractional excretion ratio in patients, 2 years after a water borne outbreak of gastroenteritis involving *Campylobacter jejuni* and *Escherichia coli*.[7,8] These changes suggest a pathophysiological model of PI-IBS and genesis of symptoms of IBS, where symptoms start after a bout of infection rather than its absence. An increased number of mast cells in rectal mucosa and mucosal cellularity were significantly higher in patients of PI-IBS as compared to patients of IBS, a fact confirmed by rectal-sigmoid and ileal mucosal biopsy.

Risk Facors for Development of PI-IBS

Female sex is associated with 2.2 times higher risk. Smoking is not considered a risk factor. Prevalent anxiety and depression at the time of infective enteritis is associated with PI-IBS development more often. Similarly, somatization and neuroticism, at the time of infection, are risk factors.[6,9] Host immune status of elderly persons protects against infection and thus lowers risk of its development.[2]

The nature of pathogen too influences the risk of developing IBS, post infection. The hazard ratio is 4.3 for *E. coli*, 2.9 for *C. jeuni*, 2.5 for Salmonella spp, and 2.2 for viral gastroenteritis. The mechanism of low-hazard ratio for viral etiology is poorly understood. It is possible that viral enteritis is associated with less mucosal damage and poor structural and immunological alteration.[10] However, the high incidence of PI-IBS after an attack of protozoal enteritis (Giardiasis) merits attention as it shows the prevalence much higher, i.e. 39–89%.[11]

Clinical Features

The diagnosis of IBS is always symptom based and is mostly challenging. Similarly, there are no definite diagnostic criteria for post-infectious IBS. The element of "new onset IBS after an episode of acute gastroenteritis in patients who never had IBS previously" should always be given significance. There is strong relation between traveler's diarrhea (TD) and PI-IBS. Self reported TD was associated more often than laboratory confirmed TD (1.5-fold rise in RR).

There might be some subtle differences in PI-IBS from IBS, which has greater stool frequency and loose stools as compared to IBS. All different subtypes of IBS are recognized, and the frequency is IBS-mixed, 46%, IBS diarrhea, 39%, and IBS constipation, 15% in some studies.[12,13] Emphasis should be laid before making a diagnosis of PI-IBS to exclude alarm signs and checking for preliminary investigations, that is, CBC, ESR, CRP, stool culture, etc. in one study, PI-IBS was found to be associated with post-infectious malabsorption syndrome (PI-MAS), popularly known as tropical sprue.[14] Small

intestinal bacterial overgrowth (SIBO) has been linked with IBS, particularly IBD-D type.

Other similar conditions like acquired lactase deficiency following gastroenteritis, bile acid malabsorption, inflammatory bowel disease, or lymphocytic colitis should always be taken into account as differential diagnosis.

Prognosis

PI-IBS too lasts for a long time. In one study, the rate of spontaneous remission was 27% in a year. The proportion of patients who improved (as assessed by ROME III criteria) varied across the age group (23% in younger population of 21–30 years and 37.5% in older population if more than 70 years (p=0.18). Other factors responsible for poor recovery are female sex, patients from North America and Europe, and those with history of somatization.[12] Patients with longer history of IBS symptoms exhibited poor recovery. Despite different pathogenesis, surprisingly, prognosis in PI-IBS does not differ much from non PI-IBS with recovery of one in four patients in first year. Still, it is very encouraging to learn that over half of patients of PI-IBS return to their preinfection state. However, it may take years for symptoms to disappear completely.

Treatment

It is legitimate to think that traditional approach of treatment aiming only at attenuating symptoms, must give place to addressing new pathological targets (intestinal permeability, microinflammation, mast cells, serotonin, visceral hypersensitivity, etc.) However, approaches to tackle such anomalies have not met with much success. In a small study, treatment with prednisolone, in PI-IBS, on presumption of immunological genesis has not shown any benefit.[15] Another RCT of an anti-inflammatory agent, mesalazine, showed overall no benefit in IBS patients with IBS with diarrhea, but a post hoc subgroup analysis did suggest some response in PI-IBS.[16] Furthermore, treatment with *E. coli* 0147 infection with mesalazine appeared to reduce the risk of developing PI-IBS.[17] Increased 5HT available in small intestine in PI-IBS patients enhances visceral hypersensitivity which can be blocked by 5HT receptor antagonist, ondansetron. This theory encouraged randomized trial of ondansetron in IBS with diarrhea, which showed relief of symptoms, particularly urgency.[18]

SIBO is seen in rats of PI-IBS after campylobacter infection. A recent study in India suggested that PI-IBS might overlap with tropical sprue in which SIBO is common.[14] Rifaximin is a locally acting antibiotic, which targets SIBO, has shown benefit in IBS-D patients. Bile salt malabsorption may develop following acute gastroenteritis. Several studies have demonstrated that PI-IBS can respond to cholecystokinin. However, intolerance to this drug discourages its use.[19]

Despite all these novel and experimental therapies, treatment of PI-IBS is frequently symptom directed and matches closely with treatment of IBS. **Table 2** summarizes measures, which help treating patients of PI-IBS.

TABLE 2 Major classes of drugs in IBS management

IBS symptom	*Drugs in therapy*
Abdominal pain	• Antispasmodics
Diarrhea	• Loperamide^ • Diphenoxylate^ • Cholestyramine^ • Probiotics^
Constipation	• Bulking agents • Polyethylene glycol • Osmotic or stimulating laxatives^ • Prucalopride^ • Lubiprostone^ • SSRIs^ • Probiotics^
Bloating/abdominal distension/meteorism/ flatulence	• Probiotics^ • Rifaximin^

^Recommended in a few patients based on individual clinical profile
SSRIs, selective serotonin reuptake inhibitors.
Source: Adapted from Tripathi BK, Soni A. Irritable bowel syndrome in patient management. In: Arulrhaj S (Ed). Medicine Update. New Delhi: Jaypee Brothers Medical Publishers; 2020. pp. 633-7.

Diet

Many patients describe a chronological link between onset and worsening of symptoms with a particular food. However, in majority of patients there is no compelling data to recommend an exclusion diet. The knowledge of enhanced intestinal permeability may suggest food allergy on the premise of penetration of food antigens and their contact with immunocompetent cells. Possible exclusion of such items by patients may be helpful rarely.[20] A low fiber diet with soluble fiber will help to some extent. The consumption of poorly absorbed fermentable oligo-, di-, mono-saccharide and polyols (FODMAPs) may be a trigger for symptoms too. FODMAPs and insoluble

TABLE 3 FODMAP (high and low dietary sources)

	High FODMAP foods	*Low FODMAP foods*
Vegetables	Asparagus, onions, garlic, sugar, peas, beetroot, cabbage, cauliflower, celery, sweet corn, and mushrooms	Alfalfa, bean sprouts, green beans, capsicum, carrot, fresh herbs, cucumber, lettuce, tomato, and zucchini
Fruits	Apples, apricots, figs, pears, mango, watermelon, peaches, and plums	Banana, blueberries, strawberries, cherries, kiwi, orange, grapes, and melon
Grains	Rye, wheat containing breads, wheat-based cereals with dried fruit, wheat pasta, and barley	Gluten-free bread, oats, gluten-free pasta, rice, and quinoa
Meat		Meats, fish, and chicken
Dairy	Cow's milk, custard, and ice cream	Lactose-free milk and yoghurt
Alternatives	Legumes/pulses, cashews, and pistachios	Tofu, almonds (<10 nuts) and pumpkin seeds

Source: Adapted from Tripathi BK, Soni A. Irritable bowel syndrome in patient management. In: Arulrhaj S (Ed). Medicine Update. New Delhi: Jaypee Brothers Medical Publishers; 2020. pp. 633-7.

fibers may enhance osmotic pressure in large intestine and provide a substrate for bacterial fermentation. Low FODMAPs can change intestinal microbiota and reduce IBS symptoms **(Table 3)**. More so, different gastrointestinal cell types that produce hormones, which regulate appetite and food intake, show dysfunction too. This, in turn, increase food intake and weight gain. Though, linkage of IBS and obesity is poorly understood, low FODMAPs and insoluble fibers, probiotics, and regular exercise are to be recommended.[21]

Probiotics and Fecal Microbial Transplantation

A number of probiotics are tested in IBS. The results are encouraging, particularly in relieving excessive flatulence. In fact, administration of probiotics during an attack of acute gastroenteritis of bacterial origin has a protective effect on intestinal epithelial barrier. The role of probiotics is seen in animal model of PI-IBS in a favorable manner. Fecal microbial transplantation (FMT) may be, probably, more beneficial as human feces is the ultimate human probiotic. A number of studies have proved its beneficial role in diseases like IBS, IBD, chronic constipation, etc. In one study role of FMT was studied in recurrent *Clostridium difficile* infection (CDI) by Mattila et al.[22] In this study, symptoms resolved in all patients who did not have strain 027 CDI during the first three months Out of 36 patients who had 027 infection, 32 (89.7%) had a favorable response. Unfortunately rest four patients had history of long standing diarrheal disease with comorbidities did not improve and died. However, no human trial of FMT is available in PI-IBS but success in other areas offers legitimacy for using this therapy and conducting a large trial.

Conclusion

Post-infectious IBS represents a frequently occurring new clinical entity which has led to better understanding of the factors involved in pathophysiology of IBS. ROME IV recognizes post-infectious IBS, a multidimensional clinical chronic inflammation triggered by enteric infection. Present literature on IBS is very descriptive and large randomized trials are lacking. Future research is needed to establish a link between hosts and microbes in which participants are subdivided according to underlying mechanisms. The response of each subgroup will provide new tools for prevention and management.

CHAPTER

146 Management of Hypertension in Chronic Kidney Disease

Mritunjay Kumar Singh

Abstract

The relationship between hypertension and chronic kidney disease is phenomenal hypertension (HTN) which is considered as most important modifiable risk factor for chronic kidney disease (CKD). Personalized and individualized HTN therapy using standardized office BP and home BP monitoring hold great promise. Angiotensin converting enzyme inhibitor (ACEI) or angiotensin receptor blocker (ARB), Calcium channel blocker (CCB), appropriate diuretic therapy, dietary salt restriction, and ensuring proper adherence to therapy make up the foundation for the treatment of HTN in CKD.

Introduction

Studies from India and abroad have provided concordant data on high prevalence of chronic kidney disease (CKD) worldwide. Up to 1 in 10 people world wide has CKD. It is a silent killer like other metabolic diseases and engages major human and economical resources. Association of CKD and hypertension (HTN) is bidirectional. There is a cause and effect relationship between them. HTN is considered as most important modifiable risk factor for CKD. Managing HTN effectively not only retards the progression of CKD, but also reduces the cardiovascular risk significantly.

Pathophysiology of HTN in CKD[1-3]

Pathophysiology of HTN in CKD is multifactorial. It contains components of neural and hormonal pathways. The important mechanisms include:

- Impaired sodium excretion—Guyton and his team have shown that HTN can be generated in partially nephrectomized dog (renal mass reduced to 30%) with salt loading.[4] The elevated blood pressure (BP) in this setting is induced by increased cardiac output (volume expansion) initially, and later on sustained by increased peripheral resistance which is due to autoregulatory peripheral vascular bed vasoconstriction in response to increase peripheral perfusion due to extracellular volume expansion. So sodium retention can induce HTN in two ways—at first by volume dependent mechanism (extracellular fluid expansion) and later on mainly through volume independent mechanism like increased peripheral vascular resistance.
- Increased rennin angiotensin aldosterone activity (RAAS)—Hypersecretion of rennin in a sclerosed kidney leads to increased angiotensin II and RAAS activity leading to increased systemic vascular resistance, sodium retention, and high BP.
- Increased activity of systemic nervous system (SNS)—The kidney is richly innervated sensory organ. Several studies from animal and human subjects establish the kidney-brain axis theory. Sensory inputs from kidney transmitted to central nervous system in turn lead to increased activity of SNS leading to vasoconstriction, rennin secretion, sodium retention, and HTN.
- Endothelin dysfunction—CKD is a chronic low-grade inflammatory state and so endothelial dysfunctions are commonly observed in CKD. Endothelial dysfunction leads to impaired nitrous oxide production and

increased endothelin level leading to increased peripheral vasoconstriction and HTN.

- Vascular stiffness—The distensibility of resistance arteries is affected by certain functional and morphological changes. It includes intimae hyperplasia, medial calcification, smooth muscle cell hyperplasia, and endothelial dysfunction. These changes are largely contributed by disturbed calcium-phosphorus balance, secondary hyperparathyroidism and other neurohumoral components discussed above. Vascular stiffness leads to increased systolic BP and wide pulse pressure, which is a strong predictor of cardiovascular mortality in CKD.
- The erythropoietin induced HTN and obstructive sleep apnea (OSA) are important causes of HTN in CKD, especially in dialysis population. The erythropoietin or erythropoietin-stimulating agents used for treatment of anemia in CKD can induce HTN or require change in antihypertensive regimen in approximately 30% of the cases. Besides rapid and over correction of anemia, HTN in this subset is thought to be caused by vasoconstrictor effect of erythropoietin, which is independent of hemoglobin.[5] OSA is common in advanced CKD population. Chronic intermittent nocturnal hypoxemia provoke sympathetic nervous system activity, RAAS activity, and increases nocturnal BP.
- Medications like over-the-counter nonsteroidal anti-inflammatory drugs, herbal supplements, steroids, and decongestants can provoke HTN in the CKD population.
- The worsening of HTN has been reported in CKD patients with the use of potent anti-tuberculosis drug rifampicin. Rifampicin is a potent enzyme inducer and decreases the level of commonly used antihypertensive drugs—amlodipine, metoprolol, and prazosin. So it is advisable to monitor HTN in CKD patients, once they have been put on rifampicin.[6]
- The HTN is the most common complication of CKD as well as major factor responsible for progression of CKD. Renal autoregulatory mechanism protects renal vasculatures from elevated BP. Maintenance of afferent arteriole tone in response to elevated systemic pressure and increased sodium chloride delivery to macula densa are part of this autoregulatory mechanism. However, it is impaired in patients with diabetes and non-diabetics CKD, thus leads to progressive renal damage with even moderate elevation of BP.

Measurement of BP in CKD[3,7-9]

The proper BP measurement is the first step toward the effective BP management in CKD. BP measurement can vary depending on the setting (e.g., casual office, standardized office, or home) and type of device used (e.g., aneroid or Oscillometric). Standardized office BP (SOBP) is 5–10 mm Hg lower than casual office BP. Most of the recent trials on optimum BP goals have used SOBP as a method of measurement. For standardized office BP measurement certain preparations are required—(e.g., 5 minutes of quite rest/no nicotine, caffeine, and exercise 30 minutes prior to measurement/well validated and periodically calibrated device/correct cuff size/middle of the cuff should be placed at the level of right atrium/average of more than two readings obtained on two occasions) as laid down by 2017 ACC/AHA high BP guidelines.

The out of office BP measurement (ambulatory BP and home BP monitoring) is required to diagnose white coat HTN (defined as elevated office BP with controlled out of office BP, prevalence in CKD ranges from 2% to 41%) and masked HTN (defined as controlled office BP and elevated out of office BP, prevalence in CKD ranges from 6% to 51%). Additionally 24 hour ambulatory BP gives clue about the nocturnal BP. Physiological nocturnal dipping is absent in 14–75% of the CKD population. Thus in CKD out of office BP accurately define the clinical problem and predicts more accurately about the cardiovascular and renal outcomes than office BP.

KDOQI (kidney disease outcome quality initiative) US commentary on the 2017 ACC/AHA HTN guideline commented that home BP monitoring can accurately predict target organ damage and better placed than ambulatory BP monitoring and office BP monitoring. HBPM can also help to overcome the therapeutic inertia.

In our limited resource setting we should prefer standardized office BP, because it requires nothing but our little patience (pre-measurement preparation as mentioned above).

Target BP in CKD[2,3,10-14]

The management of HTN in CKD is a dynamic process, as estimated glomerular filtration rate, comorbidities

and risk changes with time. Due to presence of vascular stiffness and wide pulse pressure in CKD, achieving a BP target rapidly may lead to postural hypotension. So a cautious and gradual approach is required to reach a desired BP target.

From 1994 till 2010, there were four landmark trials compared the standard versus intensive BP control in patients with CKD. These were:

- MDRD (modification of diet in renal disease), year 1994
- AASK (Africans American study of kidney disease and hypertension), year 2002
- REIN-2 (Ramipril efficacy in nephropathy-2), year 2005
- ACCORD (Action to control cardiovascular risk in diabetes), year 2010

Results of all these trials favored standard BP control rather than intensive control in most of the CKD patients, exceptions are patients with proteinuria more than 1 g/day, which were benefited from intensive control of BP. On the basis of these trials, KDIGO (kidney disease initiative global outcome) 2012 suggested a lower BP for significant proteinuria.

- Albuminuria (<30 mg/24 hr): ≤140/90 (1B)
- Albuminuria (>30 mg/24 hr): ≤130/80 (2D)

Till year 2015, it was thought that controlling BP to less than 140/90 mm Hg is likely to be beneficial in CKD population. But with the advent of SPRINT (systolic BP intervention trial) study in 2015, intensive control of systolic BP (<120 mm Hg) has gained momentum. SPRINT has included data from 9,361 adults age 50 or older with systolic BP of 130 mm Hg or higher and at least one additional cardiovascular disease risk factor. Around 28% of participants had CKD without significant proteinuria. The highlights of SPRINT study are:

- intensive reduction in SBP reduces cardiovascular events
- intensive reduction in SBP has mortality benefit in CKD population
- the subgroup analysis of older patients with CKD in SPRINT has also favorable outcome
- with adoption of SBP <120 mm Hg in all CKD population, separate BP target for proteinuria is not required

However, it should be noted that more than 50% of participants in intensive arm of SPRINT had not achieved SBP target after 1 year. So targeting and achieving a lower SBP is a big challenge. Additionally the benefit of lower BP is less certain in diabetic CKD and advanced CKD population. The 2017 American College of Cardiology (ACC) has adopted the result of SPRINT and suggested more intensive BP control in CKD population. In light of SPRINT and other newer studies KDIGO controversies conference 2017 has also suggested for revision in BP diagnosis threshold and BP treatment target.

In our setting, we should target lower BP:

- If SOBP/HBPM is the method used for measurement of BP
- If patient is tolerating the target BP well without postural hypotension or other adverse effect
- If patient is having non-diabetic CKD

Secondary HTN in CKD[3]

Secondary causes of HTN are potentially treatable and should be searched in following conditions:

- If the onset of elevated BP occurred before puberty and preceded the development of CKD.
- Severe or malignant HTN that is out of proportion to the degree of CKD is present.
- Acute worsening of BP control occurs in a previously hypertensive patient with good BP control, or resistant HTN is present.
- Persistent hypokalemia off diuretic treatment (primary aldosteronism).
- Development of tremor and palpitation (pheochromocytoma).
- Flash pulmonary edema (renal artery stenosis).

Non-pharmacological Therapy[1-3]

Early institution of non-pharmacological therapy in the form of dietary modification and life style modification is the first step to the treatment of HTN in CKD.

- Dietary salt restriction (sodium intake <1.5 g/day)—Reduce BP and proteinuria; potentiate the action of ACEI/ARB.
- DASH (Dietary approach to stop HTN) Diet—Diet rich in fruits and vegetables, low in saturated and unsaturated fat can lead to modest reduction in BP. But it is not appropriate to use DASH Diet in advanced CKD because of the potential for hyperkalemia.
- Modest physical activity of 150 minutes duration/week is useful for CKD population. It can be modified

depending on the cardiorespiratory fitness status and physical limitation of the individual.
- Other life style interventions include weight loss in obese people, limiting alcohol intake, and avoidance of over the counter medications such as non-steroidal anti-inflammatory drugs.

Choosing Antihypertensive Drugs in CKD[2,3,8,15]

Most of the CKD patients require multiple antihypertensives for adequate control of HTN. Certain classes of antihypertensives are preferred because of their renoprotective, cardioprotective, and diuretics actions apart from antihypertensive effects. Before choosing antihypertensive agents in CKD we should look for comorbidities, risk benefit ratio of individual drug, volume status, and age of the patient.

- Angiotensin converting enzyme inhibitors (ACEIs)/angiotensin receptor blockers (ARBs)—
  - ACEI/ARB are the agent of choice to treat HTN in diabetic CKD with severely increased proteinuria (>300 mg/day). But the superiority of ACEI/ARB over other agents (calcium channel blockers, diuretics) is questionable in non-proteinuric CKD. However, as majority of CKD patients require multiple agents to achieve adequate control of HTN, it is reasonable to include ACEI/ARB as add on therapy in non-proteinuric CKD patients.
  - The common side effect of ACEI/ARB is hyperkalemia particularly in advanced CKD hence limiting their use despite their proven benefit. Novel potassium binding agents (patiromer and sodium zirconium cyclosilicate) in combination with ACEI/ARB could change the way of pharmacotherapy in HTN in CKD. But further research is required before their routine clinical use.
  - Another potential problem with the use of ACEI/ARB is acute kidney injury. Recent guidelines suggest that up to 30% increase in serum creatinine in first few weeks and later on stabilization is an acceptable physiological change which confers long-term renoprotection.
  - Combination therapy (ACEI+ARB) has failed to show any cardioprotection and renoprotection in major studies. Additionally this combination is associated with increase risk of hyperkalemia, acute kidney injury, and hypotension.
- Calcium channel blockers (CCB)—dihydropyridine (DHP)-CCB (amlodipine) are frequently prescribed antihypertensives in CKD because:
  - they are the potent antihypertensive agents,
  - can work synergistically with ACEI/ARB,
  - work well in volume expanded states, and
  - minimal side effect (pedal edema).
- Diuretics—
  - Sodium retention and volume overload are the main concerns of the majority of CKD patients. Diuretics act by natriuresis (promote sodium excretion through kidney), thus reduce extracellular volume and has been shown to improve left ventricular mass index (LVMI) and arterial stiffness in CKD patients. Diuretics also enhance the BP lowering effect of ACEI/ARB. Thiazide diuretics (hydrochlorothiazides and chlorthalidone) are less effective at lower glomerular filtration rate so switching to loop diuretics (furosemide and torsemide) with frequent dosing is done in advanced CKD. Some times loop diuretics can be combined with thiazide diuretics to treat refractory edema in advanced CKD.
  - Diuretics should be avoided in end stage renal disease with no residual function and polycystic kidney disease as they can lead to accelerated cyst growth and decreased renal function. The major adverse effects of diuretics are volume depletion and electrolyte imbalance.
  - Mineralocorticoid receptor antagonists (MRA) are effective drugs for resistant HTN but may cause hyperkalemia in patients with low-estimated glomerular filtration rate, so better to avoid at estimated glomerular filtration rate below 45 mL/min/m^2.
- Beta blockers—
  - Although beta blockers has lost credential in treatment of primary HTN in general population, but still they are found to be useful adjunctive therapy in CKD population because they decrease sympathetic over activity and are cardioprotective. A recent trial named HDPAL (HTN in hemodialysis patients treated with atenolol or lisinopril) has concluded that atenolol arm has less cardiovascular

events and better BP control than lisinopril arm in hemodialysis patients.
  - Other antihypertensive agents for patients with CKD include direct vasodilator (minoxidil and hydralazine), centrally acting alpha adrenergic agonist (clonidine), alpha blockers (prazosin), and direct rennin inhibitors (aliskiren).
- Resistant and refractory HTN in CKD[1,3,16]—
  - The prevalence is up to 40% as shown in CRIC Study. It has got poor prognosis—increases the risk of death by 30% and the risk of heart failure by 59%. The selection of complementary medications and ensuring drug adherence often resolve treatment resistance. Thiazide and thiazide-like diuretics in combination with ACE/ARB or MRA can be very effective in treatment of CKD populations with apparent drug resistant HTN.

Adherence[2,9]

Adherence to therapy is poor due to frequent dosing of pills, pill burden, drug interaction, and adverse effects. Strategies to improve adherence include:
- Patients should be communicated regarding treatment and its importance.
- Use of combination pill and whenever possible long acting, once a day medication to be used.

Nocturnal Therapy[2,17,18]

Non-dipping is detected more frequently in later stages of CKD and associated with significant CV death. Multiple clinical trials have shown an improvement in nocturnal dipping of BP by dosing at least one antihypertensive medication at bedtime.

Management of HTN in Patients on Dialysis[2,3,19,20]

The relationship between BP and CVD in this group is more complex. There is U-shaped relationship between 24-hour ambulatory SBP and all cause mortality as noted by Mayer et al. So BP treatment should be individualized in this group keeping in mind of comorbid conditions. Besides pharmacotherapy, these are the novel measures to treat HTN in dialysis patients:
- Dry weight reduction (DRIP trial)
- Dietary sodium restriction
- Dialysate sodium restriction
- Adequate time on dialysis
- Consideration of frequent dialysis

Managing HTN Following Kidney Transplantation[1-3]

HTN is common in post-transplant period. It has been reported that HTN is prevalent in more than 90% of calcineurin inhibitors treated kidney transplant recipient. The higher BP is associated with poor graft survival, increased CVD risk, and most common cause of death post-transplant. KDIGO and the ACC/AHA guidelines currently recommend a BP target <130/80 mm Hg. Some useful tips to manage HTN following kidney transplants are:
- Weight control
- Steroid and CNI dose optimization
- During 1st year after transplant, CCB (DHP) is the preferred antihypertensive agent over ACEI/ARB
- In patient with mild graft dysfunction with proteinuria, ARB are the preferred drug
- In case of post-transplant hyperuricemia losartan is the preferred drug

Future Perspective[21-25]

In recent years, the underlying mechanism and unmet therapeutic needs to halt the progression of CKD and CVD have been better understood. Due to this few promising therapeutic measures have emerged. They are:
- *Sodium glucose transport 2 inhibitor (SGLT-2I):* Interest in molecules of this group has intensified following the result of EMPA-REG OUTCOME (Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients) and CREDENCE (Canagliflozin and Renal Outcomes in Type 2 Diabetes and Nephropathy) trials, which demonstrated significant slowing of CKD progression and a reduction in the composite outcome of death from CVD. Combining ACEI/ARB with SGLT2I may further reduce intraglomerular pressure by their synergistic effects.
- The DUET (Dual Endothelin Receptor and Angiotensin Receptor Blocker) trials with sparsentan and irbesartan have shown promising results in control of HTN and proteinuria in IgA nephropathy and focal segmental glomerulosclerosis (FSGS).

- *Renal denervation therapy (RDN):* After initial hiccups this radio frequency energy based therapy for ablation of the networks of nerves around renal arteries has shown promising results in newer trials. However, this strategy is still in experimental stage.

Conclusion

The Prevalence of HTN in CKD is very high, but HTN control rate is far from optimal. When CKD and HTN coexist, CV morbidity and mortality is substantially increased. Personalized and individualized HTN therapy using standardized office BP and home BP monitoring holds great promise. ACEI or ARB, CCB, appropriate diuretic therapy, dietary salt restriction, and ensuring proper adherence to therapy make up the foundation for the treatment of HTN in CKD.

CHAPTER

147 Prevention of Progression of CKD—What Is New?

Krishnaswamy Sampathkumar

Abstract

Chronic kidney disease (CKD) afflicts approximately 7–10% of adult population of India. It is a silent killer due to its far reaching ill effects on the cardiovascular system. The manifestations of CKD are varied and can mimic a variety of medical and surgical conditions. Early recognition is of paramount importance since preventive strategies are successful only if applied before irreversible renal fibrosis sets in. This article gives an overview of recent evidences. Dietary protein restriction should be applied to meat based diets and not for vegetable proteins. Plant-based protein intake has been shown to be renoprotective due to its alkaline nature and fiber content. RAS blocker therapy, and antihypertensive therapy are the inseparable duo of prevention. A dose escalating strategy of RAS blockade aiming for proteinuria reduction has been successfully applied in the Indian context. However, it requires close serum creatinine and potassium monitoring to prevent harm. Based on well conducted large trials, SGLT2-inhibitors have provided substantial benefits in terms of renal, cardiac, and all cause mortality. Their use is recommended for both diabetic and non-diabetic renal diseases. Sodium bicarbonate and statin usage have shown benefits. However, uric acid lowering therapy has failed to provide beneficial effects in recent trials.

Introduction

Chronic kidney disease (CKD) is a silent killer, which afflicts approximately 7–10% of world's adult population. It means that India which makes up 17% of world population carries a large burden of the disease.[1] It is commonly mistaken for a number of conditions such as nutritional anemia, nutritional rickets, peptic ulcer disease, dysfunctional uterine bleeding, etc. In the absence of a National Registry, the exact prevalence of the disease is open to conjecture. A population based study showed incidence of End Stage Renal Disease (ESRD) to be 159 per million population.[2] Once a patient reaches ESRD the treatment is not only prohibitively expensive but survival rates are worse than advanced malignancy. Thus every physician should update himself with current practice guidelines for optimal prevention of progression of CKD.

Contributors to Accelerated GFR Loss

The glomerular filtration rate (GFR) falls at a rate of approximately 0.5 mL/min/year in the normal adult population. Patients with progressive CKD the loss of GFR may be as steep as 5–15 mL/min/year. In addition to non-alterable factors such as age, gender, and genetics a number of factors which are potentially treatable contribute to the risk of progression. A recent work showed genetic polymorphisms involving intracellular antioxidant systems can accelerate the progression and mortality dramatically.[3] Dietary factors, lack of exercise, albuminuria, hypertension, hyperglycemia, lipids, morbid obesity, and metabolic acidosis, mini AKIs, and gut dysbiosis are some of the modifiable risk factors.

Lifestyle Modifications

Diet

Earlier view—Restricting all forms of proteins in the diet retards the progression of CKD.

Current view—Plant based proteins are renal friendly and should be promoted.

In a community-based study of adults without CKD, higher adherence to a healthy plant-based diet or a provegetarian diet was associated with lower CKD risk.[4] Higher consumption of healthy plant foods (fruits, vegetables, whole grains, nuts, legumes, coffee, tea) was associated with a lower risk and slower eGFR decline in GFR. Dietary red meat contains cardiotoxic metabolites from lecithin and carnitine such as trimethylamines. Plant-based proteins are recommended for a variety of reasons such as higher fiber content, lesser diet acid load, less phosphorus and uric acid generation, enhanced vitamin K (reduction of coronary calcium scores), and promotion of healthy gut microbiome. Dals, lentils, and Soya beans can be substituted for dietary animal proteins such as meat and dairy products. Daily intake of locally available fruits and vegetables are recommended in CKD Stages 3–4. Compensatory potassium excretion from the colon increases when dietary fiber intake is liberalized. Vegetable diet also inhibits the enzyme 11-beta-hydroxysteroid dehydrogenase type 2 in the distal convoluted tubule cells which increase the cortisol induced K excretion in addition to aldosterone effect.

Physical Exercise

Physical deconditioning sets in during progressive CKD, which results in muscle energy dysmetabolism. A reduction in mitochondrial activity develops even in earlier stages of CKD, which is progressive. Oxidative stress, inflammation, erythropoietin, vitamin D, and testosterone deficiencies are possible reasons. The symptoms include easy fatigability and proximal muscle weakness. Later, muscle atrophy sets in. As in general population, the cardiovascular benefits of exercise cannot be ignored in CKD patients. Regular moderate intensity exercises involving all the major core groups of muscles are recommended. Both endurance and weight bearing exercises are indicated in Stage 3 CKD.

Albuminuria

Earlier view—Albuminuria is a marker of severity of renal disease.

Current view—It is both a marker and maker of progression of renal disease.

Albuminuria is both a marker and maker of glomerular injury. A direct quantitative relationship exists between the higher proteinuric CKD and faster progression. Filtered albumin is taken up by the proximal convoluted tubule cells where it is toxic and inflammatory. Tubulointerstitial fibrosis sets in faster when the rates of proteinuria are higher. RAS blockers have shown to reduce proteinuria and prevent progression of renal disease. Highest tolerable doses of angiotensin receptor blockers (ARBs) and angiotensin converting enzyme (ACE) inhibitors are recommended to provide optimal renoprotection. Higher doses are accompanied by hyperkalemia. An important advance has been the clinical entry of New K binding agents like zirconium and patiromer, which permit continued and safe use of RAS blockade in the face of hyperkalemia. In the OPAL-HK study involving CKD patients with hyperkalemia, treatment with patiromer reduced the serum potassium levels and enabled significantly more patients to continue RAS blockers without interruption than placebo.[5] The drug was well tolerated.

Hypertension

Earlier target—BP reduction below 130/80.

Current view—More intensive BP reduction below 120–125/<80 in proteinuric CKD.

Long-term follow-up of 15 years in MDRD and AASK trials highlighted that intensive BP control reduced both overall mortality and progression to ESRD. The recently released SPRINT trial data showed that in CKD subgroup the all cause mortality was lower in the intensive arm.[6] However, the incidence of ESRD or a 50% decline in GFR was not altered in the intensive arm. However, a note of caution is that diastolic BP reduction below 70 mm Hg is not recommended in older adults with atheromatous central arteries, which can lead onto coronary insufficiency.

ARBs and ACE inhibitors are the preferred first-line agents. Maximally tolerated doses of these drugs should be given. As an example losartan is started on 50 mg OD and titrated up depending on proteinuria reduction and BP reduction to 50 mg BID. Supra pharmacological doses

can be prescribed with a close, watch on serum K and BP. The dose required to optimize GFR reduction was 150±88 mg/day in an Indian Study.[7] Though combinations of ACEi and ARBs are prohibited by most of the guidelines, individualization of therapy can result in better outcomes.

Since multiple drugs are required in CKD, calcium channel blockers, diuretics (Thiazides in Stage 3 and loop diuretics in Stage 4), are added in a stepwise fashion. Dietary sodium restriction to below 2–3 gm/day is an important adjunct to improve BP control. Due to concerns about hyperkalemia, there is reluctance to start spironolactone therapy in those with resistant hypertension. Recently published AMBER study showed that when patiromer is added to spironolactone more patients could continue the latter drug without developing hyperkalemia.[8]

Canrenone and Finerenone are novel non-steroidal aldosterone receptor antagonists with low risk of hyperkalemia. Current prospective trials are testing their efficacy and safety in CKD patients.

Glucose Control

Earlier view—Insulin therapy for Stage 3 CKD onward.

Recent view—SGLT2 inhibitors are strongly recommended to prevent progression of CKD and reduce cardiovascular morbidity and mortality.

CREDENCE trial on canagliflozin versus placebo on CKD patients has shown remarkable renal and cardiovascular benefits for patients with diabetic nephropathy.[9] All the patients had an estimated GFR of 30 to less than 90 mL/minute and albuminuria and were treated with renin-angiotensin system blockade. The primary outcome was a composite of end-stage kidney disease, or a doubling of the serum creatinine level, or death from renal or cardiovascular causes. Over a 2.6-year period, the relative risk of the primary outcome was 30% lower in the canagliflozin group than in the placebo group (hazard ratio, 0.70). The relative risk of the renal-specific composite of end-stage kidney disease, a doubling of the creatinine level, or death from renal causes was lower by 34% (hazard ratio, 0.66) and the relative risk of end-stage kidney disease was lower by 32% (hazard ratio, 0.68). Cardiovascular events were also significantly less in the treatment arm. Risk of amputations or fractures were not significantly elevated in the treatment arm. Sodium reabsorption is inhibited in the proximal convoluted tubule cells following SGLT2 inhibitor therapy. This results in more sodium ions reaching the DCT and thereby producing afferent arteriolar vasoconstriction. This ultimately results in renal preservation since intraglomerular pressure is lessened.

GLP1 analogs (liraglutide) have also shown both renal and cardiovascular benefits in trials. In the LEADER trial involving liraglutide new onset of persistent macroalbuminuria, occurred in significantly fewer participants in the liraglutide group than in the placebo group (hazard ratio, 0.74).[10] The reduction in GFR in the placebo arm was –5 mL/min/year, which reduced to –0.3 mL/min/year in the treatment group.

In contrast, DPP4 inhibitors have not shown reno- or cardioprotective benefits in trials. But they are still useful agents since the incidence of hypoglycemia is less, which enhances the acceptability of the drug in CKD population.

The recommended target HbA1C level for the prevention of progression of CKD is between 6.5–7%. However, in those with higher comorbidities who are prone for complications of hypoglycemia, one can opt for a compromised target of 7.5–8%.

Acidosis Correction

Recent view—Sodium bicarbonate therapy is nephroprotective.

The serum bicarbonate levels are ideally maintained above 22 meq/L in patients with CKD. Acidosis correction improves bone health and retards progression of renal disease. The latter is due to reduced ammonia generation, which is linked to inflammation by stimulation of alternate complement pathway. A condition called normobicarbonatemic acidosis develops in CKD, which is characterized by reduced urinary excretion of citrate.[11] This can be addressed by providing fruits and vegetables, which are a rich source of citrate.

Sodium bicarbonate is commonly given by oral route in tablet or capsule forms. Adult dose is between 1.5–2.5 gm/day depending on the degree of acidosis. Each gram contains 12 mEq of base. The potential side effects include gastic distension and metabolic alkalosis. Aggravation of hypertension is uncommon. It decreases the absorption of ranitidine and increases the propensity of quinolones for crystalluria. It is contraindicated in hypocalcemia and hypokalemia.

Management of Hyperlipidemia

Earlier view—Statin therapy is beneficial at the earlier stages of CKD. No new data have emerged recently.

Observational studies among apparently healthy individuals or in patients with preexisting cardiovascular disease (CVD) have shown a roughly linear relationship between risk of cardiovascular-related death and serum total and low-density lipoprotein (LDL) cholesterol. Among patients with CKD, however, this relationship is much less obvious. The cardiovascular abnormalities in Stage 4–5 CKD are progressive medial vessel wall calcification, left ventricular hypertrophy (LVH) and diastolic dysfunction. These are poorly responsive to statin therapy. There are no new evidences in the last decade in this field in the aftermath of SHARP trial, which showed a significant, 17% reduction in major atherosclerosis events and a 15% reduction in major cardiovascular events in the entire cohort of 9,000 patients. The earlier the statin therapy is initiated, the better were the cardiovascular protection benefits.

Prevention of AKI

Earlier view—Recovered AKI patients regain normal renal function.

Current view—Up to 30% of patients with comorbidities who develop AKI may progress to CKD.

In CKD patients multiple episodes of AKI are the cause of accelerated decline in GFR.

The downtrending of GFR slope from above 90 mL/min to 10 mL/min does not occur in a straight line if plotted against time. There are periods of flattening interspersed with periods of acute reduction. These "Mini AKIs" due to volume depletion, cardiac failure, UTI, hypotension, and NSAID drug toxicity result in incomplete recovery to original levels. It is critically important that these events are aggressively managed.

Intestinal Microbial Flora

Recent view—It is beneficial to alter the dysbiosis, which is prevalent in CKD patients.

Human gastrointestinal (GI) tract is home to trillions of bacteria, which undergo both a qualitative and quantitative alterations in CKD. Products of bacterial metabolism are linked to inflammation, uremic syndrome, and cardiovascular disease. Oral ingestion of probiotics has been shown to reduce the serum levels of products of protein metabolism like p-cresol and indoxyl sulfate, which induce cardiovascular toxicity.

Obesity

Earlier view—Weight loss should be routinely advised in CKD patients.

Recent view—Mildly overweight category of patients show best survival.

The association between body mass index (BMI) and mortality has shown some surprising findings. In a large observational study from US veterans found that best survival of Stage 3–4 CKD was seen in those with BMI between 25 and 35 kg/m^2. In morbidly obese patients, when bariatric surgery was undertaken, both proteinuria and GFR reduction are attenuated.[12]

Uric Acid

Earlier view—Treatment of hyperuricemia is reno-protective.

Recent view—Hyperuricemia correction does not result in renal benefits.

Uric acid produces inflammation and proliferation of afferent arterioles in mouse models of CKD. Extracellular precipitation in the form of microscopic crystals and macroscopic urate stones can cause structural damage. Intracellular mechanisms show its propensity to precipitate injury relating to its oxidative properties. Humans and other primates are prone to hyperuricemia because enzyme uricase was lost in evolutionary mutation. To lower uric acid levels, xanthine oxidase inhibitors (XOIs) such as allopurinol and febuxostat are commonly used in clinical arena.

Does Reduction of Uric Acid Produce Renal Benefits?

The short answer seems to be no. Based on many observational studies which reported that higher serum uric acid levels heightened the risk for new-onset CKD as well hastened its progression, a commonly held view was that a level above 7 mg% required intervention for renal benefits. However, two large, high-quality trials, which were published recently refuted a causal relationship and revealed that urate-lowering therapy neither prevents CKD nor slows down its progression.

PERL trial randomized over 500 adults with type 1 diabetes and early-to-moderate diabetic kidney disease, with allopurinol versus placebo. At 3 years treatment with allopurinol had no effect on the change in measured GFR compared with placebo; worryingly, allopurinol increased albuminuria, and nonsignificantly increased the rate of fatal or nonfatal cardiovascular events. In the CKD-FIX study of over 350 adults with more advanced CKD, the rate of decline of estimated GFR at 2 years was the same with allopurinol and placebo.

Anemia correction and correction of calcium phosphorus dysmetabolism have not been shown to have any effect on the progression of CKD, and hence they are not discussed at length. But they have to be addressed all the same since cardiovascular and skeletal health are inseparable sufferers from renal dysfunction.

Thus a multipronged strategy implemented with attention to minutiae will be needed. Though the task looks daunting, it is achievable if pursued with dedication as shown by Prof. M. K. Mani at Chennai.

Conclusion

CKD can be termed as An Orphan Disease since awareness levels are low even amongst the physicians. The four most effective strategies for its prevention are RAS Blockade, SGLT2 inhibitor therapy, Hypertension control, and Blood Glucose control. In the years to come personalized medicine looking at the genetic makeup of the patient may become an added tool to decide the therapeutic options.

CHAPTER

148 Lupus Nephritis—Current Understanding and Management

Krishan Lal Gupta, Joyita Bharati

Abstract

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease, and lupus nephritis (LN) is associated with increased morbidity and mortality. Kidney biopsy is essential and the "gold standard" for diagnosing LN. Extra-glomerular involvement is seen in up to two-thirds of patients with LN and is associated with poor outcomes. The revised 2018 International Society of Nephrology/Renal Pathology Society classification for LN has changed parameters for activity index and redefined few pathological parameters. Repeat kidney biopsy is done for resistant disease or during flare, usually when atypical features are present. Protocol biopsy is a promising tool to monitor patients with LN and decide maintenance therapy. Newer therapies like multi-targeted therapy and biological agents such as obinutuzumab have shown promise in treating LN.

Introduction

Lupus nephritis (LN) is seen in 25–50% of patients at the outset of systemic lupus erythematosus (SLE) and about 60% of the patients are affected during the disease course, which varies with race and ethnicity.[1-3] The probability of a new renal flare is 20–30% per patient-year of follow-up.[4] Patients with LN, particularly those with proliferative histology, are at 2.28 times higher risk of mortality as compared to those without LN and up to one-third of them progress to end stage renal disease (ESRD) within 15 years.[5,6] The prevalence of SLE and the chances of developing LN vary considerably between different regions of the world, with higher rates in Africans and Hispanics.[7] Most often, LN occurs early (within 5 years) in the disease course of SLE.[8] SLE is more prevalent in women than men across all age groups and populations; the female-to-male ratio is highest at reproductive age, ranging between 8:1 and 15:1, and is lowest in prepubertal children at about 4:3.[9-11]

Pathology of Lupus Nephritis

LN is initiated by deposition of circulating immune complexes and by binding of autoantibodies to antigens in the glomerulus and vessel walls. This interaction activates complement mediated cytotoxicity, macrophage, and natural killer cell-induced cell cytotoxicity along with Fc receptor-based T-cell mediated cell damage. Anti-phospholipid antibodies can result in thrombotic lesions in the glomerulus and in the vessels. In 20–30% of patients with LN, anti-neutrophil cytoplasmic antibody can be positive and may contribute to the development of vasculitic lesions.[12]

Value of Renal Biopsy

Treatment of LN is guided by the histological patterns described in the classification system 2003 International society of Nephrology/Renal Pathology Society (ISN/RPS) classification. Clinical severity does not always correlate with histological severity and is shown in **Table 1**.

TABLE 1 Clinicopathological correlation in lupus nephritis

Lupus nephritis class (ISN/RPS)	*Proteinuria*	*Active urine sediment*	*Increased serum creatinine*	*Active lupus serology*	*Hypertension*
Class I	–*	–	–	+/–	–
Class II	+/– *	–	–	+/–	–
Class III	++ (NS: 30%)	+	+/–	+/–	+/–
Class IV	+++ (NS: 50%)	++	+/–	++/–	++/–
Class V	+++ (NS: 60%)	–	+/–	+/––	+/–
Class VI	++	+/–	+	+/––	+

(+) represents frequent occurrence of symptom/sign, (–) represents infrequent occurrence of symptom/sign, NS: Nephrotic syndrome; * NS is seen in class I/II LN in presence of podocytopathy

Therefore, renal biopsy remains indispensable and the "gold standard" to correctly classify LN. The Kidney Disease Initiative Global Outcomes (KDIGO),[13] American College of Rheumatology (ACR),[14] and European League Against Rheumatism/European Renal Association-European Dialysis and Transplantation Association (EULAR/ERA-EDTA)[15] guidelines recommend that a renal biopsy should be performed to confirm and classify LN in cases of SLE with clinical manifestation of proteinuria (>500 mg/day), urinary red blood cells (>5 per high power field) or cellular casts (any), or unexplained renal dysfunction.

Classification of LN: The classification of LN (based on histology) has been in place for over five decades with the latest modification in 2018.

2003: ISN/RPS[16] proposed a new classification system that would provide better clinical correlation, uniformity in reporting and reproducibility. The classification schema is based on glomerular pathology, which includes assessment by light microscopy (LM) and immunofluorescence (IF). Class IV LN is the commonest pattern seen worldwide. In a study from our center, of total 232 patients, Class II was seen in 21, Class III in 36, Class IV in 130, and Class V in 30 patients.[17]

2018: Changes in the 2018 ISN/RPS[18] revision were: the distinction between class IV-S and IV-G was not evidence based and hence, has been removed; the threshold for defining crescent is lowered and various types of crescents are defined in addition; activity and chronicity scores are modified and are required to be mentioned instead of A (activity) or C (chronicity).

Extraglomerular Involvement

Tubular atrophy and interstitial fibrosis (IFTA) are one of the strongest predictors of renal failure. Various studies reported vascular involvement in LN to indicate increased risk for progression to renal failure. In a study from our center,[9] of total 197 patients, thrombotic microangiopathy (TMA) was found in 25.4% with 10% having concomitant APS. Patients of LN with TMA had significantly higher rates of oliguria (p=0.035), advanced renal injury, that is, serum creatinine more than 3 mg/dL (p=0.002), fibrocellular and fibrous crescents (p=0.01), and tubular atrophy (0.001) compared to non-TMA patients. They also had higher rates of treatment failure (p=0.02) compared to the group without TMA.[9] Another study (unpublished data) from our center included 241 patients with LN with 60% having tubulointerstitial involvement, 32.3% having vascular involvement. Those with tubulointerstitial and vascular involvement had lower rates of remission.

Role of Repeat Biopsy

Repeat biopsy is done during renal flare for refractory LN or as a protocol after induction and/or maintenance therapy for LN. Repeat biopsy is useful as histological transformations are common and may affect treatment decisions. It has also been shown to be predictive of long-term outcomes. Protocol re-biopsies can guide therapeutic decision as 20–50% of patients in clinical complete response after therapy were shown to have histological activity on the biopsy.[19] Furthermore, protocol biopsy after prolonged clinical remission can help in deciding safe withdrawal of maintenance therapy, as

was shown recently in a prospective study on clinically quiescent LN patients.[20] Recently, the **EULAR 2019**[21] guideline has recommended repeat biopsy in those with incomplete renal response defined as 24-hour proteinuria more than 0.8–1 g/day with stable/improved renal function despite at least 1 year of immunosuppressive treatment. In a study from our center, which included 62 patients who underwent repeat biopsy for clinical indications, we found histological transformations in 61.3% of the patients.[22] Class switch from proliferative to non-proliferative occurred in 13.7% and 18.2% of patients with non-proliferative histology switched to proliferative classes. On repeat biopsy, endocapillary proliferation and fibrinoid necrosis decreased whereas glomerulosclerosis and IFTA increased (P<0.001). Presence of IFTA more than 30% and TMA on the second biopsy correlated with worse long-term outcome.[22]

Management of Lupus Nephritis

Treatment of LN involves use of aggressive immunosuppressive therapy in the induction phase to achieve rapid control of inflammation in the kidneys followed by less intense immunosuppression to maintain remission. The initial phase for induction is for a duration of 3–6 months followed by a maintenance phase of 3–5 years usually.

Induction Agents

Corticosteroids: Steroids form the backbone of induction therapy of active LN. However, there is an increasing concern about the side-effects with high and prolonged doses of steroids. Many newer trials have investigated this by trying to compare regimens, which include introduction of lesser toxic novel agents to allow reduction of steroid dose versus the standard induction therapy. Based on these concerns and the existing literature, the 2019 EULAR-ERA/EDTA guideline[23] for LN has recommended the use of methylprednisolone pulse (at doses between 500–2,500 mg) followed by oral prednisolone of 0.3–0.5 mg/kg/day and a rapid taper to reach less than 7.5 mg/day by 3–6 months.

Cyclophosphamide: Intravenous cyclophosphamide (CYC) along with corticosteroids became the standard of care for treatment of LN based on randomized control trials conducted by the National institute of health (NIH). The NIH regimen includes monthly intravenous pulses of CYC at a dose of 500–1,000 mg/m^2 for 6 months followed by maintenance with quarterly infusions at same dose for the next 2 years.[24] Using this protocol, remission could be achieved in 61% of patients at the end of induction phase and there were no relapses in the 2-year follow-up period. A similar study at our center revealed overall response rate of 70% (Complete + Partial remission) and 30% failure rate (Failure 20% + Death 10%).[25] Major side effects associated with CYC such as leukopenia, infections, gonadotoxicity, hemorrhagic cystitis, and risk of malignancies in long-term are associated with cumulative dose received. Fixed low-dose intravenous CYC, that is, six doses of 500 mg every 2 weekly followed by azathioprine (2 mg/kg) as maintenance agent was compared with NIH regimen in the European Lupus Nephritis Trial (ELNT).[26] This trial, which included predominantly Caucasians and excluded severe renal involvement, showed no difference in long-term outcomes like patient survival, renal survival, or doubling of serum creatinine in the two arms. Another trial[27] done at our center comparing CYC given as ELNT protocol with mycophenolate mofetil (MMF) for induction in patients with LN showed similar renal outcomes in both the arms. A total of 100 patients were equally randomized to receive either CYC or MMF. At 24 weeks, 37 patients in each group achieved the primary end point. The complete remission rate was 50% in CYC and 54% in MMF group.

Mycophenolate mofetil: MMF was first used in induction phase in a pilot study conducted in Chinese patients with class IV LN and was shown to be non-inferior to oral CYC.[28] Subsequently, a multiethnic study comparing MMF with intravenous CYC, by Ginzler et al.[29] showed non-inferiority of MMF as compared to CYC. One of the largest multicentric randomized control trials by Appel et al.,[30] Aspreva Lupus Management Study (ALMS) involving 370 patients comparing intravenous monthly CYC with MMF showed similar clinical response rates (53% vs. 56%, respectively) at the end of 6 months in both the arms. MMF had better response rates compared to CYC in Blacks and Hispanics (60% vs. 39%).

Although guidelines for management of LN including ACR, EULAR/ERA-EDTA, and KDIGO recommend CYC or MMF as agents for induction in LN, high dose CYC (NIH regimen) is routinely reserved for severe renal disease (Sr Creatinine >3 mg/dL), crescentic glomerulonephritis, TMA, and in the presence of concomitant extraglomerular

lesions like central nervous system (CNS) lupus or diffuse alveolar hemorrhage.

Calcineurin inhibitors (CNIs): CNIs act by inhibiting T-cell activation and, in turn, decreasing B-cell activation and antibody production. Furthermore, it stabilizes the actin cytoskeleton in podocytes, thus contributing to reduction in the degree of proteinuria. However, long-term uses of CNIs are associated with nephrotoxicity and there is a higher chance of relapse once the drug is withdrawn.

Cyclosporine: Cyclofa-Lune study[31] involved 40 patients of proliferative LN who were randomized to Cyclosporine A and intravenous CYC. Clinical outcomes at the end of induction phase and maintenance phase were similar between two groups; response rates were 52% versus 43% in CYC and Cyclosporine arms, respectively at the end of induction, and they were 38% versus 58% for overall response at the end of maintenance phase. The extended follow-up (median: 7.7 years) of these patients showed similar rates of renal survival, patient survival, and proteinuria in the two arms.[32]

Tacrolimus: Comparison of tacrolimus with MMF for induction in active LN patients showed similar rates of complete remission at the end of 6 months.[33] In those with pure membranous LN, tacrolimus resulted in higher response rates of 100% as compared to 75% in MMF group. However, the rates of relapses by the end of 5 years were higher in those who received tacrolimus (62%) than those who received MMF (42%).[34]

Voclosporin: Voclosporin is a structural analogue (trans-isomer) of cyclosporine which is fourfold more potent than cyclosporine and is associated with lesser off-target side effects such as cosmetic effects and nephrotoxicity. In addition, it does not require drug level monitoring owing to stable pharmacokinetics. In a recently completed phase 2 trial on patients with LN, voclosporin, added to MMF and low-dose steroid achieved complete renal remission in 32.6% patients with 23.7 mg twice a day dosage regimen as compared to 19.3% in placebo group.[34] The phase III AURA-LV trial evaluating the efficacy and safety of voclosporin in patients with active LN is ongoing, with interim analysis showing promising results.

Multitargeted therapy: Combination of tacrolimus (4 mg/day) with MMF (1 g/day) and steroids (intravenous methylprednisolone 500 mg for 3 days followed by 0.6 mg/kg/day of prednisolone), called multitargeted therapy (MTT), as induction therapy was compared with intravenous monthly CYC (0.75 g/m^2) in 368 Chinese patients with active LN. MTT was superior to CYC, with complete remission rates being 46% versus 26% at the end of 6 months. However, rates of serious infections were higher in the MTT group.[35]

Maintenance Therapy

After the induction phase, maintenance immunosuppressive agent is necessary to reduce the risk of flares and further renal damage. NIH trials showed that maintenance with quarterly pulses of intravenous CYC for a period of 2 years had lesser episodes of relapses in comparison to no maintenance.[24] Contreras et al.[36] showed that maintenance with MMF or azathioprine was better than quarterly pulses of CYC in terms of efficacy and side effects.

MAINTAIN trial:[37] It included 105 predominantly white patients induced with intravenous CYC by ELNT regimen and were followed up for 5 years. There was no statistical difference between rates of renal flare between MMF (19%) and azathioprine (25%) maintenance, respectively.

ALMS maintenance trial:[38] It included 227 patients who achieved remission with MMF induction and were randomized to MMF and azathioprine maintenance. At 36 months, composite outcome which included renal flare, ESRD, doubling of serum creatinine, death, or use of rescue therapy was significantly lesser in the MMF group than the azathioprine group (16.4% vs. 32.4%). The ALMS maintenance trial, which included multiethnic patients, larger number of patients, and had compared composite outcomes, favors use of MMF as maintenance agent over azathioprine. The ACR[14] and KDIGO[13] guidelines recommend use of either MMF or azathioprine as maintenance agent; however, 2019 EULAR/ERA-EDTA[23] guideline recommends MMF maintenance specifically for patients induced with MMF. Duration of maintenance immunosuppression is recommended to be at least 3 years in patients who achieve complete remission at the end of induction therapy.[23] In those with high risk of deterioration of renal function such as failure to achieve complete remission after induction therapy, frequent renal flares, and high disease activity index, prolonged immunosuppression is given usually.

Newer Therapies

Biological Agents

Despite the use of conventional immunosuppressive agents, response rates of LN are only 60–70% at the end of induction therapy. High rates of relapses after achieving remission and reduction of drug toxicity have been unmet needs in the management of LN. Hence, there is need for newer drugs which are safer and more effective. Biological agents with specific targets in the immune system have been used as alternative options for conventional drugs for achieving higher rates of remission, managing refractory disease and as steroid sparing agents.

Rituximab: This is a chimeric monoclonal antibody against CD20 on the B-cell surface. Several nonrandomized studies have shown efficacy of rituximab in managing patients with LN. **LUNAR** (Lupus nephritis assessment with Rituximab) trial[39] was a placebo-controlled phase 3 RCT. Those in rituximab arm received 1,000 mg of rituximab 2 weeks apart at the start and it was repeated after 6 months. All the patients received three pulses of intravenous methylprednisolone followed by oral steroids along with MMF at a dose of 2–3 g/day. Renal response at the end of 52 weeks was not different between both the arms (57% vs. 46% in rituximab vs. placebo arms). However, rituximab was shown to be effective in refractory LN.[40] Rituximab has also been proven to be effective as a steroid sparing agent in a pilot trial of 50 patients of active LN who were given two doses of 1 gm/dose rituximab 2 weeks apart along with MMF and single dose of intravenous methyl prednisolone (500 mg). About 86% of patients achieved response (52% complete response and 34% partial response) at the end of 52 weeks.[41] Based on the encouraging results, an open label, multicentric RCT (RITUXILUP) was being carried out using rituximab for steroid sparing effect. Rituximab or any B-cell depleting agent causes B-cell activating factor/B lymphocyte stimulating agent (BAFF/BLyS) to increase, which in turn can lead to early repopulation of remnant B-cells. So, combination of agents to block both would have the maximum effect. To test this hypothesis, CALIBRATE (ClinicalTrials.gov Identifier: NCT02260934) trial was conducted where in patients with resistant active LN were treated with CYC and rituximab followed by belimumab. An interim analysis[42] of data from CALIBRATE shows:

- Anti-BAFF following anti-CD20 for LN did not improve clinical outcome at week 24;
- Anti-BAFF delayed blood B-cell reconstitution following B-cell depletion; and
- Anti-BAFF following anti-CD20 was not associated with hypogammaglobulinemia or an increase in serious infections. Further analyses at 48 weeks and beyond are awaited.

Belimumab: This humanized monoclonal antibody binds to BAFF leading to decreased activation of B-cells. Belimumab is the only biological agent approved for treatment of active SLE. The BLISS-LN (Efficacy and safety of Belimumab in patients with Active Lupus Nephritis) study was recently announced to have favorable findings; although, the results are yet to be published (https://www.clinicaltrialsarena.com/news/gsk-benlysta-sle-phaseiii-data/). It met its primary endpoint demonstrating that a statistically significant greater number of patients achieved Primary Efficacy Renal Response over 2 years when treated with belimumab plus standard therapy compared to placebo plus standard therapy in adults with active LN (43% vs. 32%, odds ratio (95% CI) 1.55 (1.04, 2.32), p=0.0311). Based on the positive post hoc analyses from trials in non LN patients and the benefits of belimumab in observational studies involving LN, it has been suggested to be used as add-on in treating extrarenal flares/disease activity in LN patients by the 2019 EULAR/ERA-EDTA guideline.[23] It can also be used as steroid sparing agent.

Obinutuzumab: NOBILITY trial[43]—In patients with proliferative LN, Obinutuzumab (intravenous) in addition to MMF (2–2.5 g/day) and steroids (0.5 mg/kg/day of prednisone followed by taper) versus placebo in addition to MMF and steroids at same doses as intervention arm—overall renal response was higher than placebo arm at 52 weeks. Obinutuzumab was as safe when compared to placebo. From this trial, it becomes apparent that more effective B-cell depletion results in better clinical outcome, unlike the LUNAR trial. More stringent CD19 B-cell depletion could be achieved with Obinutuzumab as compared to Rituximab as Obinutuzumab is a type II monoclonal antibody known to enhance antibody dependent cytotoxicity of B-cells and therefore, better and deeper response.

Other biological agents that were tested or being tested in clinical trials for Lupus Nephritis are—

Trials which failed or were terminated:

- Abatacept (CTLA4-Ig)—(ACCESS trial)—failed to meet the endpoint
- Bortezomib (plasma cell proteasome inhibitor)—trial terminated
- Rituximab (anti-CD20)—failed to meet endpoint
- Ocrelizumab (anti-CD20)—failed to meet endpoint
- Sirukumab (anti-IL6)—failed to meet endpoint
- Tabalumab (anti-BLyS)—failed to meet endpoint

Trials which showed encouraging results or are ongoing:

- Laquinimod—encouraging phase 2 trial results
- Obinutuzumab: humanized anti-CD20 antibody: NOBILITY—phase 2 clinical trial—encouraging results—show better overall renal response than placebo arm
- Belimumab—anti-BLyS/BAFF antibody: BLISS-LN—phase 3 clinical trial-met the primary endpoint
- Rituximab and cyclophosphamide followed by belimumab: CALIBRATE—phase 2 clinical trial
- Anifrolumab—anti-IFN alpha-R antibody: phase 3 clinical trial—TULIP-LN1-ongoing
- Voclosporin—calcineurin inhibitor: AURA-LV-phase 2 trial—met its primary endpoint; AURORA phase 3 clinical trial (https://www.clinicaltrialsarena.com/news/aurora-trial-lupus-kidney-disease-drug-therapy/): met the primary endpoint

Conclusion

LN is characterized by flares and about 30–40% of patients do not respond to conventional induction therapy. Protocol repeat biopsy is a promising tool to monitor LN. Less toxic and more effective agents are the unmet needs in the management of LN.

CHAPTER

149 Diagnosis and Management of Nephrotic Syndrome

Deepti Sharma, Sandeep S, Gopikrishnan R

Abstract

Nephrotic syndrome is an important presentation of glomerular disease featured by heavy proteinuria, hypoalbuminemia, and edema. The etiology of nephrotic syndrome is more complex and heterogenous in adults compared to children. The renal function is often normal but can progress to chronic renal failure which depends on the duration and amount of proteinuria. Acute renal failure is rare and mostly caused by a precipitating event. Early recognition is possible through urine protein estimation, but a renal biopsy is often recommended. Current treatment recommendations are mostly based on randomized control trials (RCTs) in children, and there are only small RCTs and a few case series studies in adults. Diuretics are required in large doses due to the low-serum albumin levels. Immunosuppressive treatment is often used with little evidence. Prophylactic treatment to prevent infection or thrombosis is not recommended routinely unless indicated.

Introduction

Nephrotic syndrome is a glomerular disease, defined as a pentad of proteinuria more than 3.5 g/day, hypoalbuminemia less than 3.5 g/dL, edema, hypercholesterolemia, and lipiduria.[1] Patients present with edema, typically periorbital or at dependant sites or as a complication of nephrotic state such as thromboembolism.

Etiology

Nephrotic syndrome may be due to a primary glomerulopathy, secondary to systemic diseases or as a result of genetic mutations. The primary disorders are minimal change disease, focal segmental glomerulosclerosis, and membranous nephropathy (MN). Secondary causes are elaborated in **Table 1**.

Pathophysiology and Clinical Manifestation

Proteinuria

Protein loss is due to glomerular proteinuria. Electrical potential differences generated by transglomerular flow may modulate the passage of macromolecules across the glomerular capillary wall.[2] The podocyte appears to be the major target of injury in idiopathic nephrotic syndrome. Adult-onset primary MN and focal segmental glomerulosclerosis (FSGS) may be due to autoantibodies to podocyte or circulating factor that affect the podocyte.

Hypoalbuminemia

Most of albumin loss is due to urinary excretion leading to reduction in total protein and serum albumin with increased $\alpha 2$-globulin and reduced γ-globulin fraction. Hepatic albumin synthesis is increased in response to the albumin loss mediated by an increase in gene expression and the release of an unidentified circulating factor.[3]

Edema

Two major mechanisms have been thought to be responsible for the development of edema. One is "**underfill** hypothesis" where secondary sodium retention due to low plasma oncotic pressure causes shifting of fluid into the interstitium leading to underfilling of the

TABLE 1 Secondary causes of nephrotic syndrome

MCD	*FSGS*	*MN*	*Others*
Drugs • NSAID • Interferon-α • Lithium • Gold **Allergy** • Pollens • House dust • Insect stings • Immunizations • Poison oak **Malignancy** • Hodgkin disease • Mycosis fungoides • CLL	**Virus associated** • HIV-1 • Parvovirus B19 • Simian virus 40 (SV40) CMV **Drug induced** • Heroin • Interferon • Lithium • Pamidronate • Sirolimus • Anabolic steroids • Tyrosine kinase inhibitors **Hyperfiltration injury** • Renal agenesis	**Autoimmune diseases** • Class V lupus nephritis • Rheumatoid arthritis • Sarcoidosis • Sjogren **Infections** • Hepatitis B • Hepatitis C • HIV • Syphilis • Malaria • Schistosomiasis **Malignancy** • Solid tumors (colon, stomach, lung, prostate)	• Diabetes • Plasma cell disorder • Paraprotein deposit disease • AA amyloidosis • Pre-eclampsia

vasculature and activation of the renin–angiotensin–aldosterone system (RAAS) causing further sodium and water retention. Second mechanism is "**Overfill** hypothesis" where primary sodium retention occurs due abnormalities in tubular function like increased activity of the Na-K-ATPase pump, epithelial sodium channel (ENaC),[4] and relative resistance to ANP and urodilatin due to increased phosphodiesterase activity.

Hypercoagulability

Patients with the nephrotic syndrome have an increased incidence of arterial and venous thrombosis, particularly deep vein thrombosis (DVT) and renal vein thrombosis. Thrombotic state occurs mainly due to urinary loss of antithrombin III, plasminogen, protein C and S. Increased platelet activation, thrombocytosis, hyperfibrinogenemia, and inhibition of plasminogen activation also contributes. Renal vein is a common site of thrombosis in nephrotic syndrome, possibly due to stimulation of thrombin production in the glomerular efferent vessels as a result of glomerular injury.

Hyperlipidemia

Hyperlipidemia is triggered by the reduction in plasma oncotic pressure. The severity of the hyperlipidemia is inversely related to the fall in oncotic pressure and resolves with the remission of nephrotic syndrome. Enhanced hepatic synthesis of lipoproteins containing apolipoprotein B and cholesterol and diminished catabolism caused by inhibition of lipoprotein lipase due to elevated levels of sialylated angiopoietin like-4 (especially triglycerides) is thought to be the mechanism behind this. Lipoprotein glomerulopathy is a rare form of glomerular disease that is associated with dyslipidemia and lipoprotein deposits in the glomeruli.

AKI and CKD in Nephrotic Syndrome

Acute kidney injury (AKI) is less common in nephrotic syndrome. Most cases of nephrotic syndrome have a risk of progression to chronic kidney disease (CKD) except minimal change disease (MCD). Greatest risk factor is the degree of proteinuria (>5 g/day). **Table 2** shows various causes for AKI in nephrotic syndrome.

Diagnosis

Urine Analysis

- *Twenty-four hour urine protein estimation:* More than 3.5 g/day is considered nephrotic-range proteinuria.
- *Protein-to-creatinine ratio:* It is only an alternative to the 24-hour urine protein estimation. The total protein-to-creatinine ratio (mg/mmol) on early morning sample of urine is calculated. This ratio correlates closely with daily protein excretion in

TABLE 2 Various causes for AKI in nephrotic syndrome

• AIN secondary to drugs (including diuretics)
• ATN due to volume depletion or sepsis
• Hemodynamic response to NSAIDS, ACEI, ARBs
• Nephrosarca
• Pre-renal failure due to volume depletion
• Renal vein thrombosis
• Transformation of underlying glomerular disease

g/1.73 m^2 of body surface area. A value more than 300 mg/mmol is considered nephrotic range. But this method has limitations and 24-hour urine protein estimation is more preferred.

Serologic Studies

A number of serologic studies often are obtained in the evaluation of patients with the nephrotic syndrome depending upon clinical setting **(Table 3)**.

Renal Biopsy

In adult nephrotic syndrome, biopsy is indicated when the etiology of persistent nephrotic-range proteinuria is in doubt in order to determine management decisions.

Indication for biopsy:
- Adult with nephrotic syndrome
- Children with:
  - age <1 year or >12 years
  - Gross hematuria
  - Marked hypertension
  - Renal failure without severe hypovolemia
  - Low C3 level

Imaging

- *Ultrasound:* It must be done routinely before planning renal biopsy to rule out small kidneys or kidneys with severe cortical thinning, as they indicate chronic irreversible disease. These findings can limit renal biopsy and aggressive immunosuppressive therapy.
- *2D Echocardiography:* When infective endocarditis is suspected.
- *Renal Doppler:* Indicated in patients with flank pain, hematuria, and rapid worsening of renal function to rule out renal vein thrombosis.

TABLE 3 Serologic studies (marker and diagnosis)

Serological marker	*Diagnosis*
Anti-PLA_2R	Primary MN (70–80%)
Anti-THSD7A	Primary MN (5%)
ANA, anti-dsDNA, anti-Ro/La	Lupus nephritis (MN), Sjögren (MN)
HB_sAg, Anti-HCV, HIV, VDRL/FTA-Ab	Secondary MN
PSA	Ca prostates (MN)
CEA	Ca colon (MN)
HIV antibody	FSGS >> MN
Low C3.C4 levels	MPGN Type 1
Plasma-free light chains	Multiple myeloma (MN)
RA factor, Anti-CCP	MN
RBS, HbA1c	Diabetic nephropathy

Histological Patterns

See **Table 4**.

Management

Management of nephrotic syndrome consists of general supportive measures, disease-specific therapy for the underlying cause in secondary nephrotic syndrome, and immunosuppression in case of primary nephrotic syndrome.

General Supportive Treatment

It includes measures to reduce proteinuria, edema, control blood pressure, and to address other metabolic consequences of nephrotic syndrome.

Treating Edema

All patients with nephrotic edema are initially treated with diuretics and dietary sodium and water restriction. It is recommended to restrict salt intake to less than 3 g per/day and water intake less than 1.5 liter/day.[5] Most patients respond well to loop diuretics. They are highly protein-bound but this bonding is reduced with hypoalbuminemia resulting in a slower rate of delivery to the kidneys. Loop of Henle may be relatively resistant to loop diuretics. Gut edema also limits the oral absorption of diuretics. Thus, the effective diuretic dose is usually higher in patients with nephrotic syndrome. Intravenous infusion can also

TABLE 4 Histopathological patterns

	MCD	*FGGS*	*MN*
LM	Normal	Sclerosis in parts (segmental) of some (focal) glomeruli	Homogenus thickening of capillary wall (H&E)
			Spikes in GBM (Silver stain)
EM	Diffuse foot process effacement	Diffuse foot process effacement	Sub-epithelial deposit on surface of GBM
		Wrinkling and retraction of GBM	Foot process effacement
		Hyaline accumulation	
IF	No deposits	IgM, C3, C1q (Classical)	Diffuse global finely granular deposits of IgG along outer surface of all capillary walls
Pathology	Circulating permeability factor	Podocyte injury	Immune complex and complement mediated podocyte injury (Secondary MN)
	Abnormal regulation of T-cell	Nephron loss	Autoantibody mediated podocyte injury

be tried as it increases the diuretic efficacy. Furosemide 40 mg orally twice a day or bumetanide 1 mg twice daily is a reasonable starting dose and may be increased up to a dose of 600 mg/day according to need. Patients who do not respond adequately to loop diuretic require the addition of a thiazide diuretic. Alternatively, amiloride[6] or acetazolamide[7] can be combined with loop diuretics in patients with refractory edema. Prior administration of albumin increases the efficacy of diuretics.[8]

Proteinuria

Progressive loss of renal function can be reduced if proteinuria can be reduced below 0.5 g/day. It can be controlled by either blocking efferent arteriole vasoconstriction or decreasing the preglomerular pressure (antihypertensives). Angiotensin converting enzyme inhibitors (ACEIs) and angiotensin-receptor blockers (ARBs) are the agents of choice. They reduce proteinuria independent of blood pressure and can be safely used in normotensive patients. If proteinuria persists in spite of ACEI/ARB, aldosterone antagonists can be added. They can raise the serum creatinine by 30–40% as glomerular filtration rate (GFR) is reduced, but should not be stopped unless serum creatinine levels are continuously increasing.

Hypoproteinemia

Adequate dietary protein intake of 0.8–1 g/kg/day with high carbohydrate to maximize the use of that protein is recommended. In heavy proteinuria, add the amount of urinary protein loss to dietary protein intake. As a last resort, nephrectomy and renal artery embolization can be done if protein loss cannot be managed medically.

Hypertension

Hypertension in nephrotic syndrome requires strict control to delay the progression of renal disease and prevent cardiovascular complications. Initially life style modification can be adopted. High dose diuretics and dietary salt restriction are necessary. The KDIGO guideline recommends a target BP <130/80 mm Hg,[9] but recent SPRINT trial suggests a target of 120/80 mm Hg. ACEIs and ARBs are the first choice. DHP-CCBs are not preferred as they increase GFR causing worsening of proteinuria and also add to peripheral edema.

Hyperlipidemia

Control of hyperlipidemia is important in preventing cardiovascular complications. Dietary modification alone has only a moderate effect on hyperlipidemia. Statin alone is preferred in patients more than 50 years of age with early stage CKD and in late stages, addition of ezetimibe is recommended. In young adults, consider statin if having significant comorbidity.

Prophylaxis for Thrombosis

The decision to prescribe prophylactic anticoagulation must be balanced against the risk of bleeding. If the

bleeding risk is unclear, ATRIA Risk score or HAS-BLED risk can be used to take a decision. Prophylactic low-dose heparin is indicated in cases with high risk for thrombosis, like in pregnancy or an immobilized patient, with a serum albumin less than 2.5 g/dL. If albumin is less than 2 g/dL, full anticoagulation with low-molecular-weight heparin (LMWH) or warfarin should be considered.[10] Patients with MN are at high risk for thrombosis, and if the albumin level is very low and even if the risk of bleeding is intermediate, they may benefit from anticoagulation. Warfarin is preferred over LMWH because of low levels of antithrombin III impeding efficacy.

Management and Prevention of Infection

Risk of infection is exacerbated by nephrotic immunodeficiency caused by T-cell transformation dysfunction and urinary loss of immunoglobulins including IgG and alternate pathway complement factors. Patients may develop recurrent respiratory and urinary tract infections, peritonitis, and sepsis; particularly with encapsulated bacteria. Antibiotic with pneumococcal coverage is the mainstay in infections and prophylactic pneumococcal vaccination is recommended. In case of repeated infection, IgG level should be estimated and if low IVIgG should be given to maintain a level above 600 mg/dL.[11]

Treating MCD

Initial Treatment

Low dose oral prednisolone (1 mg/kg/day up to maximum 80 mg/day) should be started according to KDIGO guideline and recommends it to be continued up to 6 months. Initial dose should be maintained for a minimum of 4 weeks if full remission achieved or 16 weeks if full remission not achieved. Once remission has been achieved, dose should be tapered at least within 4 weeks of response. Induction with methylprednisolone pulse therapy may lead to rapid response and fewer relapses. If the patient has not achieved remission even after 12–16 weeks of treatment, consider repeating biopsy, as it can be FSGS which might have been missed due to limited number of nephrons in earlier specimen. If MCD presents with non-nephrotic range proteinuria, it can be managed with ACEIs/ARBs and there is no need for starting steroids.

Steroid Dependent (Table 5), Frequently Relapsing and Resistant MCD

These patients should be started on second-line therapy. This includes:

- *Cyclophosphamide:* 2–2.5 mg/kg/day orally for 12 weeks is given. Due to risk of infertility, banking of sperm and ova is to be considered before starting therapy.
- *Calcineurin inhibitors:*
  - *Cyclosporine:* 4–6 mg/kg/day for at least 12 months is given. Nephrologists prefer calcineurin inhibitors over cyclophosphamide in young adults to prevent infertility.
  - *Tacrolimus:* A dose of 2–4 mg twice daily, adjusted to maintain a target level of 5–10 ng/mL is given. It may be considered as a first line or second line in patient with contraindication for or intolerance to high dose corticosteroid.[12]
- *MMF:* 750–1,000 mg twice daily for 6 months may be used in cyclosporine dependant cases but did not appear as effective as cyclosporine in studies.
- *Rituximab:* It is a B-Lymphocyte depleting agent (anti-CD20) and is used when disease is unresponsive to all

TABLE 5 Terminologies regarding treatment outcomes of nephrotic syndrome

Complete remission	Reduction of proteinuria to ≤0.20 g/day and serum albumin >3.5 g/dL
Partial remission	Reduction of proteinuria to between 0.21 g/day and 3.4 g/day ± decrease in proteinuria of ≥50% from baseline
No remission	Failure to reduce urine protein excretion by 50% from baseline or persistent excretion uPCR >2000 mg/g (>200 mg/mmol)
Steroid resistance	Persistence of proteinuria despite prednisolone therapy, 1 mg/kg/day for 16 weeks
Relapse	Proteinuria ≥3.5 g/day occurring after complete remission obtained for >1 month
Infrequent relapse	One relapse within 6 month of initial response, or one to three relapses in any 12-month period
Frequent relapse	Two or more relapses within 6 month of initial response, or four or more relapses in any 12-month period
Steroid dependence	Two consecutive relapses during corticosteroid therapy, or within 14 days of completing corticosteroid therapy

Reference: Comprehensive Clinical nephrology - 6th edition

other treatments, but RCT have not been performed. Non RCT studies have shown benefit and reduction in relapse in corticosteroid dependant and frequent relapse cases.[13] A dose of 375 mg/m^2 weekly for 4 weeks.

FSGS

It is very difficult to distinguish between primary and secondary FSGS and most of the times they are treated as primary FSGS. All patients will benefit from good supportive treatment and immunosuppression.

Initial Treatment

It consist of 6 months of continuous corticosteroid (1 mg/kg/day), later tapered over 4–8 weeks.

Steroid Resistant Cases

- *Cyclosporine:* Low dose of 3–6 mg/kg/day is given for 2–6 months. Recent studies show that combination of cyclosporine and corticosteroids has a higher remission rate.[14]
- *Tacrolimus:* Used in cases resistant or intolerant to cyclosporine.
- *MMF and Dexamethasone:* As per KDIGO guidelines, they can be given in corticosteroid resistant cases that are intolerant to calcineurin inhibitors.
- *Rituximab:* Used when all other treatments fail and this drug has shown promising results in steroid-dependent cases.
- *Abatacept (CTLA-4-Ig):* An inhibitor of T-cell costimulatory molecule B7-1(CD-80) showed remission in some patients and further studies are in progress.[15]

Secondary FSGS

Patients with primary FSGS typically present with an **acute onset nephrotic syndrome**, whereas slowly increasing asymptomatic proteinuria and renal insufficiency over a period of time without profound hypoalbuminemia or edema are characteristic of secondary FSGS. Unlike primary FSGS, these patients are less responsive to immunosuppression and the mainstay of the treatment is to correct the primary cause and provide supportive treatment.

Membranous Nephropathy

It is very difficult to treat MN due to its chronic nature, the tendency for spontaneous remission and relapse and the variability in clinical severity. Specific immunosuppressive therapy should not be considered unless the patient has a persistent nephrotic-range proteinuria (>4 g/day) and it has not declined more than 50% from baseline, over a minimum period of 6 months, despite maximum antihypertensive and antiproteinuric therapy.[16] Treatment of secondary MN focuses on cessation of the offending drug or effective treatment of the underlying disease.

Immunosuppression

- *Corticosteroids:* RCTs showed no significant long-term benefit on proteinuria or rate of disease progression. Therefore, use of oral corticosteroids as a single agent is not recommended.
- *Cytotoxic agents with corticosteroids (PONTICELLI REGIMEN):* Benefitted in patients at moderate risk for progression. It starts with methylprednisolone pulses 1 g IV for 3 days at the beginning of months 1, 3, and 5 followed by oral methylprednisolone 0.4 mg/kg/day for 27 days, and each cycle followed by 1 month of cytotoxic agent (cyclophosphamide or chlorambucil).[17] Cyclophosphamide-based regimen is preferred because of a better safety profile.
- *Calcineurin inhibitors:* Given in patients with corticosteroid-resistant MN but has a higher relapse rate.
  - *Cyclosporine:* It is used along with low-dose corticosteroids. It may reduce proteinuria not only through its immunosuppressive effects but also by direct effects on the podocyte.
  - *Tacrolimus:* It can be used as monotherapy, but relapse rate was found to be high.
- *MMF:* Along with steroids, it showed good initial response, but relapse rate was high.[18]
- *Rituximab:* Used in steroid resistant cases. Decline in anti-PLA2R antibody and proteinuria was achieved, subsequently resulting in a partial or complete remission.

Plasma Exchange

It may be useful in resistant MN, severe nephrotic syndrome, and high anti-PLA2R antibody titer cases. A

study in such type of patients, treated with a "rescue" regimen consisting of four plasma exchanges, 20 g of intravenous (IV) immunoglobulin, and 375 mg/m^2 of rituximab showed shorter remission time compared to previous regimens.[19]

Adrenocorticotropic Hormone (ACTH)

ACTH acts via melanocortin 1 receptor expressed on podocytes. Synthetic form of ACTH, 1–2 mg weekly intramuscularly for 1 year showed prolonged remission in the majority of patients with MN.[20]

Conclusion

Nephrotic syndrome includes a wide spectrum of primary glomerular disorders and secondary diseases. Early recognition through urine protein estimation and bringing out the histological variant through renal biopsy aids in planning treatment properly in order to prevent progression into renal failure. At present, reducing proteinuria and immunosuppression remains the mainstay in most of the cases and larger RCTs are lacking. Many new treatment targets have been identified, which needs further studies. A proper recommendation for management of nephrotic syndrome needs to be postulated.

CHAPTER

150 Dietary Salt and Hypertension

PP Varma

Abstract

Epidemiological data suggests that dietary salt is a modifiable risk factor for hypertension; especially in those with salt consumption in the highest tertile. WHO recommends 5 gm of salt intake per day but we in India are consuming 9–12 gm of salt per day. Besides hypertension, salt is also incriminated for CV mortality, stroke, and obesity. Hence, there is need to restrict salt consumption to check the menace of hypertension. Here we bring the update on association of salt and hypertension.

Introduction

Today over 30% of world's adult population has hypertension (HT). Over 60% of the cerebrovascular diseases and about half of ischemic heart diseases are attributable to HT. Dietary salt is one of the modifiable culprits in causation of HT. Present commentary is about data on dietary salt and its association with HT.

Historical Perspective

During paleolithic times, hunter gathering man was dependent on raw meat and his dietary salt intake was less than 1 gm a day. Around 5,000 years back, Chinese learnt that food can be preserved with the help of salt and Egyptian used this knowledge for preservation of mummies. Civilizations started developing along the salt routes, which was considered a precious entity. In Libya, salt was exchanged for equivalent amount of gold. French salt tax "gabellee" probably incited French revolution. In India, Britishers did not allow Indians to make their own salt and wanted them to buy expensive salt brought from England. This was the genesis of famous Dandi March, an important event in the freedom struggle of India. Salt (NaCl) crystals are white in color and readily dissolve in water. The molar mass is 58.5 g/mol.

With agricultural revolution our food habits changed, and from 100% animal food, now plant based food formed 50% of our diet; however, salt intake remained less than a gram per day. Earliest comment relating to dietary salt and HT came from Chinese doctor, Huang Ti Nei Ching Su Wen, who wrote in The Yellow Emperor's Classic of Internal Medicine—"therefore, if large amounts of salt are taken, the pulse will stiffen or harden." However, over the years with civilization and changing food habits our dietary salt intake has increased and this is being correlated with increasing prevalence of HT. Today average Indian salt intake is 9–12 gm/day against WHO recommendation of 5 gm.[4] In this article we shall review the available data showing correlation between salt intake and HT.

Consumption and Its Source

A study reported by George Institute from India found that average Indian is taking 10.98 gm of salt per day. Salt consumption is higher in south Indians than north Indians. If one looks at the source of consumed salt, there

are three sources: our natural food (cereals, vegetables, fruits, non-vegetables) contains less than a gm of salt and makes 10% of daily intake. Another 2–3 gm (20–30%) is added as cooking salt in our food and vegetables. However, 70% of our consumed salt comes from processed food—snacks, bread and bread products, pizza, French fries, pasta, pickles, sauces, etc. It may be interesting to know that each large slice of bread has 500 mg of salt in it. Twenty-four hour urinary sodium estimation is the best marker of salt consumption.

Data on Salt Studies and Hypertension

- *Epidemiologically:* It is known that areas with low salt consumption have lower incidence of HT. Solomon islanders consume less than 2 gm of salt per day and have an HT prevalence of 1%. Among Yanomamo Indians from Brazilian amazon, 84% have urinary sodium excretion of 1 mmol/24 hours. Their mean BP is 96/60.0 mm Hg (78/37–128/86 mm Hg) and there is no change in BP with age. In tribes with salt intake of 3 gm/day, prevalence of HT is 3%. Interestingly in Newfoundland average salt intake is of 6.7–7.3 gm and HT prevalence is 15%. Its coastal area where salt consumption is of 8.4–8.8 gm/day, HT prevalence is 27%. This data suggests that with increasing salt intake prevalence of BP increases.
- The effect of life style change and migration is exemplified by Yi community living in southwestern China. Those still living in mountainous environment and eating sodium-poor diet had yearly rise of systolic and diastolic BP by 0.13 and 0.23 mm Hg, respectively. In contrast, Yi community who had migrated in urban areas and consumed sodium-rich diet had a yearly rise of 0.33 mm Hg for both systolic and diastolic BP, stressing the importance of life-style change on BP.
- First good animal study about salt and its correlation with HT came from chimpanzees that are phylogenetically similar to humans. Normally chimpanzees eat diet rich in fruits/vegetables with dietary salt content of 0.5 gm/day. Study was done on 26 chimpanzees.[1] To their normal diet ~15 gm of salt was added. BP started rising and after 84 weeks BP rose by 33/10 mm Hg. Again chimpanzees were reverted back to their original diet, without added salt. BP reverted back to normal 6 months later. Study shows the effect of salt on BP in chimpanzees.
- The first double-blind controlled study of moderate salt restriction on human was from MacGregor et al.[3] They recruited 19 patients with mild to moderate HT (average supine BP of 156/98 mm Hg). Patients were advised not to take sodium laden food. After 2 weeks of dietary salt restriction, patients entered an 8-week double-blind randomized crossover study. One group was given "Slow Sodium Ciba" (Ciba-10 mmol of sodium per tablet) and other group received "Slow Sodium Placebo." In fourth week, the mean supine BP was 7.1 mm Hg (6.1%) lower in slow sodium placebo group ($p<0.001$). Urinary sodium excretion in the fourth week of slow sodium ciba was 162±9 mmol/24 hours and that in the fourth week of slow sodium placebo was 86±9 mmol/24 hours ($p<0.001$). They suggested that moderate sodium restriction should become part of the management of essential HT and one should avoid sodium-laden foods.
- First large international study on salt and HT was "Intersalt study."[2] The study was conducted in 52 centers from 22 countries; each with sample size of 200 with a total of 10,079 participants. Four of these 52 centers, were tribal belts with very low salt consumption. Data from 48 centers showed an insignificant trend but pooled data from 52 centers showed that higher salt consumption was associated with age-related rise in BP. This study prompted lot of debate whether to reduce salt consumption or not. A revisit of study inferred that 100 mmol of extra salt intake (70 mmol vs. 170 mmol) was associated with higher BP by 5–7/2–4 mm, stressing the need to reduce salt intake.
- A community trial was done to study the effect of salt on HT in Portugal. Two communities with 800 persons each were selected. Both had salt intake of 21 gm/day and HT prevalence of 30%. In one of the two communities with extensive health education, salt intake could be reduced to 12 gm/day. By the end of second year BP dropped in intervention community by 13/6 mm Hg. BP drop was across all age groups and in both normotensives and hypertensives alike. Those with greatest fall in salt excretion had the largest fall in BP.
- *Trials of hypertension prevention (TOHP I & II):* TOHP I was conducted over 18 months' duration and TOHP II for over 36 months. Lower salt intake (lower by 44 mmol and 33 mmol/day) in intervention group was

associated with 25% lower CV events. So, besides lowering BP, lower salt intake is associated with lower CV events also.[6] A metanalysis of 13 studies, with 177 025 participants (FU 3.5–19 years) showed that higher salt intake was associated with greater risk of stroke (RR1.23) and cardiovascular disease (RR 1.14). A Finnish study on impact of salt and CV events, comprising of 1,173 men and 1,263 women found that increased sodium intake by 100 mmol/day increased the hazard ratio for coronary artery disease, CV disease, and all-cause mortality by 50% (HR of 1.51).

- *INTERMAP study:* A recent study (Hypertension 2018;71:631-37)[9] included 4,680 persons from China, Japan, UK, and the USA. This study addressed the effect of dietary salt intake on BP and its possible modulation with other dietary factors. Study found that group with two SD higher sodium excretion was associated with rise in BP by 3.5/1.7 mm Hg (p<0.001) and most other 26 micro- or macronutrients in diet had only a modest countervailing effects on Na-BP relationship. The study again emphasized the need for salt restriction as other micro- or macronutrients did not make much difference.
- Prospective urban rural epidemiology (PURE) study (Mente et al., 2018)[10] was conducted in 18 countries on a population of 1,68,000, in the age group of 35–70 years. The 664 communities from low, middle, and high income countries were selected. A 24-hour sodium excretion was divided into three tertiles: low—4.04, middle—4.70, and high tertile—5.75 gm. The study found that mean systolic BP increased by 2.86 mm Hg per 1 gm increase in salt intake. Sodium intake was also associated with cardiovascular disease and strokes. This association was however significant only in those falling in highest tertile of salt intake (p<0.0001). Study suggested that those in highest tertile of salt consumption had significant detrimental effect.
- *Dietary approaches to stop hypertension (DASH):* In this study 412 normotensive and hypertensive participants were assigned to eat either typical American diet (control diet) or DASH diet. DASH diet is rich in fruits, vegetables, and has low-fat dairy products. Aim of the study was to test if DASH diet reduced BP and if salt reduction in patients on DASH diet had an additional advantage. Study population was divided in three groups:
  - high salt intake—150,
  - intermediate salt intake—100, and
  - low salt intake—50 mmol/day.

In control group, reduction of sodium intake from the "high to the intermediate level" over 30 days, resulted in reduction of systolic BP by 2.1 mm Hg (p<0.001) and in the "from intermediate to the low level" by 4.6 mm Hg (p<0.001). In DASH group salt reduction resulted in drop of BP by 1.3 mm Hg (p=0.03) and 1.7 mm Hg (p<0.01) "from high to intermediate" and "intermediate to low salt" group respectively. Benefit of salt reduction was observed in both sexes, all races and in normotensives also. The study inferred that participants in DASH diet had a significantly lower systolic BP at each sodium level. If one compares control diet group with high salt intake and DASH diet group with low salt intake, there is a BP difference of 7.1 mm Hg in normotensives and 11.5 mm Hg in hypertensives.

Few important points emerge from these studies:

- Epidemiological data clearly shows low prevalence of HT in areas with low salt intake.
- Animal and human trials show drop in BP with reducing salt intake and increase in BP with increased salt intake.
- Cardiovascular mortality also increases with increase in salt intake.

An important inference is that prevalence of HT and risk of CV mortality is prominent and significant in group with highest tertile of salt intake.

- *Salt intake and obesity:* It has been observed that excessive salt intake is associated with obesity. As small as 1 gm of extra salt consumption per day by children and adolescents has been found to be associated with consumption of 27 gm of sugar-sweetened soft drink. There has been controversy, if obesity is due to consumption of extra sugar or processed food or due to extra salt. However, increasing evidence suggests that there is direct link between salt intake and obesity independent of total energy intake. Even after adjusting variables like ethnic group, social status, energy intake, educational status, smoking, alcohol consumption, etc., 1 gram a day of extra salt increases the risk of obesity by 28% (p=0.0002) in children and 26% (p<0.0001) in adults.
- *Is very low salt intake detrimental:* In the "Framingham Offspring study"—a 16-year follow-up data, of 2,632

men and women between 30–64 years, showed that very low intake of salt (<2.5 gm) is associated with increased BP. This is in line with many workers who feel that there is J-shaped curve between salt consumption and hypertension **(Fig. 1)**.

Salt Sensitive Hypertension

An important and debatable issue is that should salt restriction advise be universal or only for those having inappropriately high consumption/salt sensitive population. Luft et al studied 14 subjects (7 white and 7 black) and gave them increasing doses of salt, 10-1500 meq/day. He found mean rise in blood pressure in both groups but rise in blood pressure was higher in blacks **(Fig. 2)**; showing the racial difference. Salt sensitivity can be studied by giving high and then low salt—1 week of 200 mmol and another week of 30 mmol of salt and then seeing the BP response. A 24-hour urinary sodium is collected on last day of the week to see compliance. However, long 29 days compliance for this test is an issue, so an abbreviated version (7 day test) has been suggested. Rise and drop in BP by 5–10% is taken as positive test.[7] Castiglioni et

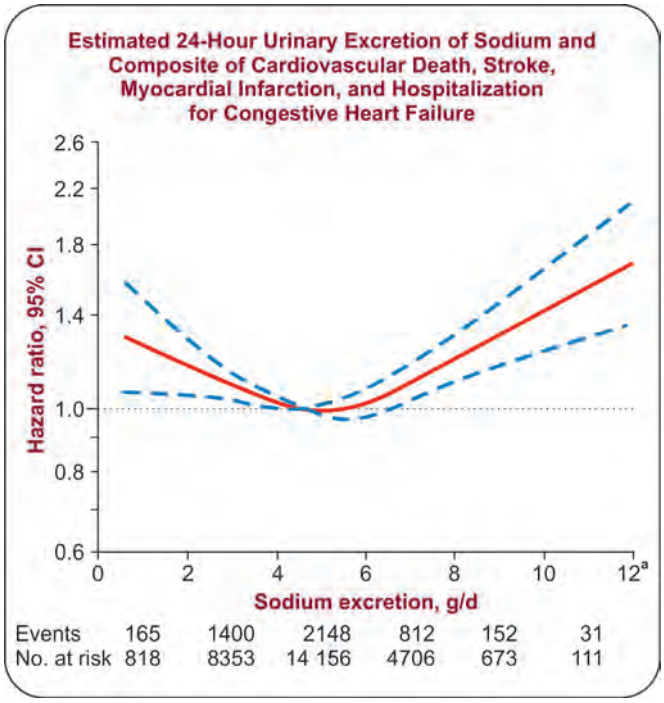

Fig. 1: Graph shows J-shaped relationship between salt and hypertension

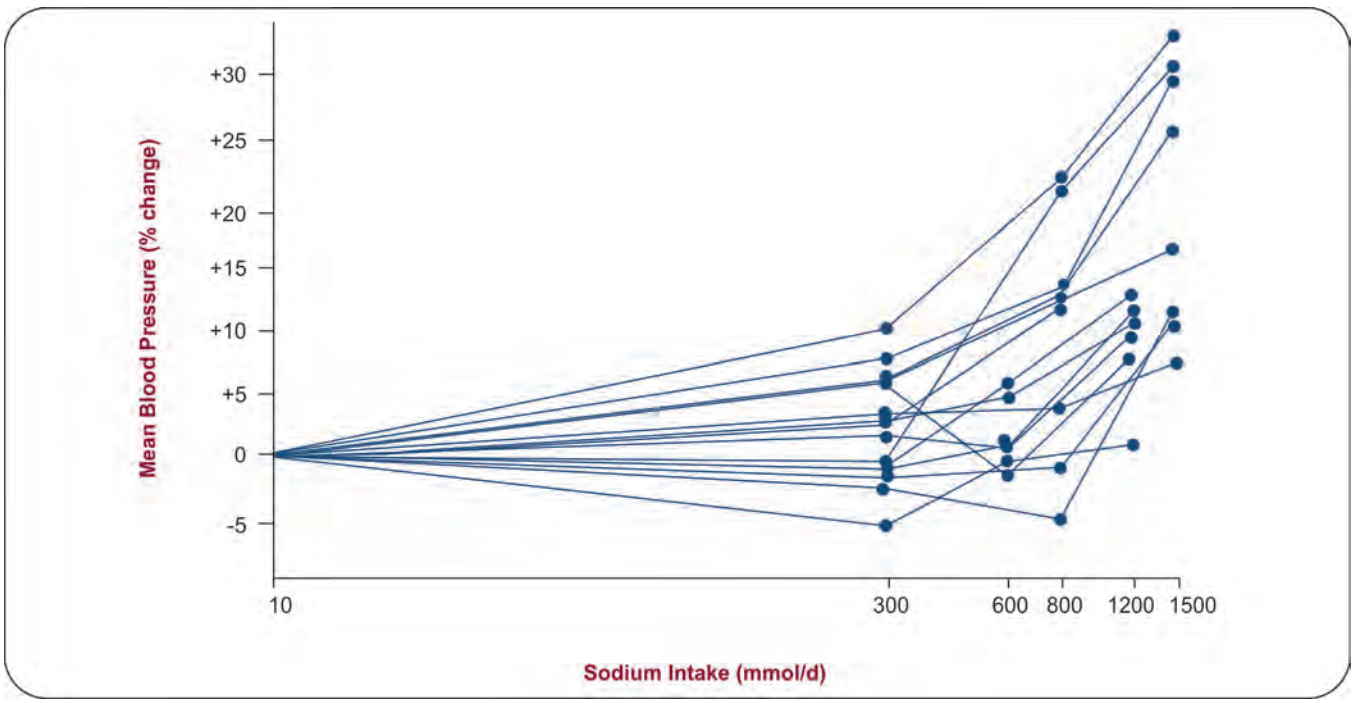

Fig. 2: Percentage change in mean arterial pressure in normotensive subjects receiving incremental increases in sodium. Blood pressure at the end of 7 days of low (10 mmol/d) salt intake was taken as baseline. All subjects demonstrated an increase in blood pressure with salt loading

al.[8] suggested that ambulatory BP monitoring (ABPM) is a better option and more practical. It is assumed that patients who are salt sensitive retain salt and water with resultant loss of circadian nocturnal dip of BP and higher mean heart rate. No salt restriction is required in this test. Based on these two parameters Indices have been devised and patients have been divided into mild, moderate, or highly salt sensitive. Most workers believe that 25% of general population and 50% of hypertensive population is salt sensitive. Salt sensitivity is largely genetic.

