COVID-19

CHAPTER

1

COVID-19 and Hypertension

K Tewary

Abstract

The COVID-19 pandemic has taken us unprecedented, and management of comorbidities has become challenging as a consequence. Presence of comorbidities has shown to be an increased risk factor for critical illness. Since it's a relatively new disease, there is a lack of robust clinical data concerning COVID-19 infection and presence of comorbidities. Among the COVID-19 patients who died in Italy, it was observed that those with comorbidities including hypertension (69%), diabetes (31%), ischemic heart disease (27%), atrial fibrillation (21%), and heart failure (16%) were the most important factors for the increased mortality rates observed (Gruppo Della database, 2020).

Introduction

The COVID-19 pandemic has taken us unprecedented, and management of comorbidities has become challenging as a consequence. Presence of comorbidities has shown to be an increased risk factor for critical illness. Since it's a relatively new disease, there is a lack of robust clinical data concerning COVID-19 infection and presence of comorbidities. Among the COVID-19 patients who died in Italy, it was observed that those with comorbidities including hypertension (69%), diabetes (31%), ischemic heart disease (27%), atrial fibrillation (21%), and heart failure (16%) were the most important factors for the increased mortality rates observed (Gruppo Della database, 2020). The highest percentage of association was with hypertension. In a meta-analysis done, it was shown that the extent of hyperglycemia was lower in survivors and non-severe subset of patients. Similarly, presence of hypertension was associated with higher mortality rates and necessity of ICU care.[1] So far there is no evidence to show that hypertension reduces immunity or increases the predisposition toward getting infected with COVID-19.[2]

Management of Hypertension in the COVID-19 Era and the Possible Role of RAAS Inhibitors

With the current scenario, it becomes very crucial to manage cardiovascular risk factors to reduce significant morbidity and mortality. A significant proportion of these patients are on renin-angiotensin-aldosterone system (RAAS) inhibitors as therapy for their hypertension. The European Society of Cardiology (ESC) has come up with a recent guidance document under the expert panel of health-care professionals managing COVID-19 concomitantly with cardiovascular disease. Multivariable adjusted models have shown cardiac injury, especially elevated cardiac troponin-T levels to be a significant mortality indicator. Studies have reported that in a significant proportion of COVID-19 patients, direct myocardial injury resulting in elevated cardiac troponins is the main effect seen (approximately 8–12% patients). Presence of pre-existing cardiac disease tends to worsen this.[3,4] Additionally, COVID-19 associated pneumonia

has shown to induce long-term hypercoagulable state, which again contributes to worsening cardiovascular outcomes. The viral myocarditis has also been responsible for precipitating arrhythmias. Taken into consideration all these factors, ESC has suggested that it's vital to communicate to seek immediate medical guidance if a patient has been diagnosed with COVID-19 and has significant cardiovascular comorbidities. The emphasis is not to discontinue any of the drugs, either aspirin or RAAS inhibitors unless as advised by the treating specialist.

In a large retrospective study in 2,877 patients admitted with COVID-19 at Huo Shen Shan hospital, Wuhan, 29.5% presented with a history of hypertension. Interestingly, it was observed that in patients who had a history of hypertension but were not under current therapy for the same, the mortality rate was twice as those who were being managed with pharmacotherapy for the same [HR:2.17,(1.03-4.57, p=0.04)]. In fact, the mortality rates were similar for those on RAAS inhibitors versus those on other classes of antihypertensive drugs [HR: 0.85, (0.28-2.58,p = 0.774)], although the results were not statistically significant.[5] In the largest study of its kind, 884 COVID-19 positive patients were enrolled out of which 149 had hypertension, and interestingly majority of the patients were treated with calcium channel blockers. Compared to those without a history of hypertension, this subgroup of patients presented with more severe respiratory symptoms requiring more intensive therapy including use of intravenous immunoglobulin therapy and ultimately longer ICU stay. This again emphasizes the importance of aggressive BP management for better outcomes.[6] In another study from Wuhan province, Yang et al. attempted to understand the role of hypertension further. To remove the possibility of bias due to various confounding variables that may skew the analysis, a propensity score matching (PSM) was done. In the cohort of 226 COVID-19 patients studied, analysis revealed that presence of hypertension could increase death rate significantly (HR: 3.317, CI: 1.709-6.44, p<0.001). Interestingly, elevated D-dimer levels and higher neutrophil-lymphocyte ratio was found to increase mortality risk overall. However, this difference was not significant across the age groups, whether less than 65 years of age or above.

In a larger scale epidemiological study from Spain, involving 1,139 COVID-19 patients on concurrent therapy with RAAS inhibitors, further attempt was made to understand the effect of this class of drugs (cases) as compared to those on other classes of antihypertensives acting as control subjects. The cases were control matched by a factor of 10 to give a total of 11,390 controls. Interestingly, there was no increase in the severity of COVID-19 symptoms requiring hospital admission or increase in the complication rate leading to more fatality for the cases relative to the controls (OR: 0.94, CI: 0.77–1.15). In another large cohort study of 5,700 COVID-19 patients from the Northwell area, New York, it was seen there was no significant difference in mortality rates between those managed with RAAS inhibitors versus those on other classes of antihypertensives. It's an established fact that these drugs increase the mRNA expression of cardiac ACE2, but yet their role in determining outcomes in COVID-19 patients remains ambiguous.[7] Although the data studied were observational studies and not randomized control trials (RCTs), there is a certain degree of reassurance that RAAS inhibitors can be safely continued in spite of the infection.[8] One of the studies reportedly employed a Bayesian method of analysis in COVID-19 subjects to determine whether any of the five classes of antihypertensive drugs (ACE-inhibitors, ARBs, beta-blockers, calcium channel blockers and thiazide diuretics) played a role in the severity of infection. One of the advantages of using a Bayesian analysis is that unobserved variables can be accommodated in the process whenever there's a diagnostic or clinical error thus rendering the analytic process more robust. None of these classes of drugs were associated with worsening outcomes in COVID-19 disease.[9] There has also been reports of usage of RAAS inhibitors resulting in attenuation of inflammatory markers like IL-6; the authors have also reported that calcium channel blockers as a class has also shown mortality benefits;[10] they have also emphasized the use of telemedicine platforms in this pandemic era to provide better access to health-care resources and for better outcomes. Mobile health services have been emphasized especially for the populations with limited access to health-care resources. With just an application on the mobile phone, patients can continuously communicate with the health-care providers as long as self BP monitoring (SBPM) training is provided. In another retrospective review based in Shenzen Third People's Hospital, 42 COVID-19 positive patients were categorized as those on RAAS inhibitors versus other classes of antihypertensives.

The percentage of patients ending up with severe disease was lower for those RAAS inhibitors (23.5%) with no mortality numbers whereas those on non-RAAS inhibitors the percentage was higher (48%) and one patient died. Also levels of inflammatory markers, IL-6, CRP were lower in the former; in addition the CD3+, CD4+, CD8+ cell count was higher for those on RAAS inhibitors with lower viral load. Although no direct causality can be established with use of RAAS inhibitors and severity of disease, the authors assume that the differences observed could be attributed to the higher levels of Angiotensin-II for those on non-RAAS inhibitors.[11] In a similar retrospective study, 282 hypertensive patients admitted for COVID-19 were identified, out of which 41 subjects were managed with RAAS inhibitors versus 241 who were on alternate class of drugs. Primarily, the authors noted that hypertensive patients as a group were more likely end up critically ill. All cause mortality was higher in this group as per cox regression analysis. Additionally, use of RAAS inhibitors was associated with lower CRP levels and higher CD4+ cell count, with better outcomes.[12] Hence, they emphasize on a holistic approach on managing patients and continuing the antihypertensive therapy no matter what the class of drugs being used.

RAAS Inhibitors Mechanism of Action and the Pathway of COVID-19 Infection

There are multiple mechanisms through which RAAS inhibitors work on the cardio-metabolic axis and could potentially interfere with the clinical course of COVID-19 infection.

As far as the discussion above is concerned, there is couple of factors that needs to taken into account. Firstly, how much does hypertension play a definite role in the severity of COVID-19. Sisnieguez et al. has commented in a review study about the possibility of confounding factors that could possibly lead to false conclusions about the association between hypertension and COVID-19 outcomes. They go to explain that the increased mortality observed in the elderly with COVID-19 could be confounded due to increased prevalence of cardiovascular disease in the elderly which has been well established in the multivariate model (where the association between cardiovascular disease and COVID-19 is well established), but this has not been established with hypertension per se. Therefore, before any conclusions could be made concerning hypertension and severity of COVID-19 infection, these confounding factors should be adjusted appropriately.[13] Secondly, the role of RAAS inhibitors in the outcomes of COVID-19 infection seems ambiguous and more research is needed to ascertain further as to whether their use results in better or adverse clinical outcomes in the COVID-19 scenario **(Fig. 1 and Flowchart 1)**.

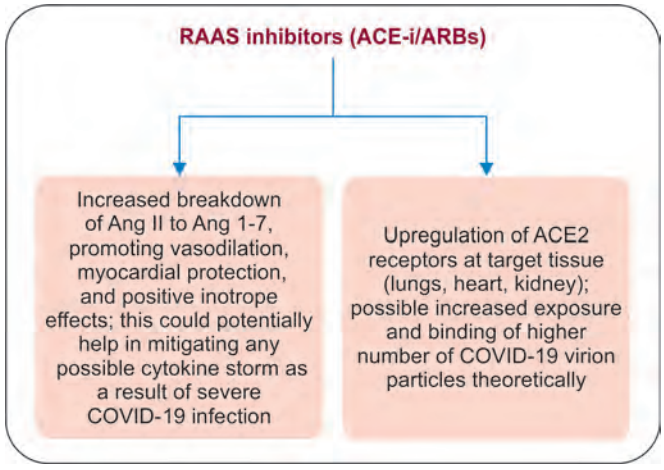

Fig. 1: Ambiguous role of RAAS inhibitors in the COVID-19 disease pathogenesis

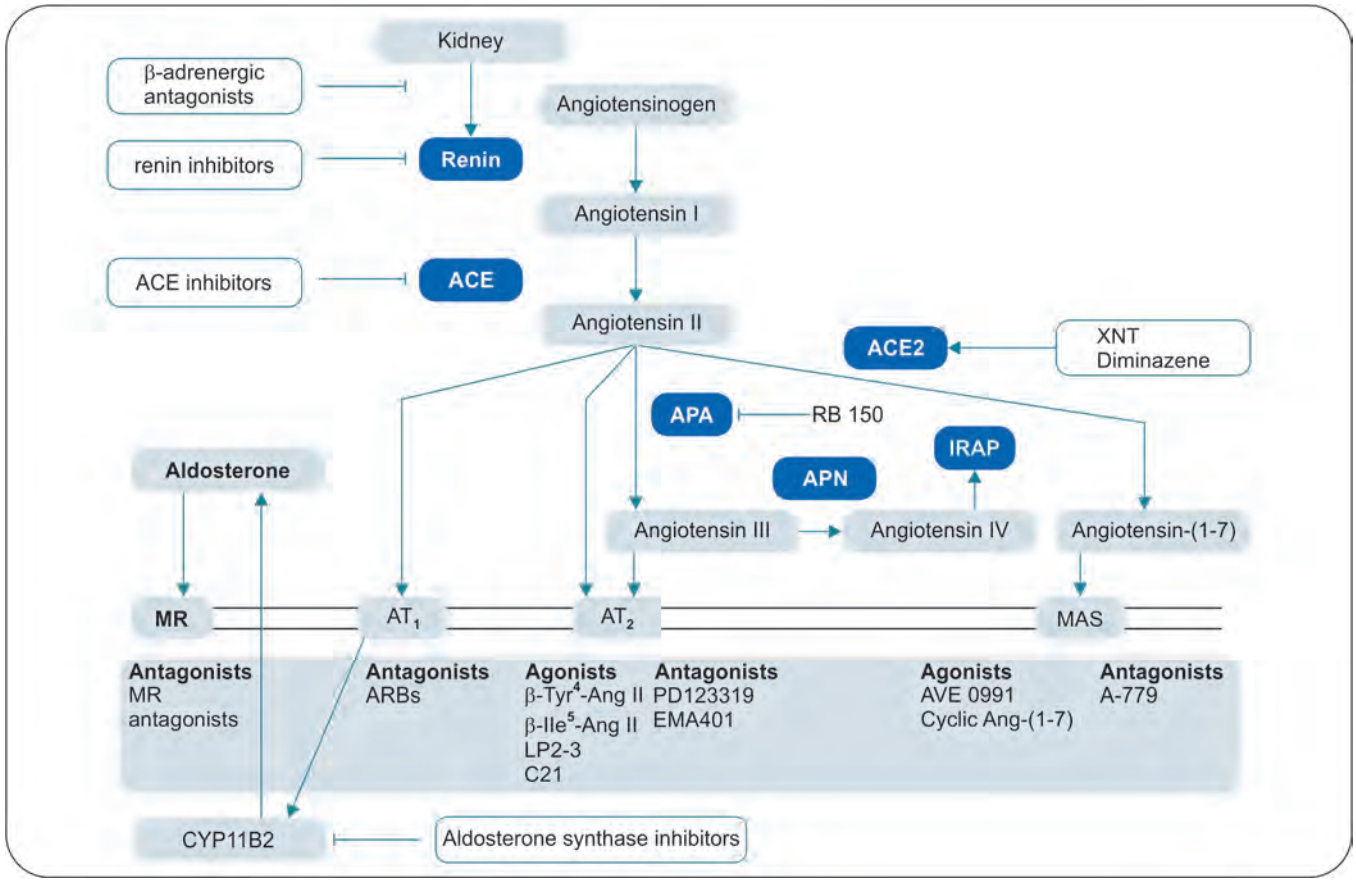
Where do we Stand with the Available Data?

It's not surprising that majority of COVID-19 patients are hypertensive and does not necessarily imply any causality between the two conditions. It just is a finding that hypertension as comorbidity is very common in the elderly and COVID-19 is an infection that the elderly are particularly vulnerable to and prone to develop severe clinical presentation of the disease.[14] Hence, most of the data that's available so far is more of a clinical guidance and not conclusive evidence. In the current pandemic situation, owing to the limited allocation of time and resources so far to deal with the unprecedented situation, most of the data that's available is observational study data and not RCTs and may not be the best in terms of hierarchy of evidence. We have had prior scenarios where there was discordance between observational and RCT studies, which was attributed to various factors including selection bias, presence of confounding factors, differences in

Flowchart 1: Should ACE-inhibitors and ARBs be stopped with COVID-19



statistical power of the study, and issues with study adherence throughout. A classic example was the finding that bisphosphonates decrease risk of postmenopausal breast cancer as ascertained by observational study which was later refuted based on the results from a couple of RCTs.[15] Hence, one needs to be careful in forming conclusions about the association of hypertension and COVID-19 infection and also about the use of RAAS inhibitors. Yet, it would be reasonable to assume that managing hypertension and other comorbidities would be of high priority. Since there's no conclusive data showing the deleterious effect of any class of hypertensive drugs, it would be wise to continue the drug to maintain BP control. As discussed earlier, for newly detected hypertension, classes of drugs other than RAAS inhibitors could be considered for initiation of therapy due to the paucity of conclusive evidence concerning either the benefits or possible deleterious effects of RAAS inhibitors on the severity of COVID-19 infection.

Conclusion

For newly detected hypertension, classes of drugs other than RAAS inhibitors could be considered for initiation of therapy due to the paucity of conclusive evidence concerning either the benefits or possible deleterious effects of RAAS inhibitors on the severity of COVID-19 infection.

COVID-19: An Overview

Madhulata Agarwal, Mayank Gupta, Lavina Chandwani, Sangeeta Choudhary, Somyata Somendra, Sajna Choudhary, Sunil Kumar Mahavar, Bharat Bhushan Sharma, Arvind Palawat, Raman Sharma

Abstract

Emerging and reemerging infectious diseases have plagued mankind and have been potential killers since historic times. The current pandemic of COVID-19 is the latest crisis that has challenged leadership and health infrastructures globally. COVID-19, caused by SARS-CoV-2, began as an outbreak of pneumonia of unknown cause at a local seafood market in Wuhan, China, and soon spread globally claiming more than a million of lives. The virus has a wide spectrum of symptoms due to the ability of its S protein to bind to h-ACE2 receptors on various tissues like lung, heart, kidneys, GI tract, and olfactory epithelium. It transmits predominantly as a respiratory droplet infection from person to person and by direct contact with contaminated surfaces. COVID-19 encompasses a spectrum of asymptomatic/presymptomatic, mild, moderate, and severe to life threatening critical illness. Most common symptoms are cough (53%), fever (43%), myalgia (36%), headache (34%), dyspnea (29%), and sore throat (20%); less common are diarrhea, nausea, vomiting, anosmia, dysguesia, and dermatological manifestations. Risk factors for severe disease are old age, uncontrolled hypertension, diabetes, COPD, cardiovascular disease, obesity (BMI > 30), and malignancy and immunocompromised status. Patients of COVID-19 develop complications like pneumonia with or without respiratory failure, cardiomyopathy, acute myocardial ischemia, arrhythmias, thromboembolic complications, cytokine release syndrome, encephalopathy, ileus, mesenteric ischemia, secondary bacterial infection, sepsis, and septic shock in second week of illness due to inflammatory cytokines. Lab findings reveal lymphopenia, elevated transaminases, CRP, LDH, D-dimer, serum Ferritin, and Troponin-T with most common imaging finding being bilateral peripheral lower lung zone ground glass opacities on HRCT chest. RT-PCR of nasopharyngeal or oropharyngeal swab confirms the diagnosis. There is no magic bullet yet to treat COVID-19 with available options of antivirals (Remdesivir) and immunomodulators (Dexamethasone and Tocilizumab). Even with effective vaccine stringent measures like social distancing, mask wearing, and hand hygiene are our only defense against this infection. Effective governance and efficient health sector alone can help combat the pandemic by dispersing the facts and curbing the myths.

Introduction

Twenty-first century saw the advent of several infectious diseases that wreaked havoc on human civilization leading WHO to generate a list of blue print priority[1] diseases including a disease "X" with a pandemic potential to be caused by an organism yet unknown **(Table 1)**.

Soon enough Disease "X" emerged in late December 2019, when a bunch of pneumonia cases with unknown etiology emerged from the local seafood market in Wuhan, capital of Hubei province in China and heralded a global pandemic of zoonotic origin engulfing most countries of the world except the Antarctica continent. The novel pandemic was christened as Coronavirus disease or COVID-19 caused by the *betacorona* virus SARS-CoV-2, closely akin to SARS-CoV-1 (2002) and the MERS (2012). The virus was isolated from human respiratory epithelial

TABLE 1 Blueprint priority diseases by WHO

Blueprint Priority Diseases*
Given their potential to cause a public health emergency and the absence of efficacious drugs, vaccines, or both, there is an urgent need for accelerated research and development for the following diseases: • Crimean–Congo hemorrhagic fever (CCHF) • Ebola virus disease and Marburg virus disease • Lassa fever • Middle East respiratory syndrome coronavirus (MERS-CoV) and severe acute respiratory syndrome (SARS) coronavirus • Nipah and Henipaviral diseases • Rift Valley fever (RVF) • Zika • Disease X

*From the World Health Organization. Known diseases are listed in alphabetical order.

cells and after genomic sequencing was identified as seventh member of the family *betacoronavirus*, subfamily *Orthocoronavirus*, quite similar to bat coronaviruses.[2] This virus has several dynamic facets from causing asymptomatic to critical life threatening respiratory manifestations. Our understanding of COVID-19 has ever been evolving since its emergence. This formidable foe with its contagiousness and virulence abetted by global trade and tourism was declared a global pandemic on March 11th, 2020, by WHO and continues to be a global threat with both cure and prevention not yet distinctly visible (at the time of writing this chapter). Combating this malevolent virus requires sifting of facts from myths by means of worldwide available accurate scientific information that takes high moral ground and conveys research driven narratives.

Virology, Epidemiology, and Transmission

SARS-CoV-2 is a positive sense ssRNA enveloped virus with viral spike(S) peplomers, belonging to the human *betacoronavirus* family, order Nidovirales, and subgenus Sarbecovirus similar to SARS-CoV-1 and MERS but a different clade.[2] The S protein contains the region that binds the human-angiotensin converting enzyme 2 receptor ACE-2 (h-ACE2) receptor on respiratory epithelial cells.[3] Phylogenetic analysis[4] of the virus revealed two different strains designated as the L type (70%) and S type (30%). High viral titers are detected in nasopharyngeal secretions in the early phase of illness (in first week post exposure) and decline after that.[5] Virus is also detected in other body fluids such as blood, saliva, semen, and stools but role in transmission is unclear.[6] The virus after its initial emergence in Wuhan, spread rapidly across whole of China and to Italy, Iran, Japan, South Korea, the US, and across the globe by means of community transmission and super spreading events. It predominantly affects middle aged adults and elderly and males.[7] Though no gender or age group has been spared. Usually respiratory coronavirus outbreaks are seen during winter in northern hemisphere but in some parts of the world like Thailand they persist throughout the year, whereas SARS-CoV-2 shows no such seasonality.

Early transmission dynamics revealed the major mode of transmission to be large droplet mediated direct person to person (within ~6 ft distance) as well as through direct contact with contaminated surfaces. Aerosol (droplets of size 20–500 μm) transmission is a major mode of transmission to health care workers in hospital settings.[8] Airborne and animal to human transmission is yet debatable. SARS-CoV-2 has a median survival of ~1.1–3 hours in aerosol and up to 72 hours on inanimate objects.[9] Asymptomatic or pre-symptomatic viral shedding is the major mode of disease transmission since, serial interval (SI) (mean 5.8 days) is shorter than the incubation period (IP). Infectiousness begins 2.3 days before symptom onset (pre-symptomatic transmission), peaks 0.7 day before symptom onset and declines within 7 days.[10] Shorter SI (SI<IP), higher reproductive numbers (R0: 2.2–2.7 in initial phase) and secondary attack rate of up to 15%[11] make the virus highly contagious and difficult to contain.

Pathogenesis

SARS-CoV-2 virus enters human respiratory epithelial cells through attachment of its spike (S) protein to the h-ACE2, similar to SARS-CoV-1 aided by cellular protease TMPRSS2. This is followed by the initial replicative phase and phase of innate immunity in the early phase causing influenza like illness with mild symptoms due to direct cytopathic effect of the virus. If no intervention occurs at this stage, it leads to phase of adaptive immunity leading to massive cytokine release syndrome and complications like acute respiratory distress syndrome (ARDS) and multi-organ dysfunction.[12]

TABLE 2 Stages of severity of COVID-19 infection

Mild	*Moderate*	*Severe (14%)*	*Critical illness (5%)*
Fever and/or uncomplicated upper respiratory tract infection without dyspnea or hypoxemia	• Pneumonia with no signs of severe disease • Chest X-ray: Bilateral lung infiltrates involving <50% of lung fields • RR ≥24/min • SpO_2 <94% on room air	• Severe respiratory distress requiring mechanical ventilation (invasive or noninvasive) • Chest X-ray: Bilateral lung infiltrates involving ≥50% of lung fields • RR ≥30/min • SpO_2 <90% on room air	• Rapidly progressive Type 1 respiratory failure • Sepsis and septic shock • Multi-organ dysfunction (MODS) • Altered mental status

Clinical Features

Asymptomatic Infection

This has been well documented in several studies to an approximate magnitude of 30–40% across the globe but not systematically studied.[13] Objective findings on HRCT chest are seen even with asymptomatic infection. Several of them develop symptoms (they are pre-symptomatic) over the period of 3–7 days.[14]

Spectrum of Illness (Table 2)

It ranges from mild to severe and critical illness. The overall case fatality rate is 2.3% with no fatality in mild cases.[15] High case fatality has been documented in those with multiple underlying comorbidities.

Clinical Signs and Symptoms (Table 3)

IP is 14 days[16] (median IP is 5.1–5.2 days) with interquartile time (IQT) of 2–7 days implying dispersion of 50% cases in this period.[17] Though predominantly a respiratory pathogen SARS-CoV-2 has myriad extra-pulmonary manifestations.

Clinical course of COVID-19: Patients infected by the SARS-CoV-2 virus develop symptoms usually after a mean IP of 5.1–5.2 days (14 days) and majority (80%) recover without further progression or complications. Amongst the hospitalized patients 40% progress to develop dyspnea after 7 days of symptom onset and yet a minority (14%) and (5%) progress to develop severe and critical illness respectively after approximately 10 days of symptom onset **(Fig. 1)**.[20]

Laboratory findings **(Table 4)**:[21] Most common lab findings in COVID-19 are severe lymphopenia, elevated aminotransferases, CPK, Troponin T, and elevated inflammatory markers like CRP, serum LDH, Ferritin, IL-6, and D-dimer. They are associated with worse prognosis and mortality.

TABLE 3 Clinical spectrum of COVID-19: Constitutional, pulmonary and extrapulmonary

General[18]
• Cough (50%)
• Fever (43%), subjective or >100.4°F/38°C; course may be prolonged and intermittent
• Myalgia or Fatigue (36%)
• Headache (34%)
• Dyspnea (29%)
• Sore throat (20%)
• Diarrhea (19%)
• Nausea and Vomiting (12%)
• Loss of taste (dysgeusia) or smell (anosmia) (<10%); possible symptom in early infection, but not distinctive of COVID-19, may also be seen with other viral infections
• Abdominal pain & rhinorrhea <10% each
Extrapulmonary[19]
Cardiac: Takotsubo cardiomyopathy, Myocardial injury/myocarditis, Cardiac arrhythmias, Cardiogenic shock, Myocardial ischemia, Acute cor pulmonale
Thromboembolism: Deep vein thrombosis, Pulmonary embolism Catheter-related thrombosis
Renal: Acute kidney injury, Proteinuria, Hematuria
Neurologic: Headache, Dizziness, Encephalopathy, Guillain-Barré, Ageusia, Myalgia, Anosmia, Stroke
Gastrointestinal: Diarrhea, Nausea/vomiting, Abdominal pain, Anorexia
Endocrine: Hyperglycemia, Diabetic ketoacidosis
Dermatological: Petechiae, Livedo reticularis, Erythematous rash, Urticaria, Vesicles, Pernio-like lesions (COVID TOE)

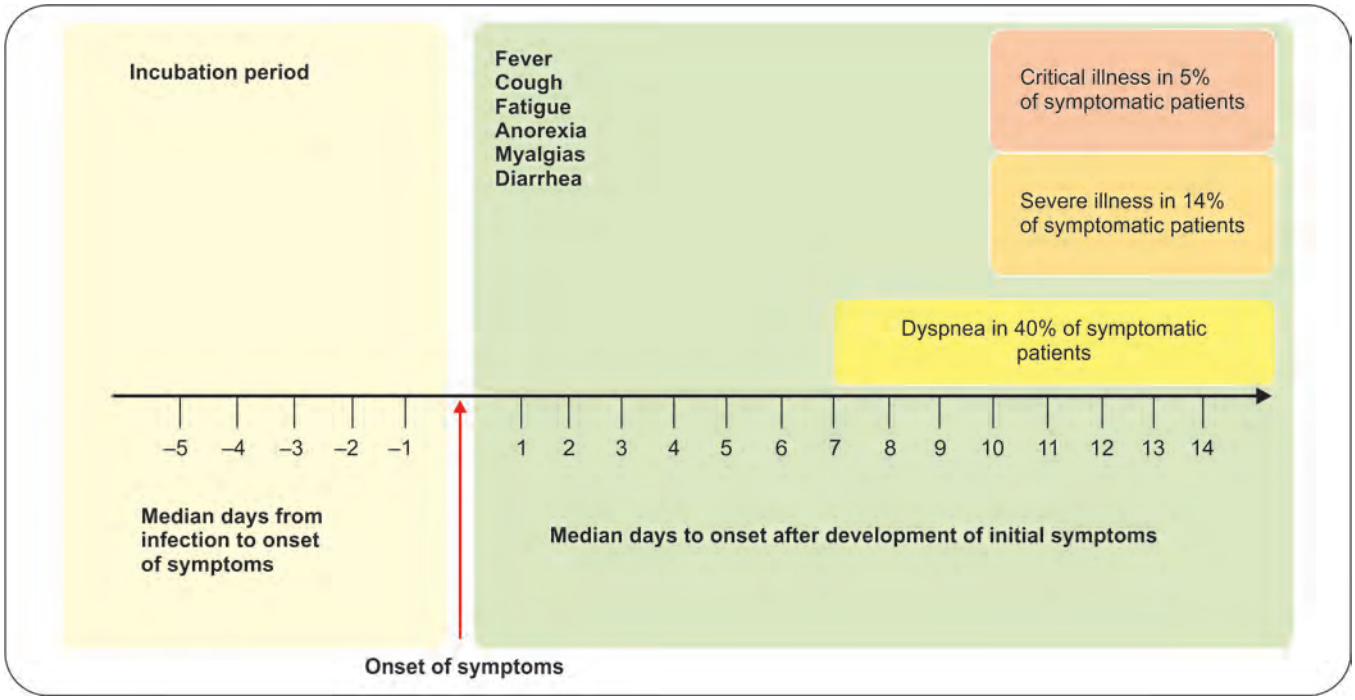

Fig. 1: Timeline of symptoms of coronavirus disease (COVID-19)

TABLE 4 Laboratory findings in COVID-19

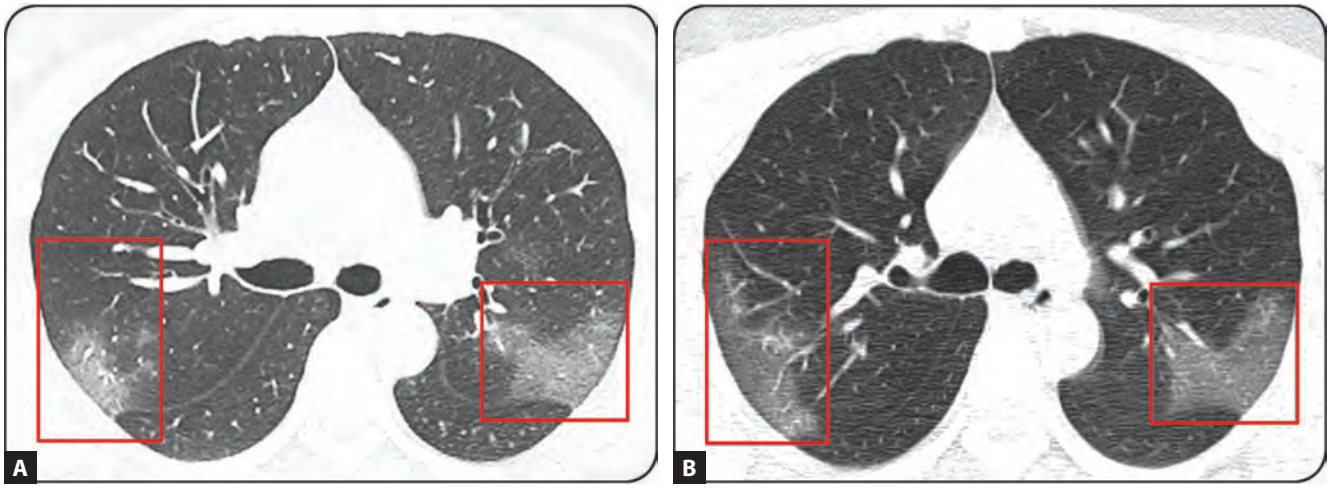
Laboratory findings
• Leukopenia, Leukocytosis, and Lymphopenia (N:L Ratio 3.1)
• **absolute lymphocyte count < 0.8 × 10^9/L**
• Elevated Aminotransferases
• Elevated Procalcitonin (remains low in first 7–10 days; can rise later without sepsis)
• Elevated CRP (**>10 times normal** implies poor prognosis)
• High D-dimer (**>1 µg/mL** implies poor prognosis)
• Elevated Troponin T-mortality is higher in patients with elevated TnT (59.6% vs. 8.9%)
• Elevated CPK (**Twice the ULN** implies poor prognosis)
• Elevated IL-6
• Decreased Albumin
• Elevated LDH (**>245 U/L** implies poor prognosis)
• Ferritin **>500 µg/L**

Imaging:

- Chest X-ray: During early or mild phase of the illness chest radiographs are normal. Common abnormal findings are consolidation and ground glass opacities in bilateral, peripheral lower lung fields with a peak in severity 10–12 days post-symptom onset.[22]
- HRCT Chest: In a systematic review by *Bao et al.*[23] of 2,700 patients of COVID-19 most common abnormalities were ground-glass opacifications (83%), ground-glass opacifications with mixed consolidation (58%) and adjacent pleural thickening (52%) followed by interlobular septal thickening (48%) and air bronchograms (46%). Less common findings are crazy paving pattern, bronchiectasis, pleural effusion, pericardial effusion, and lymphadenopathy **(Figs. 2A and B)**.

Risk factors for severe disease **(Table 5)***:* These include epidemiological, clinical, and laboratory factors. Age is a major factor impacting case fatality; with mortality rate being 8% and 15% amongst those aged 70–79 years and ≥80 years respectively according to a report from the Chinese Centre for Disease Control and Prevention. Other factors are:[24]

Complications of COVID-19: Major complications of COVID-19 are ARDS in almost 17–29% cases developing at a median of 8 days post-symptom onset in most cases;[25] acute kidney injury, cardiac complications



Figs. 2A and B: HRCT images showing bilateral ground glass opacities (GGO's) in peripheral lower lung zones

TABLE 5 Underlying risk factors and prognostic factors of COVID-19

Epidemiological category 1	*Vital signs category 2*	*Labs category 3*
Age ≥65 years	Heart rate >125/min	Admission absolute lymphocyte count <0.8 × 10^9/L
Pre-existing pulmonary disease	Respiratory rate >24/min	LDH >245 U/L
Chronic kidney disease	PaO_2/FiO_2 <300 mm Hg	CRP >100
Diabetes with HbA1c >7.6%	SpO_2 ≤94% on room air	CPK >Twice the ULN
History of hypertension		Elevated troponin T
History of cardiovascular disease		D-dimer >1,000 ng/mL
Obesity (BMI ≥30 kg/m^2)		Ferritin >500 µg/L
Use of biologicals		
History of transplant or other immunosuppressive medications		
Uncontrolled HIV (Viremic or CD4 <200)		

like cardiomyopathy (33%), arrhythmias (17%), acute cardiac injury (7%), and shock (9%);[25] thromboembolic complications such as pulmonary thromboembolism and acute cor pulmonale, acute stroke; inflammatory syndromes such as cytokine release syndrome and multisystem inflammatory syndrome; secondary bacterial and fungal infections (8%);[26] sepsis, septic shock, MODS, and DIC; coagulopathy; and APLA and CNS encephalitis. Cytokine release syndrome (CRS) is the most devastating complication characterized by increased levels of inflammatory cytokines such as IL-6, TNF-α, and IL-10 and activation of T lymphocytes, macrophages, and endothelial cells leading to fever and multi-organ dysfunction. Severe form of CRS needs rapid intervention with steroids and immunomodulators such as Tocilizumab[27] (anti IL-6 antibody).

Differential Diagnosis[28]

COVID-19 pneumonitis must be differentiated from other respiratory infections like bacterial, fungal, and viral pneumonias (influenza, parainfluenza, rhinovirus, other coronavirus, human metapneumovirus, adenovirus, etc.). Most of these have similar clinical and laboratory features and only molecular test can clinch the diagnosis.

Diagnosis

COVID-19 cannot be definitively distinguished from other respiratory viral illnesses based merely on clinical symptoms and laboratory findings. A high clinical suspicion in people presenting with respiratory tract symptoms as well as those who have resided in or travelled from areas of community spread as well as those who have had close contact with a suspected or confirmed case must be subjected to testing **(Table 6)**. Tests currently approved by the FDA are molecular tests such as RT-PCR which are confirmatory and serological tests have been approved under emergency usage. Viral cultures are not recommended. Rapid antigen tests though easy to perform are not recommended due to high false positive and negative rates.

RT-PCR of nasopharyngeal swab specimens has a sensitivity of ~63%, depending on assay used, sample procurement method and stage of illness.[29] False-negative rates[30] have ranged from <5% to 40%. Hence, negative results must be correlated clinically and if suspicion is high the test may be repeated after 24–48 hours after the initial negative result. Lower respiratory tract samples such as BAL yield better results. The test yield of RT-PCR is maximum from day 1–3 of symptom onset.

TABLE 6 Triage for ensuring optimal testing in COVID-19

Triage testing
PRIORITY 1: Ensure optimal care options for all hospitalized patients, reduce the risk of nosocomial infections and maintain integrity of the health care system: • **Hospitalized patients** • **Symptomatic health-care workers**
PRIORITY 2: Ensure rapid identification and appropriate management of those who are at highest risk of complications of infection: • **Patients in long-term care facilities with symptoms** • **Patients ≥65 years of age with symptoms** • **Patients with underlying conditions with symptoms**
PRIORITY 3: If resources allow, test individuals in the surrounding community of rapidly increasing hospital cases to decrease community spread and ensure health of essential workers: • **Critical infrastructure workers with symptoms** • **Individuals who do not meet any of the above categories with symptoms** • **Health care workers and first responders** • **Individuals with mild symptoms in communities experiencing high COVID-19 hospitalizations**
NON-PRIORITY: Individuals without symptoms

The reliability of *serological tests* depends on the duration of illness, seroprevalence and specific assay. According to a study, serological response in the form of IgM occurs after median of 5 days and IgG after 14 days of symptom onset.[31] Useful when patient presents after 2 weeks into the illness, when RT-PCR is negative. A positive test for IgM and IgG is diagnostic for COVID-19, but a negative result does not rule out the disease. False positive results may be obtained due to past or present infection with non-SARS-CoV-2 coronavirus strains, such as HKU1, NL63, OC43, or 229E. Thus, serological tests should not be used as confirmative tests and must be interpreted with caution.

Management of COVID-19 (Fig. 3)

Outpatient

Suspected and mild cases can be managed on an outdoor basis by telemedicine and home isolation along with good hand and respiratory hygiene. Since, 80% cases are asymptomatic or have mild to moderate illness which can be managed on an outpatient basis, thereby reducing the burden on our already pummeling health system. Home isolation is recommended for 10–14 days post-symptom onset and post-positive test result in symptomatic and asymptomatic individuals respectively.

Hospitalized Patients

- General measures include oxygenation, hemodynamic resuscitation, and awake prone positioning. Empirical antibiotics are not recommended unless there is evidence of coexisting bacterial or fungal infection. Statins and ACEI and ARBs to be continued if already prescribed. Prophylaxis for thromboembolic complication is mandatory. Steroids to be used in patients who need supplemental oxygen early in the course of illness.
- Specific treatment: Include *Antivirals* and *Immunomodulators*. None of them are a recommended specific therapy though and are under trials. Like influenza antivirals if effective need to be initiated early in the course of illness. Drugs are as follows:

Hydroxychloroquine/Chloroquine: Prevents binding to ACE-2 receptors, interferes with cellular acidification in the phagolysosome and blocks endosomal transport.

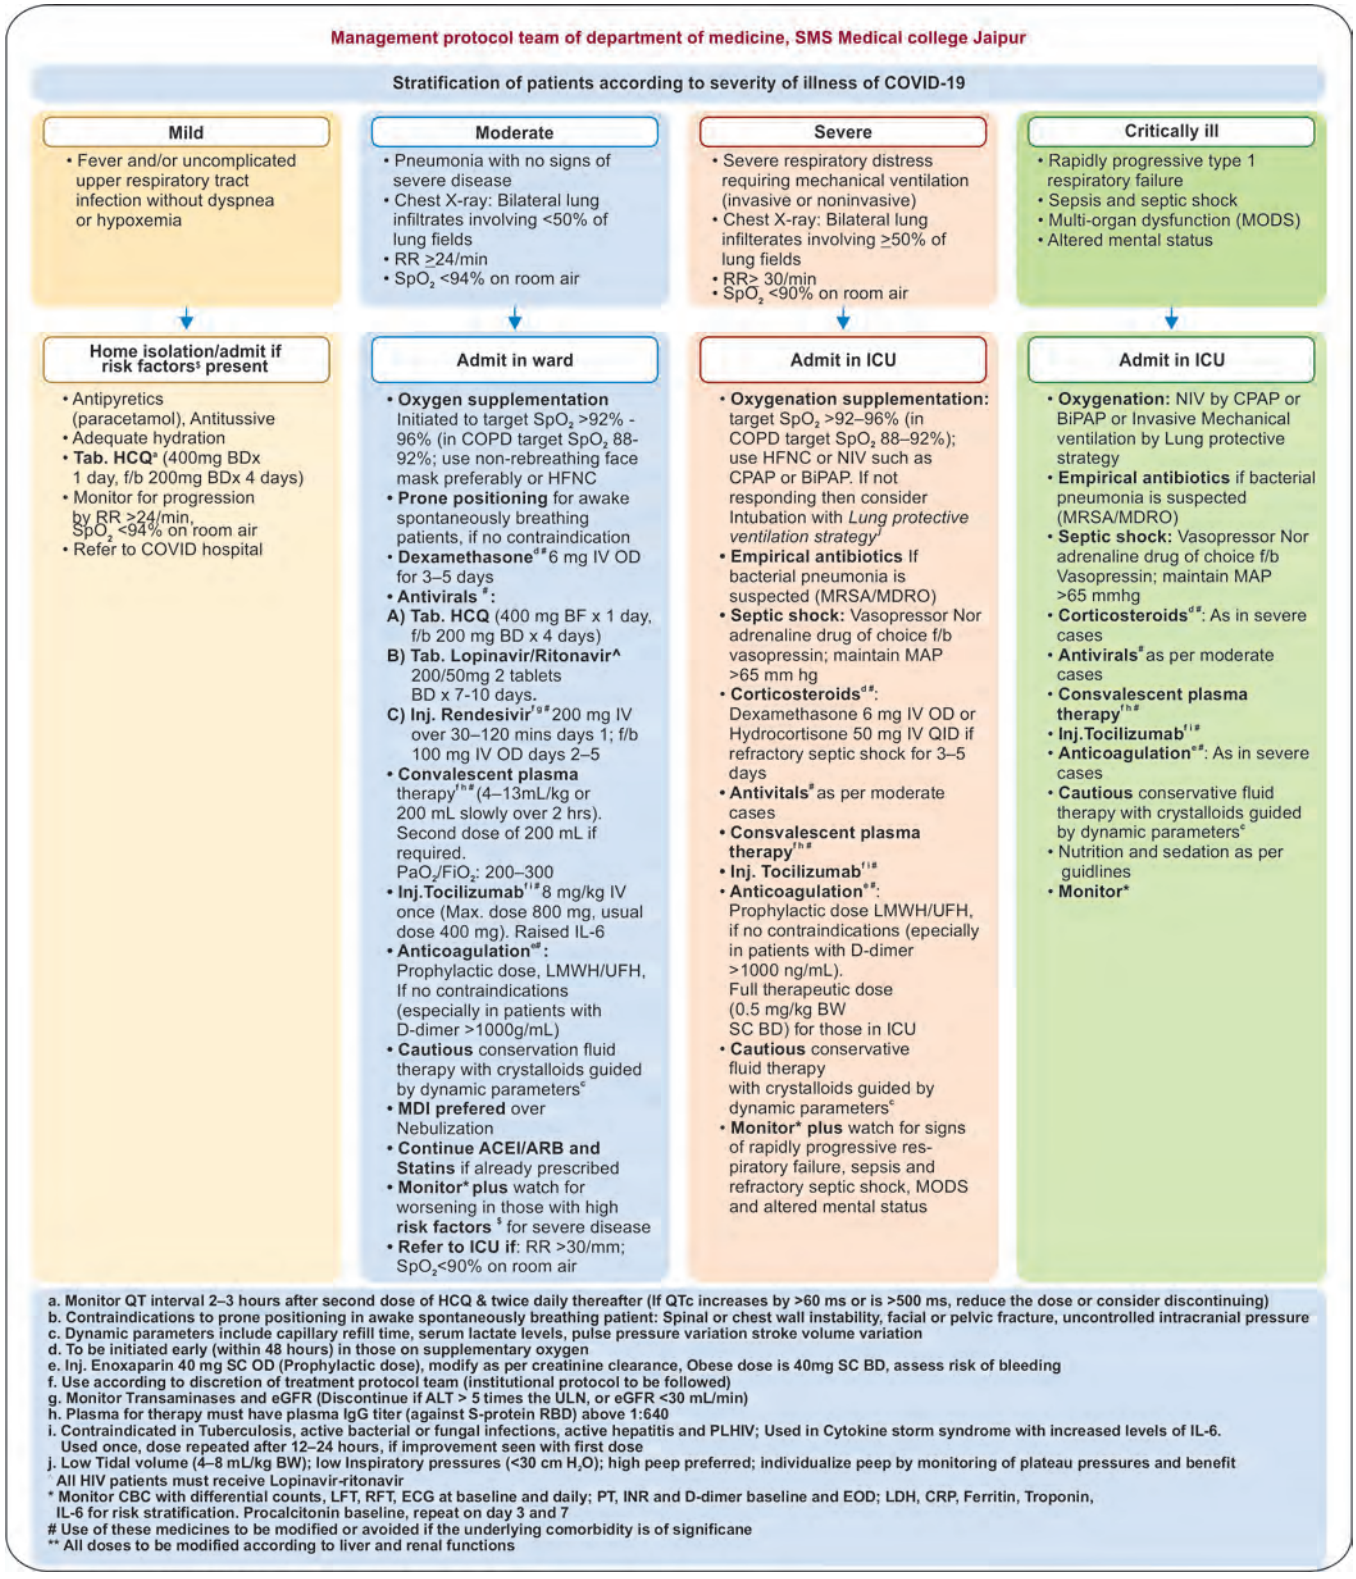


Fig. 3: Management of COVID-19: Institutional protocol

Very low quality evidence for treatment of COVID-19. May cause QT prolongation and needs monitoring. A large multicentre study[32] concluded that use of a regimen containing hydroxychloroquine (HCQ) or chloroquine (with or without a macrolide) was associated with no evidence of benefit, but instead was associated with an increase in the risk of ventricular arrhythmias and a greater hazard for inhospital death with COVID-19. As per ICMR recommendations, it should be used in moderate to severe and critically ill and in mild cases associated with comorbidities like elderly, DM, hypertension, CKD, and others mentioned earlier in the chapter. About 821 individuals were randomly assigned to HCQ or placebo folate within 4 days of a household or occupational exposure to SARS-CoV-2 in a double-blind trial,[33] HCQ did not reduce the rate of RT-PCR confirmed COVID-19 or consistent symptoms within 14 days (11.8 vs. 14.3% with placebo).

Lopinavir-ritonavir: A randomized controlled trial[34] in hospitalized adults who also received other medications yielded no benefit but was given relatively late in the disease course. May be considered in moderate to severe cases, especially in those with multiple comorbidities and HIV patients.

Remdesivir: It was used in treatment of Ebola. It is a nucleotide analogue that inhibits viral RNA polymerase with in vitro activity against SARS-CoV-2 and MERS. A placebo-controlled, double-blind, randomized trial[35] of IV Remdesivir in hospitalized adults with COVID-19 pneumonitis concluded that Remdesivir was better compared to placebo in shortening the time to recovery in patients with COVID-19 pneumonitis. It is recommended that if available it should be used in severe and critical cases of COVID-19. Combination with HCQ is not advisable due to adverse drug interaction.

Favipiravir: Anti-influenza drug, RNA polymerase inhibitor which is available in India for treatment of mild COVID-19. In a study[36] use of Favipiravir in patients with mild disease was associated with rapid rates of viral clearance and radiographic improvement as compared to Lopinavir-ritonavir.

Interferon beta: In one open-label randomized trial from Hong Kong,[37] in 127 adults hospitalized with nonsevere COVID-19 use of INF-β within 7 days of symptom onset along with Ribavarin and Lopinavir-ritonavir was associated with early recovery and viral clearance. It needs further study, and is currently under evaluation in the WHO "*SOLIDARITY*" trial.

Immunomodulators (Tocilizumab): An FDA approved anti-IL6 agent for CAR-T cell cytokine release syndrome. It is more effective if used early in ARDS before more advanced lung and multi-organ dysfunction sets in. An unpublished study from China of 21 severe and critically ill patients concluded that use of Tocilizumab was associated with improved oxygenation, better CT findings, and survival in 1 week. Other immunomodulators under study are Sarilumab, Anakinra, and Siltuximab.

Convalescent plasma therapy: FDA approved for use in severe and critical COVID-19 cases. Early usage in treatment within 5–6 days of symptom onset is advocated before patients own antibodies form. Eligibility of donor includes age ≥18 years, male or nulliparous female >55 kg weight, prior RT-PCR documented diagnosis, and complete resolution of symptoms at least 28 days prior to donation or 14 days prior to donation with two negative RT-PCT results 24 hours apart. A randomized controlled trial[38] among patients with severe and critical COVID-19 convalescent plasma therapy added to standard therapy versus standard therapy alone did not result in a statistically significant improvement in time to clinical improvement within 28 days. Adverse events include pathogen transmission, allergic reactions, transfusion-related acute lung injury, and circulatory overload. To be avoided in those with IgA deficiency and immunoglobulin allergy.

Intravenous immunoglobulin (IVIg): Pooled IVIg reduces inflammation via multiple mechanisms such as lessening interrupting complement cascade and reducing activated CD4+ and CD8+ T-cells. It has been proposed in viral mediated lung injury or ARDS due to disordered regulatory T-cell hyperimmune response. It needs further studies.

Prevention

Numerous vaccines are being evaluated including viral-vector vaccines, nucleic acid-based (DNA and mRNA) vaccines and inactivated or recombinant protein vaccines. Impact of *BCG immunization*[39] on COVID-19 is unknown; hence, its use in COVID-19 is not recommended by WHO.

Prognosis

Recovery from the illness and its long-term sequelae depend on age, underlying comorbidities, and severity of illness. According to WHO, mild cases recover in 2 weeks and severe cases recover in 3–6 weeks.[40] The overall global mortality of COVID-19 is 3.4% as of March 3rd 2020. The mortality rate attributed to SARS-CoV-2 is less than that commonly ascribed to community acquired pneumonia (12–15%), but more than seasonal influenza (~0.1%). Critically ill COVID-19 cases face the perils of post-intensive care syndrome (persistent impairments in mental health, physical function, and cognition), although the incidence is unknown.

Conclusion

Escalated globalization, expanding human population, increasing human-animal interactions, altered ecosystems clubbed with viral genetic recombination, mutation, and reassortment have led to emergence of several novel pathogens that have wreaked havoc on not just the global economy but on the very existence of a healthy life. The emergence of global pandemic of COVID-19 exposed the Achilles heel of our preparedness toward unanticipated epidemics and pandemics despite use of spatial epidemiology or mathematical models to predict such emerging and re-emerging pathogens. In an era of universal distrust and rising global tension with overload of information it becomes imminent that we as medical fraternity aid the public in sifting out facts from myths by sceptically scrutinizing every bit of life saving scientific research that is disseminated globally without ourselves getting swindled by availability bias. Rising global panic, financial market hysteria, constantly evolving data on SARS-CoV-2 with misinformation has only made this petrifying pandemic more grim. Our only bastion of defense in this conundrum is worldwide dissemination of truthful and accurate scientific data. The knowledge of the disease is changing so fast that what seems true today, might not be so in the future.

CHAPTER

3 Hydroxychloroquine for Cytokine Storms: Pros and Cons

Daya Kishore Hazra, Padmamalika Khanna nee Hazra, Ratnamalika Kumar, Suratwant Hazra

Abstract

Hydroxychloroquine is a most economic therapeutic agent with a proven track record in rheumatoid arthritis, systemic lupus erythematosus, and for the last 6 years in Diabetes Mellitus. Its clinical value in abating or preventing the cytokine storm in COVID-19 is a subject of controversy: in India we continue to use this agent both for prevention and for management albeit Western reports on arrythmias have installed a caution in its use if there is QT prolongation. Possible mechanisms of its action in correcting inflammation and hyperglycemia are discussed. Like corticosteroids and ivermectin, hydroxychloroquine is likely to remain a part of the low cost anti COVID-19 strategies.

Introduction

One of the most keenly argued facets in the context of Coronavirus Disease 2019 (COVID-19) is the use of hydroxychloroquine (HCQ/HYQ) for management or prophylaxis, and this is evidenced by sharp swings in WHO/FDA recommendations as well as the marked divergence between advisories and regimes in different countries.[1-15] ICMR continues to approve the prophylactic use of this in asymptomatic healthcare workers/ surveillance workers and asymptomatic contacts of laboratory confirmed cases.[2] It has been in use since 1955 in rheumatoid arthritis and lupus, and figures in the WHO Essential List of Medicines. The Central Drugs Standard Control Organization approved its use in rheumatoid arthritis in 2001, polymorphic light eruptions in 2006, lupus erythematosus in 2008 and diabetes mellitus in 2014. Its action was regarded as anti-inflammatory. When the COVID-19 pandemic emerged it was suggested as of being of possible benefit both for prophylaxis as well as for treatment.

However, some reports suggested that it predisposes to cardiac arrhythmia by causing QTc prolongation and even Torsades de Pointes—a dangerous disorder. This led to various recommendations for prior QT assessment before instituting chloroquine/HCQ demarcating green/ orange/red zones for use analogous to traffic signals.[16-18] Because HCQ had often been used with azithromycin in COVID-19, and azithromycin had itself been incriminated for sometimes causing QT prolongation, the combined use of these two was especially controversial.

But HCQ had been used in rheumatoid arthritis for 65 years, and in diabetes for the last decade and had not been cited for causing rhythm disorders. The anti HYQ article in the Lancet which led to the WHO initially suspending the HCQ arm of the solidarity anti COVID trials was discovered to be based on dubious data by Surgisphere, and was subsequently retracted. The WHO resumed this arm after this retraction, but again suspended this arm after UK reports about the lack of benefit by HCQ. Some of the anti HCQ comments were allegedly related to pressure by the makers of more expensive anti COVID

drugs[19] as well as the political controversies aroused by the endorsement of HCQ by the US President! The recent FDA withdrawal of permission for the use of HYQ[7] was based on a randomized trial on postexposure prophylaxis,[8] showing lack of benefit, but not cardiac rhythm disorders.[8]

We have suggested that a detailed analysis of the experience of persons on prior HCQ use for diabetes or rheumatoid arthritis during the pandemic should be rewarding.[20]

Chloroquine has an even longer history of use as an antirheumatoid and antimalarial drug as compared to hydroxychloroquine, but HYQ has overshadowed it as its hydroxyl group limits the crossing of the blood retinal barrier and further, HCQ clears faster from the retinal pigment cells and accumulates less than chloroquine. An ophthalmological cohort of 526 patients showed no retinopathy in the first 6 years, and 0.5% after 8.7 years.[21,22]

HCQ as an Anti-inflammatory Reagent

The anti-inflammatory action of HCQ has been attributed to inhibiting the formation of the cytokines IL1, IL6, and TNF alpha, reducing C reactive protein, inhibition of leukocyte migration, and activation, as well as of prostaglandin synthesis and an antiplatelet effect.[23,24] It also inhibits nitric oxide and extracellular oxidant production from neutrophils and macrophages.[25,26]

The cardiovascular effects of HCQ in the diabetes context, which include lowering of cholesterol[27] both total and LDL, lowering of triglycerides, and antiplatelet, antithrombotic, and antihypertensive effects are worth recalling in the context of its alleged cardiovascular deleterious effects in COVID-19.

Postulated Mechanisms of Action of HYQ in COVID-19

HYQ causes alkalization of the intracellular milieu. This inactivates the insulin degrading enzymes making it released from the cell ready to act again.

Patients with diabetes, elevated BMI, high cortisol levels have a higher mortality rate in COVID! Diabetes is the most prevalent comorbidity in COVID-19, second only to obesity!

Hyperglycemia Worsens Viral Respiratory Diseases

Hyperglycemia increases glucose content of airway secretions, increases influenza virus infection in vitro in pulmonary epithelial cells, increases vascular permeability, and a collapsed alveolar epithelium in the lungs, and may suppress the antiviral immune response.

The role of anti-inflammatory agents including HCQ in management of diabetes type 2 has been recently reviewed.[28]

Postulated mechanisms of action of HYQ in COVID-19 other than anti-hyperglycemia action are also related to its rendering the cytosol alkaline. The increased pH of the endosomes and lysosomes inhibits endolysosome function prevents the fusion of virus with the host cells and subsequent replication.[7] HCQ also enters the antigen presenting cells and prevents autoantigen presentation to T cells. It attenuates the possibility of the cytokine storm by inhibiting the transcription of pro inflammatory genes. HYQ interferes with terminal glycosylation of ACE 2 and reduces binding of spike protein coronavirus to host cells.

The beneficial actions of HCQ in human disease according to a Pub Med search through MESH is multifaceted including diabetes mellitus, dyslipidemias, coagulopathies, infectious diseases, and malignancies may have multiple mechanisms, including altered signaling through cellular receptors, post-glycosylation modifications of infectious agents, changes in levels of inflammatory mediators, and inhibition of autophagy.[29] Since COVID-19 behaves like an infectious agent induced inflammatory coagulopathy with hyperglycemia and cytokine release, several of these actions can be involved!

Dosage

Hydroxychloroquine dosage recommended has varied. The ICMR national task force on 22/5/2020 suggested 400 mg twice daily on Day 1, followed by 400 mg once weekly for next 7 weeks to be taken with meals for asymptomatic health-care workers involved in care of suspected or confirmed COVID cases. The same regime was advised for asymptomatic household contacts of laboratory confirmed cases. This also can be used weekly beyond 8 weeks with strict monitoring of clinical and EKG parameters under medical supervision.[2]

For patients the AIIMS COVID-19 preparedness Document Version 1.3 dated 10th June, 2020, suggests 400 mg BD × 1 day followed by 400 mg OD × 4 days for high-risk cases testing positive. For moderate disease, AIIMS suggests to consider 400 mg BD for 1 day, then 400 OD × 4 days.[5] Exclusions/contraindications include retinopathy/hypersensitivity/G6PD deficiency/preexisting cardiomyopathy and cardiac rhythm disorders. Rarely the drug causes a self limiting blurring of vision which improves on discontinuation of the drug.

Role of HCQ in Cytokine Storm

Whether HCQ is of value in the prevention or control of cytokine storms in COVID is most important to consider! The jury is still out!

A number of agents are now in use in the prevention and/or treatment of the cytokine storm. Corticosteroids are the sheet anchor of therapy and prevention, and a dropping pO_2 measured by a pulse oximeter is an early indicator of silent hypoxia. Other acute phase reactants that are looked for include elevated Trop T, C reactive protein, ferritin, D dimer, neutrophil/lymphocyte ratios. High resolution chest CT has now been supplemented by chest X-ray to diagnose lung involvement,[30] and artificial intelligence is being explored to enable remote diagnosis on the chest X-ray (Shukla AK: Personal Communication).[31]

Since immunosuppressive drugs are of value in therapy, but also can promote infections there was an initial apprehension that during prophylaxis HCQ immunosuppressive action may even promote infection?

However, today in India HYQ is being used for immunoprophylaxis,[2,5] except in subjects with contraindications such as cardiac arrhythmias or QT prolongation.

Whether HCQ can prevent cytokine storms is moot as evident from the variety of opinions.[1-15]

The respiratory syndrome in HCQ is now categorized into H and L subtypes—the former with water logging, which usually demands ventilation and the latter without waterlogging in which ventilation can damage the lungs!

Tocilizumab blocking interleukin 6, Kineret (Anakinra) blocking interleukin 1, Prazosin an alpha blocker, which blocks IL6 production by interrupting a self amplifying feed forward loop, Calquence (acalabrutinib), which blocks cytokine production by inflammatory macrophages. Remdesivir and Favipiravir are all under evaluation both for the cytokine storm, and even more important, for reducing viral RNA production.

Another approach is extracorporeal adsorption of cytokines using cartridges such as CYTOSORB/DEPURPO and OXIRIS: these are expensive but Indian analogues patented by our group for endotoxin removal need to be developed![32] These can be used in series with ECMO-extracorporeal membrane oxygenators.

Other agents being evaluated are herbs such as Turmeric, Tinospora cordifolia (Giloy), Ashwagandha (Withania somnifera), Cinnamon, and Boswellia.

Ultraviolet blood irradiation biophotonic therapy, rapamycin, low dose lung irradiation, nicotine, electroacupuncture, Cox 2 inhibitors, ibuprofen are other approaches that have been suggested!

The hypotension is managed by inotropes: noradrenaline being preferred to dopamine.

Azithromycin and doxycycline are antibiotics that have been used.

There are Australian and Bangladesh reports on the use of ivermectin to prevent or treat COVID infection.

Convalescent serum and injectable hyaluronidase and niacin are beneficial in anecdotal cases.

BOX 1 Changing clinical pictures and multi-system features

Observing the changing clinical picture of the COVID pandemic, from a flu-like lung illness to a multisystem picture, one is reminded of Lorraine Daston's historical perspective[33]

To quote her,

Historically:

It's natural to cast about for answers at the dawn of a pandemic

"At moments of extreme scientific uncertainty"

"Observation, usually treated as the poor relation of experiment and statistics in science, comes into its own"

Confronting a new disease, doctors have no choice but to turn to "suggestive single cases, striking anomalies, partial patterns"

Slowly, as our ideas about "what works and what doesn't" help tell us "what to test, what to count," the picture clarifies

Until then, "we are back in the seventeenth century, the age of ground-zero empiricism, and observing as if our lives depended on it"

One patient at a time, we have to work our way into the present!

Conclusion

The value of HCQ in preventing and treating COVID-19 is being extensively evaluated, ever since the French report and the US Presidents advocacy.

India which produces the majority of the world's HCQ was recently extolled and thanked for making it available to countries around the world, including the USA, Brazil, and African countries.

Its inexpensive character suggests that, like corticosteroids, it will play an important role in the COVID pandemic, albeit with care, prudence, and cautious medical supervision including periodic QT measurement from ECG or monitors.

The changing clinical picture especially the multisystem involvement including: gastrointestinal, neurological, renal, endocrine, and dermatological presentations is discussed in **Box 1**.

CHAPTER

4 Hematological Manifestations of COVID-19

Sudhir Mehta, Nidhi Sharma

Abstract

COVID-19 disease has prominent manifestations on the hematopoietic system. Complete blood count parameters that may assess the worsening of COVID-19 infection are: absolute neutrophilia, absolute decrease in lymphocyte count, absolute decrease in monocyte count, and an increase in neutrophil to lymphocyte ratio (NLR). In addition, the coagulation system needs to be evaluated by regularly monitoring of hemostatic markers—D-Dimer, prothrombin time, and platelet count—in all patients presenting with COVID-19. Risk stratification for venous thromboembolism should be performed for all inpatients with COVID-19. In the absence of contraindications, the vast majority of inpatients, including with severe COVID-19 should receive prophylactic anticoagulation. Delay in recognizing the hematological manifestations may have a negative impact on the clinical conditions and outcomes of patients, especially those with more aggressive diseases.

Introduction

On 11th March 2020, Dr Tedros Adhanom Ghebreyesus, WHO Director-General, declared COVID-19 as a pandemic. As we stand today, COVID-19 has spread globally. The Coronavirus Study Group of the International Committee on Taxonomy of Viruses named the etiologic agent of COVID-19 as "Severe Acute Respiratory Syndrome related Coronavirus 2", or SARS-CoV-2.[1]

The lungs are the initial target organ for COVID-19. However, the infection has a significant impact on the hematopoietic system and hemostasis. The involvement of hematopoietic system in patients with novel coronavirus pneumonia was brought to light by Guan et al.[2] This was followed by a series of case reports and papers further highlighting the involvement of hematopoietic system in the pathogenesis of COVID-19.

It is very important to analyze the hematological parameters critically to pick up the essential diagnostic and prognostic information. The effect on each lineage and the various hemostatic mechanisms is discussed here.

Effect on Neutrophils

Neutrophilia has been described in most of the COVID-19 patients. The median peak absolute neutrophil count (ANC) impacts the possibility of ICU admission (11.6×10^9/L in ICU patients as compared to 3.5×10^9/L in the non-ICU group (P value < .001).[3] Rather, than the absolute neutrophil count; an elevated neutrophil to lymphocyte ratio (NLR) correlates more with pneumonia progression.[4] In addition, the myeloid series shows a left shift, which is manifested in the peripheral blood as a leukoerythroblastic picture.[5]

Effect on Lymphocytes

Earlier in the course of the disease (1–4 days), peripheral blood leukocyte and lymphocyte counts are normal or slightly reduced. Lymphocytopenia sets in 83.2% infected patients around 7–14 days after the incubation period.[2] Nadir of lymphocytes counted on day 7 from symptom onset followed by its restoration serves an important

prognostic marker. Therefore, instead of a single value of lymphocyte count, it is the serial assessment which may be predictive of outcome. In particular, two readings are given importance. If the percentage of lymphocytes is less than 20 at days 10–12 from the onset of symptoms and less than 5 at days 17–19, it depicts as the worst prognosis.[6] Hence, repletion of lymphocytes plays a role in recovery.[7]

The activated lymphocytes are seen morphologically as lymphoplasmacytoid cells (69%).[8] However, there is no change in the $CD4^+/CD8^+$ lymphocyte ratio as depicted by immunophenotyping. Functionally though, impairment of the function of $CD4^+$ helper and regulatory T-cells occurs which promotes an initial hyperactivation of cytotoxic $CD8^+$ T-cells followed by its rapid exhaustion.[9]

Why does Lymphopenia Ensue?

- Expression of the ACE2 receptor on lymphocytes surface causes SARS-CoV-2 to directly infect these cells and causes their lysis.
- Cytokine storm, which sets in later in the disease course, may promote lymphocyte apoptosis and atrophy of lymphoid organs and spleen impacting lymphocyte turnover tremendously.
- Coexisting lactic acid acidosis, in debilitating conditions like cancer puts these patients at an increased risk for complications from COVID-19 by inhibiting the lymphocyte proliferation.[10]

Effect of COVID on Platelets

Thrombocytopenia is not uncommon and has been shown to be present in 36.2% COVID positive patients.[2] A meta-analysis of nine studies has suggested that thrombocytopenia is significantly associated with the severity of the COVID-19.[11] Those presenting with a peak in the platelet count during the disease course also had poorer prognosis. But what has emerged as a stronger parameter than the absolute platelet counts is the platelet to lymphocyte ratio at the time of platelet peak as this may give a reflection of the ensuing cytokine storm.[12]

Coagulation Anomalies in COVID Patients

COVID-19-associated coagulopathy (CAC) is common in patients with COVID-19. CAC manifests as elevated levels of D-dimer (46.4%) and fibrin degradation products, reflecting a highly prothrombotic state.[2] The prothrombin time (PT) and activated partial thromboplastin time (aPTT) are only mildly prolonged. Later, if progressive consumptive coagulopathy continues, there is a decrease in antithrombin III, a rise in PT and aPTT, and further increase of D-dimer (>15.0 µg/mL). Fibrinogen levels are usually high in the initial phase, but returns to normal and decreases further in non-survivors. One study has reported disseminated intravascular coagulation (DIC) in 15 out of 21 non-survivors (8% of the total cohort).[13] **Table 1** summarizes the risk of various complications at different D dimer levels.

TABLE 1 Risk of various complications at different D-dimer levels

D-dimer value	*Risk*
Greater than 0.5 µg/mL	60% of patients with severe disease[2]
D-dimer level of 3.0 µg/mL	Severe disease with a reported sensitivity, specificity, and positive predictive value of 70.0%, 96.7%, and 87.5%, respectively
D-dimer >1 µg/mL vs <0.5 µg/mL on admission	An odds ratio of death of 18.42 (2.64–128.55)
D-dimer >1.5 µg/mL	Increased risk of venous thromboembolism (VTE)[14]
Median D-dimer 2.4 mg/L	Patients requiring ICU treatment

Venous Thromboembolism in CAC

Critically ill COVID-19 patients who do not have any predisposing risk factors for thrombosis can also manifest various thrombotic events including microvascular thrombosis, deep vein thrombosis (DVT) (25%), pulmonary thromboembolism, and acute arterial thrombosis (31%).[14,15] The reported incidence of thrombotic complications is between 16–49% in patients with COVID-19 admitted to intensive care. Thrombotic complications include stroke, acute limb ischemia, and acute coronary syndromes. However, data supporting routine screening for VTE using either lower limb ultrasound or computed tomography pulmonary angiography for all patients of COVID-19, is lacking. But the clinical suspicion for VTE should always be always there. It might be possible that the reported prevalence of VTE and PE is far less since the access to imaging techniques may be limited in critically ill patients.

Autoimmune Thrombotic Thrombocytopenic Purpura-Like Syndrome Associated with COVID-19

COVID-19 associated acute respiratory distress syndrome (ARDS) probably results from endotheliopathy-associated vascular microthrombotic disease (EA-VMTD).[15,16] This could be secondary to an imbalance between low ADAMTS13 and excessive exocytosis of ultra large von Willebrand factor multimers (ULVWF) from Weibel-Palade bodies present on endothelial cells. Endothelial derived ULVWF multimers bound to the endothelial surface of the vascular wall recruit platelets and might initiate microthrombogenesis thus leading to large microthrombi composed of platelet and eULVWF complexes.[17] Platelets adhered to eULVWF strings get activated resulting in platelet aggregation and recruitment of leukocytes dependant on P-selectin. The aggregates grow further and ultimately enter circulation. Numerous circulating complexes of endothelial derived ULVWF and platelet microthrombi result in the genesis of EA-VMTD triggering complement activation and resulting in a thrombocytopenic purpura (TTP)-like syndrome. This would require a recombinant Anti-CD59, recombinant ADAMTS13, Glycoprotein IIb/IIIa receptor blocker, therapeutic plasma exchange, and anticomplement therapy.

Lupus Anticoagulants in CAC

There is perhaps more to CAC as numerous reports of positive tests for lupus anticoagulant is being documented in COVID positive patients (91% of cases of elevated aPTT).[18] One case series of three patients with lower-extremity ischemia described an association of antiphospholipid antibodies (Apl Ab) and coagulopathy of COVID-19.[19] The interference of heparin on lupus anticoagulants (LAC) could lead to false positive detection of lupus anticoagulant.[13] However, Bowles et al. have noted that the dilute Russell's viper venom time (DRVVT) assay contains heparinase, which neutralizes any heparin effect.[18] The presence of aPL Ab alone is not a specific indication for anticoagulation and nor does the presence of aPL Ab represent a clinical diagnosis of antiphospholipid syndrome (APS). Hence, presence of aPL Abs in COVID-19 patients should be cautiously interpreted. It is perhaps too early to determine the role, if any, of lupus anticoagulant in the pathogenesis of COVID-19 thrombosis.[20]

Pathogenesis of CAC

The few proposed pathways are as follows:[21]

- Immune deregulation and endothelial dysfunction
- Prolonged immobilization, dehydration, coexisting comorbidities, presence of cardiovascular disease, previous history of VTE and genetic predisposition such as heterozygous Factor V Leiden mutation may increase VTE risk.
- Activation of ACE2 receptor in the endothelium could result in endothelial cell activation/damage due to the virus binding.
- The release of a large amount of inflammatory mediators may lead to an increased blood viscosity may cause further hypercoagulability.
- Interventions like mechanical ventilation, central venous catheterization, and surgery may induce additional vascular endothelial damage and activation of coagulation system.

Management of CAC

Risk assessment models (RAM) such as IMPROVE-VTE/modified IMPROVE-VTE RAM should be used to identify high VTE risk patients requiring thromboprophylaxis. Dynamic D-dimer evaluation and ultrasound venous echo-Doppler or bedside echocardiography can further risk stratify the patients for VTE.[22,23] If there are no contraindications, all patients with severe COVID-19 should receive prophylactic anticoagulation.

Low molecular weight heparins (LMWH), or unfractionated heparin (UFH) should be preferred over direct oral anticoagulants (DOACs) as drug-drug interactions with concomitant antiviral (especially anti-HIV protease inhibitors such as ritonavir) and antibacterial (such as azithromycin) treatment is a risk. Such treatments interfering with CYP3A4 and/or P-gp pathways can augment the bleeding risk or reduce the antithrombotic effect.[24]

Cytokine Release Syndrome in COVID-19

Cytokine release syndrome (CRS) also known as cytokine storm syndrome, macrophage activation syndrome, and haemophagocytic lymphohistiocytois are the terms used for the frequently fatal hyperinflammatory conditions seen in COVID-19. The most accepted pathophysiological pathways that result in CRS is the defective lymphocyte

killing via the perforin pathway. Homozygous defects in perforin pathway genes cause familial hemophagocytic lymphohistiocytosis, and heterozygous mutations are associated with secondary hemophagocytic lymphohistiocytosis. However, the role of similar or novel genetic defects in the severity of COVID-19-associated CRS is unknown. Perhaps, genomic sequencing of patients with COVID-19-associated CRS would provide an insight.[25] Elevated proinflammatory cytokines (IL-1, IL-6, and interferon-γ) produced by a dysregulated host immune response sets the soil for CRS. COVID-19-associated CRS, however, has early acute respiratory distress syndrome and clotting and surprisingly higher serum ferritins and lower IL-6 concentration.[25] Hyperferritinemia and high LDH levels are common. Usually, low fibrinogen levels and cytopenias of more than two cell lineages by hemophagocytosis are not reported in COVID-19 in contrast to CRS associated with other causes. So, the pathophysiology of COVID-19 overlaps with low-grade HLH. Anticytokine management should be used for treating COVID-19-associated CRS. Ruxolitinib, a JAK1/2 inhibitor, tyrosine kinase inhibitors (TKIs), and the anti-CD26 antibody begelomab have proved efficacious in this setting. IL-1 blockade with anakinra (a recombinant human IL-1 receptor antagonist) notably improved survival.[26]

Conclusion

The pathogenetic pathways discussed are evolving as our understanding of this disease is becoming clearer day by day. There is still much to be learned about the manifestations of COVID-19, and hence the literature is adding up new information. There is still a long way before we demystify this organism and are well acquainted by its effects. Whether there will be any chronic conditions or whether any further mutation in the virus would bring in some more acute complications, only time will tell.

CHAPTER

5 Effect of COVID-19 on Health-care Workers

KC Shashidhara, Spoorthy Raj

Abstract

COVID-19 (Corona virus disease 2019) is a respiratory viral infection, caused by SARS-CoV-2 (Severe acute respiratory syndrome Corona virus 2) that has spread across the world and has assumed a pandemic status. With ever increasing case load, lack of efficient treatment and vaccine for prevention, there is increased demand on health-care workers, in terms of work hours, and also, they are faced by, increased risk of infection, physical stress, and associated physical illness due to use of personal protection equipment, mental health issues, and social issues.

Thorough understanding of the impact of the ongoing pandemic on health-care work force is pivotal in appropriate management of the pandemic, as well as in ensuring the physical and mental well-being of health-care workers and prevent attrition of health-care work force.

Introduction

COVID-19 (Corona Virus Disease 2019) is a viral respiratory illness caused by novel corona virus, SARS-CoV-2. It is an RNA virus, belonging to the subgenus Sarbecovirus of the genus beta coronavirus of the family coronaviridae. The virus was first detected, while investigating the cause of cluster of pneumonia cases in Wuhan, Hubei province, China. Since then the virus has spread exponentially all around the world. Human to human transmission has found to be via respiratory droplets.[1] COVID-19 was declared as pandemic by WHO on February 11th, 2020.[2]

Health-care Workers (HCWs): All people serving in health-care settings, either paid or unpaid, who are at risk of getting exposed, either directly or indirectly to infectious materials, contaminated medical equipment, hospital surfaces, or contaminated air are considered as health-care workers. This includes doctors, nursing staff, technicians, pharmacists, students, trainees, administrative personnel, and engineering and facilities management staff.[3]

HCWs work in contaminated environment and stay in close contact with virus infected individuals, and hence face higher risk of getting infected. Also, excess work load, risky working environment, social stigma exert deleterious effects on their mental health.[3]

Problem Statement

COVID-19 is a rampantly spreading pandemic. Globally, total number of cases (as on 24 July) were 15,659,529 with 6,36,599 deaths. India is burdened with 12,91,623 cases with 30,658 deaths. The exact statistics pertaining to infection and deaths among HCWs is not available; however, as per CDC reports, there are more than 71,000 cases and 375 deaths among US health professionals as on June 2020. In India, according to the study published in IJMR, the incidence rate of COVID-19, among HCWs was 0.8%. The number of deaths is estimated to be 104 among doctors, 10 among nurses, and 15 among other health-care workers; however, the exact numbers are suspected to be much higher.[4]

Effect of COVID-19 on Health-care Workers

COVID -19 is a fast spreading pandemic and currently there is enormous ongoing research to understand the disease dynamics and develop safe and effective vaccine and treatment strategy. However, in the absence of such vaccine and clear treatment guidelines there is increased pressure on global health-care work force **(Fig. 1)**. This occurs in two forms:

- Overwhelming case load
- Loss of health-care work force due to adverse effects on health of HCWs

The effects on health-care workers can be conceptualized as follows:

- Risk of hospital acquired infection
- Effects on physical health due to demanding work environment
- Effects on mental health
- Social issues

Risk of Hospital-acquired Infection

HCWs are at increased risk of hospital acquired infection due to following reasons:

- Work environment, demanding close contact with infected patients
- Longer duration of exposure due to long working hours
- Inadequate supply of personal protection equipment
- Inadequate training, preparedness, and motivation regarding use of personal protection equipment.

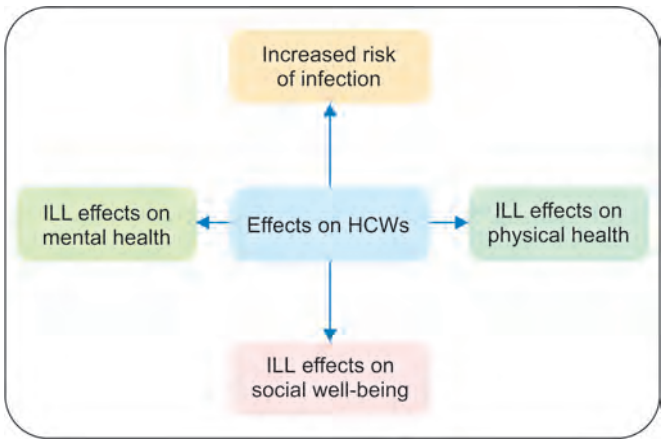

Fig. 1: Effects on HCWs

Effects on Physical Health due to Demanding Work Environment

It is mandatory for HCWs to use proper PPE for prevention of nosocomial spread of infection. However, prolonged use of PPE is associated with side effects like:

- PPE (N95 mask and protective eye wear) associated de-novo headache as well as worsening of pre-existing primary headache syndromes like migraine, which affect the work efficiency and sleep quality.[5]
- PPE associated dermatosis like: Heat stress, dehydration, Acne, skin irritation, irritant contact dermatitis, allergic contact dermatitis, contact urticarial dermatitis, pigmentation, and frictional erosions.[6]

Effects on Mental Health

Health-care workers work in demanding work environments during times of crisis, like the present COVID-19 pandemic. Due to increased work load and stress they face increased risk of mental health disorders like depression, generalized anxiety disorder, obsessive compulsive disorder, panic attacks, post-traumatic stress disorder, insomnia, and a wide array of somatic symptoms.

Features responsible for mental health problems among HCWs include:[7]

- Speculations about unforeseen modes of transmission of disease
- Rapidity of spread
- Spread from asymptomatic patients
- Lack of definitive treatment protocol and non-availability of vaccines
- Widespread global connectivity and extensive media coverage resulting in catastrophic reactions to outbreak
- Complete uncertainty
- Unprepared health infrastructure

According to the study conducted by Chatterjee et al.,[8] the prevalence of depressive symptoms among HCWs, during COVID-19 was 35%. The prevalence of symptoms related to stress and anxiety was 39.5% and 33%, respectively. Similarly, Korean study showed the prevalence of depressive symptoms among doctors to be 26.6%,[9] and a study conducted in Singapore showed the prevalence of anxiety, depression, stress, and post-traumatic disorder to be 14.5%, 8.9%, 6.6%, and 7.7%, respectively.[10]

With further loss of health-care work force due to acquisition of nosocomial infection, the work load on prevailing work force will manifold by several times and further worsens their mental health status.[8] Mental health issues are more prevalent among HCWs working in emergency, ICUs, and infectious diseases wards.

Social Problems

- Violence on doctors
- Concern regarding being source of spread to family members especially among those caring for elderly and children
- Social stigma

Measures to Safeguard Health and Safety of HCWs

Measures to Reduce Infection among HCWs[11]

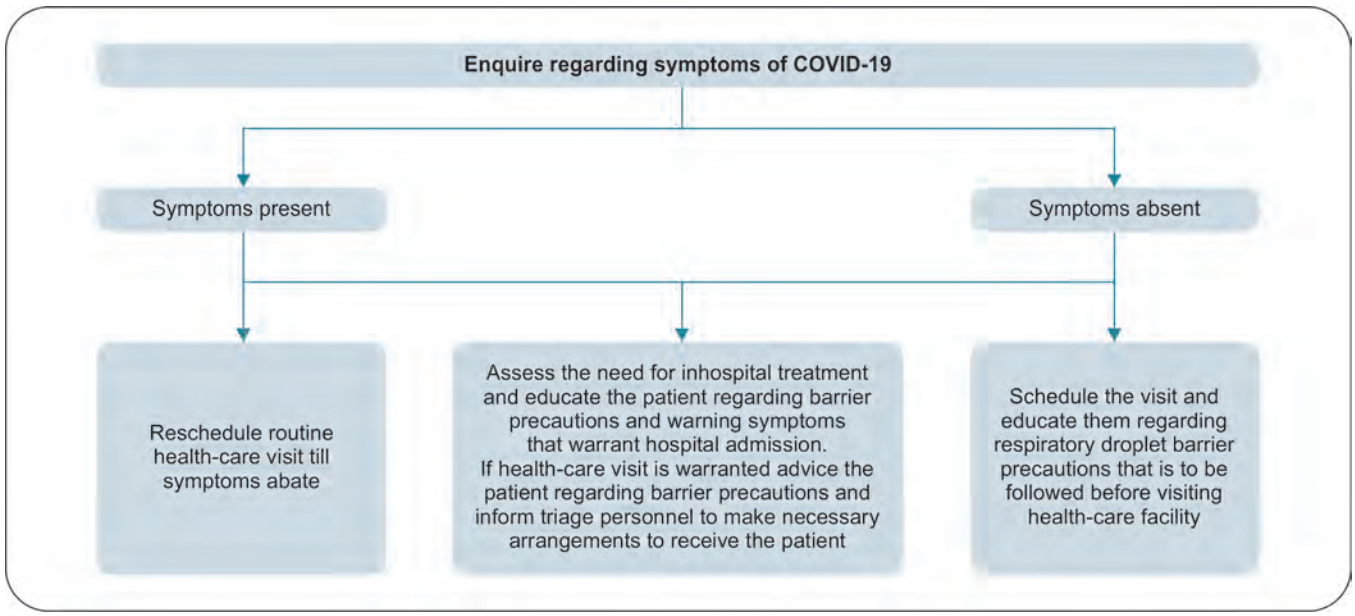
CDC recommendations include:[12]

- Recommendations for routine health-care delivery
- Recommendations for care of suspected and confirmed cases of COVID-19

Recommendations for routine health-care delivery include:

- Use of telehealth and nurse directed triage protocols **(Flowchart 1)**. It is advised to schedule appointments for routine medical care through phone call. At the time of scheduling such appointments for routine health-care delivery, care should be taken to prevent crowding of patients in waiting areas.
- All patients and visitors entering a health-care facility are to be screened for signs and symptoms of COVID-19.
- Visual alerts, regarding use of face mask, hand hygiene practices and cough and sneeze etiquette are to be posted at entrance and strategic places to ensure compliance for the same.
- Provision of alcohol-based hand sanitizers and face masks to patients entering health-care facility.
- Patients waiting for consultation should be placed in such rooms, which allow for adequate social distancing, are well ventilated and have easy access to respiratory hygiene supplies.
- Provision of a separate area at the heath-care facility for provision of services to patients with symptoms of COVID-19.
- Admitted patients are to be revaluated every day for development of signs and symptoms of COVID-19.
- Application of source control measure such as use of cloth face covering or face mask to all patients and visitors, considering the potential for transmission from asymptomatic and pre-symptomatic patients.

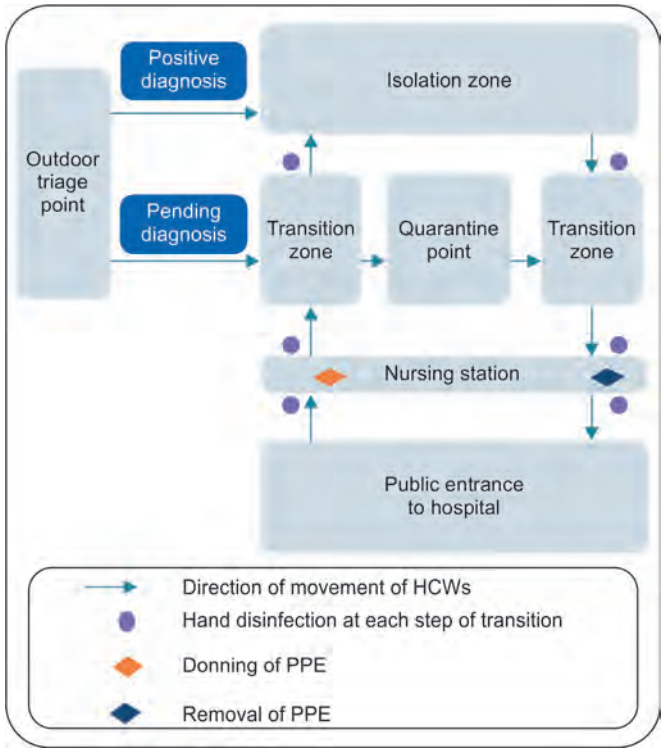
Flowchart 1: Algorithm for use of telehealth and nurse directed triage protocol



- Health-care workers to maintain adequate physical distancing whenever possible.
- Health-care workers to practice source control measures and physical distancing even in non-patient care areas so as to prevent transmission from unprotected exposures to asymptomatic or pre-symptomatic coworkers.
- HCWs to be provided with break areas, which allow scope for maintaining adequate social distancing.
- HCWs to be advised to wear protective eye wear in addition to facemask during patient care encounters.
- HCWs are advised to use N95 or equivalent or higher-level respirator while aerosol producing procedures like intubation.
- It is advisable to perform targeted SARS-CoV-2 testing for asymptomatic patients to further reduce the transmission risk in health-care setting.
- Engineering controls are to be optimized to reduce or eliminate exposures to HCWs and other patients from infected individuals. For example, use of physical barriers and dedicated pathways to guide symptomatic patients through triage areas.

  Traffic control bundle: It begins with outdoor triage. Patients are grouped into three categories at the triage station which is established at the entry to health-care facility. *Hot zone:* Patients with symptoms and consistent for COVID-19 or who are already tested positive for COVID-19 are directed to individual isolation rooms for further care. *Intermediate zone:* Patients with atypical symptoms and inconclusive SARS-CoV-2 test results are directed to quarantine ward and observed for the extent of their incubation period. *Clean zone:* patients without symptoms or signs consistent of COVID-19 are placed in clean zone. Patients designated to hot zone and intermediate zone are provided separate paths so that they do not cross the paths of health-care workers or patients moving to clean zone. HCWs while transiting from clean zone to intermediate and hot zones are instructed to follow appropriate hand hygiene and use personal protection equipment. Also while moving from hot zone to clean zone they are advised to de-gown and practice hand hygiene. Each transition zone is to be clearly labeled and necessary personal protection measures to be followed is to be clearly mentioned to ensure compliance **(Flowchart 2)**.[11]

Flowchart 2: Traffic control bundle



- Air handling systems to be optimized.
- Portable solutions like HEPA filtration units can be added to augment air quality.
- Each health-care facility to be equipped with designated staff to address health-care related exposures among HCWs.

Recommendations for care of suspected or confirmed cases of COVID-19:

- Assess for the need for hospitalization. If deemed necessary, it is advisable to give separate rooms with door and dedicated bathroom to each patient. If not feasible then all COVID-19 patients are to be placed in one room which is equipped with enough facilities to maintain physical distancing and source control precautions.
- Patients on whom aerosol generating procedures are planned are to be placed in airborne infection isolation room.
- There should be dedicated HCW assigned for care of COVID-19 patients and same HCW should not be used to provide care to other patients during the same duty shift.

- All HCWs providing care to COVID-19 patients should use personal protection equipment, which includes protective eyewear, NIOSH approved N95 or equivalent or higher respirator, clean non-sterile gloves and isolation gown.
- Health-care workers are advised to practice hand hygiene measures like washing hands with soap and water for at least 20 seconds or using alcohol-based hand sanitizer with 60–95% alcohol, before and after patient contact, contact with potentially infectious material, and before putting on and after removing PPE, including gloves. Hand hygiene supplies are to be made easily available to all health-care personnel at every care location.
- HCWs are advised to monitor themselves for signs and symptoms of COVID-19 and report promptly to the designated team in the health-care facility and refrain from providing patient care during the period of infectious symptoms.
- It is advised to minimize the movement of COVID-19 patients outside their designated wards. Whenever moving the patient is necessary, the information regarding the same should be communicated to respective departments and necessary precautions are to be taken before transferring the patient.
- It is advised to refrain HCWs from entering the patient rooms soon after discharging or transferring the patient. Sufficient time should be provided for adequate number of air exchanges and then should be appropriately cleaned and surface disinfection to be carried out before returning it back to routine use.
- It is advised to minimize the number of visitors to health-care facility. Alternative measures like video calls can be encouraged to ensure patient visitor interactions.
- Use of dedicated medical equipment for provision of care to COVID-19 patients.
- It is advised to follow routine cleaning and disinfection of all non-dedicated medical equipment.
- It is advised to follow cleaning and disinfection of the environment consistently.
- Routine standards are to be maintained while handling laundry, medical waste, and food services.
- It is advised to redeploy health-care workers who have medical conditions which predispose them to severe infection or death, if infected with SARS-CoV-2, away from high-risk sites.

Measures to improve mental health among HCWs:[12]

- Prompt screening for presence of mental health concerns.
- Use of proper duty roster to reduce long working hours.
- Educational interventions targeting nonmedical health-care workers enabling them to understand and use infection control measures.
- Psychological support including counseling services and development of support systems among colleagues.
- Provision of enough scope for rest breaks, food breaks, and decompression time for health-care workers and ensuring adequate communication and feedback sessions with local managers to help HCWs maintain compliance with personal safety measures and stay focused on provision of care.

Measures to improve social health of HCWs:

- Improving awareness among public to reduce social stigma and marginalization of those involved in care of COVID-19 patients.
- Strengthening social support systems to provide care for elderly and children.
- Provision of adequate information and practical solutions for health-care workers to improve environmental safety at home and prevent transmission to family members. For example, changing from hospital scrubs to personal clothing during return to home from work, showering on return to home, separation of living spaces, and bathrooms.

Conclusion

Health-care workers are the main personnel involved in the management of this raging pandemic; however, as individuals they are faced with increased risk of infection, physical and psychological stress. They are also constantly worried by the concern about family transmission, specifically to elderly members with chronic medical conditions, and immunocompromised which needs to addressed in a better way. It is therefore essential to promptly address physical, mental, and social health concerns affecting the health-care workers and take appropriate measures to improve the same.

CHAPTER

6 Diabetes and COVID-19: What Is the Connection?

Viswanathan Mohan

Abstract

Diabetes and COVID-19 have a lot of interactions. Uncontrolled diabetes can make outcomes and prognosis in a person with COVID-19 worse. Conversely, COVID-19 can precipitate diabetes or worsen pre-existing diabetes in several ways. This article discusses the relation between Diabetes and COVID-19. It also deals with the treatment of diabetes in a person with COVID-19. Finally, it talks about how COVID-19 and the lockdown changed the way diabetes is treated and led to the growth of Telemedicine in India.

Introduction

The COVID-19 pandemic is one of the most unprecedented in the recent history of mankind. Already, millions have been affected in all continents of the world (except Antarctica) and hundreds of thousands have died due to COVID-19. There is convincing evidence that uncontrolled diabetes and hypertension and cardiovascular disease are associated more severe outcomes and higher mortality in COVID-19.

This article will deal with the connection between diabetes and COVID-19 and will try to answer the following questions:

- Are people with diabetes more prone to COVID-19?
- Are those with diabetes likely to have worse outcomes compared to those without diabetes?
- How does diabetes worsen COVID-19?
- Are any changes to treatment of diabetes to be made if they develop COVID-19?
- How did COVID-19 and lockdown change the practice of diabetes?

Are People with Diabetes more Prone to COVID-19?

It is well known that individuals with diabetes are more susceptible to viral, bacterial, and fungal infections as compared to those without diabetes. This is mainly because those with diabetes (especially uncontrolled diabetes) have less robust immune function. Moreover, glucose can serve as a medium for microorganisms to grow. With respect to respiratory infections, it has been recognized that while individuals with diabetes are more likely to get lower respiratory infection, no such increased predisposition when it comes to upper respiratory infection such as rhinitis, sinusitis, and pharyngitis. Therefore, it is probably not surprising that there is no evidence to suggest that people with diabetes are actually more prone to COVID-19, which starts off as an upper respiratory infection in most cases. The American Diabetes Association (ADA) has also issued a statement that people with diabetes are not more prone to COVID-19 than the general population.[1]

Are People with Diabetes Likely to Get more Severe Form of the Disease and are Outcomes Worse in those with Diabetes?

If those with diabetes do contract COVID-19, they are indeed likely to develop more severe form of the disease particularly if the diabetes is uncontrolled.[2] Data from Wuhan, China, confirms that approximately 20% of severe cases of COVID-19 do show diabetes, as comorbidity.[3] Data from Italy also showed similar findings in that more than two-thirds of those who died due to COVID-19 had diabetes.[4] Another retrospective study from Wuhan revealed that out of 41 COVID-19 patients, 32% of them had an underlying disease among which 20% was accounted for by diabetes.[5] A retrospective study focusing on outpatients at Fujian Provincial Hospital, China, included 135 elderly patients and concluded that those with type 2 diabetes (T2D) had worse outcomes. According to reports from India, of the first 125 deaths on COVID-19, 56% had diabetes, 47% had hypertension, and over a third had both diabetes and hypertension.[6]

A large observational report from China including showed that of the 173 patients with severe COVID-19, comorbidities like hypertension, diabetes, or cardiovascular disease were seen frequently.[7] In another study of 140 COVID-19 inpatient admission, hypertension and diabetes were present in 30% and 12%, respectively.[8]

Of the 72,314 COVID-19 cases reported from China, the overall fatality rate was 2.3% but this increased to 10.5% if CVD was present and to 7.3% and 6%, respectively if diabetes or hypertension were present.[9]

Another worrying finding is that people with diabetes potentially have milder early symptoms of COVID-19, which makes the subsequent rapid deterioration much more difficult to predict and prevent.[10]

What are the Mechanisms by which Diabetes Worsens COVID-19?

An important feature of T2D is low-grade inflammation. There is long-term immune system imbalance, metabolic syndrome, or nutrient excess associated with obesity.[11,12] Also, in individuals with diabetes, there is an exaggeration of proinflammatory responses, especially interleukin (IL)-1, IL-6, and tumor necrosis factor-α (TNFα). This may be further worsened in those with severe COVID-19. Prolonged hyperglycemia alters the host immune system. Dysfunctions in leukocytes, monocyte and macrophage chemotaxis and phagocytosis, and damaged specific immunity have also been reported in subjects with diabetes.[13,14] Moreover, diabetes shares the common features promoting disease progression with infectious disorders such as the proinflammatory state and endothelial dysfunction.[15]

Role of ACE2 in Diabetes and COVID-19

The role of ACE2 has been discussed in earlier articles[16] and hence is not dealt with in detail here.

Drugs like ACE inhibitors (ACEi) and angiotensin-receptor blockers (ARBs) are widely used in diabetes since hypertension and albuminuria are common in people with diabetes. ACE2 is the receptor to which the Spike (S1) protein of the virus binds to gain entry into the respiratory tract epithelial cells. It is believed that ACE2 receptor stimulation might ease the entry of SARS-CoV-2 into the pneumocytes and thus result in worse outcomes in diabetic patients.

One study from China by Chen et al.[2] claimed that viral clearance is delayed by diabetes, hypertension in males and in old people, which may worsen the prognosis of COVID-19 infection, likely due to the increased expression of ACE2. The authors recommended that the use of ACE1 inhibitors be carefully considered in such population, as it may lead to upregulation of ACE2. However, there is another school of thought that ACE2 overexpression may in fact help as it converts angiotensin-2 into angiotensin 1-7, which has effects exactly opposite to that of angiotensin-2, meaning that it can balance angiotensin-2 in the body so that it is potentially *useful* or *protect* against ARDS and the cytokine storm.[2] Therefore, ACE2 seems to attract the virus into the pneumocytes, but on the other hand, perhaps also equips the cells against a cytokine storm. Thus, some authors have contended that blockage of the renin angiotensin aldosterone system (RAAS) by ACEi/ARBs can actually be beneficial in protecting against COVID-19.[17]

Current evidence does not support the discontinuation of ACE inhibitor treatment due to concerns regarding Coronavirus infection.[18] Moreover, the European Society of Cardiology, Council on Hypertension; ACC/AHA/HFSA (American College of Cardiology, the American Heart

Association and the Heart Failure Society of America) and the American Society of Hypertension have stated that patients should continue treatment with their usual antihypertensive therapy because there is lack of scientific evidence to incriminate ACE inhibitors or angiotensin receptor blockers in COVID-19 infection.

Other drugs like pioglitazone and liraglutide can also lead to upregulation of the ACE2 in animals.[19,20] It is not clear whether these drugs should be discontinued in COVID-19 but pioglitazone is not favored in COVID due to the chances of fluid retention.

Management of Diabetes: What Changes Need to be Made?

Glycemic control is the first and foremost factor in diabetes management; otherwise, complications associated with long-term hyperglycemia are not only frequent causes of premature mortality but also virtual drivers of indirect costs. Some studies have shown that the glucose concentration in the airway secretion is directly proportional to the blood glucose concentration.[21]

Can all Anti-diabetic Drugs be Continued?[22]

There is as yet no direct evidence on the effects of the various categories of antidiabetic medications on the risk of developing COVID-19 infection or the adverse outcomes of the same.

In those with Mild or Well-controlled Diabetes

In general, patients with T2D, who have mild symptoms of COVID-19 and asymptomatic patients, can continue their usual dose of medications, with appropriate titration if necessary so as to maintain good glycemic control. If the control is inadequate, addition of insulin would be warranted. There is no data on whether use of metformin, sulfonylurea, DPP4 inhibitors alpha-glucosidase inhibitors or insulin influences outcomes of COVID-19 over and above their effects on glycemic control.[16] As regards the other classes of antidiabetic agents:

- SGLT2 inhibitors are best avoided in severely symptomatic and hospitalized COVID-19 patients, primarily on account of the risk of dehydration and diabetic ketoacidosis. Also, these agents are known to upregulate renal ACE2, although the implications of this upregulation in the context of COVID-19 are unknown.
- Hydroxychloroquine (HCQ), approved and used as a third-line antidiabetic agent in India, also seems to have beneficial effects in COVID-19, and in India has been approved for prophylaxis of COVID-19 among health-care professionals treating COVID-19 patients and for asymptomatic close contacts of such patients. However, issues related to QT prolonged must be kept in mind. Also recent reports suggest that HCQ may not be beneficial in COVID-19 management and HCQ use remains a contention issue.[23-25]
- Many patients with COVID-19 infection report loss of taste and smell sensation, and hence have poor appetite. Many also have GI symptoms such as nausea, diarrhea, and vomiting. The antidiabetic drug regimen should be closely titrated so as to account for fluctuations in food intake caused by these symptoms.

Role of Anti-diabetic Drugs in COVID-19

Table 1 shows the role of anti-diabetic drugs in COVID-19.[26]

If Diabetes is Severe or in Hospitalized Patients and those in ICU

Severe COVID-19 infection can lead to deterioration of glycemic control and some patient could develop diabetic ketoacidosis on account of the excessive outpouring of counter regulatory (stress) hormones. In all such severe cases or in hospitalized patients, insulin would be the antidiabetic agent of choice. Treatment with basal-bolus insulin regimens or IV insulin infusion will usually be needed in such cases. However, the treatment has to be individualized on a case to case basis.

How did COVID-19 and Lockdown Change the Practice of Diabetes?

Following the COVID-19 pandemic many countries introduced a total lockdown and did not permit movement of people outside of their houses. This means that routine in person diabetic clinics applicants were not possible.

In India, the lockdown was introduced on March 25th 2020 initially for a period of 21 days but this was extended thrice and as of now the lockdown is in force till May 17th. With India's population currently at 1.366 billion, this is probably the largest lockdown in human history.

TABLE 1 Role of anti-diabetic drugs in COVID-19[26]

Drugs	*Benefits*
Metformin	• Has anti-proliferative and immunomodulatory effects—Protective[27] • Decreased mortality in lower respiratory infections[28] • Risk of lactic acidosis
Thiazolidinediones (TZDs)	• Seen to increase risk of pneumonia compared to sulphonylureas[29] • Increase ACE2 expression[30] • Therefore avoid in COVID-19
Glucagon like peptide-1 receptor agonists (GLP-1 RAs) [Liraglutide]	• Also increases ACE2 expression in lungs[31] • Best avoid
DPP 4 inhibitors	• In MERS—COV: Reduced viral entry • Increased upper respiratory infection with DPP 4 inhibitors known, but no increased risk of pneumonia • No evidence for or against use of DPP 4i in COVID-19
SGLT2 inhibitors	• Better to discontinue because of risk of dehydration and euglycemic ketosis
Sulphonylureas and insulin	• Dose may have to be adjusted based on blood glucose levels

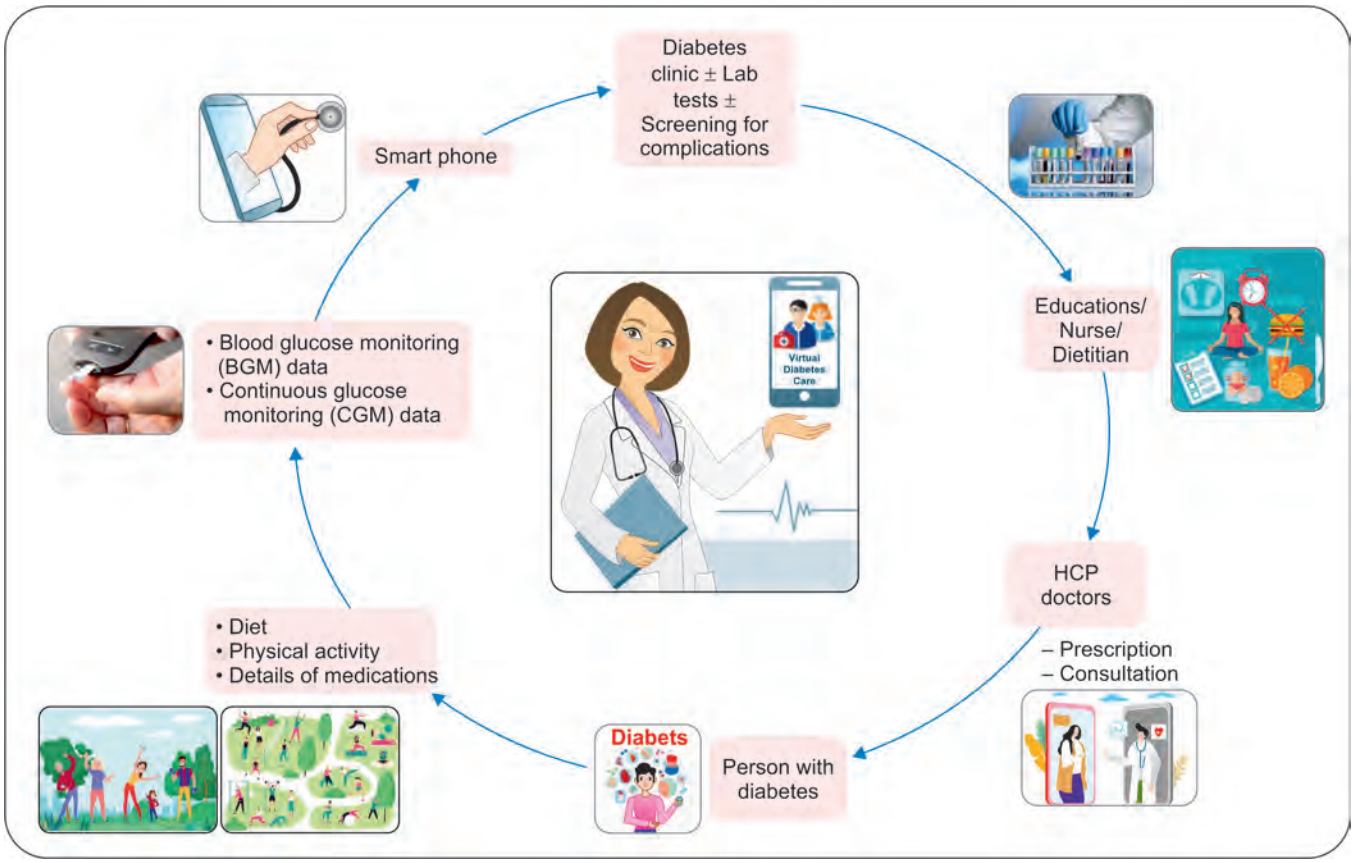

Fig. 1: Interaction of the person with diabetes and health-care providers using technologies

Telemedicine which was not legally permit until the COVID-19 set in was rapidly legalized by the Board of Directors of the National Medical Council of India and guidelines for the same were rapidly drawn.[32] With this, telemedicine for diabetes too off in India. Many government and private hospitals and clinics rapidly adopted telemedicine in India.

In a study conducted by us currently, it was seen that 82% of patients who availed the teleconsultation were happy with it.[33] However, only 58.1% stated that they would be keen to continue it in the future.

It is reasonable to assume that if the COVID-19 or similar pandemic arise in the future, telemedicine will become a most accepted method of diabetes treatment.

In the future, we could see the integration of the person with diabetes and the health-care provider (doctor/nurse/educator/dietitian), thanks to using technologies as shown in **Figure 1**.

Glycemic Control during COVID-19

There have been several predictions regarding the diabetes control during COVID-19. One school of thought believes that due to disruption of lifestyle (diet/exercise), there could be disastrous effects on glycemic control. There were even predictions that A1c could be worsen from around 8% to 12% or even 16%.[34] In a study of 2,500 persons with diabetes in India, it was seen that the reverse is also true. It was seen that glycemic control actually improved from 8.2% to 7.7% in this set of individuals. Reduced frequency of eating out (and eating healthier home meals), timing meals, less stress, better sleep, possibly lower exposure to pollution (because of working from home), and reduced smoking and alcohol (because of non-availability) could be some of the factors which contributed to the improved diabetes control in this study.[33]

Conclusion

In conclusion, the COVID-19 has taught us many things about diabetes. The worse outcomes and increased mortality points to the obviously need for tighter diabetes control. On the other hand, as a silver lining to the difficulties due to the lockdown, many people's health and lifestyle seem to have improved, resulting in better diabetes control and to the birth of telemedicine.

CHAPTER

7 COVID-19-associated Renal Injury

Shashidhar Shree Niwas, Ramya Vedula, Prateek Kumar, Madhuri, Shashank Jain

Abstract

SARS-CoV-2 related renal disease is common in severe cases. Common presentations are proteinuria, hematuria, oliguria, and renal dysfunction. Emerging data from case reports and autopsy series of COVID-19 suggests that it causes acute kidney injury (AKI). Intrinsic renal pathology including viral mediated tubular cell injury, thrombotic vascular processes, and glomerulonephritis. Predominant pathways of renal injury are due to hemodynamic changes, direct cytopathic effect, and cytokine storm syndrome. The indications for RRT in AKI largely remain the same regardless of the COVID-19 status of any given patient.

Introduction

The Corona Virus Disease (COVID-19) pandemic which is rapidly evolving and expanding has infected a population of more than 77 million across the globe and around 10 Million in India as of 25th December, 2020.[1] This virus was first recognized in December 2019 in Wuhan of China when pneumonia of unknown origin came into limelight.[2] It was identified as COVID-19, a neovirus causing severe pneumonia that rapidly led to a major health crisis with devastating consequences not only in India but also in major developed countries of the world.[3,4]

Initially data from China and Italy, which was identified as caused by COVID-19, shows that death rate worsens in persons with increasing age more than 50 years and also leads to higher risk due to comorbidities like hypertension (HTN), cardiac disease, diabetes mellitus, chronic renal disease, cancer, etc.

Diagnosis

The diagnosis of COVID-19 is mainly based on epidemiological factors (history of contact), clinical manifestations, laboratory examination (hemogram), chest computed tomography, and virological investigations. Incubation period varies between 4–15 days. The virus is highly contagious and mode of transmission is respiratory droplet, contact, aerosol.

Infection has been reported in all ages, but lesser in children. The majority of infections are mild, presenting with a flu-like illness. The common clinical presentations of COVID-19 are fever (98%), cough (76%), myalgia and fatigue (18% each), loss of smell and taste, accompanying leukopenia (25%), and lymphopenia (63%). About 16–20% cases have been classified as severe which includes pneumonia, multiorgan dysfunction, and cytokine storm syndrome.[5,6]

Renal Manifestations of COVID-19

Data indicates SARS-CoV-2 has particular organotropism beyond the respiratory tract, including the kidneys, liver, heart, and brain, and this influences the course of COVID-19 disease and, possibly, aggravates preexisting conditions.[7] Emerging data from case reports and

autopsy series of COVID-19 suggests that it causes acute kidney injury (AKI). Intrinsic renal pathology including viral mediated tubular cell injury, thrombotic vascular processes, and glomerulonephritis have been reported. AKI also resulted from extrinsic factors such as fluid depletion, multiorgan failure, and rhabdomyolysis.[7,8] Clinical reports have emerged of proximal tubular injury, in association of Fanconi syndrome that manifests as hypokalemia, hypophosphatemia. It also has features of normal anion gap metabolic acidosis, hypovolemia due to salt wasting manifestation. The USA, France, and China reported incidence of AKI that varies from 3% to 37% of patients in retrospective, observational.[8-11]

Pathogenesis of Renal Injury

The incidence of renal manifestations and impact and outcome of COVID-19 on kidney is not completely known. Studies describe the clinical manifestations, associated risk factors, and course of acute renal injury in hospitalized patients with COVID-19.[7-12] The largest available published data was in 13 New York metropolitan city hospitals.[9] Total 5,449 patients got admission in these centers with COVID-19, AKI was diagnosed in 36.6% cases. Out of them, 14.3% needed kidney replacement therapy (KRT). Acute renal injury was mostly observed in conditions with respiratory failure. Renal injury was more common (89.7%) of patients on mechanical ventilation as compared to those of non-ventilated patients (21.7%).

Surprisingly 96.8% of patients requiring renal replacement therapy were on ventilators. The onset of AKI was observed within 24 hours of intubation in 52.2% of those who needed mechanical ventilation. Major factors for AKI were higher age, diabetes mellitus, cardiac disease, black race, HTN, and requirement of mechanical ventilation and inotropic agents.[6] Out of them 35% died, 26% discharged among all patients with AKI but 39% were still hospitalized. This study clearly shows AKI occurs early in course, and is in temporal association with respiratory failure and have a poor prognosis. Hematuria (46%) and proteinuria (42%) were documented which are mostly part of glomerulonephritis, AKI, thrombotic microangiopathy.

There are predominantly three pathways of renal injury:

- Renal impairment due to hemodynamic changes,
- direct cytotoxic effect, and
- cytokine storm syndrome.[9]

Expression of viral receptor ACE2 on tubular epithelial cells might suggest direct cytopathic effect in renal injury. There may be a role of immunological and prothrombotic factors, which may be triggered by infection. Angiotensin converting enzyme (ACE) both expressed on renal tubular cells was identified as binding partners for SARS-CoV.[9] Viral RNA has been identified in kidney tissue in infected persons. Higher plasma cytokine levels granulocyte-colony stimulating factor were present in patients requiring intensive care unit admission.[9]

Histopathology

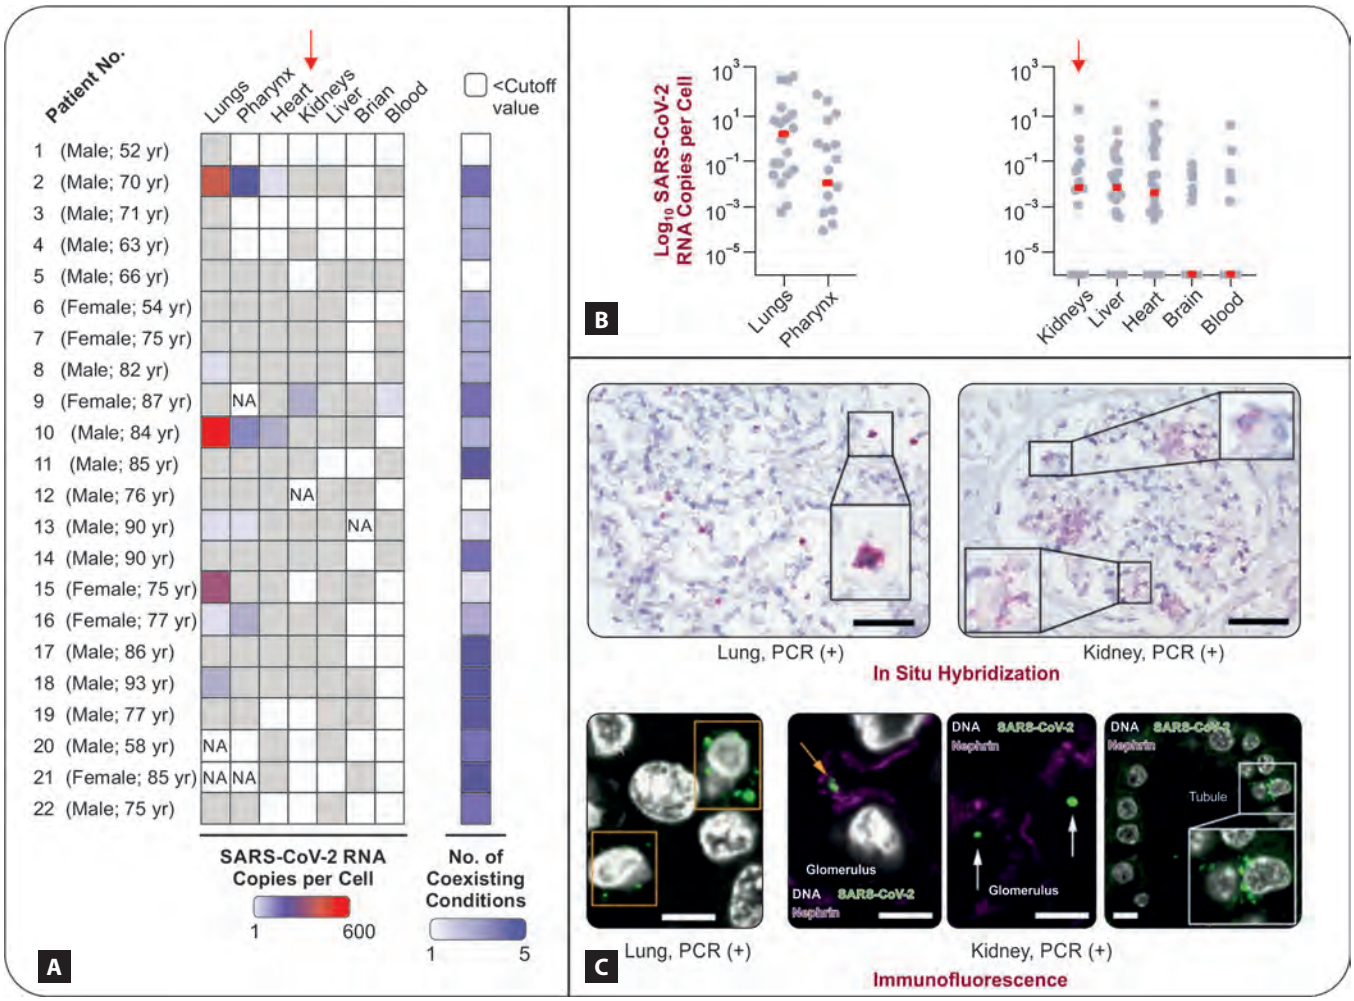
Largest series of 26 cases of postmortem renal biopsy samples were studied by light microscopy described proximal tubule injury, non-isometric vacuolar degeneration, and even frank tubular necrosis was observed.[13] There were red blood cells accumulation obstructing the capillary lumen in absence of platelets and fibrinoid material. There was no evidence of vasculitis, interstitial inflammation or hemorrhage **(Figs. 1A to C)**.

Assessment of Renal Injury in Suspected or Confirmed COVID-19

In patients with COVID-19, AKI is quiet common except in mild cases especially with high risk factors. Its incidence increases as severity increases further. Up to 31% on ventilators and 4% not on ventilator needed renal replacement therapy (RRT). AKI is an independent predictor of mortality.[9-12] Common causes may include volume depletion, hemodynamic changes, viral infection leading directly to kidney tubular injury, overzealous diuretics, thrombotic vascular processes, glomerular pathology, or rhabdomyolysis. In management of COVID-19, maintaining euvolemia is critical in prevention and management of AKI, overzealous diuretics, hyperpyrexia, and increased respiratory rate increases insensible fluid loss and hypovolemia may also increase risk of coagulopathy. Assessment of hemodynamics, volume status, monitoring intake output charts, identifying risk factors for AKI, history of pre-existing comorbidities in all patients is essential.

Patients with Dialysis-requiring AKI

COVID-19 infection presents particular challenges for patients on dialysis. The indications for RRT in AKI largely



Figs. 1A to C: (A) Clinical information of 1-26 patients affecting different organs. (B) SARS-CoV-2 RNA copies in different organs. (C) Expression of SARS-CoV nucleoprotein in renal tubules

remain the same regardless of the COVID-19 status of any given patient. Continuous variant of renal replacement therapy (CRRT) is modality of choice in providing dialysis wherever this facility is available among seriously ill patients with AKI.[14,15] Sustained low-efficiency dialysis or SLED may be performed in hemodynamically stable patients to rapidly changing hemodynamics, deteriorating clinical condition, multiorgan dysfunction, hyperkalemia, metabolic acidosis, shock, inotropic, and ventilator support, which depends upon facility and skilled staff.[14-16]

In resource constrained situation there are strategies to reduce cost and better utilization of available resources like: colocalization of desired dialysis patients on same floor/ICU and time, SLED instead of CRRT, extended tubing and putting dialysis machine outside of room.

Figure 2 shows a simple overview of continuous venovenous filtration (CVVH), which is a most commonly used form of CRRT.[17] A dialysis filter, which is used as a permeable membrane that filters patient's blood, and then the ultra-filtrate is removed, resulting in clearance of nitrogenous waste products; however, blood cellular components and large proteins like albumin are not removed. Isotonic fluid is used as replacement volume and provides base equivalents like bicarbonate or citrate. The replacement fluid is commonly given prefilter than postfilter to avoid hemoconcentration which can lead to clotting of the membrane.[15] To increase clearance of waste products during intermittent hemodialysis the rate of replacement fluid and filtrate turnover is increased.[16]

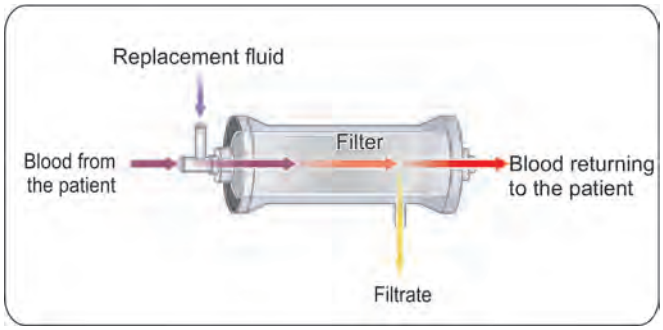


Fig. 2: Depicting simplified overview of continuous renal replacement therapy

Studies have suggested that circuit thrombosis is more common in COVID-19 than noncovid patients.[15] In the absence of major contraindications, patients with COVID-19 should receive anticoagulation during RRT. If available, remote monitoring with audio and video streams should be used to troubleshoot alarms.

When resource constrained setting or overburdened hemodialysis centers due to increasing COVID cases, peritoneal dialysis is a good alternative in AKI cases.[17] Patients with AKI who are treated with peritoneal dialysis have similar rates of all-cause mortality, kidney function recovery, and infectious complications compared with patients treated with other modalities.

Pharmacological Agents for COVID-19

High-quality evidence showing the effectiveness of treatments for COVID-19 is scarce, but over 400 studies are now registered in ClinicalTrails.gov testing a range of therapies.[18] Given the abundance of scientific research and clinical, clinicians require accurate evidence for effective medical treatment of COVID-19 infection.

Antiviral Agents

- *Remdesivir:* It is an enzyme inhibitor of RNA polymerase which acts against SARS-CoV-2. Randomized controlled trial has been performed of IV Remdesivir in patients admitted with COVID-19 with evidence of pneumonia. It has shown superior effect in reducing the time to recovery in admitted patients with COVID-19 and pneumonia.[19-20]
- *Hydroxychloroquine:* It has shown in vitro activity against SARS-CoV-2, an immunomodulatory benefit. However, several clinical trials have not shown very convincing data against COVID-19.[21,22]
- *Ivermectin:* This has been recently approved by FDA in COVID-19 infection. It also shows antiparasitic activity previously shown to have broad-spectrum antiviral activity in vitro.[23] It is an inhibitor of the causative virus (SARS-CoV-2). Ivermectin therefore warrants further investigation for possible benefits in humans.
- *Tocilizumab:* Disproportionate and excessive immune response to infection with the SARS-CoV-2 virus has been found to be part of cytokine storm in the ARDS and multiorgan failure in some patients. Cytokine IL-6 inhibitor, tocilizumab is part of several randomized, double-blind, placebo-controlled phase 3 clinical trials as well as uncontrolled trials to evaluate the safety and efficacy of tocilizumab plus standard of care in hospitalized adult patients with severe COVID-19 pneumonia with some promising initial results.[24,25]
- *Plasma therapy (convalescent plasma):* It is a type of passive antibody therapy in which blood plasma is isolated from people who have recovered from the COVID-19 infection and is administered to those with the disease to suppress viremia and improve clinical symptoms.[26]
- ICMR has regularly updated the clinical management of COVID-19 in India. Recently it has included the role of remdesivir, favipiravir, tocilizumab, and convalescent plasma on selected group of patients. The document states, "Remdesivir (under Emergency Use Authorization) may be considered in patients with *moderate* disease (those on oxygen)... tocilizumab (Off Label) may be considered in patients with moderate disease with progressively increasing oxygen requirements and in mechanically ventilated patients not improving despite the use of steroids. Long-term safety data in COVID-19 remains largely unknown... Convalescent plasma (Off Label) may be considered in patients with moderate disease who are not improving (oxygen requirement is progressively increasing) despite the use of steroids."
- Though the revised protocols allow hydroxychloroquine to be prescribed to patients in the *early* course of the disease, evidence for its use "remains limited."

Conclusion

The COVID-19 pandemic has posted major challenges around the globe. Renal clinical presentation ranging from mild proteinuria, hematuria to progressive AKI necessitating renal replacement therapy (RRT), thrombotic microangiopathy, and rhabdomyolysis. International collaboration and interdisciplinary research is needed to obtain adequate evidence to support current clinical approaches and to develop new approaches to management. Multiple pathways might play role in AKI including direct renal injury. AKI is independent predictor of mortality in COVID-19. Strategies to enhance the antiviral potency of antiviral agents, vaccine, and ways to mitigate immunopathological host responses contributing to COVID-19 severity require further research in patients of COVID-19.

CHAPTER

8 Sahaja Yoga Meditation for Reduction of Stress during the Present Corona Pandemic

Sandeep Rai, Devdutt Rai, Madhur Rai

Abstract

The world is fighting against the COVID-19 outbreak, which is now spread to more than 200 countries worldwide. There has been a huge loss of life, drastic changes in our way of life, disrupted plans due to travel restrictions and social distancing. Health experts say, during this time of heightened stress, anxiety, and fear, finding ways to cope up and to create stability is the key to maintaining a healthy body and mind. Pandemic-related stressors may be difficult to change; nevertheless an enhancement in one's coping abilities to combat the deleterious effects of stress on the body and mind can be definitely brought about. In fact, new studies have now revealed that by practicing only 15–20 minutes of Sahaja Yoga meditation daily, you can remain stress-free.

Introduction

When stress does not let up and is paired with the feeling that we have very little or absolutely no control over the circumstances that are creating it, that's called chronic stress. Chronic stress zaps brain power by damaging neural pathways and hampering judgment. It damages the immune system and many other organs including the heart and the brain. Presently robust evidence exists for the Mind-Body medicine practices like meditation and yoga for improving one's psychological and physical health.

Sahaja Yoga is indeed a very unique meditation developed by Dr. Nirmala Devi Srivastava, popularly known as H.H. Shri Mataji Nirmala Devi in 1970. This meditation causes a transformation inside a person by which one becomes balanced and de-stressed. It offers a practically easy method of understanding one's own energy systems and harnessing the innate powerful energy, present in all human beings, for improving one's own health. Scientific researches have now clearly shown that Sahaja Yoga meditation acts by reducing the activity of the sympathetic system (*Stress*) and increasing the parasympathetic activity (*Relaxation*) in an individual.

Sahaja Yoga meditation practice for 12–16 weeks, in subjects who had never practiced any form of meditation before, has shown a slowing of the heart rate, decrease in the respiratory rate, decrease in both BP and in the production of urinary vanillymandelic acid (VMA), which is a breakdown product of stress hormone adrenalin and an increase of Galvanic Skin resistance.[1] Changes in all these parameters reflect a de-stressed state of body. These parameters indicate activation of a deep parasympathetic state, which in turn indicates a physiologically relaxed state of the body and mind, and this may play a very big role in the prevention of stress-related diseases.

Electrophysiological studies (EEG) and analysis, on SY meditators, have shown specific brain activation patterns, which indicate a relaxed state of mind, a subjective feeling of happiness, and an enhanced interconnectivity of different brain regions.[2,3] In an interesting study examining emotional reactions of Sahaja Yoga meditators compared to non meditators, a decreased electrophysiological,

physiological, and psychological reactions were seen in meditaors when exposed to stressful stimuli, compared to non meditators, thus showing for probably the first time in the world, the neurophysiologic proof, to support the hypothesis, that Sahaja Yoga meditation leads to development of greater resilience in an individual to deal with stressful life events.[4] Many other randomized trials on Sahaja Yoga meditation have demonstrated beneficial effects on depression and work-related stress.[5]

In other researches conducted on Sahaja Yoga meditation, very good results were achieved in patients suffering from anxiety and depression,[6] enhancing QOL[7] and significant improvement in psychological health of a mixed population consisting of subjects from different countries and of age groups **(Fig 1)**.[8] Encouraging results have also been recorded in patients with hypertension, asthma, and perceived stress, after a couple of weeks of Sahaja Yoga meditation practice. SY meditation practice also showed a significant reduction in epilepsy attacks, attacks of bronchial asthma. and improvements in the control of diabetes and blood pressure.[6,9-16]

Chronic stress in known to increase cortisol levels in body which in turn decreases immunity and consequently impairs a person's ability to fight infections. Two randomly controlled studies conducted in the Dept. of Medicine & the Dept. of Physiology at the MGM Institute of Health Sciences, Navi Mumbai by the authors of this article, on effects of Sahaja Yoga on perceived stress and serum cortisol levels recorded a very robust reduction in perceived stress and serum cortisol levels in Sahaja Yoga meditation practitioners as compared to non-meditating healthy population.[17] More over an exciting new research has shown that practice of Sahaja Yoga resulted in increase in gray matter volume of brain, in many cortical and sub-cortical brain regions of the right hemisphere. These regions are associated with self-control, compassion, and stress modulation.[18]

Modern medicine's understanding of the human immune system, as a complex multidimensional interaction among different organ systems, is slowly expanding, throwing its light on new facets like neuroendocrine and psychoemotional aspects governing its effective functioning. Chronic stress, although mental in origin, has many detrimental effects on the body as well as on the immunity by creating an imbalance in the neuroendocrine pathways. These chronic stressors overwhelm the immune system of our body thus weakening the immune system's ability to activate a strong immunological response to an infectious organism and thus making the individual susceptible to life threatening medical consequences. It is now amply proven that practice of meditation establishes moderation in the person's psychological and emotional spheres and corrects the imbalance in the neuroendocrine pathways.

Both health and yoga experts now firmly believe that meditating on a regular basis can help to improve the immunity of the body, thus creating a shield in a fight against the highly infectious diseases, like COVID-19. Scientific research has already shown that meditation produces remarkable effects on the brain and immune

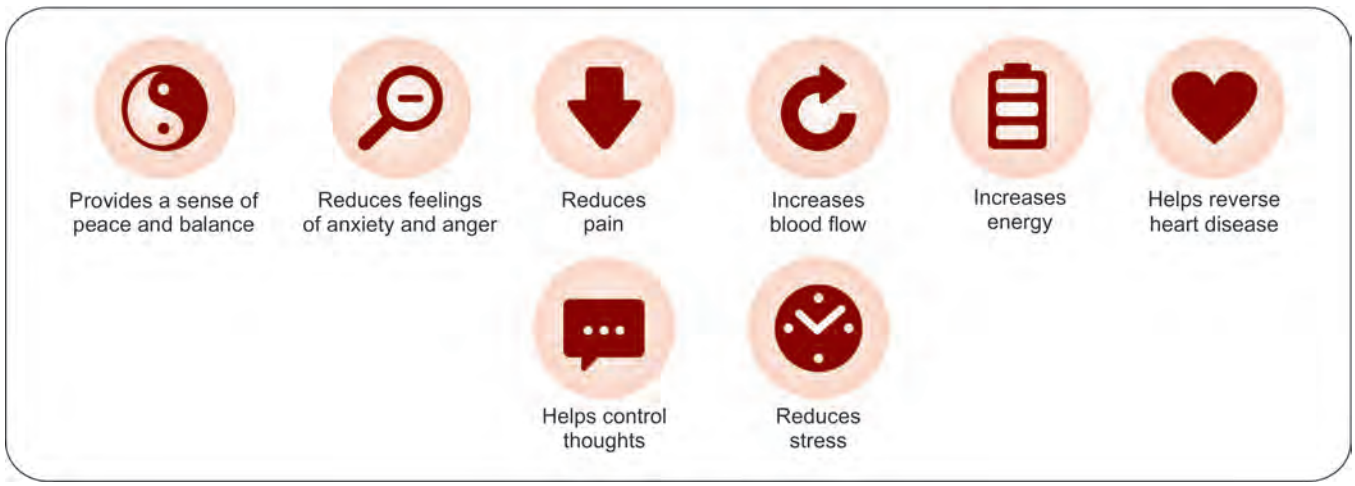

Fig. 1: Benefits of meditation

functions.[19-21] Recent studies have now shown that the relaxation produced after meditation reduces the levels of IL-6, a proinflammatory cytokine which plays a major role in the pathophysiology of several diseases including COVID-19.[22]

Meditation has shown to increase the telomerase activity of chromosomes and lengthens telomeres and thus promotes immune cell longevity.[23] Meditation has shown to reduce the activity of nuclear factor-kB (NF-kB), which is a known mediator in the pathogenesis of inflammation and in generating C-reactive protein which increases in inflammatory conditions including COVID-19.[24,25] Meditation has shown to boost the levels of salivary immunoglobulin A, which is an immune mediator at mucosal surfaces such as GI tract, respiratory tract, and genitourinary tract.[24,25] Meditation has also shown to increase the levels of antibody titer against influenza virus thus increasing immunity against some of the common viral infections.[23,26] Regular meditation practice has also shown an increase in the absolute lymphocyte count which is an important predictor of the risk of opportunistic infections and is now increasingly used to grade the severity of COVID-19 infections.[27] A very recent review analyzing various studies, for the effects of meditation and yoga on immune system has found the evidence of enhancement of immunity in an individual, by the practicing some forms of yoga and meditation.[28]

How Sahaja Yoga Meditation Reduces Stress?