Conclusion

In India, average salt intake is between 9–12 gm/day, against recommended 5 gm by WHO. Most of the epidemiological animal and human data show that high sodium intake in both normotensive and hypertensive individuals is associated with age related HT. Excessive salt intake is also associated with increased cardiovascular mortality and obesity. Reduction of salt intake reduces BP and CV mortality. Some limited data also suggests that very low salt intake (<3 gm) may be detrimental. It is recommended to consume salt in moderation (approx. 5 gm per day). Maximum benefit of salt restriction occurs in population consuming high/very high amount of salt.

CHAPTER

151 Newer Avenues in Management of CKD Anemia

Manish Rathi, Rudreshwar Prabakaran

Abstract

Anemia remains one of the challenging aspects in the management of chronic kidney disease (CKD) till date. Oral/intravenous iron and erythropoietin stimulating agents (ESAs) remain the key modalities in the management of anemia in CKD. Traditional forms of oral iron therapy are limited by poor oral tolerance and insufficient absorption from the gut in dialysis population. Newer forms of oral iron such as sucrosomial iron and ferric citrate offer advantages such as alternate mechanism of absorption from the gut, relatively better oral tolerance, and additional properties such as phosphorous binding. Newer forms of intravenous iron preparations have the advantage of higher stability, lesser risk of infusion reactions, and bolus dosing. ESAs are being used for the treatment of anemia in dialysis patients since the 1980s. Although they are effective, higher doses, and higher hemoglobin targets are associated with significant risk of adverse cardiovascular events such as myocardial infarction and stroke. Studies have shown that though anemia predisposes to a poor quality of life and high cardiovascular risk in CKD, correction of anemia does not reduce the cardiovascular risk in these patients. This could be because of the limited options of therapeutic agents available at present and higher doses of both intravenous iron and ESAs have been shown to predispose to higher cardiovascular risk. Thus, there is a need for agents which can not only correct anemia but also not contribute to the pre-existing cardiovascular risk in CKD patients. Hypoxia inducible factor (HIF) stabilizers are one of the newer agents being studied at present in various trials. Studies have shown that these agents can not only reduce the dosages of intravenous iron and ESAs needed to maintain hemoglobin levels in dialysis patients but can also reduce cardiovascular risk. They also have beneficial effect on iron profile such as reduction of hepcidin levels, thus enabling better iron absorption. Thus, research for newer modalities of anemia management in CKD aims to address not only the hemoglobin levels but also improving the quality of life and longevity of CKD patients.

Introduction

Anemia in Chronic Kidney Disease (CKD) predisposes to low quality of life, increased mortality, and cardiovascular disease risk.[1] The incidence of iron deficiency anemia increases with the progression of CKD. Cornerstone of anemia management in CKD so far has been iron therapy and use of erythropoietin stimulating agents (ESAs). Traditional oral iron therapy is limited by poor tolerability, gastrointestinal adverse event, and poor absorption in dialysis dependent patients.[2] Intravenous iron although rapidly restores iron stores is limited by infusion reactions, infections, oxidative stress, iron overload, and increased cardiovascular risk.[3] ESAs, though they reduce the need for blood transfusions, are associated with increased cardiovascular risk when hemoglobin levels exceed 13 g/dL.[4] Thus, at present, search is ongoing for agents which not only increase hemoglobin levels, but also reduces the risk of adverse cardiovascular events seen with the present agents.

Erythropoietin-stimulating Agents

Traditionally used ESAs include epoetin alfa (half-live, $t_{1/2}$ 6.8–19.4 hours, 50–100 u/kg/week dosing), darbepoetin alfa ($t_{1/2}$ 25.3–48.8 hours, 0.45 µg/kg per week to every 2–4 weeks dosing), and methoxypolyethylene glycol-epoetin beta ($t_{1/2}$ 130 hours, 0.6 µg/kg every 2–4 weeks). Longer half-live are achieved through subcutaneous route for epoetin and darbepoetin preparations. Dose escalations beyond double the initial weight based dose are discouraged by KDIGO due to risk of adverse cardiovascular events as observed from the TREAT study. Recently the MIRCERA PASS trial,[5] a multicentre randomized non-inferiority trial, randomized 2818 CKD patients to methoxypolyethylene glycol-epoetin beta (MIRCERA) and reference erythropoiesis stimulating agents. The primary outcome of the study was composite of time to occurrence of death, non-fatal myocardial infarction, or nonfatal stroke. This occurred in 45.4% in the MIRCERA group and 45.7% in the reference group. Higher dose of ESAs was associated with higher risk of primary outcome.

Iron Deficiency Anemia in Chronic Kidney Disease

Iron deficiency is one of the important causes of anemia in CKD. The NHANES (National Health and Nutrition Examination Survey) 1988 to 2004 data of non-dialysis dependent CKD showed that low iron stores defined as TSAT less than 20% or serum ferritin less than 100 ng/mL were present in 57.8–58.8% of men and 69.9–72.8% of women.[6] Causes of iron deficiency in CKD include gastrointestinal bleeding, retention of blood in dialyzers and blood lines, repeated sampling, surgical procedures such as arteriovenous fistula creation, drugs such as proton pump inhibitors and phosphate binders and reduced absorption.[7]

Transferrin saturation (TSAT) and serum ferritin are widely used as indicators of iron status in CKD population. KDOQI 2006 guidelines recommend maintaining serum ferritin more than 200 ng/mL with TSAT more than 20% in dialysis dependent CKD population and serum ferritin more than 100 ng/mL and TSAT more than 20% in non-dialysis dependent CKD population.[8] ERBP (European renal best practice)[9] and NICE guidelines[10] recommend iron therapy when serum ferritin is less than 100 ng/mL and TSAT less than 20%. KDIGO 2012 guidelines recommend iron therapy if TSAT less than or equal to 30% and serum ferritin is less than or equal to 500 ng/mL.[7]

However, TSAT is not an ideal marker of iron status. Levels can increase in the setting of inflammation and decrease in the setting of malnutrition predisposing to low and high TSAT respectively if the circulating iron levels are constant. Transferrin levels also exhibit diurnal variation.[11] Serum ferritin being an acute phase reactant can be increased in later stages of CKD because of systemic inflammation and by itself may not reflect true iron status at high levels.[12] As a result of these variations NICE guidelines in 2015[10] recommend not to use TSAT or ferritin levels alone to assess iron deficiency status in CKD. The guidelines recommend the use of percentage of hypochromic red cells (<6%) and reticulocyte hemoglobin content (CHr, <29 pg), if possible, in the place of TSAT and ferritin levels.

Newer Forms of Oral Iron Therapy

KDIGO 2012 guidelines recommend that 1–3 months trial of oral iron therapy can be considered in non-dialysis dependent CKD population with anemia and TSAT less than or equal to 30% and serum ferritin less than or equal to 500 ng/mL.[7] Elemental iron (200 mg) per day is the recommended daily dosage for these patients. In a normal individual 1–2 mg of dietary iron is absorbed per day and with oral iron supplementation. The maximum absorption of iron per day during oral iron supplementation is around 25–30 mg/day.[13] This is impaired in patients with uremia[14] due to rising hepcidin levels,[15] hence oral iron therapy is not very effective in dialysis dependent CKD population.

Oral iron supplementation comes in ferric and ferrous forms. The bioavailability of ferrous form is 10–15% whereas that of ferric forms of iron is three to four times lower due to reduced solubility of ferric iron in the alkaline media of the gut.[16] Several forms of oral iron are available with wide variations in their extent of absorption and adverse effects **(Table 1)**.

The most common forms of side effects with oral iron therapy are gastrointestinal like nausea, heartburn, pain, constipation, and diarrhea. This is seen in 30–70% of the cases. Among all the oral iron formulations, this risk is highest with ferrous fumarate.[10]

Ferric Citrate

Ferric citrate is ferric iron preparation, which was approved as a phosphate binder by US FDA in 2014 for

TABLE 1 Different forms of available oral iron preparations[17]

Agent	*Elemental iron per tablet*	*Salt content per tablet*
Ferric sulfate	65 mg	325 mg
Ferrous fumarate	106 mg	325 mg
Ferrous gluconate	37.5 mg	325 mg
Ferric citrate	210 mg	1 g
Ferric citrate hydrate	45 mg	250 mg
Liposomal iron	30 mg	30 mg

dialysis dependent CKD patients. The formation of ferric citrate coordination inhibits the precipitation of ferric iron and enables better absorption. Formation of oligomeric complexes in acidic pH enables phosphate binding and monomeric complex formation in alkaline pH of duodenum enables ferric iron absorption.[17] Ferric citrate is always administered with meals.

Non-Dialysis Dependent CKD (ND-CKD) Population

Phase 3 multicenter double-blind randomized placebo-controlled trial with primary end point as change in serum phosphate showed significant reduction of serum phosphate and FGF23 level and significant increase in serum iron, ferritin, and TSAT compared to placebo.[18] Placebo controlled phase 2 (n=149)[19] and phase 3 (n=233)[20] trials with primary end point as mean change in TSAT/phosphorous and more than or equal to 1 g/dL hemoglobin rise showed positive results for patients in ferric citrate arm with similar rate of adverse events between the two groups. Mean drug doses used in the two studies were 5.4 g and 5.7 g/day. Pooled analysis of both the trials showed that the percentage of adverse events were not different from that seen with older conventional forms of oral iron with gastrointestinal events being the commonest.[21] To our knowledge trials with head to head comparison with other oral forms of iron do not exist. Ferric citrate was approved for the treatment of iron deficiency anemia in ND-CKD patients in 2017.

Dialysis Dependent-CKD (DD-CKD) Population

In a randomized trial of 441 patients, ferric citrate was compared with active control (sevelamer and calcium acetate). The trial showed ferric citrate significantly raised hemoglobin levels, TSAT, and serum ferritin and had a comparable phosphate binding ability when compared with active control. Those in ferric citrate arm received less intravenous iron and dose of erythropoietin also significantly reduced with similar adverse events between the two groups.[22] Median daily dose was 1680 mg of elemental iron per day. Similar results were shown in 2019 by the ASTRIO study which compared ferric citrate with non-iron based phosphate binders in 93 hemodialysis dependent patients.[23]

Ferric Maltol

Ferric maltol is novel preparation consisting of ferric iron complexed with maltol (3-hydroxy-2-methyl-4-pyrone). Its hydrophilic and lipophilic properties enable higher bioavailability and better absorption of ferric iron. Since it is not a salt-based formulation, iron is directly absorbed from the complex, and the adverse effects due to free iron seen in salt-based formulations are reduced. Although this compound was described as early as 1980s, it was approved by US FDA for the treatment of iron deficiency anemia in CKD in 2019.

AEGIS-CKD study[24] is a placebo controlled double blind randomized trial conducted in non-dialysis dependent CKD patients, which showed that the compound was well tolerated and produced a significant rise in hemoglobin at week 16. The dose used was 30 mg twice daily.

Sucrosomial Iron

Sucrosomial iron consists of a ferric pyrophosphate core surrounded by a phospholipid bilayer consisting of lecithin and sucrester matrix. Ingredients such as starch and tricalcium phosphate further the coat the structure forming the sucrosome. The phospholipids allow the iron to be absorbed in a vesicular form through transcellular and paracellular routes. The absorption is mediated by 'M' cells of the Peyer patches.[25] Thus, bioavailability of iron is high with less free iron mediated gastrointestinal adverse effects. Cell culture studies using the Caco-2 cell lines showed threefold higher absorption rates for sucrosomial iron when compared to ferrous sulfate.[26] Animal studies with iron deficient mice have shown that increase in hepcidin that is seen with other oral iron formulations is not seen with sucrosomial iron.[27] An open label randomized control of 99 ND-CKD patients[28] compared sucrosomial iron (30 mg/day for 3 months) and IV ferrous

gluconate (1 g) in a 2:1 ratio. The study found that at the end of 1 month, greater number of patients in the IV iron group had increase in hemoglobin, but this difference was absent at the end of 3 months. On discontinuation, hemoglobin levels were stable in IV iron group whereas it fell to baseline in sucrosomial iron group. Adverse events such as hypotension, headache, and infusion reaction were more common in IV iron group. Only 5% of patients experienced gastrointestinal side effects in the sucrosomial group. Thus, although sucrosomial iron is a safer formulation and high bioavailability, iron stores repletion may be slower when compared to conventional iron formulations.

Dialysate Iron (Ferric Pyrophosphate Citrate)

This water-soluble preparation consists of ferric iron tightly complexed to citrate and pyrophosphate to reduce the amount of free iron released into the circulation.[29] This form of iron is administered via the bicarbonate component of the dialysate. On entering the circulation, the iron component is directly transferred thus raising TSAT levels. The advantage of this preparation is that it reduces risk of iron overload. For an individual patient 5 mL (5.44 mg/mL) is added to 9.46 liters of bicarbonate concentrate, which gives a concentration 110 µg/L of iron in the dialysate. The drug is administered in each HD session with TSAT and ferritin levels being done every 3 months. Doses are held if TSAT more than 50% or serum ferritin more than 1000 ng/mL. PRIME,[30] a phase 2 prospective randomized double blind trial with primary end point as change in ESA dose showed that dialysate iron significantly reduced the need for IV iron and increase in ESA dose. Phase 3 CRUISE 1 and 2 studies[31] showed that dialysate iron significantly raised hemoglobin when compared to placebo. The study had three stages: Stage 1—run in period, Stage 2—randomization without change in ESA dose (no IV iron), and Stage 3—open label. Hypotension, headache, and muscle spasms were commonly reported side effects.

Intravenous Iron

Intravenous iron preparations contain an iron hydroxide core surrounded by a carbohydrate shell.[10] The stability of this determines how much iron is released into the circulation at a time. In older preparations such as iron sucrose, adverse effects like infusion reactions and oxidative stress frequent due to low stability of the core and higher release of free iron. Newer preparations **(Table 2)** have a more stable core and thus relatively fewer adverse effects.[10] **Table 2** shows the different intravenous iron preparations used over the years.

KDIGO guidelines 2012 suggests that a trial of intravenous iron may be considered in adult CKD patients with anemia and TSAT less than or equal to 30% and serum ferritin less than or equal to 500 ng/mL, who are not on ESAs or in those who are on ESA and increase in hemoglobin or reduction in ESA dose is desired.[6] The guidelines were based on short-term studies with small number of patients and there were very few trials which looked at the safety of giving IV iron in patients with TSAT more than 30% and ferritin more than 500 ng/mL. In 2007, DRIVE[33] study randomized 134 hemodialysis patients

TABLE 2 Properties of different intravenous iron preparations[32]

Roxadustat	20–250 mg	• Phase 3[41] (n=154) multicentre, double blind trial comparing roxadustat with placebo in non-dialysis dependent CKD • Phase 3[42] (n=305) study comparing roxadustat and epoetin alfa in dialysis dependent CKD	Mean change in hemoglobin over week 7 through 9. Mean change in hemoglobin level from baseline during weeks 23–27	1.9±1.2 g/dL raise in hemoglobin in roxadustat group (p<0.001) Greater mean change in hemoglobin in roxadustat group	• Significant reduction in hepcidin and cholesterol levels in roxadustat group. Hyperkalemia and metabolic acidosis seen more in roxadustat group • Significant reduction in mean hepcidin and cholesterol levels in roxadustat group. Hyperkalemia and upper respiratory tract infection seen more in roxadustat group. Greater rise in Hemoglobin in those with higher CRP
Molidustat	25–200 mg DIALOGUE 1: 25, 50, or 75 mg once daily/25 or 50 mg twice daily DIALOGUE 2: 25, 50, or 75 mg once daily (plus additional 15, 100, or 150 mg) DIALOGUE 3: 25, 50, 75, or 150 mg once daily (plus additional 15, 100, and 200 mg once daily)	• Phase 2b trial[43] (16 weeks) • DIALOGUE 1(n=121): randomized double-blind control trial comparing molidustat and placebo for patients not in dialysis • DIALOGUE 2(n=124): open label molidustat in previously darbepoetin treated patients versus continuing darbepoetin for patients not on dialysis • DIALOGUE 3 (n=199): open label molidustat in previously epoetin alfa or beta treated patients versus continuing epoetin for patients on dialysis • DIALOGUE EXTENSION STUDIES: – DIALOGUE 4[44] (<36 months): all patients from DIALOGUE 1 and 2 who achieved their mean Hb targets were made to continue their respective treatment for 36 months – DIALOGUE 5:[44] patients from DAILOGUE 4 who achieved mean Hb targets were continued on their treatments for 36 months	Change in hemoglobin level between baseline and the mean value from the last 4 weeks of the treatment period Change in hemoglobin from baseline to each post-baseline visit	DIALOGUE 1: Significant number of patients achieved the estimated mean hemoglobin in the molidustat group DIALOGUE 2: Mean hemoglobin was maintained in the target range for each dose in molidustat group DIALOGUE 3: Mean hemoglobin levels were maintained for 75 mg–150 mg daily as a starting dose Mean hemoglobin concentration during study were 11.10±0.508 g/dL in molidustat group and 10.98±0.571 g/dL in darbepoetin group Mean hemoglobin concentration during study were 10.37±0.56 g/dL in molidustat group and 10.52±0.47 g/dL in epoetin group	Estimated difference in mean change in hemoglobin between molidustat and darbepoetin was 0.6 g/dL Lower starting doses were associated with a fall below target range in hemoglobin in the first week. Small increase in hemoglobin was seen with starting dose of 150 mg/day *Side effects:* Adverse effects were comparable between both the groups and were mild to moderate in intensity in all three trials. Numerically more number of patients had hypertension and nasopharyngitis in molidustat group Mean hemoglobin levels were maintained from baseline and throughout the study period in both the groups. Similar percentage of adverse events in both the group (85.6% vs. 85.7%). 21% discontinued drug in molidustat arm when compared to 10% in darbepoetin arm Mean hemoglobin levels were maintained from baseline and throughout the study period in both the groups. Similar percentage of adverse events in both the groups (91.25% vs. 92.2%). More number of patients experienced severe adverse events in molidustat arm (51% vs. 37%). More number of patients discontinued in molidustat arm (23% vs. 7%)

Contd...

Contd...

Drug	Dosage used in studies	Trials	Primary end point	Results	Other observations
Vadadustat	450–600 mg 300 mg OD, 450 mg OD and 450 mg thrice weekly	1) Phase 2b study (non-dialysis dependent CKD, n=210)[45] 2) Open label phase 2 trial (n=94)[46] comparing vadadustat and epoetin alfa	Percentage of patients who in the last 2 weeks achieved Hb ≥11 g/dL or an increase in Hb ≥1.2 g/dL over the predose average Mean change in hemoglobin concentration	54.9% patients in vadadustat arm achieved primary endpoint compared to 10.3% in placebo No statistically significant in hemoglobin from pre-baseline average was observed for all three doses	More number of patients had serious adverse events in the vadadustat arm compared to placebo (23.9% vs. 15.3%). Three deaths occurred in vadadustat arm Nausea, diarrhea, and vomiting were the common adverse effects noted in the vadadustat group. No serious adverse event was noted in the same
Daprodustat	10, 25, 50, and 100 mg 0.5, 2, and 5 mg	1) Multicenter, single blind, placebo-controlled study (n=70, NDD-CKD and 37, DD-CKD)[47] 2) Phase 2a placebo-controlled study (n=73, NDD-CKD and n=83, DD-CKD)[48]	Increase and response rates in achieving target hemoglobin, plasma Erythropoietin level and reticulocyte count Change in hemoglobin over 4 weeks of treatment	Both non dialysis and dialysis dependent population showed a dose dependent increase in hemoglobin, plasma EPO concentrations and reticulocyte count compared to placebo NDD-CKD group: Dose dependent increase in hemoglobin DD-CKD group: 5 mg once daily dose maintained mean hemoglobin levels after switch from erythropoietin	Treatment was discontinued in 33% in the ND-CKD group and 22% in DD-CKD group due to high rate of hemoglobin rise (≥1 g/dL in any 2 week period) or high absolute Hb value (≥13 g/dL). Hepcidin level decreased and TIBC and unsaturated iron binding capacity increased significantly in the daprodustat group Hemoglobin rise occurred with concurrent rise in endogenous erythropoietin levels in daprodustat group. The drug was well tolerated
Enarodustat	2 ,4, and 6 mg	1) Phase 2 study placebo controlled randomized trial in nondialysis dependent CKD (n=94, ESA naïve group and n=103, who previously received ESA)[49]	Rate of rise in hemoglobin per week in ESA naïve group and proportion of patients who maintained change in hemoglobin in previously ESA treated group	ESA naïve group: Dose dependent increase in hemoglobin in enarodustat group Previously ESA treated group: 70% of subjects in enarodustat arm maintained their hemoglobin levels over 24 weeks	Ferritin and hepcidin levels decreased TIBC increased in enarodustat group

with ferritin 500–1200 ng/mL and TSAT less than or equal to 25% to intravenous ferric gluconate and no iron. The study found that hemoglobin increased significantly in the IV iron group with similar side effects between both the groups. FIND-CKD study in 2014 found that hemoglobin rise was significant in ND-CKD patients randomized to high ferritin targets (400–600 µg/L) when compared to lower targets. REVOKE[34] trial in 2015 which randomized patients to oral ferrous sulfate and IV iron sucrose found similar results but with increased serious adverse events in the Intravenous group. PIVOTAL,[35] an open label multicenter trial in 2019 randomized 2141 patients on maintenance hemodialysis less than 1 year to IV iron sucrose in a proactive fashion (400 mg monthly, unless TSAT ≥40% or ferritin ≥700 µg/L) or reactive fashion (400 mg if ferritin ≤200µg/L or TSAT <20%). The primary end point was composite of nonfatal MI, stroke, death, and hospitalization for heart failure. The study found that hemoglobin rise was rapid, blood transfusion, and ESA dosage was reduced in the proactive group. Adverse effects were similar between the groups and the most common adverse event was infection. Thus, higher ferritin targets than that proposed by 2012 KDIGO guidelines, may reduce the need for blood transfusion and higher ESA exposure.

HIF Stabilizers

Hypoxia inducible factors (HIFs) are transcription factors made of α (1α, 2α, and 3α) and β subunits.[36] HIF 1α is widely expressed across all normal tissues whereas HIF 2α expression is restricted to endothelium, selected cells in the kidney, gut, lung, liver, and carotid body. During normoxia, the enzyme prolyl hydroxylase (PHD1, PHD2, and PHD3) hydroxylate prolyl residues in the alpha subunit of HIF. Hydroxylation leads to recognition by von Hippel Lindau (VHL) ubiquitin E3 ligase and subsequent proteosomal degradation of HIF. During hypoxic conditions, the PHDs are inactive and this leads to dimerization of α and β subunits of HIF and target gene expression. HIF 2α regulates erythropoiesis. HIF 2 binds to hypoxia response elements of genes encoding proteins such as duodenal cytochrome B and ferroportin and enables iron absorption.[37] HIF 2α also suppresses hepcidin levels which are elevated in chronic inflammatory states such as ESRD.[38] HIF alpha stabilizers which are currently under study are mentioned in **Table 3**. Most of the trials related to HIF stabilizers are phase 2 in nature **(Table 3)**. Phase 3 studies are ongoing. So far, phase 2 studies have shown that these drugs are well tolerated in both dialysis dependent and dialysis independent CKD population. Apart from correction of anemia, other effects such as reduction in cholesterol levels have been documented in studies.[38] Preliminary data from phase 3 trials (DOLOMITES study, NCT02021318) of Roxadustat has shown that it reduces major adverse cardiac events by 30%. Despite their beneficial effects shown in the studies, other proposed harmful effects such as promotion of tumor growth[39] by increasing VEGF levels are yet to be studied. Long-term studies with large numbers of patients are required to enable safe introduction of these drugs into clinical practice.

Other Upcoming Therapeutic Strategies

Lexaptepid pegol is a pegylated L-oligo-ribonucleotide, which inactivated hepcidin. Phase 1 studies[40] of the compound have shown good safety profile and dose dependent reduction of hepcidin levels in healthy volunteers and in hemodialysis patients. Activins are dimmers, which belong to transforming growth factor beta (TGF-β) family which influence erythropoiesis. *Sotatercept* is a fusion protein of Fc domain of human IgG1 and activin receptor IIa. Phase 2 studies in hemodialysis patients have shown acceptable safety profiles, stable hemoglobin levels, and lower rates of rescue with ESAs.

Conclusion

Newer modalities of management of anemia in CKD patients are aimed at development of agents, which can reduce the need for blood transfusion, need for escalation of dose of ESAs and maintain stable hemoglobin levels for prolonged periods of time without increasing the risk for adverse cardiovascular events associated with the current available agents.

CHAPTER

152 SGLT2 Inhibitors—Mechanisms of Cardiorenal Protection

Ashwini Balasaheb Gadde, Vijay Kher

Abstract

Sodium Glucose co-transporter-2 (SGLT2) inhibitors are a class antihyperglycemic agents, which act by selectively inhibiting SGLT2 present in the proximal tubules in the kidney causing glucosuria and to some extent natriuresis. Though originally invented as one of the oral hypoglycemic agent (OHA), many randomized controlled trials have confirmed their role far beyond this, in cardiovascular (CV) and renoprotection. This is in sharp contrast to other OHAs which were associated with either mild CV benefits or rather harm. The benefit possibly extends to nondiabetic population as well.

Though SGLT2 inhibitors act mainly by causing glucosuria, natriuresis, and by inhibiting tubuloglomerular feedback (TGF), these effects are insufficient to explain the impressive CV and renal outcomes. In this review we aim to explain the possible mechanisms of cardiorenal protection of SGLT2 inhibitors.

Introduction

Sodium Glucose co-transporter-2 (SGLT2) inhibitors (-gliflozins) are a class antihyperglycemic agents, which act by selectively inhibiting SGLT2 present in the proximal tubules in the kidney, leading to increased glucosuria and thereby decreasing blood glucose levels. Though initially approved in 2013 as one of the oral antihyperglycemic agents for type 2 diabetes, the outcomes in EMPA-REG OUTCOME trial opened a window to its role far beyond glycemic control.[1] This study established a remarkable and unexpected cardiovascular (CV) and renal benefits of empagliflozin in patients with type 2 diabetes with clinical cardiovascular disease (CVD). Later many studies supported and strengthened their role in wide class of patients, including those without established CVD proving their beneficial effects in diabetes mellitus as primary as well as secondary prevention for CV & renal endpoints.[2-7] **Table 1** summarizes the CV and renal outcomes in major trials. These trials have established SGLT2 inhibitors as a paradigm shift in the management of CV and renal complications of type 2 diabetic patients[2-5] and may be in nondiabetic CKD patients as well.[6]

Basic Mechanism of Action of SGLT2 Inhibitors[9]

Approximately 90% filtered glucose reabsorption is mediated by SGLT2 channels located on S1 segment of proximal convoluted tubules (PCT). These channels are also responsible for 5–14% of Sodium reabsorption depending upon the glycemic status. Thus, the physiological effects of SGLT2 inhibitors are a consequence of both glucosuria and natriuresis.

Before going in detail, let's concentrate on the glucose absorption in diabetes mellitus and effects of SGLT2 inhibitors on tubuloglomerular feedback (TGF)—an important mechanism for glomerular hemodynamic alteration of in type 2 diabetes and diabetic nephropathy **(Fig. 1)**.

TABLE 1 Cardiovascular and renal outcomes of SGLT2 inhibitors in trials

Trial	*Population*	*Cardiac end point Hazard ratio (confidence interval)*	*Renal end points Hazard ratio (confidence interval)*
EMPA-REG OUTCOME[1] N=7020	T2D+CVD eGFR>/30	3-point MACE* 0.86 (0.74–0.99)	Doubling of serum creatinine with eGFR<45, initiation of RRT or kidney-related death 0.54 (0.40–0.75)
CANVAS program[2] n=10,142	T2D+CVD (if>/30 yrs) or >2 CV risk factors if >/50 yrs	3-point MACE* 0.86 (0.75–0.97)	Progression of albuminuria 0.73 (0.67–0.79) 40% reduction in eGFR, RRT, or renal-related death 0.60 (0.47–0.77)
DECLARE -TIMI58[4] N=17,160	T2D+CVD/>2 CV risk factors	3-point MACE* 0.93 (0.0.84–1.03) non-significant. Composite of CV death or HHF 0.83 (0.73–0.95)	>40% decrease in eGFR to <60, ESRD or renal-related death 0.53 (0.43–0.66)
CREDENCE [3] N=4401	T2D+ eGFRof 30 to <90, albuminuria and on stable dose of ACEi/ARBs for >/4 weeks 3	Composites of CV death or HHF 0.69 (0.57–0.83) 3-point MACE 0.80 (0.67–0.95) HHF 0.61(0.47–0.80)	Relative risk of the primary outcome composite of ESRD, doubling of the serum creatinine level from baseline or death from renal or cardiovascular disease. Was 30% lower (hazard ratio, 0.70 (0.59–0.82)*
DAPA-HF[5] N=4744	Heart failure and an ejection fraction of 40% or less (irrespective of the diabetes status)	The primary composite outcome of worsening heart failure or CV death 0.74 (0.65–0.85)	A composite of worsening renal function 0.71 (0.44–1.16) [§]
DAPA-CKD[6] N=4304	Adults with CKD with an eGFR ≥25 but ≤75 mL/min/1.73 m^2 and a UACR ≥200 mg/g but ≤5000 mg/g on stable dose of ACEi/ARBs for >/4 weeks	The composite of CV death or HHF 0.71 (0.55 to 0.92).	Primary composite endpoint • Time to ≥50% eGFR decline from baseline (confirmed by ≥28-day serum creatinine) • Time to ESRD defined as eGFR <15 mL/min/1.73 m^2, need for chronic dialysis (both confirmed after ≥28 days) and renal transplantation • Time to renal or cardiovascular death 0.61 (0.51 to 0.72)

*Primary outcome, §Not significant

3-point MACE, major adverse cardiac events (composite of nonfatal stroke, nonfatal MI, cardiovascular death); ACEi/ARB, angiotensin converting enzyme inhibitors/aldosteron receptor blockers; CKD, chronic kidney disease; CVD-cardiovascular disease; ESRD, end stage renal disease; HHF, hospitalization for heart failure; RRT, renal replacement therapy; T2D, type two diabetes; UACR, urine albumin creatinine ratio

In hyperglycemic state, filtered glucose load is increased. To handle that load, there is increased expression of SGLT2 on PCT. Along with glucose, sodium reabsorption also increases. This increased work of Na and glucose reabsorption leads to increased cortical oxygen consumption and also tubular hypertrophy, resulting in renal cortical ischemia, which promotes interstitial fibrosis.[8] As more glucose and sodium are absorbed in PCT, less sodium will be delivered to distal convoluted tubules (DCT), which is sensed by macula densa. This causes increase in single nephron glomerular filtration rate (SNGFR) via TGF. Due to the decreased sodium in DCT (TGF), there is afferent arteriolar dilatation and efferent arteriolar vasoconstriction due to increase in renin secretion and increased renin–angiotensin–aldosterone system (RAAS) activation.[8] High SNGFR further increases the work of reabsorption continuing this vicious cycle. Hyperfiltration and increase in intraglomerular pressure also causes proteinuria which is nephrotoxic and contributes to progression of diabetic nephropathy.

SGLT2 inhibitors interfere with these essential pathophysiological effects in a diabetic kidney **(Fig. 2)**. By inhibiting SGLT2 channels, hyper-reabsorption of Na and glucose reabsorption is inhibited thus decreasing the tubular work load and oxygen consumption avoiding cortical ischemia. Because of the inhibited Na and

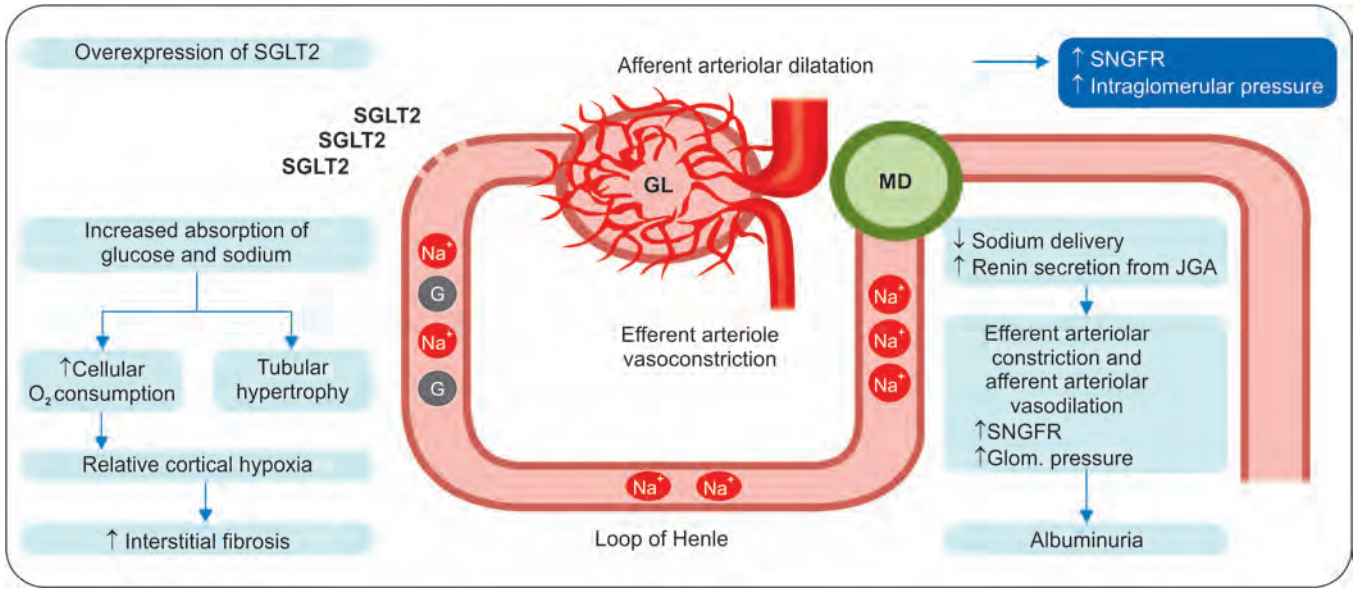

Fig. 1: Glucose absorption in diabetes mellitus and effects of SGLT2 on tubuloglomerular feedback and in evolution of diabetic nephropathy
JGA, juxtaglomerular apparatus; SNGFR, single nephron glomerular filtration rate; MD, macula densa

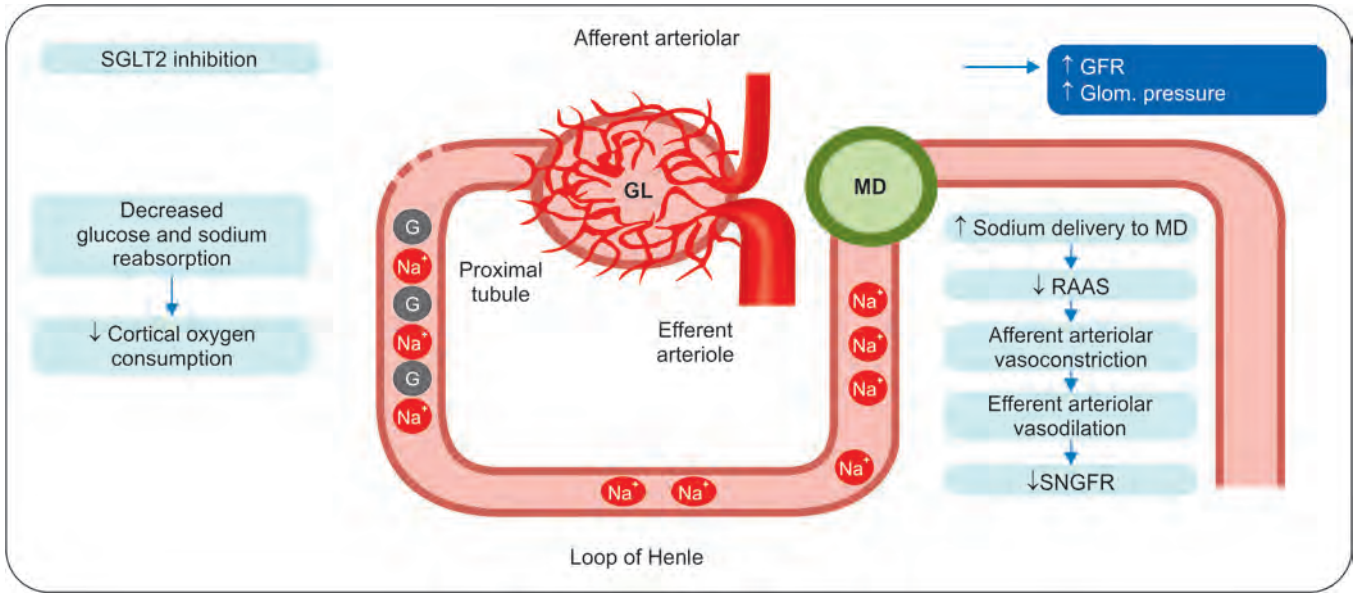

Fig. 2: Effect of SGLT2 inhibitors on pathophysiological mechanisms on diabetic nephropathy

glucose reabsorption in PCT, more is delivered the DCT. This causes afferent arteriolar constriction and decreases SNGFR via TGF mechanism. Also because of increased load of sodium and potassium in DCT, tubular backpressure in the Bowman's capsule increases, leading to decrease in SNGFR. These effects together lead to decrease in intraglomerular hypertension, glomerular blood flow leading to decrease in proteinuria.

These effects to some extent do explain the renal benefits of SGLT2 inhibitors but may be inadequate to explain the mechanism for CV benefits. Although the glucose lowering efficacy of SGLT2 inhibitors declines at

the lower eGFR range, the CV benefits are persistent across wide spectrum kidney disease (eGFRs of 30–60 mL min–1 [1.73 m]–2, 60–90 mL min–1 [1.73 m]–2 and >90 mL min–1 [1.73 m]–2).[10] Also, beneficial effects of SGLT2 inhibitors extend to nondiabetic population as well **(Table 1)**.[6] This implies that many "extrarenal" effects might play a role.

Metabolic Effects Secondary to Glucosuria

Reduction in HbA1c

Placebo substracted HbA1c difference in EMPA-REG was mild (0.4%) but it showed impressive 38% reduction in CV death, 35% reduction in heart failure, and 46% risk reduction was seen in composite renal outcome. This is in sharp contrast with other oral hypoglycemic agents (OHAs), which were associated with either mild CV benefits or sometimes even harm.[11-13] So, mechanisms other than this need to looked into.

It is important to note that SGLT2 inhibitors do not cause hypoglycemia. This is due to intact counter-regulatory mechanisms including upregulation of hepatic gluconeogenesis. Also, SGLT1 downstream prevents glucose excretion during SGLT2 inhibition when the filtered glucose falls below the transport capacity of SGLT1.[7]

Weight Loss

SGLT2 inhibitors reduce body weight and fat mass, especially epicardial fat which is important for leptin (a proinflammatory adipokine) secretion. In a 52-week study comparing canagliflozin with glimepiride, canagliflozin reduced serum leptin levels by 25% and increased the levels of the anti-inflammatory adipokine adiponectin by 17%.[14] The antinatriuretic, anti-inflammatory and antifibrotic effects of SGLT2 inhibitors (discussed further) antagonise the deleterious effects of leptin on heart and kidneys.[14]

Decrease in Uric Acid[15]

Though benefit of this effect on CV protection is unclear.

Hemodynamic Effects Secondary to Natriuresis

Blood Pressure Reduction

Along with SGLT2 inhibition, direct inhibition of the cardiac sodium-hydrogen exchanger (NHE)1 by SGLT2 inhibitors is another pathway hypothesized in natriuresis and reduction in BP.

In EMPA-REG trial, SGLT2 inhibitors reduced systolic/diastolic BP by around 5/2 mm Hg.[1] A recent meta-analysis of 43 randomized controlled trials with 22,528 patients assessed the seated clinic blood pressure effects of SGLT2 inhibitors in patients with type 2 diabetes mellitus. The reduction in blood pressure was over and above the already receiving antihypertensive therapy.[16]

Diuretic Effect

SGLT2 inhibitors decrease preload by both natriuresis and osmotic diuresis secondary to glucosuria. But those are different from other conventional loop/thiazide diuretics. They do not cause reflex sympathetic activity thus causing no compensatory tachycardia.[17] It is postulated that as opposed to diuretics, SGLT2 inhibitors promote a greater decrease in interstitial fluid relative to blood volume.[18] This may have significant benefits in reducing neurohormonal activation via their effects on RAAS. Also, thiazide/loop diuretics are known to cause hyperuricemia and sometimes hyperglycemia, but these parameters are positively affected by SGLT2 inhibitors.

Decrease in Intraglomerular Hypertension

As explained earlier, natriuresis also causes increased delivery of sodium to macula dense which will lead to afferent arteriolar constriction via TGF mechanism. This decreases the intraglomerular hypertension and hyperfilteration occurring in early diabetic nephropathy. This will also decrease proteinuria but at the cost of initial dip in eGFR (around 4–6 mL/min) in initial 3–4 weeks,[1] which is reversible either after stopping medication or sometimes even after continuous prolonged treatment. This suggests that it's related to a functional change rather than structural changes, similar to angiotensin-converting enzyme inhibitor (ACEi)/angiotensin receptor blockers (ARBs).

Currently, ACEi/ARBs are the standard treatment for this purpose, which dilates efferent arteriole. In EMPA-REG as well as other studies related to SGLT2i, most of the patient population (almost 80%) was already on ACEi/ARBs. Benefits of SGLT2i are additive to current optimal therapy. RAAS blockers are active through neurohormonal pathways of hyperfiltration whereas SGLT2 inhibitors work via tubular pathway.

Though above mentioned hemodynamic and metabolic effects have positive impact on CV outcome, in practice, this impact is unexpectedly strong. Previously it was thought that these CV benefits are because of the effect on atherosclerosis, but benefits are seen as early as 3 months from the start of treatment. It is very unlikely that atherosclerosis-related effect will show impact so early. So, more possible mechanisms have been proposed and are getting tested.

Cardiac Fuel Energetics

So to explain these remarkable cardiac and renal benefits, Ferrannini et al. came up with a "Thrifty substrate" hypothesis.[19] Glycosuria lowers insulin levels and raises fasting and post-meal glucagon concentrations. This causes restriction of glucose utilization and increase in lipid mobilization. Increased delivery of free fatty acids (FFAs) to the liver stimulates *ketogenesis*. In conditions of prolonged hyperketonemia, b-hydroxybutyrate is freely taken up by the heart and oxidized in preference to fatty acids. The benefit of preferential fuel selection was demonstrated in a study of 3-hydroxybutyrate versus placebo in humans with chronic HF in which ketone infusion increased *stroke volume, cardiac output,* and LVEF in a dose responsive fashion.[20] This fuel selection improves work efficiency with respect to oxygen consumption especially, in failing heart and also in kidneys.[21] But recently this theory has been challenged. Animal studies to prove this change in cardiac energetics have been inconclusive. Also, the stressed heart already preferentially utilizes ketone bodies, and the diabetic kidney is a ketogenic organ[21,22] so what difference does SGLT2 inhibitors do? It needs to be delineated and explored further.

Cellular Reprogramming to "Dormancy State"

Another theory seems to be that instead of postulating a drug-induced enhancement of fuel supply, Avogaro et al. suggest that SGLT2 inhibitors induce a "dormancy state" that mimics starvation.[23] When cells are stressed by starvation or by hypoxia or reactive oxygen species, injured organelles, and misfolded proteins, they activate a transcriptional program to adapt to this low-nutrient conditions. Sirtuin 1 (SIRT1) and adenosine monophosphate–activated protein kinase (AMPK) are the key enzymes in this respect. SIRT1 decreases oxidative stress by enhancing antioxidant activity, AMPK reduces the formation of reactive oxygen species, In addition, both enzymes inhibit energy storage (glycogen synthesis and lipogenesis) while promoting energy utilization (fatty acid oxidation leading to ketonemia). Coordinated activation of two signaling stimulates autophagy which is a lysosome mediated pathway that removes potentially dangerous constituents and recycles cellular components. Since type 2 diabetes is perceived by cells as a state of nutrient excess, it is accompanied by suppression of SIRT1 and AMPK. SGLT2 acts as a sensor of energy overabundance in this situation. SGTL2 inhibitors block this sensing mechanism and inhibits suppression of this SIRT1/AMPK pathway.

Hemoconcentration/Erythropoietin Activation

SGLT2 inhibitors may not only deceive cells into believing that they are fasting but also that they are hypoxic, which activate hypoxia-inducible factor-2α (HIF-2α) via this SIRT1/AMPK pathway. Also, decreased reabsorption in early PCT causes compensatory increased transport work in late PCT and medullary thick ascending loop. This leads to relative medullary hypoxia and stimulation of HIF 1&2 which cause increase in erythropoietin secretion. Elevated hematocrit is also a surrogate marker of reduced plasma volume as well as of recovery of tubulointerstitial function associated with SGLT2 inhibitor therapy. In mediation analysis of EMPA-REG, changes in hematocrit contributed 51.8% of the effect of empagliflozin versus placebo on the risk of CV death, maximum of all the effect of SGLT2 inhibitors.[24]

Direct Effect on LV Mass

Along with decreasing preload and afterload, it is possible that SGLT2 inhibitors have direct beneficial impact of cardiac remodeling. The EMPA-Heart trial which included patients with T2D and coronary artery disease demonstrated a reduction in LV mass indexed to body surface area in patients treated with empagliflozin. This was thought to be in part due to a reduction in wall stress.[25]

Effect on NLRP3 Inflammasome

Activation of the NLR family, pyrin domain-containing 3 (NLRP3) inflammasome in the innate immune cells and

subsequent interleukin (IL)-1β release has been proposed as one of the pathogenic mechanisms in diabetes, atherosclerosis, and heart failure. SGLT2 inhibitors have been shown to inhibit this effect with respect to sulfonylureas.[26]

Effect on Arterial Stiffness

A post-hoc analysis of trials and study comparing dapagliflozin with hydrochlorothiazide demonstrated that empagliflozin was associated with not only decreased BP, but showed positive effects on markers of arterial stiffness and vascular resistance, that is, aortic pulse wave velocity, brachial flow mediated dilation, and shear rates.[27,28]

In addition to these mechanism, many others are being considered and getting investigated in animal/human-inhibition of sodium-hydrogen exchanger 1 on cardiac myocytes,[29] increase in Circulating Pro-Vascular Progenitor Cells.[30]

Conclusion

To conclude, though the exact mechanism of cardiorenal protection is still unclear, one thing is clear that we need to expand the horizon of SGLT2 inhibitors from a "glucose lowering agent" to "organ protective" agent. Studies are underway trying to find its use in nondiabetic population (DAPA CKD, EMPA-KIDNEY, TRANSLATE). Results of DAPA-HF trial have shown positive results in nondiabetic heart failure patients.[5] There were initial safety concerns with respect to acute kidney injury, diabetic ketoacidosis, amputations, urinary and genital tract infections, bladder cancer, and bone fractures. However, recent trials have downplayed these risks, and benefits are found to outweigh risks.

CHAPTER

153 Optimizing Renal Care in Elderly

Narinder Pal Singh, Rahul Mishra, Shaurya Kaul

Abstract

The global burden of chronic kidney disease (CKD) is increasing particularly among elderly. Aging itself increases vulnerability for poor renal health. High cost of management and poor outcomes of CKD necessitate optimization of renal care to be started early in the course of the disease. Collaborative involvement of patient, caregiver, primary care provider and multidisciplinary clinics is required to achieve optimal conservative care and renal replacement modality. Dietary changes, lifestyle modification, managing the pill-burden, appropriate nutrient supplementation, and vaccination to take care of risks and complications of CKD are key steps as per latest evidences available. For those progressing to end-stage renal disease (ESRD), an approach, taking into consideration of patient's perspectives and functional and cognitive status, to decide appropriateness of renal replacement therapy (RRT) or end-of-life care is a very essential particularly for elderly patients. There is need of progressive work for optimizing various facets of renal care in elderly patients particularly in economically constrained regions where most of the CKD patients fail to receive appropriate care.

Introduction

The global burden of kidney disease, which has been rising consistently, poses a major challenge to the primary care physician. Recent GBD reported that out of 697.5 million worldwide CKD patients, India harbored 115.1 million.[1] As per latest census in India (2011), around 104 million people were 60 years or above and by 2021 this number is predicted to reach 133.32 million. So, the likely CKD burden among elderly is expected to rise proportionately. Indian CKD registry[2] reported that diabetic nephropathy was most common cause (31%) for CKD and mean age of CKD patient was 50 years. Prevalence of CKD and its risk factors like diabetes, hypertension, obesity, and cardiovascular disease increases with age. Age-related changes in kidney include structural changes like macrostructure changes (decrease in cortical volume, increase in surface roughness, and size of simple renal cysts), microstructure changes (nephrosclerosis-arteriosclerosis, glomerulosclerosis, interstitial fibrosis, tubular atrophy), and functional decline in total-kidney GFR due to decrease in total nephron count.[3] Optimal care of CKD risk factors can delay or even prevent this progression of healthy aging of kidneys into CKD. Elderly population needs special attention to their physical and functional deficits including multiple co-morbidities (hypertension, diabetes), cognitive impairment, frailty and progressive sensory impairment. Owing to high cost and poor outcomes of CKD management, there is a definitive need for optimization of care in elderly CKD patients on individual basis. Optimal care goals include best outcomes at individual, population and society levels for betterment of survival and quality of life. The management of advanced CKD in the elderly can be challenging in regards to prediction of disease progression to ESRD, selection of RRT modality, and choice of optimal vascular access (VA) for hemodialysis (HD). There is a

need for collaborative efforts between patient, caregiver, primary care provider, and interaction of multidisciplinary clinics. Current review will focus on optimizing renal care including conservative medical management and selection of RRT modalities such as HD, peritoneal dialysis (PD) and kidney transplant (KT) for elderly to maximize functional status and minimize treatment-associated morbidity.

Pre-RRT Phase: Elderly Focused Conservative Care

In India, a country with 1.3 billion people and around two thousand nephrologists, practices that promote renal health and prevent renal disease progression are important. Optimal care for elderly involves mix of pharmacological and non-pharmacological interventions. Diet may be important in deciding course of CKD before dialysis. Moderate intake of protein, especially dietary strategies that increase plant protein, low sodium, dietary fiber, vitamin D, and reduction in obesity may limit worsening of CKD.[4] Renoprotective effects of maintaining muscle health, especially among elderly who have high prevalence of sarcopenia, are documented and they must be stressed upon in routine care.[5] Life style changes can be recommended based on specific comorbidity of CKD patients, for example, increasing the aerobic exercise capacity in those with cardiovascular disease, high dietary fiber and moderate intensity exercise for patients with chronic lung disease or rheumatoid arthritis and weight reduction for diabetic patients.[6] CKD patients are likely to encounter polypharmacy risks, potential drug-drug interactions (pDDI) and inappropriate prescriptions. Incorporating procedures and pharmacists to determine pDDI into the kidney care model could help dealing these challenges.[7,8] Non-adherence is a possible outcome of multiple pill burden among CKD patients. Whenever possible during clinical management, tapering thereafter deprescription strategies should be planned. Recommendations have been made on approach to deprescribe PPIs, statins and oral hypoglycemic agents in CKD patients to reduce pill burden.[9] Practices involving identification and avoidance of agents like nephrotoxic antimicrobials, radio-contrast exposure, combining ACEI and ARBs, NSAIDs and diuretics that might precipitate AKI should be promoted.[10] Providing recommended vaccinations—hepatitis B, pneumococcal, influenza, and other routine vaccines are essential for optimum care of CKD patients.[11] Focus should be laid upon patient's values and perspectives about the disease, as deficiency about health literacy is widespread in CKD population.[12,13] Information should be provided using simple terms and techniques like "teach back" to ensure attention and understanding.[14] Routine screening for anxiety, depression, and cognitive impairment may be important because CKD is associated with increased risk for dementia in elderly and poor functional status (including poor overall cognition, language, and memory). Various mediators accounted for cognitive derangement like anemia, increased oxidative stress, inflammatory markers, and changes in lipid and homocysteine metabolism are found in CKD patients.[15] Identifying functional changes is important in order to optimize the management outcome, as studies have shown association of cognitive impairment with negative outcome and increased risk of 1-year mortality among elderly severe CKD patients who were in-hospital.[16-18] The conservative pharmacological management is sometimes the only choice in elderly patients who are declining or not fit for RRT **(Flowchart 1)**.

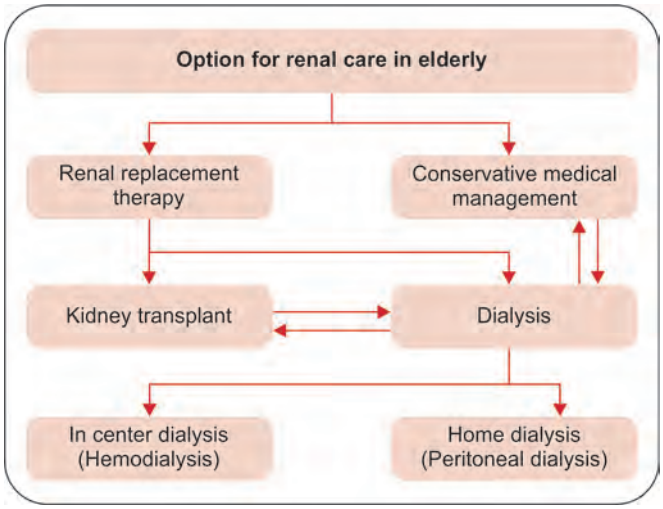
Risks and Complications of CKD

CKD, due to any cause, can progress through I to V stages. Complications and their management begin usually by stage III onward, and by stage IV aim is to prepare the patient for dialysis with suitable measures like VA to be needed during stage V. Appropriate timely management is required, particularly in elderly patients who may have multiple modifiable risk factors that could prevent or delay this progression.

Diabetes Mellitus

Diabetes mellitus is the most common cause of CKD and this holds true for both the developed and the developing world. Diabetic glomerulopathy might be contributing to over half of the ESRD cases. Bringing down of blood glucose levels (to preserve average HbA1c 7%) reflects as delay in urinary albumin excretion, GFR decline, and requirement for dialysis. The use of ACEI/ARBs can further prevent kidney damage in normotensive diabetics with proteinuria.[19] In the elderly, frail, and CKD patients,

Flowchart 1: Options for renal care in elderly



the consequences of hypoglycemia are very serious including injury, myocardial infarction, stroke, and death. Therefore, a tailored approach for target HbA1c levels should be followed for elderly CKD patients to avoid risk of hypoglycemia.[20] Metformin is usually the first antidiabetic to begin with. For reducing risk of lactic acidosis, a rare event, FDA recommends avoiding its use if creatinine in men >1.5 mg/dL and women >1.4 mg/dL. Sulfonylureas undergo renal clearance; therefore, risk of hypoglycemia is more in advanced CKD patients and their use should be avoided if GFR <30 mL/min/1.73 m^2. Among meglitinides, repaglinide is safe to use in CKD. Thiazolidinediones are hepatically metabolized so can be used in CKD with caveat that fluid retention and increased risk of fracture rates in women especially with underlying renal osteodystrophy could be concerning. Insulin is safe for all CKD patients and long acting single dose can be used when oral agents fail to obtain target sugar levels. However, more complicated regimens with multiple insulin dosing may increase chances of error and hypoglycemia, especially among elderly with cognitive impairment. Among GLP1 agonists, no dose adjustments are needed for dulaglutide or albiglutide in CKD while exenatide and liraglutide should be avoided with eGFR <30 mL/min/1.73 m^2 due to poor renal clearance. DPP4 inhibitors (sitagliptin, saxagliptin, linagliptin, vildagliptin) are well tolerated and have some renal clearance and require dosage adjustment.[21] Cardioprotective and renoprotective effect of SGLT2 inhibitors (Empagliflozin, Canagliflozin, Dapagliflozin) have been demonstrated in diabetic kidney disease.[22]

Hypertension

With regards to CKD, hypertension is related as both the cause and effect. Hypertension is a major risk factor that increases the risk of progression of kidney disease and increase the risk of cardiovascular complications. The KDIGO (2012) guidelines have described the general management strategies for controlling blood pressure in non-dialysis-dependent CKD patients. A combination of lifestyle changes and pharmacological management are the key approach to achieve target BP goal in CKD patient. Gradually lowering of blood pressure should be recommended. Blood pressure readings based upon ambulatory and self-measurements better reflect hypertension compared to office blood pressure readings and allow individualizing of antihypertensive treatment. Blood pressure targets need to be individualized and medical management should be based on the age, presence of illness and end-organ damage (cardiovascular and retinopathy), progression of renal disease, and tolerance to treatment. Vascular stiffness necessitates periodic monitoring for postural hypotension as it causes higher systolic blood pressure whereas the diastolic blood pressure could still decline. Slowing of the progression of kidney disease and reduction in CVD risk are the goals of antihypertensive therapy and target BP, as suggested by KDIGO guidelines for non-dialysis patients, 140/90 mm Hg in nondiabetics/diabetics without proteinuria and 130/80 mm Hg in patients with proteinuria, is a key strategy to prevent further renal function decline. Initial fixed dose RAAS inhibitor (ACEI/ARBs) based combination therapy (coadministration of CCB, diuretic, α-blocker, or β-blocker) is more effective and efficient than sequential monotherapy for achieving target blood pressure and reduces risk of adverse events by allowing use of lower doses of each drug.

Anemia

In the elderly especially frail elderly with CKD, anemia is related to poor function and quality of life, increased frequency and duration of hospital stays and mortality.[23] Normocytic normochromic anemia a common complication seen in CKD patients. A thorough assessment of other causes of anemia starting with

complete blood count, peripheral smear, iron studies, B12 and folate levels should be performed before labeling anemia of CKD. As per KDOQI 2012 guidelines, target hemoglobin between 10–11.5 gm/dL is desired in all CKD patients. Consider ESA in pre-dialysis and dialysis patients with Hb below 10 g/dL and between 9–10 g/dL, respectively.[24] KDOQI Anemia Work Group recommends sufficient iron supplementation to maintain serum ferritin concentration >200 ng/mL in HD patients and >100 ng/mL in non-dialysis or on peritoneal dialysis CKD patients for optimal erythropoiesis.[24]

Vitamin and Electrolyte Abnormality

Vitamins and minerals supplementation is critical for elderly care. For CKD patients who are already deficient (S.vit. D <20 ng/mL) or insufficient (S.vit. D = 20–29 ng/mL) in vitamin D, adequate vitamin D is absolute requirement for preventing secondary hyperparathyroidism (SHPT) and its complications. Supplementation with ergocalciferol or cholecalciferol should be done as per individual needs. However, once SHPT develops, vitamin D receptor agonists and/or calcimimetics are required. Ensuring normal reference levels of electrolytes like calcium and phosphorous is essential for prevention of bone disorders among CKD patients. Dyselectrolytemias including hypo- and hypernatremia and hyperkalemia are well associated with aging kidneys.[25] Caution with use of potassium sparing drugs among CKD patients is required to avoid serious adverse events. Metabolic acidosis in CKD patients is often due to impaired ammonia excretion and its management, for example using sodium bicarbonate, improves nutritional parameters as well as CKD progression.[26]

Renal Replacement Therapy

CKD patients are prone to progress to ESRD. Options of RRT include HD, which can be provided in-center or at home, PD, and KT. Economic constraint limits RRT availability to majority of ESRD patients in India. Elderly patient on HD are physically frail with multiple comorbidities and functional dependencies. Initiation of dialysis in elderly should use multidisciplinary approach taking into account various factors including life expectancy, pros and cons of each dialysis modality, quality of life, and patient and caregiver preferences. Possibility of survival benefit for elderly patients on dialysis as compared to those with no RRT patients cannot be ruled out; however, they tend to spend lot of time around health-care facility and may not get life satisfaction.[27] Assessing HD accessibility for each elderly patient opting for RRT is necessary as caregivers and patients feel overwhelmed and burdensome about frequent multiple visits (at least thrice weekly) to a faraway located dialysis center. The approach of incremental dialysis in elderly may assist them in adjusting to dialysis and sustaining residual kidney function.[28] Suggested incremental dialysis approach involves 1–2 dialysis session weekly, each around 1.5–2.5 hours duration until worsening of renal function necessitates further modification. Home dialysis can be suitable for those able to perform it by themselves or with a family member support. However, it may not be preferred choice for elderly with multiple comorbidity, frailty, and lack of support. Exploration of ideal RRT has led to understanding that diverse modalities are used by patients during the entire course of CKD. A term coined as "Integrated Care" has been popularized.[29,30] Originally, it suggested starting with PD and then changing to in-center HD (CHD). The centers pursuing this approach had reported survival benefits and cost optimization.[31,32] PD needs assistance and can be preferred as home based dialysis modality in presence of an assistant. However, PD may not be suitable for elderly having poor functional status and declining vision. PD is relatively contraindicated among those with severe pulmonary disease, irreducible hernias, active inflammatory bowel disease, significant scar from previous abdominal surgery, colostomy, ileostomy, or gastric tubes.[33] Decision about choice of dialysis modality should also match patient's values with treatment characteristics in order to maximize achievable quality of life in elderly.

Vascular Access

An effective VA is very essential for carrying out HD and comprises of arteriovenous fistula (AVF), arteriovenous graft (AVG), and central venous catheter (CVC). For long, as first choice, AVF has been created in the non-dominant hand. Procedure began at a distal site to safeguard proximal blood vessels for future use, thus radiocephalic fistulas became initial choice.[34] This site also reported to have higher failure rate because of thrombosis and inability to mature, requiring more surgeries and use of tunneled catheter for dialysis. Moreover, preserving a venous

location in a frail elderly may not be prudent due to fixed life anticipation, so, the most appropriate AVF, utilizing the most excellent vessels should be created first.[35,36] Complications such as stenosis, thrombosis, and distal hypoperfusion ischemic syndrome (DHIS) are concerning and add to heavy cost and morbidity with access. Therefore, varying views arise stating creation of upper arm AVFs in elderly as standard care or preferring AVGs and CVCs as more suitable options depending on individual patient. De Silva et al. found similar survival for elderly aged >80 years using either AVFs or AVGs, though, that could be attributed to lesser number of patients receiving AVG (25.4%) as compared to AVF (43.2%) that were chosen for tunneled dialysis.[37] Risk of death is more than risk of progression to ESRD in most elderly CKD, especially if age >85 years, so benefits of an invasive procedure should be weighed against associated complication and additional cost arising out of any potential unnecessary procedure.[27] O'Hare et al. demonstrated that only about 25% and 33% of patients started dialysis within 6 month and 1 year, respectively, after access creation in 85–100 year old patients with eGFR <15 mL/min/1.73 m^2.[38] Therefore, life expectancy and rate of deterioration of disease should form basis for timing and type of access creation in elderly. For example, a tunneled catheter usually not the most appropriate access choice, could be considered for those with a life very limited life expectancy (e.g., <6 months). CVCs are preferred in IJV and femoral vein since subclavian vein has high risk of thrombosis. Infections, as the complication, amount to about 30–60% of HD CVCs removal and also, hospitalization rates are higher with CVCs than AVF.[39] Active surveillance and monitoring of AVF is recommended. Physical examination of VA is very useful tool to assess inconvenience during cannulation or clot aspiration, bleeding at cannulation sites post dialysis or failure to attain target blood flows while dialysis. If any such sign present, further evaluation with direct flow rate [using Doppler US and magnetic resonance angiography (MRA)], or indirect flow rate measurement modality [UD (Transonic), timed ultrafiltration methods, ionic dialysance, differential conductivity, and glucose infusion] should be considered.[40] A low-cost method using hemoglobin dilution test was described by Tiranathanagul et al. which can be used in the resource limited areas where ultrasound dilution test (UDT) is costly and unavailable.[41]

Kidney Transplant—An Option in Elderly?

Although, age itself is not a contraindication to KT, but poor accessibility and associated comorbidities could make elderly ineligible for getting a transplant organ. There is lower 5-year survival probability among KT recipients aged >65 years compared to aged 35–49 years (61% vs. 75% respectively).[42] Though Kaul et al. reported, in a retrospective study of ESRD patients, that after adjusting for albumin and BMI, KT group had better short-term and long-term survival as compared to PD group.[43] So, despite increased age, in the absence of other significant factor limiting the life expectancy, KT could be beneficial for elderly.[44] Factors that reduce KT rate in elderly may be strict selection criteria, health-care providers' apprehensions and decreased willingness among older patients for kidney transplantation.[45] Thus, instead of kidney transplantation, most of the elderly with ESRD undergo dialysis.

Social Support and End-of-Life Care

Like most non-communicable diseases, the treatment for CKD is non-curative, thus patient has to learn living with it. This creates functional restrain thereby limiting social involvement and a feeling of being isolated. Increased requirement of assistance for executive functions, dependency for care including dialysis, adjusting to new pattern of daily routine and cognitive changes of ageing may cause a lot of stress, resulting in a feeling of helplessness. Social support including emotional and instrumental is essential for overcoming. Instrumental support helps patient carrying out all routine and financial activities while emotional support enables person to feel loved and cared.[46] Ultimately, terminal patient-care needs interdisciplinary management. End-of-life care discussion involving patient and family members, taking care of their preferences to reach a consensus regarding accepting any intervention or simply withdrawing dialysis for palliative care and reviewing goals of advance care should be considered. Kirchhoff et al. observed that after intervening with patient-centered advance care planning, a significant percentage of ESRD patients withdrew dialysis as compared to those without intervention.[47] Informed choice about all available options, including their pros and cons, can augment decision-making especially for patients on HD among whom 9–13% succumb within 1 year.[48]

Conclusion

Optimization of renal care in a developing country, where health-care infrastructure is already struggling, is challenging. Regardless, perpetual efforts for active care, prevention from and preparation for deteriorating CKD stages and befitting RRT are needed. Optimal care of elderly patients with CKD may be rewarding by decelerating fall in renal functioning, better care of complications, and enabling a rational choice of RRT with well-timed carried out VA.

CHAPTER

154 Understanding the Role of Vitamin D in Diabetic Nephropathy

Srinath KM, Spoorthy Raj, Manjunath S Shetty

Abstract

Diabetes mellitus includes a group of metabolic disorders which share the common phenotype of hyperglycemia. Diabetes mellitus is the leading cause of end stage renal disease. With the prevalence of diabetes mellitus increasing enormously in present times, the burden of end stage renal disease caused by diabetes mellitus assumes significance.

Three major pathways are implicated in the development of DKD (Diabetic Kidney Disease) initiated by hyperglycemia. They are Activation of Protein Kinase C and polyol pathways, formation of advanced glycation end products, and glomerular hyperfiltration leading to glomerular hypertension.

Vitamin D is known to prevent beta cell apoptosis, increase insulin synthesis and enhance peripheral insulin sensitivity. Also, it is known to suppress RAS (Renin Angiotensin Aldosterone System), prevent podocyte loss and structural derangement of slit diaphragm, suppress inflammation and prevent glomerulosclerosis.

Hence, addition of Vitamin D supplements to ACE inhibitors/ARBs is proposed as a novel mechanism to prevent and halt the progression of Diabetic Kidney disease.

Introduction

Diabetes mellitus (DM) poses a major global public health problem with ever increasing incidence and prevalence in recent years.

At present, diabetes is the most common cause of end stage renal disease (ESRD).

Increasing burden of diabetic kidney disease (DKD) is secondary to widespread prevalence of diabetes.

According to International Diabetic Federation, the number of diabetics is expected to exceed 435 million by 2030, with more than 90% having type 2 diabetes.[1]

The increased risk of all cause and cardiovascular mortality in patients with diabetes is due to the presence of DKD.[2]

Approximately, 25–40% of type 1 DM patients and 5–40% of patients with type 2 diabetes develop this microvascular complication.[3]

Over 20% of the newly diagnosed T2DM have concurrent DKD and a further 20–40% develop diabetic nephropathy mostly within 10 years of diagnosis.[4]

Several genetic and environmental factors lead to pathogenesis of DN.

Hyperglycemic state of diabetes leads to various hemodynamic, biochemical, metabolic changes in kidneys including inflammation and oxidative stress.[5]

Considering the burden imposed by diabetes and DKD, extensive research is done in search of therapeutic agent, which can reduce or stop the progression of diabetic kidney disease. One such novel therapeutic agent for diabetic nephropathy is vitamin D and its analogues.

Risk Factors Associated with DKD

Multiple factors are responsible for the development of diabetic nephropathy and its progression.

These factors can be categorized as susceptibility factors—which predispose patients to the risk of developing DKD and are considered as non-modifiable factors. Acute kidney injury (AKI), dietary factors, hyperglycemia, and hypertension which initiate kidney damage and worsen the DKD are considered as modifiable factors.[6]

Hence, the risk factors for DKD are summarized as:

- *Susceptibility factors:* Old age, male sex, African-American race, and significant family history
- *Initiation factors:* Hyperglycemia and AKI
- *Progression factors:* Hypertension, obesity, dietary factors, and smoking[7]

Among the various risk factors hyperglycemia and hypertension are the most predominant risk factors.

Natural History of DKD[8]

The progressive model of the natural history of DKD has been shown in **Figure 1**.

Pathogenesis of Diabetic Nephropathy

Hyperglycemia is the necessary factor in the initiation of renal injury. Abnormal intracellular metabolism, involving three major pathways that are associated with the development of diabetic nephropathy shown in **Flowchart 1**.[9]

- Activation of protein kinase C and polyol pathways
- Advanced glycation end-products formation
- Glomerular hyperfiltration leading to intra-glomerular hypertension

It is also implicated that there is an excessive production of mitochondrial reactive oxygen species. Interactions between metabolic changes induced by hyperglycemia with hemodynamic factors, including vasoactive hormones such as angiotensin II, play a critical role in inducing renal injury. These mechanisms result in cell injury and activate inflammatory cascade which further perpetuates cell injury and results in vicious

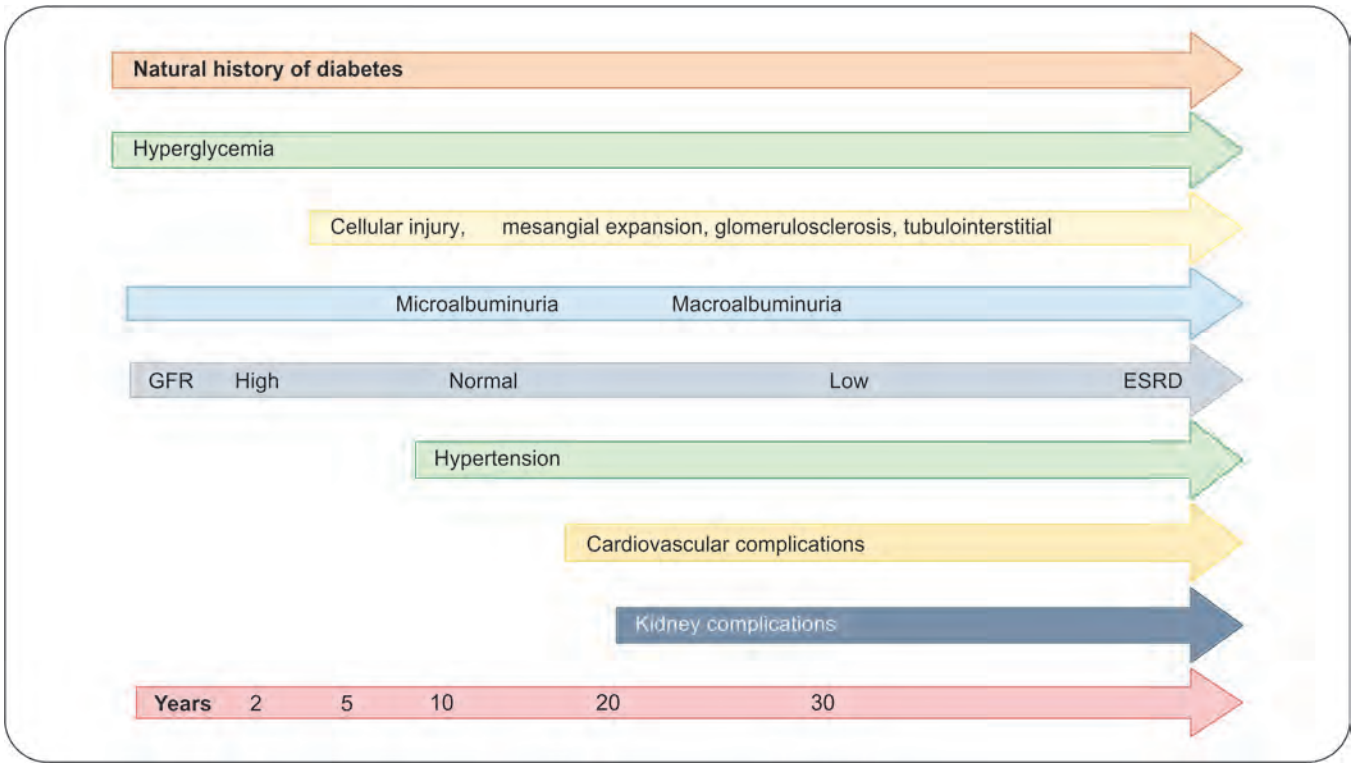

Fig. 1: The progressive model of the natural history of diabetic kidney disease. Duration of diabetes, in years, is presented on the horizontal axis. Timeline is well characterized for type 1 diabetes mellitus; for type 2 diabetes mellitus, timeline may depart from the illustration due to the variable timing of the onset of hyperglycemia

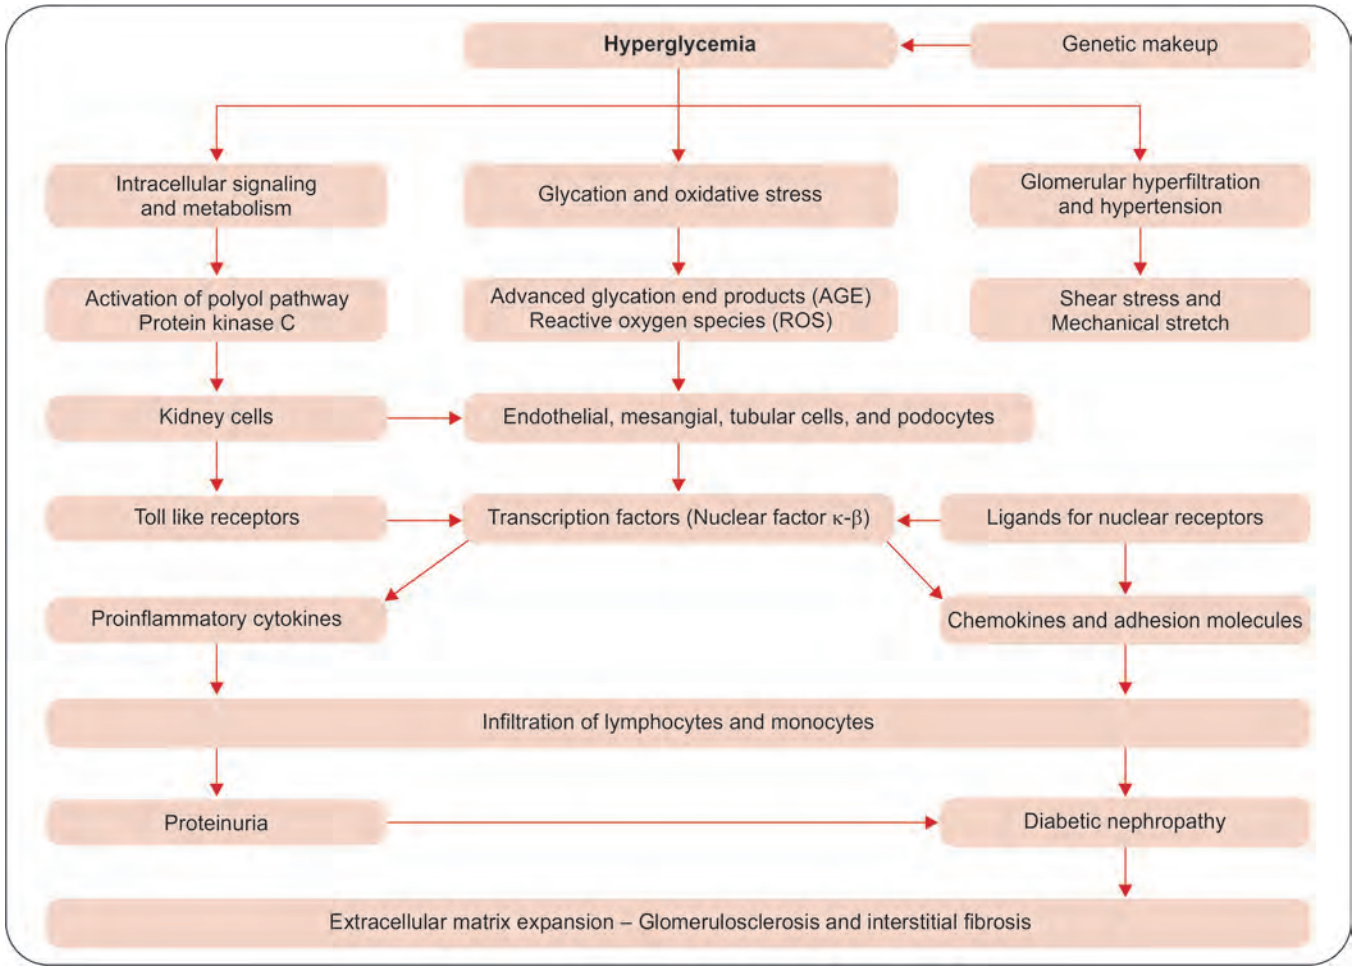
Flowchart 1: Pathophysiology of diabetic nephropathy



Source: Wada J, Makino H. Inflammation and the pathogenesis of diabetic nephropathy. Clinical science. 2013 Feb 1;124(3):139-52.

cycle of cell injury—inflammation—further cell injury—fibrosis.[9]

The molecules responsible for inflammation in diabetic nephropathy include:

- Transcription factors, NF-κB
- Proinflammatory cytokines & signaling molecules—IL-6, IL-18, IL-1, TNF, JAK2, & STAT 1&3
- *Chemokines* CCL2 (MCP-1) and CCR2, CXCL12 (stromal-cell-derived factor-1), CX3CL1
- Fractalkine and CX3CR1
- *Adhesion molecules:* Intercellular adhesion molecule 1 (ICAM1), Vascular cell adhesion protein 1 (VCAM1), E-selectin (SELE); Toll like receptors—(TLR2, TLR4)
- *Adipokines:* Adiponectin, Leptin; Nuclear receptors—VDR, NR1H4 (FXR) PPARα PPARγ, PPARδ
- TGF-β1 (transforming growth factor-β1) is a well determined molecule for the accumulation of ECM glycoproteins and subsequent glomerulosclerosis[10]

Pathology of Diabetic Nephropathy

Diabetic nephropathy was first described as glomerulopathy, mainly affecting mesangial cells; however, with further research it is found that glomerular epithelial cell abnormalities like podocyte dysfunction (angiotensin II mediated reduced expression of Nephrin), apoptosis, ultimately resulting in depletion of podocytes is central to development of proteinuria which is a hallmark feature of diabetic nephropathy. Also identified are the important changes in other sites like tubules, interstitium, medulla, and papilla. Renal function and prognosis correlate better

with structural lesions in tubules and cortical interstitium than with classic glomerular changes.[11]

The steps resulting in diabetic nephropathy are:[12]

- Hypertrophy of glomerulus and hyperfiltration
- Glomerular and tubulo-interstitial inflammation
- Decrease in number of cells by apoptosis and accumulation of ECM.

Vitamin D

Fat soluble vitamin D exists in two major forms, namely ergocalciferol (D2) and cholecalciferol (D3).

The main source of vitamin D for human body is endogenously biosynthesized in the skin. Vitamin D absorbed from diet and synthesized endogenously is biologically inert. Vitamin D in liver is converted into 25-hydroxyvitamin D (25(OH) D3) by liver enzyme 25-hydroxylase, which can be measured clinically. 25(OH) D3 is further hydroxylated to 1, 25(OH)2 D3 by kidney-derived 1-alpha-hydroxylase which is an active form of Vitamin D.

The activated form of vitamin D (1,25(OH)2D3) further binds with vitamin D receptors (VDRs) and activates various transcription factors. It is now found that, VDRs and 1-alpha-hydroxylase is expressed in tissues like islets of pancreas, hepatocytes, vascular smooth muscle cells, macrophages, mesangial cells, and podocytes. Vitamin D acts in autocrine manner and exerts multiple non-calcemic effects through VDRs. This includes vascular, immunomodulatory, anti-inflammatory effects, suppression of RAS, and control of glucose homeostasis.[13]

Role of Vitamin D in Insulin Synthesis and Regulating Insulin Sensitivity

Hyperglycemia results in endoplasmic reticulum stress, inflammation (lipotoxicity) and loss of insulin sensitivity.

Thus, hyperglycemia plays a key role in causation of resistance to insulin and β-cell failure.[14-16] Diet induced hypovitaminosis D in animal mice models revealed this hypovitaminosis D is a result of impaired glucose tolerance, decreased islet function related gene transcription, and increased RAS expression.[17]

The postulated molecular mechanism behind regulation of insulin homeostasis by Vitamin D includes:

- Promoter regions of insulin receptor genes have VDR response elements (VDREs).[18]

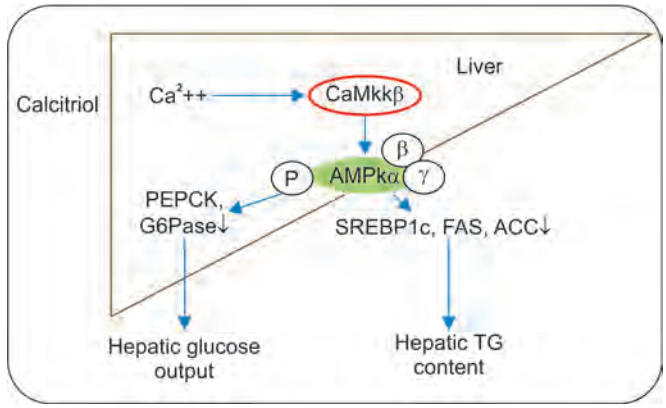


Fig. 2: Role of vitamin D in hepatic glucose homeostasis

- Calcitriol in liver is known to induce calcium flux and activate calcium/calmodulin dependent protein kinase (CaMkkB), which further activates 5' AMP (Adenosine monophosphate) activated protein kinase (AMPK). This results in down regulation of Phosphoenol pyruvate carboxy kinase (PEPCK) and Glucose 6 phosphatase (G6Pase) and thus reduce hepatic glucose output. AMPKa activation can also downregulate sterol regulatory element binding protein 1 (SREBP1c),FAS and Acetyl co-A carboxylase (ACC) which further reduces the hepatic triglyceride content shown in **Figure 2**.
- Increased intracellular ionized calcium and subsequent downstream signaling mediated by vitamin D is known to enhance glucose and arginine mediated insulin release from β-cells of pancreas.[19]
- Suppress the transcription of renin, angiotensin receptors and serve to inhibit local RAS mediated beta cell injury.
- Hyperglycemia and increased free fatty acids result in endoplasmic reticulum stress and reduced activity of Akt pathway, which ultimately results in β-cell apoptosis.

  Vitamin D helps in beta cell survival and also increases compensatory beta cell growth in insulin resistant states by enhancing activity of Akt pathway.[20]
- Vitamin D also reduces accumulation of hepatic triglyceride and glucose output through Ca^{2+}/CaMKK/AMPK signaling activation.
- Vitamin D also inhibits VDR mediated PPAR activity thus inhibits adipogenesis.[21]

Vitamin D Role in Inflammation

Activation of NF-kB pathway results in increased transcription and production of proinflammatory cytokines like TNF-α, IL-1, and IL-6. This proinflammatory milieu leads to leukocyte infiltration of pancreas resulting in reduced β-cell mass, reduced insulin synthesis, islet amyloid deposition, altered downstream insulin signaling through IRS/AKT/PI3K resulting in insulin resistance and also affects the maintenance of energy and blood sugar balance in hypothalamus.[22]

VDD promotes inflammation through NF-kB pathway as evidenced by animal model, whereas vitamin D supplementation has shown beneficial effects in preventing the same.[22]

Vitamin D Role in Diabetic Nephropathy

Diabetic nephropathy is associated with increased incidence of vitamin D deficiency. Probable explanation for the same includes reduced sunlight exposure (e.g., in elderly, sick, dark-skinned people, people wearing veil, losses of vitamin D-binding protein in proteinuric states).

Vitamin D is known to ameliorate the harmful effects of hyperglycemia on kidney by following mechanism:[23]

- Vitamin D inhibits RAS by downregulating renin, angiotensinogen and angiotensin II receptor expression.
- Enhances the expression of nephrin and prevents structural derangement of slit diaphragm.
- Inhibits activation of ERKs, p38-MAPK, Wnt-b catenin pathway, and down regulates proapoptotic signals Bad, Bak, and upregulate anti-apoptotic signal Bcl2 and prevent podocyte apoptosis and podocyte loss.
- Inhibits the expression of Smad 3 protein or by the physical interaction of VDR with Smad 3 protein downregulates the intracellular level of Smad 3 and thus, reduce the expression of TGF-β, and prevent glomerulosclerosis.
- Inhibits the expression of fibronectin and extracellular matrix proteins from mesangial cells and protect against glomerulosclerosis.
- Inhibits the expression of MCP-1 (Monocyte Chemotactic Protein 1) which results in decreased leukocyte recruitment to kidneys and reduces the renal inflammation.

Evidence from Clinical Studies

Clinical trial evidence indicates that combined treatment with losartan and paricalcitol completely prevented albuminuria as well as markedly reduced glomerulosclerosis while restoring glomerular filtration barrier structure.[2] The vitamin D receptor activator (paricalcitol) in albuminuria lowering (VITAL) study showed that addition of two micrograms of paricalcitol to RAS inhibitors safely lowers albuminuria in patients with diabetic nephropathy and can be a novel approach to reduce residual renal risk in patients with diabetic nephropathy who are already on treatment with optimal doses of RAS inhibitors.[24]

Conclusion

Diabetic nephropathy is a common renal complication of DM and a major cause of ESRD. RAS is the predominant mediator of progressive injury to renal system in DN. Hence, RAS inhibitors are being used as the mainstay of treatment for DN; however, RAS inhibition leads to compensatory rise in the renin due to the disruption of renin feedback inhibition. Vitamin D plays a renal protective role in DM by suppressing rennin expression by negative regulation of RAS. Combination therapy with RAS inhibitors and active vitamin D and its analogue markedly ameliorates renal injury.

However, Vitamin D is currently only recommended in treatment of patients with moderate CKD associated with secondary hyperparathyroidism and vitamin D insufficiency. Hence, further study is required to answer many questions and thereby uncover the potential renoprotective role of vitamin D and its analogues in treatment of patients with CKD.

CHAPTER

155

Anti-malarial Drug Resistance

Neha Agrawal, Anup Singh, Shyam Sundar

Abstract

Anti-malarial drug resistance is a major public health problem which hinders the control of malaria. In India, resistance of *Plasmodium falciparum* (Pf) to chloroquine, the cheapest and the most used drug was first reported in the year 1973. Resistance to commonly used antimalarial drugs like choloquine (CQ), mefloquine (MQ), sulfadoxine/pyrimethamine (SP) have been reported across the country. Emergence of artemisinin resistance in *P. falciparum* strains from Combodia and neighboring countries is a major setback to the antimalarial program of these countries and an ominous sign.

Various drug-resistant genetic markers identified for *P. falciparum* and *P. vivax* antimalarial drugs, like Plasmodium falciparum Multidrug Resistance Protein 1 (PfMDR1), Plasmodium falciparum Chloroquine Resistance Transporter (PfCRT), The K76T mutation in PfCRT protein is a potent molecular marker of CQ resistance and susceptibility. Antimalarial drug susceptibility and resistance to quinine, amodiaquine (AQ), piperaquine, and lumefantrine is affected by variation in the PfCRT protein mutation. Mutation in C-terminal region of K13 protein is associated with the artemisinin resistance. Detection of drug-resistant parasites in *P. vivax* malaria is also prevalent worldwide. Prolonged courses of artemisinin-based combination therapies for 6 days are currently efficacious in areas where standard 3-day treatments are failing.

Introduction

Malaria is a major cause of morbidity and mortality in the tropical countries. Malaria cases in India have reduced from 2 million annually in the 1990s to 1 million in 2012, with a declining trend since 2002. However, the *Plasmodium falciparum* (Pf) cases reported has increased to 50.01% in 2012 from 39% in 1995.[1] Notably, antimalarial drug resistance is becoming a major public health problem throughout the globe. In India, chloroquine-resistance in *P. falciparum* was first reported in 1973 from Assam. The National Vector Borne Disease Control Programme (NVBDCP) has been monitoring the response of antimalarial drugs in *P. falciparum* malaria since 1978 throughout India. This helps in formulation of National Drug Policy and recommends necessary changes in the control strategy including treatment policy to contain resistant *P. falciparum* foci.[1] National Drug Policy recommends the use of ACT as first-line of treatment for *P. falciparum* since 2010 as resistance to commonly used antimalarial drugs like chloroquine (CQ), Mefloquine (MQ), sulfadoxine/pyrimethamine (SP) has been reported across the country.[2,3]

Tools for Monitoring

Drug sensitivity status in India was being assessed following conventional WHO in-vivo protocol till 2002. This is changed in 2003 since when WHO protocol on "Therapeutic efficacy of antimalarial drugs in uncomplicated *P. falciparum* malaria" is being used. The criteria classify response in three categories:

- Adequate Clinical and Parasitological Response (ACPR),
- Early Treatment Failure (ETF), and
- Late Treatment Failure (LTF).[1]

Criteria for Change of Drug Policy

The treatment drug policy is changed for the area/Block PHC, which reports ≥10% total treatment failure (ETF+LTF) to the tested drug, that is, the currently used antimalarials in a sample of minimum 30 *P. falciparum* test cases. To reduce emergence of drug resistance, the National Drug Policy on Malaria recommends use of combination therapy in chloroquine-resistant areas, that is, Artesunate plus Sulfadoxine-Pyrimethamine (AS+SP) for treatment of *P. falcipuram* cases.[1]

Genetic Markers of Drug Resistance

The various drug-resistant markers identified for *P. falciparum* and *P. vivax* antimalarial drugs are discussed here.

Plasmodium falciparum Multidrug Resistance Protein 1 (PfMDR1)

The PfMDR1 gene located on chromosome 5, encodes for P-glycoprotein homolog 1 protein,[4,5] which belongs to the ATP-binding cassette (ABC) superfamily. Resistance to antimalarials is believed to be due to polymorphism, amplification, or variation in mRNA expression level of the PfMDR1 gene.[5]

Drug susceptibility to chloroquine, quinine, mefloquine, halofantrine, lumefantrine, and artemisinin are affected by mutations in Pfmdr1 gene at the following positions (N86Y, Y184F, S1034C, N1042D, and D1246Y). Amodiaquin resistance is associated with PfMDR1 mutations at N86Y and N1042D position. Chloroquine resistance is associated with K76T and A220S mutation in the Pf chloroquine resistance transporter (PfCRT) gene and N86Y mutation in the PfMDR1 gene.[6-10]

Plasmodium falciparum Chloroquine Resistance Transporter

As discussed, PfCRT gene mutation has potential role in chloroquine resistance. This gene is localized to chromosome 7 and PfCRT protein belongs to the drug/metabolite transporter superfamily and chloroquine resistance transporter-like transporter family with ten putative transmembrane domains spanning the digestive vacuole membrane of the parasite.

The K76T mutation in PfCRT protein is a potent molecular marker of CQ resistance and susceptibility.[11] K76T mutation located in the first transmembrane domain of PfCRT protein, allows the efflux of diprotonated chloroquine out of the digestive vacuole by active transport.[12] Other mutations cause resistance only in association with K76T mutation and include C72S, M74I, N75E, A220S, Q271E, N326S, I356T, and R371I.[12]

Antimalarial drug susceptibility and resistance to quinine, amodiaquine (AQ), piperaquine, and lumefantrine is affected by variation in the PfCRT protein mutation.[13-16] There is cross-resistance of chloroquine with AQ and quinine mainly mediated by 76T, and lumefantrine has an inverse cross-resistance having reduced susceptibility in association with wild-type K76.[17]

Plasmodium falciparum Multidrug Resistance-Associated Protein (PfMRP)

PfMRP is a transmembrane protein produced by PfMRP gene located on chromosome 1. This multidrug resistance-associated protein aids the parasite in transporting out of drug and organic anionic substrates like oxidized glucuronate, glutathione, etc. from its inside, thus effecting resistance.[18,19]

Chloroquine and quinine resistance are associated with two mutations in PfMRP at position Y191H and A437S. High sensitivity to various antimalarial drugs such as chloroquine, quinine, primaquine, piperaquine, and artemisinin can be demonstrated by genetic knocking out of PfMRP gene in the resistant parasite, and more accumulation of chloroquine and quinine is observed in the sensitive parasite. Thus, PfMRP is not only involved in determining the drug resistance but has role in varying the antimalarial response to resistance.[19]

Plasmodium falciparum Sodium Hydrogen Exchanger (PfNHE)

This gene on chromosome 13 codes for a protein associated with quinine resistance in Pf, and is involved in active efflux of protons in the parasite to maintain pH at 7.4, in response to acidification by anaerobic glycolysis, the primary energy source for the parasite.[20] Polymorphism in the microsatellite ms470 region exhibited a decrease in quinine susceptibility with an increase in DNNND repeat motif, whereas increase in quinine susceptibility is observed with a rise in NHNDNHNNDDD motif. Three mutations at 790, 894, and 950 codons and polymorphism in the microsatellite region (msR1 and ms3580) showed

no association with quinine resistance.[21] Thus, repeat polymorphism in PfNHE gene may be used as a valid genetic marker to determine quinine resistance in some regions.

Plasmodium falciparum Bifunctional Dihydrofolate Reductase-Thymidylate Synthase (PfDHFR-TS)

The PfDHFR-TS gene has one exon located on chromosome 4 encoding for PfDHFR protein and is a bifunctional enzyme involved in two main folate metabolic activities—biosynthesis of dTMP by thymidylate synthase activity and the reduction of dihydrofolate to tetrahydrofolate by dihydrofolate reductase (DHFR) activity. The folate mechanism of PfDHFR-TS enzyme is inhibited by the action of antifolate drugs such as pyrimethamine and cycloguanil, thus reducing the production of pyrimidine for DNA replication.[22]

Pyrimethamine resistance is mainly associated with point mutation in the PfDHFR protein at S108D codon, and further mutation at N51I, C59N, and I164L positions strengthens the resistance besides amplification of gene.[23,24]

Plasmodium falciparum Dihydropteroate Synthase (PfDHPS)

The PfDHPS gene is located on chromosome 8 and encodes for PfDHPS protein. PfDHPS synthesizes dihydrofolate, a folate precursor that is essential for the synthesis of pyrimidine in the parasite by catalyzing the reaction of pterin derivative and p-aminobenzoic acid (PABA).[25] This catalytic enzyme action to synthesize dihydrofolate is inhibited by sulfa drugs (sulfadoxine and dapsone), which act as an analog to PABA.[25]

Resistance to sulfadoxine in *P. falciparum* is due to S436A/F, A437G, L540E, A581G, and A613T/S mutations in the PfDHPS protein.[24] Sulfadoxine is always provided in combination with pyrimethamine (SP) as monotherapy is associated with antimalarial drug resistance. Point mutation in both PfDHFR and PfDHPS gene is associated with resistance to SP.[23]

Cytochrome B

Cytochrome b (Cytb) gene is a subunit of cytochrome bc1 complex present in mitochondrial inner membrane of the parasite. It catalyses the transfer of electrons across the inner mitochondrial membrane to maintain the electrochemical potential of the membrane. The antimalarial drug atovaquone disrupts the electrochemical potential by binding to the ubiquinol binding site of cytb, and hence is lethal for the parasite. Mutation at the ubiquinol binding site confers atovaquone resistance.[26,27] Single mutation at Y268N/S/C codon in the cytb gene leads to resistance to atovaquone in *P. falciparum* field isolates.

Kelch

Kelch-13 (K13) protein has one exon located on chromosome 13. Mutation in C-terminal region of K13 protein in this region is associated with artemisinin resistance in both clinical and field isolates by disrupting the domain scaffold. However, the exact function of K13 protein, and the effect of various mutations on the protein will only be known after several studies are conducted to ascertain its nature completely.

Nonsynonymous polymorphism at Y493H, R539T, I543T, and C580Y positions observed in the kelch repeat region of K13 propeller domain is associated with higher artemisinin resistance. Mutations at codons F446I, Y493H, P574L, R539T, and C580Y confer a higher degree of resistance to artemisinin, and the frequency of C580Y allele mutation is higher and takes longer time for parasite clearance when compared to variation in other sites. Therefore, K13 propeller protein polymorphism can serve as a potent molecular marker indicating emergence and spread of artemisinin-resistant *P. falciparum*.[28]

Drug Resistance in Vivax Malaria

Drug-resistant *Plasmodium vivax* malaria is also prevalent worldwide. Its treatment primarily consists of two drugs: Chloroquine (blood schizonticide) targeting the asexual blood stages of the parasite, and Primaquine (tissue schizonticide), which targets the dormant live stage (hypnozoites) of the parasite, responsible for relapse.

P. vivax is also associated with molecular markers of drug-resistance, like *P. falciparum*. Increased susceptibility to chloroquine in *P. vivax* is strongly associated with the Y976F mutation in PvMDR1 gene, which is a homolog of PfMDR1. However, the PfCRT gene homolog in *P. vivax*, that is, the PvCRT gene, is not associated with chloroquine-resistance (unlike in *P. falciparum*). Mefloquine resistance

in *P. vivax* is associated with amplification of PvMDR1 gene. Mutation at Y976F position of PvMRD1 *in vitro* has been shown to be associated with resistance to mefloquine and artesunate, in addition to chloroquine.[29,30]

Point mutations at F57L/I, S58R, T61M, and S117T/N codons of PvDHFR gene are linked to pyrimethamine resistance and consequently treatment failure with pyrimethamine in *P. vivax*. The wild type residue V585 in PvDHPS gene has shown innate resistance to sulfadoxine and is enhanced by the mutation in A383G and A553G codons in PvDHPS, which is similar to PfDHPS mutation at codons A347G and A581G.[31,32]

Conclusion

Antimalarial drug resistance poses a major hurdle to our victory over the malarial parasite and contributes to failure in treatment of malaria. Combination therapies targeting different mechanisms of action can delay the emergence and spread of drug-resistant parasites. Molecular markers of drug resistance play a vital role in the detection of resistance in clinical and field isolates when compared to the *in vivo* efficacy studies and *in vitro* tests. Thus, earlier clinical isolates will aid in employing immediate and appropriate treatment that in turn reduces treatment failure and thereby mortality, and also prevents the spread of resistance. Hence, continuous monitoring and surveillance of drug-resistant molecular markers in malaria endemic regions is important in determining and assisting an effective national drug policy for malaria treatment. Therefore, more research is necessary to find new antimalarial drugs/vaccines for multidrug resistance parasites.

CHAPTER

156 Controversy in Vaccination

Anil Manchanda, Ruchika Manchanda, Veronica Manchanda

Abstract

Ever since the advent of vaccination against communicable diseases there has been concern in the mind of certain people about its adverse outcome. While there is no doubt about efficacy of the time-tested vaccines which have been able to either eradicate or minimize many dangerous communicable diseases but the apprehension remains there, which were not unfounded. There was apprehension of increased incidences of Autism (MMR Vaccine), GBS (DPT, Influenza vaccine) which later on proved wrong. Dengvaxia saga (2015 with Dengue vaccination), Cutter polio incident (1955), and currently Covid vaccine related adverse effects are few examples which were highlighted out of proportion despite their numbers were few and statistically insignificant. In this article we highlight the various aspects of various controversies revolving around the vaccinations and their scientific explanations which would help us to overcome these apprehensions for future vaccination strategies.

Introduction

Ever since Edward Jenner had introduced the first vaccine in 1796, the global use of vaccines has been detrimental in reducing or eradicated the incidence and spread of childhood diseases.[1,2] Despite the fact that there are a lot of evidences behind the benefits of vaccines, to provide immunity against diseases, there has been opposition in certain quarter against the use of vaccines.[3] Some of these biased views are based on perception of personal, religious, or cultural beliefs that vaccines can be more harmful than good in people who receive them. The Controversy of vaccination is about:

- Safety
- Efficacy
- Dosing
- Availability of different vaccines for different region. This can be attributed to lack of awareness, political and vested interests. However, this fear was not without reasons. Following is the historical facts of various concerns against the vaccinations.

The Cutter Incident:[4] In 1955 Cutter Laboratories produced 120,000 polio vaccines (in which the process of inactivating the live virus proved to be defective), which caused 40,000 cases of polio, 53 cases of paralysis, and 5 deaths. This in turn also infected the family members of the recipients leading to additional 113 cases of paralytic polio and another 5 deaths. It has been rightly described as the worst Pharmaceutical incident.

Other historical facts are given below which created doubts and suspicion in the mind of people regarding efficacy and side effects of vaccinations **(Table 1).**

Despite all the rebuffs to the Antivax (Anti-vaccination) lobby the concerns raised were not without reasons due to the emergence of certain adverse effects in the ensuing

TABLE 1 History of controversies in vaccination and evidences for and against them[5]

Issue	*Allegation*	*Evidence*
MMR vaccine and autism[6]	MMR vaccine can cause autism	• Initial report suggesting an association between vaccination and autism was drawn back • Autism usually occurs in early age group than before recommended age of MMR vaccination (12 months) and is genetically determined • In studies conducted by the epidemiologists there is no increased risk of autism associated with MMR vaccine
DPT	Neurological conditions following immunization[7,8]	• Commission on Vaccination and Immunization (JCVI) confirmed that the risks or neurological problems due to DPT were quite low • With universal childhood immunization, the number of reported cases fell by >95%, and mortality rates decreased even more dramatically[9]
Thimerosal[10]	Increases risk of autism and other neurodevelopmental disabilities may be increased by Thimerosal	• Ethyl mercury (an active ingredient of thimerosal) does not accumulate in the body to harmful levels with consecutive vaccinations • Even after removal of thimerosal from childhood vaccines, incidence of autism continued to increase • Studies have not found an increased risk of autism or other neurodevelopmental disabilities associated with thimerosal-containing vaccines in epidemiological studies[11]
Influenza vaccines may cause GBS[12]	GBS (1978)	It is observed that risk of GBS is greater following natural influenza infection than possible vaccination
Meningococcal vaccine and can cause GBS[12]	GBS (2005–2008)	A large study proved there was no link between Menactra and GBS
Autoimmunity[13]	Vaccines may be responsible for chronic diseases of autoimmune etiology	There is no established mechanism to explain how vaccinations cause autoimmune disease and epidemiologic studies have failed to supported the hypothesis that vaccines cause autoimmune diseases
HPV vaccine: Safety	Risk of autoimmune and other disorders may be increased with HPV vaccination	• Several large studies have not established increased risks of autoimmune or neurologic diseases • Other studies failed to establish increased risks of POI, POTS, or CRPS
Aluminum	Autoimmune diseases and a variety of other disorders, including Macrophagic Myofasciitis can be attributed to aluminum in vaccines[14]	• The serum levels of aluminum are well below the toxic range due to aluminum containing vaccines • There is hardly any correlation between infant blood or hair aluminum concentrations and vaccine history • There were lower incidence of autoimmune disease with higher quantities of injected aluminum adjuvants • Systemic symptoms of MMF secondary to aluminum salts at injection sites have never been established[15]
Too many too soon	Too many vaccines given early in life might interfere with the immune system	• Infants can handle as many as 10,000 vaccines at one time • Long-lasting, gross alterations of the immune system has been found with childhood vaccinations • The number of vaccines or vaccine antigens received in early childhood did not increase risk of disease or developmental delay as per many epidemiological studies
Hepatitis vaccine 1998[26]	Multiple sclerosis	The IOM committee concluded that there is no link between MS and hepatitis B vaccination

CRPS, complex regional pain syndrome; GBS, Guillain-Barré syndrome; HPV, human papillomavirus; IOM, Institute of Medicine; MMR, measles, mumps, and rubella; POI, primary ovarian insufficiency; POTS, postural orthostatic tachycardia syndrome

years. To highlight these concerns, few following events throw insight into the safety and concerns about the vaccination.

Dengue Vaccine Controversy[16,17]

About 400 million people are infected with Dengue every year, out of which almost 25000 people die of dengue hemorrhagic fever (DHF). Due to lack of cure for Dengue and high mortality rate in the countries with less advanced medical system, scientists have since long been on a quest to develop a vaccine. Recently, Dengvaxia (Vaccine against Dengue) was approved by Food and Drug Administration (FDA) to prevent dengue. Despite the fact that this vaccine has the capability to save millions of lives , its approval was not without controversy.

Philippines in 2015 launched a massive campaign to immunize children against the dreaded disease. After about 1 million children were vaccinated, the controversy was raised as the vaccine was associated with the deaths of three children in the Philippines. However, before addressing this issue it is imperative, we understand how the immune system reacts to dengue virus. There are two types of antibodies generated against any pathogen—neutralizing and non-neutralizing. The dengue virus has four serotypes and the antibodies generated against one serotype while it may react with another serotype as well, it does not always neutralize the antigen. This may be acceptable for other pathogens since the antibody-pathogen complex reach the macrophage and is eventually destroyed. However, dengue virus is unique as it primarily infects the macrophage. Thus, antibodies that have developed against one variant of dengue can make subsequent infections far more lethal. The preexisting non neutralizing antibodies bind to dengue virus antigen and attract macrophages facilitating spread. In this manner the non-neutralizing antibodies allow the virus to infect multiple cells with ease, thus causing the severity of the second infection with respect to the first one. This phenomenon is referred as antibody enhancement.[18]

Now, though dengvaxia was indeed engineered to protect against all four serotypes of dengue, many people did not develop neutralizing antibodies against all the serotypes. In this unfortunate people, the vaccine acted as a primary infection thus making the second infection far more lethal **(Fig. 1)**.

Current recommendations of dengue vaccine: Despite these shortcomings, dengvaxia has been approved by FDA for use in the following conditions—

- Children 9–16 years old in endemic areas
- Laboratory confirmed previous infection

Controversies Surrounding HPV Vaccination

The controversy surrounding HPV Vaccine is about its—

- Safety concerns
- Dose scheduling
- Two strains/four strains vaccine
- Whether males should be vaccinated
- Till what age one should be vaccinated

Safety concerns: The main adverse reactions reported with HPV vaccination were: headaches (70%), general fatigue (53%), coldness of the legs (53%), limb pain (50%), limb weakness (48%), difficulty in getting up (48%), fainting (43%), decreased capability to learn (43%), arthralgia (43%), tremulousness (40%), gait disturbances (40%), disturbed menstruation (35%), and dizziness (30%). Besides this, it was associated with enhance autoimmune response and CNS side effects including syncope. Possibility of presence of the active aluminum adjuvant might be contributing to these side effects.[19]

In India, with regards to HPV vaccine, Program for Appropriate Technology in Health (PATH),[20] a nonprofit based in Seattle, in 2009 launched a $3.6 million HPV trial, funded by the Bill & Melinda Gates Foundation, in 24,777 adolescent girls in Andhra Pradesh and Gujarat states; however, it was prematurely terminated by the government when news outlets reported the death of seven girls. However, on further analysis it was found that five of those deaths were evidently unrelated to the vaccine itself. The causes attributed to their death were drowning (1 girl), snake bite (1 girl), suicide (2 girls), malaria (1 girl). The other two deaths were still uncertain.

Dosing of vaccine and cost: Another dilemma with respect to the HPV vaccine is the dosing schedule.[21] While one dose by itself is quite immunogenic so as to provide lasting protection from HPV 16 and 18, data regarding long-term protection after 7 years and protection from HPV and cervical precancerous lesions is lacking. Conversely the immunogenicity produced by two-dose and three-dose HPV vaccine schedules, measured using antibody responses in young females, is comparable.[21]

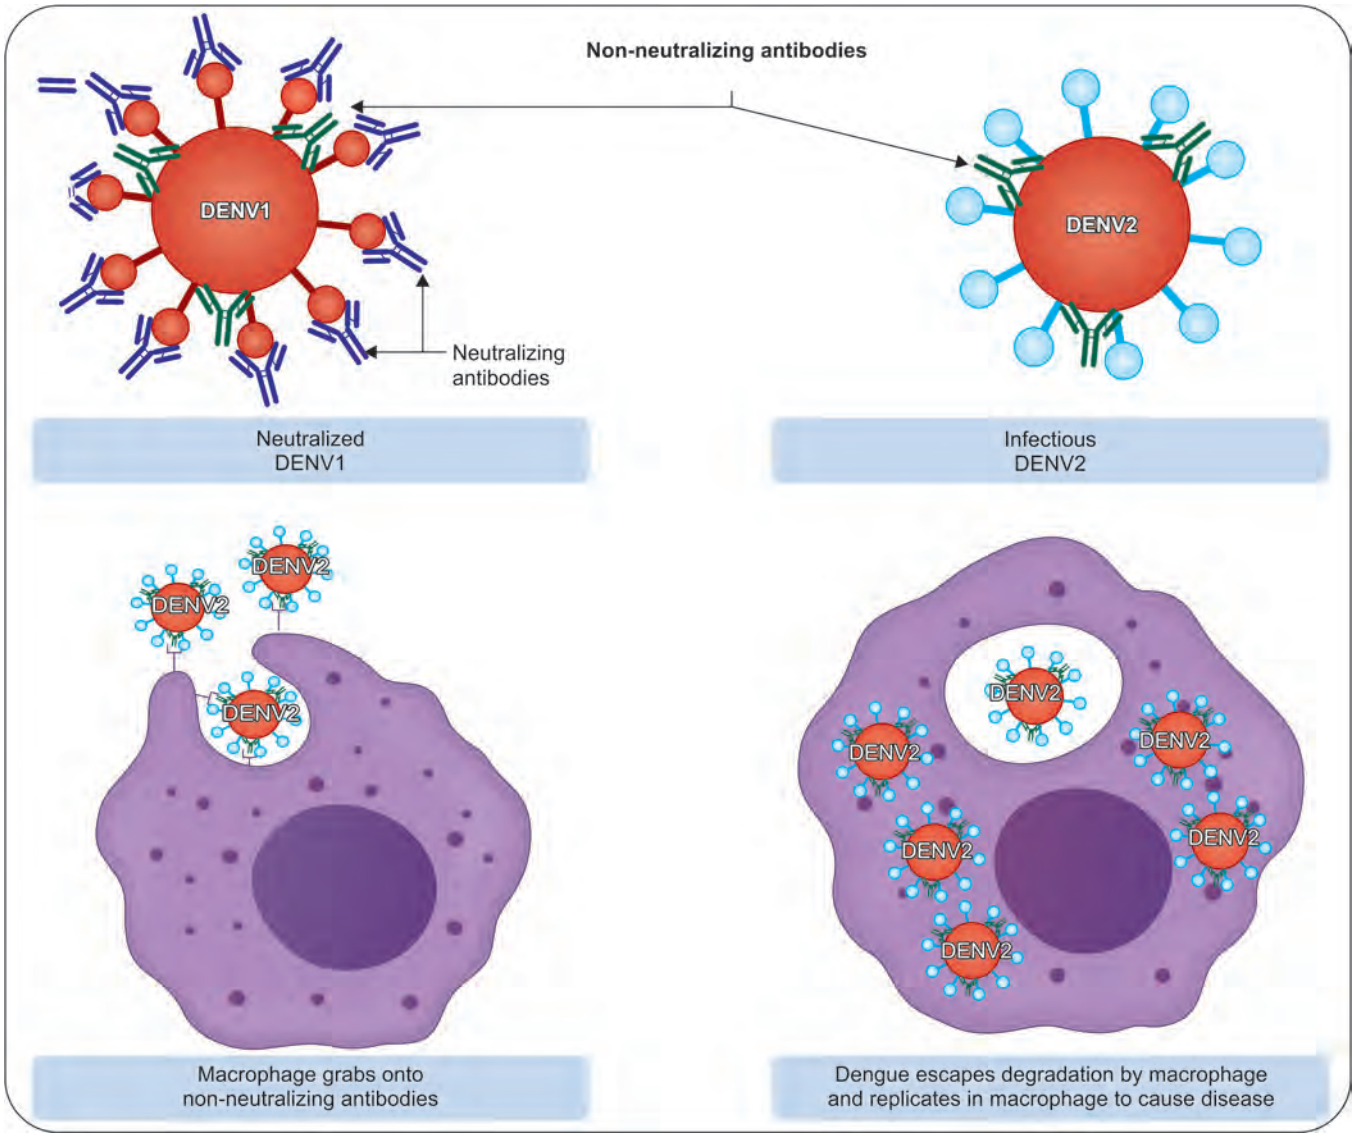

Fig. 1: Neutralizing and non-neutralizing antibodies in dengue infection

Current Recommendations

Children and adults ages 9 through 26 years: HPV vaccination is routinely recommended at age 11 or 12 years; although it can be started as early as age 9 years. HPV vaccination is recommended for all women before attaining 26 years of age who were not adequately vaccinated earlier. Children below 15 years require only two doses to be fully protected. People who start the series at age 15 or older and people with weakened *immune system* need three doses to be fully protected.

Adults ages 27 through 45 years: Despite the facts that HPV vaccine is approved by FDA to be given through age 45 years, HPV vaccination is not recommended for all adults ages 27 through 45 years as effect of vaccination starts to diminish by age 18. Therefore, its benefit for cancer prevention is doubtful as people get older. The ACS (American Cancer society) does not recommend HPV vaccination for persons older than age 26 years.[22] Instead, ACIP[23] recommends that because more people have already been exposed to the virus. HPV vaccination

in this age range provides less benefit; clinicians consider discussing with their patients in this age group about the benefits of the vaccination.

Male HPV vaccination: The US Advisory Committee on Immunization Practices (ACIP)[23,24] licensed HPV4 for boys and young men in 2009. HPV vaccine in males can help prevent genital warts as well as a variety of cancers associated with HPV.

Influenza Vaccination

Influenza (flu), which caused a pandemic in 2009 accounting for 100,000–400,000 deaths, still remains a cause of global concern. According to the World Health Organization (WHO), 1 billion cases surface every year globally, causing about 200,000–600,000 deaths.[25] According to Flu Net, the WHO Global Influenza Surveillance and Response System (GISRS) laboratories; out of total cases 98.6% were influenza A and 1.4% were influenza B cases. Out of these influenza A viruses, 65.2% were influenza A H1N1 and 34.8% were influenza A H3N2. Influenza A H3N2 infection was *more virulent* than influenza A H1N1. In India also the strain influenza A (H1N1) has accounted for most cases—which peaked in the third week of February 2019.[23] Although the report said that vaccination was the most effective tool to create immunity against the disease, but certain doubts remain there about vaccination.

- Which type of vaccination in India should be used? Northern hemisphere/Southern hemisphere.
- High dose versus routine dose in 65 year plus people (High dose vaccination not available in India).
- Serial vaccination and do annual vaccination cause less immunization in subsequent vaccination? Antigenic distancing hypothesis.
- Universal vaccination: Will single vaccination for lifetime (like other vaccines) see some light in time to come?

Seasonal Influenza Vaccine Recommended for the Season of 2019-2020 in India[26]

In India, ICMR and Ministry of Health and Family Welfare, Government of India, have recommended Northern hemisphere quadrivalent/tetravalent vaccine.

Due to the constant changing of antigenicity, the efficacy of influenza vaccination is potentiated when circulating viruses and vaccine viruses correspond to each other. Even when they do correspond, efficacy of vaccine is not beyond 40–60%. But, if the vaccine virus as recommended by WHO is different from the locally circulating virus, it may be partially effective or not effective at all. Hence, vaccines are not foolproof method of protection against influenza. Instead due attention must be given to personal hygiene, frequent washing of hands, social distancing, use of proper masks, etc. should not give a false sense of security.[27]

In various studies it was found that high-dose vaccine (fluzone) was 24.2% more effective (CI 9.7–36.5%) in preventing flu in adults 65 years of age and older relative to a standard-dose vaccine[28] and high-dose influenza vaccine can reduce risk of respiratory-related hospital admissions from nursing home residents aged 65 years and older.[29]

In people who received vaccination in two consecutive seasons, protection against H3N2 was lesser than those who had only been vaccinated in current season suggesting that repeated vaccination against influenza may weaken the immune system[30] However, as per CDC recommendations, annual flu vaccination remains the first and most important step in protecting against flu and its complications. One of the studies[31] postulated that twice annual influenza vaccinations in elderly population of tropical and subtropical areas has improved efficacy. However, the observations were in contradiction to the above said postulation.

Future Vaccine Considerations[32]

An ideal universal vaccine should be:

- Effective for longer duration of time and 75% effective against all strains of Influenza A virus in all age groups.
- A cell based or a recombinant formulation should be favored over an egg-based vaccine.
- The hemagglutination inhibition response for a nanoparticle vaccine formulated with a saponin-based adjuvant was greater than a high dose vaccine.
- Traditional influenza vaccine target IgG portion. However, since different parts of IgA trap many parts of influenza virus simultaneously, IgA may be a more effective target.
- Manufacturing time should be shortened.

Universal Influenza Vaccine

A ball and spike model depicts well of a structure of influenza virus where hemagglutinin protein on the surface represent as spikes. Each spike having a stalk and a cap.

While all current influenza vaccines target at the cap portion of the hemagglutinin proteins which change its antigenicity frequently requiring annual vaccination. Instead the stalk portion of the hemagglutinin protein is stable among different influenza viruses and does not alter antigenicity annually. Therefore, a vaccine targeted at the stalk portion of the hemagglutinin protein can turn out to be a universal vaccine.

Measles Cases in 2019[2,33]

It is worth understanding the mechanism of transmission of measles as it is highly contagious like COVID-19 virus. It has been noted that the viability of the virus lasts for about 2 hours and individuals who have not been vaccinated against measles have a 90% chance of contracting measles. These people now have the potential to spread the disease to 9–18 other people.[2] However, in the global scenario, measles is the leading cause of vaccine-preventable disease and deaths despite the widespread use of vaccines and in fact every year 100,000 people die from measles.[2] World Health Organization reports that there were 1,234 cases of measles in the US and 91 cases in Canada from January 2019 to September 2019. On the other hand, in 2018, 372 cases were reported in the US and 28 in Canada. The recent spike in measles outbreak is due to vaccine deterrence (out of fear of Autism and ignorance and inertia). This along with increase in international travel has facilitated the disease to enter into areas where it was once considered eliminated.[34]

Current Recommendations for Adults

It is advisable for the adults including students at post high school educational institutions, health-care personnel, international travelers who do not have significant evidence of immunity to get a single dose of MMR vaccine. However, certain adults especially students at post high school educational institutions may need two doses separated by at least 28 days. Also, the killed measles vaccine available in 1963–1967 was not very effective. So, they should be vaccinated again.

Tdap/DTaP Vaccination[35,36]

Bordetella pertussis may be the etiologic agent in 12–30% of adults with cough that does not improve within 2 weeks. This is a highly contagious disease with attack rates of 80–100% among unimmunized household contacts and 20% within well immunized household contacts. Despite their efficacy whole-cell pertussis vaccines have been associated with adverse events both common (fever, pain at injection site, erythema and swelling; irritability) and uncommon (febrile seizures, hypotonic hyperresponsive episodes). There have also been alleged associations of whole-cell pertussis vaccine with encephalopathy, sudden infant death syndrome, and autism, which although not substantiated, have succeeded in initiating an active anti-immunization lobby.

Low dose diphtheria toxin along with acellular pertussis vaccine in otherwise previous DPT vaccine has reduced its dreaded side effects. Currently, diphtheria toxoid vaccine is coadministered with tetanus vaccine (with or without acellular pertussis). DTaP (full-level diphtheria toxoid, tetanus toxoid, and acellular pertussis vaccine) is currently recommended for children up to the age of 6 years. DTaP replaced the earlier whole-cell pertussis vaccine DTP in 1997. Tdap is formulated for adolescents and adults and consists of acellular pertussis, tetanus toxoid and reduced diphtheria toxoid, and acellular pert Tdap was licensed for use in the US in 2005 and is recommended for children ≥7 years old and for adults. It is recommended that all adults who have never received Tdap before; a single dose of Tdap should be given regardless of the fact that they got Td vaccine before. This should be followed by either a Td or Tdap booster every 10 years.

Efficacy of vaccine can be ascertained by certain historical events. During the 1990s, an epidemic affecting 150,000 people occurred in the former states of the Soviet Union out of which 5000 had died. This was associated with a clonally related strain of ET8 complex. This outbreak was attributed to the failure of the public health infrastructure to vaccinate the people.

Controversy: In the United States, routine vaccination that started in 1940s led to a 100-fold reduction in the incidence of pertussis, and the disease appeared to be on the road to elimination.[2] However, since the mid-1970s, the disease has once again resurfaced,[2] steadily increasing in incidence to 15.1 cases per 100,000 in 2012.

The recent surge of pertussis in developed countries led to a controversy as to its cause. Domenech de Cellès et al. modeled the transmission of pertussis using incidence data from Massachusetts, US. They found that it was not the switch to acellular pertussis vaccine but rather the waning vaccine conferred immunity that contributed to the Massachusetts outbreak This could be explained by the local increased incidences in pertussis cases in the subpopulation who were not vaccinated. Simulations suggested that administration of existing boosters to children may be an effective strategy to halt the transmission of pertussis.

Current recommendation: Every Adult >10 years of age should be given Tdap followed by booster dose of Td or Tdap every 10 years including pregnant women in early pregnancy.

COVID-19 Vaccination

Three types of mechanisms are involved for manufacturing of Covid SARS 2 vaccines (as depicted in **Figure 2**) which are being developed by more than 300 drug companies.

As of now following vaccines **(Table 2)** are at various stage of development:[38]

Controversy and Concern[39-41]

The development of a new vaccine usually takes around 10–15 years.[40] Mumps was the fastest vaccine which was developed in 5 year time. During this pandemic era there is lot of pressure by public and government agencies on the pharma companies to develop vaccine at a faster pace. Therefore, the vaccines are being developed in a very short period and on trial basis on smaller groups. As a result

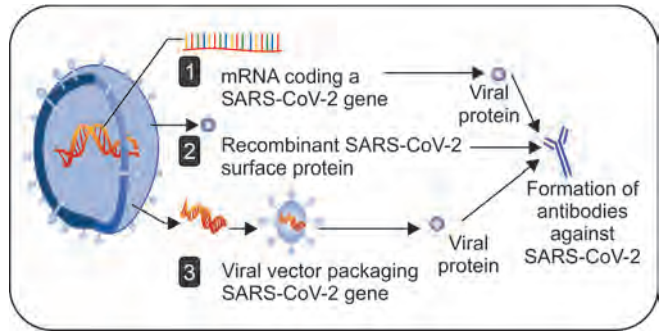

Fig. 2: Vaccine candidates use different mechanisms, such as those shown above, to prompt the body to produce antibodies against SARS-CoV-2
(*Source:* GAO-20-583SP)

TABLE 2 Vaccine types and current stage of development

Vaccine candidates, developers, and sponsors	*Mechanism*	*Sponsor*	*Approved/phase*
mRNA-1273	mRNA-based vaccine	Moderna, Pfizer, BioNTech, Fosun Pharma	• UK: MHRA (December 2, 2020) • Bahrain: NHRA (December 5, 2020) • Saudi Arabia: SFDA (December 10, 2020) • US: FDA (December 11, 2020) • MX: COFEPRIS (December 11, 2020)
Ad5-nCoV	Recombinant vaccine (adenovirus type 5 vector)	CanSino Biologics	**Approved** China
AZD1222	Replication-deficient viral vector vaccine (adenovirus from chimpanzees)	The University of Oxford; AstraZeneca; IQVIA; Serum Institute of India	Phase 3
Covaxin	Inactivated vaccine	Bharat Biotech; National Institute of Virology	Phase 3
JNJ-78436735 (formerly Ad26.COV2.S)	Non-replicating viral vector	Johnson & Johnson	Phase 3
NVX-CoV2373	Nanoparticle vaccine	Novavax	Phase 3
Gam-COVID- Vac (Sputnik V)	Non-replicating viral vector	Gamaleya Research Institute of Epidemiology and Microbiology	Russia: Ministry of Health

when the vaccines are released for public use on mass scale, the side-effects which were unnoticeable during trial phase may become overt.[39] RNA-based vaccines are a major new tool to combat pandemics like COVID-19 outbreaks as they require only viral genetic sequence information to initiate development.

In the past DNA and RNA vaccines have not been successful for human diseases and m-RNA based vaccines will be used for the first time in human being and that too in the pandemic period with trials done for less than a year duration.

The vaccine candidates using human adenovirus as vector such as Cansino Biologics (Wuhan, China) could reduce immune response as there is lot of pre-existing immunity to Adenovirus.[41] Mutations of virus is another important factor that can result in having limited effectiveness of vaccines. There is also concern that vaccines may cause antibody dependent enhancement ADE (as was seen in Dengue Vaccines) or antibody dependent cellular cytotoxicity (ADCC).

Response to vaccines may differ in various age groups and in people with different status of immunity. During phase II trial Sanofi's recombinant DNA derived vaccines did not yield adequate antibody titer in people aged 50 years or more.

The trial so far has been conducted in non-pregnant and younger population. Therefore, side effects and concerns in extremes of age and pregnancy are still to be decided.

Cost of vaccine, hesitancy, manufacturing capabilities, logistics, maintenance of cold chain, and transportation are other issues which may burden our country in terms of money and manpower in delivering vaccines to target population. (At the time of submitting of this article FDA has approved **Tozinameran** (BioNTech, Pfizer) on 11 December 2020, while on the same day Sanofi has postponed phase III trial due to poor antibody titer in people aged 50 years or more.)

Conclusion

This is an established fact that due to proper immunization of masses we have been able to either eradicate certain diseases like smallpox or polio or incidences of many communicable diseases like measles, pertussis, etc. have been brought to minimum. But due to lack of communication between people and HCP there has been apprehension and doubts in the mind of public at large which precludes them of using vaccines. Affordability of certain vaccines and Inertia on the part of HCP is another reason for underutilization of vaccination. The adverse effects of vaccines are so highlighted and dramatized by media (including social media) that it overshadows the efficacy of vaccinations. Need of the hour is to remove this misconception in mind of people with help of HCPs, Govt. agencies, media, etc. to help us overcome this menace as was done in case of polio and smallpox.

CHAPTER

157 Infections in Critically ILL Patients

Nitin Sinha

Abstract

Critically ill patients are prone to many infections due to multiple interventions being carried out in them by means of indwelling catheters, endotracheal tube, etc. These infections lead to increased morbidity and mortality among critically ill patients. It is, therefore, imperative that these are recognized early and treated appropriately. More important than treating these would be to prevent them from occurring. This chapter deals with various infections in critically ill patients, their pathogenesis, diagnostic, and treatment guidelines and also the preventive guidelines.

Introduction

Critically ill patients are those who suffer from a critical illness that requires them to have intensive monitoring. This intensive monitoring entails them to have complete dependency on caregivers for their daily activities. These patients often are in coma/drowsy, mechanically ventilated, bed-ridden, and have many indwelling catheters. These factors make these patients prone to infections, which can be multi-drug resistant. This chapter deals with different infections that can occur in critically ill patients, their pathogenesis, and their preventive strategies.

Different Types of Infections Seen in Critically Ill Patients

Catheter-associated Infections

Pathogenesis and Risk Factors

Critically ill patients mostly have multiple catheters inserted. It may be urinary catheter, peripheral intravenous cannula, arterial catheter, or central venous catheter. These help in critical monitoring of the patient. In a certain survey in the United States, 87% of blood stream infections were associated with central lines. In the same survey, catheter associated urinary tract infection (CAUTI) was responsible for 95% of urinary tract infections.[1] Mortality attributable to central venous catheter-related infections is 12–25% and mortality attributable to CAUTI is less than 5%.[2]

A biofilm formation is critical in pathogenesis of catheter-associated infections. A biofilm is basically composed of a conditioning film (formed by the body fluid bathing the catheter) and the microbes that attach to it (sessile), which secrete an extracellular polysaccharide matrix on the condition film. This biofilm facilitates growth of microbes of different species and it is from here that some microbes become mobile (planktonic) and lead to infections. The biofilm leads to decreased penetration of antibiotics, local alteration in the microenvironment leading to decreased susceptibility to antimicrobials and antimicrobial resistance. Many microbiological culture results are only of planktonic organisms and these do not apply to sessile organisms embedded in the biofilm. It is because of this that sometimes antibiotics merely suppress the infection.[2]

The intravascular catheters get infected on their outer surface by the microbes present on the skin, especially within 10 days of the insertion. So, short-term intravascular catheters like peripheral intravenous cannula, arterial catheters, and non-cuffed central venous catheters mainly get contaminated on outer surface. The common organisms that migrate to outer surface of catheters from skin are coagulase negative staphylococci and *Staphylococcus aureus*. The hub of intravascular catheters gets contaminated by microbes that chiefly come from caregiver's hands. This especially occurs if the catheter is in situ for greater than 30 days or more. Intraluminal spread to catheter can also occur from a distant source (e.g., urinary tract) or from an infected infusate. Most common organisms implicated in these instances are *Stenotrophomonas*, *Candida*, *Pseudomonas*, enterococci. Immune compromised and elderly patients are more likely to develop contamination. Multilumen intravascular catheters and catheters inserted at femoral site are more likely to get contaminated. Internal jugular central venous catheter is more likely to get contaminated than the subclavian counterpart. Peripheral intravenous lines are more likely to get contaminated if inserted in lower extremities. Catheters inserted by non-sterile/improper techniques are more likely to get contaminated.[2]

The urinary catheter can also get externally contaminated either at the time of insertion or later by fecal matter. Intraluminal contamination can occur by reflux of microbes from the container bag or due to a break in collecting system. Commonly isolated organisms are *Escherichia coli*, *Pseudomonas*, *Enterobacter*, *Candida*, *Klebsiella*, and enterococci.[2] *Staphylococcous* and coagulase negative staphylococci have also been isolated. As with intravascular catheters, immune compromised patients are more likely to develop contamination. The other risk factors for developing bacteriuria in catheterized patients is longer duration of catheterization, diarrhea, female gender, renal insufficiency, improper catheter insertion technique, and improper catheter care.[3]

Diagnosis of Catheter-related Blood Stream Infection (CRBSI)

The Infectious Disease Society of America (IDSA) has published updated detailed guidelines for diagnosing intravascular CRBSI in 2009.[4] The commonly used terminologies for intravascular catheter-related infections are catheter colonization, phlebitis, exit site infection, and blood stream infections. The details regarding all these can be read from the guidelines. From the guidelines it was noteworthy that catheter tips should be cultured only quantitatively and not qualitatively and that catheters to be cultured only after removal.

Diagnosis of CAUTI

The 2009 IDSA Guidelines define CAUTI in catheterized (urethral, suprapubic, and condom) patients and in those in whom catheter (urethral, suprapubic, and condom) has been removed in last 48 hours by the presence of symptoms and signs of urinary tract infection with no other identified source of infection and having 1,000 or more colony-forming units (CFU)/mL of 1 or more bacterial species.[5]

Pulmonary Infections

Definitions, Etiological Agents, and Risk Factors

Pulmonary infections are major causes of mortality in critically ill patients. Among intubated patients, ventilator associated pneumonia (VAP) diagnosis is made if pneumonia develops 48 hours after intubation.[6] Any pneumonia other than VAP developing in hospital is called hospital-acquired pneumonia (HAP).[7] VAP occurrence rates are quite different in different studies. This is due to use of different diagnostic criteria, variations in study population, differential evaluation of radiological images, and different methods of sampling. Fever, leukocytosis, purulent secretions, new infiltrates on chest x-ray/worsening infiltrates on chest X-ray carry high sensitivity in suspecting VAP, but at the cost of low specificity. Clinical Pulmonary Infection Score (CIPS) of greater than 6 strongly suggests VAP.[8] Common risk factors for developing VAP are advanced age (>60 years), male gender, increased mechanical ventilation time (>2 weeks), prolonged hospital stay, altered consciousness, burns, comorbidities (diabetes, CAD, COPD, chronic renal failure, Hashimoto's thyroiditis), prior antibiotic use (leading to MDR pathogen infection), placement of gastric tubes, invasive procedures in ICU (reintubation, tracheostomy, fiberoptic bronchoscopy), smoking, raised intra-abdominal pressure, hypoxia, and gene polymorphisms (single nucleotide polymorphisms of TNFα gene, ATG16L1 gene, and TREM 1 gene). Commonly

organisms causing early VAP (occurring within first 4 days of hospitalization) are *Enterobacteriaceae* and *Staphylococcus aureus* and those causing late VAP are non-fermenting bacteria and *Enterobacteriaceae*. *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, *E. coli,* and *Klebsiella* are commonly isolated. Mortality from early VAP is nearly 19% and that of late VAP is 31.4%.[6]

Common organisms causing HAP are *Pseudomonas aeruginosa*, *S. aureus*, *Klebsiella pneumonia*, *E. coli*, *S. marcescens*, *Stenotrophomonas maltophilia,* and *Acinetobacter baumanii*.[9]

Diagnosis of VAP and HAP7

Diagnosis of VAP should be made preferably by noninvasive sampling (endotracheal aspiration, spontaneous expectoration) rather than invasive sampling [protected specimen brush (PSB), bronchoalveolar lavage (BAL), and blind bronchial sampling (mini-BAL)]. Also, semiquantitative culture should be used for diagnosis. Diagnostic threshold for diagnosing VAP is more than 10^3 CFU/mL by PSB or more than 10^4 CFU/mL by BAL.

Dermatological Infections

Skin infections are also common in critically ill patients. In a study by Malheiro et al. in ICU patients, it was observed that immunosuppressive drug use, intravenous drug abuse, Type 2 diabetes mellitus, previous cutaneous or soft tissue infection (STI), HIV, cirrhosis, obesity, renal failure, etc. were risk factors for developing skin and soft tissue infections.[10] They, however, included patients with necrotizing fasciitis, abscesses and cellulitis only. Fournier's gangrene and cervicothoracic fasciitis were two most commonly observed fasciitis. Abscesses were commonest in cervical/thoracic region and cellulitis was observed in abdomen and lower limb. Myriad of organisms from *E. coli* to *Staphylococcus aureus*, Proteus, *Klebsiella*, etc. were isolated from different infection sites.

In a prospective analysis of ICU patients admitted due to surgical causes, 12.1% developed dermatological disorders out of which 28.8% had infectious dermatological lesions, 26% had dermatosis and 45.2% had drug reactions. Longer ICU stay (>10 days) was associated more with dermatological disorders. Comorbidities like diabetes, CAD, hypertension, etc. were commoner in patients who developed dermatological disorders. Wound infection was the commonest infection observed, frictions blisters were most commonly observed dermatoses, and maculopapular drug eruption was the commonest drug reaction observed.[11]

Almost similar findings (though with different proportions) were observed in patients admitted in Medical ICUs. The only difference from surgical ICU patients was that fungal skin infection was the most commonly observed infectious dermatological lesion. Mortality was significantly more in those who had dermatological lesions as compared to those who did not.[12]

Treatment

Treatment of any infection that develops in a critically ill patient depends upon the etiology, site, severity, and antibiotic sensitivity. Some infections like cellulitis, fasciitis may also require surgical intervention. Catheter removal might sometime need surgical assistance. Empirically started antibiotics must be according to the antibiogram of the hospital/institute.

Prevention of Infection in Critically Ill Patients

This is the utmost important part in critical care. Prevention is always better than cure.

Prevention of CRBSI[13]

Centre for Disease Control and Prevention has laid down extensive guidelines for prevention of CRBSI. Some salient points are:

- Staff should be adequately trained and educated regarding insertion, care, and removal of catheters.
- Peripheral catheters to be inserted in upper extremities.
- Use midline catheters/PICC line if duration of intravenous therapy is likely to exceed 6 days.
- Do not remove gauze dressing at insertion site daily. Palpate the site for any tenderness or swelling. Remove peripheral catheter if there are signs of phlebitis.
- Use subclavian site for central venous catheter (CVC) insertion for nontunneled catheters to minimize infection. There is no recommendation for site for tunneled CVC insertion.
- Use CVC with minimum ports.
- Remove CVC as soon as its use is over.

- Perform hand hygiene before and after catheter insertion, dressing, removal, guide wire change or catheter site palpation. This can be achieved by washing hands with soap and water or by applying alcohol based hand rubs (ABHR).
- Use maximum sterile barrier precautions (sterile gown/drape, sterile gloves, mask, and cap) while inserting arterial catheter, PICC, or CVC.
- Insert CVC preferably by using ultrasound.
- Clean skin with antiseptic (70% alcohol, tincture of iodine or alcoholic chlorhexidine gluconate solution) before peripheral venous catheter insertion. Prepare clean skin with more than 0.5% chlorhexidine preparation with alcohol before inserting CVC, PICC, or arterial catheter.
- Use 2% chlorhexidine wash for patients daily skin cleansing.
- Use a chlorhexidine/silver sulfadiazine or minocycline/rifampin-impregnated CVC if the catheter is likely to be in place for more than 5 days and only if the Central Line Associated Blood Stream Infection (CLABSI) rate is not decreasing despite using a comprehensive strategy, which at least should include these three components: educating persons who insert and maintain catheter, using maximum sterile barrier precautions (as detailed in point 9) and more than 0.5% chlorhexidine preparation with alcohol for skin preparation before CVC insertion.
- There is no need to use antibiotic prophylaxis while catheter is in-situ. Also, there is no need to use anticoagulation.
- Use antibiotic lock solution prophylaxis in patients who have long-term catheters and have history of multiple CRBSI despite optimal and maximal adherence to aseptic precautions.

Certain recommendations (apart from those mentioned above) in CDC guidelines were changed/added in 2017. The details can be checked from CDC website.

Prevention of CAUTI[14]

- Insert catheter only for appropriate indication and leave in place for only as long as needed. Even for operative patients, use catheter only if required.
- In males with bladder outlet obstruction/urinary retention, consider using external catheter in place of indwelling catheter. Intermittent self-catheterization can be done in patients with bladder dysfunction or with spinal cord injury.
- Catheterization to be done by well-trained persons and hand hygiene to be practiced prior to insertion or after any manipulation of the catheter. Sterile technique to be used for insertion of catheter which entails using sterile gloves, gowns, and sponges and cleaning of periurethral area with appropriate antiseptic solution. There is no need to use antiseptic lubricants routinely. Catheter needs to be secured adequately after insertion.
- Maintain a closed drainage system. Avoid kinking of catheter and collecting tube and ensure that collecting bag does not rest on the floor. Collecting bag to always be below the level of urinary bladder. Empty the container bag regularly using separate clean container. There is no role of systemic antibiotic prophylaxis while catheter is in-situ. There is again no role of putting antiseptic/antimicrobial solution in collecting bag routinely. There is no recommendation for using urinary antibiotic (methanamine). Routine use of any catheter with antibiotic release cartridge installed in the catheter's drain port is not necessary. There is no need to clean periurethral area with antiseptic solution daily when catheter is in place; cleaning of meatal area while daily bathing/sponging is sufficient.
- Use antibiotic impregnated catheters only, if CAUTI rate is not improving despite using a comprehensive strategy.
- Silicone catheter might be preferable over other catheter materials in long-term catheterized patients who have frequent obstruction as it prevents encrustations. Hydrophilic catheter might be preferable to standard catheter in patients requiring intermittent self-catheterization.

Prevention of VAP[15]

VAP can be prevented by following methods:

- Avoid intubation, if possible. Use noninvasive positive pressure ventilation (NIPPV).
- Minimize sedation. Try to give off to sedation once a day (awakening trial). Give spontaneous breathing trials. Try to club the two trials together.
- Provide early exercise and mobilization.

- Use endotracheal tubes with subglottic secretion draining ports if intubation is likely to last for greater than 48–72 hours.
- Elevate head end of the bed to 30–45 degrees.
- Change ventilator circuits only if visibly soiled.
- There are certain special approaches but they have insufficient data. These are selective oral or digestive decontamination, regular oral care with chlorhexidine, and use of prophylactic probiotics.
- Certain approaches like using ultrathin polyurethane cuff endotracheal cuffs, saline, automated control of endotracheal cuff pressure, saline instillation before tracheal suctioning, and mechanical tooth brushing have low quality evidence to prevent VAP.

Conclusion

Infections in critically ill patients can increase the morbidity and mortality in these patients. Appropriate preventive measures can curtail occurrence of such infections.

CHAPTER

158 Current Controversies in Sepsis Management

Atul Bhasin, RK Singal

Abstract

Sepsis syndrome, a dysregulated host response in infection, has multimodality and multifaceted treatment which has been changing over the decades since its recognition. Advances in management of the syndrome brought along with it many controversies and failures in treating it. The advances made in treatment kept changing with emergence of newer definitions, its assessment scores, role of infusion and combination empiric antibiotic therapy. The prognostic value of biomarkers to guide duration of antibiotics, fluid therapy, its role in endothelial glycocalyx protection along with antioxidant therapy and steroids is being evaluated.

Introduction

Sepsis is a life-threatening syndrome of a dysregulated host response to infection. Despite advances in diagnosis and treatment, sepsis still remains a significant cause of morbidity and mortality. Many aspects of the diagnosis and clinical management of sepsis require further study and remain controversial. Relevant literature and controversies regarding the overall evaluation and management of sepsis and septic shock need to be revaluated time and again for management.

Newer Definitions of Sepsis and Its Impact on Diagnosis

The last two decades have seen ever changing definitions of sepsis, thus creating "more controversies" in the minds of bedside clinicians and emergency physicians. The changing clinical scenarios for the treating physicians at bedside further add to the already complicated issues of labeling the patient in sepsis. The effort to simplify the definition or criteria for defining sepsis, in recent times, has lead to increased diagnosis of this life-threatening syndrome of a dysregulated host response to infection. As of 1991, the initial definition stated that systemic inflammatory response syndrome (SIRS) to infection would be called sepsis. While subsequent revision of the definitions in 2001 specified the organ damage. Similarly, the new definitions 2016 defined it as a life-threatening organ dysfunction due to dysregulated host response to any infection. Later the role of Sequential Organ Failure Assessment (SOFA) was brought in where an organ dysfunction is assessed as an acute increase in total SOFA score by two points as a consequence of infection. Further adding to dilemma, the Sepsis-3 investigators introduced a new bedside index, called the quick Sequential Organ Failure Assessment (qSOFA). This was introduced to identify patients evolving into sepsis or could be in early sepsis in suspected infections. The qSOFA has just three easily measured physiological variables, that is, systolic arterial blood pressure ≤100 mm Hg, respiratory rate >21 breaths/min and altered mental status (GCS ≤ 13), with each receiving one point and range being zero to three. It is quite obvious that by these parameters there is a tendency to over diagnose sepsis in many patients having above

variables. As any two of these constitute a "positive" result and an indication that the patient is at risk of sepsis. The difficulty here is that it has a very low threshold (all that is needed is tachypnea and a slightly low blood pressure) to over diagnose sepsis. It needs to be understood that it is not a surrogate definition of sepsis but just an indication of increased risk.

Though this was a step to increase specificity of definition and has eliminated SIRS as was there in previous definitions, but it still has its own deficits. In absence of gold standard definition, the clinicians still adopt various parameters to diagnose sepsis by combining non-specific physiological and laboratory anomalies.

Similarly, the statement of definition as "life-threatening organ dysfunction caused by a dysregulated host response to infection" is more controversial in defining the terms like life-threatening, dysregulated, quantitative assessment of dysregulation.

Though the new Sepsis-3 definitions have reduced complexity, removed terms like severe sepsis, defined the role of qSOFA and has helped the emergency team categorize patients early into sepsis but still has major drawbacks. The controversies around microbiological confirmation, quantitative assessment of dysregulated syndrome, a syndromic approach, and over sensitivity of qSOFA remains to be further evaluated in bedside practices and epidemiological studies.

Sepsis or Septic—Is there a Difference in Assessment

The word "Sepsis" is being confused with "being septic." As understood over the decades, sepsis by definition is bacteriological culture positivity of disease in any previously sterile body tissues or blood. While the word Septic signifies presence of any viral, protozoan, fungal, or any other illness leading to a diseased state. While SIRS also included non-infectious cause's of sepsis syndrome. Simplicity of the term sepsis, defined as an invasion of normally sterile tissue or fluid or body cavity by pathogenic or potentially pathogenic microorganisms can never be disputed, in spite of the fact that a microbiological confirmation is difficult at times. All the definitions of sepsis do not differentiate or distinguish between viral, parasitic, and other causes of sepsis. Similarly, regional infections, which necessitate the treatment variations, also need to be catered to especially when planning the health-care policies of the region. This will specifically target and reduce the mortality and morbidity in a particular region due to endemic diseases causing critical illnesses.

Abandoning terms like severe sepsis, septic shock, MODS, and septicemia have further widened the difference in concept of ideal or specific management strategies of these illnesses. Emergency physicians need to think more broadly and initiate appropriate management strategy on the basis of differential diagnoses, which is important factor in management and this has obviously been neglected in initial resuscitation strategies. In our endeavor to simplify criteria, there is a deficit in understanding disease pathophysiology and its impact on management strategies. The practical guidelines for the management in accordance with specific etiologies and organ involvement need to be considered and managed accordingly.

Combination Empiric Antibiotic Therapy

Combination of antibiotics is usually initiated on a clinical diagnosis of sepsis and this is usually done with broad spectrum antibiotics, in optimal doses. This is done with a view to have maximal coverage with a perspective to de-escalate once the organism is recognized and antibiogram available for further management. Though there are both advantages and disadvantages of using combination therapy, but no measurable survival benefit has been seen on routinely using a combination therapy except in few instances. The current recommendations for combination therapy as per Surviving Sepsis Campaign are only meant for the neutropenic patients, patients with suspected multidrug resistant organisms especially (Acinetobacter or Pseudomonas) and respiratory failure with sepsis. Though the combination therapy, for many multidrug resistant Gram-negative sepsis infections, is essential, but this cannot be followed as rule in light of studies suggesting that combination therapy was only effective if the drugs were effective in vitro too. Thus negating the suggestion that combination was always logical, as together the combinations overcome the so-called target attainment minimum inhibitory concentration (MIC) threshold, despite in vitro resistance. The definite advantage of combination therapy in form of a broad spectrum of activity, reduction in development of drug resistance, and synergism can never be denied but all this adds to the risk of toxicity, super infections, and additional cost.

Antibiotics Infusion in Sepsis

Different antibiotics differ in their mechanism of action, and in the case of β-lactams, the time above the MIC (T > MIC) (i.e., the duration of time that the antibiotic concentration in the relevant tissue space exceeds the minimal inhibitory concentration required to kill the bacteria) is the critical pharmacokinetic characteristic that determines its efficacy. This makes it pharmacokinetically more effective if it is administered as a continuous infusion to optimize the T > MIC. Dulhunty et al. showed that continuous infusion improved the pharmacokinetics but it did not improve the ICU survival rate or the statistically significant clinical cure.[1] Similarly, the BLISS trial reached nearly, identical conclusions. A meta-analysis of 632 patients concluded that there was a statistically significant benefit of continuous infusion for both the clinical cure and its survival benefits. When this was analyzed by multivariate analysis the independent effect of continuous infusion was lost. Arguably it stands to reason that this intervention improves the clinical cure of infection, but as the survival of critically ill patient is a multifactorial variant thus the outcome may not be as expected in view of its dependency on various other factors.[2]

Biomarkers to Guide Duration of Antibiotics

Duration of an antibiotic therapy has always been based on the evidence of clinical course, cure, and the outcome of the infectious disease being treated. The duration of antibiotic therapy has been, as controversial as its initiation without a documented infection, and that too in critically ill patients. Though there is no conflict on the general principle that, it should be given for the shortest duration, but the exact duration of therapies have always been controversial except in few clinical conditions. The same holds for the patients being treated in critical care units.

The role of biomarkers in the last decade have changed the guidelines and treating principles, but the controversies in their potential use a sole criteria to guide a therapy also exist. The role of procalcitonin has been much studied, with over more than eight thousand papers defining its role in treatment of sepsis. The question which haunts any treating physician after the normal Procalcitonin report is whether the patient is infected and should an antibiotic be withheld. In case of abnormal reports even after adequate antibiotic therapy is whether the physician can de-escalate it. And obviously the answer stands to a good reason of clinical assessment.

As per recommendations of the Surviving Sepsis Campaign all biomarkers, including procalcitonin can be used by clinicians to assist him in withdrawal of antibiotics in septic patients especially those who have not been proven to have an infection on subsequent investigations after the initial therapy under septic bundle protocol therapy.

Procalcitonin

Among other biomarkers Procalcitonin has been advocated the most. Procalcitonin is up regulated by the cytokines that are secreted in bacterial infections in sepsis. Thus ideally it should not be used as guide in such patients, especially as a guide to decision-making regarding initiation of antibiotics. However, its use as in guiding de-escalation of antibiotic therapy after initial rise has more significance. All the studies, that is, PRORATA, ProGUARD, and SAPS trial's found a non-significant reduction in days of antibiotic use in their intervention arms, while the impact on mortality showed no differences. However, in view of false positive levels in non-infectious inflammatory diseases and false negative in severe infections clinical decision and judgment should always be used to override the importance of serum levels.[3]

Fluid Therapy and Its Role in Endothelial Glycocalyx Protection

As controversies in fluid resuscitation in sepsis and septic shock exist even after three decades of active management, it is still eluding the question whether, under or over resuscitation is beneficial or not for sepsis management.

Endothelial glycocalyx, an endothelial cell surface layer composed of membrane anchored proteoglycans and heparan sulfate, essentially acts as a endothelial barrier and opposes leukocyte-endothelial adhesion.[4] During sepsis, activation of heparanase in vessel wall leads to degradation of glycocalyx heparan sulfate thus furthering the endothelial dysfunction and injury caused due to sepsis. A hormone, released due to volume loading causing atrial stretching, that is, atrial natriuretic peptide furthers the degradation of endothelial glycocalyx, thus aggravating the septic vasoplegia. Though this phenomenon has not been explored much in humans,

but animal models have proved beyond doubt the amount of injury caused and the aggravation of the vasoplegia. Intravenous fluid resuscitation is associated with septic endothelial glycocalyx degradation. As expected, injurious effects of fluid therapy following resuscitation would worsen the outcome primarily by causing microcirculatory dysfunction. The potential beneficial hemodynamic effects of fluid resuscitation, thus being negated. Several recent randomized trials have demonstrated such worsening of sepsis after initial bolus intravenous fluids.[5] The exact mechanisms by which such harm is caused need to be further evaluated and documented. Few studies also documented an association between volume of fluid used in resuscitation and intubation in high risk patients of heart failure, ESRD and Cirrhosis having sepsis. But similarly no differences in such events were detected in these patients who had received as per recommended guideline of 30 mL/kg of fluid for initial therapy.

Steroids in Sepsis

The immunosuppressive effects of steroids have harmful effect on severe sepsis but its role as anti-inflammatory and vasoactive substance cannot be denied. The controversies on the dose and duration are the most important issues in the management of sepsis. Though the harmful effects of high dose therapy have been well documented, but its therapeutic effects in low dose in sepsis are also less clear. The critical illness-related corticosteroid insufficiency has been well known. The ongoing efforts to prove the insufficiency as a diagnostic modality and the therapeutic options to correct have neither been proved or validated.[6] The two studies, CORTICUS in 2008 and HYPRESS in 2016, evaluated the low-dose hydrocortisone *versus* placebo for their role in sepsis. Both the studies could not show any survival benefit over 28 days. Corticus trial did show faster resolution of shock but there was a non-statically significant increase in infections within the corticosteroid arm. Various other trials also lacked the uniformity in proving efficacy of steroids with respect to improvement in the severity of shock; along with ideal time of initiation of this therapy.[7] Similarly, the duration and dose of therapy could not be ideally evaluated. The Surviving Sepsis Campaign guidelines in 2016 recommended the use of this therapy in septic shock refractory to fluid resuscitation. The meta-analysis of various studies showed reduction in 28-day mortality but such an effect could not be proven in all cause mortality in 90 days. Similarly, steroids therapy was associated with more-rapid resolution of shock and shorter duration of ICU stay. Therefore, in respect to above, an adjunct dose with 200 mg per day intravenous therapy was used in a study.[8]

Antioxidant Therapy with Vitamin C and Thiamine

Protective effects of vitamin C against oxidative-stress-mediated cell damage and organ dysfunction in sepsis and septic shock are well known.[9] Similarly, its deficiency has been observed in critically ill patients. During sepsis there is production of reactive oxygen species leading to endothelial injury and dysfunction, which is seen along with mitochondrial injury and both of these together lead to organ failure.

Antioxidant activity of vitamin C helps in scavenging free radicals prevents production of the reactive oxygen species, acts as a neuroprotector, and helps as cofactor for synthesis of vasopressors, thus reducing the oxidant injury to vessel walls in sepsis. As humans cannot synthesize vitamin C, there develops a state of hypovitaminosis due to increased vitamin C consumption and reduced recycling, which needs to be corrected. This deficient state can only be restored efficiently with parenteral high-dose administration.

Decrease in multi-organ failure and improvement in SOFA scores was documented in critically ill patients when treated with high dose of the antioxidants like vitamin C and E. Marik et al. in study concluded in 2017 that there was a significant decrease in mortality when vitamin C, hydrocortisone, and thiamine were used.[10] Two prospective trials are currently underway that may shed more light on the efficacy of vitamin C as a treatment for sepsis.

Similarly, thiamine levels are reduced in 20–70% of the septic patients, and this is associated with worse outcome. Thiamine deficiency decreases the activity of enzyme involved in aerobic glycolysis, Krebs cycle, and pentose phosphate pathway. These in turn lead to reduced ATP production. ATP helps in maintenance of cellular pH and preservation of neurotransmitters both of which are important for cellular metabolism in critical illnesses. Thiamine also helps in protecting the kidneys from oxalate nephropathy due to high-dose vitamin C. Thus, thiamine

played an important role in improvement of renal function without any impact on mortality.[11]

Hydrocortisone and vitamin C, both together improved the endothelial barrier and microcirculation, and therefore together they increase the production of catecholamines and thus augment its vasopressor effects. Vitamin C also restores glucocorticoid expression of the vitamin SVCT2 transporter thus in turn improving glucocorticoid receptor function.[12] And similarly both when combined showed higher in vitro barrier-protective effect after lipopolysaccharide exposure.[13]

Choice of Vasoactive Agents

Several vasoactive agents can be used to support perfusion in septic shock. Catecholamines and vasopressin both function by stimulation of cardiac contractility and/or peripheral vasoconstriction, depending upon individual mechanism of actions. The Surviving Sepsis Campaign suggests norepinephrine, a potent agonist of both alpha and beta receptors, as the initial vasopressor of choice in septic shock. Norepinephrine is an endogenous catecholamine that stimulates alpha and beta receptors, while dopamine an endogenous catecholamine stimulates dopaminergic alpha, and beta receptors. Initiation of vasopressor therapy after initial fluid resuscitation is done to achieve an adequate mean arterial pressure (MAP). Norepinephrine has been used as a first-line vasopressor agent for a long now.[14] As per the new recommendations, the vasopressors should not be delayed until fluid resuscitation is completed, but should be started rather early to achieve a target MAP of 65 mm Hg or more. During the recent decades, terlipressin, vasopressin V1A agonist, and even Ca^{2+} sensitizer have been increasingly used to treat septic shock. A meta-analysis of forty-three trials with 5,767 patients assessing seventeen treatment modalities showed vasopressor therapy with norepinephrine plus dobutamine to be most effective followed by norepinephrine plus epinephrine or terlipressin.[15] The studies have proved beyond doubt that norepinephrine should be used as a first-line treatment, but when followed by addition of dobutamine it would reduce the 28-day mortality. The serious potential adverse effect of precipitating ventricular and supraventricular arrhythmias needs to be actively monitored during its use especially with individuals having low-cardiac output due to impaired contractility.

Conclusion

Sepsis a multifaceted disease needs to be managed with simpler and universal guidelines, which are appropriate and can be delivered at all categories of health-care system. Initial approach needs to be aggressive and time bound even if diagnosis is underway as per clinical bedside guidelines and the clinical scenario. Initial resuscitation with fluids and in responsive patients the fluid therapy needs to be modified. Role of vasopressor is well documented and it should not be denied early in treatment with its weaning as per documented response. Initial antimicrobial therapy with a goal to target pathogens found in the suspected disease followed by change in antibiotics as per antibiogram and susceptibility should be done. Antimicrobial therapy guided by the relevant biomarkers reduction should be administered for a total duration of 7–10 days. Though, this can be of shorter or longer duration as per the clinical scenarios. Antioxidants and steroids have been documented to improve the outcomes and should be administered till further studies evaluate their role.

CHAPTER

159 Viral Hemorrhagic Fever: Indian Perspective

Ghan Shyam Pangtey, Chinmaya Murthy KR, Paramjeet Singh

Abstract

Viral hemorrhagic fevers (VHFs) are a group of severe multisystem syndromes that are caused by several distinct families of viruses. Five distinct families of RNA viruses *Arenaviridae*, *Filoviridae*, *Bunyaviridae*, *Flaviviridae*, and *Paramyxoviridae* are well known for various VHFs in different geographic regions. The recent ongoing pandemic of SARS-CoV-2 Coronaviridae virus primarily presents with high-grade fever, cough, and breathlessness due to primary involvement of lungs. But COVID-19 has been found to have multisystem inflammation with Kawasaki Disease like presentation in children, human-to-human transmission, and thromboembolic phenomenon; therefore, it can be considered as emerging VHFs. The CDC-USA defines VHF as acute onset fever (>40°C) with any one of the following clinical finding: severe headache, muscle pain, erythematous maculopapular rash on the trunk with fine desquamation 3–4 days after rash onset, vomiting, diarrhea, pharyngitis (arenavirus only), abdominal pain, bleeding not related to injury, retrosternal chest pain (arenavirus only), and proteinuria (arenavirus only). VHF viruses spread in a variety of ways, but share some common pathogenic features. They have the potential for aerosol dissemination via respiratory droplets and are dependent on an animal or insect host for survival. These viruses are usually restricted to some geographic place of domicile of the host species. After the accidental transmission from the host, human-to-human transmission is possible in some viruses. The mortality rate is highly variable, 0.5% for dengue to 90% for Ebola virus disease. The VHF outbreaks cannot be easily predicted, as they are sporadic and irregular. The blood, urine, vomitus, pus, stool, semen, and saliva from the VHF patient are usually infectious. Barrier nursing practices (such as wearing personal protective equipment) help in reducing the risk of transmission to health-care workers. There is no specific treatment for majority of VHFs, except supportive care.

Introduction

The term "viral hemorrhagic fevers" (VHFs) depicts a group of diseases that are caused by several distinct families of viruses. In general, it is used to describe a severe multisystem syndrome.[1] The VHFs is mainly caused by six distinct families of RNA viruses *Arenaviridae* (lassa), *Filoviridae* (ebola), *Bunyaviridae* (Crimean-Congo hemorrhagic fever, CCHF), *Flaviviridae* (dengue), *Paramyxoviridae* (nipah), and Coronaviridae (COVID-19). The SARS-CoV-2 virus (family-coronaviridae) with the recent pandemic has shown to cause multisystem disease with respiratory illness as the primary organ involvement. The properties of multisystem involvement with Kawasaki like disease presentation, aerosol transmission, human to human spread, and various thromboembolic phenomenon reported from autopsy series, makes COVID-19 a new candidate for VHF. The SARS-CoV-2 virus has already spread to more than 216 countries and territories and was declared pandemic by WHO on March 11, 2020, it has already caused >550 million infections and 13 million deaths worldwide.

Though VHF viruses spread in a variety of ways, they share some common pathogenic features. They have the

potential for aerosol dissemination via respiratory route (except dengue), but they are dependent on an animal or insect host for survival. However, these viruses are geographically restricted to the place of domicile of the host species. After the accidental transmission from the host, human-human transmission is possible in some viruses. VHF may impair the blood clotting ability and can also damage the walls of small blood vessels.[2] The mortality rate of viral hemorrhagic fever ranges between 0.5–90%, depending on the pathologic agent.[3] The VHF outbreaks cannot be easily predicted, as they are sporadic and irregular.

Clinical Criteria for VHF

The Center of Disease Control (CDC), USA, has made the VHF definition (2010).[4] A person with acute onset disease with ALL of the following clinical finding:

- A fever >40°C, and
- One or more of the following clinical finding: Severe headache, Muscle pain, Erythematous maculopapular rash on the trunk with fine desquamation 3–4 days after rash onset, Vomiting, Diarrhea, Pharyngitis (arenavirus only), Abdominal pain, Bleeding not related to injury, Retrosternal chest pain (arenavirus only), Proteinuria (arenavirus only).

The predominant signs and symptoms noted in common VHFs are listed in **Table 1**.[5]

TABLE 1 Predominant signs and symptoms noted in common VHFs

Disease	*Signs and symptoms*
Ebola virus disease	Fever, headache, muscle pain, fatigue, weakness, diarrhea, vomiting, abdominal pain, conjunctival injection, chest pain, hemorrhage
Marburg virus disease	Fever, chills, headache, muscle pain, maculopapular rash, nausea, vomiting, chest pain, sore throat, abdominal pain, diarrhea, jaundice, hemorrhage
Lassa fever	Fever, nausea, vomiting, diarrhea, retrosternal chest pain, sore throat, muscle pain, enlarged cervical lymph nodes, abdominal pain, bleeding, maculopapular rash, conjunctivitis, headache
Crimean-Congo hemorrhagic fever	Fever, headache, back pain, join pain, abdominal pain, vomiting, conjunctival injection, facial flushing, petechial rash, jaundice, bleeding, photophobia, sore throat

Ebola Virus Disease

Ebola virus disease (EVD) is a rare, but deadly disease commonly affecting humans and non-human primates. The EVD viruses are mainly located in sub-Saharan Africa and their periodic emergence has caused several outbreaks in African countries. The EVD gets transmitted to humans through direct contact with an infected animal (bat or non-human primate) or a sick or dead person infected with the virus. Ebola virus was first described in 1976 near the Ebola River, which currently belongs to the Democratic Republic of Congo (formerly Zaire).

In 1995, an outbreak of Ebola hemorrhagic fever affected more than 300 people in and around the city of Kikwit, Democratic Republic of the Congo. The outbreak caused the death of approximately 80% of the patients and more than one-fourth of all the patients were health-care workers.[6] The 2014–2016 outbreak of EBV caused a mortality rate of up to 80–90%, and the death of many health-care workers were due to human-to-human infection.[7] On March 23, 2014, the World Health Organization (WHO) reported the EBV disease within the forested rural region of southeastern Guinea. It was the beginning of the West Africa Ebola epidemic, the largest in history. On August 8, 2014, WHO declared the Public Health Emergency of International Concern (PHEIC), which is designated only for events with a risk of potential international spread or that require a coordinated international response.[7] Over the duration of the epidemic, the disease had spread to seven more countries: Italy, Mali, Nigeria, Senegal, Spain, UK, and the US.

EBV: Ecology and Transmission

Humans get initially infected with EBV through contact with an infected animal, such as a fruit bat or non-human primate. This is called a spillover event. After the spillover event, the virus can spread from person to person through the following routes:

- Direct contact (such as through broken skin or mucous membranes in the eyes, nose, or mouth)
- Blood or body fluids (urine, saliva, sweat, feces, vomit, breast milk, and semen) of a person who is sick with or has died from EVD
- Objects (such as needles and syringes) contaminated with body fluids from a person sick with EVD or the body of a person who died from EVD

- Infected fruit bats or non-human primates (such as apes and monkeys)
- Semen from a man who recovered from EVD (through oral, vaginal, or anal sex)
- Handling and consumption of bushmeat (wild animals hunted for food)

There is no treatment for EBV and only supportive management can be adopted. Ebola survivors mostly complaint of myalgia and muscle pain even after treatment.

Dengue Fever

Dengue fever, the most important mosquito-borne viral disease with global epidemic potential, occurs mainly in tropical and subtropical areas of the world. The virus is transmitted to humans through the bites of infected female mosquitoes of the species *Aedes aegypti*.[8] It is a mild to fatal disease with no cure and only palliative care. The following factors have contributed to the emergence of dengue as the classic disease of 21st century: urbanization, increase in travel/trade, highly efficient and adaptive mosquito vector, thriving of larvae and adults in urban areas, inability to avoid day biting of *Aedes* vectors, and difficulty in effectively implementing environmental vector control.

A 30-fold increase in the dengue cases has been recorded globally during the past 50 years, and it is associated with substantial social and economic burden.[9] An average dengue episode results in a loss of 14.8 days for ambulatory patients, at an average cost of USD 514. However, the mortality rate is less than 0.5%, and it is asymptomatic in nearly 80% of the subjects.

The first evidence of occurrence in India was reported in 1956 from Vellore district in Tamil Nadu. In 1996, one of the most severe outbreaks of dengue fever occurred in Delhi, with 10,252 reported cases and 423 deaths. In 2006, the country witnessed an outbreak of dengue fever with 12,317 cases and 184 deaths. During 2014, a total of 40,571 cases were reported, which increased to 1,29,166 in 2016 and 1,88,401 in 2017.

Clinical Presentation

The clinical presentation of dengue progresses through the following three phases:

- Febrile phase (4–7 days after exposure): Headache, eye pain, nausea/vomiting, myalgias, arthralgias, and macular rash
- Critical phase (may develop following resolution of febrile phase, lasts 24–48 hours): Shock, hemorrhage, organ failure, and acute respiratory distress syndrome (ARDS)
- Recovery phase: Clinical stabilization, may develop confluent rash

Diagnosis and Management

Initial diagnosis may be established by clinical suspicion. Serum RT-PCR or viral antigen testing within first week of illness, followed by enzyme-linked immunosorbent assay (ELISA), may assist in concluding the diagnosis.

The national vector borne disease control program (NVBDCP) 2014 guideline revised the case definition and made a new classification with moderate dengue **(Flowchart 1)** and guidelines also modified clinical management of severe dengue with bolus fluid regimen. The bolus infusion of 10–20 mL/kg crystalloid infusion and frequent monitoring drastically reduced mortality in dengue patients with profound shock **(Flowchart 2)**.[10]

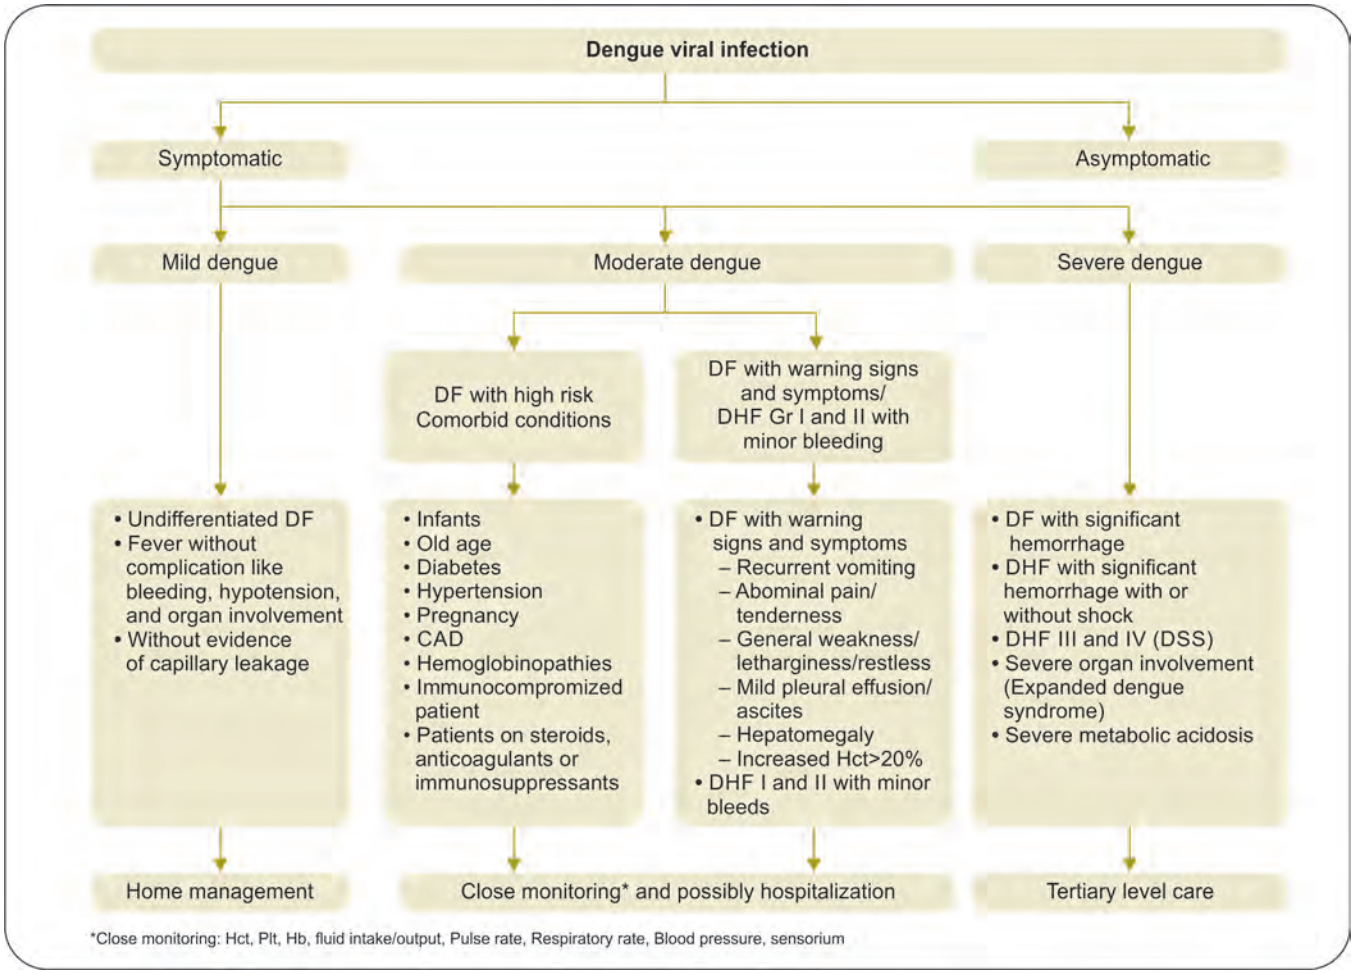
Chikungunya Fever

Chikungunya virus is a self-remitting febrile viral illness transmitted through the bite of infected mosquito *Aedes aegypti*.[11] The clinical presentation includes acute infection, high-grade fever, polyarthralgia (typically bilateral/symmetric, distal > proximal joints), and macular rash. The severe complications are meningoencephalitis, respiratory failure, renal failure, hepatitis, hemorrhagic, and heart failure/cardiomyopathy. The disease can be diagnosed by RT-PCR or serology. Testing for dengue and Zika can also be considered. Management includes supportive care and fluid therapy. Aspirin and other non-steroidal anti-inflammatory drugs should be avoided to reduce the risk of hemorrhage, until patient is afebrile for 48 hours, and there are no additional warning signs for dengue.

Zika Virus Infection

Zika virus is spread mostly through the bite of an infected *Aedes* species mosquito (*Aedes aegypti* and *Aedes albopictus*). Common symptoms of Zika infection include fever, pruritic rash, and arthralgia.[12] The severe complications of the disease are Guillain-Barré syndrome and neurologic complications including encephalitis and transverse myelitis. The recent ongoing outbreak

Flowchart 1: The NVBDCP dengue case definition[10]



in Madhya Pradesh and Rajasthan (Oct-Nov, 2018) has claimed two lives. Diagnosis and management strategies are similar to that of dengue and chikungunya.

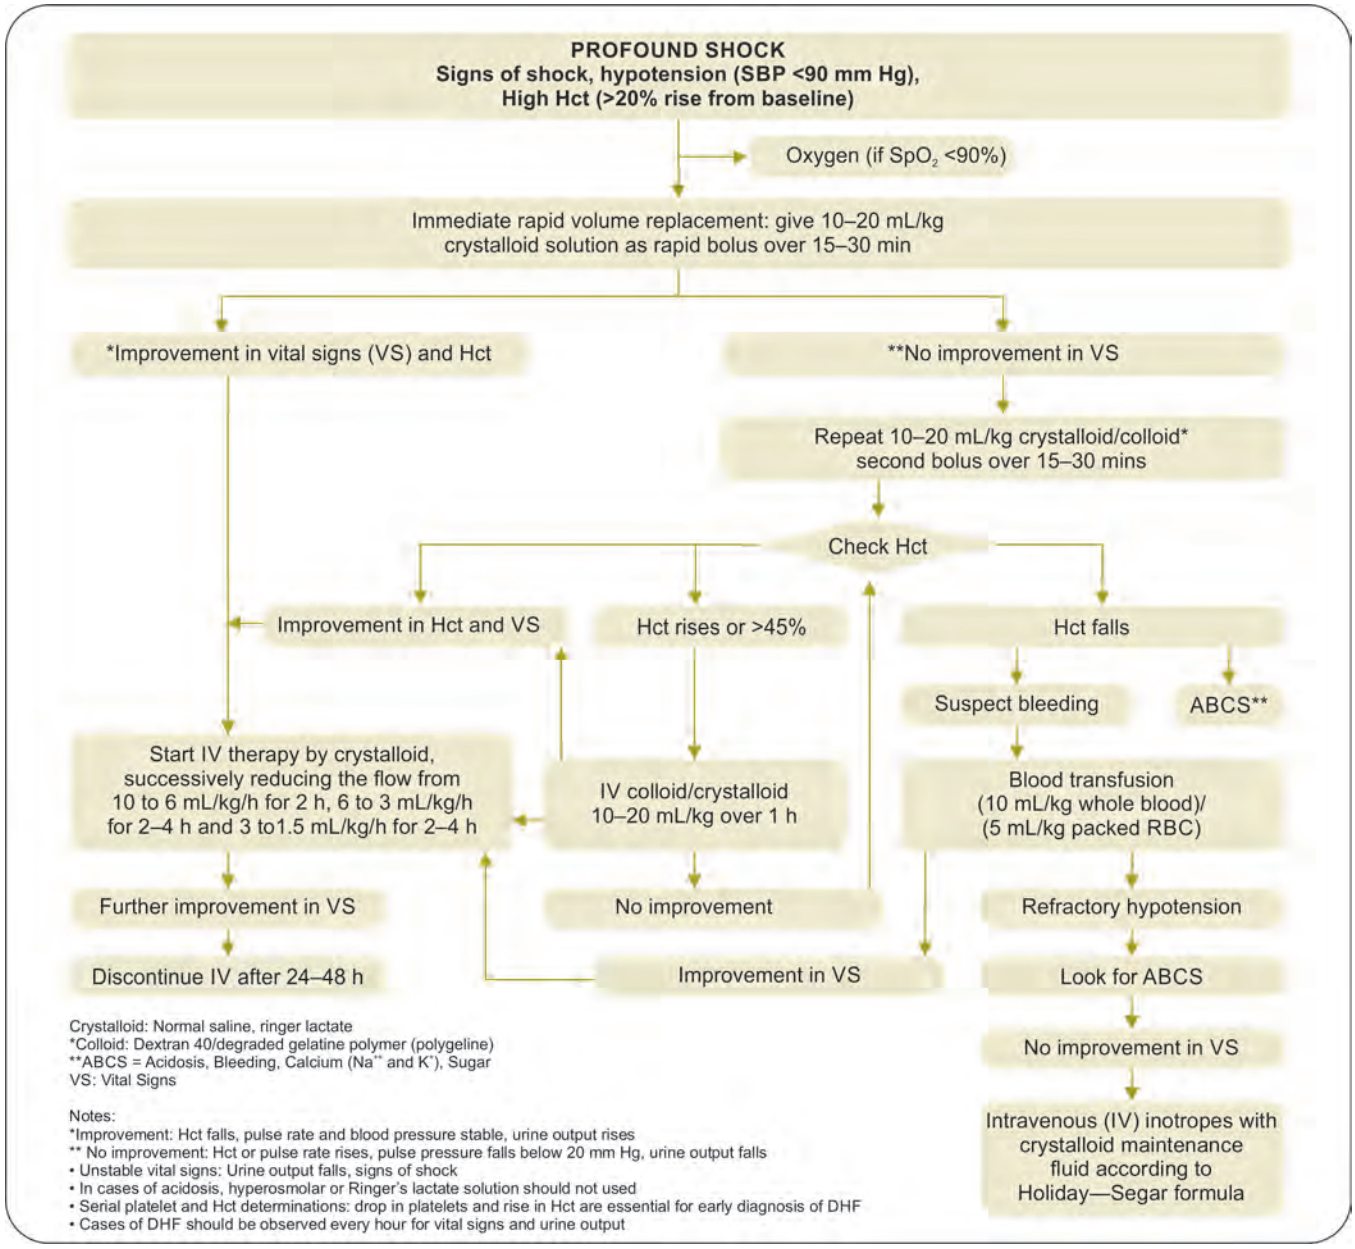
Crimean-Congo Hemorrhagic Fever

Crimean-Congo hemorrhagic fever (CCHF) is caused by a tick-borne virus (Nairovirus) belonging to the family *Bunyaviridae*. The disease is usually seen in Crimea, Africa, Europe, and Asia; and human-to-human transmission occurs through direct contact with infectious blood/body fluids. In India, the first confirmed case of CCHF was reported during a nosocomial outbreak in Ahmadabad, Gujarat, in January 2011. The outbreak claimed the death of 3 health-care workers due to multiple organ failure, specifically failure of the liver and kidney. During the period of 2012–2015, several outbreaks of CCHF infections were reported in the states of Gujarat and Rajasthan.[13]

Kyasanur Forest Disease

Kyasanur forest disease virus (KFDV) was first identified in 1957 when it was isolated from a sick monkey from the Kyasanur forest in Karnataka (formerly Mysore) state, India. Since then, around 400–500 human cases per year have been reported. KFDV is a member of the virus family *Flaviviridae*. Hard ticks (*Haemaphysalis spinigera*) are the reservoir and rodents, shrews, and monkeys are common hosts for KFDV. The disease is endemic to South Asia and the human transmission may occur after a tick bite or contact with an infected animal. No person-to-person transmission has been reported.

Flowchart 2: Volume replacement algorithm for patient with dengue with profound shock[10]



The disease begins with chills, fever, and headache. Severe muscle pain with vomiting, gastrointestinal symptoms, and bleeding problems may occur 3–4 days after initial onset of symptoms. Patients may experience abnormally low BP, low platelets and red blood cells, and leucopenia. However, after 1–2 weeks of symptoms, some patients recover without complications.

Nipah Infection

Nipah virus (NiV) infection is an emerging zoonotic disease of public health importance in the WHO Southeast Asia region. The possible routes of transmission include consumption of fruit contaminated by the saliva of infected bats, from direct contact with infected bats or their feces/urine. NiV was first recognized in 1998–1999

during an outbreak among pig farmers in Malaysia and Singapore, and it was first recognized in India and Bangladesh in 2001. In July, 2018, a total of 19 NiV cases, including 17 deaths, were reported from two districts in Kerala state (Kozhikode and Malappuram).[14]

COVID-19

The recent outbreak of COVID-19 in Wuhan city, Hubei province, China caused by severe acute respiratory syndrome Coronavirus 2 (SARS-CoV-2) mainly leads to the respiratory illness. The virus is transmitted mainly by respiratory droplets[15] and causes mild symptoms (asymptomatic/fever/cough/myalgia/sore-throat/anosmia) to severe symptoms (ARDS, shock, respiratory failure, multi-organ dysfunction) and deaths. The COVID-19 can cause some cutaneous manifestations which can be grouped into five major clinical patterns:

- Acral areas of erythema and edema with vesicles or pustules (pseudo-chilblain),
- Vesicular eruptions,
- Urticarial lesions,
- Maculopapular lesions,
- Livedoid or Necrotic lesions.

This is significant as it tells about the severity with pseudo-chilblains in mild disease to livedo-necrosis in severe disease.[16] The current epidemiological update by WHO for COVID-19 (30th October, 2020) showed 4,48,88,869 confirmed cases and 11,78,475 confirmed deaths. The diagnostic laboratory studies are rtPCR, rapid antigen testing, Antibody Testing (IgG,IgM), viral culture, computed tomography, chest X-ray. Laboaratory tests of serum LDH, CRP, Serum Ferritin, D-Dimer, and CBC may be helpful in severe diseases with cytokine storm. The various antiviral therapies are only approved as emergency use authorization with no survival benefit. Steroid and oxygen therapy have been found to be effective in reducing mortality in hypoxic patients with moderate to severe COVID-19 (SpO_2 <95%). The general measures for infection control: handwashing, wearing masks, social distancing, and isolation of infected individuals have been found to be effective in controlling the infection in hospital and society.

Differentiating COVID-19 from other tropical disease (dengue/chikungunya) is a challenge for clinician. Similarly, coinfection of COVID-19 with other VHF dengue fever etc. is another big problem in endemic regions of vector borne diseases **(Table 2)**.[18]

Management of VHF

VHFs are a group of distinct RNA viral diseases and it needs individualized care. The EVD has the highest mortality rate, while COVID-19 disease has affected maximum number of countries and population. The blood, urine, vomitus, pus, stool, semen, and saliva from the VHF patient are infectious. Barrier nursing practices (such as wearing protective clothing) help in reducing the risk of transmission to health-care workers.

No specific treatment, except supportive care, is available in most of VHFs. Correction of coagulopathies is needed. Antiplatelet drugs and IM injections are contraindicated due to the risk of hemorrhage. Investigational treatment approaches include ribavirin for 10 days for *arenaviridae* and *bunyaviridae*, and convalescent plasma within 8 days of onset for alkhurma hemorrhagic fever. Upon percutaneous/mucocutaneous exposure to infected blood or body fluids, wash thoroughly with soap and water, and irrigate mucous membranes with water or saline. Medical surveillance for all potentially exposed persons is needed for up to 21 days in ebola infection. The surveillance measures include: reporting hemorrhagic symptoms, recording fever 2×/day, reporting temperatures ≥101°F (38.3°C), and initiating presumptive therapy.

Viral hemorrhagic infection can be prevented using N-95 mask or powered air purifying respirator (PAPR). Keeping the patient in negative pressure room and using personal protective equipment (PPE) while handling the patient are essential. The health-care workers should be trained on the use of PPE.

Assessment for VHF Risk

The following CALM (Consider, Act, Laboratory, Monitor) algorithm is used to assess the risk of VHF infection in travelers:

- *Consider:* Travelers return from a region endemic for and/or currently experiencing VHF outbreaks are considered infected.
- *Act:* Isolate the patient. Limit the health-care workers who enter the room. Appropriate PPE should be

TABLE 2 Differentiating clinical features between COVID-19 and other similar viral diseases[17]

	COVID-19	*Dengue*	*Chikungunya*	*Seasonal influenza*
Incubation period and onset	Ranges 2–14 days (onset of symptom average 5–7 days). Acute onset of low-to-moderate grade continuous fever	Ranges 3–14 days (onset of symptom average 4–7 days). Acute onset of high-grade continuous fever	Ranges 1–12 days (onset of symptom average 3–7 days). Acute onset of moderate-to-high grade continuous fever	Ranges 1–4 days (onset of symptom average 2 days). Acute onset of moderate-to-high grade continuous fever
Clinical presentation symptoms	Cough, dyspnea, fever, myalgia, headache, sore throat, diarrhea, abdominal pain, anosmia, ageusia, fatigue, confusion	Fever, headache, Nausea, vomiting, retro-orbital pain, myalgia, arthralgia, rash, bleeding	Fever rash malaise arthralgia myalgia red eyes	Fever, cough, sore throat, and nasal discharge, headache, myalgia and malaise
Signs	Tachypnea, decreased oxygen saturation, multi-organ involvement	Signs of hypotension and shock, hemorrhagic manifestations (petechiae), positive tourniquet test	Swelling and tenderness of joints	Pharyngeal wall hyperemia, cervical lymphadenopathy
Warning signs	Respiratory distress SpO_2 <94%	Persistent vomiting, abdominal tenderness, fluid accumulation, mucosal bleed	High grade fever, progressive increase of myalgia and arthralgia	Respiratory distress SpO_2 <94%
Complications	ARDS arrhythmias acute cardiac injury shock pulmonary embolism shock acute stroke	Hypotensive shock, bleeding, organ involvement, metabolic derangement	Respiratory failure, cardiovascular decompensation, myocarditis, acute hepatitis, renal failure, hemorrhage, meningoencephalitis acute flaccid paralysis GBS	ARDS myositis rhabdomyolis acute MI myocarditis pericarditis encephalitis myelitis GBS

worn by all personnel entering the patient's room. Immediately notify your state/local health department.

- *Laboratory:* Inform the laboratory. Decision to test for VHF should be made in consultation with relevant health department/CDC viral special pathogens branch.
- *Monitor contacts:* Facilities should maintain a log of all the persons entering the patient's room, including full name and contact information.

Conclusion

VHF is a diverse group of illnesses caused by RNA viruses belonging to various viral families. Though, the diseases differ by geographic occurrence and vectors/reservoirs, they share some common clinical features. The diseases are considered as having international health risk due to their potential for aerosol dissemination and human-to-human transmission. Management is only through supportive treatment. Infection control in health-care workers and relatives is of utmost importance. Surveillance of returning travelers by CALM algorithm is important to prevent any outbreak in other geographic area.

CHAPTER

160 Antimicrobial Stewardship in Clinical Practice—Role of Biomarkers

Anupam Dey

Abstract

Antimicrobial stewardship focusses on interventions to improve and measure the appropriate use of antimicrobial agents. To fight antimicrobial resistance, timely diagnosis of infections, justifiable use of drugs, and avoidance of antimicrobial overprescribing and overuse are of paramount importance. Novel biomarkers aid in this process and are thereby gaining prominence. Biomarkers may be included into clinical guidelines to make their roles clear. This chapter discusses various biomarkers specific to bacterial, viral, and fungal infections which can be used for point of care testing. Biomarker based clinical algorithms prepared using regional data will help in clinical decision-making, thereby aiding rational prescription of antimicrobials.

Introduction

Antimicrobial stewardship is defined as "coordinated interventions designed to improve and measure the appropriate use of antimicrobial agents by promoting the selection of the optimal antimicrobial drug regimen including dosing, duration of therapy, and route of administration."[1]

In the background of increased incidence of antimicrobial resistance throughout the world, antimicrobial stewardship programs are focusing on timely diagnosis of infections and the justifiable use of drugs. Frequently, ignorance of the etiology of infection leads to antimicrobial overprescribing and overuse. This diagnostic dilemma may also result in late initiation of antimicrobial therapy and poor outcomes. Recently new biomarkers have been used to help making a clinical diagnosis. Novel biomarkers are an important addition in the repertoire of antimicrobial stewardship program, to aid in timely diagnosis and appropriate antimicrobial use.

In one estimate from the USA it was observed that close to 50% of antibiotic prescriptions in the outpatient scenario were avoidable,[2] thus leading to unnecessary expenditure, antibiotic resistance, adverse drug reactions, and secondary infections with Clostridium difficile. Rapid biomarker testing is need of the hour. However, till now the rules for integrating biomarkers in antibiotic prescription decisions are not well known. Defined reference values for bacterial infections are often absent, thus affecting the sensitivity and specificity of biomarkers.[3] Use of biomarkers may be included into clinical guidelines to make their roles clear. This will be particularly helpful in the primary care setting where patient turnover is quite high and antibiotic prescription is widespread.[4,5]

Biomarkers

The following biomarkers will be discussed further and their use particularly for suspected pneumonia or sepsis will be defined:

- Bacterial—C-reactive protein (CRP), procalcitonin (PCT)
- Fungal—1,3-beta-D-glucan (BDG), *Candida albicans* germ tube antibody (CAGTA), and Galactomannan (GM)

- Viral markers—Myxovirus resistance protein A (MxA)
- Others—Adrenomedullin (ADM), Triggering receptor on myeloid cells 1 (TREM 1), Urinary clusterin, etc.

Bacterial Infection Biomarkers

C-reactive Protein

An acute phase reactant that indicates inflammation due to multiple causes. Use of CRP in differentiating between bacterial and viral etiology has been studied widely. It has been proven that CRP is very sensitive in identifying infections of bacterial etiology and thus helps in taking decision on instituting antibiotics.[6]

In a study of patients in Vietnam suffering from acute respiratory tract infections it was found that using CRP threshold of 20 mg/L in adults, there was reduction of antibiotic prescription from 78% to 64%. Similarly, in primary care setting, rapid CRP testing with a threshold of 40 mg/L resulted in a significant reduction in antibiotic prescription.[7,8]

Procalcitonin

PCT is an amino acid prohormone of calcitonin. On exposure of body to bacterial toxins, serum PCT becomes detectable in blood. Interferon-gamma released in viral infection downregulates its release. Other inflammatory states usually do not affect the serum concentrations of PCT. False positive increase of levels have been seen in burns, post-surgery, trauma, and renal dysfunction. False negative results may occur in too early testing or in loculated infections.[9]

Role in Respiratory Tract Infections

PCT has been used as a tool to help in diagnosis of bacterial pneumonia when there is clinical dilemma or negative culture results. Serial PCT concentrations have helped in deciding escalation/de-escalation/discontinuation of antimicrobial therapy. Various guidelines (Surviving Sepsis guidelines and IDSA) recommend repeating PCT levels serially to decide duration of antibiotic therapy in critically ill patients.[10] Standard reference value of PCT in adults is usually 0.15 ng/mL or less. PCT rises within 2–6 hours and peaks at 12–24 hours.[2,11]

Role in Sepsis

Meta-analyses have established PCT as superior to CRP for the diagnosis of sepsis. Levels of 1–2 µg/L are considered for diagnosis of sepsis.[12] Serial PCT measurements should be taken in sepsis and levels of less than or equal to 0.5 µg/L should signal the need for discontinuation of antibiotics.