The Possible Mechanisms: Mammals, including humans, have over millions of years evolved the ability to deal quickly and reflexively with perceived threats to their survival and this ability has conferred a robust survival advantage to this group of animals. In humans however, the same stress response can be triggered in situations which, while they do not necessarily threaten survival but occur fairly frequently over a prolonged period of time. Such a typical situation is in the present day stress of Corona pandemic which we all are facing on a daily basis. Repeated activation of the stress response is thought to result in dysregulation of the immune system which hampers the body's own survival mechanisms and this in turn damages health. The changes in mind and body achieved by Sahaja Yoga meditation are characterized by the relaxation response. Psychophysiological studies on Sahaja Yoga meditation, suggest that indeed it elicits a relaxation response. The hypothesis is that the innate energy, called Kundalini energy, described in detail in the ancient Indian scriptures, actualizes in limbic area of the brain and modulates the stress response of an individual through the limbic system **(Fig. 2)**. The limbic system has intricate connections with hypothalamus and via hypothalamus the autonomic nervous system is modulated. The limbic system by its action on the HPA axis modulates the release of various important hormones including cortisol which is secreted in response to stress. Practicing Sahaja Yoga meditation balances the energy systems of the body for its optimum functioning.

Sahaja Yoga is now a practiced in many corporate offices and is an integral part of wellness programs. It is also increasingly being incorporated in many youth development programs around the world. In this ongoing Corona pandemic, technology has enabled to teach and conduct online Sahaja Yoga collective meditation programs for lakhs of people in India and across the world, and these online programs have become hugely popular.

The Harvard Medical School also, in its latest health guideline released on COVID-19 pandemic, has said that, Yoga and meditation are "some tried and true ways to relax and to remain stress free in these difficult times." There have been numerous medical researches conducted in India and abroad on Sahaja Yoga. Sahaja Yoga is now available free of charge,on the various online platforms, to learn and practice, and it is also taught free at all the Centers of Sahaja Yoga which are present today in more than 150 countries of the world.

H.H. Shri Mataji Nirmala Devi ji has received numerous Prizes and recognitions from all over the world for her significant contribution to the understanding of subtle energy systems of the human body. She was conferred with the Honorary membership to the prestigious Presidium of Petroyaska's Academy of Art and Science, Russia (Einstein being one of the members). She has been conferred the United Nations Peace Prize and had been nominated for Nobel Peace Prize, twice. For any further information on Sahaja Yoga you may visit www.freemeditation.com or write to doctorsandeeprai@gmail.com.

Prof., Sydney Med School; Dr. Sheng Chia, Epidemiologist, London; Dr. Sergio Elias Hermandez, University de La Laguna, Tenerife, Spain; Prof. U. Panjwani, DIRDO, New Delhi; Dr. D. Chug, Neurologist, USA; Prof. K. Rubia, Kings College London; and all the doctors and subjects who participated voluntarily in research projects for their active participation, cooperation, and valuable contribution.

Conclusion

The world is fighting the COVID-19 pandemic and people are desperately looking for ways to cope up with this unrelenting stress. Chronic stress zaps brainpower by damaging neural pathways, compromises the immune system besides taxing many other organs of the body. It may not be an easy task to change the present day stressors, but coping abilities to combat negative effects of stress on health and disease can definitely be enhanced. In fact, new research reveals that simple 20 minutes of Sahaja Yoga meditation a day can keep stress away. By practicing this meditation, an inner transformation takes place by which one becomes energized and de- stressed. Studies show that Sahaja Yoga meditation acts by reducing sympathetic activity (Stress) and enhancing the parasympathetic activity (Relaxation). Rigorous researches on Sahaja Yoga meditation have demonstrated significant benefits on depressive mood, anxiety, and work stress and have shown improvement in Psychological health, Perceived Stress levels, and overall Quality of life. Sahaja Yoga meditation is taught free of charge in more than 150 countries around the world. The simple technique of Sahaja Yoga can be learnt free from internet and through online meditation programs also. For learning Sahaja Yoga meditation or for any more information please visit site -www.freemeditation.com or www.sahajayoga.org.in

CHAPTER

9 Diagnosis and Management of Corona Infection

Sandeep Garg, Avishkar Agarwal, Sunita Aggarwal

Abstract

The current pandemic caused by SARS-CoV-2 (COVID-19) began in China and has taken over 4,00,000 lives, putting every country to a standstill. Its manifestations range from mild symptoms to respiratory failure and multi-organ damage in those with risk factors. Spreading mainly by person-to-person transmission, it reached every part of the world within 3 months. Management of the disease is based on case severity and symptomatic treatment. While several new drugs are being developed, many drugs have been repurposed for the same. Other than low dose steroids, no drug has shown proven benefit in preventing severe disease so far. As of now, prevention is the best strategy against this disease. There are universal preventive measures for everyone including health-care workers to be followed even outside health-care facilities. Certain vaccines are being developed all around the world, but that might be a long road ahead. Even after development of a specific drug/vaccine, this new disease is here to stay. Past experiences have taught us to learn to live with it and adjust our lifestyle accordingly.

Introduction

In 2019, a novel coronavirus disease 2019 (COVID-19) began in Wuhan, China, and spread worldwide and was declared a pandemic by WHO. It is caused by severe acute respiratory syndrome-coronavirus-2 also called as—SARS-CoV-2. As of the first week of June, 7 million reported cases and 400,000 deaths in more than 200 countries. In India, there is 250,000 reported case with approximately 6,000 deaths. This is a *Betacoronavirus* and is similar to Middle East respiratory syndrome coronavirus (MERS-CoV) and severe acute respiratory syndrome coronavirus (SARS-CoV).

Clinical Features and Transmission

The spectrum of disease ranges from mild to critical:[1]

- Mild (no or mild pneumonia)—81%
- Severe disease (dyspnea, hypoxia, or >50% lung involvement on X-ray)—14%
- Critical disease (respiratory failure, shock, or multiorgan dysfunction)—5%

The median incubation period is 4 days (2–14 days). However, about half of the population seems to be asymptomatic. Clinical presentation is mostly of upper respiratory illness **(Table 1)**.[2]

There are certain risk factors and laboratory parameters, which predispose to severe or critical disease **(Box 1 and Table 2)**.[1]

Transmission

There are two main modes.

Person to Person

It is the predominant method that occurs via respiratory droplets spread through close-contacts. These respiratory droplets do not travel more than 6 feet. Although airborne precautions are recommended, the transmission via

TABLE 1 Clinical features

Typical clinical features		*Atypical clinical features*	
Dry cough	68%	Nausea & vomiting	5%
Fever*	44%	Nasal congestion	5%
Fatigue	38%	Diarrhea	4%
Sputum	34%	Tonsillar enlargement	2%
Dyspnea	19%	Conjunctival congestion	1%
Myalgia	15%	Hemoptysis	1%
Sore throat	14%	Lymphadenopathy	0.10%
Headache	14%		
Chills	12%		

*Low grade, about 88% developed during hospitalization
Some patients also reported of anosmia and dysgeusia

TABLE 2 Laboratory parameters in critically ill/severe cases

Increase in:	
Ferritin	>500 ug/L (normal: females 10-200 ug/L; males 30–300 ug/L)
CRP	>100 mg/L (normal: <8.0 mg/L)
D-dimer	>1000 ng/mL (normal: <500 ng/mL)
CPK	>2× ULN (normal range: 40–150 units/L)
Troponin	>2× ULN (normal: females 0–9 ng/L; males 0–14 ng/L)
LDH	>245 units/L (normal range: 110–210 units/L)
Decrease in:	
Absolute lymphocyte count	<800/uL (normal: 1800–7700/uL)

BOX 1 Risk factors for severe disease

- Age >65 years
- History of hypertension
- History of cardiovascular disease
- Diabetes mellitus
- Obesity (BMI ≥30)
- Biologics (eg, TNF inhibitors, interleukin inhibitors, anti-B cell agents)
- History of immunosuppression (e.g., Transplant)
- CD4 cell count <200 cells/microL (e.g., HIV)

BOX 2 List of Aerosol generating procedures

- Open suctioning of airway
- Sputum induction
- Tracheal intubation
- Noninvasive ventilation
- Tracheostomy
- Cardiopulmonary resuscitation
- Manual ventilation before intubation
- Bronchoscopy

this route is still unclear. Airborne precautions are recommended when high-risk aerosol-generating procedures are in place **(Box 2)**.

SARS-CoV-2 has been detected in other specimens as well, including stool, tear film, blood, semen. However, the role of these sites in the transmission is still not known. No feco-oral transmission has been detected as of yet.

Period of Infectivity

It can be transmitted 2–3 days before the onset of symptoms and then throughout the disease. Maximum transmission has been reported in the first 7 days. Infectivity peaks 1 day before the onset of symptoms.[3]

Environmental Contamination

If susceptible individuals come in contact with contaminated surfaces, then it serves as a potential source of contamination. The survival time of viral particles has been demonstrated to be different on different surfaces.

Diagnosis

Given the high transmission and prevalence of COVID-19, an efficacious strategy for quick diagnosis and prompt response is the need of the hour. An overview of the strategies is discussed below.

Whom to Test

In this time of the pandemic, a high clinical suspicion of the COVID-19 case is necessary. It should be suspected in any patient with new symptoms. ICMR has prioritized a certain group of symptomatic individuals to be tested and apart from this, testing of asymptomatic cases may be advocated in special circumstances **(Table 3)**.[4,5]

TABLE 3 Individuals to be tested

Symptomatic	*Asymptomatic*
• International travel in the last 14 days • Contacts of laboratory-confirmed cases • Health care workers involved in management of C0VID-19 • All patients of Severe Acute Respiratory Infection (SARI) • All symptomatic Influenza-Like-Illness (ILI) • All hospitalized patients who develop ILI symptoms • All symptomatic ILI migrants within 7 days of onset of illness	• Involved in public health monitoring, screening or sentinel surveillance • Immunocompromised who are admitted to hospitals • Before any immunosuppressive procedures • Undergoing major surgeries • High-risk contacts of a confirmed case to be tested once between day 5 and day 10 of coming into contact • Undergoing an aerosol-generating procedure

Testing Methods

There are two main testing methods approved:

RT-PCR

It is a confirmatory test based on the detection of unique sequences of virus RNA by NAAT polymerase chain reaction (RT-PCR).[6] The gene targets tested are: spike (S), nucleocapsid (N), envelope (E), and RNA-dependent RNA polymerase (RdRp), and certain regions in the first open reading frame.[7,8]

Specimen: Upper respiratory tract samples are collected usually (most commonly from nasopharynx or oropharynx). Lower respiratory tract specimens have higher viral load but are reserved for patients with initial negative test on an upper respiratory tract specimen but high clinical suspicion.[5] The specificity of most of the RT-PCR tests is about 100%.[9] The yield from these specimens is variable **(Table 4)**.

Timing of testing: In nasopharyngeal specimens, viral load becomes detectable earliest by first day of symptom-onset and peaks within the first 7 days. This positivity starts to decline by week 3 and subsequently becomes undetectable.[10] A "positive" PCR result indicates only the detection of viral RNA and it does not necessarily indicate the presence of viable virus.[6] PCR positivity remains longer in sputum and stool may remain positive even after nasopharyngeal samples; however, it is not related to the clinical severity of the disease.[11]

Truenat testing: Recently ICMR approved Truenat for screening. It was originally developed for the detection of tuberculosis. It has advantages of giving results in 30–60 mins. All positive results are confirmed with RTPCR.[12]

TABLE 4 Detection of COVID-19 in different samples

Bronchoalveolar lavage	93%
Sputum	72%
Nasal Swab	63%
Fibrobronchoscope biopsy	46%
Pharyngeal Swab	32%
Feces	29%
Blood	1.0%

Antibody Testing

Antibody against COVID-19 is likely to be reactive in the first several days to weeks of infection, and thus may have less utility for diagnosis in the acute setting. It is used mainly for screening purposes and those who present late, beyond the first 2 weeks of illness onset.[13] There are no data regarding the specificity of these serological tests. Cross-reactivity is a potential concern, and IgM tests are prone to false-positive results.

In India, ICMR has advocated the use of rapid antibody testing in hotspot areas **(Flowchart 1)**.[14]

Management

Case Severity and Level of Care

In India, ICMR has advised classifying the cases based on their severity into three groups, and further, the management of each group has been planned at a different level of care known as COVID dedicated facilities **(Table 5)**.

Treatment of Cases

Most of the cases of COVID-19 are mild and only a small proportion of them are severe. The management is mainly

Flowchart 1: The use of rapid antibody testing

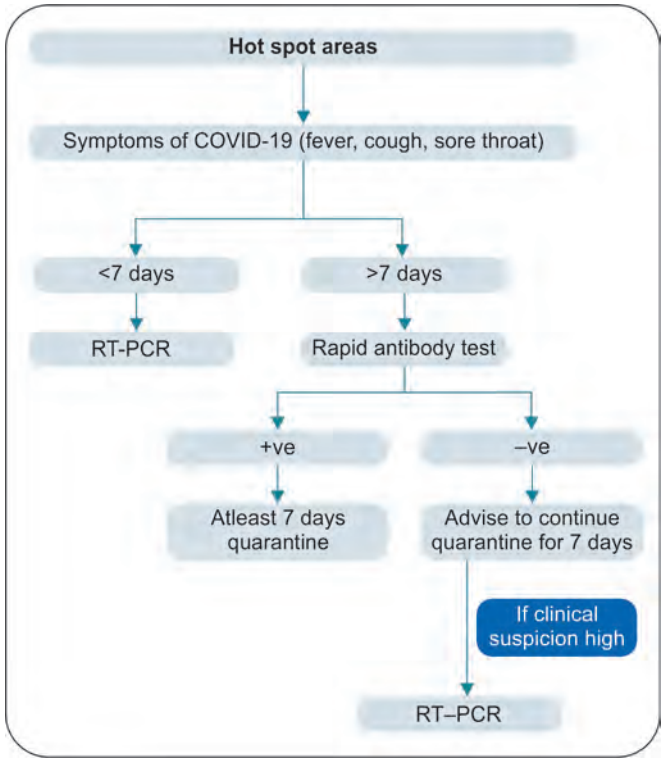

TABLE 5 Classification of cases and level of care

Severity of case	*Description*	*Level of care*
Mild and very mild case	All the cases presenting with fever and/or upper respiratory tract illness	COVID Care Centre (CCC)
Moderate case	All the cases who are confirmed to have pneumonia with **all** of the following: • Respiratory rate <30/min and/or SpO_2 >90% • Hemodynamically stable • <50% lung parenchymal involvement in X-ray	Dedicated COVID Health Centre (DCHC)
Severe case	All the cases with any of: • Respiratory rate >30/min and/or SpO_2 <90% • Acute respiratory distress syndrome (ARDS) • Septic Shock • >50% of lung parenchymal involvement in X-ray • Any other complication	Dedicated COVID Hospital (DCH)

symptomatic. The specific treatment consideration is as follows.[15]

Supplemental Oxygenation

Most of the severe cases require oxygenation. Oxygen can be given by nasal cannula or non-rebreathing mask. The target oxygen saturation is above 94%.[16]

The use of prone position can improve oxygenation. During prone positioning, there is relative recruitment of nondependent dorsal alveoli and because of a higher density of pulmonary vessels in the dorsal lung region, it results in improved $\dot{V}/\dot{Q}$ matching and oxygenation.[17]

Specific Pharmacotherapy

No specific drug therapy has been proven against COVID-19. Several therapies are being evaluated. Some of which are already clinically available for other indications. The potential treatment options in COVID-19 under consideration are given in **Table 6**.[15]

"Solidarity Trial" is an international clinical trial launched by the World Health Organization to find an effective treatment of COVID-19. It compares four treatment—chloroquine versus remdesivir versus lopinavir/ritonavir versus interferon beta 1a. Recently, India also became part of this trial.

Other Specific Issues

Hemodynamic stabilization: Patients with SARI with no evidence of shock should be treated cautiously with intravenous fluids, because aggressive fluid resuscitation may worsen oxygenation. If BP further falls, the use of inotropes and vasopressors should be considered.

Venous thromboembolism prophylaxis: COVID-19 is associated with profound inflammation and this can cause endothelial injury and subsequent thrombosis, a phenomenon also termed as thrombo-inflammation.[18] It is advised to use pharmacological (UFH, LMWH) in all hospitalized patients with d-dimer more than 1,000 ng/dL unless contraindicated.[26]

Steroid: The recent results from RECOVERY trial has shown remarkable improvements from low dose dexamethasone (6 mg/day), following which the use of same has been

TABLE 6 Specific pharmacotherapy against COVID-19 under consideration

Name	*Dose*	*Remark*
Chloroquine and Hydroxychloroquine (HCQS)	Chloroquine: 600 mg BD × 10 days *HCQS:* 400 mg BD on day 1 200 mg BD × 4 days	Inhibits endocytosis and blocks viral entry into cell HCQS is more effective than chloroquine[18] Latest studies have shown no benefit[19] Less in-hospital survival observed More chances of arrhythmia FDA has recommended against the use of this drug in COVID-19[20]
Azithromycin and HCQS	Azithromycin 500 mg OD × 5 days *HCQS:* 400 mg BD on day 1 200 mg BD × 4 days	The only drug approved by ICMR for severe cases A large multicentre cohort study observed no significant difference in in-hospital mortality[21] Both drugs associated with QTc prolongation and combined use may potentiate this. American College of Cardiology issued a warning and score-based approach to using these drugs[22]
Remdesivir	200 mg i.v on day 1 100 mg i.v × 10 days (for patients on mechanical ventilation) 100 mg i.v × 5 days (for other patients)	Nucleotide analogue which inhibits viral RNA dependent RNA polymerase Originally developed by company Gilead for EBOLA FDA has issued an approval for emergency use for hospitalized patients with severe disease[23] Not recommended in: • ALT >5x normal • eGFR <30 mL/min per 1.73 m^2 • Lactating or pregnant female • Children <12 years of age However, not available in the Indian market as of now
Lopinavir/Ritonavir	400 mg/100 mg BD × 14 days	Inhibits main viral protease Administration during early peak of viral replication has proven more efficacious[24] Drug-induced transaminitis is a major side effect. ICMR has approved off-label emergency use in:[25] • Severe patients • >60 years • With comorbidities
Convalescent Plasma	4 to 13 mL/kg (usually 200 mL single dose given slowly over not less than 2 hours)	Contains antibodies from the serum of patient who has recovered from COVID-19 Clinical trials undergoing (including in India) to prove efficacy May be considered in those who are not improving despite steroid therapy The early result showed an early time to recovery
Tocilizumab	8 mg/kg (up to a maximum of 800 mg per dose).	COVID-19 is characterized by a marked inflammatory response—the cytokine storm Markedly elevated inflammatory markers (e.g., D-dimer, ferritin) and elevated pro-inflammatory cytokines (including interleukin IL-6) are associated with poor outcome Studies from Wuhan showed clinical benefits and a decrease in C-reactive protein, D-dimer, and ferritin levels
Ivermectin + Doxycycline	Ivermectin – 200 ug/kg on day 1 Doxycycline- 200 mg stat on day 1 100 mg BD × 4 days	Both drugs inhibit viral replication and have proven efficacy in in-vitro studies Initial case reports from Bangladesh described promising results Clinical trials are undergoing to further evaluate the efficacy

recommended by all major societies including WHO and ICMR.

Use of ACE inhibitors: For patients already taking these drugs, it is advised to continue treatment, if there is no other reason for discontinuation.[27]

Critical Care and Other Complications

Acute respiratory distress syndrome (ARDS) and critical care: Among those who are critically ill, ARDS is the dominant finding. Age appears to be the major risk factor that predicts progression to ARDS.[28]

Oxygen target of 94% is preferred. Low flow via nasal cannula is appropriate (i.e., up to 6 L/min). Higher flows (up to 10–20 L/minute) may be administered using a simple face mask, venturi face mask, or non-rebreather mask. However, oxygenation at higher flow is associated with a higher risk of aerosolization.

Refractory hypoxemia is a major issue. Use of high-flow nasal cannula oxygen therapy (HFNO) or noninvasive ventilation (NIV) can be considered. No study is available regarding the comparative efficacy of the two.

The decision to intubate the patient against the risk of salvageability and risk of spread of infection is challenging. A low threshold for intubation in the following patients:

- Rapid progression over hours
- Lack of improvement on high flow oxygen >40 L/minute and FiO_2 >0.6
- Increasing work of breathing or tidal volume, worsening mental status or if developing hypercapnia
- Hemodynamic instability or multiorgan failure

However, given the high risk of aerosol generation, certain precautions must always be practiced **(Box 3)**.[29]

Septic shock: Sepsis, shock, and multiorgan failure occur but are less common than ARDS. The management of septic shock in COVID-19 is essentially in line with surviving sepsis guidelines.

Acute kidney injury (AKI) and dialysis: AKI among hospitalized patients with COVID-19 ranging from 5% to 23%. It usually manifests during the second week of infection.

Cardiac complications: The most common cardiac complications include myocardial injury leading to myocarditis, arrhythmia, and conduction system abnormalities, acute coronary syndromes, etc.

BOX 3 Precautions while intubating

- The most skilled person should perform the procedure
- Use of preoxygenation and rapid-sequence induction protocols
- An antiviral filter should be placed
- Use of video laryngoscopy
- ETCO2 measurement by continuous-wave capnography is the best method to confirm tracheal intubation

TABLE 7 Criteria for discharge

Mild/very mild/pre-symptomatic cases	• After 10 days from symptoms onset and afebrile for last 3 days • No need for repeat testing • Home isolation advised for further 7 days after discharge
Moderate cases	• After 10 days of symptoms onset and asymptomatic for last 3days • No need for repeat testing • Advised to follow home isolation for further 7days after discharge
Severe	• After clinical recovery, and • After the patient has been tested negative once by RT-PCR

Coagulopathy: Many studies have described hypercoagulability in COVID-19 and a low risk of bleeding in such patients.

Discharge of the Patients

In contrast to the initial "test-based strategy," the Govt. of India eventually shifted to "symptom-based strategy" or "time based strategy." The ICMR laboratory surveillance data also indicated that patients became negative after a mean duration of 10 days **(Table 7)**.

Prevention

Prevention is the best and the only proven strategy that can be adopted against COVID-19. Some of the preventive advises are enlisted in **Table 8**.

Future Perspective

Future of the COVID-19 management depends mainly on two pillars—discovery of an optimal drug and development of an efficacious vaccine. Many government agencies are funding researches in this field.

TABLE 8 Preventive measure against COVID-19

In healthcare setting	• For all patients/visitors: – Screening before entry – Universal use of masks • While dealing with suspect or confirm case: – Patient to be kept in a single occupancy room with a separate bathroom and no positive pressure. – Healthcare working entering the room should wear PPE comprising at least: ♦ Gowns and gloves ♦ Respirator or masks ♦ Eyes or face mask – Maintaining hand hygiene – Regularly Clean with sodium hypochlorite (for floor and surfaces) and 70% alcohol for metallic surfaces and doorknobs)
Personal preventive measures	• To practice social distancing • To maintain at least two meters distance • Proper hand washing • Respiratory hygiene (e.g., covering while coughing or sneezing) • Cleaning and disinfecting objects and surfaces

TABLE 9 Potential pharmacological therapies

Virus-based	
Main protease inhibitor	Lopinavir/ritonavir , Cinanserin, flavonoids
Papain-like protease(PL2pro) inhibitor	Disulfiram
RNA-dependent RNA polymerase inhibitor	Favipiravir, Ribavirin, Remdesivir, Galidesivir
Viral S spike protein inhibitor	Umifenovir
Viral Nucleic acid inhibitor	Mycophenolic acid
Other drugs	Loperamide
Host-based	
Viral endocytosis inhibitor	Chloroquine/Hydroxychloroquine
Host protease inhibitor	Camostat mesylate, Nafamostat
Inhibitor of viral nuclear transport	Ivermectin
Host immunity enhancer	Interferon alpha and interferon beta, Nitazoxanide
Host Matrix metalloproteinase(MMP) inhibitors	Tetracyclines (doxycycline, minocycline, etc.)
Immune-based	
Convalescent plasma	
IL-6 inhibitors	Sarilumab, Siltuximab, Tocilizumab
IL-1 inhibitors	Anakinra,
Anti CD6 monoclonal antibody	Itolizumab
JAK inhibitors	Baricitinib, Pacritinib Fedratinib, Ruxolitinib

Potential Pharmacological Therapies

Several treatments are being investigated for COVID-19. Some of these treatments are already available for other indications (repurposed drugs), while many new drugs are being developed specifically for COVID-19 **(Table 9)**.

Among the therapies mentioned in the table, the following are under trial in India:[30]

- Disulfiram
- Remdesivir
- Favipiravir
- Loperamide
- Convalescent plasma
- Tocilizumab (IL-6 inhibitor)
- Itolizumab
- Mycobacterium w

Potential Future Vaccines

Several vaccines are under development against COVID-19. As of May 2020, more than 150 vaccine candidates are under development.[31] The majority of these are in the preclinical or exploratory phase. Only a few have entered phase 1. Leading the race for a new vaccine, eight vaccine candidates have already entered human trials across the world **(Table 10)**.

In India, there are at least 30 attempts to develop an effective vaccine against the COVID-19 by six Indian companies.[32]

Recently, BCG vaccination has garnered a lot of interest. Studies have suggested that BCG immunization induces a non-specific immune response in the hosts that may have protective effects against non-mycobacterial, including viral, infections. However, more data is needed and this vaccine is under trial as of now.

TABLE 10 Vaccines

Name of vaccine	*Developing insitute*	*Country*	*Remark*
mRNA-1273	Moderna	US	Encodes for a full-length, prefusion stabilized spike (S) protein of SARS-CoV-2
Adenovirus Type 5 Vector (Ad5-nCoV)	CanSino Biological Inc	China	Based on engineered replication-defective adenovirus type 5 vector to express the SARS-CoV-2 spike protein
ChAdOx1 nCoV-19	University of Oxford	UK	An engineered adenovirus-based vaccine to express the SARS-CoV-2 spike protein
PiCoVacc	Sinovac Biotech	China	Inactivated vaccine
Wuhan Institute of Biological Products Vaccine	Sinopharm	China	Inactivated vaccine
Beijing Institute of Biological Products	Sinopharm	China	Inactivated vaccine
INO-4800	Inovio Pharmaceuticals	US	DNA vaccine
BNT162 vaccine	Pfizer and BioNTech	Germany	mRNA-based vaccine to encode spike protein

Conclusion

The development of a vaccine or an efficacious drug is not reality as of now and seems to be a farfetched option. It is impossible to predict when the pandemic would be controlled. The new coronavirus might be here to stay. Moreover, it may take years to build up sufficient levels of immunity. Coronavirus is just another novel disease like HIV, which has not disappeared but measures have been developed by people to live by it. We need to learn to live with coronavirus and adjust ourselves to it.

CHAPTER

10 Clinical Presentation and Systemic Manifestations of COVID-19 (Coronavirus Disease 2019)

Rajib Ratna Chaudhary, Sarda Mukund Shyam

Abstract

COVID-19 (Coronavirus Disease 2019) was reported in December, 2019, and the first case was reported in India on 30th January, 2020, in Kerala and declared pandemic on 11th March, 2020, by World Health Organization (WHO). SARS-CoV-2 virus is a single-stranded RNA virus and is the seventh member of the betacoronavirus family. SARS-CoV-2 virus is an airborne virus, spreads by an infected person on sneezing or coughing small droplets in the air so the person who inhales such droplets or touches the infected surfaces is infected. The incubation period of COVID-19 is 14 days and a median incubation period of 4–5 days (interquartile range 2–7 days). The clinical presentations of COVID-19 are cough, fever, malaise, myalgias, gastrointestinal symptoms, and anosmia or ageusia. COVID-19 diagnosis is based on clinical features and to be confirmed by RT-PCR of nasopharyngeal or oropharyngeal swabs. Management of COVID-19 depends on the severity of disease; with mild disease by home isolation and moderate or severe disease, patients are hospitalized and supportive treatment given. Frequent hand washing with soap and water, face mask, social distancing, testing, and self isolation are important for prevention of COVID-19 until the vaccine becomes available.

Introduction

COVID-19 (Coronavirus Disease 2019) was reported in December 2019 and the first case was reported in India on 30th January, 2020, in Kerala. COVID-19 was declared pandemic on 11th March, 2020, due to its rapid spread in the world by World Health Organization (WHO).[1] India has now more than 88,72,203 infected cases, 4,43,794 active cases with more than 1,32,162 COVID-19 related death (20th November, 2020, MoHF, India).

The common symptoms of COVID-19 in mild cases are fever and cough, in moderate cases, shortness of breath, and in severe cases, the infection can cause pneumonia, multiorgan inflammatory failure, and death.

Frequent handwashing with soap and water, face mask, social distancing, and self-isolation are important for prevention of COVID-19 until the vaccine becomes available.

Transmission

SARS-CoV-2 virus is an airborne virus, spreads by an infected person on sneezing or coughing small droplets in the air so the person who inhales such droplets or touches the infected surfaces is infected.[2]

The transmission is high at the onset of symptom due to high quantity of viral shedding and low over the course of 7–10 days.

SARS-CoV-2 virus has been detected in the stool of COVID-19 patients and consumption of virus-contaminated food may cause infection and transmission is yet not confirmed.[3]

SARS-CoV-2 virus has also been found in semen, but sexual transmission is not yet confirmed.

Pathogenesis

SARS-CoV-2 virus is a single-stranded RNA virus and is the seventh member of the betacoronavirus family, subfamily orthocoronavirinae and sarbecovirus subgenus.

SARS-CoV-2 virus was isolated from epithelial cells of the human airway and its genome consists of ten open reading frames (ORFs), and consists of four structural proteins, that is, S (spike), E (envelope), M (membrane), and N (nucleocapsid) protein to make complete virus particle. SARS-CoV-2 virus virion is about 70–90 nm in size.[4]

SARS-CoV-2 virus enters the host target cell receptor, angiotensin-converting enzyme 2 (ACE2) by attaching with the S protein, which is expressed on alveolar epithelial cells type II (AECII), and on other tissues such as endothelium, heart, kidney, and intestine.[5]

SARS-CoV-2 virus has demonstrated novel glycosylation sites in the spike glycoprotein and the virus may utilize different glycosylation sites to interact with its receptors.[6]

The pathogenesis associated with hypercoagulability is not clear, but hypoxia and systemic inflammation may activate coagulation pathway due to high levels of inflammatory cytokines in COVID-19.

SARS-CoV-2 virus after entry in human system moves through replicative stage due to direct cytopathic effect and presents with mild symptoms and is followed by a stage of adaptive immunity in which virus level decreases as the immune system takes over and after that there will be sudden clinical deterioration in a stable patient due to tissue destruction because of inflammatory cytokine strom.[7,8]

Clinical Presentation and Systemic Manifestations

The incubation period of COVID-19 is 14 days and a median incubation period of 4–5 days (interquartile range 2–7 days).[9] COVID-19 patients reported symptoms in one study within 11.5 days of infection.[10]

Asymptomatic infection was reported in 50% of the Diamond Princess Cruise ship where out of the 619 people (17%) who were positive for SARS-CoV-2 virus.[11]

The most common presentation of COVID-19 is fever, headache, muscular pain, running nose, sore throat, breathlessness, tightness of chest, dry cough, hemoptysis, nausea/vomiting, and diarrhea. Loss of taste and smell precedes the onset of respiratory symptom.[9]

Delayed fever and respiratory symptoms may be atypical presentations in older adults and persons with medical comorbidities.

The systemic manifestations of COVID-19 are bilateral pneumonia (91.1%), which may progress to acute respiratory distress syndrome (ARDS) (3.4%), acute kidney injury (AKI) (0.5%), arrhythmias, heart failure, myocardial infarction, coagulopathy (0.1%), rhabdomyolysis, hyponatremia, acidosis, and septic shock (1.1%).[9]

Skin Manifestations

New onset pernio-like lesions of the feet and/or hands in the absence of any other clear cause (American Association Dermatology guidelines). They are usually asymmetrical.

Rashes of COVID-19 could be classified as:[12]

- Pseudo-chilblains (acral erythema with vesicles or pustules).[13] Pseudo-chilblains (COVID toes) occurs in warmer climate and presents with itching, burning, pain, and is more likely to ulcerate where a classic cold-induced chilblain is a benign and self-limited condition presenting with acral erythema of the toes and fingers with swelling.
- Vesicular (chicken pox-like) eruptions occur in middle-aged adults, which typically lasted for 10 days.
- Maculopapular eruptions are perifollicular in distribution and varying degrees of scaling. Some were described as like pityriasis rosea.
- Urticaria.
- Livedo or necrosis. Livedo and necrosis indicate severe illness and poor prognosis.

Ocular Manifestations

Nasal cavity and conjunctival sac are anatomically connected through nasolacrimal duct and most of the respiratory organism harbor inside nasal mucosa, so the patient of COVID-19 may present with conjunctivitis and SARS-CoV-2 virus was detected in conjunctival secretions but was absent in those without conjunctivitis. Tears sample may be used for diagnosing COVID-19.[14]

Hypercoagulability in COVID-19[15,16]

Hypercoagulable state developed in some patients of COVID-19 and small and large vessels were at increased risk of developing thrombosis. The patients may develop mild thrombocytopenia, prolonged prothrombin time, elevated D-dimer levels, myocardial injury, large vessel strokes, microvascular thrombosis in toes and clotting of catheters.

The high risk of death was strongly associated with elevated D-dimer levels. The thrombotic complications were most frequently reported venous thrombosis and pulmonary embolism.

The major comorbidities associated with COVID-19 are hypertension, diabetes mellitus, ischemic heart disease, cerebrovascular disease, chronic obstructive pulmonary disease, hepatitis B, chronic kidney disease, malignancy, and immunodeficiency, which increase the severity of illness.[9]

Severity of Illness

The illness may range from mild to moderate, severe, and critical.[17]

- Mild to moderate 81% (mild symptoms to mild pneumonia).
- Severe 14% (shortness of breath, hypoxia, or >50% lung involvement with pneumonia on imaging).
- Critical 5% (acute respiratory failure, septic shock, or multiorgan inflammatory failure).

Psychoneural Manifestations

Psychoneural manifestations can be broadly classified in four categories.

Among General Population

The general population may develop fear and helplessness, depressive disorders, somatic symptoms, and even suicidal tendency.[18]

Among Covid Patients

Quarantined people feel loneliness, depression, insomnia, may cause self-harm, suicidality, and survivors are prone to develop Post Traumatic Stress Disorder (PTSD).[19,20]

Among Relatives of Covid Patient and Close Contact

Family member and close contact of patient generally develop psychological problem as they are isolated and quarantined. The patient's family member feels shame, guilt, or stigmatized and may suffer from PTSD.

Among Healthcare Workers

Healthcare workers may develop physical exhaustion, sleep disturbances, and emotional disturbances.[21,22]

Diagnosis

COVID-19 diagnosis is based on clinical features and to be confirmed by RT-PCR of nasopharyngeal or oropharyngeal swabs.

The RNA of SARS-CoV-2 virus has also been found in stool and blood and may be a marker of severe illness.

The routine investigations demonstrated lymphopenia, neutrophilia, elevated serum aspartate aminotransferase and serum alanine aminotransferase level, elevated lactate dehydrogenase, high C-reactive protein (CRP), and high-ferritin levels, which may be associated with severity of illness.[9,23]

Lymphopenia and elevated D-dimer indicate high mortality. Procalcitonin was elevated among those admitted in the ICU, but the level was normal at the time of admission.[24] Potential immune dysregulation was associated with high levels of plasma inflammatory markers.[23,25]

The X-ray chest and HRCT thorax may demonstrate patchy consolidation, extensive exudative infiltrates, and bilateral peripheral ground-glass opacities (GGOs), but may not be remarkable in the early stage of the disease.

Differential Diagnosis

The differential diagnosis of COVID-19 is another viral pneumonia caused by adenovirus, influenza, human metapneumovirus, parainfluenza, respiratory syncytial virus (RSV), rhinovirus, and bacterial pneumonia.[24]

Treatment and Prevention

There are investigational treatments for COVID-19 and treatment data is limited on hydroxychloroquine, azithromycin, remdesivir, and favipiravir on the course of disease, severities of illness and hydroxychloroquine as prophylaxis in exposed people.[26]

Frequent handwashing with soap and water, face mask, social distancing, and self-isolation is important for prevention of COVID-19 until the vaccine becomes available.

Prognosis

The predictors of high mortality are age 80 years and above, hypertension, diabetes mellitus, ischemic heart disease, chronic obstructive pulmonary disease, malignancy, severe lymphopenia, and elevated level of D-dimer.

Conclusion

- SARS-CoV-2 virus is a single-stranded RNA virus and is the seventh member of the betacoronavirus family, subfamily orthocoronavirinae and subgenus sarbecovirus infecting humans and was isolated from the epithelial cells of human airway.
- The clinical presentations of COVID-19 are cough, fever, malaise, myalgias, gastrointestinal symptoms, and anosmia or ageusia.
- Diagnosis of COVID-19 is usually confirmed on detection of SARS-CoV-2 virus by RT-PCR testing of a nasopharyngeal and oropharyngeal swab.
- Management of COVID-19 depends on the severity of disease; with mild disease by home isolation and moderate or severe COVID-19 patients are hospitalized and supportive treatment given.
- There is investigational treatment available for COVID-19 and so critical patients may be referred for investigational treatment.
- Frequent handwashing with soap and water, face mask, social distancing, testing, and self-isolation is important for prevention of COVID-19 until the vaccine becomes available.

CHAPTER

11

Post-Acute COVID-19 Syndrome

Yash Pal Munjal, Anupam Prakash

Abstract

Symptoms of acute-COVID-19 illness can persist for more than a couple of weeks, wherein we refer the syndrome as "post-acute COVID-19 syndrome." It may encompass symptoms localized to a single organ system or multiple organ systems. Post-COVID-19 fatigue, body aches, cough, lung fibrosis, bronchiectasis, myocarditis, coronary ischemia, pulmonary thromboembolism, stroke, microvascular coagulopathy, Guillain-Barré syndrome, cognitive dysfunction, anosmia, ageusia, gastrointestinal upset, psychological distress, depression, sleep disturbances, secondary infections (bacterial and fungal), rash, and asymptomatic liver and/or pancreatic enzyme elevations have been observed. The persistence of symptoms can be witnessed irrespective of the initial severity of COVID-19 illness, though "post-acute COVID-19 syndrome" is commoner subsequent to moderate and severe COVID-19 illness, compared to mild COVID-19 illness; and is commoner in at-risk groups (diabetes, hypertension, obesity, heart disease, and pre-existing pulmonary disease). Persistence of symptoms post-COVID-19 has been reported to be variable and can last for up to 6 months. The exact management is yet not known, but rest, gradual resumption of activity, nutritious diet, and symptomatic management form the mainstay. Specific therapies like steroids, antifibrotic agents (pirfenidone or nintedanib) for pulmonary fibrosis, and anticoagulants for elevated D-dimer levels to prevent coronary and cerebrovascular ischemia and pulmonary thromboembolism (post-ARDS) are being investigated and their role may be discernible in the times to come.

Introduction

COVID-19 is an acute infective illness. It was declared a pandemic in March 2020. Although the world has witnessed pandemics earlier too, but COVID-19 was like none before and it shook human beings out of their comfort levels. Man is a social animal, but the lockdowns, social distancing, wearing face mask, and restrictions on travel and social gatherings disturbed the social fabric of mankind. Managing COVID-19 illness in hospitals and isolation centers, by health-care personnel in personal protective equipment (PPE) or by video or teleconsultation became the order of the day, and resulted in a paradigm shift for the patients, who were so used to the "healing touch" of doctors and nurses. COVID-19 proved to be an acute mental distress to the patients, and also to the family members and the health-care workers involved in imparting care to the ill.

The Genesis and the Pathophysiology

To the patients, COVID-19 was largely asymptomatic in 80–90% of the cases, but 5–15% did have moderate or severe illness. The classification in to mild, moderate, and severe illness was based upon the presence of pneumonia manifesting as tachypnea and hypoxia.[1] However, COVID-19 proved to be a respiratory illness, inhalation of droplet nuclei being the primary mode of spread, but with systemic manifestations.

As the pandemic unfolded, several systemic manifestations were observed:[2,3]

- High CRP levels and elevated interleukin-6 and serum ferritin indicated a severe inflammatory state.
- Elevated D-dimer levels pointed towards presence of intravascular thrombosis, and this was evident in lungs in post-mortem of COVID-19 patients, and also stroke and coronary ischemia were seen in convalescent COVID-19 patients.
- Elevated liver functions and pancreatic enzymes were witnessed during the acute phase.
- Anosmia and ageusia were also witnessed as atypical manifestations.
- Lung involvement showed diffuse peripheral ground-glass opacities mimicking an acute respiratory distress syndrome (ARDS) like picture.

Most viral illnesses cause a self-limiting acute illness; however, acute COVID-19 illness was associated with significant morbidity and mortality among symptomatic patients, and more importantly, a sizable proportion of these reported delayed recovery and persistent symptoms. Risk factor groups for COVID-19 severity and associated mortality included higher age (>50 years), presence of diabetes, hypertension, obesity and cardiovascular disease, premorbid lung diseases, apart from factors like smoking, alcohol, and patients on immunosuppressive medications or suffering from immune-mediated disorders or cancers. These risk group patients are more prone to moderate and severe COVID-19 illness, and also to greater mortality including sudden deaths. Complications of COVID-19 especially the ARDS with worsening of hypoxia and surge in inflammatory markers akin to the cytokine storm were usually witnessed early in the 2nd week of illness, that is, 8th to 10th day of symptomatic illness. However, the deterioration in the form of respiratory failure was witnessed comparatively earlier, that is, in the latter half of 1st week of illness, in the presence of comorbidities like heart disease and/or diabetes, especially if uncontrolled.

A unique feature of acute COVID-19 illness is being witnessed, with the persistence of symptoms beyond the initial phase of 2 weeks, and at times taking months to resolve.[4] These patients have been variably called as "long-haulers" or suffering from "post-acute COVID-19 illness," "post-COVID illness," "long-COVID." Delayed recovery and greater persistence of symptoms are witnessed primarily in moderate or severe COVID-19 patients, and in those who have any of the aforementioned risk factors for COVID-19. However, this long-COVID syndrome has also been witnessed in mild COVID-19 patients.

The exact pathophysiology of the persistence of symptoms is yet not known. It is possible that some manifestations could be due to direct viral injury, or alternatively due to the systemic inflammatory response generated by the virus. Persistent viremia due to weak or absent antibody response, relapse or reinfection, inflammatory and other immune reactions, deconditioning, and mental factors such as post-traumatic stress singly or together contribute to the post-COVID syndrome. Long-term respiratory, musculoskeletal, and neuropsychiatric sequelae have been described with other coronaviruses (SARS and MERS). Apart from viral infiltration and inflammation, microthrombi and downregulation of ACE-2 receptors may be involved in the pathophysiology of cardiopulmonary complications.[5]

The severe inflammatory reaction witnessed in acute COVID-19 illness can lead to a dysregulated innate immune response, ciliary dysfunction, cytokine storm, thrombo-inflammation, microvascular coagulation, and immune exhaustion. This can lead to post-COVID-19 sepsis and predisposition to secondary bacterial and fungal infections, more so in diabetic patients and critically ill patients, who have anyway been administered steroids, anti-interleukin therapies, CRRT/ECMO, prolonged hospital stays with indwelling catheters and emergency procedures, mechanical ventilation, and, at times, breaches in asepsis. Covid-19 associated pulmonary aspergillosis (CAPA) has been reported, and recently, invasive mucormycosis (rhino-orbito-cerebral and pulmonary) has also been brought to the attention of physicians managing COVID-19 and post-acute COVID-19 patients.[6] Tuberculosis has also seen a resurgence in patients afflicted with COVID-19,[7] especially in the post-COVID immunosuppression phase.

The frequency of post-COVID-19 syndrome could vary from as low as 10% to as high as 70%. The exact frequency is difficult to state, as majority of the infections could have passed being asymptomatic, and so the true denominator is not known to calculate the true prevalence.

Clinical Features

Our own experience has shown a spectrum of findings, and **Table 1** outlines the manifestations seen in post-

TABLE 1 Symptomatology of "post-acute COVID-19 syndrome"

• Post-COVID myalgias, arthralgias, or body aches
• Post-COVID fatigue
• Anosmia/ageusia
• Chronic cough, pulmonary fibrosis, bronchiectasis, and reduction in pulmonary functions
• Gastrointestinal upset
• Transaminitis
• Asymptomatic elevation of pancreatic enzymes
• Thromboembolic conditions, viz. stroke and myocardial infarction/ischemia
• Asymptomatic elevation of D-dimer
• Guillain-Barré syndrome
• Other neurological syndromes, viz. seizures, encephalitis, PRES, delirium, cognitive dysfunction including difficulty in concentration
• Myocarditis, pericarditis, dysrhythmias, and pulmonary thromboembolism
• Metabolic disruption such as poor control of diabetes
• Psychological distress
• Psychiatric morbidity—depression
• Sleep disturbances
• Weight loss and malnutrition, including sarcopenia in elderly
• Low-grade fever
• Skin rashes—vesicular, maculopapular, urticarial or chilblain-like lesions on the extremities (COVID toes)
• Secondary infections (secondary to viral-illness induced immunosuppression), viz. post-COVID sepsis and mucormycosis
• Residual renal dysfunction (secondary to acute kidney injury)

acute COVID-19 illness. Post-COVID fatigue with or without myalgias/arthralgias is the commonest persistent symptom seen in clinical practice, and is associated with decreased capacity to perform activities of daily living. Many patients of mild COVID-19, who joined back after the mandatory 14–17 day isolation period, were unable to do even 6-hour desk work, and had to be advised rest again. Likewise, few patients did have severe myalgias or arthralgias and headache requiring prescription of potent analgesics to obtain relief. Persistent cough was seen across all severities including mild cases, while persistent dyspnea was more frequently encountered in moderate and severe COVID-19 patients. There were a couple of mild cases past middle-age, who were discharged after the requisite isolation period, but died during sleep around 3rd or 4th week of symptom onset. COVID-19 has been associated with a severe inflammatory process, and sudden cardiac deaths probably due to myocardial infarction or dysrhythmias, triggered by the inflammatory processes in the coronaries/myocardium could be the plausible mechanism. Similarly, most patients lost weight, indicating that COVID-19 is a severe catabolic stress on the body. Inflammatory mediators have taken weeks to months to revert back to normal. Transaminitis, pancreatic enzyme elevations, and D-dimer elevation have persisted for as long as 8–12 weeks, even in mild to moderate cases. Further, atypical symptoms like ageusia and anosmia have also been noted to persist for months together, taking their own sweet time to resolve. Psychological stress and sleep disturbances have been witnessed in many patients, and psychiatric mood disorders may be attributed to the illness, delayed return of normal health, loss of job, and financial losses incurred. Several other associated neurological syndromes are coming to light like headache, loss of concentration, cognitive dysfunction, Guillain-Barré syndrome, posterior reversible encephalopathy syndrome, apart from increase in cases of stroke.[4,8-10]

In a 6-day outcomes assessment of COVID-19 patients in Michigan, USA,[11] 488 telephonic contacts could be established, of which 159 patients (32.6%) reported cardiopulmonary symptoms such as cough or dyspnea, 92 (18.8%) of these had new onset cough or worsening of pre-existing cough, while 65 (13.3%) had persistent loss of smell or taste. 58% patients telephonically contacted reported new or worsening difficulty in the conduct of activities of daily living. In the study cohort, 195 patients were employed before hospitalization, 78 (40%) could not return to work because of health issues or loss of jobs. 30 (25.6%) of the remaining 117 who returned to work, reported reduced work hours due to health issues. Out of the 488 surveyed, 238 (48.8%) reported emotional impact, with 28 (5.7%) seeking consultation from mental health practitioner.

In another study[12] among 150 noncritical COVID-19 patients, two-thirds of patients had some or the other symptom at day 60 of symptom onset. The proportion of patients who still had asthenia, dyspnea, and anosmia/ageusia at day 30 respectively was 49.3%, 36.7%, and 28% and on day 60 respectively was 40%, 30%, and 23%. In a

telephonic survey[13] among French patients conducted at 3 months, the most common persistent symptoms were—fatigue (55%), dyspnea (42%), memory loss (34%), sleep disorders (30.8%), and difficulty in concentration (28%). 30% of the active workers could not join back because of their health issues. In an Italian study[14] on 143 patients, 87% of patients had persistent symptoms at 60 days after onset of first COVID-19 symptom—32% had 1 or 2 symptoms, while 55% had 3 or more symptoms. Fatigue (53.1%) was the commonest symptom followed by dyspnea (43.4%), arthralgias (27.3%), and chest pain (21.7%), with 44.1% reporting a deterioration in the quality of life.

Investigations

It is general consensus that asymptomatic patients may need not be investigated. Blood tests need to be ordered appropriately for specific clinical conditions. Anemia may need to be ruled out in patients having dyspnea, apart from a chest X-ray/CT scan and an echocardiography. C-reactive protein and leucocyte counts may be elevated suggesting infection or ongoing inflammation. Concomitant fever, especially if moderate to high grade should prompt rethink of a concurrent infection. Elevated troponin may suggest myocarditis or ischemia and needs to be correlated with the clinical picture, while elevated natriuretic peptides may indicate heart failure. Although troponin and D-dimer tests may be falsely positive, but negative test results can remove the clinical uncertainty from the minds of treating physicians. Serial chest radiographs and CT scans of the thoraces can aid in picking up pulmonary lesions, but at times indicate disproportionately greater severity compared to what the clinical picture suggests. The exact role will only be clear over a period of time.

Prognosis

As already stated, more the number of risk factors present, longer may be the persistence of the symptoms, and more number of symptoms are likely to persist. However, how long will the symptoms persist is difficult to state at the present moment. Some manifestations like stroke and myocardial infarction or sudden cardiac death are catastrophic or considered the end-points, while Guillain-Barré syndrome may go either way depending upon the extent of progression and responsiveness to management strategies. COVID-19 ARDS survivors are at risk of long-term impairment of lung function. Serious interstitial lung disease is rare in patients who are not hypoxic, but it may be too early to comment upon the pulmonary involvement and spontaneous reversibility of fibrosis. However, the experience with influenza-associated pulmonary fibrosis and the previous coronavirus illnesses (SARS and MERS) indicates that residual damage at 1 or 2 years may not be that alarming.[4,15] What sequelae will post-acute COVID-19 syndrome leave behind are yet not known, but symptoms do improve over time, and presently symptoms have been documented to persist for as long as 6 months.

Management

It is evident from the manifestations of COVID-19 and the universality of persistent symptoms, which can be attributable to virtually all the organ systems, that COVID-19 is a systemic illness. There is no definitive management for COVID-19, apart from oxygen therapy, steroids and awake proning in moderate and severe COVID-19 patients. Therefore, to talk about management of the persistent symptoms, that is, post-COVID syndrome is still very difficult. Several drugs are being tested for specific system abnormalities, and there is no specific management.

It was observed that moderate/severe COVID-19 patients, especially those suffering from diabetes, heart disease, or morbid obesity, continued to remain oxygen dependent even after 3–4 weeks of symptom onset. These patients had to be discharged on bed rest and domiciliary oxygen. Home pulse oximetry can be helpful in monitoring these patients with post-COVID lung fibrosis, and rate of oxygen flow may be accordingly adjusted. Prolonged course of steroids and antifibrotic agents like pirfenidone and nintedanib are being tried to reverse lung fibrosis in COVID-19 patients where CT scan has showed fibrotic changes. Deep breathing exercises and steam inhalation help tackle persistent cough in convalescent patients, although cough mixtures (with antitussives) may be prescribed in irritating cough conditions.

Rest, gradual increase in activity and good nutrition including a balanced diet with adequate micronutrient supplementation holds the key to improving fatigue, weight loss, and helps in reversing the catabolic process associated with COVID-19 illness.

Analgesics (non-steroidal anti-inflammatory drugs and paracetamol) can help get rid of body aches, headache, arthralgia, myalgia, and low-grade fever. However, antidepressant medications like amitriptyline, fluoxetine, and duloxetine may be very helpful to overcome depression and the body pain in patients who have associated psychological distress too. Sedatives hypnotics may be used for inducing sleep. Patients with diabetes, obesity, hypertension, and coronary heart disease who have persistent D-dimer elevation can be prescribed aspirin or alternative anticoagulants, although the duration of therapy in these patients is not yet defined.

Psychotherapy and counseling can be very helpful in tiding over the psychosocial issues related to the post-COVID syndrome. Fungal infections may add to the burden of COVID-19 management and contribute to increased morbidity and mortality. Treatment involves antifungal agents, surgical debridement, control of associated comorbidities, and withdrawing of treatments, which contribute to immune suppression. Amphotericin B is the drug of choice for invasive mucormycosis, but posaconazole or isavuconazole may be used in patients with concomitant renal dysfunction.

Conclusion

Post-acute COVID-19 syndrome requires attention to detail, and treating physicians should actively seek for the varied symptom profile that may be witnessed and comprise this syndrome. Physicians managing COVID-19 and following up these patients post-discharge need to be very attentive and carefully seek symptoms, so as to outline this syndrome and its behavior over time. This will help to determine the progression of individual symptoms and their subsidence over what period of time will be unraveled. Further, management options as part of various clinical trials and also as part of observational studies will guide us to devise management protocols for post-acute COVID-19 syndrome.

Hypertension

CHAPTER

12 Home Blood Pressure Measurement

BR Bansode

Abstract

Home blood pressure measurement (HBPM) is self-measurement of blood pressure. Because easy technique, accepted by majority of people and awareness of complication of hypertension patient get adhere to treatment of hypertension.

The International Society of Hypertension also recognized usefulness of HBPM in the management of hypertension. HBPM improves adherence to drug treatment. HBPM helps treating doctors to modify or reduced the doses of antihypertensive drugs.

Introduction

Hypertension is major cause of morbidity and mortality worldwide.[1,2] Accurate and reproducible of blood pressure measurement by reliable and authentic blood pressure devices is an important clinical skill, which every clinician should acquire it. The correct diagnosis of hypertension is based on proper measurement of blood pressure **(Fig. 1)**. The complication of raised blood pressure if someone aware than he will be more adherence to the treatment of hypertension, and further hypertension management is easy and can avoid, delay the complication of hypertension.

Since 1960, the pioneering work by George Pickering and Maurice Sokolow, the several techniques developed to the measure blood pressure like clinic/office BP, 24-hr ambulatory blood pressure (ABPM), and home blood pressure. Out of these, home blood pressure is gaining important method because of easy technique, self-monitoring blood pressure, wider acceptance, and availability of HBPM devices also increasing awareness of importance of regular blood pressure monitoring and early recognition of morbidity due to hypertension **(Fig. 2)**

Why we should Know about Hypertension?

Hypertension is silent killer often patients are asymptomatic and when symptomatic it may be too late to revert the progress of disease process. Increased blood pressure may be leading cause of death globally.

Most guidelines recommended that when person's SBP $\geq$ 140 mm Hg and DBP $\geq$ 90 mm Hg then the condition termed as hypertension.

American College of Cardiology (ACC) and American Heart Association (AHA) recently gave guidelines[3] that when SBP > 120 mm Hg and DBP > 80 mm Hg have hypertension. White coat hypertension-office blood pressure more than home blood pressure. Mask hypertension when office or clinical blood pressure is normal and home blood pressure is more (10–15%).

Patients with hypertension are often asymptomatic and disease progress so much that complications slowly and silently develop like stroke, heart failure, CAD, and sudden death. Hence, every effort should be made to protect people at large by creating awareness of hypertension, educating them, train them in taking home blood pressure measurement (HBPM), aware them classification, and complication of hypertension.

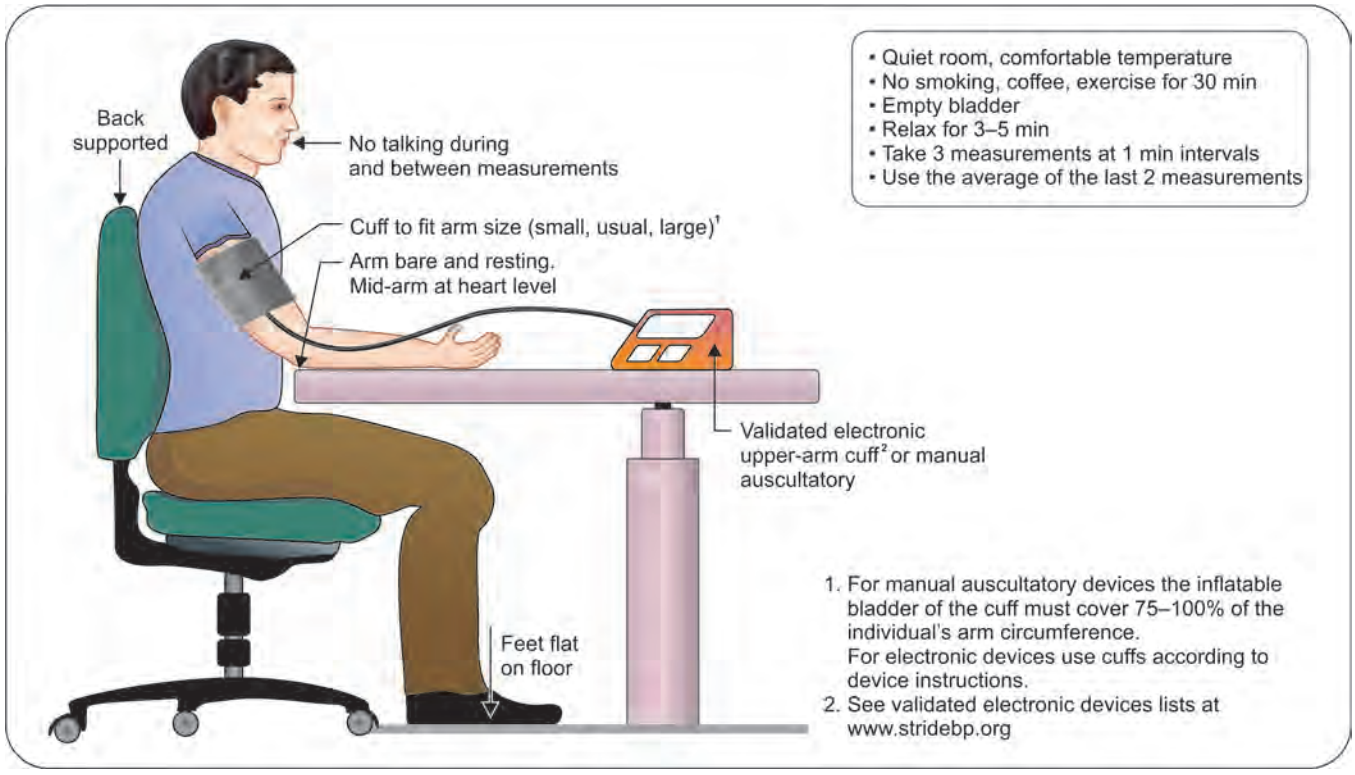

Fig. 1: Technique blood pressure measuring at home

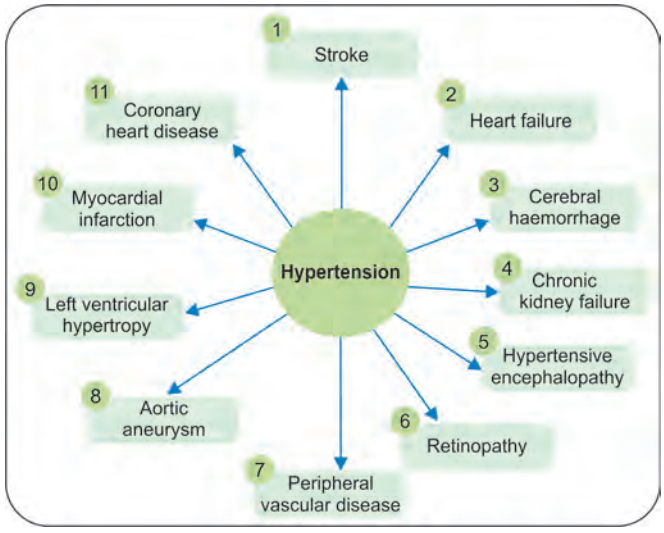

Fig. 2: Vascular complications of hypertension

Hypertension is major cause of morbidity and mortality globally account for 10.4 million death/year **(Fig. 3)**. There for (KSH) International Society of Hypertension has develop worldwide practice guidelines for clinician in 2020 for uniform and better management of hypertension in adult age 18 years and above.[4,5] There is clear shift of trend of hypertension from high income group to low income group[6,7] due to education, awareness improved living conditions, and following lifestyle measurement.

These large disparities in regional load of hypertension is due to low level of awareness, non-adherent to treatment and low control rates of hypertension in these groups. Therefore, the International Society of Hypertension launched the global campaign to increase awareness of hypertension mainly the May measurement month initiatives along with Hypertension Society India, Association of Physicians of India, and other hypertension societies took several initiative like lifestyle modification, home blood pressure monitoring, and meditation to reduce mental stress level and regular follow-up with appropriate lab investigation to treating physicians.

To describe hypertension and its complication and management is beyond the scope of this topic; therefore, we restrict our self to "Home Blood Pressure Measurement", that is, how to measure blood pressure, what is proper technique, how to create awareness of hypertension in

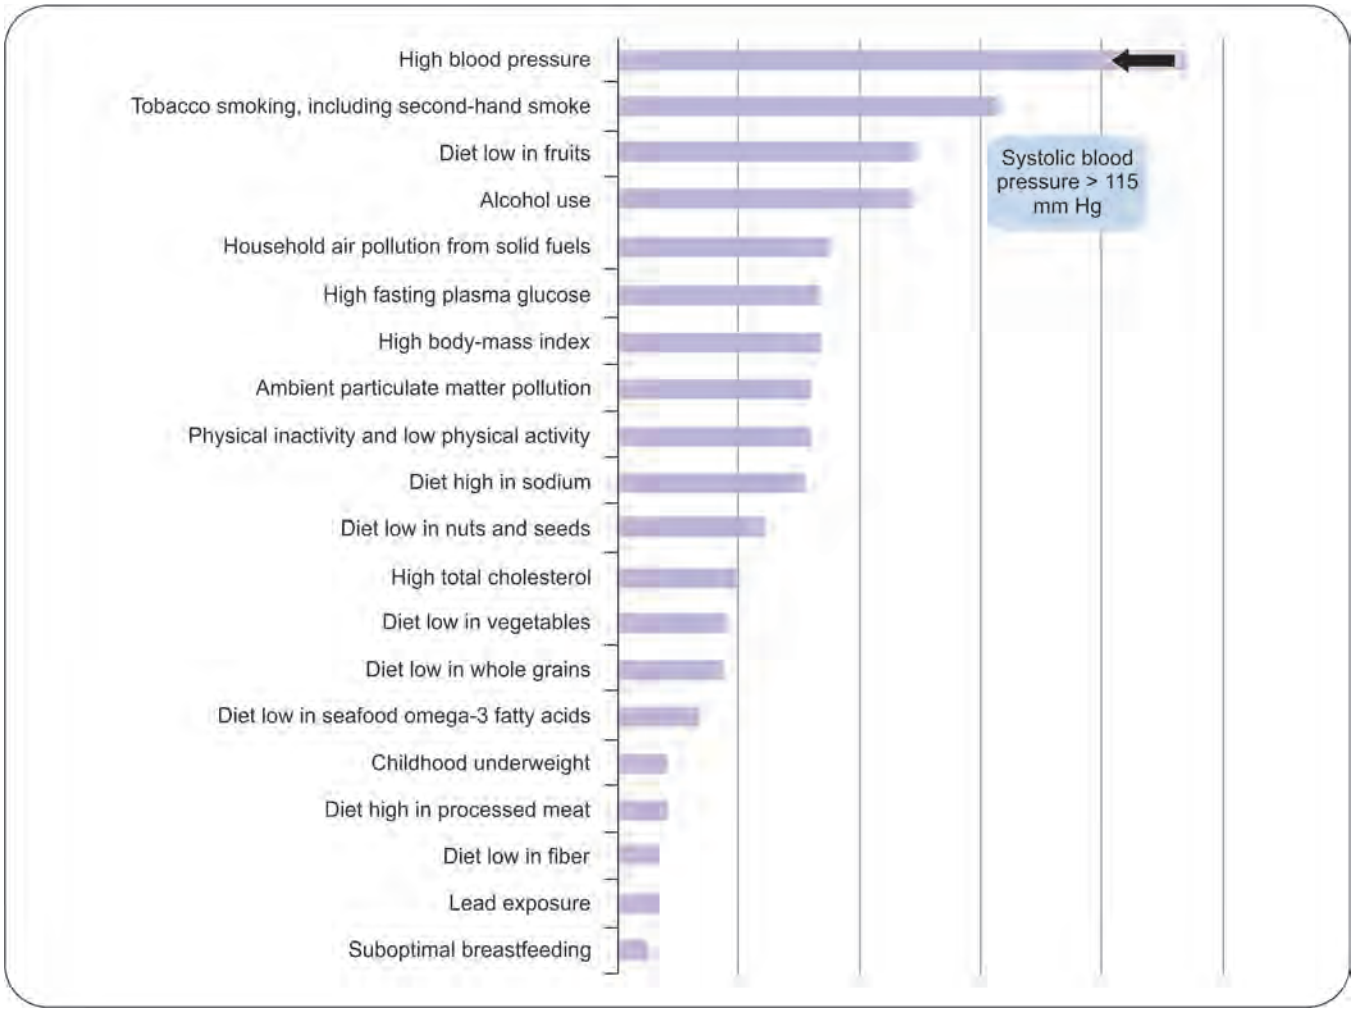

Fig. 3: Global leading risk for death

masses and high-risk populations, how the standard method should be applied for measuring blood pressure. The good equipment, appropriate blood pressure cuff and proper training of personnel are very important. Lastly, compare these HBPMs with other standard method like ambulatory blood pressure measurement. These devices should be calibrated regularly with mercury sphygmomanometer once in 6 months or 1 year.

The measurement of blood pressure is the clinical procedure of greatest important that is performed in the sloppiest manner (Norman Kaplan). Equipment for HBPM—the fully automatic with big screen should be used, brachial artery (arm) should be used for blood pressure measurement. Wrist or other Oscillometric devices may not work well with patient in atrial fibrillation.

Types of Blood Pressure Measurement

- Home blood pressure measurement
- Average blood pressure measurement
- White coat hypertension
- Mask hypertension

In some patient's non adherent to treatment, hypertension and diabetes mellitus, anxiety prone patients s/s hypotension, smoker, obese, hypercholesterolemia and non-dipper the ambulatory blood pressure measurement is more useful than HBPM.

High blood pressure is single major cause of death globally accept 10.4 million death/year.

In 2010 the estimated figure was 1.39 billion had high blood pressure.

In recent year raised blood pressure (hypertension) clearly shift from high income group to low income group[8,9]

- Checking blood pressure yourself at home is the first important step in managemet of hypertension which raised your confidence for correct diagnosis of hypertension.
- It is low cost, easy acceptance of techniques, and reproducible.
- Home blood pressure monitoring is more closely related to office blood pressure which induces target organ damage and better predictor of CV events.
- It detects mark hypertension, white coat hypertension.
- It improves adherence to antihypertensive therapy.
- It improves closing of antihypertensive drugs.

Guidelines for Home Blood Pressure Measurement

- Checking blood pressure yourself at home is the first important step in management of home blood pressure, which will help to raised your confidence, awareness, and help to consult your treating doctor early.
- Thirty minutes before taking home blood pressure avoid Tea, Coffee, Smoking, Tobacco, Alcohol Food, Physical exercise, and Medication.
- Sit 5 minutes in upright chair quietly with feet flat on floor before measuring blood pressure.

Once you know correct technique and choose proper device, it is early help you and your physician to control hypertension reduce cost and visit to clinical for measuring blood pressure.

Blood pressure reading should be taken twice daily. Two reading should be taken with a gap of 3–5 minutes. In irregular heart rate HBPM may not give correct Blood pressure measurement other method (tentative) or blood pressure true should be used for getting current blood pressure reading.

HBPM improve the patient's compliance adherence to treatment helps in preventing complications of hypertension.

In some patients non-adherence to treatment, hypertension, and diabetes mellitus anxiety prone patients e/o hypertensive s/s, smoker, abase, hypercholesterolemia and non-dipper average blood pressure measurement is more useful than HBPM.

What is the Value of Home Blood Pressure Monitoring?

It is inexpensive to monitor blood pressure of home, especially before and after changing the therapy. It is more accurate than office blood pressure monitoring. It helps to confirm the smooth control of blood pressure with therapy. It correlates more closely with ambulatory blood pressure monitoring than clinical blood pressure measurement. It helps to confirm diagnosis of hypertension in untreated patient.

Five prospective studies have compared home blood pressure monitoring, office blood pressure monitoring for predicting CVS outcome. All studies have found that home blood pressure monitor is significant predictor of CVS outcome, than office blood pressure monitoring. Home blood pressure monitor product is better TOD than office blood pressure monitoring. Home blood pressure monitoring is reproducible, it differentiate between White coat, sustained hypertension, and detect mask hypertension.

In older people where blood pressure variably is high and WCH is common and in DM, CKD blood pressure control is very important to reduce complication of hypertension home blood pressure monitoring is very helpful.

Home blood pressure is also helpful in pregnancy for early detection of pre-eclampsia, in CKD blood pressure fluctuation is very high; in patients with hpertension for early detection and diagnosis home blood pressure is helpful.

Despite of advances made in treatment of hypertension over last 60 years. There is still room for improvement in the management of hypertension.

Home blood pressure readings are very often lower than office blood pressure readings, that is, <135/85, or <130/80 mm Hg in high risk group.

Indications for ABPM

- Suspected White coat hypertension
- Suspected masked hypertension (normal clinic blood pressure and elevated ABPM)
- Suspected nocturnal hypertension or non-dippers
- Suspected episodic hypertension (e.g., pheochromocytoma)
- Resistant hypertension

- Titrating antihypertensive therapy
- Hypotensive symptoms while taking antihypertensive medications
- Autonomic dysfunction
- Hypertension detected early in pregnancy
- Suspected or confirmed sleep apnea

ABPM:

- Can be expensive
- Should be comfortable for patient to wear (light and quiet)
- Use of correct cuff size
- Need to be familiar with equipment
- Time to instruct patient, full explanation to patient of what is required
- Requires patient cooperation in order to obtain as many readings as possible
- Twenty-four-hour blood pressure correlates most closely with TOD (compared to clinic or casual blood pressure)
- Higher incidence of cardiovascular events when blood pressure remains elevated at night (non-dippers)
- Blood pressure variability is an independent determinant of TOD
- Highest incidence of cardiovascular events occurs in morning hours

The upper limit of normal for home blood pressure monitoring is 135/89 mm Hg. It corresponded to 140/90 mm Hg.

Equipment:

- Fully automated monitors that use the *Brachial Artery (Arm)* for measurements are the most reliable
- Wrist monitors are not recommended
- Proper documentation of reading by patient/automated by machine—*Date, Time,* and *blood pressure*
- Oscillometric devices may not work well with patients who have atrial fibrillation or other arrhythmias
- Patients HBP monitoring device should be calibrated against mercury sphygmomanometer every 6–12 months

Equipment cuff size: See **Table 1**.

Benefits:

- HBPM is easy to use, more reproducible, more accurate, and has higher prediction of target organ damage than clinic blood pressure (Class IIa LOE B)

TABLE 1 Equipment cuff size

Cuff name	*Bladder width*	*Bladder length*	*Mid arm circumference*
Small arm	10	24	22 to <27 cm
Average arm	13	30	27 to <33 cm
Large arm	16	38	33 to <41 cm
Extra large	17	43	41 to <52 cm

- Differentiates between White coat HT and Sustained HT
- In patients with prehypertension, detects masked HT
- Used to determine response to treatment
- Improves adherence (patients who use HBPM are more likely to take medications regularly)
- Improves quality of treatment and reducing the cost

Benefits in special subsets:

- Elderly: Blood pressure variability tends to be high, and White coat hypertension is common.
- Diabetics: Tight blood pressure control is important and home monitoring may help achieve this.
- Pregnancy: The early detection of pre-eclampsia might be facilitated by HBPM.
- Chronic kidney disease: Blood pressure may fluctuate a lot and home monitors help with management.
- Children: White coat hypertension occurs in children, and there are some data on normal home blood pressure levels at different ages.

Support for Home Blood Pressure Measurement

- Measurements taken by patients at home are often lower than readings taken in the office and closer to the average blood pressure recorded by 24-hour ambulatory monitors.
- Home blood pressure reading predicts risk better than office blood pressure
- In a 2005 Gallop poll:
  - 35% of hypertensive patients now check their blood pressure at least once per week.
  - 86% of patients who had been advised to purchase a blood pressure monitor had done so.
  - 55% of patients were monitoring their blood pressure an increase of 17% from 2000.

Conclusion

- Home blood pressure monitoring is very important for controlling the hypertension in masses. Therefore, the education of masses and training of taking home blood pressure to individual are also essential. The treating physician is also getting help for changing therapy for hypertension.
- ABPM can be regarded as the gold standard for the prediction of risk related to blood pressure.
- ABPM predicts clinical outcome better than clinic blood-pressure measurements.
- It is recommended that HBPM should become a Routine Component of blood pressure measurement in the majority of patients with known or suspected hypertension.
- HBPM has minimal cost, enhances self-confidence and compliance.
- HBPM can *improve blood pressure control.*
- HBPM *Correlates More Closely* with the results of Ambulatory blood pressure monitoring than clinic blood pressure.
- HBPM is more *Predictive of Adverse Outcomes* [e.g., stroke, end-stage renal disease (ESRD)] than clinic blood pressure.

CHAPTER

13 Orthostatic Hypotension

Priti Gupta, Ankur Gupta, Sunita Aggarwal, Bhawna Mastebhakti, Pritam Gupta

Abstract

Orthostatic hypotension (OH) is an important but underrecognized entity. It is associated with an increased risk of cardiovascular diseases, and contributes to recurrent falls, syncope, and mortality, more so in the elderly population. A fall of 20 mm Hg or more in systolic blood pressure and/or 10 mm Hg or more in diastolic blood pressure is termed as Orthostatic hypotension. It can be a sign of autonomic dysfunction (neurogenic OH) or intravascular volume depletion (non-neurogenic OH). Orthostatic hypotension may also be classified in to initial, classic, and delayed. Diagnosis of OH can be made using the bedside standing test, head-up tilt table test, and the 24-hour ambulatory blood pressure measurements. Management of OH can be difficult, and constitutes both pharmacologic (midodrine, droxidopa, and fludrocortisone) and non-pharmacologic measures.

Introduction

Orthostatic hypotension (OH) or postural hypotension is an important, though an underrecognized entity in clinical practice. Its importance is evident because of its association with increased risk of cardiovascular diseases, recurrent falls, syncope, and mortality. Besides, it is also associated with prothrombotic state, chronic kidney disease, fragility fractures, and cognitive decline. However, in the SPRINT trial, OH was not found to be associated with a higher risk of CVD events, falls, or syncope.

A recent meta-analysis demonstrates that OH affects nearly one in five older persons living in the community, and almost one in four persons living in long-term residential care facilities. It is common in patients with diabetes, affecting an estimated 30% of individuals with type 1 diabetes and 25–30% of individuals with type 2 diabetes. In the in-patient setting, prevalence as high as 64% can be observed.

Definition of OH

It is defined as a fall of at least 20 mm Hg in systolic blood pressure (BP) and/or of at least 10 mm Hg in diastolic BP within 3 minutes of active standing or head-up tilt table testing (HUTT) at an angle of at least 60°. However, this traditional definition of OH is recommended for normotensive persons. In hypertensive individuals, a reduction in systolic BP of 30 mm Hg is required to define OH. In addition, European Society of Cardiology proposed an additional criterion for OH: a fall in systolic BP to <90 mm Hg irrespective of magnitude of the BP drop.

Clinical Features

The inability to tolerate the upright posture because of signs and symptoms, which are relieved by recumbency is termed orthostatic intolerance (OI). OI generally results from either ineffective regulatory mechanisms or environmental conditions that exceed the ability of these

homeostatic mechanisms to compensate appropriately for the environmental stress. The clinical manifestations can be:

- Light-headedness or woozy sensation
- Visual (blurring/dimming) and hearing difficulties
- Syncope/presyncope
- Deficits in memory, reasoning, information-processing speed, and concentration
- Fatigue
- Headache
- Tremulousness
- Sweating
- Weakness
- Neck cramping or "coat-hanger headache," due to hypoperfusion of the trapezius and shoulder girdle muscles
- Nausea and chest/abdominal pain
- Exercise intolerance

OH Classification

According to the period of occurrence, OH is classified as initial, classic, and delayed.

Initial OH is defined as a transient drop of >40 mm Hg in systolic BP and/or >20 mm Hg in diastolic BP within 15 seconds of active standing. The proposed underlying pathophysiologic mechanism is a temporal and abrupt mismatch between cardiac output and total peripheral resistance. Initial OH is frequently symptomatic and a common cause of situational syncope, which may be underrecognized.

Classic OH is the most common and typical variant of OH. It is defined as a sustained decline in systolic and/or diastolic BP (according to the current criteria for OH) within 30–180 seconds of active standing or HUTT. Classic OH is caused by decreased total peripheral resistance and/or an excessive fall of cardiac output, such that compensatory vasoconstrictor mechanisms are not sufficient to restore postural BP decline.

Delayed OH is defined as a sustained fall in BP (according to the current criteria for classic OH) occurring after 3–45 minutes of active standing or HUTT. The possible pathophysiologic mechanisms of delayed OH include increased pooling in the lower body capacitance vessels and gradual impairment of compensatory mechanisms during prolonged orthostatic stress, resulting in slow progressive declines in venous return to the heart, cardiac output, and BP. Delayed OH is considered a mild form of classic OH and may progress to classic OH.

OH can also be classified based on underlying pathophysiological mechanisms as neurogenic or non-neurogenic.

Neurogenic OH is due to primary neurological disorders like Parkinson's disease, multisystem atrophy, pure autonomic failure, Lewy body dementia or secondary polyneuropathies like endocrine disorders (diabetes mellitus, adrenal insufficiency, and hypothyroidism), malignant diseases (amyloidosis, multiple myeloma, and paraneoplastic syndromes), autoimmune diseases (lupus, Sjogren's syndrome, rheumatoid arthritis, celiac disease, Guillain-Barré syndrome and multiple sclerosis), toxins (alcoholism, chemotherapy, and poisoning by industrial chemicals), nutritional deficiencies (vitamins B1, B6, B12, and E), infections (herpes zoster, human immunodeficiency virus), uremia, and cirrhosis.

The causes of *non-neurogenic OH* are aging, volume depletion (blood loss, dehydration), venous pooling (prolonged immobility, deconditioning, postprandial, exposure to hot and humid environment, varicose veins), cardiovascular disorders (hypertension, heart failure, cardiac arrhythmias, aortic stenosis, hypertrophic obstructive cardiomyopathy), renal failure, medications like diuretics, vasodilators (alpha-receptor blockers, calcium channel blockers, hydralazine, nitrates, angiotensin-converting enzyme inhibitors and angiotensin receptor blockers), central sympatholytics, beta-receptor blockers, psychotropic agents (antidepressants, tranquilizers, antipsychotics), and anti-Parkinsonian agents.

Diagnosis of OH

The clinician should have a high degree of suspicion and careful history should always be obtained. The three recommended methods to evaluate OH are explained below.

- *Schellong test or bedside standing test:* The test is named after Fritz Schellong, a European pioneer of cardiovascular autonomic neuroscience. Active standing-up from the supine position is the "gold standard" method for initial evaluation of OH. There is no universal standardized protocol for performing a standing test, although this usually consists of a supine phase of 5–10 minutes, followed by an active standing phase of at least 3 minutes, ideally 5–10 minutes.

Blood pressure and heart rate are measured at the end of the supine phase and at 1-minute intervals during the orthostatic challenge. If the patient is unable to stand up from the supine position, a sitting-to-standing protocol is acceptable, although less sensitive than the supine-to-standing one. A sustained decrease of at least 20 mm Hg in systolic blood pressure or at least 10 mm Hg in diastolic or an absolute systolic blood pressure below 90 mm Hg after 3 minutes standing qualifies for OH.

- *Head-up tilt table test (HUTT):* It is a specialized method which largely depends on an expert to interpret the findings. It is performed if bedside standing test is negative in presence of strong clinical suspicion of OH. Moreover, its methodology is not standardized, and it is a less sensitive test. Protocols for performing HUTT vary in the durations of the supine pre-tilt and the passive head-up tilt, the tilt angle, and the monitoring of hemodynamic parameters.
- *24-hour ambulatory blood pressure measurements (ABPM):* Diagnosis of OH by ABPM is based on diurnal variation of systolic and diastolic BP. Reduced dipping (night/day fall 10% in mean values of BP) and reverse dipping (night/day increase in average BP levels) are patterns of diurnal BP variation that associate strongly with OH. ABPM may be helpful for diagnosing masked OH (OH that is not detected in the office) and postprandial OH. In addition, ABPM is recommended for patients with established OH, for assessment of nocturnal hypertension, drug induced OH and OH severity, and for tailoring treatment and diagnosing of additional comorbidities such as obstructive sleep apnea.

Treatment

It consists of both pharmacological and non-pharmacological measures.

Non-pharmacologic Measures

Patient education is the cornerstone of the management of neurogenic OH. The provocative factors that might precipitate or exacerbate OH [e.g., warm ambient temperatures; hot baths or showers; straining, especially with breath holding (the Valsalva maneuver); sudden moves from the supine or seated position to the upright position; and ingestion of large meals] should be sought for. Physical activity and exercise should be encouraged to avoid deconditioning. Simple activities like leg-crossing; stooping; squatting; and tensing of the muscles of the legs, arms, abdomen, buttocks, or whole body reduce venous pooling and thereby increase central blood volume and cardiac filling, with resultant increases in cardiac output, BP, and cerebral perfusion. Additional non-pharmacologic measures include increased salt and water intake, slow rising, raising the head of the bed during sleeping, and the use of compression garments on the abdomen or lower extremities. Rapid ingestion of approximately 500 mL of tap water (e.g., over 3–4 minutes) elicits a marked press or response and improvement in symptoms in patients with neurogenic and non-neurogenic OH. In fact, acute water ingestion is the only class I recommended treatment for OH. All other measures (including pharmacologic treatment as well) have class II recommendations.

Pharmacologic Measures

Midodrine (class IIA): Patients with neurogenic OH report improvement in symptoms after taking midodrine. A dose-dependent effect is seen, usually corresponding to an increase in standing blood pressure. Though an important drug, several side effects may limit its use. Some of them are supine hypertension, scalp tingling, piloerection, and urinary retention. The dose usually used ranges from 5 to 10 mg per oral three times a day (the last dose at least 3 hours before bedtime).

Droxidopa(class IIA): It is mainly used for neurogenic OH that occurs in patients suffering from Parkinson's disease, pure autonomic failure, and multiple system atrophy. According to some small studies droxidopa might reduce falls. Concomitant use of carbidopa in patients with Parkinson's disease may decrease the effectiveness of droxidopa. Some side effects such as supine hypertension, headache, dizziness, and nausea may limit its use and titration. Usual dose is 100 mg per oral three times a day slowly increased to 600 mg three times a day over 3–7 days.

Fludrocortisone (class IIA): The improvement of symptoms of OH is primarily seen due to increases in plasma volume. If taken regularly, at least in astronauts after space flight, fludrocortisone may prevent OH. Since supine hypertension is a limiting factor for its use, other medications should be used before fludrocortisone. Commonly seen side effects

include edema, hypokalemia, and headache. Adrenal suppression and immunosuppression, which are serious side effects can also occur with doses >0.3 mg daily. The starting dose is 0.1 mg per oral daily, maximum being 0.3 mg daily.

Pyridostigmine (class IIB) and octreotide (Class IIB) may be beneficial in certain refractory cases.

Conclusion

OH is an important diagnosis, which is likely to be missed in day-to-day clinical practice. A high index of suspicion, with good history and evaluation, is helpful in confirming the diagnosis. Apart from patient education and other non-pharmacological strategies, acute water ingestion is the recommended Class I treatment. Certain medications (Class IIA) like midodrine, droxidopa, and fludrocortisone form the basis of adjunct therapies in managing OH.

CHAPTER

14 Cooking Oil: Making the Right Choice

Rudrajit Paul, Shibendu Ghosh

Abstract

Edible oil is an essential component of daily Indian food. However, there are a lot of wrong notions about the relative health benefits of different cooking oils. In a culturally diverse country like India, people in different communities have been using different sources of vegetable oil for hundreds of years and it is very difficult to come to a consensus for 1.4 billion people. In this article, the authors have discussed the biochemistry of edible oils including smoke point, the Omega 3:6 ratio, presence of phytosterols and the merits and demerits of refining these oils. Without selecting any particular oil, the authors have tried to discuss the health benefits and risks of various types of vegetable oil with special emphasis on the PUFA and MUFA content, the importance of omega-3 fat and the presence of saturated fat. The scientific basis of health risks associated with saturated fat and trans-fat has also been touched upon. The authors have also discussed the harmful effects of the commonly used cooking medium, Vanaspati. Finally, the authors have also discussed in brief, the problem of edible oil adulteration in India. There is no one correct option when it comes to choosing cooking oil. Sometimes, mixing two oils or using particular varieties of oil on particular weekdays may be the answer.

Introduction

The daily diet in India usually has curries as an indispensable component. Boiled, grilled, or steamed food, although popular for occasional feasts, is not preferred as daily food in India and most Indians prefer cooked items.

But India is a land of diversity. There are many tribes of Northeast India who prefer boiled food. In their cuisine, there is often very little oil. We must be aware of this culinary tradition of our country too. Thus, generally, the cooking medium, viz. oil, is an integral component of quotidian Indian diet. This is one of the main sources of fat in Indian food.

However, there is almost no scientific study or rational discussion on this indispensable dietary element and most Indians get their half-baked ideas on cooking oil either from family tradition or from the so-called "diet experts" online. The void left by the lack of proper scientific discourse is filled by pseudoscientific gibberish or advertisement gimmicks released by the processed food industry. The Indian cuisine varies radically throughout the length and breadth of this incredibly diverse country and any discussion on the "Indian" diet must be aware of this diversity. Otherwise, making just one dietary recommendation for the entire country is likely to be eschewed by various cultural groups and will never be acceptable for all sections of the population. The authors of this article recognize this dietary multiplicity of the country and will shape their discussion in an inclusive manner.

The Indian Culinary Culture

First of all, the authors will describe the prevailing culinary culture of the country with reference to cooking oil. But

it must be remembered that the choice of cooking oil is shaped by a lot of factors like family tradition, education level, socioeconomic status, place of residence, and accessibility. The Indian media or movies have a harmful tendency of clubbing various cultures of this country together as "North India" or "South India". But clubbing such diverse cultures as Malayali, Konkani, or Tamil together under the broad heading of "South Indian culture" is like describing British, French, and Italian cultures together. In the southern part of the country, in Kerala, coconut oil is the most popular cooking oil. They would never think of using mustard oil. But in the eastern part of the country, in Bengal, mustard oil is the oil for popular fish or meat dishes.[1] Again, in Tamil Nadu, the state bordering Kerala and having a lot of cultural similarities, they prefer sunflower oil, groundnut, and sesame oil, but not coconut oil. If you go to Gujarat, you encounter sunflower oil and ghee for cooking. In Kerala or Tamil Nadu, mustard oil is used for pickles only, not for cooking. Similarly, in Bengal or Gujarat, coconut oil is used for applying on hair, not for preparation of food. Ghee is popular in Punjab, Haryana, and Madhya Pradesh for cooking. Groundnut oil is also used in Karnataka. In Goa, for the traditional dishes, they use coconut oil but for daily cooking, sunflower oil is preferred.

However, the cooking habit of urban Indians is radically changing with time. All across India, the upwardly mobile middle class is now shifting toward safflower oil, olive oil, rice bran oil, or soyabean oil. The earlier popularity of cottonseed oil or rapeseed oil is now dwindling. This is not specific to any culture and mainly reflects Western influence. Especially, the use of olive oil is seen as a status symbol by many Indians; but as subsequent discussions will show, this really does not have much health benefit to justify the cost. Over the last two decades, India has been importing millions of tons of palm oil as a cheap vegetable oil. This oil is used for making roadside food, biscuits, and many packaged food items. Millions of Indians are unknowingly consuming palm oil every day, although they don't buy it for their home. Vanaspati, hydrogenated vegetable oil, is used in many hotels or restaurants of India. This is mainly prepared by processing palm oil. *Thus, while discussing the cooking oil of Indians, not only the domestic food but also the outdoor food items must be discussed.*

The discussion below is designed to be a scientific discourse on the pros and cons of various cooking oils and is not intended to be judgmental on any culture.

Some Important Physical and Chemical Properties

If the reader wants to make an informed choice about his/her cooking oil, then some preliminary knowledge on the biochemistry of this product is needed.[2] Some important terms are discussed first.

Smoke Point

This is the temperature at which oil starts to emit smoke or starts to burn. If the smoke point is low, that oil will burn in the frying pan easily. This gives a bad smell, bad taste, and also can generate free radicals. Thus, if the reader wants to deep fry something, obviously oil with high smoke point will be needed. Otherwise, the oil will burn and the frying will be half-done. **Table 1** gives the smoke point of some commonly used cooking oils.

The authors would like to discuss two points on this table. Firstly, as seen here, butter is not a good frying medium. It has low smoke point and will burn easily. On the other hand, ghee has smoke point of 480°F. Thus, ghee can be used safely for frying. Secondly, the term "refined" is very important while discussing the smoke point.[2] Unrefined safflower oil has smoke point of 225°F, while refined one has smoke point of 510. Thus, the final smoke point is also dependent on the degree of refining of the oil. This is one of the advantages of refining oil, although the disadvantages of refining will be discussed later.

PUFA

These are organic acids with more than one double bond in their backbone. Many of them are essential in nutrition. These acids are further divided into Ω-3 and Ω-6 acids.

TABLE 1 Smoke point (in Fahrenheit) of some cooking oils

Oil/Fat	*Smoke point*
Mustard Oil	480
Butter	302
Coconut oil	450
Virgin olive oil	410
Refined safflower	510
Refined sunflower	450
Sesame oil	450

They will be described later. In high temperature cooking, the polyunsaturated fatty acids (PUFA) in cooking oil can degrade into hydroperoxide and other harmful products.

Some studies have found cardiovascular benefit with consumption of some varieties of PUFA, like the Ω-3 variety. This is thought to be due to the antiatherogenic effect of long chain Ω-3 PUFA.[3] Also, it raises HDL and lowers triglyceride in blood. The LDL particles in blood are also modified with alteration in their apolipoprotein levels, which make them less atherogenic. It is also thought that these varieties of PUFA may alter gene expression in the early stages of atherosclerosis.[3]

In the website of the American Heart Association, three oils are mentioned as good sources of PUFA: soybean oil, sunflower oil, corn oil. Of these, corn oil is not found in India till now. But in the future, it may be imported and sold here. Also, the AHA recommends nuts like Walnut and soybean as sources of good PUFA. *But there is a problem with PUFA-rich vegetable oils. During the process of refining, the PUFA in these oils may be oxidized, which may be harmful for the body.*[4]

MUFA

These are fatty acids that have only one double bond in their carbon skeleton. Some studies have shown decrease in blood LDL levels with monounsaturated fatty acids (MUFA) intake. But studies on diet are at best imperfect and it is often impossible to separate the relative benefits of each dietary component. The Mediterranean diet is rich in MUFA.[4] Some studies have found that high MUFA intake may be associated with decreased risk of malignancy, diabetes, and neurodegenerative diseases.

Food rich in MUFA: Olive, Avocado, Cashew nut, tea-oil, whole grain wheat.

Cholesterol

Cholesterol is a compound which is found only in animal sources of food. *Any plant product is expected to be free of cholesterol. Thus, the advertising gimmick of brandishing vegetable oil as "cholesterol-free" is basically a redundant message.* Rather, if vegetable oil was not cholesterol free, it would be abnormal and we would suspect contamination with some animal fat!!

Saturated Fat

Saturated fat is the type of lipid which contains no double bond in the carbon skeleton. Usually, these are solid at room temperature (although this is not universally true). Animal products like ghee are usually high in saturated fat. Saturated fat is considered to be bad for the vascular system. A Cochrane database review, published in May, 2020 found that cutting down on saturated fat led to a significant reduction in cardiovascular events.

Food high in saturated fat: butter, ghee, coconut oil (87%), palm oil (50%), sausage. All the commonly used vegetable oils contain very little saturated fat except rice bran oil, which has 25% saturated lipids.

Interesting fact: Ghee, constituted of 62% saturated fat, has a very long shelf life. That is why, in the Ayurvedic system of medicine, old Ghee was considered a valuable component. In India, two types of Ghee are in use: Cow and Buffalo products. Both are similar in fat content and only difference is the high carotene content in Cow milk Ghee.

Trans-fat[5]

A trans-fatty acid is an unsaturated fatty acid in trans-geometric configuration. Trans-fatty acids have no known metabolic function in human body. They increase LDL in blood. This is produced mainly as a result of hydrogenation of vegetable oil. In the USA, the government has issued a guideline that there is no safe limit of consumption of trans-fat. It is to be completely eliminated from diet. Studies have shown that the concentration of trans-fat in adipose tissues of individuals who died of IHD were 8–10% higher compared to others. *Studies in New York have shown that restriction of trans-fat in food industry led to significant reductions in the incidence of AMI and CVD mortality*. The effects of trans-fat are shown in **Figure 1**.

Common food with trans-fat: Margarine, butter, some cake products. In Indian context, trans-fat is mainly found in foods that are cooked with reused oil. *In roadside eateries of India, it is very common to find the same oil being used to fry a variety of products throughout the day. Constant reheating of oil produces trans-fat.* Vanaspati, hydrogenated vegetable oil, is used commonly in India as a cheap substitute of ghee. This product contains trans-fat and is harmful. *The reader of this article should be aware that Vanaspati is the commonest cooking medium in hotels and cafes and thus many Indians are unknowingly consuming the trans-fat of Vanaspati every day in canteens.* Deep fried commercial food also contains trans-fat. For large multinational food companies, the quality of food is improved by regulation. But in the small scale industries

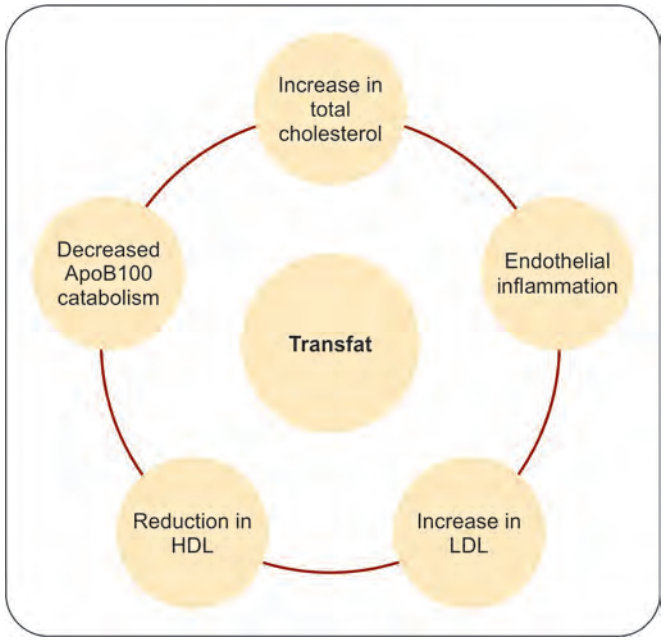

Fig. 1: The metabolic effects of trans-fat

in remote parts of the country, the quality of local food industry is largely unregulated and those items may have trans-fat.

Oryzanol

This is a product of rice bran. Thus, Oryzanol is available only in rice bran oil. This is sometimes marketed as a health supplement but benefits are doubtful. It may have some antioxidant action.

Ω-3 and Ω-6 Ratio

As discussed earlier, these are varieties of PUFA. A particular specimen of oil (any oil) contains various types of PUFA. The nomenclature is based on the position of the double bond in the carbon skeleton. For example, Ω-3 acids are those where the double bond is three atoms away from the terminal methyl group.

Ω-3 acids include DHA, EPA, and alpha linolenic acid (ALA). Common sources are flaxseed oil, hemp oil, fish oil, and eggs. Animal sources are the sole supplier of EPA and DHA, while plant sources supply ALA. ALA can be converted into the other forms. Thus, vegetarian diet is enough to get the required Ω-3 acids. *The enzymes required for conversion of ALA to other PUFA are δ6 desaturase and elongase in the liver endoplasmic reticulum.*

Ω-6 acids include linoleic acid, calendic acid, etc. Most of the vegetable oil contain Ω-6 acids.

Ω-9 acids include oleic acid, erucic acid. *These are MUFA, not PUFA like the two previous ones.* Sources include mustard, olive, and rapeseed.

The reader must not assume that one particular oil contains one type of PUFA or MUFA. Usually, it is a combination and the relative percentages vary with processing. For example, mustard oil contains 60% MUFA (erucic acid etc.), 21% PUFA (Ω-6 more than Ω-3), and the rest saturated fat.

Ω-3 fatty acids are considered to be better for our health. Oil like hemp oil is rich in this variety, but it is not popular for cooking due to low smoke point. So, some authors have suggested blending two or more varieties of oil to make a more nutritionally healthy mixture. This can also overcome the problem of low smoke point.

The main aim is to increase the proportion of Ω-3 acids in our diet. Some cooking oil with good Ω-3 content are: canola oil and ghee. Fish oil, like cod liver oil, contains excess Ω-3 fraction. But fish oil is not used for cooking in India. Fish oil, like cod liver oil, is also a rich source of vitamins A and D. *But in India, fish oil is not popular due to its smell and also due to vegetarian culture of many communities in the country.* Coconut oil does not contain any Ω-3 acid. Sunflower oil, the most popular oil in urban India, has very high Ω-6 to Ω-3 ratio. Ω-6 acids are proinflammatory and thus, may have adverse effects on the blood vessels. But they don't act in isolation. Other dietary factors are also responsible in tandem for the cardiovascular morbidities. Thus, it may be a suggestion to mix sunflower oil with some other oil like canola oil to improve Ω-3 content.

Tocotrienols

When oil is extracted from seeds, along with the lipids, some other compounds also get extracted. One of them is tocotrienols, a type of tocols (which also include tocopherols). It is mainly found in palm oil, rice bran oil, wheat germ oil and soybean oil. These are one of the most important antioxidants in vegetable oil. If a sample of oil is high in tocols, then the PUFA in that oil will resist oxidative damages. α-tocopherols are the major tocols in most oils like almond, olive or sunflower. In some varieties like soybean and canola oil, γ-Tocopherol is higher. Palm oil, although considered a cheap and inferior quality of edible

TABLE 2 Tocopherol content of some common edible oil

Oil	*Tocopherol (mg/100 g)*
Wheat germ oil	150–190
Sunflower	33–60
Safflower	37–50
Coconut	0.2–2

oil, contains high quantity of all types of tocopherols. The α-tocopherol content of some common oils that are given in **Table 2**.

Tocols have neuroprotective and anti-cancer properties and also prevents vascular changes in diabetes. However, during the refining process of vegetable oil and the deodorizing process, tocopherols are lost. The only exception being extra-virgin olive oil, which is prepared by a separate method without heat application. This retains the tocopherol content. Physical refining of oil reduces phenolic compounds more than chemical refining.

Phytosterol

Phytosterols are plant compounds which are analogous to animal cholesterol. It has beneficial effect on blood cholesterol and reduces LDL levels. It is a good antioxidant and may also be beneficial in reducing the incidence of cancers. During lipid extraction from plant seeds, phytosterols are also added to the oil.

Rich sources of phytosterol include corn oil (990 mg/100 g), rapeseed oil (893 mg/100 g) and sunflower oil (253 mg/100 g). Prolonged cooking and high temperature food processing reduces the phytosterol content in oil.

Carotenoids

These are another group of important compounds in edible oil. Cold-pressed oil is a better source of carotenoids than heat-extracted variety. Palm oil is a good source of carotenoids. There is a variety called red palm oil, which has particularly high carotene content. But it is costly due to its rarity. Carotenoids are good antioxidant and have a role in diet complementary to tocopherols.

In a recent study, it was found that only cold-pressed oils contain appreciable amount of carotenoids. The oils with higher carotene content are rapeseed oil, soybean oil and linseed oil.

Cold Pressing

Cold pressing is the process of extracting oil from plant seeds like olive by pressing at room temperature, without applying any extra heat. This prevents thermal degradation of phenolic and other useful compounds. However, the yield of oil is less and thus, for a burgeoning consumer market of India, quicker heat extraction method is preferred. Some consumers also prefer the better smell and taste of heat-pressed oil. Only olive oil and sesame oil are suitable for cold press production on a large scale.

Making the Right Choice

So, in the preceding discussion, the reader has been introduced to the essential principles based on which edible oils should be chosen. There is no single correct answer for this topic. *Besides the scientific points mentioned above, the other important factors in the choice of any food are cultural, tradition, smell, taste, etc.* Those issues cannot be neglected because they influence human behavior to a large extent. It must be remembered that any oil or ghee is 100% lipid by chemical composition and yields 9 kcal/g when metabolized. So, there is no "low-fat" oil and all varieties of oil, whether high in PUFA or high in saturated fat, yields the same number of calories.

Mustard oil is preferred in parts of Eastern India due to its distinctive smell and taste. This pungent smell is due to allyl isothiocyanate. This compound has no nutritional value. Mustard oil has about 21% PUFA, which is higher than coconut oil (2%). But mustard oil has high erucic acid, which is not digested by human intestine. This can also cause other metabolic problems**.** *That is why the USFDA has banned the import of mustard oil in their country*. Coconut oil, on the other hand, contains medium chain triglycerides, which have better absorption and metabolism. Also, these MCTs are less likely to be stored as fat and there is less weight gain.

Olive oil is the staple component of Mediterranean diet. It has high MUFA, which is good for the heart. Also, it contains other beneficial compounds like tocopherols. But Ω-3:Ω-6 ratio of olive oil is not optimal. Soybean oil has good PUFA content. But one disadvantage is that it gets rancid very quickly. *Mustard oil also has high PUFA but due to presence of other antioxidants, it can be stored without rancidity for long.* Safflower oil has high smoke point which is good for frying. But it contains high PUFA

and this can be oxidized to toxic compounds in prolonged cooking. Also, high PUFA content means that it gets rancid very easily. In this context, coconut oil is better for frying as it has high saturated fat and is thus, less prone to oxidation.

Palm oil has high saturated fat. But it also has high levels of tocopherols which are essential for human body. Avocado oil and peanut oil are high in MUFA content but these are not popular in India till now.

So, how should a consumer make the choice? It is often a delicate balancing act. For example, ghee is high in saturated fat, which is bad for the cardiovascular system. But at the same time, ghee has long shelf life, high smoke point and Vitamins A and D, which are points in its favor. Similarly, mustard oil has high smoke point, contains 21% PUFA but it has erucic acid, which is not digested in our intestine. Again, the Ω-3:Ω-6 ratio in mustard oil is better than most other oils. This is how a consumer will have to make the choice. If a consumer cannot make a single choice, then it may be advisable to mix two or three oils. For example, 3 days a week the cooking may be done with mustard oil and the rest 4 days, olive oil can be used. Or if the vitamin content of ghee is considered important, occasional ghee products may be consumed. This is how a diet plan is made.

Last but not the Least: The Problem of Adulteration

In India, one major problem is food adulteration.[1] Consumers here have very little say over the quality of food items they get, especially outside the metro cities. Some common adulterants used in edible oil in India are:

- Since palm oil is cheaper, it is often added to costlier oils like groundnut oil or sunflower oil
- Liquid paraffin in coconut oil
- Argemone to mustard oil
- TOCP (an incident of TOCP addition to rapeseed oil led to mass paralysis in west Bengal in the 1980s, this is one reason why rapeseed oil is not popular in India)
- Coloring chemicals

Thus, a consumer of India, while selecting edible oil, has to remember not only the chemical properties or cultural factors, but also the problem of adulteration.

Conclusion

The choice of oil for cooking is a contentious issue. A lot of considerations like cultural acceptability, cost, availability, and health effects are taken into account while making the choice. Some people consider mixing a variety of oils for the optimum health benefit. Some people also consider opting for exotic varieties like olive oil or peanut oil. The final decision should be based on informed choice and scientific judgment.

CHAPTER

15 Expanding Role of Combination Therapy in Hypertension

Girish Mathur, Ashutosh Chaturvedi, Divyansh Mathur, Rahul Ramchandani

Abstract

Hypertension is a major risk factor for cardiovascular (CV) disease, cerebrovascular accidents, chronic kidney disease, peripheral vascular disease, and heart failure. As per the recommendation of latest guidelines, monotherapy may not work in most patients, and to achieve optimal BP targets, most of the hypertensive patients eventually require a combination of two or more antihypertensive drugs. The combination therapy looks like a lucrative option than increasing the dose of single agent and offers several advantages over high dose monotherapy to treat hypertension. The aim of a physician treating hypertension should always be a cost-effective, long-term therapy to control BP with drugs that are effective, safe, well tolerated, and must also actually reduce the CV risk.

Introduction

Hypertension is a tremendous public health burden globally affecting millions of patients. It is estimated that 26% of the world's population suffer from hypertension, and the prevalence is expected to increase to 29% by 2025, mainly attributed to increase in economically developing countries.[1] Hypertension is a major risk factor for cardiovascular (CV) disease, cerebrovascular accidents, chronic kidney disease, peripheral vascular disease, and heart failure.[2] Significant reduction in clinical CV end points can be achieved with meticulous control of blood pressure (BP) in hypertensive patients, more importantly in the presence of comorbidities like diabetes mellitus, chronic kidney disease, etc. In recent times, newer antihypertensive agents have come on the scene and there has been a rise in awareness among both patients and physicians, but a significant percentage of hypertensive patients continue to have suboptimal BP control.[3]

Recently, evidence suggests that for control of hypertension, monotherapy may not work in most patients, and to achieve optimal BP targets as per the recommendation of various guidelines, most of the hypertensive patients eventually need a combination of two or more antihypertensive drugs. The fact that multiple factors are involved in etiology of hypertension also favors the use of combination drugs acting through different mechanisms to control the BP. Latest international guidelines also recommend to initiate a double-drug combination therapy for patients with a systolic BP (SBP) more than 20 mm Hg and/or a diastolic BP (DBP) more than 10 mm Hg above the target BP and also for those patients who are at increased CV risk.[4,5]

Combination Therapy: Need of the Hour

The rise in BP is controlled by diverse mechanisms. The three factors that primarily determine the BP are: renal sodium excretion and resultant plasma and total body volume, cardiac output, and vascular tone.[6] The sympathetic nervous system and renin-angiotensin-aldosterone system (RAAS) chiefly control these parameters on a real-time basis. Apart from that BP in

individual patients is also influenced by diet, genetic, and environmental factors. Due to this multifactorial etiology involved in genesis of hypertension, many a times it is very difficult, if not impossible, to control the BP by using a single antihypertensive drug. On the other hand, combination of two drugs with different mechanisms of action can provide two to five times greater antihypertensive effect than with monotherapy.[7]

Various clinical trials report that achieving BP goals is usually not possible with monotherapy. *As per the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), only 26% of the patients could achieve target BP with a single drug*—despite the fact that the goal BP for diabetics (36% of the patient population) was <140/90 mm Hg rather than <130/80 mm Hg as per recommendations of latest guidelines.[8]

In the Losartan Intervention for Endpoints Reduction (LIFE) trial, more than 90% patients with left ventricular hypertrophy needed at least two antihypertensive drugs to achieve target BP of <140/90 mm Hg.[9] In the Hypertension Optimal Treatment (HOT) trial, the target BP (diastolic only) with a single drug was achieved by only 33% patients, 45% needed two drugs, and 22% required three agents.[10] The average SBP at the end of the study was 141 mm Hg, indicating that even a greater number of patients would have required combination therapy as per current treatment guidelines.

Apart from achieving target BP control, time taken to achieve it is also important in patients having hypertension with high CV risk. As demonstrated in a post hoc analysis of the Valsartan Antihypertensive Long Term Use Evaluation (VALUE) trial, patients who reached their BP goals at 6 months had lesser subsequent CV events.[11] In a randomized controlled trial in patients with hypertension and metabolic syndrome, starting treatment with a combination of valsartan and amlodipine achieved BP goal more rapidly than initiating with a high dose of valsartan monotherapy.[12] In a cohort study of hypertensive patients 34% risk reduction in CV events was mainly attributed to the more rapid achievement of BP target with combination therapy.[13] Combination therapy can even be effective in hard-to-treat patients in achieving normal BP. This early normalization of BP also motivates the patients to be more compliant to lifelong treatment. Single pill combinations (SPCs) containing two or three drugs in the same tablet offer additional advantage by improving adherence and potentially reducing the cost of therapy.

Theoretical Considerations of Combination Therapy

Efficacy

By combining drugs that either effectively block the counter-regulatory responses or interfere with clearly different pressor mechanisms, BP lowering is possible to a greater extent than with monotherapy. Usually combining agents from harmonious classes is about 5 times more effective in reducing BP than increasing the dose of one agent. Another important need to make a good combination is that the combined-drug administration should produce additive and continuous BP reduction throughout the dosing interval.[14]

The beta-blocker/calcium channel blocker (CCB) combination is a good example to show the harmonious action of two agents where on one side beta-blocker attenuates the CCB-induced activation of the sympathetic nervous system, and on the other hand, the vasodilatory effect of CCB weakens the alpha-mediated reflex vasoconstriction induced by beta-blockers.

Tolerability

Most drug combinations are designed so as to improve the tolerability of therapy by neutralizing the dose dependent side effects (that occur due to use of higher doses) of a single agent, by the pharmacologic effects of an added drug. For example, hypokalemia produced by thiazide diuretic can be counter-balanced by addition of a potassium-sparing diuretic, such as amiloride, triamterene, or spironolactone, or a RAAS inhibitor.

Adherence

Combination therapy can improve the adherence and compliance to treatment by simplifying regimen in terms of reducing the number of medications, frequency of dosing, and also being cost effective most of the times. This definitely helps in control of BP. In a meta-analysis of nine studies, the adherence rate was improved by 26% in patients receiving SPCs in comparison to those taking their components separately.[15] **Table 1** summarizes

TABLE 1 Comparison of various hypertension treatment strategies[7]

	Low-dose monotherapy	*High-dose monotherapy*	*Free combination therapy*	*Single-pill combination therapy*
Effectiveness	×	✓	✓✓	✓✓
Tolerability	✓	×	✓	✓✓
Adherence	✓	✓	×	✓

BP variability	×	×	✓	✓
Flexibility	✓	✓	✓	✓
Fast attainment of target BP	×	✓	✓✓	✓✓

the benefits and drawbacks of various drug prescribing strategies in hypertension management.

Indications of Combination Therapy[16]

- Unable to achieve the target BP with monotherapy.
- Presence of adverse effects of single drug that may be improved by the addition of a second agent (e.g., adding an angiotensin-converting enzyme inhibitor to a CCB to reduce peripheral edema).
- The SBP is ≥20 mm Hg and/or DBP is ≥10 mm Hg above the target BP.
- Presence of convincing indications that may get benefitted from different mechanisms of action of multiple antihypertensives.

Advantages of the Combination of Antihypertensive Drugs

The combination therapy looks like a lucrative option than increasing the dose of single agent. The advantages of combination therapy are summarized in **Box 1**.

Specific Drug Combinations Available

Various trials have been used and studied different classes of drugs in combination for treatment of hypertension. Angiotensin receptor blockers (ARBs), thiazide diuretics, alpha and beta-blockers, calcium channel blockers (CCBs), and angiotensin-converting enzyme inhibitors (ACEIs) are the most commonly used classes of antihypertensive agents for combination therapy. On the basis of these large, result oriented trials, various international guidelines have classified the different available combinations as preferred, acceptable, or not acceptable **(Box 2)**.[17,18]

BOX 1 Advantages of combination therapy

- Rapid and sustained control of blood pressure due to additive effect of combined drugs
- Minimization of the dose dependent side effects that occur due to use of higher doses of a single agent thus improving the tolerability of therapy
- Many other pathophysiological mechanisms of increased blood pressure are simultaneously blocked
- Much better protection to target organs
- Other beneficial effects independent of antihypertensive action of drugs:
  - Anti-inflammatory action
  - Metabolic anti-counter regulatory actions
  - Nephro- and cardiovascular protection
- Homologous blood pressure lowering and good safety profile
- Reduced pill burden and most of the times economically effective

RAAS Inhibitors (ACEI/ARB/DRI) + CCB

The addition of RAAS inhibitors to a DHP-CCB leads to greater degree of BP reduction and increased tolerability by significantly reducing the incidence of tachycardia and peripheral edema observed with CCB monotherapy. In the Avoiding Cardiovascular Events Through Combination Therapy in Patients Living With Systolic Hypertension (ACCOMPLISH) trial, the ACE inhibitor/CCB combination was found to reduce the CV complications and stroke incidence by 20% as compared to the ACE inhibitor/diuretic combination.[19]

RAAS Inhibitors (ACEI/ARB/DRI) + Diuretics

The RAAS inhibitor reduces the incidence of diuretic induced hypokalemia and new onset glucose intolerance. Most outcome trials have shown the thiazide-like

BOX 2 Specific drug combinations used in hypertension[17,18]

Preferred:
- ACEI/DHP (dihydropyridine) CCB
- ARB/DHP CCB
- ACEI/Diuretic
- ARB/Diuretic

Acceptable:
- Beta-blocker/Diuretic
- DHP CCB/Diuretic
- DHP CCB/Beta-blocker
- Thiazide diuretic/Potassium-sparing diuretic
- Direct renin inhibitor (DRI)/DHP CCB
- DRI/Diuretic

Not acceptable:
- Centrally acting agent/Beta-blocker
- CCB (non-dihydropyridine)/Beta-blocker
- ARB/Beta-blocker
- ACEI/Beta-blocker
- ACEI/ARB

diuretic chlorthalidone to be more effective than hydrochlorothiazide (HCTZ) in controlling 24-hour BP along with better night time protection.[20]

Beta-blockers/Diuretics

Although various outcome studies have shown reduction in morbidity and mortality with this combination but due to increased incidence of new onset diabetes, erectile dysfunction and fatigue with both beta-blockers and diuretics this combination is not recommended for use in patients with metabolic syndrome or in those who are at increased risk for developing diabetes.[17]

CCBs + Diuretics

Due to the natriuretic effect of CCBs, this combination of a CCB leads to a partially additive BP reducing effect. However, the combination does not have a favorable effect on either drug's adverse effect profile. So, this combination is classified as an acceptable combination.

CCBs + beta-blockers

The combination of a beta-blocker and a dihydropyridine CCB is acceptable and results in additive BP reduction. In the HOT study a beta-blocker added to felodipine was the second combination used to achieve BP goals.[10]

Other Combinations

Other drug combinations like Centrally acting agent + Beta-blocker, CCB (non-dihydropyridine) + Beta-blocker, ARB + Beta-blocker, ACEI + Beta-blocker, and ACEI + ARB are considered as non-acceptable or ineffective either because of increased incidence of some serious side effects or inability to produce significant additive BP reduction when they were used in various clinical studies.

Single Pill Combinations

Single pill combinations (SPCs) offer several potential advantages, including simplification of the treatment regimen, convenience, and sometimes decreased cost of therapy. The choice of combined agents can be used to minimize the adverse effects of each individual agent. The disadvantage like the risk of causing orthostatic hypotension is mainly observed in older patients and patients with diabetic autonomic neuropathy.

After the success of two drug combinations, researchers are moving toward three-drug therapy at a lower dose. In a 2018 study in Sri Lanka, treatment with a three-drug SPC in mild hypertensive patients resulted in 15% better BP control in the combination group without any statistically significant difference in adverse effects after 6 months of therapy.[21]

In the TRINITY (triple therapy with Olmesartan Medoxomil, Amlodipine, and Hydrochlorothiazide in hypertensive patients study) trial, at 12 weeks, the triple-combination therapy resulted in significantly more BP reduction when compared with three different dual combinations, made by using two of these three drugs, with no significant difference in adverse events in patients with moderate to severe hypertension.[22]

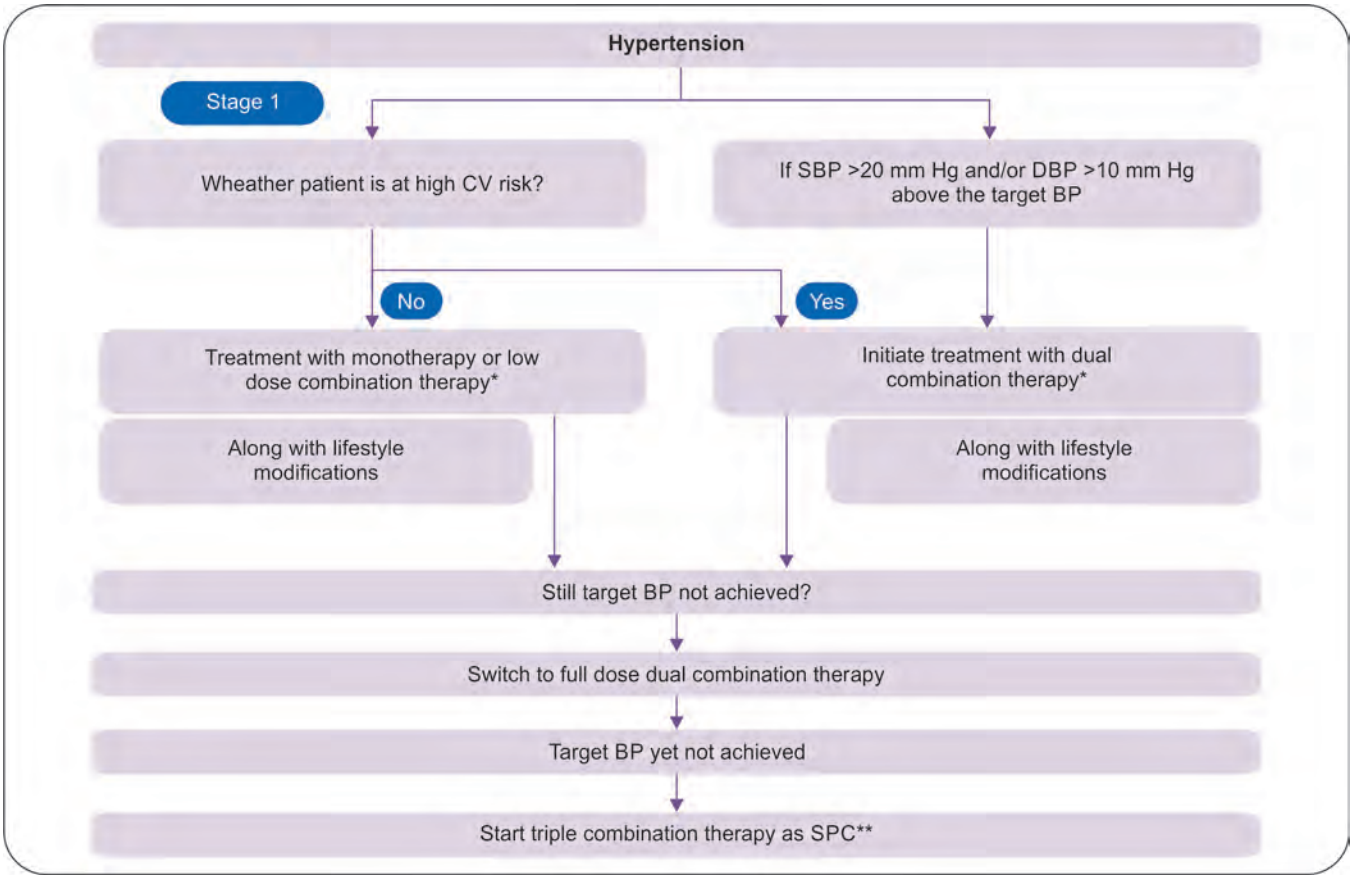
A simple algorithm for the use of monotherapy and combination therapy has been depicted in **Flowchart 1**.

Effects of Combination Therapy Independent of Antihypertensive Action

Anti-inflammatory Effects

Studies have shown that combination of an ACEI with a CCB is more protective than monotherapy in decreasing the various inflammatory mediators such as interleukins, tumor necrosis factor, etc.[23]

Flowchart 1: Algorithm for management of hypertension using combination therapy



*Preferred and acceptable dual-combination should be used only **(Box 2)**.
**If BP goal is not reached on triple SPC, consider secondary causes of hypertension and add a fourth BP-reducing drug if required.

Hemodynamic Effects

Matsui et al. in their study showed that the combination of the ARB plus CCB reduced the central aortic pressure to a greater extent than the combination with the diuretic agent.[24]

Nephroprotective Effect

Studies have found that the combination of an ACEI with a CCB was better than ACEI monotherapy in reducing proteinuria and taper down rate of renal deterioration in hypertensive patients who do not respond to monotherapy.[25]

Uricosuric Effect

It has been consistently shown in studies that the combination of losartan plus a CCB more significantly reduce uric acid levels than the combination of losartan plus HCTZ providing additional benefits in hypertensive patients with hyperuricemia.[26]

Metabolic Effects

Among the various antihypertensive agents, ACEIs and ARBs improve insulin resistance whereas beta-blockers and diuretics are associated with insulin resistance and increased glucose intolerance. CCBs increase high-density lipoprotein levels while beta-blockers and thiazides raise triglyceride levels.[27] These pleiotropic effects were also observed when these drugs were used in combination therapy.

Vascular Effects

In a study, combination of benazepril plus amlodipine more effectively resulted in improved arterial compliance,

reduced arterial stiffness, and decreased left ventricular mass than high doses monotherapies of both drugs.[28]

Conclusion

The goal of a physician treating hypertension should always be a cost-effective, long-term therapy that controls BP with drugs that are effective, safe, and well tolerated and should also actually reduce the CV risk. All major current guidelines suggest that ≥1 antihypertensive agent is needed in most hypertensive patients to reach desired BP targets. *Summarized recommendations are as follows:*

- Combination therapy must be routinely used to achieve BP goals.
- Initiate combination therapy in patients who require ≥20/10 mm Hg decrease in BP to achieve desired BP.
- Preferred or acceptable drug combinations should be maximally used.
- Combination therapy in stage 1 patients should be started, especially when the second drug improves the tolerability of initial therapy along with additive BP reduction.
- Use SPCs rather than separate individual agents to improve convenience and compliance of treatment.
- Triple therapy including a RAAS inhibitor, a CCB, and a natriuretic should be initiated in those patients who do not respond to dual therapy in 6–8 weeks.

Although the basis of treatment is guideline recommended medical therapy, still individualized treatment and expert advice should be preferred because each and every patient is a unique subject with a specific CV profile and not merely a statistically derived number in clinical trials.

CHAPTER

16 Management of Hypertension with Increased Sympathetic Activity—A New Way Forward

BB Thakur, Smita Thakur

Abstract

Hypertension is one of the most important preventable causes of morbidity and mortality across the globe. It is estimated that 25–35% of modern population suffer from hypertension and is estimated to cause over seven million deaths each year. Evidence from randomized controlled trials (RCTs) has shown benefit of antihypertensive drug treatment in improving outcomes in persons with hypertension. Since hypertension does not have any specific symptom and most of the time, the symptoms do not cause any inconvenience, it remains an insufficiently treated disease with only 10–20% patients having controlled blood pressure in spite of availability of so many drugs.

It has long been known that Sympathetic Nervous system plays a crucial role in blood pressure control through several reflex and non-reflex mechanisms including its effect on renal sympathetic outflow. It plays an important role in the development and progression of the essential and all grades of hypertensive state and end-organ damage. We now know conclusively that Sympathetic over activity is the leading cause of stroke, chronic kidney failure, left ventricular hypertrophy, and sudden cardiac death.

Some pharmacologic classes of antihypertensive drugs (such as beta-blockers, ACE-inhibitors, and angiotensin II receptor blockers) may elicit profound sympathoinhibitory effects, while long-acting CCBs have no effect on it and diuretics and short-acting calcium antagonists further increase the adrenergic cardiovascular drive.

The unmet need of controlling blood pressure in those patients whose pressure is not controlled to target with usual drugs may be addressed, in part, by developing new drugs and devices/procedures to treat hypertension and its comorbidities.

Alongside pharmacological therapy, device-based approaches to modulate SNS have demonstrated beneficial effects on BP control. In the past few years, two new procedures have been developed for the treatment of resistant hypertension by modulating SNS: catheter-based renal denervation and electrical stimulation of carotid baroreceptors. However, the interventional procedures are still in experimental stage.

Introduction

Hypertension is a complex and progressive cardiovascular syndrome of multiple etiologies that result in functional and structural changes in the heart and vascular system and it remains one of the most important preventable contributors to disease and death in the world.[1,2]

Most patients with hypertension have other risk factors including lipid abnormalities, glucose intolerance and diabetes, family history of early cardiovascular events, obesity, and tobacco use with or without alcohol excess.

There is unholy alliance between obesity, type 2 diabetes, the sympathetic nervous system (SNS), and hypertension in young/middle-aged subjects.

It is estimated that one-fourth to one-third of the population is afflicted with this condition[3-5] and is estimated to cause over seven million deaths each year, which is about 13% of the total number of deaths worldwide.[6] According to a review on "The Global Burden of Hypertension," the estimated prevalence of hypertension (in people aged 20 years and over) in India

in the year 2000 was 20.6% among males and 20.9% among females and is projected to increase to 22.9% and 23.6% respectively by year 2025. These trends are increasingly been seen with aging populations.[7]

Evidence from randomized controlled trials (RCTs) has shown benefit of antihypertensive drug treatment in improving outcomes in persons with hypertension.[8-10] Since hypertension does not have any specific symptoms, and most of the time, the symptoms do not cause any inconvenience, it remains an insufficiently treated disease with only 10–20% patients having controlled blood pressure levels.[5]

SNS has always been implicated in causation of hypertension, but there has been a renewed interest because of:

- Sympathetic abnormalities influence the development and progression of TOD;
- New therapeutic approaches for control of blood pressure have been developed by modulating SNS; and
- SNS overdrive has impact on morbidity and mortality in CVD.

Sympathetic overactivity is presently recognized as a major contributor to development and sustenance of hypertension.[11] Several pathophysiological changes lead to increased vascular tone and resistance, tachycardia, compromised central and peripheral hemodynamics, renal vasoconstriction, oxidative stress, metabolic abnormalities, and adverse remodeling of cardiac and vascular smooth muscle. Notably, many antihypertensives result in reflex SNS activation, which can result in elevated resting heart rate, and this is one of the newly recognized cardiovascular risk factors. Secondary causes of hypertension can also increase sympathetic activity.

It is well acknowledged that sympathetic overactivity is the leading cause of stroke, chronic kidney failure, left ventricular hypertrophy, and sudden cardiac death.

Understanding the mechanisms involved in the regulation of the SNS has currently lead to novel approaches in hypertension treatment **(Fig. 1)**.

A distinct feature of the SNS is the immediate regulation of peripheral vascular resistance through modulation of the vascular tone. In addition, the release of sympathetic neurotransmitters contributes to adaptive mechanisms through regulation of cell proliferation, transformation, and apoptosis, and these are all blood pressure independent.[12-15]

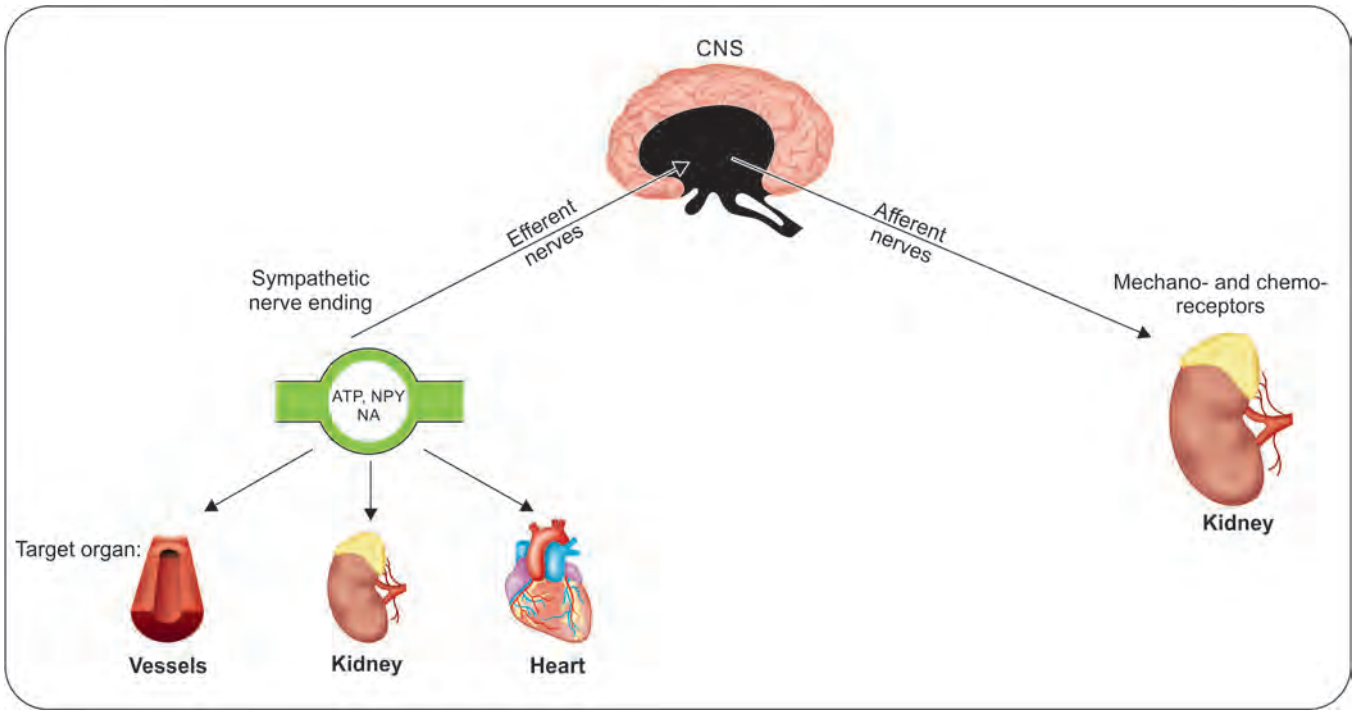

Fig. 1: Schematic of sensory, afferent and sympathetic efferent neurons, and target organ innervations

The renin-angiotensin-aldosterone system (RAAS) is responsible for the central nervous feedback in sympathetic activation, angiotensin II and nitric oxide (NO) are important effectors of this system.[16] In chronic kidney disease, RAAS inhibition leads to decrease in efferent sympathetic activity.[17] All RAAS inhibitors do not have the capability to penetrate through the blood-brain barrier; therefore, it is likely that peripheral actions of angiotensin II modulate afferent signal transduction.

Renal ischemia releases adenosine as a paracrine transmitter, leading to potent activation of afferent neurons.[18] Severing afferent and efferent sympathetic nerve fibers prevent no hypertension in animal model with chronic kidney injury.[19] Independent from CNS-effects, chronic kidney injury leads to a neither increase of presynaptic or epinephrine release in the heart and kidney. This might be due to an increase in angiotensin II through RAAS activation.[20-22]

Multiunit sympathetic nerve activity (MSNA) is equivalent to the sympathetic activity. This can be measured as "bursts" per minute, and helps establish the concept of kidney as a pacemaker of sympathetic activity. Converse et al. analyzed the sympathetic activity in dialysis patients versus healthy controls.[23] Interestingly, in kidney transplant patients with normal serum levels of creatinine and urea, the sympathetic overactivity persisted. Only bilateral nephrectomy was able to abolish the pathologic sympathetic overactivity.[24]

Sympathetic Overactivity

The SNS plays a pivotal role in rapid adaptation of the body to ongoing events, orthostatic reaction is a glorious example of its instant activation.[25] However, it is the long-term gradual modification in the sympathetic activity, which contributes to development of hypertension. There is an increase in sympathetic activity with an increase of MSNA of 1 burst/min per year, with advancing age.[26] Female subjects have a lower MSNA, but they exhibit more significant annual increase, compared to their male counterparts.[27] A good correlation between blood pressure and MSNA has been observed above 40 years of age, which does not exist in younger patients.[27] Diminished compensatory mechanisms in the elderly population (endothelial dysfunction, diminished baroreflex, etc.) could be the reasons. Sympathetic overactivity could be the underlying factor linking heart failure, sleep apnea, metabolic syndrome, and hypertension.

Sympathetic Overactivity in Sleep Apnea

Sleep-related respiratory dysfunction is much more common in patients with hypertension compared to the common population.[17] Sleep apnea patients demonstrate an increased blood pressure. Apnea causes an immediate rise in sympathetic activity that leads to increase in blood pressure.[28] In chronic sleep apnea, this activation of the SNS persists during daytime also which results in increased MSNA and norepinephrine release.[29] Denervation of the carotid body abolishes the blood pressure increase after hypoxia.[30] Desensitizing chemoreceptors through respiration of 100% oxygen lead to a decrease in sympathetic activity, heart rate, and blood pressure in wake sleep apnea patients but not in healthy controls.[31] Dysfunction of baroreceptors also exists in sleep apnea patients, similar to what is observed in chronic heart failure patients.

Sympathetic Overactivity in Metabolic Syndrome

Baroreflex dysfunction could be the cause of sympathetic overactivity in overweight patients.[32] Accumulation of visceral fat is associated with an increase in MSNA and greater cardiovascular risk.[33] An increase in MSNA is often observed in type 2 diabetes patients.[34] Overweight people suffer more from hypertension and type 2 diabetes, thus interlinking together to manifest as metabolic syndrome. Administration of an increasing dose of insulin increased MSNA in euglycemic individuals, suggesting that hyperinsulinemia plays an important role.[35]

Sympathetic Overactivity in Hypertension

Almost all studies measuring microneurographic sympathetic nerve activity in hypertensive patients could demonstrate the central role of sympathetic overactivity.[36] MSNA increase is more pronounced in patients with observable target organ damage[37] **(Fig. 2)**.

The associated conditions with hypertension like chronic kidney disease, heart failure, obesity, and sleep apnea are all associated with increased sympathetic overactivity and tend to coexist. It is postulated that sympathetic reactivity might be genetically determined. Children of hypertensive individuals show normal MSNA levels, but when subjected to mental stress show

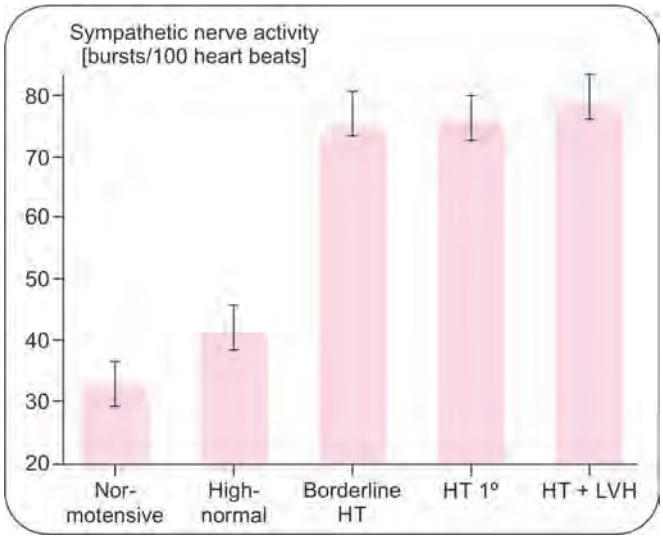

Fig. 2: Microneurographic measurements confirm a significant increase in sympathetic nerve activity (MSNA) in patients with hypertension (HT) compared to healthy individuals. An increased MSNA can already be found in high-normal blood pressure patients (130–139/85–89 mm Hg)[37]

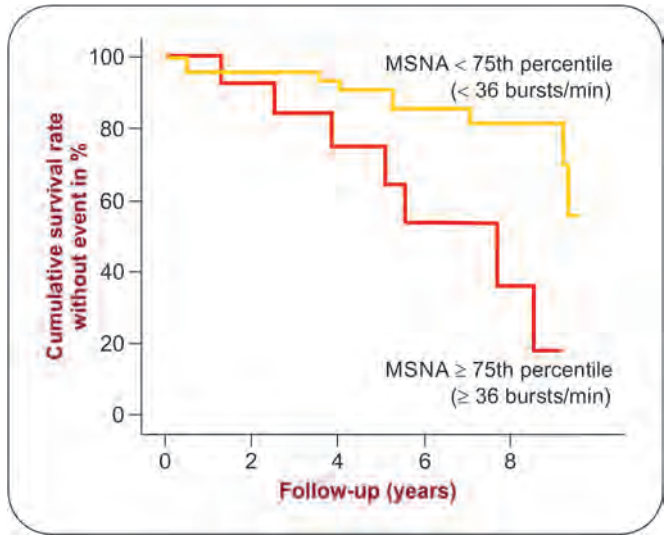

Fig. 3: Kaplan-Meier curve for adverse cardiovascular events in dependence of MSNA above (≥ 36 bursts/min) and below (< 36 bursts/min) the 75th percentile (modified)[47]

a significantly increased MSNA, compared to children of non-affected parents.[38]

Diastolic (± systolic) hypertension in young/middle-age is accompanied by increased sympathetic nerve activity, particularly in presence of metabolic syndrome or type 2 diabetes. Hypertension in preeclampsia[39] or pulmonary arterial hypertension[39] also shows an increased activity in microneurography.

Currently chronic kidney injury is conclusively linked to pathogenesis of hypertension. As seen in Figure 1, activation of afferent neurons in the injured kidney leads to increased sympathetic activity through central nervous mechanisms. It is well established that there is reduced norepinephrine clearance and an increase of serum norepinephrine levels in chronic kidney failure.[40] Kidney through release of a soluble monoamine-oxidase (Renalse) degrades circulating catecholamines and thereby might regulate blood pressure.[41]

Therapeutic Approach

Non-pharmacological Treatment

Aerobic exercise training and calorie restriction both inhibit SNS activity, and are the two most commonly applied and effective non-pharmacological therapies for hypertension. This is especially important for metabolic syndrome and obesity-related hypertension, where there is a contribution of sympathetic inhibition for reductions in both blood pressure and insulin resistance.[42] Another non-pharmacological approach with an antiadrenergic component is the regular application of continuous positive air pressure (CPAP) ventilation in patients with obstructive sleep-apnea-related resistant hypertension at night. This therapeutic approach has been shown to prevent nocturnal obstruction of upper airways, reduce sympathetic activity, and favor blood pressure reduction.[43-46]

Pharmaceutical Approach

In patients with chronic renal failure, the severity of disease correlates very well with sympathetic activity.[47] An increase of MSNA of 10 bursts/min increases the event rate by 60%. Adverse cardiovascular events are also increased in these patients **(Fig. 3)**.

Some pharmacologic classes of antihypertensive drugs (such as beta-blockers, ACE-inhibitors, and angiotensin II receptor blockers) may elicit profound sympathoinhibitory effects, while long-acting CCBs have no effect on it and diuretics and short-acting calcium antagonists further increase the adrenergic cardiovascular drive.

Pharmacological intervention can be achieved with RAAS-blockade (Renin- or ACE-inhibitors, or AT1-blockers), which leads to a reduction in the efferent sympathetic activity.[48,49] However, normalization of sympathetic activity can only be achieved if a central sympatholytic drug (moxonidine) is added to this treatment.[50]

The initial antihypertensive drugs had antiadrenergic effects and were potent, but their side effects made them fall out of favor. Beta- and alpha-adrenergic blocking drugs are similar and effective. Centrally acting sympathetic suppressants, imidazoline-binding agents, such as moxonidine and rilmenidine can be prescribed in patients with essential hypertension as both produce the desired sympathetic inhibition in the sympathetic outflows to the heart, kidneys, and skeletal muscle vasculature.[51] Moxonidine also has renoprotective properties in chronic renal failure and reduces MSNA,[52,53] independent of blood pressure reduction. These are largely free of the side effects witnessed with clonidine, most notably rebound hypertension seen with clonidine when doses were missed.

In patients with resistant hypertension, target goal of <140/90 mm Hg cannot always be achieved using oral antihypertensive medication. Therefore, alternative approaches for blood pressure control have been researched, especially concentrating on novel treatment strategies to alter sympathetic overactivity.

Antiadrenergic Devices

Alongside pharmacological therapy, device-based approaches to modulate SNS have demonstrated beneficial effects on BP control.

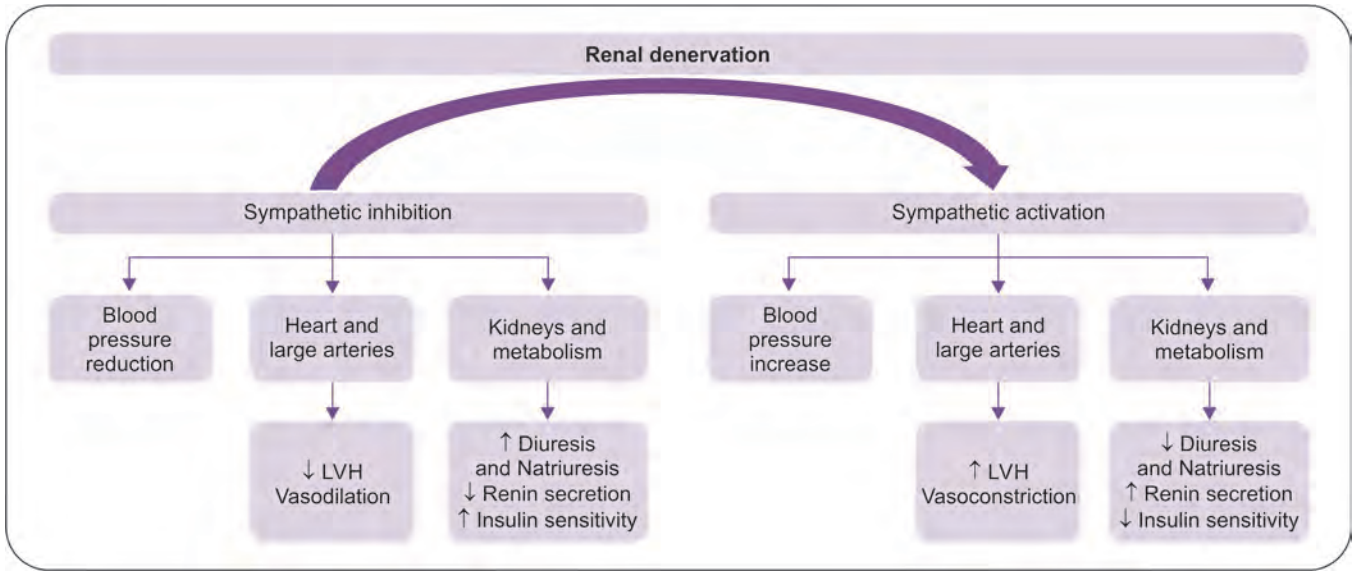
In the past few years two new procedures have been developed for the treatment of resistant hypertension: catheter-based renal denervation and electrical stimulation of carotid baroreceptors.[54-57]

Renal Denervation Therapy

Traditional surgical sympathectomy proposed in early forties has been discarded due to unacceptable severe side effects like voiding dysfunction, intestinal dysfunction, impotence and orthostatic dysregulation, and operative risks.[58,59] Due to pharmaceutical alternatives, surgical sympathicolysis was replaced by antihypertensive drugs.

This novel and recently introduced therapeutic approach **(Flowchart 1)** to RH involves bilateral destruction of the renal nerves travelling along the renal artery, using percutaneous catheter-based radiofrequency ablation **(Fig. 4)** via femoral artery.[60-64] The basis for renal denervation lies in the importance of sympathetic influences on renal vascular resistance, renin release, and

Flowchart 1: Scheme illustrating the possible mechanisms through which renal denervation may exert blood pressure-lowering effects: increase (up arrow) and reduction (down arrow)



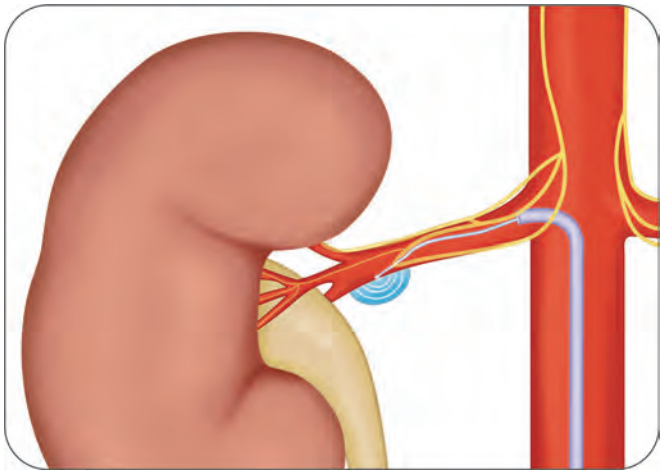


Fig. 4: Catheter-based renal denervation. The tip of the catheter is placed in the distal renal artery via vascular access through the femoral artery. Radiofrequency energy is applied via the top of the catheter to target the renal nerves in the surrounding adventitia. Four to six radiofrequency ablations are performed in each artery and separated both longitudinally and rotationally to achieve circumferential coverage

sodium reabsorption, the increased sympathetic tone to the kidney and other organs displayed by hypertensive patients[65-67] and the pressor effect of renal afferent fibers, seen in experimental animals.[68,69]

The Symplicity HTN-1 and HTN-2 trials have shown substantial blood pressure reductions in response to renal denervation,[70] in the order of 30/15 mm Hg, maintained beyond 2 years. Although renal denervation resulted in improved blood pressure control, the patients continued to take antihypertensive drugs at a reduced number or dose.

However, surprisingly, the very recently reported Symplicity HTN-3[71] has failed to achieve its primary efficacy endpoint and has not found favor on merit and it is still under scrutiny.[72] Following the initial hype[73] on the basis of initial results of Symplicity HTN-1 and HTN-2, the Symplicity HTN-3 study[74] was terminated in February 2014 by Medronic, because the primary endpoint that is lowering of the systolic occasional blood pressure by ≥5 mm Hg—was not achieved after 6 months compared with a control arm. The study, published online in March 2014, showed only a difference of 2 mm Hg for office and 24-hour ambulatory systolic blood pressure.[75] The European Society of Hypertension and national expert teams have not come out so far regarding the indication for this interventional method.[76-79] A subsequent position paper statement by the European Society of Hypertension Working group[80] has very elegantly summarized the current status of this therapy and ways forward. Currently one should refrain from referring further patients for treatment with this method. As there is no safety concerns except for vascular issues and no major complications (impairment of renal function, renal artery stenosis/thrombosis) have been reported,[75] the method may be useful for the small patient population with true treatment resistance, provided all contraindications are observed and after rigorous investigations and treatment.

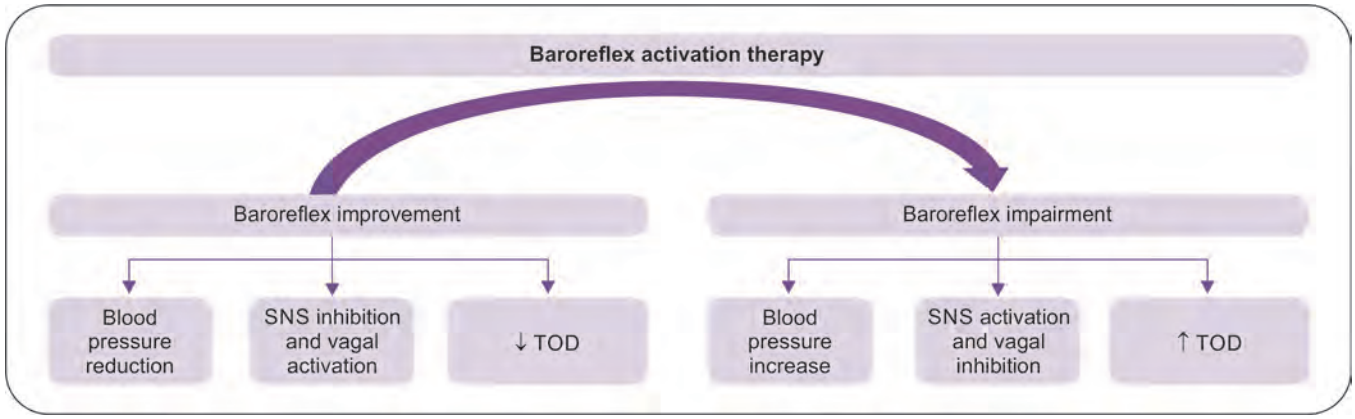
Although there remain many questions to be answered regarding its long-term success, clinical outcomes, and technical issues, further renal denervation therapy trials are very likely to be conducted with new devices at various stages of development.

Carotid Baroreceptor Stimulation

Another invasive method is baroreflex stimulation (electrical stimulation of the carotid sinus nerve), which underwent a revival based on two studies.[3,82]

Dysfunction of the baroreceptor reflex causes an increase in sympathetic activity in a variety of diseases such as sleep apnea and chronic heart failure. This option **(Flowchart 2)** allows appropriate physiologic adaptation to elevated SNS activation and reduced parasympathetic activation by electrically stimulating the carotid baroreflex, the carotid sinus nerves via implanted devices (baroreflex activation therapy—BAT). This device-based therapy **(Fig. 5)** has proved very effective in lowering blood pressure[56] and recently been reported to reduce SBP and DBP in resistant hypertensive individuals also[56,81,82] the reduction was quite marked when initial BP values were very high and the effect included ambulatory BP and persisted for up to 53 months. However, long-term observations have so far involved only a restricted number of patients and further data on larger numbers of individuals with an elevation of BP unresponsive to multiple drug treatments are necessary to confirm the persistent efficacy of this procedure. It seems to be safe with only a few remediable and local side-effects (infection, nerve damage, pain of glossopharyngeal nerve origin) and no effect on renal function[83] and even a positive effect on structural and functional cardiac parameters was demonstrated.[84] Previously, baroreflex activation therapy

Flowchart 2: Possible mechanisms by which electrical stimulation of carotid baroreceptors might help lower blood pressure



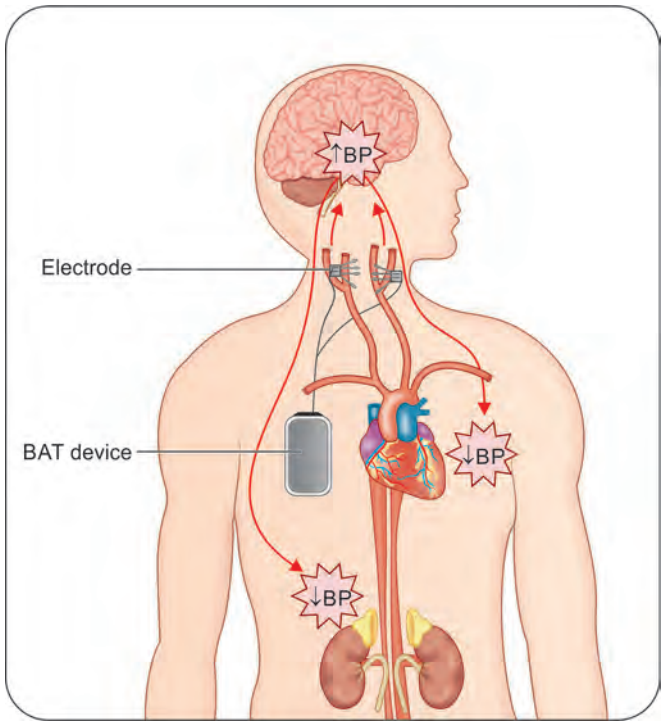


Fig. 5: This device-based treatment consists of an implantable pulse generator; bilateral carotid sinus leads to stimulate the area of greatest response. There is an external programmable device for noninvasive control of the pulse generator. Carotid sinus stimulation acts via a negative loop mechanism via central nervous system, leading to reflex blood pressure lowering

required bilateral carotid preparation and implantation of electrodes and the corresponding pacemaker aggregate. Due to the approach of bilateral activation, battery power of pacemakers lasts only for 2 years with the need of replacement after this period. Ongoing technical innovations to reduce the inconvenience caused by the surgical implantation of the stimulating devices, and to prolong the duration of the battery providing the stimulation, are being studied.

Baroreflex stimulation has been approved in Europe for the treatment of patients with resistant hypertension and a high-cardiovascular risk;[85] however, it should be applied in selected centers with great expertise in the treatment of hypertension and undertaken in close collaboration with vascular surgeons.

In contrast to renal sympathetic denervation, baroreflex stimulation is a reversible procedure; the system can be switched off in the event of hypotension or shock and be adapted to the requirements of a circadian blood pressure rhythm by external programming via radiofrequency telemetry.[82,86]

Slow Breathing Technique

Non-pharmacological approaches are recommended for all individuals with hypertension, regardless of drug therapy. Among several behavioral interventions, the device-guided slow breathing (SLOWB) exercise using RESPeRATE (Intercure, Ltd. Northern Industrial Area, Israel) has been introduced as a non-pharmacological approach in the prevention or treatment of elevated BP. It has been suggested that a decrease in breathing frequency may have beneficial effects on BP and autonomic CV regulation through the modulation of central mechanisms at the brainstem integrating cardiopulmonary receptors, arterial baroreceptors, and efferent sympathetic outflow.[26]

RESPeRATE aims to lower BP with ad hoc regular paced therapeutic breathing (slow and deep breathing) below 10 breaths per minute accumulating ≥40 minute of therapeutic breathing training per week. Madanmohan et al. (1983) studied the effect of shavasan and savitri pranayam (a yoga-breathing technique characterized by slow, rhythmical and deep breathing cycles) in trained subjects (yoga training >1 year) and found significant decrease in oxygen consumption, heart rate, and diastolic blood pressure. They attributed it to the ability of the subjects to achieve a state of deep psychosomatic relaxation. Shavasan alone has been shown to be effective in the treatment of hypertension (Datey et al., 1969; Patel and North, 1975). This was attributed to a decrease in the frequency and intensity of proprioceptive and enteroceptive impulse traffic reaching the hypothalamus. Practice of yoga has been found to be beneficial in many current trials.

Whether the device-paced breathing represents an adjunctive treatment to state-of-the-art drug therapy for hypertension requires further clinical investigation in a larger patient cohort. However, this method appears unlikely to reduce sympathetic activity alone over the longer term.

Deep Brain Stimulation

Deep brain stimulation (DBS) is an exciting interventional therapy designed to modify pathological activity within the SNS. This approach has gained significant recognition in the treatment of Parkinson's disease, recently entering clinical practice. Besides the promising therapeutic effects in a wide range of neurological disorders, DBS of the ventrolateral periadeuquotal grey/periventricular grey matter has been successfully demonstrated in refractory hypertension.[36,37,87] While this approach was primarily performed to treat chronic central pain syndrome that was unresponsive to pain-relief drugs, there was also an unexpected effect of sustained BP lowering. While costly, and associated with a 1% stroke risk, DBS appears to be an attractive approach for treating severe forms of uncontrolled hypertension in patients unresponsive to device-based interventional strategies. Whether DBS may be offered widely as a therapeutic tool for RH to improve CV outcomes merits further investigation.

Conclusion

Hypertension is one of the most significant health burdens in present day societies, affecting 25–35% of the population. Due to increasing life expectancy, incidence of hypertension is likely to increase in the future. The associated diseases (obesity, diabetes, and CKD) are also on rise. Despite the wide range of available non-pharmacological and pharmacological BP lowering approaches, hypertension is poorly controlled worldwide with a substantial impact on morbidity and mortality.

There is a distinct correlation between sympathetic activity, stage of disease, and hypertension. Almost every hypertensive subject shows sympathetic overactivity that correlates well with the adverse cardiovascular event rates (heart failure, myocardial infarction, and stroke).

Kidney plays an important role in the control of sympathetic nerve activity. There is increased sympathetic nerve activity in chronic heart failure, sleep apnea, and obesity also that can be measured by microneurography.

The well established contribution of sympathetic overactivity to human hypertension has led to the development of novel device-based and procedural interventions that favorably modulate autonomic neural mechanisms underlying hypertension. An additional approach currently being investigated to attain BP control in patients with RH is carotid body removal. Given the invasiveness, the cost of device-based strategies, and the different responsiveness of different patients, pre-procedural markers to stratify patients for the specific approach need to be identified. Future large scale clinical trials will determine the long-term safety and effectiveness of these various antihypertensive approaches in terms of BP control, hypertension-related end organ damage, and hard CV endpoints including death, myocardial infarction, and stroke.

CHAPTER

17 Morning Surge Hypertension: A Treatable Hypertensive Variability

Shikhar Garg, AK Singh

Abstract

Morning surge hypertension (MSH) is among one of the most important hypertensive variabilities and its attenuation is very important. It is a short-term hypertensive variability. It is mainly controlled by the sympathetic neural output to the cardiovascular system, which is influenced by circadian rhythm. It seems like MSH is the main culprit behind the highest occurrence of cardiovascular and cerebrovascular events in the morning hours. For diagnosing MSH, ambulatory BP monitoring (ABPM) is the most appropriate method. Home blood pressure monitoring (HBPM) 2 hours after awakening is the practically available and largely affordable means in our country for MSH. Morning HBP recording in standing posture is a better predictor of MSH than morning HBP recording in sitting posture. For managing MSH, long acting antihypertensive a better choice. Long acting CCBs (especially amlodipine) are better than all other drugs. Long acting ACEIs, ARBs, β-blockers like nebivolol, etc. are good alternatives. For better management of MSH antihypertensives should be given in evening.

Introduction

Hypertension is a well known cause of cardiovascular, cerebrovascular, and all cause mortality and target organ damage (TOD). It is also among one of the most important preventable causes of death globally.[1] Blood pressure is not always the same rather it varies from time to time. This hypertensive variability is an independent risk factor for TOD and cardiovascular and cerebrovascular events. Thus, while choosing antihypertensive therapy, attenuation of hypertensive variability must be kept in mind. Morning surge hypertension (MSH) is among one of the most important hypertensive variabilities and its attenuation is very promising.

Blood Pressure Variability

We all diagnose and treat hypertension on the basis of clinic blood pressure measurement, but researchers showed that assessment and quantification of blood pressure variability (BPV) is of paramount importance. Ample evidences are there which show that increased BPV is independently associated with increased risk of TOD, cardiovascular events, and mortality.[2,3] Hence, for reducing hypertensive complications (e.g., cardiovascular and cerebrovascular events and TOD), attenuation of BPV is also required with reduction in average blood pressure values. BPV is directly proportional to mean BP values, and hence it is more in higher stages of hypertension as compared to lower stages of hypertension. White-coat hypertension and masked hypertension are well known BPV and there clinical and prognostic significance are well recognized.

On the basis of timing of changes in blood pressure, BPV can be divided into three types:

- Very short-term BPV (beat to beat oscillations in blood pressure)
- Short-term BPV (oscillations in BP within a day)
- Long-term BPV (oscillations in BP on day to day, visit to visit, or seasonal variation).

Causes and prognostic significance of all types of BPV differ with each other. According to definition MSH is a short-term hypertensive variability. Other short-term hypertensive variabilities are morning hypertension, nocturnal dipping, and nocturnal hypertension.

The circadian pattern in BP is well recognized. In night time during sleeping, BP values are usually low, which rise in early morning post-awakening period and usually coincides with transition period from sleep to wakefulness.[4] A moderate rise in BP in morning hours is physiological, but if it became much more then it is pathological and is termed as MSH, morning blood pressure surge (MBPS), or morning hypertension.

In the normal individuals, BP usually falls by 10–20% during sleep and this phenomenon is known as nocturnal dipping. In hypertensives this dipping status differs and on the basis of this difference they are categorized into four different groups namely:

- Dippers—in whom BP falls in the range of 10–20% during sleep
- Extreme dippers—in whom fall in BP is more than 20% during sleep
- Non-dippers—in whom fall in BP is less than 10% during sleep
- Reverse dippers or risers—in whom instead of falling BP rises during sleep.[1]

The suprachiasmatic nucleus (SCN) situated is hypothalamus is the master body clock. It has direct control over peripheral molecular clocks present in almost every cell of our body.[5] Due to a complex interaction of SCN with environmental and behavioral factors, a definite circadian pattern occurs in almost all physiological functions of our body.[4] The SCN receives inputs from our body (behavioral factors) from environment (temperature and light) and from cerebral cortex and then synchronizes autonomic output, hormone secretion, and behavior. At the morning hours or arousal time certain neurohormonal changes occur in our body. The most important among them are the activation of sympathetic nervous system. The MSH is mainly controlled by the sympathetic neural output to the cardiovascular system, which is influenced by circadian rhythm.[6] The occurrence of major cardiovascular and cerebrovascular events, e.g., myocardial infarction (MI), angina, stroke, transient ischemia attack (TIA), and sudden cardiac deaths are more common in morning as compared to other parts of the day. The exaggerated morning BP surge further increases the existing TOD in hypertensives. This might be the reason behind increased cardiovascular and cerebrovascular events in the morning.[7] It seems like MSH is the main culprit behind the highest occurrence of cardiovascular and cerebrovascular events in the morning hours.

The most widely accepted definition of MBPS is given by Kario et al.,[8] which can be calculated as follows:

- Sleep-trough MBPS—For getting it we have to take two values. First one is an average of the mean SBP of 2 hours after awakening and second one is an average of 3 lowest SBPs in the night. The difference is the sleep-trough MBPS.
- Prewaking MBPS—Here we again take two values. Fist one is a mean of SBP of 2 hours after awakening and second is mean SBP of 2 hours before awakening. The difference is prewaking MBPS.

For diagnosing MSH, ambulatory BP monitoring (ABPM) is the most appropriate method. Unfortunately, ABPM is neither available at every corner of our country nor is affordable by everyone. Home blood pressure monitoring (HBPM) 2 hours after awakening is the practically available and largely affordable means in our country for MSH.[4]

We can diagnose morning hypertension if the clinic BP values are more than or equal to 140/90 mm Hg in the morning or HBP values are more than or equal to 135/85 mm Hg in the morning.[9] One can also diagnose MSH, if the difference in morning and evening BP is more than 15 mm Hg, or if the difference in morning and nocturnal BP is between 35 and 55 mm Hg.[9-11] Nocturnal hypertension is diagnosed if average nocturnal BP is more than or equal to 120/70 mm Hg.[11] Usually it is found in non-dippers or reverse-dippers due to failure of nocturnal dipping.[11] In the beginning, night BP or BP during sleep could only be recorded by ABPM but now, with the development of newer home BP monitoring devices, which can intermittently (2, 3, and 4 AM) record nocturnal BP accurately during sleep, it is possible to get nocturnal hypertension by home BP monitoring also.[11]

According to consensus statement of the Asian expert panel, BP should be recorded two or three times every morning for 5–7 days and then average of these values should be used for evaluations.[9] According to the Japanese Society of Hypertension guidelines, morning HBP should be recorded within 1 hour after awakening and passing urine but before doing exercise or taking medicine or meal and evening HBP should be recorded just before going

to bed.[12] Morning HBP recording in standing posture is a better predictor of MSH than morning HBP recording in sitting posture.[13]

Pathophysiology of MSH

Many physiological changes occur in the morning but they themselves only are not capable of producing MSH or increased incidence of cardiovascular and cerebrovascular events in the morning. MSH and increased incidence of cardiovascular and cerebrovascular events in the morning occur due to a complex interaction among physiological, environmental, and behavioral factors.

Physiological Factors

These include hemodynamic, vascular, and hemato-rrheological changes.

Hemodynamic changes: In the morning, the most important hemodynamic changes are increase in heart rate and BP. Morning hours are also associated with increased cortisol secretion, activation of renin-angiotensin-aldosterone system (RAAS), and enhanced systemic vascular resistance. In the morning atherosclerotic plaques become more vulnerable to rapture and may cause thrombosis due to decreased vagal tone, increased catecholamine levels, and activation of RAAS. This may be the reason behind increased incidence of cardiovascular and cerebrovascular events in the morning.

Vascular changes: The main vascular changes in the morning are increased vascular tone and increase in the sensitivity of vascular receptors.[14,15]

Hematorrheologic changes: In the morning platelet aggregability is increased. According to Brezinski et al.[16] assumption of upright posture itself in the morning after sleep is responsible for increase in platelet aggregability. Other important hematorrheologic changes in the morning are increase in blood viscosity and decrease in fibrinolytic activity. These physiological changes all together make early morning prothrombotic state.

So, in the morning hours, physiologically there is

- early morning prothrombotic state
- the existing atherosclerotic plaques are more vulnerable to rupture, which may lead to thrombosis, and
- there is increase in vascular tone and vascular receptor sensitivity, which further increases the danger.

The physiological changes in the morning are like fuel ready to burn out, which needs only egniter (behavioral and environmental factors) to kindle the fire (producing cardiovascular or cerebrovascular events).

Behavioral and Environmental Factors

The most important factors are start of activity, heavy physical exertion, psychological stress, bursts of anger, smoking, alcohol consumption or salt intake, and cold temperature. Preexisting cardiovascular risk factors like aging, hypertension, dyslipidemia, and glucose abnormality further increases the risk. Increase in sympathetic nervous system activation and endothelial dysfunction, which may lead to increased surge in morning BP, may also be caused by poor sleep quality, sleep apnea or nocturnal hypoxia. Otto et al.[17] reported impaired endothelial function in morning hours in normal individuals. This impaired endothelial function reduces capacity for vasodilation, which further increases the risk.

According to Kario[18] vascular damages like small artery disease (increased vascular tone) and endothelial dysfunction and large artery disease (arterial stiffening) and baroreflex dysfunction are not only the consequence of exaggerated BP but are also the leading cause of exaggerated surge in morning BP and produces a vicious cycle of further damage. If BP is increased in normal individuals then vasodilation of small arteries occur which counter-balance the rise in BP, but in hypertensives this buffering capacity is reduced due to remodeling of small arteries, and hence lead to exaggerated surge in morning BP.[19] In response to any surge in BP in normal individuals baroreceptor-reflex, due to stretching of arterial baroreceptors situated in aortic arch and carotid arteries, occur which reduces BP but in cases of arterial stiffening this baroreceptor-reflex is impaired due to reduced stretching of baroreceptors, and hence will not be able to reduce surge in BP. Okada et al. observed an association between morning BP surge and arterial stiffening in elderly hypertensives.[20]

As most of the hypertensives take their drugs just after breakfast, so its effect is minimal in the morning and may lead to MSH. If the person is taking short-acting or intermediate-acting antihypertensive drug after breakfast then on next morning the effect will be lost and result in MSH.

The concept of morning hours is different in our country as compared to western world due to differences in climatic, geographical, and sociocultural factors. Most of the western researchers of circadian pattern divided the whole day into 4, 6 hourly quadrants and inferred that maximum cardiovascular and cerebrovascular events occur in second quadrant of the day (0600–1200 hours). This pattern is not suitable for our country. For circadian pattern study in our country the whole day should be divided into 6, 4 hourly intervals from 0000 to 2400 hours.[21] The factors responsible for morning events depend upon timing of awakening rather than on any hour or quadrant of the day. Ridker et al. observed that the risk of MI is twice more common within 3 hours after awakening than any other time of the day.[22] Rocco et al. found maximum number of transient myocardial ischemic attacks in 1–4 hours after awakening than any other comparable part of the day.[23] Above studies show importance of time of awakening. In our country, the time of awakening is in between 4 and 5 AM in rural and in between 5 and 6 AM in urban areas as compared to late awakening in western world. Most of the cardiovascular and cerebrovascular events in our country occur in between 6 and 7 AM (4 and 8 AM), that is, in between 2 and 3 hours after awakening.

Management

If we keep a target of morning HBP values less than 135/85 mm Hg then it will produce a strict 24-hour BP control and also provide a better effective protection than clinic BP values with same target.[24]

For managing MSH long-acting antihypertensives are better choice. Long-acting CCBs (especially amlodipine) are better than all other drugs. CCBs have a unique BP reducing property. It reduces higher BP values more than lower BP values, hence reduction in morning BP values is more as compared to night BP values, which results in higher reduction in surge in morning BP. Long-acting ACEIs, ARBs, β-blockers, like nebivolol etc. are good alternatives. As diuretics predominantly reduce night BP more than morning BP, hence they are not suitable for control of MSH. Timing of antihypertensive drug is also very important. For better management of MSH antihypertensives should be given in evening. Kario et al. observed a significant reduction in morning BP values and albuminuria by adding bed time doxazosin (α-blocker) on the top of base line antihypertensive therapy.[25]

Conclusion

Cardiovascular and cerebrovascular events occur more commonly in morning, which may be due to MSH. Proper management of MSH is essential to prevent these complications and TOD. Long-acting CCBs (especially amlodipine) is best among all drugs. Others are long-acting ACEIs, ARBs, Nebivolol, etc. For better results antihypertensives should be given in evening.

CHAPTER

18 Hypertension in Elderly

Mahabir Thakur, Manas Thakur

Abstract

The most rapid section is the elderly population and for the development of hypertension, age is a major risk factor. Variations in SBP/PP depend on various factors like arterial aging, frailty, multimorbidity, and polypharmacy.

Evaluation: Diagnosis of hypertension depends on various ways in assessment of blood pressure, cardiovascular (CV) risk factors, secondary causes, comprehensive geriatric assessment (CGA), etc.

Therapy: Lifestyle modifications and pharmacological treatment.

Conclusion: Elderly patient is the most rapidly increasing section in the society and age is a major risk factor for the development of hypertension. These population are associated with multiple comorbidities, frailty, cognitive decline, and loss of autonomic functions and has to be managed from a life-course perspective with proper investigations and timely treatment of high BP as compared with younger age groups.

Introduction

Elderly patients represent the most rapid increasing section of the population. For the development of hypertension (mainly systolic), age is a major risk factor. The rising number of older population (especially over 80 years) also leads to elevated blood pressure (BP) as well as at the same time they are more prone to multimorbidity, frailty, cognitive dysfunction, multiple medications, and partial/complete loss of autonomic functions.[1,2]

During aging, high BP (mainly systolic) is a clinical expression of arterial stiffness[3,4] and some studies have also indicated the association of neurocognitive disorders, like Alzheimer and vascular types, with elevated BP.[5]

According to some data, risks and benefits of correction of high BP are obtained in younger as well as selected older individuals.[6]

There are two major differences between these two age groups:

- The incidence and prevalence of comorbidities, frailty, and loss of autonomy increases mostly after 80 years; and
- In the "younger" old patients (60–70 years), evidence supports benefits of reducing BP, while there are limited evidence in patients (over 80 years).

Therefore, the management of older patients with high BP must be the following differences as compared with younger age groups.

Elevation in Systolic BP in Older Age Groups: Due to Arterial Aging

Both (systolic blood pressure) SBP and (diastolic blood pressure) DBP are independent predictors of cardiovascular disease (CVD) in younger age groups (<50 years), epidemiological studies suggest that SBP is a strong risk factor and DBP is inversely related with the risk in age group of 50 years or more.[4]

Increase in Pulse Pressure with Age

Both SBP and DBP increase as individual gets older. In the majority of cases, SBP and pulse pressure (PP) increase disproportionally to DBP with age and the most common cause is progressive stiffening of arterial wall.[3,7]

Causes like hypertrophy of wall, deposits of calcium, changes in the extracellular matrix, which include increase in collagen, fibronectin, fragmentation, disorganization of the elastin network, nonenzymatic crosslinks, and cell-matrix interactions, are responsible for decrease in elastic properties as well as the development of artery wall stiffness.[8] The duration of the diastolic interval and the rate at which pressure falls helps in determination of the DBP.

The speed of propagation of the pressure wave of artery (pulse wave velocity-PWV) and the timing of the reflections of the wave also depend on the viscoelastic properties of the arterial walls.

So the stiffening of the arteries increases PWV and there is an early return of the waves which are reflected, and then overlap with the incidental pressure wave, which further contributes to the increment in SBP and PP.[3,7]

Diabetes is also responsible for accelerated aging of arteries (due to increase in arterial stiffness) leading to an increase in PP as compared with nondiabetics.[9,10]

Increase of SBP/PP in Old Age

As SBP and PP better reflect the CVD risk in older age, whereas DBP better reflects the risk in younger age.[4] DBP in young patients is mostly depends on peripheral resistance (PR), and hence low DBP reflects low PR. In addition to this, there is hyperkinetic circulation in young age, so, DBP is less variable than SBP, thus reflects better CV risk.

In old age groups, a low DBP may reflect high arterial stiffness (major manifestations as compared to low PR).[3,7]

Few Terms: Frailty, Multimorbidity, and Polypharmacy

Frailty is a syndrome (biological) of decrease in reserve and resistance to stress factors, which result from collective decline across multiple physiological systems and cause adverse outcomes.[1]

It increases mostly after the age of 80 years. Susceptibility to stress factors is also influenced by behavioral, environmental, social, and biological risks, consequently resulting in an increase in multiple adverse health outcomes.

Few studies have indicated that there is increase in morbidity and mortality in very old frail subjects and are mainly observed in treated hypertensives (mostly on several antihypertensives) and not in normotensives.[11,12]

Polypharmacy (taking more than 4 drugs) and side effects related to drugs are major problems in this age group that may contribute to morbidity, increased rates of hospital admissions, as well as mortality.

Clinical Evaluation

- Diagnosis of hypertension should be based on:
  - At least three different BP measurements, which should be taken on two visits of office separately.
  - At least two measurements, which should be obtained while the patient is sitting comfortably for 5 minutes with the support of back, feet on the floor, arm in horizontal position, and the BP cuff (of adequate size) at the level of heart.
  - Assessment of BP by self at home and 24-hour ambulatory BP measurements, if needed, can contribute in detection of white coat hypertension and recognition of CV risk related to high BP levels.
  - White coat hypertension (exaggerated BP measurements) in the office is more common in older subjects.
- Secondary hypertension is uncommon; therefore, extensive workup for every old patient with hypertension is not needed. But if there is, sudden deterioration of hypertension (previously well controlled), resistant hypertension, etc., then the causes which are reversible should be investigated.
- CV risk factors and target organ damage should be assessed to check the overall risks of CVD.
- Physical examination, which includes fundus examination, abdominal bruits auscultation, peripheral pulses, and palpation of abdomen, should be done thoroughly.
- BP should be taken in supine position in older hypertensives (independent of the symptoms suggestive of orthostatic hypotension).
- An ECG should be done (to look for LVH, IHD, arrhythmias, and conduction disturbances) and urine examination for determination of concentration of albumin should be done.

- Comprehensive geriatric assessment (CGA), a proposed methodology to provide an approach (globally) to complex older age groups and their related problems, and allowing a specific and organized plan of care, which should be implemented for each and every patient.
- CGA permits for a complete assessment of drugs, which recognize and prevent drug-related problems and improve the quality of prescription.

Antihypertensive Therapy

Lifestyle Modifications

- Changes in lifestyle are beneficial for older patients who are being treated for hypertension.
- In obese patients, reduction in weight is the most effective intervention for lowering of BP.
- As older patients are more prone to have salt-sensitive hypertension; so sodium restriction is recommended.
- The Dietary Approaches to Stop Hypertension (DASH), reduction in alcohol intake (as it can lead to increased risk of falls and confusion), and increase in physical activity should be recommended. Weight reduction alone without exercise should not be recommended as it could induce loss of muscle mass and even can lead to cachexia.[13]

Pharmacological Treatment

Few Trials

Clinical trials (meta-analysis) as shown in **Table 1**, indicated that antihypertensive treatment in patients (>65 years) produces similar proportional reductions in the CV risk as that of in young patients,[14] but in older patients, the immediate benefits of treatment were more pronounced (because of a more average risk).

Target BP

In European-2013 guidelines, which stated higher SBP (>160 mm Hg), a definite evidence for reduction of SBP between 150–140 mm Hg is present.[15]

Later these were challenged by SPRINT Trial,[16] which was conducted in patients (with high CV risk and using antihypertensive drugs already), showed that keeping SBP of 120 mm Hg resulted in lowering of CV events and the total mortality as compared with patients with the target SBP of 140 mm Hg.[17]

Further it indicated that keeping a target of 120 mm Hg showed a significant rise in adverse effects in very old patients and frail patients like hypotension, syncope, dyselectrolytemia, failure of kidney, etc.

A group of experts on hypertension and geriatric medicine proposed few rules for the hypertension management in very old patients with partial/complete loss of autonomy.[18] It suggested that decisions regarding therapy should be taken after proper information of cognitive status, functional capacity, multi drug intake, frailty status, etc. of the patient. It also suggested keeping SBP (on treatment) between 150–130 mm Hg is safe range.

Older Hypertensives: Any Specific Drugs?

- JNC-7 recommended five drug classes (thiazides/thiazide-type diuretics, ACEIs, beta-blockers, CCBs, and ARBs) to be used initially.
- JNC-8 recommended four drug classes specifically (ACEIs, ARBs, CCBs, and diuretics).
- Additionally, the JNC-8 recommended these classes based on the evidences like race, CKD, and diabetics. So, the change between these two (JNC-7 & JNC-8) was the non-inclusion of beta-blockers in the 1st list treatment of JNC-8 with the exception like presence of associated indications (history of MI, chronic angina, or heart failure). It suggested that the beta-blockers may not be as beneficial as compared to other classes in the reduction of stroke, mostly in older patients.[19]
- Majority of older patients require dual antihypertensives but it is preferable to initiate with a single drug.[18]
- Increased risks of adverse effects are there with combination drug therapy, mostly among very older age patients with comorbidities.
- Cautious addition and titration of drugs are important, especially in the groups of older age, renal failure, or associated with hypotension and falls.

Other Issues in Older Hypertensives

Postural Hypotension and Nocturnal Dipping of BP

Older individuals are more prone to orthostatic hypotension, which is frequent with increasing age, and is associated with increased risk of death, CV events, and falls.[20-22]

TABLE 1 Design and main results of placebo-controlled trials designed to evaluate the benefits of treatment in individuals 60 years and older with systolic-diastolic hypertension or isolated systolic hypertension

	EWPHE	*MRC*	*STOP*	*SHEP*	*SYSTEUR*	*HYVET*
Number of subjects and age at enrollment	n = 840 Age > 60	n = 4396 Age = 65–74	n = 1627 Age = 70–184	n = 4736 Age > 60	n = 4695 Age > 60	n = 3845 Age > 80
Inclusion BP criteria (mm Hg)	SBP: 160–239 and DBP: 100–119	SBP: 160–209 and DBP < 115	SBP: 180–230 DBP > 90 or DBP 105–120	160–219/<90	160–219/<95	160–199/<110
Active treatment medication	HCTZ + triamterene	Atenolol or HCTZ + amiloride	Beta-blockers or diuretics	Chlorthalidone ± atenolol	Nitrendipine ± enalapril	Indapamide ± perindopril
Goal SBP levels (mm Hg)		SBP < 150 or SBP < 160	< 160/95	>20 from BL or SBP < 160	>20 from BL or SBP < 150	<150/80
BP reduction (mm Hg) with active tt compared with BL	30/15	33/15	28/15	27/9	23/7	29.5/12.9
BP reduction (mm Hg) (Active tt vs. Placebo)	20/9	13/10	19.5/8.1	12/4	10/5	15.0/6.1
Achieved BP (mm Hg) with active treatment	150/85	152/76	167/87	143/64	151/79	144/78
Mean follow-up (years)	4.3	5.8	2.1	4.5	2.0	1.8
Percent reduction in events						
Stroke	36	25[a]	47[a]	33	42[a]	30
CAD	20	19	13[b]	27	30	28
CHF	22	–	51[a]	55[a]	29	64[a]
All CVD	29[a]	17[a]	40[a]	32[a]	31[a]	34[a]

[a]Statiscally significant
[a]Myocardial infarction only
BL, baseline; BP, blood pressure; CAD, coronary artery disease; CHF, congestive heart failure, CVD, cardiovascular disease; EWPHE, European Working Party on Hypertension in the Elderly; HCTZ, hydrochlorothiazide; MRC, Medical Research Council; SBP, systolic blood pressure; STOP, Swedish Trial in Old Patients; tt, treatment

Hence, the suggestion of standing BP measurement and its evaluation and use in treatment goals in older age groups was given by National High BP Education Working Group.[23]

Antihypertensives should be started in low doses and later titrated and added cautiously in older patients (as compared with young patients) in view of postural hypotension, syncope, and falls and frailty.

Some older patients on antihypertensives may have an increased nocturnal dipping of BP, which may lead to cerebral hypoperfusion so BP is routinely measured in waking hours. These patients have more risks of CV events.

Cognitive Impairment

Many studies have suggested an association between elevated BP in mid-age groups and the impaired cognition risk.

Duration of hypertension, levels of BP, cognitive profile, and testing may contribute in the discrepancy in the relationship between hypertension and decline of cognition.

Few studies have shown that markers of aging of arteries may recognize patients at higher risk of cognitive decline, whereas BP alone does not appear in having a significant predictive value.[24-26]

Conclusion

Elderly patients are the most rapidly increasing section in the society and age is a major risk factor for the development of hypertension. These population are associated with multiple comorbidities, frailty, cognitive decline, and loss of autonomic functions.

For diagnosis, clinical examination, physical examination, lab investigations, as well as complete geriatric assessment should be done properly.

While treating the patients, lifestyle modifications should be advised initially. Later, drug therapy should be started after consideration of factors like age, sex, comorbidities, frailty, and cognitive status. Adverse effects of the drug should be kept in mind while starting the drugs and the patient should be continuously monitored.

So finally, it should be noted that hypertension in older age groups has to be managed from a life-course perspective with proper investigations and timely treatment of high BP as compared with younger age groups.[27]

CHAPTER

19 Apparent Treatment Resistant Hypertension—What a Physician Needs to Ponder

Amitesh Aggarwal, Ankur Chikara

Abstract

Treatment resistant hypertension (TRH) and apparent treatment-resistant hypertension (aTRH) are two different identities. Compared to overall hypertensives, people with TRH have more poor outcomes, and hence BP control is much more important in such population. Low adherence to the medication intake is the major modifiable patient-related barrier in achieving controlled blood pressure. aTRH is used when issues of dosing, medication adherence, and white coat hypertension have not yet been ruled out, and have measurements as systolic BP ≥140 mm Hg and/or ≥90 mm Hg diastolic on ≥3 BP medications. The prevalence of controlled hypertension in India is 35% and, in the world, it ranges between 6% and 17%. MMAS-8 (Morisky Medication Adherence Scale) with 93% sensitivity and 53% specificity is used in validating medication non-adherence in very low-income patients who were being treated for hypertension in routine care clinic setting. The patients with aTRH were significantly associated with older age groups (>55 years), obesity (BMI >27.5 kg/m^2), diabetes mellitus, prolonged hypertension (>10 years), female sex, black race, and comorbidity like ischemic heart disease, depression as risk factors as compared to patients with non-resistant hypertension. The prognosis of the patients suffering from aTRH compared with controlled hypertension should be impaired in aTRH as such patients typically have longstanding history of sub-standardly controlled BP and usually have other associated comorbidities and cardiovascular risk factors like diabetes, obstructive sleep apnea, left ventricular hypertrophy, and/or chronic kidney disease. Among aTRH patients, decrease adherence to antihypertensives is a significant problem and, spreading awareness for better medications adherence and proper measurement of BP can easily tackle it. This article discusses about the various causes of aTRH, role of medication adherence in aTRH, and factors affecting it, risk factors of aTRH and workup of aTRH in detail.

Introduction

Treatment resistant hypertension (TRH) and apparent treatment-resistant hypertension (aTRH) are two different identities. Term aTRH is used when issues of dosing, medication adherence and white coat hypertension have not yet been ruled out. The prevalence of TRH and aTRH internationally is found to be 11.8% and from 6% to 17%, respectively. More poor outcomes are noted in TRH patients compared to the overall hypertensive population, and hence BP control is much more important in such population. Low adherence to the medication intake is the major modifiable patient-related barrier in achieving controlled blood pressure. This article mainly focuses on various aspects of evaluation of a case of aTRH.

Definition

Hypertension by definition is an office systolic blood pressure (SBP) more than equal to 140 mm Hg and/or diastolic blood pressure (DBP) more than 90 mm Hg.

Treatment resistant hypertension (TRH) by definition is blood pressure reading more than 140/90 mm Hg in spite of simultaneous use of three antihypertensive

medications of various classes. Ideally one drug should be diuretic and all the three antihypertensives must be taken in their optimal doses.[1] This number of medications is arbitrarily and not scientific. It is to note that patients having controlled blood pressure (i.e., <140/90 mm Hg) with ≥4 antihypertensive drugs should also be categorized as having TRH.

Apparent treatment-resistant hypertension (aTRH) is used when issues of dosing, medication adherence, and white coat hypertension have not yet been ruled out. In different studies, uncontrolled aTRH has been described as systolic BP ≥140 mm Hg and/or ≥90 mm Hg diastolic on ≥3 BP medications. Controlled aTRH by definition is BP <140 mm Hg systolic and <90 mm Hg diastolic on ≥4 antihypertensives drugs unless specified otherwise.[1]

Optimum dose of a medication is the quantity of the drug that will produce the desired effect without any unfavorable side effects. It is not necessarily a maximum dose.

The purpose of defining TRH and aTRH is to find out patients having reversible causes of hypertension and who will be benefitted with special diagnostic and therapeutic considerations.

Prevalence of TRH and aTRH

The prevalence of true TRH is unknown. Nearly 10% of the patients with diagnosed hypertension have true TRH. Above the BP value of 120/70 mm Hg, cardiovascular diseases (CVDs) mortality doubles usually with every 10 and 5 mm Hg increase in SBP and DBP respectively.

Prevalence of aTRH: International Scenario

The prevalence of aTRH varies from 6% to 17% **(Table 1)**.

aTRH: Indian Scenario

The prevalence of controlled hypertension in India is 35%.[2] Since at present there is unavailability of good and robust data from India, thus the exact prevalence of resistant hypertension is difficult to quote. In a study by Mandal et al. in Kolkata, among 300 hypertensive subjects, 23.33% were identified as aTRH.[9]

Causes for aTRH and TRH

The causes of resistant hypertension are divided into apparent cause and true cause **(Table 2)**.

Role of Medication Adherence in Hypertension

Adherence to medication is a crucial part of patient care and indispensable for reaching goals. Medication adherence is defined as "The extent to which the medication taking behavior of a patient corresponds with agreed recommendations from the health-care provider."[15] The different factors that affect patients' adherence to the drugs are demographic features, disease severity, complexity of drug regime (number and frequency of the drug prescribed), drug classes (tolerability and side effects profile of the drug), patients' forgetfulness, and lack of understanding on the nature of disease.[16]

TABLE 1 The prevalence of aTRH in various international studies

Study (reference)	*Study location*	*Study period*	*Prevalence of aTRH % (N=sample size)*
Cushman et al.[2]	North America	1994–2002	9.4% (N=33,357)
INVEST[3]	Canada, South Africa, United States, Spain, Mexico, New Zealand, Israel, Italy, Australia, Germany, France	1997–2003	12.9% (N=22,576)
McAdam-Max et al.[4]	United States	2002–2005	12.4% (N=29,474)
Persell[5]	United States	2003–2008	9.2% (N=15,968)
Sim et al.[6]	United States	2006–2007	9.4% (N=470,386)
Sarganas et al.[7]	German	2008–2011	6.8%. (N=7,115)
Choi et al.[8]	Korea	2015	11.9% (N=2,439)

TABLE 2 Listing the causes of TRH and aTRH

Apparent cause (Pseudoresistance or aTRH)	***True cause (True TRH)***
Pseudoadherence to antihypertensive drug therapy	*High risk patients—which includes following:* • Female sex • Elderly • Black race • Comorbidities like obesity,[1,10] diabetes mellitus, chronic kidney disease, left ventricular hypertrophy, and high baseline blood pressure
Improper technique to record BP	*Lifestyle which include:* • Increase dietary salt intake (>10 gm/day)[11,12] • Increase alcohol consumption[13,14] • Lack of exercise
White coat hypertension	*Drug related cause which include:* • Following medications can cause difficulty in controlling BP— • Non-steroidal anti-inflammatory agents—Aspirin • Selective COX-2 inhibitors • Sympathomimetic agents—decongestants, diet pills, cocaine • Stimulants—amphetamine, modafinil, methylphenidate, methamphetamine • Alcohol[13,14] • Erythropoietin • Cyclosporin • Natural licorice • Oral contraceptives • Herbal compounds—ma-huang or ephedra
	Secondary causes include: • Renal parenchymal disease • Primary aldosteronism • Obstructive sleep apnea • Renal artery stenosis • Drug induced or heavy alcohol use • Thyroid disorders
	• *Genetic causes*—CYP3A5 allele (CYP3A5*1)[1]

Adherence to treatment can be measured using different methods:

- Pill counting
- Drug concentration in the body fluids and response to therapy.
- Measures which involves Electronic Medication Packaging (EMP's) devices, clinician assessments and self-report.

World Health Organization (WHO) reports that secondary to substandard availability and accessibility of medications and health-care services, adherence to drugs in patients who are chronically ill averages nearly 50% in developing countries.[17] The asymptomatic nature of the disease augments the issue of non-adherence to medications in hypertension.[18]

In cohort study, which retrospectively studied the variance in medication adherence among hypertensive patients, it was noticed that the factors like duration of hypertension (shorter duration corresponds with better adherence) and use of newer agents (like calcium channel blockers and ACE inhibitors) had the strongest positive effect on medication adherence.[19]

Choosing a Suitable Medication Adherence Measure

An ideal medication adherence measure should have the following characteristics—low cost, practical, user friendly, highly reliable, easy to carry out and flexible. Eight-item MMAS-8 (Morisky Medication Adherence Scale) is the one easy and validated tool.[20] In 2008 using Medication Adherence Questionnaires (MAQ), Morisky et al. developed this 8-item MMAS (MMAS-8) tool which has 93% sensitivity and 53% specificity in validating

TABLE 3 Studies which studied medication adherence using MMAS (4 points/6 points/8 points)

Studies (reference)	*Results as percentage of non-adherence to medication*	*Factors responsible for non-adherence*
Irvin et al.[21]	The distribution of MMAS scores of 0 (best adherence) and 1, 2, 3, or 4 (worst adherence), was 68.8%, 24.1%, 5.0%, and 2.0%, respectively	After adjustments for age/gender/geographic region of residence, blacks were found to have low medication adherence. Also women compared to men, have low drug adherence
Pandey et al.[22]	Adherence score less than 6 was seen in 26% of patients. The actual prevalence of non-adherence using therapeutic drug monitoring was 51%	This study suggested that there is limited accuracy of the MMAS-8 tool in detecting drug adherence in patients of aTRH
Hema et al.[23]	Adherence was seen as— • High—15.3% • Low adherence—(62%, n=248) (majority of study population) • Medium adherence—22.7% (n=91)	Higher adherence was found in— • 50 years & above age group (46.6%) • Among females (51.6%) • Among nuclear families (47.1%) • Among literates (44.2%)
Nagarkar et al.[24]	Using MMAS-8, 23.4% were high adherent and 76.5% showed low adherence to the medication	Medication adherence was found— • Significantly associated with age, family type, and experience of symptoms • Not associated with gender, education, frequency, and number of medications
Behnood-Rod et al.[25]	49.6% showed MMAS-8 score less than 6	Following has been noted— • Negative linear association between systolic BP as well as diastolic BP • Factors recognized to have statistically significant association with the MMAS-8 score were—overweight/obesity/previous history of admission to emergency services due to hypertensive crisis/getting medication directly from drugstore without revised prescription

TABLE 4 Non-adherence to medication in aTRH

Study	*Location*	*Method of non-adherent assess*	*Baseline blood pressure*	*Non-adherent*
Yakovlevitch and Black[26]	New Haven, CT, USA	MD interview	176/103	9/91 (9.9%)
De Souza et al.[27]	São Paulo, Brazil	Pill count	163/103	16/44 (36%)
Cereal et al.[28]	Prague Czech R	Serum level	171/97	55/84 (65.5%)
Jung et al.[29]	Frankfurt, Germany	Urine level	Not stated	40/76 (53%)
Blinker et al.[30]	Dallas, TX, USA	Urine level	169/103	23/40 (57.5%)

medication non-adherence in very low-income patients who were being treated for hypertension in routine care clinic setting.[20] Soon similar success was obtained in validating MMAS with high reliability in patients with other chronic illnesses **(Table 3)**.[11]

Role of Medication Adherence in aTRH

There is risk of poor outcomes in patients with aTRH. Drug adherence and intensification ameliorate BP control in the patients who receive pharmacological treatment; however, less is studied about the outcomes of these processes in aTRH. Substandard adherence or failing to take ≥75% of prescribed drug, influence ~10–60% of aTRH **(Table 4)**.[1]

Factors Affecting Medication Adherence in aTRH

There are very few studies which studied about factors affecting medications adherence in aTRH. **Table 5** comprises few studies which have studied these factors.

TABLE 5 Studies related to the factors affecting medications adherence

Study (reference)	*Year of study*	*Results as prevalence of non-adherence (%)*	*Results as factors responsible for poor adherence of the medications*
Bhandari et al.[33]	2015	≥80	The following patients were more likely to be adherent to treatment: • Patients hypertensive for ≥5 years (2.98 times) • Whose hypertension was detected during checkups for conditions related to hypertension (2.35 times) • Patients living with ≤4 family members (2.01 times) • Family income of ≥3,000 rupees (2.56 times) • Who were getting free drugs (4.16 times) • Patients perceiving current blood pressure to be under control (2.23 times) • Those satisfied with current treatment (3.77)
Venkatachalam J[34]	2015	24.1	Adherence was found to be higher in following groups: • Age groups 30–39 years (27%) and above 60 years (27.1%) as compared with other age groups • Among female (25.5%) respondents than male respondents (22.6%) • Married (24.8%) respondents than unmarried respondents (21.1%)
Patel and Taylor[35]	2002	32	No statistically significant differences in medication adherence based on: • Age • Gender • Education • Total household income • Living arrangements • Total number of years with hypertension • Number of medications
Karakurt et al.[36]	2012	57.9	Significant association between old age and non-adherence
Ramli et al.[37]	2012	46.6	Female were one and a half times more adherent than male
Gupta et al.[38]	2016		• Age has an inverse association with non-adherence to antihypertensive treatment • Every 10-year increase in age was associated with more than 30% reduction in the odds of non-adherence in the UK and the Czech populations • Females were found to be more non-adherent compared to males
Yang et al.[39]	2016	43.5	Better medication adherence seen in: • Older participants • Patients having more knowledge of hypertension

Alsabbhag et al. extracted data of 40 cohorts in 30 studies reporting socioeconomic status (SES) variable and did a structured review and meta-analysis study to discover the relationship between SES with adherence to antihypertensives.

They noticed that higher SES was associated with a lower risk of non-adherence in 31 cohorts (77.5%), with no difference in 1 cohort, and with an increased risk of non-adherence in 8 cohorts.[31] A study by Siegel et al. entitled "Antihypertensive medication adherence in the department of veterans affairs," which comprised of 95% of all patients included in this review noticed that patients with an ICD-9 diagnosis of depression were found to be less likely adherent to medication in multivariate analysis.[32]

Risk Factors for aTRH

The patients with aTRH were significantly associated with older age groups (>55 years), obesity (BMI >27.5 kg/m^2), diabetes mellitus, prolonged hypertension (>10 years), female sex, black race, and comorbidity like ischemic heart disease, depression as risk factors as compared to patients with non-resistant hypertension.

Workup to Differentiate aTRH from TRH

Peudo or aTRH

In clinical practice it is the most common form of resistance.[1] It inferred absence of true resistance to drugs and is due to either wrong technique of measuring

BP, substandard adherence to treatment or white coat hypertension.

Poor Measurement Technique

Faulty measurement techniques can result in false high readings of BP and thus can result in aTRH. The two most common mistakes in clinical scenario are—

- Measuring the BP immediately and not allowing the patient to sit calmly
- Use of inappropriate size cuff

This results in falsely high BP readings of the patients who otherwise are having normal or controlled BP.

Substandard Adherence

One of the major reasons of inadequate BP control is poor adherence to antihypertensives. It is seen that substandard adherence is usual at primary care level and it is less frequent among patients who are being treated by specialists. Inadequate BP control and treatment resistance are two different identities. Before labeling failed antihypertensive regimen, it is mandatory and wise to ensure that the regimen was taken correctly as advised by the treating physician.

White Coat Effect

White coat hypertension is persistently higher values of clinic BP while home recordings are significantly lower. Studies specify that significant white coat effect is as usual in aTRH patients as in more general hypertensive population. Patients of resistant hypertension on the basis of white coat effect show less severe target organ damage and have less cardiovascular risk compared with patients who have persistently higher ambulatory BP values.

Fragmented Health Services

India like other developing countries is facing an important problem of lacking access to chronic care. Patients shift to different physicians at will and the majority of primary and secondary care physicians have no robust system to track patient's data. This effects in inappropriate care, substandard lifestyle advice, and revising pharmacological therapy with substandard BP control.

Workup for TRH/aTRH

Workup of TRH and aTRH is summarized in **Table 6**.

Guiding Principles or Clinical Pearls to Evaluate Resistant Hypertension

What a clinician should know to evaluate a case of resistant hypertension is summarized below:[1]

- 1. Confirm TRH—
  - Clinic BP >130/80 mm Hg
  - Patient taking ≥3 antihypertensive agents (including a long acting calcium channel blocker,

TABLE 6 Resistant hypertension (TRH and ATRH) workup[40]

Find out and correct pseudohypertension (aTRH)	• Properly measure BP • Check white coat effect with help of authentic home or 24-hour ambulatory BP measurements • Evaluate treatment adherence and boost it with—education and awareness Prescribing cost effective drug regimen Prescribing drugs with least and tolerable adverse effects Prefer once daily fixed-dose combination products
Life style changes	• Whether patient is using any pharmacological/herbal substances that may cause increase in BP—if yes, remove it • Find out the amount of daily alcohol intake and advise to cut down it to zero or recommended daily intake • Find out daily dietary salt intake and recommend sodium restriction to <100 mmol (2.4 gm) per day • Evaluate the degree of obesity, abdominal obesity, and physical activity. Also advise weight reduction and regular aerobic exercise (at least 30 min/day, most days of the week)
Find out contributing factors to true resistant hypertension	• Evaluate renal function (estimate glomerular filtration rate) and modify treatment accordingly • Find out causes of secondary hypertension
Treatment should be customized as per the patient characteristics with optimal doses of suitable medications. Refer to the hypertension specialist if everything fails.	

a blocker of renin-angiotensin system, and a diuretic)
  - Medications are at maximal or maximally tolerated doses
- Assess for pseudo or aTRH—
  - Confirm adherence to antihypertensive treatment
  - Monitor 24-hour ambulatory BP to eliminate white coat effect
  - Use home BP monitoring in case of non-availability of 24-hour ambulatory BP monitoring
- Assess for secondary hypertension—look for the following—
  - Primary aldosteronism
  - Renal parenchymal disease
  - Renal artery stenosis
  - Pheochromocytoma/paraganglioma
  - Cushing syndrome
  - Obstructive sleep apnea
  - Coarctation of aorta
  - Other endocrine causes like—hypothyroidism, hyperthyroidism, hypercalcemia, and primary hyperparathyroidism, congenital adrenal hyperplasia, acromegaly
- Assess for target organ damage—
  - Ocular: fundoscopic exam
  - Cardiac: left ventricular hypertrophy, coronary artery disease
  - Renal: proteinuria, decreased glomerular filtration rate
  - Peripheral arterial disease: ankle/brachial index

Prognosis

The prognosis of the patients suffering from aTRH compared with controlled hypertension has not been particularly studied in detail. Uncertainly but likely, prognosis should be impaired in aTRH as such patients typically have longstanding history of sub-standardly controlled BP and usually have other associated comorbidities and cardiovascular risk factors like diabetes, obstructive sleep apnea, left ventricular hypertrophy, and/or chronic kidney disease. It is also unknown so far that post-successful treatment of aTRH in such patients, how much this cardiovascular risk will reduce. However, the advantage of successful treatment is likely considerable as suggested by hypertension outcome studies in general and by the early Veterans Administration cooperative studies, which illustrated a 96% reduction in cardiovascular events over 18 months with help of triple antihypertensive regimens compared with placebo in patients with severe hypertension (diastolic BP 115–129 mm Hg).[41]

Conclusion

Spreading awareness for better medications adherence and proper measurement of BP can easily tackle the aTRH, which is otherwise a significant issue. Among aTRH patients, decrease adherence to antihypertensives is a significant problem. Thus, it is emphasized that health-care professionals should pay attention to this fact while developing a treatment program for aTRH patients in order to enhance adherence to antihypertensive medications and improve health outcomes.

CHAPTER

20 Resistant Hypertension

Jai Bhagwan, Ayush Bansal, Nikhil Gupta

Abstract

Resistant hypertension refers to elevated blood pressure above the target level in spite of concurrent use of three antihypertensive agents from three different classes (including a diuretic) in the maximum tolerated/recommended doses. It is important to exclude pseudo-resistant hypertension before making a diagnosis of resistant hypertension. Adverse cardiovascular event rate is almost 50% higher in cases of resistant hypertension than in general hypertensive patients. Chlorthalidone/indapamide is the agent of first choice while selecting a diuretic. It is important to uptitrate the doses of three existing antihypertensive agents to the maximum permissible/tolerable levels before adding the fourth agent. The fourth preferred agent of choice is spironolactone provided the serum potassium is $\leq$4.5 mmol/L. Next comes the role of beta blockers, alpha blockers, centrally acting agents, direct vasodilators, and direct renin inhibitors. Device-based therapies like renal denervation and carotid baroreceptor stimulation have a very limited role restricted to highly specialized centers.

Introduction

Hypertension is one of the most common ailments seen by a primary care physician and failure to detect and treat it timely leads to many complications like stroke, myocardial infarction, and chronic kidney disease. It is unfortunate that in spite of having well established diagnostic and therapeutic protocols, more than half of patients are not controlled to target levels. Resistant hypertension refers to elevated blood pressure above the target goal of 140/90 mm Hg in spite of using three antihypertensive agents from three different classes, including a diuretic, in the maximum permissible/tolerable doses.[1] Target goal of blood pressure is 130/80 mm Hg for patients of chronic kidney disease and established cardiovascular disease. Here, it is worth mentioning that a proper combination means a combination of three antihypertensive drugs having synergistic action—angiotensin converting enzyme (ACE) inhibitors or angiotensin receptor blocker (ARB) plus a calcium channel blocker (CCB) and a thiazide like diuretic.

Prevalence

Exact prevalence of resistant hypertension is not known but 20–30% of patients become resistant to treatment with the passage of time.[2] In largest hypertension trial (ALLHAT), only 67% patients attained a systolic blood pressure of less than 140 mm Hg and 92% attained a diastolic blood pressure of less than 90 mm Hg. Refractory hypertension is not synonymous to resistant hypertension as refractory hypertension is much more severe form of disease where the blood pressure cannot be controlled even with five or more drugs including spironolactone and have to be referred to specialized centers for more invasive/devised based therapies.

Pseudo-resistant Hypertension

As the name indicates it is not truly resistant, but looks like resistant and one must rule it out before making a diagnosis of resistant hypertension. Important causes of pseudo-resistance are as follows:

- Improper blood pressure measurement technique or inappropriate sized blood pressure cuff.
- Poor compliance to prescribed medicines due to cost, side effects, or inadequate counseling. A renal denervation trial revealed that only 20% of patients were adherent to the prescribed medicines.[3]
- Inadequate/suboptimal doses or improper combination of drugs. A general practitioner's prescription review of uncontrolled hypertensive patients revealed that only 18% of these patients were prescribed three antihypertensive agents including a diuretic.[4]
- Non-adherence to diet and lifestyle modification like reduction of salt intake, cessation of cigarette smoking, and moderation of alcohol intake.
- White coat hypertension—here the blood pressure is high in doctor's chamber but otherwise it is normal. Best way to diagnose white coat hypertension is either ambulatory blood pressure monitoring (ABPM) or home blood pressure monitoring (HBPM). White coat hypertension should be suspected in patients having orthostatic hypotension and in those having very high blood pressure readings in the absence of target organ damage.

Medications Interfering with Hypertension Treatment

A variety of drugs can raise the blood pressure or interfere with the working of antihypertensive drugs making them less effective.[5] Commonly used such drugs are:

- NSAIDs
- Oral contraceptives
- Glucocorticoids
- Sympathomimetics including nasal decongestants
- Antidepressants
- Cocaine
- Erythropoietin
- Amphetamine

Secondary Hypertension

About 5% to 10% of total hypertensive patients have secondary hypertension and it is more prevalent in resistant hypertension.[5] Common causes of secondary hypertension are obstructive sleep apnea (OSA), renal artery stenosis (RAS), chronic kidney disease (CKD), primary aldosteronism. Less common causes are pheochromocytoma, Cushing's syndrome, hyperthyroidism, hypothyroidism, coarctation of aorta, and drugs.

Obstructive Sleep Apnea (OSA)

Clinical features of OSA are obesity, snoring, and day time sleepiness. Sleep apnea is more severe and more common in men than women.[6] Sleep apnea gives rise to hypoxia which stimulates sympathetic nervous system and is responsible for resistant hypertension.

Continuous positive airway pressure (CPAP) is the treatment of choice for OSA. Once OSA is treated with CPAP, the blood pressure starts coming down and lesser and lesser medicines are required to control blood pressure.

Primary Aldosteronism

As the name indicates, primarily there is excessive production of aldosterone from the adrenal cortex. Control of hyperaldosteronism can control the blood pressure to a reasonable level. It is of two types:

- Bilateral adrenal hyperplasia or idiopathic hyperaldosteronism (IHA)
- Unilateral aldosterone producing adenoma (APA)

Bilateral hyperplasia (IHA) is much more common than unilateral adenoma (APA). 10% to 20% patients of resistant hypertension are found to have primary aldosteronism.[7]

Clinical indicators of primary aldosteronism include:

- Hypertension with hypokalemia
- Adrenal mass on ultrasound in patients with hypertension
- Resistant hypertension especially in young individuals

Usually there is high plasma aldosterone concentration (PAC) and low plasma renin activity (PRA), and therefore PAC/PRA ratio is elevated. Aldosterone antagonists like spironolactone or eplerenone can effectively control blood pressure in such cases. Surgical treatment is restricted to patients who do not respond to medical management and have unilateral adrenal mass.

Renovascular Hypertension[8]

Overall prevalence of significant renovascular disease is 6–8%. Here the hypertension is due to an obstructive lesion in the renal artery.

- Atherosclerotic RAS—this is the main cause of RAS found in 80–90% of cases. It is typically seen after the age of 55 years and is usually associated with atherosclerotic lesions elsewhere like coronary or cerebral vessels.
- Fibromuscular dysplasia—this is second most important cause of RAS, responsible for 10–20% cases of RAS. It is more common in young females.

Clinical indicators of RAS:

- Onset of high blood pressure after 55 years of age
- More than 25% increase in serum creatinine after starting ACE inhibitors or ARBs
- Unexplained atrophic kidneys or difference of 1.5 cm or more in the size of two kidneys
- Abdominal bruit

Diagnosis is confirmed by renal Doppler studies and CT/MR angiography.

Aim of treatment is to control blood pressure mainly with the help of antihypertensives like ACE inhibitors or ARB, diuretics, especially chlorthalidone or indapamide and CCBs, keeping a close watch on serum creatinine and serum potassium.

Stenotic lesions unresponsive to medical treatment are treated with revascularization. However, ASTRAL study[9] could not produce evidence that interventional therapy with angioplasty is a better choice.

Chronic Kidney Disease (CKD)

CKD has a very strong association with resistant hypertension. It is both a cause and complication of resistant hypertension.[10] Resistant hypertension in cases of CKD is due to salt retention, increased action of renin angiotensin aldosterone system, and increased activity of sympathetic nervous system. ACE inhibitors and ARBs are the drugs of first choice. Initially, there is mild increase in serum creatinine/serum potassium levels after starting these agents and the same needs to be monitored closely. Diuretics along with fluid and salt restriction are also very effective. However, thiazides lose their potency once the GFR is below 40 mL and should be substituted with loop diuretics.

Other Causes of Secondary Hypertension

See **Table 1**.

TABLE 1 Other causes of secondary hypertension

Disorder	*Clinical features*
Cushing's syndrome	Moon shaped facies, obesity, hirsutism, and hyperglycemia along with hypertension
Coarctation of aorta	• Higher blood pressure in arms and lower blood pressure in legs • Weak femoral pulses
Hypothyroidism	• Weight gain, fatigue, anorexia, dry skin • Amenorrhea • Increased TSH • Decreased free T4
Hyperparathyroidism	• Fatigue, constipation, joint pains • Nephrolithiasis, heartburn, polydipsia
Pheochromocytoma	• Paroxysmal hypertension • Spikes of headache, sweating, tremors, and palpitations

Work Up for a Patient of Resistant Hypertension

Once the diagnosis of resistant hypertension is made, it is very important to record a detailed history and clinical examination to exclude pseudo-resistant hypertension.

- Confirm that the patient is taking all prescribed medicines
- Review the prescription for proper drug combination and doses
- Confirm adherence to lifestyle measures
- Exclude white coat effect by ABPM or HBPM
- Look for consumption of excessive salt or alcohol or smoking
- Look for consumption of offending drugs like NSAIDs, oral contraceptives, or corticosteroids
- Look for secondary causes of hypertension

Management

Non-pharmacological Intervention

Lifestyle modifications can significantly decrease the blood pressure.

- Dietary sodium—it has been found that restriction of sodium to 2.4 gm/day or salt to 6 gm/day reduces both systolic and diastolic blood pressure by reducing extracellular volume.[11]
- Restrict the use of alcohol and smoking.

- Weight loss if overweight.
- Consume high fiber and low fat diet.
- Increase physical activity.

Antihypertensive Drugs

It is presumed that when the patient is diagnosed as having resistant hypertension, he is already taking a synergistic combination of three antihypertensive drugs, that is, a combination of ACE inhibitors or ARB plus a CCB plus a thiazide like diuretic.

First of all, one should optimize the doses of the three antihypertensive agents as a large majority of patients are taking suboptimal doses. It is worth mentioning that chlorthalidone is twice as potent as hydrochlorothiazide and so, those patients who are taking hydrochlorothiazide should be changed to chlorthalidone or indapamide.

Spironolactone

Spironolactone is the fourth agent of choice in resistant hypertension provided serum potassium is ≤4.5 mmol/L. Its dose is usually 12.5–50 mg/day. It has got a long half-life and maximal effect is seen after 3–4 weeks. Therefore, dose titration needs to be done every 4–6 weeks. It has an additional property of regressing left ventricular hypertrophy. The main side effect of spironolactone is breast tenderness and hypertrophy which is both dose and duration dependent, and is reversible once the drug is withdrawn. The second important side effect is hyperkalemia, especially in combination with ACE inhibitor or ARB. It is important to monitor serum potassium before starting and 2 weeks after drug initiation. Another side effect is hyponatremia, especially in elderly population after long-term use.

Beta Blockers

A beta blocker like metoprolol, nebivolol, or carvedilol is the next choice in resistant hypertension. These agents are of special use in cases of coronary artery disease, heart failure, and tachyarrhythmias.

Alpha Blockers

An alpha blocker can be used especially in the presence of benign enlargement of prostrate.

Centrally Acting Agents

Centrally acting agents like clonidine and alpha methyldopa can also be used in the management of resistant hypertension if the patient is refractory to other classes of drugs. Rebound hypertension can occur if the drug is suddenly stopped.

Direct Vasodilators

A vasodilator like hydralazine is the next agent to be used. Main side effect of hydralazine is fluid retention and tachycardia, and therefore concomitant therapy with a diuretic and beta blocker is usually required.

Direct Renin Inhibitors

Aliskiren is particularly useful in patients of resistant hypertension associated with features of metabolic syndrome.

Newer Drugs for the Management of Resistant Hypertension[12]

Endothelin receptor antagonists like darusentan gave promising results initially but could not show similar results in subsequent studies. Nitric oxide donors are other promising agents for the management of resistant hypertension. Nitrates with phosphodiesterase-5 inhibitors showed good results in a small study of six patients suffering from resistant hypertension. However, these agents can drastically lower the blood pressure, and hence are to be used with great caution.

Night Time Administration of Antihypertensives

Early morning fall of blood pressure (nocturnal dipping) is a normal physiological process and this is impaired in all hypertensive patients and more so in cases of resistant hypertension. Night time administration of at least one antihypertensive medication can restore the impaired night time dipping and reduces cardiovascular risk.[3] American Diabetes Association in 2013 recommended in its guidelines to administer at least one antihypertensive medication at bedtime in cases of resistant hypertension.[13]

Procedures and Devices for Resistant Hypertension

Renal Denervation (RDN)[14]

As the name indicates, this procedure involves bilateral destruction of renal nerves travelling along the renal arteries using radio frequency ablation. The underlying principle is to decrease the renal sympathetic tone and thereby reduce the renal vascular resistance.

The initial Simplicity HTN-1 and HTN-2 RDN trials showed quite good results and the blood pressure was reduced by 30/15 mm Hg and the results were maintained for more than 2 years. However, the subsequent trial (Simplicity HTN-3) did not show any significant reduction in blood pressure after 6–12 months of renal denervation.

Carotid Baroreceptor Activation

It has been observed that carotid baroreceptor activation by implanting an electrical device (Baroreceptor Activation Therapy—BAT) in the carotid sinus can significantly reduce both systolic and diastolic blood pressure. Moreover, this procedure gives an additional benefit of reducing left ventricular hypertrophy and arterial stiffness. However, these studies have involved only a limited number of patients. This is an expensive and invasive procedure and more randomized controlled trials with larger number of individuals are required to establish the safety and beneficial effects of this procedure.

Conclusion

Resistant hypertension is an established entity and it is important to diagnose it because of its close association with the complications of hypertension. One should exclude pseudo-resistant hypertension especially white coat hypertension and uptitrate the doses of all the three existing antihypertensive agents to the maximum recommended/tolerable levels before labeling resistant hypertension. Compliance to treatment need to be re-emphasized along with lifestyle changes before adding further antihypertensive agents. Role of procedures like renal denervation and carotid baroreceptor stimulation is still in the experimental stage and large randomized controlled studies are required to establish their usefulness.

CHAPTER

21

Role of ARB in Hypertension

Sangram S Biradar

Abstract

Hypertension being one of the important diseases and risk factors of CVD and stroke in India. In management of hypertension all Indian guidelines recommend (ARBs) as an initial angiotensin receptor blockers or add-on drugs therapy. Hence, ARBs have demonstrated evidence-based benefits in management of hypertension, heart failure, and diabetic renal disease. ARBs are very well tolerated as monotherapy as well as in combination with other antihypertensive medications that improve adherence to therapy and have become a mainstay in the treatment of stages 1 and 2 hypertension.

Introduction

Hypertension is one of the risk factors of (CVD) and leading to disability and death in spite progresses happened in management in past three decades. In India up to 33% of urban and 25% of the rural population are afflicted with the disease. Attainment of (BP) goals in the population at large is a major challenge and area of focus of health systems worldwide.

Angiotensin II receptor blockers (ARBs) are advocated for people with stage I–II hypertension and type 1 or 2 diabetes. Since 1995, the role of ARBs has been in clinical use. ARBs are supposed to be better antihypertensive agents with good tolerance. ARBs have additive BP-lowering effects when they are combined with thiazide diuretics and dihydropyridine calcium channel blockers (CCBs), ARBs have proven mortality and morbidity effects in heart failure and chronic renal disease, particularly when associated with T2DM, concerns were raised surrounding the association of ARBs with development of solid cancers and coronary artery disease.

Pharmacology of Angiotensin Receptor Blockers

The renin–angiotensin–aldosterone system has been a major target pathway for development of antihypertensive medications. The major four groups of medications, like ARBs aldosterone antagonists, and direct rennin inhibitors, and ACE inhibitors, act on the same pathway. The interest in this pathway is due to the action of angiotensin II on the vascular system, renal sodium and water handling, and cellular proliferation. Inhibition of ACE only partially inhibits formation of angiotensin II. Angiotensin II activates two types of angiotensin II receptors (ATR): ATR1 and ATR2. ATR1 are abundant in the vessels, brain, heart, kidney, adrenal gland, and nerves, while ATR2 are prominently expressed in the fetus but decrease in number during the postnatal period, where they are only available in small numbers in the adult kidney, adrenal gland, heart, brain, uterus, and ovary. Activation of ATR1 increases inositol triphosphate and various arachidonic acid metabolites, and decreases cyclic adenosine monophosphate.[1,2]

TABLE 1 Pharmacological characteristics of angiotensin receptor blockers[10]

ARB	*Half-tife (h)*	*T_{max} (h)*	*Bioavailability (%)*	*Route of elimination: renal % (R) biliary/ faecal % (B)*	*Food interaction*	*Drug interaction*	*CYP metabolism*
Losartan	2	1–1.5	33	35 R; 60 B	Yes	Rifampin fluconazole	2C9, 3A4
Candesartan cilexetil	9	2–5	42	33 R; 67 B	No	None	2C9 (negligible)
Eprosartan	5–9	1–3	63	7 R; 90 B	Yes	None	No
Irbesartan	11–15	1.3–3	60–80	20 R; 80 B	No		2C9, 3A4 (negligible)
Telmisartan	24	0.5–1	43	<1 R; >97 B	No	Digoxin	No
Valsartan	6	2–4	23 (capsule) 50 (capsule)	13 R; 83 B	Yes	None	2C9 (weak)
Olmesartan medoxomil	12–14	1.7–2.5	26	35–50 R; 50–65 B	No	None	No
Azilsartan medoxomil	12	1.5–3	60	42 R; 55 B	No	None	2C9, 2B6 (negligible), 2C8 (negigible)

The mechanism of generalized vasoconstriction of vascular smooth muscle from contraction, which intern increases aldosterone thereby increase in reabsorption of sodium in the proximal tubal and cell growth in arteries and heart occurs. Therefore, angiotensin II which facilitates release of catecholamine from adrenal medulla and nerve endings thereby increasing hyperactivity from sympathetic nervous system occurs. Angiotensin II is believed to have an important mechanistic role in promoting CV diseases that is unrelated to its effect on BP. Several animal studies have shown that it causes cardiac hypertrophy in the absence of elevated BP.[3]

Individuals with a high renin–sodium profile have a greater risk of myocardial infarction than those with a normal or low profile. The function of ATR2 (Alderman) remains unclear, but it inhibits cell growth by stimulation and differentiation of cell and apoptosis leads to vasodilation,[4] However, ATR2 studies in animal show cardiac function improvements by stimulation and thereby preventing remodeling of cardiac post-myocardial infarction **(Table 1)**.[5]

Angiotensin Receptor Blocker Available

Presently ARBs available in the market for hypertension and cardiac indications, that is, losartan, valsartan, candesartan, eprosartan, irbesartan telmisartan, olmesartan, and azilsartan. All these above are accepted for hypertension treatment.

Losartan and irbesartan are approved in diabetic nephropathy, losartan in stroke prophylaxis, candesartan and valsartan for heart failure and also reduce CV mortality in left ventricular failure patients or left ventricular dysfunction followed by myocardial infarction. ARBs also have demonstrated reducing proteinuria by preserving kidney function in diabetic patients and also decreasing endothelial dysfunction thereby increasing fibrinolysis and have demonstrated their effectiveness in preventing atheromas.

The eight ARBs approved for use in the USA and Europe are nonpeptide compounds having biphenyl, tetrazole, benzimidazole or non biphenyl non tetrazole groups. Candesartan, olmesartan, valsartan, losartan, and irbesartan have a common tetrazolobiphenyl structure; telmisartan, and candesartan have a benzimidazole in common group; and eprosartan has a nontetrazole and nonbiphenyl, chemical structure. Whereas the irbesartan as an exception, and all have free carboxylic acid group. ARBs have more affinity for ATR1 than for ATR2 and can block the activities of angiotensin II on ATR1 regardless of whether it was created from ACE or other enzymes such as cardiac chymase **(Table 2)**.[5]

TABLE 2 Doses for hypertension and other indications of the angiotensin receptor blockers[5]

ARBs	*Starting dose (mg/day)*	*Maximum dose (mg/day)*	*Dosing interval*	*Other approved indications, aprat from hypertension*
Losartan	50	100	Once daily or twice daily	Diabetic nephropathy when serum creatinine is increased and proteinuria is present in patients with hypertension and type 2 diabetes; strok reduction in patients with hypertension and left ventricular hypertrophy (non-black only)
Candesartan cilexetil	16	32	Once daily or twice daily	Treatment of heart failure (NYHA classes II-IV)
Eprosartan	600	800	Once daily or twice daily	None
Irbesartan	150	300	Once daily	Diabetic nephropathy when serum creatinine is increased and proteinuria is present in patients with hypertension and type 2 diabetes
Telmisartan	40	80	Once daily	Cardiovascular risk reduction in patients unable to take ACE inhibitors
Valsartan	80 or 160	320	Once daily	Treatment of heart failure (NYHA classes II-IV); reduction of cardiovascular mortality in clincally stable patients with left ventricular failure or dysfunction following myocardial infarction
Olmesartan medoxomil	20	40	Once daily	None
Azilsartan medoxomil	40 or 80	80	Once daily	None

ARBs and their Pharmacological Characteristics

The mechanism of action of ARBs is by blocking the angiotensin II via the AT1 receptor irrespective of the biochemical pathway lead by angiotensin II formation.

ARBs cause a several-fold rise in circulating angiotensin II levels, AT2 receptors are activated by ARBs. Because AT1 receptors are blocked by ARBs, the increase level of angiotensin II activates AT2 receptors. Hence, AT2 receptor is thought to activation the opposite effect of AT1 receptor, which are protective for cardiovascular system and for protection of target organs damage.[5,6]

Pharmacokinetic Considerations

Lithium is increased by affect of all ARBs in renal reabsorption; hence, ARBs with concomitant use with lithium should be avoided.

Peak action of ARBs on BP occurs at 3–6 hours after intake. Losartan metabolism occurs in liver via CYP system to its metabolite EXP3174, which has 10–40 times potent than IV losartan; hence, its dose is given half in severe hepatic impairment.

Although food delays its absorption and reduces its maximum plasma concentration (Cmax), this is not clinically significant. As such, any CYP2C9 enzyme inhibitors or inducers may reduce the effectiveness of losartan, and this must be considered during drug selection.

The ARBs (olmesartan medoxomil, candesartan cilexetil, and azilsartan medoxomil) require GIT and liver for activation as all three are prodrugs (olmesartan, candesartan, and azilsartan, respectively). The drug irbesartan has highest bioavailability among the ARBs. Telmisartan has longest action available in the market with half-life of 24 hours and has mechanism action rapidly about 0.5–1.0 hour **(Table 3)**.[5]

BP Reductions Trials in ARBs

In patients with T2DM with proteinuria and/or renal insufficiency, ARB-based treatment is recommended because these agents delay the progression of nephropathy.

ARBs in Diabetic and Kidney Disease

The intraglomerular hypertension is reduced in patients with diabetic nephropathy by ARBs. By reducing the gradient in glomerulus and thereby fibrosis of the nephron is averted (IRMA 2) that over 1 year trial.

The endpoints of reduction in NIDDM with angiotensin II antagonist losartan (RENAAL) trial showed losartan reduced incidence of doubling of serum creatinine (risk reduction 25%, p=0.006), 35% proteinuria reduction occur in end-stage renal disease (risk reduction 28%, p=0.002). Except for lowering the rate of first hospitalizations for heart failure (risk reduction 32%, p=0.005), the composite endpoint was similar after 3.4 years of therapy.[1,7,8]

CKD and ARBs

The important aim was preservation of renal function. In 2007, a scientific statement by AHA developed on treating hypertension and CKD population as a high (CAD) risk group as recommended blood pressure less than 130/80 mm Hg as goal. (ACEIs) or (ARBs) antihypertensive drugs were preferred agents CKD.[9]

Post-MI Survival

After acute MI, approximately 50% of patients show signs and symptoms of heart failure and approximately 10% have asymptomatic LV systolic dysfunction. Post-MI patients with heart failure, LV dysfunction, or anterior Q-wave MI have poor prognosis. Although large clinical trials show that ACE-inhibitors can reduce mortality and cardiovascular events, the prognosis of these high-risk patients is not satisfactory.[10]

Vascular Remodeling

Most vascular actions of angiotensin II are mediated through the AT1 receptors located on vascular smooth muscle and endothelial cells. The hallmark of vascular injury by hypertensive patients and vascular hypertrophy indeed may involve AT1 activation of receptor. And novel mechanism of AT2 receptor is by nitric oxide generation which promoted by AT2 receptors, which help in and induce apoptosis.[3]

Conclusion

All ARBs are highly proven effective class of drugs in treatment of hypertension and its associated comorbid condition from two decades. Presently there are eight ARBs approved for treatment of hypertension. There longer half-lives and high potency made BP reductions into enhanced duration of action, combining ARBs with other antihypertensive drugs like beta-blocker nebivolol made better BP control in some studies.

While there are added benefits by combining ARBs with ACEi (e.g., reduction in proteinuria), whereas some studies show combining these demonstrated increases in adverse renal events. Therefore, no clinical benefits seen by combining ARBs with ACE inhibitors (or direct rennin inhibitors) in treatment of hypertension.

The excellent safety and tolerability profile of the ARB class have improved the adherence to antihypertensive therapy and enhanced our ability to manage hypertension in those patients with sensitivities to other antihypertensive drug classes, including ACE inhibitors

CHAPTER

22 Novel Calcium Channel Blockers: What's New

Nikhil Gupta

Abstract

Novel calcium channel blockers have shown a promising role in management of hypertension due to their antisympathetic actions and their renoprotective, cardioprotective and neuroprotective effects. There are six subtypes of calcium channels L, N, P, Q, R, and T-type. They are differentiated on basis of their electrophysiological properties. N type calcium channels are found at nerve endings. T-type Ca channels are found in pacemaker cells, atrial cells, purkinje fibres, juxtamedullary efferent, and afferent arterioles. The novel calcium channel blockers predominantly act on N and T type calcium channels along with L type calcium channels and decreases norepinephrine release which leads to vasodilatation, decrease in heart rate, and increase in renal blood flow.

Introduction

Hypertension accounts for major stroke and cardiovascular deaths all over the world. Globally an estimated 26% of world population has hypertension and prevalence is expected to increase to 29% by 2025. Hypertension is widely prevalent in India with significant variations in urban and rural population and regional variations. Prevalence is 20–40% in urban and 12–17% in rural adult population in India. But it is also the most modifiable factor with effective lifestyle changes and pharmacotherapy. A 2-mm Hg decrease in blood pressure can prevent 1,51,000 stroke and 1,53,000 coronary heart disease deaths in India.

Calcium channel blockers (CCBs) are one of the first-line drugs used in hypertension. Novel CCBs have further shown a promising role in the management due to their antisympathetic actions. Further their renoprotective, cardioprotective, and neuroprotective effects have also been demonstrated with lesser side effects.

Classification of Calcium Channels

There are six subtypes of calcium channels L-, N-, P-, Q-, R-, and T-type. They are differentiated on basis of their electrophysiological properties. The T-type Ca^{2+} channels are low voltage activated Ca^{2+} channels that activate and deactivate slowly and other five types of Ca^{2+} channels are high voltage-activated Ca^{2+} channels, which depolarize approximately at –40 mV. These channels consist of four subunits, $\alpha 1$, $\alpha 2\text{-}\delta$, β, and γ. An $\alpha 1$ subunit is the most dominant component of the calcium channels. Each $\alpha 1$ subunits are of 10 different types and each of them has specific distribution in body and ion conductance of its channels as mentioned **(Table 1)**.

Calcium Channel Blockers: Classification and Mechanism of Action

CCB are classified into three categories:

- Benzothiazepines (e.g., diltiazem)

TABLE 1 Distribution and ion conductance of calcium channels

Current	*α1 subunit*	*Channel*	*Distribution*
P	α1A	CaV2.1	Neurons
Q	α1A	CaV2.1	Neurons
N	α1B	CaV2.2	Neurons
R	α1E	CaV2.3	Neurons
L	α1S	CaV 1.1	Skeletal muscle
	α1C	CaV1.2	Heart, endocrine, neurons
	α1D	CaV1.3	Endocrine, neurons
	α1F	CaV1.4	Retina
T	α1G	CaV3.1	Neurons, heart
	α1H	CaV 3.2	Neurons, heart
	α1I	CaV3.3	Neurons

- Phenylalkylamines (e.g., verapamil)
- Dihydropyridines.

Dihydropyridine are classified into four generations:

- First generation—Nifedipine, Nicardipine
- Second generation—
  - Slow release formula—Nifedipine SR (slow release), Felodipine ER (extended release)
  - Newer chemical structures—Benidipine, Manidipine, Nilvadipine, and Nitrendipine.
- Third generation—to avoid reflex tachycardia:
  - Long acting—Amlodepine
  - Lipophilic—Lercanidipine, Lacidipine, and Azelnidipine
- Fourth generation—block multiple calcium channels:
  - Cilnidipine and Efonidipine

CCBs bind to α1 subunit and prevent release of internal calcium stores into cytosol of cell thus inhibiting cell excitability. Traditionally CCB acted on L-type calcium channels which are predominantly expressed in heart and vessels so they regulated cardiac contractility, sinus node function and vascular tone. Novel CCBs act on N- and T-type calcium channels also. N-type calcium channels are found at nerve endings so they regulate the release of neurotransmitters norepinephrine. Hypertension is closely related to increase sympathetic nerve activity so decrease in norepinephrine release helps in decreasing blood pressure and their other effects. T-type Ca channels are found in pacemaker cells, atrial cells, Purkinje fibers, juxtamedullary efferent and afferent arterioles and regulates afferent and efferent arteriole and adrenal secretion. **Table 2** shows different CCB and types of calcium channels blocked.

TABLE 2 CCB and Ca channel blocked

Drugs	*L-type*	*T-type*	*N-type*
Nifedipine	+	–	–
Amlodipine	+		
Cilnidipine	+	–	+
Efonidipine	+	+	
Azelnidipine	+	+	
Benidipine	+	+	+

Novel Calcium Channel Blockers

Cilnidipine

Cilnidipine has got both L- and N-type channel blocking property. It prevents excitation and contraction coupling in vascular smooth muscle cell leading to arterial vasodilatation with reduction in peripheral resistance, same mechanism in cardiac muscle leads to negative ionotrophic effect, results in slowing of sinus rate and inhibits the release of sympathetic neurotransmitter norepinephrine. Recommended dose is 5–20 mg once daily.

Morning hypertension involves increased sympathetic activity and the renin-angiotensin system (RAS). In ACHIEVE-ONE trial, 2,319 hypertensive patients were divided into four quartiles depending upon baseline SBP and were treated with cilnidipine for 12 weeks. Cilnidipine reduced both morning SBP and PR more markedly in patients with higher baseline morning SBP and PR. Cilnidipine independent BP- and PR-lowering effects were due to neuronal N-type Ca channel blocking.[1] In achieve one subanalysis hypertensive patients were classified into four groups according to nocturnal SBP reduction rate (%), extreme dippers, a nocturnal SBP reduction rate of 20%, dippers, a nocturnal SBP reduction rate of 10% to <20%, nondippers, a nocturnal SBP reduction rate of 0% to <10% and risers, a nocturnal SBP reduction rate of <0%. Cilnidipine reduced nighttime BP more than daytime BP in risers, nighttime and daytime BPs equally in nondippers, and daytime BP more than nighttime

BP in dippers.[2] It does not cause reflex tachycardia as it attenuates norepinephrine release.

Cilnidipine dilates afferent and efferent arterioles by inhibiting N-type Ca channels and causing no increase in intraglomerular pressure. It causes reduction in urinary protein excretion and suppression of any serum creatinine increase.[3] A study comparing cilnidipine and amlodipine effect on renal function and proteinuria showed significant decrease in proteinuria in cilnidipine group at 12 months of treatment.[4] It causes less pedal edema as it causes venodilation so that the pressure in the afferent capillaries peripheral to the resistance arteries decreases.

Cilnidipine can provide synergistic effect with angiotensin II receptor blockers as it suppresses RAS through sympathetic N-type Ca^{2+} channel blockade. Cilnidipine is beneficial for the suppression of pathological cardiac remodeling, at least partly, via a superior improving effect on ambulatory BP profile compared with control CCBs in hypertensive CKD patients.[5]

Cilnidipine improves LV diastolic function in hypertensive heart disease by suppressing cardiac sympathetic over-activity. It exerts vasodilatory action without stimulating sympathetic nervous activity, thus improving insulin sensitivity. Antioxidant activity of cilnidipine and amlodipine was compared by measuring ionomycin-stimulated superoxide production in cultured human mesangial cells. Cilnidipine showed a significantly higher antioxidant activity than amlodipine.

Azelnidipine

It is a CCB with a half-life of about 8 hours. Dosage is 8–16 mg orally once daily. It blocks L- and T-type calcium channels Azelnidipine primarily undergoes first-pass hepatic metabolism and has no active metabolite product. It is highly lipid soluble so it is retained in the vascular wall after clearance from the blood and continues to elicit a hypotensive effect. So it causes a gradual and prolonged fall in blood pressure in hypertensive patients and no reflex tachycardia. It has a strong anti-arteriosclerotic action in vessels and antioxidative activity due to its high affinity for vascular tissue. Azelnidipine reduces heart rate and proteinuria in hypertensive patients by inhibiting sympathetic nerve activity and also prevents insulin resistance.

CALVLOC trial studied effect of azelnidipine on diastolic function left ventricular filling pressure in patients with preserved ejection fraction and diastolic dysfunction. Results showed it is associated with improvements in LV diastolic function, a reduction in LV filling pressure, and a decrease in the brain natriuretic peptide level.[6]

Benidipine

Benidipine blocks all the three L-, N- and T-type calcium channels. It has a strong and long effect due to its high affinity for the DHP binding site. There is slow binding and slow dissociation from the DHP binding site. This is known as "membrane approach" (approach to the cell membrane followed by long retention in the DHP binding site). This state contributes to the long-lasting antihypertensive effects of benidipine. Its cardio- and vasoprotective effects are due to vascular selectivity and enhanced nitric oxide (NO) production. It is absorbed rapidly and reaches maximum drug concentration within 2 hours.[7] Dosing is 2–8 mg once daily.

Benidipine renoprotective effects are due to

- Dilation of the efferent arterioles due to inhibition of T-type Ca^{2+} channels
- Marked increase in renal plasma flow rate
- Natriuretic effect by acting on both the upper segment of tubules and the distal tubules
- Increased NO formation in the renal parenchyma
- Suppression of increased expression of transforming growth factor (TGF)-β and α-smooth muscle actin in the glomeruli.

It has an anti-oxidant effect. In a study using cultured endothelial cells, benidipine suppressed endothelial damage induced by lysophosphatidylcholine [one of the lipids constituting oxidized low density lipoprotein (LDL)] more potently than nifedipine and amlodipine.[8] Benidipine suppresses the progression of atherosclerosis by stimulating the formation of NO by its direct action on vascular endothelial cells.

Benidipine increases coronary blood flow as it increases NO production during ischemia. Vascular selectivity of various CCBs was evaluated using isolated coronary arteries and the right ventricular papillary muscles of dogs; the coronary artery selectivity of benidipine was 14.4 times higher than that of nifedipine[9] and 19 times higher than that of amlodipine. These effects protect the myocardium, contributing to better prognosis for angina pectoris. It also stimulates the differentiation of osteoblasts, suppresses the proliferation of vascular smooth muscles, suppresses

the proliferation of mesangial cells, and protects the myocardium.

Efonidipine

Efonidipine blocks both, L- and T-type Ca^{2+} channels. It prolongs the late phase 4 depolarization of the sinoatrial node action potential through blockade of both L- and T-type Ca^{2+} channels, leading to its potent negative chronotropic effect. It has long lasting vasodilator actions and less reflex tachycardia.[10] It increases adiponectin levels without a corresponding change in BMI. Increasing adiponectin levels are predicted to improve both insulin sensitivity and endothelial function by multiple mechanisms.[11]

Conclusion

Thus, novel CCBs due to their action on N- and T-type calcium channels along with L-type calcium channels decrease norepinephrine release and lead to vasodilatation, decrease in heart rate, and increase in renal blood flow. They cause prolonged antihypertensive action, less reflex tachycardia, less pedal edema, better control of proteinuria, increase insulin sensitivity and, more antioxidation activities.

CHAPTER

23 Beta-adrenergic Receptor Blockers in Hypertension

Amit Kumar Das

Abstract

Hypertension remains one of the most important preventable causes of morbidity and mortality because of cardiovascular disease. Beta adrenergic receptor blockers are one of the most used and easily available antihypertensive agents. By blocking the beta receptors, they reduce the cardiac output and cause bradycardia. Selective beta 2 receptor agonism can lead to peripheral vasodilatation and reduce peripheral vascular resistance. All of these and decreased rennin all lead to effective lowering of blood pressure without decreasing cardiac output. Apart from that some drugs in this category lead to prolongation of phase 2 (repolarization) of action potential and give additional antiarrhythmic advantage. As antihypertensive agents, beta adrenoreceptors are particularly suitable in hypertensive patients with coexistent Ischemic Heart Disease. They are also valuable antihypertensive agents when used in combination with other agents like CCB, ARB, and diuretics. Certain contraindications like Bronchial Asthma, COPD, High Degree AV block, etc. need to be taken care of before prescribing these agents. Despite its share of controversies, beta blockers still remain useful antihypertensive agents.

Introduction

Despite its high prevalence, associated morbidity, and increased mortality, hypertension still remains inadequately treated in the majority of patients. From epidemiological perspective, several data have clarified the importance of blood pressure as a risk factor for CVD.[1] In the largest and the most detailed analysis, information from one million adults with no known vascular disease at baseline, included in 61 prospective observational studies of the relationship between blood pressure and mortality, was observed.[1]

Primary goal of treatment of hypertension is to prevent cardiovascular disease and death based on results of recent trials the choice of antihypertensive can be adjusted according to the presence or absence of associated conditions.

Beta (β)-adrenergic receptor blockers are among the most widely used agents in clinical medicine. Since 1976 after availability of propranolol for treatment of hypertension, quite a few β-blockers have been introduced.[2]

In this article I will deal with the role of β-blockers in the management of hypertension.

Types and Mode of Action

These drugs act as competitive inhibitors of the binding of epinephrine and norepinephrine to β-adrenergic receptor sites. Two subtypes of β-adrenergic receptors exist: the β_1 subtype (predominates in the heart) and the β_2 subtype (predominates in the peripheral vasculature and bronchial smooth muscle). Most β-adrenergic receptor blockers exist as pairs of optical isomers. Almost all clinical activities are due to the levorotatory (negative) stereoisomer.

By reducing systemic vascular resistance β-blockers decrease blood pressure while maintaining cardiac output

TABLE 1 β-blockers pharmacology

Property	*Description*	*Drugs*
Selectivity	Greater β_1 affinity at common therapeutic ranges (selectivity is dose dependent: at high doses even selective drugs interact with β_2-receptors	Acebutolol, atenolol, bisoprolol, betaxolol, esmolol, metaprolol
Intrinsic symptomatic activity (ISA)	Partial β-adrenergic agonist activity in the absence of catecholamines (milder rest bradycardia)	Acebutolol, oxprenolol, pindolol
β_1-Receptor inhibition	α-β-blocked; vasodilation is due to β-blockade	Carvedilol, labetalol, nebivolol
Additional antiarrhythmic properties	Prolongation of phase 2 (repolarization) of action potential (class III)	Sotalol

and cardiac afterload and preload reduced due peripheral vasodilation.[3] Compensatory peripheral vasoconstriction due to reduced cardiac output abets increased peripheral resistance **(Table 1)**.[4]

β-blockers in the Treatment of Hypertension

Effects of various β-blockers on outcomes in hypertensive patients have already evaluated in many trials. When β-blockers were compared with diuretics it has observed that there was no statistically significant differences between the two treatments and three-fourths of patients achieved their DBP goals receiving either drug class.[5] Recent clinical data suggest that although brachial (arm) blood pressure effectively reduced by traditional β-blockers but compared with other antihypertensive classes they may have less effect on reducing central aortic pressure.[6-8]

There were several trials which confirm the potency of labetalol to rapidly lowers of blood pressure.[9,10] Carvedilol in a placebo-controlled, double-blind trial in 338 patients with essential hypertension shows statistical significant reduction in mean 24-hour systolic blood pressure (SBP) and diastolic blood pressure (DBP) assessed by ambulatory blood pressure monitoring compared with placebo ($p \leq 0.001$ for all).[11] In an open-label, 6-week trial significantly lowered mean systolic blood pressure and diastolic blood pressure from baseline (–24 and –13 mm Hg, respectively, $p < 0.001$ for both) by nebivolol (5–10 mg/day) in 6,356 patients with mild hypertension (defined as DBP of 90–115 mm Hg) and mean baseline SBP of 162 mm Hg.[12] In 2,838 patients with type 2 diabetes mellitus for ≥3 months and hypertension nebivolol (2.5–10 mg/day) was also assessed as monotherapy or as add-on therapy and lowered SBP and DBP from baseline by 21 and 11 mm Hg, respectively.[13] Nebivolol has already documented to exhibit safe and well tolerated profile and higher achievement of blood pressure targets or goal reductions than that of ACE inhibitors (odds ratio 1.92, $p = 0.001$) and similar to that of other β-blockers, CCBs, and losartan.[14-16]

Combination Therapy with β-blockers

Single drug therapy remains the preferred way to begin treatment of hypertension although in many patients this is unable to bring blood pressure to goal levels. It is increasingly being seen that the elusive goal of a "Normal BP" is achieved only if multidrug therapy is employed.

β-blockers and calcium channel blockers combination offers a potential therapeutic benefits for uncontrolled hypertensive patients. These two interacted by complementary hemodynamic mechanisms with the calcium channel antagonists reducing α adrenergic reflex vasoconstriction induced by β-blockers and the β-blockers acting through a reduction in cardiac output. Combination products do not employ non-dihydropyridine calcium channel blockers due to concern for excessive effects on sinus and AV nodal junction.[17] The commonly employed combinations contain the CCB amlodipine and metoprolol for which the response rate is good and which preserves the normal diurnal BP rhythm.[18] Adverse effects like β-blockers related cold extremities are less common.

β-blockers blunt RAA axis activation produced by diuretics while the latter curb any Na^+ retention provided by β-blockers. β-blockers and diuretics reduce BP additively not synergistically.[19] Dose dependent adverse effects occur less frequently with low dose combinations and less so with β selective antagonists.

Why β-blockers Recommended in Hypertension with Ischemic Heart Disease

A combination of effects accounts for the efficacy of β-blockers in ischemic heart disease (IHD). β-blockers are competitive antagonists of β-adrenergic receptors. β-receptors inhibition slows the heart and atrioventricular conduction and lowers blood pressure and contractility, thus decreasing myocardial oxygen demand. The slower heart rate also enhances diastolic perfusion time.

β-blockers are also effective antihypertensive agents and antiarrhythmics. They reduce the risk of death and major cardiovascular events after myocardial infarction (MI). They also relieve symptoms at rest, increase exercise tolerance and prolong survival in many groups of patients. For this reasons they are a first-line choice in IHD.

A few small randomized studies have tested β-blockers in patients with stable angina, normal blood pressure and no history of MI. The Total Ischemic Burden European Trial (TIBET) reported nonsignificant reduction of the risk of death and MI with the combination of atenolol and nifedipine.[20] The results did not differ from those with either drug in monotherapy. The Angina Prognosis Study In Stockholm (APSIS) found no difference between metaprolol and verapamil in terms of death, major cardiovascular events, or quality of life.[20] The Atenolol Silent Ischemia Study (ASIST) versus placebo showed that atenolol decreased cardiovascular events and the frequency and duration of ischemic episodes and increased event free survival.[20] The Total Ischemic Burden Bisoprolol Study (TIBBS) showed bisoprolol to be more effective than nifedipine in reducing the frequency and duration of ischemic episodes.[20] The International Multicentre Angina Exercise (IMAGE) study showed that both nifedipine and metoprolol increased time to ischemia during exercise.[20] The combination of the two drugs was more effective than either as monotherapy.

Controversy

Few recently published data have argued that use of β-blockers is not beneficial for treating hypertensive patients as a first-line treatment mainly because there is no significant reduction in mortality or coronary heart disease as well as due to their modest effect on stroke as compared to placebo or other antihypertensive agents.[21]

As compare to traditional β-blockers (atenolol, metoprolol, and propranolol), vasodilatory β-blockers (carvedilol, nebivolol) lower blood pressure to a similar degree as other antihypertensive drugs and are associated with neutral or favorable metabolic effects. In most of the metanalysis and even guidelines consider mainly these traditional β-blockers in which data are not favoring the use of β-blockers in uncomplicated hypertension as a first-line agent.

High dose of β-blockers may worsen diabetic control, by increasing insulin resistance. β-blockers, by blunting the catecholamine response, mask hypoglycemic symptoms so that hypoglycemia manifests only when severe.[22] Poorly controlled diabetes mellitus, particularly if treated with insulin: β-blocked can interfere with receptor sensitivity to insulin, causing hypo- or hyperglycemia; in addition, its sympathetic effect may conceal symptoms of endogenous hypoglycemia, preventing correction, and thus endangering the patient. With pooled data of 94,492 patients with hypertension, the traditional β-blockers atenolol and propranolol compared with placebo ($n = 16,372$, $p = 0.33$), reported a 44% increased new-onset diabetes risk.[22] β-blocker–based therapies (atenolol, metoprolol, and any β-blocker and diuretic together) increase the new-onset diabetes risk by 21% as compared with CCBs ($p < 0.0001$) and 23% as compared with ACE inhibitors or ARBs ($p = 0.007$).[6] In contrast, GEMINI[23] (Glycemic Effect in Diabetes Mellitus: Carvedilol-Metoprolol Comparison in Hypertensives) trial conducted on 1,235 patients confirms that with same BP control the discontinuation rate because of poor glycemic control was only 0.6% with carvedilol ($p = 0.04$) and no adverse effect on glycosylated hemoglobin values as compare to traditional β-blockers like metaprolol. In another study with nebivolol arm there is statistical significant reduction in glycated hemoglobin (HbA1c%) and fasting blood glucose ($p < 0.001$).[13]

β-blockers exacerbate asthma and should not be used in patients with asthma. Severe chronic obstructive pulmonary disease (COPD) due to broncho stenosis and increasing hypoxia and hypercapnia: selective β_1-blockers can be used at very low doses if there is a strong indication of β-blocked, but they not tolerate; β-blockers may worsen symptoms even in mild COPD and have to be withdrawn.

β-blockers should be administrated with caution in first degree atrioventricular block. Well recognized

side effects include asthenia, fatigue, insomnia, and nightmares. Some erectile dysfunction is relatively common (in up to 25% of patients), but persistent impotence is rare (1%). Lipid effects are mild and not a reason for treatment withdrawal. Though most β-blockers increase triglyceride and decrease HDL-cholesterol levels, they certainly reduce the incidence of sudden death, overall mortality and recurrent MI. In summary, the vast majority of patients are eligible for β-blockers therapy, provided the drug is carefully chosen and titrated.

Conclusion

More than 45 years in various other clinical situations along with the treatment of hypertension β-adrenergic receptor blockers have been used extensively. From 1973 to till date numerous clinical trials and meta-analysis were performed to evaluate the functional role of β-blockers in the management of hypertension and it has established their efficacy in the reduction of cardiovascular morbidity and mortality associated with hypertension. In modern clinical practice, clinicians require combination of two or multiple drugs to control hypertension and require more aggressive goal especially with comorbidities. To achieve target goal in hypertension patients with comorbidities like high coronary artery disease risk or even with diabetes β-blockers are a beneficial, guideline-recommended treatment option. Thus, in conclusion, the vast majority of patients are eligible for β-blockers therapy, provided the drug is carefully chosen and titrated.

CHAPTER

24 Centrally-acting Agents in Hypertension

Girish Verma, Ashee Verma, Abdul Wahid Qureshi

Abstract

Centrally-acting antihypertensive is usually used as add on therapy in a patient who requires multiple drugs to control the hypertension.

Various available drugs (Clonidine, α-Methyldopa, Guanfacine, Guanabenz, Moxonidine, and Rilmenidine) though belong to same group, act with subtle different mechanism and thus one drug has advantage over other for its use in specific condition.

Clonidine being the non selective (acting on α-2 Adrenoceptors and imidazoline-1 receptors) has more adverse effect and sometimes intolerant for the patients (causing sedation, postural hypotension). Methyldopa can be used safely in pregnancy as it maintains the uterine blood flow. Guanfacine and guanabenz can be used and better tolerated in cases where patient is intolerant to clonidine.

The moxonidine and rilmenidine due to their mechanism of action (selective for imidazoline receptor) cause less adverse effects thus better tolerated. However, both drugs are cautiously given in advanced renal failure and moxonidine is avoided in advanced heart failure.

Introduction

Patient suffering from hypertension may require multiple drugs, if they are labelled suffering from resistant hypertension. These patients frequently respond to centrally acting antihypertensives.[1]

Drugs that block sympathetic activity within the brain called centrally acting sympatholytic drugs.

Various presently available centrally acting antihypertensive (centrally acting sympatholytic) drugs are **(Table 1)**:

- Clonidine
- α-Methyldopa
- Guanfacine
- Guanabenz
- Moxonidine
- Rilmenidine

Mechanism of Action

The centrally-acting antihypertensive (clonidine, α-methyldopa, guanfacine, guanabenz, moxonidine, and rilmenidine) have different antihypertensive actions,[2,3] which result in sodium excretion and decrease in cardiac output, heart rate, total peripheral resistance, and renin release **(Flowchart 1)**.

These centrally acting antihypertensive agents cross the blood brain barrier and stimulate imidazolin-1 (I_1) receptor and/or central postsynaptic α_2 adrenoceptor in the brain stem's sympathetic nervous control centers, the rostral ventrolateral medulla (RVLM) and the nucleus tractus solitarii.

Clonidine non selectively stimulates both α_2 adrenocepters and I_1 imidazolin receptors as compared to methyldopa, guanabenz, and guanfacine, which

TABLE 1 Centrally-acting antihypertensive agents[5,6]

Drug	*Preparation*	*Pharmacodynamics*	*Daily dose*	*Adverse effect*	*Contraindication*
Clonidine	• 0.1 mg • 0.2 mg • 0.3 mg	• Onsete 0.5–1 hour • Peak 3–5 hours • Plasma half-life, 12–16 hours • Metabolism—Lliver	• Initial—0.1 mg • Range 0.2–1.2 mg • Max 1.2 mg • Usually BID	• Sedation drowsiness, dry mouth • Withdral syndrom, • Rebound hypertnesion (Uncommon with dose <1.2 mg daily)	• Sick sinus syndrome • 2nd and 3rd degree AV block
Transdermal	• Containing 2.5 mg • Containing 5 mg • Containing 7.5 mg	Duration of BP lowering 1 week	1, 2, 3, once weekly	• Headache, bradycardia, orthostatic hyportension • Impotence (Uncommon 4%), hepatitis	
Methyldopa	• 125 mg • 250 mg • 500 mg	• Onse —2–3 hours • Peak—5 hours • Plasma half-life 12 hours • Metabolism —Renal	• Average: 250–300 mg • BID • Max 3000 mg	• Sedation, Drowsiness, Dry mouth • Positive Coomb's test and anemia, Lupus like syndrom withdraw syndrome • Rebound hypertension	Active hepatic disease
Guanabenz	• 4 mg • 8 mg	• Onse—1 hour • Peak—4 hour • Plasma half-life—6 hours • Metabolism 76% • Excretion: Renal 80%	• Average 16 mg • Range 8–46 mg • Max 48 mg	• Sedation, Drowsiness, Dry mouth widhrawal syndrome • Rebound hypertension • Impotence	Pregnancy
Guanfacine	• 1 mg • 2 mg	• Onset—1 hour • Peak—4 hour • Plasma half-life—12 hours • Excretion: Renal	• 1 mg at bed time • Max 3 mg	Same as clonidine	Allergy to Guanfacine
Moxonidine	• 0.2 mg • 0.3 mg	• Peak—0.5–3 hours • Plasma half-life—2–3 hours • Excretion: Renal 57–75%	• Average 0.2 mg • once daily • Max 0.6 mg		• Several renal impairment • GFR <30 mL/min • Advanced heart failure
Rilmenidine	1 mg	• Peak—1.7 hour • Plasma half-life—8.5 hours • Excretion: Renal 52–93%	1–2 mg/day		Advanced stage of CKD (relatively contraindicated) 1 mg alternate day if, GFR < 15mL/min

selectively stimulates α_2 adrenoceptor more than the Imidzaolin (I_1) receptors.

Moxonidine and Rilmenidine selectively stimulate Imidazolin (I_1) receptors.

α-Methyldopa blood pressure lowering mechanism requires specific mentioning here, it is converted into active metabolite. α-Methyl norepinephrine, which dislodges nor-epinephrine from Alpha adrenergic receptors,[4] while other molecules belonging to this group are effective as their intact molecules.[5]

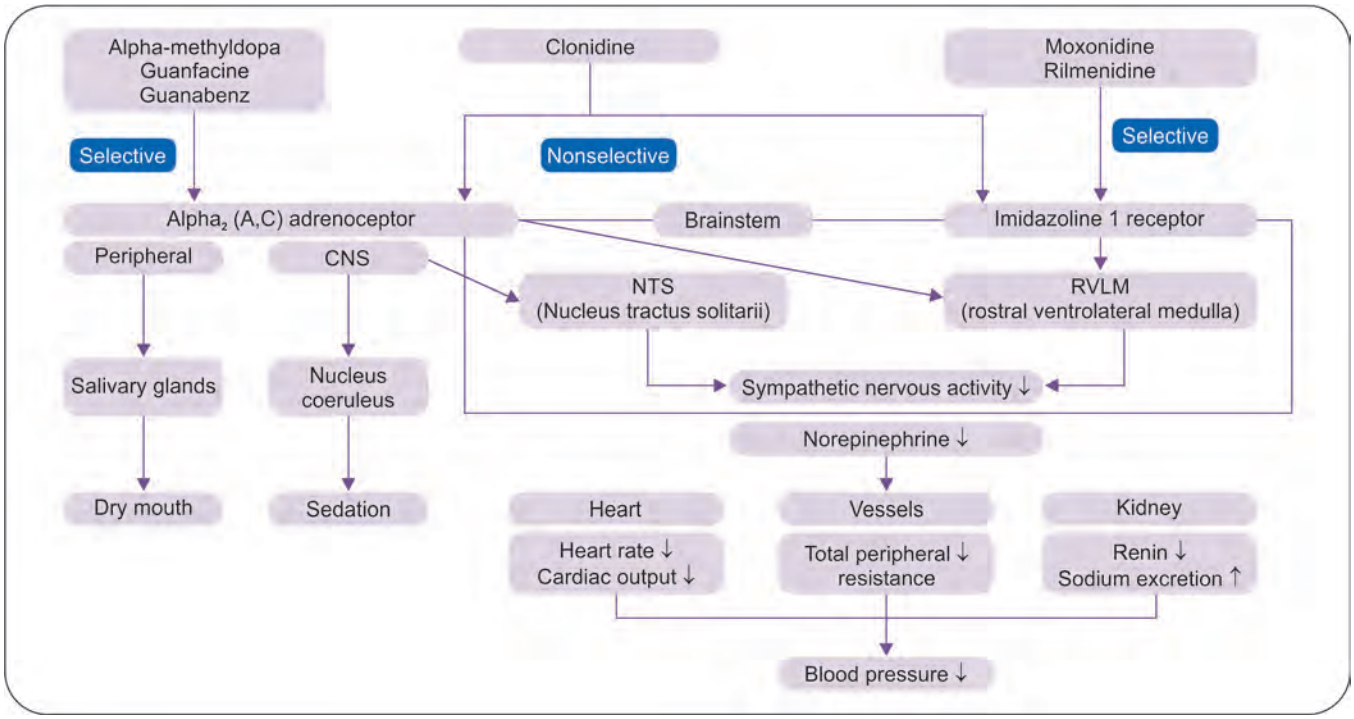
Individual Characteristics of Centrally-acting Agent in Hypertension

Clonidine: This drug has 30–60 minutes onset of action so it can be used in hypertensive emergencies; however, requires frequent dosing due to its shorter duration of action.[6,7]

The clinical indications of clonidine:

- Primary hypertension—as fourth or fifth line drug
- Menopause associated vasomotor syndrome

Flowchart 1: Mechanism of action, centrally acting antihypertensive agents



- Hypertension with restless leg syndrome

Clonidine is also available as Transdermal patch and is of particular utility for management of:

- The labile hypertension which require multiple medication,
- The hospitalized patient unable to take oral medication, and
- The patient with prominent early morning blood pressure surge.

Transdermal clonidine patch is best absorbed from the chest or upper arm[8] and it causes more dose dependent salt and water retention as compare to oral clonidine.[9]

Transdermal patch delivers drug daily for 7 days, but it starts its action at least 1 day later after its application; hence oral clonidine is given for 1–2 days after application of clonidine transdermal patch. Even when transdermal patch is removed drug present in the skin continue its antihypertenive effect.[10]

Clonidine has its suppressing effect on sinus as well as atrioventricular nodal function sometimes causing significant bradycardia. Hence, this drug should be best avoided in patients with sinus node dysfunction and those suffering from CKD who are at risk of developing significant bradycardia.[11]

When clonidine is suddenly stopped it causes rebound hypertension,[12] which may be quite significant if patient is also receiving beta-blocker but not in the presence α/β adrenergic antagonist like labetalol or carvedilol.[6] This rebound hypertension has not been observed with moxonidine and rilmenidine.[13,14]

Methyldopa: Indications of using this drug are—

- In patient who are intolerant to clonidine[15]
- Pregnancy induced hypertension[16,17]
- In hypertensive emergencies—used intravenously dose 20–40 mg/kg/day 6 hourly

However, intravenous use of methyldopa is infrequent due to availability of other effective drugs.

As it is excreted through kidneys, reduced doses are desirable in renal failure; however, methyldopa is dialyzable.

Methyldopa, besides its common side effect somnolence and depression, causes hypersensitivity reactions leading to hepatitis and coombs positive hemolytic anemia. It occurs only 10–20% patients receiving

methyldopa.[18] If patient has coombs test positive but no hemolytic anemia, it is not wise to stop methyldopa.

Flu like symptoms, lupus like syndromes and enhanced prolactin release (pseudo lactation) have also been observed.[5,6]

Guanabenz: This drug acts similarly as that of clonidine, but its duration of action is prolonged. It is less frequently associated with rebound hypertension, salt, and water retention and/or significant postural hypotension.[19] Guanabenz is broadly biotransformed and does not accumulate in the patient with significant reduction in renal function.[20] Guanabenz reduces total cholesterol level 10–20%.[21] Sedation with this drug is dose-dependent decreases over the period of time.

This drug has been found to reduce left ventricular hypertrophy in hypertensive patients and also reducing morning hypertension when given at night time.[5,6]

Guanfacine: This drug has longer duration of action (24 hours) hence given once daily.[22] Guanfacine has its antihypertensive effect longer than guanabenz. It is preferably given in the evening so as to suppress early morning surge of catecholamines and blood pressure. Its blood pressure effect is enhanced when given with diuretic. This drug can be used instead of clonidine when excessive sedation is the problem.[23]

Moxonidine: This drug when used alone or in combination with other antihypertensive agents, it significantly reduces the blood pressure.[13] It does not decrease heart rate like clonidine. This drug is mainly excreted through kidneys. Its dose adjustment according to the glomerular filtration rate (GFR) is mandatory.[24]

This drug should not be used when GFR falls 30 Ml/min or less and also in advanced heart failure.[25]

Rilmenidine: This drug is used in the treatment of mild to moderate hypertension. Rilmenidine can be use alone (1–2 mg/day) or in combination with other antihypertensive and has been well tolerated and effective in studies.[26] This drug does not affect heart rate while reducing blood pressure as it increases parasympathetic tone.[27]

Treatment withdrawal rebound hypertension does not appear to occur with rilmenidine. It is much less frequently associated with sedation and dry mouth. The low rate of orthostatic hypotension with rilmenidine may be related to an enhancement in baroreflex sensitivity.[28] Rilmenidine is relatively contraindicated in advance stage chronic kidney disease.

Usefulness of Centrally-acting Antihypertensive in Other Clinical Conditions

Clonidine has been used:

- In migraine prophylaxis.
- Post-traumatic stress syndrome.
- To reduce postmenopausal flushes.
- In moderate alcohol and opioid withdrawal syndrome.
- To secondarily reduce aqueous humor production in open angle glaucoma.
- In short gut syndrome and/or high output proximal ileojejunostomies for effectively reducing fecal output.[29]
- In diagnosis of pheochromocytoma: After administration of 0.1 mg clonidine per hour for 3 hours, plasma, nor-epinephrine levels decreases in patient with essential hypertension but remained unaffected in patient with pheochromocytoma.[30]
- In new onset of atrial fibrillation can control the ventricular rate.

Similarly guanfacine can be used in:

- Attention deficit order
- The fragile X-syndrome

Drug Interactions[5]

Certain catecholamine assay can be disturbed by methyldopa and its metabolites. This also interferes with levodopa, bromocriptine, and monoamino oxidase inhibitors. Therapeutic effect of methyldopa is reduced with coingestion of iron.

Guanabenz may increase the absorption of hydrochlorothiazide when given concomitantly.

The antihypertensive effect of clonidine and guanfacine is reduced by tricyclic antidepressents (imipramine, amitriptyline, etc.) because they are antagonist to central α_2 receptors.

The moxonidine and rilmenidine should not be given with monoamino oxidase inhibitors.

Conclusion

In the present context centrally acting antihypertensive agents can be used as add on therapy in the treatment of hypertension, especially resistant hypertension. However, in sympathetically mediated hypertension they can be used with preference.

Though due to dose dependent side effects, the use of clonidine and methyldopa is now less; however, methyldopa is an agent that can be used safely in pregnancy induced hypertension. Guanfacine and Guanabenz can be used and better tolerated in cases where patient is intolerant to clonidine.

The moxonidine and rilmenidine due to their mechanism of action (selectively for imidazoline receptors), causeless sedation, dryness of mouth, and postural hypotension, thus better tolerated.

Hypertension in Young Adults

Abhishek Kumar, Anupam Prakash

Abstract

Hypertension in the young is commonly essential hypertension and is on the rise because of rapid urbanization, increasing stress, addictions (tobacco and alcohol), and changing lifestyles. However, secondary hypertension also needs to be ruled out as it is remediable and appropriate management can obviate the need for lifelong treatment. It is imperative that a judicious approach is adopted while evaluating the young hypertensive and pharmacological as well as non-pharmacological measures are adopted while managing these patients. Anxiety levels are high in young patients, and renin-angiotensin system (RAS) activity also is heightened. Drug usage should therefore be chosen to inhibit the RAS, have long-term control, and minimize side-effects.

Introduction

Cardiovascular disorders are the leading cause of morbidity and mortality worldwide. Nearly 30% of global deaths are attributable to cardiovascular disease (CVD). Systemic hypertension is the leading root cause of premature mortality and morbidity among the patients of CVD.[1] Prevalence of hypertension is rapidly increasing in the community and it is estimated that the world will have about 1.5 billion adult hypertensives by end of this decade.

In India, the situation is alarming as its prevalence is about 33% in urban part and about 27% in rural area. The overall prevalence of hypertension is about 29% suggesting urban rural convergence due to rapidly changing lifestyle.[2] The current BP control rates of less than 10% in the rural and less than 20% in the urban areas is itself a big challenge. India has wide variations in race, ethnicity, socioeconomic status, and cultural practices. The lifestyle is rapidly changing becoming more sedentary due to rapid urbanization. Thus, the incidence of chronic illness like diabetes, hypertension, and CVD are increasing.

Weight gain, obesity, and physical inactivity are important risk factors for development of hypertension in young adults. These patients are more likely to respond to lifestyle changes and weight management but they are less likely to believe that they have disease. In Indians, hypertension develops relatively early in life. In individuals aged between 15 and 49 years, the prevalence is about 18% with variations between rural/urban and amongst different regions of country.[3] Moreover, only about 44% of young hypertensives are aware of their diagnosis and only 14% are receiving treatment.

Definition and Classification

Definition of "Young adults" for hypertension is not defined, but age between 20 and 49 years may be taken as in Framingham Offspring Study.

There is a continuous relationship between the level of blood pressure and the risk of complications starting at BP of 115/75 mm Hg. As Asian, Indians are more prone to CVDs, the risk for cardiovascular events is higher and

TABLE 1 Classification of blood pressure for adults age 18 and older

Category	*Systolic (mm Hg)*		*Diastolic (mm Hg)*
Optimal	<120	and	<80
Normal	<130	and	<85
High-normal	130–139	or	85–89
Hypertension			
Stage 1	140–159	or	90–99
Stage 2	160–179	or	100–109
Stage 3	≥180	or	>110
Isolated systolic hypertension			
Grade 1	140–159	and	<90
Grade 2	>160	and	<90

commence at relatively lower levels of BP. The recent ACC/AHA guidelines changed the definition of hypertension at 130/80, but European guidelines and recently published Indian guidelines for hypertension IV continue with the previous definition of 140/90 mm Hg.[4] The same definition of hypertension applies in young adults. Classification is for adults more than 18 years of age, who are not on antihypertensive medication and have no acute illness. It is based on the average of two or more office blood pressure readings taken at least on two occasions **(Table 1)**.