From available literature, use of PCT for antibiotic stewardship in respiratory infections (specially LRTI) has been found to reduce initial prescription of antibiotics by 40–50% in emergency patients and by 70–80% in ambulatory patients. It has also reduced antibiotic prescription in pneumonia (CAP) by 40–50%.[13-15]

Fungal Infection Biomarkers

Detection of invasive candidiasis is challenging. High cost of new antifungals adds to the problem. Traditional culture methods are unable to detect close to 50% of cases. Thus, fungal infection biomarkers may improve patient outcomes.[16]

1,3-beta-D-glucan

BDG is a component of the cell wall of most fungi including Candida species. Elevated levels in blood can act as a biomarker to diagnose candidemia or invasive fungal infection and thus rationalize antifungal administration. False-positive results can be found with intravenous immunoglobulin, intravenous albumin, certain hemodialysis filters, and with some antibiotics. Serial BDG assays have a greater negative predictive value thereby guiding discontinuation of empirical antifungal therapy.

Candida Albicans Germ Tube Antibody

Candida albicans germ tube antibody can be released during invasive candidal infection. Its sensitivity and specificity to detect invasive candidiasis has been reported as more than 75% and more than 90%, respectively.[17] Although study results are variable, CAGTA with or without BDG can aid in diagnosis of invasive candidiasis. However, the utility of CAGTA on course of illness is debatable.[18]

Galactomannan

Blood assay for GM has improved detection of invasive aspergillus infection at an early stage, particularly among the immunocompromised. Sensitivity and specificity of this marker are more than 70% with cut-off value of 0.5.[19] The IDSA guidelines recommend use of GM for prompt diagnosis of invasive aspergillus infection especially in

patients with hematological malignancy or post-stem cell transplant state.[20]

Viral Infection Biomarkers

Viral (Myxovirus Resistance Protein A)

Myxovirus resistance protein A is induced by interferons and is specifically elevated in patients with viral infections. It has the potential to allow rapid differentiation between viral and bacterial respiratory infections. In combination with CRP or PCT, elevated levels of MxA can help identify patients with likely viral infection, thus helping antibiotic stewardship activities.[21]

Other Biomarkers

Adrenomedullin

ADM is a peptide hormone. Its half life is very less; hence pro ADM (cut-off values 3.5–5.5 nmol/L) is often measured clinically. ADM has been used clinically as a mortality predictor and prognostic marker in inflammation and particularly in Community acquired Pneumonia.[22] Increased ADM concentrations will indicate increased severity and mortality in SIRS and septic shock. Pro-ADM may be better in this regard.

Triggering Receptor Expressed on Myeloid Cells 1

TREM 1 is an immunoglobulin expressed on the surface of macrophages, neutrophils, and monocytes. Phagocytes release soluble TREM 1 (sTREM 1) on stimulation, which acts as a marker of infection specifically for pneumonia and sepsis.[23] Measurement thresholds are 725 pg/mL to diagnose sepsis (sensitivity up to 70% and specificity up to 60%),[23] and 5 pg/mL in the diagnosis of pneumonia (sensitivity of 98% and specificity of 90%).[24]

Urinary Clusterin

Its use has been studied as a biomarker of nephropathia epidemica (a type of hemorrhagic fever with renal syndrome) caused by Puumala virus infection.[25]

Methicillin-resistant *Staphylococcus Aureus* (MRSA) Nasal Screens

It can be used in de-escalation of MRSA therapy, mainly in patients with suspected or confirmed pneumonia. The ATS/IDSA guidelines endorse the routine use of MRSA nasal PCR screening for the de-escalation of MRSA coverage. This has been shown to allow a median decrease of 2.1 days of vancomycin therapy.[26]

Other Potential Bacterial Biomarkers in Development

These are Amyloid A, Liposaccharide binding protein, Interleukin-10, and nCD64.[27]

Conclusion

Point-of-care biomarker testing allows rational antimicrobial use. Stewardship programs should analyze regional data of local population for using biomarkers in clinical decision-making. More regional studies are required for preparing biomarker based clinical algorithms.

CHAPTER

161 Misutilizing Medicine for Biological Warfare

Jayanta Kumar Panda, Biswojit Behera

Abstract

Biological Warfare is the intentional use of biological agents to cause morbidity and mortality in humans. The Bioweapons, those used in wars and by terrorist groups are attractive because of their ability to produce wide range of diseases, low production costs, no easy accessibility by routine security systems, and their easy transport from one place to another. In addition, after development of novel technologies that are primarily designed for use in early diagnosis and treatment and decreases the burden of diseases and its consequences on humans health, but this development of medicinal novel technology has often been used in wrong direction to produce more Bioweapons which ultimately threaten the well-being of the whole mankind.

Introduction

From ancient ages to modern era, history reveals there were multiple number of biological wars among persons, among states, and among nations to empower over others. There was an intention behind use of biological agents like microorganisms, and toxins, generally of microbial, plant, or animal origin to produce not only disease and/or death in humans and damaging live stocks and crops but also to create fear, panic, and paralyze uncertainty.

To protect this there were developments of biodefense in the form of biological weapons convention from time to time, but still there is continuous research on development of bio-weapons by the nations. Now for protection against biological warfare each nation continued research along counter measures, including vaccines and antisera.

Definitions

Bioterrorism: It is an action by a non-state actor to achieve a political, ideological, or religious goal. (Desire to terrorize as much or more than causing casualties.)[1,5]

Biocrime: Biological agent used by a person/group against a person/small group often for revenge or extortion.[1]

Biological warfare: A state actor uses a biological agent as part of its armamentarium in waging war.[1,5]

Biological agents: Biological agents (bio-weapons) are living organisms or replicating entities (viruses) that reproduce or replicate within their host to cause harm.[2,3]

CDC category[4] of biological agents:

- *Category A:* These are high priority agents that easily disseminated or transmitted from person to person with high mortality rates. With a potential for major public health impact, might cause public panic and social disruption.
- *Category B:* Second highest priority. These are moderately easy to disseminate. They have moderate morbidity rates and low mortality rates. These agents require specifically enhanced diagnostic capacity.
- *Category C:* Emerging pathogens that could be engineered for mass dissemination in the future because of availability, ease of production, and

TABLE 1 CDC categories of biological agent

Category A	*Category B*	*Category C*
Anthrax (*Bacillus anthracis*)	Psittacosis (*Ch. psittaci*)	(Emerging infections)
Botulism (*Cl. botulinum* toxin)	Epsilon toxin of *Cl. perfringens*	Hantavirus
Plague (*Yersinia pestis*)	*Melioidosis* (*B. pseudomallei*)	SARS coronavirus
Smallpox (*Variola major*)	Glanders (*Burkholderia mallei*)	Pandemic influenza
Tularemia (*Francisella tularensis*)	Food safety threats (e.g., *Salmonella* spp., *E. coli* O157; H7, *Shigella*)	Nipah
Viral hemorrhagic fevers: Lassa, New World (Machupo, Junin, Guanarito, Sabia), Crimean Congo, Rift Valley, Ebola, Marburg	Viral encephalitis [alphaviruses (e.g., Venezuelan, eastern, and western equine encephalitis)]	
	Brucellosis (*Brucella* spp.)	
	Q fever (*Coxiella burnetii*)	
	Ricin toxin from Ricinus communis (castor beans)	
	Staphylococcal enterotoxin B	
	Water safety threats (e.g., *V. cholerae, Cr. parvum*)	

dissemination and potential for high morbidity and mortality rates and major health impact.
The category and agents are shown in **Table 1**.

Anthrax (*Bacillus anthracis*)[6]

- The most misused agent in biological warfare
- Rout of transmission: By cutaneous and inhalation
- Signs and symptoms:
  - Prodermal—fever, headache, tiredness
  - Cutaneous (95%)—pustules, eschar **(Figs. 1A to C)**
  - Pulmonary (5%)—cough, chest pain, dyspnea

Diagnosis:
- Skin biopsy for cutaneous lesions
- Blood culture
- ELISA, PCR
- Chest X-ray- widened mediastinum (Hilar and mediastinal lymphadenopathy) with or without infiltrate and pleural effusion **(Figs. 2A and B)**

Treatment:
- Ciprofloxacin, Penicillin, Doxycycline
- Treated for 60 days

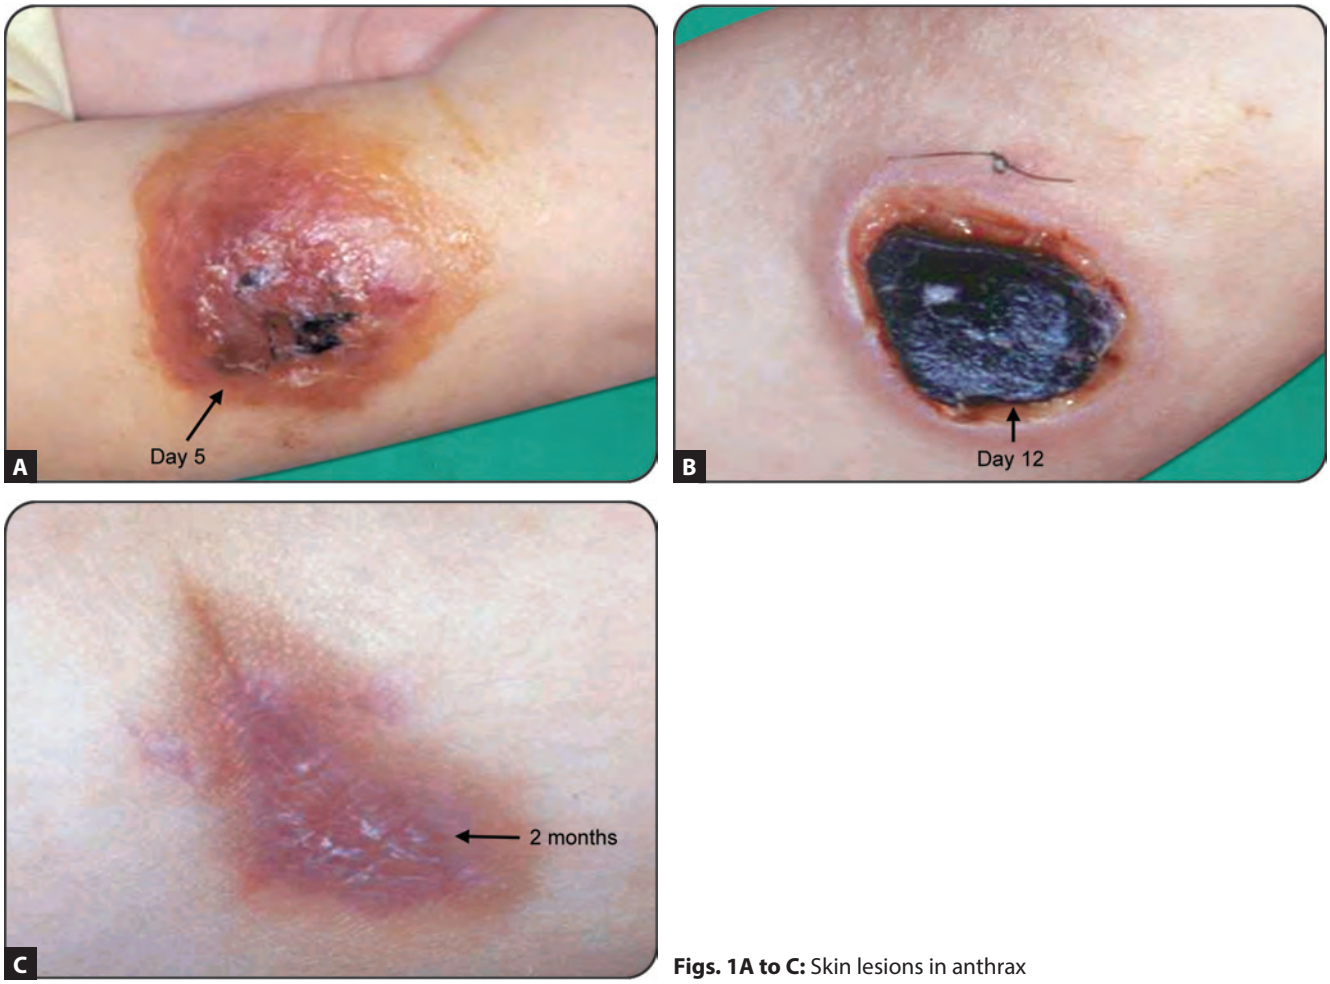
Prevention:
- Vaccination—6 doses over 18 months, booster annually
- Chemoprophylaxis—Cipro/Doxy 4 weeks before exposure
- Infectious form: Spores-Hardy, resistant to environmental conditions
- Relatively easy to weaponize

Example:
- September 2001, Anthrax used as bio-weapon through US Postal system
- 22 cases (18 confirmed)—11 inhalational + 11 cutaneous.
- 5 deaths (all among inhalational)
- Ames strain used (beta lactamase + cephalosporinase), but luckily susceptible to antibiotics
- Maximum amount of spore in a letter—2 g (100 billion to 1 trillion spores) (LD 50 = 10,000)

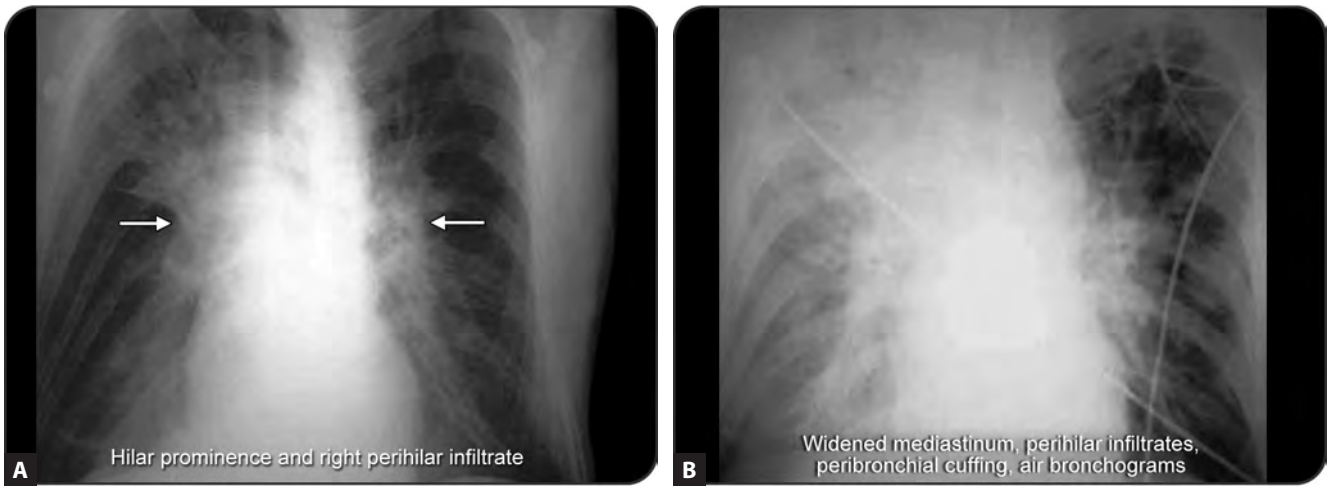
Plague (*Yersinia pestis*)[7]

Highly contagious. Pneumonic plague is most severe.

Signs and symptoms:
- *Pneumonic plague:* Due to inhalational exposure. Cough with blood tinged sputum.
- *Bubonic plague:* Due to infection through skin causes ulcers **(Fig. 3)**, Fever, Chills, Nausea, Vomiting, Buboes **(Fig. 3)** (1–8 days).
- *Septicemic plague:* Usually from bubonic plague fever, chills, nausea, vomiting, bleeding in skin, ischemia in limbs.



Figs. 1A to C: Skin lesions in anthrax



Figs. 2A and B: X-ray findings in anthrax

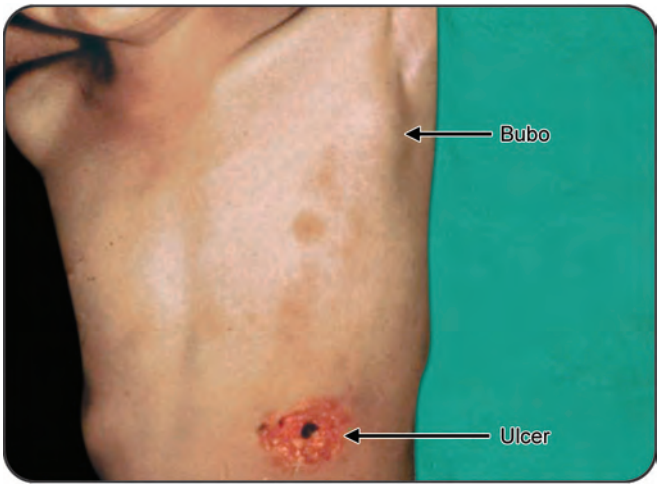


Fig. 3: Skin lesions in plague

Fig. 4: Eruptions in small pox

Diagnosis:
- Clinical features: Microscopic examination of bubo fluid/sputum
- Cultures and PCR/DFA

Treatment:
- Gentamicin, Streptomycin, Doxycycline

Prevention:
- Formalin fixed vaccine, Flea control measures

Spread:
- Through bite of infected fleas
- Through droplet spread from pneumonic plague patients
- Through direct contact with non-intact skin

Weapon potential:
- Labile in environment (1 hour)
- Highly contagious, person to person spread
- Can be weaponized as aerosols (10 km)

Smallpox (*Variola*)

By 1980, close to whole world population was immune and not important as bio-weapon then. Now susceptible population (50%).

High infectivity, can spread at a factor of 10–20
Between 10–30% mortality in untreated

Signs and symptoms:
- Incubation period: Between 7–17 days (12–14)
- Fever, malaise, headache, backache, emesis, maculopapular to vesicular to pustular skin lesions. Centrifugal, same stage of development, hemorrhagic and malignant forms (5–10%) **(Fig. 4)**

Diagnosis:
- Culture, PCR, Electron Microscopy

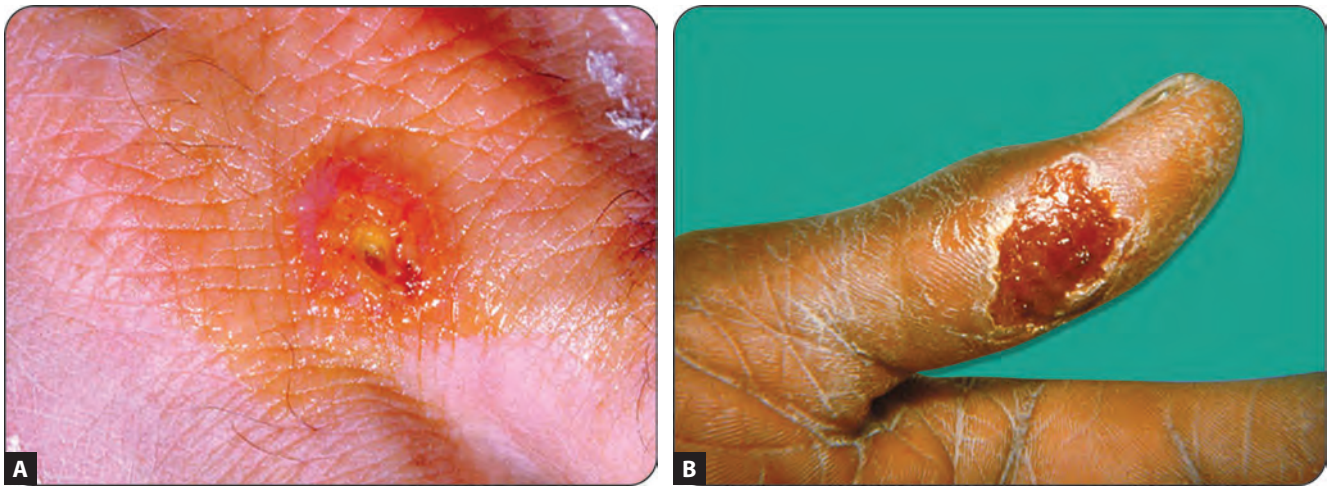
Treatment:
- Supportive treatment—Cidofovir, Anti-vaccinia immunoglobulin

Prevention:
- Vaccinia immunization
- Weaponization—Infected fomites (historical use), Aerosol sprays

Tularemia (*Francisella tularensis*)[9]

- Extremely infectious (10–50 by inhalation)
- Infection through non intact skin, mucous membrane, GI tract, Respiratory tract
- Vactors: Rabbits, ticks, water rats, deer.

Signs and symptoms:
- Incubation periods 1–14 days
- Ulceroglandular (75%) **(Figs. 5 and 6)** and Typhoidal (25%)
- Fever, chills, malaise, myalgia, headache, chest discomfort, dyspnea, skin rash, pharyngitis, conjunctivitis Hilar adenopathy on chest X-ray



Figs. 5A and B: Skin lesions in tularemia

Fig. 6: Glandular lesion in tularemia

Diagnosis:
- Gram stain, culture (blood, ulcer discharge, sputum), immunohistochemistry, PCR

Treatment:
- Streptomycin, Gentamicin, Doxycycline, Ciprofloxacin

Prevention:
- Chemoprophylaxis: Doxycycline, 100 mg PO bid × 14 days or Ciprofloxacin, 500 mg PO bid × 14 days
- Weaponization—Aerosol sprays

Hemorrhagic Fever Viruses

- *Arenaviridae:* Lassa, New World (Machupo, Junin, Guanarito, and Sabia)
- *Bunyaviridae:* Crimean Congo, Rift Valley
- *Filoviridae:* Ebola, Marburg

Transmission:
- Person-to-person transmission through direct contact with body fluids (Lassa, Ebola, Marburg)
- Aerosol sprays infectious (animal studies)
- Up to 90% mortality

Signs and symptoms:
- Fever, myalgia, prostration, and DIC with thrombocytopenia and capillary hemorrhage
- Maculopapular or erythematous rashes
- Leukopenia, temperature-pulse dissociation, renal failure, and seizures

Diagnosis should be suspected in anyone with temperature >38.3°C for <3 weeks who also exhibits at least two of the following: hemorrhagic or purpuric rash, epistaxis, hematemesis, hemoptysis, or hematochezia in the absence of any other identifiable cause.

Diagnosis:
- RT-PCR, Antigen isolation

Treatment:
- Supportive therapy: Ribavirin, IFα, Hyperimmune Ig

Prevention:
- No known chemoprophylaxis, no vaccines
- Strict isolation and PPE (N95 mask or PAPR)

Botulinum Toxin (*Clostridium botulinum*)[8]

- One of the most potent toxins. Produced by *Clostridium botulinum*

- Toxin is labile in atmosphere (1% per min), Organism is easily destroyed (chlorine, heat)
- Botulism can occur: infection in a wound or the intestine, the ingestion of contaminated food, or the inhalation of aerosolized toxin

Signs and symptoms:
- Incubation period: 12–72 hours
- Dry mouth, blurred vision, ptosis, weakness, dysarthria, dysphagia, dizziness, respiratory failure, progressive paralysis, dilated pupils

Diagnosis:
- Mouse bioassay and toxin immunoassay

Treatment:
- Supportive—Intubation, mechanical ventilation, TPN
- Equine antitoxin (only against A & B)

Prevention:
- Botulinum toxoid is available for high-risk workers, lab workers, military personnel.

Examples of use: Botulinum toxin was the primary focus of the pre-1991 Iraqi bio-weapons program. (19000 l conc. toxin.), Aum Shrinrikyo cult unsuccessfully attempted on a least three occasions to disperse botulism toxin into the civilian population of Tokyo.

1990—Outfitted a car to disperse botulinum toxin through an exhaust system and drove the car around Parliament.

1993—Attempted to disrupt the wedding of Prince Naruhito by spreading botulinum in Tokyo via car.

1995—Planted three briefcases designed to release botulinum in a Tokyo subway.

Cholera (Vibrio Cholera)

- Causes acute, potentially severe gastroenteritis
- Spread through contaminated drinking water

Signs and symptoms:
- Begins in 12–72 hours
- Watery rice water diarrhea, abdominal pain, cramps, dehydration, electrolyte imbalance, seizures and cardiovascular collapse in children

Diagnosis:
- Stool microscopy—dark field

Treatment:
- Fluid and electrolyte replacement
- Antibiotics—Doxycycline, Ciprofloxacin, Erythromycin

Prevention:
- Live vaccine—50% efficacy, 2 doses + booster
- Inactivated vaccine—rapid protection, 2 doses, 85% efficacy, 2–3 years

Spread:
- By contamination of drinking water supply. Easily destroyed by heat, boiling, chemical disinfectants.

Corona Viruses

They are mostly contagious in nature mainly causing three dangerous diseases: SARS, MERS, COVID-19.

Severe Acute Respiratory Syndrome (SARS)

Caused by SARS-CoV corona virus.

In November 2002, it started from Guangdong province of Southern China, eventually reaching Hong Kong. From there it rapidly spread, causing infections in more than 24 countries.

Spreads—by aerosols

Signs and symptoms:
- Begins over 7 days
- Dry cough, chills, diarrhea, breathlessness, body ache, pneumonia
- Mortality rate of 9.6%

Diagnosis:
- RTPCR, cell culture

Treatment:
- Supportive—Corticosteroids, oxygenation, ribavirin, lopinavir and ritonavir, ET tube intubation
- Prevention—Hand washing, PPE wearing, using face mask (N95, 3-layered surgical)

Middle East Respiratory Syndrome (MERS)[10]

Caused by MERS-CoV corona virus

First recognized by scientist in Saudi Arabia after severe respiratory illness. Since then it has spread to other countries

Spread by—Aerosols

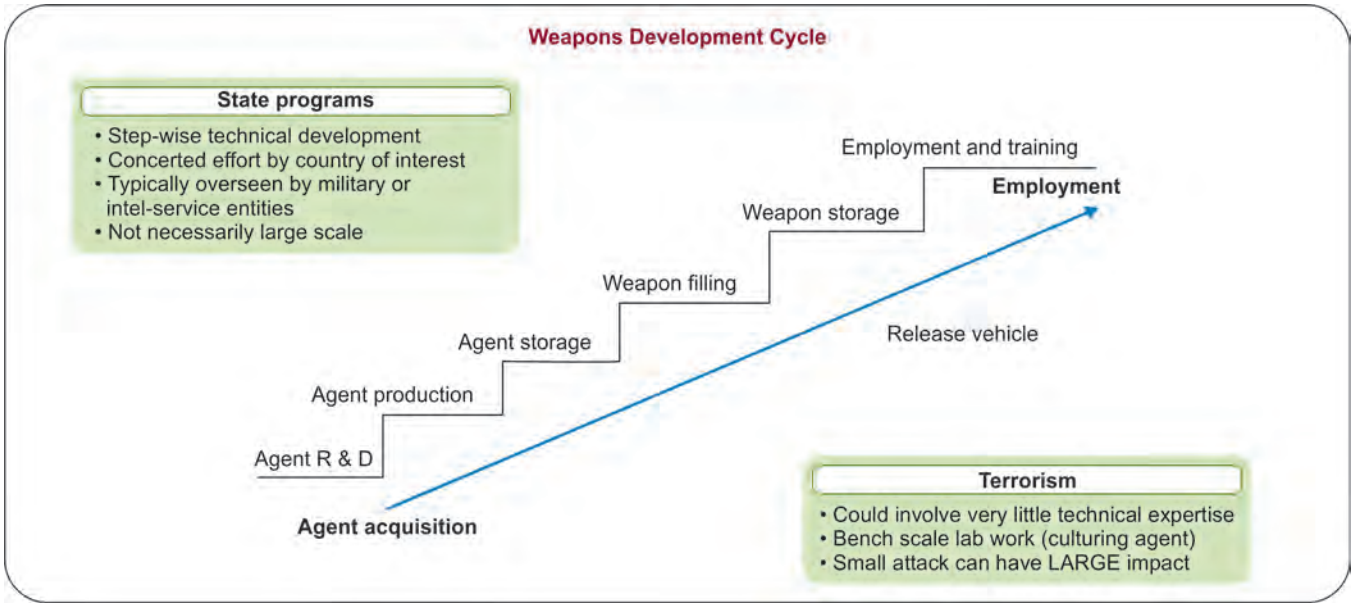


Fig. 7: Weapons development cycle

Signs and symptoms:
- Fever, cough, breathlessness
- Mortality rate—35.2%

Diagnosis:
- RTPCR

Treatment:
- Supportive—ET tube intubation, NSAIDs, oxygenation

Prevention:
- Hand washing, PPE wearing, using face mask (N95, 3-layered surgical)
- No vaccine available

COVID-19[10]

In December 2019, CDC started monitoring the outbreak of a new corona virus named SARS-CoV-2, which started from Wuhan city of China and then spread to nearly every country leading the WHO to declare a pandemic.

Spreads by—Aerosols

Signs and symptoms:
- Fever, cough, breathlessness, loose motion, loss of taste and smell, body ache, chest pain
- Mortality rate—Varies among countries
- 6% in the US
- 3% in India

Diagnosis:
- Rapid antigen test, RTPCR

Treatment:
- Supportive—Azithromycin, doxycycline, ivermectin, HCQs, favipiravir, remdesivir, corticosteroids, LMWH, ET tube intubation

Prevention:
- Hand washing, PPE wearing, using face mask (N95, 3-layered surgical)
- Weaponization—It is the process of converting the biological agent into a usable weapon.
- Delivery device—Bombs, Missiles, Spray systems – Aerial, Aerosol based.
- Non-traditional—Food, water supplies, animals, insects.

Treaties and Conventions

Geneva protocol,[5,13] *1925:* Geneva Protocol for the prohibition of the Use in War of Asphyxiating, Poisonous or Other Gases and of Bacteriological Methods of Warfare was adopted by international community on 17th June, 1925. It banned the use but didn't proscribe the research, production, or possession. It was appeal by international Red Cross and Poland. It was customary international law. A no first use agreement only.

Biological weapons convention[5,13] *1972:* Eighteen-Nation Disarmament Committee in 1969. Convention on the prohibition of the development, production, and stockpiling of bacteriological and toxin weapons and on their destruction was signed on 10th April 1972. Entered into force in 1975. First treaty to ban an entire class of weapons doesn't address non-state actors, e.g., terrorists. No protocol to monitor compliance **(Fig. 7)**.

Prevention Against Biological Warfare

It is necessary to be aware of common epidemiological clue for detecting early of a biological attack.

- At particular time there is a single cause of certain disease of unknown cause in a large area which may not have epidemiological explanation.
- Genetically engineered agent.
- High morbidity and mortality rates with the same or similar symptoms.
- In a particular geographical or seasonal distribution.
- Transmission through aerosols, food, water.
- Rare illness affecting large population or certain age group; with unusual trends of mortality and morbidity.
- Clustering of cases for treatment.

Primary Prevention

By creating a strong global norm that rejects development of such biological weapons.

Secondary Prevention

Early detection and prompt treatment of disease. There is important role of medical community by participating in disease surveillance and reporting, and thus providing the first indication of biological weapons use. In addition, continued research to improved diagnostic capabilities, therapeutic agents, and effective response plans[14,15] will further strengthen secondary prevention measures.

Tertiary Prevention

Prevention of disability from disease.

Biological warfare with India:[11,12]

- Nodal agencies—DRDO (MoD), NDMA, MoHA, MoHFW
- Indian Biodefence Program—started in 1973

Conclusion

Time and again Medicine has been misutilized for biological warfare to satisfy human ego and the desire to harm the mass by the knowledge and the commodities of healing. We misutilize our discoveries to injure and kill innocent people in the name of war instead of fighting against the microbe to prevent the diseases and save the suffering mass. The recent pandemic of COVID-19 has originated at Wuhan state of China from a virology lab with similar attempts and the whole world has suffered for a year and we don't know what is there in future. At least now the pandemic should open the vision of our world leaders to resolve to stop such heinous suicidal act for the benefit of everyone.

CHAPTER

162 Antimicrobial Resistance: Is It Worrisome?

Ritu Karoli

Abstract

Antimicrobial resistance (AMR) is said to occur when microbes are protected from effects of antimicrobial agents by evolving genetic or acquired mechanisms. Rising AMR is a global threat to public health across the globe. There are various causes of AMR in community, health-care system, and agriculture industry. The need of the hour is to identify and remove these causes, prevent the misuse of antimicrobial agents by antibiotic stewardship, and apply the knowledge of novel research and technology to address this growing menace.

"There is probably no chemotherapeutic drug to which in suitable circumstances the bacteria cannot react by in some way acquiring 'fastness' [resistance]."

–Alexander Fleming, 1946

Introduction

The discovery of antibiotics was an important landmark in the history of medicine that revolutionized treatment and saved countless lives. Antibiotics are one of the most commonly prescribed drugs in clinical practice. Unfortunately, resistant strains of microbes have religiously followed the path of these "magic bullets" antimicrobial resistance (AMR) is the ability of microorganisms such as bacteria, fungi, or protozoans to grow despite exposure to antimicrobial substances designed to inhibit their growth. Reduction in or loss of an agent's antibacterial effect is referred to as resistance, and the properties of or alterations in the bacterium that result in reduced antimicrobial activity are termed resistance mechanisms. AMR is one of the biggest public health problems of recent decades that poses significant challenge to prevention and treatment of various infections. It is a complex issue that affects different sectors of society and is multifactorial in origin. Coordinated action is required to minimize the emergence and spread of AMR.

Antimicrobials have made the management of infectious diseases easier thereby decreasing morbidity and mortality. If current trends continue, it is projected that, by 2050, AMR could result in over 10 million deaths per year and over 100 trillion USD in lost output globally.[1] World Health Organization (WHO) is coordinating a global campaign to raise awareness of antibiotic resistance and encourage best practices among the public, policymakers, health and agriculture professionals, to avoid further emergence and spread of antibiotic resistance.[2]

What is Superbug?

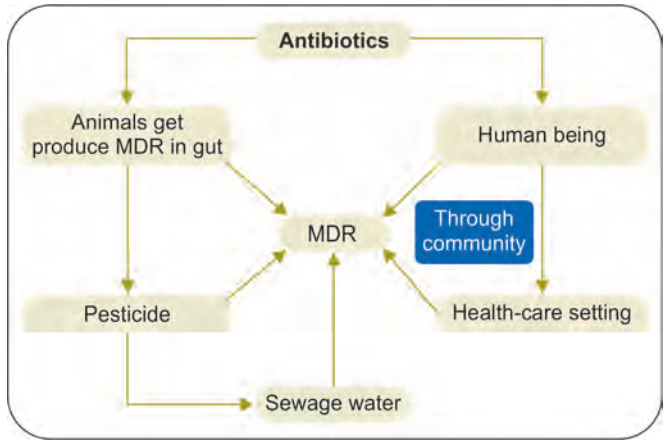
There has been emergence of microbes which are resistant to multiple antimicrobials are called as superbugs. They cause difficult to treat life threatening infections and require higher doses of antimicrobials along with alternative or adjuvant medications. They increase rate of hospitalization, duration of stay at hospital, and lead to economic burden on society and health-care system. Many of them are multidrug resistant infections such as *Mycobacterium tuberculosis, Acinetobacter, Enterobacter*

spp., Enterococcus, Escherichia coli, Pseudomonas, and *Staphylococcus aureus*. These infections are caused by a range of opportunistic pathogens (organisms that only cause disease in immunocompromised individuals). Device-associated infections, ventilator-associated pneumonia (VAP), and urinary tract infections (UTI) account for approximately 60% of all hospital-associated infections.

Causes of AMR

- Community—
  - Overuse of antibiotics—Over the counter availability of antibiotics in absence of valid prescription by a qualified medical professional
  - Inappropriate use/misuse of antibiotics
  - Inappropriate choices because of diagnostic inaccuracy
  - Inadequate dosing/timing and noncompliance
  - Self-medication
- Hospital-acquired infections—
  - Intensive and unjustified/irrational use of antimicrobial drugs
  - Emergence and spread of multidrug resistant nosocomial infections
  - Immunocompromised patients
  - Prolonged stay in hospitals/intensive care units, treatment of immunocompromized patients
  - Failure to implement effective infection control measures
  - Absence of antimicrobial stewardship programs
- Environmental causes of AMR (as shown in **Flowchart 1**)
  - Overwhelming use of antibiotics in animal husbandry and agriculture. This results in the evolution of multidrug-resistant organisms that act as reservoirs. These organisms or their genes can spread to humans either through direct contact or through the environment.
  - Organic pesticides used in agriculture may persist in the soil.
  - Sewage-water contamination with soil and environment.
  - The excessive use of antiseptics and biocides leads to resistance against these compounds and cross-resistance to antibiotics.
  - Many antibacterial drugs are derived from natural products of environmental microbial species.

Flowchart 1: Environmental factors of MDR (multidrug resistant strains)



Exposure to antibacterial agents results in the selection of resistant strains within an otherwise susceptible bacterial population.

Mechanisms of resistance—Microbes have outstanding quality to survive among variety of environmental adversities. Plasmids are extrachromosomal DNA, mostly present in bacteria. They replicate autonomously. The size varies from a few base pairs to thousands base pairs. Many antibiotic resistance genes are present in plasmids. It is common that resistant bacteria have combinations of resistance mechanisms[3] either within one category or among categories, and many plasmids contain more than one resistance gene. Thus, plasmid acquisition itself can in many cases confer resistance to multiple antibacterial agents.

Mechanisms of resistance have been shown in **Figure 1**.

- Reduced penetration and permeability and increased efflux pumps—Some bacterial species are intrinsically resistant to certain group of antibiotics because of reduced penetration and permeability of cell membrane and increased efflux pumps. TetA efflux pumps specifically pump tetracycline out of the cell. Mutations in Porin (protein channels present incell membrane) lead to porin los or change in size and conductance or decrease in expression results in less concentration of antibiotic in the cell and can lead to AMR.
- Enzyme inactivation and chemical modification—Enzymes produced by certain bacteria inactivate the target site, such as β lactamase enzyme, which prevent β lactam to bind to target site. Another mechanism mediated by bacteria in which they acquire an

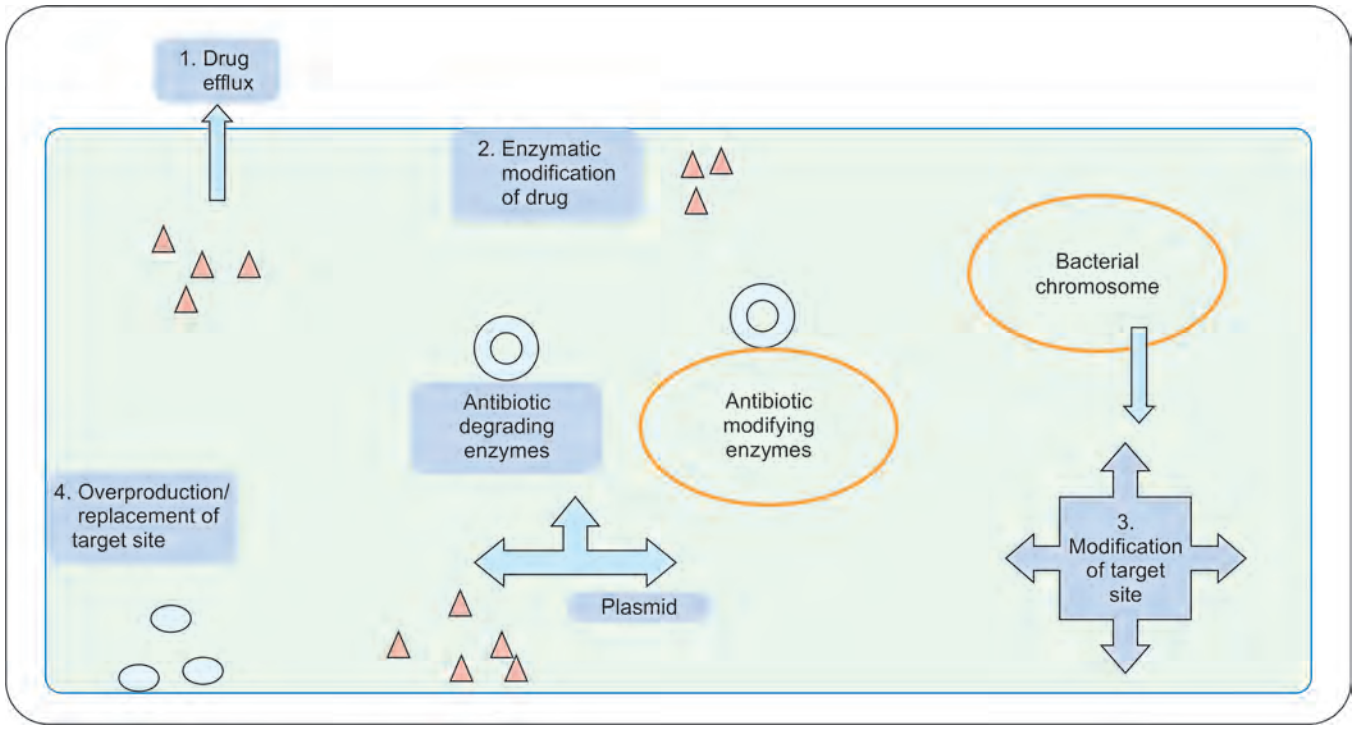


Fig. 1: Mechanism of antibiotic resistance

enzyme that chemically modify the target of the antibiotics. Ribosomal methylation of erythromycin makes it ineffective and N Acetyltransferase modifies aminoglycosides.

- Modification of antibiotic target site—Mutations in the bacterial genes, which encode for the protein that is target of an antibiotic. Resistance to penicillin in streptococcus species is due to acquisition of mutation in penicillin binding proteins.
- Overproduction/replacement of target site—Sometimes there is overproduction of target sites by replication of bacteria, which is found in combination with mutation that lowers the ability of antibiotics to bind to bacteria, e.g., trimethoprim resistance in *E. coli*. Some of mutations cause replacement of target site of bacteria for a particular antibiotic and result in resistance. *S. aureus* is resistant to most of the β lactam antibiotics.

Implications of AMR

Management of critically ill, cancer chemotherapy, organ transplantation, orthopedic surgery, intensive care for preterm newborns are being affected.

- Economic burden on patient and health-care system.
- Infections caused by multidrug-resistant bacterial strains lead to increased societal costs in terms of mortality and loss of productivity.

Antimicrobial Stewardship[4]

"Using the right antibiotic at the right time at the right dose for right duration."

Goal of antimicrobial stewardship to optimize clinical outcome while minimizing toxicity and emergence of resistance. Antimicrobial stewardship programs are the need of the hour to limit indiscriminant use of antimicrobials. These programs require leadership commitment, accountability, and drug expertise. They include systemic evaluation of ongoing treatment, tracking and monitoring of antibiotic prescription and resistance pattern and education to clinicians about AMR and optimum prescription.

Antimicrobial stewardship programs are typically multidisciplinary and often include infectious disease physicians, pharmacists, pharmacologist, clinical microbiologists, administrators, and epidemiologists. It is

for practice of promoting the selection of the appropriate drug, dosage, route, and duration of antimicrobial therapy.

Solutions to Combat Antibiotic Resistance

AMR is a major concern globally. Infections due to drug-resistant pathogens are becoming difficult and a challenge to treat. Following strategies can be adopted:

- Mitigation of emergence of MDR strains and prevent spread
- Strengthen National one health surveillance program
- Rapid and innovative diagnostic facilities to be made available
- Antibiotic stewardship programs should be mandatory in health-care systems
- Accelerate applied and basic research to develop new antibiotics and new treatment options
- Capacity building across the globe by improving international collaborations to prevent AMR
- Novel therapeutic options can be explored such as antimicrobial peptides, biologics, nanoparticles, polymer-controlled delivery

Conclusion

AMR is increasing due to overuse and misuse of antibiotics in human beings and animals. There should be societal commitment to fight against AMR. Health-care professionals should demonstrate dedication and accountability to optimize antibiotic prescriptions and patient safety.

CHAPTER

163 Chikungunya Arthropathy

Liyakat Ali Gauri, Somya Goyal, Asim Khan, Nadeem Liyakat, Qadir Fatima

Abstract

Chikungunya is a vector born disease transmitted to humans by the bite of infected female Aedes aegypti or Aedes albopictus. It causes a multisystem disorder with predominant involvement of musculoskeletal system. Chikungunya arthropathy can develop into chronic phase which may lead to disability and debilitating joint pain. Current treatment options include NSAIDs, Opioids, Anticonvulsants/Antidepressants, Colchicine, DMARDs, Methotrexate. Biologicals, Ultrasound, and Transcutaneous Electrical Current Stimulation have shown promising results. Newer researches are undergoing to provide evidence-based therapeutic options.

Introduction

The word chikungunya, in Makonda language, means "that which bends up" or "to become contorted." It refers to the prostrated appearance of affected patients.[1]

Chikungunya virus **(Fig. 1)** is an alpha virus belonging to *Togaviridae* family. ChikV was first isolated in 1953, in Newala District, Tanzania. The vector-borne disease is transmitted to humans by the bite of infected female Aedes aegypti (tropics) or Aedes albopictus (temperate).[2]

Fig. 1: Aedes albopictus or Asian tiger mosquito

Clinical Features

ChikV is a multisystem disorder with a predominant involvement of musculoskeletal system. Incubation period is 5–7 days:[1]

- Neurological manifestations are meningoencephalitis, myelitis, peripheral neuropathy, Guillain-Barré syndrome (GBS).
- Ophthalmology-keratitis, episcleritis, optic neuritis, uveitis, and renal detachment.
- Cardiac—uncommon, but serious arrhythmias, vasculopathy, myocarditis, pericarditis, or dilated cardiomyopathy[1]
- Sepsis and septic shock
- Renal failure
- Toxic hepatitis
- Pneumonitis
- Bullous dermatosis, alopecia[3]

Mother-to-child Transmission

A study of pregnant women concluded in Reunion Island, 2005–2006 epidemic showed that vertical transmission rate was 50% when ChikV infection occurred during intrapartum period (2 days either side of deliver). Cesarean section did not prevent this transmission.[4]

Chikungunya Arthropathy

Clinical manifestations can be divided into:

- Acute phase (<3 months)
- Chronic phase (>3 months)

Acute phase is further divided into viremic (5–10 days) and subacute post-viraemic phase (6–21 days).

Viremic phase is characterized by sudden onset high grade fever, severe polyarthralgia, myalgia, conjunctivitis, exanthema.[5]

Subacute phase is in which fever settles but articular symptoms persists.

There is symmetrical, peripheral polyarthralgia involving small, medium, and large joints, which tends to be more intense in morning and worsens with physical activity.[6]

Chronic Phase

Prevalence of ChikV arthritis progressing to chronicity is 4.1–78.6%. This phase is similar to rheumatoid arthritis (RA), spondyloarthritis.[7] Various joints are involved in chikungunya. There have been many studies studying involvement of joints **(Fig. 2)**.

Chikungunya has been reported with changes similar to rheumatoid arthritis. Similar case was reported by jose kennedy Amaral **(Fig. 3)**.[16] Study from Colombia reported 25% patients remained symptomatic for joint pain after 20 months follow-up.

Similar findings were reported in a meta analysis, chronic inflammatory rheumatism (CIR) was present in 25% cases and chronic arthritis in 14%.[8]

In study involving 121 patients from Martinique Island in Caribbean, 21% patients progressed to seronegative RA in 1 year, 37% had flare of underlying degenerative arthritis, 35% had relapse of previous inactive spondyloarthritis and 7% had fibromyalgia.[9]

An observational study from Kerala found 57% patients had chronic polyarthralgia, 19.5% chronic tenosynovitis after 15 months of ChikV.[1]

Risk Factors for Developing Chronicity

- Comorbidities: RA, diabetes mellitus
- Age more than 45 years
- High viral load (>10^9/mL) during acute phase
- In a study involving 140 patients with ChikV, smoking, and female gender were identified as main risk factors for severe joint pain in acute disease as well as chronicity as similar to RA
- Genetic predisposition
- Viral persistence
- Auto immune diseases[6,10]

Immunopathogenesis of Chikungunya Arthropathy

The mechanism of chikungunya arthropathy is unclearly understood.

In acute phase, there is an intense viremia, which is associated with activation of Type I IFN & IL-6. Proinflammatory cytokines and chemokines are activated.

This strong immune response clears the virus by CD+4 T cells, NK cells and macrophages and within 7–10 days of acute infection virus levels become undetectable.

For this reason, ChikV PCR for diagnosis after 7 days is not useful.[2]

Il-17 is also implicated in chronic joint disease, which upregulates IL-1,6, TNF alpha, RANK-L. RANK-L osteoprotegerin ratio is disturbed, which further increases bone erosions. Whether ChikV persists in synovial tissue in chronic phase is unclear.[1]

Sixteen patients from Reunion Island epidemic were studied for persistent viral infection by synovial fluid RTPCR in 10 patients and tissue biopsy in 6 patients. All samples were negative suggesting viral replication is not the cause of chronic articular disease.[11]

In a study conducted by Dr Chang on 38 patients during 2014–2015 Colombian epidemic, no evidence of viral persistence was found by synovial fluid RTPCR, mass spectrometry, and viral culture.[8]

Diagnosis

- *Clinical:* ChikV should be suspected in endemic areas or in travelers from affected areas or in patients presenting with high grade fever and joint pain

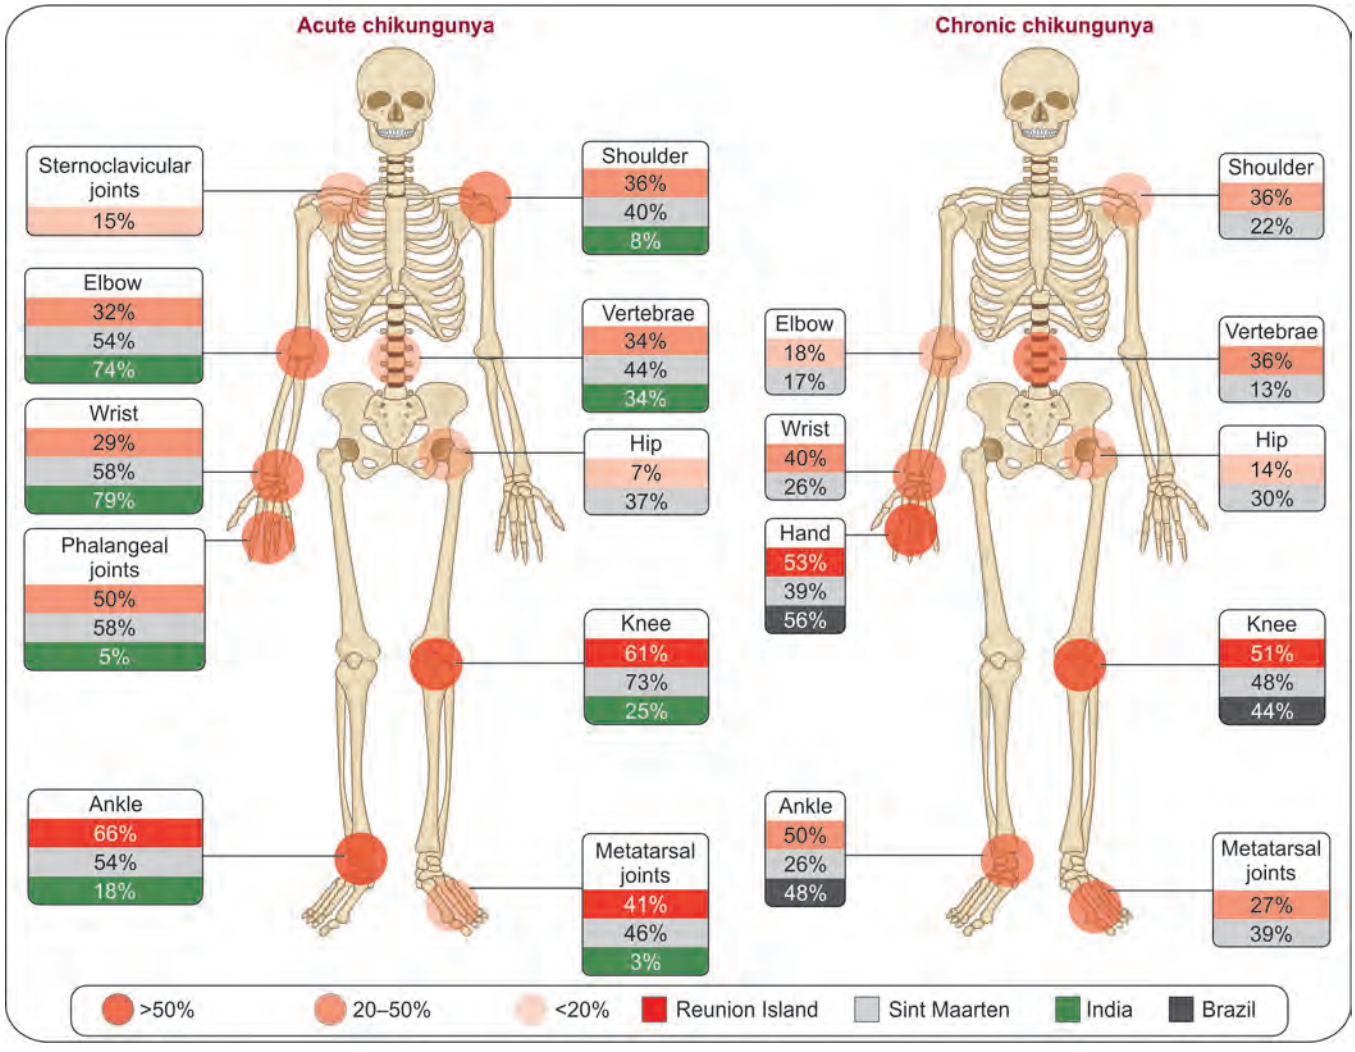

Fig. 2: Joints involved in chikungunya as observed in various studies[3]

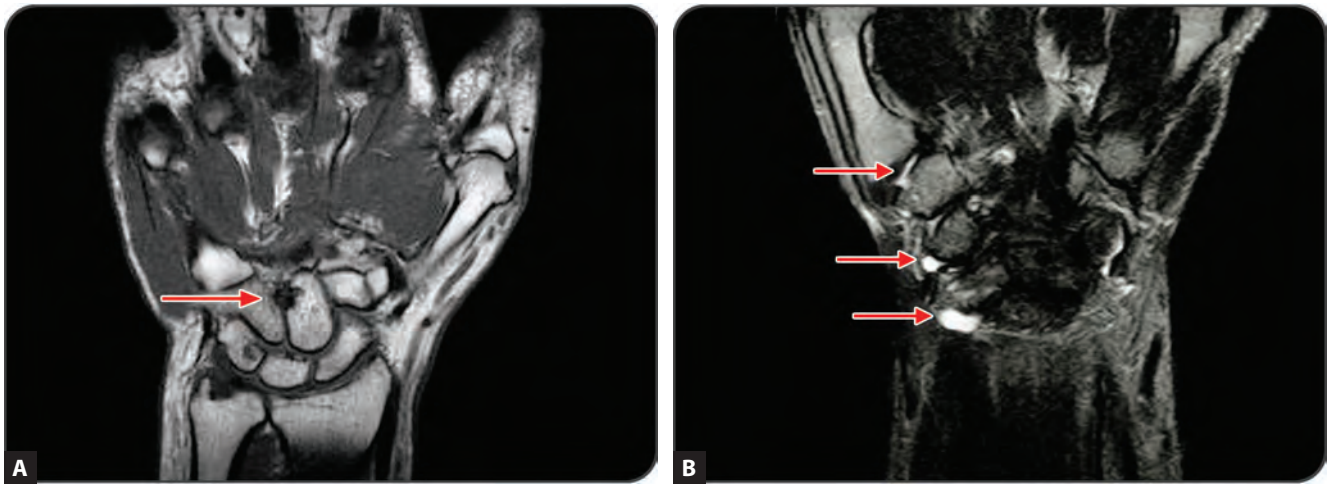
Fig. 3: A 50-year-old woman with CCA and synovitis of right 3rd PIP and left 2nd PIP joints. She had acute Chik F 3 years prior and subsequently developed CCA



Figs. 4A and B: Coronal magnetic resonance (MR) T1 image (A) reveals extensive intermediate-signal-causing carpal styloid erosions (arrow), similar to those of rheumatoid arthritis. Axial MRT2 image (B) reveals small fluid collections in the wrist (arrows)

- *Complete blood count:* Anemia, leukopenia, lymphopenia, mild thrombocytopenia
- *Biochemistry:* Increase in liver enzymes and serum creatinine levels
- *RT-PCR:* Sensitive from 0 to 7 days after which it is unreliable
- *IgM ChikV:* Detectable in 5–10 days after onset of infection, maximally positive after 3 weeks. May remain positive up to 2–3 months
- *IgG:* Positive after first week of infection and remain positive for years

As a general rule, serological markers (IgM & IgG) should not be checked in first week of infection:

- RA factor, anti CCP antibodies, HLA B27, ANA in chronic arthritis
- MRI—greater sensitivity. Can show synovial thickening, bone marrow edema, effusions, tenosynovitis **(Fig. 4)**.[24]

Treatment

NSAIDs

PCM remains the initial choice for fever and arthralgia. NSAIDs should be avoided until dengue has been ruled out as dengue can be complicated by hemorrhage.

Corticosteroids

Low dose prednisone starting at 5–10 mg OD followed by gradual tapering over weeks can be used for intractable symptoms in subacute phase and chronic phase. Maximum dose of steroids recommended is 0.5 mg/kg.

Use is not advised in acute phase.

In an uncontrolled case series during 2005–2006 Indian Ocean pandemic, short-term corticosteroids showed improvement in arthritis and tenosynovitis and decreased disability in patients with CCA.[1]

Long-term use is discouraged due to side effects.

Opioids

Weak opioids like codeine and tramadol can be used as adjunctive.

Anticonvulsants/Antidepressants

Pregabalin, amitriptyline, and gabapentin can be used for peripheral neuropathy and intractable pain.

Colchicine

Study by Rendel showed that colchicine used at 0.6 mg/kg/day in a patient with persistent ankle and wrist arthralgia showed significant improvement.[12]

After 2–3 days, there was resolution of swelling and improvement in joint pain. After 2 months, symptoms were resolved.

Patient continued treatment for 6 months with no adverse effects. Study suggested colchicine as a treatment option.[12]

DMARDs

Study on 50 chikungunya patients by Gauri LA et al. shows that chikungunya patients who had persistent arthralgia on 5-year follow-up mimicked rheumatological disorder Like rheumatoid arthritis in 70.58% cases. Therefore, disease-modifying anti-rheumatic drugs (DMARDs) can be effective.[13]

Methotrexate (MTX)

In a study from Reunion islands by Javelle et al. on a patient with post-chikungunya CIR with 21 months follow-up, 15 mg weekly MTX lead to clinical improvement in 75% (54/72) patients and 8%(6/72) achieved partial recovery while 9% (7/72) had radiographic worsening of joints. Remaining had to stop MTX due to side effects.[14]

In another small study, MTX given to patients with poor response to HCQ and SSZ combination therapy led to improvement in 93% cases after 3 months. Only 7% were symptomatic at the end of 2 years.

Bouqillard & Combe treated 19 patients with acute chikungunya with MTX, 13 patients (68.4%) had good clinical response.[15]

Combination DMARD Therapy

Amaral et al. treated 48 CCA patients with 7.5 mg weekly MTX with dose escalations for refractory symptoms at 4 weeks. Final MTX dose was 9.2+3.2 mg/week.

MTX was combined with oral prednisone at 9 weeks with 6.1+2.2 mg for 9 patients (18%). Two patients received 400 mg daily HCQ with MTX and one received SSz 1,000 mg. Pain VAS score decreased to 3.0 & 2.6 at the end of 4 & 8 weeks respectively from a baseline value of 7.7+2.0.[16]

An open label study by Ravindran & Alias randomized patients on HCQ who had persistent arthritis (>1 year) patients were divided into two groups:

Group A: Received fixed dose combination (MTX 15 mg weekly + SSz 1,000 mg OD + HCQ 400 mg daily.

Group B: Continued to take HCQ 400 mg OD.

Both groups also took prednisolone for 6 weeks. At 25 weeks, combination therapy showed significant improvement in both disease activity & disability. VAS score was significantly less in combination therapy group.[17]

Pandya treated 149 patients with MTX 15–20 mg weekly with HCQ. At 16 weeks, ACR20 was seen in 48.9%, ACR50 in 18.8%, ACR70 in 4% patients. One patient achieved clinical remission (DAS28-ESR <2.6) and 4/149 showed good clinical response (DAS28-ESR <3.2).[18]

Biologicals

No human trial to evaluate the efficacy.

Bouqillard & Combe treated patients of acute Chik developing CIR, with TNF alpha inhibitors. These patients were refractory to initial MTX therapy. All Patients had good clinical response.[15]

Ultrasound and Transcutaneous Electrical Current Stimulation

Ribeiro et al. reported the efficacy of ten sessions of continuous ultrasound with 1 MHZ OD applied from Monday to Friday followed by infrared laser at dose of 4J & 3S per hour. TENS burst with a pulse width of 250US and frequency of 2 HZ.

This association showed post-intervention improvement in quality of life, which was assessed by SF36 (medical outcome study 36) and VAS.[19]

Ultrasound transmits heat by convection causing vasodilation and increased blood flow, hence increasing metabolic rate of the cell.

TENS stimulates large afferent sensory fibers that block first degree nociceptive fibers by releasing endorphins.

Laser therapy causes photochemical reactions within cells, increasing mitochondrial function and ATP productions, cell proliferation, and accentuating the healing process.

When to Give? What to Give?

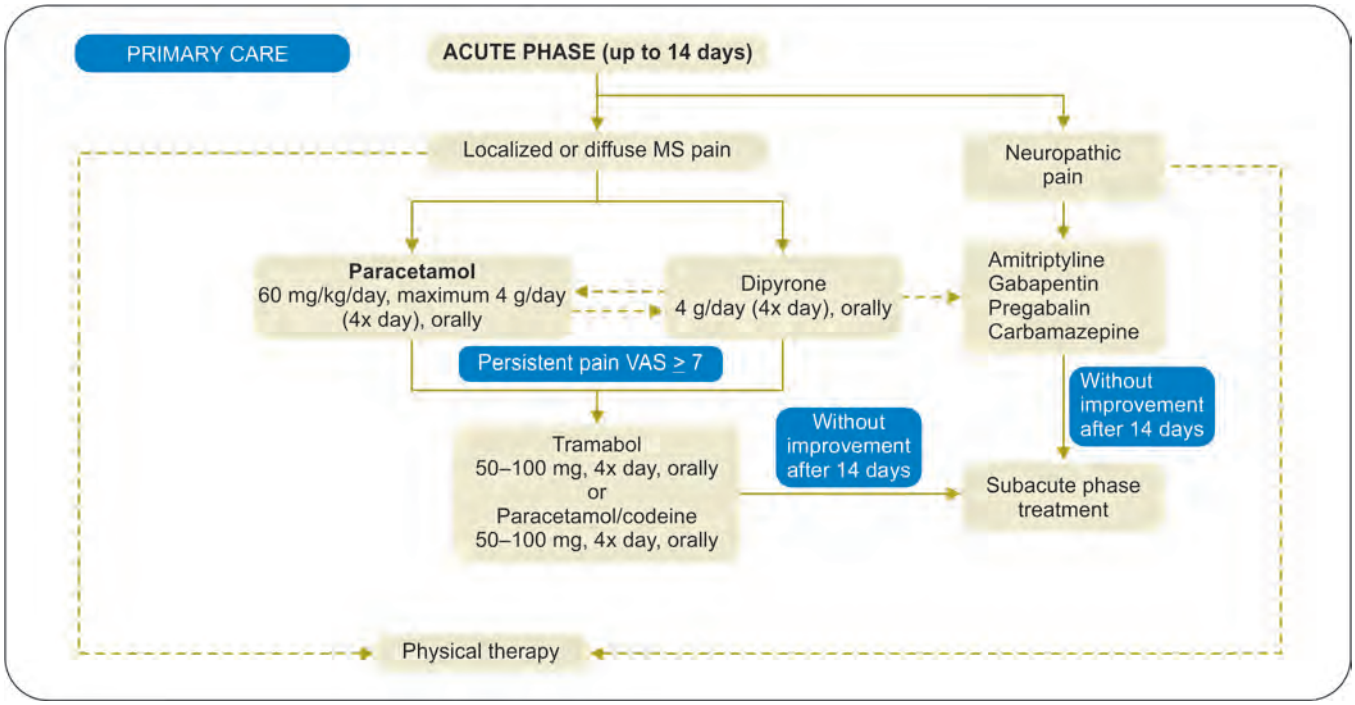
Based on French, Brazilian, and WHO guidelines as well as the studies conducted in India, we can follow these points:[20,21]

Acute Phase

Acute viremic phase **(*see* Flowchart 1)**:

- Supportive care, hydration
- WHO recommend home treatment for non-complicated acute cases
- Common analgesics, weak opioids should be used
- NSAIDs to be avoided until dengue has been ruled out

Flowchart 1: Treatment algorithm for patients presenting in acute phase of chikungunya arthropathy[2]



- Guidelines do not recommend use of steroids during acute viremic phase
- Use of heat generating rehabilitative procedures should be avoided in acute phase

Subacute phase ***(see* Flowchart 2)**:

- NSAIDs, opioids, or adjunctive treatment for pain management
- Anticonvulsant/antidepressants like pregabalin and amitriptyline in cases refractory to opioids, NSAIDs.
- Use of prednisolone at 5–20 mg/day with gradual tapering
- WHO guidelines support use of HCQ 200 mg OD or CQ 300 mg Od for 4 weeks for resistant symptoms

Chronic phase ***(see* Flowchart 3)**:

- Analgesics
- Weak opioids
- NSAIDs
- Oral corticosteroids may be used at 5–20 mg/day with gradual tapering
- HCQ with or without MTX or sulfasalazine (SSZ)
- Corticosteroid dependent disease—use of MTX at 10–25 mg/weekly is recommended
- SSZ 2–3 g/day with or without MTX. SSZ should especially be used in failure or contraindications to MTX
- Biological therapy (particularly TNF alpha) may be used after rheumatological evaluation or in patients refractory to treatment of corticosteroids or DMARDs
- A dictum is—"if it looks like RA, treat like RA" should be followed

Rehabilitation intervention in all phases of ChikV is recommended as a complementary non-pharmacological measurement.

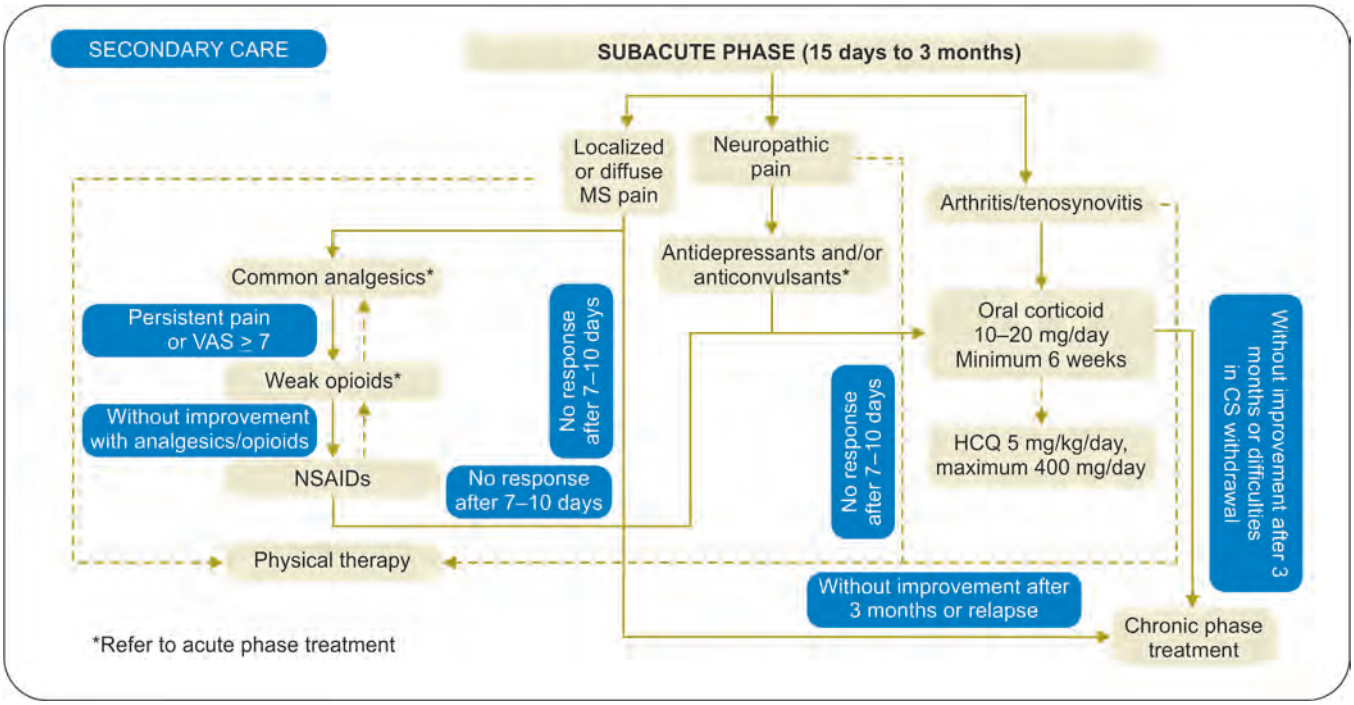
Newer Therapeutic Approach

Ribavirin

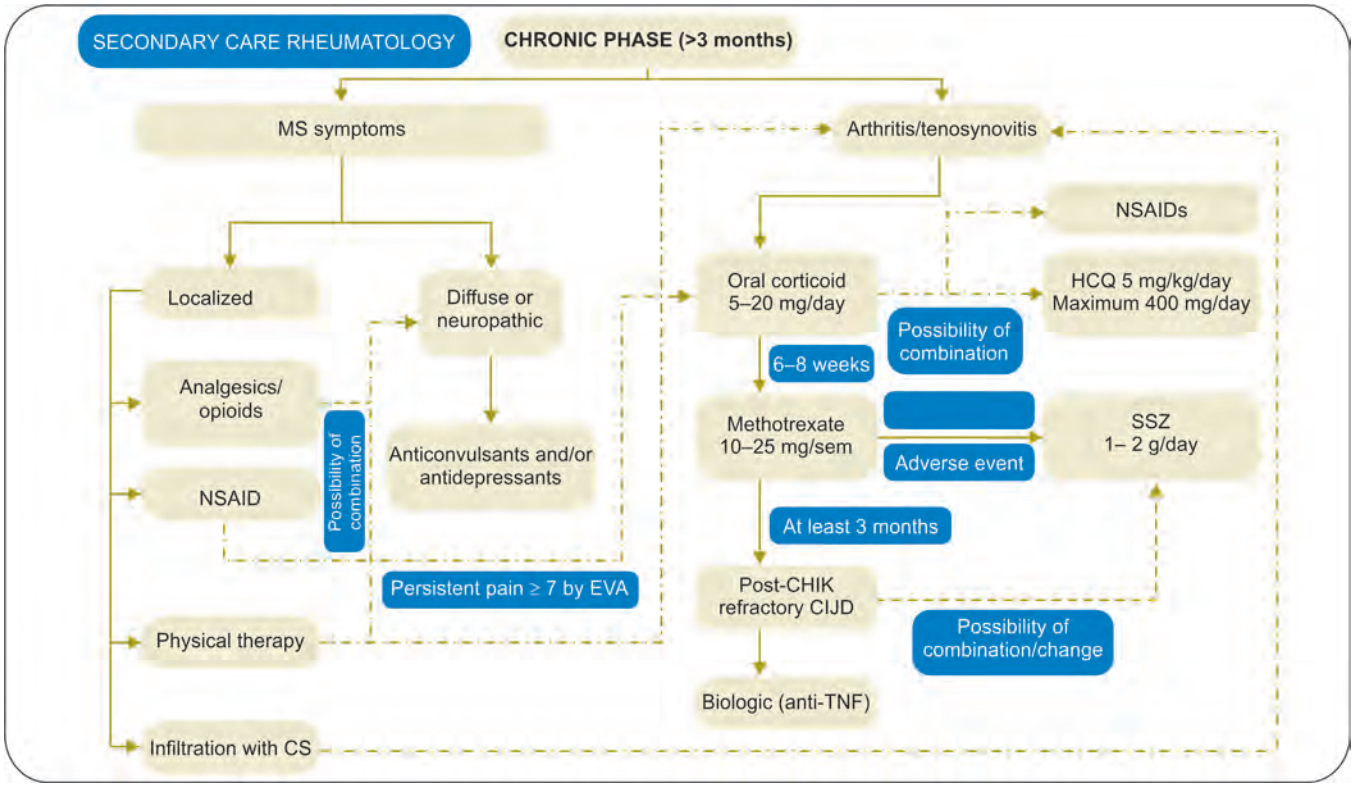
In studies by Ravindran et al., Ribavirin was used in a group of patient with chronic ChikV, analgesics discontinued, and Ribavirin started at 200 mg BD for 7 days. All patients reported improvement in pain.[6]

Favipravir, Ribavirin with a combination of IFN alpha, *umifenovir* (antiviral) and *Suremein* (anti-protozoal) have shown some benefit.[2]

Flowchart 2: Treatment algorithm for patients presenting in subacute phase of chikungunya arthropathy[2]



Flowchart 3: Treatment algorithm for patients presenting in chronic phase of chikungunya arthropathy[2]



Abatacept

T-cell costimulation blocker. In mouse models has shown a significant decrease in periarticular swelling and proinflammatory cytokines.[2]

Pentosan Polysulfate

NOVEL glycosaminoglycan like molecule developed for the treatment of alpha virus infection. Treatment of ChikV infected mice reduced cartilage thinning and immunological infiltration of joints.

Intra-articilar levels of proinflammatory cytokines were decreased and anti-inflammatory IL-10 increased through unclear mechanism.[1]

Fingolimod

Sphingosine-1-phosphate receptor agonist used in multiple sclerosis. In ChikV infected mice, Fingolimod treatment decreased migration of CD4 T-cells into joints without affecting viral replication. However, its utility in CCA is unknown.[1]

Curcumin

Turmeric derived compound used as food additive. Treatment exhibited antiviral properties through inhibition of virus binding to cells in vitro studies.[22]

Pimozide and 5-Tetra Decyloxy-2 Fusoic Acid

Found to exhibit synergistic antiviral activity in studies causing genomic wide loss of function screen.[22]

Neutralizing Monoclonal Antibodies-SVIR001

Neutralizing IgG MAB to E2 envelope glycoprotein inhibit entry, fusion, and egress of virus. Robust viral clearance and decreased cytokines and chemokines level have been observed.

Renders protection against multiple alpha virus including ChikV.[22]

E2 Glycoprotein Mutation

Studies showed the presence of highly conserved amino acid on E2 glycoprotein, which promoted ChikV persistence in mouse joints.

Mutation of this conserved region allowed viral clearance in mice.[22]

Prophylaxis with MDEF201

It is an adenovirus vectored IFN alpha.

Studies have shown decreased cytokines and decreased footpad swelling in mice treated with intranasal MDEF 201.

Prophylaxis with MDEF201 may have clinical potential in endemic areas of ChikV. Especially during outbreaks, it would be useful as a single prophylactic agent that could protect over several weeks to those at high risk.[23]

Vaccine

- Recombinant measles and chikungunya vaccine (MV-Chik)
- Virus like particle (VLP) vaccine

Vaccines induce neutralizing antibodies against E1 and E2, which may block viral entry into cells.

2018, CEPI (coalition for Epidemic Preparedness Innovation) reported that four vaccines are in phase I trial and two in phase II trial (VLP, MV-Chik).

Phase III field trials are complicated by inability to predict the geographical location and size of next outbreak.

Newer Mosquito Control Measures

- *Biotechnology:* Introducing insect toxin into fungus that infects mosquitoes
- *Wolbachia:* It is a gram negative bacteria affecting mosquitoes. Large field trial of Wolbachia is underway in Yogyakarta, Indonesia, with hope that transmission of DENV, ChikV can be decreased.

Conclusion

ChikV is an arboviral multisystem disease primarily affecting joints. Chikungunya arthropathy can develop into chronic phase, which may persist for months to years creating distress, disability and debilitating joint pain. Available research on treatment options is limited based on which use of DMARDs, corticosteroids, NSAIDs is advised. Newer researches are undergoing to provide evidence-based therapeutic options. Vaccine development is under phase II trial. Newer therapies have shown benefit in animal models and are being studies in human subjects. To prevent the economic burden that the disease causes, there is an urgent need to formulate universal guidelines and to test newer drugs as well as vaccines.

CHAPTER

164 Atypical Manifestations of Dengue

Ashok Kumar, Shubha Laxmi Margekar, Purnima Margekar, Urvashi Khan

Abstract

Globally dengue is the most common arboviral disease being transmitted. Since past five decades disease is rapidly spreading in the world with a 30 fold increase in incidence. The common manifestations of dengue fever includes, fever, retro-orbital headache, generalized body ache, petechial rashes, and bleeding manifestations. Over the period of decades there has been occurrence of other manifestations which are different from typical dengue fever. These manifestations have been called as atypical manifestations and it has been observed that almost all the organ system of body has been affected by dengue fever. Focus of this article is to elaborate the atypical manifestations of dengue fever which also includes the expanded dengue syndrome. Knowledge of these manifestations is necessary to recognize the disease process, limit the complication, and prevent the morbidity and mortality associated.

Introduction

Worldwide dengue is the most common arthropod borne disease, which is being transmitted by the bite of mosquitoes. Since past five decades disease is rapidly spreading in the world, and incidence of dengue infections has been rise by approximately 30 times. There is estimated 100–400 million people gets infections each year. The first confirmed epidemic of dengue hemorrhagic fever (DHF) was recorded in the Philippines in 1953–1954 and in India it occurred in Calcutta in 1963. Although it is a preventable disease but it also has high mortality and morbidity. Due to lack of awareness among the health-care personnels, atypical presentation is often missed and goes unreported. Dengue virus belongs to the virus of genus flaviviruses of Flaviviridae family. There are various serotype of dengue virus are there namely DEN 1-4. The vector responsible for the spread of dengue virus is mosquito *Aedes aegypti* (*A. aegypti*).[1] Infected Aedes mosquitoes, especially *A. aegypti*, transmit various serotypes to humans through their bites.

The dengue virus infection produces the myriad of clinical symptoms clinical ranging from mild asymptomatic to febrile illness of unknown origin (can be of viral origin), DHF, or dengue fever (DF), or dengue shock syndrome (DSS) **(Table 1)**.[2]

Infection in people who are never been infected is known as primary or first infection, usually causes classical dengue fever. Subsequent or secondary infection by different dengue virus serotype causes more severe illness like dengue DHF/DSS. Major pathophysiologic changes occurring in DHF/DSS are:

- Plasma leakage
- Rising hematocrit
- Thrombocytopenia, and
- Bleeding manifestations.

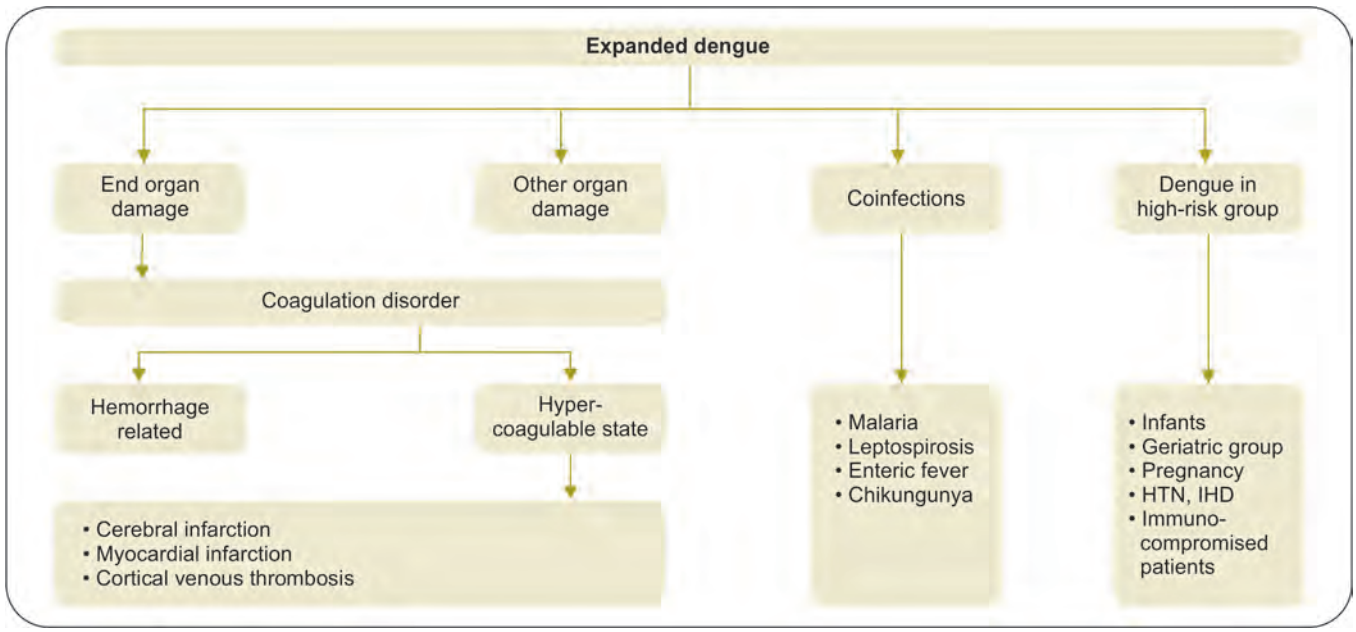
It's an acute febrile illness with rash, arthralgia, leukopenia, headache, retro-orbital pain, hemorrhagic manifestations.[2] As per WHO clinical diagnosis of DHF is made by the following criteria:[1]

- Continuous spikes of high grade fever for 2–7 days

TABLE 1 Manifestation of dengue virus infection

Asymptomatic	*Symptomatic*					
	Undifferentiated fever (Viral syndrome)	*Dengue fever (Classical)*		*Dengue hemorrhagic fever (Classical)*		*Expanded dengue syndrome/ Isolated organopathy (Unusual presentation)*
		Without hemorrhage	With unusual hemorrhage	Without shock	With shock dengue shock syndrome (DSS)	

Flowchart 1: Expanded dengue



- Positive tourniquet test or presence of bleeding tendency
- Platelet count <100,000/μL
- Evidence of hemo-concentration, i.e., 20% rise in hematocrit as per average for age, sex, and population, presence of ascites and pleural effusion

One of the life threatening complications is DSS, which is characterized by DHF (meeting all four criteria) along with circulatory failure. Circulatory failure is manifested by rapid and weak pulse, cold clammy skin and restlessness and narrow pulse pressure (<20 mm HG) or hypotension for age.[2]

Atypical Manifestations

The classic presentation of dengue has been expanded with involvement of various organ systems. Due to diagnostic dilemma some atypical manifestation are often missed and being underreported. Henceforth, a new term Expanded Syndrome has been coined by WHO, in the revised classification in 2012 as shown in **Flowchart 1**.[2,3] Atypical manifestations are correlated with neurological, renal, hepatic, cardiovascular, and other organs involvement **(Table 2)**. It has been reported increasingly in DHF and also in dengue patients with no evidence of leakage of plasma. Most DHF patients who have unusual manifestations are the result of prolonged shock with organ failure or patients with comorbidities or coinfections.

Neurological Manifestations

The association between DHF and neurological disturbances were first described in 1976.[4,5] Different

TABLE 2 Atypical manifestations of dengue

Neurological	*Gastrointestinal/Hepatic*	*Renal*	*Cardiac*	*Respiratory*
• Febrile seizures • Encephalitis • Encephalopathy • Transverse myelitis	• Hepatic failure (Fulminant) • Acalculous cholecystitis • Acute pancreatitis • Acute parotitis	• Acute renal failure • HUS	• Myocarditis • Pericarditis • Conduction abnormalties	• Acute respiratory distress syndrome • Pulmonary hemorrhage
Lymphoreticular/bone marrow		***Musculoskeletal***	***Eye***	***Others***
• HLH • ITP • Spontaneous splenic rupture • Infarction of lymph node		Rhabdomyolysis	Optic neuritis	Psychosis

manifestations including neurological signs may occur due to neurotropicity, which is due to direct invasion of tissue, release of cytokines damaging the blood brain barrier, brain edema, capillary leakage can be leading to bleeding manifestations involving intracranial hemorrhage, and due to extended period of shock there could be hypoperfusion of brain, acute renal injury, liver dysfunction, and electrolyte imbalances like decrease in the sodium levels, i.e., hyponatremia and decrease in the blood glucose levels, i.e., hypoglycemia.[6,7] In the study by Pancharoen and Thisyakorn (2001) they explained that altered sensorium is the most usual neurological finding subsequently seizures were noted among 75% of patients with DSS.[5] Various other patients had manifestations of PN (polyneuropathy), Encephalitis, memory loss, and myelitis.[8] Meningitis was found in (1.2%).[9] In a study conducted by Pothapregada et al. (2016),[10] neurological manifestations were observed in 28 children (11%). In the same study total six deaths (2.4%) were there and out of them four presented with impaired consciousness (66. 6%) during admission with their GCS < 8. Multiorgan failure, refractory shock, and encephalopathy were accounted for the poor outcomes. Mohanty et al.[11] described in his study that fever and altered sensorium were related to typical presentation of the virus, CSF analysis suggestive of viral encephalitis, five deaths due to multiorgan dysfunction, cerebral infarct in neuroimaging seen in one patient. Potassium redistribution in the cells also played an important part in neurological manifestation caused by dengue, which leads to a rare entity described as Hypokalemic periodic paralysis. In the study by Mohanty et al.[11] they found that patients responded well with potassium infusion who had features suggestive of hypokalemic paralysis and whose NCV, i.e., nerve conduction velocity and EMG, i.e., electromyography were completely normal.[11,12] Further unusual manifestation observed in the same study was that of spinal cord involvement including ATM, i.e., acute transverse myelitis, which was managed with steroid, i.e., methylprednisolone and IVIG. Muscle involvement also seen in the form of Myalgia cruris, which may be due to direct muscle invasion by virus causing damage to muscle or may be due to released cytokines.[13] Another rare manifestation is dysarthria clumsy hand syndrome.

Gastrointestinal Manifestations

Gastrointestinal presentations of virus are such as febrile diarrhea, fulminant liver failure, inflammation of pancreas, i.e., acute pancreatitis, cholecystitis mostly acalculous, severe inflammation of parotid gland, i.e., acute parotitis. Severe pain abdomen is one uncommon manifestation seen in dengue. With such presentation, acute peritonitis, acute pancreatitis, or acalculous cholecystitis should be ruled out. Diverse involvement of virus in liver scales from advancing from meagre symptoms of increasing liver enzymes to a full-blown liver failure or fulminant hepatic failure. Elevation of liver enzymes (AST/ALT) is seen commonly in dengue infection. Elevation of liver enzymes like AST/ALT is commonly seen in patient with dengue fever and 9th day of the illness is the most crucial day where the liver enzymes tend to increase from the day of onset of symptoms and it gradually progresses toward normal within 3 weeks.[6,7] Another illustration of acalculous cholecystitis introduces abdominal pain specifically localized to the upper quadrant in the right side, uninterrupted fever and positive elicitation of Murphy's sign. Exact mechanisms are not known, it might be due to invasion by the virus in the gall bladder wall

giving rise to edema of gall bladder and microangiopathic injury, which itself is self-limiting.[10] Cholecystectomy not recommended due to thrombocytopenia as postoperative bleeding. Except in case of peritonitis, gangrene and perforation where surgical intervention is required.[6]

Cardiovascular Manifestations

Cardiac demonstrations of the virus are uncommon though cardiac rhythm abnormalities like AV blocks, Atrial fibrillations, dysfunction in sinus node and ectopic beats in ventricles have been noticed during DHF incidents. The physiopathology of cardiac leads to inflammation causing cytokine storm of both structural and functional integrity by the virus.[11] If clinically and ECG findings are suggestive of myocarditis, CPK-MB is considered the most precious investigation to correlate, whereas tachycardia and volume depletion are suggestive of poor outcome.

Renal Manifestations

Dengue virus also affects renal system leading to acute kidney injury and it exhibits as acute tubular necrosis (ATN), which is a rare manifestation and mostly attributed due to shock. ARF in these individual is of pre-renal origin. There could be various methods but the approved ones are that of invasion by the virus directly into the renal system, i.e., kidneys or immune mediated. Management with appropriate fluid in hyperkalemia unresponsive to conventional treatment, decrease urine output, and uremia hemodialysis is to be used for management.

Respiratory Manifestations

Unexceptional manifestation in the respiratory system caused by the dengue virus is that of ALI, i.e., acute injury to lung and acute distress to the respiratory system, i.e., ARDS. These manifestations in turn lead to edema of alveolus and also there is increased permeability in the alveolar capillary membrane. Better outcomes can be achieved by early identification and treatment. If pulmonary hemorrhage occurs, it becomes the fatal complication.

Musculoskeletal Manifestations

Dengue myositis: It is manifested as break bone fever, severe muscle, bone, and joint pain. There is elevated SGOT, SGPT, and creatine phosphokinase. Direct invasion of muscles by viruses has not been proven and may appear to be myotoxic cytokines, particularly TNF.

Coinfections

It modifies the presentation of dengue clinically and results in delayed diagnosis and treatment of dengue shock.

Malaria

Malaria is the most common infection, which can be found with dengue infection. Because of the similar seasonal variations in the incidence of both infections and similar clinical presentation and even similarity in laboratory parameters sometimes the diagnosis of dengue can be very challenging and coinfection with malaria can be missed which can lead to fatal outcome. Among the four species of plasmodium, as per Indian studies *P. faliciparum* is commonly associated. Its presenting features are headache, myalgias, backache, hypotension, hepatosplenomegaly. Suspicion and treatment of complicated malaria is necessary for prevention of fatal outcome.

Zika Virus Disease

It is confirmed after exclusion of dengue infection with serological tests. As compared to dengue virus infection, symptoms in Zika virus infection are mild fever, mild body ache, ill-defined rashes but no hemorrhage.

Chikungunya

Aedes aegypti is common vector for both Chikungunya as well as dengue. Arthralgia common in both, but in dengue it is self-limiting and latter can progress to disabling arthritis, which may persist for months. Also thrombocytopenia can be found in both infections.

Conclusion

The most effective way to prevent dengue virus transmission is to combat the disease-carrying mosquitoes. Effective vector control strategies appear to be promising for dengue prevention and control. Risks associated with the disease can be assessed with the timely diagnosis and initiation of medical care. Recognizing expanded dengue syndrome in early stage is crucial for optimizing treatment strategies. A high index of suspicion of features of expanded dengue syndrome (EDS) is very important for targeting treatment option. Alteration in sensorium is most devastating atypical manifestation in case of severe dengue infection, which, if not recognized in time, may lead to fatal outcome.

CHAPTER

165 Cholera and Plague—Is the Threat Over?

Shyam Chand Chaudhary, Chitranshu Pancholi, Kamal Kumar Sawlani, Deepali Mohanty

Abstract

Cholera and plague both are communicable diseases which are preventable by targeted multisectoral approach including improvement of sanitation, education regarding good hygiene practices, improvement of housing, and quality of life. As per the WHO, cholera cases have decreased globally and there is a significant downward trend in incidence. WHO has planned a global road map to reduce the cholera-related deaths by 90% till 2030. Plague can also be controlled by breaking the chain of transmission, proper application of insecticides, early identification, notification, isolation, and treatment by appropriate antibiotics.

Introduction

Cholera is often predictable and preventable public health problem, which poses a global threat. It is an indicator of lack of access to clean water and sanitation facilities. Good hygiene practices can eliminate cholera.[1] Pandemics of plague occurred from time to time in the past, but nowadays it can be treated and prevented easily by use of effective antibiotics and standard measures for prevention.[2]

Cholera

Cholera is caused by toxin producing strain of Vibrio cholerae, which is curved shaped Gram-negative, highly motile with single polar flagellum bacterium. It causes acute diarrhea and is known as "Father of public health." There are more than 200 serogroup of V. cholera. Of these, only two toxigenic serogroups O1 and O139 cause outbreaks. El Tor and classical are the two biotypes of serogroup O1. In comparison to classical strains, El Tor biotype causes more of asymptomatic cases and exists in environment for longer time. Classical strain was responsible for previous six pandemic and El Tor was responsible for seventh one starting in 1961. In 1992, O139 was identified as a cause of extensive cholera epidemic in various part of South Asia including India and Bangladesh. Humans become infected incidentally but, once infected, can acts as a vehicle for spread. There is no animal reservoir. Ingestion of contaminated water and food by human feces are the common means of acquisition of V. cholera. Risk factor include poor hygiene, poor water supply, lack of sanitation (peri-urban slums, refugee camps), etc.[3]

Epidemiology

WHO standard case definition: *Suspected cholera case*—when a patient aged ≥5 years develops severe dehydration or dies because of acute diarrhea in an area where the disease is not known to be present or when patient aged ≥5 develops acute watery diarrhea with or without vomiting in cholera epidemic area. *Confirmed cholera case*—any suspected case in which Vibrio cholerae O1 or O139 is confirmed by culture or polymerase chain reaction (PCR) test. *Cholera endemic area*—an area

where cholera confirmed cases have been detected in last 3 years due to local transmission. *Cholera outbreak* is defined by the occurrence of at least one confirmed case of cholera and evidence of local transmission or unexpected increase (in magnitude or timing) of suspected cases over two consecutive weeks, of which some are laboratory confirmed cases in an area with sustained (year-round) transmission.[4]

In 19th century, cholera spread across the world from Ganges delta in India and killed millions of people in seven subsequent pandemics. More than 40% of cholera cases reported annually to the WHO are from Africa, more than 35% from Asia, and more than 20% from the Americas.[3] Researchers have estimated that every year, there are 1.3–4.0 million cases of cholera, and 21,000–143,000 deaths occurs worldwide due to the infection.[5] In year 2017, 34 countries reported 5,644 deaths and 122,7391 cases which came down to 2,990 deaths and 499,447 cases in the year 2018. As per WHO, number of cholera cases decreased globally (60% in 2018) and significant downward trend is continued; however, outbreaks are still ongoing in various countries.

Symptoms

Incubation period is 2 hours to 5 days. Most of the cases (around 75%) are asymptomatic and shed bacteria for 1–2 weeks in their feces. Those who are symptomatic, the majority have mild to moderate symptoms and few patients' presents with sudden onset explosive, painless, non-bilious "Rice water stools". It is not associated with blood and typically fishy, inoffensive odor. Stool of cholera patient contains higher concentration of sodium, potassium, and bicarbonate. It is usually associated with vomiting and severe dehydration even can be life threatening (*cholera gravis*).[3] It can lead to hypotensive shock, renal failure and that can be fatal in 50–70% cases, if dehydration is not addressed properly. Other clinical symptoms are parallel to volume contraction **(Table 1)**. Severity of illness depend on various factors including number of V. cholera bacteria ingested, neither exposed previously nor vaccinated, lack of passive immunity in new born (no breast feeding), pregnancy, immunocompromised conditions, malnourishment, reduced gastric acid production, and blood group O.