In addition to classifying stages of hypertension on the basis of average blood pressure levels, clinicians should specify presence or absence of target organ disease and additional risk factors.

The screening for hypertension in all adults is recommended.[5] All adults (18 years or older) should have their office BP measured at every point of contact with health professionals or allied health staff. This will include all points and levels of care—the village/multipurpose health worker, trained non-physician staff at sub-centers, primary health center, community health center, and referral hospital (District hospital, Medical College). This screening will enable people with high normal BP to be identified, so that they can be prevented from developing hypertension by use of appropriate lifestyle modifications.

Risk Factors of Hypertension in Young Adults

Incidence of hypertension is higher among young men than women, increasing threefold from second to fifth decade in men and eightfold in women.[6] Under age 40, men were twice as likely as women to develop hypertension, but after age 40, 8-year incidence rates were similar in men (14.2%) and women (12.9%). The proposed ominous octet of "S," a constellation of risk factors starting with the letter "S," leading to development of non-communicable diseases are sex, salt, sugar, sleep, smoking, stress, sunlight, and sedentary behavior. These become more prominent in today's tech savvy young adults. Consumption of saturated fat and prolonged sitting may be added to complete the list.[7] Risk factors like physical inactivity, weight gain, obesity, metabolic syndrome, and obstructive sleep apnea are more common in these patients. Smoking, alcohol, illicit drug intake, and psychosocial stress are becoming more common in this age group. High sodium intake, low potassium and calcium in diet are the other factors responsible.

Psychosocial stress is a major contributor to development of hypertension in young. This group has enormous work, travel related, and domestic pressure leading to busy and erratic schedule.[8] This must be considered in planning treatment strategies.

Causes of Hypertension in Young Adults

Most of the hypertension in young adults are essential hypertension having no identifiable cause. Secondary cause of hypertension should be ruled out if blood pressure is very high at first presentation, episodic rise in blood pressure, non-responding hypertension, or poorly responding hypertension despite good adherence and resistant hypertension. Some endocrine disorders causing hypertension have their obvious signs and symptoms at presentation. Special enquiry of illicit drug use, oral contraceptive pills, and other medications must be made in this group of patients. The important etiologies of hypertension are enumerated in **Table 2**.

Approach to the Patient

The key elements of evaluation of a patient of hypertension are accurate measurement of blood pressure, focused medical history and physical examination, and laboratory investigations. These are aimed to determine presence of end-organ disease, possible causes of hypertension, cardiovascular risk factors, and to get baseline values for starting and judging biochemical effects of therapy.

TABLE 2 Causes of hypertension in adults

Essential hypertension (80–95%)	
Secondary hypertension (5–20%)	
Renal	Parenchymal disease, polycystic kidney disease, renal tumor, obstructive uropathy
Renovascular	Fibromuscular dysplasia, atherosclerotic
Adrenal	Primary aldosteronism, Cushing's syndrome, pheochromocytoma
Neurogenic	Psychogenic, raised intracranial tension (acute)
Miscellaneous	Obstructive sleep apnea, thyroid disorders, acromegaly, preeclempsia/eclampsia
Medications	Estrogens, adrenal steroids, appetite suppressants, cyclosporine, tricyclic antidepressants, decongestants, NSAIDs, cocaine, Herbal medicines

Baseline investigations are urine dipstick, blood urea and electrolytes +/- eGFR, 12 lead ECG, fundoscopy, blood glucose, and serum lipid profile.

A judicious search for secondary causes warrants in this age group. A secondary etiology may be suggested by symptoms like flushing and sweating in pheochromocytoma, by clinical findings; a renal bruit in renal artery stenosis, or laboratory abnormalities, for example, hypokalemia suggestive of aldosteronism. In the absence of clinical signs to suggest possible secondary hypertension, indications for further evaluation are if blood pressure having early onset, rapid onset, or resistant hypertension. In young women, renal artery stenosis caused by fibromuscular dysplasia is one of the most common secondary etiologies. It can be detected by abdominal magnetic resonance imaging or computed tomography. For aldosteronism, the recommended initial diagnostic test is an aldosterone/renin ratio.[9] Obstructive sleep apnea can be a secondary cause of or contribute to hypertension. The standard diagnostic test is polysomnography, but clinical assessment tools (e.g., Epworth Sleepiness Scale, Sleep Apnea Clinical Score) with nighttime pulse oximetry may be used to get initial clue particularly in places of limited availability.

Counseling of patients for lifestyle changes and modification and/or treatment of contributory risk factors should start once the blood pressure crosses 130/80 mm Hg. In absence of comorbid conditions in patients with stage 1 hypertension at first visit lifestyle modifications should be started and blood pressure reading should be repeated within 2–3 weeks. Drug treatment may need to be started after 1 month. For stage II hypertension shorter repeat interval is desirable. And in stage III hypertension BP should be repeated after few hours to start pharmacological management. The target blood pressure should be 130/80 mm Hg.[4]

Young patients with secondary causes may have first presentation with hypertensive crisis. A wise clinical examination is needed to rule out hypertensive emergency and target organ damage.

BOX 1 Measures to reduce sedentary behavior

- Daily physical activity like covering short distance by foot, taking staircase instead of lift and use of cycle for nearby activities
- Avoid prolonged sitting in the office, practice the norm of leaving the chair hourly and walk for 5 minutes
- Reduce the screen time to <30 min/day, less use of mobile, and electronic gadgets

Management of Hypertension in Young Patients

Non-Pharmacological Therapy

The young hypertensives are better responders to non-pharmacological measures. Regular physical activity, weight loss, avoidance of tobacco, excessive alcohol, and stress management are important component of such therapy. Daily brisk walking for 30 minutes and outdoor games have proven to reduce blood pressure. Just adding few habits in daily routine may amount for few miles of activity as listed in **Box 1**.

The patient who is having raised blood pressure either in high normal or hypertension range is encouraged to adopt dietary approaches to stop hypertension (DASH)-type dietary plan which is rich in fruits, vegetables, and low-fat dairy products with reduced content of saturated and total fat. The total salt intake is to be restricted to less than 6 gm/day **(Box 2)**. Young working persons are relatively more habituated to outside food. Avoidance of fast food, excessive tea, coffee, and aerated drinks are key components of dietary advice. Adequate sleep, yoga, and meditation have proven to be beneficial in stress management.[10] Young adults should be advised to spend some quality time in these activities.

BOX 2 Measures to limit salt intake

- Avoid processed food, cheese, sandwiches, pizza, and salty snacks
- Avoid red meat, tinned food products, and aerated drinks
- Use olive oil and avoid salted butter
- Use vinegar and lemon juice instead of the salt where possible

Pharmacological Management

Unwillingness to take medicines and not believing the seriousness of raised blood pressure are more common in young adults. Besides these, inadequate counseling of patients and physician's inertia to start medicines are factors responsible for not getting desired blood pressure control. A patient centered approach should be followed while choosing drug for blood pressure management. As per current guidelines, the choice of medicines is similar in young adults and relatively older individuals but emphasis must be laid upon tolerability. Various classes of medicine may be associated with side effects like increased micturition, fatigue, sexual dysfunction, and peripheral edema. Many young working patients may find these inconvenient and troublesome. Side effects must not reduce the work capability of these young achievers. All these should be discussed prior to prescription and drug should be tailored accordingly. This will increase acceptability and adherence of medicines. Any of the first line medicines, viz. diuretics, calcium channel blockers, and renin angiotensin system (RAS) blockers, ACE inhibitors/ARBs may be used first. Young persons are having higher sympathetic tone and renin secretion, so ACEIs and ARBs are the preferred agents in young if not having any contraindication of its use. However, in young females who may be planning conception, due counseling to discontinue ACEIs and shift to alternative antihypertensive agent needs to be provided. A long half-life medicine with once daily dosing is preferred. Combination therapy in single pill is encouraged for better compliance.

Comprehensive Approach

Significant numbers of young patients having hypertension have other components of metabolic syndrome like diabetes/pre-diabetes, dyslipidemia, and obesity. Targeting other components of metabolic syndrome is an opportunity in these patients. Lifestyle changes like diet control and physical activity should be targeted to achieve good control of other components. Even modest weight loss may lead to reduction of blood pressure. The selected medicines should help control other metabolic risk factors or at least must be neutral. Thus, the beta blockers and diuretics should be avoided in patients with dyslipidemia and glucose intolerance.

Young and Technology

On an average a young patient is more technology savvy than their older counterparts. There are gadgets and mobile applications available in market, which monitor diet, physical activity, and act as reminder to support adherence to the treatment.[11] Online counseling, telehealth projects, and related services are easily accessible and offer help in management of hypertension. However, they have their own limitations. Many awareness programs and activity are conducted by various national and international societies of hypertension and social organizations are now focusing on primary prevention to educate the masses.

Conclusion

Hypertension in the young needs to be carefully considered and evaluated, as it is a significant cause of morbidity and mortality. Young individuals have a variable lifestyle, and are difficult to convince that they have the disease. Therefore treatment needs to be individualised. Lifestyle management, salt restriction, ACE-inhibitors/ARBs (unless contraindicated) need to be initiated and re-inforced for compliance on each visit.

Biosensors in Hypertension

HK Aggarwal, Deepak Jain, Taruna Pahuja

Abstract

Hypertension is recognized as one of the leading risk factors for human morbidity and mortality. It puts an individual at the risk of myocardial infarction, heart failure, cerebrovascular accident, and end stage renal disease. These diseases can thus be prevented and controlled early by screening and timely diagnosis of hypertension. Both the korotkoff sound and oscillometric method of blood pressure (BP) measurement require cuff. Also, BP changes can occur according to operator and prevailing conditions, for example. White coat hypertension. Hence new technologies which allow BP monitoring without the use of cuff are being developed. This chapter describes the fundamentals of current technology in cuffless blood pressure measurement using nanosensors or photoplethysmography (PPG) to monitor blood pressure frequently and accurately for outpatient care and general health monitoring.

Introduction

Hypertension (HTN) is an epidemic affecting around one billion people. Globally 29.2% of males and 24.8% of females have HTN.[1] It has been ranked on the top as a cause of disability-adjusted life years. However, awareness, treatment, and control rate for HTN are low. Approximately half of the total hypertensives are aware of having HTN and 50% of known hypertensives are not on any treatment. Moreover adequate control of BP is present only in 50% of patients taking treatment. Hypertensives patients are precarious to develop heart attack, stroke, coronary artery disease, chronic kidney disease, and congestive heart failure and thus are at increased risk of premature death. Early detection and timely initiation of treatment regime for adequate BP control is a major step toward reducing complications and deaths due to HTN. Conventional blood pressure measurement techniques change according to conditions and are operator dependent. Ambulatory monitoring was introduced to overcome the problems associated with current manual office blood pressure measurement. A 24-hour ambulatory monitoring can help identify "white-coat" HTN, masked HTN, nocturnal HTN, labile HTN as well as postural hypotension, thus providing improved estimates of true blood pressure to guide decisions about treatment. Ambulatory blood pressure monitoring (ABPM) is done with a portable version of conventional oscillometer, the cuff of which fits around upper arm and inflates periodically as programmed while the person continues regular daily activities. However, patient is required to keep the arm static while the cuff inflates, which interferes with sleep and other activities of person. Also, in rare cases, continuous BP monitoring via cuff has been reported to cause hematomas, bursitis, phlebitis, and acute neuralgia. Hence, a wearable cuffless BP technology that offers continuous and noninvasive measurements has gained more attention. Handheld and wearable apparatus, which are small, comfortable, and less expensive, are now being used to measure other physiological vitals as well like oxygen saturation, body temperature and respiratory rate.[2]

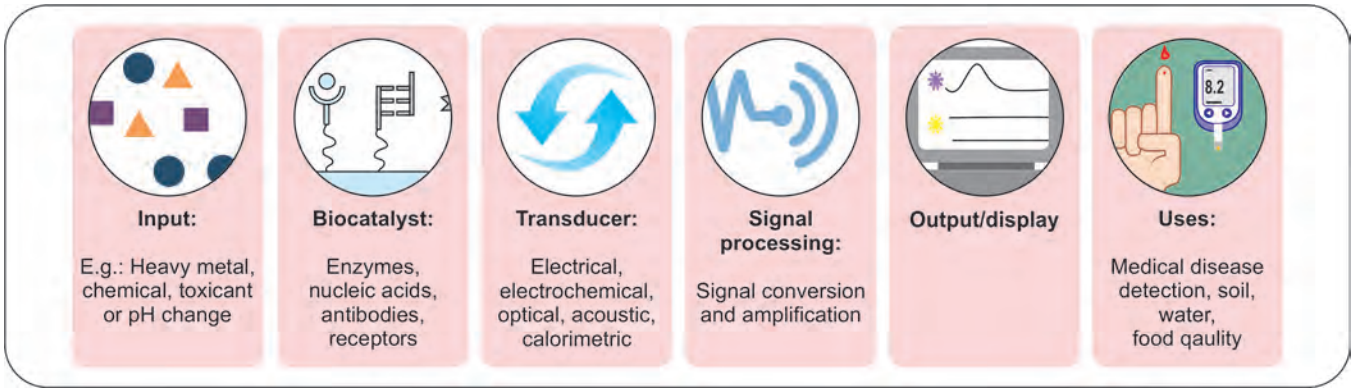

Fig. 1: Schematic description of biosensor

Biosensors

Biosensors are devices that convert a biological response into an electrical signal. These estimate the level of biological markers or any chemical reaction by producing the signals that are associated with the concentration of an analyte in that reaction. Biosensors consist of a biocatalyst that can detect a biological element/analyte and a transducer which converts the combination event of the biocatalyst and the analyte into discernible parameters **(Fig. 1)**.[3]

An ideal biosensor should be specific, sensitive, stable, and reproducible to detect a specific analyte in very small concentrations without being affected in and around the biosensing system with the ability to program identical output after replenishment of experiment. Linearity, which is defined as a considerable change in the signal with little change in concentration of an analyte, is considered an important component of the biosensor.

Types of Biosensors

Depending on the method of signal transduction, biosensors are classified into different groups. These are as follows:

- Optical/visual biosensors which detect changes in properties of light such as refraction index, fluorescence, or light scattering resulting from the interaction between an analyte and receptor. Photoplethysmography (PPG) sensor is an optical biosensor that measures the blood volumetric changes and can be used in wearable devices to monitor blood pressure.[4]
- Electrochemical biosensors consist of electrodes that translate the chemical signal into an electrical signal.
- Calorimetric biosensors measure the heat released or absorbed by the reaction.

Wearable biosensors (WBS) have gained attention recently with the use of technology for health monitoring, especially cardiovascular monitoring. These devices measure BP while person is performing routine daily activities, without creating any disturbance. By sensing elevated blood pressure, they can predict a missed dose of medication. Some of these devices are fitted with an alarm that is triggered by change in BP and serve as a reminder for patients to take medicine. WBS can be used in triage in waiting lobby of emergency rooms of hospital. In the era of COVID pandemic where telemedicine has become the "new normal," WBS fitted with alarm can allow increased surveillance by cardiovascular monitoring for patients at home and this data can be digitally shared with treating physician for the ease of teleconsultation and further reference.

Photoplethysmography

PPG is an optical biosensor used for measuring the amount of light that is absorbed or reflected by blood vessels in animate flesh, which depends on the amount of blood that is present in the optical path. It is a high-fusion signal that covers the activity of the heart's systolic and diastolic periods, the hemodynamics and network information of the peripheral microcirculation system. Thus, it is the external manifestation of various physiological processes in the cardiovascular system like heart rate, BP, cardiac output, and microcirculatory blood flow. PPG is a

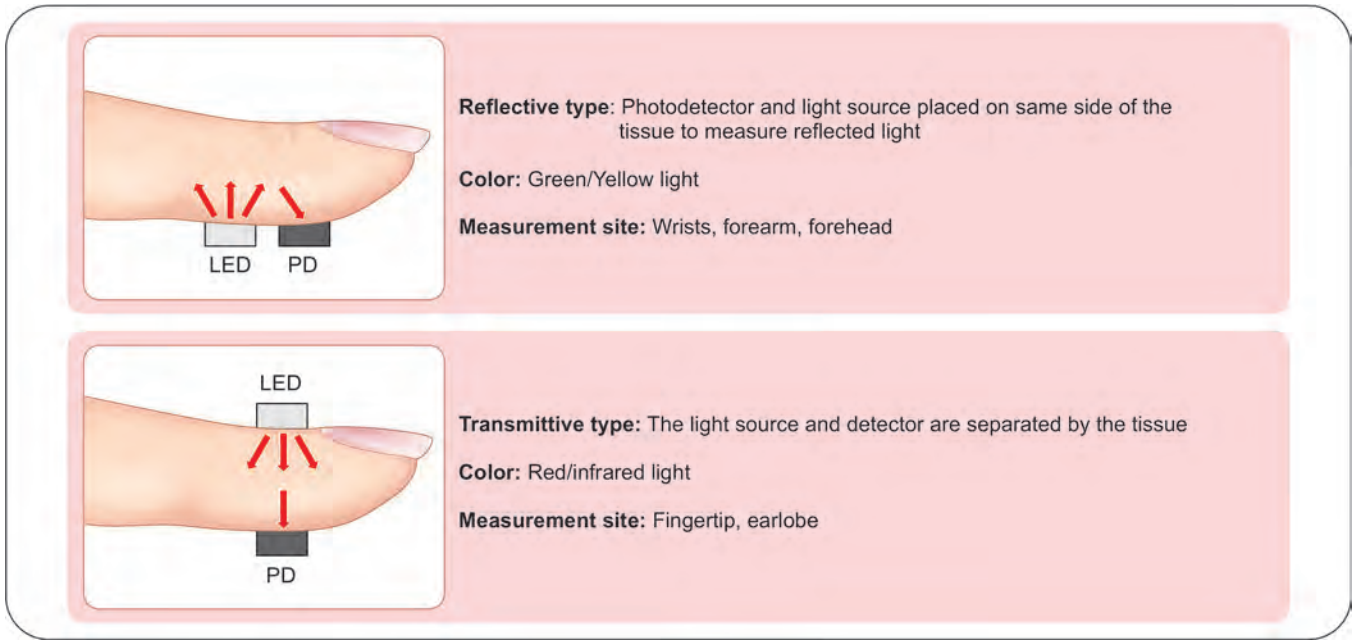

Fig. 2: Schematic representation of transmittive type and reflective type (PPG sensor and the light source)

convenient and inexpensive technique and its principles can be utilized for development of wearable cuffless BP monitoring devices.

PPG Signal Formation, Preprocessing, Feature Extraction

WBS is fitted with a LED (light emitting diode) transmitter, which either transmits or reflects red/infrared light to read PPG signal **(Fig. 2)**.

The raw PPG is corrupted, of poor quality and is difficult to access. This signal undergoes preprocessing via normalization and denoising/filtering with the help of median and notch filter. This uncorrupted PPG waveform contains the systolic phase and diastolic phase separated by dicrotic notch as shown in **Figure 3**.[5] It is used to extract useful features like peak to peak interval, systolic peak, stiffness index, crest time, and pulse area.

The systolic peak defined by the amplitude of PPG waveform is used to calculate heart rate. Systolic amplitude gives an indication of the pulsatile changes in blood volume. Stiffness index is a measure of arterial stiffness and depends on the height and age of person. It is obtained as the time interval between systolic peak and diastolic peak. Crest time is defined as duration of time from the base of PPG waveform to its peak. These parameters of PPG signal

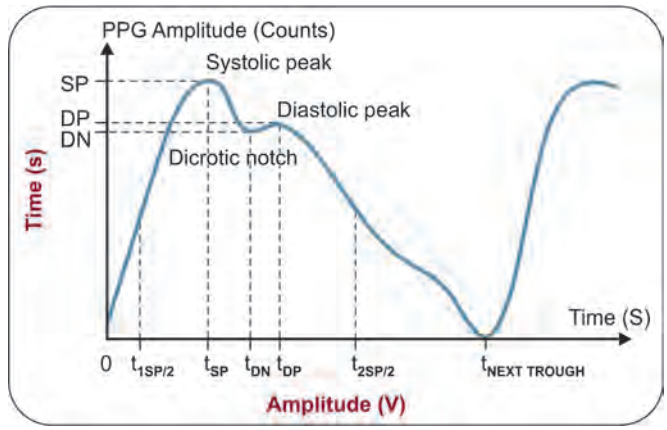

Fig. 3: PPG signal waveform consists of systolic phase, diastolic phase which are separated by dicrotic notch[5]

are used in various time-domain processing methods like peak detection, transition point calculation, etc.

PPG in Hypertension

Methods used for the continuous and cuffless measurement of BP via PPG are as follows:

- PTT based methods
- Non PTT based methods
- PTT based methods combined with non PTT based methods

PTT-based Methods

BP can be estimated by measuring pulse transit time (PTT), which is defined as the time taken by the pressure wave to travel from one point to another in the arterial tree within a particular cardiac cycle. The velocity of this pressure wave is termed as pulse wave velocity (PWV). PTT can be used to estimate PWV. The speed of transmission of pulse wave depends on the rigidity and resistance of the vessel wall. HTN causes an increase in thickness in the arterial media that leads to the rise in wall tension. Thus, PWV is influenced by BP. BP can therefore be estimated by measuring PTT and PWV.[6] PTT can be obtained by following methods.[6]

PPG Combined with Other Cardiovascular Signals

PTT can be calculated from PPG when it is combined with other cardiovascular signals, for example, electrocardiogram (ECG), ballistocardiogram (BCG), and phonocardiogram (PCG). PTT is measured as the temporal distance from one distinct point of the other signal to a specific point in the PPG waveform.

- *Electrocardiogram (ECG):* When PPG is combined with ECG, PTT is measured by calculating pulse arrival time (PAT). PAT can be measured as the distance between R wave of ECG and systolic peak of the PPG waveform. PAT = PTT + PET (Pre-ejection time). PET is the time elapsed between the electrical depolarization of the left ventricle (QRS on the ECG) and the beginning of mechanical ventricular ejection. PET is variable and gives different reading of BP. To avoid this variability, efforts are being done to establish PTT directly from multiple PPG signals instead of PPG-ECG combination **(Fig. 4)**.
- *Phonocardiogram (PCG):* It records the sounds produced by the movement of cardiac valves. When PPG is combined with PCG, PTT is measured by calculating vascular transit time (VTT). VTT can be measured as the distance between S1 (first heart sound produced by closure of atrioventricular valves) of a PCG and systolic peak of corresponding PPG.[4,6,7]
- *Ballistocardiography (BCG):* It records the movements of the body caused by contraction of the heart. When PPG signal is combined with BCG, PTT is measured by calculating time difference (TD). Mainly three waves (I,J,K) are defined in BCG. J wave peak corresponds approximately to the foot of the BP waveform at the outlet of the descending aorta. Time difference is measured as the time between J peak and systolic peak in PPG waveform **(Fig. 5)**.

Dual-Channel PPG

In this, PTT is measured at different peripheral sites, as the distance between the corresponding characteristic points of two PPG signals.

Single-Channel PPG

In this, PTT is measured as the distance between the forward and reflected wave of the second derivative of the PPG waveform.

Once PTT, PAT, and PWV parameters are estimated, mathematical models are used to derive BP. These models require two measurements from two sensors, for example, PPG and ECG signals. These sensors might have different sampling rates in real time, plus their operability depends on complicated arterial wave propagation models. Also, the extraction of feature points of each heartbeat correctly is a cumbersome method. It is very difficult to continuously monitor different physiological parameters in different point in time. This huge data can be well managed by artificial intelligence (AI). AI is a computer system that simulates human intelligence and performs tasks like speech recognition, decision-making, and visual perception. Machine learning (ML), a subset of AI, is a set of algorithms that analyzes data, learns from it and then applies what it has learned to make intelligent decisions. Machine learning requires various algorithms known as neural networks. Neural networks are built on the idea of human brain neural networks and consist of multiple layers, for example, input, output, and hidden layers to process, understand and produce result in a large data in continuous fashion, keeping in view the knowledge from previous result and modifying new results accordingly. Common pre-trained neural networks methods include GoogleNet, VGGNet, and AlexNet, which are trained based on ImageNet Large Scale Visual Recognition Challenge (ILSVRC).[8] PPG equipped with NN (Neural network) can deduce data from PPG signals which can be used to identify and classify HTN. This can provide real-time data and thus reduce morbidity and mortality. A mobile app named HeartSense was developed using a neural network to produce BP readings.[4]

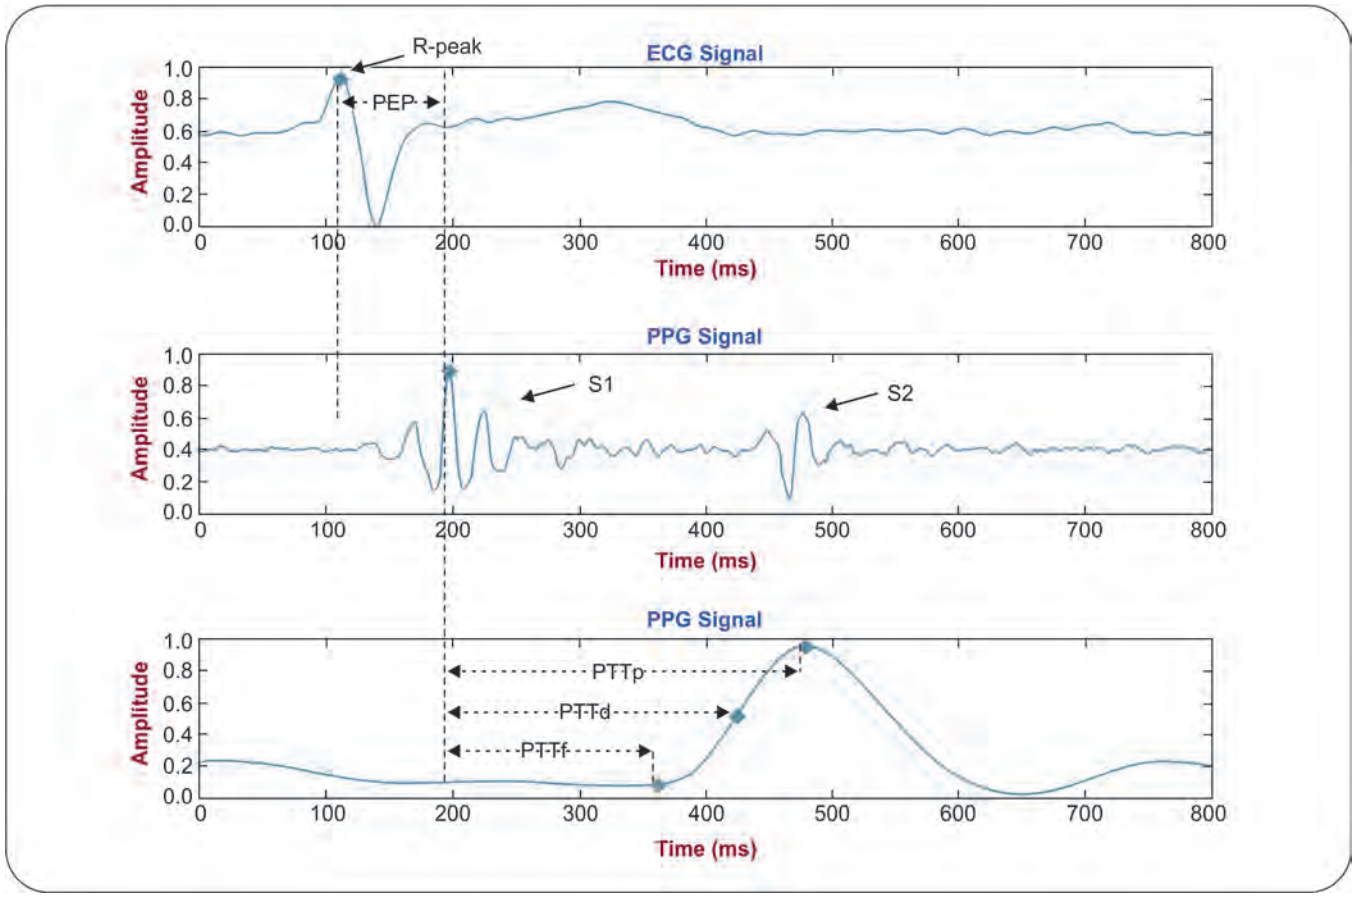

Fig. 4: ECG and PPG (first and third waveform, PAT = PEP + PTT); PCG and PPG (second and third waveform, VTT = S1 of PCG to systolic peak of PPG)

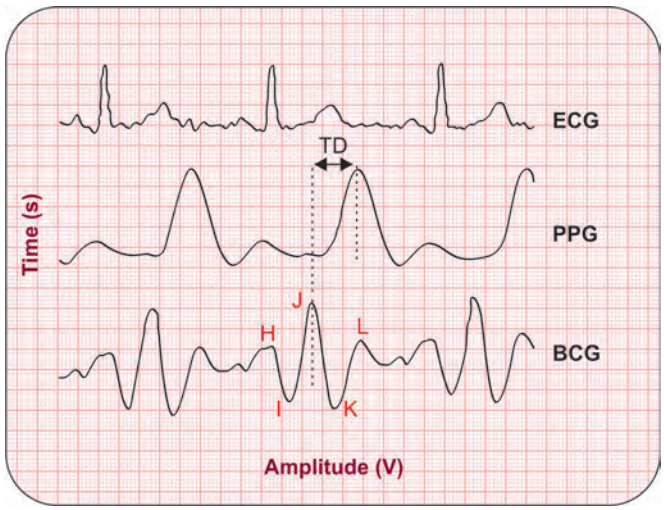

Fig. 5: PPG (Photoplethysmography) and BCG (Ballistocardiography). (TD = J peak in BCG to systolic peak in PPG)[4]

Non-PTT-based Method

In this method, morphological features of PPG such as pulse amplitude, signal steepness, peak to onset interval, signal amplitude, and many other time domain and frequency domain features have been used to estimate blood pressure.[6]

PTT-based Methods Combined with Non-PTT-based Methods

This method improves accuracy.

Implementation of PPG in Mobile and Wearable Health Devices

Out of hospital and continuous BP monitoring using handy and inexpensive instruments have become an

area of growing interest. Many companies have tried incorporating PPG in mobiles and wearable devices like wristband, armband, wristwatch, finger probe, eyeglass frame, chest belt.[9,10]

Wearable Rings

Wearable ring fitted with biosensor is an optimal device for measuring BP as the finger vasculature lies in proximity to the skin surface. It works on the concept of measuring arterial blood flow using PPG by optical biosensor that consist of LED, which illuminates the vessel of finger and photodetector that detects the amount of light transmitted/reflected.[11] This device can be worn by persons at all times for 24-hour BP measurement without the fear of finger necrosis, as the cuff is not used.

BP Monitoring Watch

Proximal timing (blood ejected from left ventricle into aorta) is obtained by an accelerometer, which measures the thoracic vibrations when user places the face of watch on his sternum for about 15 seconds. Distal timing (arrival of pulse wave at the radial artery on wrist) is obtained by PPG signal on the watch. The delay between these proximal and distal timing provides PTT, which is used to estimate BP. This device cannot be used for continuous measurement as one fiducial point is user dependent, but it can serve as a handy cuffless BP measurement technique where person can monitor BP as and when required by placing arm near chest wall.[12]

Eyeglasses

Especially designed eyeglasses are fitted with small-sized PPG sensors that sample pulse waveform at bridge of the nose (for angular artery pulsations), on side of the head (for temporal artery pulsations) and behind the ear (for occipital artery). The time delay between pulse time from one artery to the other provides PTT.[13] However, no clinical setting has validated this product to date.

Biosensor in Phone

By using the oscillometric mechanism, mobile phones can also be used as a tool for BP monitoring. The pressure of finger's vessel is increased when person presses his finger against the rear camera of phone. Pulsatile blood volume oscillations within the artery are measured via PPG and transducer, embedded in the phone. The amplitude of these oscillations is used to compute BP. Both android and iPhone have mobile applications based on this method to measure BP **(Fig. 6)**.

Smartphone devices can also measure BP using PPG signals by measuring PTT and VTT.[14] Phone cameras provide the proximal timing of PPG signal from person's finger. Another fiducial distal point is derived from heart sounds collected by microphone instilled in mobile phones. VTT is calculated between two points to estimate BP. Mobile applications like instant blood pressure (IBP) and wello, released by Auralife (Newport Beach, CA) and iPhone respectively, estimate BP using the above mentioned method of wave propagation.

Electrochemical Biosensors

Electrochemical sensors can be used for the quantification of various biological compounds that indirectly serve as markers of HTN. Cortisol, increased nitric oxide, galectin-3, ghrelin in saliva and inflammatory markers like C-reactive protein (CRP), tumor necrosis factor-alpha (TNF-α), interleukins, etc. are a few examples of such biological compounds.[15] Sodium-sensitive electrode is employed for the potentiometric detection of sodium from sweat samples based on the fact that high levels of sodium increase the stiffness of the endothelial cells leading to HTN. Kidneys control total sodium content through epithelial sodium channel (ENAC) and its deregulation is associated with HTN. Fabricated anti ENAC conjugates were detected by optical sensors. The fluorescence intensity enables discriminating between normotensives and hypertensives. Thus, represents a useful diagnostic tool for HTN.[16] Development of nanosensors for point of care diagnostics has led electrochemical sensors to display superior sensitivity, response time, precision time, and wider range for specific and reproducible detection of key markers that aid in diagnosing HTN. Although there are many hand-held or field biosensors available, most of these technologies have not been fully utilized for the detection of HTN and is used for research purpose only. The direction is yet to be explored as it holds immense promise for clinical applications but their specificity and cost efficiency are a major issue.

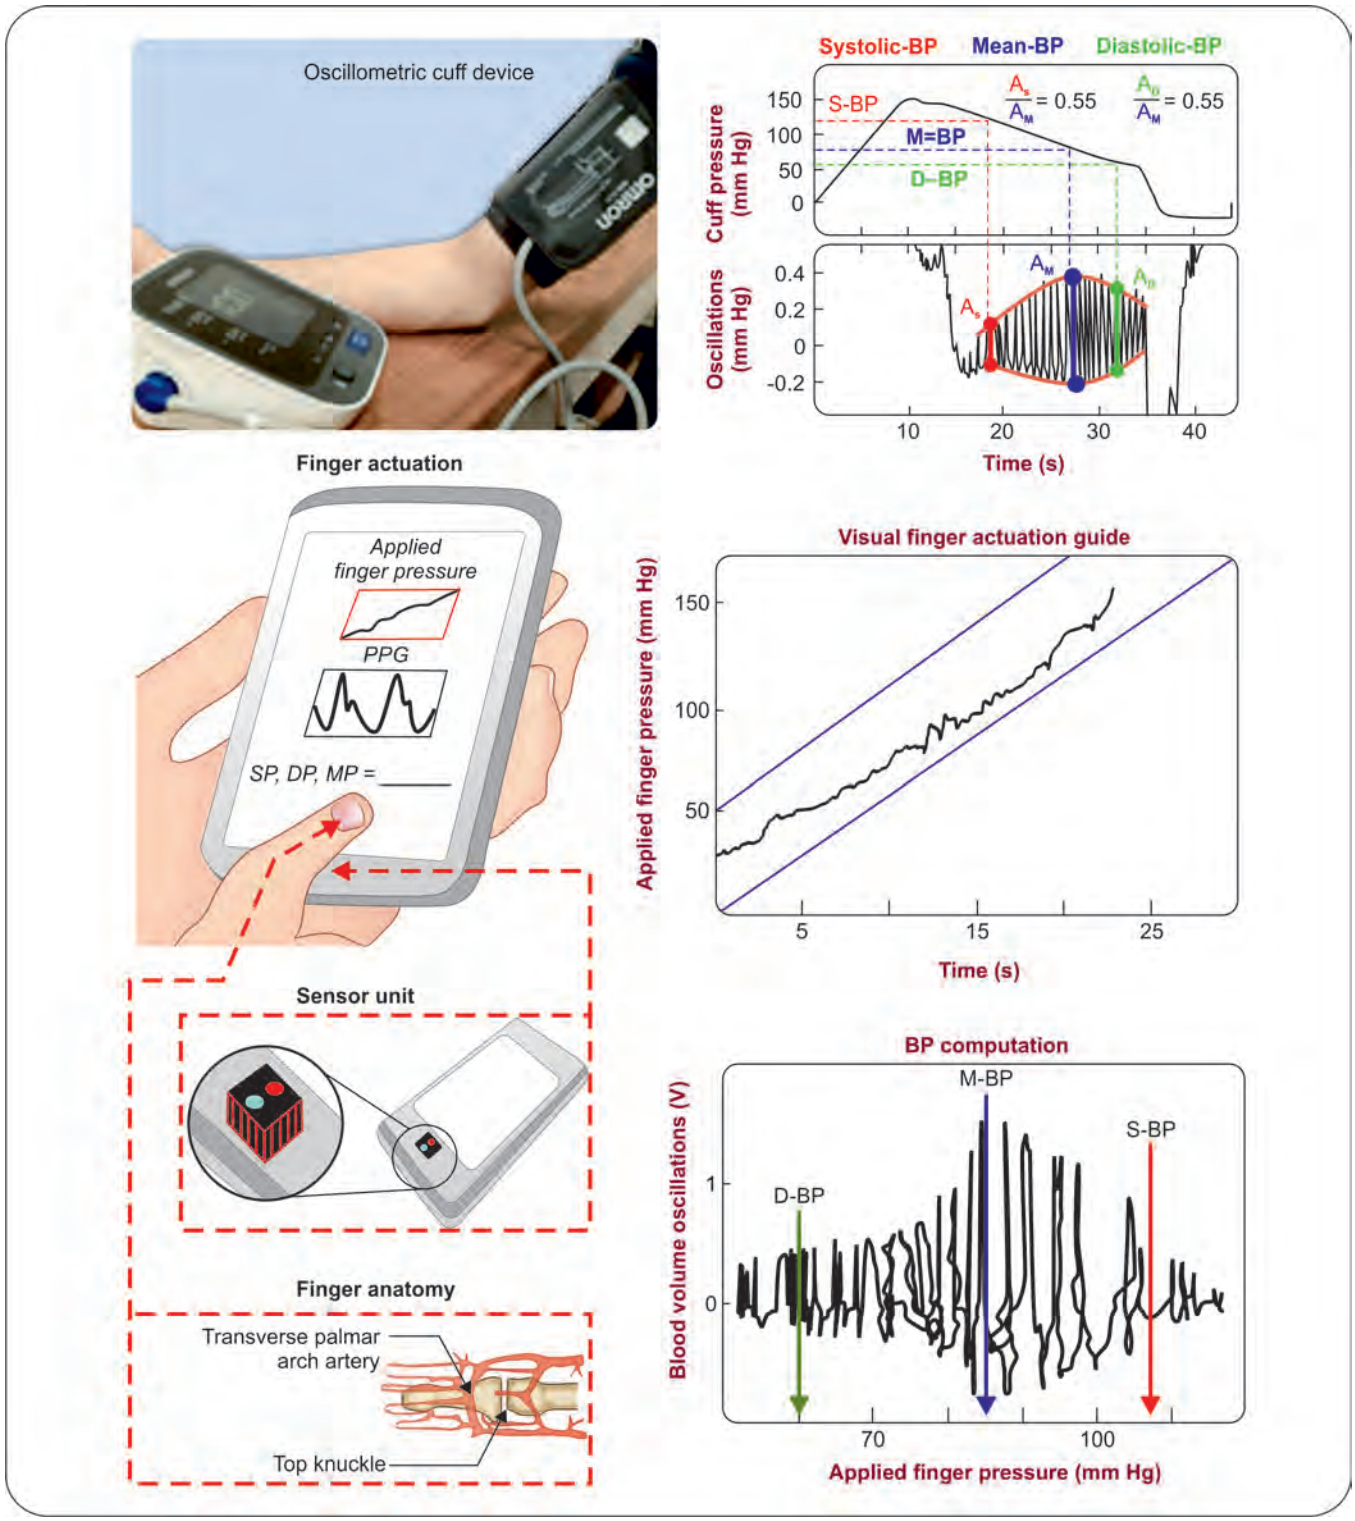

Fig. 6: Topmost figure shows conventional oscillometer. In second figure person places his finger on phone's camera, and phone embedded with photoplethysmography (PPG) and force transducers serves as the sensor to measure the blood volume oscillations and applied pressure[14]

Conclusion

The principle of PPG is widely used for measuring oxygen saturation. However, its use in clinical setting for BP is relatively new. Major phone companies like iPhone and Samsung have developed mobile applications that measure BP using PPG waveform that is obtained by pressing finger against phone camera. The widespread use of portable and wearable health devices allow timely BP measurement and monitoring, guides the health-care personnel of fluctuations patterns of person's BP, for example, nocturnal HTN and in some cases also reminds the person of missed dose by ringing an alarm. This prevents the complications related to HTN, prolongs customer's expected life span and also improves quality of life. In addition, these will bring down health costs in long run. However, high initial cost, less selectivity and a limited number of physiological parameter monitoring limit their use. A comprehensive understanding of PPG is required so that researchers can successfully develop advanced technologies for better care of hypertensive patients.

Cardiology

CHAPTER

27 Coronary Intervention: What a Physician Should Know?

Nihar Mehta, Harish Surwade

Abstract

Coronary Intervention is a continuously evolving field. Over the last four decades, the innovations in this field have made coronary intervention a safer, more effective, and widely available procedure. A combination of physiological and anatomical evaluation is possible for detailed objective evaluation of the coronary tree. The refinement in the hardware and stent technology as well as the imaging modalities have lead to better outcomes in even complex coronary anatomies. As physicians, it is essential to know the basics of coronary anatomy and hardware along with the indications and options of revascularization, individualized to every patient.

Introduction

The use of coronary interventions has grown rapidly over the last few years. New improvements in techniques, hardware, operator experience, pharmacology, and safety as shown by clinical studies have expanded the use of coronary interventions. First Percutaneous Transcatheter Coronary Angioplasty (PTCA) was performed by Dr Andreas Gruntzig on 16 September 1977 in Zurich, Switzerland, with a balloon catheter. Since then use of PTCA has grown leaps and bounds. Balloon angioplasty was replaced by Bare Metal Stent implantation to reduce the incidence of recoil, restenosis, and complications like dissections. Drug eluting stents (DES) were the next innovation, which have replaced the bare metal stents (BMS) since 2003. The DES consisted of an antiproliferative drug, which was slowly released into the vessel to further reduce the rate of restenosis. Over the last two decades, several refinements have been made to DES such as reduction of stent strut size, use of newer anti-proliferative drugs, bioabsorbable stents, etc. This has led to improved outcomes of PTCA over the years. The indications have expanded to more complex coronary lesions, which were previously treated by surgery as a default.[1-4]

Epidemiology

The problem of coronary artery disease (CAD) or atherosclerotic lesions in coronary arteries has grown fourfold in India during last 40 years. Current epidemiological studies estimate its prevalence to be between 7% and 13% in urban and 2% and 7% in rural regions.[5-8]

According to epidemiological studies over 30 million cases of CAD are present in India. Of more than 10.5 million deaths reported in India annually, cardiovascular disease (CVD) led to 20.3% deaths in males and 16.9% deaths in females.[5] As per 2010–2013 data, the proportionate mortality from CVD increased to 23% of deaths. The mortality varies from less than 10% in rural locations in less developed states to more than 35% in more developed urban locations.[5] A study by Gajalakshmi et al. during 1995–1997 showed that CVD deaths are the highest (38.6%) in urban Chennai.[8] Similar data are published by Joshi et al. from Andhra Pradesh.[6]

Indications[9]

See **Table 1**.

Relative Contraindications

- Congestive cardiac failure
- Acute or chronic renal failure (unless dialysis is planned)
- Acute stroke
- Active gastrointestinal bleeding
- Electrolyte imbalances
- Bleeding diathesis
- History of allergic reaction to iodinated contrast agent
- History of allergy or bronchospasm to aspirin
- Bacteremia

Coronary Angiography and Percutaneous Coronary Intervention

Preprocedure

Preprocedural wearing of a lead apron, thyroid shield, lead goggles, and a lead cap protects against potential radiation hazard. A preprocedural evaluation should include a note of the last oral intake, a history of drug and a history of previous experience with sedative or contrast agents.[10]

The patient should be kept fasting for at least 3–4 hours before the start of the procedure. For diabetic patients, medications should be adjusted. Metformin should be stopped 48 hours before and after PCI to reduce the likelihood of lactic acidosis. Adequate hydration with IV fluids and N-Acetyl cysteine starting 12 hours before procedure in patients with mild renal dysfunction is advised for nephroprotection.

Strict aseptic precautions and cleaning and draping of the access sites should be done. The procedure is performed under local anesthesia in most cases with or without mild sedation.

Vascular Access

The procedure is usually preformed via the femoral or radial artery approach. Femoral artery access has a fairly straight course to the descending aorta, is larger and gives better catheter support during the procedure. However, complications like bleeding, pseudoaneurysms, retroperitoneal hematomas, or arteriovenous fistula are possible in 3–7% of cases. The radial artery is increasing in popularity as an access site due to early patient mobilization, reduced complications rates and fairly direct access into ascending aorta.[11,12] Smaller sheath and catheter sizes (4F, 5F) have replaced the larger catheters (8F), which lead to lower access site complications.

TABLE 1 Indications for coronary angiography

Coronary artery disease:
• *Asymptomatic*: – At high risk of coronary event based on noninvasive testing • *Symptomatic:* • Stable Angina with Canadian Cardiac Society Class II, III, or IV symptoms • Unstable angina or Non-ST Elevation Myocardial Infarction (Acute Coronary Syndrome) • ST Elevation Myocardial Infarction (STEMI): Reperfusion with a primary percutaneous coronary intervention (direct intervention without thrombolysis) or pharmaco-invasive approach (within 2–24 hours after thrombolysis) or Rescue PCI (in case of failed thrombolysis) • Complications of STEMI: Acute pulmonary edema, Cardiogenic shock, Mechanical complications (Ventricular septal defect or Mitral regurgitation)
Valvular heart disease:
• Prior to valve replacement surgery in patients suspected of having coronary artery disease
Cardiomyopathy:
• Newly diagnosed cardiomyopathy suspected to be due to coronary artery disease • Hypertrophic cardiomyopathy with angina
Congestive cardiac failure:
• New onset angina suspected to be due to coronary artery disease
Congenital heart disease:
• Suspected associated coronary artery anomalies
Cardiac transplantation:
• Preoperatively and post-transplant to detect coronary artery vasculopathy
Others:
• Survivors of sudden cardiac arrest • Sustained monomorphic ventricular tachycardia or non-sustained polymorphic tachycardia

Coronary Angiography/Arteriography

Once the vascular access has been secured by modified Seldinger technique, especially shaped coronary catheters are advanced up to the ascending aorta. They are engaged

into the left or right coronary artery (RCA) and hand injections are made using a radiopaque contrast material. The radiographic images (cine angiography) are recorded in several different orthogonal views. The anatomy of the epicardial coronary arteries and coronary bypass grafts can be outlined.

Normal Coronary Anatomy and Coronary Artery Disease

Although coronary anatomy can be variable between individuals, in general there are two coronary ostia—the left and right. The left main coronary artery divides into the left anterior descending (LAD) and the left circumflex artery (LCx). The LAD gives septal and diagonal branches whereas the LCx gives obtuse marginal branches **(Fig. 1A)**. In about 1–2% of individuals, a ramus intermedius branch directly arising from the left main coronary artery, between the LAD and the LCx.

The RCA divides distally into the posterior descending artery (PDA) and the posterior lateral artery/posterior left ventricular artery (PLV). This anatomy is called the right dominant circulation and is found in 85% of individuals **(Fig. 1B)**. In about 5% of individuals, the PDA arises from the LCx, which is defined as left dominant circulation. The remaining 10% have a codominant circulation.

Coronary artery stenoses are visualized by coronary angiography as luminal narrowing and the degree of narrowing is referred to as percentage stenosis. The percentage stenosis is determined visually by comparing the most severely diseased area to the distal normal artery segment. A coronary stenosis of 40–70% is considered intermediate and more than 70% is considered significant.

Coronary calcification can be visualized during angiography before injecting the radiocontrast material. Collateral blood vessels can also be seen between one vessel and the distal part of a severely stenosed vessel. Other abnormalities like dissections, thrombus, coronary ectasia, and myocardial bridges can also be visualized during coronary angiography.[9]

Patient Selection for Percutaneous Coronary Intervention (PCI)

Patients with significant CAD can be revascularized by percutaneous transluminal coronary angioplasty (PTCA/PCI) or coronary artery bypass graft (CABG) surgery. The choice between PCI and CABG vary depending on the type of presentation and characteristics of coronary anatomy.

- Chronic stable angina: The main aim of treatment is to improve symptoms or reduce mortality:
  - In asymptomatic or mildly symptomatic patients, revascularization can be deferred if procedural risks/bleeding risks are high. PCI is warranted only if symptoms worsen or there is evidence of severe ischemia on noninvasive testing in spite of optimal medical therapy.

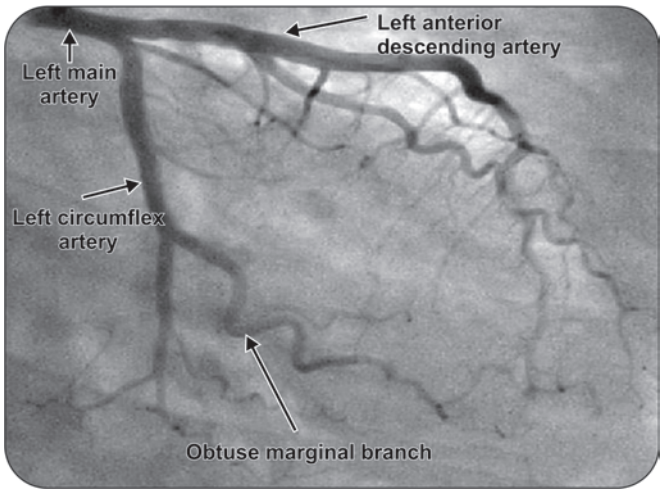

Fig. 1A: Left coronary artery anatomy
(*Source:* PJ Mehta's Practical Medicine, 20th edition)[13]

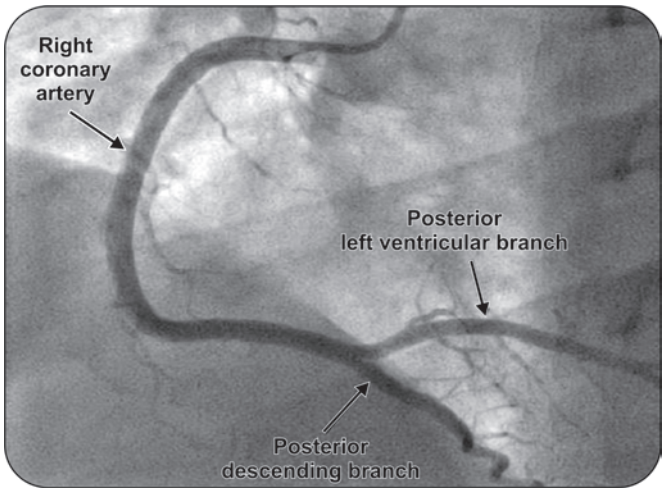

Fig. 1B: Right coronary artery anatomy in a right dominant circulation
(*Source:* PJ Mehta's Practical Medicine, 20th edition)[13]

  - Moderate to severely symptomatic patients should undergo ischemia-guided revascularization.
  - Left main CAD, triple vessel disease or diabetic patients have better outcomes with CABG surgery.
  - Less severe multi-vessel disease with or without diabetes have equal outcomes with PCI and CABG.
- Acute coronary syndromes: PCI is superior to optimal medical management due to high risk of mortality. PCI is preferred over CABG surgery except in case of severe multi-vessel disease or anatomical factors which are not amenable to successful treatment.
- ST elevation myocardial infarction (STEMI):
  - Primary PCI (Primary angioplasty in Myocardial Infarction—PAMI) is a preferred strategy (direct intervention without thrombolysis).
  - In the pharmaco-invasive approach, patients are thrombolyzed followed by PCI within 2–24 hours after thrombolysis.
  - In case of failed thrombolytic therapy (patients in whom there is ongoing angina 90 minutes after fibrinolysis and/or ECG persistently shows ST elevation), Rescue PCI should be performed.
- In patients presenting with cardiogenic shock or heart failure (HF), PCI is class I indication that increases survival.[14]
- Several coronary arterial anatomical factors influence success and safety of PCI such as location of the lesion (proximal or distal), tortuosity, calcification, length of lesion, size of vessel, thrombus, or chronic total occlusion (>3 months in duration). Patients with unfavorable anatomy are candidates for CABG surgery.
- Conversely, some patients are inoperable for CABG surgery due to comorbidities such as advanced age, frailty, chronic obstructive pulmonary disease (COPD), or poor LV function.

PTCA Procedure (Figs. 2 and 3)

Prior to the procedure, patients are given a loading dose of dual antiplatelet medications: aspirin (325 mg) and a P2Y12 inhibitor (clopidogrel 300–600 mg or prasugrel 60 mg or ticagrelor 180 mg) to prevent thrombotic complications.

The procedure is carried out under local anesthesia with or without mild sedation. Vascular access is obtained in the same way as outlined earlier using Seldingers technique. During the procedure, anticoagulation is achieved by using unfractionated heparin or bivalirudin (direct thrombin inhibitor). In the case of STEMI or large thrombus in the coronary arteries, intravenous glycoprotein IIb/IIIa inhibitors (abciximab, tirofiban, or eptifibatide) is used.

The most commonly used PCI equipment consists of four basic elements: a guiding catheter, a balloon catheter, a coronary guidewire, and a stent **(Fig. 4)**.

Via the introducer sheath at the vascular access site, a guiding catheter is used to selectively cannulate the culprit coronary artery. All subsequent coronary hardware is passed into the coronary artery through the guiding catheter. A flexible guidewire is passed into the coronary artery across the stenosis and is positioned in the distal coronary artery. The guidewire acts as a guiding "rail" for all subsequent hardware to be passed in and out of the coronary arterial tree.

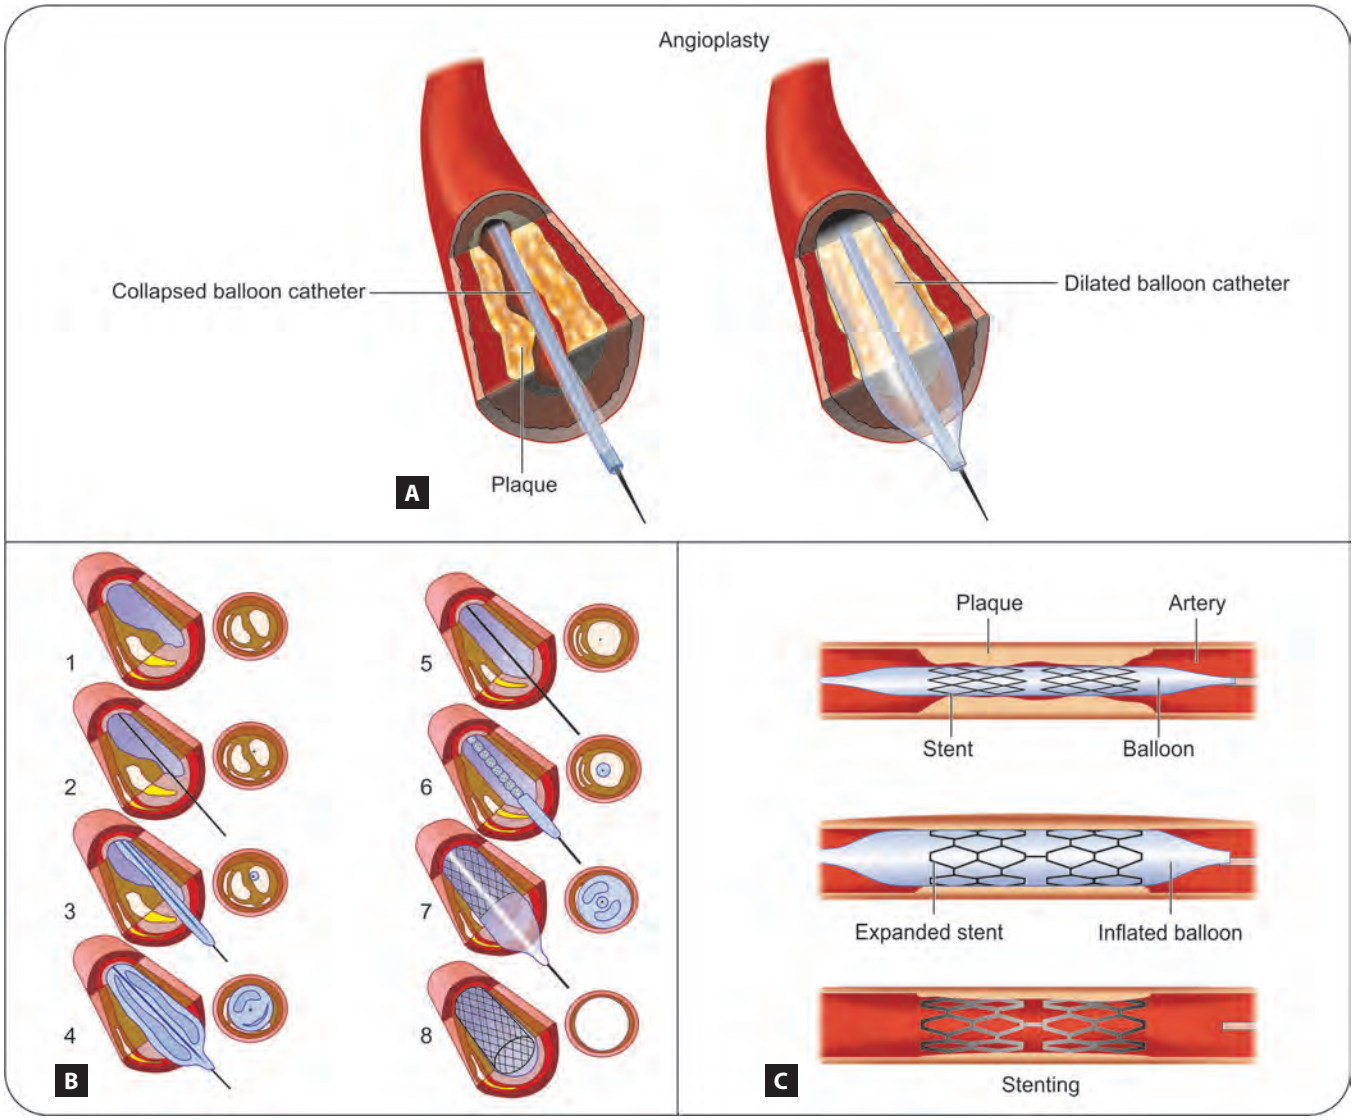
A balloon catheter is passed over the guidewire, positioned across the stenosis, and then dilated to stretch the coronary artery and displace the plaque to enlarge the coronary lumen thus improving blood flow. The balloon catheter is then removed over the guidewire, maintaining the position of the guidewire in the coronary artery.

A coronary stent is a stainless-steel mesh/scaffold which is available in a compressed state over a balloon catheter. It is passed over the guidewire, positioned across the stenosis and deployed by inflating the balloon. When the balloon is deflated, the stent stays in place in the coronary artery and the balloon catheter is removed. Normal blood flow is restored to the coronary artery. The guidewire, guiding catheter, and introducer sheath are subsequently removed. Hemostasis is achieved using manual pressure or vascular closure devices.[10,15]

The patient is then transferred to a recovery area and then to the patient's room. If no complications occur, the patient is discharged the next morning. The patient usually returns to work shortly (<7 days) thereafter.

Mechanism of Angioplasty and Stenting and Stent Composition

Mechanism of balloon angioplasty: The inflated balloon exerts pressure against the plaque and the arterial wall, causing fracturing and splitting. Concentric (round or circumferential) lesions fracture and split at the thinnest and weakest points. Eccentric lesions split at the junction of the plaque and the normal arterial wall. Dissection



Figs. 2A to C: Schematics of angioplasty and stenting

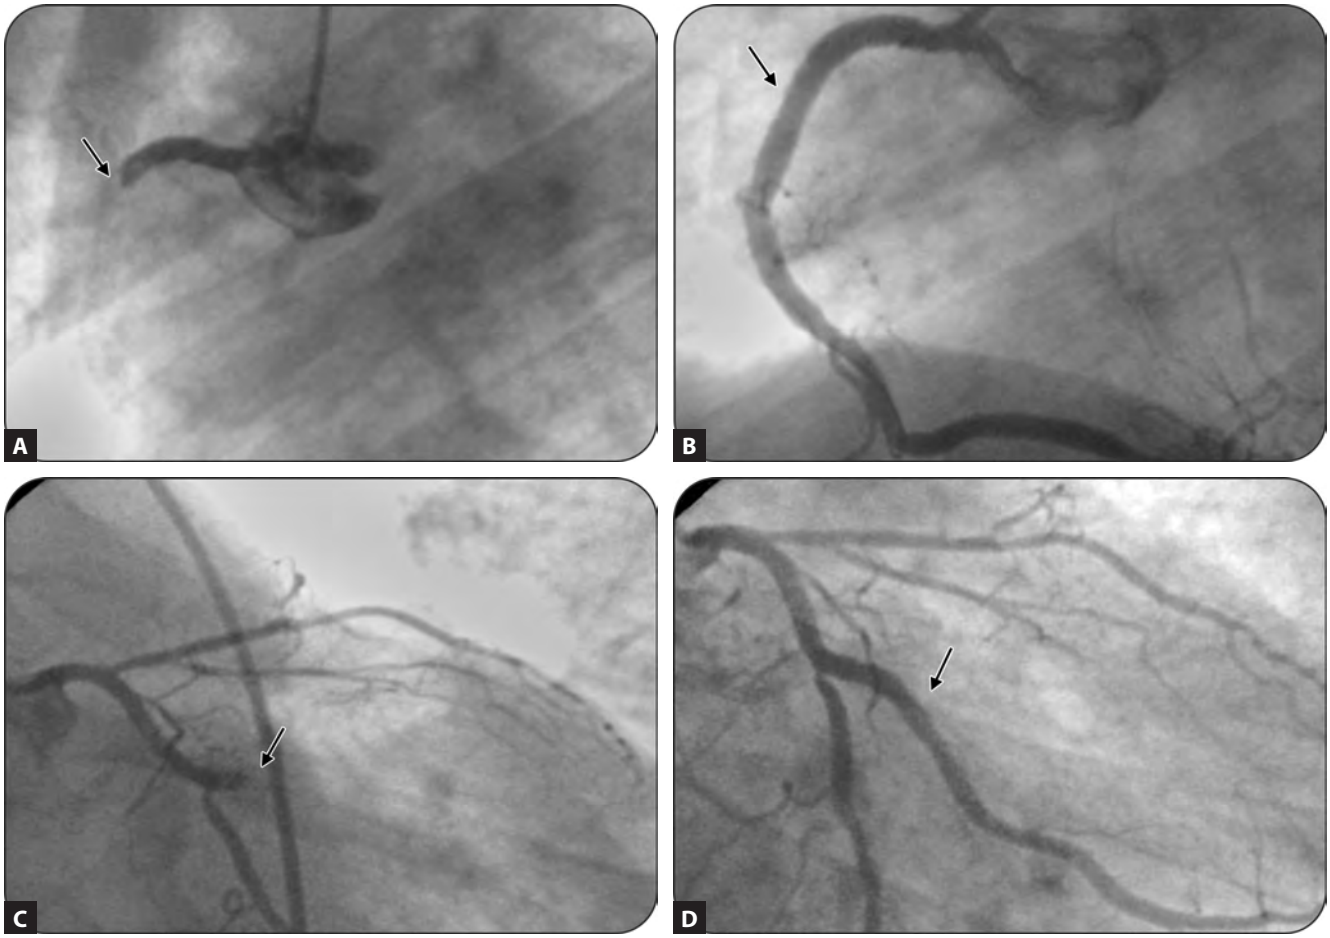
or separation of the plaque from the vessel wall releases the restraining effect caused by the lesion and results in a larger lumen.

Mechanisms of stenting: Placing a stent in the coronary artery leads to disruption and fracture of atheromatous plaque. The scaffold prevents elastic recoil of artery and leads to longitudinal compression of plaque material against the wall. The anti-proliferative drug inhibits the intimal proliferation and reduces the restenosis rates.

DES are made of a stainless-steel mesh/scaffold. They have a thin polymer coating, which holds an anti-proliferative drug, which is released into the atherosclerotic plaque slowly for 1–3 months. This reduces the rate of restenosis. The anti-proliferative drugs used are paclitaxel, sirolimus, everolimus, zotarolimus, or biolimus. Bioabsorbable vascular scaffold (BVS) stents were initially available, which gradually degraded over 2 years; however, the BVS stents were withdrawn due to late stent thrombosis.[9]

Additional Interventional Devices

Several other interventional devices are available such as thrombus aspiration catheters (to aspirate thrombus



Figs. 3A to D: (A and B) Primary angioplasty (PAMI) of right coronary artery (RCA) and (C and D) obtuse marginal (OM) branch of the left circumflex artery. Black arrows in A and C show thrombotically occluded RCA and OM arteries, respectively. Black arrows in B and D show final result after stenting the respective arteries

in case of a STEMI), distal embolic protection devices (to protect the distal vasculature from embolization in case of heavy thrombus burden in STEMI or degenerated saphenous vein graft intervention), rotational atherectomy or directional atherectomy or orbital atherectomy (devices used in heavily calcified lesions, which are resistant to balloon dilatation), among others.

IVUS, OCT, and FFR

In the case of intermediate stenoses (40–70%) additional modalities are to be used to determine if the stenosis is flow limiting. Intravascular Ultrasound and Optical Coherence Tomography provide an anatomical assessment of the coronary arteries, whereas fractional flow reserve (FFR) provides a physiological assessment of the coronary flow.[9]

Intravascular ultrasound (IVUS) is an ultrasound device mounted catheter that is advanced into lumen of diseased artery. It gives atherosclerotic plaque burden, reference vessel diameter and area, and morphology of stenosis **(Figs. 5A and B)**. IVUS can also be used after angioplasty to determine the adequacy of the stent placement.

Optical coherence tomography (OCT) is infrared-based imaging technique that has a higher resolution than IVUS, but has limited penetration (depth of visualization) **(Figs. 6A and B)**.

FFR is a ratio of pressure distal and proximal to the stenosis respectively when there is maximal vasodilation of the coronary microvasculature. It gives the physiologic significance of a borderline stenosis and can guide PCI

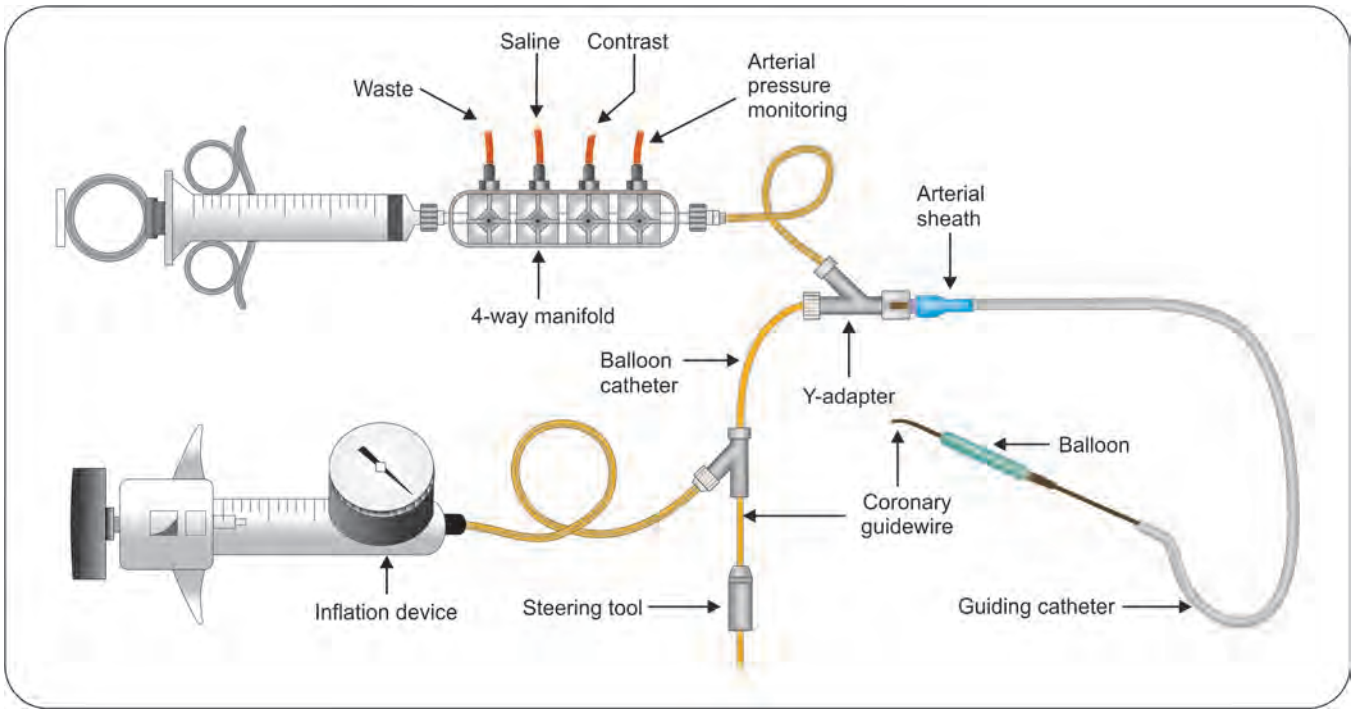


Fig. 4: PCI equipment

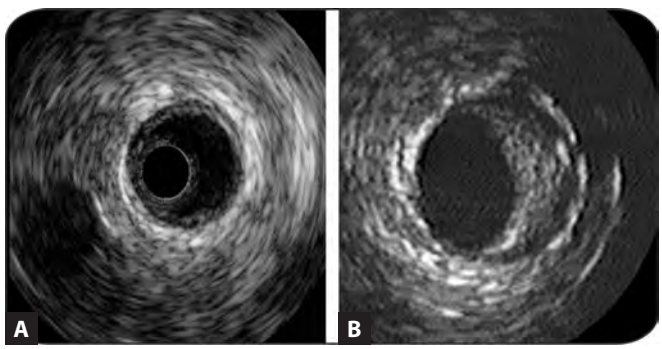
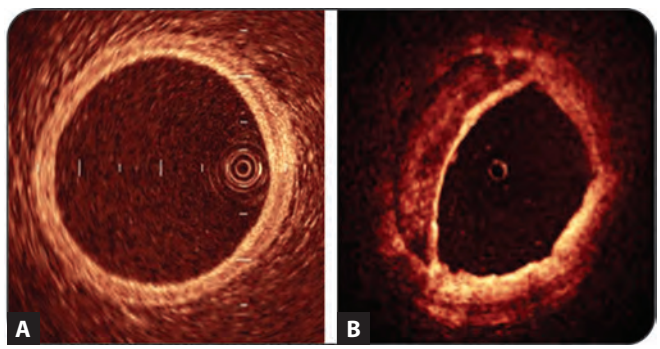


Figs. 5A and B: Intravascular ultrasound (IVUS) images: (A) Normal coronary artery with three layers: the intima, media, and the adventitia. The lumen is the dark central area within the intima. (B) Coronary artery with an atherosclerotic plaque encroaching into the lumen from 12 o'clock to 6 o'clock position

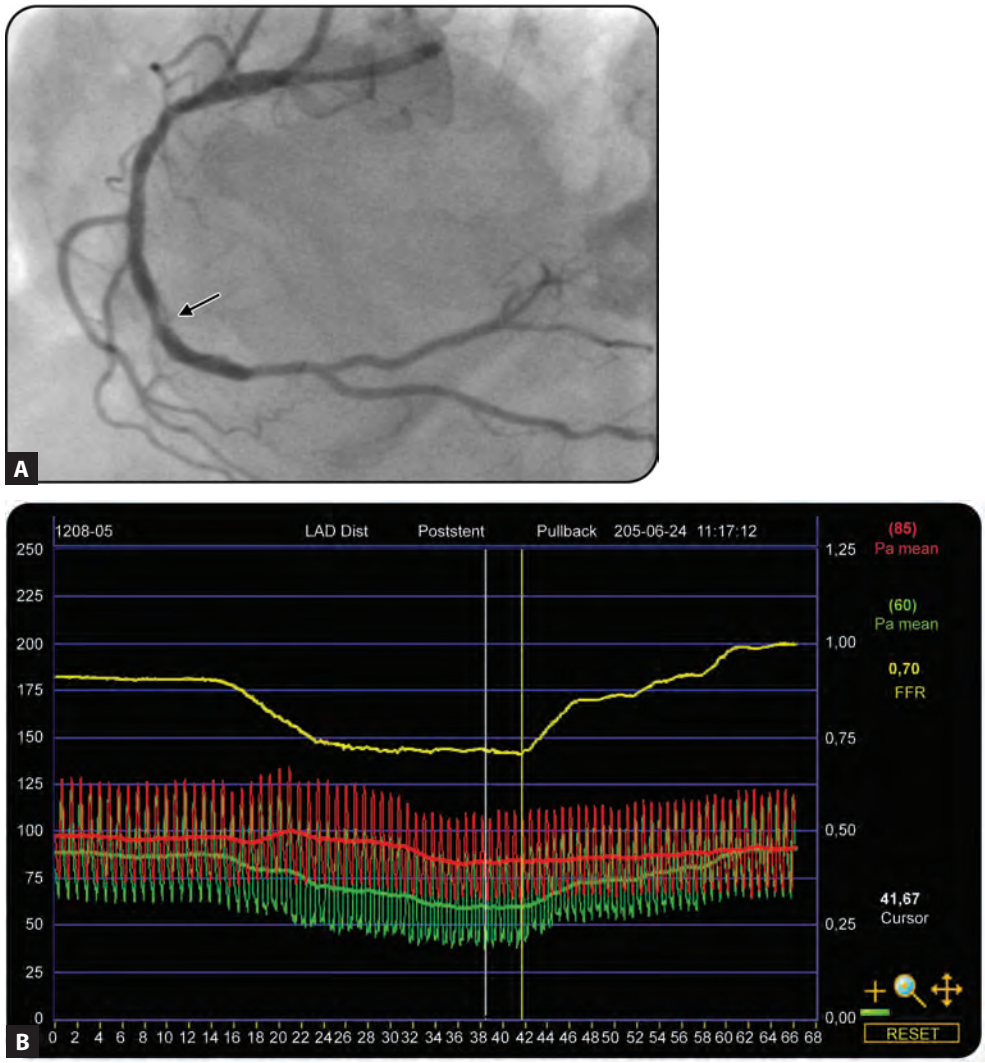


Figs. 6A and B: Optical coherence tomography images: (A) Normal coronary artery with three layers, the intima, media, and adventitia. The lumen is the inner black central area within the intima. (B) Coronary artery with a calcified atherosclerotic plaque from 7 o'clock to 1 o'clock position

decision. FFR less than 0.80 indicates a flow limiting stenosis that would benefit with revascularization **(Figs. 7A and B)**.[16]

Complications and Risks[17-19]

- *Vascular complications:* Bleeding, hematoma, pseudoaneurysm formation
- *Contrast induced nephropathy:* Rise in the serum creatinine by 0.5 mg/dL or by 25% above the baseline that occurs 48–72 hours after the procedure
- *Contrast allergy:* Severe anaphylactoid reaction, urticarial, nauseas, vomiting
- *Acute myocardial infarction:* Due to stent thrombosis, dissections, distal embolization or side branch closure



Figs. 7A and B: Fractional flow reserve (FFR): (A) Right coronary artery with an intermediate stenosis (black arrow). (B) Pressure tracing from the pressure wire across the lesion. FFR is ratio of the mean distal pressure (Pd)/mean pressure in aorta (Pa) at maximal hyperemia. In this case the Pd/Pa = 0.79, which shows that the lesion is flow limiting and should be revascularized

TABLE 2 High-risk PCI

Anatomic	*Clinical*
• Left main coronary artery disease • Triple vessel disease • Associated valvular disease (especially severe aortic stenosis) • Left ventricular dysfunction (EF <40%) • Severe peripheral vascular disease • Post CABG—Saphenous vein graft/Arterial graft interventions • Past PCI • Complex subsets: Chronic total occlusions/Calcified lesions/ Tortuous lesions	• Acute myocardial infarction • Cardiogenic shock/Hemodynamic instability • Atrial/Ventricular arrhythmias • Poorly controlled hypertension • Decompensated heart failure • Diabetes mellitus • Renal dysfunction • Pulmonary disease (COPD/Asthma/OSA) • Bleeding diathesis/Anemia/Thrombocytopenia/Deranged INR • Cerebrovascular disease • Contrast allergy • Elderly/Frail • Medications: Oral anticoagulants/Insulin/Diuretics • Emergent procedures

- *Cerebrovascular accident:* Acute or delayed stroke
- Stent thrombosis
- Restenosis due to neointimal hyperplasia
- *Tachy- or bradyarrhythmias:* Requiring pharmacotherapy, cardioversion or pacing
- *Death:* Relatively low risk

The risks associated with coronary angiographies are relatively low when performed electively. The risks are higher in certain subsets such as when done in an emergency or in hemodynamically unstable patients **(Table 2)**.

Considering the multiple factors in an individual patient, which dictate the decision of PCI versus CABG in multi-vessel CAD, it is ideal to have a heart team approach involving the interventional cardiologist, cardiac surgeon and physician while decision-making.

Conclusion

With the continuous innovations in the field of interventional cardiology, we have come a long way in the last four decades to make PTCA a safer and more effective procedure. The refinement in the hardware and stent technology has led to higher success rate in more complex anatomies with better long-term outcomes. As a physician, the decision to intervene is essential as well as offering the ideal mode of revascularization keeping in mind the risks, clinical and anatomical factors, individualized for every patient.

CHAPTER

28 Current Status of Management of Rheumatic Heart Disease in India

Kunal Mahajan, Prakash Chand Negi, Sachin Sondhi

Abstract

Rheumatic heart disease continues to be a significant cause of cardiovascular morbidity and mortality in India and other low-middle income countries. In most endemic regions, the disease is often neglected and diagnosed late, with majority of the affected patients presenting for the first time with complications like heart failure, atrial fibrillation, and cardio-embolism. Echocardiography screening based on World Heart Federation echocardiographic criteria holds promise to identify patients earlier, when prophylaxis is more likely to be effective. This review focuses on the diagnostic and management approach to the patients with acute rheumatic fever and rheumatic heart disease based on the available literature and guidelines.

Introduction

Rheumatic heart disease (RHD) is a neglected disease which leads to significant cardiovascular morbidity and mortality in India and other low-middle income countries.[1] RHD occurs in response to rheumatic carditis either due to initial or recurrent episodes of acute rheumatic fever (ARF) and seen in 60% of patients with ARF.[2] ARF is a nonsuppurative sequelae of group A beta-hemolytic streptococcus (GAS) pharyngitis. ARF occurs in 0.3–3% of patients after a streptococcal sore throat.[3] Therefore, early detection and management of ARF is pivotal in the prevention of RHD.[4] Once it occurs, RHD causes significant morbidity and results in various long-term complications like stroke, peripheral embolism, heart failure, and premature death.[4] This review will highlight the diagnostic and management approach to the ARF/RHD patients based on the available literature and guidelines.

Epidemiology of RF/RHD

Despite a global decline in the incidence of RHD, it remains endemic in regions with overcrowded living conditions and inadequate health-care services. Worldwide, there is a gross disparity in the incidence rates in endemic versus non-endemic areas. The incidence rate varies from 3.4 per 100,000 population in the non-endemic countries to as high as 444 per 100,000 population in the endemic countries.[4] Unfortunately, India is the "RHD Capital" of the world, with nearly 40% of the global RHD burden.[4] However, in India, gross disparities exist in the socioeconomic statuses and the availability of health-care facilities across different states, within the states, and between the urban and the rural areas.[2] As a result, the burden of RHD in India is likely to differ widely within and across the states. Unfortunately, there are hardly any data from the worst affected states like Uttar Pradesh, Bihar, Jharkhand, West Bengal, and Odisha.[2]

Diagnosis and Management of Rheumatic Carditis

The ARF is most frequent in the age group of 5–15 years.[2] The diagnosis of ARF is based on Jones criteria, which were last revised in the year 2015 **(Table 1)**.[5] Carditis is the most severe manifestation of ARF because it may lead

TABLE 1 The 2015 revised Jones criteria for the diagnosis of acute rheumatic fever[5]

2015 Revised Jones criteria for the diagnosis of ARF		
For all patient population with evidence of preceding GAS infection		
Diagnosis of Initial ARF – 2 major or 1 major plus 2 minor manifestations Diagnosis of recurrent ARF – 2 major or 1 major plus 2 minor manifestations or 3 minor		
	Low-risk population: ARF incidence ≤2 per 100,000 school-aged children or all-age RHD prevalence of ≤1 per 1,000 population year	***Moderate to high-risk population: Children not clearly from a low-risk population***
Major criteria		
Carditis	Clinical and/or subclinical*	Clinical and/or subclinical*
Arthritis	Polyarthritis	Monoarthritis, polyarthritis, and/or polyarthralgia
	Chorea	Chorea
	Erythema marginatum	Erythema marginatum
	Subcutaneous nodules	Subcutaneous nodules
Minor criteria		
Carditis	Prolonged PR interval#	Prolonged PR interval#
Arthralgia	Polyarthralgia	Monoarthralgia
Fever	≥38.5°C	≥38°C
Markers of inflammation	Peak ESR ≥60 mm in 1 h and/or CRP ≥3.0 mg/dL	Peak ESR ≥30 mm in 1 h and/or CRP ≥3.0 mg/dL

*Subclinical carditis: Seen only on echocardiography without auscultatory findings.
#Accounting for age variability and only if carditis NOT counted as a major criteria.
ARF, acute rheumatic fever; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; GAS, group A beta hemolytic *Streptococcus*; RHD, rheumatic heart disease.

to chronic RHD with its attendant complications of heart failure, atrial fibrillation, thromboembolism, infective endocarditis, and death.[3] Clinical features depend on whether there is the involvement of the pericardium, myocardium, or heart valves. Myocarditis always occurs in presence of valvulitis, and isolated myocardial involvement in absence of valvular involvement, should raise doubts over the diagnosis of rheumatic carditis.[4] The mitral regurgitation is a dominant valvular lesion in 90% of ARF cases, causing an apical pansystolic murmur.[3] It may be accompanied by aortic regurgitation (AR). Isolated AR is seen in less than 5% of cases.[3] Stenotic lesions occur in the late stages of the disease. Among patients with previously diagnosed RHD, recurrence of acute rheumatic carditis is clinically suggested by a new murmur or a change in the character of the previously heard murmur. Nevertheless, echocardiography is strongly recommended in all patients with definite/suspected acute rheumatic carditis since it is more specific and sensitive than cardiac auscultation.[5] The aim of treatment in ARF is

- to suppress the inflammatory response and thus minimize the effects of inflammation on the heart and joints
- to provide symptomatic relief
- to eradicate the GAS harboring the pharynx
- to commence secondary prophylaxis.

The management of carditis during an episode of ARF aims at diagnosing and assessing the severity of cardiac involvement using echocardiography, and management of cardiac manifestations like congestive heart failure, and heart blocks.[5] Available literature does not suggest that anti-inflammatory treatment improves cardiac outcomes; however, glucocorticoids may prove beneficial in patients with acute cardiac failure secondary to severe carditis.[6] Prednisolone is preferred with an initial dose of 1–2 mg/kg/day, given for 2–3 weeks followed by gradual tapering and the total duration of therapy should be 8–12 weeks. Some recommend the introduction of salicylates as the dose of steroids is reduced to prevent rebound. In patients with clinical signs and symptoms of heart

TABLE 2 Secondary prophylaxis for rheumatic fever (drugs and duration of therapy)[7]

Antibiotic	*Route*	*Dose*
Benzathine benzylpenicillin	Single deep intramuscular injections every 3–4 weeks	If weight >30 kg then 1,200,000 IU If weight <30 kg then 600,000 IU
Penicillin V	Oral	250 mg twice daily
Sulfonamides (sulfadiazine, sulfisoxazole, sulfadoxine)	Oral	If weight >30 kg them 1 gm daily, if weight <30 kg then 500 mg daily
Erythromycin	Oral	250 mg twice daily
Duration of secondary prophylaxis for rheumatic fever		
In patients with no cardiac involvement	For 5 years after last attack or until 21 years of age (whichever is longer)	
In patients with preceding carditis and mild residual mitral regurgitation or valve lesion which resolved completely	For 10 years after last attack or until 21 years of age (whichever is longer)	
In patients with preceding carditis with moderate to severe valve damage	For 10 years after last attack or until 40 years of age (whichever is longer); Lifelong in high-risk patients	
In patients with relapses or high risk of infection	Lifelong	
After valve surgery	Lifelong	

failure, conventional treatment that includes diuretics and renin-angiotensin system blockers should be initiated. Valve surgery is rarely necessary in acute setting, and is usually reserved for patients with valve leaflet or chordae tendineae rupture where surgery can be lifesaving.[7]

The eradication of GAS from pharynx can be done by penicillin, which can be administered as a single intramuscular dose of benzathine penicillin or oral penicillin for 10 days.[7] Once the diagnosis of ARF/definite RHD is established, penicillin (preferably in form of 3 weekly intramuscular injections of benzathine penicillin) is recommended for secondary prevention **(Table 2)**. The benzathine penicillin can cause allergy and/or anaphylaxis in 3% and 0.3% of cases, respectively. There are few concerns with the use of intramuscular injections of penicillin, like difficulty in ensuring round-the-year availability in remote areas, fear associated with allergy/anaphylaxis, pain at the local site, and the long duration for which injections have to be administered on the 3–4 weekly basis. Azithromycin (once a week orally) and other oral drugs like erythromycin and sulfonamide are potential substitutes but are less effective.[8]

Diagnosis of Chronic RHD

Chronic RHD usually affects the patients in their most prime and productive years. In one of the most extensive contemporary Indian data on RHD patients, the HP-RHD (Himachal Pradesh rheumatic heart disease) registry, the mean age of patients was 40±14 years, and 70% of affected patients were females, and multivalvular disease was present in 67% of patients.[1] Early diagnosis of RHD, before the symptoms/manifestations become overt, along with early initiation of penicillin prophylaxis, can halt the disease progression and improve the outcomes. Criteria have been developed by "World Heart Federation (WHF) 2012" for echocardiographic diagnosis of RHD and to differentiate it from normal physiological variants **(Table 3)**.[9]

Management of Individual Valve Lesions

Mitral Stenosis

Medical Management

The medical management of mitral stenosis (MS) is directed at

- the prevention of recurrent rheumatic fever
- management of complications like atrial fibrillation, embolic complications, infective endocarditis, pulmonary artery hypertension (PAH) and right heart failure
- monitoring disease progression and allows intervention at an optimal time.

Asymptomatic patients with mild-moderate MS should be monitored annually. The management of severe

TABLE 3 Morphological features of rheumatic heart disease and the criteria for pathological regurgitation as defined by the World Heart Federation[9]

A. Morphological features of RHD	
Features in the MV: • AMVL thickening* ≥3 mm (age-specific) • Chordal thickening • Restricted leaflet motion • Excessive leaflet tip motion during systole	*Features in the AV:* • Irregular or focal thickening • Coaptation defect • Restricted leaflet motion • Prolapse
B. Criteria for pathological regurgitation	
Pathological mitral regurgitation (all four Doppler echocardiographic criteria must be met): • Seen in two views • In at least one view, jet length ≥2 cm* • Velocity ≥3 m/s for one complete envelope • Pan-systolic jet in at least one envelope	*Pathological aortic regurgitation:* (all four Doppler echocardiographic criteria must be met) • Seen in two views • In at least one view, jet length ≥1 cm* • Velocity ≥3 m/s in early diastole • Pan-diastolic jet in at least one envelope

*A regurgitant jet length should be measured from the vena contracta to the last pixel of regurgitant color (blue or red).
AMVL, anterior mitral valve leaflet; AV, aortic valve; MV, mitral valve; RHD, rheumatic heart disease.

disease includes the use of diuretics, beta-blockers, and/or digoxin for rate control. The anticoagulation with warfarin should be given to patients of MS having atrial fibrillation, LA/LAA (left atrium/left atrial appendage) clot, history of embolization, and if LA is grossly dilated (LA >55 mm).[10] The target INR (international normalized ratio) should be maintained between 2–3. The role of newer oral anticoagulants in the management of MS is controversial and needs further evaluation.[3,11] The factors responsible for acute worsening like anemia, pregnancy, infection, infective endocarditis, and ARF recurrence also need consideration while managing mitral stenosis.

Mitral Valvotomy

The older techniques of closed mitral valvotomy (CMV) and open mitral valvotomy (OMV) have now been replaced by percutaneous balloon mitral valvotomy (BMV), also known as percutaneous transvenous mitral commissurotomy (PTMC). BMV is strongly recommended in symptomatic and suitable patients with moderate to severe MS (i.e., valve area <1 cm^2/m^2 of BSA or <1.5 cm^2 in normal-sized adults with pliable noncalcified valves, no more than mild MR and with no evidence of LA/LAA thrombus).[12] Besides, BMV is a favorable option for asymptomatic patients with valve area less than 1 cm^2 or when MS results in the development of AF. BMV is done through the femoral vein approach, and after doing trans-septal puncture, the "Inoue balloon" is inflated across the orifice of mitral valve, which results in the fracture of nodular calcium, and separation of the mitral commissures, and as a result, increase in the orifice area of the mitral valve. BMV is, however, contraindicated in the presence of persistent left atrial or LAA thrombus, more than mild (moderate to severe) mitral regurgitation, and severe or bicommissural calcification. A meta-analysis comparing BMV with surgical commissurotomy suggested that, compared with surgical commissurotomy, BMV results in slightly smaller mitral valve area, a comparatively higher risk of developing MR, and an approximately threefold risk of reintervention.[13] However, with an increase in operator experience and familiarity, refined hardware, relative procedural ease, and perhaps being a cheaper option compared with surgical options, BMV remains the preferred treatment option for rheumatic MS.[3] The possible complications of BMV include cardiac perforation (1%), cerebral emboli (1%), development of MR (15% develop MR out of which 2% require surgery), and even death in 1–2% of patients.[3]

Mitral Valve Replacement

Valve replacement may be needed if the valve is severely calcific and non-pliable with echocardiography based Wilkins score greater than 8 (Wilkins score is based on leaflet mobility, leaflet calcification, leaflet thickening, and

subvalvular deformity), and also in the presence of more than grade 2 MR, and/or persistent LA/LAA clot.[12]

Mitral Regurgitation

The chronic mitral regurgitation (MR) has a long asymptomatic course, and usually symptoms appear after two decades of an ARF unless complicated by infective endocarditis or recurrent rheumatic fever.[12] The most common symptom of chronic MR is exertional fatigue due to low effectual cardiac output. However, acute MR causes a sudden increase in LA pressure and pulmonary venous hypertension, which requires treatment with afterload reducing agents and urgent surgical intervention. The mild to moderate degree of MR requires an annual follow-up with echocardiography to assess the progression of the disease, whereas the management of chronic severe MR is done based on the patient's symptom status. The drugs like beta-blockers and renin-angiotensin system blockers are recommended only once left ventricular dysfunction ensues, and their role in mild to moderate MR is controversial. The indications of surgical interventions in chronic severe mitral regurgitation are following:[12]

- Presence of symptoms with LVEF >30% [Class 1]
- Asymptomatic chronic severe MR with LVESD (left ventricular end-systolic diameter) ≥40 mm and or LVEF ≤60% [Class 2a]
- Asymptomatic chronic severe MR with either new-onset atrial fibrillation and/or pulmonary hypertension with pulmonary artery systolic pressure >50 mm Hg [Class 2a]

The decision to replace or repair the valve is of critical importance. Although repair is better than replacement, it maintains "annular-chordal-papillary muscle continuity" and prevents LV remodeling; however, it requires a steep learning curve. Furthermore, the repair is less successful in older patients with rigid, calcified and deformed valves due to RHD.[12] Furthermore, in countries with poor resources like India, where re-do surgeries are seldom performed, valve replacement is often the preferred option compared with valve repair, despite the possible consequences associated with prosthetic valves in the presence of inadequate INR monitoring and irregular warfarin supplies. The repair of primary degenerative MR is most often successful in

- Children's and adolescents with pliable valves
- Adults with MR secondary to MVP
- Cases of annular dilatation, chordal rupture, and leaflet perforation secondary to infective endocarditis.[12]

Aortic Stenosis

Unlike degenerative aortic stenosis (AS), isolated rheumatic AS occurs rarely.[3] The cardinal symptoms of AS are exertional angina, exertional dyspnea, syncope, and, ultimately, heart failure. Overall, the average survival without aortic valve replacement (AVR) is only 1–3 years after symptom onset.[12] Symptomatic AS is an indication for valve replacement. Patients undergoing concomitant surgery for other indication, and having associated moderate to severe AS should also undergo AVR. Patients with severe AS and left ventricular dysfunction and an EF (ejection fraction) of less than 50% can also be taken up for AVR. Patients with an abnormal response to stress testing should also undergo AVR. Aortic valve repair is not consistently possible with rheumatic AS, and replacement is needed. Over the last decade, transcatheter AVR (TAVR) has revolutionized the treatment of degenerative AS. However, the use of TAVR in RHD does not look promising, since AS in RHD seldom occurs as an isolated lesion and secondly because AS in RHD occurs at younger age compared with degenerative AS.[3]

Aortic Regurgitation

The isolated involvement of the aortic valve is rare and often accompanied by rheumatic mitral valve involvement.[3] There is a long latent period of the disease, and patients may only complain of uncomfortable awareness of heartbeat, especially on lying down. The exertional dyspnea and paroxysmal nocturnal dyspnea are only noticed when there is an onset of LV dysfunction or simultaneous mitral valve involvement. The mild to moderate degree of AR requires to follow-up by echocardiography, whereas severe AR requires treatment with renin-angiotensin system inhibitors to decrease the regurgitant fraction of AR and beta-blockers and diuretics in case of LV dysfunction.[12] The indications of AVR are following:

- Severe symptomatic AR [Class 1]
- Severe asymptomatic AR with LVEF <50% [Class 1]
- Severe asymptomatic AR with other cardiac surgery [Class 1]
- Severe asymptomatic AR with LVEF >50% with LVESD (LV end-systolic dimensions) >50 mm [Class 2a]

TABLE 4 Major highlights and implications from the HP-RHD (Himachal Pradesh Rheumatic Heart Disease) Registry[1] and the REMEDY registry[14]

	HP-RHD registry	*REMEDY registry*	*Implications*
Study population	2,005 patients (All Indian patients from the state of Himachal Pradesh)	3,343 patients (293 patients were Indians). This comparison includes patients from low-middle income countries (n=1,370)	Two of the largest contemporary data involving RHD patients
Age	Mean age = 40.3±14.3 years	Median age = 28 years	RHD involves young people mostly in their reproductive age groups
Female sex	72.3%	63%	High number of young women in childbearing age is a major concern
Schooling up to primary level only	40.4%	27.4%	A low level of education and socioeconomic status is often associated with RHD
Past history of ARF	25.1%	44.3%	Past history of ARF is elicitable in less than half of the patients. Therefore, the diagnosis relies more on detailed clinical and echocardiographic criteria and less on the past history of ARF
CHF PAH AF Stroke Peripheral embolism	15.7% 30.5% 24.4% 3.9% 4.1%	21% 34.2% 22% 3.8% 0.2%	High incidence of complications occurs before the patients seek medical care. This is mainly due to lack of awareness and early diagnosis
Multivalvular heart disease Moderate to severe valvular involvement	43.2% 69.3%	NA 63.9%	Majority of patients develop severe and multivalvular disease before they first seek tertiary level care
Use of secondary prophylaxis	28.5%	59.7%	Grossly inadequate use of secondary prophylaxis, probably the reason for high recurrence and prevalence of RF/RHD
Use of OAC in high risk patients	77.8%	69.5%	Inadequate use of OAC probably the reason for high rates of stroke and cardio-embolism
Use of valvuloplasty Use of valve surgery	16% 9.7%	4% 28%	Higher rates of surgical/percutaneous interventions are needed to decrease the morbidity and mortality

AF, atrial fibrillation; ARF, acute rheumatic fever; CHF, congestive heart failure; OAC, oral anticoagulant; PAH, pulmonary artery hypertension; RHD, rheumatic heart disease.

- Severe asymptomatic AR with LVEDD (LV end-diastolic dimensions) >65 mm [Class 2b]

If AVR is needed for stenosis or regurgitation, concurrent aortic root replacement is recommended if a maximum aortic dimension exceeds 45 mm.

Management of Tricuspid Valve Disease

The involvement of the tricuspid valve in RHD is most common due to PAH secondary to left-sided valve lesions (hypertensive tricuspid regurgitation). It has been increasingly recognized that the concept that "correcting

the left-sided lesion" will restore the tricuspid competence in hypertensive tricuspid regurgitation (TR) is not always true since, in the majority of patients, TR recurs in short/medium term follow-up and usually requires another intervention. Therefore, it is recommended to do tricuspid annulus repair using various annuloplasty techniques among patients undergoing left valve surgery[12] in the presence of:

- Severe TR
- Mild to moderate TR with annular dimensions >40 mm or 21 mm/m^2

Patients with normotensive TR (without PAH), organic tricuspid valve disease, and associated with tricuspid stenosis need to have their valves repaired or replacement (if repair not possible) preferably with a bioprosthetic valve. Patients with organic tricuspid stenosis and right heart failure should undergo tricuspid valvotomy at the time of their surgery. Isolated tricuspid stenosis should undergo balloon valvotomy if feasible.[3]

Current Situation in India

The available data suggests that the major reasons for high morbidity and mortality associated with RF/RHD include inadequate adherence to secondary prophylaxis, insufficient use and monitoring of oral anticoagulant therapy, and the limited access to surgical/percutaneous interventions.[1] Despite being home to 40% of the world's RHD burden, there are limited contemporary Indian data on

- RF/RHD mortality
- Complications of RHD (atrial fibrillation, cardio-embolism, heart failure, infective endocarditis, pregnancy morbidity)
- Treatment practices
- Long-term outcomes among RF/RHD patients.[1,2]

This is hugely disappointing since there is enough evidence that the existing preventive and therapeutic strategies can decrease the morbidity and mortality secondary to RHD. The focus of cardiovascular research has unfortunately shifted from RHD to coronary artery disease, despite India losing more than 100,000 patients to RHD every year.[4] The HP-RHD registry provides the most extensive published contemporary Indian data on the clinical characteristics, treatment practices, and outcomes in patients with RHD.[1] The other significant contemporary data comes from the REMEDY registry which included RHD patients from 25 hospitals across 12 African Countries, India, and Yemen.[14] Indian patients constituted 8.8% (293 patients) of the study population in REMEDY registry. The salient features of both the registries have been highlighted in the **Table 4**.[1,14]

Conclusion

Despite being one of the major causes of cardiovascular morbidity and mortality in low- and middle-income countries like India, RHD is often neglected cardiovascular disease, which causes significant morbidity and mortality. It primarily affects young patients in their most prime and reproductive ages. Although strategies for preventing RHD are proven, simple, cheap, and cost-effective, they are, unfortunately, adequately implemented. Furthermore, there is a gross inadequacy of data, especially from the worst affected regions. Percutaneous and surgical valve interventions are not available to the majority of the patients. There is a gross inadequacy in the availability and use of optimal preventive and therapeutic drugs and strategies. Patients are often not detected early and usually present to tertiary care centers when their disease is advanced and severe. The reasons for ARF and RHD remaining a burning problem in India are poor socioeconomic conditions, lack of hygiene and awareness, inadequate use of secondary prophylaxis, lack of vaccine, and absence of a national program to control RF/RHD in our country. These issues need to be addressed along with the encouragement of RF/RHD related research to make informed policies and programs to make India "RF/RHD free."

CHAPTER

29 Role of Stress ECG in Preoperative Evaluation for Non-Cardiac Surgery

Neelima Singh, Sushma Trikha

Abstract

Acute coronary events lead to high risk period from few weeks to months before performing non-cardiac surgery. Exercise Stress test helps to estimate functional capacity and has prognostic implications. The aim of this review is to offer an approach in the preoperative evaluation of patients undergoing non-cardiac surgery and to stress the importance and indications of stress testing in patients with heart diseases.

Introduction

Perioperative cardiac mortality and morbidity are increased in adults and elderly population undergoing major surgery. Preoperative evaluation provides assessment of both short-term and long-term cardiac risks in addition to evaluation of current medical status. Acute coronary events lead to a high-risk period from few weeks to months before performing non-cardiac surgery.[1]

Multidisciplinary team should ideally be involved for assessing perioperative cardiac risks.[2] Cardiac stress testing is an important tool for diagnosis and management of patients with known or suspected heart disease. While stress testing can be performed in many ways, the most commonly used stress testing modalities are exercise electrocardiography (TMT non-imaging) and exercise or pharmacologic stress test combined with imaging [stress echocardiography or stress radionuclide myocardial perfusion imaging (MPI)].

The aim of this review is to offer an approach in the assessment of patients undergoing non cardiac surgery and stress the importance and indications of stress testing in preoperative patients with heart disease.

Cardiac Stress Tests (Stress ECG) for those who can Exercise

Stress Testing (TMT)

It is a simple and widely available tool. For those who can exercise. Noninvasive tests, Exercise stress test, Tread Mill Test (TMT) also called Stress ECG or Exercise ECG is a preferred component of stress testing in most patients.

Exercise capacity is a very important determinant of prognosis particularly in elderly. The ability to achieve 4 METs (metabolic equivalent of tasks) of activity without symptoms is thought to be a good prognostic indicator.

The onset of myocardial ischemic response at low exercise is associated with increased risk of perioperative and long-term cardiac events. In contrast, myocardial ischemia at high workload is associated with only a minor risk increase.

With normal baseline ECG, an exercise ECG test is able to produce a reliable and reproducible result almost comparable to Technetium 99m sestamibi perfusion—imaging.

Exercise ECG test is economical with reliable disease interpretation.[3] Stress testing is not a routine test for

preoperative patient. However, some clinicians prefer preoperative stress imaging in patients who are scheduled for major vascular surgery.

Exercise Stress Echocardiography

It is usually advised in patients scheduled for intermediate or high-risk surgical procedure. The choice of stress testing modality depends on many factors, including ability to perform adequate exercise.

Cardiac Stress Tests for those who cannot Exercise

- Stress echocardiography
- Myocardial perfusion studies

In patients with indications for stress testing who are unable to exercise, pharmacological stress testing with either DSE (Dobutamine Stress Echo) or MPI (Myocardial Perfusion Studies) may be appropriate. Intravenous dipyridamole and adenosine should be avoided in patients with heart block, bronchospasm, critical carotid occlusive disease.

Dobutamine should be avoided in patients with serious arrhythmias or severe hypertension. All stress agents should be avoided in unstable patients.[4] Imaging stress testing is generally not recommended before low-risk surgery.[5]

Stress Echocardiography

Stress echocardiography is 2D echocardiography with a physical, pharmacological, or electrical stress. Stress echocardiography is today the most cost-effective and risk-effective imaging technique for diagnosis of coronary artery disease.[6] Other advantages are low cost, wide availability, and lack of radiation exposure.[7]

Objectives of exercise stress echocardiography are diagnosis of CAD, assessment of residual myocardial ischemia after a revascularization and relationship with chest symptoms on exertion.[8]

Cardiac magnetic resonance perfusion stress testing may be appropriate for the testing patients with intermediate probability of coronary artery disease.[9]

Myocardial Perfusion Studies

Often called nuclear stress test is a noninvasive imaging technique that examines perfusion of heart muscles during exercise or at rest. There are two techniques for MPI, single-photon emission computerized tomography (SPECT), and positron emission tomography (PET).

Cardiac Nuclear Stress Test

Stress/Rest MPI uses PET or SPECT imaging of patient's heart before and after exercise to determine the effect of physical stress on blood flow through coronary arteries. MPI is the most appropriate test for diagnosing coronary artery disease early in patients at risk for MI. It also offers improved diagnostic accuracy over exercise. TMT, myocardial perfusion studies can be done in combination with exercise or with a pharmacologically induced stressor. Once the target heart rate is reached, the radionuclide is injected intravenously. The difference in the uptake of the radionuclide is then assessed either by SPECT or PET. Myocardial perfusion study can detect areas of ischemia or myocardial infarction.

Normal heart will have a normal uptake of radiotracer and a rapid wash-out time. Ischemic areas or reversible lesions will have a slow uptake of tracer, as well as a prolonged wash-out time. An infarcted region will not take up the tracer either at rest or during stress.[10]

Systematic Approach for Preoperative Evaluation

Issues Related to Cardiac Evaluation

- What are the underlying cardiac risk factors?
- Will such evaluation change the management plan of the patient?
- Will it postpone surgery?
- What will be the management in the postoperative period?

Determine the Cardiac Risk Factors

Valvular Heart Disease: Patient with severe aortic stenosis due to fixed cardiac output do not tolerate either spinal or general anesthesia because of associated vasodilatation. Patients having moderate to severe mitral stenosis do not tolerate surgery well. Patients with aortic and mitral regurgitation having preserved left ventricular function are less likely to have an adverse cardiac event.

Congestive Heart Failure: Preoperative congestive heart failure (CHF) increases the risk of pulmonary edema from

3% in New York Heart Association (NYHA) Class 1–25% in patients with NYHA Class IV CHF. Elective surgery should be deferred for at least a week after the signs of heart failure have settled.

Arrhythmias: Patients with arrhythmias may not tolerate surgery well. In supraventricular arrhythmias, rate needs to be controlled prior to surgery. Patients with ventricular arrhythmias should be evaluated by a cardiologist prior to surgery. Those with first-degree heart block and Mobitz type I heart block may tolerate surgery well, while patients with Mobitz type II and third degree heart block might require intraoperative pacing.

Major Clinical Predictor of Cardiac Risks: They include decompensated heart failure, acute coronary syndrome, arrhythmias, and severe valvular heart disease.

Intermediate Clinical Predictor of Cardiac Risks: Angina, heart failure, history of myocardial infarction, diabetes mellitus, and renal insufficiency.

Minor Clinical Predictor of Cardiac Risks: Advanced age, ECG changes, reduced functional capacity, history of cardiovascular accident, high blood pressure.

Revised Cardiac Risk Index (RCRI): For assessing preoperative cardiac risks—two models are often used. The RCRI is also called Lee index or the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) risk model. The RCRI is simple and has been widely used. The NSQIP calculator is more complex.

Evaluation of Surgical Patients and Different Categories of Surgery

Evaluation starts with history taking and clinical examination. An essential skill is the identification of high-risk patients, whose pre-existing condition need to be optimized prior to surgery.

Emergent Surgery—Where little or no time for clinical evaluation, e.g., life saving limb surgery.

Urgent Surgery—Limited time for clinical assessment prior to life saving or limb saving procedure (6–24) hours.

Time sensitive Surgery—A delay of 1–6 weeks is acceptable, e.g., oncologic surgeries.

Elective Surgery—Procedure were delay up to 1 year is acceptable.

Surgeries on the Basis of Risk

High Risk Surgeries: The American Society of Anesthesiologist (ASA) have stratified the surgical risk based on patient's functional state, comorbid diseases, and urgency of surgery.

High cardiac risks surgeries include emergency surgeries which are major in elderly, aortic and vascular surgeries, and peripheral arterial procedures.[11]

Intermediate Risk Surgeries: They include head and neck surgery, carotid endarterectomy, abdominal surgery, intrathoracic surgeries, prostate surgery, and orthopedic surgery.[11]

Low Risk Surgeries: They include endoscopic procedures, breast surgery, cataract surgeries, and superficial procedures.[11]

Functional Status

Energy expenditures for following activities such as eating, dressing, walking around the house, and dishwashing range from 1 to 4 METs, scrubbing floors, climbing a flight of stairs, running a short distance, walking on level ground at 6.4 km per hour represents 4–10 METs.

Strenuous sports such as singles tennis and football often exceed 10 METs. Every operation elicits a stress response triggered by tissue injury. Surgery also causes change in balance between prothrombotic and fibrinolytic factors leading to increased thrombogenicity.

The mortality rate overall of all surgeries is 0.3%. The mortality rate is less than 1% for major surgical procedures in patients younger than 65 years, but 5% for patients between 65 and 80 years. The incidence of myocardial infarction in postoperative general surgery patients over 50 years is 0.7%, and is 3.1% in those undergoing vascular surgery.

Death in the first 48 hours in the postoperative period is mainly due to cardiac causes, while death between 48 hours and 6 weeks is often due to pneumonia, sepsis, pulmonary embolism, renal failure.

Stress testing is not a routine test for pre operative patient. However, some experts routinely obtain preoperative stress imaging in patients who are scheduled for major vascular surgery.

Stepwise Approach

Step 1: Decide the Urgency of Surgery

In emergent situation, where little or no time for clinical assessment proceed directly to surgery. If surgery is not urgent proceed to Step 2.

Step 2: Assess for Unstable Cardiac Condition

If high cardiac risk predictors, e.g., acute coronary syndrome or MI, CCF, etc., present, cardiological evaluation is required. In unstable cardiac condition, patients can proceed for coronary artery intervention in addition to dual-antiplatelet therapy if the surgical procedure can be postponed, or may go directly for surgery if delay is impossible. If there is no unstable cardiac condition proceed to Step 3.

Step 3: In Cardiac Stable Patients Determine the Risk of Surgical

Procedure for (Major Adverse Cardiac Event (MACE) which includes MI or death).

For Low Risk Procedure: Proceed to surgery. In patients with ischemic heart disease low dose beta-blocker may be advised before surgery. In patients with heart failure ACE inhibitors should be given before surgeries.

For intermediate or high risk procedure assess functional capacity of the patient proceed to Step 4.

Step 4: Assess Functional Capacity of the Patient

If patient's functional capacity is good or more than 4 METs, in intermediate risk surgeries with one or more risk factors, it is appropriate to go for surgery. If the functional capacity is less than 4 METS proceed to Step 5.

Step 5: Consider the Risk of Surgical Procedure

Intermediate Risk Surgeries: Noninvasive stress testing may be considered in those with one or more risk factors. These patients can be taken for surgery. Baseline ECG is required to monitor changes during surgical procedure.

High Risk Surgeries: Assess RCRI.

Proceed to Step 6.

Step 6: Assess Revised Cardiac Risk Index (RCRI)

- Ischemic Heart Disease like previous MI or angina
- Heart failure
- Stroke or TIA
- Renal dysfunction serum creatinine 2 mg/dL or above
- Diabetes mellitus requiring insulin therapy.

If two risk factors and patient scheduled for high risk surgery consider non invasive testing. If three risk factors proceed to Step 7.

Step 7: Consider Noninvasive Testing

If no, mild, or moderate stress induced ischemia proceed with planned surgery. If extensive stress induced ischemia is present, an individualized perioperative management is indicated considering the potential benefit of the recommended surgical procedure compared with the predicted adverse outcome, and the effect of conservative management and/or coronary revascularization.

When to Perform Stress Tests in Preoperative Cases

Noninvasive (stress test) is indicated in those with major clinical predictors, or those with intermediate clinical predictors and poor functional capacity (4 METs) scheduled for high surgical risk procedures.

OR, in cases with minor clinical predictors and poor functional capacity undergoing high risk procedure.

Conclusion

Clinical risk factors should form the basis of risk assessment. Exercise stress test helps to estimate functional capacity and has prognostic implications. Thus, cardiac stress testing can be a valuable tool in determining whether a patient can safely proceed to surgery or a further consultation with cardiologist is needed before proceeding with intermediate or high risk surgery.

Acute coronary events, like new onset ischemia, infarction, or revascularization, lead to a high-risk period of 6 weeks, and an intermediate-risk period of 3 months before performing non-cardiac surgery.

CHAPTER

30 Screening for Atrial Fibrillation for Stroke Prevention: Clinical Perspective

SB Gupta

Abstract

Atrial fibrillation, an important risk factor for stroke, is quiet prevalent in general population, especially in the elderly group. It remains silent, therefore remains undiagnosed and not treated adequately. Screening general population for silent atrial fibrillation is not feasible because of cost constraints and treating all silent atrial fibrillation patients may cause more harm than benefits. However, identifying atrial fibrillation in high-risk individuals and elderly population is a viable option. Various screening tools are available and proper utilization of such assets is the key to success.

Introduction

Atrial fibrillation (AF) is the most common type of cardiac arrhythmia and affects 1–4% of the general population and is important risk factor for stroke.[1] Prevalence of AF is predicted to double over the next 30 years and is associated with a fivefold increased risk of ischemic stroke.[2] People with ischemic stroke, approximately one-third die within a year and approximately one-third of the survivors have some type of permanent disability.[3] Prevalence of AF keeps on rising as age advances and is about 3% in men and 2% in women of age 65–69 years and is about 10% of adults of age 85 years or above **(Fig. 1)**. Unfortunately, AF is diagnosed in 20% of the cases of ischemic stroke at the first presentation of stroke.[4]

Further, if AF detected early and treated with anticoagulants in eligible patients, the risk of stroke is reduced by around 65%. Unfortunately, AF in many people goes undetected and therefore untreated because either such patients are asymptomatic or have paroxysmal AF.[2]

Screening is logical one such approach to detect AF early and thereby initiating anticoagulant therapy early to reduce the incidence of ischemic stroke. However, the current recommendations of various international task forces are against mass screening, mainly because of the cost implications and the uncertainty of the benefits of the systematic screening vis-à-vis usual care.[2] US Preventive Services Task Force (USPSTF) in their latest recommendations have concluded that the current evidence is insufficient to assess the balance of benefits and harms of screening for AF with ECG.[4] In high-risk individuals, screening has been recommended as the strategy to detect AF early and start anticoagulant therapy at the earliest. European Society of Cardiology (ESC) and National Institute for Health and Care Excellence (NICE) have recommended the screening for AF by opportunistic pulse palpation and/or electrocardiogram in all patients above the age of 65 years and who have symptoms suggestive of AF, respectively,[5,6] based on the landmark SAFE trial, showing 60% improvement in AF detection compared to routine care over a period of 12 months.[7]

Currently, AF remains undiagnosed in a vast population and, if detected, at least 75% of such individuals will be eligible for anticoagulation. In general population above the age of 65 years, systematic review of AF screening found the incidence of 1.4% of previously undiagnosed AF.[8]

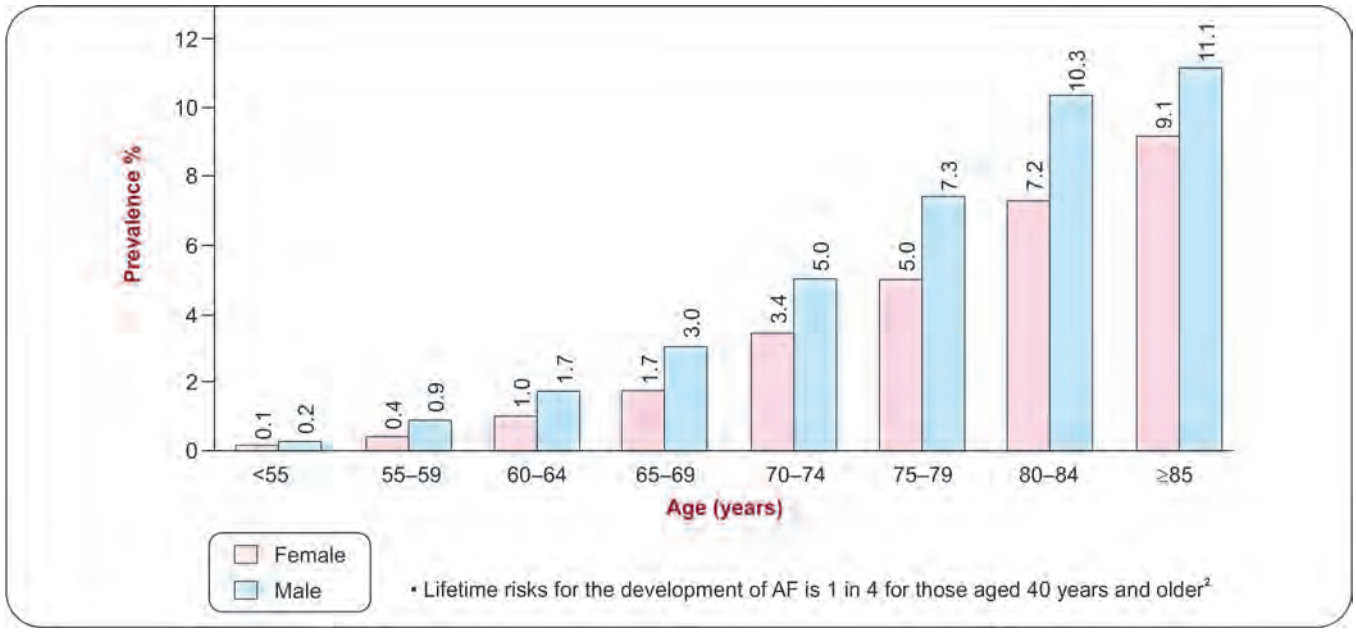

Fig. 1: Increasing incidence of AF as age advances

Repeat serial ECGs over 2 weeks improved the detection rates by fourfold.[9] Detection rate of asymptomatic AF may go up to 50% if patients having pacemakers or implantable cardiac devices where prolonged ECG monitoring happens **(Fig. 2)**. Detection of asymptomatic AF depends upon the definition of AF and duration of screening. 2,455 participants aged more than 65 years in the ASSERT study who have received either a dual-chamber pacemaker or internal cardioverter-defibrillator (ICD) with no prior history of AF showed asymptomatic AF in 18.8% when followed up for 2.5 years and in 11% of the patients had an episode of AF lasting for more than 24 hours in a 3-year follow-up **(Fig. 3)**.[10]

Patients with asymptomatic AF compared with no AF, showed 2.5-fold increased risk of stroke or systemic thromboembolism over a mean of 2.5 years follow-up.[10] There appears no doubt that asymptomatic AF carry increased stroke and mortality risk as compared to the persons having sinus rhythm. But whether the risk will be higher in the persons with silent AF, detected on screening in the general population, remains to be seen.

As compared to sustained AF, approximately 25% of the people have paroxysmal AF[11] and persons with persistent and permanent AF are at higher risk of thromboembolism and all-cause mortality as compared to the persons with paroxysmal AF.[12] In the ASSERT study, a significant increased risk of stroke and thromboembolism was noted in persons with asymptomatic AF of more than 24 hours duration as compared to those without AF and there was no increased risk with asymptomatic AF of less than 24 hours.[10]

Currently, if AF lasts for more than 30 seconds, the diagnosis of AF is established. And if treatment guidelines for treating AF will be followed, then people with low burden of AF will be put on anticoagulants[13] and under these circumstances, then the bleeding risk from anticoagulants will outweigh stroke risk reduction.

AF is not only linked to higher risk for ischemic stroke, but also for the cognitive decline. One such study from Korea, of 10,435 people diagnosed with AF, showed that anticoagulation was associated with a 39% reduction in the incidence of dementia.[14]

Screening Tools

A range of electronic devices are available to screen for AF. And the detection rate of silent AF improves as the duration of screening increases.

Following is the list of devices currently available:

- ECG
- Serial ECGs
- Holter monitoring (24–72 hours)
- Patch ECG monitors (external loop recorders)

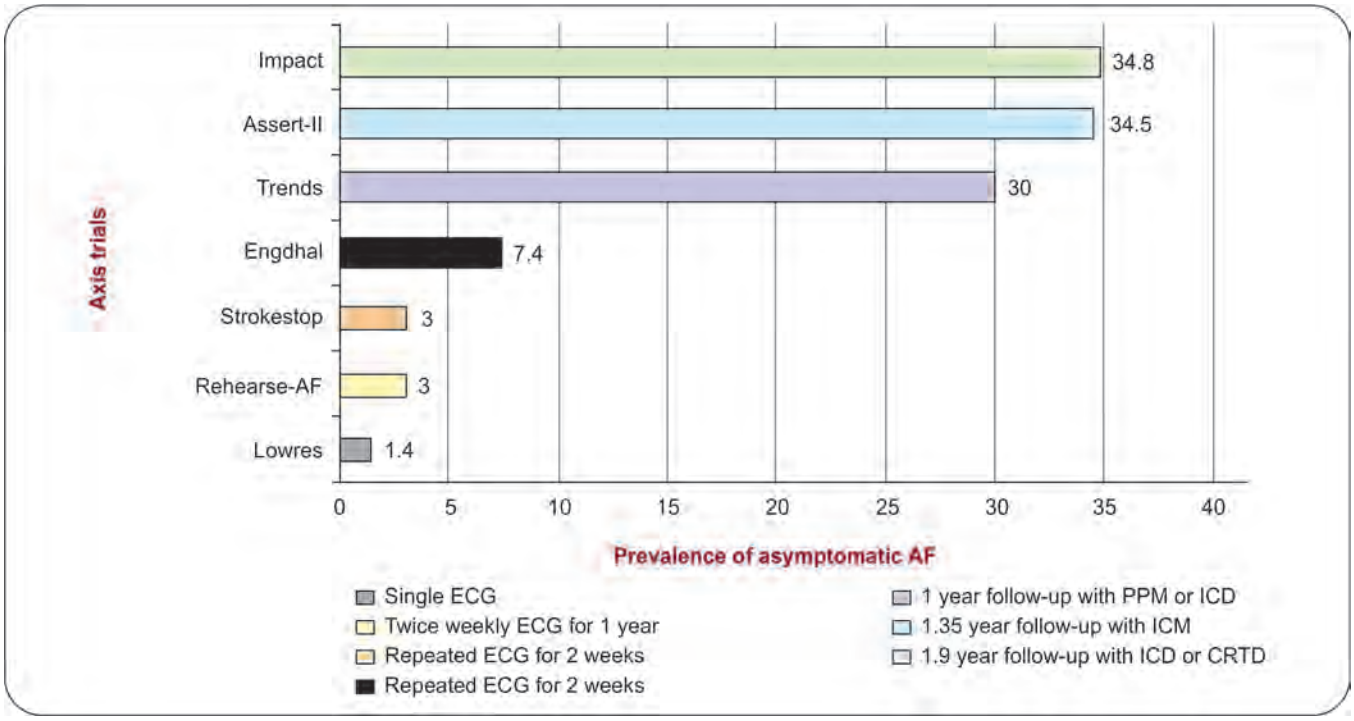

Fig. 2: Prevalence of asymptomatic atrial fibrillation by screening method and stroke risk score

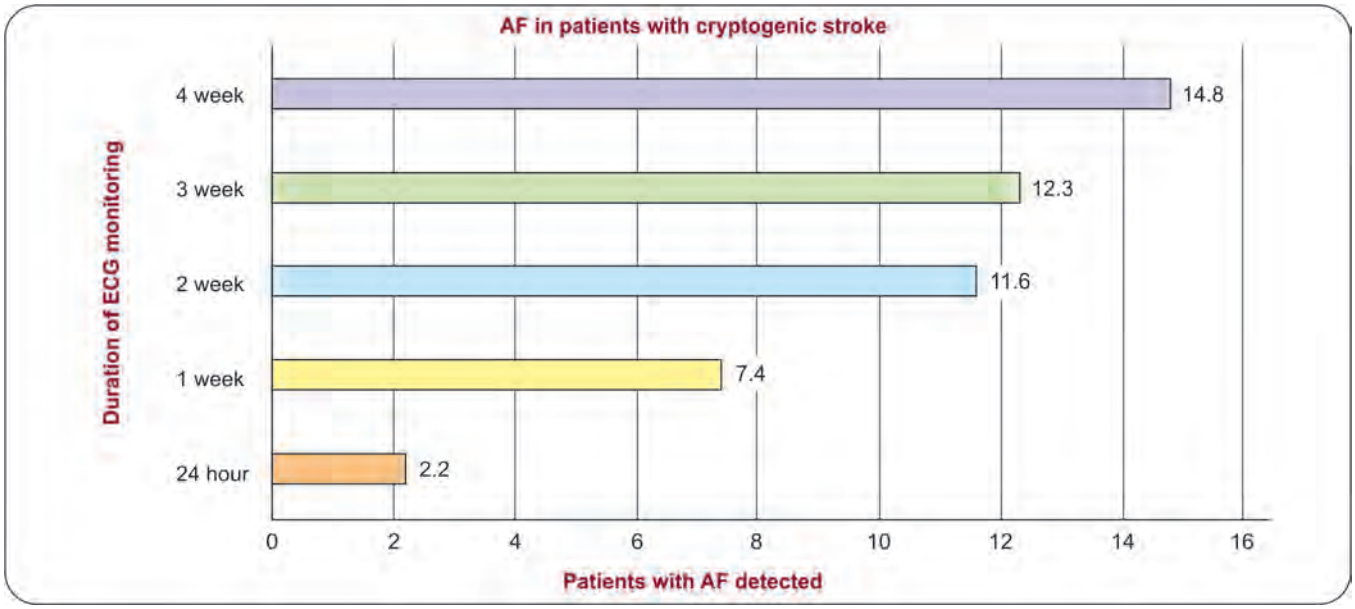

Fig. 3: Atrial fibrillation in patients with cryptogenic stroke

- Implantable cardiac loop recorder
- Pacemakers/ICDs
- Smartphone compatible ECG recorder
- Hand-held devices
- BP monitors
- Apple watch

mHealth devices have been categorized into the following three groups:

- App based, using Smartphone or tablet app, either by direct or indirect photoplethysmography (PPG). "Cardio Rhythm" is one of the most common Smartphone apps.
- "Wrist-Worn Wearables" like Apple Watch or HUAWEI Band 2.
- Hand-held devices like "AliveCor"

mHealth devices are convenient and have a high accuracy. However, after detection of AF by such devices, AF needs to be confirmed by standard 12-lead ECG Holter monitoring.[15]

Smartphones and smart watches have the sensitivity and specificity of above 90% for detection of AF.[16,17] Recently, the data of Apple Watch study, of nearly 420,000 people with no prior history of AF or on current anticoagulation was presented. Approximately 3% of the people above the age of 65 years received irregular pulse notification. The people who received the notification were advised to wear an ECG patch, 450 participants wore the patch and returned. Of which, 153 (34%) had AF detected showing the positive predictive value of 84% for irregular pulse notification.[18]

However, there are no randomized studies to compare the harm of systematic screening to no screening, but potential harms do exist from population screening.[19] Screening method which may have 95% specificity for AF diagnosis, can result in 50,000 false positive cases per million screened.[20] Unnecessary investigations, anxiety related to health, and the increased bleeding risk because of guideline directed anticoagulant therapy are the potential hazards. Further, cost-effectiveness by systematic population screening programs is always an area of big concern, hence systematic opportunistic screening has been recommended as the best strategy as on date.[7] All over the world, it has been noticed that anticoagulation has always remained suboptimal in large numbers of cases. The Risk-Stroke registry, having 94,000 people who suffered ischemic stroke, with over 22% AF population, only 16% received anticoagulation, 6 months prior to their stroke.[21] Cost-effectiveness of anticoagulation vis-à-vis economic impact of suboptimal anticoagulation in reducing stroke risk is burning issue and will be the area of future research. Changes in the stroke rates, major bleeding, and mortality are the areas of interest in the upcoming studies which are duly powered.[22]

Obesity, physical inactivity, and hypertension are preventable risk factors and control of hypertension and life style modification shall be advised regarding maintaining ideal body weight and doing regular exercise in general.

A large number of uncertainties have been pointed out and remain to be sorted:[2]

- Prevalence of undiagnosed AF.
- Which population to screen and how to screen?
- Stroke risk for people with AF detected via screening.
- Is screening the most effective way to reduce AF stroke incidence?
- What burden of AF is associated with significant stroke risk?
- Duration and frequency of screening
- Which screening device?
- What are the harms of screening?

Several ongoing trials, STROKESTOP, SCREEN-AF, IDEAL-MD, and D_2AF, in future will definitely be enlightening the physicians to deal with the issue of screening for asymptomatic AF and then the treatment strategy.

Conclusion

Atrial fibrillation is quiet a common arrhythmia and asymptomatic AF (subclinical AF) is also common and both AF and subclinical AF (SCAF) remain important risk factor for stroke and other thromboembolic complications and are growing health problem. Highly specific treatment strategies like anticoagulants are available, which can reduce this risk. Need to identify and treat SCAF to reduce the stroke risk and subsequent disability and death is logical, but with so many uncertainties, currently systemic population screening is not recommended. However, systematic opportunistic screening and screening of high-risk individuals need to be done. Large scale randomized trials are needed to understand the evidence gaps and cost-effective strategies to address SCAF management.

CHAPTER

31 Prevention of CVD in Diabetes: Taming the Dragon

Prabhash Chand Manoria, Pankaj Manoria, Sharad Kumar Parashar

Abstract

With better control of infective and metabolic complications, diabetes has become a cardiovascular disease (CVD). About 52–80% of diabetics die because of CVD and acute myocardial infarction accounts for 70% of deaths. The conventional anti-diabetic medications do not provide cardiovascular risk reduction but the two new block busters GLP-1 RAs and SGLT2 inhibitors are powered to improve cardiovascular and renal outcomes. The GLP-1 RA decreases atherosclerotic cardiovascular disease (ASCVD) but has no impact on heart failure. The SGLT2 inhibitors improve heart failure and renal outcomes. Besides this attention should be focused on lipid control with statins, ezetimibe, PCSK9 inhibitors, icosapent ethyl, etc., tight BP control, antiplatelet drugs in patients with high ASCVD risk, cessation of smoking, bariatric procedures, and lifestyle modification. A multipronged approach must be followed and this provides improvement in the outcomes on a long-term basis as shown STENO-2 trial and its extension follow-up.

Introduction

Diabetes is a den of cardiovascular disease (CVD). Globally, CVD occurs 10–15 years earlier in diabetics, is two times more common than non diabetics and a major chunk of diabetics succumb to CVD mainly acute myocardial infarction. Cardiovascular risk reduction (CVRR) is therefore of paramount importance and we are running a race against CVD for several decades. The conventional anti-diabetic agents do not provide CVRR but the two new anti-diabetic medications sodium-glucose cotransporter-2 (SGLT2) inhibitors and glucagon-like peptide-1 receptor agonist (GLP-1 RA) has shown improved CV outcomes in several dedicated trials. Both these new antidiabetic medications are hitting the headlines in all current guidelines for diabetes. CVD in diabetes requires a multipronged approach targeting all risk factors like blood pressure, lipids, smoking cessation, weight management, lifestyle modification coupled with good and sustained glycemic control from early stage of the disease also utilizing the new antidiabetic medications.

New Antidiabetic Medications and Cardiovascular Risk Reduction

The conventional antidiabetic medications only provide glycemic control and do not offer cardiac protection. Among the new antidiabetic medications SGLT2 inhibitors and GLP-1 receptor agonist have shown cardiorenal protection in various cardiovascular outcome trials (CVOTs).

SGLT2 Inhibitors

These drugs are very useful in providing benefit to patients of heart failure (HF). They have been used in several subsets of patients.

High CV Risk Patients at Risk of Heart Failure

The three landmark trials EMPA-REG, CANVAS, and DECLARE TIMI-58 have shown decreased hospitalization for HF in patients at high risk both in the primary prevention group and in patients with preexisting CVD

(EMAPREG OUTCOME trial). The EMPAREG OUTCOME trial carried out in patients with preexisting CVD also showed decrease in cardiovascular mortality and all cause mortality. This was also shown in the subgroup analysis in patients with preexisting CVD in the CANVAS and the DECLARE TIMI-58.

Heart Failure with Reduced Ejection Fraction (HFrEF)

The DAPA HF trial[1] conducted in patients of HFrEF has shown improved CV outcomes. Patients with symptomatic HFrEF LVEF <40%, mean age 66 years, both diabetic (45%) as well as non diabetics were randomized to dapagliflozin 10 mg daily (n=2,373) versus placebo (n=2,371) with a follow-up 18.2 months. The N-terminal pro–B-type natriuretic peptide was ≥600 pg/mL. The trial showed a relative risk reduction of 26% (hazard ratio [HR] 0.74; 95% confidence interval [CI] 0.65-0.85), p<0.001 in the composite primary end point of CV death *or hHF or an urgent HF visit*. The CV death was reduced by 18% (HR 0.82, CI 0.69-0.98, p=0.029) and worsening HF component decreased by 30% (HR 0.70, CI 0.59-0.83, p=0.00003). The primary outcome was same in diabetic subset (HR 0.75, CI 0.63-0.90) compared to non-diabetic subset (HR 0.73, CI 0.60-0.88). Dapagliflozin also produced benefit on top of ARNI (HR 0.75, CI 0.50-1.13, without ARNI HR 0.74, CI 0.65-0.86), which was utilized in about 11% of patients in the trial. Several other trials with these agents in HFrEF are ongoing like EMPEROR-R and EMPIRE HF, CANDLE, etc.