TABLE 1 Clinical features and treatment of cholera according to severity

Degree of dehydration	*Loss of TBW*	*Clinical findings*	*Treatment*		
			Fluid (Treatment of choice)	Adjunctive antibiotics (In moderate to severe cases)	Zinc Supplementation
Mild	<5%	Thirst	• ORS required in first 4 hours is equal to weight in kg multiplied by 75 in mL. • As for as daily requirement is concern, it should be given as much as patient can have desire to drink until signs of dehydration subsides	-	Recommended in children for 10 days • <6 month–10 mg/day • 6 months to 5 years–20 mg/day
Moderate	5–10%	Thirst, weakness, postural hypotension, tachycardia, decreased skin turgor, dry mouth/tongue, no tear		Drug of Choice • Azithromycin 1 gm single dose in adult (20 mg/kg in children) OR • Erythromycin-250 QID for 3 days • Second choice • Doxycycline in non-pregnant adult—300 mg single dose OR • Tetracycline (non-pregnant adult)—500 mg QID for 3 days • Third choice • Ciprofloxacin 500 BD in adult and 15 mg/kg BD in children for 3 days	
Severe	>10%	Unconsciousness, lethargy or floppiness, inability to drink, sunken eyes, weak or absent pulse, decreased urine output, hypotension or shock	IV Fluids • Ringer lactate (Preferred) or Normal saline • 100 mL/kg in first 3 hours (in first 6 hours for children <12 months old) to a total of 200 mL/kg in 24 hours • Further requirement of fluids depends on patient condition		

Cholera sicca, another form of cholera, presents with fluid accumulation in intestinal lumen, circulatory collapse and even death in absence of diarrhea. Fever is usually absent and muscle cramps are common due to electrolyte imbalance.[3]

Diagnosis

Diagnosis requires high index of clinical suspicion with severe acute watery diarrhea. Detection of V. cholerae from stool by dark field microscopy or isolation from stool culture on selective TSBS agar (thiosulfate citrate bile sucrose) or TTGA (taurocholate tellurite gelatin agar) remains the standard test. PCR method is also becoming available for diagnosis. Several rapid diagnostic tests (RDTs) such as immune chromatographic lateral flow devices (dipsticks), which detect the presence of the O1 or O139 antigen in rice water stool samples (sensitivity—95% and specificity—65–85%). RTDs can be performed by semi-skilled workers and it provides point of care diagnostic facility.[3]

Treatment

In severe cases, rapid rehydration (oral rehydration solution or intravenous fluid) is the primary treatment for cholera. About 90–95% of all cholera cases can be treated by oral fluid alone. Mild to moderate dehydration cases are treated by reduced osmolarity oral rehydration solution (WHO/UNICEF ORS). Composition of reduced osmolarity ORS is given in **Table 2**. Oral rehydration solution is prepared by dissolving one standard sachet in a 1 liter of clean water. In absence of ORS, mixture consisting of table salt (one level teaspoon) and sugar (6 level teaspoon) dissolved in 1 liter drinking water may be safely used until the proper solution is available. Severe cases need urgent hospitalization and intravenous fluid resuscitation (typically 10–20 mL/kg/hour). Ringer lactate is fluid of choice as it also corrects the acidosis along with electrolytes.[3] While transfusing the fluid regular monitoring for signs of dehydration including urine output, vitals, and chest examination are warranted. Though the rehydration therapy is the main stay of treatment but it neither reduces the duration of the disease nor excretion of bacteria in feces. Antibiotic are added in moderate to severe cases to decrease duration of illness, reduce volume needed for rehydration and hastens the clearance of the organism from the stool **(Table 1)**. Oral supplementation of Zinc in children of 6 months to 5 years, reduces the severity as well as prevent the recurrence of diarrhea.[3]

TABLE 2 Composition of reduced osmolarity ORS*

Constituent	*Concentration (mmol/L)*
Sodium	75
Potassium	20
Chloride	65
Citrate	10
Glucose, anhydrous	75
Total osmolarity	245

*Per sachet (to be added to 1 L of drinking water) contains: NaCl—2.6 gm; tri-sodium citrate dehydrate—2.9 gm; KCl—1.5 gm; Glucose (anhydrous)—13.5 gm

Prevention

Cholera can be prevented by access to potable drinking water, adequate sanitation, educating people regarding good hygiene practices (frequent hand washing with soap, proper disposal of excreta and avoiding consumption of food in unhygienic environment). Cholera vaccinations is a complimentary prevention and control measure **(Table 3)**.[3-8]

In 2018, WHO passed a global road map to reduce the cases of cholera by 90% till 2030 by focusing on three following strategies:[9]

- Early detection of cholera cases and contains outbreaks rapidly
- Prevention of cholera recurrence by targeting multisectoral approach
- An effective mechanism of coordination for technical support, resource mobilization, and partnership at different levels

Plague

Plague is caused by *Yersinia pestis*, Gram-negative coccobacilli, bipolar in appearance (closed safety pin), non-capsulated, facultative anaerobic, non-motile, organism of family Enterobacteriaceae. Human acquires infection via bites of infected rodents, fleas, or infected domestic cats, direct contact with infected human, animal tissue or body fluids, inhalation of infected respiratory droplets from a patient with pneumonic plague or respiratory secretions from infected animals. Consumption

TABLE 3 Oral cholera vaccine[3-8]

Oral killed cholera vaccines		*Oral live attenuated cholera vaccine*
Killed whole-cell monovalent vaccine with recombinant cholera toxin B subunit (WC-rBS)	Three bivalent whole-cell only vaccines (Biv WC), Based on sero-groups O1 and O139 of V. cholerae	**CVD 103-HgR (Vaxchora)**
• **Dukoral (First licensed in Sweden)**	**Schanchol** (licensed in India in 2009), **mORVAX** (licensed in Viet Nam in 1997 for use in endemic region in 2009 for domestic use), **Euvichol** (licensed in the Republic of Korea), Shanchol and Euvichol produced for International markets, available in single dose vials	Approved by USFDA in 2016 for travelers to cholera endemic area
• Vaccine contains a mixture of the recombinant B subunit (rBS) of cholera toxin (1 mg per dose) plus formalin/heat killed whole cell of V. cholera O1 (classical and El Tor, Inaba and Ogawa) • Because of toxin, vaccine provides some protection to Enterotoxigenic *E. coli* (ETEC) • To protect the toxin from gastric acid, it must be given with bicarbonate buffer	WC vaccines do not contain the bacterial toxin B subunit and therefore do not protect against ETEC	Engineered attenuated V. cholerae O1 classical Inaba strain CVD 103-HgR
• Vaccine is available in 3 mL, single dose vials together with the bicarbonates buffer (effervescent granules in sachets) • Vaccine and buffer should be dissolved in 150 mL of water in children >6 years and adult, in 75 mL for children <5 years • Intake of food and water should be avoided 1 hour before and after the vaccination	Euvichol and Shanchol: 1.5 mL glass vial with rubber stopper and aluminum lid	• There are two sachets, one contains lyophilized vaccine and another as buffer powder • Reconstitution is done by mixing the both sachet in 100 mL water and it should be consumed within 15 minutes of reconstitution in a single dose
Primary immunization • Not licensed for use in <2 years of age • Children 2–5 years of age, 3 oral doses given 7 days—6 weeks apart • Two doses are recommended in adults and children >6 years. Interval between the dose should be at least 7 days but not >6 weeks • If second dose is not administered within 6 weeks after the first dose, whole schedule should be repeated	Two doses are given at an interval of 14 days in persons with age ≥1 year	Approved for the use in 18–64 years of age
Booster dose • **Children 2–5 years—**booster dose every 6 month of primary immunization. If booster dose is not administered in time, whole schedule should be repeated • **Children age >6 years and adults—**booster dose every 2 years. If booster dose is not administered in time, whole schedule should be repeated	No recommendation regarding booster dose exists	No recommendation regarding timing and use of booster is currently available, probably because it provides long-term immunity after a single oral dose
Protection • Provides 60–85% protection for the first few months • 60% protection over 5 years among recipient of all age • 40% protection among children ≤5 years of age		Between 80–90% efficacious against severe cholera at 10 and 90 days after vaccination respectively
• If cold chain (2–8°C) is maintained. Self-life is 3 years. It stable only for 1 month at 37°C	Self-life is 2 years at maintenance of cold chain (2–8°C) and remains stable for 14 days at 42°C	Cold chain temperature (–25 to –15°C)
• Can be safely given in among populations with high rate of HIV infection and in pregnancy		Safety in pregnancy is not established

of contaminated food and laboratory exposure are also the source of infection. During bioterrorist attack, primary pneumonic plague caused by aerosolized *Y. pestis* bacteria in non-endemic areas is a public health problem.[10]

Epidemiology

- Three major plague pandemics have been recorded in human history: the "Plague of Justinian" in the 6th century, again in the 14th century (known as the "Black Death," which killed up to one-third of the European population or an estimated 17–28 million people, and at the end of 19th century following the spread of infection from China.
- Plague is prevalent in all part of the world except, Oceania.
- Peru, Madagascar, and the Democratic Republic of Congo are the most endemic countries.
- Plague does occur in Asia, but is restricted to breeders and hunters since the reservoir consists mainly of gerbils in the steppe and marmots in the mountains.
- During epidemic season, cases of bubonic plague are reported every year in Madagascar.

Symptoms

Symptoms of plague usually develop after an incubation period of 1–7 days. Initial symptoms are nonspecific including high grade fever, headache, sore throat, body ache and generalized weakness. Specific symptoms depend upon types of plague.[11]

Bubonic Plague: Most common form (80–95% cases) of plague. Apart from nonspecific symptoms, there is rapidly progressive, painful lymphadenitis (known as "bubo"). The common sites for lymphadenitis are regional lymph nodes, and near the site of flea bite. Suppuration over buboes can occur and it is differentiated from other conditions by absence of cellulitis and ascending lymphangitis. Case fatality rate in untreated bubonic plague is higher (50–90%) in comparison to treated cases (10–20%), mostly because of disseminated infection. In advanced stage it causes secondary pneumonic plague and meningitis due to spread to the lungs and brain, respectively. Bubonic plague patients can presents with abdominal discomfort.

Pneumonic Plague: Depending on the type of exposure it is of two types; Primary pneumonic plague—caused by the direct inhalation of bacteria into the lungs. It manifests earlier, having incubation period of few hours to few days. It starts with non-specific symptoms, then progresses to dyspnea, chest pain, cough, sputum production, hemoptysis, tachypnea, and signs of hypoxemia and toxemia. Secondary pneumonic plague—It is more common form and is caused by hematogenous spread of bacteria to the lungs from a bubo or other source. Ten to fifteen percent of bubonic plague patients develop secondary pneumonic plague, if treatment of bubonic plague is delayed. Diffuse alveolar infiltrates of chest X-ray, and interstitial pneumonitis on computed tomography are typical of pneumonic plague. Untreated pneumonic plague is almost always fatal, and mortality is very high.

Septicemic Plague: It occurs in 10–20% of cases in advance stages of the disease. Patient is febrile having gastrointestinal symptoms and present as Gram-negative septicemia (hypotension, shock, disseminated intravascular coagulation, and multiorgan failure). Risk factors for septicemic plague include, age more than 40 years, diabetes mellitus and hemochromatosis. Their diagnosis is difficult because it occur without any preceding bubo.

Other Types

Meningitis: It can occur as primary manifestation as result of occult bacteremia or associated with bubonic, pneumonic, septicemia plague. It resembles to bacterial meningitis by symptoms and CSF examination (low glucose, increased protein with neutrophilic pleocytosis).

Pharyngitis and Tonsillitis: Manifest with nonspecific symptoms along with anterior cervical lymphadenitis. Patient with no symptoms can act as carrier for bubonic plague cases. In approximately 14% cases, involvement of GIT and urinary tract is also seen. Some patients may present with multiple organ failure and die without diagnosis, if symptoms are non-specific without bubo and there is no outbreak of plague in that geographical area.[10,11]

Laboratory Investigations

In plague endemic areas, neutrophilic leukocytosis (10,000–100,000/μL) with left shift, normal or low-normal platelets and symptoms (fever, unexplained regional lymphadenitis, and hypotension) with known contact with dead rodents is diagnostic clue. Blood culture is positive

in 27–96% cases. *Y. pestis* can be cultured from pus from bubo in bubonic plague, from sputum or broncoalveolar lavage sample in pneumonic plague, from blood in septicemic plague and from CSF in meningitis. Peripheral blood smears, microscopic aspirate of bubo may show rod shaped organism with Wright-Giemsa stain and typical bipolar staining as "closed safety pin" on Wayson's stain. Serologic testing of single titer of >1:16 of F-1 antigen of *Y. pestis* by passive hemagglutination test is diagnostic. Rapid diagnostic test can detect F-1 antigen of *Y. pestis* (0.5 ng/mL) within 15 minutes in serum and sputum in field testing.[8,9] WHO case definition is given in **Table 4**.[10]

Plague Outbreaks Managements[12]

- *Find out the suspected case:* During epidemic situation diagnosis of suspected case is based on clinical ground (acute febrile illness with painful lymphadenopathy) and in other situation rat falls (dead rats) provide a useful warning of a possible outbreak. Suspected case should be confirmed bacteriologically.
- *Notification* of each and every human or rodent plague case.
- *Isolation:* Isolation of suspected pneumonic plague patients is recommended until either the pneumonia is excluded or patient is treated for 48 hours with effective drugs, because they can spread the disease by aerosol generation.
- Maximum infectivity is in final stage of disease when patients are coughing sputum with plenty of blood or pus. Though simple cotton mask or surgical masks usually provides barrier protection against droplets but WHO recommends personal protective equipment's for potential aerosol generating procedures and should include an N-95 face mask, a gown, gloves, and a face shield or goggle.[8]
- *Appropriate antibiotic treatment of cases:* It should be initiated within 24 hours, ideally after specimen for culture are obtained. It is continued for 10–14 days or a course can be continued until 2 days after fever subsided **(Table 5)**.[10,11,13]
- *Surveillance:* Identification and monitoring of individuals having history of close contact.
- *Disinfection:* Disinfection by hand washing with soap and water, use of alcohol based hand rubs or house made disinfectant (10% diluted bleach).
- *Ensure safe burial practices:* Proper disposal of dead body of a suspected pneumonic plague patient should be ensured.

TABLE 4 WHO case definition of plague[10]

Suspected case	Compatible clinical presentation *and* consistent epidemiologic features, such as exposure to infected animals or humans and/or evidence of flea bites and/or residence in or travel to a known endemic focus within the previous 10 days
Presumptive case	Meeting the definition of a suspected case *plus* *Putative new or reemerging focus:* ≥2 of the following tests positive • Microscopy: Gram-negative coccobacilli in material from bubo, blood, or sputum; bipolar appearance of Wayson or Wright-Giemsa staining • F1 antigen detected in bubo aspirate, blood, or sputum • A single anti-F1 serology without evidence of previous *Yersinia pestis* infection or immunization • PCR detection of *Y. pestis* in bubo aspirate, blood, or sputum *Known endemic focus:* ≥1 of the following tests positive • Microscopic evidence of Gram-negative or bipolar (Wayson, Wright-Giemsa) coccobacilli from bubo, blood, or sputum • A single anti-F1 serology without evidence of previous plague infection or immunization • F1 antigen detected in bubo aspirate, blood, or sputum
Confirmed case	Meeting the definition of a suspected case *plus* • Identification of an isolate from a clinical sample as *Y. pestis* (colonial morphology and two of the following four tests positive: phage lysis of cultures at 20–25°C and 37°C; F1 antigen detection; PCR; *Y. pestis* biochemical profile) or • A fourfold rise in anti-F1 titer in paired serum samples or • In endemic areas when no other confirmatory test can be performed, a positive rapid diagnostic test with immunochromatography to detect F1 antigen

TABLE 5 Treatment of plague cases

Drugs	*Dose*
Streptomycin (Preferred-FDA approved)	30 mg/kg/day (up to total dose 2 gm) in two divided doses intramuscular
Gentamicin	2 mg/kg loading dose followed by 1.7 mg/kg every 8 hourly intravenously (in children 2.5 mg/kg IV every 8 hours)
Doxycycline	200 mg loading dose on first day followed by 100 mg every 12 hourly orally or intravenously in adult and child ≥45 kg, child <45 kg—2.2 mg/kg (maximum, 100 mg/dose) IV every 12 hours
Tetracycline	Oral 2 gm loading dose followed by 2 gm/day in four divided doses (not indicated in children <7 years of age)
Levofloxacin	Adult and child ≥50 kg—500 mg OD oral or intravenously, child <50 kg and ≥6 months of age—16 mg/kg (maximum 250 mg/dose) oral or intravenously every 12 hours
Ciprofloxacin	400 mg IV every 12 hours or 500 mg orally every 12 hours in adult In children—15 mg/kg IV every 12 hours or 20 mg/kg orally every 12 hours
Chloramphenicol	In adult and child >2 years—100 mg/kg (maximum, 4 gm) in four divided doses (oral or intravenous), very useful in plague meningitis because of its ability to penetrate the blood brain barrier

- *Protect health workers:* Training of health workers about infection prevention and control measures. Workers having history of close contact with pneumonic plague patients should take 7 days chemoprophylaxis. Disinfection, distancing, and PPE should be used appropriately.

Prevention

Prophylaxis: Post-exposure prophylaxis is recommended to individuals with unprotected close contact (face to face or 1–2 meter) with suspected or confirmed pneumonic plague and family members of a bubonic plague patient. Oral doxycycline 100 mg twice daily for 7 days or oral levofloxacin 500 mg once daily for 10 days are used for this purpose. In pregnancy double strength tablet of co-trimoxazole twice daily and in children trimethoprim 4 mg/kg twice daily has been used safely.[11]

Vaccination: A whole cell killed vaccine given at least a week before anticipated outbreak as its immunity starts after 5–7 days of first dose vaccine. Two subcutaneous doses of 0.5 mL and 1 mL, at an interval of 7–14 days are given. Booster dose is recommended 6-monthly for persons at continuing risk of infection as its immunity persists for 6 months. Vaccination is also recommended for travelers to endemic areas and those having increased risk of disease.

Control of Fleas: To break the chain of transmission (rodent->flea->man) proper application of insecticides (dust containing DDT 2%, BHC 2%, Malathion 5%, and Carbaryls 2%) are used. Rat borrows should be insufflated with the insecticidal dust. This must precede or coincide with anti-rodent measures.

Control of Rodents: Control of rodents is an important plague preventive measure. It improves with improvement of general sanitation, improvement of housing and quality of life.[14]

Conclusion

Though the number of cholera cases has been decreased in India, but the social, epidemiological, and ecological conditions in remote areas continue to favor the occurrence. World Health Organization has planned to reduce the cholera-related deaths by 90% till 2030. They focused on three important strategies; early detection of cholera cases and rapid response to contain outbreaks, prevention of recurrence by targeted multi-sectoral approach, and an effective mechanism of coordination for technical support, resource mobilization, and partnership at different levels. Like cholera cases, a number of plague cases are also reduced due to good availability of effective drugs, improvement of sanitation, improvement of housing and quality of life. Primary pneumonic plague caused by aerosolized *Y. pestis* is having high fatality rate. As *Y. pestis* has the capacity to infection through aerosol, it fits into the category of a potential agent of bioterrorism. Its outbreak should be identified as soon as possible and appropriate steps should be followed for its management.

CHAPTER

166 Cryptococcal Disease: A Review

VK Sashindran, Rajneesh Thakur

Abstract

Cryptococcosis is an opportunistic mycosis which was uncommonly identified before the HIV/AIDS pandemic. It is responsible for high mortality among people living with HIV/AIDS (PLHA) and also among other non-HIV immunocompromised people. Cryptococcus is one of the four fungal species accounting for almost 90% of fungal infection-related deaths in the world, the other three being Candida, Aspergillus, and Pneumocystis. *C. neoformans* is found in high concentrations in bird guano and *C. gattii* in decaying vegetation especially that of the Red River gum trees (*Eucalyptus camaldulensis*). The preferred sites of infection by *C. neoformans* and *C. gattii* are lungs and central nervous system. In an immunocompromised person, cryptococcus can disseminate widely involving skin, bone/joints, prostate, and eyes. The most severe clinical manifestation of cryptococcal infection is meningoencephalitis. There are three mechanisms by which infection can spread from the lungs to brain: one, by disruption of vascular integrity leading to passive hematogenous transport; two, by endothelial cells phagocytosing spores from blood stream and later expulsing them to circulation; and three, by movement of the yeasts from the bloodstream into CNS within macrophages using the Trojan Horse mechanism. Diagnosis of cryptococcosis is based on direct visualization of the yeast, histopathology of tissue specimens, culture, and detection of cryptococcal antigen (CrAg). Cryptococcal meningitis (CM) in PLHA is associated with high mortality. Timely diagnosis and optimal therapy are both required to prevent deaths. Treatment of CM is divided into three phases: induction, consolidation, and maintenance. Three drugs have been traditionally used in the treatment of CM: amphotericin B (AmB) or liposomal amphotericin (L-AmB), fluconazole (FLU), and flucytosine (5FC). A number of strategies have been evaluated and implemented to prevent CM in PLHA with low CD4 cell counts in resource-limited settings like starting preemptive fluconazole therapy in CrAg-positive patients with low CD4 cell count.

Introduction

Cryptococcosis is an opportunistic mycosis which was uncommonly identified before the HIV/AIDS pandemic. It is responsible for high mortality among people living with HIV/AIDS (PLHA) and also among other non-HIV immunocompromised people. The ability to detect cryptococcal antigen (CrAg) has enabled us to estimate the global prevalence of the infection. Cryptococcal antigenemia is prevalent in about 6% (95% confidence interval 5.8–6.2%) of PLHA with CD4 cell count ≤100 cells/μL (severely immunocompromised). In absolute numbers this is a staggering 2,78,000 people. Of these, 2,23,000 developed cryptococcal meningitis (CM) in 2014 and 73% of these cases occurred in sub-Saharan Africa (SSA). It is estimated that 1,81,000 PLHA die of CM every year with 75% of these deaths occurring in SSA.[1] About 50% of PLHA with CM die within a year of contracting infection mainly due to unsuccessful/inadequate treatment.[2] AIDS-related CM causes 20–25% of AIDS-related deaths every year.[3] Cryptococcosis has been increasingly recognized in non-HIV immunocompromised people. In countries with good health-care systems with equitable access to timely care,

25% of all CM-related hospitalizations and deaths occur in non-HIV patients. In the US, CM is the commonest cause of non-viral meningitis now.[4] Different serotypes of *Cryptococcus neoformans* have been associated with CM in PLHA and those without HIV/AIDS. However, the boundaries are getting increasingly blurred now.

Cryptococcus is one of the four fungal species accounting for almost 90% of fungal infection related deaths in the world, the other three being *Candida, Aspergillus,* and *Pneumocystis.*[5] There are 37 species of Cryptococcus in the genus Filobasidiella of the phylum Basidiomycota. Most human infections can be attributed to *C. neoformans* or *Cryptococcus gatti.*[6] Based on the capsular polysaccharide, glucuronoxylomannan (GXM), the yeast form of *Cryptococcus neoformans* is classified into four serotypes, A through D. Serotypes A and D of *C. neoformans* are responsible for most human infections.[7] *C. neoformans var. grubii* (serotype A) accounts for 90% of human infections. It is worldwide in distribution and is especially associated with CM in people with CD4+ T cell deficiency (mainly HIV-infected and also in transplant recipients and those with rheumatological disorders requiring immunomodulatory therapy).[8,9] *C. neoformans var. neoformans* (serotype D) is also global in distribution but is mostly identified amongst human cases in Europe. *Cryptococcus gattii* (serotypes B and C) was for long thought to be a tropical/subtropical fungus but it has now been discovered in high temperate zones like Northwestern US, Vancouver, and other parts of British Columbia in Canada. *C. gattii* causes disease among those with "normal" immune system. It is now also being recognized as a pathogen in PLHA, and people with other immunodeficiencies especially those with autoantibodies against granulocyte-monocyte colony stimulation factor (GM-CSF).[10]

CM in both HIV-infected and HIV-negative with immune deficiencies is plagued by IRIS which causes considerable morbidity and mortality. IRIS as a disease entity came into its own only in the course of the HIV pandemic when highly active antiretroviral therapy was introduced. About 10–25% PLHA without a known opportunistic infection (OI) starting ART develop IRIS.[11,12] Most IRIS events occur within the first 2–3 months of initiating ART. But delayed IRIS has been reported with cryptococcal and CMV infections and these can occur many years later. Approximately 25% of CM patients receiving ART and antifungal therapy will develop IRIS and mortality associated with Cryptococcal IRIS (cIRIS) varies from 0% to 67%.[13-16] In HIV-negative patients with CM, IRIS has been reported with reversal of iatrogenic immunosuppression especially with TNF-α inhibitor therapy.[17] IRIS has triggered a deep study of the immunobiology of HIV-associated OIs and new insights have opened up new immunomodulatory interventions.

Pathobiology

C. neoformans is found in high concentrations in bird guano, especially in the droppings of pigeons and chicken. *C. gattii* is found in decaying vegetation especially that of the Red River gum trees (*Eucalyptus camaldulensis*).[7,18] Cryptococcus survives in the environment as a yeast (sexual form), producing hyphae with terminal basidiospores which may break off and then become aerosolized. Since their average diameter is 3 microns, they are small enough to travel right up to the alveoli. In most hosts, the infection is asymptomatic. A seroprevalence study done among children in New York revealed that 70% had antibodies against cryptococcal antigens. It seems that asymptomatic colonization of airways and latent infection of lungs and airways maybe common.[19,20] Autopsy studies have shown granulomatous lesions in lung parenchyma and sub-pleural nodules containing yeast forms.[21,22] Just as in tuberculosis (TB), a robust immune system keeps the infection from manifesting as clinical disease. The most severe clinical manifestation of cryptococcal infection is meningoencephalitis. There are three mechanisms by which infection can spread from the lungs to brain: one, by disrupting vascular integrity leading to passive integrity leading to passive hematogenous transport, two, by endothelial cells phagocytosing spores from blood stream and later expulsing them to circulation, and three, by movement of the yeasts from the bloodstream into CNS within macrophages using the Trojan Horse mechanism. On crossing the blood brain barrier, the fungal cells are released by vomocytosis. Just as in TB, hematogenous spread can occur during primary infection or due to reactivation when immunity is lowered. Severe disease can develop many years after primary infection.[3,23] Pirofski and Casadevall proposed a mechanism which allows the host to tolerate infection for long periods without manifesting disease. They termed it the disease tolerance and damage response framework (DRF). This system mainly evolved to mitigate and avoid damage to the lungs and brain.[24,25]

The DRF is based on the interplay of microbial and host factors that may either cause disease or produce a net benefit to the host. The highly dynamic and complex interaction between the fungal virulence factors and host's immune response can result in a variety of outcomes ranging from debilitating disease to colonization, latency and commensalism. *Cryptococcus sp*. have an array of mechanisms that enable them to survive, proliferate, and disseminate in a mammalian host. The fungus produces numerous enzymes which cause damage at a molecular level. These include proteases, phospholipase, urease, and nuclease. At a cellular level, cryptococcus can damage host cells by interfering with phagolysosome maturation, increasing permeability of phagosome membrane, interfering with organelle function, causing cytoskeletal alterations, cytoplasmic vacuolation and both lytic and non-lytic exocytosis. The first step in the protective response against cryptococcal infection is the production of proinflammatory cytokines, then followed by generation of an effective Th1/Th17 adaptive immune response and classical activation (M1 type) of macrophages. All these processes lead to fungal clearance. A robust response commensurate with fungal burden can lead to excessive tissue damage. A good example of this is cryptococcal IRIS. In immunocompromised patients, both inflammatory response and immune function are compromised enabling unbridled fungal replication resulting in high fungal burden. The ideal scenario is one where the host resistance mechanisms are balanced by the host tolerance mechanism. This leads to minimal/or no clinical disease and probably fungal latency. The host resistance mechanisms, namely proinflammatory cytokine production, activation of dendritic cells (DCs), generation effective Th1/Th17 response, and M1 type macrophage polarization are balanced by cryptococcal and host disease tolerance mechanisms.

Cryptococcus-associated disease tolerance strategies can be grouped as metabolic adaptions to physiological conditions in the host, evasion, and interference with innate and adaptive immune responses. Cryptococcus can activate gene expression that enables it to survive in human cells at 37°C and also in nutrient-poor environments like the CNS. The fungus van produce meaning using host catecholamines. This reaction is mediated by fungal phenoloxidase. It is this ability to use catecholamines that gains the fungus a niche in the CNS. The capsule serves as a principal defense against innate immune mechanisms. The capsule conceals cell wall carbohydrate antigenic epitopes, inhibits antibody binding to fungal cell wall, and activates and depletes complement factors. The capsule modulates cytokine production and suppresses T cell proliferation. It also induces apoptosis of host cells. During active infection, cryptococcal cell capsule can enlarge leading to formation of giant "Titan" cells. The size of these cells varies from 50 to 100 microns and this large size inhibits phagocytosis. Fungal cells can release their capsular glucuronoxylomannan (GXN) and this causes shedding of L-selectin from neutrophils. Loss of L-selectin inhibits neutrophilic migration, endothelial adhesion, and extravasation into tissues. Other capsular factors can interfere with maturation and activation of neutrophils, DCs, and macrophages. The yeast cells secrete a number of enzymes that enable them to survive in the harsh environment of the phagolysosome. These are mainly involved in nitric oxide detoxification and neutralizing oxidative stress. Other enzymes and substances that enable the fungus to survive intracellularly include urease, phospholipase B1, laccase, melanin, and heat shock protein70 homolog Ssal 1. The ability to escape from host cell without causing its lysis is the most important mechanism for persistence of cryptococcus in host tissue. This non-lytic escape from phagocytes is also called vomocytosis. This enables the organism to prevent the inflammatory response that would be associated with host cell death. *Cryptococcus sp.* are able to swing cellular immune response toward a non-protective Th2 response by two main mechanisms: cryptococcal urease recruits immature DCs to lymphoid tissue in the lungs, and host chiotriosidase cleaves fungal chitin and triggers CD11 b^+ conventional DCs to undergo Th2 differentiation. *C. neoformans* secretes prostaglandin E2 (PGE2) that suppresses Th17 differentiation. A strong Th17 response is critical for a sterilizing immune response. In fact, this process facilitates latent infection.

The host immune response to cryptococcal infection that leads to disease tolerance is due to T regulatory (Treg) cells, IL-10 signaling, DC response, role of tryptophan pathway and T cell exhaustion. Tregs are involved in the production of anti-inflammatory cytokines like IL-10, and transforming growth factor-β. Severe pathology occurs when there are mutations in Treg-associated transcription factor fork head box protein P3 (FOXP3). CrAg-specific

Tregs can colocalize with Th2 effector cells in infected lungs and thereby limit inflammatory damage. IL-10 is an anti-inflammatory cytokine that is secreted by Tregs and DCs. It inhibits production of IL-1, Il-6, IL-23, IFN-γ, TNF-α in fungal infections. In PLHA with cryptococcal infection, high levels of IL-10 correlate with fungemia and dissemination. Therefore, IL-10 levels can be a surrogate marker of progressive or persistent cryptococcal infection. Among the antigen presenting cells, DCs are the ones that can present cryptococcal antigens most efficiently to T cells. Development of a Th1/Th17 immune response greatly depends on classical activation of monocyte-derived DCs (MoDCs). As mentioned earlier capsular characteristics can affect DC activation. The local cytokine and chemokine milieu also affects their activation. Immunomodulatary DCs have been known to evolve in the course of infection and they can lead to Th1/Th17 suppression, reduced macrophage activation and impaired fungal clearance. Indoleamine 2,3-dioxygenase (IDO) is an enzyme involved in tryptophan metabolism. It plays an important role in balancing the activity of Tregs and Th1/Th17 cells. Expression of IDO by DCs leads to a tolerogenic phenotype in experimental models. The same has not been demonstrated in humans with cryptococcal infection. Its significance is still to be explored. A state of chronic immune activation can lead to T cell exhaustion. One of the mechanisms that promotes this is the upregulation of cytotoxic T lymphocyte-associated protein-4 (CTLA-4). T cell activation and function depend on a double signal: the binding of antigen presented by MHC to T cell receptor and binding of CD80 and CD86 on anitigen-presenting cell to CD-28 on T cell. CTLA-4 binds to CD80 and CD86 and thus blocks CD-28. In the absence of this co-stimulatory signal T cells become anergic. In murine cryptococcal infection models, upregulation of CTLA-4 has been demonstrated. Sustained expression of programmed cell death protein-1 (PD-1) on CD4 T cells, DCs and macrophages is also associated with persistence of infection. Modulation of levels of CTLA-4 and PD-1 could be strategies for treating cryptococcal IRIS (cIRIS).[4,26,27]

Cryptococcal IRIS

T cell depletion in HIV infection severely compromises adaptive immune response and this can lead to unbridled fungal dissemination to the meninges. Immune restitution with ART predisposes patients with CM to IRIS. Evolution of cIRIS goes through three stages: pre-ART paucity of inflammatory response, innate cell activation, and immune dysregulation. During the pre-ART phase both innate and adaptive immune responses are compromised. Migration of neutrophils into the meninges and their fungistatic activity is compromised. Poor antigenic clearance and risk for IRIS are linked to decreased levels of IL-6, IL-8 and TNF-α (innate inflammatory cytokines) and IFN-γ (adaptive inflammatory cytokine). Risk of cIRIS increases with higher expression of CCL2 and CCL3. Natural killer cells with increased expression of CXCR3 and CX3CR1 also participate in the initial response to cryptococcal infection in CNS. When ART is started, T cell immunity takes some time to develop. In this interim, antigenic burden causes a buildup of proinflammatory signaling by antigen presenting cells. This is demonstrated by increased IL-6 and CRP levels in weeks preceding development of IRIS. When ART associated immune restitution reaches a critical level, a powerful Th1 response and cytokine storm herald the onset of IRIS. Phagocytic killing of intracellular pathogens is also defective due to absence of IFN-γ signaling from CD4 T cells in the pre-ART phase. But a buildup of partially primed myeloid cells occurs in the CNS during this time. When CD4+ cell reconstitution occurs with ART, activation of these myeloid cells with production of proinflammatory cytokines occurs. Myeloid cells that accumulate in CNS prior to IRIS are mainly proinflammatory intermediate monocytes. The final phase of IRIS is marked by immune dysregulation. In a normal response to a fungal infection classical activation of monocytes leads to increased fungal kill. However, this does not occur in immunocompromised people. Here the buildup is of intermediate monocytes with increased expression of programmed death ligand-1 (PD-L1). Their activity results in a powerful inflammatory response and less efficient fungal kill. Lymphopenia associated with HIV infection results in a homeostatic response to cryptococcal infection regulated by IL-6 and characterized by proliferation of naive T cells which resemble effector memory T cells. Later, during IRIS, these cells ramp up secretion of IFN-γ and push the immune activity toward a powerful Th1 response. Immune restitution also results in a robust increase of highly-differentiated memory $CD4^+$ T cells with no inhibitory control. The net result is severe inflammation, tissue destruction, and functional impairment.[28-32]

Clinical Features

The preferred sites of infection by *C. neoformans* and *C. gattii* are lungs and CNS. In an immunocompromised person, cryptococcus can disseminate widely. They can involve skin, bone/joints, prostate, and eyes. A retrospective study of cryptococcosis in Denver, Colorado, USA, showed that patients with cryptococcosis had, apart from features of CM, respiratory symptoms, hyponatremia, prior lung disease, or history of corticosteroid therapy.[33]

Respiratory System

The main route of entry of cryptococcus is through the respiratory tract. Clinical manifestations are varied and depend on immune status. In an immunoscompetent person it can be just a symptomless colonization of the airways or a pulmonary nodule detectable only on a radiograph. In the immunocompetent, the infection is accidentally discovered on imaging in up to one-third of the cases. The radiological manifestation maybe a solitary nodule or multiple nodules without calcification or pulmonary infiltrates. Hilar lymphadenopathy, pleural effusion, and cavitary lesions are also described. The presentation is more florid and dangerous when the immune system is compromised. In this setting the manifestation can be a severe pneumonia or a life-threatening acute respiratory distress syndrome (ARDS).[34,35] Isolated pulmonary cryptococcosis can occur in the absence of CNS involvement in the immunocompromised. In the presence of cryptococcal meningoencephalitis, pulmonary involvement is seen in 10–55% of PLHA. But here, neurological symptoms usually dominate.[35] A Chinese study in HIV-negative subjects reported slightly different findings. In this study, 49.3% of the subjects with CM had evidence of pulmonary cryptococcosis. They usually presented with fever, cough, expectoration, and lower limb edema rather than with CNS symptoms. Subjects with lung infection were also younger (<30 years) than those who did not have lung infection.[36] Serum CrAg is usually negative in truly isolated pulmonary cryptococcosis. Whenever cryptococcus is isolated from the lungs or other sterile body sites in an immunocompromised individual, a lumbar puncture to exclude CNS disease is recommended regardless of the patient's symptoms or serum CrAg titer results. The only exception for a diagnostic LP would be an immunocompetent person without CNS symptoms. Here, infection can be presumed to be limited to the lungs.

Central Nervous System

The presentation of CM is usually subacute with symptoms developing over weeks. Clinical symptomatology may include fever, lassitude, headache, altered sensorium, and focal deficits like cranial neuropathies. In severely immunocompromised patients, fungal burden in the CSF can be very high (>1 million yeast cells/mL of SF). In these patients presentation is usually acute and features of raised intracranial pressure maybe present. Their CSF will also show high CrAg titers. A study from SSA showed that seizures occurred at presentation in 28% (231/821) HIV positive subjects with CM and 15.5% developed seizures during the course of illness. Seizures at presentation were associated with lower GCS scores, lower CD4 cell counts increased CSF opening pressures when compared to HIV+ patients with CM but without seizures. CSF fungal burden was higher in those with seizures at presentation than in those developing seizures during course of illness.[37] *C. gattii* infections can cause cryptococcomas in the brain and can also cause obstructive hydrocephalus. In the lungs also it can cause mass lesions. Focal neurological deficits and cranial neuropathies due to cryptococcomas are common manifestations. These patients respond poorly to antifungal therapy and decompressive surgery may be required to relieve raised ICP. *C. neoformans* is less likely to cause such lesions.[38-40]

In the absence of a definite microbiological diagnosis, TB meningitis (TBM) is the commonest differential diagnosis for CM. In both, fever, headache, and vomiting are common presenting complaints. Altered mental status is more common in CM than in TBM in HIV-negative individuals. Altered vision and hearing are commoner in CM and cough is more likely in TBM. CM is associated with corticosteroid use, pulmonary infection, hepatobiliary disease and diabetes. Those with TBM are likely to have TB elsewhere outside CNS or disseminated TB.[36,41] In the Denver study, risk factors associated with CM were HIV infection, prior use of corticosteroids, malignancy, transplant status, lung disease, and active smoking.[33]

In HIV negative children with CM, fever, nausea, vomiting, and headache are the commonest symptoms. Meningeal signs, altered consciousness, and fundal changes are common findings. CSF opening pressure is

raised in most. Involvement of other organs is common with the lungs being the commonest.[42]

Among the elderly, those older than 65 years are more vulnerable to developing CM. There is a female preponderance and altered consciousness and cerebral infarction are more common than in the young.[36]

Skin

After pulmonary and CNS involvement, cutaneous manifestations are the commonest presentation of cryptococcosis. Usually the lesions are non-specific and similar to those seen in other infections. Primary cryptococcosis is uncommon and is due to direct inoculation of the fungus into the skin by injury or laboratory accidents. The lesions are single and occur at the site of innoculation. They can present as whitlow, papule, nodule, ulcerated lesion or cellulitis. In immunocompromised patients, dermal cryptococcosis is secondary to disseminated infection. Here the lesions tend to be multiple. Lesions often resemble those of molluscum contagiosum. They are flesh-colored papules/nodules with central umbilications. Pustules, acneiform lesions, abscesses, cellulitis, and gralulomata have all been described. Regional lymphadenopathy and discharging sinuses may occur. Skin biopsy and cultures are required to culture and identify the fungus. Solid organ transplant recipients on tacrolimus are prone to cutaneous cryptococcosis and osteoarticular involvement. Tacrolimus inhibits a protein required for cryptococcal growth at 37°C. It acts by interfering with calcineurin signaling pathway in the fungus. However, at lower temperatures (<24°C), this inhibitory activity is lost making patients on calcineurin inhibitors prone to cryptococcal infection.[43,44]

Immune Reconstitution Inflammatory Syndrome

Antiretroviral therapy leads to immune restitution in PLHA. When this process occurs in a severely immunocompromised person, it leads to a rebound of pathogen-specific immunity. This manifests as a clinical entity called immune reconstitution inflammatory syndrome. When there is a "paradoxical" deterioration of a known OI or appearance of the OI in new sites or "recurrence" of OI while on ART, it is called paradoxical IRIS. In unmasking IRIS, ART leads to an accelerated manifestation of an occult infection. In the context of cryptococcosis another entity is described and that is post-infectious inflammatory response syndrome which is a clinical deterioration in a previously healthy individuals. All of them also have an exaggerated anti-cryptococcal immune response. Cryptococcal IRIS causes severe morbidity and is associated with a high mortality.[14,45-47] Cryptococcal IRIS is a diagnosis of exclusion. Progressive infection secondary to suboptimal antifungal therapy, primary antifungal drug resistance or persistent immune deficits, other coexistent OIs (like TB), malignancy, and drug toxicity need to be excluded. Risk factors for IRIS include severe immune deficiency at baseline with rapid immune restitution with ART, high fungal burden at baseline and ineffective immune repose in the host during initial infection. The commonest time period for cIRIS is within first 3 months of starting ART. Classical features of cIRIS in HIV infected patients with low CD4 cell counts include little or no meningeal irritation despite high cryptococcal load, extremely high serum and CSF CrAg tiires, muted inflammatory response in CSF manifesting as low CSF WBC count, and high yeast burden on CSF microscopy and ease in culturing yeast from CSF or serum.[48]

Laboratory Diagnosis

Diagnosis of cryptococcosis is based on direct visualization of the yeast, histopathology of tissue specimens, culture, and detection of CrAg. Molecular methods, although available and extensively used for research purposes, are not used currently in routine clinical practice.

Direct visualization is traditionally by India ink staining. The fungus appears as a globular, encapsulated yeast cells which may or may not be budding. The yeast cell size varies from 5 to 20 μm in diameter. India ink staining is the most rapid method for diagnosis of CM and has been the method in vogue in low-income countries for a long time. The sensitivity is only 80–85% for AIDS-related CM, meaning that 1 in 7 diagnoses will be missed. Sensitivity falls to about 40% in patients with low fungal burden (<1,000 CFUs/mL of CSF). Detection of yeasts is operator dependent. Lysed WBCs can be mistaken for fungal elements.[49,50]

Histopathology

Cryptococcus can be detected from a variety of tissue samples like lungs, brain, skin, bone marrow, lymph nodes,

and other organs.[51] Histopathology is more sensitive than India ink staining. Special staining techniques are available to visualize different fungal elements. Mucicarmine, Alcian Blue, and Periodic-acid-Schiff stain the fungal polysaccharide capsule. The melanin in the yeast cell wall is delineated by Fontana–Masson stain. Gomorri-methenamine-silver stain also enables visualization of the cell wall. Calcofluor binds to fungal chitin.[52,53]

Culture

Cryptococcus can be cultured readily using routine fungal or bacterial culture media. CSF, sputum, and skin biopsy sample all yield the fungus easily. The sensitivity of CSF and blood cultures in adult PLHA with CM is 90% and 50–70% respectively. Volume of inoculum determines the culture sensitivity. It is 82% for 10 μL of CSF and 94% for 100 μL.[54,55] Fungal culture remains relevant even today for clinical, therapeutic, and research reasons. For the clinician, cultures help confirm clearance of the yeast from CSF after induction therapy, and to distinguish between relapse of CM and paradoxical IRIS. Serial cultures have a log 10-linear clearance. This enables computation of early fungicidal activity (EFA). EFA is a useful marker of drug regimen potency and is also used as an efficacy endpoint in phase II trials. Quantitative cultures allow measurement of fungal colony forming units (CFUs) from CSF. The disadvantages of using culture for diagnosis are that results become available only in 3–7 days, and in a setting of low fungal burden, cultures can be negative.[56]

Serology

Serological tests to detect cryptococcal capsular antigen has made diagnosis of cryptococcal infection easy and fast. CrAg has been detected in CSF and serum using latex agglutination and enzyme immunoassay (EIA) techniques for more than two decades. The sensitivity of CrAg-Latex for serum and CSF is 83–97% and 93–100%, respectively. The specificity for serum and CSF is 93–100% and 93–98%, respectively. For EIA, the sensitivity for serum and CSF is 94% and 100% respectively and the specificity is 96% and 98% respectively.[55,57] Both CrAg-Latex and EIA have some disadvantages. The CrAg-Latex is a manual test and there is a high degree of subjectivity in its interpretation. Both require laboratory infrastructure, and refrigeration of reagents thereby making the tests expensive. CrAg-Latex has lower sensitivity for CrAg of serotype C (*C. gattii*). EIA had a lower sensitivity for serotypes C and D. False positive test results are low but known (<1%). These are due to technical issues, contamination or infection with *Trichosporon beigelli, Capnocytophaga canimorsus,* and *Stomatococcus mucilaginosus*. False negatives can be seen early in infection due to a low fungal burden, due to poorly encapsulated organisms and due to prozone effect in the setting of extremely high antigen titers, which can be overcome with dilution.[58] False-negative results in latex agglutination tests can occur in the early stages of infection when fungal burden is low and also because of improper storage of clinical sample.[49,52,54,59]

The US FDA has approved a lateral flow immuno-chromatographic dipstick assay (LFA) for serum and CSF. The European Union has approved it for serum, plasma, and CSF. It can detect CrAg of all species of cryptococcus. The test uses a combination of two monoclonal antibodies. The first one is reactive one against CrAG of serotypes A, B, and C. The other is highly reactive against CrAg of serotypes A and D. The test can be done in five easy steps **(as shown in Fig. 1)** and and takes 10 minutes to give the result. The test meets the World Health Organization's (WHO) "ÁSSURED" çriteria. It is *a*ffordable (i.e., cheap), *s*ensitive (equal to or better than other CrAg tests), *s*pecific (similar to other CrAg tests), *u*ser-friendly (just as easy as the pregnancy test), *r*apid and robust (done in 10 minutes), *e*quipment-free, and *d*elivered (i.e., it is portable and light-weight with a long shelf-life and requiring no refrigeration).

CrAg LFA can be used both qualitatively and semiquantitatively. A schematic representation of CrAg LFA is shown in **Figures 2A and B**. The test has been validated in a large muticentric study in South Africa and Uganda. The test has a sensitivity and specificity of 99.3% and 99.1% respectively. The data provided by the manufacturers state that LFA has a sensitivity and specificity of 99.5% and 99% respectively and, positive predictive and negative predictive values of 98% and of 99.7% respectively with serum, plasma, urine, or CSF samples when compared to cultures. There is 100% concordance for serum and plasma tested by fingerstick LFA test and 100% negative predictive value for excluding CM. The finger stick LFA can show false negative result in a scenario of asymptomatic patient with a low fungal burden. Pipetting whole blood on to the LFA can increase diagnostic yield over direct application of blood to CrAg

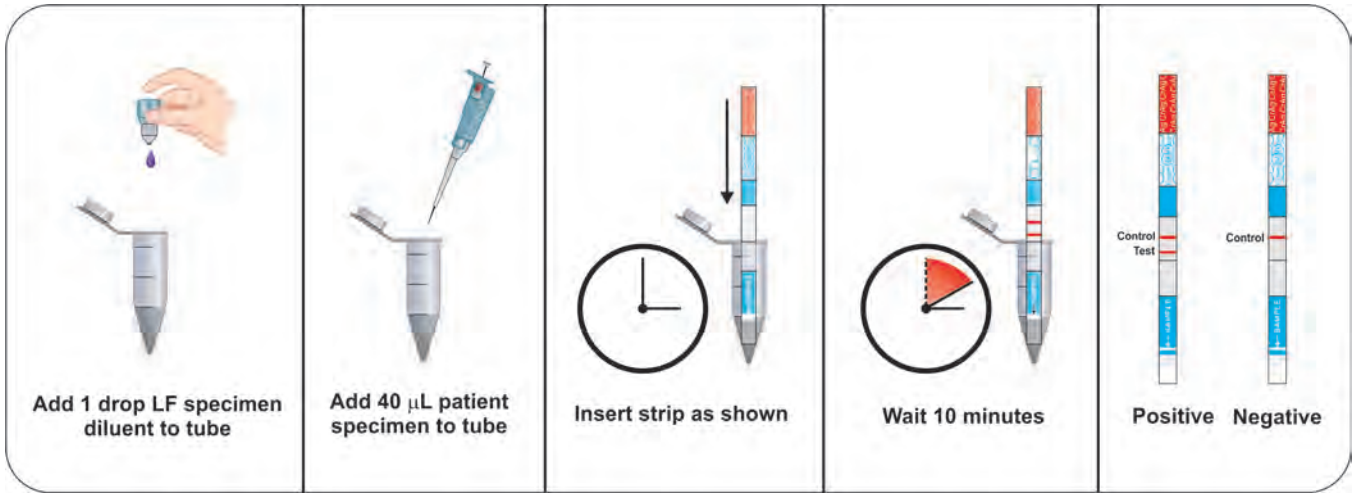

Fig. 1: Five easy steps to detect cryptococcal antigen using LFA. Step 1: add one drop of specimen to a tube. Step 2: add of 40 µL (1 drop) of patient specimen to the tube. Step 3: insert the LFA strip into the tube. Step 4: incubate for 10 minutes. Step 5: interpret results[60]

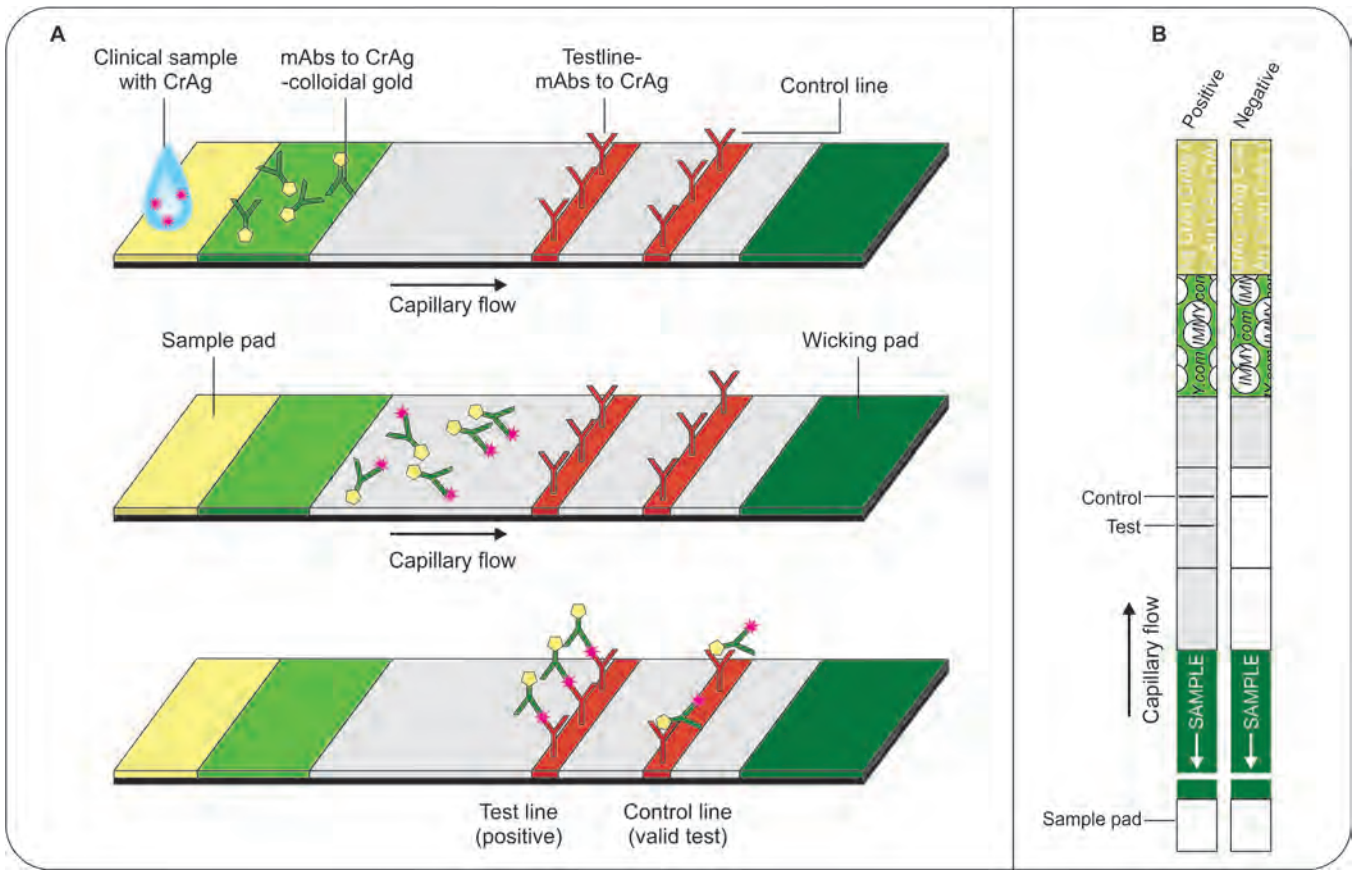

Figs. 2A and B: (A) Schematic representation of lateral flow immunochromatographic assay for detection of CrAg. (B) Images of positive and positive and negative controls[61]

LFA sample pad.[62] CrAg LFA is about 5 times more sensitive than CrAg-Latex when comparing semi-quantitative titers by serial dilution. This means that a specimen positive by CrAg-Latex at 1:8 dilution will be positive by CrAg LFA at 1:40 dilution. The semiquantitative assay reports the highest dilution that gives a positive result.

CrAg detection is used for detecting early CM, screening PLHA for cryptococcal infection, and for prognostication and therapeutic decision-making (when it is done semi-quantitatively).

Detection of Early Cryptococcal Meningitis

A study in Uganda investigated 1201 HIV positive individuals hospitalized for suspected meningitis. Fifty-six percent of these patients (671/1,201) had CM confirmed by CSF CrAg positivity. Four percent of the subjects with neurological symptoms and CSF analysis negative for CrAG were found to have serum CrAg positivity. Cryptococcus was identified by culture or PCR in 9% of these serum CrAg+ and CSF CrAg- patients. This subset of patients with neurological symptoms, serum CrAg positivity, and CSF CrAg negativity constitute the early cryptococcal meningo-encephalitis' group. In-hospital mortality was 32% in symptomatic cryptococcal antigenemia and 31% in CM. These findings suggest that immunocompromised patients with suspected CNS infections should always have serum tested for CrAg especially when no CSF pathogen is detected and that in early cryptococcal meningoencephalitis, yeasts maybe present in brain parenchyma without meningeal involvement.[63]

Screening for CrAg

CrAg appears peripheral blood many weeks to months before the onset of symptomatic disease. There is thus an opportunity for early detection and pre-emptive action. Serological prevalence studies for CrAg in PLHA have been done in various parts of the world. The serological prevalence of CrAg in ART-naive asymptomatic PLHA with CD4 cell count <100/μL is 6.8% (95% CI: 2.2–21%) and 4–12.9% in Africa and Southeast Asia respectively. In Brazil, the prevalence in hospitalized PLHA with CD4 cell count <200/μL is 3.1% and 11.4% in two different studies. The global average prevalence in severely immunocompromised PLHA is 6%. The mathematics of cryptococcal screening for PLHA has been worked out. There are 110,500 severely immunocompromised PLHA in Uganda at risk of cryptococcal disease. Screening them and pre-emptively treating 15,500 people with fluconazole would cost $822,600 which is 15% cost of treating meningitis that would occur otherwise. It would also lead to 40% better long-term survival.[64] The low cost of LFA makes screening for CrAg compellingly cost-effective even in areas of prevalence as low as 1%. WHO recommends screening of all ART-naive PLHA with CD4 cell count <100/μL for cryptococcosis by CrAg testing in serum/plasma. It also recommends antifungal therapy if CrAg is positive to prevent development of disease.

CrAg Titer

Semi-quantitative estimation of antigenemia can be done by both CrAg-Latex and LFA by serial dilution titers. Unfortunately the test is not standardized and results can vary with kits from different manufacturers. The variability is more for the latex test. The CrAg LFA manufactured by IMMY is considered the gold standard diagnostic.[56] Semi-quantitative assays are clinically useful because antigenic titers correlate with disease severity and mortality. Plasma/serum CrAg titers of <1:80 are unlikely to be associated with CNS disease. The probability of CNS involvement increases beyond a titer of 1:160 and there is near-universal concordance with CNS disease at titers of 1:1,280. It is suggested that laboratories run test at two dilutions, namely 1:160 and 1:1,280. This will enable risk stratification of patients into low risk (<1:160), intermediate risk (1:160 to 1:1,280) and high risk (>1:1,280) of infection. All those in high risk group should be considered to have disseminated disease regardless of symptoms.[10] Rajasingham and colleagues pooled data from four cohorts and found that survival decreased as plasma CrAg titer increased from <1:160 to >1: 2,560 (log rank P <0.0001). Worryingly, mortality rates were high in asymptomatic individuals with CrAg >1:160 despite their receiving pre-emptive fluconazole therapy.[1,50,65]

Programmatic challenges exist to screen severely immunocompromised PLHA for CrAg. The strategy of ordering the test for people who have got a CD4 count report of ≤100/μL is not efficient and many patients will miss the test. This is known as the "provider-initiated testing" strategy. A study from South Africa showed that only 27% of those eligible actually got screened by this strategy.[66] It also increases the work of the clinic staff because they have to raise another investigation form

and draw another blood sample. The best strategy that has evolved is one known as "reflexive screening." Testing for CrAg is a part of the laboratory protocol. Whenever the laboratory finds a CD4 test result of ≤100/μL, it will automatically run the CrAg test on the remaining blood sample. The laboratory will also report it in along with the CD4 count result and will also offer a brief explanation as to what to do with a positive CrAg report.

Other Tests

1-3β-D Glucan (BDG): It has been long believed that Cryptococcus does not produce enough BDG to be detected easily. A study done in Africa showed that BDG can be detected in the CSF of PLHA with CM with a sensitivity and specificity of 89% and 85% respectively. Sensitivity increases to 98% when fungal burdens are high (>10,000 CFUs/mL). Unlike CrAg, BDG levels decline fast with treatment and thus and thus it can potentially be used to monitor therapy, detect relapse, and also differentiate relapse from cIRIS.[67]

Uses of film array system of multiplex PCR have been tried for detecting common pathogens causing meningitis. Cryptococcal infection can be detected with a sensitivity of 96% when fungal burden is high (>100 CFUs/mL of CSF) but only with a sensitivity of 50% at low fungi burdens (<100 CFUs/mL of CSF). The high cost and sophisticated laboratory facilities preclude its widespread use.

Ribosomal DNA genes and their internal transcribed spacers (ITS) have been found to be a good common marker for bacteria and fungi. It is possible to detect inter- and intra-specific variations. Deep sequencing of rDNA amplicons from CSF can diagnose CM. Metataxonomics of ITS amplicons may be the test of the future for rapid diagnosis and genotypic recognition of *Cryptococcus sp.*[68]

Treatment

Cryptococcal meningitis in PLHA is associated with high mortality. Some strategies to decrease morbidity and mortality include: early diagnosis of HIV infection and early initiation of ART; ART adherence and retention in care; CrAg screening and treatment approach; and improved CM care.

Despite the global coverage of ART being about 60%, CM remains a therapeutic challenge. The incidence of CM remains high and more than 50% of CM cases occur in ART-experienced patients. Timely diagnosis and optimal therapy are both required to prevent deaths. Treatment of CM is divided into three phases: induction, consolidation, and maintenance. The induction phase is meant to drastically reduce fungal burden in the CSF within 2 weeks and is critical for good outcomes. Three drugs have been traditionally used in the treatment of CM: amphotericin B (AmB) or liposomal amphotericin (L-AmB), fluconazole (FLU), and flucytosine (5FC). Of these FLU is the cheapest and most widely available drug. FLU monotherapy, even the highest doses, is associated with high mortality (50% during 10 weeks of treatment).[69] Various 2-week induction regimes have been tried. The main aim was to reduce the serious adverse effects (SAEs) associated with AmB. The dose and duration of therapy have both been modified in various studies. For a long time AmB 1 mg/kg/d + 5FC 100 mg/kg/d for 14 days was accepted as standard induction therapy for HIV-associated CM. But delivering a 2-week course of AmB remains a challenge due to SAEs, and cost. Phase II trials have demonstrated that a shorter course of AmB is associated with fewer SAEs than a 2-week course without reduction in rates of fungal clearance by 2 weeks. This is attributed to long half-life of AmB in the brain.[70,71] The Advancing Cryptococcal meningitis Treatment for Africa (ACTA) trial looked at survival rates at day 14 and day 70 of a 1 week course of AmB combined with either high dose FLU or 5FC, 2 weeks of oral therapy with 5FC and high-dose FLU and 2 week AmB combinations. The study showed that 1-week combination of AmB and 5FC had the lowest 10-week mortality of all regimens and that 5FC was superior to FLU as a partner drug to AmB (10 week mortality HR 0.62, 95% CI: 0.45–0.84, p=0.0020).[72] A systematic review and meta-analysis has looked at data from 13 studies with 2,426 patients. It found that at 10 weeks a 1-week course of AmBd plus 5FC was superior to other regimes for induction treatment of HIV-associated CM. In the case of non-availability of AmB a combination of 5FC and high-dose FLU was the next best alternative.[73] These two regimens have now been accepted as the standard first-line treatment regimens by WHO for HIV-associated CM. The standard WHO recommended treatment regimen for HIV-associated CM is shown in **Table 1**. The alternate regimens that can be used during the induction phase are: 5FC + high-dose FLU for 2 week or AmB + high-dose FLU for 2 weeks (high-dose FLU=1,200 mg/d).

TABLE 1 WHO-recommended first-line antifungal therapy for treatment of cryptococcal meningitis

Medication and dose	*Week 1*	*Week 2*	*Week 3 - 10*	
AmB (1.0 mg/kg/d) + 5FC 100 mg/kg/d	X[a]			
FLU 1200 mg/d		X		
FLU 800 mg/d			X	
FLU 200 mg/d				Through 12 months
Treatment phase	Induction		Consolidation	Maintenance

[a]Therapeutic lumbar puncture and electrolyte supplementation are most critical during the first week of therapy.[74]

Efforts to further shorten AmB exposure and thus cut down on cost and minimize SAEs are on. L-AmB is associated with fewer SAEs than AmB. The AMBITION trial was a phase II trial looking at efficacy of different doses and durations of L-AmB in treatment of CM. L-AmB in a dose of 3 mg/kg/d and FLU 1,200 mg/d were administered for 14 days in the induction phase in the control arm. This was compared with LAmB 10 mg/kg on D1 and 5 mg/kg on D3 + FLU 1,200 mg/d for 14 days; LAmB 10 mg/kg/d on D1 + 5 mg/kg on Ds 3 and 7 + FLU 1,200 mg/d for 14 days and LAmB 10 mg/kg on D1 with FLU 1,200 mg/d for 14 days. The primary outcome was early fungicidal activity and it was non-inferior in all the three short course arms as compared to the control arm. The mortalities in all arms were comparable. Encouraged by its results, AMBITION II phase III trial has been rolled out. This study compares the new WHO first-line regimen of AmB 1 mg/kg/d + 5FC 100 mg/kg/d for 7 days followed by high-dose FLU 1,200 mg/d for 7 more days with a single dose of L-AmB 10 mg/kg on day 1 along with 14 days of 5FC and high-dose FLU. The results will be out in mid-2021.[75]

Management of Raised Intracranial Pressure

An intracranial pressure of >250 mm of water is associated with poor short-term survival in patients with CM.[76] Repeated lumbar punctures improved survival in the COAT study.[29] The raised ICP is due to a strong inflammatory response in the CNS. Though dexamethasone is known to decrease levels of TNF-α, it also decreases the rate of fungal clearance and causes poor outcomes.[77] It is thus contraindicated in treatment of CM.

Advances in Initiating ART in PLHA with CM

Cryptococcal meningitis signals a severely immunocompromised state in PLHA. But starting ART precipitately can do more harm than good. IRIS occurs in 15–20% patients initiating ART. The Cryptococcal Optimal ART Timing Trial (COAT) provided some definitive guidance to delaying initiation of ART in patients with CM for a minimum of 4 weeks after starting antifungals. This trial demonstrated improved survival in patients with CM in whom ART initiation was deferred for up to 5 weeks after diagnosis as compared with immediate ART (within 1–2 weeks).[29] A Cochrane Review further concluded that there is higher all-cause mortality if ART is initiated early in CM in HIV-infected people in low- and middle-income countries.[78] The 2018 WHO guidelines recommend that ART should be started 4–6 weeks after starting antifungal treatment.

Newer Adjuvant Therapies for Treatment of CM

Sertraline, tamoxifen, INF-□, and steroids have all been tried. Steroids are associated with slower fungal clearance and increased mortality and are thus not recommended. Sertraline adjunctive therapy led to faster CSF cryptococcal clearance, and decreased IRIS and relapses when compared to historical data.[79,80] Neurapheresis is the extracorporeal filtration of yeasts from CSF in CM. A proof-of-concept study in murine models has demonstrated its efficacy. Human trials have not been encouraging.[81,82]

Newer Drugs

Flubendazole is an imidazole anti-parasitic drug. It acts against cryptococcus by binding to fungal tubulin. Though studies in mice were encouraging, the results in rabbit studies were disappointing due to poor CSF penetration. An oral formulation is under development and could still serve as an adjunctive therapy.[83] VT1129 is a tetrazole which has also demonstrated *in vitro* activity against both susceptible and FLU-resistant cryptococcal species. It

acts by inhibiting fungal cytochrome P450 enzyme Cyp51 thereby inhibiting biosynthesis of ergosterol. The unique feature of this drug is its high selectivity for fungal enzyme and thus its lack of SAEs and drug interactions.[84] Some more exciting drugs are under clinical trials and results should be out in 2021. These include an orally bioavailable form of AmB, and a glycophosphatidylinositol-anchored wall transfer protein (G wt 1) inhibitor which inhibits transfer of mannoprotein from the golgi complex to cell wall.[56]

Prevention

A number of strategies have been evaluated and implemented to prevent CM in PLHA with low CD4 cell counts in resource-limited settings. A widely accepted one is the "screen and treat" approach. Here, serum CrAg testing is used to decide on starting preemptive fluconazole therapy in CrAg-positive patients. Fluconazole is administered in a dose of 400 mg BD for 2 weeks followed by 400 mg OD for 6 weeks. It is continued at a dose of 200 mg OD till CD4 cell count rises to >200 cells/μL.[85] This approach is associated with a decreased incidence of CM and improved survival among those with advanced HIV disease. It has been successfully implemented in several resource-limited settings, with a baseline prevalence of asymptomatic cryptococcal antigenemia of 5–13%.[86-88] The cost saving and survival benefit of screen and treat strategy has been validated by many studies when compared with standard of care or universal fluconazole prophylaxis, even at CrAg prevalences of as low as 0.6%.[89,90] The WHO recommends implementation of CrAg screening and preemptive fluconazole therapy in ART-naive adults with a CD4 count <100/μL before initiating ART in endemic settings.[91] This strategy has been incorporated into existing HIV-care programs of many countries in sub-Saharan Africa. It has been shown that fluconazole monotherapy is inadequate to prevent CM deaths in asymptomatic CrAg positive with undiagnosed cryptococcosis. This is because fluconazole monotherapy is suboptimal for treatment of CM. In all asymptomatic CrAg positive PLHA, every effort should be made to diagnose cryptococcosis. Investigations should include CSF examination and blood cultures. A suggested approach is to give combination antifungal therapy for all CrAg positive patients or at least those with CrAg >1:160.[92,93] A Thai study showed that in settings where ART is widely available and PLHA with CD4 count <100/μL are regularly started on ART and are CrAg negative, primary prophylaxis with FLU offers no mortality benefit and may not be necessary.[94] Primary anti-cryptococcal prophylaxis is not recommended in high-income regions like Europe and the USA, where ART is widely available and CrAg prevalence in population is low.[95] There is some data that "screen and treat" would be cost-effective, even in resource-rich settings, although this is currently not part of standard practice.[96] Another vexing issue that has risen because of the widespread use of primary prophylaxis for CM in Africa is that of emerging fluconazole resistance in Uganda.[97]

Secondary Chemoprophylaxis

Suppressive or maintenance therapy is offered to all CM patients on completion of intensive and consolidation phases of treatment because relapse rate of CM is 50% in the first year.[98] Fluconazole at 200 mg daily is the suppressive therapy of choice. WHO recommends continuing till CD4 count rises to more than 200/μL. IDSA recommends that suppressive therapy can be stopped after 12 months if CD4 count is more than 100/μL and there is virological suppression sustained for ≥3 months (undetectable or very low viral RNA). Therapy should be restarted if CD4 dips below 100/μL.[99]

Outcomes

HIV associated CM has a 3-month mortality of 70% in Africa. The major risk factors for mortality are: longer duration of symptoms, altered mental status, concomitant cryptococcal lung infection, disseminated disease, high fungal burden with low rate of clearance, low CSF WBC count (<20 × 10^6/mm^3, raised ICP on admission and lack of facilities to perform therapeutic lumbar puncture (LP) to control ICP and abnormal brain imaging. Mortality is higher in low- and middle-income countries than in high-income countries because of the high proportion of late testers and late presenters, CM being the presenting illness in HIV disease, severe immunosuppression compounded by anemia, malnutrition, delayed diagnosis due to lack of optimal laboratory services, non-availability of good combination antifungal therapy and lack of facilities for therapeutic LP.[10,36] The study from the USA showed that seizures in HIV+ patients with CM were associated with increased 10 week mortality (adjusted hazard ratio 1.45, 95% CI: 1.11–1.89). Patients with seizures also had more

cognitive deficits after 3 months when compared to those without seizures.[37,100] TB confection with CM is associated with an increased hazard of death (HR 1.75, 95% CI: 1.33–2.32, p<0.001).[101]

A study from Uganda and South Africa showed that the estimated hazard of death at 18 weeks was 10% lower for every 50 cells/μL increase in absolute CD4 cell count at the time of diagnosis. Mortality was lowest when CD4 cell count was between 50–99 cell/μL (mortality 35%) and higher if CD cell count was <50 cell/μL (47%) or if it was >100 cell/μL (40%). These findings were consistent with the DRF theory.[102]

Cryptococcal antigenemia has a strong association with CM/mortality in PLHA with cryptococcosis and CD4 cell count between 100–200 cells/μL (Hazard ratio 10, 95% CI: 2.2–45.3, p=0.003).[103] A high fungal burden of >100,000 CFUs/mm^3 is also associated with increased mortality.[56] The outcome of CM is bad even in Latin America. In one 15 year-follow up study, with 340 enrolled patients, 42% died during follow-up. More deaths were seen after starting ART than in treatment naive HIV-CM.[104] Another study from the USA showed that CM led to hearing impairment, muscle weakness, and cognitive deficits.[33,34]

In elderly patients, mortality directly correlates with age (>65 years). The presence of cryptococcaemia is the most significant prognostic factor in these people.[105]

Conclusion

Cryptococcal disease in PLHA continues to be a big public health problem in low and middle income countries. Routine CrAg screening and pre-emptive antifungal therapy, can significantly reduce CM associated morbidity and mortality in these regions. Exclusion of cryptococcosis in asymptomatic PLHA with advanced disease and high CrAG titers is a good strategy. Combination antifungal therapy has made a significant difference in outcome of HIV-associated CM. The regimes are becoming more affordable, shorter, and safer. cIRIS continues to be a problem in immunocompromised persons with cryptococcosis.

CHAPTER

167 Enteric Fever—Challenges to Overcome

Rupali Malik, Anupam Prakash

Abstract

Enteric fever is an important resilient community-acquired systemic bacterial infection, commonly seen in resource limited tropical countries with overcrowding and poor sanitation, causing significant morbidity and mortality, and thus posing a grave public health challenge to reckon with. Enteric fever includes infections caused by *Salmonella typhi* (typhoid fever) as well as those caused by *Salmonella paratyphi* A, B, and C (paratyphoid fevers). Its prevention, diagnosis, as well as management pose major challenges with limited options available for empirical treatment. Thus, there is an urgent need to monitor the burden of this disease and antimicrobial resistance to guide empirical therapy and devise newer diagnostic, as well as preventive public health strategies for containment of its spread.

Introduction

Enteric fever is an important differential of acute undifferentiated febrile illness in developing countries. It causes around 14.3 million infections annually with over 135,000 deaths worldwide.[1] Its annual incidence in our country is 493.5/100,000 persons per years with 340.1/100,000 cases per years occurring in children of 2–5 years, the higher incidence in children reflecting active transmission in the community.[2] The burden of typhoid and paratyphoid fever in India as per a meta-analysis in laboratory-confirmed enteric fever cases is estimated to be a prevalence of 7% for *Salmonella typhi* and 0.9% for *Salmonella paratyphi* A.[2-5]

Human beings are the only reservoir of this infection and the transmission can occur either through direct contact or indirectly via contact with fecal contaminated food or water. Sexual transmission between male partners has also been reported. Both genders and all age groups are infected throughout the year with a peak during the summer and rainy seasons, that is, from May to October. Although the gastric acid serves as a barrier to the entry of Salmonella through the oral route, but an excess bacterial load along with the lack of gastric acid in persons on proton pump inhibitors or achlorhydria or *Helicobacter pylori* infection, allows bacteria to traverse through the stomach and reach the small intestine, where these are localized in the Peyer's patches. However, once the barrier of Peyer's patches is passed, these can reach different parts of the body, and cause enteric fever and its varied manifestations, which can involve any organ system of the body. Some factors which predispose to severe infection include—primary immunodeficiencies like chronic granulomatous disease, neutropenia, organ transplant recipients.

Incubation period can range from 6 days to 21 days (usually 2 weeks). The clinical presentation of typhoid and paratyphoid fever is the same except milder manifestations and shorter incubation in paratyphoid fever. Most cases of enteric fever are caused by the gram negative bacilli *S. typhi*; however, incidence of *S. paratyphi* A cases is rising in Asia, perhaps as a result of vaccination for *S. typhi*, and

it now accounts for up to one-third of enteric fever cases in India and Nepal.[1,6,7]

Clinical Features

Fever is the most common presenting symptom in 90%[8] patients and is prolonged (>4 weeks) in untreated patients. It is usually moderate to high grade and remittent nature, without touching baseline or continuous, which rises every 3rd or 4th day, in what is classically defined as step-ladder fashion. However, due to frequent use of antipyretics and antibiotics early in the course, this pattern may not be evident always. High-grade continuous fever is associated with toxemia. Non-specific abdominal symptoms, like vomiting, diarrhea, and occasionally constipation, may also occur during the first week of illness. Soft splenomegaly is characteristic (to differentiate from the firm splenomegaly seen in malaria) and can be easily missed. Patients with enteric fever usually have a coated tongue and relative bradycardia. Patient can also have jaundice because of liver involvement (*enteric hepatitis*), breathlessness, and wheezing (*enteric bronchitis*), obtundation, delirium and coma (*enteric encephalopathy*), bone marrow depression, cholecystitis, loose motions, that is, classically pea-soup diarrhea (*enteritis*), intestinal perforation, and skin rash (*Rose spots*—2–5 mm diameter macular lesions seen transiently during the second week of illness, considered to be due to bacterial emboli). Serious complications usually occur in the second week of illness. Intestinal perforation occurs in about 1–3% of hospitalized patients with enteric fever, with common site being terminal ileum (70–80%) followed by less commonly involved sites like jejunum, ceacum, colon, or gall bladder. Gall bladder may remain a preserved focus in partially treated patients of enteric fever, and lead to a carrier state, wherein the patient may keep shedding bacteria in stools for months or years, becoming a public health hazard. The prolonged asymptomatic carrier state can be seen in about 10–15% of patients.[9]

Atypical manifestations of enteric fever have also been reported including ataxia, sensorineural deafness, meningism, Guillain-Barré syndrome (GBS), myocarditis, acute respiratory distress syndrome (ARDS), osteomyelitis, etc. Complications, like osteomyelitis, mycotic aneurysms, and soft tissue abscesses, are reported more often in paratyphoid infections.[10] Renal complications, like glomerulonephritis, pyelonephritis, cystitis, and mild proteinuria, have also been reported rarely. Hematological involvement can lead to bone marrow suppression, disseminated intravascular coagulation (DIC) and hemophagocytic lymphohistiocytosis (HLH).[9]

Reinfection may occur, if primary infection is terminated using early intervention with antibiotics.

Differential Diagnosis

Various tropical infections, like malaria, dengue, chikungunya, leptospirosis, and scrub typhus, are common differentials. However, continuous high grade fever, coated tongue, relative bradycardia, toxic looks, and soft splenomegaly should definitely be considered a pointer to enteric fever.

Diagnostic Challenge

Diagnosis of enteric fever poses an immense challenge as blood culture, which is considered the gold standard, has a low sensitivity of 40–60%.[11] Moreover, in our country, delayed presentations with pre-exposure to inadequate and unnecessary antibiotic therapy prior to visiting a proper health-care facility hinders its performance. Though it is positive in the first week itself and also provides sensitivity testing for antibiotics, it takes longer time, thus delaying treatment. Newer commercially available rapid serological tests, like TUBEX TF® (IDL, Sweden) and Typhidot® (Malaysian Biodiagnostic Research, Malaysia), can also be used as point of care tests in an emergency setting for early diagnosis. The former is an antibody-based test based on the principle of inhibition reaction between host and in vitro antibodies that compete for *S. typhi* specific lipopolysaccharide, while latter is a qualitative enzyme-linked immunosorbent assay (ELISA) based test that detects immunoglobulin G (IgG) and immunoglobulin M (IgM) antibodies against *S. typhi* outer membrane protein. They have sensitivity of 55–70% and specificity of more than 85%.[12] These kits perform better among hospitalized patients than those evaluated in the community setting. Serum Widal test provides the titers of antibodies to somatic 'O' and flagellar 'H' antigens, and is helpful in the second week of fever onwards. A titer more than or equal to 1:160 is considered positive in endemic areas as in India, although rising titers in paired sera can be very helpful. Third week stool culture and fourth week urine culture may be helpful; however, untreated patients

are more likely to develop complications in the third and fourth week of fever. In partially treated patients, blood culture may not be positive, but bone marrow culture may still be positive. Directed investigations may be dictated by the suspicion of various complications. Thus, the existing diagnostic tests suffer from limitations regarding time cycle, sensitivity, infrastructure need, *etc*, emphasizing the need for newer, more accurate, and rapid point-of-care diagnostic tests.

Complete blood counts usually suggest leukocytosis, but bone marrow suppression can be associated with normocytic normochromic anemia, leukopenia, and thrombocytopenia. Transaminitis with mild elevation of serum bilirubin levels may be observed. Kidney functions are normal, but insensible losses due to high fever and anorexia because of toxemia can result in prerenal azotemia.

Management Challenge

Mainstay for management of enteric fever is to give antibiotics along with use of antipyretics and maintenance of hydration and adequate nutrition. Conventionally, chloramphenicol 1–2 g IV 8-hourly used to be the gold standard of treatment; however, with advent of newer potent antibiotics in the 1990s and due to idiosyncratic complication of chloramphenicol, like aplastic anemia, its use was abandoned. Cotrimoxazole and ampicillin were other agents used. Use of aminoglycosides was precluded as they were injectable drugs with well-known neurotoxicity, nephrotoxicity, and ototoxicity. Multidrug-resistant (MDR) strains resistant to ampicillin, trimethoprim-sulfamethoxazole, and chloramphenicol, soon became prevalent worldwide, though they are now decreasing with wider use of other antibiotics, but development of increasing resistance to fluoroquinolones as well as even cephalosporins is a growing challenge now.

Quinolones are an effective group, and ciprofloxacin, ofloxacin, lomefloxacin, and levofloxacin were all rampantly used with great effect. But due to rising fluoroquinolones resistance, ciprofloxacin is no longer the empirical choice of treatment in our country.[13]

Ceftriaxone and cefixime are currently considered the treatment of choice, but there are also reports on increased minimum inhibitory concentration (MIC) to ceftriaxone causing delayed defervescence and even reports on the full resistance.[14]

Oral azithromycin 20 mg/kg once daily (to a maximum of 1 g daily) for 7 days has been recommended for treatment of uncomplicated enteric fever, and is considered to be equiefficacious to intravenous ceftriaxone (75 mg/kg/day to maximum 2.5 g/day) given for 7 days, with less chances of relapse and similar adverse effect profile.[15] A 5-day course of azithromycin has also been reported to be efficacious.[16]

In a study from Delhi, India,[15] resistance to co-trimoxazole, chloramphenicol, ceftriaxone, and azithromycin were reported to be 6.1%, 13.8%, 16.1%, and 5.78%, respectively over a 7-year period. Multidrug-resistant *S. typhi* and *S. paratyphi* A were reported to be 2.73% and 1.91%, respectively. In a recent systematic review and meta-analysis, multidrug-resistant *S. typhi* was reported to be 9% and multidrug-resistant *S. paratyphi* as 2% in South Asia. Besides, fluoroquinolone non-susceptible *S. typhi* and *S. paratyphi* were pegged at 70% and 53%, respectively in South Asia.[17] Resistance rates for various agents are highly variable from study to study and region to region, but resistance rates to azithromycin appear lowest among all the antibiotics.

There is a decrease in culture positive cases these days, which may suggest a decrease in the burden of disease, but can also be a reflection of the early empirical antibiotic use to treat typhoid fever in the community. There is a possibility that due to the emerging antibiotic resistant strains, under the selective pressure of antibiotic use, only patients who fail to respond to empirical therapy visit tertiary care hospitals. Thus, culture positive cases may represent only a small proportion of total number of cases in a community and this may lead to skewing of antimicrobial susceptibility data toward resistance.

Some treating physicians prefer to use two agents simultaneously to treat enteric fever. But this seems justifiable only in patients who have enteric fever with complications and in patients having no clinical improvement with monotherapy. It may be prudent to start with a single agent in uncomplicated enteric fever, and once susceptibility report is obtained decision on adding a second agent or switching to another agent can be taken. Role of various fixed drug combinations available still needs further evaluation.

Prevention and Control Challenge

Three vaccines are commercially available for typhoid fever, one live attenuated oral vaccine and two injectable

inactivated vaccines, with limited efficacy (50–72%). Ty21a, is an oral live attenuated *S. typhi* vaccine (given on days 1, 3, 5, and 7, with a booster every 5 years). It is not given in children less than 6 years. Vi CPS is a parenteral vaccine consisting of purified Vi polysaccharide from the bacterial capsule (given in one dose, with a booster every 2 years). It is not given in children less than 2 years. Third, is an injectable typhoid conjugate vaccine (TCV), consisting of Vi polysaccharide antigen linked to tetanus toxoid protein. It can be used in children from 6 months of age and adults up to 45 years of age. No vaccine for paratyphoid fever is presently available.[12]

Public health measures like availability of safe food and *wa*ter, adequate *s*anitation services, and proper personal *h*ygiene (WASH) are important to prevent enteric fever.[12] The challenge of controlling typhoid fever is often compounded by the lack of adequate nationwide surveillance in the affected countries. Recently in India, a study titled "National Surveillance System for Enteric Fever in India (NSSEFI)" is being done to estimate the incidence of typhoid fever in age-specific manner in children between 6 months and 15 years.[18]

Conclusion

In this era of emerging antibiotic resistant strains, with no new drug in the horizon, there is an imperative need for continuous surveillance to inform clinicians regarding early diagnosis and better management of infections with use of effective antibiotic policies and also government policymakers for strengthening preventive strategies like adequate sanitation with safe food and water supply, along with development of new vaccines that are effective against both *S. typhi* as well as *S. paratyphi* A infections. Though challenges persist in all these aspects hindering implementation of facilities available, an integrated approach with a comprehensive policy framework is required for prevention, control, and elimination of enteric fever.

CHAPTER

168 Leptospirosis and Brucellosis—Can These Be Difficult to Diagnose?

Saurabh Srivastava, Amit Gupta, Indal Chauhan

Abstract

Zoonotic diseases are important for humans as they may cause disease in them and are recognized as important public health issue. Brucellosis and leptospirosis are important zoonotic diseases of public health importance. The clinical presentation of these disorders mimics many other common diseases. The present chapter summarizes the important manifestation of these disorders and there differentiating aspects with other diseases.

Introduction

Zoonoses are diseases transmitted from animals to man have been recognized as important public health issues for centuries. Brucellosis and leptospirosis are important infections in animal handlers causing wide range of similar clinical manifestation. Butchers and slaughterhouse workers are at high risk of contracting zoonotic diseases due to handling of animals or by ingestion of unpasteurized milk or milk products. Non-specific symptoms including fever lead to chronic disease due to misdiagnosis. Zoonoses should be suspected if there are infection's protean manifestations along with appropriate exposure history. Hence, in this chapter, we seek to summarize brucellosis and leptospirosis infection in human.

Brucellosis

Livestock animals are mainly affected by brucellosis. It is caused by the small, Gram-negative coccobacilli of the genus *Brucella*. Main species causing disease in humans are *Brucella melitensis* (sheep and goat), *Brucella suis* (pigs), and *Brucella abortus* (cattle). The disease has worldwide distribution and is mainly seen in rural areas. Relapses can occur after primary infection and disease can also be chronic.

Pathogenesis and Modes of Transmission

Human transmission in brucellosis occurs through direct contact with infected animal, ingestion of unpasteurized milk and milk products, or carcasses of infected animal.

Human brucellosis is usually associated with domestic or occupational exposure to infected animals or their products. Veterinarians, shepherds, farmers, goatherds, and employees of meat-processing plants and slaughterhouses in endemic areas are occupationally exposed to infection. Laboratory workers who handle cultures or infected samples are also at risk. Travelers and urban residents usually acquire the infection through consumption of contaminated foods. The most frequently implicated sources of infection are dairy products, especially soft cheeses, unpasteurized milk, and ice cream, under exceptional circumstances raw meat and bone marrow can also be source of infection. Infections acquired through cosmetic treatments using materials of fetal origin have been reported. Person-to-person transmission is extremely rare, as is transfer of infection

by blood or tissue donation. No evidence of increased severity and prevalence of *Brucellosis* in immunodeficient individuals and persons infected with human immunodeficiency virus, even though it is a chronic intracellular infection.[1]

Clinical Features

The severity of brucellosis is related to infecting species, biotype, and host factors. *B. melitensis* and *B. suis* can cause severe disease in humans, with *B. abortus* usually being associated with milder disease. Human infection with *B. canis* is rare. Human brucellosis can be associated with acute, sub-acute, relapsing, and chronic manifestations. The incubation period is normally between 2 and 4 weeks, but it may be months.

Acute brucellosis can present as a non-specific febrile illness characterized by intermittent or remittent fever (39–40°C). The fever may be associated with chills, night sweats, joint and muscle pain, weight loss, fatigue, malaise, headache, and adenopathy mainly in children.

It may also be associated with non-specific gastrointestinal disorders, hepatomegaly and/or splenomegaly, cough, arthritis (knee), and orchitis.[2]

Waxing and waning type of fever is characteristic of sub-acute brucellosis and is also known as undulant fever. It is often low grade, persists for weeks, accompanied by arthralgia, arthropathy and diminished well-being. Undulant fever is more common in adults than in children and can involve specific organ systems. Intrauterine infection, miscarriage, premature delivery, and spontaneous abortion are common during infection of human brucellosis in pregnancy.[3]

Localized Form

Primary infection may progress to localized infection (even several months or years later):

- *Osteoarticular:* Sacroiliac joint, lower limbs joints, spine (vertebral osteomyelitis, intervertebral disk infection)
- *Genitourinary:* Orchitis, epididymitis
- *Pulmonary:* Bronchitis, pneumonia, pleurisy
- *Neurological:* Meningitis, encephalitis, polyneuritis

Complications of Brucellosis

- *Osteoarticular complications:* Affect 20–40% of patients. Sacroiliitis is the most common reported complication, especially when *B. melitensis* predominates.[1,4]
- *Pulmonary complications:* Respiratory symptoms are reported by 15–25% of patients but radiological changes are seen in less than 10%.[5] They range from flu-like symptoms to bronchitis, lobar pneumonia, interstitial pneumonitis, lung abscesses, hilar lymphadenopathy, and lung effusions.
- *Genitourinary complications:* Complications from the genitourinary tract are rare. Acute orchitis or epididymo-orchitis with signs of systemic infection can occur in males and there can be pyelonephritis resembling tuberculosis, particularly in females.
- *Neurologic complications:* Depression is a common complaint, but invasion of the central nervous system occurs in only 2–4% of cases. It usually presents as acute or chronic meningitis. Encephalitis, polyradiculopathy, psychosis, and meningovascular complications have also been described, as well as rarer complex abscesses.[6]
- *Cardiovascular complications:* Endocarditis, although rare, is the main cause of death related to brucellosis.[1,4] The aortic valve is more often involved than the mitral valve. Other complications include mycotic aneurysms, myocarditis and pericarditis.
- *Cutaneous involvement*: Cutaneous manifestations of brucellosis consist mainly of transient nonspecific lesions including erythema nodosum, petechiae, vasculitis, papules, and rashes.

Diagnosis

The diagnosis should be considered in a case of chronic febrile illness having epidemiological risk factors along with osteoarticular involvement (axial spine or sacroiliac joints), uveitis or other focal lesions described earlier. Confirmatory diagnosis is usually based on microbiologic culture of blood, tissues, or bone marrow.[7] Blood culture, which is gold standard for diagnosis, is positive only in the acute phase and has sensitivity of less than 50–70%.[2] Bone marrow cultures are more sensitive than blood cultures in acute brucellosis and remain positive even in later course of the infection, along with antimicrobial treatment.[8,9]

Body fluids, such as cerebrospinal fluid (CSF) or joint fluid, show lymphocytosis, low glucose levels and high protein concentration. Elevated CSF adenosine deaminase levels are also present. Biopsied samples of tissues such as lymph node or liver may show noncaseating granulomas without acid/alcohol-fast

bacilli. In recent years, matrix-assisted laser desorption ionization time-of-flight spectrometry (MALDI-TOF MS) has emerged as a powerful tool in bacterial identification. The peripheral blood-based polymerase chain reaction detects bacteremia, to predict relapse, and to exclude "chronic brucellosis."[10]

Serologic tests are more sensitive than culture. The serum agglutination test (SAT) remains the best standardized and most widely used serologic test.[8] Other serological tests are indirect immunofluorescence, Wright agglutination test, Rose Bengal, ELISA, etc. and provide presumptive diagnoses.

Malaria and tuberculosis are to be ruled out in endemic regions.

Radiography

Small erosions or destruction or joint space narrowing is seen in ankles, knees, hips, vertebrae, and sacroiliac joint. Chest radiograph is often normal but sometimes pleural effusion can be present.

Management (Table 1)

The goal of medical therapy is to control symptoms quickly, in order to prevent complications and relapses.

High relapse rates reported with monotherapeutic approaches so multidrug antimicrobial regimens are the mainstay of therapy. The risk of relapse is not well understood and resistance is not a significant issue in treatment of brucellosis.[11]

Same treatment is to be given for localized forms of the infection, but for a period of 6 weeks to 4 months depending on the focus.

Leptospirosis

Leptospirosis is an important zoonotic disease globally caused by spirochetes of the genus Leptospira. Leptospirosis affects almost all domestic and wild animals worldwide except Antarctica. Rodents (rat), dogs, and cattle are mainly affected. It is a disease of public health importance in tropics and is seen in agricultural workers[14] as well as urban slum residents.[15] Disease is endemic throughout the world; however, outbreaks superimposed on endemic disease activity are regularly linked to severe hurricane and flooding events.

Pathogenesis and Modes of Transmission

Human transmission of leptospirosis occurs by contact of moist soil or freshwater contaminated with urine of

TABLE 1 Management of brucellosis

Children under 8 years[12]	Rifampicin + Co-trimoxazole or Gentamicin + Co-trimoxazole
Children 8 years and over	Rifampicin + Doxycycline or Gentamicin + Doxycycline
Adults[13]	Rifampicin + Doxycycline or Doxycycline + Streptomycin or Gentamicin
Pregnant/breastfeeding women	Rifampicin occasionally Rifampicin + co-trimoxazole
Sacroiliitis	Doxycycline + Rifampin + Gentamicin—2–3 weeks Then Doxycycline + Rifampicin for 6 weeks
Nervous system infection	Doxycycline + Streptomycin + Rifampicin or Doxycycline + Co-trimoxazole + Rifampicin
Co-trimoxazole: PO for 6 weeks Children < 8 years: 20 mg SMX + 4 mg TMP/kg 2 times daily **Doxycycline:** PO for 6 weeks Children ≥ 8 years: 1–2 mg/kg 2 times daily Adults: 100 mg 2 times daily **Rifampicin:** PO for 6 weeks Children: 15–20 mg/kg once daily (max. 600 mg daily) Adults: 600–900 mg once daily **Gentamicin:** IM for 2 weeks Children and adults: 5 mg/kg once daily **Streptomycin:** IM for 2 weeks Adults: 1 g once daily	

an infected animal (indirect contact) or direct contact of blood, urine, and other body fluids or tissues of an infected animal through skin lesions or mucous membranes.

Leptospires are shed in urine as they colonize proximal renal tubules of mammalian hosts. They can survive for several months in the environment under moist conditions; factors affecting survival are the presence of warmth (above 22°C) and neutral pH (pH 6.2–8.0). Rodents are a particularly important reservoir. Some serovars appear to be preferentially adapted to select mammalian hosts; examples are the serovar *Icterohaemorrhagiae* which is primarily associated with the Norway rat, *pomona* with swine and cattle and *canicola* with dogs. However, a particular host species may serve as a reservoir for one or more serovars, and a particular serovar may colonize different animal species. Transmission of infection in humans usually occurs through contact with contaminated water or moist soil. Organisms enter humans through the mucosal surface of the nasopharynx, mouth, eye, or esophagus or through abrasions of the skin. Risks of leptospirosis transmission and exacerbation are increased due to migration of the rural poor to urban slums. Intense exposure to leptospires has been documented in workers of sugarcane, rice, and rubber plantation. Leptospirosis is also acquired by direct contact with the urine, blood, or tissues of infected animals but is less frequent.

Clinical Features

Severe, icteric illness occurs in less than 10% of symptomatic infections; however, subclinical infection is very common. Majority of cases of leptospirosis are mild, presenting as febrile illness, but disease can be potentially fatal leading to multiorgan dysfunction. The incubation period is usually 1–2 weeks but ranges from 1 to 30 days.[16]

Leptospirosis is classically described as biphasic.

Acute phase (leptospiremic/septic/anicteric phase): characterized by:

- High fever with chills of sudden onset (3–10 days duration)
- Headache
- Muscle pain (especially calf pain)
- Photophobia
- Ocular pain
- Bilateral conjunctival hemorrhage is very frequent
- Organism can be cultured from blood and detected by polymerase chain reaction
- May be associated with:
- Gastrointestinal symptoms (abdominal pain, nausea, anorexia, vomiting)
- Non-productive cough
- Adenopathies
- Hepatomegaly

Immune phase:

- The signs of the acute phase regress after 5–7 days then reappear for a few days but are usually mild (milder fever, less severe myalgia) and then disappear.
- Coincide with the appearance of antibodies, and leptospires can be cultured from the urine.
- Aseptic meningitis is the hallmark of immune phase of leptospirosis but is not associated with mortality. Cerebrospinal fluid pleocytosis can be demonstrated in 80–90% of patients during the second week of illness. Clinical signs and symptoms of meningitis are seen in only 50% cases.
- Uveitis is a late manifestation of leptospirosis. It is generally seen after 4–8 months of illness. Most frequently affected area is anterior uveal tract. Common symptoms of uveitis are photophobia, pain, and blurring of vision.

Severe or Ictero-hemorrhagic Form (Weil's Disease)

The onset is the same but a few days later the symptoms worsen:

- Renal disorders (oliguria or polyuria or anuria)
- Hepatic disorder (jaundice—appears 5–9 day of illness, hepatomegaly)
- Widespread hemorrhages (ecchymoses, haemoptysis, purpura, epistaxis, etc.)
- Pulmonary signs (chest pain)
- Cardiac signs (myocarditis, pericarditis)
- Refractory shock
- Death occur from subarachnoid hemorrhage or gastrointestinal bleeding
- Eye signs: Conjunctival hemorrhage, scleral icterus, and conjunctival suffusion
- Leptospirosis-associated severe Pulmonary Hemorrhage Syndrome is as a widespread public health problem having a case fatality rate of about 50%
- Apparent critical threshold for severe outcomes such as SPHS and death is leptospiremia of 10,000 or more bacteria per milliliter of blood

Diagnosis

Leptospirosis may be difficult to distinguish from other infectious causes of fever, and a high index of suspicion is required based on the local epidemiology. Modified World Health Organization (WHO) Faine's criteria (with amendment) 2012 Criteria for Diagnosis of Leptospirosis is summarized in **Table 2**.[17]

Laboratory diagnosis is difficult to obtain. The routine investigation demonstrates:

- *Complete blood count:* Anemia, polymorphonuclear leukocytosis, or thrombocytopenia.
- *Urine:* Leukocyturia, proteinuria, possible microscopic hematuria.
- Enzyme markers of skeletal muscle damage are elevated in the sera of 50% of patients during the first week of illness, such as creatine kinase, aldolase, etc.
- Hyperbilirubinemia, prolongations of the prothrombin time, and modest elevations of serum alkaline phosphatase are typical. There is mild hepatocellular necrosis in Weil's disease.
- Elevated markers of inflammation (C-reactive protein level, procalcitonin level, and erythrocyte sedimentation rate).