Several trials of SGLT2 inhibitors are also ongoing in the subset of HFpEF like DELIVER, PRESERVED HF, EMPERIOR-P, EMPERIAL-P, but none of them have been completed as yet.

Renoprotection with SGLT2 Inhibitors

All SGLT2 inhibitors have shown renoprotection. Canagliflozin was tested in the dedicated chronic kidney disease (CKD) trial CANVAS.[2] The trial was carried out in 4,401 patients with canagliflozin compared to placebo in patients of T2D and established CKD. Half of them were put on canagliflozin and the remainder served as control. The duration of follow-up was 2.62 years. The trial was prematurely terminated because of immense benefit. The primary end point was end stage, kidney disease, doubling of serum creatinine, renal, or CV death.

The DAPA CKD trial with dapagliflozin was carried out in diabetic as well non-diabetic subset and has been terminated prematurely because of immense benefit. The top line results show that both diabetic and non-diabetic patient benefited from it. The EMPA CKD trial with empaglflozin is ongoing.

GLP-1 RAs Trials

Of the six completed CVOTs with GLP-1 RAs, four trials have shown positive results, that is, LEADER,[3] SUSTAIN-6, HARMONY, and REWIND in terms of reduction of primary end point of atherosclerotic MACE, that is, cardiovascular death, non-fatal myocardial infarction and non-fatal stroke. The EXSCEL trial narrowly missed the primary end point while the ELIXA trial was negative.

The oral semaglutide was tested for its CV safety in a small trial in a dose 14 mg orally versus placebo. The trial was found to be non inferior in terms of atherosclerotic MACE. However, there was strong signal of reduction in cardiovascular death was by 51% (HR, 0.49; 95% CI, 0.27-0.92) and all cause mortality by 49% (HR, 0.1; 95% CI, 0.31-0.84). The oral semaglutide showed similar reduction in weight and HbA1c like the injectable semaglutide. The drug has been approved by FDA for treatment of diabetes and also going to be launched in India in near future. The CV OUTCOME trial SOUL with oral semaglutide is ongoing and is expected to complete by 2023/2024.

Lipid Control

Statins are the corner stone of treatment for diabetic dyslipidemia. All type 2 diabetics should be on moderate intensity statins. For high-risk patient the LDL-C goal is less than 70 mg/dL and he/she requires high intensity statins like atorva 80 mg or rosuva 40 gm. For the very high-risk patient the LDL-C goal is less than 55 mg/dL. If the goal is not achieved with high intensity statins than ezetimbe 10 mg/day can be added. If still the goal are not achieved PCSK9 inhibitors should be utilized. Bempedoic acid is not yet available in India but this can also be tried prior to initiation of PCSK9 inhibitors.

PCSK9 Inhibition

Monoclonal antibodies to PCSK9 have been tried in two CV OUTCOME trials.[4,5] The PCSK9 inhibitors produce an additional reduction of LDL-C by 40–60%, LP(a) is reduced by approximately 25% and other lipoprotein are also favorable altered. Both these molecules have been

approved for clinical use. Evolocumab is commercially available in India.

Evolocumab

This molecule was evaluated in FOURIER trial,[4] which compared evolcoumab with placebo in 27,564 patients with ASCVD having an LDL-C of more than 70 mg/dL with a median follow-up 2.2 years. There was a 15% relative risk reduction in the primary end point of CV death, myocardial infarction, stroke, hospitalization for unstable angina, or coronary revascularization (HR, 0.85; 95% CI, 0.79-0.92; P<0.001).

In FOURIER study, LDL-C decreased from median base line value of 92 mg/dL to 30 mg/dL, i.e., approximately by 60% (P<0.001), 42% had LDL-C <25 mg/dL. Despite such low levels of LDL-C there was no evidence of muscle or liver toxicity, diabetogenecity or neurocognitive decline. The dedicated sub-study, EBBINGHAUS also confirmed lack of neurocognitive decline with its use. The only side effect which was more common with evolocumab was injection site reactions, 2.1% (evolocumab) versus 1.6% (placebo). The study therefore demonstrated incredible safety on top of statins. The benefit was seen across the range of LDL up to 20–25 mg/dL. All quartiles benefitted, highest as well as lowest. There was no J curve so lower is better is also validated for super low LDL-C. The FOURIER trial showed reduction in MI by 27% p≤0.001, stroke by 21%, p=0.01, and coronary revascularization by 22%, P≤0.001. There was no significant decrease in all cause or CV mortality.

It is available as 1 mL pen containing 140 mg. It is given in doses of 140 mg biweekly/420 mg monthly sc.

Alirocumab

The ODYSSEY OUTCOMES[5] alirocumab with placebo in post ACS patients 1–12 months after the acute event in 18,924 having LDL-C level of more than 70 mg/dL. The median duration of follow-up was 2.8 years. The composite primary end-point of ischemic event showed a relative risk reduction of 15% (hazard ratio, 0.85; 95% CI, (0.78-0.93; P<0.001). There was no statically significant decrease in CHD mortality or all cause of mortality. Patients with LDL-C >100 mg/dL benefited more and also showed decrease in all cause mortality.

This is approved for clinical use and is commercially available as 1 mL pen containing 75 mg, which is given every 2 weeks or 150 mg, which is given monthly.

BOX 1 Indications of PCSK9 inhibitors

- Failure to achieve LDL-C goals despite optimal doses of statins in patients with ASCVD
- Statin intolerance
- Familial hypercholesterolemia

The SPIRE 1 and 2 trial with bococizumab was prematurely terminated because of presence of neutralizing antibody in 29% and antidrug antibodies in 48% of patients taking the drug. This is because bococizumab is partially murine monoclonal antibody unlike evolocumab and alirocumab which are fully humanized monoclonal antibodies.

Although both SPIRE I and SPIRE II trials were prematurely terminated, the SPIRE II, which had LDL-C >100 mg/dL showed a reduction in CV events by 21% at 12 months hinting that the drug is also useful for primary prevention. The SPIRE I trial which enrolled cooperatively lower risk population (LDL-C >70) did not showed any benefit.

The current indications PCSK9 MoAbs are outline in **Box 1**.

Given the lack of long-term safety and efficacy data on these agents, they are not recommended for use for primary prevention except in patients with familial hypercholesterolemia. The data of PCSK9 for primary prevention like high-risk diabetics is yet to evolve out.

Role of Triglyceride (TG)

TG is commonly elevated in diabetes. All randomized trial of TG lowering with fibrates on top of statins has failed to show any CV benefit. The ACCORD LLA trial did not show benefit of fibrates on top of statins. The subgroup analysis of TG more 204 mg/dL and HDL-C <34 mg/dL has shown reduction in the CV events. This is hypothesis generating but is not yet tested in any randomized control trial. A meta-analysis of fibrates has shown benefit but all trials in this meta analysis were not done on top of statins. The REDUCE IT Trial[6] evaluated patients with established CVD or with diabetes and other risk factor who have been on statins with LDL-C levels of 41–100 mg/dL and TG levels were between 135 and 499 mg/dL. Icosapent ethyl 2 gm twice daily was compared with placebo over a period of 4.9 years and showed reduction of 25% in the composite primary end point of ischemic events (HR, 0.75; 95% CI,

0.68-0.83; P<0.001). Atrial fibrillation was more often seen with icosapent ethyl compared to placebo (3.1% vs. 2.1%, P=0.004). Serious bleeding was also observed in more number of patients with icosapent ethyl compared to placebo, 2.7 versus 2.1 (P=0.06). The trial was positive but subgroup analysis showed that the benefit was similar in groups with TG<150 mg/dL and >150 mg/dL indicating the mechanism of benefit is not related lowering of TG. Saroglitazar in dose of 4 mg/day has been used to treat hypertriglyceridemia, but there is no outcome data with it.

Newer Agents for Lipid Management

Besides PCSK9 inhibitors bempedoic acid is also approved for clinical use by US FDA and is likely to be available in our country in near future. It decrease LDL by 15–20% and is not associated with muscle toxicity. Inclisiran a small interfering RNA inhibits synthesis of PCSK9 and single injection of 300 mg decreases LDL-C levels by 50% and this remains there for 6 months. It is emerging as an important competitor for PCSK9 monoclonal antibodies but it is still undergoing evaluation. A single injection of PCSK9 vaccine decreases LDL-C by 50% which lasts for 12 months. If the human trial comes to out to be positive a yearly booster dose of this vaccine will be the new modality to target atherosclerotic cardiovascular disease (ASCVD).

Blood Pressure Control

The target for blood pressure control as per all current guideline is 130/80 mm Hg. RAAS blockers are the preferred agents but most of the diabetics in the long run require multiple drugs.

Antiplatelet Drugs

Currently antiplatelet drug are not recommended for primary prevention group unless the patient belongs to a very high risk group, that is, the 10-year ASCVD risk more than 10%. The three major trials released in 2018 have not shown any benefit in primary prevention of cardiovascular events.

Lifestyle Modification

All patients of diabetes must strictly adhere to lifestyle modification including cessation of smoking. The LOOK AHEAD Trial carried out with intensive lifestyle intervention, focused on weight loss, improved CV risk factors in T2D did not improve CV risk in T2D.

Bariatric Procedures

Bariatric surgery is recommended in obese diabetics and produces significant decrease in weight and blood glucose along with improvement in other concomitant risk factors. Currently great advances have been made in endoscopic bariatric procedure like intragastric balloon, endoscopic bypass, endoscopic gastroplasty, etc. The advantage of these procedures is that they are safe and have fewer complications than bariatric surgery.

Multipronged Approach

The STENO-2 trial[7] carried out a multipronged approach in T2DM patient and showed marked benefit in the long run. The composite endpoint of ischemic events decreased by 53% in this study and on follow-up after 5 year the benefit escalated to 59%. A 21-year follow-up of the trial showed a survival benefit of 7.9 years and CVD-free survival of 8.1 years.

Conclusion

Prevention of CVD in diabetes requires a multidisciplinary approach targeting all risk factors for ASCVD coupled with optimum glycemic control and increasing use of new antidiabetic medication like SGLT2 inhibitors and GLP-1 RA. Endoscopic bariatric procedures are also making their way in the treatment of obese diabetics and helps in CV risk reduction.

CHAPTER

32 Heart Failure 2021

Amal Kumar Banerjee

Abstract

As we progress into 2021, health-care delivery, particularly for heart failure patients, becomes even more complicated and challenging. However, this poses opportunities in the path of an uncertain future. There has been remarkable progress in the science and management of heart failure recently. A key emerging theme in the science and medicine of heart failure is the need to identify and target specific causes of heart failure, defined by phenotype or genotype, which will respond to a particular intervention. QRS duration (a marker of cardiac dyssynchrony), mitral regurgitation, iron deficiency, and amyloidosis each identifies patients that will respond to a specific intervention. Although the evidence base for the treatment of HFrEF has expanded substantially, much work remains for the other forms of HF. New therapies for HF with preserved EF are under exploration, and the evidence base addressing HF with improved EF is just emerging. Adherence to recommendations can be enhanced by shared decision-making between health-care providers and patients, with patient engagement in selecting interventions based on individual values, preferences, and associated conditions and comorbidities.

Introduction

Heart failure (HF) can be defined in several ways, viz., ischemic and nonischemic cardiomyopathy based on the underlying cause and to determine outcomes. Of late, genetic information has been employed to sub-classify different forms of nonischemic cardiomyopathy. Iatrogenic forms of HF have also been recognized in patients undergoing cancer therapy.

However, the simplest and most widely used classification is based on left ventricular ejection fraction (LVEF) and, notably, it provides important diagnostic and prognostic information.

The usual HF is a condition with reduced ejection fraction (HFrEF), but it has been noted that patients with near normal or normal ejection fraction could also present with symptoms of HF, and this is known as HF with preserved ejection fraction or HFpEF, which remains an enigma and a challenge for clinicians. In between there is a gap, and this has been filled in the recent ESC Guidelines on Acute and Chronic HF[1] with the introduction of a novel category, that is, HFmrEF or HF with mid-range ejection fraction. Possibly, mild HFrEF may be much more appropriate terminology than HFmrEF.

As we progress into 2021, health-care delivery, particularly for HF patients, becomes even more complicated and challenging. HF has recently undergone major changes, while HFrEF is declining due to effective revascularization of patients with acute coronary syndromes, the prevalence and incidence of HFpEF, mainly characterized by diastolic dysfunction, is increasing due to ageing Indian societies.

Initiating Therapy

Established therapies for chronic HFrEF include angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), beta-blockers, loop diuretics, aldosterone antagonists, and hydralazine/isosorbide dinitrate (HYD/ISDN); with the exception

of loop diuretics, all have been shown in randomized controlled trials to improve symptoms, reduce burden of hospitalization, and/or provide survival benefit.[2] Recently, in addition to established guideline directed medical therapy (GDMT), an angiotensin receptor-neprilysin inhibitor (ARNI) and the hyperpolarization channel blocker ivabradine have been added to the treatment guidelines for HFrEF.[3]

ACEI or ARB initiation is usually better tolerated when patient is congested whereas beta-blockers may be better tolerated when patient is relatively dry with adequate resting heart rate. Only beta-blockers with evidence of benefit in HF should be used in HFrEF. In selected patients with HFrEF, low dose of a beta-blocker and an ACEI/ARB may be started; while in persistently symptomatic patients who tolerate an ACEI or ARB, switching to ARNI, would be recommended.

In one recent study[4] LVEF increased and cardiovascular mortality improved with beta-blockers in all groups in sinus rhythm except in those with a value of ≥50%. In patients with atrial fibrillation, beta-blockers increased LVEF when <50% at baseline, but did not improve prognosis. The data are most robust in HFrEF, but similar benefit was observed in HFmrHF. These relevant findings reinforce that HFrEF and HFmrEF are part of the same spectrum of HFrEF.

Mineralocorticoid receptor antagonists (MRAs) also improve HFrEF prognosis and possibly of HFpEF.[5] The role of MRAs in reducing inflammation and fibrosis, which cause progression of HF, is currently under investigation.

Angiotensin Receptor-Neprilysin Inhibition

Neprilysin, also known as neutral endopeptidase, is a zinc-dependent metalloprotease that inactivates several vasoactive peptides, including the natriuretic peptides, adrenomedullin, bradykinin, and substance P, each of which has an important role in the pathogenesis and progression of HF.[6] Because angiotensin II is also a substrate for neprilysin, neprilysin inhibitors raise angiotensin levels, which explains the rationale for coadministration of ARB. Neprilysin inhibitors are not combined with ACEI due to a higher risk of angioedema. When making the transition from an ACEI to ARNI, a 36-hour washout period should be strictly observed to avoid angioedema, a delay that is not required when switching from an ARB to ARNI. Starting dose of sacubitril/valsartan: 24/26 mg to 49/51 mg twice daily and target dose is 97/103 mg twice daily.

With accumulating clinical and research experience, there is a strong argument to consider them as first-line agents, in place of ACEI/ARB for the treatment of HFrEF. The benefits of sacubitril/valsartan are severely attenuated at LVEF above 60%, and therefore ARNI should not be used in HFpEF.

Sodium Glucose Cotransporter 2 (SGLT2) Inhibitors

Although sodium glucose cotransporter 2 (SGLT2) inhibitors were developed for control of glycemia, but their cardiovascular benefits have caught the clinicians' attention. Dapagliflozin, reduced the combined risk of cardiovascular death and hospitalization for HF by 26% and the risk of cardiovascular death alone by 18% in the DAPA-HF trial.[7] SGLT2 inhibitors are presently being explored to treat HFrEF regardless of diabetic status of a subject in ongoing clinical trials. It is almost sure that, another drug would be added to the portfolio of cardioprotective agents. These disease-modifying drugs target important, but distinct, pathways that promote cardiomyocyte dysfunction and death.

Ivabradine

Ivabradine is a specific inhibitor of the *If* current involved in sinoatrial nodal activity and reduces the heart rate of patients in normal sinus rhythm without lowering blood pressure. In the SHIFT (Systolic HF Treatment with the If Inhibitor Ivabradine Trial) study, ivabradine therapy, when added to GDMT, resulted in a significant reduction in HF hospitalizations in stable, chronic, and HFrEF patients predominantly in NYHA class II and III.[8]

Ivabradine is recommended[3] to reduce the risk of HF hospitalization in patients with HFrEF (LVEF < 35%) already receiving GDMT (including a beta-blocker at maximally tolerated dose), and who are in sinus rhythm with a heart rate greater than 70 bpm at rest.

Biomarkers—When to Order Natriuretic Peptides

B-type natriuretic peptide (BNP) and N-terminal pro–B-type natriuretic peptide (NT-proBNP) are the most studied biomarkers in HF. They play a role in diagnosis and prognostication. Higher concentrations of BNP or NT-proBNP in an ambulatory patient with HFrEF inform high risk, particularly when the concentrations

are rising. Current clinical practice guidelines give a Class I recommendation to measure NT-proBNP or BNP to support a clinical diagnosis of HF, to assess disease severity, or to establish prognosis.[2]

More recently, biomarkers have been examined for their role as a marker of clinical responsiveness to GDMT. This is, in part, due to the fact that a wide range of GDMT may reduce BNP and NT-proBNP concentrations, in parallel with the benefits of these therapies. Patients whose natriuretic peptide concentrations do not fall with GDMT (nonresponders) have a worse prognosis and more deleterious LV remodeling.[9] Therefore, measurement of BNP or NT-proBNP is useful to monitor risk, to assist in decision-making regarding the ordering of imaging studies to evaluate LV remodeling, to support clinical judgment with respect to prescription of GDMT, and to provide helpful objective data regarding decision-making for referral to advanced HF therapies. In the setting of worsening symptoms, the reassessment of BNP or NT-proBNP may be informative. However, serial assessment of BNP or NT-proBNP to guide aggressive titration of GDMT is not indicated and not warranted.[10] Severe renal dysfunction may interfere with the interpretation of natriuretic peptide concentrations.

While rising natriuretic peptide concentrations are correlated with adverse outcomes, this relationship can be confounded with the use of sacubitril/valsartan. Due to neprilysin inhibition, concentrations of BNP rise in patients treated with sacubitril/valsartan and tend not to return to baseline despite chronic therapy. In contrast, NT-proBNP concentrations typically decrease, as NT-proBNP is not a substrate for neprilysin.[11] Therefore, it may be more prudent to check only NT-proBNP in patients on ARNI. Also, transient increases in natriuretic peptide levels have been documented in the initial phases of beta-blocker initiation; such changes should not preclude up-titration of beta-blocker therapy, which should be guided by patient tolerance instead of asymptomatic change in natriuretic peptide levels.

Cardiac Resynchronization Therapy (CRT) and Implantable Defibrillator (ICD)

Cardiac resynchronization therapy is a key therapeutic strategy in eligible patients, but requires multiple lead implantations and a significant subset do not respond or technically cannot receive a coronary sinus lead. There is emerging evidence supporting His-bundle pacing using a single lead in the right ventricle as a means to provide resynchronization. Clinical trials comparing traditional resynchronization therapy with His-bundle pacing are ongoing.

Since the addition of ARNI to the already existing drug armamentarium and declining sudden death rates in HF, the requirement of prophylactic defibrillator implantation may require a rethink.

Functional Mitral Regurgitation in Chronic Heart Failure

Left ventricular (LV) remodeling and subsequent papillary muscle displacement resulting in mitral valve (MV) leaflet tethering, dilatation, and flattening of the mitral annulus and reduced closing forces can lead to functional mitral regurgitation (FMR)[12] in cases of chronic HF.

FMR is associated with HF symptoms, increased hospitalization rates and worse long-term prognosis of patients with chronic HF. However, it remains debated whether FMR is a central driving force of HF progression or rather a bystander, reflecting the severity of the disease. Nevertheless, driven by recent advances in percutaneous MV repair (PMVR), significant efforts are currently undertaken to reduce FMR in patients with HF in the hope to improve prognosis.[13] Similar to HF patients without FMR, it is recommended to prescribe optimized guideline-directed HF therapy (OMT) targeting LV dysfunction including cardiac resynchronization therapy.

However, whether OMT is able to counterbalance maladaptive processes and the adverse effects of FMR on long-term survival remain unknown.[14] Likewise, the impact of MV repair on outcome in HF patients with severe FMR by interruption of the presumed maladaptive effects is unknown.

The COAPT trial[15] suggested that a percutaneously delivered mitral clip could reduce functional (secondary) regurgitation with a subsequent substantial improvement in morbidity and mortality, while two-year follow-up of MITRA-FR suggested no benefit.[16]

Periodic longitudinal follow-up of patient populations with FMR will be needed to have a deeper understanding of its relation to long-term mortality in patients with various stages of HF, which in turn will help identify those that will benefit most from MV repair.

Left Ventricular Dysfunction in Cancer Treatment

Cancer therapies today have significantly improved survival but at the cost of treatment-related cardiovascular toxicity, including LV systolic dysfunction. Anthracyclines and radiation therapy were the only known cancer treatments with significant cardiotoxicity earlier. However, modern targeted cancer therapies, including HER2 inhibitors, tyrosine kinase inhibitors (TKIs), proteasome inhibitors, and immune checkpoint inhibitors, are known to have adverse cardiovascular events.

People with cardiomyopathy-related gene mutations may be more prone (7.5% compared to 1.1% of those without a titin gene mutation) to develop ventricular dysfunction after the administration of chemotherapy.[17]

Normal LVEF is a prerequisite for antineoplastic therapies, but it has limitations for risk prediction, and has prompted investigation of serum and imaging biomarkers in patients receiving cardiotoxic therapies. In patients receiving high-dose chemotherapy, early elevations in cardiac troponin I (cTnI)-predicted cardiac events at 3 years,[18] and troponin-guided initiation of enalapril in a similar cohort was associated with reduced risk of LVEF decline.[19] Decreases in global longitudinal strain (GLS), an echocardiographic marker investigated in breast cancer patients receiving doxorubicin and trastuzumab, have also been shown to predict subsequent LV dysfunction in combination with ultrasensitive cTnI.[20] In a systematic review, a 10–15% reduction in GLS predicted subsequent LV systolic dysfunction,[21] supporting the American Society of Echocardiography (ASE) recommendations to include GLS and cTnI in risk stratification of patients before and during treatment with anthracyclines or trastuzumab.[22]

Beta-blockers, ACEI, and ARBs have been mostly investigated in patients receiving lower anthracycline doses and overall have demonstrated feasibility, safety, and varying degree of LVEF decline attenuation, which has been the most common endpoint.

Conclusion

The prevalence of HF is escalating rapidly. Compounding this, HF is an illness that consumes significant health-care resources, inflicts significant morbidity and mortality, and greatly impacts quality of life. Important breakthroughs have redefined opportunities to change the natural history of the disease with a broad range of medical therapies, devices, percutaneous interventions along with different implants and care strategies, including readmission reduction programs and ambulatory outpatient disease management for those with more advanced disease.

CHAPTER

33 Asymptomatic Left Ventricular Dysfunction

Asha Mahilmaran

Abstract

Asymptomatic left ventricular dysfunction (ASLVD) is more widely prevalent than overt clinical heart failure. ASLVD represents a huge opportunity but is under diagnosed and there are no clear cut trial data or guidelines for management. Symptomatic heart failure carries high morbidity and mortality and appropriate interventions to prevent or delay overt heart failure at the stage of ASLVD is critical in improving the prognosis.

Introduction

Heart failure is increasing in incidence as there is an increase of diabetes, hypertension, coronary artery disease and people surviving to advanced age. Heart failure continues to remain a major threat, an important cause of hospitalizations due to cardiac causes and mortality worse than many cancers despite advances in medical, interventional, and device therapy. The economic and social burden of the disease is immense and it is worthwhile to dwell upon early diagnosis at the asymptomatic stage of left ventricular dysfunction and if it is possible to prevent progression to overt heart failure.

Definition

Asymptomatic left ventricular dysfunction (ASLVD) is defined as depressed left ventricular dysfunction in the absence of overt symptoms and signs of heart failure.[1] The ejection fraction used as cut-off have varied in different studies, but we would use a left ventricular ejection fraction (LVEF) less than 50% as used in definition of heart failure reduced ejection fraction (HFREF).

American Heart Association Classification of Heart Failure

Stage A: At risk for heart failure like obesity, diabetes, hypertension, CAD, but no evidence of structural disease.

Stage B: Asymptomatic, but having structural abnormalities such as left ventricular dysfunction, left ventricular hypertrophy, and valvular lesions.

Stage C: Symptomatic heart failure.

Stage D: End stage heart failure.

ASLVD is classified as stage B heart failure and has the risk of progression to stage C or D heart failure.

Prevalence

The prevalence of ASLVD ranges from 7.3% to 23%. The heterogeneity is compounded by different cut-offs of LVEF used in various studies. The prevalence of ASLVD was 6.0% in men and 0.8% in women in the Framingham sub-study of 4,257 subjects who were followed for up to 12 years. Mild ASLVD-EF-40–50% was present in 61%, moderate

TABLE 1 Prevalence of ASLVD by age

Age	*Men (No.: 1860)*	*Women (No.: 2397)*
40–59	2.1	0.5
60–69	7.2	0.8
70–79	11.3	1.0
80+	14.3	1.9

EF-30–39% in 33%, and only 6% had severe ASLVD with EF less than 30% **(Table 1)**.

The risk of progression to overt heart failure was greater in patients with LVEF less than 40% as compared to mid-range ejection fraction of 40–50%.The relative risk of progression to clinical heart failure was 4.6 in patients with ASLVD in a meta-analysis of 11 studies comprising of 25,369 patients. The risk of progression was 1.7% in patients with asymptomatic left ventricular diastolic dysfunction (ALVDD). The major factors predicting an increased risk of progression from an asymptomatic stage were age, sex, blood pressure, diabetes, and body mass index. In the David-Berg study, patients with mild ASLVD had higher risk of overt HF on follow-up when there was associated diastolic dysfunction in patients with LVEF 40–52%. The HR for HF was 3.3 for patients with mild ASLVD (EF 40–50%), and HR of 7.8 for patients with moderate-to-severe ASLVD (EF < 40%) in the Framingham sub-study. The median survival of ASLVD was 7.1 years in this study **(Fig. 1)**.[2]

Etiology of Heart Failure

The major underlying causes of heart failure include hypertension, CAD, diabetes, obesity, and rheumatic heart disease (RHD). Quantitatively hypertension plays the most important contributing factor in isolation or alongside of CAD and RHD. A tight control of blood pressure is therefore one of the important early preventive intervention **(Fig. 2)**.[3]

Neuroendocrine Activation in ASLVD

Neuroendocrine activation has been shown to occur much earlier than symptomatic HF. In the SOLVD prevention arm, patients with asymptomatic LVEF less than 35% had higher plasma nor epinephrine levels than normal people, but lower than patients with clinical heart failure, the extent of nor epinephrine elevation correlated with future

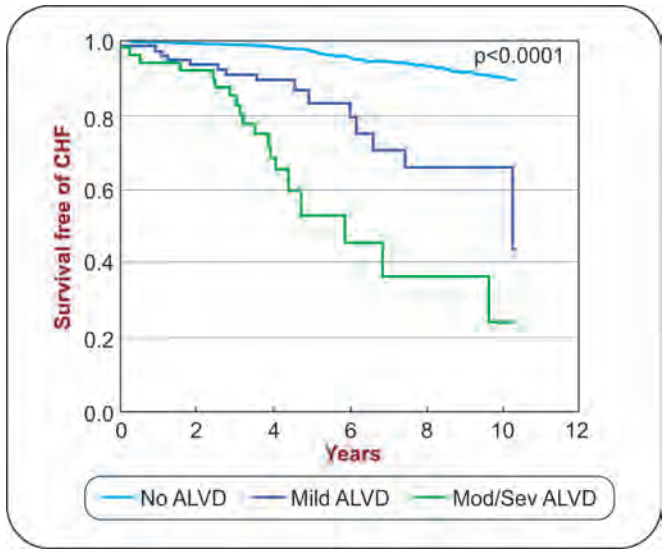

Fig. 1: Kaplan Meir survival curves of patients with no ASLVD and mild and moderate to severe ASLVD

death, overt heart failure development and ischemic events.[4] Plasma atrial natriuretic peptide, plasma arginine vasopressin levels were also increased but not plasma renin activity, suggestive that sympathetic activation occurs earlier than renin angiotensin system. This may help us plan strategy of treatment in ASLVD **(Fig. 3)**.

In the SAVE trial in patients with LVEF less than 40% following acute myocardial infarction (AMI), all neurohormones (PNE, PRA, AVP, and ANF) were all increased in asymptomatic patients, hence suggestion of benefit from early targeted therapy in ASLVD.[5-8] Neurohormonal modulation preemptively in the stage of ASLVD may prevent progression to overt heart failure.

Prognostic Significance of Preoperative ASLVSD and ASLVDD

In a study of 1,005 patients undergoing vascular surgery, both asymptomatic LV systolic dysfunction and diastolic dysfunction were associated with increased 30-day morbidity and long-term mortality. There was 17% incidence of non-fatal MI at 30 days, 10% in patients with normal LV function, 18% in ASLVDD, 23% in ASLVSD, and 49% in patients with symptomatic heart failure. Long-term follow-up revealed decreased survival in overt HF, HR-10.3, followed by ASLVSD HR-4.6, then ASLVDD, HR-3.0 as compared to normal LV function **(Fig. 4)**.[9]

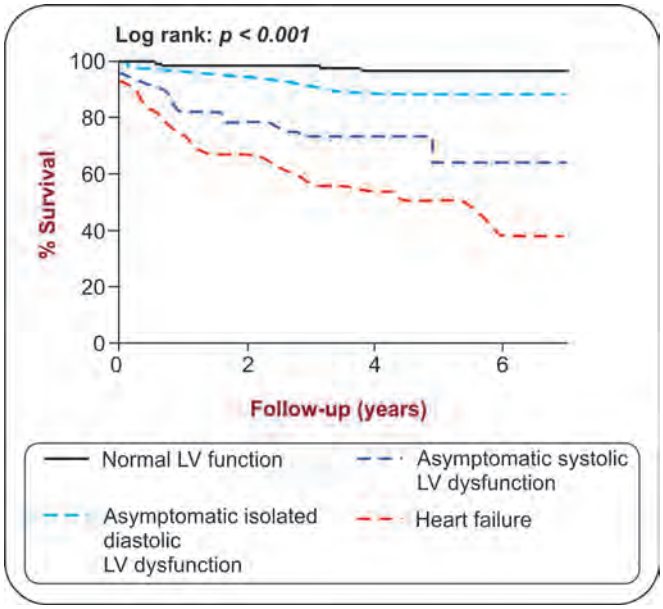

Fig. 4: Preoperative prevalence of asymptomatic isolated diastolic dysfunction, asymptomatic systolic LV dysfunction and heart failure and long term outcomes of patients undergoing vascular surgery[9]

Screening for ASLVD

Tests

ECG: Presence of Q-waves, old MI, left atrial enlargement, LVH, Conduction blocks, IVCD, and AF should prompt an evaluation of left ventricular function.

Chest X-ray: Presence of cardiomegaly, pleural effusion, pulmonary congestion, aortic calcification, posterior mitral annular calcification, aortic valve calcification merit further evaluation.

NT-ProBNP: Patients with elevation of NT-ProBNP had ASLVD in 6.6% of screened population in the SCREEN-HF study in a cohort of 3,550 patients with high risk for HF (AGE > 60 years with one other added risk factor for HF). In the David-Berg study, prevalence of ALSVD increased with age and CV risk. The prevalence was 5.3% and NT-ProBNP was more predictive than a combination of Framingham heart failure risk score (FHFRS) and ECG abnormalities.[10-12]

ECHO: ECHO screening should be done for patients with prior myocardial infarction, long standing DM, CKD, uncontrolled hypertension, presence of LVH, elderly patients above 60 years.

Global longitudinal strain (GLS): GLS is a more sensitive modality to diagnose early left ventricular function, it is load independent and less inter-observer variability is present. It is calculated by speckle tracking and GLS is the sum of peak longitudinal strain of 18 LV segments calculated from three standard two-dimensional ECHO views, apical long axis, Apical 4 chamber and Apical 2 chamber views. The normal value is -21 and a low value is ≤17. It is especially valuable in patients undergoing cancer chemotherapy as early detection may enable change of drug regime, initiation of early heart failure therapy. A decrease of 10–15% GLS is a reliable predictor of cancer chemotherapy induced cardiotoxicity. Low GLS has been noted in patients with uncontrolled hypertension, uncontrolled DM, obesity, hypercholesterolemia even with preserved LVEF. The low GLS is a predictor of future HF in these patients.[13]

Treatment of ASLVD

ACEI are the cornerstone of therapy of ASLVD. SOLVD prevention trial in patients with LVEF less than 35% had decreased HF hospitalization and overt HF when treated with enalapril as compared to placebo. SOLVD 12 year follow-up study showed decreased mortality in ASLVD patients on enalapril.[14] The SAVE trial, captopril in patients with ASLVD following AMI and in the TRACE trial following AMI, ASLVD patients on trandolapril were shown to have reduced CV events, HF, and mortality.

Angiotensin receptor blockers (ARB): ARB can be used in ACEI intolerant patients as shown in OPTIMAAL trial with losartan versus captopril and VALIANT trial with valsartan to be non-inferior to captopril in patients with LV dysfunction following AMI, a subset of whom were asymptomatic.

Beta blockers have been shown in the retrospective analysis of SOLVD and SAVE trials to have synergistic benefits when used with ACEI in ASLVD patients. In ANZ study and CAPRICORN trial, carvedilol has been shown to benefit post MI patients with LVEF less than 40%. In the REVERT trial, metoprolol has been shown to result in improvement in ejection fraction and ventricular remodeling in LV dysfunction of ischemic and non-ischemic etiology. Hence, beta blockers should be used in ASLVD to decrease the sympathetic over activation and slow progression of HF in both ischemic and non-ischemic etiologies.

Statin has been shown to reduce heart failure in patients with ischemia in the 4S study.

Diabetic patients with ASLVD had a higher risk of overt HF (HR-1.53) and HF hospitalization (HR-2.04) in the sub-analysis of SOLVD prevention trial patients with DM who developed HF had a mortality of 37% versus 29% in patients without DM. Sodium-glucose cotransporter inhibitor 2 (SGLT2) is the new class of diabetic drug, which prevents heart failure by 23% in a meta-analysis even in patients without pre-existing heart failure. The mechanism of benefit in heart is due to multiple modalities of action. They act by inhibiting glucose and sodium reabsorption in the proximal convoluted tubule causing glucosuria and natriuresis. The diuretic action of SGLT2 inhibitors is more on the interstitial fluid rather than intravascular fluid, so that there is no sympathetic activation and preload to heart is maintained. There is an increase in hematocrit by stimulation of erythropoietin, there is a uricosuric effect as well. The reduction in uric acid contributes to reduced oxidative stress. They inhibit NA^{+}-H^{+} ion exchanger in the heart resulting in prevention of cytosolic calcium excess which leads to apoptosis, shift the heart energy substrate to energy efficient ketone bodies instead of glucose. They also prevent cardiac fibrosis and hypertrophy and prevent adverse ventricular remodeling, which leads to progression of heart failure **(Flowchart 1)**.[16]

In addition, by increasing the sodium delivery in the distal tubule due to decreased proximal tubule reabsorption of sodium, through a tubule glomerular feedback, SGLT2 inhibitors lead to decreased glomerular pressure and have a renal protective effect as well, they also reduce renal fibrosis and hypoxia, which have favorable effects on the cardiorenal syndrome in HFREF **(Table 2)**.[16]

SGLT2 inhibitors have been shown to decrease HF hospitalization and CV mortality in the EMPAREG,

Flowchart 1: Mechanism of benefit of SGLT2 inhibitors

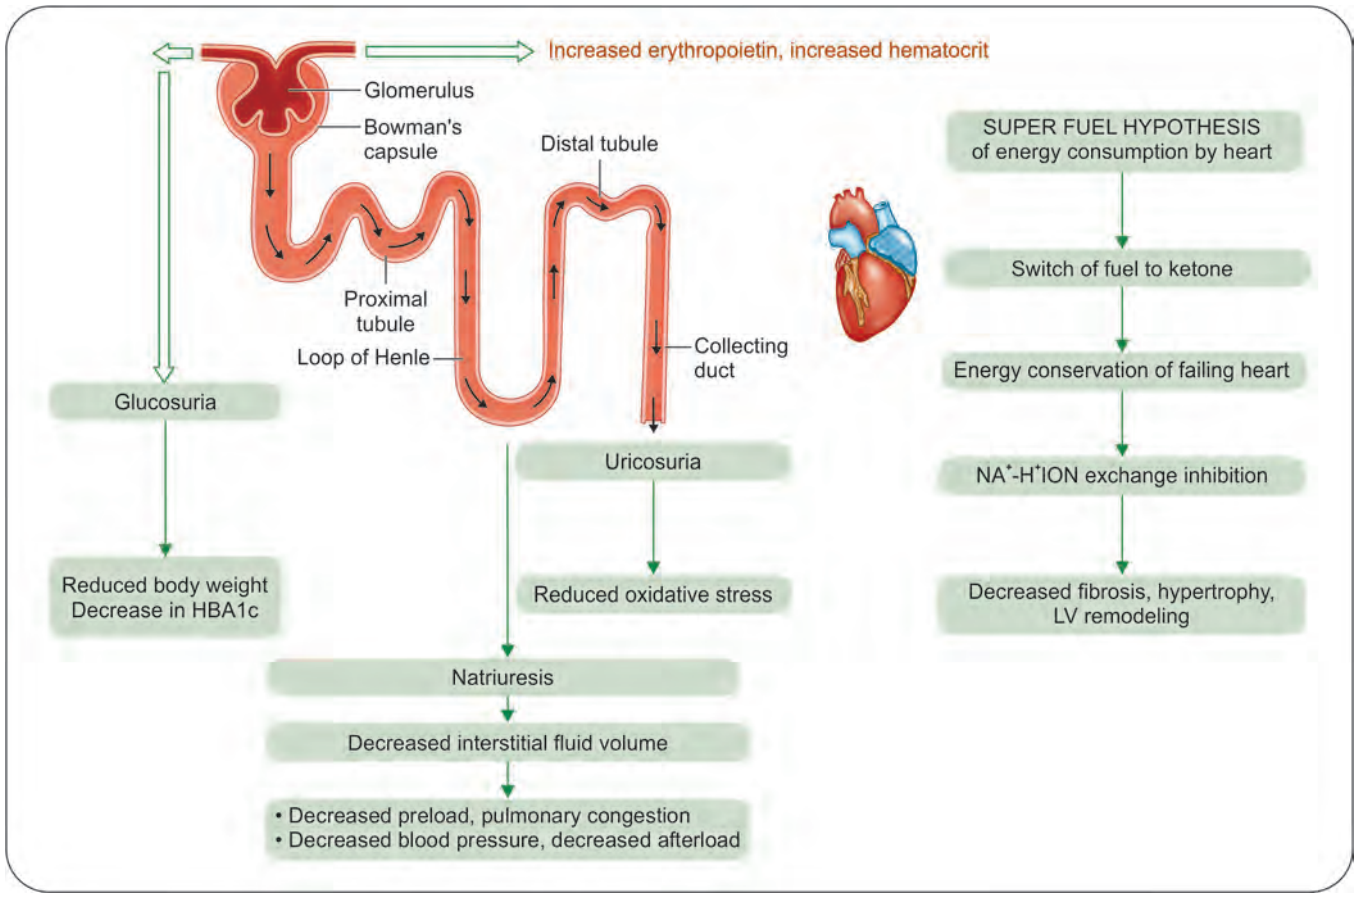

TABLE 2 Mechanism of cardiovascular benefits of SGLT2 inhibitors

Direct myocardial effects	Indirect systemic effects
Decreased NH exchanger	Decreased blood glucose
Decreased CAMKII	Natriuresis
Autophagy increased, lysosomal degradation increased	Increased hematocrit
Decreased inflammasome	Decreased plasma volume—greater decrease in interstitial fluid
Prevention of adverse cardiac remodeling	Increased uricosuria
Prevention of ischemia-reperfusion injury	Decrease in body weight
Decreasing of epicardial fat	Decrease in arterial pressure
Ketone utilization as substrate, more energy efficient	Decrease in arterial stiffness
Decreased SGLT1 activity	Improved renal function
	Increased vascular progenitor cells
	Inhibition of SNS
	Reduction of oxidative stress

CAMKII, calmodulin-dependent protein kinase II; NH, sodium hydrogen ion exchanger.

CANVAS, CREDENCE, and DAPA-HF trials. The DAPA-HF trial showed benefit in HFREF patients with or without DM. SGLT2 inhibitors added at the stage of A, B, or C has shown benefit and should be included for all diabetic patients with LV dysfunction with or without symptoms. It is probably worthwhile to explore their use in all patients with ASLVD with or without DM.[15,16]

Device Therapy

Patients with LVEF less than 30% for more than 1 month after an AMI have been shown to have survival benefit as shown in the MADIT II trial which included 40% of asymptomatic patients.

Cardiac resynchronization therapy (CRT) has been shown to reverse ventricular remodeling in REVERSE trial in patients with NYHA class II and III, but data not strongly showing benefit in NYHA class I patients.

The PACE trial showed better outcomes in patients with atrioventricular sequential pacing as compared to RV pacing in patients with LVEF less than 45%. Biventricular pacing has been shown to be superior to right ventricular pacing in patients with LVEF less than 50% in the BLOCK HF trial in patients with atrioventricular block with decreased combined end point of mortality, HF hospitalization or more than 15% increase in LV end systolic volume index.

His Bundle Pacing (HBP) is a new pacing strategy, which avoids the adverse consequences of RV pacing and ensures atrioventricular and intraventricular synchrony. It has been found to preserve left ventricular function and reduce mitral regurgitation in patients with heart failure and pacing indication. HBP is also being explored as an alternative to CRT in patients with LBBB and CRT indication.[15-18]

Conclusion

Asymptomatic left ventricular dysfunction occurs twice as common as overt heart failure. ASLVD carries a good prognosis until the development of overt HF and presents with a huge window of opportunity to implement therapy and mitigate the progression and adverse consequences of overt HF. Early screening with ECHO, GLS, and NT-ProBNP will help catching the patients early. RAAS inhibitors, Beta blockers, SGLT2 inhibitors, statins in patients with CAD prevent progression of heart failure and should be initiated in this stage. Avoidance of RV pacing, use of His bundle pacing in patients with left ventricular dysfunction improves LVEF.[19]

AICD prevents sudden death and decreases mortality in patients with LVEF less than 30% irrespective of their symptom status.

CRT and HBP are useful in patients with LBBB, broad QRS, and mitral regurgitation with LV dysfunction with stage C HF, but data not adequate in ASLVD. The use of ARNI also needs to be explored in ASLVD and if it is superior to ACEI in preventing adverse LV remodeling.

CHAPTER

34 Cardiovascular Risk Assessment Tools

Ravikeerthy M

Abstract

Cardiovascular disease is the major non-communicable disease in both developed and developing countries. Its prevalence is increasing with the change in lifestyle factors. It is one of the preventable conditions. The disease remains asymptomatic till advanced stages in majority of the population. Early intervention with lifestyle changes and medication can prevent these cardiovascular events, need tools to identify the people at risk, and these tools are used to calculate an individual's risk of developing a CV event from risk factors obtained from history, physical examination, or investigations. There are several tools available for the risk assessment but very few tools like JBS3 identify the risk more accurately and this is applicable for Indian population also.

Introduction

Cardiovascular disease (CVD) has overtaken infection as a leading cause of death all over the world. It is the leading cause of not only mortality but also the morbidity, and is a major economic burden. With changing life styles and increased life span, the burden of disease is also increasing. India is no different from this because of the increase in its prevalence and that of CVD risk factors.[1]

The Global Burden of Disease study estimates suggest higher age-standardized CVD death rate of 272 per 100,000 population in India compared to the global average of 235 per 100,000 population.[2]

CVDs include coronary heart disease, cerebrovascular disease, peripheral artery disease, aortic atherosclerosis, and aneurysm of aorta (thoracic or abdominal).

Cardiovascular risk factors are divided into modifiable and non-modifiable risk factors. Modifiable risk factors are further classified as health conditions and life style factors **(Table 1)**.[3]

Various studies have shown that early intervention with lifestyle changes and medication can prevent these cardiovascular events. So accurate estimation of CV risk is important as it affects health behavior and medical decision-making, and helps improve patient compliance to the treatment.[4] As per the world health organization prevention is classified into the following type:

- Primordial prevention
- Primary prevention
- Secondary prevention
- Tertiary prevention
- Quaternary prevention

TABLE 1 Classification of CV risk factors

Non-modifiable risk factors	*Modifiable risk factors*	
	Health conditions	*Lifestyle factors*
• Age • Sex • Family history	• Hypertension • Dyslipidemia • Diabetes mellitus • Chronic kidney disease	• Smoking • Poor diet • Physical inactivity • Obesity • Psychosocial factors

The main aim should focus on Primordial or Primary prevention.[5]

Definition

Cardiovascular risk stratification by definition is the assessment to estimate the risk of developing cardiovascular event or estimating the risk of developing cardiovascular event during noncardiac surgery by perioperative risk assessment.

So we need tools to identify the people at risk and these tools are used to calculate an individual's risk of developing a CV event from risk factors obtained from history, physical examination, or investigations. Most guidelines recommend the use of risk scores to predict global risk rather than focusing on single risk modification. Studies from different parts of the world have reported that the rates of use of CV risk scores range from 17% to 65%. A study conducted in the United States, showed that 92% of physicians were aware of risk stratification tools; however, it was used in only 41% of patients, with only a part of the latter being used to guide the subsequent treatment decisions.

Studies have shown that subjective estimation of CV risk by doctors is inaccurate. Patients and doctors generally estimate risk by risk factor profile or risk factor counting as opposed to absolute risk calculation. However, focusing on individual risk factors or risk factor counting tends to underestimate risk in those who may have slightly elevated level of multiple risk factors that synergistically increase the overall absolute CV risk.[4,6]

Another study in primary care physicians in Canada demonstrated that almost one-third were not aware of the defining point for high CV risk (>20% 10-year FRS CV risk) which leads to misclassification of risk and underestimation of truly high-risk patients.

Risk Stratification Tools

There are many different tools available. Most important are listed below:

- Framingham Risk Score (FRS)
- Prospective Cardiovascular Munster Score (PROCAM)
- World Health Organization/International Society of Hypertension (WHO/ISH) CVD risk prediction charts
- Systemic Coronary Risk Evaluation (SCORE)
- American College of Cardiology/American Heart Association (ACC/AHA) pooled cohort equations
- 3rd Joint British Societies (JBS3) risk calculator
- Reynolds score
- Assign risk score
- Qrisk risk score
- Adult Treatment Panel III

Framingham Risk Score

It is the landmark study especially for the assessment of 10 years risk and most widely adapted. This is also used to assess the composite of all atherosclerotic cardiovascular events like angina, stroke, peripheral vascular disease, and heart failure. Paramaeters used for assessment are age, sex, diabetes, smoking, hypertension, total and HDL cholesterol.

Limitations—does not predict the true values in European and Asian people. Some important risk factors like family history of cardiovascular events, chronic kidney disease and body mass index are not included. Analysis of the study show both overprediction in low risk population and underprediction in high risk population. The study relies greatly on age as a predictor of cardiovascular risk; hence, in a young individual, the estimated 10-year CV risk is invariably low, even in the presence of multiple cardiovascular risk factors.

Systemic Coronary Risk Evaluation

This study was derived from 12 cohort studied involving more than 200,000 people in Europe and accuracy for European population is good. One major plus point of this study is its prediction of first fatal cardiovascular event.

Reynolds Risk Score

This was initially developed to assess the risk in healthy women and later applied to male population with slight modifications.[7] Around 25,000 healthy health professionals were involved in the initial study to assess the composite events like myocardial infarction, stroke, coronary revascularization, and cardiovascular death. Compare FRS and score tools, inclusion of HS CRP and parenteral premature cardiac events in this gives a better predictive value.

JBS3 Risk Calculator

The joint British societies released this risk score in 2014, and end points assessed are cardiovascular death, nonfatal MI, angina, stroke, TIA, and intermittent claudication.

This score estimates both 10-year risk and lifetime risk of CVD and also the "Heart Age."

This is a more extensive risk assessment tool compared to others. It includes several additional risk factors such as obesity and family history of premature CVD. This study also includes data on ethnic Indians and is more suitable for Indian population for the CV risk assessment.

Assign Risk Score

Assessing cardiovascular risk to Scottish Intercollegiate Guidelines Network is developed in Scotland. The study group involved the asymptomatic CVD subjects aged between 30–74, both men and women. The study included most of the parameters as in other studies and a new risk factor that is social deprivation. One of the limitations of the study in not including obesity as a risk factor. This score predicted the 10-year risk of cardiovascular disease. It included all the discharges with the diagnosis of CVD and death.[8]

QRISK Risk Score

QRESEARCH cardiovascular risk algorithm a cohort of 1.3 million subjects, aged between 35–74 years and were free from diabetes and CVD. The following risk factors were considered in the study-age, sex, smoking status, systolic blood pressure, ratio of total to HDL-C, body mass index, family history of CHD, social deprivation, and antihypertensive treatment. The above score predicts the 10-year risk of CVD such as MI and also stroke, transient ischemic attack. Major limitation of the study is that it was validated on the same study subjects.[9]

The risk of CVD is classified into borderline (5–7.5%), intermediate risk (7.5–20%), and high risk (>20%) based on the different risk score. ACC/AHA Guideline on the Primary Prevention of Cardiovascular Disease-2019 recommends Cardiac Risk Assessment. By using the pooled cohort equations (PCEs), the physician should regularly assess cardiovascular risk factors and calculate 10-year risk of ASCVD of adults of age group 40–75 years. For adults 20–39 years of age, it is rational to assess traditional ASCVD risk factors at least once in 4–6 years. In adults at borderline risk (5% to <7.5% 10-year ASCVD risk) or intermediate risk (≥7.5% to <20% 10-year ASCVD risk), it is rational to use additional risk-enhancing factors to guide decisions about preventive interventions (e.g., statin therapy). In adults at intermediate risk (≥7.5% to <20% 10-year ASCVD risk) or selected adults at borderline risk (5% to <7.5% 10-year ASCVD risk), if risk-based decisions for preventive interventions (e.g., statin therapy) remain uncertain, it is rational to measure a coronary artery calcium score to guide clinician–patient risk discussion. For adults 20–39 years of age and for those 40–59 years of age who have <7.5% 10-year ASCVD risk, estimating lifetime or 30-year ASCVD risk may be considered.

The present understanding of the 10-year risk for atherosclerotic CVD identifies patients in higher-risk groups who are likely to have greater net benefit and lower number needed to treat for both statins and antihypertensive therapy. Lifetime CVD risk estimation, which measures the cumulative risk of developing the disease during the rest of an individual's lifespan, could provide a more accurate assessment of future risk of CVD than short-term risk estimates, more so in younger individuals who have low short-term risks. The guidelines now recommend stepwise stratification of disease-free and asymptomatic individuals into high short-term, low short-term/high lifetime, and low short-term/low lifetime CHD risk groups for targeting primary prevention strategies in all eligible individuals.[10]

Subclinical Atherosclerosis Assessment

Risk-scoring tools can improve the prediction of risk but their adoption in clinical practice is poor. Risk factor based approach estimate CV risk at population level and not at individual level. Hence, it is desirable to develop tools which could accurately identify individuals who are truly at risk. For example, 20% risk of cardiovascular events over 10 years means that out of 100 such individuals, 20 will develop a vascular event over 10 years; however, it is impossible to predict who are those 20 who might develop the event. Hence, all 100 patients need treatment.[11] Hence, inclusion of noninvasive tests that can identify subclinical atherosclerosis is required in improving the risk assessment.

Imaging techniques for sub-clinical atherosclerosis not only shows the evidence of sub-clinical atherosclerosis but also increases the probability of developing CVD later on, irrespective of cardiovascular risk factors and also helps benefit the patient by providing suitable preventive strategies and helps improving patient's treatment compliance.

The following is the list of tools available for the assessment of subclinical atherosclerosis:

- Carotid plaque assessment
- Carotid intima-media thickness (CIMT)
- Brachial artery flow-mediated dilatation
- Coronary calcium score (CCS)
- Ankle-brachial index
- Pulse wave velocity (PWV)
- Stress test/TMT

Coronary calcium score, carotid ultrasound imaging, and PWV are studied extensively in clinical practice. CCS is a computed tomography test which helps detect and quantify the amount of calcium in the coronary arteries. Presence of coronary calcium provides direct evidence of ongoing coronary atherosclerosis. CCS also provides prognostic information. CCS correlates with the extent of coronary artery disease in Indian subjects as well. The presence of atherosclerosis in carotid arteries shows high risk of coronary events also (since atherosclerosis is a generalized process). It can evaluate both intima-media thickness (CIMT) and carotid plaques. CIMT is associated with greater risk of vascular events, independent of common CV risk factors or FRS. CIMT is related to CV risk factors, presence of CAD, and the extent of CAD on angiography in Indian patients also. Aortic pulse wave velocity (PWV) is an indicator of arterial stiffness. It has greater value in the evaluation of pathophysiological states associated with arteriosclerosis, such as hypertension, ageing, and end-stage renal disease. A significant relationship between PWV and CV risk factors and incident CVD is shown in Indian subjects.

Other Markers of CV Risk Assessment

- High-sensitive c-reactive protein
- Lipoprotein a [Lp(a)]
- Apolipoproteins
- Inflammatory cytokines
- Fibrinogen

Indian Scenario

Indians are at a greater risk of CV disease as compared to other populations probably due to genetic make-up and early onset of conventional CV risk factors. A calibration method has been proposed to optimize cardiovascular risk estimates for Indians. A 10-year risk based on FRS can be recalibrated by multiplying the calculated risk with a correction factor. For rural Indians, the suggested correction factor is 0.8 for women and 1.0 for men, whereas for urban Indians it is 1.54 for women and 1.81 for men.[11]

WHO published series of risk prediction charts, which might be the only option available for populations for which prospective studies are not available. Another option is JBS3 risk calculator that allows separate risk assessment for people with Indian ethnicity. JBS3 risk calculator seems to have greater accuracy in Indian patients as it includes data on ethnic Indians and takes into consideration of many other risk factors such as obesity and family history of premature CVD. So it is more comprehensive risk assessment tool.[12]

Conclusion

Assessment of the risk of occurrence of future CV events is an important step in the management of the patients requiring primary prevention of CV disease. Using various risk assessment tools, people at high risk of CVD can be recognized. However, in clinical practice, cardiovascular risk assessment by primary care physicians frequently involves subjective evaluation rather than the use of risk assessment tools. Most of the cardiovascular risk assessment tools are not suitable for use in the Indian population. Therefore, there is a need for an optimal cardiovascular risk assessment tool in the Indian population. Although Framingham risk score is most widely used and accepted it is not suitable for the Indian population. Among the various risk assessment tools, the Joint British Societies (JBS3) risk calculator has been reported to provide a more accurate estimation of the cardiovascular risk in Indian population. Assessment of subclinical atherosclerosis enables more accurate identification of individuals who are at increased risk of CVD.

ARMOR–Arati's Regime for Management of Rheumatic Fever—Against Rheumatic Heart Disease—A Great Milestone

Arati Lalchandani, Prem Singh, Arvind Kumar, Taruni Lalchandani

Abstract

Rheumatic heart disease is a disease for which no significant progress has taken place as regards the diagnosis and the management for seven long decades; therefore, we find that physicians are struggling with the same dilemma in diagnosis and the age-old painful and ineffective prophylaxis with parenteral penicillin.

The ARMOR, i.e., Arati's Regime for Management of Rheumatic Fever – Against RHD will prove to be a great milestone in the management of Rheumatic Fever. The practice of ARMOR shall simplify and increase the sensitivity of diagnosis of RHD and make the treatment and prophylaxis of RHD safe, effective, and popular.

Introduction

ARMOR consists of:

I. **Diagnostic criteria for rheumatic fever (RF) rheumatic heart disease (RHD)—arthralgia or arthritis, cardiac involvement typical of RF, Echo-Doppler findings typical of RF RHD, with history of sore throat.**

II. **Use of newer anti-inflammatory drugs for arthritis of RF—aceclofenac 200 mg BD or any NSAID for 5 days or longer.**

III. **Primary prevention, treatment, and secondary prophylaxis of RF RHD with tablet azithromycin 500 mg 1 daily for 5 days followed by 1 tablet once a week for 1 year only.**

Azithromycin must be started with 500 mg/day each time even when changing over from other drugs.

Since more than five decades physicians have been struggling with the very same weapons against RF/RHD although there have been great strides in management of infections especially over past two decades.

RHD is no doubt a heart disease, but it is well established that it begins as an infection of the tonsils/sore throat which later, by still largely unexplained mechanism, destroys the heart valves irrevocably thus shortening the life span of the individual.

Since 1940s though several attempts were made to bring about changes to Jones Criteria for diagnosis and management of RF RHD, the dire changes needed were not made.

The Major Problems with Application of Jones Criteria

I. *Very complicated confusing criteria for diagnosis:* RHD is a simple disease with very typical symptoms and consistency of clinical features; therefore, should be very easy to diagnose by any practitioner. Moreover, since the introduction of Echocardiography Doppler study, a very definite diagnosis can be made by viewing the heart under direct vision.

The ARMOR regime therefore in its diagnostic limb only includes typical migratory arthritis affecting the medium and large joints, transient, recovering completely, endocarditis of heart valves resulting in regurgitant or stenotic valves, pericarditis with minimal fluid with full recovery, myocarditis with MR TR, cardiomegaly, heart failure, very often even

irreversible heart valve damage—mitral stenosis, mitral regurgitation, aortic regurgitation, aortic stenosis, tricuspid regurgitation.

The heart lesions typical of RF RHD can be easily and definitively confirmed by Echo Doppler study, which is now available as easily as X-ray of yesteryears.

The other clinical features of RF RHD viz chorea, subcutaneous nodules, and erythema marginatum have been given too much importance as major Jones criteria.

In a study of 200 patients of RF by Lalchandani et al. it was shown that out of all the Jones criteria only arthritis, arthralgia, and carditis were found in the majority of patients whereas there were no patients with chorea, erythema marginatum, or subcutaneous nodules.[1]

Since it is well known that chorea in RF occurs as an isolated feature and almost never with cardiac involvement; therefore, it should not be a major diagnostic criterion for RF. Also a patient of chorea does not have the evidence of Streptococcal infection; therefore, chorea could very well be a separate entity called Sydenham's chorea.[2,3]

The incidence of chorea has been very low in western literature and very rare in Indian patients. A patient of chorea who does not have other features of RF should not be labeled as patient of ARF as there are many other causes of chorea.

According to Jones criteria only one major and two minor criteria along with essential association of GABHS is required for diagnosis so subcutaneous nodules and erythema marginatum, which have so many other causes cannot be considered as major criteria.

The clinical profile of 550 cases of RF RHD was studied by Ravisha et al. in India where arthritis and carditis was found in 169 (67.6%) and 105 cases (42%) chorea in 47 (18.8%) and erythema marginatum in 4 only.[4]

As regards *minor criteria of Jones* they are mostly the features of infection and inflammation, which are common to many other diseases.

By thus simplifying the diagnosis of RF RHD sensitivity of ARMOR would be high compared to Jones and would help in starting early prophylaxis and curing the cases before serious organic heart disease.

It is pointed out here that even ARF can be picked up on echocardiography-echocardiographic criteria for diagnosis of RF by Dr Anita Saxena and Dr IB Vijaylaxmi.[5,6]

II. *A majority of literature on RF RHD advocate an extremely dangerous drug—aspirin as the drug of choice for rheumatic arthritis:* It is really flummoxing that even after the discovery of an array of anti-inflammatory analgesic drugs with excellent safety profile and availability the textbooks continue to advocate Aspirin. Aspirin is a very toxic drug causing peptic ulcer, hemorrhage from gastric and other sites, rhinitis, bronchial asthma, Reye's syndrome and even death.

Aspirin has been recommended in a very high dose of 8–12 g/d for 6 weeks to 6 months and needs to be tapered over weeks to avoid rebound relapse.

Therefore, Aspirin should be replaced with the newer anti-inflammatory aceclofenac 200 mg twice a day or Nimesulide 200 mg twice a day, which needs to be given only for 5 days or more according to discretion of physician. These are very safe effective easily available and can be given for very short duration without rebound or relapse.[7]

III. *The antibiotic of choice till today continues to be the age-old BPG (Benzathine Penicillin):* The mainstay of prevention and treatment of RHD is an antibiotic effective against GABHS. BPG the gold standard is given as a stat dose IM AST in a dose of 1.2 m units for treatment. For secondary prophylaxis BPG 1.2 m units is given IM AST every 21 days.

Today the best drug for GABHS is azithromycin which if started within 9 days of symptom of sore throat, almost all cases of RF can be prevented.

Azithromycin can be used for primary prevention treatment and also to prevent recurrent attacks of ARF as well as secondary prevention because of its accessibility safety, efficacy, affordability, tolerability, and oral mode of dispensation.

All cases of sore throat whether of viral or bacterial etiology resolve in 3–5 days but full course of azithromycin 500 mg or 12 mg/kg once daily for 5 days must be given to all cases to prevent RF RHD in the developing countries.[8]

BPG must be replaced with azithromycin due to the following reasons:

- Severe fatal reaction may occur with BPG in as many as 1:10000 patients, which is a considerable number

as 20 million people may be having RHD in the world today.[9]

Only a well-equipped emergency setup can deal with anaphylaxis due to BPG.

- The demand of BPG hugely outnumbers the supply.
- BPG has to be given AST each time.
- After an injection BPG the patient suffers from same features of RHD like pains, aches, and fever.
- BPG is an oily injection given deep IM 2–5 mL in quantity to cachectic patients of RHD.
- Patients have transient valvulitis of MV AV after BPG so that benefit of BPG is not seen.[10]
- Commonly co-prescribed drugs like warfarin, aspirin, diuretics interact with penicillin.
- Accidental IV can cause cardiac arrest and death.
- Severe allergic reactions are common.
- Pseudomembranous colitis can occur.
- Clostridium difficile associated diarrhea increases mortality and morbidity.

Many studies have shown that relapse and recurrence and progression of RHD is not much influenced by regular administration of BPG as substantiated in Pediatric Cardiology 2010 Division of Cardiology, University of Virginia in retrospective review of patients of ARF less than 21 years, which showed recurrence rate of 38% in 144 patients of RHD, compliance with BPG 59% and recurrence of ARF in 57%.[11]

The recurrence rate of RF from various studies is 3–8% over 5–6 years with BPG and consistently less than 3% with azithromycin.[12]

Penicillin concentration in serum of more than 0.02 μgm/mL is required to prevent recurrence compared to azithromycin, which persists in therapeutic concentration in tissues.

Azithromycin is the drug of choice in ARMOR due to the following reasons:

- Azithromycin is an azalide, chemical name is 9-deoxy-9-za9-a-methyl-9-a homoerythromycin, Molecular weight 749.
- Azithromycin if started with 500 mg OD for 5 days has to be given only weekly thereafter as its persistence in the tissues continues for about 6 days, therefore, needs to be given on the 7th day, that is, weekly dose.
- It has autoimmune suppressant and anti-inflammatory effect.
- It is acid stable so oral dose is well absorbed and is readily absorbed.
- Time to peak concentration is 2.1–3.2 hours.
- The drug is concentrated in phagocytes and actively transported to infection site thereafter released at the site of infection in large quantities.
- Concentration of azithromycin is 50 times higher in tissues than in plasma due to ion trapping and high solubility of drug. Concentration in lung and tonsils exceeds MIC 90 even after a single dose. A single large dose can eradicate the bacteria completely.
- It acts by binding to 50s ribosomal subunits and prevents translocation of peptides thus inhibiting bacterial protein synthesis.
- After single dose of 500 mg of azithromycin its concentration in plasma declines in polyphasic pattern with a plasma clearance rate of 630 mL/minute and terminal elimination half-life 68 hours due to property of large uptake and sustained slow release of drug from tissues.
- It is freely available, safe, cost-effective with excellent antistreptococcal activity.
- Has to be given with caution in renal impairment.
- Safe in hepatic impairment.
- Safe in pregnancy.

Azithromycin discovered in 1991 is extensively used for GAS with great results by physicians and ENT surgeons.

In a systematic review of 21 RCTs azithromycin 20 mg/kg/day for 3 days achieved GABHS eradication in 95% cases in streptococcal tonsillopharyngitis.[13]

In a study by Lalchandani et al., 730 patients were given azithromycin for ARF in dose 500 mg once daily for 5 days followed by 500 mg on 2 consecutive days in a week. No patient had relapse or reinfection or worsening of cardiac valve disease. Compliance was 100% and patients who had no new problem attributable to RF were given prophylaxis for 1 year only.[12]

In a correspondence with Prof A Lalchandani, Dr Stephen Marko of World Heart Federation, University of Connecticut, expressed concern over use of BPG due to alarming issues of quality and quantity of drug stating that treatment guidelines be modified by individual circumstances.

After detailed deliberations over the GABHS infection, its persistence in the bloodstream, sensitivity to the drug, a possible time-interval for causation of autoimmune

damage, the time gap between infection and carditis progressing to organic heart valve disease, conclusion is that there is no basis for RHD prophylaxis for greater than 1 year after sore throat, recurrence, or relapse or ARA.[14]

In a study by Dr BL Agarwal in 1986 the mean duration of symptoms before admission to hospital in a series of 100 cases of initial attack was 6.47±3.4 weeks, in children without carditis it was 5.0±4.03 weeks after onset of illness while in those with uncomplicated carditis it was 5.95±5.26 weeks.[15]

In view of the above facts RHD prophylaxis exceeding 1 year seems devoid of reasoning. Even in poststreptococcal reactive arthritis VHD patients should be given appropriate prophylaxis for up to 1 year (Class IIb, LOE C-AHA Scientific Statement).

Conclusion

In anticipation of infection lifelong prophylaxis with antibiotic is not only absurd but extremely harmful; that too with a drug which has to be tested each time for sensitivity, the risk incurred being greater than benefit reaped. With azithromycin prophylaxis for 1 year the disease progression is checked and even reversed.

For the past more than 12 years azithromycin is being given exclusively for treatment and prophylaxis of RF RHD in GSVM Medical College, Kanpur, with excellent miraculous results which have been documented in theses of PG students over several years. Many studies have shown azithromycin to be a much superior drug to BPG when GABHS is culprit organism of RF.[16,17]

CHAPTER

36 Evaluation and Management of Chronic Stable Angina: Physicians' Perspective

Vibhu Khanna, Ankush Gupta, Sanya Chhikara

Abstract

Chronic stable angina, while being a widely used term, is part of a much wider spectrum of chronic coronory syndromes (CCS). This spectrum consists of a dynamic and progressive disease course rather than a stable one, and hence requires thorough risk stratification and management. Risk stratification includes analyzing the demographics and clinical presentation of the patient to decide further management and testing. While ECG is the first step in making the diagnosis, there are several other modalities available to us today that supplement the ECG. These include both functional and anatomical imaging techniques like Echocardiography, Cardiac Magnetic Resonance Imaging, Coronary CT Angiography and various stress tests as well as invasive techniques like Percutaneous Coronary Angiography. The mainstay of treatment for CSA and CCS remains medical treatment. There are a variety of drug classes available that can be tailored depending on individual patient requirements. In addition to medical management, myocardial revascularization can also be attempted in specific cases using percutaneous coronary intervention or surgery.

Introduction

Coronary artery disease (CAD) or ischemic heart disease (IHD) covers a wide spectrum of syndromes that occur due to imbalance between myocardial oxygen demand and supply. The underlying pathology is most often the atherosclerotic involvement of the epicardial vessels, with varying degrees of obstruction. While the disease itself is chronic and progressive, presentation varies widely. Patients may be asymptomatic, present with a chronic stable course, or present acutely.

The most widely accepted classification of symptomatic patients includes stable coronary artery disease (SCAD) and acute coronary syndrome (ACS). Recent literature has recommended the use of the term chronic coronary syndrome (CCS) as an alternative to SCAD so as to retire the use of "Stable" and emphasize the progressive nature of the condition. The 2019 guidelines on CCS by the European Society of Cardiology (ESC) provide a comprehensive outlook on this new terminology as well as clinical practical guidelines on the approach and management of CCS.[1]

The ACS spectrum includes unstable angina, non-ST-elevation myocardial infarction (NSTEMI), and ST-elevation myocardial infarction (STEMI). SCAD/CCS also includes a variety of presentations, one of which is chronic stable angina (CSA). This is an episodic clinical syndrome caused due to transient myocardial ischemia. CSA occurs due to gradual progression of atherosclerosis in the epicardial vessels or due to supply/demand mismatch caused increased myocardial oxygen demand.[2]

Presentation

Angina refers to chest pain/discomfort attributable to myocardial ischemia. Elements of history that are critical to making the diagnosis of angina include four main categories as shown in **Table 1**.

TABLE 1 Anginal chest pain

Category	*Description*
Location	Chest pain, often retrosternal, with radiation to the epigastrium, arms, shoulders, neck and throat, jaw, and rarely interscapular *Levine sign:* Placing a clenched fist over the precordium to describe the pain
Quality	Often described as: squeezing, pressure, constricting, strangling, burning, chest fullness, band-like sensation, ache, heavy weight on chest
Duration	Classically for 2–5 minutes but usually lasts not more than 20–30 minutes
Other exacerbating or relieving factors	Provoking factors: Increased myocardial oxygen demand due to exercise, cold, emotional stress, sexual intercourse, meals, or lying down Relieving factors: termination of the provoking factor or administration of nitroglycerin

TABLE 2 Clinical classification of angina

Typical	• Substernal chest discomfort with characteristic quality and duration • Provoked by exertion or emotional stress • Relieved by rest or nitroglycerin
Atypical	Meets two of the above characteristics
Non-cardiac	Meets one or none of the typical angina characteristics

Source: Knuuti, J. et al.[1]

Symptomology can be classified on the basis of history taking into typical, atypical, or noncardiac chest pain **(Table 2)**. Atypical presentation is often seen in women and elderly.

Angina can be graded into various classes depending on severity **(Table 3)**.

TABLE 3 Canadian Cardiovascular Society grading of effort angina

Grade	*Description of angina severity*	
I	Angina only with strenuous exertion	Presence of angina during strenuous, rapid, or prolonged ordinary activity (walking or climbing the stairs)
II	Angina with moderate exertion	Slight limitation of ordinary activities when they are performed rapidly, after meals, in cold, in wind, under emotional stress, or during the first few hours after waking up, but also walking uphill, climbing more than one flight of ordinary stairs at a normal pace, and in normal conditions
III	Angina with mild exertion	Having difficulties walking one or two blocks, or climbing one flight of stairs, at normal pace and conditions
IV	Angina at rest	No exertion needed to trigger angina

Evaluation

In addition to laboratory investigations and biochemical tests to identify possible causes of ischemia and risk factors, the diagnosis of CAD can be made with the help of the several modalities. The choice of diagnostic tests should made after giving due consideration to pretest probability and the patients be stratified as high-, intermediate-, and low-risk groups. For example, a young woman presenting with atypical angina would be classified as a low-risk patient and does not warrant additional testing for CAD if the baseline ECG is normal.

Resting Electrocardiography

While a normal ECG is often recorded, ongoing angina may be accompanied by dynamic ST segment changes making this modality crucial for diagnosis of CAD. Other findings that may be indicative of underlying pathology include evidence of previous infarction (Q waves or an R wave in V1 or persistent ST-T wave inversions), conduction blocks (LBBB, AV blocks), and LV hypertrophy.

Resting Echocardiography

Echocardiography utilizes ultrasound waves to assess cardiac function and structure. In patients with CAD, ischemic myocardial damage can be correlated with LV ejection fraction (LVEF) as well as regional wall motion abnormalities (RWMA). It may also help in identifying alternative causes of chest pain like heart failure, valvular abnormalities (like aortic stenosis) or cardiomyopathies. CMR is a relatively new alternative to echocardiography and can be helpful in defining cardiac anatomy and function, especially in patients with poor acoustic windows.

Exercise Electrocardiography

Exercise ECG (Ex-ECG) is a widely utilized initial diagnostic test for SCAD and CSA. It is often conducted using a Treadmill test (TMT). The presence of exercise induced ST-T changes or chest pain is an indicator of coronary obstruction. The Duke Treadmill Score can also be of valuable diagnostic and prognostic importance, and combines multiple predictors into one composite index. Ex-ECG has a sensitivity and specificity of 68% and 77% respectively, for detection of CAD.[3] However, the diagnostic performance of Ex-ECG is inferior as compared to diagnostic imaging tests. Hence, there may be limited benefit of doing Ex-ECG testing without the addition of imaging. Other limiting factors to its use include patients who are unable to reach target heart rate and the existence of baseline ECG abnormalities that might interfere with the interpretation of ST-T changes, for example, LBBB, paced rhythm, WPW syndrome, or baseline ST depression. Nevertheless, careful interpretation of Ex-ECG in selected patients may be of considerable benefit in resource limited conditions and non-availability of imaging.

Stress Echocardiography/Stress CMR

New or worsening RWMA or LV function during, immediately before, and after stress are the diagnostic outcomes in stress echo. This stress, that is, reaching a target heart rate, can be achieved using either exercise or pharmacologic agents. In patients who have difficulty in exercising, stress can be induced by pharmacological agents, of which dobutamine is most commonly used. Alternatives are vasodilators like adenosine, dipyridamole, and regadenoson.[4] Stress echocardiography has a sensitivity of 70–85% for exercise and 85–90% with pharmacological agents and specificity of 77–89% for exercise and 79–90% with pharmacological agents.[2]

Nuclear Myocardial Perfusion Imaging (MPI)

Nuclear MPI is an excellent noninvasive modality that provides assessment of stress induced reversible perfusion defect (RPD) in the myocardium. RPD refers to decrease in myocardial perfusion after stress, which may be exercise or pharmacologically induced. The sensitivity of stress nuclear MPI ranges from 82% to 88% for exercise and 88% to 91% for pharmacological MPI, whereas the specificity ranges from 70% to 88% for exercise and 75% to 90% for pharmacological stress nuclear MPI.[2] Stress CMR MPI can also be used to assess MPI.

Coronary CT Angiography (CCTA)

CCTA is a noninvasive diagnostic test using intravenous contrast to provide a highly accurate definition of coronary artery lumen. CCTA, along with functional noninvasive imaging like nuclear MPI or Stress Echo, is recommended as the initial diagnostic test for diagnosing CAD by guidelines.[1] CCTA's high sensitivity (values ranging 93–97%) and negative predictive value make it an excellent modality to rule out CAD.[2]

Invasive Testing

Invasive coronary angiography is considered the "gold standard" for diagnosis of CAD and may be used in cases where noninvasive tests are either inconclusive or indicate a high likelihood of severe IHD. It may also be used as an initial diagnostic test in patients with high clinical likelihood of CAD or angina with minimal exertion or symptoms unresponsive to medical therapy.[1]

Treatment

Management of CSA involves a multidisciplinary approach using general measures like lifestyle management, promotion of medical adherence, and support for managing lifestyle risk factors in conjunction with medical or interventional management. Lifestyle recommendations include smoking cessation, dietary changes, regular physical activity, maintaining a healthy weight, as well as management of risk factors like hypertension, diabetes, and hypercholesterolemia.

Medical Management

This is the mainstay of treatment in CSA for both symptomatic relief and coronary event prevention. The drugs used are mentioned in **Table 4**.

Revascularisation: Myocardial revascularization should be considered in patients of CSA who are symptomatic despite medical therapy. While there is no mortality benefit of revascularization in CSA,[5,6] some patients continue to be symptomatic despite optimal medical treatment. Such patients may benefit from revascularization, leading to improvement in quality of life and endurance with

TABLE 4 Medical management of chronic stable angina[1]

	Drug	***Indication***	***MoA***
Antiplatelet	Aspirin	All patients for even prevention	Irreversible COX-1 inhibition
	• Clopidogrel • Prasugrel • Ticagrelor	• Patients in whom DAPT is recommended (e.g., Post-PCI, history of PAD/TIA/Ischemic stroke) in combination with aspirin • Clopidogrel pretreatment in patients requiring PCI	Block the platelet $P2Y_{12}$ receptor, thus inhibiting platelet activation and preventing the development and propagation of arterial thrombus
Anti-anginal drugs	**Beta-blockers** *β_1 selective:* Metoprolol Bisoprolol Atenolol Non β_1 selective: Carvedilol	Patients with recent MI or chronic heart failure	Reduce heart rate, contractility, and atrioventricular conduction, thus reducing myocardial oxygen demand and time-to-angina onset during exercise
	Calcium Channel Blockers *DHP:* Nifedipine Amlodipine	• Hypertensive patients with angina usually with a beta-blocker • Exercise induced ischemia	DHP: Reduction in peripheral vascular resistance due to arterial vasodilation
	Non-DHP: Verapamil Diltiazem	All types of angina (exercise, vasospastic, or unstable), SVTs, and hypertension. Avoided in heart failure or in patients on beta-blockers	Decrease heart rate and myocardial inotropism
	Nitrates *Short acting:* Sublingual/Spray nitroglycerin	• Acute effort angina • Prophylaxis before physical activities	Dilatation of peripheral veins, with corresponding reductions in systemic vascular resistance, coronary blood flow redistribution, and preload
	Long acting: Isosorbide mononitrate Isosorbide dinitrate	Angina prophylaxis in cases where beta-blockers or non-DHP CCBs are contraindicated, poorly tolerated or provide insufficient symptom control	
	Ivabradine	2nd line drug	Decreases heart rate and consequently myocardial oxygen demand. No effect on contractility or BP
	Nicorandil	2nd line drug	Stimulates the ATP-sensitive potassium channels of the vascular smooth muscle resulting in systemic venous and coronary vasodilation
	Ranolazine	2nd line drug in patients with refractory angina	Inhibition of calcium overload in cardiomyocytes, without substantial changes in heart rate or BP
	Trimetazidine	2nd line drug	Targets deranged cellular energetics, particularly in ischemic myocardial tissue. Improves HbA1c and glycemia in diabetics
Lipid lowering drugs	*Statins:* Atorvastatin Rosuvastatin Simvastatin	Moderate to high dose statin therapy is indicated in all patients irrespective of LDL/Cholesterol levels	HMG-CoA reductase inhibition

Contd...

Contd...

	Drug	*Indication*	*MoA*
RAAS blockers	ACEI/ARB	Patients with coexisting hypertension, LVEF ≤40%, diabetes, or CKD	Reduce mortality, MI, stroke, and HF
	Spironolactone Eplerenone	Post-MI patients who: • Are on an ACEI/ARB plus beta-blocker, • EF ≤35%, and • DM or HF	Aldosterone receptor blockers

ACEI, angiotensin converting enzyme inhibitors; ARB, angiotensin receptor blocker; BP, blood pressure; DAPT, dual anti-platelet therapy; DHP, dihydropyridine; DM, diabetes mellitus; EF, ejection fraction; HF, heart failure; MI, myocardial infarction; PAD, peripheral artery disease; PCI, percutaneous coronary intervention; TIA, transient ischemic attack.

reduced pharmacological and mental burden on the patients. Other indications of revascularization include multivessel disease, reduced ejection fraction, significant coronary artery stenosis, and large area of ischemia (>10% of LV). Revascularization may be achieved percutaneously or with CABG.

Conclusion

A patient with history of chest pain presents a diagnostic challenge for physicians because of the wide variety of causes and variability in presentation. Therefore, careful history taking and guideline dictated testing is essential for identifying possible cardiac causes without subjecting the patient to unnecessary testing and monetary burden.

While chronic stable angina often presents as a "stable" disease, it is important to carefully evaluate patients for progressive disease or risk of imminent ischemic event. Lifestyle modification and medical therapy are the mainstay of treatment of CSA. Revascularization may be considered in addition to these in selected patients with careful consideration.

CHAPTER

36 Evaluation and Management of Chronic Stable Angina: Physicians Perspective

Vibhu Khanna, Ankush Gupta, Sanya Chhikara

Abstract

Chronic stable angina, while being a widely used term, is part of a much wider spectrum of chronic coronory syndromes (CCS). This spectrum consists of a dynamic and progressive disease course rather than a stable one, and hence requires thorough risk stratification and management. Risk stratification includes analyzing the demographics and clinical presentation of the patient to decide further management and testing. While ECG is the first step in making the diagnosis, there are several other modalities available to us today that supplement the ECG. These include both functional and anatomical imaging techniques like Echocardiography, Cardiac Magnetic Resonance Imaging, Coronary CT Angiography and various stress tests as well as invasive techniques like Percutaneous Coronary Angiography. The mainstay of treatment for CSA and CCS remains medical treatment. There are a variety of drug classes available that can be tailored depending on individual patient requirements. In addition to medical management, myocardial revascularization can also be attempted in specific cases using percutaneous coronary intervention or surgery.

Introduction

Coronary artery disease (CAD) or ischemic heart disease (IHD) covers a wide spectrum of syndromes that occur due to imbalance between myocardial oxygen demand and supply. The underlying pathology is most often the atherosclerotic involvement of the epicardial vessels, with varying degrees of obstruction. While the disease itself is chronic and progressive, presentation varies widely. Patients may be asymptomatic, present with a chronic stable course, or present acutely.

The most widely accepted classification of symptomatic patients includes stable coronary artery disease (SCAD) and acute coronary syndrome (ACS). Recent literature has recommended the use of the term chronic coronary syndrome (CCS) as an alternative to SCAD so as to retire the use of "Stable" and emphasize the progressive nature of the condition. The 2019 guidelines on CCS by the European Society of Cardiology (ESC) provide a comprehensive outlook on this new terminology as well as clinical practical guidelines on the approach and management of CCS.[1]

The ACS spectrum includes unstable angina, non-ST-elevation myocardial infarction (NSTEMI), and ST-elevation myocardial infarction (STEMI). SCAD/CCS also includes a variety of presentations, one of which is chronic stable angina (CSA). This is an episodic clinical syndrome caused due to transient myocardial ischemia. CSA occurs due to gradual progression of atherosclerosis in the epicardial vessels or due to supply/demand mismatch caused increased myocardial oxygen demand.[2]

Presentation

Angina refers to chest pain/discomfort attributable to myocardial ischemia. Elements of history that are critical to making the diagnosis of angina include four main categories as shown in **Table 1**.

TABLE 1 Anginal chest pain

Category	*Description*
Location	Chest pain, often retrosternal, with radiation to the epigastrium, arms, shoulders, neck and throat, jaw, and rarely interscapular *Levine sign:* Placing a clenched fist over the precordium to describe the pain
Quality	Often described as: squeezing, pressure, constricting, strangling, burning, chest fullness, band-like sensation, ache, heavy weight on chest
Duration	Classically for 2–5 minutes but usually lasts not more than 20–30 minutes
Other exacerbating or relieving factors	Provoking factors: Increased myocardial oxygen demand due to exercise, cold, emotional stress, sexual intercourse, meals, or lying down Relieving factors: termination of the provoking factor or administration of nitroglycerin

TABLE 2 Clinical classification of angina

Typical	• Substernal chest discomfort with characteristic quality and duration • Provoked by exertion or emotional stress • Relieved by rest or nitroglycerin
Atypical	Meets two of the above characteristics
Non-cardiac	Meets one or none of the typical angina characteristics

Source: Knuuti, J. et al.[1]

Symptomology can be classified on the basis of history taking into typical, atypical, or noncardiac chest pain **(Table 2)**. Atypical presentation is often seen in women and elderly.

Angina can be graded into various classes depending on severity **(Table 3)**.

TABLE 3 Canadian Cardiovascular Society grading of effort angina

Grade	*Description of angina severity*	
I	Angina only with strenuous exertion	Presence of angina during strenuous, rapid, or prolonged ordinary activity (walking or climbing the stairs)
II	Angina with moderate exertion	Slight limitation of ordinary activities when they are performed rapidly, after meals, in cold, in wind, under emotional stress, or during the first few hours after waking up, but also walking uphill, climbing more than one flight of ordinary stairs at a normal pace, and in normal conditions
III	Angina with mild exertion	Having difficulties walking one or two blocks, or climbing one flight of stairs, at normal pace and conditions
IV	Angina at rest	No exertion needed to trigger angina

Evaluation

In addition to laboratory investigations and biochemical tests to identify possible causes of ischemia and risk factors, the diagnosis of CAD can be made with the help of the several modalities. The choice of diagnostic tests should made after giving due consideration to pretest probability and the patients be stratified as high-, intermediate-, and low-risk groups. For example, a young woman presenting with atypical angina would be classified as a low-risk patient and does not warrant additional testing for CAD if the baseline ECG is normal.

Resting Electrocardiography

While a normal ECG is often recorded, ongoing angina may be accompanied by dynamic ST segment changes making this modality crucial for diagnosis of CAD. Other findings that may be indicative of underlying pathology include evidence of previous infarction (Q waves or an R wave in V1 or persistent ST-T wave inversions), conduction blocks (LBBB, AV blocks), and LV hypertrophy.

Resting Echocardiography

Echocardiography utilizes ultrasound waves to assess cardiac function and structure. In patients with CAD, ischemic myocardial damage can be correlated with LV ejection fraction (LVEF) as well as regional wall motion abnormalities (RWMA). It may also help in identifying alternative causes of chest pain like heart failure, valvular abnormalities (like aortic stenosis) or cardiomyopathies. CMR is a relatively new alternative to echocardiography and can be helpful in defining cardiac anatomy and function, especially in patients with poor acoustic windows.

Exercise Electrocardiography

Exercise ECG (Ex-ECG) is a widely utilized initial diagnostic test for SCAD and CSA. It is often conducted using a Treadmill test (TMT). The presence of exercise induced ST-T changes or chest pain is an indicator of coronary obstruction. The Duke Treadmill Score can also be of valuable diagnostic and prognostic importance, and combines multiple predictors into one composite index. Ex-ECG has a sensitivity and specificity of 68% and 77% respectively, for detection of CAD.[3] However, the diagnostic performance of Ex-ECG is inferior as compared to diagnostic imaging tests. Hence, there may be limited benefit of doing Ex-ECG testing without the addition of imaging. Other limiting factors to its use include patients who are unable to reach target heart rate and the existence of baseline ECG abnormalities that might interfere with the interpretation of ST-T changes, for example, LBBB, paced rhythm, WPW syndrome, or baseline ST depression. Nevertheless, careful interpretation of Ex-ECG in selected patients may be of considerable benefit in resource limited conditions and non-availability of imaging.

Stress Echocardiography/Stress CMR

New or worsening RWMA or LV function during, immediately before, and after stress are the diagnostic outcomes in stress echo. This stress, that is, reaching a target heart rate, can be achieved using either exercise or pharmacologic agents. In patients who have difficulty in exercising, stress can be induced by pharmacological agents, of which dobutamine is most commonly used. Alternatives are vasodilators like adenosine, dipyridamole, and regadenoson.[4] Stress echocardiography has a sensitivity of 70–85% for exercise and 85–90% with pharmacological agents and specificity of 77–89% for exercise and 79–90% with pharmacological agents.[2]

Nuclear Myocardial Perfusion Imaging (MPI)

Nuclear MPI is an excellent noninvasive modality that provides assessment of stress induced reversible perfusion defect (RPD) in the myocardium. RPD refers to decrease in myocardial perfusion after stress, which may be exercise or pharmacologically induced. The sensitivity of stress nuclear MPI ranges from 82% to 88% for exercise and 88% to 91% for pharmacological MPI, whereas the specificity ranges from 70% to 88% for exercise and 75% to 90% for pharmacological stress nuclear MPI.[2] Stress CMR MPI can also be used to assess MPI.

Coronary CT Angiography (CCTA)

CCTA is a noninvasive diagnostic test using intravenous contrast to provide a highly accurate definition of coronary artery lumen. CCTA, along with functional noninvasive imaging like nuclear MPI or Stress Echo, is recommended as the initial diagnostic test for diagnosing CAD by guidelines.[1] CCTA's high sensitivity (values ranging 93–97%) and negative predictive value make it an excellent modality to rule out CAD.[2]

Invasive Testing

Invasive coronary angiography is considered the "gold standard" for diagnosis of CAD and may be used in cases where noninvasive tests are either inconclusive or indicate a high likelihood of severe IHD. It may also be used as an initial diagnostic test in patients with high clinical likelihood of CAD or angina with minimal exertion or symptoms unresponsive to medical therapy.[1]

Treatment

Management of CSA involves a multidisciplinary approach using general measures like lifestyle management, promotion of medical adherence, and support for managing lifestyle risk factors in conjunction with medical or interventional management. Lifestyle recommendations include smoking cessation, dietary changes, regular physical activity, maintaining a healthy weight, as well as management of risk factors like hypertension, diabetes, and hypercholesterolemia.

Medical Management

This is the mainstay of treatment in CSA for both symptomatic relief and coronary event prevention. The drugs used are mentioned in **Table 4**.

Revascularisation: Myocardial revascularization should be considered in patients of CSA who are symptomatic despite medical therapy. While there is no mortality benefit of revascularization in CSA,[5,6] some patients continue to be symptomatic despite optimal medical treatment. Such patients may benefit from revascularization, leading to improvement in quality of life and endurance with

TABLE 4 Medical management of chronic stable angina[1]

	Drug	***Indication***	***MoA***
Antiplatelet	Aspirin	All patients for even prevention	Irreversible COX-1 inhibition
	• Clopidogrel • Prasugrel • Ticagrelor	• Patients in whom DAPT is recommended (e.g., Post-PCI, history of PAD/TIA/Ischemic stroke) in combination with aspirin • Clopidogrel pretreatment in patients requiring PCI	Block the platelet $P2Y_{12}$ receptor, thus inhibiting platelet activation and preventing the development and propagation of arterial thrombus
Anti-anginal drugs	**Beta-blockers** *β_1 selective:* Metoprolol Bisoprolol Atenolol Non β_1 selective: Carvedilol	Patients with recent MI or chronic heart failure	Reduce heart rate, contractility, and atrioventricular conduction, thus reducing myocardial oxygen demand and time-to-angina onset during exercise
	Calcium Channel Blockers *DHP:* Nifedipine Amlodipine	• Hypertensive patients with angina usually with a beta-blocker • Exercise induced ischemia	DHP: Reduction in peripheral vascular resistance due to arterial vasodilation
	Non-DHP: Verapamil Diltiazem	All types of angina (exercise, vasospastic, or unstable), SVTs, and hypertension. Avoided in heart failure or in patients on beta-blockers	Decrease heart rate and myocardial inotropism
	Nitrates *Short acting:* Sublingual/Spray nitroglycerin	• Acute effort angina • Prophylaxis before physical activities	Dilatation of peripheral veins, with corresponding reductions in systemic vascular resistance, coronary blood flow redistribution, and preload
	Long acting: Isosorbide mononitrate Isosorbide dinitrate	Angina prophylaxis in cases where beta-blockers or non-DHP CCBs are contraindicated, poorly tolerated or provide insufficient symptom control	
	Ivabradine	2nd line drug	Decreases heart rate and consequently myocardial oxygen demand. No effect on contractility or BP
	Nicorandil	2nd line drug	Stimulates the ATP-sensitive potassium channels of the vascular smooth muscle resulting in systemic venous and coronary vasodilation
	Ranolazine	2nd line drug in patients with refractory angina	Inhibition of calcium overload in cardiomyocytes, without substantial changes in heart rate or BP
	Trimetazidine	2nd line drug	Targets deranged cellular energetics, particularly in ischemic myocardial tissue. Improves HbA1c and glycemia in diabetics
Lipid lowering drugs	*Statins:* Atorvastatin Rosuvastatin Simvastatin	Moderate to high dose statin therapy is indicated in all patients irrespective of LDL/Cholesterol levels	HMG-CoA reductase inhibition

Contd...

Contd...

	Drug	*Indication*	*MoA*
RAAS blockers	ACEI/ARB	Patients with coexisting hypertension, LVEF ≤40%, diabetes, or CKD	Reduce mortality, MI, stroke, and HF
	Spironolactone Eplerenone	Post-MI patients who: • Are on an ACEI/ARB plus beta-blocker, • EF ≤35%, and • DM or HF	Aldosterone receptor blockers

ACEI, angiotensin converting enzyme inhibitors; ARB, angiotensin receptor blocker; BP, blood pressure; DAPT, dual anti-platelet therapy; DHP, dihydropyridine; DM, diabetes mellitus; EF, ejection fraction; HF, heart failure; MI, myocardial infarction; PAD, peripheral artery disease; PCI, percutaneous coronary intervention; TIA, transient ischemic attack.

reduced pharmacological and mental burden on the patients. Other indications of revascularization include multivessel disease, reduced ejection fraction, significant coronary artery stenosis, and large area of ischemia (>10% of LV). Revascularization may be achieved percutaneously or with CABG.

Conclusion

A patient with history of chest pain presents a diagnostic challenge for physicians because of the wide variety of causes and variability in presentation. Therefore, careful history taking and guideline dictated testing is essential for identifying possible cardiac causes without subjecting the patient to unnecessary testing and monetary burden.

While chronic stable angina often presents as a "stable" disease, it is important to carefully evaluate patients for progressive disease or risk of imminent ischemic event. Lifestyle modification and medical therapy are the mainstay of treatment of CSA. Revascularization may be considered in addition to these in selected patients with careful consideration.

CHAPTER

37 Optimal Therapy in ST-elevation Myocardial Infarction Patients Presenting after 24 hours

Gaurav Singhal, Dinesh Gautam, Sanjiv Maheshwari, Shekhar Kunal, Shyam Sunder

Abstract

The management of ST-elevation myocardial infarction (STEMI) has undergone a paradigm shift from the initial days of thrombolysis to balloon angioplasty and percutaneous coronary intervention (PCI) along with stenting. Patients with STEMI have a time dependent myocardial injury leading to grim outcomes in delayed presenters. It has been clearly demonstrated that there is a remarkable benefit in opening of the infarct-related artery in order to salvage the ischemic myocardium within 12 hours of chest pain. There are also evidences that patients do not get benefit who present after 12 hours of STEMI. However, if patient presented with ongoing chest pain, signs of cardiogenic shock, or persistent ST-elevation, patient should be managed actively by PCI and stenting.

Guidelines also say about routine pharmacoinvasive therapy in 3–24 hours of STEMI. Most of the clinical trials either based on fibrinolysis or PCI and stenting showed suboptimal outcome after 24 hours of STEMI. Asymptomatic and stable patients do not get benefit by any reperfusion intervention after 24 hours.

Case Scenario

Case 1: A 64-year-old never smoker diabetic female presented to the cardiology outpatient emergency with complaints of a single episode of retrosternal chest pain lasting for 15 minutes a day prior to her presentation. She had initially consulted a local physician who after a thorough evaluation had got an ECG done which he interpreted to be abnormal, and hence referred her to a cardiologist. However, since the patient thought her symptoms had abated, she planned a routine visit to a cardiologist in the nearby city the day later. On evaluation, the patient was pain free, hemodynamically stable with a 12-lead ECG showing anterior wall myocardial infarction. The Cardiologist now has to make a decision regarding the treatment of this late presenter of STEMI.

Case 2: A 59-year-old former smoker hypertensive male presented in the emergency department with symptoms of chest pain (angina in character) for the past 2 days. On examination, the patient was drowsy but arousable, with tachycardia (pulse: 120/min, regular), blood pressure of 80/50 mm Hg with bibasilar crepitations. ECG on presentation was suggestive of an extensive ST-segment elevation MI. 2D echocardiogram reported severely depressed left ventricular ejection fraction with akinesia of the anterior wall with mild mitral regurgitation and no evidence of pericardial effusion. The emergency physician consulted the cardiologist on call who has to decide the further treatment plan in this patient with STEMI, cardiogenic shock, and delayed presentation.

Both the clinical scenarios presented above are not something new but reflects the problems faced by clinicians in everyday practice.

Introduction

Management of ST-elevation myocardial infarction (STEMI) is based on timely reperfusion of the occluded vasculature in order to salvage the ischemic myocardium.[1] However, a significant number of patients present late (beyond 12–24 hours) and constitute what we know as "late presenters." Data from the Western countries reveal that nearly 11% patients in the GRACE registry[2] and up to 40% patients in the TETAMI study[3] were classified as late presenters. However, the data from India is somewhat limited and showed that one third to half of STEMI patients presented to non percutaneous coronary intervention (PCI) centers and managed there conservatively and then referred to higher center.[4] A study from Lucknow (single center) is showing nearly a third of their cases were late presenters.[5] Patients presented after 24 hours of STEMI has different spectrum of presentation including totally asymptomatic to mild symptoms to cardiogenic shock (CS). Late presenters with CS constitute a subset of patients with extensive myocardial damage and poor clinical outcomes. In a another single center study from India, the in-hospital mortality rates of late presenters with CS was as high as 42.9%.[6] Hence, prompt identification of STEMI followed by urgent revascularization should be the goal of therapy. These late presenters may have completed occluded artery or may have patent infract-related artery (IRA) or severe stenosis in one, two, and three vessel disease. They can present with mechanical complication like rupture chordae, ventricular septal perforation, acute mitral regurgitation (MR), etc.

So the management of such a spectrum of presentation cannot be done in one way. Treatment strategy in such cases should be individualized with use of existing, but limited guidelines and experience. Many studies have suggested to perform primary PCI in late presenters with hemodynamic or electrical instability irrespective of time of presentation. But guidelines are not clear regarding the management of stable late presenters and there is an unmet need for well-planned clinical trials in order to have a clear understanding of the treatment algorithm in these patients. In this chapter we have discussed about management of patients presented after 24 hours of STEMI.

Reasons for Late Presentation

Multiple reasons can be laid down for late presentation in STEMI patients, which include:

- Lack of awareness or denial of the symptoms or presence of atypical symptoms
- Failure to or refusal to seek medical attention or use of alternative system of medicine
- Poor access to health care
- Incorrect diagnosis including atypical presentation
- Presentation in a non-PCI hospital[7]
- Financial issues

Proposed mechanism underlying the beneficial effects of late reperfusion: Clinical trials and meta-analysis showed the beneficial effects of reperfusion up to 12 hours from the onset of MI. After that there is no benefit to open the artery because of formation of mature thrombus and myocardial necrosis. However, this is not applicable to every patient.

There are some factors like presence of collaterals, ischemic preconditioning, subtotal occlusion, and spontaneous reperfusion, which delay the progression of infract size and prevent ventricular dysfunction.

Therapy in patients with STEMI presented after 24 hours: The goal of early management of STEMI by thrombolysis or by PCI with stent is to restore the myocardial perfusion, reduce microvascular damage, to limit infract size, and reduce mortality. It has been seen that spontaneous recanalization of occluded IRA occur in one third of patients started at 12–24 hours.[1] This delayed spontaneous reperfusion may enhance left ventricular function because it reduces infract size, prevents ventricular remodeling. In addition, interventions like thrombolysis or PCI accelerates the healing of infract. The efficacy of pharmacological agents decreases as coronary thrombus mature overtime. For every 30 minute delay in reperfusion, there is increase 8% relative risk of mortality per year.[2]

- *Thrombolysis in patients presented after 24 hours of STEMI:* Thrombolysis is based on clot lysis and establishment of the patency of the IRA leading to the salvage of the ischemic myocardium. Most of the landmark trials[8-10] on fibrinolysis in STEMI revealed that a majority of benefit is seen in patients who present early and the role of thrombolysis is limited to patients presenting within 12 hours. The meta-analysis of nine major trials (FTT Collaborative Group meta-analysis)[11] evaluated the role of fibrinolysis in 58,600 patients presenting with STEMI. The authors reported a significant decrease in mortality among patients

presenting early (up to 12 hours) post-STEMI, but no benefit in late presenters.

- *Reperfusion PCI in patients beyond 24 hours of STEMI:* Primary PCI is considered as the treatment of choice in patients with STEMI presenting within 12 hours of symptom onset. However, if patients have ongoing pain, persistent ST elevation, CS, decision of either thrombolysis or PCI should be taken accordingly and it is case dependent. A multi-centric RCT Occluded Artery Trial (OAT)[12]—involving 2,166 stable patients with total occlusion of the IRA 3–28 days post an episode of acute MI along with the presence of a high-risk criterion (i.e., LVEF <50% or a proximal occlusion of a coronary artery). The primary outcome was a composite of death, re-infarction or NYHA class IV heart failure (HF) with the exclusion criteria being (a) CS, (b) NYHA class III/IV HF, and (c) severe ischemia or left main involvement or triple vessel disease. The primary endpoint was achieved among 17.2% patients in the PCI group as compared to 15.6% of the medical therapy group with a higher re-infarction rate in the PCI group. In addition, there was no difference in event-free survival between groups with a median follow-up of 3.2 years. This trial showed no benefit of routine PCI in stable late presenters with STEMI.

  Barve II study[13] enrolled patients who were presented more than 12 hours but without any chest pain. There was significant reduction in infract size in the invasive group compared to medical therapy group but no mortality benefit. Four-year results of this study showed mortality benefit in PCI group but results of this study cannot be applied to all patients because of limitations of this study. A meta-analysis (Abbate et al.[14]) evaluated 10 RCTs comparing PCI of IRA with medical therapy in patients with delayed presentation (>12 hours–60 days) following acute MI. The PCI arm had significantly lower mortality as compared to the medical therapy arm [PCI arm: 112 (6.3%) vs. medical therapy: 149 (8.4%); OR: 0.49; P=0.03]. In addition, favorable benefits were reported in terms of significantly improved LVEF in PCI arm (4.4% increase post PCI; P=0.009).

Risk Stratification in Late Presenters after STEMI

- *Clinical:* In patients with late presentation following STEMI, clinical parameters pointing to a high risk include hemodynamic or electrical instability, and hence prompt revascularization should be performed in these patients.
- *LV ejection fraction (LVEF):* Most of the guidelines recommend assessment of resting LVEF as an integral component of risk stratification in late presenters.[15] Multiple imaging modalities including echocardiogram or cardiac MRI can be used to determine the LVEF. There is an increased cardiac mortality in patients with LVEF below 40%.[16]
- *Myocardial viability:* In clinically stable late (>72 hours) presenters myocardial viability should be assessed before a decision to revascularize is taken. A spectrum of imaging modalities, such as Thallium-201 or Technetium-99m SPECT, FDG-PET, Dobutamine stress echo (DSE), Contrast-enhanced cardiac MRI, and Dobutamine stress cardiac MRI, can be used to assess myocardial viability. The Viability-Guided Angioplasty after Acute Myocardial Infarction (VIAMI)[17] trial showed that PCI was associated with a significant reduction in ischemic event rates in patients with viability reported on low-dose DSE performed 48–72 hours post-STEMI. A decision to revascularize the ischemic myocardium should be made based on the presence of viability. CMR can very well characterize acute myocardial injury and determine the infarct size, hence has become the imaging modality of choice for the assessment of patients post-STEMI.
- *Stress testing:* Exercise testing in late presenters of STEMI is useful in determining the exercise capacity, identifying persistent ischemia as well as for future risk stratification. This has been proven in the DANAMI-I[18] and the SWISSI-II[19] trials where a beneficial effect was seen post PCI in late presenters with evidence of ischemia on stress testing. Stress testing can be combined with an imaging modality to identify high-risk patients who would benefit from delayed revascularization.

Recommendations for management of "unstable" late presenters: This subgroup of patients (clinical scenario: Case B) present with ongoing angina, CS or electrical instability following acute MI. These subgroup of patients requires the highest attention and timely revascularization in these patients, often alter the natural course of the disease.[20] Most of the guidelines[20,21] are in unison regarding the recommendations in these group of patients.

Recommendations for management of "stable" late presenters: The clinical scenario in the initial part of the chapter regarding Case A reflects the problems faced by clinicians and interventionists in deciding the tricky approach regarding revascularization in these asymptomatic/"clinically stable" late presenters following STEMI. The 2013 ACCF/AHA STEMI[20] guidelines clearly states that "Delayed PCI of a totally occluded infarct artery greater than 24 hours after STEMI should not be performed in asymptomatic patients with 1- or 2-vessel disease, if they are hemodynamically and electrically stable and do not have evidence of severe ischemia" (Class: III, LOE: B). The guidelines defined clinical stability as "absence of low cardiac output or hypotension, persistent tachycardia, apparent shock, high-grade ventricular or symptomatic supraventricular tachyarrhythmias, and spontaneous recurrent ischemia."

The 2017 ESC guidelines on STEMI[21] management states that "In asymptomatic patients, routine PCI of an occluded IRA >48 hours after onset of STEMI is not indicated" (Class: III, LOE: A). A more practical approach in this subgroup of patients would be coronary angiogram with an intent to revascularize in clinically stable early "late presenters" (<48 hours), while in patients presenting beyond 48 hours, stress or viability testing should be performed followed by a decision to revascularize.

Indian Guidelines: The 2017 Cardiological Society of India position statement[22] for the management of STEMI in India states that in late presenters of STEMI (>24 hours) with evidence of shock, pulmonary edema, electrical instability or ongoing ischemia, coronary angiogram with an intent to revascularize should be done as soon as possible. In addition, clinically stable patients with diabetes and LVEF below 40% should undergo a coronary angiogram with PCI if subtotal occlusion is there. In cases of total occlusion, myocardial viability needs to be established prior to PCI. Hemodynamically stable patients without high-risk features should undergo a stress test prior to discharge based on which a decision to revascularize should be made. Very late presenters (>72 hours) with a total occlusion and clinically stable do not have significant improvement following revascularization as seen in the OAT trial.

Conclusion

Asymptomatic STEMI patients after 24 hours should be managed conservatively, and intervention can only be done when signs and symptoms of ischemia appears. If there are complications like CS, ongoing pain, and other signs of ischemia, then intervention should be done to restore the flow. Further availability of various stress tests and myocardial viability tests would help in management of such late presenters.

CHAPTER

38 Management of Heart Failure in 2021—What Physician Must Know?

Alok Kumar Singh

Abstract

Heart failure (HF) is the final common pathway for many diseases that affect the cardiovascular system, if left untreated in the early course of disease. The lifetime risk for developing HF is about 20% for both men and women. Increasing prevalence of cardiac risk factors, such as hypertension, diabetes, and dyslipidemia as well as improved survival of patients with acute cardiovascular diseases, have resulted in HF becoming a major public health problem, across the world. The fundamental hemodynamic changes present in HF are increased pulmonary capillary wedge pressure, increased central venous pressure, and reduced cardiac output. Fluid and salt restriction (< 5 gm) is indicated in congested symptomatic HF patients in spite of diuretic therapy. RAS inhibition, beta blockade, and mineralocorticoid receptor antagonists (MRAs) are the main pillars of medical therapy of HF. At present angiotensin receptor neprilysin inhibitor (ARNI) (sacubitril/valsartan) is preferred over isolated RAS inhibition. Cardiac resynchronization therapy (CRT) and implantable cardiac defibrillator (ICD) should be utilized judicially at proper time in the disease course of HF. LV-assist devices should be considered in refractory heart failure as bridge to transplantation or as destination therapy.

Introduction

Heart failure (HF) is the final common pathway for many diseases that affect the cardiovascular system, if left untreated in the early course of disease. The lifetime risk for developing HF is about 20% for both men and women. Increasing prevalence of cardiac risk factors, such as hypertension, diabetes, and dyslipidemia, as well as improved survival of patients with acute cardiovascular diseases, have resulted in HF becoming a major public health problem, across the world. There is no exact data on HF burden in India is available at present, because of the absence of disease surveillance systems in India. A rough estimate[1] on the community-level prevalence of HF in the adult population in India is about 1%. As per the European Society of Cardiology, HF is best defined as "A clinical syndrome characterized by typical symptoms that may be accompanied by signs caused by a structural and/or functional cardiac abnormality, resulting in a reduced cardiac output and/or elevated intracardiac pressures at rest or during stress." In this chapter we restrict our discussion in the context of chronic HF only.

Pathophysiological Basis of Heart Failure

The three fundamental hemodynamic changes present in HF are increased pulmonary capillary wedge pressure, increased central venous pressure, and reduced cardiac output. Lung congestion, secondary to increase left sided cardiac filling pressure, responsible for breathlessness at rest or exertion, paroxysmal nocturnal dyspnea, orthopnea, or rales in lung during chest examination. Increased CVP secondary to left sided heart disease, or isolated right heart disease, leads to systemic congestion, leads to

clinical features such as ascites, anorexia (secondary to gut congestion), elevation of liver enzyme (sometimes can mimic viral hepatitis) and generalized body swelling. Reduced forward cardiac output secondary to ventricular dysfunction occurs relatively late in the natural history of chronic HF, although in acute HF it may occur in minute to hours. In chronic HF, as the ejection fraction decreases, heart increases stroke volume by increasing end diastolic volume of the left ventricle, until or unless ejection fraction very low (<20%), so this may be the reason, why some patients are relatively asymptomatic for longer time in chronic HF with left ventricular with systolic dysfunction.

Chronic maladaptive activation of sympathetic nervous system (SNS) and renin angiotensin system (RAS) in HF leads to ventricular remodeling. The complex alterations in the ventricle in response to various mechanical and neurohormonal stressors on the heart, resulting in alterations in volume, wall thickness and/or shape (from ellipsoid to spherical in case of left ventricle) is defined as ventricular remodeling. As a result of myocardial stretch in HF, the gene coding for brain natriuretic peptide (BNP) is activated and the prohormone pro-BNP is produced. This is cleaved to the biologically active BNP and the biologically inert but stable NT-proBNP. BNP induces natriuresis, vasodilatation, and vascular smooth muscle relaxation, because of their sympatho-inhibitory action. These three systems (SNS, RAS, and NP) are the targets of modern medical therapy, which have changed the natural history of HF by inducing reverse remodeling.

Classification of Heart Failure

HF can be classified in multiple ways,[2-5] depending on left ventricular ejection fraction **(Table 1)**, depending on presentation **(Table 2)**, and functional class **(Table 3)**. These classifications are important for management strategies as well as prognostic point of view. The NYHA functional classification has been used to describe the severity of symptoms and exercise intolerance. The symptom stages are clearly related survival, yet they correlate poorly with LV function. The American College of Cardiology Foundation/American Heart Association (ACCF/AHA) classification[3,4] describes stages of HF development based on structural changes and symptoms have been described in **Table 4**. The ACC/AHA staging is invaluable in holistic management of HF, from prevention to appropriate intervention at appropriate time.

TABLE 1 The classification of heart failure based on LVEF

Type of HF	*Characteristics*
Heart failure with reduced ejection fraction (HFrEF)	• Symptom ± sign of heart failure • LVEF < 40%
Heart failure with preserved ejection fraction (HFpEF)	• Symptom ± sign of heart failure • LVEF > 49% • Elevated level of natriuretic peptide* • Minimum one additional echo criteria – Relevant structural heart disease such as LVH and LAE – Evidence of diastolic dysfunction
Heart failure with midrange ejection fraction (HFmrEF)	• Symptom ± sign of heart failure • LVEF 40–49% • Elevated level of natriuretic peptide* • Minimum one additional echo criteria – Relevant structural heart disease such as LVH and LAE – Evidence of diastolic dysfunction

*BNP—35 pg/mL or NT-proBNP > 125 pg/mL.

TABLE 2 The classification of heart failure based on time course

Type of heart failure	*Definition*
Acute decompensated heart failure (ADHF)	Term for patients presenting acutely with HF, which can be defined as "the sudden onset of the signs or symptoms of heart failure requiring unplanned hospitalization, or emergency room visits, or unplanned office consultation"
Chronic heart failure	Term for patients presenting with insidious onset of symptom and signs of heart failure
A new-onset/de novo HF	Term used for HF patients, presenting with symptoms of heart failure in an acute or sub-acute (gradual) fashion for the first time
Stable heart failure	A treated patient of heart failure with unchanged symptomatic status for at least 1 month is said to be "stable"
Advanced HF	Term refers to patients with severe cardiac dysfunction, recurrent decompensation, and severe symptoms despite optimal standard medical therapy
Asymptomatic LV systolic dysfunction	Term used for an asymptomatic patient with reduced LVEF who never exhibited typical signs and symptoms of HF

TABLE 3 The NYHA classification of heart failure

NYHA class	*Description*
I	No limitation of physical activity. Ordinary physical activity does not cause symptoms of HF
II	Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in symptoms of HF
III	Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes symptoms of HF
IV	Unable to carry on any physical activity without symptoms of HF, or symptoms of HF at rest

TABLE 4 The ACC/AHA staging of heart failure

Stages	*Description*	*Example*
A	At high risk for HF but without structural heart disease or symptoms of HF	Risk factors for HF like hypertension, diabetes, and dyslipidemia
B	Structural heart disease but without signs or symptoms of HF	Asymptomatic patient with structural heart disease such LV hypertrophy and LV dysfunction
C	Structural heart disease with prior or current symptoms of HF	Current or prior symptomatic (NYHA classes I to IV) patients with objective evidence of cardiac dysfunction
D	Refractory HF requiring specialized interventions	End stage HF—unable to carry on any physical activity without symptoms of HF, or symptoms of HF at rest

Diagnosis of Heart Failure

Clinical Features

Breathlessness on exertion or at rest, orthopnea, and paroxysmal nocturnal dyspnea may be the presenting symptom of HF. Anorexia, generalized swelling of body, fatigue, oliguria, and altered sensorium may be the presenting feature of advanced HF. S3, S4, and murmur on cardiac auscultation may be present in HF patients. Presence of rales (usually absent in chronic HF) may be present on lung examination. Presence of raised jugular venous pressure, hepatomegaly, anasarca, and ascites may point toward the diagnosis of HF. ECG is must in all cases of HF. ECG may give clue to the etiology of HF. Perfectly normal ECG is highly unlikely in HF, although some time may be present. If history, physical examination, and ECG are suggestive of HF, then echo should be done to establish the diagnosis and classification of HF. If echo is not available at site, then assessment of cardiac biomarker followed by echocardiography can be done. For patients presenting with chronic HF, the optimum exclusion cut-off point is 125 pg/mL for NT-proBNP and 35 pg/mL for BNP, whereas for patients presenting with acute HF, the ideal exclusion cut-off point is proposed to be 300 pg/mL for NT-proBNP and 100 pg/mL for BNP. It needs to be understand that the negative predictive value of BNP/NT-pro-BNP is very high (0.94–0.98), while the positive predictive value is low (0.64–0.67), making them a good test to rule out HF but a poor tool to establish diagnosis.

Echo is invaluable in diagnosing specific valvular pathologies, pericardial diseases, and specific type of cardiomyopathies. Assessment of diastolic dysfunction (E/A ratio, E/e, Left Atrial volume, LV mass) is must for establishing the diagnosis of HFmrEF and HFpEF.

Presence of pulmonary artery hypertension is indicative of poor prognosis in HF, so it should be looked for in every case of HF.

In select cases CT or invasive coronary angiography is recommended for ruling in or out coronary artery disease. Magnetic resonance imaging is also having important role in establishing the diagnosis of specific cardiomyopathies and determining the viability in ischemic cardiomyopathy before proceeding to revascularization. Complete blood count (Hb, TC, DLC, and ESR), serum electrolyte, and serum creatinine, liver function test, and thyroid profile should be done in all cases of HF.

Treatment of Heart Failure

Fluid and salt restriction (<5 gm) is indicated in congested symptomatic HF patients, in spite of diuretic therapy. Exercise should be encouraged in early phases of HF, but in

advance stage it may not be advised. If any specific etiology is responsible for HF should be treated accordingly, such as valvular hear diseases by valvular intervention, ischemic heart disease by revascularization and pericardiectomy for constrictive pericarditis. Diuretics are recommended to relieve lung as well as systematic congestion and symptomatic benefit only. No specific therapy have been found to change the natural history of HF in HFpEF population till date, so only symptomatic treatment and associated comorbidities such as hypertension, diabetes, dyslipidemia, chronic obstructive pulmonary disease (COPD), and rhythm disorders such as atrial fibrillation should be treated. The major objective of therapy in HFrEF is to improve functional class, symptomatic status, and prevent recurrent hospitalizations and reduce mortality. It is recommended to treat HFrEF patients with ACE inhibitor [or angiotensin receptor blocker (ARB)] and beta blockers to the maximum tolerated dosages. If patient is still symptomatic and LVEF less than 35%, then mineralocorticoid receptor antagonists (MRAs) should be added. Once MRAs and angiotensin converting enzyme) inhibitors (ACEIs) or ARB are combined, then close monitoring of serum potassium and creatinine

TABLE 5 All-cause mortality reduced by treatments recommended in HFrEF

Therapy	*Number needed to treat (For 5 years)*
Beta blocker	8
ARNI	11 (compared to placebo), 21 (compared to ACEI)
MRA	15
ACE	18
ARB	24
ICD	14
CRT	14

TABLE 6 Dosages and side effects of drugs approved in heart failure

Drug class	*Dosages*	*Side effects*
Beta blockers	Metoprolol succinate (12.5–200 mg od) Carvedilol (3.125–25 mg bd) Bisoprolol (1.25–10 mg od)	Hypotension, Bradycardia, AV-block, Fatigue
ACEIs	Enalapril (2.5–20 mg bd) Ramipril (2.5–10 mg od) Captopril (6.25–50 mg tds) Lisinopril (2.5–35 mg od)	Cough, dizziness, angioedema, hypotension, renal impairment, and hyperkalemia
ARBs	Losartan (50–150 mg od) Valsartan (40–160 mg bd) Candesartan (4–32 mg od)	Same as above
ARNI	Sacubitril/Valsartan (49/51–97/103 mg bd)	Same as above
MRAs	Spironolactone (25–50 mg od) Eplerenone (25–50 mg od)	Hyperkalemia, Gynecomastia (more common with spironolactone)
If channel inhibitor	Ivabradine (5–7.5 mg bd)	Bradycardia, development of AF and rarely torsade ds pointes, visual symptoms (phosphenes)
Digoxin	(125 mg od to .25 mg od)	Nausea, vomiting, anorexia, arrhythmias (ectopic and re-entrant tachycardias with AV block), visual disturbances, disorientation, and confusion
Hydralazine and isosorbide dinitrate	(25/20–75/40 mg tds)	Headache, dizziness, and non-specific gastrointestinal complaints
Loop diuretics	Furosemide (20–240 mg od) Bumetanide (0.5–5 mg od) Torsemide (5–200 mg od)	Hypokalemia, fluid depletion, azotemia, ototoxicity
Thiazides	Hydrochlorothiazide (12.5–100 mg od) Metolazone (2.5–10 mg od) Indapamide (2.5–5 mg od)	Hyperuricemia, hyponatremia, hypokalemia, hypomagnesemia, hypercalcemia, and fatigue

is recommended, because both can increase serum potassium. If HF patient able to tolerate ACEIs or ARB, and still symptomatic and LVEF less than 35%, then ACEIs or ARB should be replaced with angiotensin receptor neprilysin inhibitor (ARNI) (Sacubitril/valsartan). ARNI should be started after 36 hour of stopping ACEIs because of increased risk of angioedema, if both are combined together. If patient is still not improving and in sinus rhythm and heart rate greater than 70, then channel current inhibitor (ivabradine) should be added. After all pharmacological treatment exhausted (3–6 months of optimal medical therapy), patient still symptomatic, LVEF less than 35%, QRS duration greater than 130 milisecond and LBB morphology, then cardiac resynchronization therapy (CRT) is recommended. If there is a history of ventricular tachycardia or fibrillation or patient LVEF is less than 35% despite optimal medical therapy, then implantation of implantable cardiac defibrillator (ICD) is recommended to prevent sudden cardiac death. As evidenced by recent analysis, among all guideline directed therapies, beta blockers are most effective in reducing mortality and promoting reverse remodeling in HF[6] **(Table 5)**. The dosages and side effect of drugs recommended in HF are summarized in **Table 6**. If patient is still symptomatic and refractory to all described therapies, then patient should be referred to specialized center for ventricular-assist devices or cardiac transplantation. Based on the result of DAPA-HF trial[7] of the US FDA dapagliflozin (SGLT-2 inhibitor) approved for the treatment symptomatic HF of LVEF 40%. Drugs known to adversely affect the clinical status of patients of HFrEF should be avoided, whenever possible (e.g., most antiarrhythmic drugs), most calcium channel blocking drugs (except amlodipine), NSAIDs, or TZDs (pioglitazones).

Conclusion

HF is the final common destination of untreated cardiovascular diseases. As the population is aging worldwide, prevalence of HF is increasing. RAS inhibition and beta blockade is the main pillar of medical therapy of HF. At present ARNI is preferred over isolated RAS inhibition. CRT and ICD should be utilized judicially at proper time in the disease course of HF. LV-assist devices should be considered in refractory heart failure as bridge to transplantation or as destination therapy.

CHAPTER

39 Atherosclerotic Cardiovascular Prevention in 2020: Consideration of Gray Areas and Ways to Remedy It

Amarendra Kumar Sinha, Ashish Sinha, Nitin Kumar Sinha

Abstract

The most important way to prevent atherosclerotic vascular disease, heart failure, and atrial fibrillation is to promote healthy lifestyle throughout life. Coronary artery disease (CAD) risk equivalents, like atherosclerotic changes in carotid artery, peripheral artery, and abdominal aortic aneurysm, should receive serious attention to prevent established atherosclerotic cardiovascular disease. A diligent search should be made to detect apparent risk and silent risk factors like coronary artery calcium (CAC) and inflammatory status (increased hs-CRP, IL-6, especially associated with visceral adiposity, etc.). Guidelines should be shorter, crisp, and user friendly. A team-based care approach is an effective strategy for prevention of cardiovascular disease. Health literacy is essential for implementation of guideline.

Introduction[1]

In the developed nations and to some extent also in developing nation, coronary artery disease (CAD) is a major cause of death and disability. Although mortality rates related to CAD have continued to decline over past years, CAD remains accountable for about one third of all deaths over the age of 35 years. Majority of CAD are due to atherosclerosis (ASCVD), which involves other major large arteries like cerebral and peripheral artery. Obviously it has huge impact on finances and health care system.

Most Americans, who have had myocardial infarction (MI), had unfavorable level of at least 1 Cardiovascular (CV) risk factor before their ASVCD event. In 2010, American Heart Association (AHA) defined "ideal CV health" and referred to as "Life's simple 7".

Risk Factors and CAD Risk Equivalents[1]

CAD Risk Equivalents

Some individuals without known CAD have risk of major CV events that is equivalent to that of patient with established CAD. They should be managed aggressively like patient of established CAD. They are:

- Atherosclerotic disease status in carotid artery, peripheral artery, abdominal aortic aneurysm. In such situation 10 years risk of developing CAD exceeds 20%.
- Diabetes mellitus (DM), insulin resistance, hyperinsulinemia, and elevated blood sugar are associated with ASCVD. The all-cause mortality risk associate with DM is comparable to all-cause mortality risk associated with prior MI.
- Hyperglycemia without overt DM correlates with CV risk.
- Chronic kidney disease (CKD) even with mild to moderate renal dysfunction is associated with substantial increase in CAD risk.

Traditional Risk Factors for Atherosclerosis

- High blood pressure
- High total cholesterol
- High LDL cholesterol

- Low HDL cholesterol
- Hypertriglyceridemia
- Increased non-HDL cholesterol
- Increased lipoprotein (a)
- Increased apolipoprotein-B
- Increased apolipoprotein C-III
- Small dense LDL particles
- Glucose intolerance
- Smoking
- Family history of premature CAD
- High BMI
- Age
- Physical inactivity
- Obesity
- Psychosocial factors, (depression, anger, stress, and other factors). They lead to premature CAD, acute coronary syndrome (ACS), and sudden cardiac death (SCD).

Novel and Emerging Risk Factors

- High Hs-CRP (high-sensitivity C-reactive protein)
- High IL-6 (interleukin) and membrane bound IL-6
- Increased level of leukocyte enzyme myeloperoxidase
- HIV-positive status
- Mediastinal and chest wall radiation
- Metabolic syndrome
- Microalbuminuria
- Remnant lipoproteins

Novel risk factors like Hs-CRP, IL-6, leukocyte enzyme myeloperoxidase denote inflammatory changes in atheroma formation and progression. They have opened new pathway for treatment. The association of microalbuminuria and CAD is established but mechanism remains unclear.

Genetic susceptibility to CAD is seen in 40–60% cases. Currently 33 genetic variants have been identified, which increase patients risk for CAD.

Borderline CAD Risk[2]

Among adults with 10 years borderline risk (5% to <7.5%) and intermediate risk (>7.5% to <20%) risk, one may consider searching additional individual risk-enhancing clinical factors. This will help to revise the 10 years ASCVD risk estimate.

Risk-enhancing Factors[2]

- Family history of premature ASCVD (male: <55 years; female: <65 years)
- Primary hypercholesterolemia
- Metabolic syndrome (MS)
- Chronic kidney disease (CKD)—eGFR 15–59 mL/min/1.73 m^2
- Chronic inflammatory conditions. Example, psoriasis, RA (rheumatoid arthritis), lupus, or HIV/AIDS
- History of premature menopause (before 40 years) or preeclampsia
- High-risk ethnicity. Example, South Asian Ancestry
- Lipid/Biomarkers associated with increased ASCVD risk
  - Persistently elevated LDLC > 160 mg/dL
  - Persistently elevated primary hypertriglyceridemia >175 mg%—non fasting
  - High Hs-CRP (≥2.0 mg/L)
  - High lipoprotein (a) (≥50 mg/dL)
  - Elevated apolipoprotein B (≥130 mg/dL)
  - ABI (<0.9)

Risk Assessment and Detection of Asymptomatic Atherosclerosis

Status of CAC[2]

Coronary artery calcium (CAC) detection by high-resolution computer tomography (CT) or CT angiography. CT angiography is burning topic, as these have additional power of treating ASCVD.

Recent evidences support that measurement of CAC is predictive of coronary heart disease death or MI at 3–5 years. Current evidence also suggests that use of CAC is independently predictive of outcome over and above traditional cardiac risk factors.

CAC scoring has been evaluated as noninvasive diagnostic technique for detecting obstructive CAD. CAC may be used as an effective filter before undertaking invasive diagnostic procedure. Score less than 100 are associated with low probability. No calcium means zero score.

Use of CAC score are not recommended for follow-up of lesion due to cost and radiation hazard.

Atheroma Progression, Regression, Vulnerable Plaque: Impact of Serial CAC and Statin[3-5]

A trend toward increasing atheroma calcification following statins use has been reported. Aside from lipid regression within plaques following long-term potent statin therapy, statin mediated atheroma calcification may improve plaque stability.

Recent research suggests that plaques containing low proportion of microcalcifications actually rupture. With more confluent and dense plaque calcification, plaque stability is improved due to low-wall stress. Cardiac CT angiography (CCTA) provides direct visualization of vessel wall, thus providing good assessment of the atherosclerotic burden. The goal is to identify vulnerable plaque, responsible for most ACS. Plaque measured by wall component is classified in Hounsfield Units (HU), as soft or lipid rich (30–60 HU), fibrous (70–120 HU), or calcified (>350 HU).

In a study of 1,059 patients, who underwent CCTA, the investigators found that those with plaques showing positive remodeling and low attenuation on CCTA were at higher risk for ACS during 27-month mean follow-up compared with patients without these characteristic.

Atherosclerosis, Inflammation, and Thrombosis

Inflammation most likely plays a causal role in plaque rupture. Vulnerable plaque has thin cap fibroatheroma (TCFA). These have very high density of macrophages (approximately 14%) in contrast to stable fibroatheroma (approximately 2.0% macrophages). These can be assessed by CCTA.[6]

Detection of inflammatory markers as discussed earlier has opened a new avenue for treating atherosclerosis and preventing impending thrombosis. Two trials are worth mentioning:

- *The Cantos Trial (Canakinumab Anti-inflammatory Thrombosis Outcome Study)*:[7] Inclusion criteria: History of MI, High Hs-CRP (≥2), Duration of study 3.7 years, Targeted level of Hs-CRP, IL-6, IL-18, IL-B. Dose of 150 mg daily was effective in preventing adverse cardiac event after median of 3.7 years with hazard ratio 0.68. Mechanism of benefit is due to decrease in Hs-CRP likely. Could not be used in practice due to cost, duration, and complication of infection.
- *Colcot Trial*:[8] Efficacy and safety of low dose colchicines after MI. A small dose of 0.5 mg daily was used in recent MI. Endpoint was composite death from CVS cause, MI, stroke, angina, cardiac arrest. Result was 5.5% in treated group versus 7.1% in placebo, with hazard ratio of 0.77.

How should we Approach Preventing ASCVD?[2]

ACC/AHA guideline (2019) on the primary prevention of CVD aims to promote the delivery of patient-centered care:

- Team based care approach for control of risk factors associated with ASCVD. (COR:1).
- Shared decision, after discussion about best strategy to reduce ASCVD risk (COR:1).
- Social determinants of health will guide better implementation of plan for prevention of ASCVD.

Assessment of Cardiovascular Risk

Tool is available online at ACC/AHA site:

- For adult 40–75 years—should routinely assess traditional CV risk factor and calculate 10 years risk of ASCVD.
- For adults 20–39 years—Assess risk every 4–6 years.
- In adult at borderline risk (5% to <7.5%) or in intermediate risk (≥7.5% to <20% 10 years risk) assess risk *enhancing factors* to guide about preventive therapy (like statin).
- In adult with intermediate risk or in borderline risk, if decision about statin remains uncertain, measure CAC for clarification (Class IIa).

Assessment of Risk Factors

- One should look for all traditional and emerging risk factors in each cases but the clinical scenario will guide the situation.
- At the same time risk-enhancing factors should be searched and assessed.

Assessment of Social Determinants of Health

This will guide us about implementation of preventive strategy in each case at grass root level:

- Psychological stressors

- Health literacy
- Social barriers of heart healthy diets
- Neighborhood environment. Facility of exercise
- Concept about health, body weight, and obesity
- Concept of lifestyle counseling for weight loss, sleep, psychosocial stressors
- Job status, family life, and mutual relation, history of depression
- Personal habits, viz. tobacco, alcohol
- Diabetes mellitus—controlled on diet, exercise of drugs? Education to maintain sugar level
- Hypertension—controlled on drug? Does he understand benefit of low-sodium diet, exercise, and proper sleep

It cannot be overemphasized that health literacy will go long way to prevent ASCVD.

Detection of Inflammatory Status and Asymptomatic Cases of ASCVD

This has already been discussed earlier in this chapter. It is very important to prevent ACS. This concept is the need of hour and is oriented toward saving life of patient. This involves detection of inflammatory marker and study by CCA or CCTA for vulnerable plaque.

Management Issues[2]

All risk factors should be dealt with as per guideline. Few very relevant points will be discussed here:

- Diet
- Exercise and physical activity (PA)
- Cholesterol management (lipids)
- Hypertension (HTN)
- Diabetes mellitus
- Tobacco abstinence
- Prophylactic ASA (aspirin) therapy

- *Diet:* It should be followed as per guideline. Salient points are:
  - Encourage vegetables, fruits, legumes, nuts, whole grain and fish
  - Replacement of saturated fat with dietary monounsaturated and polyunsaturated fats
  - Low in cholesterol and sodium
  - Avoid processed meats, refined carbohydrate, and sweetened beverages
  - Red meat should be eliminated. It increases systemic levels of TMAO (Trimethylamine N Oxide) a mocrobiome-dependent metabolite. It has been associated with increase CV risk[9]
  - Trans fats should be avoided
- *Exercise and physical activity:*
  - Should be routinely counseled in health care visits about need of active lifestyle
  - Adult should engage in at least 150 minutes per week of moderate exercise or 75 minutes per week of vigorous-intensity aerobic exercise
  - Even less than ideal goal is beneficial

  Definitions of different intensity of physical activity:
    - Sedentary, 1–1.5 mets—sitting, lying, watching TV
    - Light, 1.6–2.9—walking slowly, cooking, light household work
    - Moderate, 3.0–5.9—brisk walking (3.8–6 km/hr), biking (8–14 km/hr), active yoga
    - Vigorous ≥6—jogging, running, biking >16 km/hr, single tennis, swimming laps
- *Cholesterol management:*[2,10] Few accepted facts as per 2018 cholesterol guidelines:
  - Adults with intermediate (7.5% to <20%) risk of 10 years ASCVD—moderate intensity statin.
  - In intermediate risk LDL-C should be reduced by 30% or more.
  - In high risk 10 years group (20% or more)—LDL-C should be reduced by 50% or more.
  - In adult, 40–75 years of age with diabetes, regardless of estimated 10 years risk, moderate intensity statin is indicated.
  - In patients of 20–75 years age with LDL-C level 190 mg/all maximum tolerated dose of statin should be given.
  - In DM with multiple ASCVD risk factors. High intensity statin should be prescribed. Goal should be to reduce LCL-C by 50% or more.
  - In intermediate risk (≥7.5% to <20%) presence of risk enhancing factors favor initiation or intensification of statin therapy.
  - In intermediate or borderline risk, if CAC is measured—CAC is zero—withhold statin.