Serology

- *Between 0 and 7 days:* Real-time PCR (early diagnosis)
- *After 7 days:* Microscopic agglutination test (MAT); IgM ELISA test provides presumptive diagnosis
- *After 10 days:* MAT and IgM ELISA tests only.
  - *Culture:* Limited use (bacteria grow slowly, specific culture medium)

Radiography

The most common radiographic finding is a bilateral patchy alveolar pattern that corresponds to scattered alveolar hemorrhage. These abnormalities predominantly affect the lower lobes. Other findings include pleura-based densities (representing areas of hemorrhage) and diffuse ground-glass attenuation typical of acute respiratory distress syndrome (ARDS).

Management (Table 3)

Management should be started on high index of suspicion as early intervention may prevent the development of multiorgan failure and antibiotics are less likely to benefit once organ damage has occurred.[10]

TABLE 2 Modified World Health Organization (WHO) criteria for diagnosis of leptospirosis

Part A: Clinical data	
Headache	2 Points
Fever	2 Points
Temperature >39*C	2 Points
Conjunctival suffusion	4 Points
Myalgias	4 Points
Meningeal signs	4 Points
Conjunctival suffusion + meningism + myalgia	10 Points
Jaundice	1 Points
Albuminuria /Nitrogen retention	2 Points
Haemoptysis / Dyspnea	2 Points
Part B: Epidemiological factors	
Heavy rainfall	5 Points
Contact with contaminated environment	4 Points
Animal contact	1 Points
Part C: Bacteriological and laboratory Findings	
Isolation of leptospira in culture	Diagnosis certain
PCR	25 Points
Positive IgM ELISA	15 Points
Slide Agglutination test (SAT) Positive	15 Points
MAT single high titer	15 Points
MAT Rising titer/seroconversion (Paired sera)	25 Points
Presumptive leptospirosis if score • Part A or Part A & Part B score: 26 or more • Part A, B, C (Total): 25 or more **Possible leptospirosis if score between 20-25 points**	
ELISA—enzyme linked immunosorbent assay IgM—Immunoglobin M MAT—Microscopic agglutination test	

TABLE 3 Management of leptospirosis

Indication	*Regimen*
Mild leptospirosis	• Doxycycline 100 mg twice a day or • Amoxycillin 500 mg thrice a day or • Ampicillin 500 mg thrice a day
Moderate/Severe leptospirosis	• Penicillin 1.5 million units IV or IM 6 hourly or • Ceftriaxone 2 gm/day IV or • Cefotaxime 1 gm IV 6 hourly • Doxycycline 200 mg IV loading followed by 100 mg IV 12 hourly
Chemoprophylaxis	• Doxycycline 200 mg PO once a week or • Azithromycin 250 mg PO once or twice a week

All regimens to be given for 7 days. Aggressive supportive care in leptospirosis essential and can be lifesaving.

TABLE 4 Differentiating clinical features of various diseases

Disease	Symptoms											Physical and laboratory findings	Chest radiograph
	Fever	Cough	Sputum	Headache	Dyspnea	Rash	Sore throat	Joint pain	Myalgia	Confusion	Diarrhea		
Brucellosis	++	++	–	–	+	+	–	+	+	+	–	Hepatosplenomegaly, painful lymphadenopathy	Soft miliary mottling, Parenchymal nodules, consolidation, hilar or paratracheal lymphadenopathy, pneumothorax
Leptospirosis	++	++	+	+++	++	Hemorrhagic rash over legs	+	+	++	++	_	Hepatomegaly Icterus Hemoptysis Conjunctival suffusion	Multiple ill - defined nodules in both lungs
Malaria	++	–	–	+	–	–	+/–	+/–	+	++	+	Hepatosplenomegaly Icterus	Normal
Influenza	+	++	++	++	++	–	+/–	+	+	+/–	+	–	Bi-basal air space opacities, perihilar reticular and alveolar infiltrates
Mycoplasma pneumonia	++	++	++	-	++		–	–	–	–	–	Abnormal LFT	Bronchial wall thickening, Centrilobular nodules, Ground glass attenuation, consolidation
Dengue	++ biphasic fever	–	–	+++	+	++ purpuric rash	–	++	+	+	–	Hepatosplenomegaly Pleural effusion lymphadenopathy	Usually normal Sometimes pleural effusion
Enteric fever	++ continuous fever	–	–	+/–	–	Blanching erythematous maculopapular lesions	–	+/–	+	+/–	+	Hepatosplenomegaly	No changes
Tuberculosis	+ evening rise	++	+	+/–	+/–	–	–	+/–	+	+/–	+/– abdominal tuberculosis	Hepatosplenomegaly Pleural effusion lymphadenopathy	Consolidation Infiltrates Pleural effusion Military shadows
Legionellosis	+	+	+	–	+/–	–	–	+	+	+/–	+	Renal and hepatic dysfunction	Consolidation Infiltrates
Rickettsial Disease (Scrub Typhus)	+	+	+/–	+	+/–	Eschar for lower part of body	–	+/–	++	–	+	Renal and hepatic dysfunction Splenomegaly lymphadenopathy	Mostly normal

Differentiating Brucellosis and Leptospirosis with Other Diseases

The differential diagnosis of these infections is broad, reflecting the diverse clinical presentations of the disease. When fever, headache, and myalgia predominate, influenza, and other common and less common viral infections (e.g., dengue and chikungunya) should be considered. Malaria, typhoid fever, Rickettsial diseases may mimic the early stages of disease and are important to recognize. Dual infections have been reported. In this light, it is advisable to conduct testing for other diseases also. Some common features to differentiate these infections with other common infections are shown in **Table 4**.

Conclusion

Brucellosis and leptospirosis have diverse clinical presentations, so these diseases have to be differentiated from many common disorders like influenza, malaria, dengue, typhoid, and rickettsial diseases. Although, management of these diseases is not difficult but early diagnosis is key to better outcome.

CHAPTER

169 Growing Threat of *Klebsiella*—How to Counter?

Aditya Prakash Misra

Abstract

Klebsiella pneumoniae is an important pathogen that belongs to family *Enterobacteriaceae*. Incidence of extended spectrum beta lactamases (ESBL) producing Gram-negative bacteria has gradually increased in last 2–3 decades. Problem is further compounded by carbapenemase producing Gram-negative bacteria. Carbapenem-resistant Enterobacteriaceae (CRE) has become a global threat recently. WHO in a policy statement in 2017 had mentioned that future development of antimicrobial agents should focus on CRE.[1] Klebsiella is the most important pathogen of CRE family encountered all over the world.

Introduction

Edwin Klebb in 1875 had described Klebsiella, as a Gram-negative bacterium belonging to family Enterobacteriaceae. *Klebsiella* is part of microbiome in healthy individuals and colonizes mainly gastrointestinal system. It can cause severe infections in critically ill and immune-compromised patients. Klebsiella causes urinary tract infection, pneumonias, blood stream infections, liver abscesses, necrotizing fasciitis, meningitis and surgical site infections, mainly. Kaur et al. from a single tertiary care center in Delhi reported 69.3% mortality in patients suffering from colistin-resistant K pneumonia infections.[2] Another study from South India reported high rates of resistance to Carbapenem, Minocycline, and Tigecycline in isolates of *Klebsiella* blood stream infections.[3] Carbapenem resistance had increased during the study period. High resistance of Klebsiella to various antibiotics is also reported from China, Korea, Greece, other European countries, and the USA. Falagas et al. have shown that mortality due to carbapenem-resistant *Klebsiella pneumoniae* exceeds 60% despite the combination therapy.[4]

Klebsiella pneumoniae is the main pathogenic organism in the genus. In some cases K oxytoca have been isolated from human clinical specimens. *Klebsiella* can be differentiated into various types by biotyping, serotyping, phage typing, bacteriocin typing and molecular typing. Serotyping is most commonly used and is based on capsule antigens.

Pathogenicity

Pathogenicity of *Klebsiella* depends upon these factors—

Capsular antigens: Klebsiella has a capsule made of complex acidic polysaccharides. Capsular antigens are essential to virulence and have been divided into 79 serotypes. Klebsiella strains of K1, K2, K4, and K5 are more virulent.

Fimbriae: Fimbriae (Pili) are filamentous projections on bacterial surface by which it attaches to the host surface.

Fimbriae help in developing biofilms and also help organism to adhere to medical devices.

Lipopolysaccharide: Helps in evading host's defense mechanisms.

Siderophores: Iron is an essential factor in bacterial growth. The level of free bioavailable iron is too low for bacteria growth. Klebsiella secretes high affinity, low molecular weight iron chelators, called siderophores. These siderophores in Klebsiella belong to two different groups. More common, the phenolate group with best known representative enterobactin, and hydroxamate type siderophores with best known representative, as aerobactin and ferrioxamine.[5]

Some terms like hypervirulent Klebsiella pneumoniae (hvKp) and hypermucoviscous K pneumoniae are also being used recently. hvKp was first recognized in Taiwan in 1986,[6] although genomic studies suggest that it existed unrecognized as early as 1920s.[7] Approximately 70% of hvKp isolates are capsular types K1 or K2. Fortunately less drug resistance has observed in hvKp. The siderophore, aerobactin accounts for more than 90% of hvKp's total siderophore production. Clinical laboratories are unable to differentiate between classical K pneumoniae and hvKp. There is no commercially available assay that reliably differentiates the two. However, several biomarkers, including peg 344, iroB, iucA, MPa, mpA2, and quantitative siderophore production greater than30 mg/mL predict hvKp strains.[8]

Hypermucoviscous phenotypes may also show increased virulence, as it may prevent them from host's defense mechanisms.

Role of Clinical Microbiology

In isolates suspected to be carbapenemase producer Klebsiella, a double disc synergy test (DDST) on Muller-Hinton agar media may be done. Tests using inhibitors such as boronic acid or EDTA are being used more frequently to detect KPC or Metallo Beta Lactamase (MBL) carbapenemase respectively. The modified carbapenem inactivation method (Mcim) has replaced modified Hodge test recently, as it is easy to perform and is less expensive. Various automated systems may be employed to detect KPC producers. Various molecular methods, for example molecular antibiogram, have been used in identification of pathogens and most common resistant genes. Molecular assays though expensive, but help clinicians in de-escalation of therapy, avoiding unnecessary antibiotics, reducing length of stay and mortality.[9]

Mechanisms for Antibiotic Resistance

As early as 1970s, aminoglycoside resistant Klebsiella were noted. Since 1982, strains that produce ESBL, making them resistant to extended spectrum cephalosporins (hallmark being resistant to ceftazidime). These ESBLs were, SHV-5 in Europe and TEM-10 & TEM-12 in the USA. The first report of carbapenemase-resistant Klebsiella pneumonia in the USA was in 1996. Since then it has been widely reported in various countries of Europe, South America, and Asia. Carbapenemase produced may belong to Ambler class A (K pneumoniae carbapenemase) or class B (metallo-β-lactamases, MBL, New Delhi metallo-β-lactamases, NDM) and class D (OXA-48 like carbapenemases).[9]

Polymyxins serve as a last resort for treatment in CRE. Lately resistance to polymyxins is being encountered all over the globe. Polymyxin resistance has been reported as an independent marker for 14-day mortality in patients with KPC producing K pneumoniae. Polymyxin resistance is chromosomally mediated and takes place by addition of cationic groups to bacterial outer membrane. More recently a plasmid mediated gene (mcr-I) has been discovered, which confers resistance to polymyxins.[10] As per clinical laboratory standards institute/European committee on antimicrobial susceptibility testing (CLSI/EUCAST) both microdilution should be used as a reference model for polymyxins susceptibility testing.

The SENTRY[11] and SMART study[12] reported that in India, most common gene foe encoding carbapenemase was NDM-1 followed by OXA-48 variants. However, a study from South India, done later reported equal distribution of NDM-1 and OXA-48 like genes.[13]

Treatment

The worldwide spread of multidrug resistant Klebsiella and KPC producing strains are causing a serious threat. In our country resistance to various antibiotics is steadily increasing. Problem is further aggravated by absence of a central collating body, ineffective antibiotic stewardship program, and rampant misuse of available antibiotics. Major pharmacological companies are not doing enough

research for discovering newer antibiotics. There is no gold standard treatment for KPC producing Klebsiella. The choice of treatment depends upon site and severity of infection, local antibiogram, and host factors. Various strategies to effectively treat these infections are discussed below.

Combination Therapy

Most of the retrospective studies have found that combination therapy is associated with lower mortality. Choice of the combination should be guided by local antibiogram. For KPC producing Klebsiella, it will be prudent to use polymyxins with carbapenems. However, this combination may not show good results, if MIC levels are more than 16 µg/mL. A study from ICU patients in North India showed polymyxins resistance in Klebsiella isolates in blood, urine, and sputum samples as 8.75%, 4.26%, and 4.4%, respectively.[14]

Dual Carbapenem Therapy

It refers to the use of ertapenem with either meropenem or doripenem. Ertapenem has highest affinity for carbapenemase and may consume most of it and allowing larger part of the other carbapenem to exert its bactericidal effect.[15]

Triple Combination Therapy

Triple combination of polymyxins, carbapenem, and tigecycline has been found to significantly reduce the mortality in infections due to KPC producing Klebsiella strains. The emergence of polymyxins resistant strains during the treatment is a serious concern.[15]

Newer Agents

Avibactam is a non-beta-lactam beta-lactamase inhibitor that has activity against class A and C beta-lactamases including KPC and AmpC. Its combination with ceftazidime has been approved by FDA in 2015 for complicated UTI including pyelonephritis. It may not be effective if MIC levels are more than 8 µg/mL. Meropenem with another beta-lactamase inhibitor vaborbactam is also being tried. Imipenem-cilastatin along with relebactam, another new beta-lactamase inhibitor is also being used. Plazomicin a new aminoglycoside with efficacy against multidrug resistant Enterobacteriaceae bacteria is also available now. Eravacycline, a semi-synthetic tetracycline with efficacy against KPC and NDM carbapenemase, is showing promise.[15]

Conclusion

To conclude, the management of multidrug and pan-drug resistant Klebsiella is a serious challenge to health care. Klebsiella is a major source of carbapenemase resistance in various species through horizontal transfer of plasmids and transposons, leading to emergence of multidrug and even pan-drug resistance. We need good infection control program, antibiotic stewardship, environmental cleaning, hand hygiene, and contact precautions to prevent spread of these deadly bacteria. Tracing carriers of KPC Klebsiella and eradicating through selective digestive decontamination may be an exciting option.[16]

CHAPTER

170 Infection with *Acinetobacter*—A Challenge for the Physician

Krishna Padarabinda Tripathy

Abstract

Acinetobacter species has emerged as one of the most significantly resistant pathogens causing heath-care associated infections. *Acinetobacter baumannii*, a Gram-negative coccobacillus constitutes 85% of the infections caused by Acinetobacter species in human beings. Prolonged length of hospital stay, invasive procedures, use of third-generation cephalosporins, etc. are some of the risk factors contributing toward the infection with this resistant organism. It has been increasingly recognized as an important cause of pneumonia, septicemia, meningitis, urinary tract, and wound infections and is associated with high mortality. Due to its inherently resistant property and aptitude to develop MDR and XDR strain, it has proven to be a therapeutic challenge for the physicians. This chapter highlights the infection and disease producing factors, mechanism of antibiotic class resistance and its treatment, and an unpublished data about *A. baumannii* in brief.

Introduction

In the modern health-care system, Acinetobacter has undoubtedly emerged as one of the most significant pathogens accountable for health-care associated infections involving multiple organs. It is also known to cause community acquired infections in combat zone and disaster associated infections because of its ubiquitous nature. In 1911, Acinetobacter species were isolated from soil and first described as Micrococcus calcoaceticus. Thereafter, the genus was renamed multiple times for several years, and since 1950, it is referred as Acinetobacter. Earlier Acinetobacter was an organism of unconvincing pathogenicity, which during the last three decades has emerged as a serious infectious agent to the hospitals around the globe.

According to many studies worldwide, it has been found that *Acinetobacter baumannii* develops resistance to antimicrobials rapidly, resulting in multidrug-resistant and pan-drug-resistant strains, which may cause large outbreaks of health-care associated infections. The World Health Organization declared that the ESKAPE organisms (*Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, A. baumannii, Pseudomonas aeruginosa, and Enterobacter species*) are known to effectively escape the outcome of antibacterial drugs. *A. baumannii* is amongst the most serious ones in the group. This Gram-negative coccobacillus because of its inherent mechanism of resistance and pathogenicity has become a threat to mankind and one of the significant therapeutic challenges for the physicians.

Bacteriology

These species are strictly aerobic, Gram-negative, non-motile, oxidase negative, catalase positive, non-fermenting coccobacillus that grows at 20–30°C and could be easily recovered on standard culture media. Amongst the Acinetobacter species causing infections in human beings, *A. baumannii* constitutes about 85% of the infections in humans. Other species in the genus causing occasional infections in human beings are *Acinetobacter nosocomialis, Acinetobacter pittii*.[1] Molecular methods like Matrix assisted laser desorption-ionization-time-of-flight

TABLE 1 Risk factors for colonization and infection with the pathogen

Risk factors for colonization and infection with A. baumannii	
Health-care associated infections in ICU patients	• Prolonged length of hospital/ICU stay • Mechanical ventilation • Invasive procedures • Tracheostomy, central venous catheterization • Nasogastric tube feedings • Recipient of third-generation cephalosporins, fluoroquinolones, and carbapenems
Health-care associated infections in hospital	• Hands of the health-care worker • Respiratory therapy equipment • Infusion pumps • Fomites like bed rails, door handles, tabletops
Community-acquired infections	• History of alcohol abuse • Diabetes mellitus • Smoking • Chronic lung disease, Chronic kidney disease • Cancers

mass spectrometry (MALDI-TOF-MS) and quantitative real-time polymerase chain reaction (RT-PCR) are often required to detect *A. baumannii* because it is difficult to identify it just based on phenotype.

Acinetobacter species that have been isolated from foods, arthropods, the environment, soil, and water are known to be its natural habitats. In our day-to-day practice, Acinetobacter culture positivity should be analyzed as colonization which is the presence of bacterium on a body surface (like on the skin, oral cavity, airway, or intestines) and not causing disease in the individual, in contrast to infection, where there is invasion of a host's body tissues by disease-causing organisms. There are various risk factors for colonization and infection with the pathogen that is summarized in **Table 1**. It is hypothesized that *A. baumannii* species are ubiquitous in nature[2] as they survive in dry as well as damp environment which promotes its environmental desiccation for weeks and causes fomite contamination in hospitals.

In the United States, the Centre for Disease Control have estimated 12,000 Acinetobacter infections every year out of which multidrug-resistant strains causes 7,300 cases with high mortality.[3] The Indian Council of Medical Research estimates Acinetobacter species as the second most common isolated pathogen (45%) causing hospital-acquired infections after Pseudomonas species (52%). *A. baumannii* was found resistant to most antibiotics except colistin, it showed 70% non-susceptibility to almost every antibiotics tested. Invasive specimens from lower respiratory tract and blood had higher non-susceptibility rates against different categories of antibiotics in comparison to other specimens.[4]

TABLE 2 Virulence factors and their role in pathogenesis of *A. baumannii*

Virulence factors	*Role in pathogenesis*
Porin (OmpA, Omp33-36, Omp22, CarO, Opr D-like)	Adherence and invasion, induction of apoptosis, biofilm formation
Capsular polysaccharide	Growth in serum, prevent complement activation and delays phagocytosis, biofilm formation
Lipopolysaccharide (LPS)	Serum resistance, survival in tissue infection, evasion of the host immune response
Phospholipase (PLC and PLD)	Exert cytotoxic effect on epithelial cells and facilitate their invasion
Iron-acquisition systems	Ability to grow in iron deficiencies in human host through secretion of siderophores

Pathogenesis

A. baumannii intrinsically is more virulent in humans as compared to other Acinetobacter spp. as it grows better at 37°C and resists macrophage uptake than other species. The important virulence factors and their role in pathogenesis is summarized in the **Table 2**.

Mechanism of Resistance

Acinetobacter infections have proven to be a therapeutic challenge to physicians as it is one of the most resistant organisms known and its treatment centers upon controlling the antibiotic resistance. It is an inherently resistant organism which has the aptitude to develop multidrug-resistant and extensive drug-resistant strains. This is one of the vital contributory factors in its capability to adapt itself to changes in environmental pressures. The common mechanisms of resistance are explained in **Figure 1**.

AmpC cephalosporinase: Acinetobacter-derived cephalosporinases (ADCs) are the genomic variants of *A.*

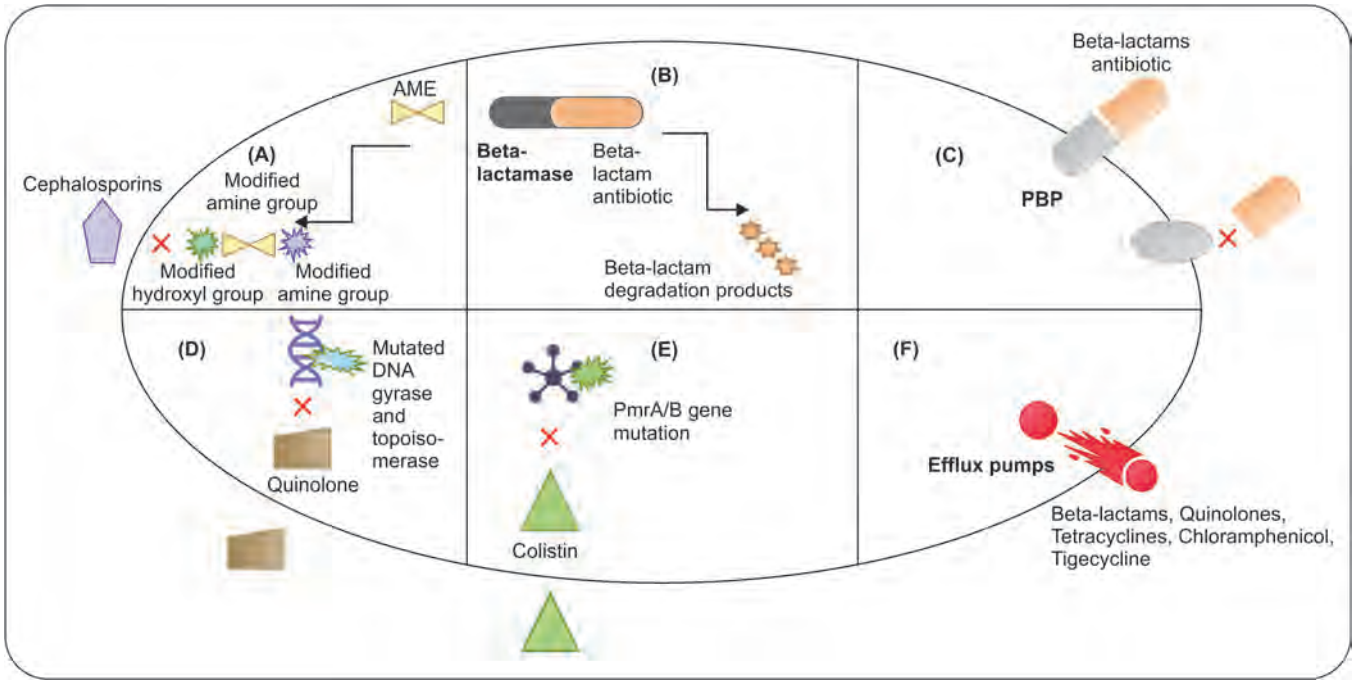

Fig. 1: Mechanism of resistance in *Acinetobacter baumannii*

baumannii which contains a non-inducible chromosomal AmpC cephalosporinase. Addition of promotor insertion sequence known as ISAba1 regulates the AmpC gene. Overexpression of AmpC cephalosporinase/ Aminoglycoside modifying enzyme (AME) and the presence of ISAba1 is intrinsically responsible for resistance to extended spectrum cephalosporin. Antibiotics like Cefepime and carbapenems, so far seems to have a stable response to these enzymes.

- *Porin channels:* Amongst the list of various mechanisms causing carbapenem resistance, the commonest are absence of penicillin binding protein 2(PBP2) and production of naturally occurring oxacillinase (OXA). Some isolates have been observed to have added downregulation of porin expression, leading to reduction in entry of carbapenem.
- *Efflux pumps:* Overexpression of bacterial efflux pumps decreases the concentration of β-lactam antibiotics in the periplasmic space. Efflux pumps usually act in association with overexpression of AmpC β-lactamases or carbapenemases causing resistance in Acinetobacter. Efflux pumps not only remove β-lactam antibiotics, but can actively remove chloramphenicol, quinolone, tetracycline, tigecycline, and disinfectants.
- Serine and metallo-β-lactamases: It confers resistance to carbapenems as they as they exhibit strong hydrolytic activity against all β-lactam antibiotics except monobactams (i.e., aztreonam).
- *DNA topoisomerase mutations:* Resistance to aminoglycosides and quinolones in Acinetobacter infections is due to the point mutations in the gyrA and parC topoisomerase enzymes which are the bacterial targets.
- *PmrA and PmrB proteins:* Due to its overexpression, resistance to colistin occurs.

Definitions in Antimicrobial Resistance[5]

- *Multidrug resistant (MDR):* When the isolate is resistant to at least three classes of antimicrobial drugs, that is, all penicillin and cephalosporins (including inhibitor combinations), aminoglycosides and fluoroquinolones, it is said to be "MDR Acinetobacter species."
- *Extensively-drug resistant (XDR):* When the Acinetobacter isolate is resistant to carbapenems and shall also be resistant to three classes of antimicrobials mentioned above (MDR), it is said to be "*XDR Acinetobacter species*."

- *Pan-drug resistant (PDR):* When the XDR Acinetobacter isolate is also resistant to tigecycline and polymyxin, it is said to be "*PDR Acinetobacter species*."[6]

Clinical Manifestations

Pneumonia

Nosocomial pneumonias occur due to aspiration, prolonged hospital stay, and mechanical ventilation, which create an ideal environment for transmission of bacteria like Acinetobacter. It adheres and forms biofilms on the tube. The clinical manifestation is fever and increased sputum production. It is diagnosed through respiratory cultures. Imaging findings are non-specific and can include lobar consolidations, pleural effusion, or rarely cavitation.

Community-acquired pneumonia is not as common as nosocomial pneumonia but a serious manifestation when caused by *A. baumannii*. Majority occurs in regions with hot and humid climates. It is caused by a diverse range of strains and is distinct from hospital strains. Symptoms and signs are similar in both the types. Without appropriate initial antibiotic therapy, mortality rate has been reported to be as high as 64%.[7]

Bloodstream Infections

Bloodstream infections due to *A. baumannii* occur mostly in the presence of central venous catheter or due to dissemination secondary to extensive pneumonia. Patients may present with septic shock and disseminated intravascular coagulopathy.

Skin and Soft Tissue Infections

Acinetobacter species are known to colonize the skin flora and it is important to differentiate colonization from nosocomial infections. Trauma-associated *A. baumannii* skin and soft tissue infections may be due to orthopedic external fixator devices, gunshot wounds, etc. There have been several recent reports regarding the occurrence of necrotizing fasciitis due to *A. baumannii*. The skin infection due to this species may evolve from an edematous peau d'orange appearance to sandpaper like, to a necrotizing process with hemorrhagic bullae.

In war-zones or after a traumatic injury to soldiers, Acinetobacter has been a significant cause of skin & soft tissue infections. These infections are also found following natural disasters (floods, earthquakes, etc.).

Urinary Tract Infections

Health-care associated urinary tract infection which is a major source of *A. baumannii* isolates occur mainly as catheter-associated infections or with percutaneous nephrostomy tubes. Community-acquired *A. baumannii* urinary tract infections are reported in post-renal transplant and nephrolithiasis patients.

Other Miscellaneous Infections

Meningitis: Majority of the cases of *A. baumannii* meningitis have been reported in post-traumatic injuries and post-neurosurgical procedures.

Osteomyelitis: Occurs typically postsurgical or trauma related. Acinetobacter can cause keratitis due to use of contact lenses, and few cases of native and prosthetic valve endocarditis have been reported.

Our institutional experience (unpublished): In our institute KIMS Bhubaneswar, a recent study was done for 1 year (July, 2018–June, 2019). Around 455 patients grew *A. baumannii* infection in various cultures, out of which 348 (76.4%) found in ICU patients and 107 (23.6%) in non-ICU patients. Respiratory tract infection was the commonest infection in ICU as well as non-ICU settings, followed by septicemia in ICU and skin and soft tissue infection in non-ICU settings. In ICU setting, 8% of isolates were pure MDR, 68% were XDR, 7% PDR, and 17% were sensitive to all classes of antibiotics while in non-ICU patients, 14% of isolates were pure MDR, 52.3% XDR, 9% PDR, and 24% were sensitive to all classes of antibiotics. This states the seriousness of infections caused by MDR and XDR *A. baumannii* organisms in a health-care setting and the spread of pan drug resistance even in non-ICU areas. **Figure 2** depicts the pattern of drug resistance as per the isolates obtained from different site of infections.

Treatment

Acinetobacter is considered amongst the most resistant organisms and initiating effective empirical therapy is challenging to the physicians. Definitive therapy should be based on antimicrobial susceptibility test results.

Empirical Therapy

Antibiotic susceptibility pattern is an important factor, which guides clinicians regarding the therapy in an intrinsically resistant organism. In *A. baumannii*

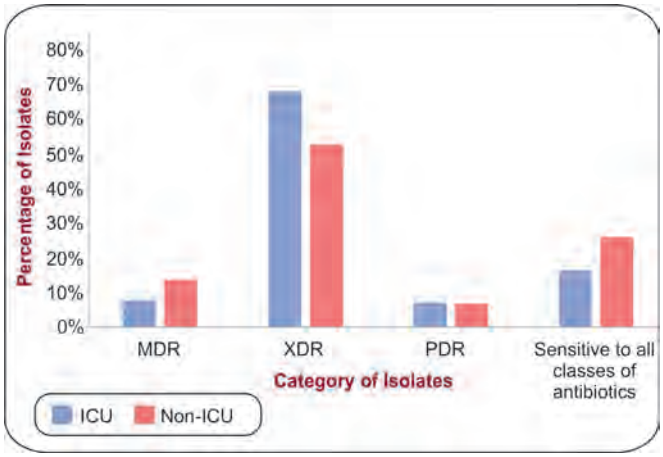

Fig. 2: Pattern of drug resistance in *A. baumannii* infection in ICU and non-ICU patients

infections, empirical therapy is advisable to initiate with carbapenems, as the probability of *A. baumannii* being resistant to cephalosporins (a common first-line antibiotics) is more. After the sensitivity reports therapy is modified accordingly.

Treatment of MDR *Acinetobacter* Species

Here the preferred drugs are Carbapenems, if susceptible.[8] Usually, imipenem is given at the dose of 500 mg q6h and meropenem at the dose of 2g q8h. The prolonged infusion over 3–4 hours is better than bolus injections.

Treatment of Extensive and Pan-drug Resistant *Acinetobacter* Species

The resistance rates of carbapenems in *A. baumannii* infections have been rising substantially globally. However, there is no consensus suggesting optimal anti-microbial treatments for such strains. The options available are: Tigecycline is a glycylcycline antibiotic and is another drug that can be used clinically against MDR *A. baumannii*; Tigecycline is usually found to have a low MIC (2 g/mL) for *A. baumannii* strains, the serum concentration of the drug is also low, and the outcome of ventilator-associated pneumonia and bacteremia associated with *A. baumannii* clinical trials have shown inferior results compared to other alternative agents.

Minocycline is a tetracycline that has good antimicrobial activity and it may even act against the strains resistant to other tetracyclines (including tigecycline). Cross-resistance has been reported with minocycline. Minocycline therapy has high treatment success once given in combination therapy.

Aminoglycosides (amikacin and tobramycin) are not of abundant use against *A. baumannii* due to its toxicity and lack of lung penetration. Inhaled tobramycin can be an adjunct as inhalational therapy in *A. baumannii* pneumonia.

Polymyxins (Colistin and Polymyxin B) being a cationic detergent disrupts bacterial cytoplasmic membranes. It was previously abandoned for its nephrotoxicity and neurotoxicity. Currently the nephrotoxicity rates are reportedly 36%, and neurotoxicity is rarely seen these days due to modified formulations. Although the dosage differs from patient-to-patient, polymyxin can be given at the dose of 1.5–3 mg/kg q12h in MDR-Acinetobacter infections.

Colistin can be given inhalational and intravenous route. For combination therapies, colistin is a key component. An important side effect of inhalational colistin is bronchoconstriction.

The rising rates to resistance are to the last-line drugs, that is, tigecycline and polymyxin against *A. baumannii* are highly reported and is of substantial concern. There is a critical need to find alternative therapeutic options for this.

Combination antimicrobial therapy: Combination therapy appears to be promising in prevention of emergence of resistance and in improving clinical outcomes. Its key component to treat MDR *A. baumannii* is Colistin. Many colistin-based combined therapies, including colistin-rifampicin, colistin-minocycline, colistin-carbapenem, colistin-sulbactam have been found to act synergistically in vivo or in vitro against *A. baumannii*.

Although polymyxin causes dose-related nephrotoxicity, Polymyxin B combination therapies when used with amplified doses of antibiotics such as carbapenem, minocycline, and tigecycline have been found to attenuate the development of polymyxin resistance.

Future treatment options: In view of increasing rates of emergence of multidrug resistance and lack of newer class of antibiotics, alternative strategies are in pipeline to control and treat *A. baumannii*.

- *Bacteriophage:* Bacteriophages therapy is being re-evaluated as an alternative management option to help counteract antibiotic resistance due to its high

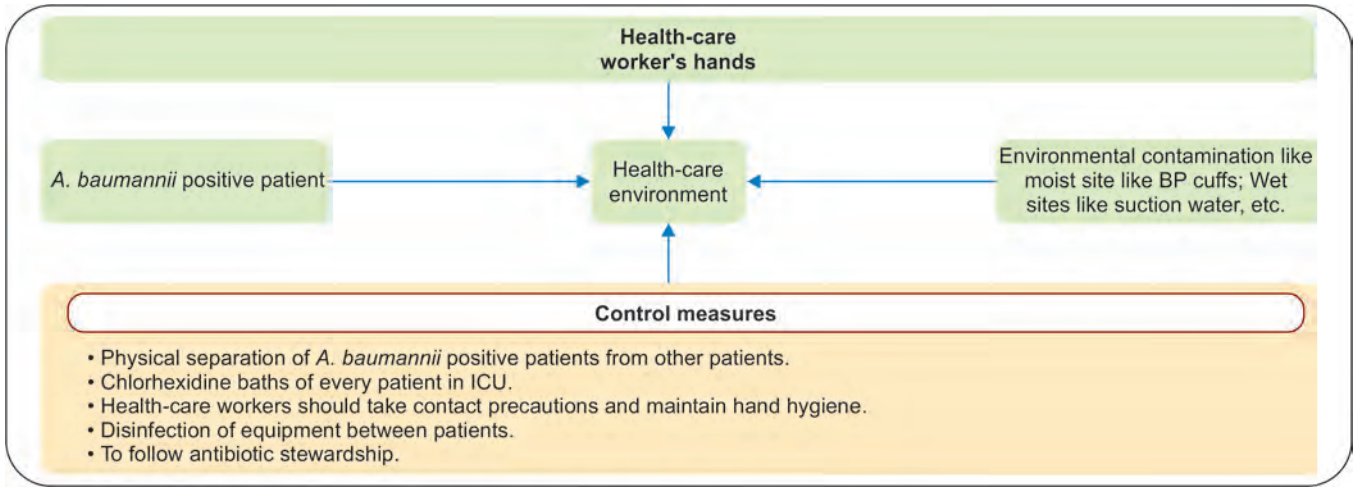

Fig. 3: Source of infections and the control measures to prevent infections

specificity and ability to work quickly. Examples—vB_Ab-M-G7 and B#-C62[8] for MDR *A. baumannii*.

- *Cathelicidins: (antimicrobial peptides):* There were positive results from a cathelicidin known as "Tammar Wallaby WAM1." It has a probability for parenteral use in Acinetobacter infections in humans.
- *Radioimmunotherapy:* It is emerging as a therapeutic possibility due to its ability to kill microorganisms as effectively as cancer cells.[9]
- *Photodynamic therapy:* A photosensitizer is topically applied into the infected tissue, followed by red or near infra-red illumination is given which penetrates and kill the infected tissue. It is used to treat localized bacterial infections.
- *Nanoparticle technology:* This novel and inexpensive technology[9] has shown effective resu[l]ts with its stable nitric oxide-releasing nanoparticle platform and it is potential option for treatment of *A. baumannii* induced complex cutaneous infections.

Infection Control and Prevention

Source of infections and the control measures to prevent infections is summarized in **Figure 3**.

Conclusion

Acinetobacter species have emerged as one of biggest challenge to physicians because of its inherent resistant strains and ability to cause extensive resistance to even the newer antimicrobials. To decrease the spread and emergence of resistance of *A. baumannii* infections, it is important to promote rationale use of antibiotics, and take adequate control measures to prevent the establishment of drug resistant endemic strains.

CHAPTER

171 Scrub Typhus—Clinical Manifestations and Management

Sudhir Kumar, Govind Kumar, Arshad Ahmad, Amit Kumar Mishra

Abstract

Scrub typhus is an arthropod born acute infectious disease that is caused by intracellular Gram-negative organism Orientia tsutsugamushi. This disease is mainly reported from states of the Himalayan terrain, Eastern and Western Ghats, and the central part of India. Scrub typhus is transmitted by some species of trombiculid mites which are found in areas of heavy scrub vegetation. The mites feed on infected rodent hosts and subsequently transmit the parasite to other rodents and humans. The main target tissue of O. tsutsugamushi is the vascular endothelium in human, leading to generalized vasculitis and perivascular inflammatory changes, and results in end-organ damage of many vital organs including nervous system, cardiovascular system, kidney, lung, and other organ. Scrub typhus presents with fever, headache, myalgia, cough, abdominal pain, conjunctival redness, altered consciousness, apathy, shin pain, lymph node enlargement, hepato-splenomegaly, macula-papular rash and eschar. Currently, the drug of choice for treatment of scrub typhus is doxycycline. Other drugs used to treat scrub typhus, includes tetracyclines, chloramphenicol, rifampicin, azithromycin and quinolones.

Introduction

Scrub typhus is an arthropod born acute infectious disease that is transmitted to humans by *Trombiculidae* family. It is caused by intracellular Gram-negative organism *Orientia tsutsugamushi*. This disease was first described in 1899 in Japan. People of all ages are affected by this disease including those at extreme of age. The term "scrub" is related to the vegetation (land between woods and clearings) where vectors are proliferating. The name *scrub typhus* is misleading, as the disease can be contracted in many other habitats, including forest, beaches, large gardens, and plantations. The word "typhus" is a Greek word which means "fever with stupor" or smoke.[1] "Tsutsuga" means small and dangerous and "mushi" means insect.

Scrub typhus is mainly distributed in the tsutsugamushi triangle, which is bounded by Australia in the south, Japan in the east, Afghanistan in the west and southern parts of the Russia in the north. The disease is mainly prevalent to south-eastern and eastern parts of Asia including India, Myanmar, Nepal, Sri Lanka, Thailand, and other areas in the region.[2] More than hundred crore people of world are at risk for scrub typhus and an estimated ten lakhs cases occur annually.[3] In India, scrub typhus is reported from states of the Himalayan terrain, Eastern and Western Ghats and the central part of India. Number of *Leptotrombidium deliense* is affected by rainfall, which may be the cause for a higher case during the Monsoon time as shown by Gurung *et al*.[4] In India, the agent of scrub typhus is *O. tsutsugamushi*. Its antigenic structure is different from other Rickettsiae. Although our country India is a part of tsutsugamushi triangle, Scrub typhus grossly remains under diagnosed owing to the non-specific variable clinical presentation except eschar, poor specific diagnostic facility and very low index of suspicion by the physician.

Vector and Host

L. deliense and *L. akamushi* are the main vectors of scrub typhus, which are found in countries of the Southeast Asian region including India. This disease is spread through the larval mites or "chiggers." The natural hosts for scrub typhus are small rodents including *Rattus* subgenus. The field rodents and the vector mites act as a reservoir and because of these two the infection continues in nature.

Transmission and Pathogenesis

The causative organism of scrub typhus is *O. tsutsugamushi*, which is an intracellular Gram-negative bacterium. Humans are accidental hosts and the infectious agent is transmitted through the skin by the bite of larval stage of infected trombiculid mites or chiggers.[5] Disease occurrence is more in rainy season and commonly seen among persons who engage in occupational or other work related to contact with mite-infested area. The mites have a life cycle of four stages: adult, egg, larva and nymph. Only stage that can transmit the disease to humans is the chigger or larva. The chigger takes up tissue fluid and lymph. Very high number of *O. tsutsugamushi* are there in the salivary glands of the chigger and these are transmitted into their host when they take up tissue fluid.[6]

Transovarial transmission is seen in mite where they pass the infection on to their eggs. Likewise, transstadial transmission is also seen in which the infection transmitted from egg to the chigger and adult.

The strain of organism and condition of the host are two most important factors that decide the severity of disease. The pathophysiology of scrub typhus is not fully understood, though in general it is thought to be due to vasculitis either localized or disseminated. The principal target site of *O. tsutsugamushi* is the vascular endothelium in human. This organism acts at vascular endothelial cells leading to generalized vasculitis and perivascular inflammatory changes, and results in end-organ damage of many vital organs.[7] Both humoral and cellular immune response are seen against *O. tsutsugamushi.*

Clinical Features

The average incubation period of *O. tsutsugamushi* in humans is around 10 days and can vary between 6 and 21 days.[8] Main symptoms of scrub typhus are pyrexia, headache, muscle pain, dry cough, and abdominal discomfort. Patients may present with subacute/chronic pyrexia and fever of unknown origin.[9] The severity of the symptoms varies widely, depending on the strain of organism and condition of the host.

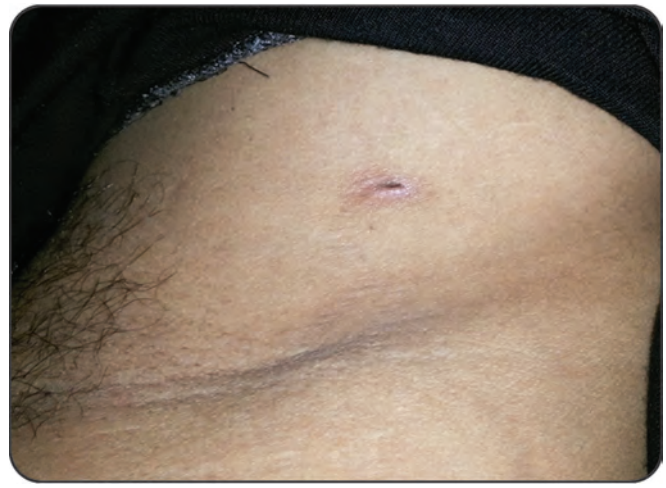

Fig. 1: Eschar at axilla

A small vesicular lesion at the chigger feeding site is usual first sign of scrub typhus, which usually changes into an eschar or an ulcer with local lymph node enlargement. An eschar is a typical lesion with black necrotic center and an erythematous border and is mainly located in the groin, axilla, genitalia, and neck **(Fig. 1)**. The eschar is found in patients suffering from scrub typhus ranges from 7% to 80% in different study. Eschar is the single most important clue for diagnosis on physical examination. The detection rate of eschar depends on multiple factors like the skin color of the infected person and site of the lesion.

Sudden onset fever is the most common symptom accompanied with conjunctival redness, severe headache, altered consciousness, apathy, myalgia, shin pain, and more characteristically lymph node enlargement and hepatosplenomegaly. Fever is usually of high grade and may be with shaking chills.

A maculopapular rash appear at end of first week which initially seen at the trunk and later on spread to the limbs. This rash is not well appreciated among dark skinned individuals.

Systemic symptoms and signs related to major organ system like the central nervous system, cardiovascular system, kidney, pulmonary, and digestive systems become evident by end of second week. Major organ system involvement may produce serious complication in the

form of myocarditis, pneumonia, meningitis/encephalitis, acute renal failure, and gastrointestinal bleeding. Acute respiratory distress syndrome development is more commonly seen in patients of scrub typhus who have high leukocyte count and late treatment. Meningitis, meningoencephalitis, or encephalitis is common form of neurological involvement seen in scrub typhus.[10]

According to Kim et al., older age (≥60 years), scrub typhus patients without an eschar, and laboratory parameters such as leukocyte counts >10,000/mm and serum albumin level ≤3.0 g/dL are potential indicators of complications.[11] Untreated patient remains febrile for about 2 weeks and have a long convalescence of around 6 weeks thereafter.

Differential Diagnosis

Differentiated and undifferentiated fever are two form of acute febrile illness (AFI). In differentiated fever there is obvious presence of focus of infection or inflammation, while in undifferentiated fever there is no obvious focus of infection and the symptoms and signs are quite nonspecific. In patient with undifferentiated fever several diagnostic possibilities are considered, especially in the tropics.[12] The differential diagnosis of scrub typhus includes typhoid fever, dengue fever, malaria, other rickettsioses, anthrax, leptospirosis, and hemorrhagic fevers. It is considered as one of the causes of fever of unknown origin (FUO) in endemic areas.

Diagnosis

Febrile illness along with eschar on physical examination almost confirms the diagnosis. Leukocytosis and decreased platelet count may be seen. Altered liver function and kidney function test may be seen in large number of cases. Ultrasonography may reveal hepatosplenomegaly.

The lab diagnosis of scrub typhus is either confirmed or supported by identifying the microbe in cell culture, presence of antigen by immune-histochemical methods or the antibodies by the indirect immunofluorescence assay (IFA) and detecting organism's nucleic acid using polymerase chain reaction (PCR).

As antigen identification tests have low sensitivity/specificity and require tissue specimens, serological tests to identify antibodies are the better diagnostic tool in real clinical scenario as they are simple and easy to perform.[13] After infection IgM antibodies against *O. tsutsugamushi* appear in the body at the end of first week while IgG antibodies appear at the end of the second week. The Weil-Felix (WF) test has better specificity but poor sensitivity and is based on the identification of antibodies to various *Proteus* species, which contain cross-reacting antigenic epitopes to antigens from members of the genus *Rickettsia*. The WF test is said to be positive when there is high titer of 1:320 or more or a fourfold rise in titer.

The standard serological test is the indirect IFA for the detection of IgM antibodies. This test has many demerit which consist of retrospective nature, availability of trained technician and equipment which may not be possible in many labs.[14] At present most lab use the enzyme-linked immunosorbent assay (ELISA) for the presence of IgM antibodies in scrub typhus as it gives an objective result and has sensitivity almost equal to that of IFA.[13] Rapid diagnostic kit to detect scrub typhus IgM antibodies have sensitivity in range of 34.7–96.7% and specificity between 93.3–99.7%.[15]

The samples from which causative microbe of scrub typhus is isolated are buffy coat of blood, defibrinated whole blood, plasma, tissue, skin biopsy, and arthropod samples. It takes around 4 weeks to detect rickettsia in cell culture. Molecular methods using PCR is possible from skin rash specimen, eschar, lymph node biopsies, or blood and is less time consuming. Nested PCR method is more sensitive than doing single PCR. This is a less time-consuming method and takes around 1 day.[16]

A positive IgM ELISA in the suspected patient with defervescence within 2 days of prescribing doxycycline or scrub IgM ELISA seroconversion on convalescent sera with other causes of acute febrile illness ruled out after proper investigations also favors scrub typhus infection.[12]

Management

There are several drugs to treat scrub typhus, including tetracyclines, chloramphenicol, rifampicin, azithromycin, and quinolones. Currently, the drug of choice is doxycycline, a member of the tetracycline family, and several studies have proved its effectiveness. The recommended therapeutic dose for scrub typhus in adult is doxycycline 200 mg/day for 7–15 days and tetracycline 2 g/day for 7–15 days in divided doses. But many case reports of natural resistance make it difficult to prescribe suitable antibiotic.[17] The use of azithromycin in pregnant

women is believed to be safe for both mothers and fetuses, and it is classified as category B by the US FDA Pregnancy Category. Azithromycin is an effective drug for the management of scrub typhus as it efficiently penetrates human white blood cells and macrophages, which are target area for of *O. tsutsugamushi*. It should be given as short course because of its longer half-life.[18]

Chloramphenicol can also be given in adults and its dose is 500 mg qid orally for 7–15 days. Rifampicin is also effective against *O. tsutsugamushi.*

Doxycycline is the drug of choice for prophylaxis and the usual prophylactic dose is 200 mg per week. Killed vaccines against scrub typhus was disappointing because of results in human studies were not as successful as they were in animal studies.

Current Status in India

Earlier Scrub typhus was an endemic disease in many pockets of our country. But because of large scale use of insecticidal later, scrub typhus cases were reported in very low number from India. Recently there had been increase in number of cases of scrub typhus in India. Resurgence may be due to changes in the human behavior, unplanned urbanization, and deforestation, which result in displacement of vectors as well host rodents. Human in town may get bitten by the disease-causing mite larvae while moving in parks or during any other recreational activities such as camping in the affected vegetation area.[19]

Conclusion

Scrub typhus is an important differential diagnosis of undifferentiated fever cases. Eschar is most important clinical sign. High index of suspicion is needed to diagnose it as India is a part of endemic zone "Tsutsugamushi triangle".

CHAPTER

172 *Burkholderia* Species

Shubhransu Patro

Abstract

Burkholderia species contain the most versatile organisms that occupy a surprisingly wide variety of ecological niches. These infections can be very difficult to treat and, in some cases, lead to death as it is considered to be one of the most antimicrobial-resistant organisms found in the clinical laboratory. These bacteria are used for the purpose of biocontrol, bioremediation, and promotion of plant growth, but safety issues regarding human infections, particularly in patients with compromised immunity, are still questionable. This chapter provides an overview of the genus *Bukholderia*, its ecological diversity, the clinical manifestations observed, and the management protocols that will guide the physician to effectively treat this infection.

Introduction

Burkholderia species continues to be one of the notorious multidrug resistant organisms among the nonfermenting gram-negative bacilli (NFGNB). First described by William Burkholder, the species majorly include plant pathogens and soil bacteria with two important exceptions, *Burkholderia mallei* and *Burkholderia pseudomallei*, which are known to be notorious pathogens in humans and animals.[1,2] Apart from being a primary pathogen in patients of Cystic fibrosis (CF), *Burkholderia* cepacia complex (BCC) has been found responsible for bacteremia in immunocompromised and chronically debilitated patients. There have been numerous documented outbreaks of BCC septicemia in intensive care units and patients with renal failure.[3] Similarly, *B. mallei* and *B. pseudomallei* have been reported as the causative agent of diseases known to be Glanders and Melioidosis, respectively, both of which carry significant mortality and morbidity.[4]

Taxonomy

William Burkholder, an American microbiologist, first discovered the organism responsible for bacterial rot of onion bulb at Cornell University in the year 1950 and was named as *Pseudomonas cepacia*.[1] In the year 1992, Yabuuchi et al. created a new genus "*Burkholderia*," and transferred *P. cepacia* and six other species belonging to rRNA group II of the genus *Pseudomonas* under the new genus.[5] Since the discovery, the taxonomy of the new genus has undergone considerable changes and presently the genus *Burkholderia* consists of 22 species.[6] All the members of the species possess a very large genome ranging between a size of 6 and 9 Mb, which renders the organism versatile and ubiquitous. In the subsequent years, Vandamme and colleagues described *Burkholderia cepacia* as a complex of closely related genomovars and genomic species and referred them collectively as BCC, which included ten different unique species. The members of the BCC are *B. cepacia, B. multivorans, B. cenocepacia, B. stabilis, B. vietnamiensis, B. dolosa, B. ambifaria, B. anthina, B. pyrrocinia, and B. ubonensis.*[2] Based on comparative 16S ribosomal RNA and recA sequencing, multilocus sequence typing (MLST), and intermediate DNA-DNA binding values, recently seven novel species of *Burkholderia* have been identified and are proposed to be included under BCC.[7] The seven new

members are; *B. latens, B. diffusa, B. arboris, B. seminalis, B. metallica, B. contaminans, and B. sabiae*.

Epidemiology

The ability of *Burkholderia* species to survive in extreme environmental conditions makes it ubiquitous. Because of minimal nutritional requirements, it can survive for months in media and solutions like antiseptics, sinks, water, and intravenous fluids. They also tend to reside on indwelling catheters, IV cannula, and nebulizers.[8] Commercial use of BCC in agriculture as a biocontrol agent, in the bioremediation of toxic agents and plant growth promotion contributed to the increased incidence of human infection by the organism. Various reports have documented person-to-person transmission by a few strains of BCC and *B. pseudomallei*.[9] Studies have shown that by the age of 18 years, 3.5% of patients suffering from CF harbor BCC.[10] Among all other *Burkholderia* species, BCC is the most frequently isolated clinical pathogen followed by *B. mallei* and *B. pseudomallei. B. pseudomallei*, the causative agent of Melioidosis, is predominantly found in the regions of Asia, Africa, Northern Australia, and South America and is isolated from soil and water. It is also known to cause outbreaks in Thailand causing significant mortality and morbidity. *B. mallei* also share the same geographical territories as *B. pseudomallei* and primarily affects horses, causing equine glanders. It was one of the first used agent as biological weapon by Germany in the World War I.[11] Human transmission occurs by percutaneous inoculation, ingestion, or inhalation from environment, contact with infected animals and even laboratory acquired infections have been reported.[12] Few other strains like *B. gladioli* and *B. pickettii* have also been reported to cause nosocomial infections and multidrug resistant outbreaks in certain communities and hospitals posing an emerging threat to the society. However, little is known about the epidemiology of these particular species.

Clinical Manifestations

BCC Infection in Cystic Fibrosis

Owing to increased life expectancy in patients with CF, BCC has emerged as a major cause of morbidity and mortality. There is chronic colonization of the major airways with BCC in these patients and it may persist for months to years. Up to 20% of the infected patients rapidly deteriorate due to necrotizing pneumonia and sepsis, which may result in death.[13] This fatal clinical decline in patients with CF is known as "Cepacia Syndrome" and it has not been observed with any other pathogens. This explains the varied outcomes amongst CF patients who are infected with same strain. Reports of "Cepacia Syndrome" have also been documented in non CF patients.[14] There has been reported mortality of 75% in patients with CF who undergo transplantation.[15]

BCC Infection in Non-CF Patients

BCC is recognized as an important pathogen in patients suffering from chronic granulomatous disease where there is inability of macrophages to produce reactive oxygen species due to mutations in NADPH oxidase complex. Mostly, it is a nosocomial infection via contaminated hospital equipment like disinfectants, antiseptics, topical anesthetics, and respiratory therapy equipment. BCC bacteremia in non-CF hospitalized patients is most often seen in patients with comorbidities such as diabetes mellitus, congestive heart failure, malignancy, and hemodialysis along with indwelling urinary catheters, central venous catheters, and endotracheal tubes. BCC pulmonary infection is mostly observed in intensive care patients who are on prolonged mechanical ventilation **(Fig. 1)**.[16] Besides this, skin, soft tissue, and genitourinary infection have been reported in patients with burns or surgical wounds, after prostate biopsy, urethral instrumentation, and exposure to contaminated solutions.

Melioidosis

It is a disease of human and animals caused by *B. pseudomallei*. Every year approximately 1,65,000 people are infected by melioidosis, resulting in death of approximately 89,000 infected patients.[17] The incubation period for the disease has been recorded to be as less as 1 day to up to a period of 62 years.[18] Because of its prolonged incubation period the disease has also been referred as "Vietnamese time bomb."[19] One or more risk factors for the disease are found in up to 80% patients. Well-known risk factors for melioidosis include diabetes mellitus, heavy alcohol use, chronic pulmonary disease, chronic renal disease, glucocorticoid therapy and cancer.[20] The spectrum of clinical manifestations is greatly varied ranging for acute fulminant septic illness to a chronic infection that may be confused with tuberculosis or

Fig. 1: Chest X-ray showing a right lower lobe pneumonia in patient with BCC infection

Fig. 2: Pus draining from a localized abscess in a diabetic patient with melioidosis

malignancy for which it has been nicknamed as "The Great Imitator."[21] The disease can manifest as an acute infection seen in 85% of the patients as pneumonia, sepsis or localized abscess **(Fig. 2)**; as chronic infection seen in 10% of the affected group, where it mimics symptoms of tuberculosis; and as a latent infection in 5% of the patients who are immunocompetent. The most common presentation is pneumonia **(Fig. 3)**, while others are genitourinary infection, skin infection, overwhelming sepsis with abscesses disseminated in multiple internal organs **(Fig. 4)**, septic arthritis **(Fig. 5)**, and osteomyelitis. Mortality rates for melioidosis are approximately 40% in Northeast Thailand (35% in children) and 14% in Australia.[22]

Glanders

Glanders is a highly contagious and fatal disease of the equine. It is caused by the organism *B. mallei*.[23] In India, it is a notifiable disease and more than 50% cases of equine glanders have been reported from Uttar Pradesh.[24] The incubation period for the acute form of disease is 1–14 days, while for the chronic form, the incubation period may be to 12 weeks. Clinically, it may manifest as a local infection with nodules and lymphadenitis when transmitted by skin inoculation. Pneumonic forms are usually transmitted through inhalational route. Patient may develop septicemia with shock when organism disseminates from the skin or lungs causing significant mortality. The mortality of pulmonary form and the septicemic form of glanders has been as high as 95% without treatment and about 40–50% with treatment.[24]

Others

Other members of the *Burkholderia* species like *B. gladioli* and *B. pickettii* have been rarely found to cause infections in CF patients and hospital outbreaks. However, a little is known regarding the clinical features and etiopathogenesis of these two species.

Diagnosis

Identifying *Burkholderia* species has been a tedious task because of poor laboratory proficiency throughout the world. A combination of selective media, biochemical analysis along with commercial kits, is being routinely used for species identification. For identifying BCC, three selective media are used; the *P. cepacia* agar (PCA), the oxidation-fermentation polymyxin bacitracin lactose agar (OFPBL), and the *B. cepacia* selective agar (BCSA). BCSA is the most recent and preferred selective media used. Apart from BCC, other members of the species like *B. gladioli*, Ralstonia spp., and Pandoraea spp. can also be grown in BCSA. Similarly, out of various culture medias used for identification of *B. pseudomallei*, the Ashdown's selective agar (containing gentamicin), is the most commonly used. The characteristic "safety pin" appearance on Gram's staining in a histopathological specimen also helps in identification of *B. pseudomallei*. Use of automated

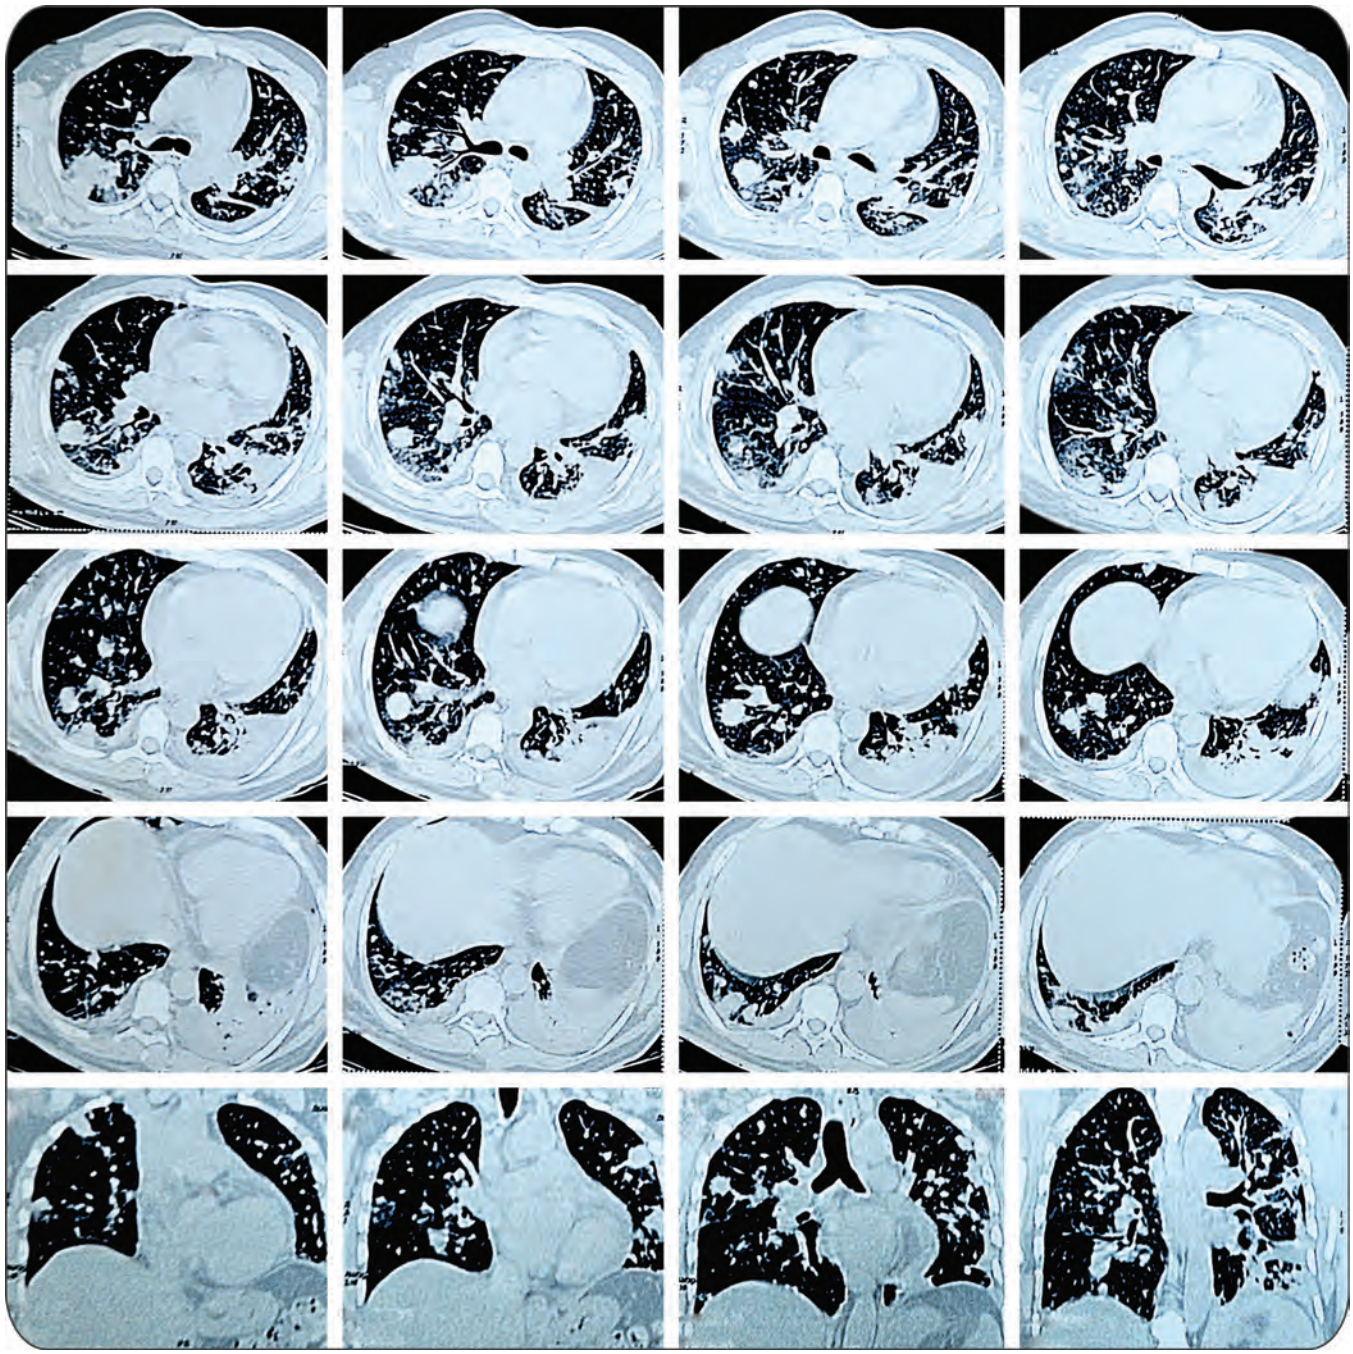

Fig. 3: HRCT thorax revealing multiple bilateral opacity in a patient suffering from melioidosis

identification systems like API 20, Phoenix, Microscan, and Vitek 2 to identify BCC complex is also on the rise nowadays, but the identification is not trustworthy as many of the species of NFGNB are misidentified as BCC. Distinguishing *B. pseudomallei* from *B. mallei* on the basis of morphology and serologic tests is also a tedious task. Molecular identification has been a breakthrough recently where identification is performed by DNA based polymerase chain reaction, which identifies the differences in sequence of 16S rRNA gene or recA gene,

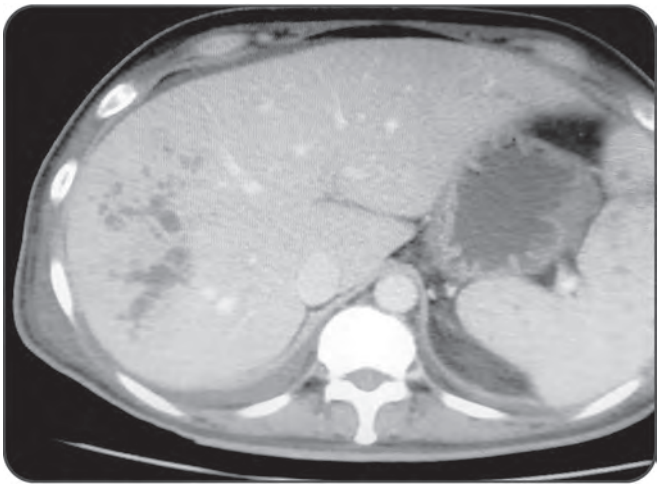

Fig. 4: CT abdomen showing multiple abscesses in liver and spleen in a immunocompromised patient suffering from melioidosis

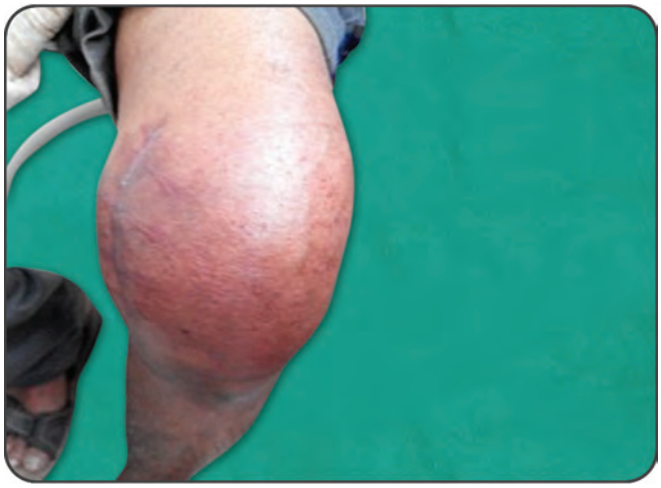

Fig. 5: Septic arthritis involving knee in a patient with melioidosis (*Source:* Patro S, Panda SS, Mishra D, et al. *Burkholderia* infections in diabetic patients emerging as a challenge for physicians: a case series. J Clin Diagn Res. 2019;13:OD04-07.)

that help in distinguishing the species. Other methods of molecular identification like MALDI-TOF MS, multilocus restriction typing, pulsed field-gel electrophoresis, and BOX-PCR have been equally found effective in identifying species.[25]

Management

Burkholderia cepacia Infections

This organism is intrinsically resistant to many of the antimicrobial agents, which pose the greatest challenge in its management. The BCC isolates from CF patients have shown to be substantially more resistant. Therefore, combination drug therapy for serious infections has been suggested. Antimicrobials that are most effective and considered first line are Trimethoprim-sulfamethoxazole (TMP-SMX), Meropenem, and Doxycycline. Some strains are also susceptible to third-generation ureidopenicillins, advanced cephalosporins, and fluoroquinolones.[16]

Burkholderia pseudomallei Infections

Treatment is divided in two phases: the "induction phase" for 2 weeks with intravenous ceftazidime or a carbapenem (either Meropenem or imipenem), and the "eradication phase" with 12 weeks of oral antibiotics such as trimethoprim-sulfamethoxazole to eradicate the infection and prevent relapse. Alternative eradication therapies include doxycycline and co-amoxiclav but both therapies have a higher rate of relapse.[21]

Burkholderia mallei Infections

This organism causes human infection rarely, so there is limited information available regarding choice of antibiotics. Because of its similarities with *B. pseudomallei*, it is postulated that the drug susceptibility would be same. Susceptibility to macrolides, azithromycin, and clarithromycin have also been reported.[16]

Conclusion

Most of the *Burkholderia* species infections are hospital acquired and potentially pathogenic in individuals with impaired host defense, which can lead to septicemia and acute respiratory distress syndrome (ARDS) with requirement of ventilator and perfusion support if not intervened at the earliest. Treatment of this infection is really a challenge to physicians as patient needs long-term antibiotic therapy and recurrence of infection is very common even after prolonged treatment. As these infections carry a very grave prognosis, hence, high risk of suspicion is required in all cases of septicemia and ARDS particularly with impaired host defense. Prompt management of the infection and the underlying conditions will definitely reduce the mortality and morbidity to a great extent.

CHAPTER

173 Managing Dermatophytosis (Tinea Infections) in Today's Scenario

Basavana Gowdappa Hathur, Garehatty Rudrappa Kanthraj

Abstract

Dermatophytosis is common fungal infection in human population. These keratinophilic fungi are restricted to the stratum corneum. The frequent strain causing infection earlier was Trichophyton rubrum; but at present, Trichophyton mentagrophyte is found to be common pathogen. Dermatophytosis requires prolonged treatment. Change in the fungal species, resistance, and steroid abuse leading to reinfection make the condition refractory to treatment. Details of treatment taken and family history are important. Appropriate combination of oral and topical antifungal agents and counseling for better adherence to treatment are needed in resistant and steroid misuse cases.

Introduction

"*Ringworm*" infection is frequently used terminology for dermatophytosis. This infection basically involves the keratinized tissue of the superficial layers of skin. There are three genera among dermatophytes: Epidermophyton, Microsporum, and Trichophyton. These fungi are keratinophilic and have capacity to invade the keratinous tissue of living animals. The involvement of epidermis, especially stratum corneum and tissue with higher keratin contents like hair and nails is common. These organisms are unable to penetrate deeper layers of skin or organs in immune-competent individuals and commonly confine to superficial non-living cornified layers. The clinical manifestations are basically dependent on response of the infected individual to dermatophytosis, which can vary between milder to significant clinical expression. These are mainly caused by reaction of host to the metabolic products of the organism, degree of virulence, anatomic location of the infection, and prevailing environmental factors.[1]

There can be lot of geographical variation in incidence and prevalence of these fungal infections. Several factors, like high humidity, hygienic practice of the individual, and risk proportion of individuals to acquire infection, can change from region to region. The dermatophytosis can have seasonal influence, with higher incidence in summer and lower in other seasons. Nearly quarter of global population is expected to have dermatophytosis as per WHO estimates. There can be 30–70% of general population who are asymptomatic carriers.[2]

Trichophyton rubrum, Trichophyton mentagrophytes, Microsporum canis and *Trichophyton tonsurans* are frequently seen pathogens to cause cutaneous fungal infection. Tinea capitis is commonly caused by *Trichophyton tonsurans*. Tinea pedis, Tinea unguium, Tinea corporis, and Tinea cruris[2] are commonly caused by *T. rubrum*.

These cutaneous fungal infections can produce significant impact on quality of life. They can be responsible for lot of social embarrassment, psychosocial discomfort, and impact on their work environment and hamper efficiency. The best way to reduce morbidity and restrict transmission is by diagnosing early and providing proper health education for prevention and adherence

to treatment. Therapy can be protracted and produce financial concerns. Disrupted therapy can be one of the important causes for relapses. There can be frustrations among treating clinician due to inadequate therapeutic response and relapse.

Changing Scenario of Dermatophytes

There is an epidemiological transition of dermatophytosis in India. *T. rubrum* was found to be common pathogen in the past by many observers in India; however, at present it is significantly less prevalent. *T. mentagrophyte* is presently found to be frequent when compared to past.[3]

Antifungal Drugs: Mode of Action

See **Table 1**.

Treatment of Dermatophytosis

Common topical antifungal cream used **(Table 2)**.[4]

Duration of treatment is given for 4–6 weeks or longer, depending on clinical severity and therapeutic response (Modified and reproduced with permission from Poojary SA).[4]

Common clinical situations for use of topical preparations:

- Infections during conception and first trimester
- Patients with renal, hepatic, and cardiovascular diseases
- Patients who are taking compelling medications for comorbidities with potential interaction

Common guidelines for improved therapeutic outcomes of using topical preparations:

- Medication should be applied over the lesion and surrounding skin, starting from outer aspect
- Choice of formulation can be variable, based on the region of the disease:
  - *Liquid preparations:* Web spaces, axilla, external genitalia, wet-lesions, and larger area of involvement
  - *Creams:* Dry lesions, lesions with prurigo
  - *Ointments:* Hyperkeratotic lesions
  - *Gels:* Over the facial region
  - *Nail lacquers:* Subungual lesions
  - *Shampoos:* As additional component in tinea capitis

TABLE 1 The Mechanism of action of antifungal drugs

Class	*Mechanism of action*
Alkylamine e.g., Terbinafine	Inhibition of squalene epoxide
Azoles	Inhibition of 14–α-demethylase
Griseofulvin	Disruption of mitotic spindle
Amphotericin B	Bind to fungal cell membrane ergosterol
Flucytosine	DNA–RNA inhibitors

TABLE 2 Common topical antifungal creams used

Antifungal class	*Formulations with concentrations*
Azoles-Imidazoles	• Clotrimazole 1% cream • Ketoconazole 2% cream • Miconazole 2% cream • Bifonazole 1% cream • Oxiconazole 1% ream • Sertaconazole 2% cream • Luliconazole 1% cream • Eberconazole 1% cream • Fenticonazole 2% cream
Triazoles	Fluconazole 0.5% gel
Alkyl amine	Terbinafine 1% cream
Benzylamine	Butenafine 1% cream
Morpholine	Amorolfine 0.25% cream, 5% nail laquer
Hydroxypyridinones	Ciclopirox 1% cream, naillaquer

Source: Modified and reproduced with permission from reference 4.

Advantages of topical versus oral antifungals:

- Insignificant side effects
- Less chances of interaction with other drugs
- Can have better psychological effect with pharmaco-economy

Disadvantages of topical preparations:

- Difficult to use in extensive infection
- Poor response due to inadequate quantity of application
- Inability to apply in difficult to reach areas, which leave a residual focus of infection[4]

Adverse Effects of Topical Antifungals

Topical applications are well tolerated with few adverse effects like pruritus, burning sensation, irritation, erythema, maceration, and fissuring.[4]

TABLE 3 Common oral antifungals used

Condition	*Drug*	*Dosage and duration*
Tinea corporis/cruris	• Terbinafine • Itraconazole • Fluconazole • Griseofulvin (microsize) (ultra-micro size)	• 250 mg/day od, 3–6 mg/kg for 2–3 weeks • 200 mg/day for 1–2 weeks • 150–300 mg/week for 3–4 weeks • 500 mg/day (10–20 mg/kg) for 2–4 weeks • 300–375 mg/day (5–10 mg/kg)
Tinea pedis	• Terbinafine • Itraconazole • Fluconazole • Griseofulvin	• 250 mg od for 1–2 weeks • 100–200 mg/day for 2–4 weeks • 150 mg/week for 1 month • 750–1000 mg/day 4–8 weeks • 660–750 mg/day

(Modified and reproduced with permission from Reference 5.)

Common oral antifungals used are summarized in **Table 3**.

Clinical situation where the systemic antifungals are required:

- Involvement of scalp (Tinea capitis)
- Involvement of the nails
- Fungal infection at many areas of the body
- Tinea corporis with extensive involvement
- Tinea pedis with extensive involvement[5]

Adverse Effects of Oral Antifungals

Gastrointestinal disturbances, altered LFT, headache, pruritus, and cutaneous allergic reactions are common. Erythema multiforme and toxic epidermal necrolysis can occur. Lupus erythematosus and psoriasis can be exacerbated.

Drug Interactions of Oral Antifungals

Terbinafine is predominantly metabolized by CYP2D6. Caution should be exercised while prescribing tricyclic antidepressants, SSRI, beta-blockers antiarrhythmics, MAO inhibitors, warfarin, cyclosporine, and rifampin. These are common drug interactions of oral antifungal agents.

Antifungals in Elderly

The presence of comorbidities and higher drug interactions warrants caution for antifungals for the elderly. Fluconazole and itraconazole being CYP3A4 inhibitors can cause several drug interactions and terbinafine is safe in elderly and can be the drug of first choice. Topical terbinafine, ketoconazole, or clotrimazole cream is preferred.

Fluconazole is the safest oral antifungal in hepatic and renal disorders. Topical terbinafine, ketoconazole, or clotrimazole cream is preferred in hepatorenal disorders.

The following are the challenges encountered in the treatment of dermatophytosis:

- Resistance
- Recurrence
- Reinfection
- Misuse of topical steroids
- Associated comorbidities
- Immunosuppression

Antifungal Resistance

Antifungal resistance can be either microbiological resistance or clinical resistance. Resistance as assessed by in vitro susceptibility testing shows resistance, with exceeding of MIC from susceptibility breakpoint. The resistance, which occurs naturally, is primary where the organism is not exposed to the drug previously. The genetic mutation basically contributes to secondary resistance and the organism would have been susceptible to the same agent previously.

Several factors can contribute to inadequate clinical response, it could be due to inadequate dose, improper adherence to therapy or altered genetic profile of pathogen, or the therapeutic agent selected may be

wrong. The resistance to griseofulvin and terbinafine in some dermatophytes have been reported in India. The clinical response and susceptibility assessment may not correlate; hence, it is not appropriate to use the term, "*resistant*" in the absence of these definitive criteria for these fungal infections. Assessment of in-vitro susceptibility to terbinafine, fluconazole, and griseofulvin as reported in many studies does not imply that there is an absolute resistance, the clinicians should think of using better dosage or prolonged treatment for adequate response. The antifungal drug susceptibility is said to be different in Indians, hence there is need to establish dose determination and MIC breakpoint guidelines by the Clinical Laboratory Standards Institute (CLSI).

Steroid Abuse in Tinea

Steroid modified tinea is a common problem in India. Permutation and combination of various antifungals, antibacterials, and topical potent corticosteroids are used. Nearly half of the sales of these combinations in India are due to self-medication or advice by unqualified persons. The combination of clobetasol propionate, ornidazole, ofloxacin, and terbinafine are frequently used in India. Irrational and non-supervised use has aggravated the problem. Long time and intermittent use result in erythema, telangiectasia, and atrophy. The clinical picture variable due to altered T-cell mediated immunity suppression. Ineffective elimination of the dermatophyte results in chronic, wide-spread, and ill-defined lesions. Constant itching and scratching result in lichenification. Improper central clearing due to topical steroid abuse results in various bizarre shapes mimicking Tinea pseudoimbricata. Supervised short duration of topical steroid is required to treat lichenification followed by antifungal treatment. Prolonged treatment needs counseling for adherence to the treatment.[6]

Recurrence

There is lack of uniformly acceptable definition of "*recurrent dermatophytosis*." Whenever there is a protracted course with variable degree of persistence of lesions, these patients contribute for easy spread of infection to family members and other closely associated people. Common contributing factors are overcrowding, living together in congested accommodation, the use of tight footwear, tight-fitting clothes, and sharing of community bath and sports facilities.

Future Directions for Prevention of Refractory Dermatophytosis

The primary factor for emergence of antifungal resistance appears to be inadequate dose and improper combination. There is need of clear guidelines for dose recommendation for prevention and treatment.

Ghannoum and Rice[7] suggested for intense clinical correlation with appropriate medication combination and acceptable dosage by using the pk/pd data and surveillance inputs. Early diagnosis with correct combination will help in reducing resistance and refractoriness.

Measures improve hand hygiene: Hand wash; clipping of nail; regular bathing, keeping the skin dry, use of proper shoes, cotton socks, and absorbent powder; avoidance of sharing of bathing facilities and cloths; avoidance of walking barefoot in public bathroom are important in preventing spread.[8]

Using appropriate combination of drugs will increase the fungicidal effect and increase the spectrum of activity and reduce refractoriness. Choose a combination of oral and topical antifungal with different mechanism of action for better clinical outcome.

Antifungal drugs in the pipeline that are active against azole-resistant isolates, like cationic peptide histatin will be important for revised treatment strategies. The combined use of azoles and cytokines will be useful in treatment of fungal infections in immune-compromised individuals.

Conclusion

- Cutaneous fungal infections are very common in humans. Dermatophytes have higher affinity to stratum corneum. The common strain is T. mentagrophytes among dermatophytes. Tinea corporis and cruris require 3–4 weeks of treatment.
- Fingernail requires 6–8 weeks; however, toenail requires 10–12 weeks of treatment.
- Patients with renal, liver, and cardiovascular diseases are treated with topical antifungal.
- Resistance, recurrences, reinfection, topical steroid misuse, and associated comorbidities pose a clinical challenge in antifungal treatment.

Contd...

Contd...

- Steroid modified tinea in India is a result of topical antifungal used in combination with potent topical steroids and antibacterial that account for about 50% of the sales of all topical steroids in India.
- Careful history taking-treatment history, combination of oral and topical antifungal with different molecules that have varied mechanism of action and counseling is needed in resistance and topical steroid misuse cases.
- Drug interactions must be considered before starting any oral antifungals.

CHAPTER

174 Rickettsial Infection

Vasantha Kamath, Shreyashi Ganguly, P Siva Karthik Reddy

Abstract

Rickettsial infections are important public health problems and are often underdiagnosed or misdiagnosed leading to the burden of morbidity and mortality due to nonspecific symptoms and signs and absence of specific diagnostic tests. The present review addresses the epidemiology, clinical features, diagnosis, complications, and management of these infections, primarily for a practicing clinician.

Introduction

The rickettsioses represent one of the important causes of febrile thrombocytopenia worldwide. Rickettsial infections which were initially seen more often had reduced in incidence with extensive use of pesticides to control vectors. Tetracycline was one of the most commonly used antibiotics which also contributed to reduction of prevalence of rickettsial infections. However, the indiscriminate use of tetracycline has declined due to adoption of better antibiotic policies.[1] Additionally, the urbanization of rural areas has exposed more of the population to potential sources of infection. These two factors have coincided with the re-emergence of this deadly scourge.[1]

These diseases can be incapacitating and difficult to diagnose in resource-poor settings. Potential cases are often under-recognized or under-tested. Adding to the burden of morbidity and mortality is the dearth of adequate laboratory testing facilities and uniformity of reporting systems.[2]

Rickettsioses present with non-specific signs. However, certain clinical features are indicative when present in a constellation, such as the presence of high-grade continuous fever, centripetal/centrifugal rash, generalized lymphadenopathy, decreased platelets, and the pathognomonic eschar (tachè noire) which is rarely seen in our setup. However, atypical presentations are also more prevalent in hyperendemic areas.[3] Clinical presentation along with positive Weil Felix test is employed to make the diagnosis of rickettsiosis.[4]

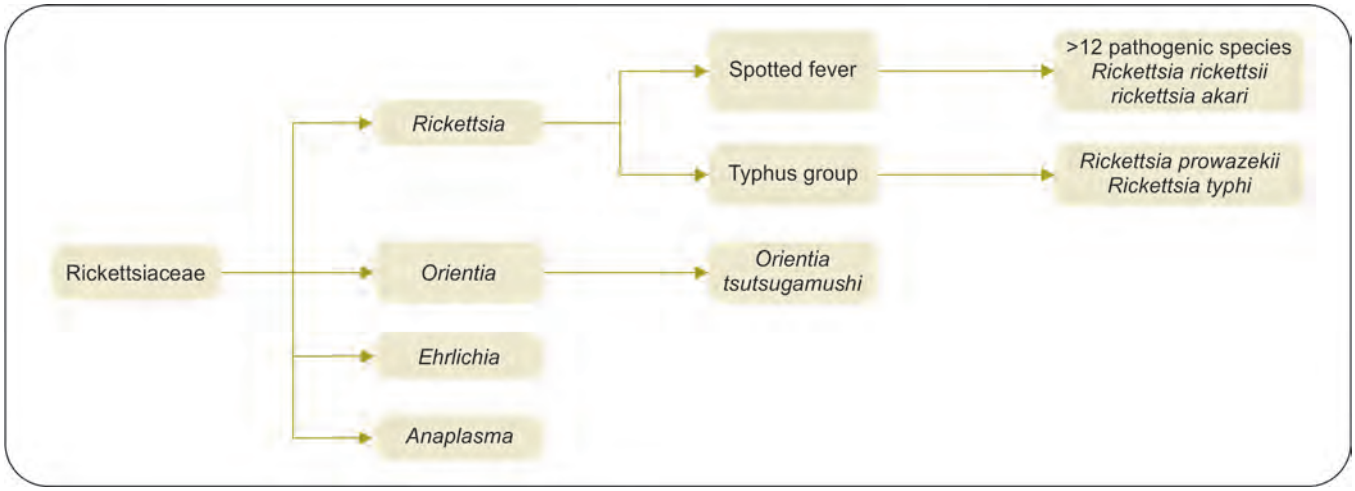
Structure and Genome

Rickettsia is small, Gram-negative coccobacillary form adapted to obligatory intracellular parasitism and transmitted by arthropod vector (lice, flees, ticks, and mites) found in their alimentary canal. In vertebrates especially humans they infect vascular endothelium and reticuloendothelial cells.[5] Rickettsiae are not evident on blood smear and do not stain with most of the conventional stains; however, it stains red with Giemsa stain.[3] Rickettsial genome is 1–1.5 Mb and is a single circular genome.

The Rickettsiaceae Family

Family Rickettsiaceae is divided based on lipopolysaccharide group antigen into four genera **(Flowchart 1)**.

Flowchart 1: Classification of rickettsial infections



Vectors

Transmission is by arthropod vectors like lice, fleas, ticks, and mites.

Distribution

The distribution is dependent on the arthropod host/vector. Tick vector dependent infections have limited geographic spread (except Antarctica).[1,2]

Risk Factors

People staying near mountains, bushes, and equatorial rain forests are at risk. Improper hygiene and rearing of domestic animals are also risk factors.[3]

Pathogenesis

Endothelial cells are primary target (exception Rickettsia akari). They cause damage to the cell causing cellular detachment. The cells in circulation when lodged in distal capillaries become the source of infection. Through antibody, mediated opsonization rickettsia can enter phagocytic cell.[3]

Clinical Features

The incubation period varies 2–21 days. Signs and symptoms are non specific. *Fever is the most common presentation which starts abruptly and is of high grade* in association with headache, muscle ache, apathy, drowsiness, photophobia, conjunctival suffusion, generalized lymphadenopathy (abdominopelvic, para-aortic, porta hepatis, splenic hilum), and hepatosplenomegaly.[6,7]

Fig. 1: Rickettsial rash

The rash: Though considered as characteristic feature of rickettsioses is not seen in all patients. It occurs on the third or fifth day of illness. It may be typical with macules, papules, hemorrhage, or petechiae or atypical asymmetrical localized to small area **(Fig. 1)**. It may be centripetal or centrifugal in distribution mainly seen over the soles of the feet and palms of the hand.[3,8]

Eschar: It is vesicular lesion at the site of inoculation which ulcerates, heals with development of black necrotic scar associated with regional lymphadenopathy. Necrotic

Fig. 2: A classical eschar

eschar **(Fig. 2)** is seen in belt area, in groin, under the arms, sometimes over the neck. Even though it is the single most important clue for the diagnosis it is recognized in less than 50% even by an experienced physician. Sometimes multiple eschars are seen under the trouser belt. Scrub typhus patients with virulent strains have lower incidence of rash/eschar, and hence severity of clinical features depend on serotype and genotype of rickettsia.

In India, three common groups of infections are seen the spotted fever group (e.g., *R. akari*), the typhus group (e.g., *R. typhi*), scrub typhus (*Orientia tsutsugamushi*). The significant clinical differences between them have been studied by the author's team.[9,10]

Scrub typhus was more likely to present with fever 7–14 days (p=0.03); splenomegaly (p=0.023), and eschar (p=0.014) were significant examination findings; in the laboratory, it presents with increased SGOT/SGPT (p=0.024), and decreased albumin (p=0.021). Spotted fever group had a preponderance toward fever less than 7 days (p=0.043), vomiting (p=0.03), and joint pain (p=0.049). Macular rash (p=0.04) was observed clinically. Pleural effusion (p=0.021) was a significant complication. Typhus group had fever more than 14 days (p=0.04), associated with cough (p=0.019), and abdominal pain (p=0.039). Hepatomegaly (p=0.045) was a significant clinical finding.[10]

Atypical presentation that may be seen in hyperendemic areas are: acute abdomen without fever, nausea, vomiting, diarrhea, and constipation.

Neurological complications of ricketsioses are encephalitis, aseptic meningitis, meningoencephalitis; respiratory symptoms like cough and breathlessness associated with ARDS and pneumonia and non-cardiogenic pulmonary edema (30–60%), gastrointestinal manifestations presenting as acute gastroenteritis, severe pain abdomen often mistaken for surgical abdomen; transaminitis with acute hepatitis and hepatic encephalopathy, coagulation factor consumption results in a DIC-like syndrome.[7]

Differential diagnosis of aseptic meningitis should include rickettsial meningoencephalitis in endemic areas, especially when associated with altered renal or hepatic functions. Acute kidney injury is associated with poor prognosis.[3]

Retinal vasculitis is commonly seen amongst females. It is asymptomatic in the early stage, resolves by 6 months. The prognosis is favorable.[3]

Without medications uncomplicated infection might recover within 14 days. Untreated cases carry a mortality rate of 30%. Persistent subclinical infection in convalescent patients occurs with *Rickettsia prowazekii*, which later presents as recrudescent typhus or Brill-Zinsser disease.[2,9]

People travelling from disease endemic region might present with symptoms within few days of return. Since the incubation period for most rickettsial infections is from 2–21 days, symptoms which begins 20 days after travel from a disease-endemic area has less probability to be a rickettsial infection.[8]

Investigations

Early stages—lymphopenia; late stages—lymphocytosis (30%), Elevated ESR, decreased platelet count in less than 50% of cases.

Later—Deranged liver function test (50%): Increased serum bilirubin, increased ALT, AST (75–95%), reduction in albumin less than 3 gm% (seen in significant number of patients); reduced sodium, increased blood urea, and serum creatinine.

Chest X-ray: Pneumonitis, bilateral infiltrates, pleural effusion, and ultrasound abdomen: Hepatosplenomegaly.[11]

Diagnosis

Early stages: It is challenging to diagnose these infections and differentiate them from other infections like dengue,

malaria. The clinical manifestations of most rickettsioses present as a continuous spectrum. In the absence of definite pathognomonic signs, there are signs and symptoms highly suggestive of the etiology. However, not all cases present with the set of typical clinical manifestations that aid in prompt recognition. As such the clinical acumen and awareness of the treating physician has a great role in the diagnosis and management of these cases. In resource poor country, fever with rash, fever with thrombocytopenia and rash Weil Felix test clinches the diagnosis.[11]

When to Suspect Rickettsial Infection?

Any patient presenting with fever and rash, fever and eschar, aseptic meningitis, acute renal failure with eschar, increased vasculitis should be suspected of having rickettsial infection.

Weil-Felix Test

This test is easily available, cheap, and easy to perform. The results are available on the same day. The sensitivity is 46%, specificity is 100%, is positive in second week. OX2, OX19, and OXK strains of agglutinins of proteus bacteria are used in the test.[3,8,11] Results must be interpreted in the correct clinical context **(Table 1)**. Value of testing two sequential serum or plasma samples together with fourfold rise in antibody level is more important in confirming acute infection.[3,8,11]

Indirect Immunofluorescence Assay/ Immunoperoxidase Assay

It is the gold standard investigation. Sensitivity is 89–100%, specificity is 100%, but major constraints being, the test is not easily available, costly, and takes more than 7 days for results. Immunoglobulin M rises at the end of first week; Immunoglobulin G rises at the end of second week.

TABLE 1 Interpretation of Weil-Felix test

Diseases	*Weil-Felix*		
	OX-19	*OX-2*	*OX-K*
Rocky mountain spotted fever	+	+	–
Rickettsial-pox	–	–	–
Epidemic typhus	+	–	–
Endemic typhus	+	–	–
Scrub typhus	–	–	+

Immunohistologic Examination

The only diagnostic test proved useful during acute illness is immunohistologic examination from cutaneous biopsy sample of a rash or biopsy of a lymph node. It is 70% sensitive, 100% specific. However, high expertise is needed to interpret biopsy result.[3,11]

Polymerase Chain Reaction

It is species specific and is positive in initial 7 days**.** It can be done on whole blood, eschar, or skin biopsy. It has a specificity of 100% for both PCR and Rt-PCR and sensitivity of 22–36% for PCR and 45–82% for Rt-PCR. Tissue sample shows higher sensitivity compared to blood sample.

Culture

Organism is grown on tissue culture Vero cell of kidney, egg yolk sac and isolation needs biosafety level III labs. However, culture is unnecessary, laborious and hazardous to lab personnel. Median time for reporting is 27 days.

Treatment

If cases are left untreated fatality may go up to 30%.[1,3] When diagnosed properly it can be treated easily, but the difficulty lies in diagnosing rickettsial infection during initial phase of the disease when antibiotic use is very effective.[12]

Doxycycline is the treatment of choice. Dose 100 mg two times a day should be used for 7–10 days. Within 24–48 hours after initiation of antibiotic, patient improves drastically. If patient fails to respond within 48 hours, it is unlikely to be Rickettsial infection.[12] Extremely sick patients (especially with MODS and ARDS) may require 10–14 days to respond to treatment. Relapse is usually seen if treatment is discontinued as soon as fever subsides. Discoloration of teeth is more common in children and depends on duration of treatment,[13] other side effects are hypoplasia of the enamel, depression of skeletal growth, and limb hypoplasia. As such, doxycycline should not be used in children less than 8 years because of these above side effects. In pregnant women due to the adverse effects on the skeletal growth of fetus. Azithromycin 500 mg once daily is used instead in this setting.[7]

If patients respond poorly to doxycycline or drug resistant serotypes: combination of doxycycline with rifampicin for 6–8 days or azithromycin with rifampicin (600 mg once a day) to be used. Rifampicin should always be used in combination as it leads to resistance when used alone. In India, rifampicin is avoided due to the prevalence of tuberculosis.

Treatment in pregnancy: Chloramphenicol is also an alternative drug and can be recommended for use in pregnancy in dose 500 mg four times a day for 7–14 days but has to be avoided in last trimester due to fear of bone marrow suppression and gray baby syndrome. Azithromycin is safer alternative in pregnancy. A macrolide, Josamycin, has been used with success in spotted fever group in pregnancy in a dose of 3 gm/day orally for 5 days. Doxycycline can be used in late pregnancy.

Vaccine

No vaccine is available for Rickettsial infection. An ideal vaccine should give protection to all biogroups in order to give acceptable level of protection. This complexity continues to hamper efforts to produce effective viable vaccine due to enormous antigenic variations among the biogroups.

Recent Developments

Rickettsiae have specific regions of oompA and oompB surface proteins and measures to detect antibodies against them, might prove beneficial in future treatment of rickettsiae.[3]

Prevention

Preventing exposure to a vector infested habitat, wearing closed-toed shoes, long pants, long sleeved clothes, topical application of insect repellents, protected pets may help in prevention.

Conclusion

Rickettsial infections are some of the covert re-emerging infections of present times generally incapacitating and notoriously difficult to diagnose. Untreated cases have fatality rate up to 30%. When diagnosed properly it is often easily treated. Greatest challenge is difficult diagnostic dilemma posed by these infections early in clinical course when antibiotic therapy is most effective; hence, physicians and pediatricians have to include rickettsial infection in differential diagnosis of acute febrile thrombocytopenia.