    CAC is 1–99—start statin in 55 years age or more.

    CAC is 100 or higher—initiate statin.

  - In borderline risk (5% to <7.5%), presence of risk enhancing factors justify statin.
- *Hypertension:* Principles of management as per guideline:
  - Non-pharmacological interventions:
    - Weight loss
    - Heart healthy dietary pattern
    - Sodium restriction
    - Dietary potassium supplementation
    - Increased physical activity and exercise
    - Limited alcohol (1–2 drink daily) (1 drink means 14 gm pure alcohol)
  - BP target of less than 130/80 mm Hg
  - In CKD and DM, treatment initiated at 130/80
  - If ASCVD 10 years risk is less than 10%, antihypertensive drugs are initiated at 140/90 or more choice of drug as per guidelines.
- *Diabetes mellitus (T2DM):*
  - One should look for diabetes specific risk enhances in DM (T2DM). These are independent of other risk factors:
    - Long duration—more than 10 years in T2DM, more than 20 years in T1DM.
    - Albuminuria + >30 mcg albumin/mg of creatinine.
    - eGFR <60 mL/min/1.73 m^2
    - Retinopathy
    - Neuropathy
    - ABI <0.9

  Such patients required high-intensity statin therapy.
  - After appropriate diet therapy and exercise cum physical activity plan, one should proceed to drug therapy:
    - Metformin is a first-line drug. It reduces 32% reduction in micro and moreover vascular DM related outcome, 39% reduction in MI, and 36% reduction in all-cause mortality rate.
    - In addition two class of drug: SGLT-2 inhibitors reduce incidence of heart failure. GLP-1R agonist reduces ASCVD events.

  Drug management of DM should be done as per guideline protocol.
- *Achieve tobacco abstinence:* It should be firmly emphasized. It is important to encourage patients to seek help from trained staff. All adult and adolescents should avoid secondhand smoke exposure to reduce ASCVD risk.
- *Prophylactic aspirin:*
  - In primary prevention:
    - Benefit seen in DM. Major vascular events decreased by 12%.
    - Between age 40 and 70 years only Class IIb recommendation. Individual approach by clinician and risk of bleeding to be considered.
    - Beyond 70 years, not recommended.
  - In secondary prevention:
    - Prophylactic ASA (aspirin) is recommended in setting of elevated ASCVD risk.
    - ASA suggested when risk is more than 10% at 10 years ASCVD risk.
    - Recent clinical trials also allow us to use low dose ASA among patient with high ASCVD risk.
    - Dose of ASA can be adjusted as per body weight.

Conclusion

- ASCVD events are avoidable through primordial prevention (i.e., prevention of risk factor development) and control of traditional CV risk factors.
- Tobacco avoidance is critically important for ASCVD prevention.
- Exercise and physical activity along with dietary management are absolutely essential.
- All these factors are better implemented with basic health education and how best dedicated persons are involved in counseling. Without these, it will go waste.
- The intensity of preventive efforts should match with individual's absolute risk of future ASCVD event.
- The clinician must balance the benefit and risk.
- Assessing appropriateness of pharmacotherapy may require search of "Risk enhancing factors" in borderline situation.
- At this point, use of "CAC" measurement can help in decision-making for cholesterol lowering or antihypertensive medication use in intermediate risk individuals.
- CCTA or CAC is now the most accurate in invasive tool for the assessment of ASCVD with highest concordance to invasive coronary angiography (CAG). CCTA is widely utilized in accurate and rapid assessment in cases of chest pain in emergency department (ED). The visualization of subclinical atherosclerosis (on either coronary calcium scanning or seeing non-obstructed plaques on CCTA) allows for targeted anti-atherosclerotic treatment strategies and improved adherence to these treatment. Possible diagnosis of vulnerable plaque is another achievement to prevent ACS.

Contd...

Contd...

- Inflammatory markers should also be taken care of to halt atherosclerosis progress and possibly prevent ACS.

There are additional challenges specific to prevention realm.

AHA in 2011 in their policy statement described about value of primordial and primary prevention in CVD:

"Assessing the value of prevention in apparently healthy patients is generally more difficult than evaluating therapy for established disease because the time horizon to the clinical manifestation of disease is generally long, many decades in the young. Thus, it is difficult, perhaps impossible, to assess long-term effectiveness in terms of survival or quality-adjusted life-years (QALYs) or associated costs because of increasing uncertainty about outcome, the further one tries to look into the future."

CHAPTER

40 SGLT2 Inhibitors in Heart Failure

NS Prasad

Abstract

The occurrence of heart failure (HF) is on the increase globally and in India. The coexistence of diabetes (DM) and HF increases the mortality risk. Various CVOT trials have proven SGLT inhibitors to reduce the hospitalization for heart failure (HHF) and CV mortality. SGLT inhibitors have proven to be useful in heart failure regardless of diabetic status.

Introduction

Patients with coexisting conditions of type 2 diabetes mellitus (T2DM) and heart failure (HF) tend to have increased mortality risk when compared to people who do not have either DM or HF.[1-3] This association of DM and HF is mainly due to mistimed and asynchronous handling of glucose and free fatty acids by the cardiac system. Another hypothesis is that the effect on heart and blood vessels, caused directly by the metabolic derangements seen in patients with diabetes mellitus (DM) may also play a vital role in this coexistence. Also, use of certain anti-diabetic agents (mainly DPP-4 inhibitors and pioglitazone) can potentiate hospitalization for HF.[4]

As high as 20% of the population is expected to develop HF at some point during their lifetime.[5] It is a global pandemic affecting an estimated 26–37.7 million people worldwide.[6,7] The burden of HF in India has become an important public health concern because of very high mortality. HF exerts a high-economic burden mostly due to hospitalizations.[8] India is the highest spending country on HF in South Asia with a total expenditure amounting to 1.7% of total health expenditure of India.[9] Recent studies have clearly shown that the prevalence of HF with preserved ejection fraction (HFpEF) is mounting significantly when compared to that of HF with reduced ejection fraction (HFrEF). Available statistics further suggest that in the year 2020, only 35% of patients with HF have reduced EF<40%, and over 65% have a preserved EF>40%.[10] Atherogenesis and endothelial damage play a very crucial role in pathophysiology of HF in DM. Insulin resistance and hyperinsulinemia cause left ventricular hypertrophy which is frequently linked to T2DM.[11] Hyperglycemia results in cardiac muscle stiffness and leading to non-compliance of the myocardium. Therefore, drugs decreasing insulin resistance and aggressively controlling the hyperglycemia should be part of therapy in order to reduce the incidence of HF in T2DM.[12] T2DM could potentially cause cardiomyopathy independent of atherosclerotic ischemia, and there is evidence of cardiomegaly in T2DM patients. Hence, therapy targeting such pathology,[13] for example, sodium/glucose cotransporter-2 inhibitors (SGLT2i), might be useful.[14,15]

Cardiorenal Association

Heart and kidney are closely related when it concerns the physiological functions and pathological conditions of both systems. Acute or chronic disorders of one of these organ systems are capable of having a deleterious effect on the other. This closely linked interplay is often called as the cardiorenal association.[16] Studies have indicated that

anywhere between 20% and 67% of patients with HF will also have chronic renal impairment as an association.[17,18] HF can also directly or indirectly lead to renal impairment or CKD. This may be due to a low cardiac output and increased venous pressure. On the other hand, renal impairment may also worsen HF. This can happen via enhanced water and sodium retention, potentiated atherosclerosis, anemia, inflammation, uremic toxins, and activation of the neurohormonal pathways.[19,20]

Evidence for Use of SGLT2i in HF Prophylaxis

SGLT2i have shown positive results when it comes to hospitalization for the sake of heart failure (HHF) and CV or overall mortality across several cardiovascular outcome trials. These favorable results have been demonstrated both in patients with and without history of pre-existing cardiac ailment. A meta-analysis has confirmed robust advantages with SGLT2i on HHF and CV mortality even in patients without CVD or HF, indicating benefits in the early HF stages as well.[21]

Empagliflozin in the EMPAREG OUTCOME study[22] and dapagliflozin in DECLARE-TIMI 58[23] study revealed a significant reduction in HHF. Analysis of the CANVAS trial[24] also exhibited a significant fall in HHF rates in both prevention groups—primary and secondary. In line with these results, the US regulatory authority has approved empagliflozin for lowering CV mortality and canagliflozin for lowering major adverse cardiac events—MACE in patients with DM who also have coexisting cardiac disease. The results of DECLARE-TIMI 58 have proven significantly lower rates of cardiovascular mortality or HHF. Further, they also mildly suggested that it may apply to primary prevention also, since clinical mortality benefits were seen in patients who did not have cardiac disease or HF at the baseline. DECLARE TIMI results when stratified by cardiac ejection fractions showed an HHF reduction.[25] Patients with previous cardiac disease had a greater absolute relative risk in DECLARE-TIMI 58.[26-30] DAPA HF trial[31] results have also shown significant fall of mortality with the use of dapagliflozin (both with and without DM). Dapagliflozin[32] significantly reduced the overall composite endpoints of CV mortality/HHF/urgent HF visit, when compared with standard arm (both with and without DM). The quality of life was also significantly improved as measured by KCCQ score.[32]

Major trials that are currently underway (such as the EMPEROR employing the use of empagliflozin) may further show the path toward SGLT2i use in patients with or without DM for HF treatment or prevention.

Safety of SGLT2i

One of the most common side effects of SGLT2i is genital infections.[22,23,33,34] DKA can also typically occur in patients treated with SGLT2i, although rare.[22,23,33,34] Current recommendations suggest that treatment should be discontinued as soon as DKA sets in.[35,36] CANVAS trial showed that lower limb amputation frequency was significantly greater in the arm with canagliflozin.[33] Accordingly, regulators have highlighted practicing doctors' need for caution when they use SGLT2i. This is more so pertinent in patients who have a history of or high risk of amputation.[37] Another major concern with canagliflozin was the higher risk of fractures in CANVAS. However, this was not replicated in the trials with other SGLT2i.[22,23,33]

Can SGLT2i be Beneficial in the Treatment of HF?

Efficacy in HF prevention need not mean that SGLT2i are also useful in HF treatment.[38,39] Dapagliflozin significantly lowered primary composite end point of CV mortality or HHF. This was more evident in patients with HFrEF than in HFpEF.[25] Patients who had reduced EF (EF<30%) had significantly higher benefit.[25] Also, CV mortality benefits in patients with HFrEF were seen in those treated with ARBs, ACEIs, and beta-blockers.[25]

Role of SGLT2i in Patients without DM

As mentioned earlier, SGLT2i might serve to be useful regardless of DM status and EF percent. While several mechanisms have been hypothesized for their cardiac benefits, the following are backed with considerable evidences:

- Reduction of cardiac preload leading to an improvement in ventricular loading (facilitated predominantly due to increased osmotic diuresis and sodium loss in urine).[40]
- Sodium/hydrogen (Na^+/H) exchanger inhibitor in the myocardial tissues.[41]

As all these mechanisms have been elucidated both in patients with and without DM,[42-44] SGLT2i may benefit all groups of patients.[45-48]

Future Directions

Impending results of the currently progressing trials on SGLT2i in HF are required to fully analyze and study the treatment/preventive ability. This will apply to all patients, irrespective of DM status and EF percent. DAPA-HF, DELIVER, EMPEROR-Reduced and EMPEROR-Preserved may help in this regard. The EMPA-HEART study showed that empagliflozin causes a significant decrease in LV mass regression, which probably suggests potential reverse cardiac remodelling.[49] SOLOIST-WHF trial, which is testing sotagliflozin (a dual SGLT1/SGLT2i), may reveal drug-specific effects due to the difference in receptor selectivity and specificity. If this class of drugs sees clinical efficacy, then there is a likelihood of moving from a multidrug-containing polypill to a single pill that will be able to target multiple pathways at the same time.[50]

Conclusion

HF and T2DM are major public health threats across the globe. SGLT2i have emerged as a potential drug group for the prophylaxis of HF in individuals with DM. Accumulating evidence suggests that SGLT2i may produce coupled renal and cardiac effects, thus ensuring promise for the treatment of HF in patients irrespective of DM status and EF percent. We will have to play the waiting game to see if this promise turns into reality in the coming times, with the results of ongoing trials in these categories.

CHAPTER

41 Dual Antiplatelet Therapy: Current Status

Sudha Vidyasagar

Abstract

The role of dual antiplatelet therapy (DAPT) has come into vogue, in the last two decades, after several clinical trials proved their superiority to aspirin alone, in the prevention of vascular events, especially in the coronary and cerebral circulations. In the heart, their use has been extensive, especially after the use of drug eluting stents for acute coronary events. In the brain, their efficacy has to be balanced against their tendency to cause dangerous intracranial hemorrhage. Several scoring systems have been devised to address this risk benefit ratio. Judicious use of these combination therapies for the appropriate duration will prevent a significant number of recurrent vascular events, without dangerous bleeding risk.

Introduction

Atherosclerosis leading to vascular complications of heart and brain are important causes of morbidity and mortality. Platelet activation has a very important role in the occurrence of ischemic events in atherosclerosis. This makes antiplatelet drugs an essential part of the armamentarium the physician has to reduce these events. Currently they are being used in cardiology for acute coronary syndromes and vascular pathologies, and in neurology for the prevention of stroke and transient ischemic attacks (TIAs). In addition, their role in the management of prevention of thromboembolism in atrial fibrillation is also to be defined.

In this chapter we will review the current status of dual antiplatelet therapy (DAPT), in cardiac and cerebral events, keeping in mind the data available on this subject, and the current guidelines on the use of DAPT.

Review of Literature on DAPT

Brief History

The concept of using DAPT therapy began when it was shown two decades ago, that they decreased vascular events, especially in the context of coronary intervention.[1] The choice of anti-platelet therapy has also changed from ticlopidine to the safer clopidogrel and more potent drugs like ticagrelor and prasugrel.

Role in Acute Coronary Syndrome

ST-Elevation Myocardial Infarction (STEMI)

In STEMI, the aim of antiplatelet therapy is to reduce the thrombotic tendency at the site of plaque rupture, and also prevent further thrombosis due the intervention in the coronaries. This has to be efficient and fast in order to serve this purpose. Hence, the combination of heparin, aspirin (325 mg, non-enteric coated, crushed or chewed for early action) and a second antiplatelet drug like prasugrel or ticagrelor is recommended. The concept of preloading before stenting is not recommended any more, based on the results of the ATLANTIC trial, which did not show any advantage in patients who received anti platelet therapy in the ambulance.[2]

The current focused update of European Society of Cardiology (ECS) recommends that ticagrelor 90 mg BD be used, along with aspirin in all patients undergoing

percutaneous coronary angioplasty (PCI). If the patient has been on clopidogrel, it is recommended to stop it and switch to ticagrelor because of its superior efficacy.[3] In STEMI patients who undergo thrombolysis, clopidogrel 300 mg loading, with 75 mg OD should be continued. In patients in whom bypass surgery is anticipated early, DAPT is avoided, and only aspirin is given.

In Unstable Angina

In NSTEMI, the need for antiplatelet therapy is to stabilize the ruptured plaque. The patient is usually taken up for intervention over the next 1–2 days. When they undergo PCI, it is advised to give DAPT, preferably ticagrelor or prasugrel with aspirin. These need not be given upfront, as the ACCOAST trial,[4] did not find any advantage in using the second antiplatelet at arrival, and in fact showed that it increased chances of bleeding.

In patients who need only medical management for acute coronary syndrome (ACS), it is advised to give ticagrelor along with aspirin for a period of 1 year. Clopidogrel is a second choice.

In Stable Angina

For stable angina patients, who are managed medically, DAPT is not needed, as shown by the CHARISMA trial.[5] For those who undergo coronary stenting, clopidogrel can be added to aspirin and continued further for 6 months. The loading dose would be 600 mg, followed by 75 mg OD along with aspirin. If they have a high risk of bleeding, DAPT can be brought down to single drug at 1 month.

Role of DAPT after Stenting

The problem of prevention of stent thrombosis encouraged the use of DAPT. The change from bare metal stents to the use of drug eluting stents further increased the danger of stent thrombosis, which led to the usage of more potent drugs. However, here, DAPT has a dual role. It serves to prevent stent thrombosis, but also prevented atherosclerotic events as a whole in the body. Ticagrelor fitted the bill adequately and is hence recommended for prevention of stent induced thrombosis.

Duration of DAPT after Stenting

The fear of stent thrombosis with DES has also come down as the stents now have thinner struts and are more biodegradable. Hence, the duration of DAPT therapy has also come down from 12 months to 6 months and even 3 months in suitable patients. The TWILIGHT trial found that 3 months of DAPT followed by ticagrelor monotherapy for 1 year, is non inferior to 1 year of DAPT.[6]

The duration of therapy needed after stenting is a delicate balance between the risk of thrombosis and recurrence of ACS, versus the danger of bleeding. The current ECS recommendations are for 6 months in patients with drug eluting stents, if they are stable. However, for patients with ACS, the risk of recurrence is higher, and hence DAPT is extended for 1 year. This can be reduced to 6 months if bleeding risk is high.

To balance the ischemic and bleeding risk, various scores have been put forth. The ischemic risk is calculated by patient characteristics and what is defined as the complexity for the coronary lesion as given below, using the DAPT score. If this score is more than 2, a longer duration of DAPT is advised.

The PRECISE-DAPT score assesses the bleeding risk. A PRECISE-DAPT score of more than 25 would indicate a high bleeding risk and may call for shortening duration of DAPT **(Table 1)**.[7]

In a meta-analysis of 9,000 patients, the PCI complexity was assessed by six interventional factors: three-vessel PCI, implantation of three or more stents, three or more complex coronary lesions, bifurcation stenting, total sent length more than 60 mm, and treatment of a chronic total coronary occlusion.[8] Further, if the LAD is involved, the duration of therapy is extended even beyond 12 months keeping in mind the recurrence risk.[9]

The bleeding risk can also be calculated by the CRUSADE score and the HAS-BleD scores to decide on duration of therapy. Treatment will have to be individualized, as has been recommended by all major guidelines.[10] In addition, all patients who require DAPT for any indication, and have a high bleeding risk, should be given proton pump inhibitors along with them. **Table 2** summarizes current recommendations.

DAPT in Patients with AF

Between 6–8% of patients who are on anticoagulation may need PCI. In such patients, the duration of DAPT plus an anticoagulant can be given up to 6 months if their bleeding risk is low and shortened to 1 month if it is high. However, prasugrel and ticagrelor are best avoided, as they

TABLE 1 Risk scores validated for dual antiplatelet therapy duration decision-making

	PRECISE-DAPT score	***DAPT score***
Time of use	At the time of coronary stenting	After 12 months of uneventful DAPT

TABLE 2 Drug of choice and duration of treatment for various vascular conditions

Clinical condition	***DAPT-aspirin + Drug of choice***	***Duration of DAPT***
MI with PCI	Prasugrel/ticagrelor	1 year
MI with thrombolysis	Clopidogrel	1 year
NSTEMI with PCI	Prasugrel/ticagrelor	1 year
NSTEMI with medical treatment	Ticagrelor	1 year
Stable angina with PCI	Clopidogrel	6 months
Stable angina with medical management	Only aspirin	Lifelong single drug

are unpredictable and cause major bleeding along with anticoagulants. There is some data, that using NOACs like apixaban and rivaroxaban may cause less bleeding risk; however, treatment is best individualized.[5]

Surgery on DAPT

Stopping DAPT for elective surgery should be a collective decision between departments involved and cardiologist. If aspirin can be continued, stopping DAPT for few days will not be difficult. If aspirin is discontinued, bridging with tirofiban or eptifibatide may be needed.

Intervention on DAPT: If a patient needs PCI on DAPT, radial access is preferred over femoral one, and aspirin can be continued. The additional use of a PPI is recommended.

DAPT in Neurology Practice

DAPT in Transient Ischemic Attacks

TIAs are the forerunners of strokes but leave no permanent neurological deficit. They give an opportunity to give antiplatelet therapy to prevent further vascular events. The risk of stroke increases with the characteristics of the TIA, which can be categorized by clinical features. Patients with TIA are risk stratified according to ABCD^2 score (age, blood pressure, clinical features, duration of TIA, and presence of diabetes). A score of more than or equal to 4 denotes a high-risk TIA and such patients are prone for recurrent stroke of up to 8%, especially in the first 48 hours.

Two major trials addressed the question of DAPT and its duration in high risk TIAs and minor strokes with National Institutes of Health Stroke Scale (NIHSS) score of

less than or equal to 3. The CHANCE (Clopidogrel in High-Risk Patients with Acute Non-Disabling Cerebrovascular Events) trial done in China, showed for the first time, that aspirin and clopidogrel for 21 days, and then only clopidogrel until 90 days decreased the subsequent ischemic events.[11] However, the POINT trial, which was conducted in North America, Australia, and other countries, did not find lesser ischemic events with DAPT, and had more bleeding events.[12]

This difference has been attributed to the different patient populations used and the varying causes of ischemic events in these groups. The POINT showed more risk of bleeding, which could be due the longer duration of DAPT used (90 days as opposed to 21 days in CHANCE). Further the Asian population in CHANCE did have genetic differences which could account for the lesser bleeding risk. The absorption of clopidogrel depends on the presence of a transporter in gut called ABCB1, which affects its efficacy but not bleeding risk. Hence, the different results may be due to ethnic variation.[12]

However, most analysis recommend the use of DAPT in high risk TIA with aspirin (160–325 mg loading dose, followed by 50–100 mg daily) plus clopidogrel (300–600 mg loading dose, followed by 75 mg daily) in the first 21 days of therapy,[13] as this is the most vulnerable period for recurrent ischemic events. From day 22 to 90 days, the ischemic events were less, and the bleeding risk was unnecessarily increased as seen in a meta-analysis including CHANCE and POINT trials. In fact, the first 10 days after TIA are crucial to prevent recurrence, though most guidelines recommend DAPT up to 21 days.[14] The bleeding risk with DAPT is minimal till 21 days, and this does not compromise the benefits of prevention of stroke. If the TIA happens on a single antiplatelet drug, the second one can be added up to 21 days as advised.

The choice of the antiplatelet drug, which should be continued after day 21, till 90 days, has been clopidogrel in most studies, anticipating aspirin resistance. However, the Indian guidelines on stroke do not specify this, and mention that either aspirin or clopidogrel can be continued based on the choice of the physician, as aspirin resistance is not well documented in the Indian population. There is also a small improvement in functional scores after DAPT in minor strokes, which may recommend their use.

Further triple therapy (aspirin, dipyridamole, and clopidogrel) was also tried in the TARDIS trial and given up, as it gave rise to more bleeding and less advantage with ischemic events. Of late, newer DAPT therapy using ticagrelor[15] and prasugrel are also undergoing trials to check their efficacy and safety. The SOCRATES trial,[16] compared the efficacy of clopidogrel to ticagrelor, and found it is non inferior, but caused more bleeding risks in the ticagrelor arm.

DAPT in Secondary Prevention of Strokes

The CAPPRIE trial was the first to demonstrate the efficacy of additional clopidogrel in secondary prevention of strokes. This was followed by the MATCH trial, which actually showed higher bleeding risk in patients on DAPT. Following this the CHARISMA trial used aspirin, versus aspirin with clopidogrel, and found DAPT to be useful in preventing ischemic events though with increase in bleeding. So DAPT is recommended for patients with acute ischemic stroke with an NIHSS score of less than 3. As of now, there is no role for DAPT in acute ischemic stroke with a higher score. In these patients, a single antiplatelet, which is aspirin in a dose of 325 mg stat, followed by 75 mg daily after that is given lifelong.

As of now, there is no evidence for continuing DAPT beyond 90 days, in any neurological situation as it results in more bleeding and less efficacy for prevention.[17]

DAPT in Lacunar Strokes

Antiplatelet therapy has no major role in lacunar strokes. However, in high risk TIAs and those with early neurological deterioration in lacunar infarcts, a study showed better functional outcomes of short duration DAPT for 5 days.[18]

DAPT in Intracranial Large Artery Thrombosis

DAPT decreases stroke and death in patients in this subgroup, if aspirin and clopidogrel are given in the first 90 days in symptomatic patients with 70–99% stenosis as shown in the SAMMPRIS trial.[19] But this is useful only when the NIHSS score is less than 3. Beyond this, there is a fear of hemorrhagic transformation and aspirin alone is recommended.

DAPT in Vascular Disease

DAPT has been used in symptomatic carotid stenosis, which is severe, for the prevention of stroke for at least 3 months. In patients with asymptomatic intracranial stenosis, DAPT can be given for 1 month, followed by single antiplatelet, if patients have TIA and minor stroke.

TABLE 3 Summary of indication on antiplatelet treatment from ESC guidelines, 2017

District	*Monotherapy (aspirin or clopidogrel)*	*DAPT (aspirin plus clopidogrel)*
LEAD		
Asymptomatic	Class III A	–
Symptomatic	Class IA	–
Endovascular revascularization	From 1 month after procedure: class IIa C	For 1 month after procedure: class IIa C
Surgical revascularization	Class IIb B	–
Carotid artery disease		
Asymptomatic (>50% carotid artery stenosis, low bleeding risk)	Class IIa C	–
Symptomatic	Class IA	–
Endovascular revascularization	From 1 month after procedure: class IA	For 1 month after procedure: class IA
Surgical revascularization	Class IA	–

ESC, European Society of Cardiology; LEAD, lower extermity

TABLE 4 Antiplatelet reversal recommendations

Reversibility	*Recommendations*
Irrversible binding agents	**Platelet transfusion** *Intracranial hemorrhage:* Platelet transfusion for patients NOT undergoing a neurosurgical procedure is associated with worse functional outcome and death with no change in volume growth **Desmopressin 0.4 µg/kg IV for 1 dose** Desmopressin can be considered for patients on antiplatelet therapy that binds irreversibly. For those undergoing a neurosurgical procedure DDAVP can be used in addition to platelet transfusaion
Reversible binding agents	**Platelet transfusion** *Neurosurgical procedure:* Allow 3–5 half-lives from the last administration of the antiplatelet agent before administering platelet transfusion to prevent inhibition of infusing platelets **Desmopressin 0.4 µg/kg IV for 1 dose** When used in combination with platelet transfuion, desmopressin may be beneficial prior to emergent procedures

In the CASPAR (Clopidogrel and Acetylsalicylic Acid in Bypass Surgery for Peripheral Artery Disease) study, subjects underwent below-knee femoropopliteal bypass received either DAPT or aspirin alone. This study showed that the patients with prosthetic grafts on DAPT did benefit.[20]

Currently, DAPT is advised for both carotid stenosis and peripheral vascular disease, for 1 month, after revascularization. If asymptomatic, there is no indication for DAPT in lower extremity atherosclerotic disease or mild to moderate carotid stenosis **(Table 3)**.

In patients with cardioembolic stroke with contraindication to anticoagulants, DAPT has been tried as an alternative, with some success, though this is not the first choice.

DAPT and Correction of Bleeding

There is always a danger of bleeding during any neurosurgical procedure for patients on DAPT for any indication. In this instance, platelet transfusion and desmopressin can be used as summarized in **Table 4**.

Conclusion

To conclude, DAPT has a definite role to play in the prevention of ischemic events in the coronary and cerebral circulation. Their efficacy in decreasing mortality and morbidity is evident from results from various trials. However, they must be used judiciously to avoid bleeding risks, for the minimum period of time, to be useful and safe.

CHAPTER

42 Novel Oral Anticoagulants: Which, When, and Where?

Vishwanath Krishnamurthy

Abstract

The new oral anticoagulants (NOACs) developed to address these limitations are backed by good trials. Beginning with Dabigatran in 2010, currently two classes of NOACs are available, the oral direct thrombin inhibitors (e.g., dabigatran) and direct factor Xa inhibitors. They have a distinct advantage of having rapid onset of action, fixed dosing, and absence of need of regular monitoring compared to VKA. Prediction tools like SAMe TTR2 score can be used in the decision-making between NOAC and VKA. In this chapter a brief description of different NOACs and its use in several situations have been highlighted. With the correct knowledge about these drugs, choosing the right patient and following the principle of therapeutic humility the benefits of these novel drugs can be passed on to the patients for better efficacy.

Introduction

Vitamin K antagonists (VKAs) have been the main treatment modality for the prevention of thrombotic episodes in atrial fibrillation (AF). Despite its significant impact to prevent strokes, there have been many limitations in its use from benign one to more serious ones. In the last several years, the new oral anticoagulants (NOACs) developed to address these limitations are backed by good trials. Beginning with Dabigatran in 2010 leads to creation of another novel oral anticoagulant rivaroxaban. Further with development of apixaban, edoxaban they changed the name to direct oral anticoagulants and is currently the term used by ISTH (International Society of Thrombosis and Hemostasis).[1]

There are several advantages and disadvantages of NOAC Vs VKA **(Table 1)**, with the correct knowledge and decision making the right NOACs can be given to the right patient.

Mechanism of Action

Currently two classes of NOACs are available, the oral direct thrombin inhibitors (e.g., dabigatran), which directly bind to thrombin, thus prevent cleaving of fibrinogen to fibrin and direct factor Xa inhibitors (e.g., rivaroxaban, apixaban, and edoxaban), which prevent factor Xa from cleaving prothrombin to thrombin. Unlike VKAs, which block the formation of vitamin K-dependent coagulation factors (factors II, VII, IX, and X), these drugs block a particular step in coagulation cascade.

Approved Indications for NOAC[3,4]

- Reduce risk of embolization events (e.g., stroke) in patients with non-valvular AF.
- Treatment of DVT and pulmonary embolism (PE).
- Reduction in risk of recurrent DVT, PE in patients at risk after initial treatment.
- Prophylaxis of DVT.

TABLE 1 Advantages and disadvantages of NOAC over warfarin

Feature	*Warfarin*	*NOAC*
Onset of action	Slow	Rapid
Dosing schedule	Variable	Fixed
Food interaction	Yes	No
Interactions	Many	Fewer
Monitoring	Yes	No
Offset	Long	Shorter
Frequency	Once daily	Once/Twice
Monitoring	INR	Uncertain
Clearance	Non renal	Renal (25–80%)
Antidote	Vit K	Idaricuzumab/Andexanet alpha/?Dialysis[2]
Familiarity	Extensive	Minimal

TABLE 2 Table showing SAMeTTR2 score[5,6]

Factor	*Point*
Sex (Female)	1
Age (<60 years)	1
Medical history(H/O more than two of the following: HTN, Diabetes, CAD, PAD, Heart failure, Stroke, Pulmonary hepatic, or Renal disease)	1
Treatment (Interacting medications, e.g., amiodarone)	1
Tobacco Use (within 2 years)	2
Race (non-caucasian)	2

Score	*Action*
0–2	Patients likely to achieve a high TTR VKA may be beneficial
≥2	NOAC would be better initial option

Emerging Indications

- Use of NOACs before and after cardioversion and catheter ablation in AF.
- Prevention of further cardiovascular events in patients after ACS.
- NVAF undergoing PCI.
- In stable CV disease and peripheral vascular disease.
- Prevention of venous thromboembolism (VTE) in acutely ill medical patients.

Considerations when starting/choosing a NOAC—think ABCDE:

A—Low weight (dose reduction might be needed)

B—Bleeding risk (GI bleeding)

C—Creatinine clearence (renal function)

D—Drug interactions (p-glycoprotein, CYP450, e.g., reduced verapamil dose with dabigatran)

E—Elderly (dose reduction might be necessary)

SAMe-TT2R2 Score (Table 2)

It is a prediction tool that predicts the quality of vitamin K antagonist anticoagulation therapy as measured by time in therapeutic INR range (TTR).It can be used in the decision-making between NOAC and VKA. It can be used in patients with CHA2DS2VASc score ≥1 where oral anticoagulation is recommended.[5,6]

Brief Description of NOACs

Dabigatran

Dabigatran belongs to group of direct thrombin inhibition, after oral ingestion inactive drug is converted to active form and reaches peak plasma levels within 2–3 hours. Onset of action is 1–2 hours, with a half-life of 12–17 hours, and is predominantly excreted by the kidneys (80%)

RE-LY trial compared dabigatran 110 mg BID or 150 mg BID with warfarin in 18,113 patients with AF with a mean CHADS score of 2.1.[7] The primary endpoints assessed were occurrence of stroke and systemic embolism. Study showed that dabigatran 150 mg BID was superior to warfarin with no significant differences in major bleedings. However, GI bleeding was found to be more with dabigatran (150 mg BID). Dabigatran 110 mg BID was non-inferior to warfarin for the primary endpoint, with a reduction of 20% in major bleedings.

An extension of RE-LY study called the RELY-ABLE study was conducted where the cases enrolled in the earlier RE-LY study were further followed up for another 2 years and 3 months from the original study period. This study confirmed the results of RE-LY and gave information on the long-term effects of dabigatran use in both the doses.

Another two studies (RE-COVER)[8,9] and RE-COVER II, which were a comparison of dabigatran and warfarin in venous thromboembolism showed that dabigatran was non-inferior to standard treatment of VTE with reduced bleeding risk (1.4%) with no differences in major bleeding.

Rivaroxaban

It is a dose-dependent direct inhibitor of factor Xa and the second NOAC approved by the FDA[10] based on the ROCKET AF study.[11]

Rivaroxaban in comparison to warfarin is effective in prevention of stroke in AF, and also in treatment and prevention of DVT with reduced risk of serious bleeding complications.[12]

The ROCKET AF[11] was a double-blinded study which showed noninferiority of rivaroxaban to warfarin in the prevention of stroke or systemic embolism; however, rivaroxaban failed to show superiority over warfarin in the intention to treat analysis. Fatal bleeding occurred less frequently in the rivaroxaban group, with no differences in the risk of major bleeding. GI bleeding and transfusion requirements were greater with rivaroxaban. The EINSTEIN DVT[13] trial showed rivaroxaban was noninferior to warfarin for DVT with similar bleeding risk among both.

Apixaban

It is a direct, reversible, competitive, and selective inhibitor of factor Xa in patients of AF. It is approved for stroke prevention. Among the NOACs, apixaban is least cleared from the kidneys and is metabolized predominantly by the liver, and hence its use in renal failure patients.[14]

The ARISTOTLE[15] study showed apixaban was better than warfarin, with fewer primary outcomes (overall strokes and systemic emboli). Apixaban was compared with aspirin in the AVERROES study. But after a mean follow-up of 1.1 years, the study was prematurely stopped as there was a clear benefit of apixaban. The primary outcome of stroke or systemic embolism was significantly lower in the apixaban group versus aspirin, with similar bleeding risk (major bleeding and intracranial bleeding) between the two.[16] The APPRAISE study assessed the effect of apixaban with placebo in addition to antiplatelets following ACS. It was stopped as it was found to have more risk of bleeding with less benefit after 8 months.[17]

Edoxaban

It is once daily dosing drug. In comparison with warfarin, once daily Edoxaban had similar efficacy to warfarin in stroke prevention and treatment of DVT AND PE with lesser risk of bleeding complications.[18] ENGAGE AF TIMI 48 trial[19] showed that both low dose (30 mg) and high dose (60 mg) were noninferior to warfarin and a dose-related reduction in bleeding as compared to warfarin.

Bleeding while Using an NOAC

Unlike in VKA fresh frozen plasma cannot be used when there is serious bleeding for reversal ,instead can be used only for volume expansion, Drugs like andexanet alfa (a recombinant human FXa analogue that competes for the FXa inhibitors with FXa), idarucizumab, (humanized antibody fragment that specifically binds dabigatran) prothrombin concentrates, can be used depending on the availability and latest evidence More importantly we have to inquire about the dosing regimen, the time of last dose as it is expected that after stopping the treatment, haemostasis is expected within 12–24 h after the last taken dose, as plasma half-life is around 12 h for most NOACs .Thus in most non serious bleeding conditions a wait and watch principle can be used.[25]

Switching from Heparin/VKA to NOAC

While Changing from heparin to NOAC, in case of conventional heparin they can be started after stopping the conventional heparin,in case of LMWH it has tob

TABLE 3 NOAC in renal disease[22]

Drug	*Criteria*	*Dose modification*
Dabigatran	Creatinine clearance <50 mL/min <30 mL/min	110 mg BD & as per ESC guidelines should not be used
Rivaroxaban	Creatinine clearance <50 mL/min	15 mg OD
Apixaban	Two of these factors: Age >80, creatinine >1.5, weight <60	2.5 mg BD
Edoxaban	Creatinine clearance <50 mL/min	30 mg OD

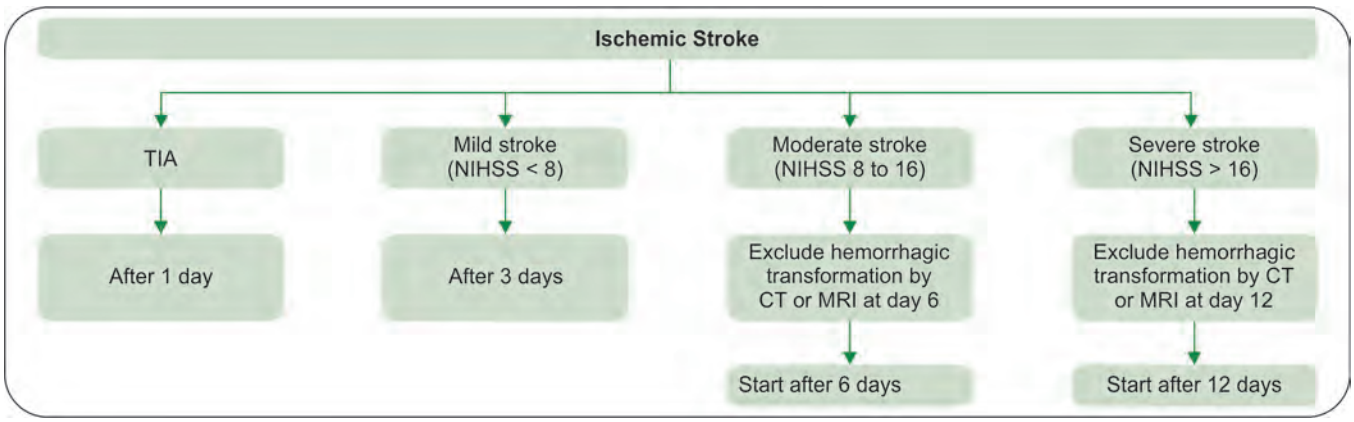
TABLE 4 NOAC before surgery[23]

Drug	*Renal function*	*Minor surgery*		*Major surgery*	
		PREOP	*POST-OP*	*PRE-OP*	*POST-OP*
Dabigatran	CrCl >50	Stop 2 days before surgery	Restart 1 day after surgery	Stop 3 days before surgery	Restart 2 days after surgery
	CrCl <50	Stop 3 days before surgery	Restart 1 day after surgery	Stop 4–5 days before surgery	Restart 48 h after surgery
Rivaroxaban	CrCl >30	Stop 2 days before surgery	Restart 24 h post-surgery	Stop 3 days before surgery	Restart 48 h after surgery
Apixaban	CrCl >30	Stop 2 days before surgery	Restart 24 h post-surgery	Stop 3 days before surgery	Restart 48 h after surgery

TABLE 5 Coagulation profile and NOAC[24]

Test	*Factor Xa inhibitors*	*Dabigatran*
Qualitative (Present/Absent)	PT (Riva>Edoxa>Apixaban)	TT>aPTT
Quantitative test	Chromogenic Anti Xa levels (Requires specific calibration to drug)	Dilute TT, Anti IIa (specific calibration)

Flowchart 1: NOAC in stroke[26]



started 2 hours prior to stopping LMWH. When it has to be changed back from NOAC to parental anticoagulants we can start 12 h after Apixaban or Dabigatran dose and after 24 hrs of last Rivaroxaban dose. From warfarin to NOAC depending on the INR (Dabigatran/Apixaban if INR <2.0 , Rivaroxaban when INR <2.5) it can be started after stopping warfarin.[27]

NOAC in Special Situations

Refer **Tables 3 and 4, Flowchart 1**.

NOAC in Asian Population

A meta-analysis which included 5 NOAC trials, 21 observational Cohort showed that NOAC were associated with decreased rates of systemic embolization, ischemic stroke, myocardial infarction, major bleeding among Asian population with consideration of rivaroxaban for myocardial infarction.[20,21]

Coagulation Profile and NOAC[24]

NOAC does not require routine monitoring of coagulation profile. However, they can significantly be affected and pose a difficulty in presence of acute overdose or significant bleeding.

Normal PT or aPTT does not guarantee absence of anticoagulant activity. Quantitative tests are not standardised or approved. Depending on the clinical situations decision on switching between anticoagulants have to be taken **(Table 5)**.

Conclusion

With increase in the armamentarium of drugs used for antithrombotic effect, it is imperative that as clinicians we need to know the mechanism of action, adverse events, studies backing the NOAC, and importantly the situation where these drugs have to be used and when are they contraindicated. We should never forget the important third dimension in the treatment which is the financial consideration as it is one of the important aspects in our setup. As most of these drugs' costs are higher compared to VKA with the correct knowledge and use of these drugs also taking into the economic aspects the benefit can be passed on to the patients for better efficacy and better compliance.

CHAPTER

43 Recent Practice Changing Landmark Trials of Cardiology

Gurbhej Singh, Ashish Kumar, Gurpreet S Wander

Abstract

Human medicine has always evolved as evident by the literature available. This change has come from scientific evidence accumulated from numerous clinical trials and studies. Cardiovascular diseases are one of the most important causes for morbidity and mortality. Most of the guidelines for management of the diseases come from the scientific data which gives us direction and insight into understanding of the disease and treatment. Hence, it becomes vital for the physicians to be updated with recently evolving scientific data in the form of clinical trials and studies. Here, we discuss briefly the recently published literature in the field of cardiology.

Introduction

Human medicine is a dynamic and ever-evolving field guided by new evidence derived from clinical studies. Cardiovascular disease is a major cause of morbidity and mortality in humans, hence it is crucial to explore this segment of medicine further to advance the aspects of diagnosis and management. Most of the clinical practice is dependent on evidence-based medicine. This evidence comes from the scientific data generated as a result of clinical trials, clinical studies, and experience of the scientific community. A clinical trial is a scientifically conducted investigation of a treatment or drug involving healthy people and patients. Clinical trials are needed to determine the correct dose of new drugs, to determine whether the drug will treat the disease effectively in humans, the safety of new drugs alone and in combination with other drugs, and to determine whether an intervention is better than the standard treatment. There are lots of trials being conducted every year and evidence-based guidelines also change, depending on the trial results. In this chapter, we discuss the recent scientific data on cardiology in the form of published landmark trials which are likely to have a significant impact on our clinical practice **(Table 1)**.

Heart Failure

Heart failure (HF) is an important cause of mortality and morbidity in patients with cardiac disease. Different treatment options exist ranging from drugs to various cardiac interventions. Sacubitril-valsartan has been studied in these patients and has shown good results. This drug was evaluated in acute decompensated HF patients.

PIONEER-HF (Angiotensin–Neprilysin Inhibition in Acute Decompensated Heart Failure) Trial[1]

Sacubitril–valsartan therapy is now widely used in chronic HF. In this trial, patients with HF with reduced ejection fraction who were admitted for acute decompensated HF were included after hemodynamic stabilization. The patients either received sacubitril–valsartan to a target dose of 200 mg (97 mg of sacubitril with 103 mg of valsartan) twice daily or enalapril to a target dose (10 mg)

TABLE 1 Summary of recently published clinical trials in cardiology

PIONEER-HF (Angiotensin–Neprilysin Inhibition in Acute Decompensated Heart Failure) trial	HFrEF patients getting hospitalized for acute decompensated HF, sacubitril–valsartan therapy causes reduction in the NT-proBNP than the enalapril therapy without an increase in worsening renal function, hyperkalemia, symptomatic hypotension, or angioedema
AUGUSTUS (Antithrombotic Therapy after Acute Coronary Syndrome or PCI in Atrial Fibrillation) trial	In patients with AF and a recent ACS or PCI on a P2Y12 inhibitor, addition of apixaban, without aspirin, resulted in lesser bleeding events, and hospitalizations without significant differences in the incidence of ischemic events than regimens that include a vitamin K antagonist, aspirin, or both
ISAR-REACT-5 (Ticagrelor or Prasugrel in Patients with Acute Coronary Syndromes) trial	In ACS patients undergoing invasive strategy, the incidence of death, MI, or stroke was significantly lower with prasugrel than ticagrelor, with no major difference in the incidence of major bleed
COLCOT (Efficacy and Safety of Low-Dose Colchicine after Myocardial Infarction) trial	Colchicine at a dose of 0.5 mg daily reduces the risk of ischemic cardiovascular events than placebo in patients with a recent MI
COMPLETE (Complete Revascularization with Multivessel PCI for Myocardial Infarction) trial	A complete revascularization strategy in STEMI but with multivessel coronary artery disease was seen to lower the risk of CV death or MI, or composite of CV death, MI or ischemia-driven revascularization
REDUCE-IT (Cardiovascular Risk Reduction with Icosapent Ethyl for Hypertriglyceridemia) trial	In metabolic syndrome with elevated triglyceride levels, the risk of ischemic events is found to be significantly lower among patients taking 2 gm of icosapent ethyl twice daily with statins as compared to statin therapy alone
CLEAR Harmony (Safety and Efficacy of Bempedoic Acid to Reduce LDL Cholesterol) trial	Addition of bempedoic acid to maximally tolerated statin therapy reduced the LDL cholesterol levels without an increase in adverse events
AFIRE (Antithrombotic Therapy for Atrial Fibrillation with Stable Coronary Disease) trial	In patients with AF and stable coronary artery disease, rivaroxaban monotherapy when compared to rivaroxaban and aspirin was seen to be similar in efficacy and superior for safety
THEMIS (Ticagrelor in Patients with Stable Coronary Disease and Diabetes) trial	In diabetic patients with stable CAD without prior ACS or stroke, ticagrelor plus aspirin was seen to have lower incidence of ischemic cardiovascular events but at a cost of higher major bleeding events than those who received placebo plus aspirin
TWILIGHT (Ticagrelor with or without Aspirin in High-Risk Patients after PCI) trial	Double blind trial. Conducted in high risk patients undergoing PCI, ticagrelor alone when compared to combination of ticagrelor and aspirin after 3 months of dual antiplatelet therapy was seen to have similar risk of death, MI, or stroke and a lower incidence of clinically important bleed
STOP DAPT-2(Effect of 1 month dual antiplatelet therapy(DAPT) followed by clopidogrel versus 12 month DAPT on CV and bleeding events in patients receiving PCI)	Multi-center, open label, randomized trial, tested a very short-term DAPT versus 12 DAPT, and found a lower rate of CV and bleeding events
DAPA-HF (Dapagliflozin in Patients with Heart Failure and Reduced Ejection Fraction) trial	Phase-3 placebo controlled trial. In HFrEF, dapagliflozin reduced the risk of worsening of HF or CV death irrespective of diabetic status
EMPA-REG OUTCOME (Empagliflozin, Cardiovascular Outcomes, and Mortality in Type 2 Diabetes) trial	Type 2 diabetic patients who are at high risk for CV events were found to have reduced CV events and mortality when they received empagliflozin as compared with placebo
ISCHAEMIA (International Study of Comparative Health Effectiveness with Medical and Invasive Approaches) trial	Among patients with stable CAD and moderate to severe ischemia on stress testing, routine invasive therapy failed to reduce major adverse cardiac events compared with optimal medical therapy. Routine invasive therapy was associated with harm at 6 months (increase in periprocedural MIs) and associated with benefit at 4 years (reduction in spontaneous MI)
POET (Partial Oral versus Intravenous Antibiotic Treatment of Endocarditis) trial	Left sided infective endocarditis patients in stable condition had similar outcomes with a shift to oral antibiotics after 10 days of intravenous antibiotics as compared to continued intravenous antibiotics
PARTNER-3 (Transcatheter aortic valve replacement with a balloon expandable valve in low risk patients)	In severe aortic stenosis patients with low surgical risk, transcatheter aortic valve replacement with balloon expandable valve had lower risk of composite of death, stroke, or rehospitalization at the end of 1 year

twice daily. Patients on sacubitril-valsartan had a greater reduction in the N-terminal pro–B-type natriuretic peptide (NT-proBNP) levels than the enalapril group from baseline till weeks 4 and 8. It was interesting to see that there was a decrease in the NT-proBNP levels as early as week 1. There was no significant difference noted in incidence of worsening renal function, angioedema, symptomatic hypotension, and hyperkalemia in the two groups.

Acute Coronary Syndrome

Acute coronary syndrome (ACS) comprises patients with angina and evidence of characteristic electrocardiographic changes and/or evidence of myocardial damage with biochemical markers. Patients may present with unstable angina, non-ST-elevation myocardial infarction (NSTEMI), or ST-elevation myocardial infarction (STEMI). Its management comprises of antiplatelet drugs and evaluation of coronaries by coronary angiogram according to clinical presentation.

AUGUSTUS (Antithrombotic Therapy after ACS or PCI in Atrial Fibrillation) Trial[2]

Patients with atrial fibrillation (AF) with an ACS or who undergo percutaneous coronary intervention (PCI) require an appropriate antithrombotic regimen requiring anticoagulants in addition to the antiplatelets. This trial evaluated such patients who need to be on a P2Y12 inhibitor, and was randomized to either apixaban or a vitamin K antagonist and to receive aspirin or matching placebo for a duration of 6 months. This trial concluded that patients with AF and ACS or post PCI who are planned for a P2Y12 inhibitor, apixaban, without aspirin, resulted in lesser bleeding events and hospitalizations, however, in the absence of significant differences in ischemic events as compared to the patients on vitamin K antagonist, aspirin, or both.

ISAR-REACT-5 (Ticagrelor or Prasugrel in Patients with ACSs) Trial[3]

In this randomized trial patients with ACS who were planned for invasive evaluation received either ticagrelor or prasugrel. The primary end-point was defined as composite of death, myocardial infarction (MI), or stroke at 12 months was seen in lesser patients on prasugrel as compared to ticagrelor (HR, 1.36; P=0.006). Bleeding event rates were similar in both the groups. Further, it was noted that the incidence of death, MI, or stroke was significantly lower in the patients receiving prasugrel than those with ticagrelor.

COLCOT (Efficacy and Safety of Low-Dose Colchicine after MI) Trial[4]

Colchicine is a mainstay therapy for hyperuricemia and is used frequently for management of pericarditis. This study tested effect of colchicine in patients with MI. Within 30 days, patients with MI were randomized to colchicines (0.5 mg once daily) or placebo. The composite of cardiovascular death, resuscitated cardiac arrest, MI, stroke, or urgent hospitalization requiring revascularization was significantly lower in the colchicine group than the placebo (P=0.02). Thus, colchicine was seen to significantly lower the risk of ischemic cardiovascular events than placebo.

Revascularization in ACS

PCI of the culprit lesion in STEMI is shown to lower risk of cardiovascular morbidity and mortality.

COMPLETE (Complete Revascularization with Multivessel PCI for MI) Trial[5]

STEMI patients with multivessel coronary artery disease undergoing PCI of the culprit lesion were randomized to complete revascularization with PCI or no further revascularization. Further, these patients according to planned timing of non-culprit PCI (either during or after the index hospitalization) were randomized in groups. It was seen that at 3-year median follow-up, the composite of MI and CV death, or composite MI, CV death, and ischemia driven revascularization was lower in the complete revascularization group. This was irrespective of the timing of the complete revascularization.

Cardiovascular Drugs

Drugs for Dyslipidemias

REDUCE-IT (Cardiovascular Risk Reduction with Icosapent Ethyl for Hypertriglyceridemia) Trial[6]

In patients with known cardiovascular disease or who are at risk of CVD, this trial evaluated the effect of Icosapent ethyl (IPE) on cardiovascular events as compared to

placebo. Elevated triglyceride levels are an independent marker for ischemic events. IPE, a highly purified and stable eicosapentaenoic acid (EPA) when used as an adjunct to the diet in patients with triglyceride levels at least 500 mg/dL, lowers the triglyceride levels and in addition has been seen to have anti-inflammatory, plaque stabilizing, and also membrane stabilizing properties. Patients were started on 2 gm of IPE in addition to statins with fasting triglyceride level of 135–499 mg/dL and an LDL (low-density lipoprotein) cholesterol level of 41–100 mg/dL were randomized to receive 2 gm of IPE twice daily (total daily dose, 4 gm) or placebo. The primary outcome of cardiovascular death, nonfatal MI, nonfatal stroke, coronary revascularization, or unstable angina was seen less in the drug group as compared to the placebo group (P<0.001). Additionally, the secondary outcome of cardiovascular death, nonfatal MI, or nonfatal stroke occurred in 11.2% in icosapent group and in 14.8% of patients in the placebo group (P<0.001). Hence, it was seen that IPE added with statins lowers the risk of ischemic events.

CLEAR Harmony (Safety and Efficacy of Bempedoic Acid to Reduce LDL Cholesterol) Trial[7]

Bempedoic acid is a prodrug, acts liver-specific, and lowers LDL cholesterol by inhibiting ATP citrate lyase, an enzyme which acts upstream of HMG-CoA reductase (3-hydroxy-3-methylglutaryl coenzyme A). This was a phase 3 randomized, double blind placebo controlled trial done in patients on highest tolerated doses of statins (alone or in combination with other drugs) with evidence of atherosclerotic cardiovascular disease, heterozygous familial hypercholesterolemia, or both. These patients were enrolled if LDL cholesterol level was at least 70 mg/dL and then were randomized to either bempedoic acid or placebo. There was reduction at 12 weeks in the LDL levels (19.2 mg/dL) translating to a change of 16.5% from baseline. The adverse events did not differ substantially between the two groups; however, more patients discontinued treatment due to adverse events in the bempedoic acid. The safety and efficacy was similar irrespective of the dose of statins used.

Antiplatelet Drugs

Antiplatelet drugs form the cornerstone of treatment in patients with coronary artery disease and patients undergoing percutaneous coronary interventions. Here, we describe the important trials evaluating the antiplatlet drugs in stable coronary artery disease, ACSs, and post PCI patients.

AFIRE (Antithrombotic Therapy for Atrial Fibrillation with Stable Coronary Disease) Trial[8]

In this trial, patients with AF undergoing PCI or coronary artery bypass grafting (CABG) more than a year back or who had evidence of insignificant coronary artery disease as documented by an angiogram were randomized to either rivaroxaban alone or a combination therapy with rivaroxaban plus a single antiplatelet agent. The primary (efficacy) end-point was a composite of MI, stroke, systemic embolism, unstable angina needing revascularization, or death from any cause. The primary end-point (safety) was major bleeding. It was decided to stop this trial early due to increased mortality noted in the combination therapy group. It was seen that rivaroxaban when given alone showed non-inferiority as compared to the combination therapy for the primary efficacy end-point. For the safety end-point, rivaroxaban alone was superior to combination therapy. Hence, to summarize rivaroxaban when given alone in patients with AF and stable CAD is non-inferior for efficacy and superior for safety when compared to the combination therapy of rivaroxban and aspirin.

THEMIS (Ticagrelor in Patients with Stable Coronary Disease and Diabetes) Trial[9]

Patients with diabetes and stable coronary artery disease have a higher risk of cardiovascular events as compared to non-diabetics. This trial tested whether addition of ticagrelor to aspirin in diabetics with a stable coronary artery disease with no previous history of MI or stroke, improves ischemic outcomes. Ticagrelor proved to reduce the incidence of ischemic events group (7.7% vs. 8.5%; P=0.04), but was associated with a higher bleeding events (2.2% vs. 1.0%; P<0.001). Further, it is to be noted that although the risk of intracranial bleed was higher (0.7% vs. 0.5%; P=0.005), but the incidence of fatal bleed was not different as compared to the placebo (0.2% vs. 0.1%; P=0.11). Hence, addition of ticagrelor to aspirin reduced the ischemic events but simultaneously increased major bleeding rates.

TWILIGHT (Ticagrelor with or without Aspirin in High-Risk Patients after PCI) Trial[10]

Post PCIs, after a period of dual antiplatelet therapy, most patients are preferrably shifted to a single antiplatelet drug. This dual antiplatelet therapy is given to reduce thrombotic risk in patients undergoing PCI, which is higher in case of certain clinical factors like diabetes or angiographic factors. Antiplatelet therapy is prescribed to maintain a balance between antithrombotic activity and risk of bleed. P2Y12 inhibitors alone have been evaluated in such patients in order to decrease the risk of bleed while maintaining safety after dual antiplatelet therapy. Here in this study, ticagrelor alone was compared to ticagrelor with aspirin after 3 months of dual antiplatelet (ticagrelor + aspirin) therapy for clinically important bleeding events or ischemic events in patients who were post PCI and had a higher risk of bleed. These patients were randomized to receive either aspirin or placebo after 3 months till 1 year. The bleeding events as defined by Bleeding Academic Research Consortium (BARC) type 2, 3, or 5 bleeding was the primary outcome. The primary end-point was 4% in ticagrelor group versus 7.1% in ticagrelor plus aspirin group (P<0.001).

The incidence of death from any cause, nonfatal MI or nonfatal stroke, was 3.9% in both groups (P<0.001 for non-inferiority). Hence, ticagrelor monotherapy after 3 months of dual antiplatelet therapy was seen to reduce clinically relevant bleeding events without an increase in death, MI, or stroke.

STOPDAPT-2 (Effect of 1-Month Dual Antiplatelet Therapy Followed by Clopidogrel vs. 12-Month Dual Antiplatelet Therapy on Cardiovascular and Bleeding Events in Patients Receiving PCI) Trial[11]

Current guidelines recommend a 12-month dual antiplatelet therapy for patients undergoing PCI. This trial evaluated a very short-term (1 month) dual antiplatlet therapy (DAPT) after PCI with a cobalt-chromium everolimus eluting (Co-Cr EES) stent in patients with high bleeding risk. Patients receiving 1-month DAPT followed by clopidogrel monotherapy were compared to 12 months of DAPT (aspirin and clopidogrel). The investigators found that very short duration of DAPT followed by clopidogrel monotherapy, compared with 12 months of DAPT, led to a significantly lower rate of a composite of cardiovascular and bleeding events, fulfilling the criteria for both non-inferiority and superiority. These findings suggest that a shorter duration of DAPT may provide benefits in patients undergoing Co-Cr EES, however, needs further testing in a larger trial involving other populations.

Diabetes and Cardiovascular Disease

DAPA-HF (Dapagliflozin in Patients with HF and Reduced Ejection Fraction) Trial[12]

Patients with diabetes mellitus type 2 have increased risk of cardiovascular disease and HF. The newer addition to diabetes treatment includes the inhibitors of sodium-glucose cotransporter 2 (SGLT2). These have been seen to reduce the rate of hospitalization for HF in diabetic patients. Whether SGLT2 inhibitors will reduce the risk of first hospitalization for HF with reduced ejection fraction irrespective of diabetic status is unknown and was studied in this trial. Patients with New York Heart Association (NYHA) class II, III, or IV HF and an ejection fraction ≤40% on recommended therapy were randomized to either dapagliflozin (10 mg once daily) or placebo. The primary outcome of composite of worsening HF (hospitalization or a visit needing an intravenous therapy for HF) was seen in lesser patients on dapagliflozin than in placebo group (16.3% vs. 21.2%, P<0.001). Death from cardiovascular causes were also less frequent in dapagliflozin group as compared to placebo (hazard ratio, 0.82; 95% CI, 0.69–0.98). These findings were similar in diabetics and non-diabetics. The frequency of adverse events also did not differ. Hence, it was concluded that in HF and a reduced ejection fraction, addition of dapagliflozin to guideline directed therapy reduced the risk of worsening HF or CV death, regardless of the presence or absence of diabetes.

EMPA-REG Outcome (Empagliflozin, Cardiovascular Outcomes, and Mortality in Type 2 Diabetes) Trial[13]

Empagliflozin, an inhibitor of sodium–glucose cotransporter 2, was studied in this trial and its effect on cardiovascular morbidity and mortality in patients with type 2 diabetes at high cardiovascular risk was evaluated. EMPA-REG outcome trial was done in patients with cardiovascular disease (10% had HF) and showed favorable outcome in terms of nonfatal MI, cardiovascular death, and nonfatal stroke. Further, a reduction in risk of hospitalization was seen, in addition to an improved renal

outcome. Among patients receiving empagliflozin, there was an increased rate of genital infection noted without an increase in other adverse events.

Trials for Stable Coronary Artery Disease

ISCHAEMIA (International Study of Comparative Health Effectiveness with Medical and Invasive Approaches) Trial[14]

Various studies have been done in the past comparing the different treatment strategies in patients with stable coronary artery disease. However, quantification of ischemia and relation to outcomes in such subset of patients has not been evaluated. In ISCHEMIA trial, these patients were tested with stress testing and a blinded computed tomographic evaluation of coronaries was done in those with moderate to severe ischemia. Patients having significant unprotected left main disease and non-significant CAD were excluded. Subsequently, these patients were randomized to two groups, one group underwent cardiac cathetrization and revascularization plus optimized medical therapy (OMT), and the other group being optimized medical therapy alone. It is worth noting that patients who failed on OMT underwent an invasive strategy. It was interesting to find that composite of CV death, MI, or hospitalization for unstable angina, HF, or resuscitated cardiac arrest was not different significantly in both the groups. Both the groups had lower incidence of death from any cause. Further, an improvement in symptoms was noted with invasive strategy more so in patients who had angina more frequently which was seen till 12 and 36 months. There are certain limitations which need to be seen, first being the power of the study which was reduced with lesser patients than was planned. Secondly, the effect of complete revascularization has not been reported as of now. Moreover, effect on left main disease, left ventricular dysfunction, ACS patients, and more symptomatic patients needs to be analyzed further.

Valvular Heart Disease

POET (Partial Oral versus Intravenous Antibiotic Treatment of Endocarditis) Trial[15]

Infective endocarditis (IE) is managed with a prolonged course of intravenous antibiotics, the duration depends on the pathogen cultured. This trial evaluated the safety and efficacy of shift to oral antibiotics from intravenous antibiotics in stable patients with left sided IE caused by streptococcus, Enterococcus faecalis, Staphylococcus aureus, or coagulase-negative staphylococci. These patients who were stable and treated with intravenous antibiotics were randomized to continue intravenous treatment or to switch to oral antibiotic treatment. All patients received intravenous antibiotics for at least 10 days. If found stable, patients in the orally treated group were discharged and followed in outpatient department. There was no significant difference noticed in the primary outcome of all-cause mortality, embolism, unplanned cardiac surgery, or relapse of bacteremia with the primary pathogen [12.1% (I/V) vs. 9.0% (oral), P=0.40], till 6 months after completion of antiobiotic treatment. Hence, in stable patients of left sided IE, a shift to oral antibiotics was seen to be non-inferior than continued intravenous antibiotic therapy.

PARTNER-3 (Transcatheter Aortic Valve Replacement with a Balloon Expandable Valve in Low Risk Patients)[16]

Transcatheter aortic valve replacement (TAVR) is widely being done for high and intermediate surgical risk patients with severe aortic stenosis. In low surgical risk patients, the benefit of balloon expandable TAVR was evaluated in this randomized trial. One thousand patients were randomized to transfemoral TAVR or surgery. At the end of 1 year the primary outcome, a composite of death, stroke, or rehospitalization was less with TAVR as compared to surgery. However, this needs to be individualized after a heart team meeting as durability, and TAVR in younger age groups need further evaluation.

Conclusion

Cardiovascular science is a vital part of medicine and is being investigated aggressively. For physicians, being updated in this period of evidence-based medicine is important. In this chapter, we have summarized the recent key trials that were published and presented in the field of cardiology. Many of these studies will help guide clinical practice and guideline updates. Others have shown encouraging early data to guide further research development.

Iron Deficiency and Iron Deficiency Anemia in Chronic Heart Failure: A High Risk

Pramod Kumar Sinha

Abstract

Iron deficiency with or without anemia in chronic heart failure remains a very important issue and is associated with increase in morbidity and mortality. Various studies and trials have convincingly proved that management of deficiency of iron by intravenous iron therapy scores over oral iron therapy in improving the different parameters of exercise capacity, morbidity, and in decreasing the overall incidence of mortality. Thus, proper evaluation and management of iron deficiency in chronic heart failure needs utmost care and attention.

Introduction

Heart failure (HF) is one of the major public health problems, overall, about 2% of adult population suffers, the prevalence increases with rising age affecting 6–10% of people over age 65. Despite many advancement and advent of newer therapeutic approaches, prognosis of symptomatic HF remains poor. This sad scenario is compounded by the occurrence of anemia in general and iron deficiency anemia or only iron deficiency in particular. *Iron deficiency (ID)* is detected to be a frequent association with *chronic heart failure (CHF)* and is an important factor for reduced quality of life (QoL), diminished exercise ability and poor prognosis including recurrent hospitalization and mortality whether present with anemia or no anemia. Management with IV iron has been convincingly shown to improve the situation in different trials. Despite these facts, looking for ID in HF is not in the priority list of physicians leading to underdiagnosis and consequently undertreatment of deficiency of iron. Thus, as per evidence from many trials, ID needs to be recognized as high-risk factor in respect to consequences of CHF and evaluation of deficiency of iron requires to be included in the routine workup for CHF with proper management.

Prevalence of ID in CHF

Thirty-five to fifty percent of patients with HF found to suffer from ID and it remains the most significant cause of anemia in HF; however, ID without anemia is found to be associated with 46% of systolic HF.[1] An international cohort of 1,506 patients with CHF observed presence of ID to be closely associated with severity of HF with reduced ejection fraction assessed by New York Heart Association (NYHA) functional class or NT-pro BNP level.[1] Similar association of ID and severity of HF is also observed by Okonko et al.[2] and Jankowska et al.[3] Women found to have higher prevalence of ID in CHF.

However, the study done for prevalence of ID in HF with preserved ejection fraction (HFpEF) is comparatively much less but then similar rate of ID is reported in HFpEF compared to HF with reduced ejection fraction (HFrEF).[1,4] A small observational study showed the prevalence of 57% in HFpEF.

Etiology of Anemia and Iron Deficiency in Heart Failure

The development of anemia with HF can result from various etiologies such as a dilutional anemia, anemia of chronic disease, and blunted erythropoietin response with ID being the most significant cause.[5,6]

The causes of ID in CHF are multifactorial. In general, less dietary intake, disturbed absorption, and chronic blood loss cause ID. But besides these, increase in hepcidin level due to the inflammatory state induced by HF and liver congestion in CHF leads to diminished iron absorption and increased reticuloendothelial block of releasing iron for utilization resulting in ID and anemia.[7]

Definition of Iron Deficiency in HF

Iron deficiency is classified as absolute and functional and patients with CHF are prone to suffer to both forms. Absolute ID represents decline in total body iron store that is reduced or absent storage iron in bone marrow, liver, and spleen caused by improper dietary intake, disturbed gastrointestinal absorption, and prolonged blood loss whereas functional ID refers to impaired iron delivery to target cells despite normal or overly abundant iron stores due to chronic inflammation via increase in hepcidin production resulting in inhibition of iron exporter ferroportin leading to impaired iron absorption and utilization.

Diagnosis of ID in HF

Diagnosis of ID in CHF based on serum ferritin level warrants consideration of HF associated inflammatory state. The standard cut-off value of serum ferritin for diagnosis of ID in general is less than 30 mcg/L. But then this value does not apply in case of CHF as serum ferritin is an acute phase reactant and CHF underlies an inflammatory state.[6]

Presently based on landmark FAIR-HF study[8] and thereafter inclusion of the very criteria in 2012 ESC Guidelines on diagnosis and treatment of HF, serum ferritin level less than 100 mcg/L defines absolute ID, and serum ferritin level between 100–299/L combined with a transferrin saturation (TSAT) less than 20% defines functional ID.

Iron Deficiency and Cardiac Function

Iron deficiency leads to well-known derangement of erythropoiesis resulting in ID anemia affecting oxygen carrying capacity of blood with its effect on cardiac function. Besides this iron is incorporated in enzymes like cytochromes, peroxidases, and others subserving important and critical role in body metabolism including cellular immunity and so chronic deficiency of iron on its own leads to derangement of cellular energy mechanism including oxidative metabolism and immunity related activity resulting in impairment of functional and structural quality of myocardium culminating in LV dysfunction.

Clinical Outcome of ID in CHF

A number of studies have convincingly shown that ID impairs exercise capacity, causes poor QoL and leads to poor prognosis with recurrent hospitalization and enhanced mortality independent of anemia and left ventricular ejection fraction.

Okonko et al.[2] and Jankowska et al.[9] found that patients with CHF and ID suffers *poor exercise capacity* irrespective of hemoglobin level and severity of heart disease.

Iron deficiency independent of anemia has been shown to be accompanied by *suboptimal QoL* as measured by Minnesota Living with Heart Failure Questionnaire (MLHFQ), lower the TSAT lower is the QoL.[9,10] In a post-hoc analysis of CHF patients showed that patients with ID presented with poorer QoL compared with those having no ID.[4]

Several studies revealed that ID is an independent and strong predictor of poor prognosis in HF. In a large study of 1,506 CHF patients by Klip,[1] patients having ID showed remarkably *higher rates of mortality* at 6 months (8.7% vs. 3.6%) persisting throughout the study duration. Okonko et al.[2] in their study on 157 CHF patients found ID to be prognostically more ominous than anemia. In a big cohort of CHF patients, Jankowska et al.[3] observed that ID is a strong predictor of poor prognosis related to hospitalization and mortality with 3 years survival of 59% for patients suffering ID compared to 71% without having ID.

A cross-sectional study of 447 patients of HFpEF, iron deficient patients showed worse performance in the 6-minute walk test and poor QoL on MLHFQ compared to patients with normal iron status.[11]

Thus, *ID with or without anemia represents a high-risk factor* for worsening of symptoms of HF including poor QoL, diminished exercise ability, and increased hospitalization and mortality.

Treatment

Obvious clinical importance of ID and its high prevalence in CHF make restoration of iron status essential together with care of the cause of ID.

Use of oral iron is not favored because of its poor absorption due to CHF induced edema and congestion of gut mucosa together with high hepcidin level besides interaction with diet or drug, and because of need of much prolonged duration of treatment needed with oral iron to achieve the target. Clinical trial also does not support oral iron therapy. IRONOUT trial[12] using oral iron did not found betterment of exercise capacity over 16 weeks and also no change observed in iron biomarker. IRON-HF trial comparing oral iron versus IV iron showed clinically relevant difference in improvement of exercise capacity favoring IV iron; however, it lacks statistical power.

IV iron proves to be effective and its use is well supported by different clinical trials. It is cost effective as it saves expenditure by cutting down the given recurrent hospitalization in ID patients and by improving the survival.

FAIR-HF trial[8] comparing *ferric carboxy maltose* (FCM) versus placebo showed unexpected significant improvement in QoL, symptoms, and exercise capacity accessed by 6-minute walk distance test on IV iron arm in patients of CHF and ID with or without anemia. All patient's subgroup based on hemoglobin level, renal function, sex, and ejection fraction showed the improvement. NYHA functional class and global assessment of patient also showed betterment with IV FCM.

CONFIRM-HF trial[13] using FCM in symptomatic HF showed significant improvement in exercise capacity accessed by 6-miute walk distance at 24th week, also led to diminished risk of hospitalization for worsening HF at week 52.

Bolger et al.,[14] Tolle et al.,[15] Usmanov et al.,[16] and Ferric-HF trial[17] used *IV iron sucrose* supplementation in patients of CHF with ID and/or anemia and observed improvement in markers of iron status and also in exercise capacity, NYHA functional class, 6-minute walk distance and QoL.

Data relating to IV Iron treatment for ID in HFpEF is limited. Ongoing FAIR-HFpEF Study and PREFER-HF trial addressing the issue of benefit of IV iron treatment in patients with HFpEF and ID will resolve the query.

Nunes data[18] revealed that FCM therapy in 459 HF outpatient with ID resulted in increase in hemoglobin and TSAT and also found FCM to be well tolerated; moreover, higher doses of FCM (1,000 mg) showed a significant higher efficacy compared with lower dose (500 mg).

Thus, IV iron needs to be used for CHF with ID with or without anemia. However, comparative data for the different IV iron compounds are not available. But then FCM provides the advantage of high dose (500 mg) formulation and is well tolerated. The therapeutic target may be achieved with one or two injections only.

Guidelines for Treatment of ID in CHF Patients

2016 ESC guidelines for the diagnosis and treatment of acute and CHF[19] recommended to include serum ferritin and TSAT evaluation to screen ID for initial assessment of newly diagnosed HF (Class 1, Level C) and also recommends IV FCM for treatment of ID-Class IIA, Level A **(Table 1)**.

2017 ACC/AHA/HAS focused update of the 2013 ACCF/AHA guideline for management of HF[20] also recommends that in NYHA Class II to III patients with ID (Class II, Level B), IV iron might be reasonable to improve QoL and functional status **(Table 2)**.

Present Scenario in Clinical Workup/ Management for ID in CHF

PReP prospective registry[21] revealed that ID and anemia many a times remain unappreciated in CHF ambulatory patients by physicians despite its well-known high prevalence and clinical implication.

In a substudy of RAID-F registry,[22] it is observed that screening for ID in CHF and IV iron therapy for treating ID in CHF is much under practiced; oral iron found to preferred to be the first choice despite the fact that evidence favors use of IV iron.

TABLE 1 2016 ESC guidelines for the diagnosis and treatment of acute and chronic heart failure

Recommendations for the treatment of other comorbidities in patients with heart failure		
Recommendations	***Class***	***Level***
Iron deficiency		
I V FCM should be considered in symptomatic patients with HFrEF and I D (serum ferritin < 100 mcg/L, or ferritin between 100-299 mcg/L and transferrin saturation <20%) in order to alleviate HF symptoms, and improve exercise capacity and quality of life.	II a	A

TABLE 2 2017 ACC/AHA/HAS focused update of the 2013 ACCF/AHA guideline for management of HF

COR	*LOE*	*Recommendations*	*Comment/Rationale*
IIb	**B-R**	In patients with NYHA CLASS II and III HF and ID (ferritin <100 ng/L or 100-300 ng/L if transferrin saturation is <20%). IV iron replacement might be reasonable to improve functional status and QoL	NEW: New evidence consistent with therapeutic benefit.
III: No Benefit	**B-R**	In patients with HF and anemia, erythropoietin – stimulating agents should not be used to improve morbidity and mortality.	NEW: Current recommendation reflects new evidence demonstrating absence of therapeutic benefit.

Conclusion

Iron deficiency with or without anemia is one of the most common and important comorbidities of CHF and evidences reveal that ID is a high-risk factor for poor consequences of CHF in terms of increased morbidity and mortality. IV iron therapy proved to improve HF symptoms, QoL, 6-minute walk distance, New York Heart Association (NYHA) functional class, and results in better survival with decrease in recurrent hospitalization for worsening HF symptoms. Oral iron is not found to have comparable efficacy.

Thus, as per the evidences and so also as suggested by guidelines, screening for ID should be included in routine workup of all cases of HF and IV iron must be considered for its treatment.

CHAPTER

45 Peripartum Cardiomyopathy

Monika Maheshwari, Sneha Garg

Abstract

Peripartum cardiomyopathy is defined as symptomatic heart failure with reduced ejection fraction in last month of pregnancy and up to 5 months postpartum. Common risk factors include older maternal age, multiparity, and preeclampsia, Suggested etiopathogenesis includes nutritional deficiencies, viral myocarditis, and autoimmune process. Treatment in acute decompensated heart failure includes intravenous vasodilators, diuretics, digitalis. Data regarding use of vasopressors and bromocriptine is limited. Prognosis is variable. Between 50–60% of women completely recover normal heart size and function usually within 6 months of delivery. Patient with severe cardiac dysfunction should be considered for heart transplantation.

Introduction

Peripartum cardiomyopathy (PPCM) that affects women of childbearing age is a type of heart failure (HF) with reduced ejection fraction (systolic heart failure). Usually PPCM affects women during pregnancy or in early postpartum period.[1] In 1930, PPCM was recognized a distinct entity although it was first described as early as in the 18th century. Demakis et al. described the syndrome as "The peripartum cardiomyopathy" in 1971.[2]

The symptoms of PPCM are like the normal findings of late pregnancy. Thus, there is a delay in diagnosis usually. The severity and mortality vary from patient to patient. It is a relatively rare disease and the exact incidence in India is not documented, but a study from a tertiary care hospital from South India reports an incidence of 1 case per 1,374 live births.[3]

Definition

In women presenting with HFrEF, PPCM is a diagnosis of exclusion. It was earlier defined as symptomatic HF in the last month of pregnancy and up to 5 months postpartum.

Now, the 2010 Heart Failure Association of the European Society of Cardiology Working Group revised the definition of PPCM to "an idiopathic cardiomyopathy presenting with HF secondary to LV systolic dysfunction toward the end of pregnancy or in the months following delivery, where no other cause of heart failure is found." This diagnostic criterion indicates that EFis less than 45% and there may/may not be ventricular dilatation.[4] Outcomes can be complete recovery or rapid deterioration, persistent myocardial dysfunction, and HF leading to urgent mechanical circulatory support and cardiac transplantation.

Risk Factors

Many risk factors like African ancestry, older maternal age, hypertension, etc. have been associated with PPCM. The risk factors are summarized in **Box 1**.

Pathophysiology

The etiology of PPCM is multifactorial. Suggested etiopathogenesis of PPCM includes nutritional

BOX 1 Risk factors for peripartum cardiomyopathy

- African ancestry
- Pre-eclampsia and hypertension
- Multifetal pregnancies
- Multiparity
- Older maternal age
- Family history of cardiomyopathy
- Obesity
- Cocaine abuse, alcohol abuse
- Smoking
- Long duration of tocolytic therapy
- Selenium/zinc deficiency

deficiencies, viral myocarditis, and autoimmune process. Two vascular-hormonal models of pregnancy-associated cardiomyopathy were developed. These models suggested novel mechanisms for PPCM in humans. The 1st model—a STAT3 knockout mouse. In this model oxidative stress led to cleavage of the prolactin. This 16-kDa prolactin fragment was vasculo-toxic and pro-apoptotic, leading to vascular and myocardial dysfunction. Treatment with bromocriptine, a suppressor of prolactin secretion, had complete reversal of the condition in mice. Human prolactin has been more resistant to cleavage than prolactin in mice.

The 2nd model—cardiac-specific genetic deletion of proliferator-activated receptor gamma coactivator-1a (PGC-1a). This led to vasculo-toxicity by activation of prolactin fragment and decreased expression of proangiogenic vascular endothelial growth factor (VEGF). In this case there is only partial reversal with bromocriptine. For complete recovery addition of VEGF is required. In pre-eclampsia the levels of soluble Fms-like tyrosine kinase-1 (sFlt1), an antagonist of VEGF and placental growth factor are elevated markedly. Elevated sFlt1 levels also have been found in women with worse outcomes in PPCM.

Genetics

Observations suggest familial clustering of PPCM. Genetic contribution can be suggested by 6% co-occurrence with idiopathic dilated cardiomyopathy (DCM). A GWAS identified a single-nucleotide polymorphism near the *PTHLH* gene, which regulates vascular homeostasis. Rare pedigree evaluation suggests that both PPCM and DCM had likely pathogenic variants in genes, which were known to contribute to DCM-TTN and BAG3. But more than 90% subjects with TTN truncating variants do not develop DCM or PPCM suggesting that additional environmental genetic or epigenetic factors play a role. Incompletely penetrant genetic origin and role of additional factors is suggested by the fact that most women with PPCM do not have a family history of cardiomyopathy and it does not always recur with a subsequent pregnancy.

Clinical Features

The presentation of PPCM is indistinguishable from non-pregnant patients with systolic dysfunction or DCM. New/rapid onset of symptoms requires urgent evaluation. Most women are diagnosed typically in the 1st month postpartum. The symptoms are cough, fatigue, palpitations, orthopnea, chest pain, hemoptysis, weight gain, and unexplained abdominal pain. Signs of PPCM are enlarged heart, tachycardia, decreased SpO_2, elevated JVP, presence of S_3, and loud P_2. Mitral and Tricuspid regurgitation and pulmonary rales are noted. Worsening of peripheral edema, hepatomegaly and ascites may be seen. Arrhythmias are commonly found, which may lead to embolic phenomenon either peripheral or pulmonary. Moderate pericardial effusion may be seen. Findings of pre-eclampsia must be evaluated. High output cardiac failure has also been reported in some patients.

Diagnosis

Various cardiac diagnostic modality including imaging and biochemical investigations are used to identify PPCM. The investigations recommended and findings associated with PPCM are:

- *Chest X-ray:* Findings suggestive of PPCM are cardiomegaly. Also pulmonary venous congestion with interstitial/alveolar edema. Pleural effusion may be found. Chest X-ray should be avoided in pregnancy as findings are not specific and if needed an abdominal shield is used.
- *Electrocardiography:* Heart rate is usually normal. Sinus tachycardia, atrial fibrillation, other conduction abnormalities with nonspecific ST segment changes may be present.
- *Echocardiography:* This is the most important tool for evaluation and follow-up for women with PPCM.

Overall features of PPCM are like primary non-ischemic DCM. The findings on echocardiography are a decrease in myocardial systolic function, as manifested by reduction in left ventricular ejection fraction (LVEF) or fractional shortening. In women presenting late, left ventricular dilatation is frequently evident. Mild compensatory left ventricular hypertrophy can be seen. In early and immediate postpartum period a small pericardial effusion is found on echocardiography. Mitral insufficiency secondary to annular dilatation is seen when there is marked LV enlargement. Other reported findings are tricuspid/pulmonary regurgitation, left atrial/biatrial enlargement and intracardiac thrombus.

- *Endomyocardial biopsy:* The usual findings are features of myocarditis. Biopsies in patients with PPCM when performed earlier after symptom onset have the highest yield. Endomyocardial biopsy is not routinely recommended yet.
- *Viral and bacterial titer & cultures:* In selected cases antibody titer of virus like Coxasckie B should be considered. This approach is more useful for research than diagnosis.
- *Cardiac MRI (CMR):* Nowadays a highly studied and used entity at higher centers. CMR can characterize the myocardium and is used to measure global and myocardial contraction. Delayed gadolinium contrast enhancement can differentiate myocarditis from ischemia as a mechanism of myocyte necrosis. Myocarditis has a subepicardial nonvascular distribution with a nodular/band-like pattern while ischemia has a subendocardial or transmural vascular distribution. Chamber measurements can also be done. CMR can also be used as a guide for biopsy. It is a useful prognostic tool as well.[5]
- *Right heart catheterization:* Used for assessment of the filling pressure and cardiac output in patients with persistent HF, hemodynamic instability/evidence of an organ dysfunction. Enlargement of atria and ventricles will also be demonstrated.
- *Biochemical evaluation:* Creatine kinase and cardiac troponin evaluation is usually not significant in diagnosis. Brain natriuretic peptide (BNP) & N-terminal pro-BNP levels are elevated in PPCM patients.

Differential diagnosis of HF in pregnancy has been listed in **Box 2**.

BOX 2 Diffential diagnosis of heart failure in pregnancy

- Takotsubo cardiomyopathy
- Familial cardiomyopathy
- Pre-existing cardiomyopathy
- Recurrent peripartum cardiomyopathy
- Pre-eclampsia
- Hypertrophic cardiomyopathy
- Myocarditis consider
- Arrhythmogenic right ventricular cardiomyopathy
- Left ventricular noncompaction
- Valvular heart disease
- Congenital heart disease
- Tachycardia-arrhythmia mediated cardiomyopathy
- Hypertensive heart disease
- Ischemic heart disease
- Cardiomyopathy related to other systemic medical diseases and acute conditions
- Pulmonary embolism

Management

The most important concern for medical treatment in PPCM is fetal safety. To prevent thromboembolic complications in PPCM superimposed by the hypercoagulable state of pregnancy, anticoagulation is required especially in severely decreased LVEF during late pregnancy and 6–8 weeks postpartum. American Heart Association recommends anticoagulation when the EF is less than 30%,[6] while European Society of Cardiology when EF less than 35% as the threshold.[7] Warfarin is avoided during pregnancy. Low-molecular-weight heparin can be used. During lactation warfarin and low-molecular-weight heparin are safe. Novel anticoagulants are not studied widely in this context and not recommended as of now.

Experimental Treatment

Bromocriptine (dopamine agonist and inhibitor of release of prolactin) has been tried in PPCM based on the research that in mouse model PPCM is caused by the antiangiogenic and proapoptotic 16-kDa form of prolactin. Many studies have been done on this approach but still evidence is lacking. Implications on breast feeding also discourage its use. REBIRTH study—a randomized double-blind, placebo control (Randomized Evaluation of BromocriptineIn Myocardial Recovery Therapy) to investigate the effect of bromocriptine on myocardial

recovery and clinical outcome in PPCM with 200 women in the USA and Canada has been proposed by the IPAC group and is under evaluation. The 2018 ESC guidelines include a Class IIb recommendation for the use of bromocriptine.[8] Its use is also associated with thrombotic complications.

Treatment of Severe PPCM

In acute decompensated HF, intravenous vasodilators like nitroglycerin may be needed in during pregnancy. Inotrope Dobutamine has adverse effects and Levosimendan was not shown to improve outcomes in PPCM. Milrinone and Levosimendan showed comparable hemodynamic improvement.

Advanced therapies for cardiogenic shock during/shortly after pregnancy are mechanical circulatory support with intra-aortic balloon pump (IABP), percutaneous left ventricular assist device therapy, and extracorporeal membrane oxygenation (ECMO). These should be used early in women with hemodynamic instability in PPCM. Cardiac transplant has been shown to have higher chances of complications.

Labor and Delivery

A combined effort of cardio-obstetrics team is required to minimize maternal and fetal mortality. Timing and mode of delivery should be discussed with experts. To avoid prematurity and associated fetal complications stabilization of mother should be done. Early delivery is prompted in the setting of hemodynamic instability despite medical therapy. Vaginal delivery is recommended in stable patients except for obstetric cesarean section indications. Invasive hemodynamic optimization before delivery and strict monitoring is benefitting in unstable patients. After delivery relieving of caval compression, autotransfusion due to uterine contractions and fluid mobilization contribute to increase in preload. Thus, risk of fluid overload and pulmonary edema must be taken care of.

TABLE 1 Subsequent pregnancies in PPCM: counseling and management[1]

Subsequent pregnancy	*Recovered (LVEF ≥50%)*	*Nonrecovered (LVEF <50%)*
Preconception/First Visit	• Risk counseling • Follow-up planning • Clinical & EF reassessment of RAAS blocking agents for 3 months • Baseline Echo & BNP/NT-proBNP level	• Risk counseling also discussion of alternative ways to build a family • If not considering termination: • Close follow-up, • Stop RAAS blocking agents Switch to hydralazine or ISDN • Baseline Echo & BNP/NT-proBNP level
Maternal Risks	• Relapse in ~20% • Rare severe deterioration • Mortality unlikely • High rate of subsequent recovery	• Higher relapse • Deterioration of LV function in ~50% • Increased morbidity & mortality • Premature delivery & abortion
Medications	• Continue beta blocker • Diuretics & hydralazine/ISDN in case of clinical/LV functional deterioration	• Continue beta blocker • Hydralazine/ISDN for hemodynamic & symptomatic improvement • Digoxin considered • Consider anticoagulation when severe LV dysfunction
Labor and Delivery	• Multidisciplinary planning • Spontaneous vaginal delivery preferred • Monitoring for fluid overload in the first 48 hours after delivery, esp. in cases of recurrent LV dysfunction	• Multidisciplinary planning • Spontaneous vaginal delivery preferred • Early delivery when further reduction in LV function & hemodynamic deterioration • Hemodynamic monitoring for optimization prior to delivery & monitoring during & after delivery • Monitor for fluid overload
Follow-up	• Close monitoring of symptoms • Echocardiographic reassessment of LV function & BNP/NT-proBNP level at the end of the 1st & 2nd trimesters, 1 month before delivery, after delivery prior to discharge, 1 month postpartum & at any time if symptoms develop	

Prior to Hospital Discharge

Lactation: Earlier some studies and 2010 ESC advised against lactation in PPCM. But recent IPAC data showed that breastfeeding did not lead to adverse outcomes, persistent myocardial dysfunction, or inflammatory markers. This suggests that continued stimulation of prolactin secretion might not be harmful. Most HF medications can be given safely with breastfeeding **(Table 1)** and should not be a reason to advise women against lactation.

Contraception: Due to increased risk of thromboembolism, it is recommended to defer the use of estrogen-containing contraceptives. Subcutaneous progesterone-releasing implants/the Mirena IUDs are safe and effective choices. Second-line consideration can be given to injectable depot medroxyprogesterone. Tubal ligation and vasectomy are other options. In patients with persistent LV dysfunction, the risk of a subsequent pregnancy is more than any risk associated with contraception. Thus, contraception must be encouraged by both cardiologist and obstetrician.

Subsequent Pregnancies

The subsequent pregnancies and their management are the most important area of consideration in a patient treated for PPCM. This is elaborated in **Table 1**.

Conclusion

In all pregnant and postpartum women, the diagnosis of PPCM should be considered. Echocardiography gives an assessment of systolic dysfunction. Prompt treatment prevents adverse outcomes. Multidisciplinary team management with optimal HF management is rewarding. The optimal duration of medications after recovery is not yet known. Women considering subsequent pregnancy must be counseled and monitored. Long-term follow-up of patients of PPCM is essential.

Diabetes Mellitus

CHAPTER

46 CVD in Diabetes: Pathophysiology and Clinical Impact

S Arulrhaj, Aarathy Kannan, Gurunadharao, Ankita Bajpai

Abstract

A close link exists between diabetes mellitus (DM) and cardiovascular disease (CVD), which is the most prevalent cause of morbidity and mortality in diabetic patients. Cardiovascular (CV) risk factors such as obesity, hypertension, and dyslipidemia are common in patients with DM, placing them at increased risk for cardiac events. In addition, many studies have found biological mechanisms associated with DM that independently increase the risk of CVD in diabetic patients. Therefore, targeting CV risk factors in patients with DM are critical to minimize the long-term CV complications of the disease. This paper summarizes the relationship between diabetes and CVD, examines possible mechanisms of disease progression, discusses current treatment recommendations, and outlines future research directions.

Introduction

Diabetes confers a two- to fourfold increased risk of coronary heart disease, stroke, and peripheral artery disease. The burden of cardiovascular disease related to diabetes has increased over the past two decades, and macrovascular events remain the leading cause of mortality. Insulin resistance is the major underlying factor for all the features of metabolic syndrome and is considered very crucial in the pathophysiology of vascular damage.[1]

The Pathophysiology of CVD in Diabetes

The two key metabolic abnormalities associated with type 2 diabetes mellitus (T2DM) are insulin-resistance and hyperglycemia .Whereas the two main pathophysiologic mechanisms in vascular wall that can lead to CV events are arterial stiffening and atherosclerosis.[2]

The patients with diabetes mellitus show both accelerated arterial stiffening as well as premature atherosclerotic changes.

Pro-Atherogenic Mechanisms Associated with Hyperglycemia (Flowchart 1)

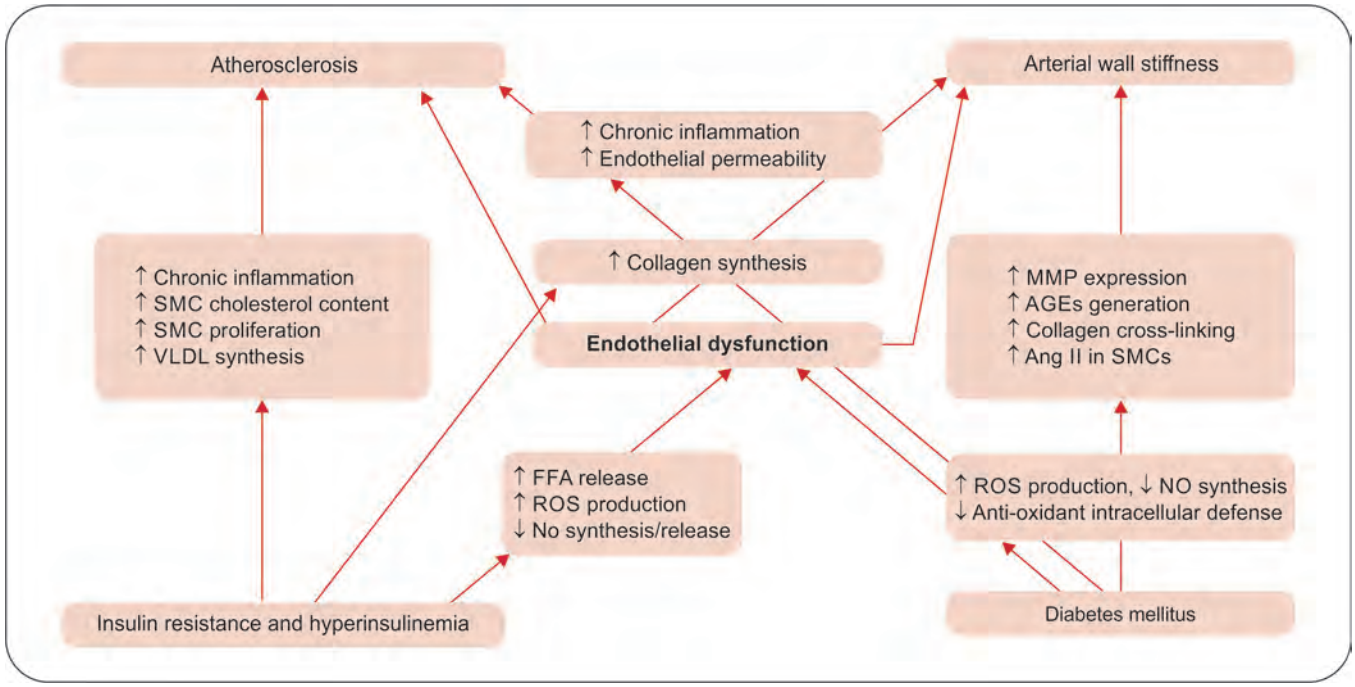
Different molecular mechanisms associated with hyperglycemia have been identified including:

- Increased glucose flux via polyol pathway
- Activation of protein kinase C (PKC)
- Formation of advanced glycation end products (AGE)
- Increased glucose flux via the hexosamine pathway, and activation of the 12/15-lipoxygenase (12/15-LO) pathway[3]
- *All these mechanisms finally result in increased superoxide formation*

Insulin Resistance (Flowchart 1)

Insulin receptors are seen in endothelial cells, macrophages, and vascular smooth muscle cells (SMCs). Insulin resistance has been shown to be due to decreased synthesis or release of NO and increased production of reactive oxygen species, as well as with an increased free fatty acids release from adipose tissue. The increased levels

Flowchart 1: Pathophysiologic mechanisms through which hyperglycemia and insulin resistance can affect the arterial wall



of free fatty acids in circulation may impair the endothelial function as well as induce a low-grade inflammatory reaction (through the activation of nuclear factor kB).[4]

Hyperinsulinemia augments the synthesis of hepatic very-low-density lipoproteins, increases cholesterol synthesis or transport in cultured arterial SMCs, stimulates the proliferation of arterial SMCs, increases collagen synthesis as well as stimulates multiple genes involved in inflammation.

Obesity and Insulin Resistance

Impaired nutrition contributes to hyperlipidemia as well as insulin resistance causing hyperglycemia. This leads to alterations in intracellular signaling and cellular metabolism that negatively impact cells.[5]

All these effects induce cellular events like:

- Modification of gene expression,
- Dyslipidemia and hyperglycemia,
- Activation of oxidative stress and inflammatory response,
- Endothelial dysfunction, and
- Ectopic lipid accumulation, which is favored by obesity and leads to metabolic deregulation.

In the cardiomyocyte, this damage can be through the following three actions:

- Alteration of insulin signaling,
- Increased substrate accessibility, and
- Inflexibility of metabolism changes.

Diabetes and Inflammation

Diabetes is a state of chronic and low-level inflammation. Insulin resistance may be preceded by some immune activation in diabetic and pre-diabetic states and may leads to increase in cardiovascular risk. Along with diabetes, obesity is also associated with increase in the levels of a number of adipokines. Diabetes accelerates the process of natural aging in arterial tree. The correlation between arterial stiffness and CV events or all-cause mortality can be explained by the hemodynamic effects of arterial stiffening. CIMT and Plaque Presence are the surrogate markers of atherosclerosis, plaque indicates an advanced atherosclerotic process **(Fig. 1)**.[6,7]

Endothelial Dysfunction

Healthy endothelium has the properties of vasodilation, anti-atherogenesis as well as anti-inflammatory. However,

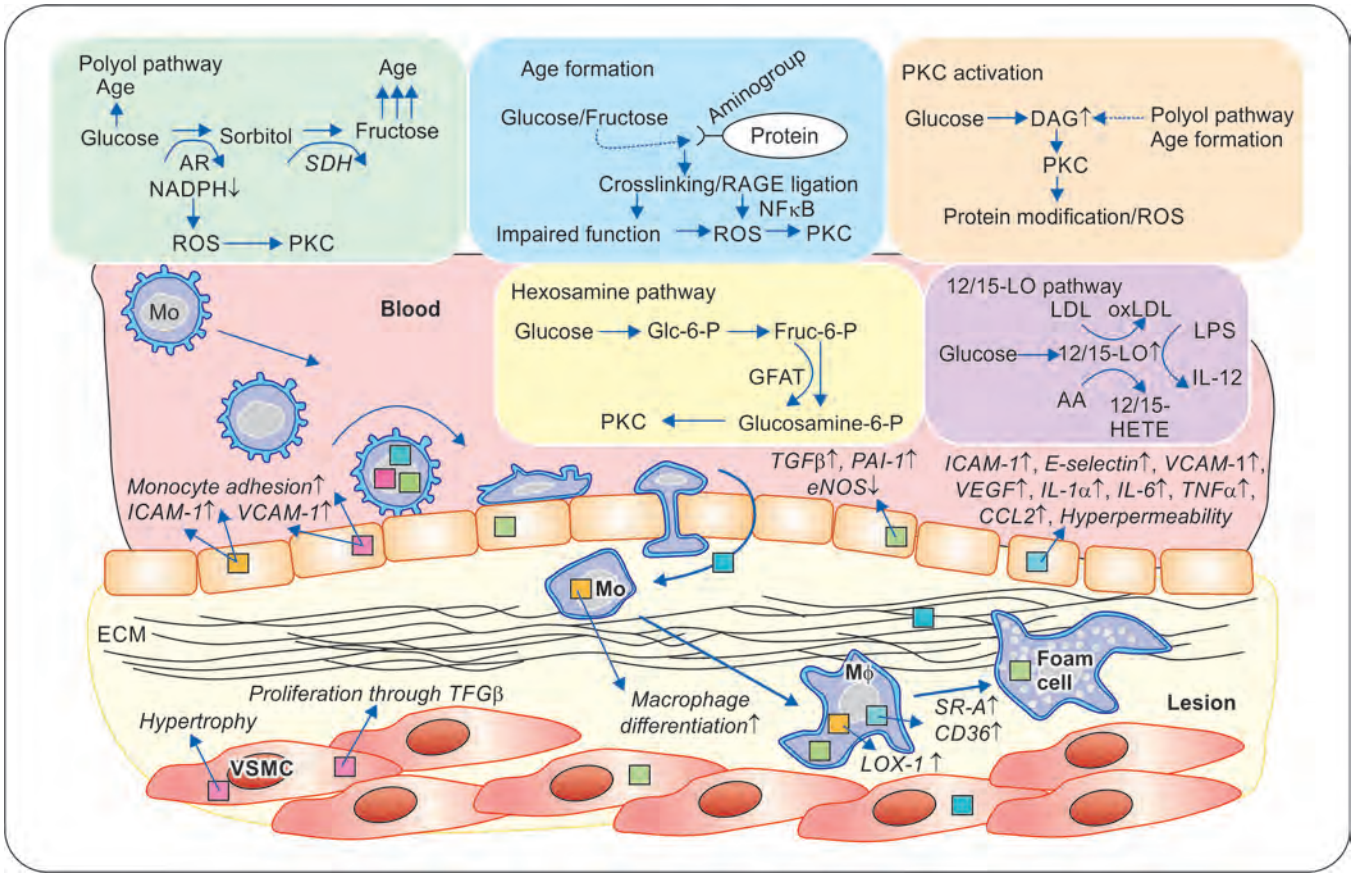


Fig. 1: Biochemistry and molecular cell biology of diabetic complications

a defective endothelium is associated with an accelerated process of atherosclerosis. Hence, both insulin deficiency as well as insulin resistance promote dyslipidemia along with increased oxidation, glycosylation, and triglyceride enrichment of lipoproteins, which further contributes to increase in atherogenicity and macrovascular disease in diabetes **(Fig. 2)**.[8]

Impaired Vascular Repair

Diabetes retards *the endothelial repair processes*, due to shortage of bone marrow (BM)-derived vascular regenerative cells like circulating progenitor cells (CPCs) as well as *endothelial progenitor cells (EPCs)*.[9] *EPCs released from the bone marrow* are involved in homeostasis of healthy as well as damaged endothelium and in physiologic as well as compensatory angiogenesis. Therefore, a reduction in their number as seen in diabetes is believed to promote the development and progression of cardiovascular disease.[10]

Hypercoagulability

Up to 80% of diabetics die of thrombotic events. In that 75% of these deaths are the result of a myocardial infarction, and the remainders are the result of cerebrovascular events and complications related to PVD.[11]

Epicardial Adipose Tissue (EAT)

EAT is an imaging biomarker (ECHO and CTA), and has gained attention due to its intimate location to the coronary vessels and the myocardium. Associated with prevalent subclinical atherosclerosis, ischemia, and future major adverse cardiac events, EAT is a transducer of the adverse effects of systemic inflammation and metabolic disorders on the heart, and thus represents an important target for therapeutic interventions.[12]

Clinical Presentations

See **Table 1**.

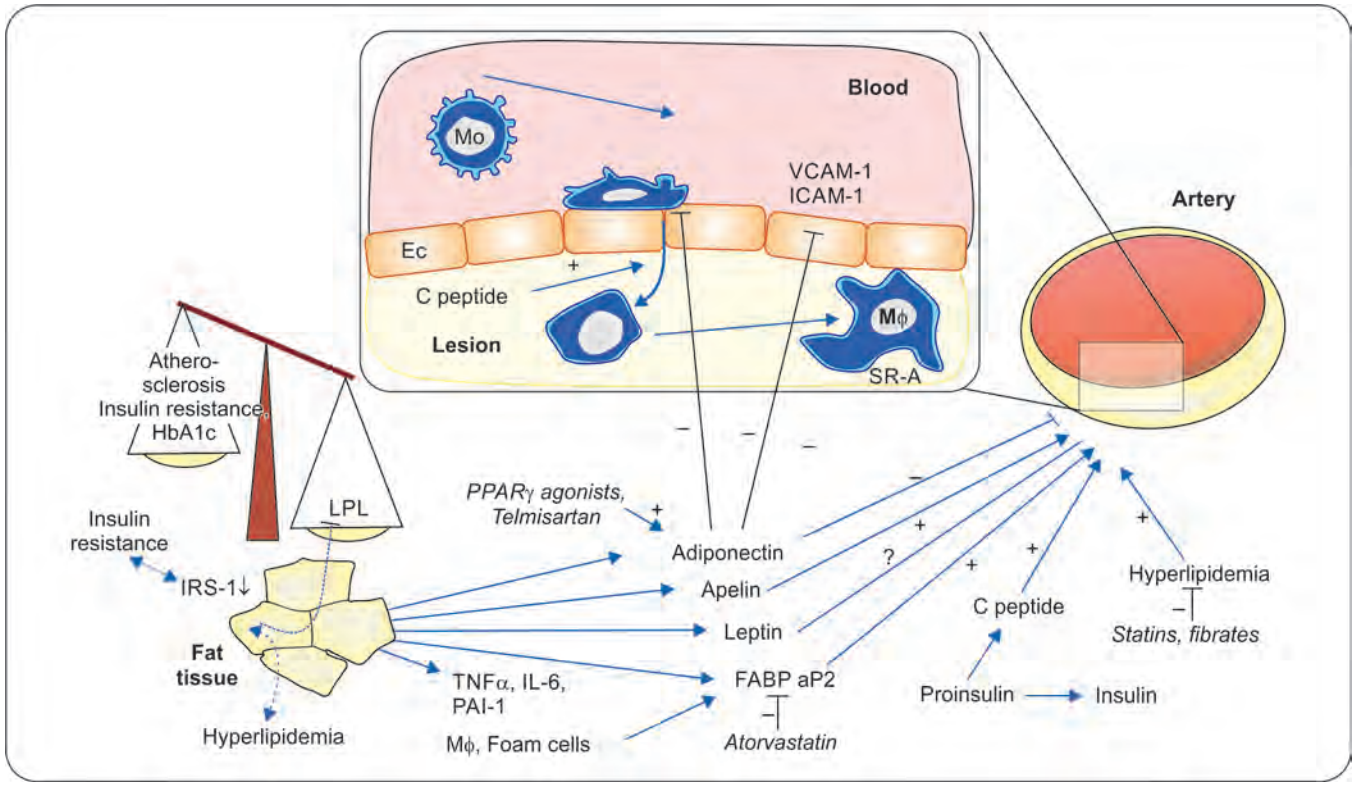

Fig. 2: Pro-atherogenic mechanisms of diabetes mellitus associated with insulin resistance

TABLE 1 Clinical presentations

Very high risk	• Patients with DM and established CVD or • Other target organ damage or • Three or more major risk factors or • Early onset T1DM of long duration >20 years
High risk	Patients with duration of DM >10 years without any organ damage plus any other additional risk factor
Moderate risk	Young patients (T1DM aged <35 years or T2DM aged <50 years) with duration of DM <10 years, without any other risk factors

Macrovascular Disease

Characterized by fibrosis and arterial thickening, as well as vasomotor and endothelial dysfunction, can *increase risk of heart failure (HF)* in diabetes mellitus. Diabetic blood is more likely to be high in triglycerides. Hypertriglyceridemia in diabetes—insulin action regulates lipid flux **(Fig. 3)**.

Premature Atherosclerosis

Multiple mechanisms are associated with insulin resistance, which may promote atherosclerosis in type 2 diabetes **(Fig. 4)**:

- *Secretion of adipokines* from adipose tissue (apelin, adiponectin, or leptin),
- *Fatty acid binding protein (FABP)* aP2 secreted from adipocytes, foam cells or macrophages (Mφ),
- *C peptide as a decomposition product of proinsulin*, and
- *Diabetic hyperlipidemia. Lipoprotein lipase (LPL)* is inversely associated with insulin resistance, atherosclerosis, and non-enzymatically glycated hemoglobin (HbA1c).[13]

Cardiac Clinical Impact

Coronary Artery Disease

Diabetes mellitus is one of the major risk factors for the development of coronary artery disease and adversely

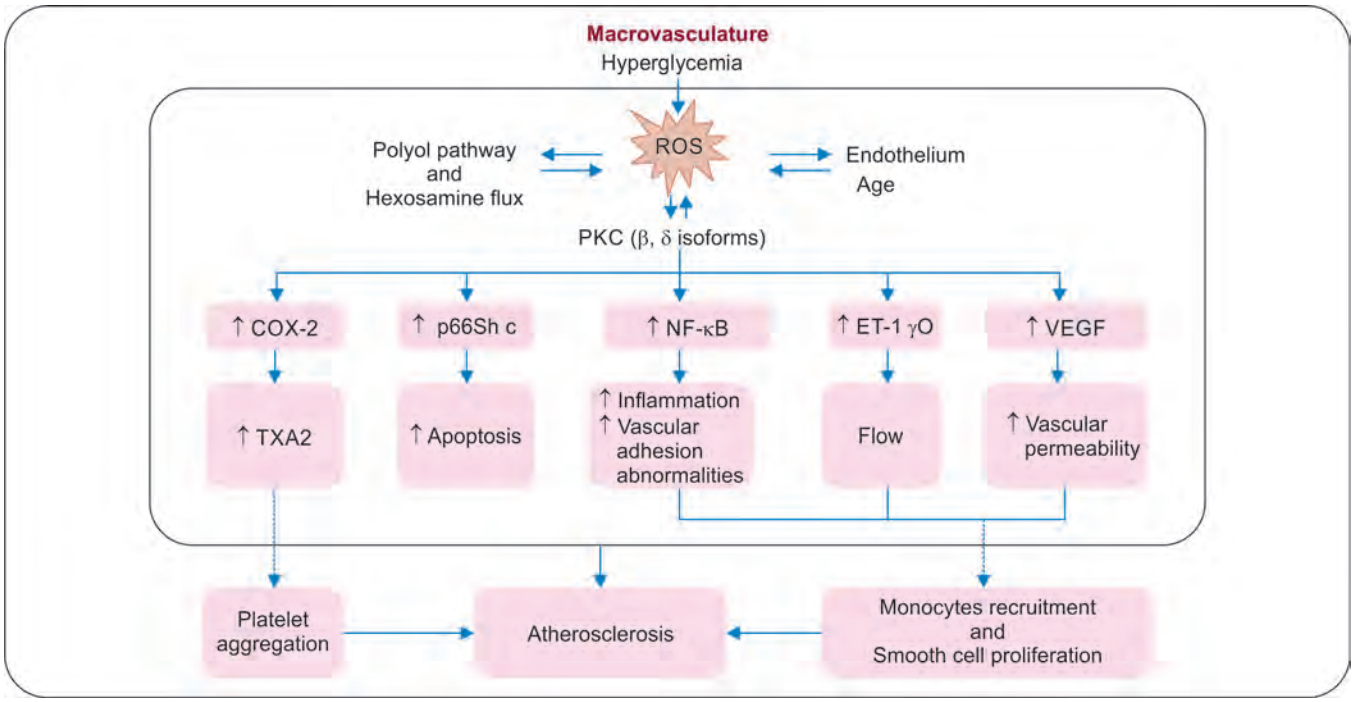

Fig. 3: Pathophysiology of macrovascular complication in diabetes

affects overall clinical outcomes. The absolute risk of death due to coronary artery disease is three to five times higher in patients with diabetes when compared to those without diabetes, regardless of their cholesterol concentration. Three-fourths of the diabetics have multivessel disease and the plaques involving multiple coronary segments. Coronary angiography of diabetic patients characterized as showing diffuse narrowing and multivessel disease. Pathologically in diabetics the plaques show larger necrotic cores, increased presence of inflammation as well as advanced coronary artery calcification. Diabetic patients show a less favorable clinical outcome after successful percutaneous coronary intervention, which will be manifested as higher incidence of restenosis of the artery or stent, a higher incidence of myocardial infarction or reinfarction, and a lower survival rate. After coronary artery bypass grafting, diabetic patients had twice the mortality when compared with those without diabetes.

Myocardial infarction: Diabetes is a prothrombotic and procoagulant state, which may be the reason for the higher incidence of myocardial infarction. The prevalence of diabetes in CAD is up to 40% in many countries.[14]

Silent CAD is far more common in patients with DM (10–20%) than those without DM (1–4%). *Diabetic neuropathy* is one of the key factors due to which there is an increased incidence of *silent ischemia* in diabetic patients. Risk for HF increases *5-fold in women* and *2.4-fold in men* in comparison with those without DM **(Fig. 5)**.

Hypertension

Hypertension is very common in patients with *T1DM* as well as *T2DM*, with prevalence rates of about 30% and 60%, respectively. Hypertension in diabetic patients is closely associated with the development of *diabetic nephropathy* (DN).

Diabetes can directly contribute to the development of *Diabetic cardiomyopathy* (CMP). Annual mortality rates up to 20%. Refer **Tables 2 and 3** for recent guidelines and management.

Heart Failure (HF)

So many observational studies have demonstrated an increased risk of HF of about 2–4 folds in diabetics compared with nondiabetics. Beyond the structural or functional changes due to diabetic cardiomyopathy, a

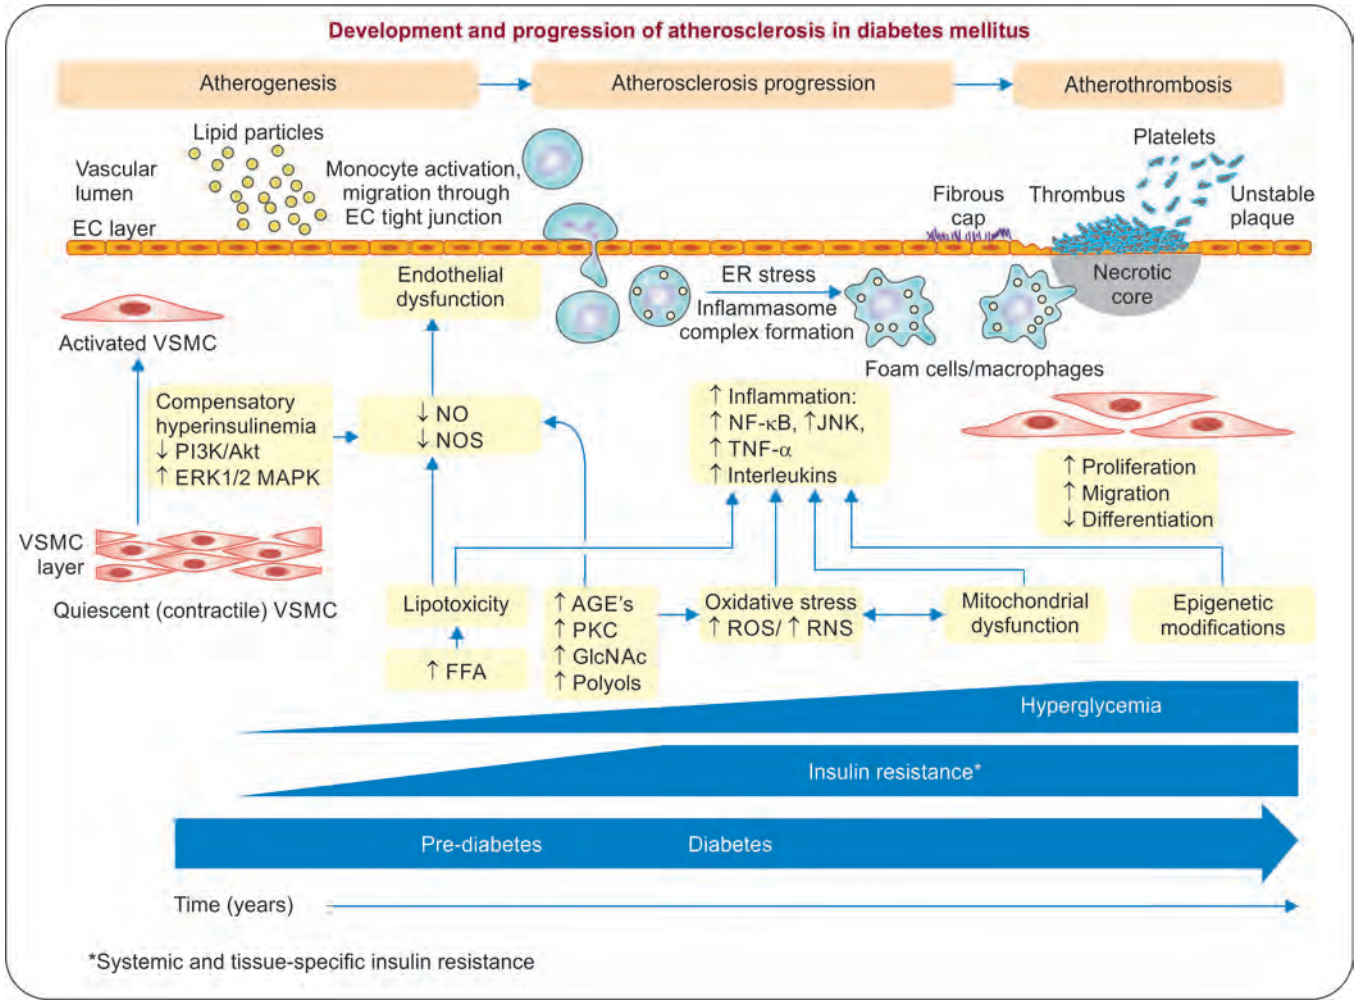

Fig. 4: Development and progression of atherosclerosis in diabetes

complex underlying, and interrelated pathophysiology exists. In spite of controlling hyperglycemia, the high prevalence of HF in T2DM persists **(Fig. 6)**. There is an increased the risk of developing HF both HF with reduced ejection fraction as well as HF with preserved ejection fraction.

A recent network analysis showed that biomarker profiles specific for HFrEF are related to cellular proliferation and metabolism, whereas those specific for HFpEF are related to inflammation and extracellular matrix reorganization. How these pathophysiological differences might translate into different outcomes in those with DM and HFpEF versus HFrEF remains unclear. Refer **Tables 2 and 3** for recent guidelines and management.

Diabetic Dyslipidemia

Low HDL, moderate to high LDL. *Dyslipidemia* is one of the factors by which *diabetes can promotes atherosclerosis and endothelial dysfunction*. Refer **Tables 2 and 3** for recent guidelines and management.

Cerebrovascular Disease

Diabetes is a major risk factor for the development of carotid atherosclerosis and stroke, both ischemic as well as hemorrhagic. Data from the Emerging Risk Factors Collaboration suggest that diabetes was associated with an increased risk of ischemic stroke for about 2.27 folds and that of hemorrhagic stroke for about 1.56 folds. Diabetes is already established as a risk factor for cognitive impairment, dementia, and Alzheimer disease **(Fig. 4)**.

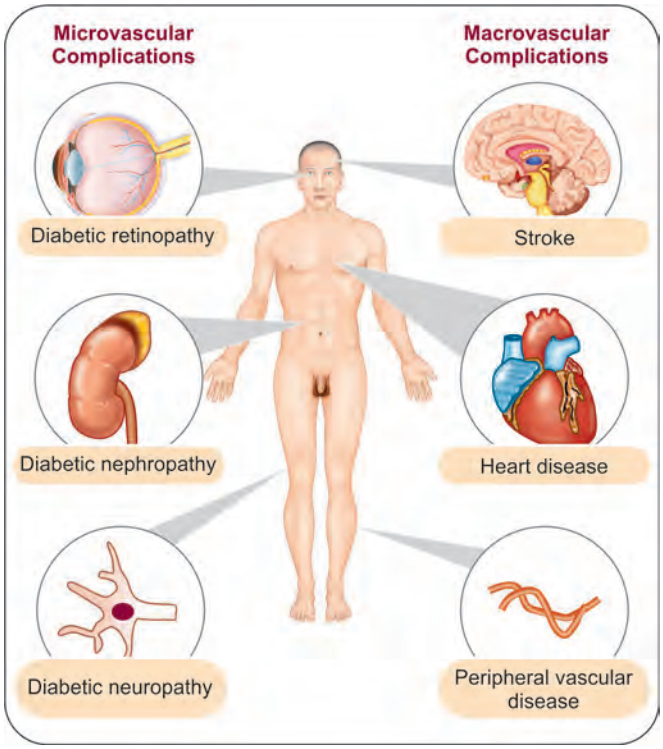

Fig. 5: Complications of diabetes

Diabetes is also associated with an *increased risk of lower limb ischemia for about twofolds*, and about 21% of diabetes patients have signs of peripheral artery disease (PAD). The *ABI* is the most widely used tool to diagnose PAD and its normal range is from 0.9 to 1.3. An ABI lower than 0.9 is commonly used to diagnose PAD both symptomatic and asymptomatic.

Diabetic Nephropathy

Efferent arteriolar hyalinosis is the major defect seen in DN. Nonspecific arteriosclerosis may be present, which is associated with more severe glomerular disease. "Matrix to Media ratio" is increased. Significant medial thickness may be associated with hypertension. Neovascularization is seen. Diabetic kidney disease includes glomerular hyperfiltration, progressive albuminuria, declining GFR, and, ultimately, ESRD.

ANS Dysfunction

Microcirculation is regulated by central as well as local regulatory mechanisms. Central regulation is through autonomic sympathetic and parasympathetic nerves.

TABLE 2 2019 ESC guidelines

Change in recommendations	
2013	***2019***
BP targets	
BP target <140/85 mm Hg for all	**Individualized BP targets are recommended** SBP to 130 mm Hg and, if well tolerated, <130 mm Hg, but not <120 mm Hg. In older people (>65 years) target SBP to a range of 130–139 mm Hg DBP to <80 mm Hg but not <70 mm Hg
Lipid targets	
In DM at high CV risk, an LDL-C target of <100 mg/dL In DM at very high CV risk, an LDL-C target of <70 mg/dL is recommended	In patients with T2DM at moderate CV risk, an LDL-C target of <100 mg/dL is recommended In patients with T2DM at high CV risk, an LDL-C target of <70 mg/dL is recommended In patients with T2DM at very high CV risk, an LDL-C target of <55 mg/dL is recommended
Antiplatelet therapy	
Aspirin for primary prevention is not recommended in DM at low CVD risk	Aspirin (75–100 mg/day) for primary prevention may be considered in patients with: DM at very high/high risk in the absence of clear contraindications
	Aspirin for primary prevention is not recommended in patients with DM at moderate CV risk
Glucose-lowering treatment	
Metformin should be considered as first-line therapy in patients with DM	Metformin should be considered in overweight patients with T2DM without CVD and at moderate CV risk
Revascularization	
DES rather than BMS is recommended in DM	Same techniques are recommended in patients with or without DM

TABLE 3 New recommendations in the 2019 guidelines

CV risk assessment
Resting ECG is recommended in patients with DM with hypertension or suspected CVD
Prevention of CVD
Lifestyle intervention is recommended to delay/prevent conversion from pre-DM to T2DM
Glycaemic control
Use of self-monitoring of blood glucose should be considered to facilitate optimal glycemic control in T2DM
It is recommended to avoid hypoglycemia
BP management
Lifestyle changes are recommended in hypertension
RAAS blockers rather than beta-blockers/diuretics are recommended for BP control in pre-DM
Home BP self-monitoring should be considered in patients with DM
24-h ABPM should be considered for BP assessment, and adjustment of antihypertensive treatment
Dyslipidemia
In patients at very high risk, with persistent high LDL-C despite treatment with maximum tolerated statin dose in combination with ezetimibe, or in patients with intolerance to statins, a PCSK9 inhibitor is recommended
Statins may be considered in asymptomatic patients with T1DM aged >30 years
Statins are not recommended in women of childbearing potential
Antiplatelet and antithrombotic drugs
Prolongation of DAPT beyond 12 months should be considered for ≤3 years in patients with DM at very high risk who have tolerated DAPT without major bleeding complications
Glucose-lowering treatment
Empagliflozin, canagliflozin, or dapagliflozin are recommended in patients with T2DM and CVD, or at very high/high CV risk, to reduce CV events
Empagliflozin is recommended in patients with T2DM and CVD to reduce the risk of death
Liraglutide, semaglutide, or dulaglutide are recommended in patients with T2DM and CVD, or very high/high CV risk, to reduce CV events
Liraglutide is recommended in patients with T2DM and CVD, or at very high/high CV risk, to reduce the risk of death
Saxagliptin is not recommended in patients with T2DM and a high risk of HF
Revascularization
Same revascularization techniques are recommended in patients with or without DM
Treatment of HF in DM
Device therapy with an ICD, CRT, or CRT-D is recommended
Sacubitril/valsartan instead of ACEIs is recommended in HFrEF and DM remaining symptomatic despite treatment with ACEIs, beta-blockers, and MRAs
CABG is recommended in HFrEF and DM, and two- or three-vessel CAD
Ivabradine should be considered in patients with HF and DM in sinus rhythm, and with a resting heart rate ≥70 b.p.m. if symptomatic despite full HF treatment
Aliskiren (direct renin inhibitor) in HFrEF and DM is not recommended
DM treatment to reduce HF risk
SGLT2 inhibitors are recommended to lower risk of HF hospitalization
Metformin should be considered in patients with DM and HF if eGFR >30 mL/min/1.73 m^2
GLP1-RAs and DPP4 inhibitors sitagliptin and linagliptin have a neutral effect on risk of HF and may be considered
Insulin treatment in HF may be considered
DPP4 inhibitor saxagliptin in HF is not recommended
Thiazolidinediones (pioglitazone and rosiglitazone) in HF are not recommended
Management of arrhythmias
Attempts to diagnose structural heart disease should be considered in patients with DM with frequent premature ventricular contractions
Hypoglycemia should be avoided as it can trigger arrhythmias
Diagnosis and management of PAD
Low-dose rivaroxaban 2.5 mg b.i.d. plus aspirin 100 mg o.d. may be used in patients with DM and symptomatic Lower Extremity Arterial Disease
Management of CKD
SGLT2 inhibitors are recommended to reduce progression of diabetic kidney disease

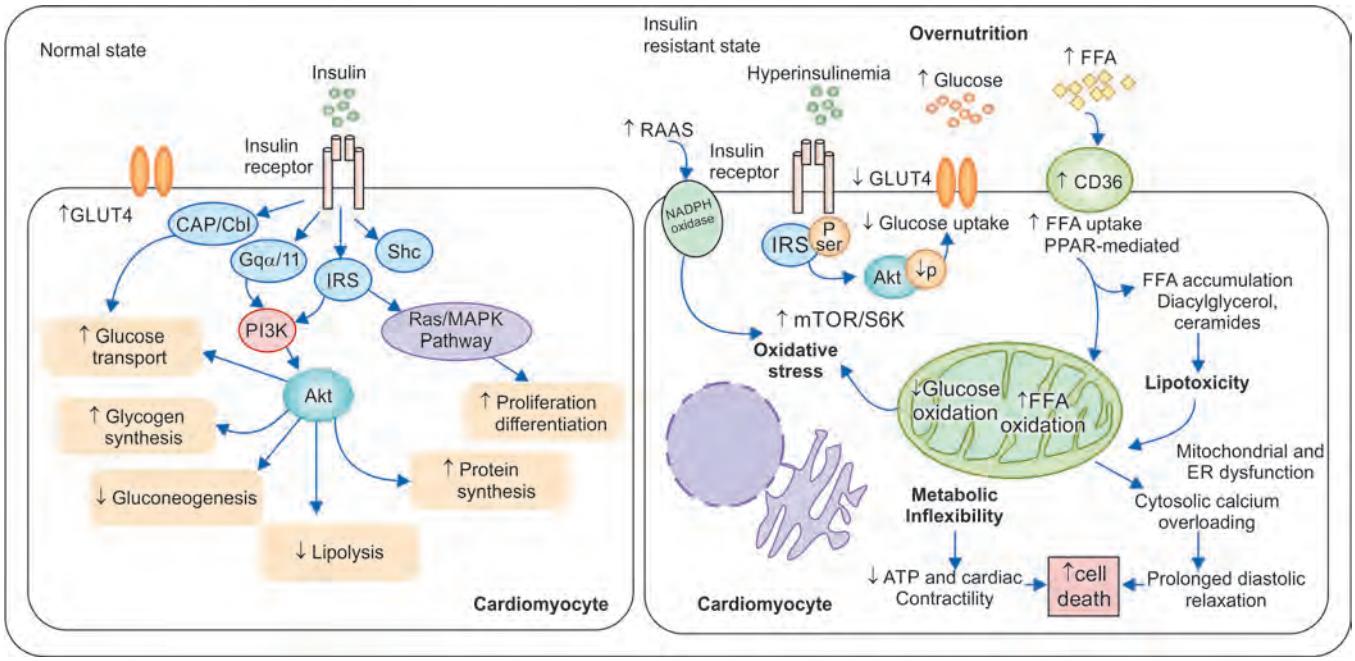

Fig. 6: Association between insulin resistance and the development of cardiovascular disease

Local regulation is by the substances produced by the endothelial cells. Diabetes contributes to defects in the autonomic nervous system, the endothelium, and local metabolism.[15]

Incidence of cardiovascular autonomic neuropathy (CAN) increases with age and inadequate glycemic control, which leads to a higher risk of developing both CAN and CVD in diabetes. It is very common in diabetes and is very well correlated with an increased 5-year mortality rate from CVD. The development and progression of CAN may be due to dysregulation of the autonomic nervous system (ANS) associated with increased sympathetic activity as well as elevated inflammatory markers.

Angiogenesis

There is a differential expression of *vascular endothelial growth factors (VEGF)* seen in diabetes, which leads to a paradoxical increase in angiogenesis in the retina and decrease in the peripheral limbs and myocardium.[16]

Conclusion

T2DM can be called as Coronary Equivalent. Hyperglycemia and Insulin Resistance are important components of metabolic syndrome and control of which will lead to a disease-free life. Main pathophysiology of DM includes Atherosclerosis and Arterial stiffness which in turn leads to various cardiac complications. Major macrovascular complications of DM are due to Lipid dependent & Endothelial Dysfunction whereas microvascular will be ANS dependent.

Strategies to prevent or delay the progression of diabetic microvascular complications mainly depends on:

- Elimination of hyperglycemia,
- Inhibition hyperglycemia induced vascular dysfunction,
- Neutralization of inflammation and oxidative stress, and
- Activation of tissue-specific protective factors.

Lifestyle management which includes Weight Reduction, Medical nutrition therapy, Physical activity, Tobacco cessation along with blood pressure control, Lipids regulation, Antiplatelet agents, and Glycemic control are recommended for Primary prevention of cardiovascular diseases in diabetic population. *Diabetic cardiovascular disease is an upcoming specialty in medicine which is rapidly growing in developed as well as developing nations.*

CHAPTER

47 Development of Insulin: 99 Years and Counting

Sarita Bajaj

Abstract

The discovery of insulin earmarked the first effective treatment for diabetes. Till today insulin is an injectable agent. Modifications in the insulin peptide chain and genetic engineering have lead to the evolution of a variety of innovative insulins. Insulin analogues have several advantages over purified animal insulin. Research is ongoing for insulins which can be injected at a reduced frequency apart from non-injectable methods of administration. This chapter highlights all the major milestones and advances in the development of insulin over the last century.

Introduction

The word "Insulin" corresponds to the Latin word "Insula" meaning "island", so-called because of its formation in the island cells of the pancreas, the islets of Langerhans. Insulin was discovered in 1921 and is soon completing 100 year of its discovery. Insulin, over many decades, has enabled us to understand what we currently know of the disease called diabetes mellitus. With the discovery of insulin, it was for the first time that we got an effective treatment for diabetes; this also led to further research, gaining of knowledge in diabetes pathophysiology and management, in turn helping us to make advances in finding out other therapy options for treatment of this disease. Insulin is the first effective treatment available for diabetes and still retains its importance, despite the advent of other drug classes like sulfonylureas, biguanides, Thiazolidinediones, DPP-4i, SGLT-2i, GLP-1RA, etc. This is the journey of insulin in the past 99 years and what the future holds for it.