CHAPTER

175 Adult Vaccination

Nirupam Prakash, Hemant Mittra, Jeevan Prakash

Abstract

Adult immunization is less talked about area of health-care practice needing regular updation and implementation. It is an easy means of disease prevention which should find place as a separate topic in the medical curriculum. While the Guidelines for Immunization of Children are routinely updated and practiced clinically, the same is not true for adult immunization. The slowly waning immunity gained from vaccination in childhood, risk of exposure from frequent travels, changing lifestyles, age related immunosenescence, increasing comorbidities like diabetes and chronic kidney disease, organ transplantation and increasing use of immunosuppressive further necessitate implementation of adult vaccination measures. API guidelines recommend routine vaccination for Pneumococcal infection, Influenza, Human papilloma virus, Measles, Mumps Rubella, Diphtheria, Pertussis, and Tetanus in Adult Indian subjects. It is imperative for the related health-care associations to work together and devise a common adult vaccination schedule which can be followed by clinicians all over the country. Physician realization, public health education about its need and government initiatives in implementation would go a long way in strengthening the infection control measures and improve the communicable disease health-related indices.

Introduction

The recent pandemic of COVID-19 has exposed the vulnerability of human race to infectious diseases and re-emphasized that prevention is an essential part of management of communicable diseases worldwide. Vaccination forms an important part of primary prevention for control of morbidity and mortality related to infectious diseases. With increasing age, adult immunity declines (immunosenescence) and therefore there is need to address it through adult immunization.[1] The susceptibility of populations has increased due to changing work environment and culture involving international travels and explorations. The increasing numbers of organ transplant recipients, diabetics, chronic kidney disease (CKD) subjects, indiscriminate antimicrobial use, emerging resistance, and growing susceptible population of subjects on chemotherapeutic agents or radiation therapy, further adds to these concerns. As on date the status of adult vaccination in India is mostly inadequate or incomplete. In contrast to pediatric vaccination guidelines, little importance is laid on Adult Vaccination in India, even when the mortality from vaccine preventable diseases is 350 folds higher in adults in comparison to children.[2] Lack of awareness amongst general public, physician's apathy, meager resources, and lack of political will are impediments to implementation of adult immunization in routine clinical practice. Organizations like API have stressed the urgent need to develop adult vaccination guidelines in India and its revision periodically.

Determinants of the vaccination needs of an individual are age, prior vaccination status, mutations in infectious agents, health or comorbid illness, lifestyle, travel, occupation, infection trends, disease burden in the

population and related health-care/immunization costs. Vaccine induced immunity is neither long lasting nor broad spectrum and declines with time, implying that childhood vaccination may need to be bolstered in adulthood to provide lasting protection. In countries where last dose of Diphtheria vaccine had been administered at less than 6 years of age, a resurgence of Diphtheria in adults more than 15 years age has been noted. Similar, increase in average age of many vaccine preventable diseases in to adult life has been observed. Further, adult individuals act as reservoirs of disease and pose a risk to the unvaccinated children and other family contacts in the household. Likewise, the role of adult vaccination gains importance in hostel facilities, residential institutions, factories, and organizations with residential campuses.

India contributes to 60% of Diphtheria, 40% of tetanus, and 44% of Japanese encephalitis cases of the world.[3] However, age wise epidemiological data relating to burden of vaccine preventable diseases and efficacy of adult vaccination strategies in India is scant. Recent outbreaks of Measles (University in Karnataka, 2013-2014), Japanese Encephalitis (West Bengal 2014), Influenza A (Rajasthan 2015), Varicella (Tamil Nadu 2016-2017), Diphtheria (Assam 2015-2016), Hepatitis A (2015-2016) have alerted us to the relevance of adult immunization in India. In early 2018, around 133 outbreaks of measles, varicella, food poisoning, and diarrhea were reported. To aggravate the issue further, there is a lack of proper disease surveillance and under reporting of outbreaks of vaccine preventable disease in India. Herein we discuss the adult vaccination guidelines as recommended by various organizations for Indian population. The recommended vaccination schedules for clinical practice are mentioned in **Tables 1 and 2**.

TABLE 1 Summary of adult immunization guidelines[7-10]

Organism/Disease	*Vaccine*	*Age of administration*	*Dosage recommendations*
Influenza	Trivalent/Quadrivalent	>19 years onward; 0.5 mL IM 1 dose annually; can be given during pregnancy (FOGSI)	
Streptococcus pneumoniae	PCV 13 PPSV 23	>50 years or <50 years in high risk; PCV followed by PPSV 23 at 1 years, repeat every 5 years	
Human papillomavirus	0.5 mL IM Merck4strain/2strain GSK	9–14 years 2 doses 0 day and 6 months (IMA) 15–45 years at 3 doses 0 day, 1 and 6 months, defer if pregnancy	
Herpes zoster	0.5 mL SC	Individuals >60 years (ISN); 2 doses 2–6 months apart	
Diphtheria, pertussis, tetanus	(Tdap/Td) 0.5 mL IM	Age group >19 years; immunized Tdap once at 10–18 years; then Td 10-yearly (IMA, API, CDC), Non-immune 3 doses, 2 does 4 weeks apart followed by third at 6–12 months Tdap during each pregnancy (API & CDC) IMA adds TT/Td early during pregnancy (2 doses); Tdap during 3rd trimester of pregnancy (1 dose)	
Measles, mumps, and rubella	MMR 0.5 mL SC	19–60 years; 2 doses 1 month apart (ACIP); 1 dose if previously immunized Pregnancy should be deferred for 3 months after immunization	

TABLE 2 Immunization schedule in special situations (routinely not used)[7-10]

Organism/Disease	*Vaccine dosage recommendations*
Hepatitis A	1.0 mL IM; 2 doses in Adults (0 & 6 months)
Hepatitis B	1.0 mL IM; 3 doses (0, 1–2, & 4–6 months) FOGSI recommends in preconception or at high risk during pregnancy
Hepatitis A+B	1.0 mL IM; 3 doses (0, 1–2, & 4–6 months)
Typhoid	0.5 mL IM; 1 dose every 3 years
Cholera	2 separate doses of oral vaccine 1–6 weeks apart for those aged over 6 years
Meningococcal	0.5 mL SC Bivalent/Quadrivalent; Adults (1 dose); At risk/asplenia 2 doses (ACIP and IMA)
Varicella	0.5 mL SC; >13 years of age; 2 doses 4–8 weeks apart

Pneumococcal Vaccination

Pneumonia and invasive pneumococcal disease are two dreaded complications of pneumococcal infection, which account for significant morbidity and mortality, especially in the immunocompromised and the elderly (subjects >50 years of age) with a case fatality of 28%. The common serotypes accounting for 55% of inpatient admissions are 1, 3, 5, 19F, 8, 14, 23F, 4, 19A, and 6B. Further emerging resistance to penicillin and macrolides has underlined the importance of adult pneumococcal vaccination. The incidence of pneumococcal disease per lakh population is 8.8 in healthy adults, 51.4 in adult diabetics, 62.9 in subjects with chronic lung disease, and 93.7 in subjects with chronic heart disease.[4] To reduce morbidity in high risk groups pneumococcal vaccination is recommend in subjects less than 50 years of age with chronic heart disease, lung disease, chronic liver disease (CLD), diabetes mellitus, chronic smokers, and alcoholics.

There are two vaccines available, viz. a PCV13 and PPSV23 name denoting the number of serotype antigens contained. The PCV13 carries a greater response, longer immuological memory, protection against nasopharyngeal carriage, but a lower protection against invasive pneumococcal disease in elderly.

A single dose of PPSV23 is recommended in immunocompetent adults over 65 years of age, to be repeated at every 5 years interval. An early institution of second dose is noted to produce hyporesponsiveness. Initial administration of PCV13 vaccine has been shown to amplify the response to subsequent administration of PPSV23. ACIP 2015 recommends a space of 1 year between the two vaccines irrespective of their order. In individuals who have already received PPSV23, vaccination with PCV13 can be undertaken after 1 year interval. A prior pneumococcal conjugate vaccine (PCV13) vaccination followed by unconjugated capsular polysaccharide vaccine (PPSV23) vaccination is recommended for high risk group with cochlear implant, CSF leaks, sickle cell hemoglobinopathy, asplenia, congenital, or acquired immunodeficiency syndromes.

Influenza Vaccination

Annual influenza vaccination by itself has been shown to reduce cardiac mortality by 19–45% and hospital admissions by 54%, which is comparable to benefit gained from CV risk reduction by smoking cessation or statin therapy. Influenza vaccines are available as trivalent (two strains of Influenza A and one strain of influenza B), quadrivalent (two strains of influenza A and two strain of influenza B) or live attenuated (lyophilized) nasal spray vaccines. Influenza vaccination is recommended in high risk subjects, viz. CKD, chronic obstructive pulmonary disease, heart disease, immunosuppressed subjects, diabetics, and hematological disorders. Single dose needs to be administered annually to gain protection. The timing has to be 2 weeks before the peak season for influenza from October to May.

Measles, Mumps, and Rubella

In 2018, around 55,000 cases of Measles and 1000 cases of Rubella were reported in India.[5,6] Around 16% of Indian population was found to be susceptible to Rubella infection. Incidence of Mumps outbreaks has been reported mainly from hostel facilities, colleges, and schools in poor socioeconomic settings. A single dose of triple vaccine MMR in already immunized individuals and two doses separated at interval of 1–2 month in unimmunized subjects is noted to provide adequate protection.

Diphtheria, Pertussis, and Tetanus

Childhood protection through vaccination is not lifelong and has been found to increase the proneness of adults to Diphtheria Pertussis and Tetanus. India accounts for the majority of these cases in the world. A single dose of triple antigen vaccine followed by booster every 10 years is noted to provide adequate protection in already vaccinated individuals.

Human Papillomavirus Vaccination

Cervical cancer is the second most common cause of cancer and second leading cause of mortality in India. Human papillomavirus (HPV) virus accounts for 90% of cervical and anal cancers, 70% of vulval and vaginal cancers, and 60% of penile cancers. HPV serotypes 16 & 18 are noted to account for 77% of cervical cancers in India.[4] HPV vaccine is recommended before the onset of sexual activity in the age between 9 and 24 years. In the age group of 9–14 years two doses of HPV vaccine are to be administered at 6 months interval. In those over 15 years of age three doses at 0, 1, and 6 months are advocated.

Hepatitis A and B Vaccination

While Hepatitis A virus (HAV) accounts for 10–30% of acute hepatitis and 5–15% of acute liver failure cases, hepatitis B virus (HBV) accounts for 20–30% cases of Cirrhosis and 40–50% cases of hepatocellular carcinoma.[4] The high prevalence of chronic Hepatitis B carrier state in the population also increases the risk of transmission. Hepatitis A vaccination is indicated for candidates for kidney or liver transplant with chronic hepatitis B/C to decrease the risk of fulminant liver failure. Also vaccination for Hepatitis A is indicated in illicit drug users, homosexuals, animal handlers, persons with CLD or other hepatitis virus infections, recipients of clotting factor concentrates. Two doses of Hepatitis A vaccine administered at 6–12 months interval gives adequate protection. Hepatitis B vaccine schedule is 20 µg at 0, 1, and 6 months. Booster dose is not recommended in immunocompetent adults. Combination vaccines for HAV and HBV can also be administered in a three dose (0, 1, and 6 months) or four dose (0 day, 7 days, 21–30 days, and booster at 12 month) schedule.

Meningococcal Vaccination

Three Meningococcal vaccine are available, viz. two quadrivalent vaccine (against four antigens A, C, Y, and W135) for polysaccharide (MPSV4) and conjugate (MCV4) or a bivalent vaccine (antigen A and C). While MCV4 produces lasting immunity, and reduces nasopharyngeal carriage it cannot be used in adults more than 55 years of age and does not provide protection against Meningococcus B strain. Therefore, MPSV4 may be preferred in subjects more than 55 years of age or those requiring single dose, viz. travelers.

Conclusion

The common perception that vaccination is meant only for children has to give way to the understanding that vaccination has to be continued well in to adulthood. Most of adults above 40 years of age have not received universal childhood vaccination, which was started in 1978 and could attain 65% coverage only in 2014.[7] Hence, the realization that adult vaccination is urgently required needs to creep in to the community and a national program has to be carved to reduce the menace of vaccine preventable diseases. As much as two-thirds of Indian population is still unaware of need of vaccination in adulthood.[1] Further the introduction of adult vaccination is cost effective as demonstrated in cost benefit analysis of HPV vaccine in India.[11] The cost of adult vaccination is lower than the cost for childhood vaccination and implementation of many other secondary preventive measures (lipid lowering therapy, antihypertensives, antidiabetics, and bisphosphonate treatment). For the adult vaccination to be successful it needs to overcome the barriers of vaccine hesitancy (4Cs of complacency, convenience, confidence, and cultural acceptance) which can be achieved by widespread health education, evolving consensus on national guidelines and incorporating them in routine clinical practice. Although, as on date adult immunization is not being routinely observed in clinical practice, achieving complete adult vaccination to vaccine preventable diseases through widespread implementation by medical professionals, society's acceptance, government realization, and making vaccines affordable would make this dream come true.

CHAPTER

176 Neurocysticercosis—Clinician Recap

Alok Gupta, Deepak Kumar

Abstract

Neurocysticercosis (NCC) is most common central nervous system parasitic infection caused by Taenia solium. NCC is a common cause of adulthood epilepsy with signification disease burden in developing country like India. The precise knowledge of epidemiology, clinical features, radiological correlation with stage of parasite is very helpful in effective management and reducing the burden of disease. Relational use of anti-parasitic drugs and steroids are effective in cure of NCC. This chapter is focused on clinical and radiological finding and guideline on management of NCC.

Introduction

Neurocysticercosis (NCC) is caused by *Taenia solium* and this is the most common helminthic infection of the central nervous system (CNS). *Taenia solium* is a parasite and transmission of larva stage from pig is responsible for infection in human.[1] NCC is most severe form of cysticercosis and this is a most common cause of acquired epilepsy in adult.[2] NCC is associated with substantial morbidity due to epilepsy, strokes, and associated side effects of long-term drugs therapy for seizures. This disease is a major health problem in India and its prevalence in epilepsy with NCC is around 3.48/1,000 persons.[3] Prevalence of NCC is higher in northern part of India as compare to southern part of India, particularly in urban population.[4] The health and economic impact of disease have not been assessed in depth. Past study has shown that Rs. 5,916 is the direct cost of treatment of solitary cysticercus granuloma per patient.[5]

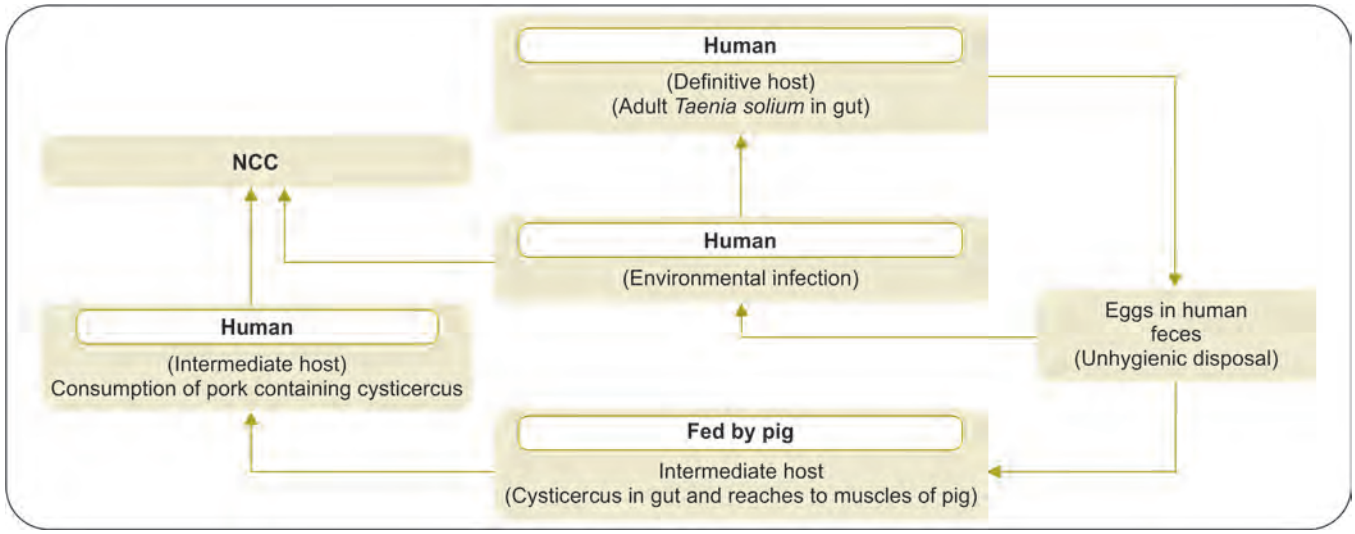
The important factors responsible for occurrence of disease in India are poor personal and social hygienic conditions. This increases scavenging pigs with use of partially cooked unhygienic pork.[6] Further studies will require for measuring the impact of this disease on economy and human health in India. Worldwide estimation of NCC prevalence has relatively less studied and the disease is common in India, Indonesia, most of Southeast Asia, part of China, many sub-Saharan Africa, and regions of Eastern Europe.[7,8]

Even with advancement still there is gap between basic and practical aspects of disease focusing, especially diagnosis of active lesion and appropriate timing of antiparasitic treatment in NCC. This chapter is especially focused on better understanding of disease, diagnosis, and treatment in clinical scenario.

Etiopathogenesis

Taenia solium, also called tapeworm, is the causative parasite of NCC. Both human as well as pig both act as intermediate host for *Taenia solium*. Adult tape worm releases the thousand of eggs in human feces. The pig fed the eggs contenting feces due to poor hygienic condition. The eggs lose their covering in pig's intestine and converted into oncospheres. These oncospheres distributed in muscles of pig via blood after penetrating intestine and form cysticercus. Consumption of uncooked pork that contained cysticercus in muscle of pig leads to

Flowchart 1: Life cycle of *Taenia solium* and etiology of NCC



infection in human. In human stomach digestive enzyme leads evagination of their scolices. These scolices penetrate the gut and reach in brain and produce parenchymal cystic lesion **(Flowchart 1)**. Recent studies also showed that there are person-to-person transmission of human cysticercosis is also equally important as environmental source.[9] Distribution of cysts in brain parenchyma occurs mainly at watershed areas between gray and white matter. Other common sites of cyst lodgment in brain are choroid plexus and 4th ventricle, that give rise ventricular cyst.[10]

In brain parenchyma, cyst has two components, first is vesicular and second is scolex. The first vesicular part is a viable phase consists of a transparent membrane and clear vesicular fluid and with transposed scolex. The initial phase of cysticerci in brain is a colloidal stage, which may survive for many years and finally due to immune response scolex get mineralized and converted into calcification nodule. Inflammatory response of parenchymal cyst is very less and generally limited to only surrounding tissue. But meningeal cyst mostly provokes a severe inflammatory response in subarachnoid space and land up with thickened leptomeninges.[11]

Clinical Manifestation of Neurocysticercosis

Clinical manifestations of NCC are varied from asymptomatic state to life threatening seizure and encephalitis-like stage due to cerebral edema.[2,12] Symptomology is primarily depended up on location and number of lesion as well as parasite load. Higher the parasite load associated with strong immune response and more severe symptoms.[12] Population-based studies have been shown that a substantial number of patients in endemic area were asymptomatic with lesion on imaging of brain.[13]

Most common clinical presentation of NCC is seizures and detected in up to 80% of symptomatic individual.[14] NCC is the leading cause of epilepsy in adult age 25 years and more. Initially it was postulated that only viable cystic stage is responsible for symptoms and not due calcified nodules. The recent studies have been suggested that seizures could occur in any stage of cysticerci. Headache may be associated with or without seizure and may mimic the migraine. **Table 1** is depicted the stage of parasite and possible mechanism of clinical manifestations.

Focal neurological signs may be a presenting feature of NCC. This has been seen up to 20% cases of NCC. The disease course in focal neurological deficits is commonly subacute or chronic and may resemble brain tumor. Pyramidal tract signs are the commonest, but other signs like sensory disturbances, involuntary movements, abnormal muscle tone, signs of brainstem dysfunction, and aphasias may occur in few patients.[17] Acute stroke is uncommon manifestation and occurs due to infraction in internal capsule, corona radiata,

TABLE 1 Mechanism of clinical manifestations in NCC[15,16]

Stage of parasite	*Clinical manifestations*	*Pathogenesis*
Viable cysts	Seizures, hydrocephalus, focal neurological defect	Mass effects cyst on the brain parenchyma
Colloidal and granular cysts	Seizures, encephalitis like stage due to cerebral edema	Degeneration of parasite and host inflammatory response
Calcified nodule	Epileptogenic focus	Gliosis formation around dead parasites

TABLE 2 Pathognomonic finding according to stage to parasite in neuroimaging

Stage of parasite	*Neuroimaging finding of brain parenchymal lesion*
Viable cysts	A well outlined small and rounded cyst with no abnormal enchantment on contrast imaging. Invaginated scolex has seen as eccentric hyperdense nodule and called "hole-with-dot" appearance
Colloidal and granular cysts (degenerating)	The lesions are ill-defined and may be single or multiple with surrounding edema. Contrast imaging showed a ring enhancing or a nodular pattern of enhancing
Calcified nodule	Non-enhancing hyperdense nodule (better detected in CT)

and/or brainstem.[18] Intracranial hypertension is a rare but dreaded manifestations; either due to mass effect or host immune response leading to arachnoiditis or encephalitis.[19] Neurocognitive manifestations are though rare and ranging from psychiatrics symptoms to severe dementia.[20]

Diagnosis

Diagnosis of NCC is improved significantly with increased availability of computed tomography (CT) and magnetic resonance imaging (MRI). These investigations can be able to differentiate the stage of parasite in brain parenchyma and this may be helpful for selection of antiparasitic therapy. **Table 2** shows the pathognomonic finding according to stage to parasite in neuroimaging.[21]

The MRI imaging delineates better subarachnoid NCC, and hydrocephalus is the most common finding. The cause of hydrocephalus is due to diffuse leptomeningeal inflammation and thickening and occlusion of the foramina of Luschka and Magendie.[17] Diagnosis of ventricular cyst is also better MRI imaging and this easily missed in CT scan. Contrast in MRI imaging shows the mobility of cyst within the cavities and this is called "ventricular migration sign."[17]

Serological method of detection of *Taenia solium* specific antibody by enzyme linked assay may be helpful in diagnosis of NCC. The major disadvantage of serological assay is high false negative results. Due to poor sensitivity this cannot be used as diagnostic test but this is a very useful for monitoring of therapy, if positive in NCC.[22]

Even with the advances in neuroimaging and laboratory immunological test, the diagnosis of NCC is still a challenging task for clinician. To improve the diagnosis accuracy of NCC, Del Brutto et al. developed a criteria based on clinical, radiological, immunological, and epidemiological data **(Table 3)**. The diagnostic accuracies of NCC are classified on the basis of these criteria into definitive diagnosis and probable diagnosis. Presence of major criteria is highly suggestive of the diagnosis but minor criteria though non-specific but required.

Treatment

Because of variable presentation of the disease, a single approach is not possible for treatment. The factors affected the tailoring of treatment in NCC are location, numbers, and stage of cysticerci in nervous system.[23] The basis of NCC treatment consist both antiparasitic treatment and symptomatic treatment. The preferred antiparasitic drugs are albendazole (15 mg/kg/day) or praziquantel (50 mg/kg/day) with standard duration of treatment is 10–14 days.

In **Table 4** there are some peculiar point in treatment guideline given by Infectious Diseases Society of America (IDSA) and the American Society of Tropical Medicine and Hygiene (ASTMH).[24]

TABLE 3 Diagnostic criteria for NCC

Absolute criteria:
• Parasite visualization either by histopathology or funds examination of retinal or neuroimaging (scolex in cystic lesions)
Major criteria:
• Radiology imaging of CNS or spine strongly suggestive of neurocysticercosis • Positive immunoblot serology for parasite • Resolution of suspected cystic lesion either spontaneously or after anti-parasitic therapy
Minor criteria:
• Radiology imaging of CNS or spine strongly suggestive of neurocysticercosis • Clinical features are indicative of neurocysticercosis • Positive parasitic antibody or antigen in CSF • Presence of extra-neuronal cysticercosis
Epidemiologic criteria:
• Patient from high prevalent area of cysticercosis • History of frequent travel to high prevalent area of cysticercosis • History of household contact with Taenia solium infection
Definitive diagnosis (any one):
• One absolute criterion • Two major plus one minor or one epidemiologic criteria • Probable diagnosis (any one): – One major plus two minor criteria – One major plus one minor and one epidemiologic criteria – Three minor plus one epidemiologic criteria

TABLE 4 Summarized treatment guideline of NCC given by IDSA and ASTMH

Location of NCC	***Treatment recommendation***
Viable Intraparenchymal NCC	• In patients with hydrocephalus or diffuse cerebral edema, treat raised intracranial pressure (ICP) (Corticosteroids) and **NOT** use antiparasitic treatment • If ICP not raised, use antiparasitic treatment with adjunctive corticosteroid therapy
Solitary cysticercus granuloma	• Antiparasitic treatment with adjunctive corticosteroid therapy (Albendazole preferred)
Calcified parenchymal neurocysticercosis	• Symptomatic therapy alone, **NOT** use antiparasitic drugs and adjunctive corticosteroid
Intraventricular neurocysticercosis	• Surgical removal and/or shunt surgery with use of corticosteroids for treatment of brain edema in the perioperative period • Antiparasitic drugs only in failure cases
Subarachnoid neurocysticercosis	• Strong recommendation of antiparasitic treatment with adjunctive corticosteroid therapy till resolution of cyst (methotrexate could be use as steroid sparing therapy)
Spinal NCC	• Surgery with strong recommendation of antiparasitic treatment with adjunctive corticosteroid therapy

Conclusion

- Neurocysticercosis is caused by helminthic infection due to *Taenia solium*.
- Most common cause of adulthood epilepsy.
- Environmental human-to-human transmission is also important mode of transmission.
- Diagnosis is improved with neuroimaging, but accuracy required diagnostic criteria.
- Effective antiparasitic treatment with adjuvant corticosteroid therapy is most effective treatment.
- Detection of stage of parasite by neuroimaging is very helpful in selection of treatment.

CHAPTER

177 Rabies: A Comprehensive Overview

Shashi Sinha, Naresh Kumar

Abstract

Rabies is one of the most typical zoonotic, fatal, and acute progressive neurological infections that has been well known since ancient ages. It is avertable deadly viral disease of Rhabdoviridae family, Genus Lyssavirus. The virus uses nerve cells for their multiplication and produces mutation in the nervous system. There is no treatment for rabies, but we can avoid this by taking preventive measures. Vaccination for dogs is also available. The purpose of this comprehensive overview is to summarize the rabies and its medical importance.

Introduction

Rabies is a disease transmitted to humans through infected animal bites (all mammals) mainly dogs (reservoirs of infection) pets (40%) and stray (60%).

Myths about Rabies in India:

- Some herbal extracts and concoctions will cure rabies.
- People also resort to witch crafts and religious practices.
- Washing of wounds can cause hydrophobia.
- Dietary changes can cure, that is, shift from vegetarianism to non-vegetarianism or vice-versa; stopping consumption of white things, etc.
- A single dose vaccine will prevent rabies.
- Vaccines are more effective if taken in empty stomach.
- One should avoid bathing or eating meat or eggs during vaccination.
- Gems and stones have magical properties against rabies.

Avoid:

- To watch dog for 10 days (practically not feasible) is risky and treatment should be initiated as early as possible.
- Keeping vaccine in freezer. If accidentally kept it should not be used.
- Cauterization of the wound.
- Suturing and bandaging the wound because it may inoculate the virus deeply in to the wound.
- Debridement of the wound too much as this may cause problem with wound closure and appearance.
- Storage of vaccine at room temperature.
- Exposure to the Sun light, heat, or dust (vaccine should be stored at +2–8°C)
- Mixing of IMR and ID schedule.
- Using IG and rabies vaccine in same syringe and at same anatomical sites (it should never be practiced).
- Vaccine should be diluted with the diluent provided.

Clinical Features

See **Table 1**.

Prophylaxis and Treatment

Questions to be Asked/to Start PET?

The animal which bit you was pet (immunized or non immunized) or stray.

TABLE 1 Clinical features

Human beings	*Animals*
• Hydrophobia is fear from water and difficulty in swallowing liquid, typically unique to human beings. There are violent jerky contractions of the diaphragm and accessory muscles of respiration start working • Prodromal stage (2–10 days) • Local pain, fever, with an inclination to vomit • Skin is sensitive to temperature, air currents • Neuroloical stage (2–7 days): Aphasia, incoordination, paresis, paralysis, change in mental status, hyperactivity • Late stage—Hypotension, coma, DIC, cardiac arrhythmia, cardiac arrest, fatality	• Rabid dogs are able to drink liquid, swim (no hydrophobia) • If a rabid dog is not able to drink water, it is because of the paralysis of jaw muscles and not due to hydrophobia • Inability to drink is because of paralysis of jaw muscles • Attacks without provocation and lacks direction, remains isolated and refuses to eat/drink, with excess salivation

Was the bite provoked or unprovoked?

Did you clean/wash the wound gently/thoroughly? (This helps wash away the virus.)

Decision to Initiate PET?

Should be taken well in time, as delay may increase the risk for developing clinical rabies. PET is nearly 100% effective when used appropriately. Factors that should be taken into consideration when deciding whether to initial PEG include:

- The epidemiological likelihood of the implicated animal being rabid.
- The category of exposure (I-III)
- The clinical features of animal.

Diagnosis

Availability of the Animal for Observation and Lab Testing

During life, the diagnosis is usually made on clinical grounds but rapid immunofluorescent techniques can detect antigen in corneal impression smears or skin biopsies.

But for most cases in developing countries, the vaccination status of the implicated animal alone should not be considered when deciding whether to give or withhold prophylaxis.

Examination of CSF often reveals mild mononuclear-cell pleocytosis with a mildly elevated protein level. The presence of rabies virus-specific neutralizing antibodies in CSF suggests rabies encephalitis, regardless of immunization status.

Detection of rabies virus RNA by RT-PCR is highly sensitive and specific. This technique can detect virus in fresh saliva samples, skin biopsy specimens, CSF, and brain tissues.

Direct Fluorescent Antibody Testing with rabies virus antibodies conjugated to fluorescent dyes is highly sensitive and specific. The test can be performed quickly and applied to skin biopsy and brain tissue samples. In skin biopsy samples, virus antigen may be detected in cutaneous nerves at the base of hair follicles

Golden rule: It may be safest to assume that the animal that bits you has rabies and treatment includes—

- Local
- Rabies shots

  Fast acting shot (Rabies immunoglobulin)

  -A series of rabies vaccines.

Local Treatment (Wound Toilet)

Wash the saliva containing rabies virus and clean the wound with soap/detergent (soaps are viricidal) and flush the wound under running water for at least 15 minutes. After cleaning, anti-microbial agents, disinfectant, sanitizer can be applied.

Rabies Immunoglobins

The protective antibody takes 7–14 days to develop after initial dose of vaccine; hence, RIG should be started as soon as possible because it provides activity against rabies virus by providing passive immunity, beginning immediately after administration and lasts for about 7–10 days during which period active immunity to rabies develops and protects the individual.

Severe multiple bites on head, neck, face hands, and genitalia in particular have a short incubation period of only 4 days. Thus, these individuals are vulnerable to rabies despite the timely and full course of any modern rabies vaccine and proper wound care. In these individuals only RIGs are lifesaving, as their timely and proper administration neutralizes the virus in the wounds and prevents its progression into CNS. RIG provides protection, which begins immediately after administration and lasts for about 7–10 days, during which period active immunity to rabies develops and protects the individual.

Often, this failure of modern cellular vaccines in most cases has been because RIG was not use in high risk category III cases

There are two types of RIGs:

- ERIG (Equine Rabies Immunoglobulion):
  - It is heterologous in origin
  - Produced from hyper immunized horses
  - Economical as compared to HRIG; hence, more affordable
  - The currently manufactured ERIG are highly purified with least adverse effects. Most of the ERIG available are F(ab')2 fragment free from reactogenic Fc fragment
  - Dose is 40 iu/kg body weight up to a maximum of 3,000 iu (given after sensitivity test)
- HRIG (Human Rabies Immunoglobulin):
  - Homologus in origin
  - Longer half-life when compared to ERIG; hence, given in half the dose of ERIG
  - Does not require prior skin testing

  HRIG are imported, expensive, and scarce.
- Dose is 20 iu/kg body weight up to a maximum of 1,500 iu.

RIGs should be given as a single dose and should not be repeated.

Vaccines

Human rabies vaccines are made from inactivated or attenuated rabies virus and have gone through successive improvements since the time of Pasteur. The first rabies vaccine was developed by Pasteur, which was nerve tissue based and virus was inactivated by drying, but this vaccine had a risk of activation of the virus and allergic reaction to the presence of nerve tissue or myelin. Myelin-free vaccine prepared from neonatal mouse brains were introduced by Fuenzalide et al.

Subsequently purified duck embryo vaccine (PDEC) was developed, which was highly immunogenic rabies vaccine that can be used safely and effectively at low doses, both for primary immunization and for treatment after exposure. Subsequently, more second generation rabies vaccine were developed like human diploid cell vaccine (HDCV), vero cell, purified chick embryo cell (PCEC). PCEC vaccine with PM (Pit men-moore) strain.

Advantages:

- It is more advantageous than many other cell line based rabies vaccines.
- It is more readily scalable to large scale commercial vaccine production.
- The vaccine produced by the present process has a very large yield, efficacy safety as well as the process is much cost-effective than many of the other processes known for the preparation of rabies vaccine.
- It has unique stabilizing agents, which make the vaccine more stable even at accelerated temperature.
- This method provides vaccine with high yield, greater potency, and immunogenicity, which make the vaccine cost-effective and unique.

All modern anti-rabies vaccines are freely interchangeable. The safest vaccine, free of complications, is human diploid cell stream vaccine.

Vaccines can be given:

- In pregnant woman
- In lactating woman
- Along with other vaccine (EPI, i.e., expanded program on immunization) vaccines
- To a child with chicken pox or measles
- To HIV +ve or AIDS patients
- To patient with jaundice
- To patients who are on antimalarials or steroids or taking immunosuppressive drugs. Generally, vaccine should be avoided with these drugs but if cannot be avoided then vaccine on day 0 may be doubled and given at two sites
- With a higher potency

Indications for doubling the first dose (0 dose) of rabies vaccines:

- Patients who seek treatment after a delay of 48 hours or even months after having been bitten should be dealt in the same manner as it expose occurred recently.

- Patients with very high risks exposures on extensive bites.
- Immunodeficient patients, or those on immunosuppression drugs, e.g., antimalarials, anticancer drugs, etc.
- Severely malnourished patients.
- Patients with underlying chronic disease like cirrhosis of liver.
- Patients where RIG is indicated but unavailable.

Discussion: Rabies is one of the oldest diseases known in recorded medical history. It is caused by a bullet shaped RNA rhabdovirus that is a member of the rhabdoviridae family, genus lyssavirus. Generally, rabies is transmitted by saliva from infected animal bites but may also be transmitted by scratches, secretions that contaminate mucous membranes, aerosolized virus that enters the respiratory tract and corneal transplants.

Rabies is a neglected disease of poor and vulnerable population whose deaths are rarely reported. It occurs mainly remote rural communities where measures to prevent dog to human transmission have not been implemented. Under reporting of rabies also prevents mobilizations of resources from the international community for the elimination of human dog mediated rabies.

Prevention of Rabies

This consists of:

- Elimination of stray dogs
- Registration and licensing of dogs
- Immunization of dogs and pets

Since dogs are the major reservoir of rabies transmission in India **(Table 2)**, there population must be controlled. Way back in 1985, the dog population was estimated to be 80 million as per census by agriculture ministry. It appears this population might have grown substantially.

For killing of dogs strychnine had been in use for long time, its use is not advocated these days because drugs being very hazardous and in humane. Saturated solution of magnesium sulfate administered IV is the ideal and recommended method for killing dogs. After destroying the dogs, the concass should be hygienically disposed off. But this is not allowed.

The dog destruction used to be one of the pivotal activities at the primary health center in India. Sanitary inspectors used to destroy dogs in rural areas after obtaining the requisition from village panchayats. Now this has been stopped. Human way of dog destruction is in practice in municipal areas. No solution seems to be in hand to destroy stray dogs in rural areas, the menace continues to grow. Similarly, monkey menace has been additional burden in urban areas, besides dogs.

Municipal authorities hold the responsibility of dog catching licensing and dog destruction by humane way to prevent cruelty against animals.

Sterilization of dogs and monkeys has been attempt to reduce their population.

TABLE 2 Reservoir animals

Frequently	*Sometimes*	*Occasionally*	*Not reported*
Dogs Cats	Monkeys, Horses, Sheep, Cow, Buffaloes, Donkeys, Pigs	Camels, Elephants, Foxes, Mangoose, Jackals, Bears	Bats, Rodents, Birds

Pre-exposure Immunization in Animals

Pre-exposure immunization of pet animals against rabies is recommended.

Single dose: The vaccine is prepared as 20% suspension of brain from sheep infected with modified rabies virus. The virus in the brain suspension is inactivated phenol or B-propiolactone (BPL). It's only used for pre-exposure immunization.

Veterinary Antirabies Vaccine Multiple Dose

This vaccine is also prepared from sheep brain infected with modified rabies virus. The virus in the vaccine is killed with phenol or BPL. The vaccine is given in multiple doses and can be used for both pre- and post-exposure immunization of dogs, cats, and other domestic animals. This vaccine confers higher degree of protection than conferred with single dose vaccine.

Epidemiological cycles:

- *Urban:* As many as 99% of human cases in India are due to bites by urban rabid animals, which maintain a cycle amongst themselves. DOG→DOG→Other animals, and man being an accidental victim and dead end of infection.
- *Sylvatic:* Cycle propagates itself within wild animals who sometimes transmit the infection to urban

animals as well as man. Bat rabies has not been conclusively reported from this country. No courier state has been convincingly demonstrated in dogs and in all practical purposes it is taken as non-existent.

Mode of transmission:

- Licks on damaged skin and mucous membrane or scratch
- Directly from the bite by Rabid animals
- Handling saliva of rapid animals or patient
- Organ transplantation particularly by corneal graft etc.
- Unboiled milk of Rabid infected cow
- Urine, tears, nasal secretions, and sweat
- Aerosol contamination
- Mechanical transmission

After local multiplication at the wound site, the virus enters the nerves and travels at the rate of 3 mm/hours to the dorsal root of ganglion, then reaches the anterior horn cells of the spinal cord and brain, developing rabies encephalitis, and inevitable deaths.

Incubation period: On an average 20–90 days, but 4 days to 8 years have been reported.

Pathology

- Minimal pathologic changes
- The brain is edematous and congested on gross appearance
- Histopathologically:
  - Perivascular cuffing and gliosis
  - Minimal neuronal damage (necrosis)
  - Presence of Negri bodies is pathognomonic

Conclusion

- A much feared disease known to man since ancient times is rabies.
- A deadly disease, but also a 100% preventable disease.
- Taking right steps at right time can reduce exposure to infection and prevent rabies.
- When in doubt about the degree of exposure to rabies risk, it is safer to over treat that to under treat.
- Criterion for "protection" after immunization—is that the rabies virus neutralizing antibody (RVNA) titer of ≥0.5 iu/mL of serum in the vaccinated person which is considered protective.
- Person receiving/completed anti-rabies immunization either pre-exposure or post-exposure can donate blood, but the recipient does not benefit from the transfer of rabies neutralizing antibodies due to hemodilution.
- Health education of public on prevention and control of rabies and management of bites and their response to bite at local level is crucial to save lives. This should be through primary health-care infrastructure besides mass media as also formal and non-formal education channels.
- In developing countries, where human rabies globulin may not be obtainable, 0.1 mL of vaccine may be given intradermally into eight sites on day 1, with single boosters on days 7 and 28.

CHAPTER

178 Biomarkers for Diagnosis and Prognosis of Severe Malaria

Manoj Kumar Mohapatra

Abstract

Biomarkers are different cellular, biochemical, or molecular products, which are measured in different biological samples to assess the diagnosis and prognosis of malaria.

Introduction

Malaria is an intricate parasitic disease caused by intraerythrocytic parasite of the genus Plasmodia. Five species, *Plasmodium falciparum, Plasmodium vivax, Plasmodium malariae, Plasmodium ovale,* and *Plasmodium knowlesi,* are responsible for human malaria. Almost all deaths due to malaria are caused by falciparum malaria, and, despite all efforts, still it persists as a disease of high mortality. Improper diagnosis and development of drug resistance are two factors that make the disease difficult to control.[1]

For a long time, detection of the parasite in peripheral blood smear has been considered as the gold standard of diagnosis but with a lot of limitations. Further, definite indicators of bad prognosis factors are necessary for prognosis of patients of severe malaria. Therefore, there is necessity of detecting different biomarkers for diagnosis and prognosis of malaria.

Biomarkers

Biomarkers may be defined as different cellular, biochemical, or molecular alterations, which can be measured in different biological samples to assess the diagnosis, prognosis, or therapeutic responses of a disease. There is no suitable classification of biomarkers. However, Frank and Hargreaves have attempted to classify the biomarkers into the following three types:[2]

- *Type 0:* Measures of natural history of the disease and correlate with clinical outcome.
- *Type 1:* Determines the biological effect of therapeutic intervention.
- *Type 2:* Characteristic or variable that reflects how a patient feels/functions/survives, i.e., a clinical end point.

Biomarkers for Malaria

In malaria, host and parasite interaction is of paramount importance. Therefore, biomarkers related to the parasite may be used for diagnosis and from the host may be utilized for prognosis. When parasite enters the human body, parasitic proteins trigger the host immune systems, which are associated with malarial pathogenesis and severity. The molecules released during pathogenesis can be used as diagnostic biomarkers. *P. falciparum* severe infection has diverse effect on multiple systems causing multiorgan failure. Molecules released during complications like cardiac dysfunction, circulatory dysfunction, kidney dysfunction, and alteration of cell signaling can be used as prognostic biomarkers or biomarkers of severity.[3]

Criteria for an ideal biomarker: An ideal biomarker should be:

- Less costly
- Easy to detect and evaluate
- Can be used in low-resource settings
- It can be used at the point of care
- It should have the power to distinguish different forms of the disease like symptomatic versus asymptomatic or uncomplicated versus severe malaria
- It should provide better prognosis
- It can guide treatment

Biomarkers used for diagnosis are HRP II (Histidine rich protein II), Parasite Lactate dehydrogenase, Hemozoin, Aldolase, Haptoglobin.[4]

Biomarkers used for severity of disease are vascular dysfunction (angiopoetin-Tie-2 system), RBC membrane dysfunction (gamma GT), serum uric acid, eGFR, Procalcitonin, lipase, cardiac markers (PPARG coactivator 1 alpha, CPK-MB), Apoptosis markers (DAPK1; death associated protein kinase-1), hypoxia and cerebral malaria (HRP II, IFN-gamma, Lymphotoxin-alpha, chemokine CXCL10), neurological dysfunction (ApoE, apolipoprotein).

Biomarkers to assess protective immunity are antibodies to ICAM-1 binding *P. falciparum* erythrocyte membrane protein-1 (PfEMP-1) and to glycosylphosphatidylinositol (GPI).[5]

Diagnostic Biomarkers

Histidine Rich Protein

P. falciparum synthesizes a unique set of soluble HRPs during the asexual erythrocytic development. There are three types of HRP, namely HRP I, II, and III in the order of discovery.[4]

HRP-I is also known as knob-associated protein. It produces knob like protrusions on the cell surface of parasitized RBC that helps in cytoadherence of infected erythrocytes to venular endothelium. HRP-II helps in heme binding and heme detoxification by hemozoin formation. It is exclusively found in *P. falciparum*. HRP-III, also known as small histidine alanine rich protein (SHARP) was found to have polymorphisms in gene repeats and shares homology with HRP-II.

Amongst these HRPs, HRP-II was found to be transported from parasite through the host cell cytoplasm to the circulation and can be detected in urine of infected patients. Its release in abundance makes it an important parasite antigen for diagnosis of malaria.

Parasite Lactate Dehydrogenase (pLDH)

Normally, the requirement of glucose for the metabolism of RBC is modest. But after the invasion, plasmodium consumes an excess amount of glucose for its growth and metabolism. The extra glucose has been taken from the blood by the parasite and metabolized by anaerobic glycolysis and glucose is converted to lactic acid and excreted to circulation. The final enzyme of this glycolytic pathway is lactate dehydrogenase, and hence is over expressed and can be used for diagnosis purpose.[5]

Hemozoin

The parasite infects the RBCs and digests hemoglobin resulting in release of amino acids and toxic-free heme (ferriprotoporphyrin IX), which is polymerized to hemozoin. It helps the parasite to survive from the heme toxicity. It plays a role as a visible marker in identifying parasites; therefore, popularly termed as malaria pigment.[3]

Other Biomarkers

Apart from these, Aldolase and Glutamate dehydrogenase are two enzymes, which can be used for diagnosis purpose.

Haptoglobin

Haptoglobin (Hp) is an α2 glycoprotein that binds rapidly to free hemoglobin (Hb). After rupture of parasitized RBC and hemolysis of non-parasitized RBC, free Hb binds to Hp forming a complex which is rapidly cleared by the mononuclear phagocytic system, resulting in a state of hypohaptoglobinemia, which can be used as a clinical and epidemiological biomarker of falciparum malaria.[6]

Biomarkers of Severity and Prognosis

In addition to the diagnostic performance, biomarkers have been identified for the prognosis of severe malaria. Endothelial cell activation is crucial in pathogenesis of *P. falciparum* malaria. Activation of endothelial cells causes release of procoagulant and inflammatory proteins like tissue factor, Ang-2 (angiopoetin-2), I-CAM, and E-selectin.

Ang-1 and Ang-2 are ligands of the Tie-2 receptor which is expressed on endothelial cells. Ang-1 is constitutively produced and excreted into blood by pericytes and

smooth muscle cells and also stored in platelets. It binds to Tie-2 receptor, thereby acting as agonist resulting in anti-apoptotic and anti-inflammatory status of endothelial cell. Ang-2 is produced in endothelial cell and prestored in Weibel Palade Bodies (WPB) together with vWBF. Upon endothelial activation, there is exocytosis of WPB, Ang-2 released and replace Ang-1-Tie-2 interaction. This interaction stimulates inflammatory response. Further studies based on this pathogenesis showed that decreased Ang-1 and increased Ang-2/Ang-1 ration are robust biomarkers to distinguish uncomplicated malaria from cerebral malaria. However, they do not correlate with parasitemia.[7]

PCT is a prohormone of calcitonin containing 116 amino acids with a molecular weight of 13 kDA. Under physiological conditions, calcitonin is produced and secreted from C-cells of thyroid gland after intracellular proteolysis to circulation with plasma half-life of a few minutes. Therefore, under normal condition PCT level is low (<0.5 ng/mL). The origin of PCT in infection is thought to be extrathyroidal and the predominance of PCT without increase in calcitonin indicates the presence of a constitutive pathway within the cell that bypasses the enzymatic conversion of PCT to calcitonin.[8]

High negative predictive value of S.PCT may be helpful for a rapid exclusion of critical malaria on admission. When S.PCT was ≤2 ng/mL the patients can be managed in the general ward or domiciliary treatment may be given; with 2–10 ng/mL the patients can be managed in the general ward with special attention or in high dependency unit (HDU) and can be shifted to ICU when necessary; and if more than 10 ng/mL the patients should be shifted to ICU for management.[9] Different biochemical investigations that determine dysfunction of different organ systems can be used as biomarkers of severity.

Elevated level of gamma glutamyl transferase (GGT) was observed when there is increased RBC membrane damage contributed by oxidative stress. Markers of liver dysfunction like serum LDH and total bilirubin is significantly elevated in severe malaria. Serum lipase, a pancreatic enzyme which has been associated with acute pancreatitis, a rare complication of *P. falciparum* can be used as a biomarker.[10] Cardiac biomarkers like PPARG coactivator 1 alpha and CPK-MB are significant cardiac biomarkers indicating of severe malaria and can be used as biomarkers.[11]

DAPK1 (death associated protein kinase 1) is known as a mediator of apoptosis and autophagy. When there is an extracellular signal trigger, DAPK1 is phosphorylated, which increases its catalytic activity and causes cellular death mediated by p53 pathway. When there is an increased parasite burden, there is inhibition of DAPK1 and p53, a strategy of parasite survival during metabolic stress. Therefore, decrease in apoptotic markers DAPK1 and p53 signify severe malaria.

Apo-E is a major lipoprotein in brain and has been seen dominant in several neurological diseases. Hence, several studies have been carried out to assess its correlation with cerebral malaria as a neurological biomarker.[5]

Biomarkers of Protective Immunity

- *Antibodies to ICAM-1 binding PfEMP1-DBL beta:* Expression of diverse *P. falciparum* erythrocyte membrane protein-1 (PfEMP1) gene variants allows clonal antigenic variation and cytoadhesion to endothelium. Adhesion occurs via specialized PfEMP1 domains known as duffy binding like (DBL) and cysteine rich interdomain region (CIDR) and antibodies against them are significantly associated with protection against severe malaria. This class of DBL beta domain could be used as diagnostic antigens.[3]
- *IgG antibodies to synthetic GPI:* In malarial parasites, GPI is a glycolipid that is found both free and as an anchor sustaining many proteins on the parasite membrane including merozoites. In animal studies, it has been found that antibodies against GPI were able to delay mortality by *P. berghei*, by blocking toxic immune response. Further studies showed that GPI was found to be present across all stages of malarial parasite life cycles suggesting that antibodies against GPI could be able to prevent both erythrocytic and hepatic infection and block transmission of parasite from human to mosquito. These observations highlight that IgG to GPI can be potential biomarkers of immune status.[3]

Conclusion

Unlike other diseases biomarker research in malaria is slow. However, recently biomarker research on malarial pathogenicity has taken a leap as evidenced by discovery of HRP-II, pLDH, aldolase, hemozoin, angiopoietin, procalcitonin, etc. Further, it is now important to distinguish complicated and cerebral malaria as early as possible so that treatment can be implicated to reduce the mortality.

CHAPTER

179 How Fatal Is *Plasmodium vivax*—To Be Understood and Its Management

Smita Gupta, Neeraj Kapoor, Ankit Grover

Abstract

Malaria caused by *Plasmodium vivax* is often a life threatening disease leading to significant mortality in our society. Though severe malaria has been attributed to *Plasmodium falciparum*; however, mortalities and complications associated with vivax malaria cannot be overlooked. The ability of *vivax* to remain dormant in the form hypnozoites causing relapse and increasing complications by cytoadherence and rosette formation further adds to the disease burden. Chloroquine resistance is an emerging challenge in the management of patients with vivax malaria. Complications like hemolysis, cerebral malaria, ATN, and acute respiratory distress syndrome are also now attributed to *Plasmodium vivax* malaria.

Introduction

Malaria is a life threatening protozoal disease caused by Plasmodium parasite, which is transmitted to humans by bite of an infected female Anopheles mosquito. Of the five parasite species that cause malaria, two of them, *Plasmodium falciparum* and *Plasmodium vivax*, pose the greatest threat. World Malaria Report 2019 states that nearly half the population of the world was at risk of exposure to malaria in 2018.[1] An estimated 228 million cases of malaria were there worldwide in 2018 in contrast to 231 million cases in 2017 of which around 405,000 deaths globally due to malaria. Currently, India accounts for 4% burden of malaria globally and 87% of the Southeast Asia.[2] Most vulnerable group includes children less than 5 years of age accounting for 67% of deaths due to malaria worldwide.[1] The most prevalent parasite in African region is *P. falciparum* (99.7%), whereas *P. vivax* remains as the prevalent parasite in America, accounting for 75% of all malarial cases.[1] In India, malaria is a major health problem with 0.88 million cases occurring per year. Severe Malaria (as per the WHO guidelines) accounts for approximately 400–1,000 deaths per year[3] and most of them are due to *P. falciparum*.

P. falciparum known to cause Severe Malaria has been contributing to maximum morbidity and mortality worldwide whereas infection by *P. vivax* is always thought to be a benign disease, classically causing mild symptoms. But recently it has been seen that the infection by *P. vivax* no longer results in a non-critical illness having so many case reports showing its association with severe life threatening complications. There are historical evidences too, showing its severity which come from reports on neurosyphilis therapies in early 1990s reporting 5–15% mortality rates in America and European treatment facilities using *P. vivax* for treatment of syphilis indicating that it always had a severe outcome.[4]

Plasmodium vivax: Epidemiology

The most widespread infections of all malarial parasites is P. Vivas which affects majority of the parts of subtropical & tropical areas of the world. Nearly 2.5 billion people are affected by *P. vivax* infection in the world and 16 million clinical cases occur annually.[5,6] Highest burden is borne by Southeast Asian countries and South America out of which 53% of cases occur in South East Asia with India alone bearing around 47% of the total burden.[5,6] it has a wider

geographical variation and distribution due to its ability to stay dormant in liver cells and then cause relapses and its capability to survive in cold weather. As per the studies, it has been reported that many people in Africa are resistant to *P. vivax* infection due to absence of Chemokine Duffy antigen receptor on RBCs but this theory has been put to question by many reporting cases in Duffy negative patients also.[7,8]

In 2014, there were 2.14 million cases of *P. vivax* worldwide, 18% of them occurred in India alone.[9] In the recent past the number has been increasing accounting for nearly half of all the malarial cases. The incidence of *P. vivax* varies across India with ten states accounting for nearly 89% of total cases.[10] Out of these Jharkhand, MP, Odisha, UP, and Gujarat carry 64% of the total burden. It is becoming a problem mainly in urban settings of India probably due to construction work, migration, and ever growing slum areas, and resulting in peaks in morbidity and mortality. Within the Urban Malaria Scheme, 98% of all malaria cases were *P. vivax* in 2014.[10] Its transmission occurs throughout the year, but it peaks during rainy or post-rainy seasons.

Risk Factors and Pathophysiological Mechanisms Leading to Its Malignant Course

P. vivax infection now poses a great threat with multiple reports showing severe clinical presentations and deaths. A meta analysis[11] published in 2014 showed that *P. vivax* as a major cause of "Severe Malaria" and warranted a prompt and early detection of its clinical manifestation resulting in early initiation of therapy so that it could be life saving. Many risk factors have been discussed related to its severe course. Children below 5 years of age are at risk of developing critical illness and ultimately dying within 1 year of their initial presentation.[12] Genetic polymorphism varies and shows alpha and beta thalassemia patients having increased risk and Duffy negative and G6PD deficient patients having decreased risks of *P. vivax* infection.[13]

Relapse

The ability of *P. vivax* to persist as dormant stage as hypnozoites in liver initiates infection in the blood resulting in frequent relapses ranging from weeks to months and years.[14] The variation in time of relapse varies from one region to another and it is observed that in tropical countries the dormant period of relapse is usually 8–10 months.[15,16] The exact mechanism how hypnozoites initiate relapses is still unknown.

Increased Pyrogenicity

In contrast to *P. falciparum*, which is known to invade all stages of erythrocytes, and as a result parasitemia can exceed as high as 20–30%, *P. vivax* is known to invade the reticulocytes rather than the erythrocytes, resulting in lower parasite biomass and parasitemia, which rarely exceed 2–3% in blood even in severe infection. *P. vivax* in spite of having lower pyrogenic threshold has been observed to have higher endothelial activation, increased production of cytokines, and a proinflammatory response as compared to *P. falciparum*.[14] The main reason could be presence of higher levels of genomic content (GC) in vivax genome, and thus having higher contents of CpG motifs, which are recognized by receptor 9 leading to cell activation and inflammatory responses.[17-19] Toxins contributing to increased pyrogenicity of *P. vivax* have been found to be cholesterol or triglyceride fraction of plasma at the time of paroxysm of fever.[14] The imbalance between pro- and anti-inflammatory cytokines production is related to severe clinical conditions in *P. vivax*.[20]

Sequestration and Rosetting Phenomenon

The classical pathogenesis of severe *P. falciparum* infection leading to "Severe Malaria" shows sequestration of parasite in endothelial tissue causing microvascular obstruction, inflammation ultimately resulting in hypoxemic, and ischemic damage in organs. Similar studies are now documenting that there is binding of vivax infected RBC to endothelial cells via receptors like ICAM 1 but to a much lesser frequency than the *P. falciparum* infected RBCs.[21] They also seem to be attached to glycosaminoglycans like chondroitin sulfate and hydraulic acid.[22] Severity of *P. falciparum* is associated with the above phenomena, which is also seen in *P. vivax* but it shows a moderate level of cytoadherence to endothelial cells and ultimately resulting in inflammatory responses in organs like lungs. In fact this phenomenon of sequestration and adherence of infected RBCs and accumulation of malarial pigment deposits to the intervillous spaces of placenta has been associated with pregnancy induced malaria leading to

anemia and intrauterine growth retardation although it appears to be less severe.[14]

Apart to adhesion phenomenon, it is also known that vivax too has a tendency to form rosettes, which has been mentioned in literature more than 20 years ago,[23] although seen more frequently with falciparum. Rosettes in *P. vivax* are formed by interaction of infected RBCs containing trophozoites, schizonts, or gametocytes. The rosettes of *P. vivax* are stable even under high physiological shear stress and cause increased rigidity of infected RBCs thereby contributing to sequestration of *P. vivax* in the microvasculature.[24]

Chloroquine Resistance

The recommended drug in management of both *P. falciparum* and *P. vivax* is chloroquine, but now resistance has started developing to this drug especially in endemic areas. This is attributed to presence of polymorphism in chloroquine resistance genes pvcrt-0 and pvmdr-1 in South India.[25]

Clinical Manifestations and Complications

Fever is the main complaint of malaria and symptoms start to appear as soon as the blood stage infection starts with the invasion of RBCs by the merozoites. As the life cycle of *P. vivax* repeats every 42–56 hours, the paroxysm of febrile episodes occurs during similar intervals and classically the fever is termed as the tertian fever.[26] Fever is usually intermittent, may go as high as 40 degrees in non-immune individuals and children associated with chills and rigors followed by profuse sweating and weakness. Other non-specific clinical features include abdominal discomfort, malaise, fatigue, and muscle aches. In few patients, a prominent headache, altered sensorium, or irritability may be observed. Headache may be very severe but usually signs of meningeal irritation like neck stiffness and photophobia are absent.

In areas of high-relapse rate, anemia has been observed to be the most common finding in both children and adults. The most likely causes involved are cumulative losses of infected RBCs, lysis of uninfected RBCs, and defect in production of red cells.[27-30] It is said that for every one infected RBC in circulation, approximately 34 uninfected RBCs are removed and thereby leading to severe anemia. A higher inflammatory response, in the spleen leading to higher losses of RBC, seems to be its explanation in spite of low parasitemic index. Also its tendency to relapse usually at 3–4 weeks interval repeats the cycle before the hematological recovery takes place from previous infection. Inflammatory cytokines also result in dyserythropoiesis and bone marrow suppression.[31,32] Usually a palpable spleen is found several day after infection but many of the otherwise healthy individuals have been found to have a palpable spleen indicating repeated infections in an endemic area. Mild hepatomegaly may be observed in children. Mild jaundice may be seen in adults and usually resolves in 1–3 weeks indicating uncomplicated infection.

P. vivax also has pulmonary complications and the spectrum ranges from cough, acute breathlessness, pulmonary edema to ARDS, and death. A meta-analysis published in 2017 showed that out of 49 studies 59.1% case studies reported acute respiratory distress syndrome (ARDS), 20.4% respiratory distress, 4% respiratory failure, 2% lung injury, and 2% studies reported pulmonary edema.[33] They concluded that respiratory complications and ARDS occur in lower frequency in vivax than in falciparum, but mortality resembles that of falciparum. Female gender, presence of comorbidities, respiratory complications at time of hospital admission, and low-hemoglobin level were associated with deaths. Another meta-analysis was published in 2014[11] in which three studies showed higher incidence of ARDS among *P. vivax* as compared to *P. falciparum*.[34-36] The presence of lymphocytes, neutrophils along with phagocytosed pigments in the pulmonary vasculature is the main cause of direct damage to lung parenchyma, diffuse inflammation, and alveolar damage.[37]

Acute kidney injury (AKI) remains a major cause of morbidity and fatality with incidence ranging from 15% to 40% in numerous studies.[38,39] Mostly it is due to *P. falciparum*, but AKI has been reported in 12–20% *P. vivax* infection also, whether it is due to solely vivax or mixed infection is still debated. Mortality associated with *P. vivax* AKI is 10–15%, which is comparable with *P. falciparum*[39] and 10–20% may require renal replacement therapy. Kidney complication are mainly due to hemodynamic dysfunction and immune response and clinically they present as oligoanuria, severe metabolic acidosis, and hypercatabolic state.[40] A study conducted in 2017[41] discussing the clinic histologically profile on 30 patients showed fever in all cases, oliguria in 23%. Renal biopsy

performed among 6 patients revealed features of ATN in 4 patients, one had features of thrombotic microangiopathy, while one revealed acute cortical necrosis. Another study[42] conducted showed that a high index of suspicion for diagnosing thrombotic microangiopathy should be kept if patient has persistent anemia, thrombocytopenia, jaundice, and non-recovering renal failure, such patients usually respond to plasmapheresis. The inciting event may be the lesion in endothelium of renal microvasculature.

Cerebral malaria a complication of *P. falciparum*, characterized by diffuse meningoencephalitis, is seen to occur with *P. vivax* also.[43] The patient usually presents with signs and symptoms of acute febrile encephalopathy, seizures, and coma. Focal neurological deficits are unlikely. However, a case presenting with Status Epilepticus has been described.[43] Though the exact pathogenesis remains elusive, but similar pathogenesis of sequestration of infected erythrocytes have been described.[44] One pathogenesis regarding cerebral malaria is genetic variation resulting in variant interspersed repeats genes, the largest subtelomeric multigene super family found in *P. vivax*.[45,46]

So it is understood that features of Severe Malaria can also be seen in *P. vivax* infection as commonly found in *P. falciparum* leading to multiorgan involvement. A study conducted in 2019 among 150 patients showed Severe Malaria among 42% of cases (as per WHO criteria) with mortality of 1.33%.[47]

Management and Treatment

Main pillar in elimination of malaria is early diagnosis and treatment thereby reducing disease burden and preventing complications, and deaths. Malaria is a notifiable disease in India. For diagnosis, uses of light microscopy or immunochromatography-based rapid diagnostic tests (RDTs) are being used.[48] The gold standard for diagnosis is direct visualization of *P. vivax* parasites on Giemsa stained blood smears by light microscopy. It is a low cost with high sensitivity diagnostic test. Parasitemia is detected by thick smears and at least 200 fields should be examined well before concluding negative diagnoses. Thin smears are used to calculate the parasite density. The parasite density of *P. vivax* is lower in areas where mixed infections are common making the diagnosis more difficult.

Since the early 1990s RDTs have popularized as diagnostic tools as they can detect one or more plasmodium species and are time saving without the requirement of a skilled lab personnel.[26] This test has a high sensitivity at higher parasitic load and may give false negative at lower parasitic load. This test can be positive even 1 month after successful treatment. A new recently developed real time micro PCR based diagnostic device has been claimed to have high sensitivity and specificity.[48]

Treatment of *P. vivax*[3]

The objective of treating malaria caused by *P. vivax* is to cure both blood stage and liver stage infections thereby preventing recrudescence and relapse both, respectively. The ability of *P. vivax* to from hypnozoites possesses a great challenge in management of patients.

WHO Malaria Treatment Guidelines, 3rd edition,[3] suggest treatment of all suspected and confirmed uncomplicated malaria patients with chloroquine or Artemisinin Combination Therapy (ACT).

Chloroquine Sensitive Malaria[3]

Oral chloroquine at total dose of 25 mg/kg (initial dose of 10 mg/kg on first day followed by 10 mg/kg on second day and 5 mg/kg on third day) **(Box 1)**.

ACTs are highly effective in the treatment of vivax malaria, allowing simplification (unification) of malaria treatment, that is, all malaria infections can be treated with an ACT. The exception is artesunate + sulfadoxine pyrimethamine, where resistance significantly compromises its efficacy.

Chloroquine Resistant *P. vivax*[3]

ACTs containing piperaquine, mefloquine, or lumefantrine are the recommended treatment, although artesunate + amodiaquine may also be effective in some areas.

BOX 1 Treatment uncomplicated *P. vivax*, *P. ovale*, *P. malariae* or *P. knowlesi* malaria

- In areas with chloroquine-susceptible infections, treat adults and children with uncomplicated *P. vivax*, *P. ovale*, *P. malariae*, or *P. knowlesi* malaria with either an ACT (except pregnant women in their first trimester) or chloroquine.
  Strong recommendation, high-quality evidence
- In areas with chloroquine-susceptible infections, treat adults and children with uncomplicated *P. vivax*, *P. ovale*, *P. malariae*, or *P. knowlesi* malaria (except pregnant women in their first trimester) with an ACT.
  Strong recommendation, high-quality evidence

BOX 2 Preventing relapse in *P. vivax* or *P. ovale* malaria

- To prevent relapse, treat *P. vivax* or *P. ovale* malaria in children and adults (except pregnant women, infants aged < 6 months, women breastfeeding infants < 6 months, women breastfeeding older infants unless they are known not to be G6PD deficient and people with G6PD deficiency) with 14-day course of primaquine in all transmission settings.
  Strong recommendation, high-quality evidence
- In people with G6PD deficiency, consider preventing relapse by giving primaquine base at 0.75 mg base/kg bw once a week for 8 weeks, with close medical supervision for potential primaquine-induced adverse hematological effects.
  Strong recommendation, high-quality evidence

In pregnant or breastfeeding women, weekly chemoprophylaxis with chloroquine is recommended until delivery followed by completion of breast feeding. Treatment for future replases can then be decided on the basis of G6PD status **(Box 2)**.

Severe Malaria

All patients including adults, children, infants, pregnant women in all trimesters, and lactating women with Severe Malaria are to be treated with intramuscular or intravenous artesunate for at least 24 hours and until they are able to tolerate oral medication. Artesunate is prescribed at a dose of 2.4 mg/kg at 0, 12, 24, and 48 hours. Once a patient has received at least 24 hours of parenteral therapy and who can tolerate oral therapy, complete treatment with 3 days of an ACT should be advised. Intravenous quinine can be considered as an alternative agent at a loading dose of 20 mg/kg followed by 10 mg/kg in 8th hourly dosing only, if artesunate is not available.

Symptomatic management of ARDS, seizures, and AKI is to be done according to institutional protocols.

Conclusion

Managing patients with severe malaria should caution the mind of a clinician in view of *Plasmodium vivax* as a causative agent and potential drug resistance in the same. Patient may present with hemolysis, jaundice, acute renal failure, cerebral malaria, or acute respiratory distress syndrome. Use of artemesin-based therapy is the treatment of choice for severe and drug resistant malaria caused by *Plasmodium vivax*.

CHAPTER

180 Emerging and Re-emerging Infectious Diseases in India—This Millennium

Partha S Karmakar

Abstract

Majority of emerging and re-emerging diseases are zoonotic. Viral and parasitic infections are more common causative agents for emerging diseases than bacteria. Zoonotic diseases are more likely in our country due to our usual habit of keeping livestock in close proximity.

After the last influenza pandemic in 1918, the prevailing COVID-19 pandemic is almost over 1 year in existence. Whole world is now reeling with this emerging infectious disease along with various re-emerging diseases in between.

Introduction

Since antiquity human population have faced several epidemics of emerging & re-emerging infectious diseases with a significant death toll. Plague (in 14th century), smallpox (in 16th century) and Spanish flu (in 20th century)—were responsible for huge death to the tune of 200, 56, and 50 millions respectively.[1] With the advent of antimicrobials and effective vaccines in 20th century infectious diseases no longer remained the major threat for mortality, especially in developed countries.[2,3] But for last few decades a slew of newer infectious diseases (Avian Influenza, NIPAH, SARS, COVID-19) have emerged. Some of them have epidemic potentials with significant morbidity and mortality.[4]

Definitions

Emerging Disease

Infectious diseases are said to be EID when incidence of one Inf. disease has increased abnormally within the recent past or threatens to increase in the near future. Diseases that fall in this category are:

- *New disease*
- *Old disease with new feature:* Here new means in respect to new location or new population (prevalence in different age group), new feature (changed C/F or non-responsiveness to conventional therapy)

Re-emerging Infectious Disease

A past disease, which was once well controlled or eradicated, has shown its reappearance is considered to be re-emerging infectious disease.

Origin of Infectious Diseases

Majority of EIDs are zoonotic and over 30 new infections have emerged in last three decades globally and most common agents are viruses & prions (37%) followed by protozoa (26%).[5] Many of them have epidemic or pandemic potentials with high fatality rate and ~60% of them are zoonotic in origin, especially wildlife in origin.[5-7] *In India, zoonotic diseases are more likely as livestock usually stay in close proximity to human dwelling.*[8]

Infections from Animal to Man—How?

To get into the depth of origin of these EIDs we have to look back to our changed behavior. Human encroachment to animal habitat through deforestation and use of terrain for their personal living and farming has lead to increased interface with wild animals. This is considered to be an important or potential factor for jump of some microbes (with or without mutation) usually found in animal kingdom, to human population. Many of them have epidemic potential and spread is facilitated across countries by fast travelling and wild trafficking.

Important Diseases

Important emerging and re-emerging diseases in India in this millennium that deserve mentioning are:

Virus:
- NIPAH (2001)—West Bengal
- Chandipura (2003, 2004, 2007)—Andhra Pradesh, Gujarat, Maharashtra
- Chikungunya (2005)—Andhra Pradesh
- Influenza-H1N1 (2009)—Andhra Pradesh
- CCHF (2011)—Gujarat
- COVID-19/SARS-CoV2
- Zika Virus Disease

Bacteria:
- Diptheria (2001–2015)—Many states (Andhra Pradesh, Assam, Delhi, Gujarat, Karnataka, Nagaland, West Bengal, etc.)
- Plague (2002, 2004)—Himachal Pradesh, Uttarakhand
- MDR/XDR Tuberculosis

Protozoa:
- ACT resistant Falciparum Malaria

Abridged Information of the above Diseases are Put Forward Except Malaria and TB

Nipah Virus Disease

Nomenclature:
- Nipah virus (NiV) belongs to family Paramyxoviridae & Genus *Henipavirus*.
- Named according to its first discovery in Sungai Nipah village of Malaysia.
- It could be considered South Asian disease as all the outbreaks (more than ten) after 1999 have occurred in this region only.

Human affection: In various ways:
- More commonly found in male with history of high exposure to pigs.
- Food borne by consuming fresh date palm sap contaminated with saliva, urine of fruit bats, natural host of NiV, while they feed on it.
- Human to human transmission is possible if patient has respiratory symptoms.[9]

Clinical feature:
- Male predominant disease with M:F = 4.5:1.
- Presents with fever (97%), headache (65%) with altered sensorium and abnormal brainstem functions (50%).
- Dizziness, vomiting, hypotonia, areflexia, dysautonomia (hypertension, tachycardia, excessive sweating) may be present.[10]
- Siliguri (West Bengal) cases in 2001 showed additional feature of acute respiratory distress with tachypnea in half of the cases, making human to human transmission possible (unlike Malaysian outbreak) with high fatality of 62.5%.[11]
- NIPAH virus alert in Kerala was again found in 2018.

Management and prevention:
- Mainly supportive and barrier nursing methods are advocated.
- Ribavarin—tried but inconclusive in vivo trial.
- Monoclonal antibody targeting NiV G glycoprotein was found to be effective in ferret models.
- Vaccine—a subunit vaccine against *Hendra* virus (used in horses), a member of *Henipavirus*, offers a great potential for NiV through cross protection.[12]

Chandipura (CHP) Virus

- Named as per its first documented place of emergence, Chandipura, Nagpur of India in 1965 and possibly it is sandfly borne disease.
- In 2003, Chandipura AES (Acute Encephalitis Syndrome) outbroke in Children in Andhra Pradesh with high fatality (55%) but luckily residual neurological deficit was rare in recovered children.[13]
- After this two more focal outbreaks were observed in Gujarat (2004) and Maharashtra (2007).

Chikungunya

Chikungunya is a self limiting disease and prevalent in tropical and subtropical areas of Africa and Asia.

Chikungunya means "to be bent over" as per Swahili language of Tanzania (Africa) where from the very first case was reported.

Causative agent:

- Chikungunya virus (CHIKV) of arboviridae family of the genus *alphavirus*.
- Vector—day-biting infected Aedes Aegypti and Albopictus mosquito.
- Reservoir of infection—Non-human primates

Clinical features:

- High fever (102–05°F) with severe joint pain (patient becomes bent over) and skin rash.
- Usually follow acute self limiting course but around 10–15% of cases develop subacute (3 weeks to 3 months), or chronic Chikungunya.
- Chronic Chikungunya may present as RA or post-chikengunya-rheumatic muskuloskletal (pcRMSK) disorder.

After 1973, in 2006 re-emergence of chikungunya infection in India was found in epidemic form and affected 1.2 million Indians with high morbidity rate.[14] From 2006 to 2012 chikungunya was reported from 22 States and union territories.

Diagnostic test:

- IgM against CHIKV

Treatment:

- NSAID for 1 or 2 weeks will suffice in majority of patients.
- Chronic cases may need anti-rheumatic drugs like hydroxychloroquine or methotrexate.

Influenza Virus (H1N1)

Influenza virus is a respiratory virus and is of 4 types—A, B, C, and D.

Type A Influenza Viruses has produced several pandemics in humans and is nomenclatured depending on which one of 18 different *Hemagglutinins (HA)* & 11 different *Neuraminidases (NA)* is present as surface protein. It originates either as Avian or Swine.

Influenza A Virus caused the largest and the deadliest pandemics before the occurrence of COVID-19 and four Influenza A Virus pandemics since beginning of 20th century:

- Spanish Flu (1918)—due to H1N1 with 50 million death
- Asian Flu (1952)—due to H2N2
- Hong Kong Flu (1968)—due to H3N2
- Mexican Flu (2009)—due to H1N1 pdm09

The Mexican Flu (2009) pandemic got spread rapidly to over 214 countries worldwide including India. Globally total death toll was 18,449.[15]

A total of 1,54,259 Indians were tested for H1N1 pdm09 influenza till August 8, 2010, with 23.4% being positive including 1,833 reported deaths. Maharashtra and Gujarat were worst affected states.[16]

Treatment:

- Supportive therapy
- Neuraminidase inhibitors—Block virus release from infected cells. Used both for prophylaxis & therapy:
  - Oseltamivir—Oral
  - Zanamivir—IV
  - Peramivir—IV/IM
  - Laninamivir—Intranasal

  Formulations for use. Last two molecules are unavailable here.

Crimean-Congo Hemorrhagic Fever (CCHF)

Name was derived from the first two places of its occurrence—Crimea (in 1944) & Congo (in 1956) caused by single stranded RNA virus of Bunyaviridae family.

Virus continues its life by animal (livestock)-tick-animal cycle.

Human gets infection by:

- Infected tick bites
- Handling of infected animal tissues (Slaughter house workers, farmers, veterinarians)

Clinical feature:

- Incubation period 1–9 days.
- High index of clinical suspicion is needed. Presents with fever, myalgia, headache, lymphadenopathy, and bleeding manifestation (varying from petechial rash to internal mucosal bleeding).[17]
- Fatality rate ranges from 9% to 50%.

India saw the confirmed outbreak of CCHF in 2011 in Gujarat.[18] Total 42 cases were reported till 2013 with high death rate of 59.9%.

Important D/Ds:
DHF, leptospirosis, severe malaria, meningococcal infection, and other viral hemorrhagic fevers.

Diagnosis:
- RT-PCR—sensitive, specific
- Rapid test
- Antibody—antiviral IgG and IgM detection

Treatment:
- Supportive therapy
- Ribavirine—if instituted within 5 days possibly improves the prognosis

COVID-19/SARS-CoV2

Microbes in their quest to be ahead of human, they undergo some mutation to increase their capability of jumping to human from their animal source and human to human transmission as well to reach epidemic/pandemic potential. While this article is being written whole world is reeling under the threat of a zoonosis *COVID-19/SARS-CoV2—biggest threat in last 100 years.*

Corona Virus-related Diseases

Corona virus (CoV), a respiratory virus, normally causes diseases in mammals (including birds) like—camels, civets, bats, etc. This virus is transmitted to human through droplet/fomite & usually produces mild-to-moderate respiratory illness. But through mutation it has caused following diseases with high fatality rate:
- Severe Acute Respiratory Syndrome (SARS)—First noticed in 2002 in China, soon followed by worldwide spread with total reported 8,000 cases and 800 deaths. It was acquired from bat.[19]
- Middle East respiratory syndrome (MERS)—Acquired from dromedary camels (affected from bat). First noticed in 2012 in Saudi Arabia then spreading to other Arabian Peninsula and Republic of Korea. By 2016, over 1,700 cases detected with mortality of 35%.
- Novel Corona Virus Disease (COVID-19/SARS-CoV2)—This ongoing pandemic is being greatest threat of all infectious diseases in last hundred years. Discussed below briefly.

COVID-19/SARS-CoV2 Disease

In December 2019 in Wuhan, Hubei Province of China, an epidemic of respiratory illness with moderately high fatality of unknown etiology was noticed, later proved to be caused by *novel corona virus* (SARS-CoV-2/COVID-19) with human to human transmission.

Origin of Novel CoV Infection—Speculated to have originated *from bats, a natural carrier of CoV, but bats remain in hibernation during winter*. As low temperature prevails in December in China, so intermediate host was thought of. *The virus likely jumped to humans from pangolins (long snouted mammals often used in food and traditional Chinese medicine) along with possibly other multiple intermediate hosts.*

Burden of COVID-19 patients—Infection rate of COVID-19 per day is varying greatly from country to country. Many western countries are braced with 2nd wave of COVID.

Highest infection in a day in India till 20/12/2020 was found on 11/09/2020 and it was 97,570. Little short of 1 lakh/day. Gradually with some fluctuation it then came down to 26,624 on 19/12/2020. Total burden of COVID as on 20/12/2020 is shown in **Table 1**.

Vaccines update (till December, 2020)—Researchers throughout the world putting in great efforts round the clock to contain the devastating situation of COVID-19 pandemicity by finding an effective treatment and/or vaccine against SARS-CoV2. This has lead to an unprecedented public/private partnership to go through a fast tracked vaccine development process.

On August 11, 2020, Russia make COVID vaccine, Sputnik-V, is the world's first vaccine as per bulletin of Ministry of Health of Russian Federation. Russia has started Phase 3 and Phase 4 (administration to general people) trial simultaneously though experts has raised their concern for safety profile **(Table 2)**.

India too is progressing fast keeping pace with other countries. As per ICMR reporting on 20th August, 2020, two indigenously developed vaccine candidates—*Bharat Biotech's COVAXIN* (both intrademal & IM), *Zydus Cadilla's Zycov-D* have started human trial in India, so also *Oxford Astra-Zeneca's Covidsheild* with its Pune based

TABLE 1 Burden of COVID (on 20/12/2020)

Scenario	*Total COVID-19 cases*	*Recovered cases*	*Deceased*
Global	7,66,26,187	5,37,51,202	16,91,942
India	1,00,47,131	95,95,711	1,45,669

TABLE 2 Few more vaccines globally underway

Candidate	*Sponsor*	*Trial phase*	*Institution*
bacTRL-Spike	Symvivo	Pre-clinical	Symvivo Corporation
PittCoVacc	UPMC/University of Pittsburgh School of Medicine	Pre-clinical	University of Pittsburgh
Recombinant vaccine	Vaxart	Pre-clinical	Vaxart

manufacturing partner Serum Institute of India. *Oxford-AstraZeneca vaccine may be the first shot available for Indians by the end of 2020.*

AstraZeneca is likely to get regulatory approval from the UK's independent regulator by the end of this year for a rollout to begin in early 2021, according to the UK Oxford University/AstraZeneca vaccine company.

Trials of the Oxford vaccine show the following as per their claim:

- Stop *70% of people developing Covid symptoms*. Could increase protection up to 90%
- The data also shows a *strong immune response in older people*
- It is given in two doses
- Trials with more than 20,000 volunteers are still continuing

This may be one of the easiest vaccines to distribute, because it does not need to be stored at very cold temperature.

It is made from a weakened version of a common cold virus from chimpanzees that has been modified to not grow in humans.

WHO and most nations globally are willing to prioritize vaccine recipients as follows:

- Health-care workers (HCW)
- People >65 years of age
- People with comorbidities (like DM, Cancers, CVD, COPD)

Clinical feature:

- Incubation period—2–14 days
- Asymptomatic—some patients
- Majority shows features of fever (45.4%), headache (70.3%), dry cough (63.2%), sore throat (52.9%), asthenia (63.3%), and some developed dyspnea. Anosmia (70.2%) and altered taste sensation (49.8%) may be early symptoms in some patients.[20]
- Diarrhea may be the presenting feature of COVID-19 in ~20% of cases.

Silent Hypoxia in COVID

Silent hypoxia is a danger sign of COVID-19 infection. It means person's oxygen level in blood cells and tissue may drop due to COVID-related diffuse pneumonia without any initial warning in the form of cough, dyspnea, tachypnea, etc. until patient develops ARDS.

So arterial O_2 saturation (SpO_2) detection at regular intervals is a must for detection of silent hypoxia and to initiate supportive therapy at earliest possibility.

Treatment

No full-poof definitive but supportive therapy available at present.

Aggressive isolation measures aimed at reducing transmission in the community is our best weapon.

The followings had been tried with mixed results:

- *Hydroxychloroquine (HCQ):* Antimalarial with in-vitro activity against SARS-CoV-2 and may have immunomodulating properties. WHO recommends for prophylaxis but not for therapy (directive on 25/05/2020).
- *Azithromycin:* Shows anti-SARS-CoV-2 activity in vitro.
- *Anti-influenza agent (Favipiravir, Oseltamivir) and broad-spectrum antiviral (Remdesivir), anti-HIV agent (Lopinavir/Rtonavir):* Showing varying degree of activity against corona viruses in vitro.
- *Convalescent plasma:* Tried in severe or immediately life-threatening COVID-19 infections with favorable result in some studies.
- *HFNO (High flow nasal oxygen):* HFNO in awake prone position is considered to be win-win position to avoid invasive ventilator in some patients of declining SpO_2.
- *Other therapies:* Anticoagulant (LMWH), Anti IL6 receptor inhibitor (Tocilizumab), Invasive Ventilator, ECMO (extra-corporeal membrane oxygenation) are other therapeutic options in some specific patients.

Case fatality: Differs in different countries. In India, till August 2020 overall mortality was ~1.56.

Mortality increases significantly in:
- Patients >65 years
- Patients with comorbidities (DM, renal failure, COPD, on chemotherapy, etc.)
- Patients needing ventilatory support

Zika Virus

Zika virus disease is caused by the Flavivirus, the same family of virus causing dengue. Several Zika virus outbreaks were found in both North & South America since 2015, but it has emerged in India just with only three (3) confirmed cases in 2017—as per report of Ministry of Health & Family Welfare, Govt. of India. All these three cases were reported from Bapunagar, Gujarat.

- *Transmission:*
  - Mainly by bite of infected Aedes mosquito.
  - Sexual activity and blood transfusion can sometimes lead to this disease transmission.[21]
- *Clinical features:* Majority (80%) are asymptomatic, 20% of cases have low grade fever, myalgia, rash, and sore throat.
- Concern lies if pregnant women contract this disease in first trimester, which may lead to microcephaly and brain abnormalities of infant.[22]

Diphtheria

We all know that exotoxin-producing *Corynebacterium diphtheria is the causative agent. Its incidence has reduced to a great extent globally* due to successful implementation of childhood vaccination. *From 1 million* before 1980s to 1 lakh in 1980 and reduced to 4.5 thousand in 2015. Diphtheria is a rare disease in developed countries but global burden contributed mainly by sub-Saharan Africa, India, and Indonesia.[23]

In 15 years tenure (during 2001–2015) almost half of the global diphtheria cases were from India, and CBHI (Central Bureau of Health Intelligence) India reported 41,672 cases of Diphtheria in 10 years (2005–2014) with mortality of 2.2% cases.

Diphtheria is now considered EID as it shifts toward higher median age than its earlier preference for under five children. It could be related to lack of 100% coverage of three doses of diphtheria vaccination (80% coverage) and expected low coverage of booster dose after 10 years. This may lead to waning immunity against diphtheria among school-going children and adults.[24] Some Indian study showed higher prevalence among muslim children and it was about 38% in Delhi as stated in a study.[24]

Plague

We doctors now bear a wrong impression that plague is almost nonexistent in India and not getting proper emphasis in medical undergraduate and postgraduate teaching. So doctors are not properly aware of its consideration in differential diagnoses.

Plague infection in India continues to exist as enzootic in wild rodents and epizootic spread of plague from wild to commensal rodents facilitate human transmission. Thus, it leads to re-emergence/outbreaks of plague in India in 2002 (Shimla, HP) and 2004 (Uttarakhand) of this millennium.[25,26]

Causative Agent and Transmission in Humans

Plague is a *zoonoses* (wild rodents) and caused by Gram-negative bacilli, *Yersinia pestis*, spreading between rodents through their fleas.

Ways of transmission to man:
- By bite of infected fleas
- Coming in contact with infected tissues of rodent
- Human to human transmission through droplets in pneumonic plague

Conclusion

This has been proved beyond doubt that significant percentage of infectious diseases are zoonotic in origin. In last three decades thirty (30) emerging infectious diseases detected globally, majority of them are viral in origin and approximately 60% of them are zoonotic especially wildlife in origin. In India zoonotic diseases are more likely as here domestic/pet animals are kept in close proximity to their residence.

Through awareness and/or legislation if we can make human contact with animals (domestic/wild) scientifically modified or restricted (in some situations) emerging and re-emerging diseases could be avoided globally to a great extent.

Human Immunodeficiency Virus

CHAPTER

181 Human Immunodeficiency Virus-Tuberculosis Coinfection: Challenges

AA Mumtaz, ZA Mumtaz

Abstract

Human immunodeficiency virus (HIV)-tuberculosis (TB) coinfection is a growing concern, both nationally and Internationally. TB-related complications accounts for >25% of deaths in people living with HIV (PLHIV). Delay in diagnosis of HIV-TB coinfection could lead to emergence of MDR/XDR TB. Manifestations depend on the stage of disease and can have varied presentation. There has been significant progress made in both diagnosis and treatment of the condition. Knowledge of drug interactions, overlapping drug toxicities, as well as timing of initiation of ART following ATT administration is important. Proper ART and ATT therapy selection and dose adjustment are imperative.

Introduction

Human immunodeficiency virus (HIV)-tuberculosis (TB) coinfection is global health problem, and continues to pose challenges. World Health Organization (WHO) in 2018 estimated that, almost 8,62,000 people living with HIV (PLHIV) were coinfected with TB worldwide.[1] TB is one of the leading causes of death, among patients with HIV, and accounts for almost one-third of the deaths.[1] PLHIV are 19 times more likely to develop tuberculosis, than those without HIV. A vast majority of death (84%) due to HIV-TB coinfection were reported from Africa. Delay in diagnosis of HIV-TB coinfection can lead to emergence of MDR/XDR TB. TB continues to be a top killer among infectious diseases, with WHO report estimating that about 1.5 million people died of tuberculosis alone in 2018, including the 2,51,000 people with HIV-TB coinfection. The worldwide incidence[1] for TB for 2018 was estimated to be 10 million, amongst which only 7 million have access to antituberculosis therapy (ATT) (R1), and about 0.5 million people developed drug resistant TB. The prevalence for HIV[1] at the end of 2018 was 37.9 million, amongst which 23.3 million (62%) patients received antiretroviral treatment (ART), and 0.77 million died from HIV-related illnesses. The number of patients receiving ART increased to 24.5 million, by June 2019. TB is among the most common illnesses, among PLHIV, and is fatal, if undertreated/untreated. So early detection of TB and prompt linkage to ATT and ART can prevent or delay these deaths.

Presentation and Diagnosis of HIV

The clinical manifestation depends upon staging of HIV disease, and presence of opportunistic infections (OIs). Presentation can range from being asymptomatic, to experiencing fever, headache, rash, or sore throat. As the immune system gradually weakens, patients may develop cough, diarrhea, weight loss, or generalized lymphadenopathy. If treatment is delayed, patients can develop severe illness like tuberculosis, cryptococcal meningitis, bacterial pneumonia, pneumocystis jiroveci pneumonia, kaposi's sarcoma, and lymphoma.

Diagnosis of HIV infection: Diagnosis of HIV infection is based on following tests:

- HIV-ELISA (Enzyme-linked immunosorbent assay)—It is 50% sensitive after 22 days of HIV infection and 95% positive within 6 weeks. Sensitivity is 99.9%.
- Western Blot Test—It is confirmatory test for HIV. It is highly specific test and is based on antibody to core protein (p24) and envelope glycoprotein (gp41).
- HIV Rapid Antibody Test—It provides result within 16–20 minutes, easy to perform and is a screening test.
- Absolute CD4 Lymphocyte Count—It is predictor of HIV progression, so risk of progression to AIDS, OI, or malignancy is high with CD4 < 200 cell/μL.
- CD4 Lymphocyte Percentage—It is more reliable than CD4 Count. If less than 14%, risk of progression to AIDS to OI or malignancy is high in absence of treatment.
- HIV Viral Load—It indicates the amount of active replication of HIV, indicating disease progression and response to antiretroviral drugs.
- P24 Antigen—It indicates replication and is positive even before seroconversion.

Antiretroviral Therapy

Usually three drugs from two different groups of ARV drugs are given **(Tables 1 and 2)**.

Presentation and Diagnosis Tuberculosis

Tuberculosis is caused by infection with mycobacterium tuberculosis. The infection may be active TB or latent tuberculosis infection (LTBI). Active TB may be pulmonary TB or extra pulmonary TB. LTBI is presence of mycobacterium tuberculosis organism without symptoms or radiographic evidence of TB disease.

Diagnosis of TB in HIV-infected Persons

Screening of TB should be done using clinical algorithm, that is, cough, fever, weight loss, or night sweats and should be evaluated for TB.

- *Radiological findings:* It may show diffuse micronodular infiltrations, as in miliary tuberculosis, or show

TABLE 1 NACO (National AIDS Control Organization) recommended first-line ART regimen

ART regimen	*Recommended*
Tenofovir + Lamivudine + Efavirenz	First-line ART regimen for all ARV naïve PLHIV patients with HIV-1 infection, age >10 years and body weight >30 kg
Abacavir + Lamivudine + Efavirenz	First-line ARV regimen for all patient with abnormal serum creatinine. All adults and adolescents with body weight <30 kg
Tenofovir + Lamivudine + Lopinavir/ritonavir	First-line ART regimen for all women with single dose NVP exposure in past pregnancy, all confirmed HIV-2 or HIV-1 and HIV-2 coinfection
Zidovudine + Lamivudine + Nevirapine Zidovudine + Lamivudine + Efavirenz	All patients who are on either of these first-line regimens initiated earlier, need to be continued on same regimen unless failing

TABLE 2 WHO 2018 recommended first-line antiretroviral therapy regimen

Population	*Preferred*	*Alternatives*	*Special situations*
Adult men and adolescent boys	TDL	TLE600 TLE400	AZT + 3TC + EFV600 TDF + 3TC (or FTC) + PI/r
Pregnant (>8 weeks) and breast feeding women and adolescent girls			
Women and adolescent girls with effective contraceptive or not of childbearing potential			
Women and adolescent girls of childbearing potential who want to become pregnant and have no effective contraception	TLE600	TLE400 TDF + 3TC (or FTC) + PI/r	AZT + 3TC + EFV600 TDF + 3TC (or FTC) + RAL

TDL = TDF + 3TC + DTG, TLE = TDF + 3TC (or FTC) + EFV
TDF, Tenofovir; 3TC, Lamivudine; DTG, Dolutegravir; FTC, Emtricitabine; EFV, Efavirenz; PI/r, Protease inhibitors/ritonavir; AZT, Zidovudine; RAL, Raltegravir

pleural effusion, pericardial effusion, or tuberculous pulmonary lesions.

- *Sputum smear microscopy:* It is easy to perform and is inexpensive. There is direct microscopic examination of sputum for AFB (acid fast bacilli) after Ziehl-Neelsen staining.
- *Sputum culture:* Culture of sputum or other samples is the corner stone in definitive diagnosis of tuberculosis. Culture can be done in egg-based solid medium such as Lowenstein-Jensen or Agar based Middlebrook medium. These are sensitive but slow as it may take 6–8 weeks of incubation. It may also be cultured in liquid medium detecting growth of mycobacteria in 1–2 weeks time using carbon dioxide production or O_2 consumption with radiometric sensors = BACTEC 460, florescent sensors = BACTEC MGIT 960, calorimetric sensors = MB/BacT system, pressure sensors = ESP culture system, or Redox Reagent, such as Alamar blue.
- *Molecular assays:* Xpert MTB/RIF is diagnostic method of choice in HIV positive people. Its sensitivity in positive smear patient is 98.2% and in patients with sputum smear negative is 68%. It is more than 99% specific. It is done by nucleic acid amplification method (NAAT, real time polymerase chain reaction = RT-PCR). It detects mycobacterium tuberculosis quickly (<2 hours). In TB/HIV coinfection, its sensitivity is 79%. Some of the modified versions of NAAT are:
  - LAMP—Loop Mediated Isothermal Amplification.
  - FISH—Fluorescence In Situ Hybridization.
  - LPAs—Line Probe Assays. LPA is more than 75% sensitive and 100% specific. It detects MTB.
  - Gene Xpert/RIF—It is cartridge-based nucleic acid amplification assay, is TB specific, and detects RIF resistance with 99.1% sensitivity and exclude resistance by 100% specificity.[2,3]
- *Serological tests:*
  - Antibody detections—There is negative recommendations by WHO.
  - Antigen detection by ELISA-based assay—LAM—Lipoarabinomannan assay in urine is better in HIV infected than HIV uninfected HIV patients.
- *Other tests:* IGRA—Interferon gamma release assay. This is useful in diagnosing latent TB.
- *Quantiferon:* TB Gold Test—It is in vitro test for detecting latent TB.

TABLE 3 Antituberculous treatment schedule

Type of TB case	*Treatment regimen*
New: A TB patient who has never had treatment with anti TB drugs or has taken it for <1 month	2H7R7Z7E7 + 4H7R7E7
Previously treated: A TB patient who has received 1 month or more of any TB drugs in the past	2H7R7Z7E7S7 + 1H7R7Z7E7 + 5H7R7E7

E, ethambutol; H, isoniazid; R, rifampicin; S, streptomycin; Z, pyrazinamide

Treatment of TB

All PLHIV diagnosed with TB should be started with antituberculous treatment **(Table 3)**.

Challenges in HIV-TB Coinfection

In management of HIV-TB coinfection, the main challenges are:

- Timing of initiation of antiretroviral treatment.
- Immune reconstitution inflammatory syndrome (IRIS).
- Drug interaction in patient on antiretroviral therapy.
- Overlapping drug toxicity.

Timing of Initiation of Antiretroviral Treatment

A number of trials have shown that providing early ART to HIV-TB coinfected persons during antituberculosis treatment reduces mortality.[4] It is now recommended by Health and Human Services and Infections Disease Society of America, that ART should be started 2 weeks after initiation of antituberculosis treatment in most patients, with CD4 count less than 50 cells/mm^3. For those with CD4 count more than 50 cells/mm^3 ART should be started after 2–8 weeks time. It is reasonable to give ATT for 6 months duration; however, some guidelines favor 9 months rifamycin based therapy.

Immune Reconstitution Inflammatory Syndrome

It is an inflammatory reaction, following the initiation of effective ART, due to improvement in immune system of HIV patient, leading to paradoxical worsening of symptoms and signs, of untreated or partially treated OIs

or neoplasm (paradoxical IRIS) and undiagnosed cases (unmasking IRIS). Signs and symptom may appear 2–12 weeks after initiation of ART, and is most commonly seen, when ART is started with CD4 count less than 50/mm^3, and close to diagnosis of OI. IRIS occurs in 10% of all cases put on ART, and 25% of those who have CD4 lymphocyte count less than 50/mm^3. It manifests as fever, increase in size of lymph glands, and pulmonary infiltrates. Severe cases may be fatal. It is treated by antimicrobials for OI, corticosteroids, and continuation of ART.[5]

Drug Interactions in Patients on Antiretroviral Therapy

Rifampicin induces Cytochrome P450, and leads to increased metabolism of HIV drugs, resulting in its decreased concentration in serum, to subtherapeutic levels, that may lead to HIV treatment failure and antiretroviral drug resistance.

- *Rifampicin and NNRTIs:* Drug interaction between rifampicin and NNRTIs are important, because first line ART includes NRTIs with NNRTIs like Efavirenz or Nevirapine. Multiple cohort studies and randomized controlled trial have shown that standard adult dose of efavirenz (600 mg/day) with two NRTIs is well tolerated and highly efficacious in achieving complete viral suppression along with rifampicin-based antituberculous treatment.[6,7] Efavirenz should not be used in first trimester of pregnancy, those intolerant to efavirenz or NNRTIs, resistant strains of HIV, or children less than 3 years of age.
- *Rifampicin and Nevirapine:* Rifampicin reduces serum concentration of nevirapine by 20–55%.[8] In India in a randomized trial nevirapine 200 mg/day for 2 weeks than 200 mg/bd or efavirenz 600 mg/day with rifampicin based ATT, those on nevirapine showed more virological failure and severe toxicity.[9] So efavirenz is more effective, and less toxic than nevirapine for HIV-TB coinfection.
- *Rifampicin and Protease inhibitors:* It has been found that when protease inhibitor based ART is given with rifampicin in HIV-TB coinfected persons, concentration of protease inhibitor may be diminished by more than 90%.[10] Studies have shown adequate serum concentration of PI can be achieved by super boosting (standard those of PI + higher dose of ritonavir), or doubling the dose (doubling dose of both PI and ritonavir), that is, 400 mg/100 mg twice daily to 800 mg/200 mg twice daily (double dose), along with rifampicin 600 mg/day, but there is possibility of increased risk hepatotoxicity with the regimen.
- *Rifampicin and Triple nucleos(t)ide:* Because of lack of evaluation nucleosides or nucleotides alone are not recommended for treatment of HIV-TB coinfection.
- *Rifampicin and Integrase inhibitors:* Raltegravir when used with rifampicin, it is recommended to double the dose of raltegravir to 800 mg twice daily, because concentration of raltagravir is reduced by almost 55%. Dose of the dolutegravir should also be doubled, that is, 50 mg bd when used with rifampicin.
- *Rifampicin and CCR5 receptor antagonists:* Increased dose of maraviroc is recommended when used with rifampicin.

TABLE 4 Drug interactions between ATT and ART

ATT drugs	*ART drugs*	*Drug interaction*	*Action to be taken*
Rifampicin	NRTIs	No	Given in usual dose
	NNRTIs	Yes	Aviod nevirapine. Use efavirenz in usual dose
	Booted PI	Yes	Replace rifampicin with rifabutin (150 mg od)
	Integrase inhibitors	Yes	Double dose of integrase inhibitor Dolutegravir 50 mg bd Raltegravir 800 mg bd

NACO guideline: NRTIs, nucleos(t)ide reverse transcriptase inhibitors; NNRTIs, non-nucleoside reverse transcriptase inhibitors; PI, protease inhibitor

TABLE 5 Overlapping adverse reactions of ATT and ART

ATT	*ART*	*Adverse reactions*
RIF/INH/PZA	NEV/EFV	Rashes
PZA/ETB	ZDV/TDF/PIs/DTG	GIT intolerance
RIF/PZA	TDF/EFV/PIs	Hepatitis
INH/RIF/LZD	ZDV	Anemia
INH/CYS	EFV/DTG	CNS toxicity
STM/KANA/Capreomycin	TDF	Renal dysfunction

NACO: CYS, cycloserine; DTG, dolutegravir; ETB, ethambutol; INH, isoniazid; LZD, linezolid; PZA, pyrazinamide; RIF, rifampicin

- *Rifabutin and Protease inhibitors:* Rifabutin has less effect in comparison to rifampicin on metabolism of drugs mediated by cytochrome P450 3a enzyme.[11] Rifabutin 150 mg daily (instead of 300 mg/day) is recommended when used with ritonavir boosted lopinavir (as ritonavir also influences CYP3a metabolizing enzyme, so increases concentration of rifabutin leading to rifabutin toxicity-uveitis).
- Rifampicin, if used with nevirapine, causes concentration of nevirapine to reduce, so rifabutin should be preferred instead of rifampicin.
- Efavirenz reduces the concentration of rifabutin, so rifampicin should be preferred ATT with efavirenz.

Latent TB Treatment

LTBI should be treated in cases of HIV coinfection. INH 300 mg daily for 9 months or Rifampicin 600 mg/day for 4 months, as per recommendations. No dose adjustment of ART is needed when INH is used **(Tables 4 and 5)**.

ATT and antiretrovirals produce several overlapping toxicities, so treating clinicians should monitor for these overlapping adverse reactions.

Conclusion

HIV-TB coinfection is a curable but potentially lethal combination. Timely diagnosis and early institution of treatment in HIV-TB coinfection reduces morbidity and mortality. Both HIV and TB have the potential to exacerbate and worsen each other. ATT in proper dose along with ART is corner stone of the treatment. HIV-TB coinfection poses many challenges because of management of both diseases, and is complicated by drug interactions between ATT and ART, risk of IRIS, and overlapping drug toxicity. So ATT should be started immediately and ART should be initiated as soon as the ATT is tolerated (2–8 weeks). Proper selection and dose adjustment of both antiretroviral drugs and antituberculous drugs for HIV-TB coinfected patients are important components of patient management.

CHAPTER

182 Advanced HIV Disease: Prioritizing the Most Vulnerable among PLHIV

S Anuradha

Abstract

Although the mortality among PLHIV has shown a significant reduction with effective ART, the decline in the number of deaths has plateaued during the past few years. This is due to the persistent burden of HIV associated mortality and morbidity in a significant section of PLHIV who still present to health-care systems with "advanced HIV disease (AHD)." It has been estimated recently that nearly 30–40% PLHIV initiating ART in resource limited countries have CD4 cell count <200 cells/mm and almost 20% have CD4 <100 cells/mm. The risk of death among PLHIV with AHD is high. This risk increases with declining CD4 cell counts, particularly with CD4 <100 cells/mm. AHD also contributes to increased health-care expenditure. Hence, it is important to identify PLHIV with advanced disease early and deliver a specialized package of interventions that will prevent the morbidity and mortality.

Introduction

It is estimated that 37.9 million people globally had Human Immunodeficiency Virus (HIV) infection in 2018 and new HIV infections had decreased to 1.7 million. Out of these, 24.5 million people living with HIV (PLHIV) received Antiretroviral Treatment (ART). In India, there are 2.1 million PLHIV of which 88,000 are newly infected and 1.18 million are receiving ART (56% coverage).

The number of PLHIV dying annually from AIDS-related causes has diminished by 48% in 2018 from 2003.[1] This decline in mortality is chiefly due to increased access to ART and early initiation of ART according to the World Health Organization (WHO) 2016 guidelines on "universal use of ART," recommending "life-long ART to all children, adolescents and adults including all pregnant and breast feeding women living with HIV regardless of CD4 count or clinical stage." However, the decline in the number of deaths has plateaued during the past few years. This is due to the persistent burden of HIV associated mortality and morbidity in a significant section of PLHIV who still present to health-care systems with "advanced HIV disease (AHD)."

Advanced HIV Disease

After the WHO recommended "universal ART for all PLHIV irrespective of clinical or immune status," national programs of most countries have implemented it. Earlier initiation of ART, along with enhanced availability of HIV testing, has resulted in a betterment in overall condition at ART initiation,[2] as evidenced by an increase in the average CD4 cell count globally at the commencement of treatment.[3]

Notwithstanding this improvement, nearly half of PLHIV present with AHD to health-care systems. The WHO has developed a consensus definition for PLHIV with advanced disease at entry to the health system and those patients who are "stable on ART."[4]

According to WHO guidelines for management of AHD, July 2017,[5] advanced HIV disease is defined as—

- "having a CD4 cell count less than 200 cells/mm^3 *or*
- A WHO clinical stage 3 or 4 event
- Any child younger than age 5 years with HIV is considered to have advanced HIV disease"

The risk of death among PLHIV with AHD is high. This risk increases with declining CD4 cell counts, particularly with CD4 <100 cells/mm^3 [6-8] AHD also contributes to increased health care expenditure.[9]

Erstwhile the distinct definition of AHD, there was lack of clarity and confusion regarding the designation of the term. The term "late presenters" was used often. The patients with CD4 count <350 cells/mm^3 at presentation or those with an AIDSdefining illness (irrespective of CD4 count) were considered to be late presenters of HIV, as per the European Late Presenter Consensus definition.[10] Varying cut offs of CD4 counts <200/mm^3 or <100 /mm^3 have been used to classify PLHIV presenting late. The WHO definition has helped evolve a uniform standard definition that makes analysis and comparisons easier.

Prevalence of AHD and Risk Factors Associated with It

It has been estimated recently that nearly 30–40% PLHIV initiating ART in resource limited countries have CD4 cell count <200 cells/mm^3 and almost 20% have CD4 <100 cells/mm^3.[11,12] In some reports almost half of all PLHIV have AHD.[13]

The International epidemiology Databases to Evaluate AIDS (IeDEA), along with Collaboration of Observational HIV Epidemiological Research in Europe (COHERE) examined the CD4 cell counts of PLHIV at start of ART globally.[11] This evaluation included nearly 1 million PLHIV across North America, South America, Asia-Pacific, Sub-Saharan Africa, and Europe. Countries were classified as per the World Bank classification in 2015 as low income countries (LICs), lower middle income countries (LMICs), upper middle income countries (UMICs), and high income countries (HICs). *Overall, the median CD4 count at presentation improved across the globe*: from 78 cells/mm^3 in 2002 to 287 cells/mm^3 in 2015 in LICs, from 99 cells/mm^3 to 234 cells/mm^3 in LMICs, from 71 cells/mm^3 to 311 cells/mm^3 in UMICs, and from 161 cells/mm^3 to 327 cells/mm^3 in HICs. Although the median CD4 cell count increased significantly across all groups of countries, it continued to remain below 350. The increases in LICs and UMICs were more than that in LMICs or HICs. This increase was more noticeable in women compared to men, except in the HICs.

The proportion of people starting ART with AHD in Africa is about 55%, varying from 31% in Swaziland to almost 77% in Senegal. A study from four high burden countries in Sub-Saharan Africa Cameroon, Mozambique, Uganda, and Zimbabwe demonstrated that the fraction of PLHIV presenting with AHD persisted to be steady: 19.4% in 2012 to 16.1% in 2016. It ranged from 14.5% within Uganda to 29.8% in Cameroon.

A nationwide longitudinal cohort in the Netherlands by Eline LM et al., revealed that among the HIV patients registered into care between 1996 and 2014, 53% presented late and 35% had advanced HIV disease. Among late presenters and advanced disease, the median CD4 was 150 cells/mm^3 and 80 cells/mm^3 respectively. Late presentation was more commonly associated with being a heterosexual male (OR-1.59), injecting drug use (OR 2.0), age ≥50 years, region of origin, and location of HIV diagnosis.[14]

A cross sectional study from South-Western China by Xi Hu et al, including 46000 newly diagnosed PLHIV from 2012-2016 demonstrated 70% PLHIV were late presenters while 45.1% presented with advanced HIV disease. Higher prevalence of AHD was found among male gender, heterosexuals, older age-group, lower education, and divorced/widowed persons.[15]

Data on the precise prevalence of AHD is lacking from India. A single center study from Delhi has reported that 83.7% of PLHIV were late presenters while 33% of PLHIV had AHD with 9.5% having CD4 cell count below 50 cells/mm^3 at presentation. The median CD4 cell count was determined to be 242 cells/mm^3.[16]

This emphasizes that late presentation among PLHIV remains a major challenge all over the world.

Impact of AHD on Mortality and Morbidity

PLHIV who have AHD are prone to greater risk of mortality and morbidity due to multiple factors such as lower CD4 response after ART, increased risk of OIs and their complications, polypharmacy, non-adherence, and suboptimal virological suppression.

Morbidity and mortality are even higher in initial 3 months particularly in first 4–8 weeks. In a meta-analysis

by Alana T. Brennan et al. to determine early mortality in lower- and middle-income countries of Sub-Saharan Africa, Asia, and Caribbean it was revealed that early mortality was 6% (5.5–6.3%). When mortality estimate was calculated assuming that PLHIV who were lost to follow-up had died, the overall estimate increased to 10%.[17]

A study from Uganda and Zimbabwe by Walker AS et al. to assess mortality during first year of ART demonstrated that 5.4% PLHIV died, with half of the deaths reported in the initial 3 months. Mortality risk was highest between 30–50 days and, it reduced rapidly thereafter till about day 180. Further, it continued to decline slowly over time. One-year mortality in PLHIV was: 9.4% in CD4 <50 cells/mm^3, 4.5% in CD4 between 50–99 cells/mm^3 and 2.9% in CD4 >100 cells/mm^3.[8]

Tuberculosis, severe bacterial infections, chronic diarrhea, cryptococcal meningitis, cerebral toxoplasmosis, *Pneumocystis jiroveci* pneumonia, and anemia were the chief causes of mortality in adult PLHIV with AHD. Among children, tuberculosis, severe bacterial infections, pneumonia, diarrheal diseases, malnutrition, and wasting are the leading causes of death.[8,18,19]

A landmark study, REALITY, was conducted across Zimbabwe, Uganda, Malawi, and Kenya in ART naïve PLHIV with CD4 <100 cells/mm^3. It was found that mortality rates were highest during first 4 weeks of starting ART, decreasing through week 8 and substantially dropping further through 24 and 48 weeks. The leading causes of death were opportunistic infections: tuberculosis cryptococcal meningitis, severe bacterial infections, and immune reconstitution inflammatory syndrome (IRIS). This study also highlighted that patients with the greatest risk of dying had a high burden of symptoms, weight loss, lower CD4 count, low albumin and hemoglobin levels.[20]

Another crucial observation was that loss to follow-up is more likely among those with AHD. This increases the risk of mortality in these patients and adds to the threat of transmission of HIV.

With such life-threatening events and adverse outcomes, patients with advanced disease remain the most vulnerable among the PLHIV. It is imperative that these patients be brought into the health-care systems early. It is also crucial to initiate ART at the earliest in these patients, even on the same day as presentation. This will prevent missed opportunities for initiating treatment.

It is due to these concerns that the WHO recognized that the people with AHD are a specially vulnerable group who need a specific and specialized package of interventions for them.

Package of Interventions for PLHIV with AHD

In July 2017, the WHO released comprehensive guidelines for the management of AHD and rapid initiation of ART. The guidelines provide suggestions for a public-health-approach for managing PLHIV with AHD including timing of ART initiation.[5]

The "package of interventions" recommended include the:

- Co-trimoxazole prophylaxis,
- Tuberculosis preventive treatment,
- Use of Xpert MTB/RIF for tuberculosis diagnosis among symptomatic PLHIV,
- Using the lateral flow lipoarabinomannan (LF-LAM) antigen test for people with symptoms suggesting TB with CD4 count ≤100 cells/mm^3 or who are seriously ill,
- Cryptococcal antigen screening in all with CD4 cell count ≤100 and pre-emptive antifungal treatment for those with positive blood cryptococcal antigen.[2]

This is summarized in **Table 1**.

Two large randomized trials instituting packaged interventions among PLHIV presenting with AHD were done. The first one named REMSTART, was conducted in Zambia and the United Republic of Tanzania, and compared ART-naive PLHIV with CD4 count <200 cells/mm^3 receiving a specialized package of care versus standard care. ART initiation was done around 2 weeks (delayed beyond 2 weeks only in those with TB). A 28% reduction in mortality and a trend toward better adherence was observed in the intervention group compared to the group receiving standard care at 6 months.[21]

In the second trial, REALITY, PLHIV with CD4 <100 cells/mm^3 were enrolled from Kenya, Malawi, Uganda, and Zimbabwe. Study subjects were randomized to receive either the standard care (as per existing respective national guidelines) or an enhanced prophylaxis package of 12 weeks of fluconazole (100 mg once daily), 12 weeks fixed-dose combination of co-trimoxazole (800 + 160 mg) + isoniazid (300 mg) + pyridoxine (25 mg), 5 days of 500 mg of azithromycin once daily and albendazole (400 mg single dose). ART was started simultaneously with all drugs. In the enhanced prophylaxis package arm, there was a

TABLE 1 Diagnosis and prophylaxis components of package of care interventions for advanced HIV disease (WHO)[5]

Areas for the package	*Intervention*	*CD4 cell count*	*Adults and adolescents*	*Children*
Screening and diagnosis	Sputum Xpert MTB/RIF as first test for TB diagnosis in symptomatic patients	Any	Yes	Yes
	Urine LF-LAM* for TB diagnosis in patients with symptoms and signs of TB	≤100 cells/mm^3 Or at any CD4 cell count value if seriously ill	Yes	Yes**
	Cryptococcal antigen (CrAg) screening***	≤100 cells/mm^3 ****	Yes	No
		≤200 cells/mm^3****	Yes	No
Prophylaxis and pre-emptive treatment	Co-trimoxazole prophylaxis	≤350 cells/mm^3 or WHO clinical stage 3 or 4 event. Any CD4 cell count value in settings with high prevalence of malaria and/or severe bacterial infections	Yes	Yes
	TB preventive treatment[§#]	Any	Yes	Yes
	Fluconazole pre-emptive therapy for CrAg-positive patients without evidence of meningitis	≤200 cells/mm^3****	Yes	Not applicable (Screening not advised)
ART initiation	Rapid ART initiation	Any	Yes	Yes
	Defer ART initiation if clinical signs and symptoms are suggestive of TB or cryptococcal meningitis	Any	Yes	Yes
Adapted adherence support	Tailored counseling to ensure optimal adherence to advance disease care package, including home visits if feasible	<200 cells/mm^3	Yes	Yes

*Urine LF-LAM: lateral flow urine lipoarabinomannan assay.
**Limited data for children.
**CrAg screening and pre-emptive therapy is strongly recommended at CD4 <100 cells/mm^3 and conditionally recommended at CD4 <200 cells/mm^3.
****When cryptococcal antigen screening is not available, fluconazole primary prophylaxis should be given to adults and adolescents living with HIV who have a CD4 cell count <100 cells/mm^3 (strong recommendation; moderate-certainty evidence) and may be considered at a higher CD4 cell count threshold of < 200 cells/mm^3 (conditional recommendation; moderate-certainty evidence).
[§]Co-trimoxazole, isoniazid, and pyridoxine are now available as a fixed-dose combination tablet.
[#] For children <12 months of age, only those with a history of TB contact should receive TB preventive treatment, if the evaluation shows no active TB disease.

reduction in mortality by 27% over 24 weeks. Mortality due cryptococcus infections significantly decreased (1.5% to 0.4%), and mortality due undetermined causes decreased from 6.0% to 3.8%. The incidence of OI also reduced: TB by 28%, cryptococcal meningitis 62%, and admissions to hospitals by 17%. Majority of deaths occurred within the initial 3 weeks of the study, emphasizing the need for early prophylaxis among PLHIV with AHD.[22]

Both these large studies in patients with advanced HIV disease have demonstrated the benefits of delivering a specialized and specific package of interventions to this extremely vulnerable subset of PLHIV.

Conclusion

The world has committed toward ending AIDS as a significant public health problem by 2030. However, without rapid escalation of services, the HIV epidemic will outrun the global response. To prevent this, The UNAIDS Fast-Track strategy sets out 90-90-90 targets for prevention and treatment. This includes, reducing new annual HIV infections to fewer than 500,000 by 2020 and to fewer than 200,000 by 2030, and AIDS related deaths by 90% by 2030, in comparison to 2010 levels.

Hence, it is necessary to identify PLHIV with advanced disease and deliver a package of interventions consisting of screening, prophylaxis and treatment of OIs, early ART initiation and enhanced adherence support. This will mitigate the high, early mortality seen in advanced HIV disease and also reduce the AIDS-related mortality rate overall. At the same time this will reduce the health-care costs and reduce community transmission. It requires an effort and commitment on part of programs and governments to develop strategies for advanced HIV care in their own country's context. The National AIDS Control Organization of the Govt. of India is also developing a specialized package of interventions to be delivered to this population. These are the most vulnerable among the PLHIV. Additional and special support to this population will have far reaching implications for the country and the world.

CHAPTER

183 Antiretroviral Therapy in 2020

BB Rewari, Priyanka Ojha

Abstract

ART has changed the outlook of HIV from a virtual death sentence to a chronic manageable disease. The current guidelines are to provide ART initiation to all those infected with HIV regardless of their CD count of WHO clinical stage. The standard of care is a triple drug combination (Tenofovir +Lamivudine+ Dolutegravir) in a single pill once daily and is a lifelong therapy. Adherence to therapy is most crucial for good outcomes of therapy and to reduce chances of resistance, hence patient counseling is an important component of HIV care. Availability of high-quality generic drugs helped increase the coverage of ART significantly, thereby reducing the chances of transmission from those with HIV. Besides ART, antiretroviral drugs are also used for post exposure prophylaxis (PEP) after accidental exposure and pre-exposure prophylaxis (PrEP) for those at high risk of HIV.

Introduction

Antiretroviral therapy (ART) is seen as a panacea for People Living with HIV (PLHIV) and has helped save millions of lives in addition to improving quality of life. In addition, this has saved many countries from catastrophic economic consequences of the disease.

Zidovudine, being used for some malignancies, was the first drug shown to be effective against HIV in 1985. Soon it was felt that virus developed resistance quickly and drug becomes ineffective in less than a year with Zidovudine monotherapy. By 1995, many studies had demonstrated the clinical benefits of using a two-drug combination of Zidovudine or Stavudine in combination with Lamivudine. The year 1996 was a landmark in ART journey when results of using a triple drug combination using protease inhibitors were revealed at the International AIDS Society (IAS) conference in Vancouver. These drugs over the years have transformed lives of millions of people and have changed outlook of HIV from that of a virtual death sentence to a chronic manageable condition. The **Figure 1** shows the development of various antiretroviral (ARV) drugs over last three decades.

Besides treating those with HIV, ARV drugs are also used for preventing mother to child transmission of HIV (PMTCT), for preventing acquiring HIV infection in case of accidental exposure to the virus (post-exposure prophylaxis, PEP) and for preventing HIV infection in HIV negative individuals with substantial risk of being infected (pre-exposure prophylaxis, PrEP).

What are Options Available for ART

Highly Active Antiretroviral Therapy (HAART) or simply ART is a combination of three ARV drugs from different groups in a fixed dose combination (FDC). The “one pill a day” therapy has potential for good adherence as ART is a lifelong therapy. Production of generic formulations of these drugs have helped reduced its costs from USD 10,000 to less than USD 80 now making it affordable for most people. In addition, roll out of free ART program in countries have helped increase coverage of ART resulting

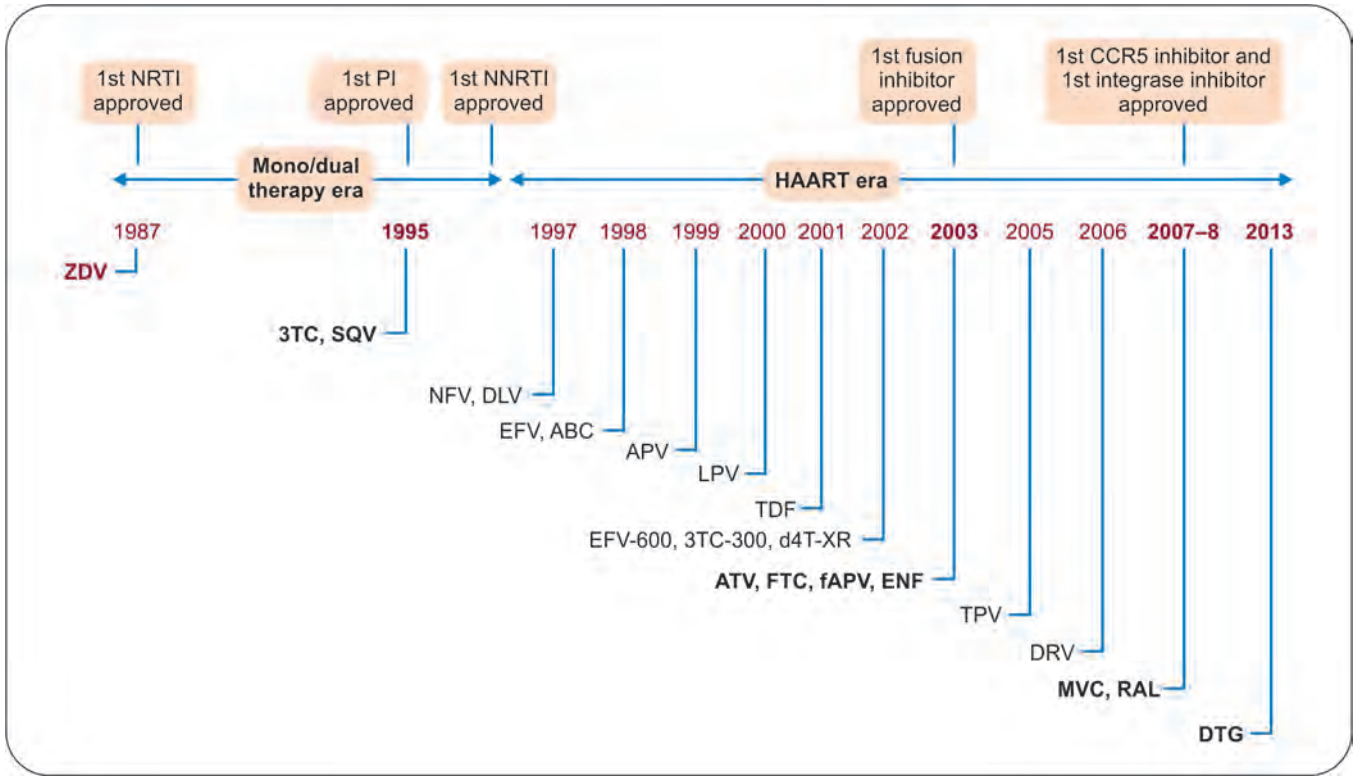

Fig. 1: Evolution of ARV therapy

in individual patient benefits, as well as, prevention of transmission of HIV due to reduction in viral load. Presently available ARV drugs cannot cure HIV as the virus remains dormant in resting states in some cells like spleen, brain, bone marrow, etc. It starts replicating again if the ART is stopped. Hence, ART is a lifelong therapy.

The ARV drugs broadly act at various steps in life cycle of virus either by blocking enzymes (reverse transcriptase, protease, integrase) needed for replication or by blocking entry of HIV into CD4 cells (Fusion inhibitors) or by blocking maturation of virions and their budding out from CD4 cells. Based on the site of action, these drugs are broadly divided into six classes **(Table 1)**. There are over 26 drugs/combinations. The drugs commonly used in India are listed in the following table.

The combinations of antiretroviral drugs inhibit the replication of HIV leading to slowing of disease progression, while reduced CD4 cell destruction leads to better immunity and fewer opportunistic infections. Over the years, the drugs have been evolving toward better efficacy, fewer toxicities, better pharmacokinetics, fewer drug-drug interactions, and lesser chances of resistance. This has led to optimization of ART, and WHO has released updated ART guidelines in July 2019.

When to Start ART is No Longer a Question or Discussion Point

In the early days when HAART was just being introduced, it was considered that a "hit hard, hit early" would be adopted. However, evidence that emerged in those years questioned the advantages of early HAART. Till about 3 years ago, treatment for HIV infected person was based largely on the CD4 count levels and clinical stage of the infection. The CD4 count cut-off point for ART initiation was less than 200 cells/cmm in 2004 and later moved to less than 350 cells/cmm in 2010. The cut-off was advanced to less than 500 cells/cmm in 2013 while in 2016, the recommendation came to TREAT ALL, regardless of clinical stage or CD4 count. The basis for these changes has been evolving evidence from various randomized clinical trials (RCTs) and large observational cohorts

TABLE 1 Classes of ARV drugs currently in use in India

Category	*Drugs*	
Nucleoside reverse transcriptase inhibitors (NsRTIs)	Zidovudine (AZT/ZDV)	Lamivudine (3TC)
	Abacavir (ABC)	Emtricitabine (FTC)
Nucleotide reverse transcriptase inhibitors (NtRTIs)	Tenofovir (TDF)	
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Nevirapine (NVP)*	Efavirenz (EFV)
Protease inhibitors (PIs)	Lopinavir (LPV)	Ritonavir(RTV)
	Atazanavir (ATV)	Darunavir (DRV)
Integrase Inhibitors	Raltegravir (RGV)	Dolutegravir (DTG)
CCR5 entry inhibitor	Maraviroc**	

*Being phased out
**Used sometimes in private sector

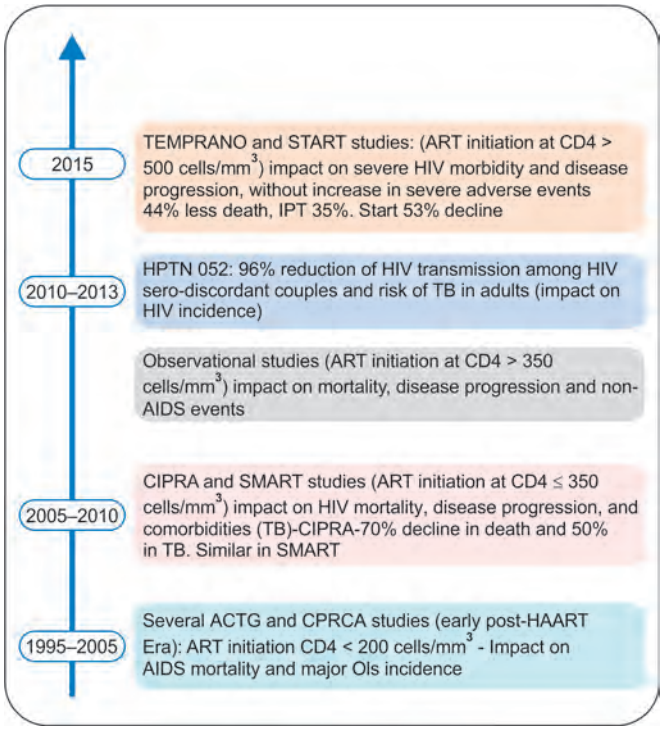

Fig. 2: Overview and timelines of "when to start ART" studies

which have revealed that with earlier ART initiation, there was a significant delay in progression to AIDS and reduction in incidence of TB. These studies are briefly summarized in **Figure 2**.

Hence, the current recommendation (since 2016) is to initiate ART for all those who present with HIV infection regardless of CD4 count or WHO clinical staging.

What is Latest WHO Recommendations on which Drugs to Start in ART

As described earlier, ART comprises of using at least three drugs from two different groups of ARV drugs in a combination, preferably in single pill, to improve adherence to therapy. The most commonly used combination is using two drugs from NRTI and one from NNRTI. So far most developing countries have been following a combination of Tenofovir (TDF 300 mg) + Lamivudine (3TC 300 mg) + Efavirenz (EFV 600 mg) in a single pill, as standard of care. In 2018 ART update, WHO recommended use of Dolutegravir (DTG) in the first-line ART based on evidence that with DTG:

- Viral suppression is faster than with EFV (Avg. 4 weeks for DTG vs. 12 weeks for EFV),
- DTG has fewer side effects,
- Fewer drug-drug interaction, and
- Patients on DTG have a higher threshold for developing resistance.

The SINGLE study compared the efficacy and safety of DTG as compared to current standard of care (Tenofovir plus Lamivudine plus efavirenz). A total of 833 participants who had an HIV-1 RNA level of >1,000 copies/mL were chosen and randomly assigned to DTG-ABC-3TC group or EFV-TDF-FTC group. The key findings from study revealed that at week 48, the proportion of participants with an HIV-1 RNA level of <50 copies/mL was significantly higher in the DTG-ABC-3TC group than in the EFV-TDF-FTC group (88% vs. 81%, P=0.003). It was also seen that DTG-ABC-3TC group had a shorter median time to viral suppression

than EFV-TDF-FTC group (28 vs. 84 days, P<0.001), as well as greater increases in CD4+ T-cell count (267 vs. 208/cubic mL, P<0.001). The proportion of participants who discontinued therapy owing to adverse events was lower in the DTG-ABC-3TC group than in the EFV-TDF-FTC group (2% vs. 10%).

The results from some other studies like FLAMINGO, SPRING2, and SAILING showed that DTG achieves viral suppression much faster than EFV (Avg. 4 weeks for DTG vs. 12 weeks for EFV). There are very few discontinuations on DTG regimen due to drug toxicity (<2%), less than with DRV/r and EFV. Main clinical adverse events seen are rash (2% vs. 13%) and neuropsychiatric events (including dizziness). These were significantly more with common with EFV (5% vs. 35%), while insomnia was reported more frequent in DTG (13% vs. 7%) (SINGLE study). DTG has a strong resistance barrier. No known treatment-emergent resistance were seen across trials. This was a very significant finding as it is well known that EFV has a very week genetic barrier to resistance.

Accordingly, the WHO guidelines on what to start were updated in 2018 to include DTG as preferred first-line drug along with Tenofovir and Lamivudine. However, an ongoing observational Tsepamo study in Botswana identified a signal of potential safety risk for developing neural tube defects among infants born to women who were taking DTG at conception. Interim analysis identified four neural tube defects out of 426 women taking DTG at the time of conception, for a rate of 0.9% (0.37–2.4%). So, 2018 guidelines specified that women and adolescents of child bearing potential who wants to become pregnant and have no effective contraception should not use DTG and continue to be provided an Efavirenz based regimen.

As new evidences from Tsepamo study became available it showed that the risk NTDs associated with use of DTG at the time of conception is less than originally signaled. The updated prevalence in the study has declined from 0.94% to 0.30%. The difference remains statistically significant compared to EFV, but the overall risk remains low. This new data presented in IAS 2020 (abstract #11299) includes 39,200 births surveyed from March 2019 to April 2020. Neural tube defects were identified in 0.19% of infants born to women on Dolutegravir at the time of conception and in 0.04% of infants born to women who started taking Dolutegravir during pregnancy. The risk-benefit models suggest that the benefits of DTG for women of childbearing potential (WCP) newly initiating ART are likely to outweigh the risks. According to WHO, the benefits of DTG outweigh the risks. Women of child-bearing age or potential should be provided informed choice about the benefits and risks for the use of DTG. DTG has been found to be in breast milk of women on DTG, resulting in significant plasma concentration in infants, and thus a potential important tool to reduce the mother-to-child transmission of HIV infection.

The ART guidelines released by WHO in July 2019 recommend that a *Fixed Dose Combination (FDC) of Tenofovir, Lamivudine (or Emtricitabine)* and *Dolutegravir (TLD)* should the *preferred first-line regimen* for all adults including women and upgraded the recommendation from "conditional" to a "strong" recommendation. It also recommended to adopt a woman-centered approach to health care should be taken that consciously adopts the perspectives of women and their families and communities, with care provided in ways that respect women's autonomy in decision-making and provide information and options to enable women to make informed choices.

Tables 2 and 3 summarize the WHO 2019 ART guidelines.

In line with these guidelines, National AIDS Control Organization has also revised its ART guidelines on 17th September, 2020, and TLD based regimen is now the preferred regimen for ART initiation in new patients, DTG is also preferred for second-line ART for those failing on NNRTI and also to be used for PEP.

Initiating and Monitoring ART

Before starting ART, a full examination of person should be done to rule out any active opportunistic infection. He should undergo basic investigations like complete hemogram, routine biochemistry, CD4 count, and viral load (if available) as per guidelines. ART should not be started in the presence of an active OI. In general, OIs should be treated or stabilized before commencing ART. A proper counseling of person needs to be done highlighting the need for high levels of adherence to therapy and person must understand it is a lifelong therapy. A nutritional assessment and required supplementation are essential part of the counseling. A caregiver should be identified for each person to provide adequate support. Caregivers must be counseled and trained to support treatment adherence, follow-up visits, and shared decision-making.

TABLE 2 WHO ART initiation guidelines (July 2019)

2019 WHO guidance: preferred and alternative 1L regimens for adults and adolescents		
Preferred 1L regimen	***Alternative 1L regimen***	***Special circumstances***
TDF + 3TC (or FTC) + DTG[a]	TDF + 3TC + EFV 400 mg[b]	TDF + 3TC (or FTC) + EFV 600 mg[b] AZT + 3TC + EFV 600 mg[b] TDF + 3TC (or FTC) + PI/r TDF + 3TC (or FTC) + RAL TAF[c] + 3TC (or FTC) + DTG[a] ABC + 3TC + DTG[a]

a. Effective contraception should be offered to adult women and adolescent girls of childbearing age or potential. DTG can be prescribed for adult women and adolescent girls of childbearing age or potential who wish to become pregnant or who are not otherwise using or accessing consistent and effective contraception if they have been fully informed of the potential increase in the risk of neural tube defects (at conception and until the end of the first trimester). If women identify pregnancy after the first trimester, DTG should be initiated or continued for the duration of the pregnancy.
b. bEFV-based ART should not be used in settings with national estimates of pretreatment resistance to EFV of 10% or higher. DTG-based ART is preferred, and if DTG is unavailable, a boosted PI-based regimen should be used. The choice of PI/r depends on programmatic characteristics.
c. NRTI backbone to be changed to unused NRTI (lamivudine can be retained as any resistance to it will make virus less fit).

TABLE 3 WHO ART guidelines for those with failure to first-line ART (July 2019)

Population	***First-line regimens***	***Preferred second-line regimens***	***Alternate second-line regimens***
Adults (≥30 kg)	2 NRTIs* + DTG	2 NRTIs* + ATV/r or LPV/r	• 1–2 NRTIs* + **DRV/r** • 1–2 NRTIs* + **DTG**

Viral load Better and simpler monitoring	No	No (Desirable)	No (Tertiary centers)	Yes (Phase in approach)	Yes (preferred for monitoring, use of PoC, DBS)	Support for scale up of VL using all technologies	VL ot 6 months, 12 months and then every 12 months

Fig. 3: Evolution of ART guidelines 2002–2020

Once a patient has been started on ART, patient needs to be monitored for signs of improvement due to ART as well as any new symptoms/signs which may indicate a side effect of a drug. It is recommended that in the initial phase of ART, patient needs to be monitored more frequently, preferably once in 2 weeks for initial 4–6 weeks, and then can be evaluated monthly.

The signs of improvement are weight gain, feeling of wellbeing, better appetite, better sleep, improvement in nutritional status, hemoglobin, etc., but more specifically increase in CD4 count and decrease in viral load at 6 months after ART initiation. Ideally the viral load should become undetectable 6 months after ART initiation. Once it becomes undetectable the viral load can be done annually and CD4 count monitoring can be stopped. It is also important to monitor lab parameters like Hb, renal functions periodically while on ART.

Conclusion

ART has been evolving rapidly toward earlier initiation with more robust and less toxic regimen. The **Figure 3** summarizes this evolution of guidelines till now.

It will continue to evolve as more evidences become available on long-term safety and efficacy of drugs. Recently US FDA has approved a two-drug therapy using only Dolutegravir and Lamivudine and many new drugs are under trial including once a month injectable option. Simultaneously lot of research is ongoing on finding a cure for HIV. Vaccine trials have been partially successful, but the best vaccine available is prevention and for those infected early diagnosis and linkage to treatment remains crucial.

In India, ART is available free of cost through 543 government-run ART centers across the country, wherein 14 lakh PLHIV are currently receiving free ART. There are additionally an estimated 1 lakh patients being treated in private sector. Being a lifelong therapy, adherence and affordability are two key issues. Hence, it is important for clinicians to carefully consider these factors before ART initiation to ensure good outcomes in long-term.

CHAPTER

184 90-90-90: Are These Mere Numbers?

Sajith Kumar R

Abstract

With many new classes of drugs and molecules and changes in strategies, HIV-AIDS has become a chronic manageable infection. Various international and national agencies have adopted mechanisms to ensure that these are translated to reach the affected people. 90-90-90 target, which was supposed to be achieved by 2020 has been delayed due to the effect of Covid on health scenario. However, it's not just the numbers only, but also various benefits to the society that matters. The outlook toward persons living with HIV has changed, but lot more needs to be done to ensure access, adherence, and persistence. Uniform practices will lead to them becoming undetectable as far as viral suppression is concerned and untransmittable for the rest of the society.

Introduction

HIV/AIDS has been with human kind for many decades now. From 1981 to 2020, the management of HIV infected persons has taken many turns. Introduction of Antiretroviral Therapy has radically changed the quality of life for all. However, there are wide variations among populations in different continents. UNAIDS launched the Fast Track strategy in 2014 aimed at enabling all HIV infected persons for a long-term survival. The motto of 90-90-90 aimed at reducing the deaths by 90% by 2030 is being actively chased in all countries. This not only means a reduction in the numbers getting listed and in the number of survivors but also improvements in the quality of life among the surviving population. The decrease in the number and severity of opportunistic infections, ability to lead a normal life, and decreased quantum of infective persons in the world are other benefits of this strategy. This will also lead to significant reduction in hospitalizations and near normal socioeconomic status for the infected. While many countries have reached this target, many others are lagging behind and the gaps are getting reduced fast.

Antiretroviral Therapy

The list of drugs effective against human immunodeficiency that began with azidothymidine (AZT, zidovudine) is expanding fast. With the advent of the drugs that act on various phases of HIV replication, viz. fusion inhibitors, reverse transcriptase inhibitors, integration inhibitors, protease inhibitors, coreceptor antagonists, etc. it has become clear that viral load can be controlled. This will enable the person to lead a longer, symptom-free survival with reduced chance for opportunistic infections, malignancies. The most important prerequisites for this advantage to be transferred to the infected persons involve the triad of early detection, quick initiation, and strict adherence with regular monitoring. A detailed description of Antiretroviral Therapy is beyond the scope of this article.

The 90-90-90 Strategy

The Millennium Development Goals were established following the Millennium Summit of the United Nations in 2000, following the adoption of the United Nations Millennium Declaration. MDG 6 was to combat HIV/AIDS, malaria, and other diseases. The year 2015 was the target at that time. In 2015, they were replaced by 17 Sustainable Development Goals. Specific targets were described to be achieved by 2030.

SDG 3 (to ensure healthy lives and promote well being for all at all ages) contains the two targets:

Target 3.3: End AIDS as a public health threat by 2030.

Target 3.8: Achieve universal health coverage, access to quality health-care services, and access to safe, effective, quality, and affordable essential medicines and vaccines for all.

In addition, the following statements also are important for HIV related activities.

SDG 4: Quality education, including targets on comprehensive sexual and reproductive health (SRH) education and life skills.

SDG 5: Gender equality, including targets on sexual and reproductive health and rights (SRHR) and the elimination of violence, harmful gender norms, and practices.

SDG 10: Reduced inequalities, including targets on protection against discrimination, and the empowerment of people to claim their rights and enhance access to HIV services.

SDG 16: Peace, justice, and strong institutions, including reduced violence against key populations and people living with HIV.[4]

In 2014, UNAIDS announced the Fast Track strategy aimed at stepping up the responses in HIV prevention, control, and care particularly in low- and middle-income countries (LMIC). This was aimed at meeting the SDC-3 target to "end AIDS by 2030." This strategy aims to catch up with the expanding infected pool by providing care including antiretroviral therapy to reducing new HIV infections and AIDS related deaths by 90% in relation to the 2010 values. The targets include reduction of new HIV infections to fewer than 500,000 per year by the year 2020 and to 200,000 or less by the year 2030—equivalent to ending AIDS as threat to public health. Once this is achieved by the treatment cascade upgradation, HIV transmission will be reduced, HIV infection may not affect the health of a person and deaths from HIV-related issues will be minimum. This is also supported by the WHO recommendation for starting ART in all HIV infected persons at all CD4 counts.

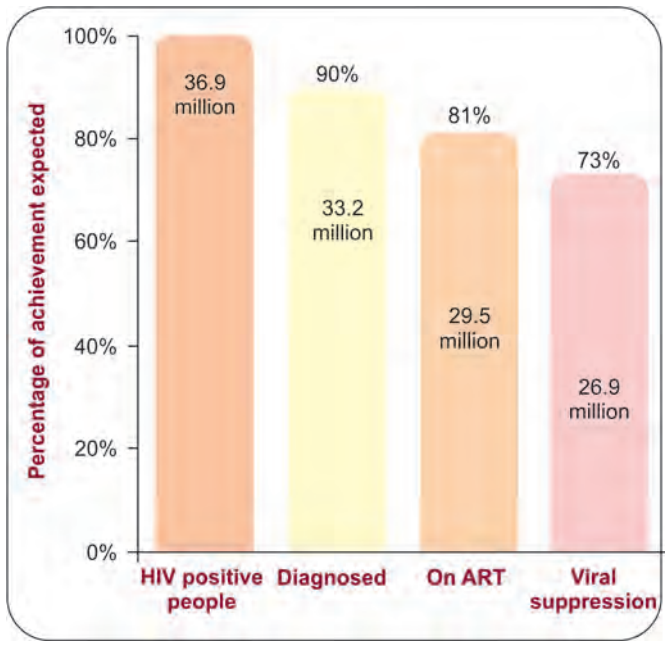

Fig. 1: The proposal as it was made in 2014

The 90-90-90 targets include aims to reach the following targets.[1,2]

- 90% of infected persons being identified,
- 90% of identified (infected) persons being started on antiretroviral therapy, and
- 90% of persons on ART achieving sufficient viral suppression **(Fig. 1)**.

UNAIDS has put forth the idea of five pillars for this project. It is actually a people centerd, rights-based approach. These include:

- Reduce new infections among women and girls to under 100,000 (current rates are approximately 700,000 per year globally),
- Ensure that 90% of people at risk of HIV can access preventive services,
- Make 20 billion condoms available annually in LMIC,
- Provide 25 million more with voluntary male medical circumcision, and
- Provide PreP (pre-Exposure Prophylaxis to 3 million people who have high risk behavior likely to lead to infection with HIV).

The fast track strategy also envisaged certain targets set for 2020, which includes:[3]

- Less than 500,000 people newly infected with HIV (75% reduction from 2010),
- Less than 500,000 people dying from AIDS-related illnesses, and
- Elimination of HIV related discrimination.

There was also a commitment to ensure that 30 million people will access antiretroviral therapy by 2020.

What has Happened?

There has been a marked scale up of antiretroviral therapy with over 28 million people on ART as of 2020, bringing the percentage from 25% in 2010 to 67% in 2019. The incidence: prevalence ratio is a metric that measures both the survival patterns and new infections. The global value for this was 7% in 2010 and has dipped to 4.4% in 2019. There were geographic variations. The ratio fell from 7% to 3.5% in Africa, while it was 3% in North America and Central Europe. Among individual countries, 25 have the value at 3%.

According to UNAIDS Global update 2020, among approximately 38 million infected persons all over the world, 81% knew their HIV serostatus, 67% were on antiretroviral drugs, and around 59% had undetectable viral loads. This is achieved by starting ART in approximately 25.4 million persons. This equates to 81-82-88% in comparison to the 90-90-90 figures.

The UNAIDS data as of 2019 is summarized in **Figures 2 and 3**.

Indian Scenario

India is one among the 193 countries participating in the 90-90-90 strategic plan. With over 2.1 million infected population, India has the third highest burden of HIV after South Africa and Nigeria. The National Health Policy (2017) and the HIV/AIDS Act (2017) explicitly states the commitment toward this. As stated therein "every person who is in the care or custody of the State shall have the right to HIV prevention, counseling, testing, and treatment services." This ensures that all including women and children, prisoners, and all irrespective of caste, creed, gender and beliefs, sexual, or otherwise will have equal access to counseling, diagnostic, and treatment services. NACO has released data, according to which 79.4% of the 21.40 lakh PLHIV in India know their status; 82.3% are on ART; 74% (among those tested) virally suppressed **(Fig. 4)**. The viral load testing is now available in ART centers across the country and the treatment cascade is being implemented effectively.[5]

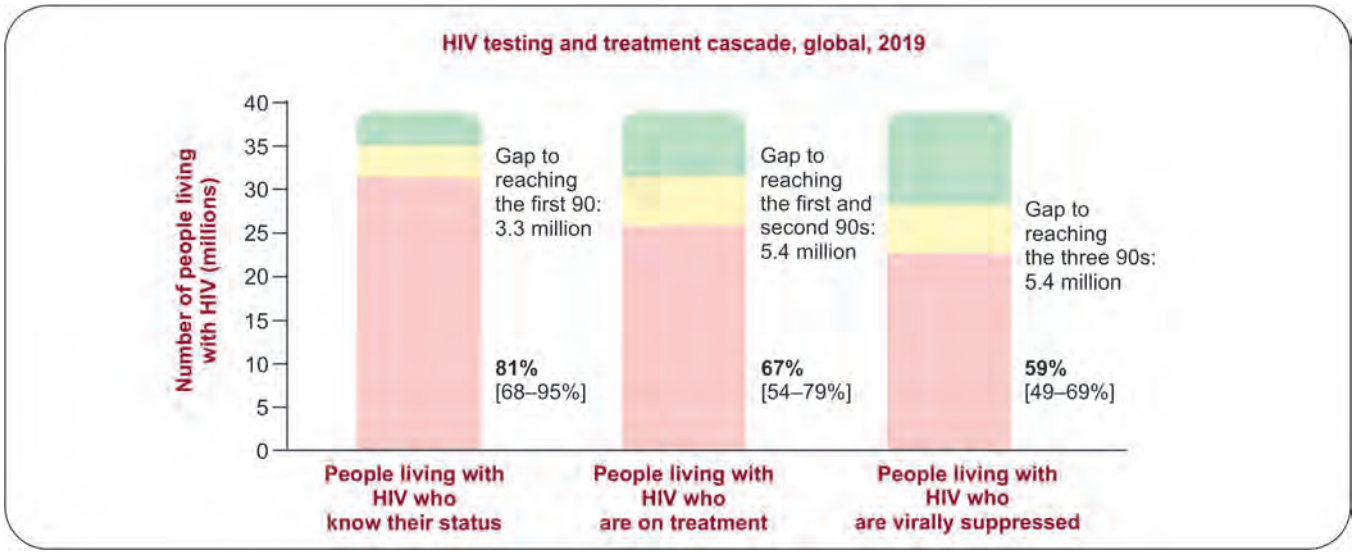

Fig. 2: HIV testing and treatment cascade, global, 2019

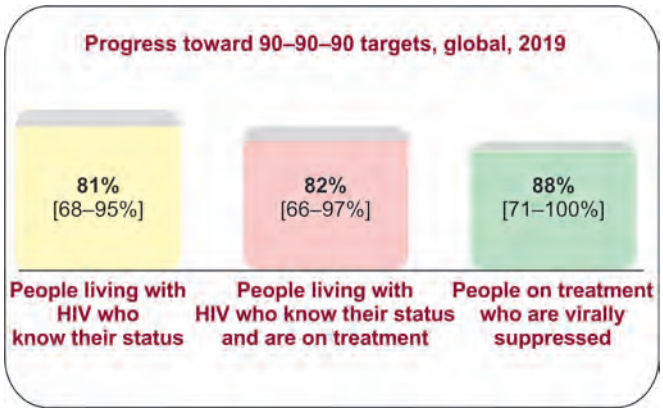

Fig. 3: HIV 90-90-90 status, global, 2019

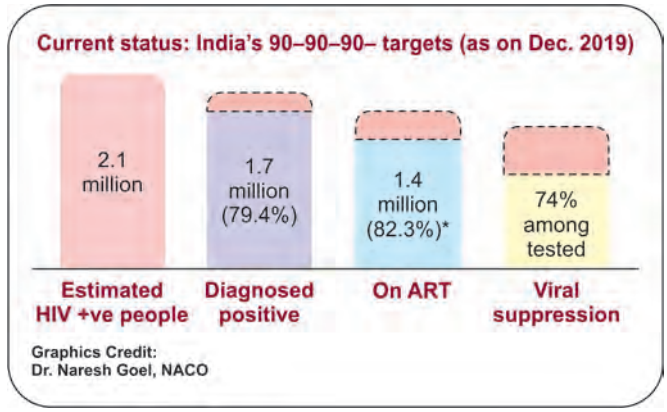

Fig. 4: 90-90-90 achievement status of India

Beyond Numbers

What the 90-90-90 strategy can achieve with full achievement of all targets is that 81% (90% of 90) of those infected will be put on treatment and 73% (90% of 81) of all infected is likely to be virally suppressed. This does not mean that 27% of infected persons are not going to be benefitted.

- Many studies have demonstrated the benefits of early detection in case of HIV infection. Test All strategy adopted by World Health Organization in 2016 has led to the following changes:
  - Supportive HIV testing policies have been accepted by most countries, an increase from 6 to 77 between 2015 and 2019. Self testing is promoted in 38 countries, as compared to 14 in 2017.
- Early and quick initiation of ART is producing wonders in the field of HIV care:
  - 60% of LMIC have started treating all infected persons regardless of CD4 count.
  - Lifelong ART for pregnant women is now standard practice in almost all countries.
  - 80% of countries have introduced treat all for children.
  - 72% countries have adopted single tablet regimen (TLE) as first line.
  - Dolutegravir (DTG) at lower price as a fixed combination drug is available in approximately 60% of LMIC.
- The cut off for start of therapy with antiretroviral drugs has been going up from the CD4 count of 200 cells/cmm to 350, 500, and has reached any CD4 count now. Starting ART early prevents the occurrence of opportunistic infections and malignancies and delays death. New data and analysis reveal the reduction in risk of developing non-AIDS events as well. This occurs regardless of age, sex, race, baseline CD4 cell counts, geographic region, or economic status. This benefit has been definitely shown to outweigh any difficulty with ART including toxicities, adverse outcomes, etc...
- Quick initiation immediately after diagnosis is another area that helps the achievement of 90-90-90 targets. Rapid initiation of ART is defined as starting therapy within 7 days of diagnosis. This has to be based on person's willingness and readiness. As early as 2017, same day initiation of ART was practiced in South Africa. This envisages the initiation of ART on the same day as diagnosis. This is reported to improve the outcomes faster but has been occasionally alleged to be associated with reduced rate of retentions.
- The quest for achieving the 90-90-90 targets has also led to more widespread availability and accessibility to viral load testing facilities. All over the world, this is now accepted as the standard monitoring tool during follow-up visits.
- The impact of the above measures on transmission need not be over emphasized. The equation "Undetectable = Untransmissible" is now widely accepted. This means that if a person takes ART and is virally suppressed (as envisaged in the 90-90-90 strategy), his undetectable Viral load is likely to be associated with a significantly less number of transmissions as well. This becomes a strong weapon for HIV prevention activities as well. Treatment as prevention thus becomes a reality.[6]

- The inclusion of lifelong treatment for women will also lead to less number of women with high viral loads and almost complete elimination of vertical transmission, offering lower incidence of HIV infection among newborns as well.
- HIV treatment saves money: Many modeling exercises show the cost effectiveness of ART as a cost-effective tool in the long run. Investments in HIV treatment scale-up lead to economic benefits at least double that of prevented medical expenses, as well as that in care of orphans and productivity in labor. The initial increase in cost attributed to cost of infrastructure, logistics, drugs, testing laboratories, etc. is expected to pay in the long run to reduce total cost of decreased morbidity and survival.

Conclusion

It is evident from the discussion above that the 90-90-90 strategy put forth by UNAIDS and embraced by all countries including LMIC is making changes not only in the counts but also in various aspects related to prevention, diagnosis, treatment, monitoring, and survival, thus ensuring better life to the HIV infected and to the upcoming susceptible generation.

CHAPTER

185 Keeping Parent-to-Child Transmission Zero for a Decade—Trichur Experience

Ajithkumar Kidangazhiathmana, Lathika Nayar

Abstract

Knowledge about the efficacy of ARV drugs in preventing parent-to-child transmission (PPTCT) helped developed countries to achieve very low mother to child transmission rate. Due to various reasons, this remained unachievable in developing countries like India. PPTCT programme in India started in 2003 with Single dose Nevirapine schedule remained suboptimal till the adoption of Option B+ in 2014.

The Southern state of Kerala with health indicators comparable with the developed countries was always been an HIV low prevalent state. A model ART care facility was initiated in Govt.Mediacl College, Thrissur with the objective of providing comprehensive HIV health care incorporated to the existing public health system. Comprehensive PPTCT care by a dedicated "Team" was introduced as part of this package addressing various aspects of PPTCT, adjusted to existing the social mileu. This model proved quite successful and lead to near Zero transmission of HIV from mother to child in the last decade. Subsequently this model was adopted to other part of the state.

Introduction

Human immunodeficiency virus (HIV) continues to be a significant public health challenge world over. The fight against this pandemic started soon after the identification of the virus in 1982. With the knowledge that antiretroviral (ARV) drugs are useful in preventing mother-to-child transmission of HIV and that this is probably the only mode of transmission that can be prevented, Prevention of Parent/Mother-to-child transmission (PMTCT/PPTCT) became the major HIV prevention strategy aiming at reducing new infections, morbidity, and mortality. Currently, the transmission of infection from mother to child is eminently preventable.

A series of interventions were tried to achieve PPTCT at various levels. This include reduction of infection in the general community especially women of reproductive age group, avoidance of unplanned pregnancies, prevention of transmission from mother to child, post-exposure prophylaxis to the child and planning infant feeding options. PPTCT became a reality in the West in the mid-1990s with the introduction of zidovudine in pregnant women. However, it took decades for PPTCT to become competent in reducing the transmission in a significant proportion, mainly due to various hurdles in implementing PPTCT programs in the developing world, and because of the lack of adequate health-care delivery and public health infrastructure. Kerala a state known for high health indices and female literacy and equitable health care facilities remained an exception keeping both HIV prevalence and mother-to-child transmission to a minimum.

History of PPTCT

Global Scenario

ACTG 076 trial marked the beginning of a new era in PPTCT with zidovudine being recognized as the first

TABLE 1 Summary of Zidovudine Trials for prevention of mother-to-child transmission of HIV

Study	*Arm*	*Antepartum*	*ARV intrapartum*	*Neonatal*	*% Transmission*
PACTG	A	ZDV at >14 weeks	ZDV	ZDV for 6 weeks	7.6
076	B	Placebo	Placebo	Placebo	22.6
PHPT-1	SS	ZDV at >35 weeks	ZDV	ZDV for 3 days	10.5
	LL	ZDV at 28 weeks	ZDV	ZDV for 6 weeks	6.5
	LS	ZDV at 28 weeks	ZDV	ZDV for 3 days	4.7
	SL	ZDV at 35 weeks	ZDV	ZDV for 6 weeks	8.6

Adapted from: World Health Organization. Anti-retroviral therapy for treating pregnant women and preventing HIV infection in infants; recommendations for a public health approach - 2010 revision. Geneva, Switzerland: WHO Press; 2010[10]

effective drug in preventing mother-to-child transmission and the USA Public Health Service recommending its use in August 1994.[1] According to the ACTG 076 regimen, HIV-infected pregnant women were recommended zidovudine, from the14 weeks of gestation until delivery, followed by peripartum zidovudine infusion. Newborns were given 6 weeks of zidovudine together with replacement feeding. The treatment regimen reduced the risk of HIV transmission by approximately two-thirds.

Since then, many clinical trials have been undertaken to find out the most effective and affordable antiretroviral therapy (ART) regimen to prevent mother-to-child transmission. This search began with various modifications of ACTG 076 recommendation, like shortening zidovudine use to 8 weeks in the antenatal period.[2,3] Various trials with zidovudine for prevention of mother-to-child transmission of HIV are summarized in **Table 1**. The effectiveness of the "long-short" course (from 28 weeks in pregnancy for the mother and the upto 3 days for the baby) and the "short-long" course (from 35 weeks in pregnancy for the mother and upto 6 weeks for the baby) did not differ from that of the "long-long" course.[4]

Subsequently, PETRA Trials proved that starting zidovudine plus lamivudine at 36 weeks of gestation, followed by oral intrapartum dosing and 7 days' postpartum dosing of mothers and infants also can significantly reduce MTCT. Two-drug and three-drug regimens were tried subsequently for antenatal mothers, which too proved to be effective in reducing HIV transmission significantly.[4] The HIVNET012 trials conducted in Uganda, which confirmed the efficacy of the single-dose nevirapine regime in preventing vertical transmission of HIV was plagued by controversies soon after the release of its results in 2004.[5-7] But gradually this regimen became well accepted primarily because of the simplicity in implementation. **Table 2** summarizes the various treatment regimens proposed for PPTCT before the current three-drug regimen.

In June 2011, the Joint United Nations Program on HIV/AIDS (UNAIDS) introduced the *Global Plan Towards the Elimination of New HIV Infections Among Children by 2015 and Keeping Their Mothers Alive*, which aimed at a 90% reduction in new childhood HIV infections and a 50% reduction in HIV-related maternal deaths by 2015.[8]

The WHO recommended two approaches for PMTCT prophylaxis. "Option A" recommended zidovudine monotherapy in the antenatal period, single-dose nevirapine during labor and a week-long tail of zidovudine and lamivudine in the postpartum period. HIV exposed infant was given daily nevirapine until the cessation of breastfeeding. An alternate option, "Option B" differed from option A in that, all pregnant women, even if not eligible for ART were advised three-drug combination ARV in the antenatal period, which was continued till the cessation of breastfeeding. Infants have advised zidovudine/nevirapine prophylaxis for the first 6 weeks of life.[9] A third option B+ that recommended triple ART for all HIV infected pregnant women irrespective of the clinical or immunological stage was also included in this update

With the recommendation for the initiation of ART at any CD4 cell count in the 2014 updated guidelines, the PMTCT Guidelines Committee also adopted the WHO option B+, so that all pregnant women would continue triple-drug therapy after delivery in the same way as all other adults.[9]

PMTCT guidelines committee of our country adopted the Option B+ in 2014 so that all pregnant and breast feeding women would be initiated on Triple ART irrespective of the stage , which would be continued lifelong.[9]

TABLE 2 Summary of various treatment regimens proposed for PPTCT before three-drug regimen

1994	*1998*		*1999*		*2000*	*2002*	*2004*
ACTG 076Trial 65% reduction of transmission	1998Thai Bangkok AP/IP AZT Trial 50% reduction	Cote d'Ivoire AZT Trial 37% reduction	PETRA AZT/3TC 50% red with long arm 38% reduction with short arm PETRA AZT/3TC 50% red with long arm 38% reduction with short arm	Two dose IP/PP NVP (HIV NET 12) 47% reduction breastfeeding	Thai long vs. short AZT4% transmission (Non breast feed)	Cote d'Ivoire AZT and IP/PP Nev 6.2% transmission	PHPT AZT + Nev <2% transmission

Infant feeding recommendations given by WHO in 2006 and later in 2010 promoted 6 months exclusive breastfeeding followed by complementary feeding with the gradual cessation of breastfeeding by 12 months when nutritionally adequate and safe alternate nutrition is established, along with ARV prophylaxis to mother and infant.[10] In 2016, infant feeding guidelines were updated, with the recommendation to continue breastfeeding to 24 months like general population along with the continuation of ART.

Indian Scenario

NACO launched India's first PPTCT program in May 2003 with the recommendation to administer single-dose NVP 200 mg regimen to all seropositive mothers not receiving highly active combination anti-retroviral therapy (HAART) at the onset of labor, and this was followed by one dose of 2 mg/kg nevirapine administered to all babies within 72 hours of delivery.[11] This was continued till 2014 after which there was a significant change in the scene with the adoption of Option B+.

Challenges in Implementation of PPTCT in India

PPTCT is not just provision for ART. It is a comprehensive care package involving various steps.

These steps include (but are not limited to) women agreeing to HIV testing, receiving their results, undergoing ART eligibility screening, initiating treatment or prophylaxis, and adhering to the prescribed regimen.[11] Infants must adhere to anti-retroviral prophylaxis regimens and undergo appropriately timed HIV testing.[12] Attrition at each point should be identified and corrected. But the implementation of PPTCT services in developing countries is not often practical due to various factors, which include:[12-16]

- Large HIV positive population
- Problems in testing
- Issues related to confidentiality, stigma, and discrimination
- Non-availability of maternal and child health services
- Low education status of mothers
- Non-availability of medicine
- Non-availability of health-care delivery system
- Lack of political commitment
- Difficulty to prioritise PPTCT among other health care services

Kerala Scenario

Kerala, a small southern state, has always maintained a coveted position in health and social development, often comparable with the developed world. Kerala has always remained a low-HIV prevalent state, and this low prevalence was no accident.[17] Kerala's health indicators are almost comparable to Western Europe, with equitable health-care facilities, very high female literacy and empowerment, and low HIV prevalence. This helped Kerala to adopt a different model of PPTCT practice silently. Various social factors like high-literacy rates, women empowerment, better socioeconomic status, good public health and MCH services, good health-care seeking attitudes, the involvement of public health in HIV prevention services, availability and accessibility to state-run ART clinics across the state, commitment from government and health-care workers in implementing the program helped the state in evolving its model.

The Trichur Experience

The Thrissur model HIV Care facility (TMHCF) evolved as a comprehensive HIV care facility in 2002. This facility was recognized as one of the models that helped the evolution of the national ART program.[18,19]

The basic principle of this model was that it is possible to provide comprehensive HIV care by making use of existing infrastructure and human resources in the public health system of India.[20] This model also suggested that provision of health care to PLHIVs at the existing health care systems would reduce the stigma and discrimination tremendously thereby improving the health care seeking attitude of the patients. These were the guiding principle for the care of pregnant women as part of comprehensive HIV care from the inception of HIV care facility in 2002. We also believed, it was possible to provide better PPTCT services in Kerala if we make use of the strengths of its health care system and the society comprehensively. One of the authors (K Ajithkumar) was instrumental in providing the zidovudine prophylaxis probably for first time in India immediately after the report of ACTG 076 was published in 1994 while he was part of HIV team at CMC Vellore. The first pregnant lady who approached this facility received ACTG 076 protocol, and this became the standard practice in the institution. The success of this approach led to the referral of many more pregnant HIV infected women from different parts of the state.

As more and more patients were approaching the center for PPTCT, the center evolved a team of health-care workers and devised its protocol for PPTCT services. The protocol thus evolved included:

- Testing and confirmation of HIV status of every pregnant lady and the partner
- Counselling of the PLWA and family addressing the confidentiality of individuals involved
- Helping the patient for disclosure to the immediate caregiver
- Offering lifelong care
- Counselling of the pregnant lady and the family by obstetrician and pediatrician and involving them in the team as early in the pregnancy as possible
- Planning feeding options early in the pregnancy
- Ensuring regular antenatal care and near 100% institutional delivery
- Initiating ART as early as possible in pregnancy
- Lower section cesarean section as the mode of delivery
- Supporting the couple/family in facing social and financial issues, including stigma and discrimination
- Linkage with PLWHA networks and other ART care centers for follow-up
- Linkage with other services like NGOs, CBOs, etc.
- Training of health-care workers in PPTCT
- Supporting private health-care providers in providing PPTCT services

All these components continue even now with appropriate modifications.

In the early days of TMHCF, there was no India specific guideline for PPTCT. So we evolved our own protocol and incorporated modified ACTG 076 protocol as part of this package. As intravenous zidovudine was not readily available, we continued oral zidovudine peripartum also. When the evidence on two drugs PPTCT became available, we shifted to it for a brief period.

Thus over the time with the evolving evidence, drug regimens for prophylaxis changed from zidovudine monotherapy through zidovudine + lamivudine and eventually to zidovudine + lamivudine + efavirenz. The time of initiation of ARV prophylaxis also changed accordingly. By 2010 every pregnant lady was receiving triple regimen as early as feasible.

Each HIV positive pregnant woman was counselled by the HIV team, pediatrician, and the gynecologist. An individualized treatment plan was charted for each patient considering their socioeconomic and health status and followed up by the counsellor. We followed planned elective cesarean section as mode of delivery. If the pregnant lady was not able to deliver in our hospital, her local gynecologist and pediatrician were contacted by our HIV team, and a suitable plan for the management of pregnancy was formulated. As far as possible, they were encouraged to bring the child to our institution for follow up, especially for nutritional evaluation and early infant diagnosis at the sixth week. Each mother-baby pair was followed up till at least the child reached 18 months and tested negative. Those women who were not registered in our center, but were referred late in pregnancy or in active labor and those who moved back to their primary care centers after delivery were also monitored.

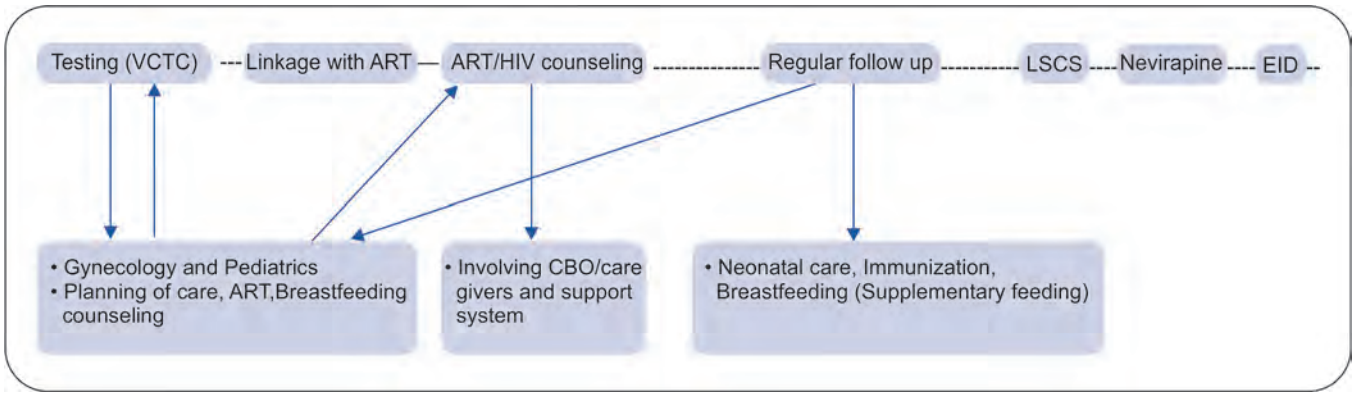
Mode of delivery: Planned LSCS was the option from the early 2000s in our institution. Vaginal delivery was resorted to only if the pregnant lady reaches the institution in advanced labor.

Flowchart 1 shows the flow of patients in PPTCT at TMHCF.

Infant feeding: We counselled not just the pregnant lady but the whole family regarding feeding options. The practical difficulties in avoiding breastfeeding, including the social stigma and confidentiality issues were acknowledged, and tailor-made plans were implemented for each family. Majority of our mothers opted exclusive replacement feeding initially, and these children were followed up regularly to make sure the children have not affected adversely by avoiding breastfeeds. Recently the infant feeding option has shifted more to breast feeding with more women getting diagnosed and initiated on ART early or prior to pregnancy, allowing well controlled disease states. The parents and families (especially in-laws) were regularly counselled and supported. The PPTCT was never a standalone service. It was synchronized and integrated with general MCH care and HIV care. So regular follow-up of mother and child was integrated with immunization services, pediatric/neonatal care, ART, etc. The strong relationship built between the pediatrician and the ART team continued until the child reaches adulthood irrespective of HIV status.

We made sure the social norms were followed by the pregnant ladies and families so that stigma and discrimination could be avoided.

Flowchart 1: Flow of patients attending PPTCT services in Thissur model HIV care



This model was helpful for both patients and gynecologists, as almost all deliveries were planned. This model addressed the medical and nonmedical problems faced by these women comprehensively and ensured adequate compliance and follow-up.

The success of Trichur team sent messages all around the state, and most ART teams followed this model across the state. This lead to the declaration of zero transmission of HIV from mother-to-child transmission in Kerala by Hon. Health Minister in 2010. Few mothers, who were lost to follow-up were all referred late in pregnancy or in labor. Till now, to best of our knowledge, only one baby, whose mother discontinued ART due to reduced tolerance and psychiatric illness, has become HIV infected.

Conclusion

Vertical Transmission of HIV is an eminently preventable infection. Like any other disease, the medical factors are equally or more critical in implementing a successful strategy. Though possible in principle, very few developing countries could reach zero PPTCT of HIV so far. The latest strategy of integrating PPTCT with HIV care and providing lifelong ART to every HIV infected individual will help in preventing mother-to-child transmission as well in the coming years.

The Govt. Medical College, Thrissur, could achieve a near-zero mother-to-child transmission rate from early 2000 itself solely due to the comprehensive, individualized HIV care by a dedicated team of health-care workers, integrating HIV care with the routine MCH services addressing the medical and psychosocioeconomic aspects of HIV infection simultaneously and not due to any significant upscaling of infrastructure. Because of this, Trichur model is one that can be adapted in most health-care settings in developing countries.

CHAPTER

186 My 30 Years Experience in HIV Medicine

Alaka Deshpande

Abstract

HIV arrived in India 5 years after the western world. There experience guided our policies. The illiteracy, poverty, population, and inadequate health infrastructure were the imposing problems. The prompt response with awareness programs, cost free testing, management of OIs did help the patients. But the game changer was free access to cARVs. It lessened the morbidity and increased the longevity. However, the newer challenges emerge from time to time.

Introduction

Alma Ata declaration of Health for All by 2000 AD was made in 1980. It was in reference to conquering the known microbes and controlling infectious diseases in the Southern hemisphere.

The Clinicians even at that time were well aware that the newer challenges will be posed by resistant microbes including bacteria, fungi, and newly emerging viruses.

Over last four decades we are experiencing various viral epidemics and as a paradox almost all of them are emerging from the Southern hemisphere.

June 1981, exactly 6 months after Alma Ata declaration, a new disease entity was reported in MMWR which baffled the medical world. Young people were dying of Opportunistic infections without any evidence of known immune suppression. However, the investigations revealed cell-mediated immune-deficiency. Clinical spectrum evolved slowly, modes of transmission became known and the etiological virus was identified.

Indian Scenario

India was in second wave countries as HIV reached India in 1986 when Prof Jacob John could procure an ELISA kit and tested few samples of CSW in Chennai and detected positivity in two of them. This heralded the arrival of HIV in India. People were ignorant about it and few who read about it boasted about our culture and prophecised that it would never come in India. But, Govt. of India promptly responded and ICMR started the serosurveillance. Due to limited resources the universal safety precautions were almost non-existent. Glass syringes were boiled and reused. By 1990, we started getting clinical cases. The HIV phobia was so much that the private sector doctors were turning away the pts. And the Govt. hospitals had to bear the brunt. Even in our tertiary care Govt. hospital, I had to first impart training to our resident doctors and all the paramedics for safety precautions. Second, I started a dedicated HIV OPD in view of keeping patients' confidentiality, avoiding discrimination and giving enough time for counseling of the patients. Gradually, the attendance in the OPD went on increasing. Many of the cases presented in critical condition and succumbed within 24 hours. Autopsy of these cases was necessary. My pathology colleague accepted the challenge and we could carry out 150 autopsies of AIDS cases. Autopsies were good learning lessons.

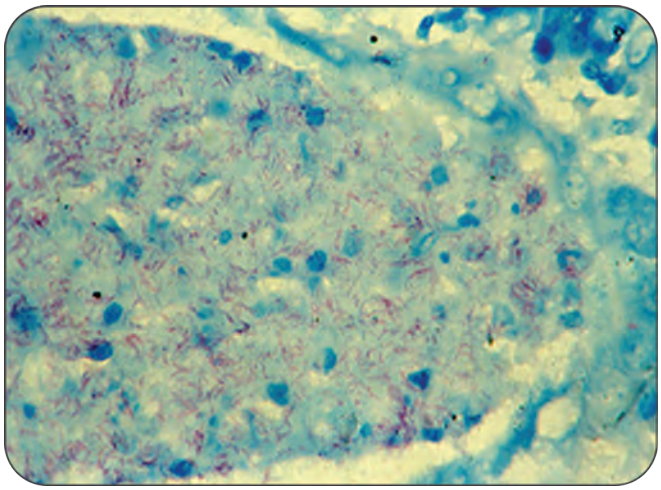

Fig. 1: Kidney teeming with mycobacteria

We could establish mycobacteriosis-organs teeming with mycobacteria **(Fig. 1)** in absence of clinical or gross pathological evidence on autopsies.

We noticed multiple pathologies in one single patient endorsing severe immunodeficiency. Sixty-seven percent showed tuberculosis along with other OIs.

All these OIs were newly seen by us; hence, we had to develop appropriate tests to diagnose them. It was a time consuming process as these OIs were not seen earlier because 1994–1995 neither long-term steroid used nor an ambitious organ transplant program was in place. Slowly we evolved.

It was necessary to share our experience of lack of preparedness for infrastructure to manage increasing number of HIV cases and how we could surmount the difficulties. A proper training had to be imparted for medical fraternity in the country. National AIDS Control Organization (NACO) was set up by Govt. of India. Under the aegis of WHO, NACO, CMAI (NGO) with support from Norad, we 21 Professors conducted training workshops in the country. It was a great experience. This was in 1992–1993.

In 1981, this new disease entity was identified as a mysterious dreadful disease. With revelation of deficiency of cell mediated immunity (CMI) presenting with various OIs (Syndrome—cluster of symptoms) the disease got its first name as Acquired Immunodeficiency Syndrome (AIDS). Now we know it as retroviral disease. It spread rapidly all over the world causing a serious pandemic without any treatment. The natural history was unfolding. Medical research finally identified the causative organism—the first human retrovirus which was called as Human Immunodeficiency Virus (HIV). After the discovery of HIV, the laboratory diagnostic tests were developed.

The serodiagnosis was based on detection of anti-HIV antibodies by ELISA technique. A positive test needed confirmation by Western Blot test, which was immunoblotting multiple antibodies. The test was cumbersome, expensive, and time consuming. Further facilitation came by using the same principle of detecting multiple antibodies using three different antigens to detect three different antibodies using technically different three tests S, R, and E—simple, rapid, and elisa.

These tests are indirect tests which detect antiviral antibodies indicating exposure to the virus. It had its window period. Science was evolving as the pandemic was spreading relentlessly. The direct tests detecting virus itself qualitatively by DNA PCR and quantitatively by RT-PCR to measure viral load developed over the time period each having its own indications.

CD4 counts were used to assess the severity of immune deficiency.

This disease no longer remained only a medical problem. It encompassed all the aspects of human life. Just to give a small example—I would recall that NACO held a special meeting of experts regarding issue of a death certificate. The discrimination was to the extent of refusing cremation/burial of a patient whose death certificate mentioned AIDS as the cause of death.

The story of evolution of HIV will remind the readers of prevailing situations with various RNA virus epidemics in last decade or so.

Clinical Spectrum

Clinical spectrum varied depending on the severity of immune deficiency. Over three decades, I have seen almost all the OIs in our patients. However, predominant was tuberculosis. It occurred minimum 2–3 times in a patient. Depending on the severity of immune deficiency the TB presentation differed. In early immunodeficiency it was like any non-HIV TB, with moderate immunodeficiency it was extrapulmonary or disseminated TB and severe deficiency (CD4 <50) it was mycobacteriosis. Multiple OIs were seen simultaneously in the stage of AIDS.

Candida albicans	03
Trichosporon	02
Ascospores	01
Geotrichum	02
Aspergillus	03
Normal	17

*Largest series of Rhodotorula from aseptic CSF compartment.

It was intriguing for me to see patients with cryptococcal meningitis treated with inj Amphotericin responding by negative test for crypto antigen. And within a week patient clinically deteriorated and showed presence of fungus in CSF on India ink preparation. So we carried out fungal culture of CSF in these cases and were surprised to note that the etiology of fungal meningitis was as shown in **Table 1**. Fungal culture positive in 75.6% of cases.

Four cases of dementia of six months duration were subjected to neuro-imaging **(Fig. 2)**.

The aspiration from these lesions demonstrated AFBs, but the culture grew Nocardia. I had a large series of various lymphomas associated with HIV. Just to cite one of them **(Fig. 3)**, with huge hepatomegaly, ptosis, with infiltration of extraocular muscles and CD4 110 cells only.

In the decade of 1991, despite all efforts of community awareness and expanding centers for HIV care, the patients used to report to the hospital very late. Antiretroviral therapy was not available; hence, the life span was limited, and morbidity and mortality were high.

During these years, some of our concepts had to be re-examined and appropriate measures had to be taken.

One such misconception was that if either of the spouses is positive the other will also be HIV infected.

We used to do couple counseling extensively so as to protect either of them from OIs and STDs. Couples were counseled regarding barrier protection with condom. But our study showed that about 25% were strictly abstinent. About 40–50% were using condom occasionally and the remaining expressed their inability to follow the protection due to hutment, poverty, fear of getting identified in a joint family, etc.

The intriguing fact was that 40% of our couples having 3–4 kids were discordant. Later on I had undertaken a

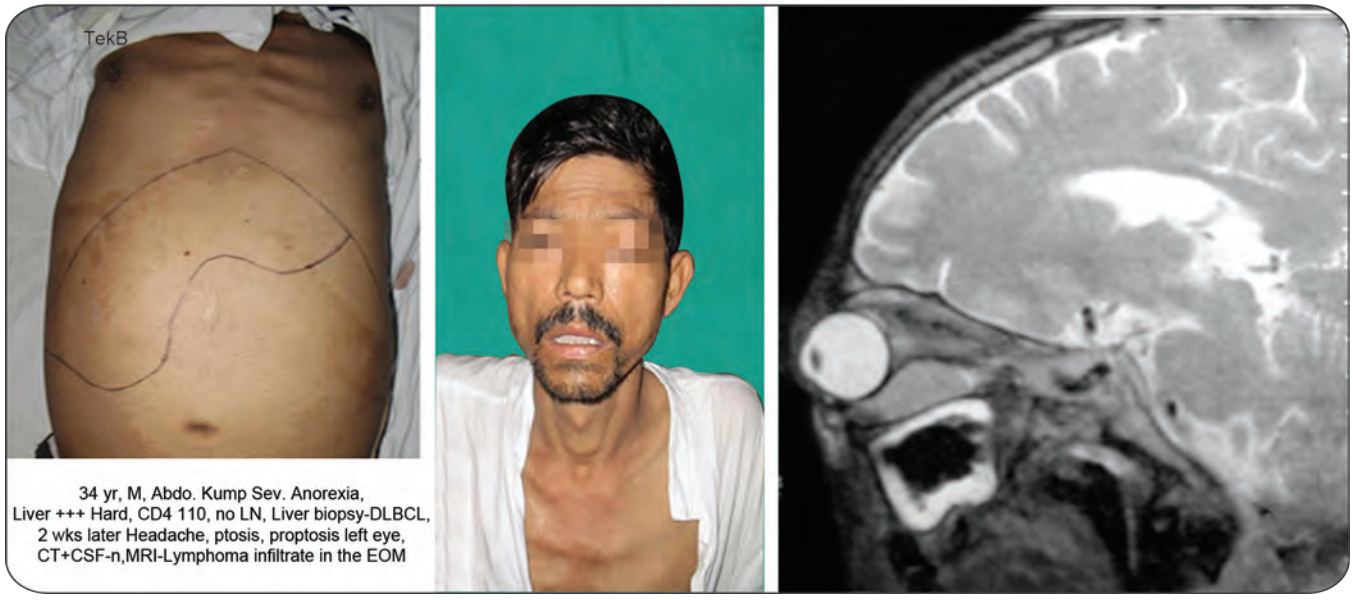

Fig. 3: A case of large diffuse B-cell lymphoma

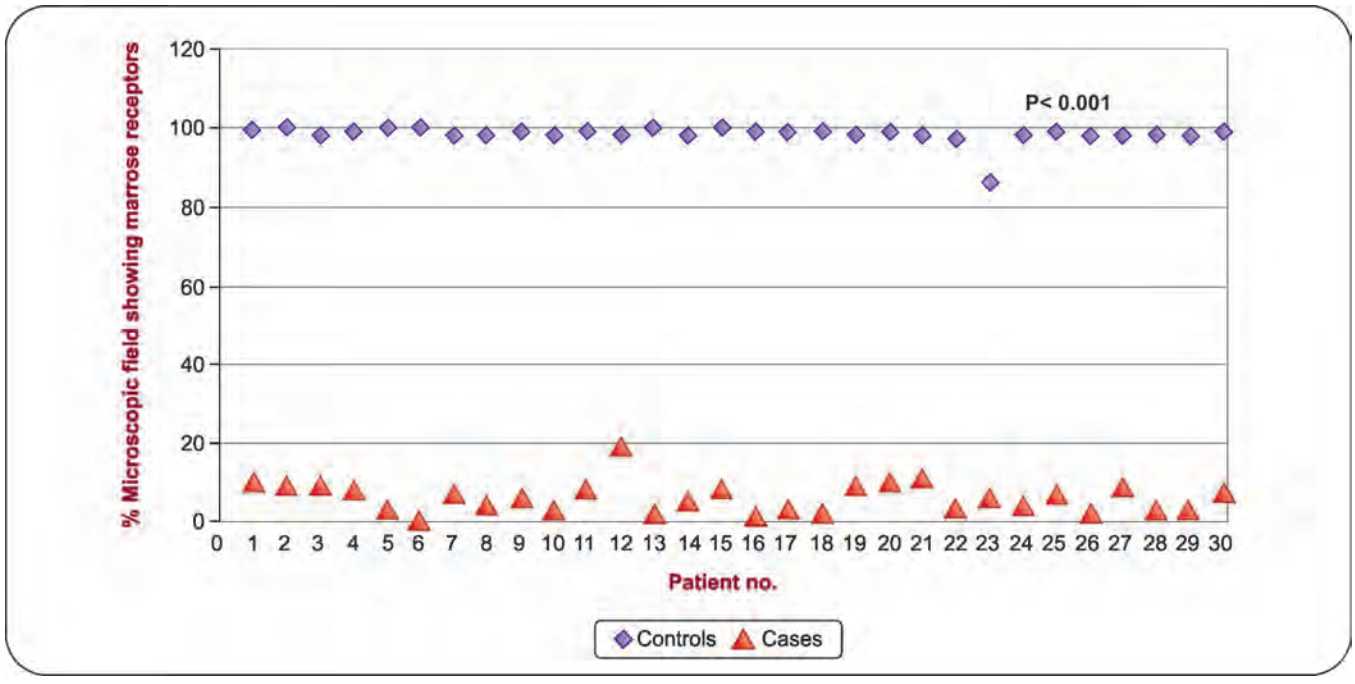

Fig. 4: Mannose receptors in vaginal epithelium

study of mannose receptors **(Fig. 4)** in vaginal epithelium of discordant couples.

The seronegative wives had mannose receptors but the seropositve wives were deficient in these receptors.

Antiretroviral Treatment

Azidothymidine (AZT): The first antiretroviral drug was discovered in 1987, had expedited approval of US FDA. HIV had just arrived in our country in 1986 so there was

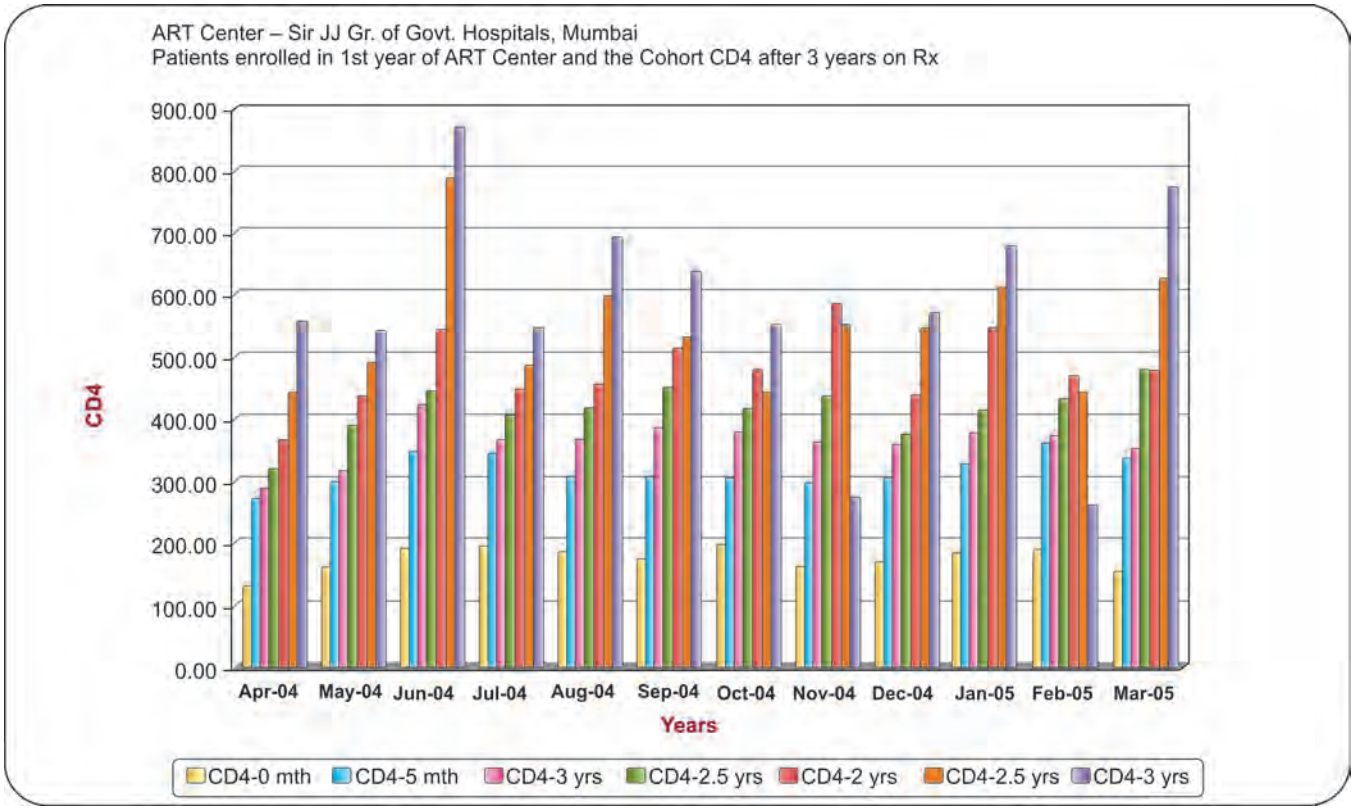

Fig. 5: CD4 rise after ART

no question of its use then. But in western world AZT being the only hope; it was used inadvertently and like penicillin within few months serious side effects and AZT resistance became apparent. Over next 3–4 years combination therapy became successful to control the viral load. Combination antiretroviral (cARV) therapy was not affordable to 95% of HIV infected people living in the developing world.

NACO was giving free therapy for OIs but treating OIs without ARVs was like amputating a diabetic gangrene without treating DM. Fortunately in 2000, the Special Session of United Nations General Assembly (UNGASS) upheld health as a basic human right and providing access to free ARVs became the responsibility of the Federal Govt. WHO launched an ambitious program of treating 3 million HIV patients by 2005.

Western world had ARV experience since 1987. With experience the guidelines were modified from time to time. There are American (DHHS), British (BHIVA), IAS (European) guidelines but as they have unlimited access to ARVs the guidelines have individualistic approach. But our National guidelines are based mainly on WHO guidelines.

A community oriented therapy program needs uniform guidelines, based on the efficacy of drugs, availability of resources including finance, apart from other factors like distribution, storage, etc. Indian National Guidelines were developed by Technical Experts of the country under the NACO initiative.

Govt. of India launched the free ART program in March 2004, the launch started from my institute having the largest number of HIV patients in J J Group of Govt. Hospitals, Mumbai.

It was a game changer. The first combination that was used for maximum number of patients was STAV + LAM + NVP being the lowest cost yet effective combination. The rise in CD4 was significant as shown in **Figure 5**. As the immunity improved the OIs almost disappeared, great improvement was seen in morbidity and mortality.

But as said earlier within a short time, a large number of side effects of cARV were seen. The most obvious was lipodystrophy **(Fig. 6)** which disfigured patients who

Fig. 6: Lipodystrophy

started looking sick although the disease status was improving. They feared being identified and discriminated.

The ARV toxicity profile to the first-line ART in my experience is shown in **Table 2**.

Patients' therapy compliance was a challenging issue. Ignorance, working pattern, inherent forgetfulness, and in few cases their alcohol addiction were major obstacles in compliance. In addition, Mumbai being the financial capital of India, a large number of the patients were migrant laborers. It was a major factor for their risk behavior and also a major factor for non-compliance because 3 months in a year they used to go back to their native place for farming. As a result the drug resistance was developing.

From 2004 to 2008, ART centers were being established all over the country. Apart from uniform therapy guidelines, the doctors had to be trained in this new arena.

Although a network of ART centers was being developed large number of the patients refused to attend the nearby centers for the fear of being identified. The social implications of the disease made the management difficult.

In 2008, first-line drug therapy was showing evidence of therapy failure mostly due to development of drug resistance. It was necessary to change the ARVs; therefore, second-line ART was initiated from 2008. The major change was introduction of tenofovir (TDF) and in few cases ritonavir boosted protease inhibitors.

TABLE 2 ARV toxicity

AZT marrow suppression	8%	Pancreatitis	2%
Lipoatrophy	34%	Lipodystrophy	5%
Toxic neuropathy	10%	Hyperlactatemia	2%
Hepatotoxicity	3%	Drug rash	6%

In first 6 months after TDF, I had 17 cases of TDF induced nephropathy. Nephropathy was not anticipated with less than 6 months exposure to TDF. Three years later a study on TDF nephropathy showed long-term exposure to STV use prior to TDF was the culprit.

For the first time NACO started estimation of viral load in selected first-line failure cases who did not show expected rise in CD4.

In this exercise I detected quite a few cases of immuno-virological discordance. These patients had low CD4 and undetectable viral load. I thought of a possibility of HIV-2 infection which so far was not identified in the country.

It was not possible in a Govt. set up at that time so I tied up with a private set up which had newly introduced HIV-2 Western Blot. I could detect 167 cases of HIV-2 which till then were receiving NNRTI in vain. After these results, diagnostic tests to differentiate between HIV-1 and HIV-2 were introduced and therapy was appropriately amended. Many newer drugs have been added to the armamentarium.

Despite offer of cost-free CD4, free viral load and free therapy, still we keep getting patients with OIs. It clearly indicates therapy failure due to non-compliant patient.

My recent data analysis showed that 31.3% of cases on ART were receiving cARV for past more than 15 years. The ART initiation criteria then was CD4 <200 cells. It can be deduced that these cases acquired the infection 8–10 years prior to initiation of ART. In earlier years, in absence of ARVs, patients were succumbing to AIDS within few days to weeks. But longevity increased so well after ART that people who acquired the infection in the age group of 25–35 years are now in their fourth and fifth decade. Quite a large number of them have crossed 60 years of age. And now apart from retroviral disease 18% of the cases are suffering from non-communicable diseases like hypertension, diabetes mellitus. It adds to the complexity of management.

In our earlier counseling in order to build up the hope and dispel their anxiety, patients were informed that soon there will be a breakthrough to wipe out the virus. We also hoped for anti-HIV vaccine but the virus is far more tricky than expected. We succeeded in controlling the viral load but could not get rid of it. The recent development of long acting injectables offers hope for improved compliance and long-term viral suppression.

HIV vaccine remained elusive over three decades. There is no breakthrough as yet because of multiple portals of entry, multiple groups and subgroups of HIV and constant mutation.

Avoidance of human risk behavior is the mainstay of prevention but it is the most challenging task, almost impossible. Safer sex practices, targeted interventions, PrEP, all have limitations and are related to human behavior. Finally, the only hope is to control human reservoir by Test and Treat!

HIV is a forerunner of all the new viruses, which emerged in last decade. For example, SARS, Chikungunya Nipah, H1N1, H5N1, Zika, Ebola they all, like HIV, are single stranded RNA viruses. No vaccine against any of these RNA viruses has so far been developed. Although HIV warned us about universal precautions, we have miserably failed in developing necessary infrastructure and safe culture! It is evident from the recent pandemic of SARS-CoV-2.

There is a long way to go!!

Conclusion

Knowledge about various aspects grew as the epidemic evolved. Though ART is a game changer, presently the main challenges are compliance of the patients and emergence of drug resistance. After all it is not possible to change the human behavior.