Diabetes—The Era before Insulin

Diabetes is not a new disease, the earliest account of its mention is found in Egyptian "Ebers Papyrus" written around 522 B.C., ancient Indian, and Chinese texts also mention this disease. The credit for naming this disease "diabetes" mostly goes to Greek physician "Demetrius of Apamea" (129–199 AD) or to "Aretaeus of Cappadocia (129–199 AD) from the word meaning "passing through."[1] Thomas Willis, a British doctor, was credited for coining the term "diabetes mellitus" in 1674, mellitus denoting the sweetness of the patient's urine. In 1776, in Liverpool, physician named Matthew Dobson discovered that "urine of diabetic patients is sweet because of the presence of sugar." In the latter part of 19th century, many scientists worked to explore the intricacies behind diabetes melltius—in 1869, Paul Langerhans, a German medical student, discovered groups of cells in the pancreas, unknown at that time and was later named as "Islets of Langerhans" once it was discovered that insulin is produced by these island of cells.[2]

Discovery of Insulin

In 1889, German researchers, Joseph von Mering and Oskar Minkowski while experimenting on dogs found out that if a dog's pancreas is removed it provokes severe symptoms of diabetes. Inferring from experiments that

pancreatic extracts can elevate the symptoms of diabetes, Minkowski tried injecting the powdered extracts of pancreas, but the toxicity of the extracts was too much to provide any suitable results. This understanding let to multiple attempts at treating diabetes. Many scholars tried using pancreatic extracts for treating diabetes like American pathologist, Lydia Maria Adams DeWitt (1906) and German physician George Ludwig Zuelzer (1908).[6]

Paulesco, a Romanian endocrinology experimenter, in 1916 reported that "the aqueous solution of pancreatic extracts leads to improvement in experimentally induced diabetes," but unfortunately he could not complete his experiments due to the ongoing World War I at that time.[6]

In 1920, Frederick Banting, a young Canadian orthopedic surgeon, got inspired by the works of other scientists in extracting insulin from pancreas and developed some of his own thoughts and theories. With his ideas, Banting approached John James Richard MacLeod, Professor and head of the department of physiology at University of Toronto. MacLeod gave him laboratory space, 10 dogs to do his experiments, a student assistant, Charles Best, and provided supervision and guidance. Banting started his experiments in May 1921, and by September they reported that removing pancreases in dogs leads to diabetes, which can be cured by giving intravenous injection of pancreatic extracts. Banting named this extract as "Isletin." In late 1921, Biochemist J. B. Collip, joined the group and was instrumental in purifying Isletin for human use. Considering the importance of these findings, MacLeod allowed human experimentation. On 11th January 1922, a young Canadian patient named Leonard Thompson became the first human being to receive an insulin injection. He was 14-years-old and dying when he received the first famous doses, but without much impact. He developed "sterile abscess" at the site of injection, there was no effect on ketosis and only a mild lowering of glucose levels is seen. Banting, Best, and Collip further purified the pancreatic extracts, and second series of injections were given on 23rd January 1922. This time the results were promising with normalization of glycemia, glycosuria, and Ketosis. Blood glucose levels dropped from 520 mg/dL to 120 mg/dL.[3-6]

This was hailed as a landmark discovery, resulting in the 1923 Nobel Prize for MacLeod & Banting. The prize also led to a controversy as Best and Collip were excluded. Banting at that time strongly criticized the Nobel Prize committee and decided to share his prize money with Best, in turn MacLeod also decided to share his with Collip. By 1923, the extraction process had been improved, and insulin was commercially available in North America and Europe.[5,6]

Insulin Era

Immediately after discovery, insulin was primarily sourced from animals; particularly bovine and porcine insulin. This was possible because all mammalian insulins are structurally similar, that is, composed of 51 amino acids in two linked polypeptide chains (A and B). In 1955, Fredrick Sanger showed "the sequence of all amino acids in the insulin molecule," a great feet since it was for the first time that a complete protein had been sequenced, this resulted in Nobel Prize for Sanger in 1959. The two commonly used animal insulins were bovine and porcine. Porcine insulin is very similar to human insulin, differing only in single amino acid difference in polypeptide chain. Bovine insulin is most similar to feline insulin.[5] Animal insulin became the first to be available insulin to treat diabetes.[6] The disadvantages were insulin reactions, antibody formation, allergies, and sacrificing a large number of animals for extracting the insulin from their pancreas.[7,8]

In the 1980s, biosynthetic insulins were produced, with human DNA using biotechnology and were made available commercially. **Figure 1** depicts the timelines in the development of insulin.

Recombinant DNA Technology and Human Insulin

The recombinant DNA (rDNA) technique was the advancement we all were waiting for and this ensured a uniform and continuous supply of insulin for the days to come. This technique involves inserting the human insulin gene and the promoter gene in the plasmids of either "*Escherichia coli* or yeast (*Saccharomyces cerevisiae*)." The genes for insulin A and B chains are isolated and then inserted as separate entity in the plasmid of two different *E. coli* cultures. The *E. coli* cells are than incubated and allowed to grow in a medium containing lactose, which induces the synthesis of chain A & B separately. The insulin chains so obtained can be isolated, purified, and joined together to give human insulin. This breakthrough provided the first opportunity to "mass-produce 'human' insulin using gene technology resulting in recombinant insulins."[9]

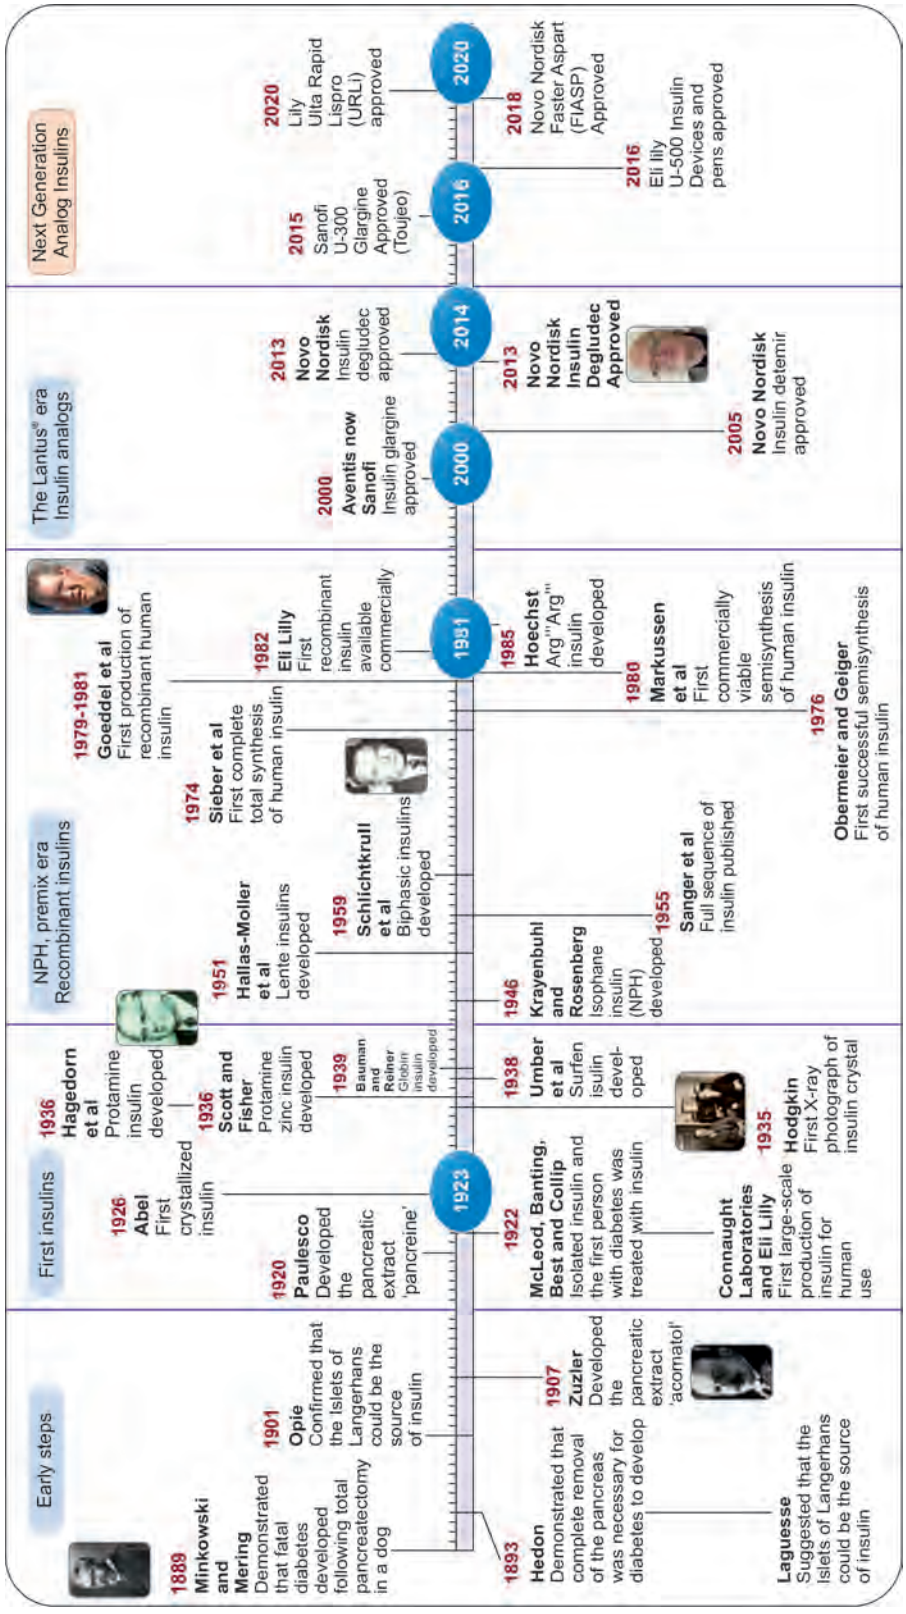

Fig. 1: Timelines in insulin development

Types of Human Insulin

Human insulin is available in three forms:

- Normal regular insulin which is short acting.
- Insulin which is crystalized using fish protein Protamine, named as "Isophane or NPH (Neutral Protamine Hagedorn)."
- Mixed insulin or premix insulin, where NPH insulin is present as suspension with regular insulin.

Short acting (regular) insulin starts to act about 30 minutes after injecting, and the peak action is reached between 2 and 3 hours of dosing. The duration is up to 10 hours. Intermediate acting insulin or NPH takes about 2–4 hours for onset of action with peak action happening at about 4–10 hours. The total duration of action can be up to 18 hours.

The main principle employed to enhance the time of action of insulin is to use protamine, which crystalizes the insulin and makes it insoluble, along with that zinc is employed to stabilize the insulin hexamers in solution. This protaminated insulin dissolves slowly, along with slow dissipation of zinc after subcutaneous injection destabilizes the hexamers resulting in slow release of insulin monomers, which readily gets absorbed.[10]

Premix insulins are suspensions of short acting soluble insulin and insoluble protaminated long acting insulin. Due to this nature before ever dose "insulin vial should be rolled or repeatedly turned upside down," this ensures the uniformity of dosing of each component whole injecting. The premix insulins are formulated generally in ratio of either 30:70 or 50:50, but other variations are also available.[10]

Human recombinant insulins have some advantages over highly purified animal insulins, namely:

- Lower immunogenicity shown by lower titers of circulating antibodies to insulin;
- Few reactions at injection site;
- Better and more rapid absorption in circulation; and
- Low breakdown at the site of injection itself.

Insulin Analogues

Insulin analogs are formed by altering the amino acid sequence such that the receptor activity is preserved while providing other benefits. Genetic engineering is employed to modify or change the amino acids of the peptide chains resulting in changed absorption, distribution, metabolism, and excretion (ADME) characteristics.[10]

These modifications are done to have better pharmacokinetic profile of the insulins in terms of their duration of action and metabolism. These are done to have two types of insulin analogs. One which are fast acting, faster than the regular human insulin and also those which provide a better basal coverage with long duration if action and no peak effect, better than what can be achieved by NPH insulin.

Basal Insulins

Glargine: First long acting basal insulin analogue which was formulated by adding two arginine residues to the C-terminus of the B-chain and the substitution of glycine for asparagine at position A21. These changes made it possible for glargine to be soluble at acidic pH (resulting in a clear insulin in the vial) and the solubility decreases once the pH becomes neutral or basic. This when injected in slightly basic environment of subcutaneous tissue forms micro-precipitates at the injection site. These micro precipitates take time to dissolve, and hence we get long duration of action.

Detemir: With insulin detemir, the threonine residue at position B30 was deleted and a myristic acid (fatty acid) side chain was added to the lysine residue at position B29. These modifications enable insulin detemir to bind reversibly to albumin with high affinity once injected. These modifications results in slow release of insulin from albumin binding thereby delaying both absorption and breakdown. This prolongs the duration of action but in few instances twice daily dosing is needed. The fatty acid side-chain not only enhances self-association of monomers in the subcutaneous depot, but also provides the added benefit of reduced glycemic variability.[11]

Glargine U-300: An advanced formulation of glargine insulin. The glargine insulin polypeptide chain is unchanged in Glargine U300, only the concentration of glargine is changed to 300 units/mL. This increased concentration leads to the formation of more compact depots in the subcutaneous tissue once injected. This more compact depots decrease the surface area and dissolution rates, further leading to an increased subcutaneous half-life. The result is a better flatter insulin profile in circulation when compared to glargine U100. This concentrated formulation results in a good half-life of 18–19 hours with action up to 36 hours.[12] **Table 1** gives action profile of basal insulins.

TABLE 1 Action profile of basal insulins[11-14]

Basal insulin	*Onset (h)*	*Peak (h)*	*Duration (h)*	*Frequency of administration*
NPH Insulin	1.5	4.0–10	10–16 hours	Twice daily
Insulin degludec	1–2	Peak less	>42 hours	Once daily
Glargine U300	6	Peak less	Up to 36 hours	Once Daily
Insulin glargine	2–4	No peak	Up to 24 hours	Once daily
Insulin detemir	2	No peak	14–21 hours	Once daily

Degludec: In insulin degludec, the threonine residue at position B30 is deleted and the ε-amino group of LysB29 is acylated with a 16-carbon fatty acid side-chain via a g-L-glutamic acid linker. In solution degludec is present in the form of stable dihexamers due to the presence of phenol. Once injected, phenol rapidly dissipates from the subcutaneous tissue and these dihexamers link up end to end to form large chains of multihexamer. These multihexamer chains increase the size and prevent the absorption of insulin, which can happen only when these mutihexamers are converted to monomers. The process happens gradually with the removal of zinc from one end of these chains.

Rapid-Acting Insulin Analogs

"Rapid-acting insulin analogs" are designed to provide rapid onset of action which also terminate early in comparison to regular human insulin. Currently, three such insulins are available commercially: insulin aspart, insulin lispro, and insulin glulisine.[13]

Rapid acting insulin analogs are administered with the meals or shortly before starting the meal, as they are rapid absorbed in systemic circulation from subcutaneous tissue. The peak action is reached in 1–2 hours of administration and it takes around 4–6 hours for their action to wean off completely. Rapid acting insulin analog therapy is directed to have a good postprandial glycemic control.

Rapid-acting insulins also found their use in insulin pumps, also known as "continuous subcutaneous insulin infusion (CSII) devices." In CSII therapy, insulin is administered as a continuous infusion in the subcutaneous tissue. This continuous supply of rapid acting insulin works to provide both bolus and basal coverage as well as correctional doses.

TABLE 2 Action profile of rapid acting insulins[13-15]

Rapid Insulin	*Onset (min)*	*Peak (h)*	*Duration (h)*
Regular insulin	30	1.5–3.5	7–8
Insulin aspart	10–20	1–3	3–5
Insulin lispro	15	2.4	2–5
Insulin glulisine	20	1	Not available
Faster aspart	5–10	1–2	3–5
Ultra-rapid lispro	5	1–3	3–5

Insulin lispro: Modifications done in insulin peptide chain include the reversal of amino acids at positions B28 (proline) and B29 (lysine). This makes it similar to the sequence seen in "insulin-like growth factor 1 (IGF-1)." This change makes the absorption faster with a definite advantage over regular human insulin.[14]

Insulin aspart: Modification to peptide chain includes replacing proline at B28 with another amino acid, that is, aspartic acid. This structural alteration results in increased monomer fraction.[14]

Insulin glulisine: Insulin glulisine is formed by "replacing glutamic acid for lysine at B29 and replacing asparagine with lysine at B3." This has resulted in addition of extra charge to the peptide chain resulting in somewhat lower isoelectric point in comparison to regular human insulin; this enhances solubility of insulin glulisine at normal body pH.[14] **Table 2** delineates action profile of rapid acting insulins. **Figure 2** shows action profile of different insulins.

Inhaled (Technosphere) Insulin (AFREZZA)

Technosphere insulin (Afrezza) was FDA approved in 2014. Its pulmonary absorption leads to a more rapid

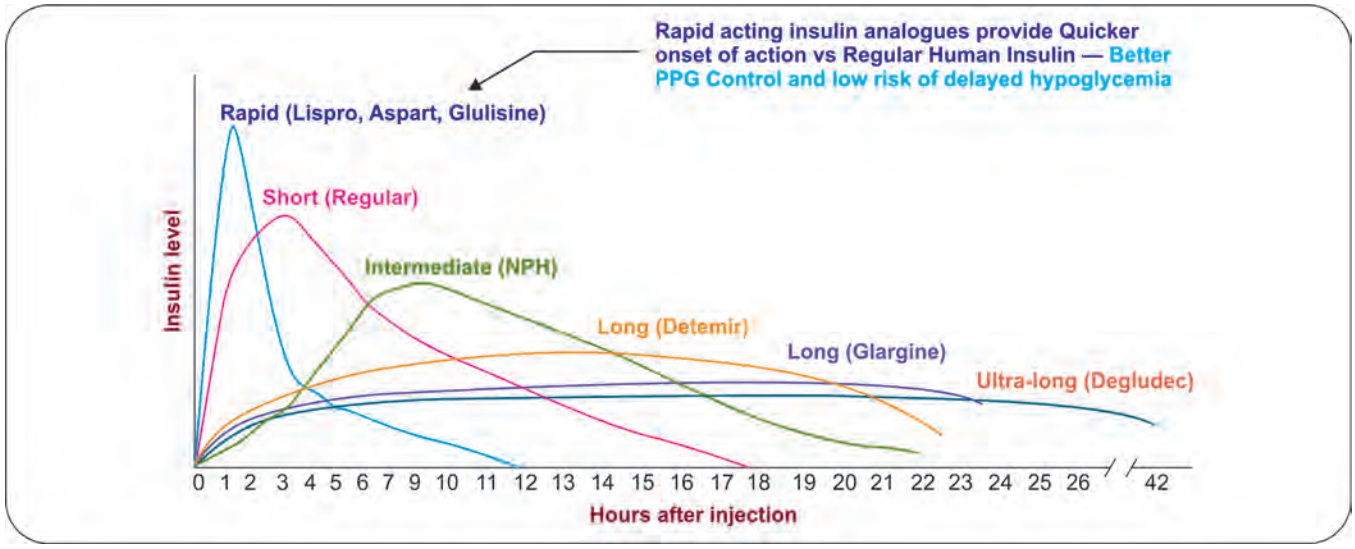

Fig. 2: Time action profile of different insulin (schematic)

absorption than currently available, subcutaneously administered rapid-acting insulin preparations but due to many side effects not preferred.[14]

Ultrafast Acting Insulin

Further development aimed at mimicking the natural physiological insulin release had resulted into the development of ultra-rapid acting insulins. Many approaches were used to make insulin act faster than available bolus insulin. Such as by increase of local blood flow, inhalation of a rapidly absorbed insulin, intradermal application or spreading the insulin into a wider area in the SC tissue (either mechanically or enzymatically), or adding excipients that promote monomerization of insulin molecules.[15,16]

Finally, after incremental research faster-acting insulin aspart was developed. Insulin Faster Aspart is a new formulation containing insulin aspart and two additional excipients (nicotinamide and arginine). Nicotinamide, commonly known as Vitamin B3, acts as an absorption enhancer in the subcutaneous tissue while arginine provides stability to insulin hexamers while in storage.[14] Its onset of action is about 6 minutes earlier, the peak is 7 minutes earlier, and it gives 74% greater action during the first 30 minutes compared to traditional aspart.[15]

Another ultra-rapid acting insulin, currently in development is Insulin Ultra-Rapid Lispro (URLi). URLi is insulin lispro with added excepients—Treprostinil & Citrate. Treprostinil increases absorption by causing local vasodilation in sub-cutaneous tissue without any systemic exposure, while citrate increases vascular permeability at injection site. The onset of action is 11 minutes faster than insulin lispro.[16]

Premix Insulin

The pharmacokinetic and pharmacodynamic limitations of the premixed human insulin formulations have been largely overcome with the introduction of premixed insulin analogues containing a rapid-acting insulin analogue for postprandial glycemic control and an intermediate-acting insulin analogue that controls basal glycemic levels. Unlike premixed human insulin formulations, premixed insulin analogues can be administered within 15 minutes of a meal, a convenience for patients with irregular meal schedules that may increase adherence to treatment.

It consists of premix human insulin or premix insulin analogue in ratio of 30:70 and 50:50. Rapid/short-acting component (30% or 50%) covers mealtime glucose excursions, while intermediate/long-acting insulin (70% or 50%) augments background insulin levels. In clinical terms this gives the added benefit of controlling both fasting (FPG), prandial (PPG), and thereby also leading to better HbA1c, all with one injection only.[17]

There is evidence that premix may be used as an option is situations like primary care. The INITIATE study showed that addition of premix insulin to oral antidiabetic drugs

(OADs) was more effective, than adding basal insulin for treatment of type 2 diabetes.[18]

- Rapid-acting insulin, Lispro, is combined with insoluble lispro protamine suspension in a 50:50 and 75:25 (75% protaminated lispro suspension and 25% insulin lispro) ratio.
- Insulin aspart combinations also are available as 70:30 mixtures (70% insoluble protamine aspart and 30% soluble insulin aspart).

Insulin Degludec Aspart Co-Formulation (IDegAsp)

IDegAsp is a co-formulation of two soluble insulins, consisting "70% of insulin degludec and 30% of insulin aspart." It consists of insulin degludec, a long-acting insulin, and insulin aspart, a rapid-acting insulin both of which function as independently acting blood-glucose-lowering agents.[19]

This co-formulation is made possible because insulin degludec, due to its unique properties, can be combined in a soluble solution with a mealtime insulin analogue without having any effect on the pharmacokinetics and pharmacodynamics of each other.[18] Because of these unique and unprecedented formulation, it is termed as a co-formulation.[19]

Analog versus Human Insulin: Are there any Advantages?

There has been a great deal of advancement in insulins over last 99 years but how this has translated into better clinical outcomes has be debated quite a number of times. In current clinical practice, though the adoption of analogue insulins has increased but a large number of patients are still using the good old human insulins. In terms of achieving the glycemic targets and lowering of HbA1c, both analogue and human insulin are many times considered similar. The difference lies in better safety with the newer analogue insulin preparations. Two aspects where the analogue insulins clearly win are:[20,21]

- Type 1 diabetic patients where the basic requirement of 24 hours of insulin coverage can be best fulfilled by using basal and bolus analog insulins in combination.
- Patients who suffer from night time or overnight hypoglycemia in type 2 diabetes. It is helpful to prescribe a rapid-acting insulin analogue before dinner if the hypoglycemia occurs early in the night or a basal analogue insulin if it occurs toward morning.

Analog insulins provide better outcomes and increases convenience over human insulins. Advantages of using analogue insulins can be summarized as:

- Better mimicking of normal physiological insulin release
- Less rate and chances of hypoglycemia
- Better flexibility in timings of dosing
- Better response at lower dose
- Less immunogenicity

The Future of Insulin

Current innovations going on in insulin development, holds a good promise for the future. A great amount of research is going on to modify the pharmacokinetics and pharmacodynamics of insulins for the better.[22,23]

Insulin icodec: A once weekly insulin, this will significantly reduce the burden of injections involved with insulin therapy. Icodec has recently finished phase 2 clinical trials with promising results.[22]

Oral insulin (ORMD-0801): An oral insulin under development from Oramed has good results in a recently released results of a pilot study with good reduction of hepatic fats.[22]

Insulin Ultra-Rapid Lispro (URLi): An ultra-rapid insulin from Lilly, it is formulated by adding Treprostinil and Citrate as excipients to insulin lispro. This given it an onset of action 11 minutes faster than the conventional insulin lispro. URLi is recently been approved in the European Union as an ultrafast acting insulin.[22]

BioChaperone lispro insulin: Again a modification of insulin lispro, this is another ultrafast acting insulin, currently in phase 3 trials. To make this faster, citrate is added along with a novel excipient with a modified oligosaccharide chain, BC222.[22]

Cone snail insulin: Another ultrafast acting insulin under development, where the insulin molecule remains in monomer state. It is being derived from the poison of certain cone snails.[22]

Other than the above mentioned, there is a good research going on to modify the action of action of insulin. One such example is the ongoing development of Smart Insulin—"Glucose responsive insulin (GRI)." This next

generation under development insulin will work on the principle of demand and supply. If the blood glucose is more, more of insulin will get activated and show its effect, while if the blood sugar goes down, activated insulin supply will be cut off.[22,23]

Conclusion

Even after 99 years of its discovery and use, insulin is still going strong. Different insulin formulations have been tried over a period of time, some are found to be quite good compared to their predecessor, others fared not so well. Some major milestones in the journey of insulin therapy include—development of NPH insulin, move from animal to human recombinant insulin, and the advent of analog insulin. Innovation is still on and what we can see in the future is a once weekly insulin or even an insulin which is glucose controlled. The future holds a lot of promise for insulin therapy. In terms of effective therapy for diabetes, insulin is sitting on the pedestal as a winner amongst all available options and will remain so for a long time to come.

CHAPTER

48 What Is in Store for Future Insulin Research?

Ajay Kumar

Abstract

Insulin is the natural therapy for diabetes and its long journey had gone through various modifications and advancements so as to suit the physiological needs and enhance the adherence among patients. The time tested, most potent drug, Insulin is still a life saving agent and documented to improve quality of life of millions of diabetics. Once weekly basal insulin, Icodec, has promising results and is expected to bring a paradigm change in the management of diabetes. The future of insulin is bright as we discuss here about the newest insulins and various delivery devices and techniques that are in research pipeline.

Introduction

Ever since, Banting and Best's novel discovery in 1921, Insulin remains the indispensable treatment in diabetes as it primarily regulates carbohydrate and fat metabolism.[1] It's the centenary celebration, this year since insulin has been described as a polypeptide hormone from the islets of Langerhans in the pancreas and yet the quest for the perfect physiological insulin remains. The increase in burden of diabetes and drawbacks in injectable insulins are leading researchers to pursue novel approaches in more effective insulin production, application and delivery. Accordingly, numerous drug candidates are being developed, evaluated and now progressing through the clinic. The development of a once-weekly basal insulin therapy that remained a dream for ages is now ready for Phase 3 trials.

Expanding Horizons with Weekly Basal Insulin—Icodec

The pursuit of the quest to develop weekly insulin remains challenging. In order to improve patient convenience and adherence without increasing hypo/hyperglycemia, a new longer acting once weekly novel insulin named icodec has been developed. It has completed three phase 2 clinical trials in March 2020 and is planned to initiate phase 3a program by the year end.

Molecular and Biological Properties of Insulin Icodec

Insulin icodec [icosaGreek numerical prefix representing 20; dec-derived from degludec] is an insulin analogue with a terminal elimination half-life of ~196 hours with a single subcutaneous injection. This insulin molecule was modified to achieve an albumin-bound circulating inactive depot which acts just as human insulin (HI) but is more slowly cleared. Strong but reversible albumin binding is ensured with the addition of C20 fatty diacid side chain at B29K via a hydrophilic linker. Three amino acid substitutions (A14E, B16H, and B25H) ensure reduced enzymatic degradation of icodec and contribute to attenuating insulin receptor (IR) binding and clearance, further prolonging the half-life **(Fig. 1)**.

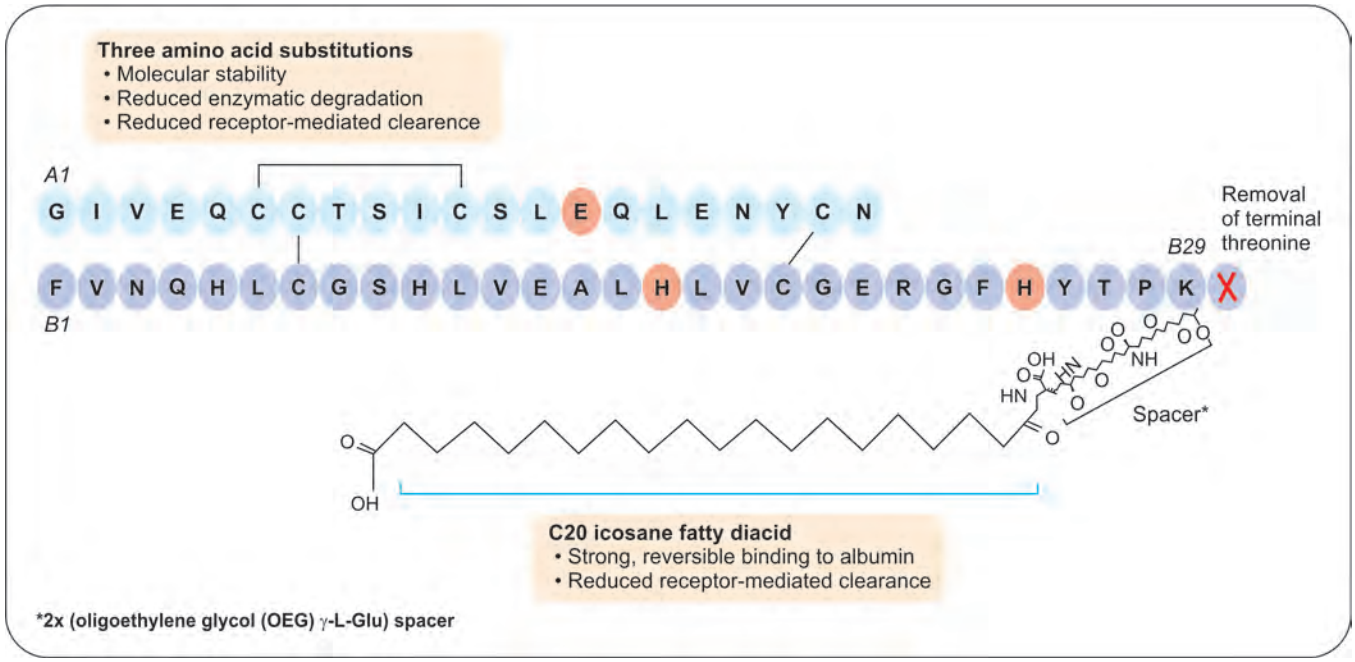

Fig 1: Key modifications in insulin icodec

The affinity of icodec for the IGF-1 receptor was found to be proportionately lower than its binding to the IR resulting to relatively low IR affinity but full activity, allowing a gradual effect over an extended time period. A steady state is achieved that provides the full therapeutic effect after three to four once-weekly injections. Icodec, in functional assays elicited metabolic effects (like glucose uptake and lipogenesis in fat cells, and stimulation of glycogen synthesis in liver cells) like HI.

Formulation and Dosing

Icodec is formulated into a concentrated concentration as 700 units per mL (700 U/mL) to ensure that the injection dose and volume is not increased. Comparable to insulin NPH and degludec, it is also coformulated with standard pharmaceutical excipients: Zinc functions as a stabilizing agent, while phenol and m-cresol are preservatives.

Phase 1 Data: PK/PD Properties Support Once-Weekly Dosing with a Good Safety and Tolerability Profile[2]

Fifty patients with T2D enrolled for phase I trial to evaluate the PK/PD parameters and safety of insulin icodec at three escalating fixed doses over a 5-week period **(Fig. 2)**. The median Tmax was 16 hours and the geometric mean T1/2 was 196 hours, with no systematic differences between dose levels. As depicted in **Figure 3**, there was relatively even distribution of glucose-lowering effect over the 7 days, irrespective of dose. The maximum effect was achieved at days 2 and 3 after administration. By day 7, the level was close to the maximum. Adverse event rates were not dose dependent. During the trial, no serious AEs or serious hypoglycemic episodes recorded.

Phase 2 Data: Insulin Icodec Provides Similar Efficacy and Safety to Once Daily Glargine[3]

This pivotal phase 2, 26-week treat-to-target trial with a randomized, double-blinded, double-dummy design evaluated the efficacy and safety of once-weekly icodec versus once-daily insulin glargine U100 (IGlar U100) in 247 insulin-naïve patients with T2D inadequately controlled (A1C 7.0–9.5%) with metformin ± DPP-4i. At end of trial period, estimated mean A1C were 6.69% and 6.87% for icodec and IGlar U100, respectively (mean change from baseline: –1.33% for icodec and –1.15% for IGlar) **(Fig. 4)**. So, no statistically significant treatment difference for change in A1c from baseline to week 26 (–0.18%, 95% CI, –0.38; 0.02) noted. Total dose of insulin glargine was

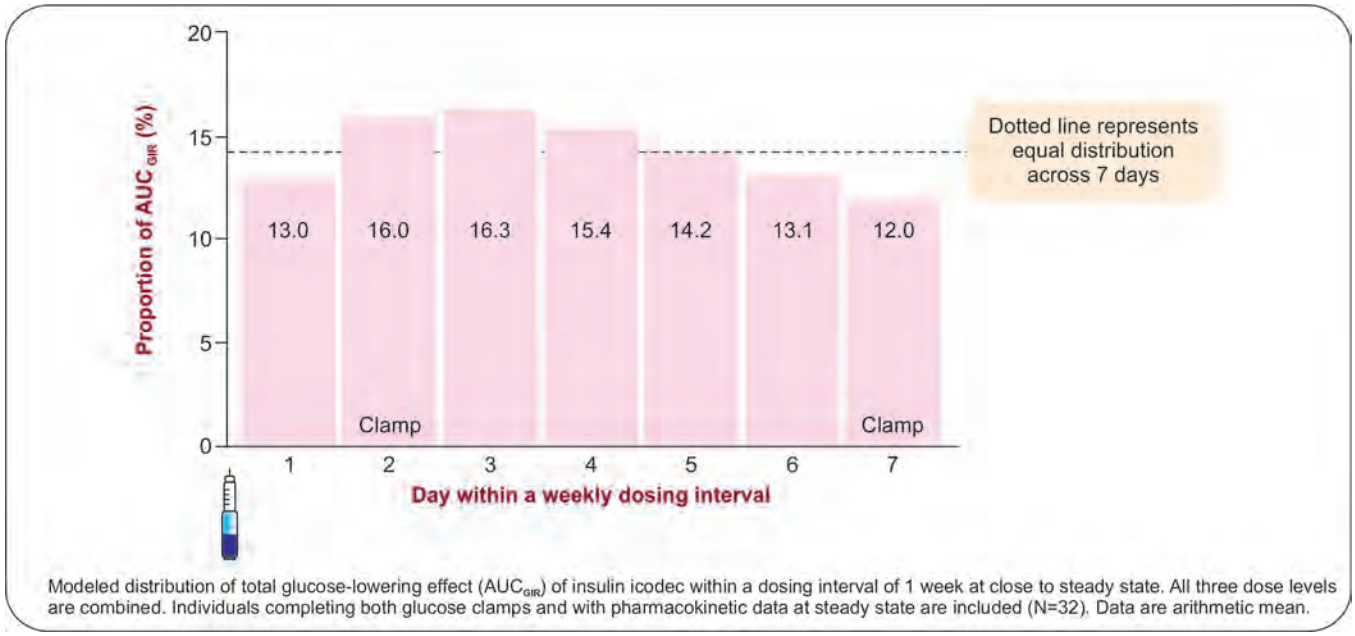

Fig. 2: Modeled glucose-lowering effect of insulin icodec
AUC, area under the curve; GIR, glucose infusion rate

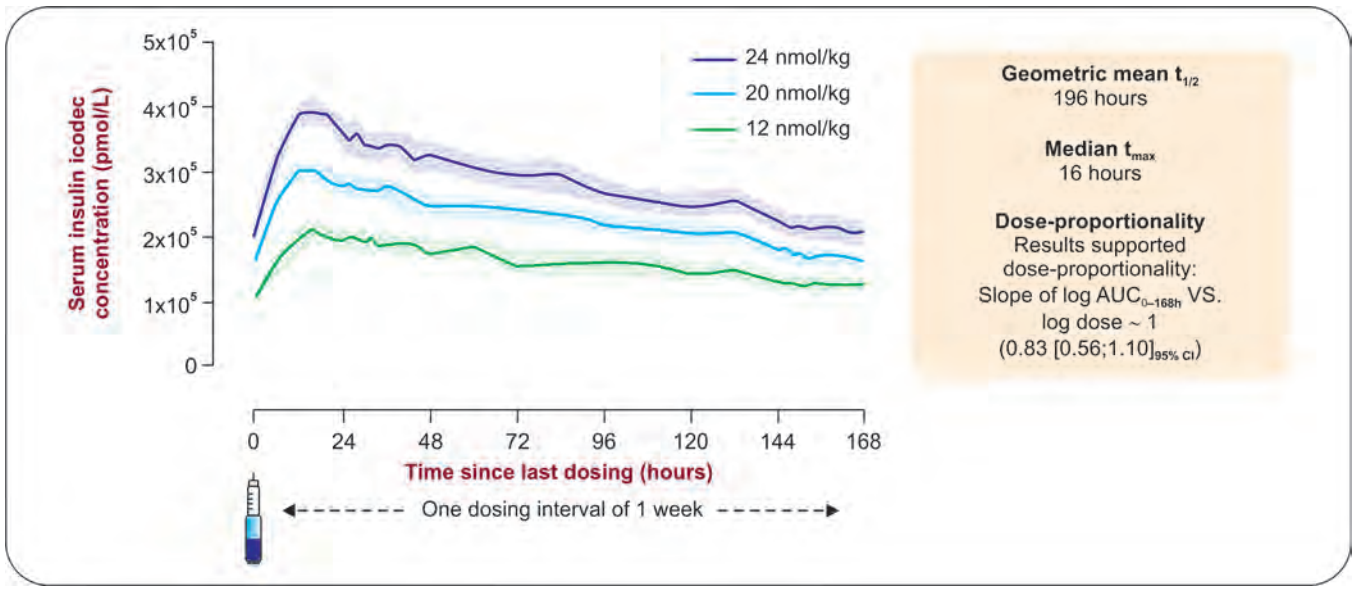

Fig. 3: Pharmacokinetic profiles of multiple dosing of insulin icodec in T2D individuals

significantly higher than the dose of insulin icodec in order to achieve similar effect. No new safety issues were identified. Observed rates of level 2 & 3 hypoglycemia were low (60.55 and 52.36 events per 100 patient years of exposure for icodec and IGlar U100, respectively). There was no increase in the rate of level 2 or 3 hypoglycemia compared with insulin glargine ($p = 0.85$).

To summarize, after promising results from Phase 1 & 2 clinical trials, a comprehensive phase 3 program will be conducted for icodec. Fewer injections, more convenience

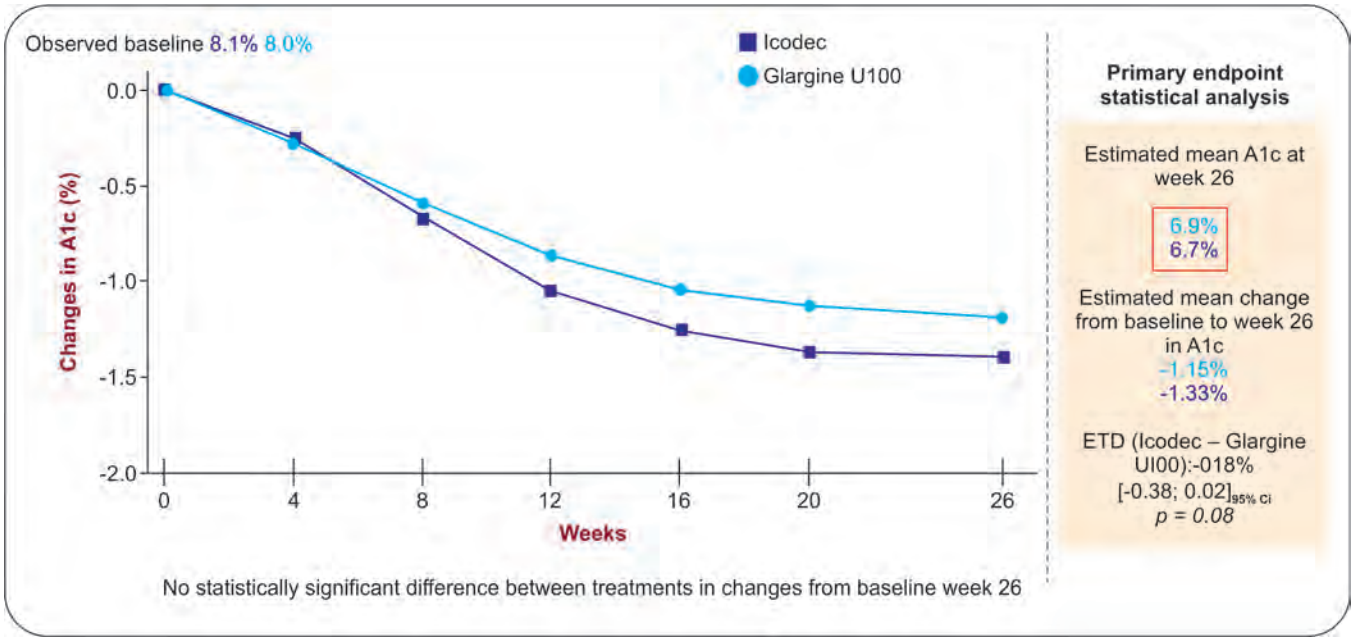

Fig. 4: HbA1c changes over time

and simplicity with insulin icodec, will overcome clinical inertia and more patients will accept initiation and continuation on insulin therapy more readily.

Newer Dimensions in Insulin Research

Newer Ultra Rapid Acting Insulins

Normally insulin glargine cannot be combined with insulin lispro as the pH required to combine them both is not viable. To overcome this challenge, a polyanionic amphiphilic polymer, BioChaperone (BC147) has been devised. With the help of this, glargine can be solubilized at neutral pH enabling it to be combined in a stable formulation with insulin lispro. A combination of 25% of insulin lispro and 75% of insulin glargine known as BioChaperone Lispro or BCLIS has demonstrated a higher significant reduction in postprandial pharmacokinetic exposure leading to significant decrease in both 1 hour and 2 hours PPG levels when compared to Insulin Lispro.[4,5] BCLIS elicited a superior earlier PPG control both against LisproMix and to Insulin Glargine, and Insulin Lispro administered separately. BCLIS also demonstrated lower hypoglycemic episodes when compared to Insulin LisproMix.[4]

Insulin is always present in the hexameric state. This state is required to help stabilize the insulin outside the human body. Once insulin is injected, it is broken down into monomers, which then act in the body. It is essentially this which hinders the insulin to act fast enough to mimic the human physiology. In the most recent developments, an Ultra-Fast-Absorbing-insulin-Lispro (UFAL) has been developed. Insulin when presents as monomers cause aggregation into amyloid fibrils. A unique acrylamide carrier/dopant copolymer excipient has been developed which helps prevent the aggregation of insulin monomers. Insulin being in the monomeric form takes a lot lesser time for absorption once inside the body.[6] Preclinical studies have already shown the molecule to be stable for a period of 25 hours in stressed conditions along with a peak action of 9 minutes. Such exciting trials make the molecule more promising in creating a breakthrough in the future treatment of diabetes.[6]

Inhaled Insulin

Technosphere technology has enabled the development of pulmonary routes of insulin drug delivery and presently, rDNA originated inhaled HIs are being reviewed by the FDA for approval.[7] Pre-metered unit doses of insulin in

breath activated inhaler devices dissipates into liquid form once exposed to the neutral pH of the alveolar epithelium. Gastrointestinal peptidases that break down insulin in the GI tract are absent in pulmonary route, hence these insulin delivery bypasses the first-pass metabolism system.[8]

Oral Insulin

Oral route supposed to mimic physiological secretion to the portal vein will definitely improve convenience and compliance. Nanoparticle-based approach improved the bioavailability by protecting insulin from proteolytic enzymes and harsh gastrointestinal environment. Anionic natural polymer blocks the release of insulin into the stomach to prevent its degradation. There occurs cellular uptake of nanoparticles or paracellular transport across tight junctions, which enhance paracellular insulin absorption.[9-11] An oral insulin formulation (ORMD-0801) elicited clinically significant reductions in HbA1c in poorly controlled T2DM (mean HbA1c levels >8%) patients on standard therapies, without increasing hypoglycemia rates or weight. Preliminary observations from a trial on oral insulin [ORMD-0801] suggested a palliative effect of on non-alcoholic steatohepatitis in T2DM patients by reducing in liver fat content and chronic hepatitis.[12,13]

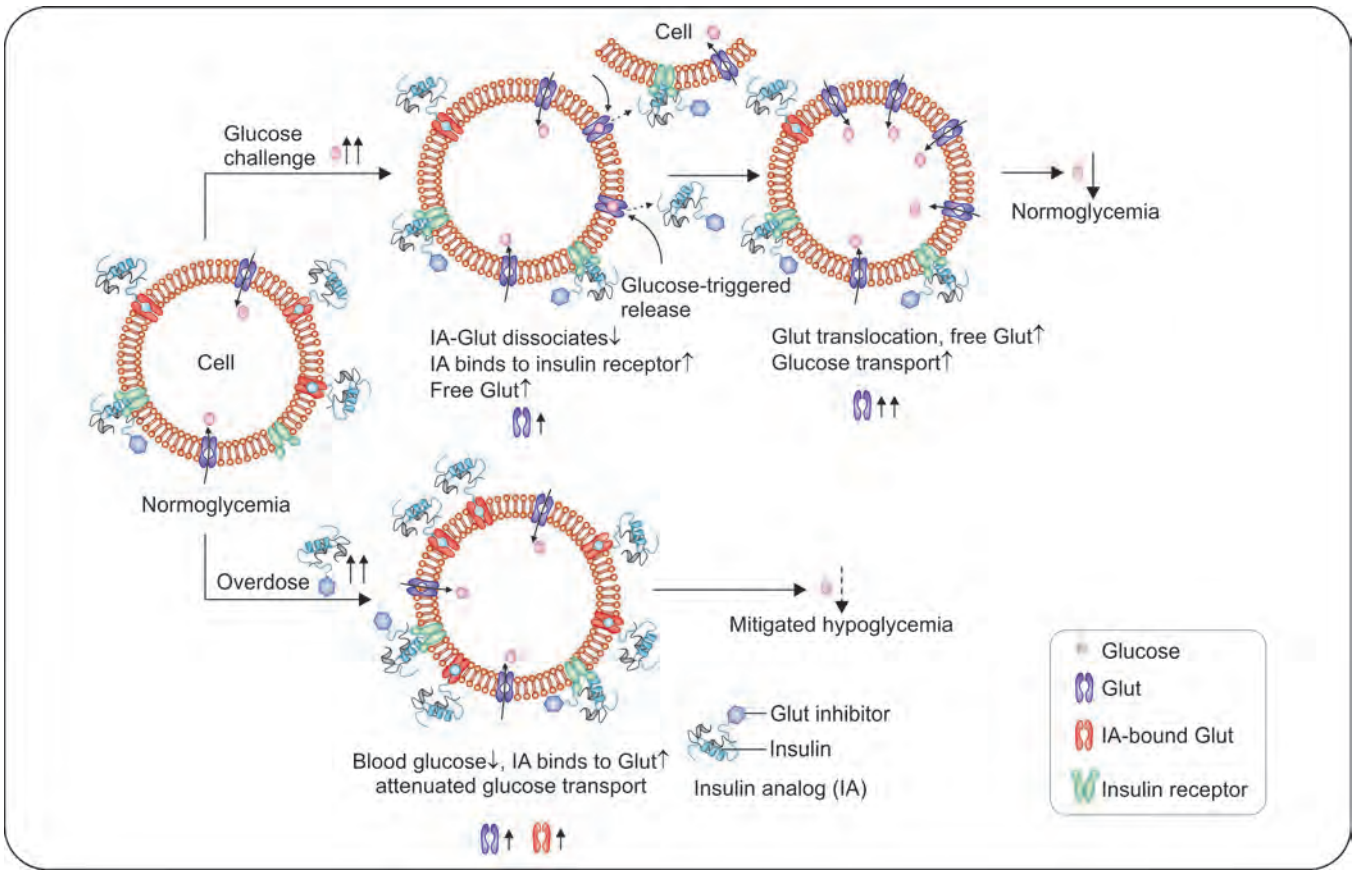

Fig. 5: Schematic of regulating the glucose-transport activity with insulin analog (IA; in this study, i-insulin serves as a model analog). Insulin analog can bind to Glut in a glucose-responsive manner. Upon injection and in normoglycemia, insulin analog achieves a regular blood glucose clearance rate, and an insulin analog–Glut complex reservoir is formed. Upon a glucose challenge, increased blood glucose levels result in the release of insulin analog from the insulin analog–Glut complex, which subsequently binds to IR to trigger the translocation of Gluts to cell membranes. With dissociation of insulin analog, glucose-inaccessible insulin analog-bound Glut becomes free Glut, enhancing excess blood glucose clearance. Upon an excess insulin analog injection (i.e., overdose), the formation of the insulin analog–Glut complex attenuates the glucose transport activity of Glut, therefore mitigating hypoglycemia risk[14]

Recently, researchers have also explored the use of liposomes, biliosomes, and proliposomes for insulin delivery, which will encapsulate the insulin using the appropriate phospholipid/cholesterol ratio and prevent degradation and enhance bioavailability of oral insulins.

Glucose-responsive "Smart" Insulins

A form of smart insulin, named as *i*-insulin, which comprises an insulin analogue attached to a glucose transporter [Glut] inhibitor is developed by bioengineers at the University of California. Endogenous Glut associated delivery reservoir of insulin that is capable of modulating glucose metabolism in a blood glucose-dependent manner could be achieved by Insulin facilitated Glut inhibitor conjugate-a long-acting insulin analogue.

Plasma and tissue glucose levels modulate its binding affinity to Glut. The in situ—generated insulin analogue—Glut complex will dissociate in states of hyperglycemia and will release insulin analogue and glucose-accessible Glut to restore normal blood glucose levels in **Figure 5**. In situations of hyperinsulinemia, glucose uptake will be reduced due to enhanced binding of insulin analogue to Glut that will suppress the glucose transport activity of Glut.[14] Thus, it prevents over-uptake of glucose into cells when there is dip in blood glucose level. When an extra dose of *i*-insulin was administered in diabetic mice, the modified insulin kept blood glucose levels within the normal range longer and protected them from hypoglycemia.[15]

Transdermal Patch

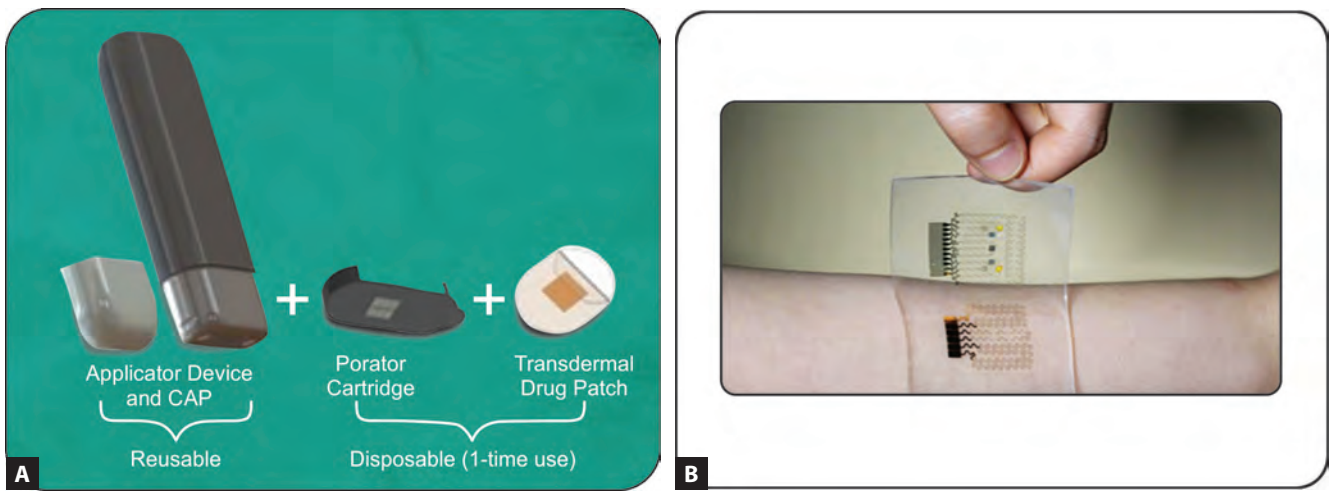
With the advent of techniques like iontophoresis, sonophoresis, or phonophoresis, transdermal administration is considered to be an encouraging approach for insulin delivery in near future **(Figs. 6A and B)**.[16,17]

Stem Cell Therapy

Stem cell therapy that aims to ameliorate insulin resistance, improve pancreatic islet β cells regeneration and protect pancreatic islets from apoptosis is looked upon as cure for diabetes. Programmed stem cells (especially, Mesenchymal Stem Cells or MSCs) differentiating into insulin-producing cells (IPCs), evolves as an alternative to islet cell transplant as it also promises to create an optimal environment by secretion of paracrine factors.[18-24]

Bioresponsive Insulin Delivery System

An artificial beta cell with a glucose-sensitive hydrogel membrane that traps glucose-oxidase enzymes in a hydrogel polymer is integrated in this system. This membrane reduces the pH of the membrane and increases the permeability of the hydrogel membrane to insulin. Thus, the system works to accelerate the release of insulin with increasing levels of glucose to ensure feedback-controlled delivery of insulin.[9,25] The development of closed-loop systems for real-time glucose sensing and controlled insulin release will aim at achieving near-physiological precision in glucose control.[26,27]



Figs. 6A and B: Transdermal application of insulin

Conclusion

Insulin therapy because of being injectable and risk of hypoglycemia is delayed inordinately even though it is considered as cornerstone of managing diabetes. It has been recommended by every guideline based upon data from several landmark trials. Once-a-week icodec may result in a major paradigm shift in patients' acceptance of insulin. Promising results have been reported from phase 2 trial demonstrating similar efficacy and hypoglycemia risk with icodec versus once daily glargine. However, search for ultimate therapy for managing hyperglycemia remains among the spectrum of new concepts of insulins and delivery systems that remains further down the road to see the light of clinical reality.

Blood Pressure Variability in Diabetes: Its Role in Development of Diabetes Complications

KK Pareek, Girish Mathur, GD Ramchandani, Ashutosh Chaturvedi

Abstract

Recently, blood pressure variability (BPV) has gained focus owing to its role in predicting cardiovascular (CV) outcomes. Additionally, alterations in BPV contribute to the progression of end organ damage and trigger vascular events in hypertensive patients. Therefore, amelioration of BPV is considered a potentially important target and different classes of drugs are used to achieve the desired blood pressure (BP) goal. Based on several studies and clinical trials, treatments with CCB such as amlodipine have been found to be most effective in the management of BPV in hypertensive patients with diabetes. Growing evidence substantiates the role of amlodipine in significant reduction of BPV, thus, lowering the risk of diabetes-related complications. This review sheds light on the importance of BPV reduction and the effectiveness of amlodipine in preventing cardiovascular morbidity and mortality in hypertensive patients with diabetes. Reduced arterial compliance in patients with diabetes mellitus has been shown in several studies, but it has not been significantly associated with either atherosclerosis or vessel wall thickness. BP variability is still poorly explored in diabetic patients. The aim of this study was to compare BP variability and arterial compliance in patients with type 2 diabetes mellitus and controls matched for sex, age, and weight.

Introduction

The coexistence of diabetes and hypertension is greatly linked to the causation of several entities, viz., cardiovascular events, microvascular complications, retinopathy, nephropathy, and increased contribution to all-cause mortality.[1] Blood pressure variability (BPV) is now considered as an important risk factor responsible for various complications occurring in hypertensive and diabetic patients. Although physiological blood pressure (BP) variations are commonly seen in most individuals, but when these variations exceed the acceptable range, they acquire pathological significance. Normal circadian BP rhythm is retained during the initial phase of development of hypertension but variability tends to increase when the target organ damage alters the regulatory mechanism of B.P. These findings become of greater importance in case of diabetic patients who are already at a significantly higher risk of development of cardiovascular (CV) events as compared with non-diabetic individuals.

Type 2 diabetes (T2D) patients usually have autonomic dysregulation of cardiovascular functions which increases BPV. In several studies it has been seen that intensification directed at multiple risk factors which are responsible for development of complications in T2D patients, have beneficial effects in respect of macro and microvascular complications.

Blood Pressure Variability

BPV, in very simple terms, can be defined as the variations in BP over time. B.P fluctuations are initiated by a complex interplay between multiple cardiovascular control mechanisms or during change between day to day

life, behavior and triggered by changed environmental situations.[2] These variations increase in patients who are having disordered cardiovascular control mechanisms.[3] Typical examples of routine fluctuations are like BP rise after physical activity or psychological stress and BP reduction when person is in sleep or relaxation.[2] Research has shown that increased BPV values are a strong predictor of CV mortality and morbidity.[4]

In addition to diabetes and hypertension, many studies have shown that like glucose variability visit-to-visit BPV is a great risk factor for macro- and microvascular complications in T2DM patients.

BP measurements undergo automatic variations due to multiple reasons. Short-term variations (within 24 hours) may be due to day-night changes. Likewise long-term variations can be due to differences between days, months, and seasons. Also, systolic BP increases with age and diastolic BP also exhibits an age-related biphasic change;[5] management of such patients with antihypertensive therapy might help to obtain normal BP control with optimal CV protection. This may be valuable in understanding the basic concepts of BPV.

Types of BPV

BPV can be classified into the following four different types:

- Short-term (24-hour BPV)
- Very short-term
- Mid-term
- Long-term

These four types are depicted in **Figure 1**.

Short-term or 24-hour BPV

Twenty-four-hour BPV is due to many factors, like physical activity, emotional stimuli, and sleep. Day and night changes can be under the influence of signals initiated by the brain. BPV can also be because of mechanical forces generated by ventilation and due to humoral and local vasomotor phenomena. Night time BP (sleep) is on an average 10–20% lower as compared to daytime (waking hours). However, in hypertensive patients, the 24-hour BPV patterns may remain different. Some show >20% or <10% decrease in BP at night, and some may even show a rise in night time BP as compared with day time BP values.

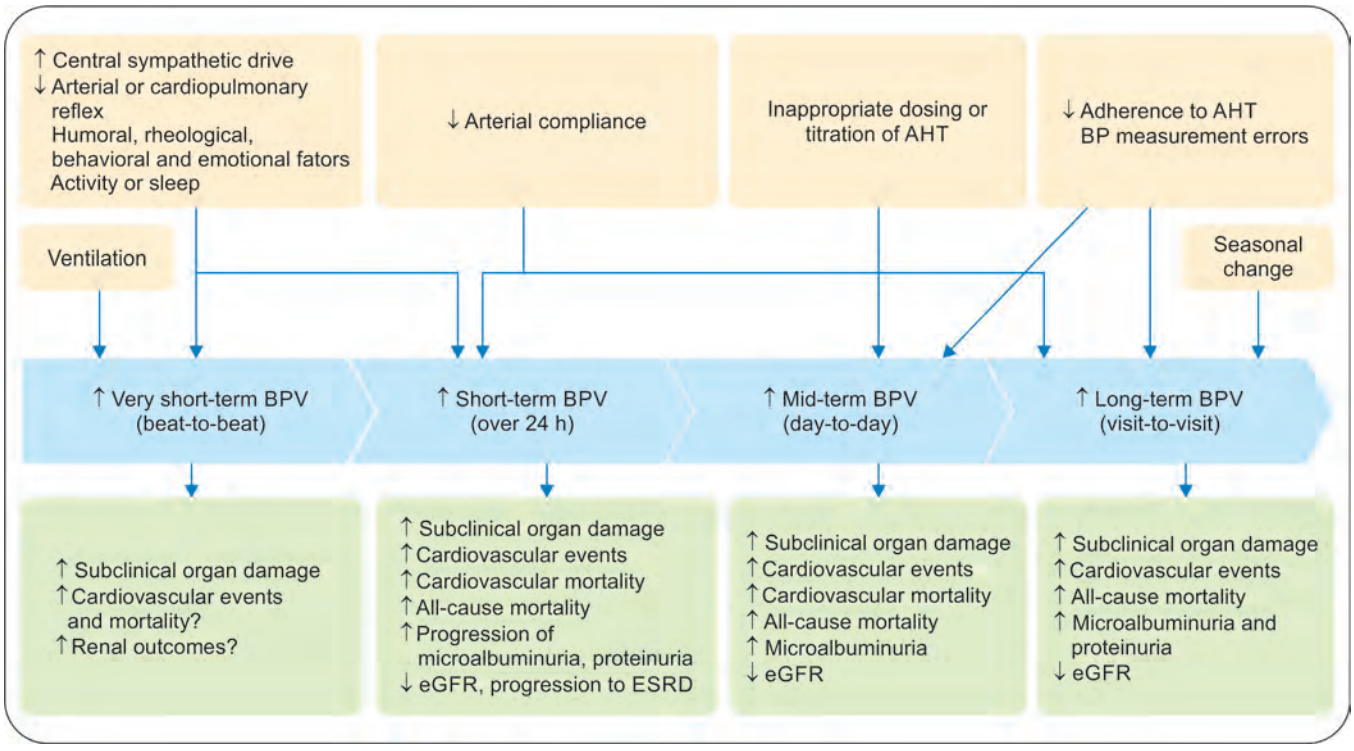

Fig. 1: Various types of BPV, their determinants, and prognostic relevance for cardiovascular and renal outcomes

TABLE 1 Salient features of morning BP surge or morning hypertension

Morning hypertension (surge) *Early morning BP ≥ 135/85 mm Hg (HBP/ABP)*	
Patterns of morning HT	***Clinical outcomes***
• Extension of nocturnal HT	• ↑ Cardiovascular risk
• ↑ BP variability over 24-hr	• ↑ Occurrence of events
• Morning surge (rapid BP rise)	• Target organ damage
Factors influencing morning hypertension	
• Physiological BP surge	• ↑ Sympathetic, neuroendocrine activities
• Associated conditions	• Stress, OSA, drinking, cold, old age
• Inadequate 24-hr control	• Loss of drug efficacy at night/over 24-hr

JSH. Hypertension Research. 2009;32:70-7.

Depending on their SBP values patients can be categorized as *extreme dippers* (night-day BP ratio ≤ 0.8), *dippers* (0.8 < ratio ≤ 0.9), *nondippers* (0.9 < ratio ≤ 1.0), and *reverse dippers* or risers (ratio > 1.0).

Reverse dippers have worse outcomes as compared to dippers, and the reasons for this rise in BP at night may be because of:

- Nocturnal autonomic dysfunction
- Disturbed baroreflex sensitivity
- Sleep apnea
- Abnormal sodium handling
- Nocturnal volume overload

Table 1 outlines the salient features of morning BP surge or morning hypertension.

Mid-term or Day-to-day BPV

Day-to-day variations in BP can be defined as mid-term BP variations. These mostly occur because of inappropriate, non-titration, and poor adherence of patients to antihypertensive therapy. Many a times errors in BP measurement by the clinicians can also lead to such variations. Other factors which can influence *mid-term* BPV are:

- Advanced age
- Increased arterial stiffness
- Female gender
- Excessive alcohol intake
- Cigarette smoking
- History of peripheral artery disease, cardiovascular disease, diabetes mellitus, and diabetic nephropathy

Long-term BPV

Long-term BPVs are seasonal variations, day-to-day variations, and also visit-to-visit (VVV) variations. Behavioral characteristics play an important role in the development of long-term BPV as seen by the clear-cut differences seen in ambulatory BP (ABP) values measured during weekdays and weekends. Insufficient antihypertensive treatment due to non compliance of BP treatment or improper dosing/titration of medications by the physician might also influence long-term BPV. In VVV BPVs, the errors in BP measurement play an important role. Also BP variations between summer and winter indicate the influence of temperature and day light hours due to changes in seasons. Multiethnic Study of Atherosclerosis (MESA) has showed that arterial stiffness can also be the cause for long-term BPV.

Very Short-Term BPV

It can be defined as beat-to-beat variability.

Mechanism of BPV

The association of BPV and all-cause mortality in patients suffering from diabetes (where this is not "dampened" by BP lowering medication) may be because of increased arterial stiffness. So, BPV may be a marker of age-related changes in arterial morphology resulting in arterial stiffness. Thus, an association between BPV and all-cause mortality in patients with diabetes but (not on BP lowering drugs) may be because of accelerated vascular aging. An increased BPV in persons with diabetes is a sign of *autonomic dysfunction*, in the form of *impaired baroreflex sensitivity*. Cardiovascular autonomic neuropathy is an important complication of diabetes, and increases mortality risk in patients where it is present. Longer duration of diabetes and evidence of target organ damage can be considered its predictors. The beat-to-beat BP changes occur due to interaction between several CV regulatory systems, such as the baroreceptor reflex, renin-angiotensin system, vascular myogenic response, and release of nitric oxide from the endothelium. But definitive evidence is lacking for the exact underlying mechanism.

Oxidative Stress

Oxidative stress itself is an independent predictor of increased LV mass and correlates with abnormal glucose and BPV. In short-term diabetic patients having optimal

metabolic control but impaired GV and BPV risk are associated with endothelial and cardiovascular damage. Not only HbA1c, high SBP, and high DBP but also glucose and BPV are significant in the clinical management of patients suffering from T2DM and hypertension.

Arterial Compliance

Many studies have shown that in T2DM patients, that hyperglycemia may affect the compliance of the vascular system, which results in large BP fluctuations. This indicates the need to control glycemic status, high BPV and reduced arterial compliance of patients to prevent increase end-organ damage.

Figure 2 outlines the mechanisms of BPV in patients with diabetes.

Methods of BPV Measurement

Various methods for BPV measurements are available:

- Continuous beat-to-beat BP recordings
- Repeated office BP measurement (OBPM)
- 24-hour ambulatory BP monitoring (ABPM)
- Home BP monitoring (HBPM) for long periods[6]

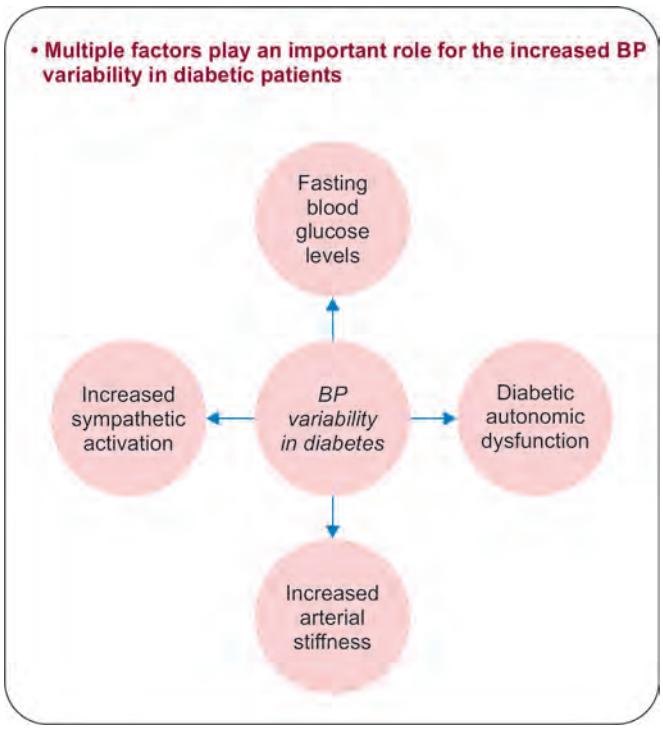

Fig. 2: Mechanisms of BP variability in patients with diabetes

The key index of short-term BPV is standard deviation (SD) of 24-hour average ABP measurements. Since night time decrease in BP interferes with accurate BPV measurements, it has been suggested that 24-hour SD can be a useful guide for the correct assessment of BPV. Day-to-day BPV can be assessed by ABPM for over 48 hours, which may not be a convenient modality for most of the patients. The alternative to ABPM assessment of BPV is use of HBPM that can gather data over many days. The availability of day-to-day BPV may be useful to our physicians in streamlining the management much earlier.[6] Visit-to-visit BPV can be assessed by ABPM or OBPM. However, OBPM is not a correct modality to assess VVV BPV since it might not reflect the BP burden during the patient's normal activities and also requires multiple visits to the physician's office. As ABPM cannot be measured frequently, it may not be a good modality to measure VVV BPV. On the other hand, HBPM looks to be an ideal tool for the assessment of VVV BPV under fairly constant conditions without the "*white coat effect*".[6]

But it is also true that ambulatory BP monitoring not only provides information regarding BP level, but also indicates changes in BP. As BPV is a multifaceted phenomenon which includes short-term as well as long-term components, the same can be estimated by the SD of the BP values over a defined period of the day or the night-to-day BP ratio, respectively. In T2DM patients, dysregulation of the autonomic control of cardiovascular functions can increase BPV.

Night Time BPV

For night time BPV in diabetic patients, it has been shown that ABP measurement is much better modality as compared to clinic BP measurement as it can also confirm the role of abnormal circadian BP variations in predicting future CV events. The SDs of sleep SBP and DBP were independent predictors for CVD risk but the SD of awake BP was not. These finding are in consonance with a study of isolated systolic hypertension which showed that increased night time SBP variability was an independent risk factor for development of stroke.

In a study in diabetic population, neither an abnormal dipping pattern nor the morning BP surge was a predictor of CVD events, whereas the night time BPV appeared to be a strong predictor of CVD risk, independent of ABP level, and other traditional risk factors. These results

indicate that in addition to ABP measurement, evaluation of night time BPV, which can suggest early change of diabetic autonomic neuropathy, may be important for the prediction of cardiovascular events in future.

BPV—Causal or Casual?

Visit-to-visit variability of BP is associated with risk of developing stroke and CAD, independently of mean BP in office visits. It is possible that this association may be causal and that BPV may be an important and significant factor especially in presence of higher autonomic imbalance[2] as it occurs in diabetes patients. This is supported by many studies that visit-visit BPV is not only an independent predictor of macrovascular and microvascular complications in patients with T2D patients, but all-cause mortality.

The observational study—"Retrospective Epidemiological Study to Investigate Outcome and Mortality with Glucose Lowering treatment in Primary Care setting" (ROSE) on 9,855 diabetic patients included the main analysis of associations between BPV and all cause mortality. It indicated that although BPV may result in little improvements in mortality prediction, but may not translate into clinical usefulness for risk prediction above and beyond that of other routinely measured predictors of BP. It was found that mean BP level is better predictor of CVD and all-cause mortality than BPV.

Recent studies have shown that BPV persisting across several clinic visits (i.e., long-term BPV) is associated with the risk of stroke,[3,4] CAD and all-cause mortality.[5] Short-term BPV measured over 24 hours by ambulatory BP monitoring is also associated with increased CVD events[6,7] but many studies have shown that within-visit BPV is associated with metabolic syndrome score,[8] target organ damage (left ventricular hypertrophy and albuminuria),[9] and the risk of stroke,[3,4] but not with overall CV events or all-cause mortality.[10,11]

Clinical Significance of BPV in Diabetes

- In a study of 8,811 patients with T2D in the ADVANCE trial it was concluded that VVV of SBP was significantly associated with the incidence of major micro- and macro-vascular events and all-cause mortality.[11]
- A retrospective cohort study which evaluated the effect of VVV of SBP on CVD and all cause mortality among 124,105 Chinese patients with T2DM identified a positive linear relationship between the VVV of SBP and the first incidence of CVD and all-cause mortality over a median follow-up time of 39.5 months.[12] Further, the patients with SD of SBP <5 mm Hg had the lowest risk of CVD and all-cause mortality, and those with SD of SBP ≥10 mm Hg had significantly higher risk.
- Study conducted on 2,161 T2D patients over 5.5 years, VVV BPV significantly predicted all-cause mortality, irrespective of mean BP values.[13]
- Ushigome et al. evaluated in 858 Japanese patients with T2D for 14 consecutive days the relationship between day-to-day variability and to macro albuminuria by HBPM. After adjusting for several factors, the analysis showed that CoVs of morning SBP and DBP as well as those of evening SBP were independently linked with the algorithm of urinary albumin excretion (UAE), so coefficient of variations of HBPM can be a novel factor which correlates with macro albuminuria after accounting for known risk factors in patients with T2D.

Table 2 depicts some of the salient studies of BPV in diabetes.

TABLE 2 Evidence indicating the effect of BPV on various parameters in diabetes patients

Study	*Population characteristics (n)*	*BPV index*	*Outcome*
Kilpatrick et al. (2010)[14]	T1DM patients (1,441)	Visit-to-visit BPV	High risk of nephropathy
Ozawa et al. (2009)[15]	Hypertensive diabetic patients (72)	Night time Systolic blood pressure variability	Increased risk of coronary heart disease
Ushigome et al. (2011)[16]	Patients with T2D (858)	Day-to-day BPV	Increased risk of macro albuminuria
Hsieh et al. (2012)[13]	Patients with T2DM (2,161)	Visit-to-visit SBPV and DBPV	High risk of all-cause mortality

Within-Visit BPV is Associated with Prediabetes and Diabetes

This study included 17,795 individuals aged 40–74 years who underwent health check-ups in Japan and completed two BP measurements. Associations between within-visit BPV and risks for cardiovascular events were investigated.

It was concluded that high within-visit BPV is significantly associated with the prevalence of prediabetes and diabetes, independent of mean SBP, in a large general population. Therefore, it was considered that blood sugar parameters should be monitored in patients with high-BPV as BPV can be assessed in a single visit and may prove to be a useful modality to diagnose patients at greater risk of impaired glycemic control.

BPV Management: Protection Provided by Antihypertensive Drugs

BPV is known to decrease with decrease in BP induced by antihypertensive management. But effect of different antihypertensive classes compared to one another is yet not known. Long acting dihydropyridine calcium channel blocker are undoubtedly the most promising drugs in the management of BPV. Many clinical studies have consistently found the advantage of these drugs in reducing ambulatory, home, and clinic BPV.[17] In fact, the smoothness index (an index that includes information on the homogeneity of antihypertensive drug effects over 24 hours) correlates with both a reduction in 24 hour BPV and the regression of organ damage in hypertension[18] with the use of long acting antihypertensive drugs. Apart from the use of specific drugs, drugs which cause iatrogenic increase in BPV (like the use of short acting antihypertensive treatment) should be avoided.

A study on hypertensive patients with diabetic nephropathy has shown that treatment with ARBs or ACE inhibitors could improve ambulatory short-term BPV. After 12 weeks of treatment 24-hours, daytime, and night-time short-term BPV were significantly decreased.[19] Evidence is also available that some classes of oral anti-diabetic drugs, that is, thiazolidinediones, may not only have a beneficial effect on 24-hour BP levels but also improve day-night BP profile in diabetic subjects.[20]

Conclusion

The concept of BPV has been there for last many years but did not get the attention and importance in routine clinical day-to-day practice. BPV has been identified as a risk factor for various hypertension-related complications, more so in diabetes patients. SD is the easiest way to calculate BPV. Mobile app can be helpful to the clinicians to calculate SD immediately. Various modalities such as ABPM, HBPM, and OBPM can be used to measure BPV depending on the availability and feasibility. The treatment of any patient of BPV and also of diabetes should be individualized accordingly. It has been shown to be beneficial if we adhere to the night time dose regimen of antihypertensive drugs. Based on several evidences the association between BPV and various complications like CV events, all-cause mortality, diabetic and renal complications, etc., it may be useful to include BPV in the diagnostic pool of hypertension management and there is a need for further research for determining the affect of BPV on CV complications and target organ damage in a patient of T2DM and hypertension.

Subjects with higher night time than day time BPV had a higher risk of death. However, reverse dippers on antihypertensive drugs were older and usually had a history of diabetes mellitus or previous CV events.

CHAPTER

50 Insulin Resistance and Ectopic Fat—A Complex Interrelationship

NK Soni, VB Jindal

Abstract

Ectopic fat is defined by excess adipose tissue in locations not classically associated with adipose tissue storage or contains only small amounts of fat, such as the liver, skeletal muscle, heart, and pancreas. Ectopic fat can interfere with cellular functions and hence organ functions and is associated with insulin resistance. Adipose tissue consists of adipocytes and the vascular fraction that contains blood vessels. Adipose tissue has the unique capacity to store large amounts of energy in the form of triglycerides. For a long time, it has been presumed that energy storage was the only function of adipose tissue. However, adipose tissue acts as an endocrine organ by secreting various hormones and cytokines known as adipokines. These adipokines have effects on glucose and lipid metabolism and energy homeostasis. It now appears that adipose tissue dysfunction plays a role in developing insulin resistance. Adipose tissue dysfunction is characterized by large adipocytes and secretion of adipokines with a proinflammatory profile. The aim of this article is to discuss the pathophysiology of ectopic fat and its effect on insulin resistance. We will elaborate on the effect of ectopic fat deposition on the cellular level as well as on the various organ level involved in the pathogenesis of insulin-resistant. Genetic, environmental, and behavioral factors are involved in excess energy intake and decreased physical activity leading to ectopic fat deposition. Physiologic versus pathologic fat accumulation also plays an important role in its dysfunction. Human adipocytes can grow up to ~20 fold in diameter and several thousand-fold in volume. Too large adipocytes will release stress signals in response to hypoxia when vascularization is inadequate for the expanded adipose tissue and endoplasmic reticulum stress which is induced by hypoxia or nutrient excess. Consequences of ectopic fat accumulation depends upon the specific organ although cellular mechanisms remain same but Visceral fat accumulation is linked to higher level of insulin resistance. We have also discussed the issue in reference to diagnosis and its prevention with diet and lifestyle intervention.

Introduction

Type 2 diabetes mellitus (T2DM) is a multifactorial disease with complex interplay of genetic, environmental, and lifestyle factors contributing to insulin resistance and impaired insulin secretion, which leads to a state of chronic hyperglycemia and its attendant complications.[1] A dramatic rise in the number of people with obesity has been witnessed in the last few decades, with doubling of individuals with body mass index (BMI) >30 kg/m^2 in the last 30 years. Obesity predisposes to the development of insulin resistance, T2DM, metabolic syndrome, cardiovascular disease, and cancer. Interestingly people with metabolic syndrome present a fivefold higher risk of developing T2DM. It is expected that incidence of diabetes will double by 2025, and in 2030 diabetes will be the seventh cause of death in the world.[2-7]

Insulin resistance is an excellent predictor for the clinical onset of T2DM and precedes occurrence of the

disease by many years. Typically in obesity, the level of circulating triglycerides and free fatty acids (FFAs) at some stage begins to exceed the metabolic capacity of adipose tissue, leading to excessive accumulation of fat in other organs, including liver, pancreas, and skeletal muscles. This results in serious metabolic and clinical consequences as increased lipid accumulation inhibits insulin-mediated glucose uptake and thereby reduces insulin sensitivity of the organs.[8]

Dysfunction of Adipose Tissue

In obese subjects that develop insulin resistance, adipose tissue dysfunction plays a major role. Adipose tissue dysfunction is characterized by large adipocytes formation and secretion of adipokines with a proinflammatory profile ultimately leading to ectopic fat deposition.[9] Ectopic fat is defined as storage of TG in tissues other than adipose tissue, that normally contain only small amounts of fat, such as the liver, skeletal muscle, heart, and pancreas. Ectopic fat can interfere with cellular functions, and hence organ function and is associated with insulin resistance.

Mechanism of Ectopic Fat-induced Organ Dysfunction

The consequences of ectopic fat accumulation depend on the specific organ involved. Firstly, it has to be noted that lipids can be dispersed intercellularly or accumulate intracellularly. Deposition of lipids in intercellular space might impair organ function via paracrine effects of the released adipokines. However, it is the intracellular lipid accumulation that is associated with decreased insulin sensitivity **(Fig. 1)**.

It appears that it is not the FFAs themselves, but metabolites like long-chain acyl-CoA (LC-CoA), diacylglycerol (DAG), and ceramides, which are deleterious for the cell. These fatty acid metabolites induce a sustained activation of serine/threonine kinases such as protein kinase C (PKC) isoforms, IKB-kinase-β, and Jun N-terminal kinase, which phosphorylate insulin-receptor substrates (IRS) on serine residues.[10] The subsequent defects in insulin signaling lead to a decrease in cellular function that depends on the cell type.

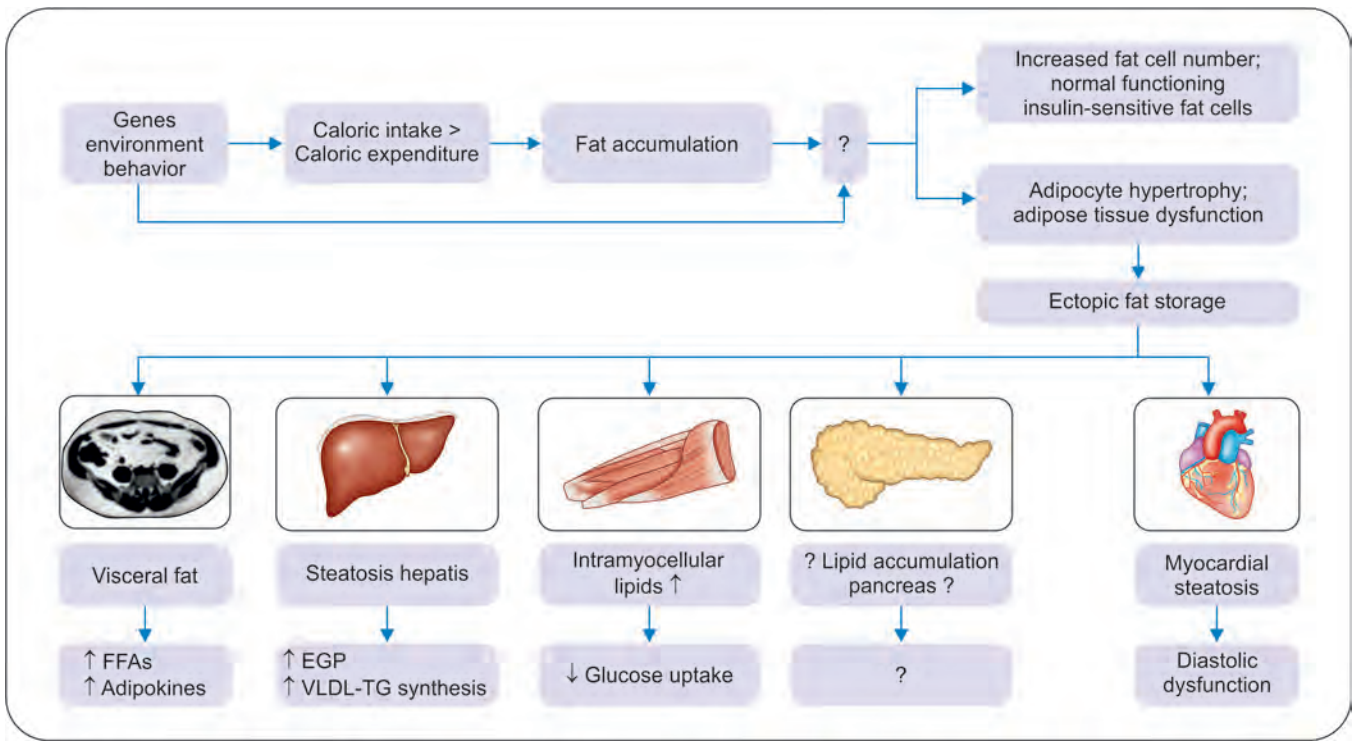

Fig. 1: Pathophysiology of ectopic fat deposition

FFAs are taken up by the skeletal muscle cell mainly by protein-mediated membrane transport, fatty acid transport protein (FATP), along with passive diffusional uptake. After uptake in muscle metabolites of these fatty acids induce a sustained activation of serine/threonine kinases leading to phosphorylation of insulin-receptor substrate (IRS1) on serine residues.[10] Serine-phosphorylated forms of IRS1 cannot associate with and activate phosphatidyl-inositol3-kinase (PI3K), resulting in a decreased glucose transporter 4 (GLUT4) regulated glucose transport over the cell membrane.

The mechanism behind hepatic TG accumulation and the development of hepatic insulin resistance are much similar to that described for skeletal muscle.[10-12]

Fatty Liver a Cause or Consequence of Hepatic Insulin Resistance?

Accumulation of TG in hepatocytes reflects an imbalance between hepatic TG synthesis and its utilization. Utilization includes mitochondrial beta-oxidation, production of ketone bodies, and secretion of TG in very-low-density lipoprotein (VLDL) particles.

Histologically, the fatty liver can be classified as *micro-* or *macrovesicular*.[13] Causes of microvesicular steatosis, such as fatty liver during pregnancy, Reye's syndrome, and certain drugs and toxins, are thought to share a common mechanistic feature—impairment of mitochondrial beta-oxidation.[13] Microvesicular steatosis is often accompanied by severe hepatic dysfunction. The causes of macrovesicular steatosis include alcohol, non-alcoholic fatty liver disease (NAFLD) associated with features of insulin resistance, total parenteral nutrition, protein-calorie malnutrition, and jejunoileal bypass. NAFLD is a term describing a large spectrum of conditions ranging from fat alone to fat plus inflammation, fat plus ballooning degeneration, and non-alcoholic steatohepatitis (NASH).[14]

Endogenous or Exogenous Factors that Affect Ectopic Fat, Liver and Muscle IR

Gender differences have been linked to ectopic fat accumulation and IR[15] and these could partly be related to differences in body fat distribution in men and in women. Generally, women have a higher percentage of subcutaneous adipose tissue (SAT) as compared to BMI-matched men, who generally have more visceral adipose tissue (VAT). The expandability of SAT also could be a critical factor in the development of insulin resistance.[16,17]

Lipids may be predominantly stored in SAT before marked VAT expansion occurs. VAT has been linked to higher levels of inflammatory markers, insulin resistance, and other cardiometabolic complications.[18,19] Moreover, in general women accumulate more adipose tissue in the gluteal-femoral regions as compared to the abdominal fat deposition. Abdominal obesity is associated with an increased risk of developing T2DM and cardiovascular diseases.[20]

Furthermore, although not completely elucidated, the metabolic differences between men and women are, also partly, a consequence of differences in hormonal status. Estrogen has been shown to reduce intrahepatocellular lipid (IHCL) accumulation and IR in both sexes. Until menopause, women have a lower risk for developing fatty liver, whereas postmenopausal women have a similar risk compared to age-matched males.

Age also seems to be a very relevant factor in the etiology and pathophysiology of IR, and seems to be positively related to ectopic fat accumulation.[21]

Imaging and Measurement of Ectopic Fat

Magnetic resonance imaging (MRI) examination which allows noninvasive assessment of lipid infiltration in various organs may become an ideal tool or gold standard imaging technique that can help to quantify and illustrate the effects of obesity. MRI will allow early detection of reversible metabolic changes as well as their further monitoring. It is believed that in the future, the method could also be used as a biomarker for indicating the development of prediabetes insulin resistance.

Effect of Macronutrients on Ectopic Fat in Distinct IR Phenotypes

There has been a debate on different dietary approaches in the prevention of T2DM and tackling insulin resistance. One of the approaches is the Mediterranean diet, rich in olive oil, which may provide cardiovascular benefits. Secondly, diets low in fat and high in complex carbohydrates with increased fiber content along with lifestyle interventions may decrease the cumulative incidence of diabetes by more than 50% over next 3–6 years.[22-26]

Available evidence clearly indicates that there is great potential to optimize the effectiveness of dietary interventions on glucose homeostasis by, for example, targeting liver- and muscle-IR phenotypes. A first step toward the development of more personalized nutrition could be to investigate the role of tissue specific IR and related ectopic fat content in the effectiveness of dietary interventions, in particular when studying the effect of manipulation of the macronutrient composition of the diet.

Conclusion

Ectopic fat accumulation in insulin-sensitive tissues is associated with insulin resistance independent of overall obesity. However, our understanding of the causes and mechanisms underlying fat accumulation in skeletal muscle and the liver are limited. Identifying why some individuals store fat in insulin-sensitive tissues, but others do not, may be of great importance for the development of new insulin-sensitizing agents and for optimal use of current therapies.

Diet and exercise are powerful tools in improving both ectopic fat deposition and the function of the organ in which the ectopic fat is deposited. Diet and lifestyle intervention, therefore, deserve more attention, both as preventive measure for obesity and T2DM as well as for the treatment of insulin resistance and T2DM.

CHAPTER

51 Acute Metabolic Complications in Diabetes Mellitus

Anuj Maheshwari, Nisha Maheshwari

Abstract

Acute increase in plasma glucose causes acute metabolic complications leading higher occurrence of morbidity and mortality in patients with diabetes. This can easily be prevented by early identification and aggressive treatment. Insulin insufficiency is coupled with rise in level of counter regulatory hormones which is usually precipitated by prolonged fasting, dehydration, pregnancy, physical stress, infection apart from missing exogenous insulin dose, and very high insulin resistance. Poor carbohydrate utilization prepares the ground of deriving energy from alternative fuel resources causing ketosis, acidosis and dehydration which is further aggravated by osmotic diuresis along with hyperglycemia and superadded electrolyte loss. Best strategy for prevention is early detection and identification of precipitating factors so they can be treated before causing acute metabolic diseases. Youngsters especially type 1 diabetes are more prone for diabetic ketoacidosis. Contrary to this, elderly individuals, especially with newly detected diabetes have higher risk for hyperglycemic hyperosmotic state, mostly in females. Raising awareness at community level is significant intervention for prevention. Treatment should be targeted to correct dehydration by restoring extracellular and intracellular fluid volume together with treating electrolytes imbalances, hyperglycemia, and acidosis.

Introduction

Diabetes mellitus (DM) is a chronic endocrine disorder, which occurs of pancreatic insufficiency to make insulin or to impaired action or both causing hyperglycemia. Acute rise in plasma glucose may lead to acute metabolic complications like diabetic ketoacidosis (DKA), hyperglycemic hyperosmolar nonketotic coma (HHNKC), lactic acidosis (LA), and hypoglycemia. These complications lead to increased mortality and morbidity, which can only be prevented by early identification and aggressive management.[1]

Pathogenesis

Underlying pathology includes raised blood sugar, metabolic acidosis, electrolyte abnormalities, hyper ketosis and water deficit for all acute metabolic complications except hypoglycemia. Mostly it is because of relative insulin insufficiency together with excess of counter regulatory hormones like glucagon, catecholamines, cortisol, and growth hormone.[2] Relative insulin insufficiency not only caused by β-cells failure but also due to abrupt deprivation caused by missing exogenous insulin and high resistance to insulin. Various precipitating factors, like prolonged fasting, dehydration, physical stress, infection, play a significant role in presence of excess of counterproductive hormones.[3,4] Poor carbohydrates utilization is further worsened by synthesis of ketones causing acidosis and dehydration. Dehydration increases further by osmotic diuresis due to glycosuria and excretion of neutralized ketoacids by kidney. In addition there is an increased load of amino acid influx from muscles for metabolism together with saturation of hepatic functioning with gluconeogenic precursors thereby leading to higher

pyruvate and lactate synthesis. Unavailability of insulin begins utilization of amino acids and triglycerides as energy source. Unregulated lipolysis gives rise to increased levels of glycerol and free fatty acids.[5,6] In state of insulin deficiency, glucagon in excess converts free fatty acids to ketones and produces glycerol and alanine while causing gluconeogenesis in liver. The culprit ketoacids that result in metabolic acidosis are acetoacetic acid and beta-hydroxybutyric acid. Acetoacetic acid converts to acetone, which is difficult to clear by respiration when accumulated. Uncontrolled hyperglycemia causes marked osmotic diuresis along with superadded loss of electrolytes under effect of ketones.[7] Despite being actually in deficit, potassium levels are initially seen normal due to shift of potassium extracellularly with regards to acidosis. However, these levels further decline with insulin treatment and thus periodic K^+ check is needed to avoid hypokalemia.[8]

Including poor compliance of insulin treatment, infection, infarction, ischemia, intoxication with alcohol or drug abuse are five important stressors to increase secretion of stress hormones, glucagon, cortisol, and adrenaline causing hyperglycemia, which may end up with DKA in invariably in type 1 DM but sometimes in type 2 DM with insulin resistance along with erratic medication and poor diet plan.[8] On the other hand the pathogenesis of hyperglycemic hyperosmolar state (HHS) differs from that of DKA as it occurs with more severe dehydration due to osmotic diuresis without significant ketosis/ketonemia.[2,9] A higher concentration of circulating hepatic insulin may keep it free from ketosis. Patients presenting with HHNKC have lower level of free fatty acids, cortisol, growth hormone, and glucagon than patients with DKA. Patients with HHNKC may have mild metabolic acidosis due to compromised kidney functions and dehydration **(Fig. 1)**.[9]

Reactive oxygen species (ROS) play an important role in synthesis of advanced glycation end products (AGEs), increased activity of protein kinase C (PKC), stimulation of hexosamine pathway together with higher contribution from the polyol pathway actually underlies the whole pathobiological process.[10] LA is an elevation of lactic acid beyond 5.0 mEq/L with acidosis (pH <7.3). Ketones are absent or very low. It accounts for 1.2% of all hospitalizations with diabetes in decade of 2001–2010 and is showing consistently rising trend from earlier data 0.6% in 1989–1991. Similar rising trend from 0.3% to 1% is noticed among non-diabetics. Hypoglycemia has also been identified as an underlying cause among 5.4% of total hospitalization with diabetes during 2001–2010. Severe hypoglycemia are increasing among patients aiming lower glycosylated hemoglobin (A1c) without enough prior education and support.[11] Hypoglycemia caused

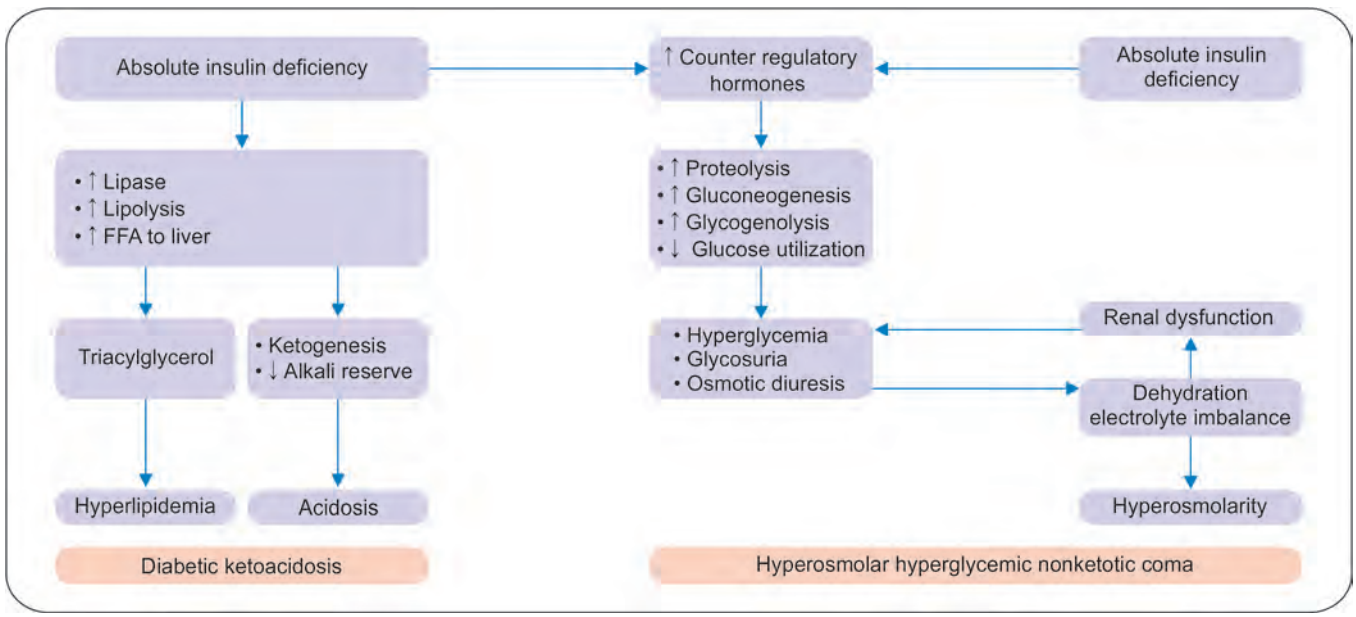

Fig. 1: Mechanism for the development of acute complications in diabetes

by sulfonylureas is more prolonged and hazardous in comparison to that caused by insulin.[10]

Predictors and Precipitating Factors

DKA occurs more commonly in younger age with established type 1 DM. Younger age can be taken as risk factor as children below 2 years of age have three times more risk than older kids.[12] It increases with age in females but not in males. It is commoner in ethnic minorities.[13] Apart from this lower socioeconomic status including low income and poor educational status and lower level of awareness of family members play an important role in causation of DKA.[12] Family history of diabetes, particularly the presence of a first degree relative of type 1 DM plays a protective role. Medications like steroids, antipsychotics like clozapine or olanzapine, diazoxide, cocaine, and lithium can precipitate DKA especially in newly diagnosed patients with diabetes. Missing dose of insulin, pump failure, or treatment error like inadequate insulin therapy during acute illness, infection, myocardial infarction, or surgery may also lead to DKA.[10,14] Ketoacidosis with normal or near normal plasma glucose level may occur during fasting, pregnancy, very young or partially treated patients, which is called Euglycemic Ketoacidosis.[15] It is also reported in modern days patients being treated with newer molecules like SGLT-2 inhibitors.[16]

Contrary to DKA, elderly individuals, especially with newly detected diabetes have higher risk for HHS with female preponderance. Most of HHNKC episodes are precipitated by an infection followed by cerebrovascular accident, alcohol abuse, pancreatitis, myocardial infarction, trauma, and medications affecting carbohydrate metabolism like steroids, thiazides, and sympathomimetic agents like dobutamine and terbutaline.[10,17]

LA is a medical emergency most commonly results from oxygen deprivation in the body's tissues, impaired liver function, respiratory failure, or cardiovascular disease. Other conditions poor oxygenation like hypoxemia, shock, sepsis, carbon monoxide poisoning, and some medications like phenformin and metformin, especially when they are used in patients with renal failure. Alcohol abuse also commonly causes LA in diabetic patients.[18]

Modifiable predictors of severe hypoglycemia include intensive insulin treatment with the intention of low HbA1c using higher dose of insulin. Patients keeping HbA1c levels below 7.0% (<53 mmol/mol), especially in patients with age of 75 years or more, with serum creatinine level more than 2.0 mg/dL or having cognitive impairment or dementia had shown higher occurrence of overtreatment translating into hypoglycemia.[13]

Prevention and Treatment

Best strategy for prevention of DKA is early detection of type 1 DM before the occurrence of DKA. Removal of precipitating factors after identifying them well should be the next. Raising awareness at community level is significant intervention for prevention. Treatment should be targeted to correct dehydration by restoring extracellular and intracellular fluid volume together with treating electrolytes imbalances, hyperglycemia, and acidosis. If there is no cardiac compromise, isotonic saline should be infused at a rate of 15–20 mL/kg/h, which must not be less than 1–1.5 L at least in the 1st hour. After that fluid replacement should be given on the basis of hemodynamic status, serum electrolyte levels, and urinary output. For hyperglycemia correction insulin treatment should be given in initial bolus dose of regular insulin intravenously at the rate of 0.1 units per kg followed by the infusion of 0.1 units/kg/h. A prospective randomized study has shown that a bolus dose of insulin can be avoided if hourly insulin infusion is given at the rate of 0.14 units/kg body weight.[2] As per ADA recommendations criteria for resolution of DKA is blood glucose less than 200 mg/dL with any two of the three including

- Bicarbonate ≥15
- pH >7.3
- Anion gap ≤12.

Patients with HHNKC should be hospitalized and treated in similar way with goals of correcting volume deficits, reducing plasma hyperosmolality to normal. Hyperglycemia will be corrected with insulin while providing intravenous rehydration to resolve HHNKC promptly. After doing early fluid replacement with 1 liter of normal saline in first hour, fluids should be given intravenously as per patient's hemodynamic and electrolyte status maintaining hourly infusion between 250 and 500 mL/h. Patients with normal or high corrected sodium can be shifted to half normal saline after 1 hour. Dextrose of 5% or 10% to be added after plasma glucose level approaches 250 mg/dL. Total body potassium deficit should be replaced after urine output is adequate. Between 20–30 mmol (20–30 mEq) potassium in each

liter of intravenous fluid should be added, when serum potassium level touches less than 5.2 mmol/L and patient start passes urine. As insulin therapy causes intracellular shift of potassium, it is recommended that insulin should not be started if the serum potassium is less than 3 mmol/L (<3 mEq/L) if it is needed, so that it may not worsen hypokalemia. Routine replacement of phosphate is not advisable. Insulin should be started only after correction of hypokalemia at the same dose as in DKA. If plasma glucose does not go down by 50–75 mg/dL/h from the initial value in the first hour, insulin infusion should be increased every hour till it touches 250–300 mg/dL and is to adjusted with dextrose to maintain this level until HHS is resolved.[9] Insulin infusion can usually be stopped once patient starts taking orally but intravenous fluids can be continued a bit longer if intake is not adequate. Normal osmolality and regaining normal mental status are the signs of recovery.

LA can easily be prevented if we can stop cardiovascular disease or sepsis in patients with diabetes maintaining optimum glucose control and augmentation of other risk factors. Most effective treatment for LA is to stop lactic acid synthesis improving tissue oxygenation. Treatment of underlying conditions like shock or myocardial infarction by restoring fluid volume, cardiac function, treatment of sepsis, and hyperglycemia are the mainstays of treatment.[19]

Risk of hypoglycemia can be reduced by using technological advances, which improve insulin delivery may it be insulin pump, sensor technology in glucose monitoring and using designer insulin analogues with intensified teaching and improving compliance. The goal of treatment of hypoglycemia is to immediately increase the blood glucose approximately ~55–70 mg/dL, which can easily be achieved with glucose tablets, sweetened fluids in patients who are not lost their consciousness and intravenous dextrose or glucagon injection in unconscious patients.[11,20]

Conclusion

Despite increasing awareness, technological advancements, development of designer insulins, and clear cut guidelines, acute metabolic complications are on the rise in last two decades. DKA is not only remained a complication of type 1 DM. With the advent of SGLT-2 inhibitors now we can see it in patients with less than 200 mg/dL plasma glucose level as euglycemic ketoacidosis. Apart from this pump failure, missing the dose of insulin knowingly or unknowingly, infections, acute illness, inadequate insulin treatment, or other treatment errors have caused not only higher occurrence of DKA but also HHNKC. LA has emerged as more frequent acute complication than earlier due to higher use of biguanides like metformin in patients with renal failure. Rising alcohol abuse has also posed a challenge of LA among people having diabetes. Intention of maintaining lowest possible HbA1c has caused an increase in hypoglycemia. Increasing use of self-monitoring of blood glucose (SMBG) devices and sensor technology has made it possible to detect and document hypoglycemia at every level. Undoubtedly it adds up the protection of patient when we can easily know overnight and early morning hypoglycemia but obviously it is affecting statistics of hypoglycemia. Sensible use of advanced technology in newer medications, insulin analogues, delivery devices, and sensors can reduce overall acute complications in diabetes. Increasing awareness among patients and their relatives is the most important step to begin with.

CHAPTER

52 Environmental Endocrine Disruptors and Diabetes: Novel Insights from Nallampatti

Krishnan Swaminathan

Abstract

There has been a huge explosion of diabetes over the last decade, especially in lower and middle income countries. While traditional risk factors like diet, lifestyle, urbanization, fast food culture, and less physical activity are extremely important risk factors, we believe that these factors alone do not explain the huge increase in diabetes in India. Our work in Nallampatti showcases the effects of endocrine disruptors, especially pesticides and heavy metals in the prevalence of diabetes and atherosclerosis. While in no way this study is confirmatory of the association, our work does highlight important unexplored aspects of diabetes pathophysiology in India that needs further large scale studies.

Introduction

South Asia, particularly India, home to around 18% of the world's population, is currently in the midst of an epidemiological transition from infectious and nutritional illness to non-communicable diseases (NCDs), especially cardiovascular disease, predominantly driven by a cluster of "traditional risk factors" like diabetes, prediabetes, obesity, diet & lifestyle, hypertension, hyperlipidemia, and atherosclerosis. Individually, each of the above risk factor has huge health care, economical, and societal implications. Collectively, this "Axis of evil" is a disaster in the making for India and a "ticking time bomb" that will wreak the nation's health.

Diabetes is a "vascular disease" and not a metabolic disorder alone. India leads the world in the numbers of patients with diabetes and has the infamous tag of being referred to as the "Diabetes Capital of the world." Currently, it would not be an exaggeration to practically define diabetes as a state of premature cardiovascular death associated with chronic hyperglycemia and in the absence of effective treatment to control glucose levels, will lead to blindness, kidney failure, and foot amputation. In fact, there is good evidence for terming diabetes as a "coronary risk equivalent." Studies have shown that diabetic patients without a previous heart attack have the same high risk of getting a heart attack as someone without diabetes who already had a previous heart attack.[1] Poorly controlled diabetes is a major risk factor for end stage kidney disease (ESRD) needing dialysis and renal transplants in India. More than 1 lakh patients enter the renal replacement therapy annually in India, but due to extremely scarce resources, only 10% of this population receives renal replacement therapy.[2-4] Poorly controlled diabetes is a leading cause of foot amputations in India. Foot ulcerations occur in 25% of patients with diabetes and approximately 15% of such foot ulcerations result in amputations.[5] With this background, we are now witnessing a huge explosion in diabetes epidemic that can have potentially catastrophic consequences for the health care of our nation. One hospital admission with a diabetes-related complication will drain the family of all their resources, especially from the, lower socioeconomic backgrounds, as 70% of Indian urban and rural households visit only private sector providers over public services.[6]

Prediabetes is the prelude to diabetes. Colloquially, this is termed as "borderline diabetes." Intuitively, one would underestimate prediabetes, as this is not yet full-blown diabetes. However, even many physicians are unaware that prediabetes is also associated with the same set of comorbidities like heart attacks and strokes, very similar to diabetes.[7] Indians also have one of the highest conversion rates from prediabetes to diabetes. Data from follow-up of patients over 10 years from the Chennai Urban Study (CURES Study) indicates a conversion rate of prediabetes to diabetes in the order of 60%.[8] Taken together based on the above discussions, Indians have one of the highest incidence rates for diabetes with rapid conversion from prediabetes to diabetes. The pressing need of the hour is to slow down and reverse this epidemic in our population.

The concern for all health-care professionals and policymakers is the fact that the transition in both the risk factors and diabetes prevalence in India has occurred over a relatively short period of time.[9] To compound this, India is a "Nation within a Nation," where many states have populations close to that of countries in Europe! Therefore, there will be huge regional variations in diseases and risk factors that will have a bearing on how scanty resources can be utilized to optimize health care. Our concern is primarily centered toward rural Indian population where the triple burden of lack of awareness, health care costs, and poor health care facilities add significantly to morbidity and mortality from non-communicable diseases. The progression of this NCD epidemic, especially in rural areas, is characterized by a multitude of factors including rapid urbanization, reversal of socioeconomic gradients, fast food culture, less intake of fruits and vegetables, tobacco and alcohol use/abuse, less access to health care in the poorer socioeconomic strata of the society, and much more.[10] Efforts to understand the pathophysiology of this transition have been traditionally focused on the above factors. However, there is growing body of evidence for the role of non-traditional risk factors, especially pesticides and heavy metals in fertilizers, in the development of diabetes, prediabetes, hypertension, atherosclerosis, and cardiovascular disease.[11-32] Our aim was to adopt and explore the burden of NCDs in a traditional rural farming village in our area, do a longitudinal follow-up, and assess the role of both traditional as well as non-traditional risk factors like pesticide and heavy metal use in this population.

Material and Methods

KMCH: Nallampatti Non-communicable Disease-I (KMCH-NNCD-I) Study

Nallampatti is a typical farming village in Tamil Nadu, South India (Latitude: 11°21'2.39" N; Longitude: 77°32'4.79" E) **(Fig. 1)** with a population of around 3,000. This study, named the "Nallampatti non-communicable disease study-I—2015 (NNCD-I, 2015)," was conducted on every Sunday during a period of 4 weeks (15 March–05 April, 2015). Advertisements were given through pamphlets, word of mouth, and through administrative heads like the Panchayat President. The study design and protocol were approved by KMCH Ethics Committee, Kovai Medical Center and Hospital Limited, Coimbatore (Approval No. EC/AP/02/2015, dated 16 Feb, 2015), and informed written consent was obtained from all participants prior to participation and followed the principles of Declaration of Helsinki.

A total of 865 participants were screened with a questionnaire, bloods including HbA1c, non-fasting lipid profile, creatinine, carotid intima thickness (CIMT) using carotid ultrasound transported to the venue along with urine for heavy metals and serum pesticides. Methodology for all the above along with definitions for diabetes and prediabetes have been published.[33-35] All subjects native to the village aged more than 20 years were invited for the study. Urine heavy metals and serum pesticides were stored at -80°C and transported to IIT Madras for analysis by ICP-MS and GC-MS, respectively.

Results

The topline results from our study showed a diabetes prevalence of 16.2%, prediabetes of 42%, hypertension 39%, hypercholesterolemia in 33%, and atherosclerosis in 10.3%. This was much higher than the ICMR-INDIAB prevalence **(Table 1)**, even though comparing both studies may be analogous to comparing apples and oranges! Allowing for the methodological variations and confounding factors, the double-digit prevalence of diabetes was very consistent with our clinical experience and other studies done by our study group in rural Madurai & Theni districts of Tamil Nadu.

On multiple logistic regression analysis, diabetes in our rural population was surprisingly not associated with traditional risk factors except for age **(Table 2)**. Generally,

TABLE 2 Multiple logistic regression with diabetes as dependent variable: non association of traditional risk factors with diabetes

	KMCH-NNCD study	
	Odds ratio (95% CI)	p-Value
Age	19.9 (8.55–46.5)	<0.0001
Male sex	1.13 (0.63–2.01)	0.672
Smoking (daily smokers)	0.71 (0.15–3.47)	0.676
Alcohol (daily drinkers)	1.92 (0.389–9.504)	0.422
Generalized obesity	1,295 (545–2356)	0.996
Hypertension	1.50 (0.98–2.30)	0.060
High LDL-cholesterol	0.83 (0.51–1.35)	0.449

one would intuitively expect diabetes to be associated with other traditional risk factors like smoking, obesity, hypertension, and hypercholesterolemia. The absence of such an association in our study raised a hypothesis generating question as to whether there may be non-traditional risk factors involved in the huge burden of NCDs in rural areas, especially in farming populations.

Urine Heavy Metals and Diabetes

Fertilizers are a big source of heavy metals especially arsenic. Arsenic has been implicated in diabetes by various mechanisms including beta cell toxicity and interference with insulin signaling. Increased level of these urinary metals, especially arsenic and zinc, were noted among the diabetic subjects in comparison with non-diabetic subjects **(Table 3)**. On correlation and regression analyses of the urinary metals with cardiometabolic risk factors (HbA1c, systolic and diastolic blood pressure, BMI, total cholesterol, CIMT-left, CIMT-right, and cystatin-c), only HbA1c, and CIMT showed significant correlation with the metals.

Pesticides and Diabetes

We noticed a significant positive correlation between all the organophosphate residue levels and HbA1c **(Table 4)** indicating the role of insecticides in glucose homeostasis. Based on detection of insecticide residue level, the population was categorized as "detected below limits of detection (LOD)" and "detected above LOD." On multivariate regression analysis between these two groups,[36] significant odds ratio was obtained for monocrotophos, methyl parathion, malathion, chlorpyrifos, and profenofos for prediabetes, while for diabetes, all the above except profenofos showed significant association.

TABLE 3 Odds ratio (95% CI) of diabetes associated with quartile of urinary metals[35]

Conclusion

The work that depicted in this chapter highlights the burden of diabetes, prediabetes, and atherosclerosis in 865 subjects more than 20 years of age in a rural farming population. It also explores the role of non-traditional risk factors like heavy metals in fertilizers and pesticides on the health of the studied population.

In summary, we showed significant associations between heavy metals in urine and pesticides with prevalent diabetes in Nallampatti village. All subjects had heavy metal analysis done in their urine samples, which was then categorized into four increasing quartiles, quartile 1 the least and quartile 4 the most. Increasing urinary levels of arsenic and zinc was associated with diabetes in this study, even after adjustment for multiple confounding factors. The results of this study raise vital research questions on link between metals, especially arsenic used in fertilizers and diabetes & vascular disease.

All of our subjects had serum pesticides measured by GC-MS and the levels were categorized into above and below LOD. Monocrotophos, Methyl parathion, and Chlorpyrifos particularly showed a significant association with diabetes after adjustment for multiple confounding factors. We conclude by hypothesizing that pesticides seem to be an attractive non-traditional "diabetogenic link" for the society at large due to ubiquitous and unscrupulous use of pesticides in the everyday fruits and vegetables we consume, apart from being a risk factor for farmers spraying pesticides without personal protective equipment (PPE).

Doctors and scientists have predominantly focused on traditional risk factors in the etiology of diabetes and vascular disease. Our work is an attempt to focus on the role of non-traditional risk factors, especially agrochemicals in the development of diabetes and atherosclerosis. We envisage progress in the future in the following areas: more focus on occupational safety, especially use of PPEs by farmers, promotion of safer regulatory policies governing the use of pesticides and fertilizers by Governmental agencies, for example, ICAR (Indian Council of Agricultural research) and Agriculture Ministry, Point of care testing devices to assess the levels of pesticides and heavy metals in the blood or urine, (Animal) Work to understand the molecular mechanisms and the efficacy of medications used to treat diabetes and vascular disease in the presence of agrochemicals. Therapeutics targeted at detoxifying diabetic agrochemicals, development of more "metabolic friendly" pesticides, and fertilizers.

We genuinely hope that this chapter has made a meaningful contribution to the health of our rural population. With more efforts, we believe that this work will be translational to make lives of millions of our rural population better.

CHAPTER

53 Type 2 Diabetes: Lifestyle Management Protocol

Ashok Taneja

Abstract

It is estimated that 415 million people are living with diabetes in the world, which is estimated to be 9.9% of the world's adult population (9.9%). Forty-six percent of people with diabetes remain undiagnosed till complications ensue. The problem is more grave in our country since our diet contains more carbohydrates than protein, chemical fertilizers, pesticides use is rampant. India will be Diabetes Capital by 2030 is a true and stark reality. As they say "Early Bird catches the worm", we should target the people with pre-clinical diabetes and people with clinical diabetes with alteration in food habits, enhanced nutrition (quality wise), encouraging people to do aerobic exercises, stopping of tobacco, alcohol moderation, good-healthy sexual life. We should guide people to adopt yoga, meditation, relaxation techniques to make their life happier and healthier. Remember, happiness comes through good quality of life. Happiness Index is directly proportional to good quality of life. Adopt these Top Ten measures for a wholesome improvement in quality of life.

Introduction

Type 2 diabetes mellitus (T2DM) is a global non-communicable lifestyle disease (NCD) prevalent all over the world. The unfortunate part of this disease is its ever increasing incidence in all socioeconomic groups of population. As per estimate of WHO, incidence of non-insulin-dependent diabetes mellitus (NIDDM) is 10% of population, the world over. Whereas in India, the incidence is 11–14%. It is manifested by a chronic hyperglycemic state in conjunction with other metabolic derangements. If left untreated or treated poorly, it leads to complications like end stage renal failure, heart failure, coronary artery disease (CAD), peripheral artery disease (PAD), strokes, retinopathy, erectile dysfunction, and many others. This leads to increased morbidity and mortality in general population.

T2DM is primarily due to either insulin deficiency or insulin resistance or both. Both the states result in increased hepatic glucose output, reduced utilization of glucose by various organs, increased renal reabsorption of glucose, reduced incretin hormones and increased production of glucagon among others.

Currently there is no known cure for the disease but can be controlled enabling the individual to have an improved quality of life. The main aim of management is directed at reducing acute and chronic complications, that is, microvascular and macrovascular.

Epidemiology: Prevalence in India and World

India: There are estimated 72.96 million cases of diabetes in adult population of India. The prevalence in urban areas ranges between 10.9% and 14.2% and prevalence in rural India was 3.0–7.8% among population aged 20 years and above with a much higher prevalence among individuals aged over 50 years (INDIAB Study). Kerala has the largest number of diabetes patients followed by Tamil Nadu and Punjab.

World: It is estimated that 415 million people are living with diabetes in the world, which is estimated to be 1 in 11 of the world's adult population (9.9%). Forty-six percent of people with diabetes remain undiagnosed till complications ensue. The figure is expected to rise to 20% worldwide by 2040. China, followed by India has the highest incidence of T2DM. Lithuania, Sweden, Estonia, Ireland, and 35 more nations have the lowest incidence.

Though, there is no sex preponderance in incidence of DM in males or females. Both are equally affected. Genetic effects, epigenetic mechanisms, nutritional factors, pregnancy and sedentary lifestyle affect the risk and complications differently in both sexes. However, obesity, psychological stress, higher incidence of myocardial infarctions are more prevalent in females.

Of concern, is the population above 18 years of age who are unaware of their diabetic status (52% of diabetics). The percentage of undiagnosed diabetes is highest among the Malays (53%) followed by the Chinese (49%) and the Indians (42%). In terms of diabetes control, only 23.8% of patients in primary care and 12.7% in tertiary institutions were able to achieve their specified glycemic targets.

Risk Factors

- *Biological risk factors:* Body mass index (BM)I; body fat distribution; Brown adipose tissue (BAT); metabolic syndrome (MetS); adipokines; imbalance of sex hormones; gestational diabetes mellitus (GDM), insulin resistance (metabolic syndrome).
- *Health related:* Smoking; alcoholism; lifestyle disorders including sedentary life; excessive intake sugar sweetened beverages.
- *Psychological:* Stress; economic status; sleep deprivation; drugs abuse.
- Pharmacological drug induced like steroids, etc.
- Genetics.

Management

T2DM is basically a combination of lifestyle disorder with genetic predisposition superimposed by pollution and other environmental factors. Obesity or metabolic syndrome further compounds the problem. Non-pharmacological measures are the most important faculties in managing diabetes. Next step is to add OHAs-Insulins. Surgery esp. in diabesity or stem cell or pancreatic transplantation is the other option, but reserved for highly morbid conditions. I hereby, postulate ten Commandants for the management of T2DM **(Box 1)**.

BOX 1 Ten commandments for lifestyle management in DM

• Nutrition therapy	• Alcohol
• Micro nutrition therapy	• Sex
• Exercise	• Stress management including sleep
• Sweetners	• Environmental pollution
• Tobacco	• Pharmacotherapy

TABLE 1 Recommended dietary composition for diabesity

Component	*Energy intake (%)*
Carbohydrates (Sucrose should be <10%)	40–50%
Proteins	20–30% (not to exceed 1 gm/kg body weight)
Fats	20–30%
n-6 PUFA	<10%
n-3 PUFA	<2%) Oily fish is the main source. Once a week
MUFA	10–20%
Saturated	7–10%

Nutrition Therapy (i.e., Diet)

Medical nutrition therapy (MNT) has a great role in preventing or delaying the onset of T2DM specifically with obesity. The basic idea is to control the calories intake as appropriate for the body weight of the individual. Calorie intake depends on work style, BMI, place of work, gender and ethnicity (decides muscle mass of the body). However, the calorie composition should be: Carbohydrates: Normal=60% (Diabesity=40–50%); Proteins: Normal=25–30% (Diabesity=30%, not to exceed 1 gm/kg body weight); Fats: Normal=25–30% (Diabesity≤30% of which MUFA=10–20%; PUFA=7–10% Saturated 7–10%) **(Table 1)**.

In weight reducing diets, a calorie reduction of 500–1,000 cal are planned with simultaneous increase in expenditure of 500–1,000 cal in the form of exercise. ADA, DCCT, RSSDI, Diabetes India recommend the healthy

BOX 2 Nutrition—broad guidelines

- Reduce saturated fats to abot 10% of total fat intake
- Increase MUFA by 40% of balance fat intake
- Increase PUFA by 40% of balance fat intake
- Eliminate transfats totally
- Increase viscous fibers in diet to min. 50 g/day
- Increase vegetable to 6 servings per day
- Reduce refined carbohydrates. Use complex carbohydrates
- Take at least one fruit per day. Daily the color of fruit must change. Preferably use low glycemic fruits
- Add plant/marine sterols or nuts to the diet
- Consume high quality proteins like soy, cold water fish, organic lean meat and poultry
- Exercie 60 minutes daily with aerobics and resistance training
- Achieve ideal body weight, BMI, waist circumference and body fat composition

choice of foods and good physical activity to decrease the risk of diabetes and prevention of CV morbidity and mortality. DASH, mediterranean, ketogenic diets are other concepts for control of diabesity **(Box 2)**.

Micronutrition Therapy

Although use of micronutrients as nutrition therapy is a cornerstone of the management of diabetes, but uncertainty prevails in its guidelines. Whether the micronutrients are causative agents of diabetes or its complications or just innocent bystanders.

Zinc, chromium, iron, vitamin D, alpha lipoic acid, carotenoids, vitamins E and C, selenium, and some of the B vitamins, notably folate, pyridoxine, and cyanocobalamin play an important role in managing diabetes.

Best source of micronutrients are: fruits, nuts, fresh vegetables, sprouts, seeds, sun-shine, fatty fish, egg, and supplements. Cooking oils, flours, rice, cereals, and juices are now being available in the market with fortified vitamin A, D, Calcium, etc. **(Box 3)**.

Exercise

Regular moderate exercise not only utilizes blood sugar but improves blood circulation removing oxidants from the body. It further reduces the development and progression of atherosclerosis; hence reduction in CVD related mortality. Exercise induces longevity by 1.1/2 years in moderate and 3.1/2 years in vigorous exercise

BOX 3 Ideal meal plan

- Reduce carbohydrates in your diet by 20%
- Change eating pattern
- Take fruits with highly glycemic index before the meal as meal prevents surge of glycemia. Daily change the color of fruit. Different antioxidants and high fibers which slow the absorption of carbs
- Nuts and dried fruits should be taken daily. This supplements Vit E & Omega FAs
- Pulses provide micro nutrients. Must include them in diet.
- Increase protein in diet: 2 Eggs or 1 cup chicken, fish, soyabeen, cheese, milk, tofu
- Substitute rice with brown rice or water drained rice
- Snacks in between meals: Should be made of less carbs, high proteins with some fat
- Curd must be taken daily as it keeps stomach healthy with probiotics
- Garlic-Ginger-Mint, Aloe Vera provide good antioxidants
- No Sugar/Jaggery/Palm Sugar—100% cut
- Refined flour—Replace with multigrain
- Increase millet, quinoa, bajra, besan in diet
- Increase high fiber veggies like beans, cabbage, spinach, etc.
- Sprouted beans, salads provide good working snacks
- **Before deciding the Diet/Meal Plan, calculate your Calorie needs**
- 20 Cals/kg Wt (Sedentary), 30 Cals (Moderate), 35–40 Cals (Heavy)
- Ideal Wt; Height in CMs-100 Maintain Proper BMI

individuals. The beneficial effects include reduction in HbA1c; blood sugar levels, triglycerides (TGs) (9.5%); LDL (13.7%), and increase HDL (9.6%). American College of Sports Medicine and AHA Current recommendation for exercise is:

- 30 minutes of moderate exercise (5–6 Scale*), that is, mild increase in HR and breathing—5 days a week.
- 20 minutes of vigorous exercise (7–8 Scale), that is, noticeable change in HR breathing—5 days a week.
- In addition resistance training (weight training × 10 minutes) daily. All major muscle groups should be involved using 8–10 repetitions.

*10-point scale: Sitting is 0 scale and all out effort is 10.
WALK WALK WALK & MORE WALK

WHO recommends 10,000 steps per day for a healthy living. Those who cannot walk should do sitting exercise,

exercise on bicycle ergometer, swimming, pushups, weight training, upper/lower body exercises depending on the deformity. Aerobic exercise especially jogging/cycling/swimming are considered the best.

Sweeteners

Sweeteners are the ingredients that are added to food to bring sweetness, which can be sugar (nutritive) or sugar (non-nutritive) substitutes. Nutritive sweeteners are those sugars which contain carbohydrates and provide calories, whereas, non-nutritive sugars provide only sweetness for taste and no calories. These are:

- Monosaccharides—Sugar, jaggery, khaand, etc.
- Disaccharides—Fruit sugars
- Polysaccharides—Honey, polyols
- Non-nutritive sugars (artificial sweetners)—Aspartame, sorbitole, stevia, tagatose, sucralose, etc.

Which Sugar to Use in DM

- Naturals: Polyols or Polysacchrides, Disacchrides with low glycemic index
- Artificial: Plant product—Stevia or Sucralose (Min. side effects)

Fresh or dried fruits can be used as adjuvants without much rise in blood sugar levels. Additional benefit is that these fruits add vitamins, minerals, and antioxidants to diet. One type (color) of fruit must be taken at least once a day. Fruits with moderate or high-glycemic index should be taken before meals as it does not increase the blood sugar levels much.

Tobacco: Chewing or Smoking

Tobacco smoking and chewing are the leading causes of preventive mortality. The acute effects of tobacco smoking are sharp rise in blood pressure acutely and enhanced risk of renovascular, malignant, and masked hypertension. The effect is due to stimulation of sympathetic nervous system. Whereas chronic use promotes atherosclerosis with fall in HDL, rise in LDL-C, rise in PFFAs levels, thickening of arterial walls, especially the peripheral arteries, increased levels of carboxyhemoglobins with resultant coronary insufficiency, high platelets adhesiveness, high plasma fibrinogen levels, increased risk of subarachnoid hemorrahges. A study from Canada indicated that women who smoke are more at risk of preeclamsia and eclamsia. Smoking in diabetes increases the risk of CV mortality and peripheral neuropathy.

Alcohol

Alcohol use has been a very debatable issue for a very long time. Safe limit, however, is no alcohol.

Mild level of alcohol intake lowers the risk of thrombosis due to decreased inflammation markers and increased HDL levels. Moderate to heavy drinking impairs insulin release and hyperglycemia with increase in CVD related mortality and liver failure and pancreatitis. Chronic and more than permissible alcohol intake is associated with increased LDL, TGs, increased inflammatory markers, insulin resistance, increased incidence of cardiomyopathy, vent, arrhythmias, and endothelial dysfunction.

One standard drink is 10 gm of pure ethyl alcohol. This amounts to 375 mL of beer (5% alcohol); 150 mL of wine (12% alcohol), and 45 mL of whiskey (40% alcohol). This is considered safe limit in a day for men. For women it is 75% of above values. Red wine offers better protection due to presence of plant sterol—resveratrol. But wines and beers contain high levels of carbohydrates, hence calorie count is must while taking alcohol.

Caution: No alcohol is the best option.

Sex

Studies show that men with diabetes often have reduced testosterone levels, which can affect their sex drive. Moreover diabetes damages the blood vessels, which affect blood flow to the penis leading to erectile dysfunction. Intimacy is ageless. It makes you young, energetic and you live longer with good quality of life. Tips for better sex in diabetics are:

- Approach sex like exercise with full emotional support.
- Use a lubricant. If a woman with vaginal dryness, a vaginal lubricant can make sex feel better.
- Creativity is sexy watch erotica together. Explore different ways to climax.
- Limit alcohol. A little alcohol may boost your desire, but drinking can also make your blood sugar level drop quickly.
- Get help for emotional issues. Depression, anxiety, poor self-image, and other emotional concerns can hurt your sex life.
- Relax: Be confident, be relaxed, do not try to force yourself. Be active.
- Use sildenafil or tadalafil, if ED is the problem.

Psychological Stress

Yoga, Meditation, Positive Thoughts Therapy, Laughter Therapy, Music, and Dancing. Stress result in imbalance of hormones and catecholamines, which has deleterious effects on blood sugar levels and blood pressure. Stress act primarily on hypothalamus pituitary axis to produce more steroidal hormones, decrease insulin sensitivity and alter calcium-vitamin D metabolism, increased sympathetic stimulation and decreased parasympathetic system. A variety of measures have been suggested to overcome stress and improve lifestyle. Yoga, meditation, music therapy, dancing, and laughter therapy are very helpful in alleviating stress. Professional counselors also play a very important role in managing stress. Enjoying holidays, family vacations, going to movies or theatres, doing arts, paintings, etc. also help in stress management. UKPDS over 12 years, observed the beneficial effects of stress management.

Lifestyle Heart Trial: Pranayam, Surya namaskar, Vrijasan asans; Meditation, Group support sessions, Music therapy all lead to correction of Glycosylated HbA1c levels, dyslipidemias with reversal of atherosclerotic plaques.

Meditation, sound sleep for 6–7 hours, listening to music, dancing all lead to reduction of stress hormones, relaxation of mind and body. This results in improving good quality of life.

Environmental Pollution

- *Air Pollution:* PM 2.5—SO_2, CO_2 are the main culprits from Prali burning, vehicles, thermal plants, increased construction activity.
- *Water Pollution:* Contamination of underground water table with heavy metals like arsenic-mercury, etc.
- *Earth Pollution:* Overuse of pesticides, chemical fertilizers, etc.
- *Noise Pollution:* Affects catecholamine secretion, stress hormones like corticosteroids, dopamine.

Pollutions affect the general health leading to anemia, hypocalcemia, Vit. D deficiency, and other micronutrients deficiency which alters sympathetic-parasympathetic axis dysfunction, and hence, poor control of T2DM. The pollutants increase stress levels also especially noise pollution. This leads to poor insulin secretion and efficacy.

BOX 4 Pharmacoltherapeutics: Oral hypoglycemic agents and insulin

- Biguanides
- Sulphonylureas
- Thiazolidines
- Meglitinides
- SGLT2 inhibitors
- Drugs working on Gut peptides
  - DPP IV inhibitors
  - Incretins
- Alpha Gluciside inhibitors
- Dopamine receptor agonist
- Others
  - Hydroxy chloroquin
  - Amylin agonist: Pramlintide
  - Probiotics like Akkermansia
- Insulins

Pharmacotherapy

It includes oral hypoglycemic drugs, incretins, insulins, surgery like bariatric surgery, duodenal mucosal resurfacing (DMR); islet cells and pancreatic transplants and genetic engineering to alter genes **(Box 4)**.

Conclusion

Goals of therapy for T2DM patients include evaluation of diabetic status, BMI, work style (i.e., sedentary or hard worker), socioeconomic status, presence of comorbidities and patient's willingness or compliance with the drugs management. Always start with lifestyle modification (LSM) followed by oral drugs with or without insulin, depending on the patient's condition and parameters. Diet prescribed to the patient must confirm to his/her tastes, availability, and affordability. Diet should be a balanced diet, rich in proteins, must include seasonal fruits. Drugs used, should also be easily available, affordable, and the regime should be tailor-made to the patient. If socioeconomic status is not good, there is no fun of writing fancy, expensive medicines, which, patient will not take in long run. Patient counseling is must so that he/she understands the modality of treatment and the need of initiating insulin therapy or undergoing surgery. The ideal target of control of diabetes is HbA1c of 6.5–7.0% in Indian population. Though, it may be difficult to achieve in elderly, but tight control always gives benefit in terms of reducing complications, and hence enhanced morbidity and mortality.

CHAPTER

54 Top Three Knowledge Gaps in Diabetes

Amit Saraf

Abstract

It's a well-accepted fact that treatment of diabetic patients has some lacunas, which may range from non-compliant patient to a busy clinician. This chapter tries to encompass these gaps in the treatment of diabetes.

Traditionally the top three knowledge gaps in clinicians include:

- Type(s) of diabetes
- Insulinization: Too early/too late
- Complications of diabetes

Similarly the top three knowledge gaps in patients include:

- Diabetes: Remission OR Cure?
- Diet
- Social media prescriptions

Introduction

Top three knowledge gaps in diabetes can be divided into:[1,2]

- Top three knowledge gaps in Clinicians
- Top three knowledge gaps in Patients

Top three Knowledge Gaps in Clinicians

Knowledge gaps in clinicians can be divided into:

- Type(s) of diabetes
- Insulinization: Too early/Too late
- Complications of diabetes

Clinician Knowledge Gap I

- *Identifying* types of diabetes:[1,2] Many a times, especially in the "gray-zone area patients," for example, patients with newly diagnosed hyperglycemia and in the age group of 20–25 years, type of diabetes is not routinely attempted to be sought. This is very important as it dictates not only treatment but also prognostication. Some ready reckoners for the type of diabetes can be—
  - Young (15–25 year old) diabetic
  - Type I (GAD +, C Peptide +)
  - MODY (Young on OADs, Genetic link)
  - LADA (Type II, GAD -, C Peptide -)
  - Elderly Type I (GAD +, C Peptide -)

Type(s) of diabetes[3,4]—

- Type 1 diabetes
- Type 2 diabetes
- Genetic defects of β-cell function—
  - Chromosome 12, HNF-1α (MODY 3)
  - Chromosome 7, glucokinase (MODY 2)
  - Chromosome 20, HNF-4α (MODY 1)
  - Chromosome 13, insulin promoter factor-1 (IPF-1; MODY 4)

- Chromosome 17, HNF-1β (MODY 5)
- Chromosome 2, *NeuroD1* (MODY 6)
- Mitochondrial DNA

In some cases the diabetes is secondary to some other pathophysiological process, which if identified, will lead to better treatment protocols in the patient. For example—

- Syndromes of Extreme Insulin Resistance
- Transient Hyperglycemia
- Diseases of the exocrine pancreas
- Endocrinopathies
  - Acromegaly
  - Cushing's syndrome
  - Glucagonoma
  - Pheochromocytoma
  - Hyperthyroidism
  - Somatostatinoma
  - Aldosteronoma

Certain medical conditions can lead to diabetes themselves, such as—

- Glucagonoma
- Chronic pancreatitis
- Cystic fibrosis

Also, certain conditions linked with Type 1 DM, such as[4,5]—

- Celiac disease
- Rheumatoid arthritis
- Addison's disease
- Autoimmune thyroid disease
- Celiac disease
- Rheumatoid arthritis
- Addison's disease
- Autoimmune thyroid disease

Similarly, certain conditions are linked with Type 2 DM, such as—

- Alzheimer's disease
- Polycystic ovary syndrome (PCOS)
- Cushing's syndrome
- Pancreatic cancer

If the "gaps" enumerated above in the etiopathogenesis/pathophysiological conditions are ascertained in all patient right at the time of diagnosis, it helps in better treatment outcomes.

Clinician Knowledge Gap II

- Insulinization: Too early/Too late
- Targeting the "Dirty Dozen"

Insulinization: Too early/Too late[5,6]—

The following pie-charts demonstrate the overall blood sugar control in diabetics worldwide. As observed, the sugar control is not very optimal. **Figure 1** demonstrates worldwide prevalence of glycaemic control.

Worldwide studies have repeatedly proven that insulin is by far the most effective drug for sugar control, as seen by the following bar chart.[6,7] **Figure 2** illustrates that early Insulanisation is the need of the hour for an effective glycaemic control.

In spite all of the above, there is a lot of inertia for initiation of insulin therapy and this inertia is from clinicians and patients alike, this "gap" in the management of diabetics need to change.

Target the Dirty Dozen[7,8]—

ADA consensus statement of 2016 says, target the treatment of organ damage early on, irrespective of initial glucose levels. Most of the clinicians in routine busy out-patients practice tend to only observe and dictate therapy depending on the blood sugar reports. This 'gap' in the mind-set needs to change to allow routine assessment of 'ominous octave', to create a wholesome treatment for the patient.

Clinician Knowledge Gap III

Complications of diabetes—Complications of diabetes can be categorized in this scenario into complications due to "infections" and complications due to "vasculopathy."

Infections—

It is very imperative to look for infections leading to & associated with diabetic ketoacidosis—

For example—

- Mucormycosis
- External otitis media
- Emphysematous pyelonephritis
- Well controlled diabetic on a OPD follow-up, acutely becomes uncontrolled—look for underlying infections (do not only control BS).

Many times, especially targeting only sugar management may cause a "gap" in the treatment of a critically ill diabetic leading to morbidity and or mortality.

Vasculopathy[8,9]—

Clinicians should not forget to correlate between organ-specific vasculopathy:

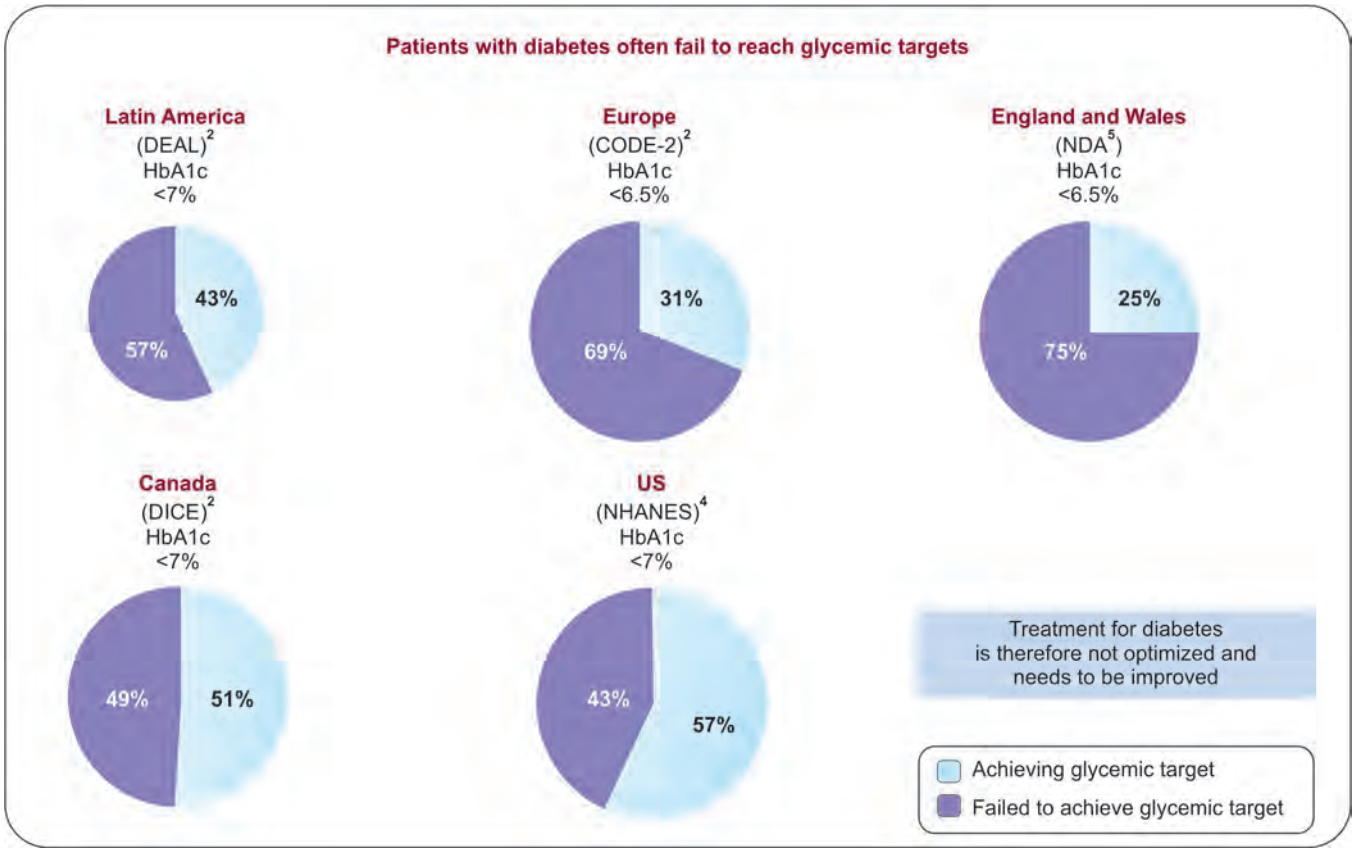

Fig. 1: Worldwide index of glycemic targets achieved

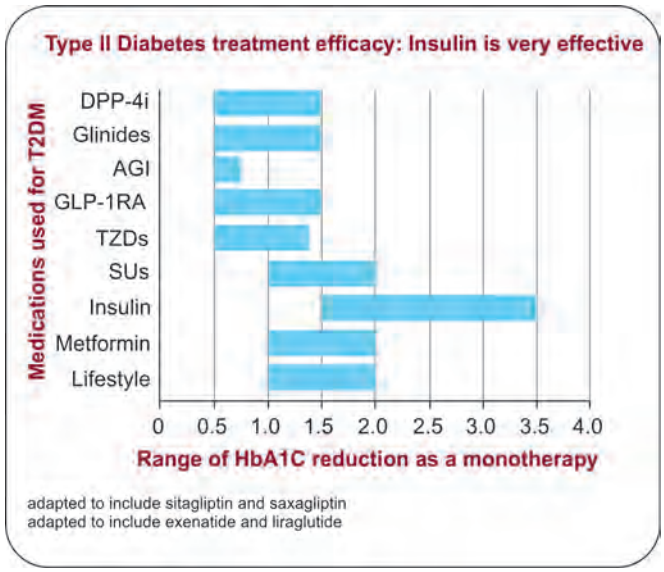

Fig. 2: Insulin effectively compared to OADs

For example—

- Retinopathy if present—look for nephropathy
- Microalbuminuria if present, retinopathy absent—look for causes beyond diabetes
- Erectile dysfunction if present—work up toward ischemic heart disease

Top three Knowledge Gaps in Patients

Knowledge gaps in patients can be classified as—

- Diabetes: Remission or Cure??
- Diet
- Social media prescriptions

Patient Knowledge Gap I

Diabetes: Remission or Cure??—Patients have to be clearly counseled that diabetes is a lifelong disease. Only remission is possible not cure!!, which in simple words means, a diabetic can go off drugs and can be controlled on

only lifestyle changes, but he does not become "Diabetes Free." This "gap" in patient knowledge will ensure better follow-up compliance.

Patient Knowledge Gap II

Diet[10]—Various diets such as intermittent fasting diet, crash diets, supplementary diet, etc. are advocated and are being followed. The "gaps" in knowledge of these diets are—

- Diet have to be under guidance—"no one single diet suits all."
- Sustainability—the patient should be clearly made aware that most of the individuals fail to keep up the dietary restrictions lifelong.

Patient Knowledge Gap III

Social Media Prescriptions—This "gap" in knowledge encompasses Doctor-Patient prescriptions over social media platforms. Though this is a very "convenient" method, it has its own inherent risks such as not involving physical examination of the patient; some medical parameters may get omitted during such communications, etc. The patient has to be made very clear that online consultation does not replace a physical consult and should be sought only in certain scenarios, such as lockdowns, etc.

Conclusion

Top three Knowledge Gaps in Clinicians:

- Type(s) of Diabetes
- Insulinization: Too early/Too late
- Complications of diabetes

Top three Knowledge Gaps in Patients:

- Diabetes: Remission or Cure??
- Diet
- Social media prescriptions

CHAPTER

55 Candid and Equitable Diabetes Care: Beyond the Bounds of Possibility?

Supriyo Mukherjee

Abstract

The prevalence of diabetes in India is enormous and remained at 11.8% in last 4 years. Approximately 77 million people are living with diabetes while nearly 43.9 million (57%) of the cases of diabetes are undiagnosed. Moreover, challenges such as malnutrition, poverty, and socioeconomic burden precipitated by communicable diseases strain the already burdened health-care system of India. Adding to this, the Indian public health infrastructure can be characterized as chronically underfinanced since 1999. The Indian health sector received only 1–1.5% of the total GDP annually and even less is allocated to public health, health promotion, and awareness campaigns. There is lack of cohesion amongst a plenty of unregulated private centers with varying level of quality, poor coordination and communication, weak referral mechanisms, poor record-keeping, negligible accountability, and transparency which promotes distrust in medical establishment. Therefore, there is large-scale inequity in terms of accessibility and quality of service provision between rich and poor. Potential solutions are private and public sectors, especially public-PCC, need to be strengthened. A strong political will and a robust, evidence-based translational research, a bridge between theory and reality, achieve this beyond the broad structural characteristics of system and make the journey worthwhile for all the stakeholders.

Introduction

Dr. Amartya Sen reflected, "Health equity cannot be concerned only with health seen in isolation. Rather, it must come to grip with the larger issues of fairness and justice in social arrangements, including economic allocations, paying appropriate attention to the role of health in human life and freedom."[1]

Equitable diabetes care means that the individuals have access to affordable, high quality culturally and linguistically appropriate care in timely manner. This includes regular preventive care, in addition to emergency care, as well as mental health support.[2]

Inadequacies in Diabetes Care: Current Scenario in India

Diabetes is a complex, chronic disease recognized as an important cause of premature death and disability, and disproportionately affects socially and economically disadvantaged population, especially poor and young sub-populations of Third World Countries.[3,4]

The prevalence of diabetes in India is enormous and remained at 11.8% in last 4 years. Approximately 77 million people are living with diabetes while nearly 43.9 million (57%) of the cases of diabetes are undiagnosed.[5] To complicate the matters more, majority of the T2DM patients have uncontrolled diabetes with HbA1c around 9%.[6] Moreover, challenges such as malnutrition, poverty and socioeconomic burden precipitated by communicable diseases strain the already burdened health-care system of India. Adding to this, the Indian public health infrastructure can be characterized as chronically underfinanced since 1999. The Indian health sector received only 1–1.5% of the total GDP annually and ranks 184th out of 191 in terms of GDP percent-spend on health care. Even less is allocated to public health, health

promotion, and awareness campaigns; consequently there is large-scale inequity in terms of accessibility and quality of service provision between rich and poor.[7]

Economic model suggests that an additional 1% in GDP spent on precisely defined proven health schemes would save 480 million healthy life years.[8]

Fee for service health seeking prevails in India and public-private fragmentation of health system results in skewed distribution of human and financial resources. Additionally, with disparity in expenses, infrastructure and manpower, drug delivery, and training are ubiquitous in India.[9] Annual health expenditure in India, 80% of which is spent in private facilities, amount to trillion Indian rupees—greatest of which is perceived by the households.[8] Thus, those who cannot afford fee can only access services characterized by poor infrastructure, overworked, and yawning personnel. In other words, poor quality service provision is left for the unprosperous.[9]

Along with these lines the inverse curve law states that "the availability of good medical care tends to vary inversely with the need of it in a population served," which holds true in low- and middle-income countries.[10]

Also, direct specialist consultation is common in India and there is no obligation regarding continuity of care from either physician or patients. There is lack of cohesion amongst a plenty of unregulated private centers with varying level of quality, poor coordination and communication, and weak referral mechanisms.[9] Poor record-keeping, negligible accountability and transparency present opportunities for unethical practice promoting distrust in medical establishment. There exist many functionally illiterate populations with consequent poor health literacy.[11] Whatever the underlying causes, inadequate glycemic and comorbid risk factors manifest in seriously disabling and life-threatening complications.[12,13]

Majority of resource constrained Indians are deprived of annual routine monitoring of health indicators, BP, BMI, eye and feet examination, serum cholesterol, serum creatinine, HbA1c, urinary albumins, smoking review, mental health evaluation, etc. which form the regular elements of diabetes care along with the access to specialist health-care professionals including ophthalmologists, podiatrist, and dietitians.

However, the ambition is to achieve universal health coverage for successful diabetes care by making the health services accessible with the targets to provide essential medicines and diagnosis to at least three-fourths of the cases by 2025.[14]

Need and Awareness

It is essential to have person with diabetes as caregivers and sustain a multitude of daily self-management decisions that include:

- Compliance with medications regarding correct dose, frequency, route, and protection against adverse effects.
- Lifestyle modification: Adequate physical activity and daily exercise with a healthy diet.
- Cessation of smoking and harmful use of alcohol.
- Self-monitoring of blood glucose.
- Foot care.

Diabetes Self-Management Education and Support (DSME/S) for educating the patient on diabetes self-care is an intrinsic and vital segment of continuous care model of primary care facilities, which is very fruitful in improving diabetes-related health outcomes.

The ADA has endorsed measuring and tracking key results of DMSE/S, comprising self-management, clinical outcomes, health status, and quality of life.[15]

Challenges in Provision of Diabetes Self-management Support through Public Sector Primary Care as Candid and Equitable Diabetes Care

- Lack of readiness of Public sector—Primary Care Centre for diabetes self-management
- Lack of awareness and understanding among patients with diabetes
- Suboptimal prescription adherence and therapeutic inertia
- Poor diabetes clinical audits and prospective registries
- Lack of inclusion of mental health services with diabetes care
- Enablement of smoking and tobacco cessation
- Dearth of diabetes educator and dietitian at the point of care level
- Lack of private public partnership
- Lack of political will

Potential Solutions

Strengthening of public sector-PCC is the key. Diabetes care research should also focus on quality of care accorded in primary care facility, especially in resource constrained settings.

Feasibility of adherence, avoidance of clinical inertia, patient counseling, peer education, provision of uninterrupted drug supply through team based DSME/S for patients in primary care need high quality trained nurses, MPWs, and diabetes educators. A robust back up of laboratory investigations also help in maintaining the flow of patient care.[11]

Depression plays an important barrier in achieving optimum patient adherence to treatment. It can be effectively managed by planned community outreach programs, by setting up of yoga or meditation centers for the patients, using a proper peer support system.[11]

A valid and practical adherence assessment system is necessary to reduce clinical inertia to a certain extent. Proper and targeted training of health workers and adequate supply of insulin and insulin syringes to avoid out of pocket expenses is of paramount importance.[11]

This surely would help to balance the economic burden on the society and cost effectiveness of diabetes therapy.

Specific Models of Sustainable Health-care Delivery and Disease Prevention in Resource Constrained Environment

Professor V Mohan et al. demonstrated in MDRF, Chennai, how framework of systemic research may be applied to diabetes in developing countries to address deficiencies in knowledge and inequities in care. The MDRF and its associated clinical facility provide a good example of this. It illustrates the value of structured research in laying a foundation of policy development through assessing burden and translating evidence into practical responsive interventions, as well as harnessing the benefits of interventional collaborations and information technology.[9]

Alternative form of financing must be sought since the cost of health care is so burdensome in most developing countries draining family and societal resources. Charging fee relative to respective income may be feasible in a context of fee for service facilities which has been hugely successful for India's Aravind Eye Hospital (AEH).[16]

Research Centre for Diabetes Hypertension and Obesity (R.C.D.H.O.), established in 2002 in district of Samastipur, is focused on serving the impoverished population of North Bihar and around. The idea to set up a non-profit centre emerged from management of diabetes and related comorbidities with huge lapses in the follow-up due to complex interplay of poverty, lack of awareness and education, daily-wage loss, misinformation, and myths. Those resource-poor patients later landed in the same clinic with life threatening infections, CKD, heart failure stroke, or blindness.

The centre detects, treats, educates, and defines timely and necessary referral pattern, and undertakes clinical and epidemiological research in sustainable and equitable manner charging fee relative to respective income.[17] The role of private sector in diabetes care also needs to be made more accessible to the general population.[18]

Role of Private Sectors in Equitable Diabetes Care

As we aspire to grow to a 5 trillion US dollar economy by 2025, private sector has a crucial role to play not only in even-handed and objective diabetes care but also in universal health coverage (UHC). It is due to widely divided and dispersed health infrastructure the voice of private sector is muddled and often goes unnoticed. This needs to change and we need to align it to our national goals of a high quality, affordable, accessible, equitable health system made in India for India.[18] Unfortunately the cost of private health care is still about four to six times greater than our country's public health care. The public health services are hugely grant-aided and supported by Indian government through interest in free capitals, interest rate subsidy, free land, electricity, and a number of other rebates and grants, all of which make it difficult to compare the real efficiency and comparable cost of service deliveries. Thus, there is large private-public gap in logistics, capacity, and delivery of care.

Conclusion

Both private and public sectors, especially public-PCC, need to be strengthened. A strong political will and a robust, evidence-based translational research, a bridge between theory and reality, achieve this beyond the broad structural characteristics of system and demonstrate if the financial benefits are reproducible, have a fair distribution and are collaborative with hand in glove approach. All of it guarantees a minimum set of core services of equitable diabetes care backed by our unified

Contd...

Contd...

common pool of national resources which make the journey worthwhile for all the stakeholders.

"Not everything that is faced can be changed but nothing can be changed until it is faced." **–James Baldwin**

CHAPTER

56 Resistant Hyperglycemia—A Practical Approach

Raveendran AV

Abstract

Blood sugar level not responding to a reasonable dose of oral anti-diabetic medication or insulin or other injectable therapies is called resistant hyperglycemia which is common in clinical practice. We will briefly review the causes of resistant hyperglycemia and practical approach to tackle this issue.

Introduction

Hyperglycemia not responding to usual doses of oral anti-diabetic medication or insulin or other injectable therapies is a common clinical challenge. In type 2 diabetes mellitus (T2DM), most of the time its transient due to coexisting acute medical condition. Hyperglycemia not responding to usual doses of medication can be due to some rare conditions associated with severe insulin resistance.

Lots of people with diabetes are not achieving treatment targets and this contributes to increased risk of development of complications. Common factors contributing to worsening of diabetes control is given in **Box 1**.

In people with T2DM, failure to respond to oral hypoglycemic agent (OHA) is a common issue. Most of the time it shows the progression of the disease, with loss of beta cell function.

BOX 1 Factors that can contribute to worsening of glycemic control

- Decreased compliance with:
  - Diet
  - Exercise
  - Medical regimen
- Weight gain
- An intercurrent illness
- The use of medicines causing:
  - Increase insulin resistance
  - Interfere with insulin release
  - Increase hepatic glucose production
- Progression of the underlying disease process:
  - Decreased insulin secretion
  - Increased insulin resistance
- Undiagnosed type 1 diabetes with gradual destruction of the pancreatic beta cells:
  - "Latent Autoimmune Diabetes in Adults" (LADA)
- Therapeutic inertia

Oral Hypoglycemic Agent Failure

Failure to respond to OHA can be of two types: primary or secondary.[1]

- *Primary failure to OHA:* When a newly diagnosed patient initially classified as T2DM has little or no glycemic response to OHA, it is called Primary OHA failure.
- *Secondary failure to OHA:* In people with diabetes, who have a fair glycemic control on oral medications initially, may subsequently fail to achieve glycemic targets. This is called secondary OHA failure. When sulphonylurea (SU) and metformin (MET), in appropriate doses and diet, lose its capacity to produce

BOX 2 Factors associated with secondary oral hypoglycemic agent (OHA) failure

- Genetics
- Chronic hyperglycemia: Glucotoxicity, Lipotoxicity
- Amyloid deposition in the β-cells
- GAD positive
- ICA positive
- Low body mass index (BMI)
- Duration of diabetes
- Type of OHA used

a desired maximal therapeutic effect (FBG < 8.0 mmol/L or HBA1c < 7.0%) after administration in the absence of other conditions causing hyperglycemia, it is called secondary OHA failure.[2] Factors contributing to secondary OHA failure are given in **Box 2**.

Insulin Requirements and Insulin Resistance

The average total daily insulin dose (TDID) requirement for patients with T1DM is around 0.3–0.8 U/kg/day, except in teenagers where it is 1.0–1.5 U/kg/day. Anyone with a TDID of <1.0 U/kg/day is considered as having normal insulin sensitivity. The average TDID for patients with T2DM is around 1.0–1.5 U/kg/day, but, it can be as high as 2.0 U/kg/day. Anyone with a TDID of 1.0–2.0 U/kg/day is considered to have insulin resistance in the range of typical T2DM.[3]

Insulin resistance is characterized by an impaired response to insulin—either endogenous or exogenous.[4] Insulin resistance is defined as "a state (of a cell, tissue, or organism) in which a greater than normal amount of insulin is required to elicit a quantitatively normal glycemic response."[5] According to TDID requirement, insulin resistance is divided into severe and extreme insulin resistance **(Table 1)**.[6]

Insulin Resistance: Measurement

Various methods to measure insulin resistance are briefly mentioned below:[6-8]

- *Insulin level at fasting:* Fasting serum insulin levels is usually less than 20 μμU/mL in normal individual whereas it is over 70 μμU/mL in those with severe insulin resistance.
- *Assessing the peak level of insulin achieved after oral glucose tolerance test (OGTT):* In normal individual peak post-OGTT insulin level is usually less than 150 μμU/mL, but it is greater than 350 μμU/mL in people with severe insulin resistance.
- *Measuring the index of insulin sensitivity (Si):* Si is the fractional clearance rate of glucose per unit change in the plasma insulin concentration. In normal individual Si is above 5 μμU/mL/min × 10^{-6} whereas in people with severe insulin resistance Si is below 2 μμU/mL/min × 10^{-6}.
- Gold standard technique is to measure insulin mediated glucose disposal, i.e., *MMM* rate by the euglycemic hyperinsulinemic clamp. In normal individual it is above 6 mg/kg/min, whereas in people with severe insulin resistance, it is less than 2 mg/kg/min.

Frequently sampled intravenous glucose tolerance test (FSIVGTT) and Homeostatic model assessment (HOMA) are also used for assessing insulin resistance.

Insulin resistance can be due to inability of the insulin to act effectively or increased destruction of insulin **(Box 3)**.

BOX 3 Mechanisms of insulin resistance

- Defects in insulin receptors:
  - Genetic defect
  - Insulin receptor antibodies
- Interference with intracellular insulin action:
  - Excess of counter-regulatory hormones
  - Inflammatory cytokines
- Increased insulin clearance

TABLE 1 Insulin resistance: Classification

Insulin resistance classification	*Total daily insulin dose (TDID) requirement (unit/kg/day)*
Insulin resistance	>1
Severe insulin resistance	≥2
Extreme insulin resistance	>3

Pseudoresistance

Insulin resistance has to be differentiated from pseudoresistance **(Box 4)**. It can be ruled out by conducting a

BOX 4 Pseudoresistance: Causes

- Nonadherence
- Poor injection technique
- Problems at the site of injection—Lipohypertrophy
- Improper insulin storage
- Malingering for secondary gain

BOX 5 Unexplained hyperglycemia: Causes

- Occult infection
- Recurrent ischemia
- Acute medical conditions
- Cushing's syndrome
- Acromegaly
- Hyperthyroidism
- Lipodystrophy
- Autoimmune diseases
- Hematological malignancy

TABLE 2 Extreme subcutaneous insulin resistance (SIR): Paulsen definition

Three criteria:
• Resistance to the hypoglycemic action of subcutaneous insulin, but not to intravenous insulin
• No increase in plasma-free insulin levels after subcutaneous insulin
• Increased insulin-degrading activity in the subcutaneous tissue

modified insulin tolerance test. During such a test, patients are administered a witnessed dose of short-acting insulin in the clinic, and their blood glucose level is monitored every 30 minutes for a period of 4–8 hours.[6]

After ruling out pseudoresistance, in people with T2DM look for cause of unexplained hyperglycemia, and correct it in order to control blood sugar level **(Box 5)**. Presence of antibodies to insulin and subcutaneous insulin resistance causes poor response to insulin **(Tables 2 and 3)**.[9,10]

Extreme Subcutaneous Insulin Resistance (SIR)

It is characterized by severe resistance to subcutaneous insulin with normal or near normal response to intravenous insulin.[11] Insulin degradation in subcutaneous adipose tissue and muscle result in extreme subcutaneous insulin resistance **(Table 2)**.

BOX 6 Causes of severe insulin resistance

Type A, due to defects in the insulin receptor gene
Type B, due to insulin receptor antibodies
Type C, cause unknown

- *Medications:*
  - Glucocorticoids
  - Atypical antipsychotics
  - Calcineurin inhibitors
  - Protease inhibitors
  - Oral contraceptives
- *Endocrine disorders:*
  - Acromegaly
  - Glucagonoma
  - Thyrotoxicosis
  - Cushing's syndrome
  - Pheochromocytoma
- Anti-insulin antibodies
- HIV-associated lipodystrophy
- Physiological causes:
  - Severe stress:
    - Trauma
    - Sepsis
    - Surgery
  - Diabetic ketoacidosis
    - Pregnancy
    - Puberty

TABLE 3 Antibodies to insulin

Insulin autoimmune syndrome	***Exogenous insulin antibody syndrome***
• Also called Hirata disease • Characterized by spontaneous hypoglycemia • Associated with the presence of insulin autoantibodies • In patients without previous insulin exposure	• Induced by exogenous insulin in diabetic patients • Associated with clinical events, such as hypersensitivity reactions, pregnancy, glycemia variability • Mainly with insulin resistance/hyperglycemia or hypoglycemia

Gustatory Insulin Resistance

Some people with diabetes who are not on diet control develop a special situation. They get into a vicious cycle of

unrestrained eating (hence the term gustatory), resulting in poor glycemic control, which leads to up titration of insulin dose, which in turn leads to further eating, and so on.[6] Because of unrestrained eating results in all these consequences it is called gustatory insulin resistance. This results in progressive weight gain, poor glycemic control, and, ever increasing, large doses of, seemingly ineffective insulin.

Lot of conditions can cause severe insulin resistance, including rare syndromes **(Box 6)**. Proper evaluation helps to find out the causes of resistant hyperglycemia.

Conclusion

Resistant hyperglycemia is a common clinical problem. Most of the time, it is due to severe insulin resistance. Modified insulin tolerance test helps to rule out pseudoresistance. In people with T2DM, any acute medical condition can precipitate resistant hyperglycemia. Severe hyperglycemia not responding to conventional therapy may be due to rare genetic condition associated with severe insulin resistance.

CHAPTER

57 Blood Pressure Targets in Diabetes

Anil Kumar Virmani

Abstract

Hypertension is the major cause of cardiovascular mortality, and it forms a sinister alliance with diabetes, leading to catastrophic results. Besides achieving optimal glycemic goals, it is imperative to treat blood pressure to mitigate any complications. Various guidelines have been published in the recent past. There is a consensus that the threshold of initiating antihypertensive therapy is a blood pressure of 140/90 mm Hg. The goal of treatment is a blood pressure <130/80–85 mm Hg. Because of various reasons, Asians are more susceptible to cardiovascular risk as compared to Caucasians. While treating blood pressure to goals, individual characteristics and the total cardiovascular risk burden should be taken into account. However, the blood pressure should not be brought down to <120/70 mm Hg.

Introduction

There are three paradoxes in hypertension:

- it is easy to detect, but diagnosis rates are dismal; what we see is only the tip of the iceberg;
- it is easy to treat, but the treatment rates are disappointing;
- several potent drugs are available, but unfortunately very few patients are controlled to the recommended goals of 130/80 mm Hg, in fact not even 15%.[1]

Hypertension is the major cause of cardiovascular mortality (about 10 million deaths per year), and resulting in a higher prevalence of strokes, heart failure, and chronic kidney disease. Similarly, hypertension is 1.5–2 times more prevalent in diabetics versus non-diabetics.[2]

The prevalence of diabetes in India is increasing at a very rapid rate, thus increasing the hypertensive burden.[3]

T2DM and Hypertension—The Vicious Twins

The prevalence of diabetes globally is about 9.3%, that is, about 463 million adults (aged 20–79 years). In India, there are about 77 million people with diabetes.[4]

As per data from World Health Organization (13 September, 2019), more than two-thirds of the global population of about 1.13 billion people with hypertension live in the developing countries which generally have low- and middle-income. In India, hypertension is seen in about 29.8% of the population (33.8% in urban and 27.6% in rural).[5]

Between 40–80% of patients with diabetes have hypertension, and patients with diabetes are twice as likely to develop hypertension.

What is Normal Blood Pressure?

In patients without any risk factors, the cut-off level of "normal" blood pressure at which cardiovascular disease develops is not known. In the Multi-Ethnic study of atherosclerosis, 1,457 patients without any risk factors like diabetes (FBS >126 mg%), dyslipidemia (LDL >160 mg% or HDL <40 mg%), and not on any treatment or current tobacco abuse, and a Systolic blood pressure (SBP) between 90 and 129 mm Hg, underwent coronary calcium scoring to detect subclinical cardiac disease, during the period of 2 years from March 2018 to February 2020.

The study concluded that the risk of cardiac disease as per the coronary artery score appears as a stepwise increment right from a SBP of 90 mm Hg and gradually increases with rising systolic BP. These results further confirm that it is important to prevent rise in SBP even within the so-called normal levels of blood pressure, as there also occurs a similar graded increase in cardiac risk with rising SBP levels.[6]

Hypertension in Diabetes

The cardiovascular risk doubles with every 20/10 mm Hg increase in blood pressure.[7] SBP is a stronger predictor of cardiovascular disease and diabetic kidney disease than diastolic blood pressure. In fact, Systolic hypertension is more common (about 65%) in patients with diabetes, and more difficult to control.[8]

Blood Pressure Guidelines: Various guidelines have been published in the last couple of years, by the European Society of Hypertension (ESH 2018), American Heart Association/American College of Cardiology (AHA/ACC 2017), and the International Society of Hypertension (ISH 2020). ISH 2020 and ESH 2018 guidelines categorize the grade 1 hypertension when SBP 140–159 mm Hg and/or DBP 90–99 mm Hg while AHA/ACC 2017 categorize the stage 1 hypertension when SBP 130–139 mm Hg and/or DBP 80–89 mm Hg. *However, the Goal of blood pressure for patients with diabetes is same in all guidelines, that is, less than 130/80–85 mm Hg.*

All guidelines emphasize that in all patients with hypertension and associated diabetes, drug treatment should be initiated at a BP of 140/90 or higher, aiming at a goal of less than 130/80–85 mm Hg.

Cardiovascular Risk in Hypertension

The 2018 ESC & ESH Joint Guidelines for the management of arterial hypertension, published on 9th June, 2018, were the first international guidelines, which not only classified patients with diabetes (asymptomatic, without organ damage) as Stage 2 Risk & Symptomatic patients with diabetes and organ damage as Stage 3 (Highest Risk), but also for the first time classified Asians at a higher risk by 40% (multiplication factor of 1.4 for correction for cardiovascular risk.[9] The ISH guidelines also emphasize the racial and ethnic differences attributed to genetic differences along with a major contribution from life-style factors, which confer a higher risk for Asians.[10]

CV Risk in Hypertension—Are Asians Different?

The association between HTN and CVD is stronger in Asians as compared to the Western population, and occurs at an earlier age. Stroke is more common than CAD in Asian people, whereas the reverse is true in Western population (2.8 times higher—HONEST Study).[11] The slope of the association between rising BP levels and CV events is also steeper in Asians vis-à-vis the Western population.[12] Moreover, Asians are more susceptible for developing high BP even with mild obesity.

Asians also have a genetic predisposition to salt sensitivity, compounded by a high dietary salt intake[13] as well as a significant seasonal variation of BP, with a rise in BP during the winter season.

Asians are more likely to have morning surge and nocturnal hypertension leading to greater BP variability.[14]

The Mumbai/India cohort study showed a 16% rise in risk of deaths and cerebrovascular accidents when SBP was in range of 120–129, but jumped to 73% higher risk, when SBP was more than 130 mm Hg. Moreover, risk of ischemic heart disease rose to 16% & 19%, respectively.[15] Hence, a SBP of less than 130 mm Hg would be more beneficial for Asians.

How Aggressive should be the Treatment of Hypertension in DM?

Overall benefits of intensive BP treatment less than 120 mm Hg were only seen in ACCORD BP study participants receiving standard glycemic control (hazard ratio, 0.71; 95%, 0.56–0.90; P=0.005). Episodes of severe hypoglycemia have interfered with the intensive lowering of BP and probably cancelled out potential benefits of lowering SBP <120 mm Hg in patients with both DM and hypertension.[16]

The participants with DM in the ADVANCE trial benefitted from more intensive BP treatment regardless of baseline BP and of 10-year estimated ASCVD risk. This is consistent with recent guidelines recommending a lower BP target than the previous target of 140/90 mm Hg.[17]

In the ACCORD BP and SPRINT trials, BP was measured using Automated Office Blood Pressure, whose values are generally lower than typical office blood pressure by approximately 5–10 mm Hg. This implies that if protocols of the ACCORD BP or SPRINT are applied to routine clinical practice, then a SBP target higher than 120 mm Hg is required.[18]

Moreover, lowering the blood pressure to less than 110/75 had excess of risk for mortality at 3.5 years.[19]

A meta-analysis of 49 trials, including 73,738 patients by Mattais Brunstrom et al., showed that antihypertensive treatment in patients with SBP >150 mm Hg, reduced risk of all-cause mortality by 11%, CV mortality by 25%, stroke by 23% and end stage renal disease by 18%. For patients with baseline SBP of 140–149, additional treatment reduced risk of all-cause mortality by 13%, MI by 16% and heart failure by 20%. However, if baseline SBP is less than 140, additional treatment increased risk of CV mortality by 15%, and likely an increased risk of all cause mortality by 5%.[20] In another meta-analysis by Mueller et al., in patients with diabetes but without cardiovascular disease, patients with a SBP of 110–119 mm Hg had a lower risk of non-fatal MI by 24% and non-fatal stroke/CHD/total CHD by 15%, as compared to patients with SBP of 130–139 mm Hg. However, risk of heart failure was higher by 20% and all-cause death by 28% in the 110–119 group as compared to 130–139 group.[21]

This basically means that the baseline systolic BP <130 mm Hg conferred significantly lower risk for adverse CV events than did systolic BP 130–139 mm Hg—the current systolic BP treatment goal for this population. It also suggests the association between low baseline systolic BP and all-cause death is not due primarily to CV disease, but rather to concomitant disease or patient factors (not measured by this study) that lead to both low BP and excess risk.

Is there a J-Curve?

J-curve implies a higher risk of cardiovascular risk in patients both with a higher BP >140/90, as well as a lower BP <120/70 mm Hg. It is thus evident that in diabetics with a higher cardiovascular risk, there is a significant and lasting risk of subclinical myocardial injury and myocardial infarction, even when extensive adjustments have been made for any underlying disease burden.[22]

Hence, the available evidence from various well conducted scientific studies suggest that in patients with preexisting CVD, specifically CHD, it is prudent not to lower SBP ≤130 mm Hg. However, for those at higher risk of stroke (such as black and Asian patients) who do not have preexisting CHD, it may be beneficial to reduce SBP <120 mm Hg if this can be done without any harm.[23] The J-curve does exist, but only for patients with preexisting coronary artery disease.

Key Points

The ideal SBP goal for all is less than 130 mm Hg, irrespective of the presence or absence of diabetes. Those having a SBP of 130–139 mm Hg should first be treated non-pharmacologically with intensive life-style modification, and for those with high cardiovascular risk drug therapy should be initiated if resources allow.[24]

However, in the majority, if the goal BP of less than 130/80 is not achieved after 6 months with intensive life style modification, drug therapy should be initiated, irrespective of their cardiovascular risk.

Younger patients less than 40 years of age with SBP of 120–129 mm Hg, and a strong family history of risk factors like hypertension, dyslipidemia or diabetes, drug therapy should be initiated if after 6 months of intensive life style modification, the goal BP of less than 120/80 is not achieved and they are able to tolerate such levels of BP.[25]

Conclusion

It is time to move beyond conflicting evidences and guidelines, derived from clinical trials that have excluded many patients due to age, comorbidities, and various social factors to a more nuanced and individualized approach based on scientific evidence and ethical principles, that can be implemented in clinical practice.

We should be treating patients and not mm Hg!!

CHAPTER

58 Keto Diets and Diabetes Reversal—Can Keto Diet Really Cure Diabetes?

Subrahmanyam Karuturi

Abstract

Based on the science and the clinical studies that have been done over the last 100 years on Keto Diet (KD), KD has made a demonstrable impact on type 2 diabetes management. Such dietary modification led to improvements in glycemic control and medication reduction/elimination in motivated volunteers with type 2 diabetes. While larger, longer-term studies are needed, the data gathered thus far make a strong case for incorporating KD into treatment guidelines for type 2 diabetes. The ADA has recognized that reducing overall carbohydrate intake for individuals with diabetes has demonstrated evidence for improving glycemia. The ADA also notes that reducing overall carbohydrate intake with a low- or very low-carbohydrate eating pattern is a viable option for those patients who are not meeting their glycemic targets or for whom reducing glucose-lowering drugs is a priority. However, the ADA does recognize that low-carbohydrate plans can be hard for diabetics to sustain in the long term and thus recommends that clinicians work with their patients and reassess their nutritional status through the life course.

Introduction

Diabetes mellitus, as defined by the American Diabetes Association (ADA), is a metabolic disease of consistent hyperglycemia, caused by either a defect in insulin secretion, a defect in insulin response, or both.[1]

The ADA has provided criteria for diabetes diagnosis as follows:[1]

- Symptoms of diabetes plus causal plasma glucose concentration more than or equal to 200 mg/dL (11.1 mmol/L). Causal is defined as any time of the day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.
- Fasting plasma glucose more than or equal to 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours.
- Two-hour post-load glucose more than or equal to 200 mg/dL (11.1 mmol/L) during an oral glucose load test. The test should be performed as described by WHO, using a glucose load containing the equivalent of 75 gm anhydrous glucose dissolved in water.

The pathophysiology behind why diabetes occurs is complex. In type 1 diabetes, the primary cause is an absolute deficiency of insulin secretion. Individuals with type 1 diabetes have evidence of an autoimmune process in the pancreas, specifically the pancreatic beta cells. The specific markers of pancreatic beta cell destructions include islet cell autoantibodies as well as autoantibodies to insulin, glutamic acid decarboxylase (GAD65), and tyrosine phosphatases IA-2 and IA-2β. There are also genetic factors include mutations in the HLA DQA and DQB genes.

In type 2 diabetes, it is multifactorial: there is a combination of insulin resistance and inadequate insulin secretory response to combat signals that there is high blood glucose. The majority of these persons with type diabetes are obese, which in of itself is a metabolic

condition that can cause insulin resistance. Even in those not classified as obese, the extent of insulin resistance, when reaches a critical threshold, can lead to the beginning signs of disease.

The degree of hyperglycemia varies by the individual and can vary over time and with the circumstances. How a particular person goes from an asymptomatic state to one where there is multiple-organ involvement is moderated by both genetics and the environment.[1] Especially with type 2 diabetes, continued elevations in blood glucose with inability to upregulate insulin secretion and insulin resistance can lead to deleterious consequences in the short- and long-terms (including macrovascular and microvascular complications).

To combat and ultimately reverse type 2 diabetes requires a multi-pronged approach customized to each individual's physiology. Insulin resistance can be improved with a combination of pharmacologic treatment as well as weight reduction. Over the past decade, there have been significant advancements in diabetic pharmaceuticals with new medications specifically focused on getting more insulin responsiveness. There have also been significant improvements in bariatric surgical techniques with improved patient outcomes. While nutrition therapy (via low-carbohydrate diet) has been considered to be the tried-and-true method to modifying carbohydrate metabolism and endorsed by many professional medical societies around the globe, diligent adherence, and continued compliance to this diet regimen remain major obstacles.

Recently, the ketogenic diet (KD) has been proposed as a potential means to achieve euglycemia and reverse diabetes altogether. This diet was initially used to treat children with refractory epilepsy in the early 19th century. However, over the last 35 years, KD has been promoted in the diet world as a fast and easy way to lose weight.

In this review, we will go through the pharmacology of ketogenesis and evaluate the origins of KD. We will also review the current evidence in humans demonstrating the effectiveness of KD in diabetes type 2 reversal as well as the potential complications. We will also review low carbohydrate high fat (LCHF) diets.

Ketogenesis: The Basics

Physiological ketosis means that the body is able to optimize its fat utilization, reducing lipogenesis, and increasing lipolysis and fat oxidation. By consuming below-average amounts of carbohydrates, the body starts to deplete its carbohydrate reserves (in the form of glycogen). Once those reserves have been exhausted, the body then starts to generate its own glucose (gluconeogenesis). After that route is exhausted, the body is put into a state of ketosis. As a result, there is a high concentration of free fatty acids (FFAs) in the bloodstream, which are directed to the liver. In the liver, these FFAs are oxidized into ketone bodies (KBs). The KBs generated include β-hydroxybutyrate (βHB), acetoacetate (AA), and acetone. The beta-oxidation of these KBs in conjunction with the FFAs can generate a large amount of energy compared to just carbohydrates alone. βHB (100 gm) can yield 10,500 gm of ATP (the main currency of energy in the body), whereas 100 gm of glucose can generate 8,700 gm of ATP. Moreover, 108 ATPs are produced per 16 carbon FAs, as compared to 32 ATPs per unit of glucose.[2] This energy-efficient process makes KBs and FFAs a good substrate for cells, especially in low-oxygen environments. These KBs are also able to cross the blood-brain barrier and can serve as energy source for brain cells, providing up to approximately 70% of the brain's energy requirements.[3] KBs are stable chemical structures and can remain in circulation for years. FFAs are especially effective in exercise, enhancing the skeletal muscle's ability to oxidize fat.[2]

It should be noted that while a person can get sufficient calories from KD, it does not necessarily mean that the body is optimally using KBs and FAAs for fuel. The body has to be primed to exclusively use KBs and FAAs. Keto-adaptation is the term used to describe the changes the body has to make metabolically to be able to completely depend on KBs and FAAs as the primary energy source.[2] For the body to be able to "keto-adapt" requires carbohydrate restriction for an extended period of time. The exact amount of time required to reach that point where multiple organs in the body have reached KB/FAA homeostasis is unclear. Goedecke et al. attempted to do a time-course of metabolic adaptations to KD among 16 elite cyclists and found that changes in glucose tolerance were identified in these cyclists between 5 and 10 days of starting the KD.[4] Looking at keto-adapted among elite athletes in the long-term (between 9 and 36 months), Volek and colleagues found that those on the KD had twofold greater peak fat oxidation rate and a higher serum KBs (indicating upregulated ketogenesis and lipolysis) compared to those on the high-carbohydrate group.[5]

The Origins of the Ketogenic Diet

KD is a eucaloric diet composed of high fat and low carbohydrates with normalized protein intake, resulting in the production of KBs.[2] This process is able to keep the body in a continued state of KB production.

KD as a diet had not been fully formulated until the mid-1930s, but only after a series of discoveries had been made.[6] Multiple clinicians in the early 1900s had observed that fasting their epileptic patients would eliminate the seizures altogether. This was formally introduced to professional medical society by H. Rawle Geyelin, an endocrinologist at New York Presbyterian Hospital. Dr. Woodyatt, another clinician from the same time period, had noted that βHB and acetone appeared in a normal subject by starvation or a diet containing too low a proportion of carbohydrate and too high a proportion of fat. It was Dr. Wilder at the Mayo Clinic who was able to put it all together: he hypothesized that a diet should be as effective as fasting for treating epileptic patients and could be maintained for a much longer period of time. Wilder conducted a small trial of patients treated with the ketone-producing diet at the Mayo Clinic and then called the diet the "ketogenic diet."

There are many types of KDs currently in use around the world (including the popular Atkins diet). However, there is no uniform guideline or professional consensus on what specific ratios of fat to carbohydrate to protein constitutes a "true" KD.

The first physiologic study looking at the long-term metabolic effects of KD was by Phinney et al. in the early 1980s.[7] This study consisted of cyclists who were given a eucaloric balanced diet for 1 week (which provided 35–50 kcal per kg per day and 1.75 gm of protein per kg per day, with the remaining calories provided as two-thirds carbohydrate-based calories and the remaining one-third fat-based). Then the cyclists were put on a eucaloric KD for 4 weeks. This diet provided less than 20 gm of carbohydrates per day but the protein was matched to the balanced diet (1.75 gm per kg per day) so that the reduction in carbohydrate-based calories was replaced with an increase in fat-based calories. The goal was to evaluate whether there was a change in maximal oxygen uptake and pedal efficiency with the KD in comparison to the balanced diet group. The study authors found that there was neither any clinical nor biochemical evidence of any hypoglycemic event occurring during the time the cyclists were on the KD, demonstrating that aerobic endurance was not compromised by 4 weeks of KD. Moreover, the there was an across-the-board reduction in blood glucose (by about 15%) as well as in glucose metabolism (by about 30%).[7,8]

Today in most nutrition circles, a KD is a state of increased fat consumption, which leads to ketosis. In the average person, the upper limit of carbohydrate intake is approximately 50 gm per day and protein intake ranges anywhere from 1.2–2 gm per kg per day in order to maintain this ketotic state.

Effectiveness of KD in Diabetes Type 2 Reversal

The potential to utilize KD in the management of type 2 diabetes has been explored primarily in small clinical populations. Even with major medical and technological advancements, the greatest challenge has been trying to control post-prandial glycemia. Focusing on the type of carbohydrate consumed and how it is metabolized has been the driving force behind the pursuit of a carbohydrate-modified diet specifically suited for type 2 diabetics.

But to understand the impetus behind KD and diabetes type 2 management, one needs to review Dr. Atkinson's work. Dr. Atkinson, a professor of Medicine at Eastern Virginia School of Medicine and Chief of the Division of Clinical Nutrition had written a series of papers and authored many books and book chapters from the late 1970s through the 1990s looking at the use of low and very low calorie diets which were low in overall calories, low in carbohydrates, and high in protein.[9] While many of them were linked to fad diets, the science behind a diet more in-line with a traditional KD had gained traction in the diabetic research community and the principles have been utilized to create targeted interventions focused on glycemic control.

There have been multiple studies looking at variations of KD and impact on hyperglycemia in type 2 diabetics.

To determine whether obese type 2 diabetics would achieve better glycemic control on a high-ketogenic very-low-energy diet (VLED) versus a low-ketogenic VLED, Gumbiner et al. conducted a small study among 13 patients over 6 weeks.[10] Gumbiner and his study colleagues enrolled seven patients and put them on the high-ketogenic VLED for 3 weeks and compared them with six patients treated with a low-ketogenic VLED. The patients were then

crossed over and treated with the alternate diet for another 3 weeks. The study authors ensured that the caloric intakes for both diets were the same, but compared to a normal diet, the protein amounts were 55% higher.[8,10] Both these diets created ketotic states, but the low-ketogenic VLED (which had more carbohydrates) reduced ketosis by about 60% compared to the high-ketogenic VLED. After dieting, the amount of weight loss was not different between the groups but fasting and oral glucose tolerance test glycemia among those on the high-ketogenic VLED were lower than those on low-ketogenic VLED.

To evaluate how a low-carbohydrate KD could be effective way to improve glycemia and ultimately reduce the number of medications in type 2 diabetics, Yancy and associates conducted the following study: 28 patients from an outpatient clinic were selected to be part of a 16-week single-arm pilot diet intervention trial.[11] The low-carbohydrate KD had a target carbohydrate amount of 20 gm per day or less. Twenty-one of the 28 participants who were enrolled completed the study. Twenty participants were men; 13 were white, 8 were African-American. The mean age was 42.2 years (BMI was 56.0). Hemoglobin A1c decreased by from an average of 7.5 to an average of 6.3 ± 1.4% to 6.3 from baseline to week 16. Diabetes medications were discontinued in 7 out of the 21 participants, reduced in 10 out of the 21 participants, and unchanged in 4 out of the 21 participants. The end results: glycemic control in patients with type 2 diabetes was optimized for the majority of the patients enrolled. However, given the rapid changes in hyperglycemia, patients on diabetes medication who use this diet were advised that they should be under close medical supervision to ensure that there were no major complications.

To be able to identify if a diet lower in carbohydrate would lead to greater improvement in glycemic control in patients with obesity and type 2 diabetes mellitus over the course of 6 months, Westman and associates recruited 84 community volunteers with obesity and type 2 diabetes from the outpatient setting.[12] These individuals were randomized to either a low-carbohydrate KD (defined as 20 gm or less of carbohydrate daily) or a low-glycemic, reduced-calorie diet (500 kcal/day deficit from weight maintenance diet). The main outcome was glycemic control (as measured by hemoglobin A1c). Out of the initial 84, 49 completed the study. While both interventions led to improvements in hemoglobin A1c, fasting glucose, fasting insulin, and weight loss, the low-carbohydrate KD group had more significant results. The low-carbohydrate KD group had an average of 1.5% reduction in Hemoglobin A1c (compared to 0.5% in the low-glycemic group), an average weight loss of 11.1 kg (compared to 6.9 in the low-glycemic group, and reduction/elimination of diabetes medications in 95.2% of the low-carbohydrate KD group (compared to 62% in the low-glycemic group).

LCHF diets had become a contentious area of nutrition, especially as it pertains to diabetes and diabetes reversal.[13]

An LCHF diet is defined as one that restricts carbohydrate intake to 130 gm per day or less whereas a very LCHF (ketogenic) diet restricts carbohydrate intake to between 20 and 50 gm per day.[14]

There have been recent studies looking at LCHF in the management and potential reversal of diabetes type 2.

In one trial, 363 overweight and obese patients were allowed to choose either a ketogenic LCHF diet or a "low calorie, high nutritional value" diet and were on their respective diets for 24 weeks.[15] About 220 (59 men and 161 women) were on the ketogenic LCHF diet and 143 (27 men and 116 women) were on a low-calorie diet, with102 of the participants had established type 2 diabetes. After 24 weeks, HbA1c and fasting blood glucose concentrations decreased significantly more with the LCHF diet (down from an average of 7.7 mg/dL to an average of 6.7 mg/dL, a 1-point drop in HbA1c).[15]

A randomized trial enrolled 34 prediabetic or type 2 diabetic patients to a calorie-restricted diet consistent with ADA guidelines or very LCHF diet.[16] The very LCHF group showed a significant reduction (6.6–6.0%) in HbA1c values compared with unchanged values (6.9% at baseline and follow-up) in the ADA group. A significant number of more participants in the very low LCHF group decreased their use of diabetic medications as compared to the ADA group. The very low LCHF group also lost more weight (–5.5 kg) as compared to the ADA group (–2.6 kg).[16]

Tay and colleagues randomized 115 obese type 2 diabetics to adults to either LCHF or LFHC diets for 1 year.[17] The outcomes measured included: HbA1c, fasting blood glucose, glycemic variability assessed with use of 48-hour continuous glucose monitoring, diabetes medication, weight, blood pressure, and lipids assessed at baseline, 24, and 52 weeks. While there were no differences in HbA1c and blood glucose levels among the groups, the LCHF-diet group achieved greater mean reductions in the diabetes medication score, and there was less glycemic variability.[17]

Conclusion

Based on the science and the clinical studies that have been done over the last 100 years on KD, KD has made a demonstrable impact on type 2 diabetes management. Such dietary modification led to improvements in glycemic control and medication reduction/elimination in motivated volunteers with type 2 diabetes. While larger, longer-term studies incorporating more people of color (including African-Americans and Hispanic-Americans, who are disproportionately affected by type 2 diabetes as compared to other racial/ethnic groups) are needed, the data gathered thus far make a strong case for incorporating KD into treatment guidelines for type 2 diabetes. The ADA has recognized that reducing overall carbohydrate intake for individuals with diabetes has demonstrated evidence for improving glycemia.[18] The ADA also notes that reducing overall carbohydrate intake with a low- or very-low-carbohydrate eating pattern is a viable option for those patients who are not meeting their glycemic targets or for whom reducing glucose-lowering drugs is a priority. However, the ADA does recognize that low-carbohydrate plans can be hard for diabetics to sustain in the long-term and thus recommends that clinicians work with their patients and reassess their nutritional status through the life course.

CHAPTER

59 Metformin: The Enigma of Diabetes

Dhiraj Kishore, Amita Diwaker, Saket Ramraika

Abstract

Metformin is the drug of choice for type 2 DM as recommended by most of scientific society dealing in diabetes. Although being one of oldest hypoglycaemic agents, the mechanism of action is still to be revealed completely, currently it is best correlated with AMPK activation and altering redox state to reduce hepatic gluconeogenesis. Recent implication of metformin in meta inflammation has opened a big vista for its use not just as a hypoglycemic agent but in other states such as dementia by decreasing effect of MPTP, in cancer by inhibiting mitochondrial respiratory chain complex 1, anti ageing by inhibiting mTORC 1, in chronic infection like mycobacterium tuberculosis by inhibiting the mammalian target of rapamycin targets p70S6K and 4EBP1, in PCOS by increasing SHBP, by reducing pulmonary fibrosis via down regulating TGFβ1-mediated fibrogenesis and most important its cardiovascular modulating actions in CHF, DCMP, cardiac fibrosis, and hypertrophy. And the story does not commence here without mentioning its noble effect on thyroid health, obesity, and osteoporosis too. Below is a concise narrative of metformin and its expanded scope in medicine.

Introduction

Metformin is the preferred first-line oral blood glucose lowering agent to manage type 2 diabetes mellitus (T2DM) by almost all diabetic and cardiological societies all over the world either ADA or ECS. Galega officinalis (also known as goat's rue), a traditional herbal medicine in Europe was found rich in guanidine. Metformin was introduced in 1920s, but came into US market in 1960s and gradually became one of the first-line oral antihyperglycemic drugs.

Pharmacokinetics and Pharmacogenetics

Drug is administered orally. It has low bioavailability 40–60%.[1] Absorption predominantly occurs in the small intestine. Drug is not metabolized and excreted unchanged in the urine. After a dose of 500 mg it gets distributed systemically within 6 hours. Peak plasma concentration occurs after 3 hours. Half-life is 4–9 hours.

Mechanism of Metformin and Hepatic Glucose Regulation

Liver is the centrally acting body in glucose lowering effect of metformin.[2]

Metformin-induced AMPK Activation

AMPK (5-AMP activated protein kinase) is a regulator of energy homeostasis. Metformin lowers hepatic gluconeogenesis through activation of AMPK. Due to metformin the ratio of ADP/ATP; AMP/ATP increases as a result of AMPK activation. Lack of energy inhibits gluconeogenesis.

Alterations of Redox State

Metformin also decreases hepatic gluconeogenesis independently of AMPK mediated and energy charge mediated effects through direct inhibition of

mitochondrial glycerol 3 phosphate dehydrogenase (G3PDH). Inhibition of this shuttle decreases the glucose production from reduced substrates but not from already oxidized substrates.

What Makes Metformin the Oldest, Most Trustful, and Still an Enigma?

Metformin and Meta Inflammation

Chronic low-grade inflammation associated with obesity is known as meta inflammation. It leads to insulin resistance, impaired lipid, and glucose homeostasis in metabolic syndrome and metformin have all potentials to reduce this meta inflammation.[3]

Metformin Action in Intestine

Gut is the primary target of metformin. It inhibits glucose absorption from intestine along with increased glucose utilization by enterocytes by the upregulation of GLUT-2 and SGLT-1.[4] Decrease glucose absorption in upper small intestine makes more glucose available in ileum, which further leads to more release of glucagon like peptide 1 (GLP-1). Fineman et al. showed primary action of metformin is in human gut. They demonstrated delayed release metformin which releases drug until pH was 6.5 in small intestine or beyond where the systemic absorption of metformin is low, resulted in more blood glucose lowering as compared to immediate releasing composition. Metformin also possess action on *gut-brain-neuronal axis*.[5] It results in more release of GLP-1, which acts on GLP receptor on vagal afferent nerves innervating gut mucosa and augments the glucose lowering effect. Metformin plays role in modulating the *gut microbiota*.[6] It causes increase in Escherichia species, lactobacillus and decrease in intestinibacter species, Bacteroides fragilis. Studies showed that altering the gut microbiota may contribute to glucose lowering effect of metformin. Metformin is also effective in type 1 diabetes as evidenced by REMOVAL TRIAL.[7]

Metformin Therapeutic Repurposing

Neurodegenerative Diseases

The search for treatments for neurodegenerative diseases is a major concern in light of today's aging population and an increasing burden on individuals, families, and societies. Therapeutic factor might be how metformin is able to balance *survival and death signaling in cells* through pathways that are commonly associated with neurodegenerative diseases.[8] Metformin has the potential to interfere with neuronal longevity mechanisms.[9] Insulin resistance and diabetes are increasingly recognized as a contributor to disease development especially in the field of dementias. Therefore, rationale for using metformin is its potential to slow aging processes. Most common dementia is *AD (Alzheimer's dementia)*. Neurofibrillary tangles and amyloid plaques (derived from amyloid precursor proteins (app)) are pathological hallmarks. Insulin signaling and glucose tolerance are altered in app in rat models. Diabetic rats showed increased levels of app, a-beta, phosphorylated tau.[10] Metformin has shown to reduce tau phosphorylation, improves memory, and cognition. Metformin *reduces the damaging effect of MPTP* (methyl phenyl tetrahydropyridine) on dopaminergic neurons shown by tyrosine hydroxylase staining (a marker of dopaminergic neurons) in the substantia nigra, pars compacta, striatum or both. ALS (Amyotrophic Lateral Sclerosis) is characterized by degeneration of first and second order motor neurons resulting in spasticity and muscle atrophy. Neurochemical imbalance and genetic mutations are known to cause ALS. A protective role of diabetes in elderly and increased risk of developing ALS in young with diabetes has been described.[11]

Cancer

Various evidences have provided that metformin has utility in cancer prevention and/or treatment.[12] It has the potential for *inhibition of tumorigenesis* as it inhibits mitochondrial respiratory chain complex.[1] In recent years, epidemiological data have shown that diabetes increases the risk of breast cancer, colorectal cancer, pancreatic cancer, endometrial cancer, and other malignant tumors. Metformin likely has an inhibitory effect on tumor progression in patients with T2DM, which can reduce the risk of tumor and tumor-related mortality of patients, improving their survival rate. *I SPY trial* is aiming that metformin hydrochloride may prevent or lower risk of breast cancer and decrease cancer cells, lower risk of cancer spreading. Metformin may also cause eradication of cancer stem cells, induction of cell cycle arrest, and inhibition of unfolded protein response, which further aids in its anti-tumorigenesis property. Recent data

suggest that diabetic patients taking metformin have a lower incidence of certain cancer, including prostate carcinoma

Aging

Metformin is likely to hold the three promises—Longevity, Rejuvenation, and Health Span. The *Targeting Aging with Metformin (TAME) clinical trial* was designed to investigate the effects of metformin on several age-related diseases in humans.[13] As supportive evidence for the TAME trial, it was stated that "metformin modulates the biology of aging and health span in model organisms." Caenorhabditis elegans showed a good evidence for metformin as a potential anti-ageing drug. *Inhibition of mTORC1 via blockage of lysosomal ATPase (V-ATPase)* was postulated as an anti-ageing mechanism of metformin. *A megatrial*, sponsored by the Veterans Administration (NCT02915198; VA-IMPACT), started on February 19, 2019. This trial plans to study 7,868 subjects with prediabetes and established atherosclerotic disease for 4.5 years in a double-blind fashion with metformin extended release versus placebo for a combined primary endpoint. Time-to-events for oncology-related diseases and diabetes are secondary endpoints.

Mycobacterium Tuberculosis Infections

Evidence has emerged that metformin significantly decreases mortality during treatment for *M. tuberculosis* infection, suggesting a role for the drug as a host-directed therapeutic adjuvant.[14] Metformin has a range of potentially beneficial effects on cellular metabolism, immune functions, and gene transcription involved in innate host responses to tuberculosis. Metformin enhances in vitro cellular metabolism while inhibiting the mammalian target of rapamycin targets p70S6K and 4EBP1, with decreased cytokine production and cellular proliferation and increased phagocytosis activity. Metformin also induces shift in myeloid cells from classical to nonclassical monocytes.[15]

Polycystic Ovarian Disease

There is excessive production of androgens that cause some of the most common clinical symptoms of hyperandrogenism (acne, hirsutism, and alopecia).[16] It is often associated with obesity and the metabolic syndrome. Metformin decreases insulin resistance and hyperinsulinemia, improves dyslipidemia and meta-inflammation, decreases blood pressure, and exerts cardioprotective benefits through pleiotropic action on the vascular endothelium.[17] In combination with lifestyle intervention, metformin treatment is also associated with a lower body weight and improved menstrual cyclicity and fertility potential in women with obesity and polycystic ovary syndrome (PCOD). Possible mechanism is increase in hepatic production of sex hormone binding globulin (SHBG), which decreases androgen levels. Alternatively, the drug directly inhibits androgen synthesis in theca cells, which decreases testosterone levels.[18]

Lung Fibrosis

A study in 2018 found that therapeutic concentrations of metformin accelerated the resolution of established fibrosis in a mouse model of lung fibrosis by promoting AMPK activation and apoptosis in fibroblasts. Metformin induces lipogenic differentiation in myofibroblasts to reverse lung fibrosis. Metformin induces lipid accumulation in IPF lung fibroblasts, inhibits TGFβ1-mediated fibrogenesis in vitro.[19]

Premature Pubarche

It refers to precocious appearance of pubic hair without other signs of puberty in girls less than 8 years, boys less than 9 years. In a study done at Ibanez et al., metformin showed to have favorable effects on abdominal adiposity, androgen levels, and insulin resistance.[20]

Cardiovascular Effect

Role in Cardiac Fibrosis

Metformin decreases cardiac fibrosis by AMPK activation and decreasing TGF beta. It inhibits myofibroblasts differentiation by suppressing reactive oxygen production by inhibition of NADPH oxidase.[21]

Role in CHF

It decreases oxidative stress induced cardiomyocyte apoptosis, improvement in insulin resistance, and left ventricular end diastolic pressures. To date metformin is the only anti-diabetic drug which has shown to decrease *the macrovascular complications by reducing the risk for MI.*

Role in DCMP

Majority of ATP for cardiomyocytes is derived from fatty acids. Normally fatty acids are oxidized as it inhibits glucose catabolism via Randle cycle. In DM heart loses this regulation and leads to development of DCMP. Metformin acts to channelize the ATP coming from fatty acids and glucose in appropriate proportion and prevents or decreases the morbidity and mortality resulting from DCMP.[22]

Role in Cardiac Hypertrophy

Anti-hypertrophic action of metformin is due to AMPK activation. It leads to negative regulation of

- protein synthesis via Motor inhibition
- gene transcription including mitogen activated protein kinase and calcineurin nuclear factor of activated T cell pathways.[23]

Non-alcoholic Fatty Liver Disease (NASH)

Non-alcoholic fatty liver disease (NAFLD) related to insulin resistance (IR) is a growing global health concern. Metformin inhibits lipogenesis, increases fatty acid oxidation in liver and adipose tissue. Metformin improves liver function, HOMA-IR and BMI to some extent, but not histological response in NAFLD patients. Studies have indicated that metformin could improve IR and may be beneficial in the treatment of NAFLD.[24]

Thyroid and Metformin

Individuals with hyperinsulinemia have larger thyroid gland and a higher prevalence of thyroid nodules and cancer. Accordingly, patients treated with metformin have a smaller thyroid volume and a lower risk of incident goiter, thyroid nodule. Metformin can inhibit thyroid dysfunction irrespective of thyroxine replacement and presence of thyroid autoimmunity. Perhaps, metformin has central action.

Obesity

It reduces the body weight independent of dosage. The mean body weight lost is in the range of 1–5 kg or 1–3% in both diabetic and non-diabetic patients. Metformin also helps to counteract the weight gain caused by sulfonylurea (SU), thiazolidinediones, and insulin.[25]

Abbreviations

AMPK, Amp activated protein kinase
CHF, Chronic heart failure
DCMP, Dilated cardiomyopathy
MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
mTORC, Mammalian target of rapamycin
SHBG, Sex hormone binding globulin
TGF, Transforming growth factor

Conclusion

Metformin is first-line agent in management of type 2 diabetes mellitus. It also possesses potential for management of other conditions like cancer, neurodegenerative diseases, obesity, ageing. Upcoming studies may change the perspective of its usage. So in true senses we can say metformin is an enigma of diabetes, which still have many more things to reveal.

CHAPTER

60 SGLT2 Inhibitors—Where to Use? Where not to Use?

Aarathy Kannan, Chandrakumar

Abstract

Diabetes mellitus is a worldwide serious health issue and an economic burden, rising in epidemic proportions over the last few decades. Although several treatment options are available, only half of the global diabetic population achieves the recommended or individualized glycemic targets. Sodium-glucose cotransporter 2 (SGLT2) inhibitors are a new class of antidiabetic agents with a novel insulin-independent action. SGLT2 is a transporter found in the proximal renal tubules, responsible for the reabsorption of most of the glucose filtered by the kidney. Inhibition of SGLT2 lowers the blood glucose level by promoting the urinary excretion of excess glucose. Due to their insulin-independent action, SGLT2 inhibitors can be used with any degree of beta-cell dysfunction or insulin resistance, related to a very low risk of hypoglycemia. In addition to improving glycemic control, SGLT2 inhibitors have been associated with a reduction in weight and blood pressure when used as monotherapy or in combination with other antidiabetic agents in patients with type 2 diabetes mellitus (T2DM). Treatment with SGLT2 inhibitors is usually well tolerated; however, they have been associated with an increased incidence of urinary tract and genital infections, although these infections are usually mild and easy to treat. SGLT2 inhibitors are a promising new option in the armamentarium of drugs for patients with T2DM.

Introduction

Diabetes is a growing epidemic due to population growth, ageing, urbanization, and westernization. Hereby, the burden of diabetes translates into substantial social and economic problems.[2] The alleviation of hyperglycemia, often by oral antidiabetic drugs, leads to improvement of insulin sensitivity, b-cell function, and reduction of microvascular complication such as retinopathy, neuropathy, and nephropathy.[1] The standard antihyperglycemic treatments do not necessarily confer full protection against coronary artery disease (CAD), stroke, and peripheral vascular disease as shown in several large, long-term outcome studies, partially explained by the risk at hypoglycemic events. Furthermore, in order to effectively reduce cardiovascular (CV) events in diabetic patients, comorbidities such as obesity, hypertension, and hypercholesterolemia must be cotargeted, in conjunction to the maintenance of glycemic control. [3] Sodium-glucose cotransporter 2 inhibitors (SGLT2i) are approved for glucose lowering in patients with type 2 diabetes mellitus (T2DM) since 2012.[4] These agents have shown benefit in cardiovascular as well as renal outcomes in T2DM patients, which make them an excellent therapeutic option and have opened a vast area of research.[5]

Mechanism of Action

Glucose reabsorption is mainly mediated by the SGLT2 transporter. The SGLT2i reduce blood glucose by blocking its reabsorption in the proximal convoluted tubules of kidneys leading to glucose excretion via the urine.[6] Apart

from the above it also causes reduction in SBP of 4–6 mm Hg and DBP of 2–4 mm Hg. Osmotic diuresis reduced renin-angiotensin-aldosterone system (RAAS):

- Reduction in body weight 1–5 kg: calorie loss in urine, dehydration in short term, fat mass loss and lesser insulin requirement
- Increase in hematocrit: dehydration, increased erythropoietin
- Lower urate concentration
- Lower triglycerides: calorie loss, glucosuria

Currently Available SGLT2i

The currently available SGLT2i are discussed in **Table 1**.

Natural History of Diabetes

Onset of macrovascular complications occurs early in metabolic dysregulation[7] **(Fig. 1 and Flowchart 1)**.

Mechanisms of Cardiovascular Benefits with SGLT2i

Mechanisms of cardiovascular benefits with SGLT2i have been discussed in **Table 2**.

Cardiovascular Benefits of SGLT2i—Evidence

- The EMPA-REG outcomes trial was the first to show not only non-inferiority but also superiority over

TABLE 1 Currently available SGLT2i

Name	*Empagliflozin*	*Canagliflozin*	*Dapagliflozin*

Flowchart 1: Metabolic adaptations following SGLT2i therapy

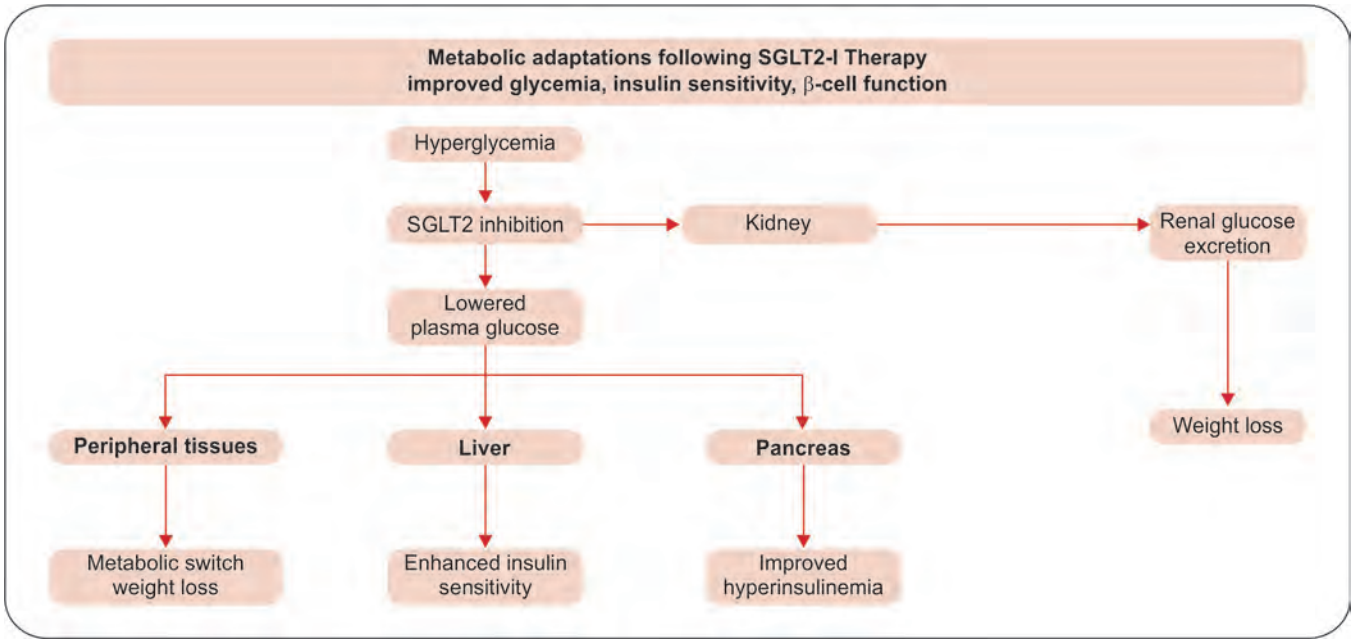

TABLE 2 Potential mechanisms of cardiovascular benefits with SGLT2i

Hemodynamic effects	*Metabolic alteration*
Osmotic dieresis and reduced preload	Glycemic control
Bp reduction	Weight loss
Local (renal) and systemic raas activity inhibition	Ketone body generation and energy efficient utilization of ketone bodies over glucose by a failing myocardium—the " thrifty fuel" hypothesis
Neprilisyn inhibition	Uricosuria
Alternation in intra and extracellular Na^+ distribution by inhibition of Na^-h exchanger in cardiomyocetes (sodium hypothesis)	Increased erythropoietin production due to reduced glycemic exposure of macula dense improved hematocrit and O_2 carrying capacity
Decreased sympathetic nervous system activity	
Improved arterial relaxation and decreased after load	

placebo in CV outcomes in patients with T2DM receiving either doses of empagliflozin (10 mg or 25 mg).

- The primary composite outcome of death from cardiovascular causes, nonfatal myocardial infarction (MI), or nonfatal stroke was reduced by 14% with empagliflozin. Interestingly, this was driven mainly by a significant decrease in CV death.[8]
- There was a non-significant reduction in nonfatal MI but a slight increase in nonfatal stroke with empagliflozin.
- There was also significant reduction in all-cause mortality by 32% and hospitalization due to heart failure by 35%.
- The CANVAS program integrated data from two trials—CANVAS and CANVAS-R patients with T2DM

on standards therapy at high cardiovascular risk were randomized to receive either canagliflozin (100 mg or 300 mg) or placebo.[9]

- Around one-third patients had high risk for CV disease while 65.8% of patients had already established CV disease.
- In the canagliflozin group, the relative risk of the primary composite outcome (3-p mace) significant decreased by 14%. There was however no significant difference in CV death, nonfatal MI, or nonfatal stroke.
- In the DECLARE-TIMI 58 trial, which was CVOT designed to satisfy the US FDA criteria of safety for dapagliflozin, 40.6% with atherosclerotic CV disease and 59.4% with risk factor for atherosclerotic CV disease.
- Though the trial showed the non-inferiority of dapagliflozin in 3-p mace but dapagliflozin did not result in a lower rate of mace than placebo in contrast to was seen in EMPA-REG and CANVAS trials.[10]

Comparison of Landmark CVOTS with SGLT2i

Comparison of landmark CVOTS with SGLT2i has been discussed in **Table 3**.

Renal Benefits with SGLT2i—Mechanisms

The mechanisms for renal benefits with SGLT2i could be multifactorial including both direct renal vascular and hemodynamic effects **(Table 4)**.

Renal Benefits—Evidence

- The EMPA-REG outcome also investigated renal outcomes in patients with T2DM, established CV disease, and an estimated glomerular filtration rate (eGFR) 30 mL/min/1.73 m^2. In spite of an initial decline in eGFR in the first 4 weeks of empagliflozin treatment, overall, there were a 39% reduction in the relative risk of worsening nephropathy, a 38% reduction in the progression of macroalbuminuria, 44% reduction in the doubling of serum creatinine, and a 55% reduction in the initial of the renal-replacement therapy.
- CANVAS-R trial was predominantly aimed to study renal outcomes with canagliflozin treatment. It showed significant reduction in the risk of progression of albuminuria, requirement for renal-replacement therapy, or renal death by 23% and 40% respectively.[11]
- Credence trial, the primary outcomes, which was a composite of ESRD , doubling of serum creatinine or

TABLE 3 Comparison of the landmark CVOTs with SGLT2i

Trial	*EMPA- REG outcome*	*Canvas program*	*DECLARE – TIMI 58*
Drug	Empagliflozin	Canagliflozin	Dapagliflozin
Doses analyzed	10 mg, 25 mg	100 mg, 300 mg	10 mg
Median follow- up (yrs)	3.1	2.4	4.2
No of participants	7020	10142	17160
Mean age (yrs)	63.1	63.3	63.9
Patients with established CV disease (%)	100	65.6	40.6
Patients with heart failure (%)	10.1	14.4	10
Patients with eGFR <60 mL/min/1.73 m^2	25.9	20.1	7.4
Reduction in 3-p mace (HR with 95% cl)			
In patients with atherosclerotic CVD	0.86 (0.74- 0.99	0.82 (0.72-0.99	0.9 (0.79-1.02)
In patients with multiple risk factors for ASXCVD		0.98 (0.74-1.30)	1.01 (0.86-1.2
Reduction in CVD/HHF (HR with 95% cl)			
In patients with atherosclerotic CVD	0.66 (0.55-0.76)	0.77 (0.65-0.92)	0.83 n(0.71-0.98)
In patients with multiple risk factors for ASCVD		0.83 (0.58-1.19)	0.84(0.67-1.04)
AMI/CVD	↓↓	↓	↓
Stroke	↑	↓	↓
Hospitalization due to heart failure	↑	↓	↓

TABLE 4 Probable mechanisms of renal benefits with SGLT2i

Hemodynamic hypothesis (or the tubular hypothesis)	Reduced Na reabsorption in PCT (SGLt2 inhibition) – increased Na delivery to macula densa– activation of tubuloglomerular feedback – reduced hyperfiltration
Reduction of serum glucose and glucotoxicity hypothesis	Reduced glycemic exposure – reduced glucotoxicity mediated damage of proximal tubular cells
Improvement of renal oxygenation hypothesis	Exaggerated glucose (and sodium) reabsorption in T2DM – increased energy consumption and tubular cell damage – secretion of inflammatory cytokines and fibrosis- decreased production of erythropoietin (epo) SGLT2i prevent this and increase epo production
Thrifty substrate hypothesis	Energy efficient utilization of ketone bodies compared to glucose by PCT cells

TABLE 5 Comparison of two main renal trials with SGLT2i

Trial	*Canvas-r*	*Credence*	
Inclusion criteria	Established vascular complications or >+2 CV risk factors	Stage 2 or 3 CKD + macroalbuminuria	T2DM, eGFR>+60 mL/min and established ASCVD or multiple risk factors for ASCVD
No. of patients	5700	4401	
Primary composite outcomes	Progression of albuminuria	ESRD, serum creatinine doubling renal/CV death	
Renal specific secondary outcomes	Regression of albuminuria, change in eGFR	Composite of ESRD serum creatinine doubling, renal CV death Dialysis/renal transplant or renal death	Composite of 40% reduction in eGFR, ESRD, renal or CV death Pre-specified additional renal composite outcome included all the criteria described for the secondary renal outcome except for cardiovascular death
RR% reduction of primary composite outcome		30	
HR primary composite outcomes (95% cl)		0.70 (0.59-0.82)	
RR % reduction of renal specific secondary outcome		34	23
HR renal specific outcome (95% cl)		0.66(0.53-0.81)	0.76(0.67-0.87)

death from renal/CV diseases was reduced by 30% with canagliflozin in patients meeting the inclusion criteria two of which were the presence of macroalbuminuria and an eGFR as low as 30 mL/min/1.73 m^2. The best results were seen in those with eGFR 45–60 and those with baseline urine ACR >1,000 mg.

- Overall, canagliflozin has shown renoprotective effect in T2DM patients, especially those at high CV risk.
- Declare-trial with dapagliflozin, the renal composite outcome (40% decrease in eGFR to <60 mL/min/1.73 m^2, ESRD, or death from renal or cardiovascular cause) significantly favored dapagliflozin with an incidence of 4.3% in the dapagliflozin group and 5.6% in the placebo group.
- Remogliflozin—the robust developmental program conducted globally for remogliflozin till its first approval in India[12] **(Table 5)**.

SGLT2i and CV Outcomes—Real World Evidence

- Real world evidence is captured in natural, uncontrolled settings and can provide date on effectiveness and safety during routine care and complement date from RCTS.

- CVD-real: compared the rates of hospitalization due to heart failure (HF) in individuals with T2DM who newly initiated on SGLT2i (canagliflozin, dapagliflozin, or empagliflozin) versus other oral hypoglycemic agents.[12] Data for 160,033 people on SGLT2i and 1,226,221 on other agents were available from six different countries (US, UK and Nordic countries). Canaglifloxzin was used in 53% of the population, 37% received dapagliflozin and 10% received empagliflozin. Results favored SGLT2i over other agents for HF or death by any cause.
- CVD real looked at CV and mortality outcomes from an additional six countries (four from Asia pacific, plus Canada and Israel). Up to 75% received dapagliflozin. Results were similar to CVD-real, with a lower incidence of the composite of HF or death by any cause.
- Embrace—real world effectiveness and tolerability of remogliflozin.[13]

Remoglifozin

Remoglifozin is an intensively researched molecule in 26 clinical studies conducted globally.

The phase III pivotal registration trial in India has demonstrated non-inferiority of remoglifozin 100 and 250 mg BID to dapagliflozin 10 mg OD.[14]

- The reduction in HbA1c at 24 weeks in RE 100 g vs. Dapa 10 mg was 0.72 vs. 0.58 (p <0.001) for non-inferiority.
- The reduction in PPG was seen to be numerically higher (39.2 vs. 32.4 g/dL) at 24weeks.
- The reduction in FBG was comparable at 24 weeks.

The reduction in non-glycemic parameters was seen comparable to dapagliflozin.

The adverse event profile was comparable to dapagliflozin 10 mg. Remoglifozin is demonstrated to be well tolerated.

Remoglifozin has equivalent PD (assessed by UGE), glycemic efficacy and real world clinical effectiveness as with other SGLT2i.

The economical costing of remoglifozin empowers for larger access to Indian T2DM patients.

The real world experiences from large scale utilization are/would be presented in various scientific forums, which underscore the efficacy and safety profile in real clinical practice.[15]

The ongoing and future studies are expected to be generated to further strength the evidence exclusively in Indian patients.

The phase III pivotal registration trial in India has demonstrated non-inferiority of remoglifozin to dapaglifozin, with comparable result in all glycemic and non-glycemic parameters.[16]

The adverse event profile of remoglifozin was comparable to dapaglifozin and is well-tolerated by patients.

Cardio-renal benefits are consistently seen with all agents of this class, and explained by mechanistic hypothesis of effective SGLT2 inhibition.

Efficient SGLT2 receptor blockage would potentially provide these benefits observed with this class of drugs.

Remoglifozin is equivalent but economical SGLT2i that would offer access to clinical benefits of SGLT2 inhibition to larger set of Indian patients.[17]

Safety Concern around SGLT2i

Safety concern around SGLT2i has been discussed in **Table 6**.

Place of SGLT2i in current guidelines: as per the 2020 guidelines, apart from affordability issues, there is possibly no reason why agents other than SGLT2i or GLP-1RA should be preferred over these two agents as the second drug of choice after metformin[18] **(Figs. 2 to 4, Flowchart 2)**.

TABLE 6 Safety concern with SGLT2i—results from landmark CVOTs

Adverse event studied	*Higher rates than placebo?*
Major hypoglycemias	No
Euglycemic diabetic ketoacidosis	No, most events in patients with autoimmune diabetes
Genital mycotic infection	Yes, all agents
Urinary tract infection, pyelonephritis	No
Lower limb amputation	With canagliflozin
Fractures	With canagliflozin
Strokes	With empagliflozin
Pancreatitis	No
Acute kidney injury	No
Cancers (bladder, renal cell, breasts)	No
Venous thromboembolic events	No

TABLE 7 SGLT2i—ongoing trials

Trial name	*Drug*	*Aim*
Vertis – CV	Ertugliflozin 5 mg, 15 mg vs placebo	To assess CV safety of ertugliflozin in T2DM
Dapa-CKD	Dapagliflozin 10 mg, or 5 mg vs placebo	To assess the effect of dapagliflozin on renal outcomes and cardiovascular mortality in patients with chronic kidney disease
Emperor preserved	Empagliflozin 10 mg vs placebo	To assess the risk of CV death and heart failure related hospitalization in patients with heart failure with preserved ejection fraction, with and without diabetes
Scored	Sotagliflozin vs placebo	CVOT of sotafgliflozin
EMPA kindey	Empagliflozin vs placebo	To assess renal disease progession and CV dealth in diabetics and non-diabetics with eGFR> 20-45 or eGFR> 45 + urine ACR > 200 mg/g

SGLT2i—The Future

See **Table 7**.

Where to Use SGLT2i

- Type 2 diabetic patients with good renal function.
- Diabetic patients with hypertension.
- Overweight and obese type 2 diabetic patients.
- Type 2 diabetic patient with recurrent hypoglycemic episodes.
- Type 2 diabetic patients experiencing therapy related limiting adverse events. For example GI side effects with GLP-1 analogs or with AGI use. Type 2 diabetic patient with poor glycemic control while on monotherapy or combination therapy.[19]

Conclusion

- SGLT2i are one of the most attractive therapeutic options in T2DM management with reasonably acceptable safety profile.
- SGLT2i offer a very second-line option following metformin monotherapy especially in individuals with established renal or CV disease or at high risk for the latter. The most common side effect is genitourinary infection, which is however easily treated.
- Canagliflozin reduced the burden of the first and total HHF events by 39% and 36% respectively in patients with T2DM and CKD.
- SGLT2i recommended as monotherapy if metformin is contraindicated or not tolerated in T2DM with unmet needs of glycemic control with metformin monotherapy.
- SGLT2i as monotherapy/add-on to metformin effectively reduce A1c, FPG, body weight and BP in patients with T2DM.
- SGLT2i significantly reduce the risk of CV morbidity and mortality; and associated with reno-protective effects—viz. slower progression to kidney disease and progression of albuminuria, and reduction of eGFR.
- SGLT2i—potential benefits on β-cell function and reduction of insulin resistance may be more useful in Indian T2DM patients.
- Insulin independent action, hence greater durability of glycemic control.
- Efficacious in all stages of T2DM.
- Additional benefits of weight loss, BP reduction.
- Beneficial for combating multiple comorbid diseases associated with T2DM.
- Requires appropriate patient selection and adequate counseling.

CHAPTER

61 Untold Story of SGLT2 Inhibitors

Nagendra Kumar Singh, Subhankar Chatterjee, Vaibhav Agnihotri, Leena Singh, Richa Manaswita

Abstract

The journey of SGLT2 inhibitors is unimaginable. As new trials keep surfacing, tremendous potential of SGLT2 inhibitors becomes obvious. Not only unmet needs in diabetes therapy, but also indications in non-diabetic conditions have come to light. Use in non-diabetic heart failure has given new hope. We have now evidence to prevent new onset diabetes, lowering gout risk, and new modality for NAFLD/NASH treatment. It has also become a new ray of hope for cardio-renal protection. In type 1 diabetic patients, taking SGLT2 inhibitors with insulin act as insulin dose modifier. Many other new indications might be visible in the coming days. The ever changing untold science of SGLT2 inhibitors has posed challenges for learned societies to make clear guidelines. Clearly, a diabetologist's drug group is becoming favorite of cardiologists and nephrologists.

Introduction

Sodium-glucose co-transporter-2 (SGLT2) inhibitors (SGLT2i) are perhaps the most exciting newer anti-diabetics, which now have garnered attention even beyond its traditional indication for type-2 diabetes mellitus (T2DM). The clinical dimension of SGLT2i is increasing apart from frontline metabolic, cardiovascular, and renal therapeutics.[1,2] A plethora of extra cardiac and renal effects are on the horizon and has not been told. Some of these untold stories related to beyond glycemic lowering need serious considerations after they have been found to have some unique features and indications in some landmark trials **(Tables 1 and 2)**.

Historical Perspective

SGLT2i has a remarkable history dating back more than 150 years. It was first isolated from the root bark of apple tree as a substance called Phlorizin as early as 1835. The first clue about how kidneys reabsorb glucose came in the early 1980s. The first SGLT2i, which was approved by FDA was canagliflozin in year 2013. Later dapagliflozin and empagliflozin were approved by FDA in January 2014 and August 2014, respectively. Ertugliflozin got approved by FDA in 2017. Remogliflozin is approved by health regulatory authority in India in 2019. Today SGLT2i are being successfully being used to treat diabetes by harnessing the kidneys. This journey of SGLT2i is going through an unimaginable curve showing tremendous benefits to meeting the multitudes of unmet needs of diabetic patients.

New Exciting Indications

Prevention of Diabetes

First evidence emerges by DAPA-HF trial with 32% reduction in new onset diabetes shown by Dr Inzucchi's new analysis. In non-diabetic subjects dapagliflozin reduced the risk of developing new onset type 2 diabetes. Remarkably it was 32% reduction in comparison to

TABLE 1 Twelve most emerging new vistas about SGLT2i[1,2]

12 most emerging new vistas about SGLT2-inhibitors
• Use in non-diabetic herat failure
• Evidence now to prevent new onset diabetes
• Nephrologist and cardiologist's love with SGLT2-inhibitors
• Gout-Lower risk with SGLT2-inhibitors
• Abdominal obesity
• NAFLD/NASH—A new ray of hope
• Role in controlling difficult hypertension and nocturnal non-dipping resistant hypertension
• Why not to use in type 1 diabetics for cardio-renal protection
• Opening new vist for primary cardio-renal prevention if used from beginning?
• Use as insulin dose modifier
• Reduce the risk of new-onset obstructive sleep apnea
• May reduce AF and flutter risk in type 2 diabetes

TABLE 2 SGLT2i, some unique facts[1,2]

SGLT2-inhibitors—Some unique facts
• SGLT2-inhibitors rduce eGFR decline in subjects with well-regulated diabetes mellitus, pre-diabetes or even non-diabetic CKD
• The data from recent trials show a pattern that suggests SGLT2-inhibitors are cardiovascular and renoprotective in patients with lower renal functions, in patients with lower HbA1c levels and in patients with non-diabetic kidney disease
• The first completed CVOT with SGLT2-inhibitors empagliflozin, the EMPA—REG presented at EASD Stockholm in 2015 is considred historic whcih changed the perspective of diabetes
• CANVAS study with cangliflozin was found to have doubled the risk of below-the-knee amputations and shoked the diabetes world but later studies do not substantiate it
• In December 2018, the American College of Cardiology issued an "expert consensus decision pathways" as a guide for cardiologist in using SGLT2-inhibitors and stressed for a "paradigm shift" away from just glycemic control
• Renal outcomes were secondary outcomes in the cardiovascular disease trials of the SGLT2-inhibitors, but the favorable results were just as surprising
• CREDENCE trial led Janssen pharmaceutical to apply FDA for a new indication for Canagliflozin to reduce the risk of end-stage kidney disease, the doubling of serum creatinine, and renal or cardiovascular death in adults with type 2 diabetes and chronic kidney disease
• Boehringer Ingelheim and AstraZeneca have launced new clinical trials aimed at expanding the use of their SGLT2-inhibitors beyond people who have diabetes
• In DAPA-HF trial 55% chort were non-diabetic and had only 0.003% Hb1Ac change from the base line at 4 months. In non-diabetic reduction is approximately 0.12% only
• DECLARE TIMI58 is the first trial using SGLT2-inhibitors in which hospitalization for heart failure was included in a primary endpoint

placebo. Just after 18 months, in placebo group 7.1% developed diabetes but in dapagliflozin group only 4.9% developed new onset of diabetes. Implications of this new finding need to be translated.[3]

Prevention of Non-diabetic HF

EMPA-REG OUTCOME trial, CANVAS trial, and DECLARE -TIMI 58 trial have brought new ray of hope in diabetes management. These trials brought a historic change and led to change in guidelines. Today diabetologist are saying goodbye to glucocentric concept. Needless to say, we give top priority to cardiovascular and renal protection. We want reduction in hospitalization for heart failure. In 2019 DAPA-HF trial results amazed the scientific community. It showed 26% relative risk reduction in primary end point, which was composite of cardiovascular death, hospitalization to heart failure or urgent heart failure visit in patients with. It also showed 30% relative reduction in worsening heart failure. Cardiovascular death reduction was 18%. It is worth to note that DAPA-HF constituted 55% non-diabetic cohort. Both diabetics and non-diabetics cohorts got benefitted in equal proportion. It clearly tells that dapagliflozin efficacy was not related to glycemic reduction. Even the all cause death reduction was 17%. The message is clear and loud. Dapagliflozin can be used as a novel therapeutic drug to treat heart failure with reduced ejection fraction (HFrEF), irrespective of the presence of diabetes. It is a great news for heart failure patients (both diabetic & non-diabetic population). Latest Canadian guidelines have already included this benefit and extended use of dapagliflozin in non-diabetics.[2]

Emerging as Nephrologist's Favorite to Treat Diabetic Kidney Disease

The evidence has emerged from unique RCTs and meta-analyses. In a patient with full blown kidney disease and base line eGFR up to 30 mL/min/1.73m^2, renoprotective

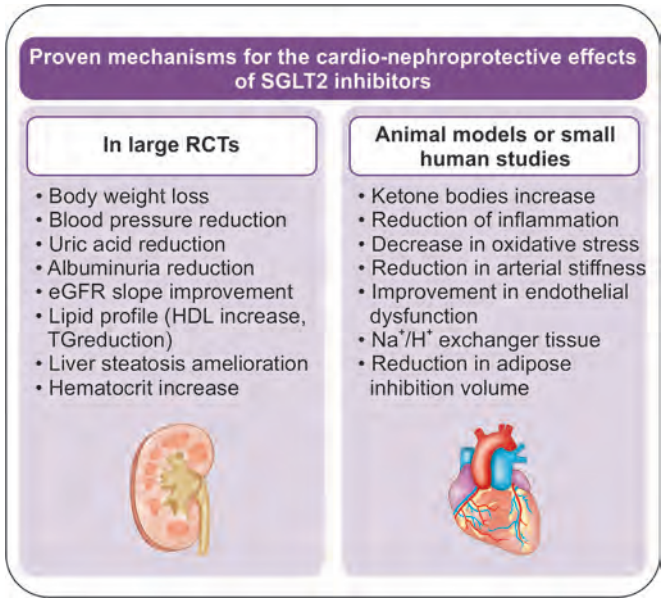

Fig. 1: Proven mechanisms for the cardio-nephroprotective effects of SGLT2i[3,4]

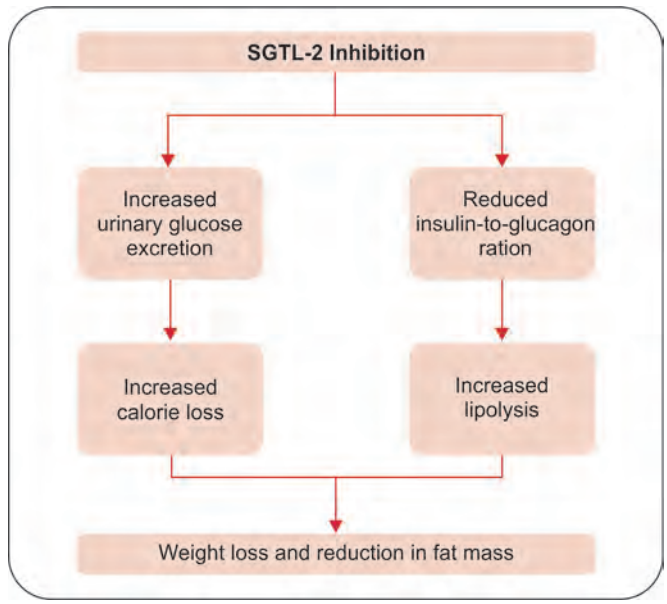
Flowchart 1: Proposed mechanisms of effects of SGLT2i on body weight and fat mass[6]



and cardioprotective effects of SGLT2i are maintained. Scientific societies have moved to recommend the preferential use of SGLT2i in patients with DKD. It is expected that regulatory authorities will increase the range of eGFR at which SGLT2i can be used, as well as modify the indications to include nephron protection **(Fig. 1)**.[4]

Lowering Gout Risk by SGLT2i

A meta-analysis of 62 studies, comprising 34,941 patients shows that any of the SGLT2i significantly decreased serum uric acid levels compared to control. When compared with GLP-1 RA, clear benefits of SGLT2i have been found. It was 4.9 events per 1,000 person-years in SGLT2i group and 7.8 events per 1,000 person-years in GLP-1 RA group. [HR of 0.64, 95% CI, 0.57–0.72]. Empagliflozin resulted in superior reduction. SGLT2i might be beneficial for diabetic patients with hyperuricemia as per this meta-analysis.[5]

Abdominal Obesity

Now it is well known that SGLT2i reduces body weight and visceral opacity. They also reduce ectopic fat deposition. Thus, they improve adipose tissue function. We have today an evidence-based therapeutic option for management of overweight and obese patients having type 2 diabetes **(Flowchart 1)**.[6]

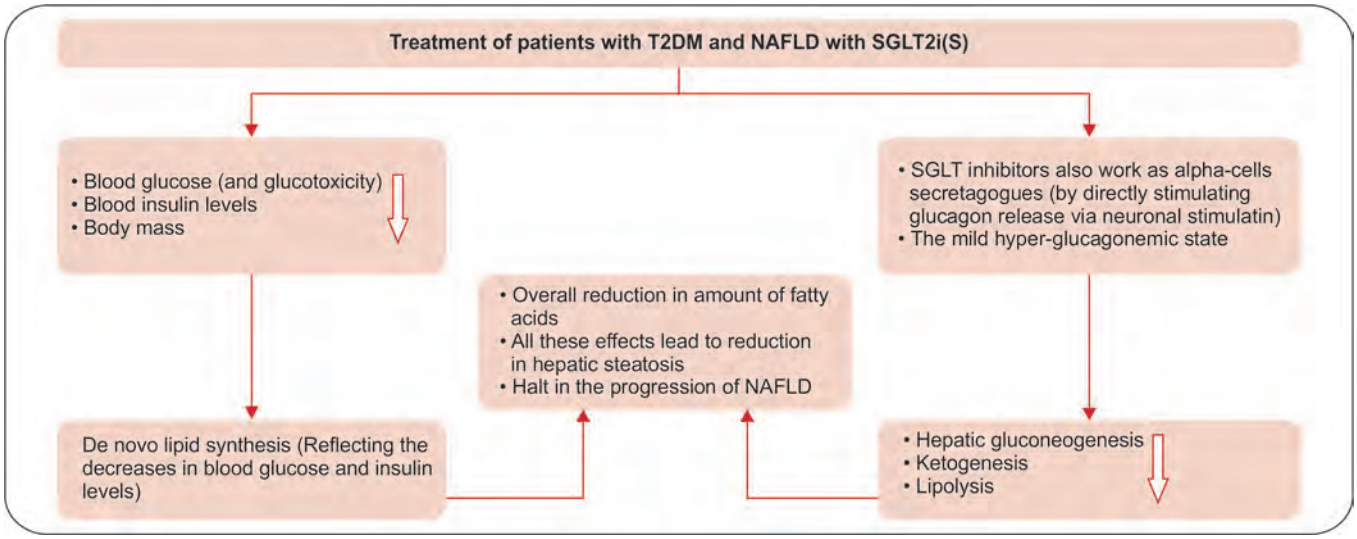
Evidence in Hypertension

SGLT2i can bring modest reduction in blood pressure. Most of studies point that 5–6 mm Hg reduction in systolic blood pressure occurs. The diastolic blood pressure reduction has been found 1–2 mm Hg. This reduction is not dependent on blood sugar control. Initial reduction is due to diuretic mechanisms. Improvement of vascular stiffness could be another mechanism later on. Interestingly SGLT2i could be beneficial in difficult to control hypertension. Non-dipping resistant hypertension is a very difficult situation in day-to-day practice. Now, SGLT2i have been found to modulate such cases. It is worth to note that SGLT2i mediates osmotic diuresis. It leads to more electrolyte-free water clearance. Thus, more prominent fluid loss from interstitial spaces ensues.[7,8] No sympathetic nervous system activation occurs while reducing blood pressure by SGLT2i. This is in contrast to GLP-1 RA, which cause increase in heart rate. Reduction in preload and afterload is unique to SGLT2i. It is thus beneficial in reducing cardiac work load and also myocardial oxygen demand. Nevertheless, BP reduction is unlikely to explain all cardiovascular benefit.[9]

Use in NASH/NAFLD

SGLT2i are showing promising results in non-alcoholic steatohepatitis (NASH) and non-alcoholic fatty liver

Flowchart 2: Proposed mechanisms of effects of SGLT2i on NAFLD and NASH[10]



disease (NAFLD). Various studies have already shown that SGLT2i improve serum level of liver enzymes, decrease liver fat, and fibrosis. And also, improvement in various metabolic parameters in type 2 diabetes patients with NAFLD. Many more studies are on the way in this aspect and indicate that SGLT2i should be used for all NASH, NAFLD cases at least in diabetics. We have to watch for more studies, research in cases of non-diabetics as well **(Flowchart 2)**.[10]

SGLT-2i in Type 1 Diabetes

At present SGLT2i are being used as off label drug in type 1 diabetes although some recent trials like DEPICT 1,2. EASE 1,2,3, and in-Tandem 1,2,3 clearly head to new indication to use SGLT2i with insulin in type 1 diabetes. In future SGLT2i may be included in guidelines to enable people with type 1 diabetes to achieve their glycemic goals. Dapagliflozin has credit to being the first SGLT2i to be approved in Europe. It has got approval from NICE (National Institute for Health and Care Excellence, UK) and SMC (Scottish Medicines Consortium) as an adjunct to insulin for people with T1DM if glucose levels are not adequately controlled with insulin alone. SGLT2i should be avoided if high risk of DKA is suspected. It should be used with utmost care if patient has difficulty in adhering to insulin regimen or having difficulty understanding and following treatment instuctions.[11] European Medicines Agency (EMA) approved dapagliflozin for use in some patients of type 1 diabetes but FDA has not approved it in the USA. Ipragliflozin has been approved in Japan for use together with insulin in adult with type 1 diabetes. The dual SGLT2i, sotagliflozin has shown improvements in Hb1Ac, weight loss and systolic blood pressure and reduction in insulin dose when added to insulin therapy.

Primary Prevention of Cardiorenal Complications in T2DM

It is now a proven fact that SGLT2i have a great affect in reduction to hospitalizations due to heart failure. DECLARE-TIMI58 trial data has thrown light that dapagliflozin has tremendous benefits in primary prevention. Taken together, cardiovascular death and hospitalization due to heart failure (HHF), we have now exciting data. The relative risk reduction in CV death was 17% and in HHF it was 27% in DECLARE-TIMI58 trial. ACC subgroup analysis further suggested and showed 16% reduction in MACE in subgroup analysis. Further, subgroup analysis of DECLARE-TIMI58 trial showed a reduction of 47% in renal outcomes. In nutshell, these drugs have shown a great promise in primary prevention of cardiorenal complications by dapagliflozin.[12]

Use in HFpEF

SGLT2i are yet to show proven benefits in HFpEF patients. Some important trials are on the way—DELIVER and

DETERMINE-preserved trials with dapagliflozin and EMPEROR-preserved and EMPERIAL-preserved with empagliflozin. It shall be a landmark development and another big feather in cap of SGLT2i if these trials show positive trend.[13]

Some Emerging Indications

- In cases of artificially-induced syndrome of inappropriate ADH secretion (SIADH), DIVE study has been done. It was done with empagliflozin. It gives an insight that SGLT2i can be used in diseases, which are associated with hyponatremia. It is so due to its effect on free water clearance.[14]
- In polycystic ovarian syndrome (PCOS), use of SGLT2i resulted in weight loss and anthropometric parameters also improved. This was shown in a small study. When metabolic and hormonal outcomes were compared with metformin, no significant difference was seen.[15]
- Now a very interesting data has emerged showing that empagliflozin can be very useful in reducing the requirement of insulin by 59%. This paper was presented at ADA virtual meeting 2020 (new-initiation of insulin, or >20% increase in insulin requirement in EMPA REG OUTCOME study). It appears SGLT2i are emerging as insulin dose modifier![16]
- The risk of new onset obstructive sleep apnea can be reduced by SGLT2i. In EMPA REG OUTCOME study, this risk was reduced by 52%. This data was presented at ADA 2020 virtual meeting.[5,17]
- In type 2 diabetes cases, dapagliflozin has been shown to reduce the risk of atrial fibrillation and flutter. In a new study it has been shown. Its effect remained consistent. There was not much effect on this regardless of previous history of atrial fibrillation, atherosclerotic cardiovascular disease or heart failure.[18]

Under-Prescription and Cost-Effective Issues

In spite of being rated among as only anti-diabetic oral drugs capable of cardiorenal prevention and having potential for primary prevention, SGLT2i remains under-

TABLE 3 DARE-19 trial[21]

Why they have DARE-19
• AstraZeneca and Saint Luke's Mid America Heart Insititue have initiated Phase II DARE-19 trial (completion date - December 2020) with Farxiga in COVID-19 patients
• An international, parallel-group, randomized, double-blind, placebo-controlled, investigator-sponsored phase III trial evaluating the efficacy and safety of Dapagliflozinin addition to background local standar of care therapy, on the riks of all-cause death or disease progression and complications in adults who are hospitalized with COVID-19
• They include 900 sickets patients of COVID with patient's history of at least one of the following: – Hypertension – T2DM
– Atherosclerotic cardiovascular disease
– HF and/or
– CKD state 3 to 4 (*eGFR ≥25 mL/min/1.73 m)
• There is a growing argument that dapaglifolzin, in particular, has shown to decrease lactic acidosis and thus has the potential to reverse acid-base balance inside the cells during hypoxi, which can prevent cell injury during the cytokine storm of COVID-19 illnes, in patients with diabetes
• Both pre-clinical and clinical studies suggest that SGLT2i may favorably impact the underlying mechanisitic processes dysregulated in the setting of acute major illness (such as COVID-19) and include favorable effect on endothelial function, inflammation, oxidative stress, tissue hypoxia, energy metabolism, and autophagey
• Some view it as a dangerous proposition as ketoacidosis in COVID-19 is associated with hypercoagubility

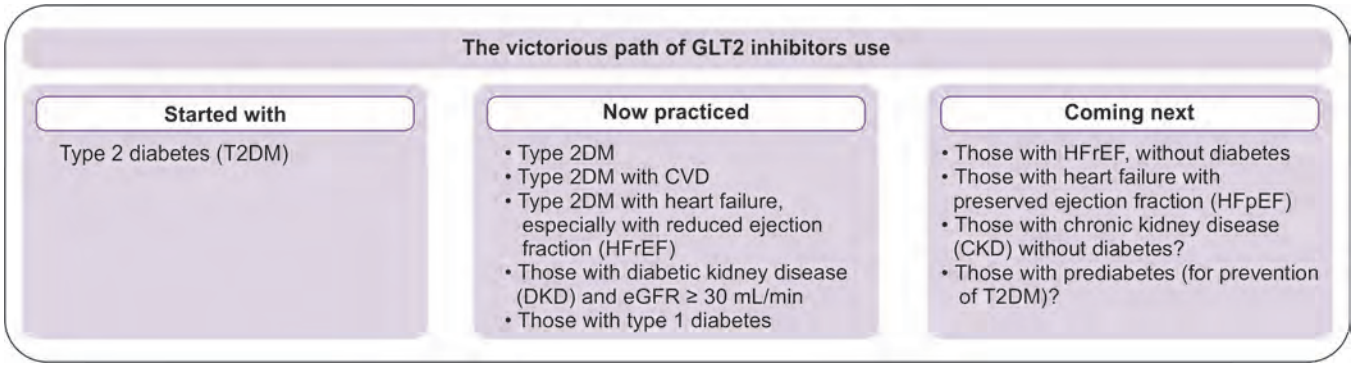


Fig. 2: The victorious path of use of SGLT2i[13]

prescribed worldwide. In the USA in patients with diabetes and CVD only 9.3% were prescribed SGLT2i as per one study.[19] As a matter of fact these are significantly cost-effective in long term by preventing cardiovascular and renal complications.

Class Effect Dilemma, are all SGLT2i not Same?

Much awaited VERTIS CV (ertugliflozin CVOT trial) was presented at ADA virtual meeting 2020 on 16th June. VERTIS CV trial did not superiority for MACE and cardiovascular death. Although the cohort population was almost similar to EMPA REG outcome trial.

There was a trend for lower HHF risk among ertugliflozin-versus placebo, with rates 2.5% versus 3.6%, but the difference was not statistically significant due to hierarchical testing sequence used. Still consistent class effect in HHF can be interpreted. It is worth to note that MACE reductions were only statistically significant only for empagliflozin and canagliflozin.

Now this trial gives suspicion that all SGLT2i are not the same. Many factors might be operating. No clear-cut answer exists. Some of debated factors are—a difference in patient population between trials, a true biological difference in drug efficacy or any other factor might be operating.[20]

DARE-19 Study with Dapagliflozin in COVID-19

You can raise your eyebrow. While consensus today is to stop SGLT2i due to fear of DKA in COVID-19, DARE-19 trial is daring to use SGLT2i in COVID-19.

Final results are expected in March or April 2021 **(Table 3)**.[21]

Conclusion

Usual indications of SGLT2i keep changing in light of latest clinical trials. Some stories are well known but immense potential has not been yet explored. SGLT2i which started its anti-diabetic journey with huge controversies has now emerged as an amazing weapon to fight not only in prevention of secondary cardiorenal complications but also in primary cardiorenal protection along with hosts of other metabolic disorders. Many new indications are emerging and these must be considered in clinical perspective **(Fig. 2)**.

CHAPTER

62 Evolution of Insulin: Old Insulin versus Insulin Analogs

Arvind Gupta, Banshi Saboo

Abstract

Insulin was available for the treatment of diabetes for human use for almost 100 years after the discovery in 1921by Prof. Macleod and Dr. Fredrick G. Banting with the help of Dr. Charles Best and Prof. J.B. Collip. The different types of insulins available today are the fruits of various innovations and modern state of art DNA recombinant technology. Evolution of insulin has been shown to start from crude animal extract insulins to the recent pure and precisely controlled formulations of insulin analogs. The modifications of the insulin formulation and of the insulin molecule have made it in such a way that approximate the natural endogenous insulin secretions. These modern designer insulins provide the peak less basal level of insulin or mimicking the spikes of meal insulin release. We have discussed in this review how pharmacokinetics and pharmacodynamics of old insulin molecules have been modified to be converted into modern new insulins. Hence, various insulin formulations like rapid-acting, short-acting, intermediate-acting, and long-acting insulins, as well as mixtures and concentrated formulations have been produced.

Introduction: Evolution of Insulin

The management of diabetes has changed significantly over the past century after the discovery of insulin around the year 1921.[1] Insulin was invented by Frederick Banting, John Macleod, and Charles Best from animal pancreas.[2] The earliest insulin preparations were largely animal-based, having either bovine or porcine origin. Eli Lilly was the major producer of animal-based insulin, which soon started falling short with the demands. To overcome this, insulin analogs gradually emerged in the picture. The main objective for developing analogs was to prolong the duration of action of insulin, which required several shots during the day. Achieving this, in the year 1983, the use of recombinant human insulin was approved, and insulin analogs were gradually developed.

Newer types of insulin or insulin analogs offer better replacement of insulin because of closer simulation to the human physiology. When compared with regular insulin, insulin analogs such as lispro, aspart, and glulisine have faster onset of action. Other analogs like glargine and degludec have longer duration of action. Both of these types have evidenced reduction in the risks of hypoglycemia.[3] The most recent advancement in insulin has been the development of the insulin pen device, which allows better patient compliance and thereby corresponds with fewer side effects. It was developed in the year 1985 marking the era of better glycemic control for patients.

This chapter compares the old types of insulin with newer insulin formulations or insulin analogs. The discussion will be along the lines of safety and efficacy and will be supported by trial data and pharmacokinetic studies.

Old Insulin

Earliest preparations of human insulin were extracted from human cadaveric pancreas (refer to **Figure 1** for its

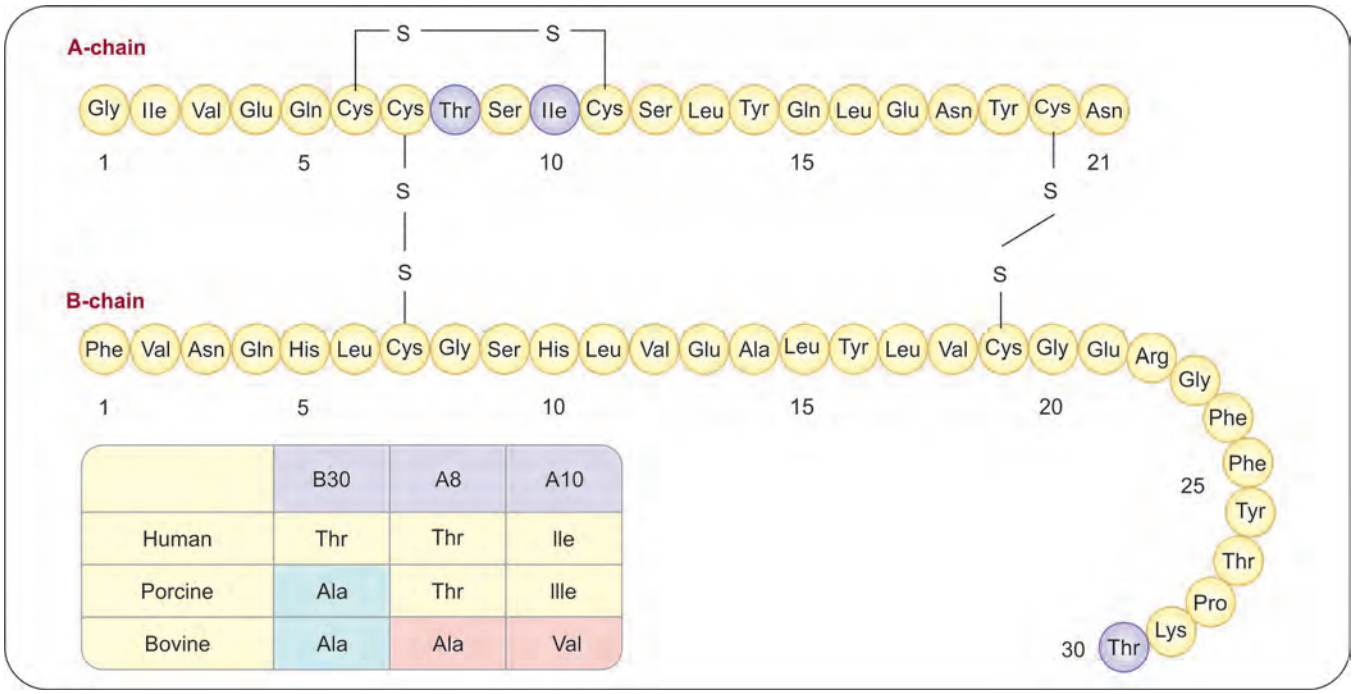

Fig. 1: Structures of animal and human insulin—old insulin types

structure) and its use was limited because of the risk of allergic reactions and lower availability. The first synthetic human insulin that was biologically equivalent to the hormone required significantly higher time and costs for production and also had lower rates of productivity (6–10%) thereby not offering higher success in terms of glycemic control of the patients. With subsequent productions, these drawbacks and side effects were gradually met.

Regular (rapid-acting), neutral protamine hagedorn (NPH) (intermediate-acting) and premixed insulin (long-acting)[4] are human insulin preparations that are now also prepared by recombinant DNA technology. They have a slow onset of action (peak after 3 hours of dosage) and may also have variability in their effects resulting in a lower predictability of the clinical outcomes of the patient.

Human insulin formulations, particularly, intermediate-acting types like NPH (reaches a peak after 4–6 hours of administration) have a major limitation concerning the risk of hypoglycemia.[5] Most particularly, nocturnal hypoglycemia is common in patients receiving this type of insulin. So, human insulins are not preferred for long-term use in patients for the stabilization of their HbA1c profiles. But, their combination with new insulin analogs supports better glycemic control in some patients and they are thus not completely obsolete.

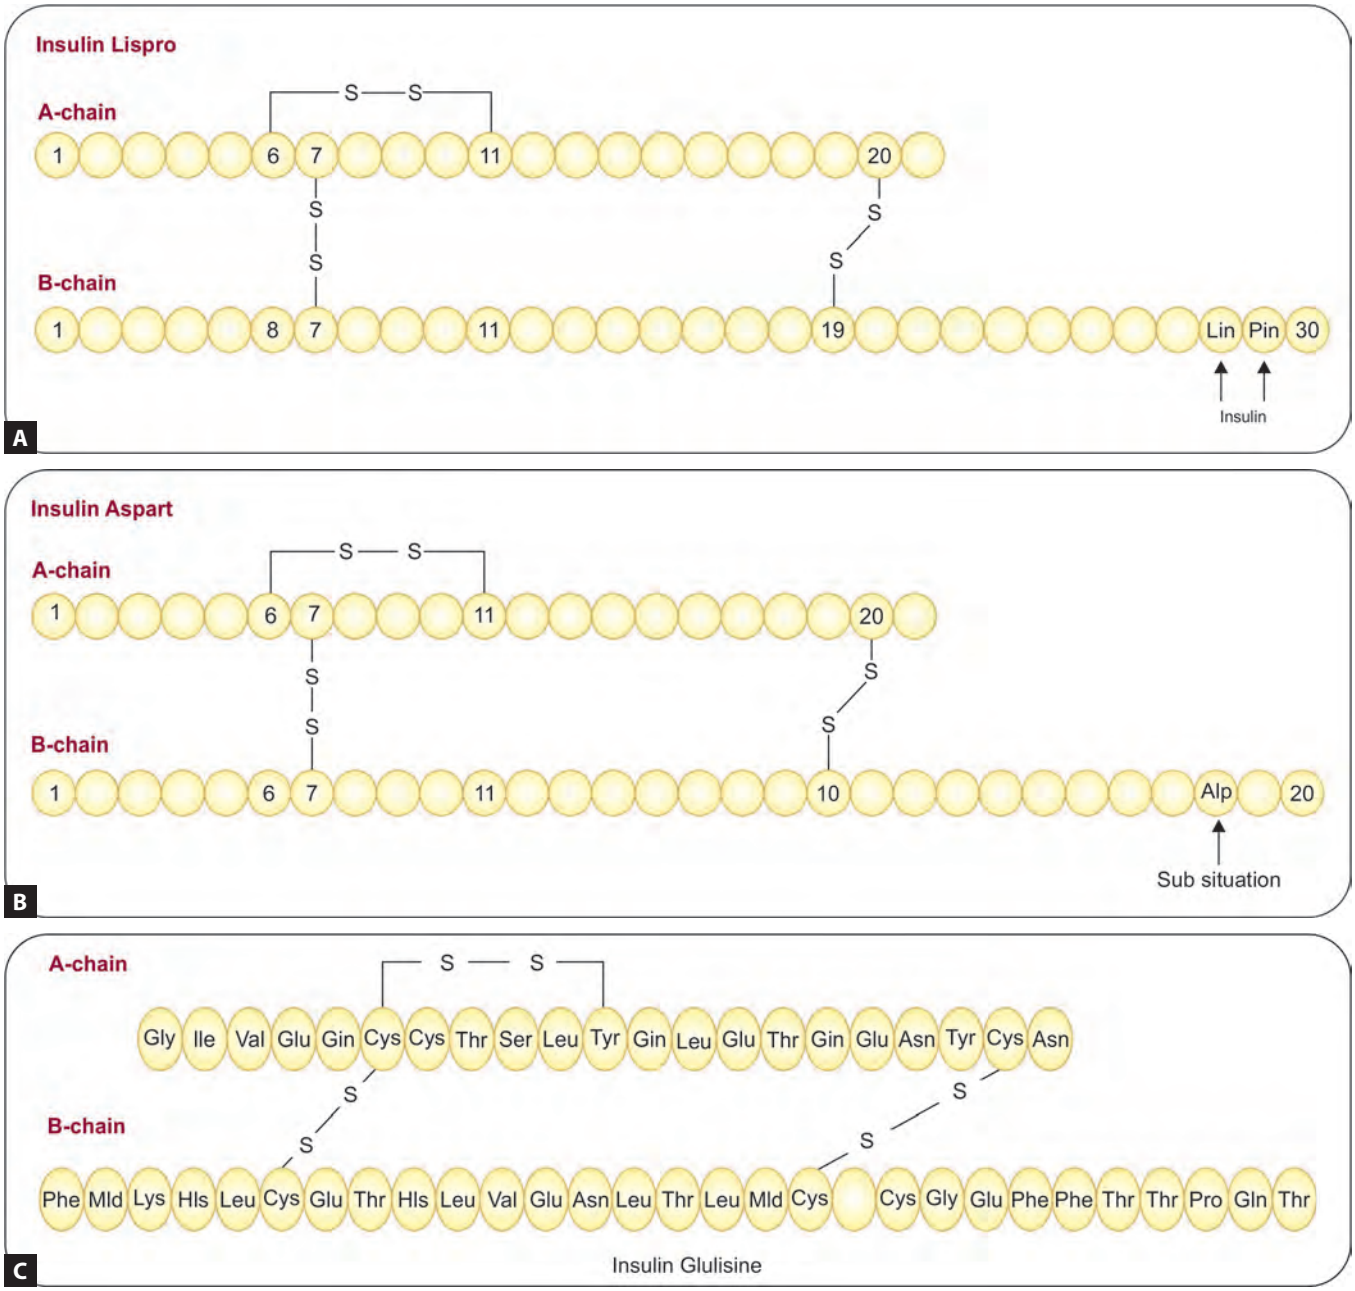
New Insulin

Insulin analogs were formed with the help of recombinant DNA technology in the presence of either *Escherichia coli* or *Saccharomyces cerevisiae*. Analogs are produced with altered pharmacokinetic and absorptive properties through the modification of binding affinity for insulin and insulin-like growth factors to meet the drawbacks of human insulin such as slow onset and limited efficacy or duration of action.

Rapid-acting Analogs

Insulin analogs such as insulin lispro (Humalog), insulin aspart (Novolog), and insulin glulisine (Sanofi) function as rapid-acting agents having a faster onset of action **(Figs. 2A to C)**.

When compared with regular insulin, rapid acting insulin had lesser risk of both postprandial hypoglycemia and nocturnal hypoglycemia thereby having a better safety profile. HypoAna trial of type 1 diabetic patients showed that treatment of patients with insulin detemir and aspart was associated with a 66% lower risk of nocturnal



Figs. 2A to C: Structures of insulin lispro, aspart, and glulisine

hypoglycemia when compared with human insulin. Other than HypoAna, 17 other clinical trials conducted worldwide have evidenced this effect.

Findings from systematic review and meta-analysis intended to compare the safety and efficacy of rapid-acting insulin analogs with regular insulin have demonstrated similar results. Insulin analogs were found here to reduce 7% of total hypoglycemic episodes, 32% of severe hypoglycemic episodes, and they also reduced nocturnal hypoglycemia by 45%.

Other than reducing hypoglycemia, the use of rapid-acting insulin analogs over prolonged periods led to more stabilized blood sugar levels because of the capability of rapid-acting insulin to closely imitate the properties

TABLE 1 The onset, peak, and duration of action of rapid-acting insulins

Insulin type	Onset (min)	Peak (min)	Duration (h)
Insulin lispro	5–15	30–40	4–6
Insulin aspart	5–15	30–90	4–6
Insulin glulisine	10–20	30–90	4–6[6]

TABLE 2 The onset, peak, and duration of action of long-acting insulin analogs

Insulin type	Onset (h)	Peak (h)	Duration (h)
Insulin degludec	1–2	No peak	>42
Insulin glargine	2–4	No peak	Up to 24
Insulin detemir	2	No peak	Up to 24

of insulin hormone in its physiological state.[7] Since postprandial fluctuation of blood glucose levels is primarily responsible for 50% of the hypoglycemic episodes and rapid-acting insulin prevents these episodes, it also results in better patient compliance to the treatment, which determines long-term glycemic control.

In a study comparing the rates of patient compliance, it was found that while only 7% of the patients adhered with the administration protocol of regular human insulin 30 minutes before their meals, for insulin lispro, the compliance rate was as high as 98% due to a more flexible protocol (0–15 minutes before meals).[8] This is a significant advantage favoring better treatment efficacy with the use of insulin analogs **(Table 1)**.

Indian data also depicts similar advantages of insulin lispro and other rapid-acting agents over regular human insulin. It confirms that the use of rapid-acting insulins more effectively manages postprandial spike in blood glucose levels and is thus associated with better glycemic control due to flexibility offered with both meals and insulin dosage.

Long-acting Analogs

Glargine and degludec are soluble long-acting analogue, which have a long duration of action (24 hours or more) **(Table 2)**. They are newer forms of insulin analogs and have also been labeled as second-generation insulin analogs **(Fig. 3)**.

Because of a long duration of action, insulin glargine only needs to be administered once daily resulting in a much higher rate of patient compliance. Since it does not have a distinct peak of action, it also has a lower risk of hypoglycemia. When compared with human insulin formulations, insulin glargine has depicted lower risk of hypoglycemia in clinical studies. At similar HbA1c levels, patients receiving glargine were found to have fewer episodes of nocturnal hypoglycemia when compared with patients receiving NPH insulin because of its favorable pharmacodynamic and pharmacokinetic properties.

As per the findings of a meta-analysis report of 15 clinical trials, it was determined that insulin degludec was superior to insulin glargine.[10] This can be attributed to its long-lasting basal insulin actions, which have twice more duration of effect than glargine, and much lower individual variability. Degludec can be administered at any time of the day without the risk of hypoglycemia in subjects, and can also be carefully combined with other types of insulin analogs such as aspart for managing the individual treatment needs of the patient. Further, it was stated that degludec resulted in lower rates of hypoglycemia in both type 1 and type 2 subjects.

The effectiveness of insulin analogs can also be judged through the results of clinical trials in insulin-naïve patients. CONFIRM trial, a large-scale non-interventional trial analyzing data from 4,056 patients depicted that the administration of degludec/glargine U300[11] significantly improved HbA1c profiles of adult type 2 diabetes patients (refer to **Table 3** to understand the implications of diabetic control on the overall health status of the patient). Further, the administration of long-duration insulin analogs even lowered the risks and frequency of hypoglycemia as well as it minimized the possibility of treatment discontinuation, which is a common finding in insulin-naïve subjects.

Compared with IGlar, IDeg is associated with equivalent glycemic control and a statistically significantly lower rate of nocturnal hypoglycemia in patients with T1DM and T2DM. In T2DM patients, IDeg also provides better results in terms of overall hypoglycemia.

Critical View of Old Insulin versus New Insulin

Human insulin is considered to be less superior to newer insulin formulations in managing blood glucose levels of the patient as well as in reducing the risks of hypoglycemia,

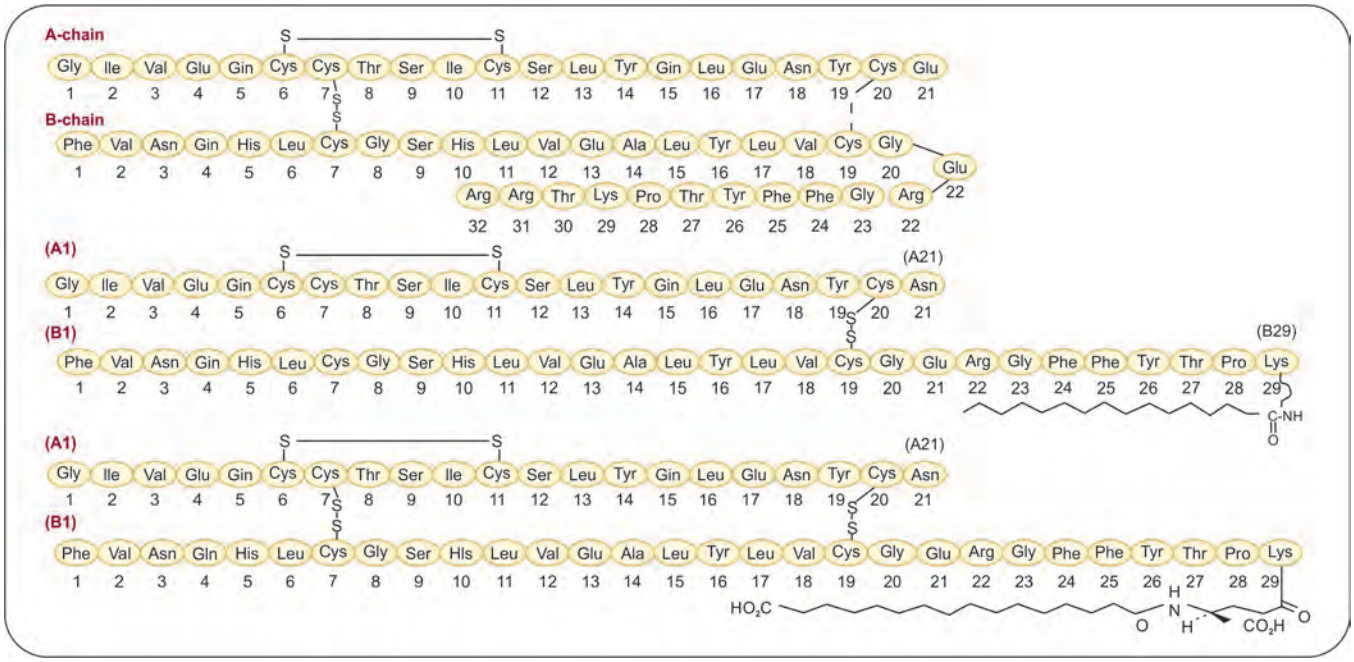


Fig. 3: Structures of insulin glargine, detemir, and degludec[9]

TABLE 3 Long-term effects of better HbA1c control on patients with type 2 diabetes

Risks	*Risk reduction for each 1% reduction in HbA1c levels*[12]
Death due to diabetes/diabetic complications	21%
Microvascular complications	37%
Risk of amputation due to diabetes or peripheral vascular disease	43%
All-cause mortality	12%
Myocardial infarction	14%
Stroke	12%
Heart failure	16%

which is a major concern hindering the long-term management of diabetes. Despite this, a recent clinical trial involving 40 pediatric type 1 subjects affirmed that regular and NPH insulin showed similar efficacy to insulin glargine and aspart.[13] In terms of glycemic control, it was noted that HbA1c levels were similar for both the groups of patients. While fasting blood glucose was better controlled for the group assigned to the glargine treatment, the result was not statistically significant implicating that human insulin could be as effective as newer insulin analogs. However, since this was a small-scale study involving only pediatric subjects and the risk of hypoglycemia was not evaluated at all, no derivations can be made in the favor of traditional insulin formulations over new insulin on the basis of this singular trial.

Because of this, it has been largely debated whether insulin analogs are better than regular or NPH insulin keeping in mind the clinical outcomes of the patient and their pre-existing awareness of old insulin. In this regard, greater evidence has been found in the favor of the use of insulin analogs when compared with regular or NPH insulin. This is because of its ability to reduce nocturnal hypoglycemia by 48% when compared with NPH, as well as severe hypoglycemic effects in patients compared with regular insulin. Both in type 1 and type 2 diabetes, detemir has proven to be better than NPH in several studies of 16–52 weeks of duration since it does not contribute to weight gain in patients.

Comparison among Insulin Analogs

Insulin degludec is an emerging treatment agent, which has is so far considered to be superior to human insulin

and analogue insulin. Findings from the multi-Centre, multi-national randomized controlled study BRIGHT trial are awaited to state with certainty that which of the insulin analogs is the most superior.

According to the large-scale blinded randomized control trial ORIGIN,[14] optimal stabilization of fasting blood glucose levels of patients and a high rate of adherence to the treatment (85%) was found with the use of degludec. Furthermore, the previous claims of the risk of cancer and cardiovascular complications with the use of insulin analogs were largely refuted by this trial. However, the risk of hypoglycemia was higher in the glargine arm when compared with the placebo, which is a considerable risk for the patient.

Insulin degludec when used alone is associated with lower risk of hypoglycemia in both type 1 and type 2 subjects as per the findings of several phase 2 trials.[15] It also has a low variability and thus is a safer alternative for individuals with blunted hypoglycemic awareness. Despite its benefits, one of the risks of insulin degludec is that it is an ultra long acting type and can be a potential risk for patients with renal or hepatic impairment. Overcoming this drawback, recent trial studies have demonstrated that the combination of degludec with rapid-acting insulin such as aspart results in significantly lesser hypoglycemia and can be regarded a safe alternative.

Pre-mixed formulations combining lispro and aspart have also been recently available, but their use is not recommended over other types of insulin.[16] This is because of their highly rigid dosage structure, which interferes with the lifestyle activities of the patient and elevates their risk of hypoglycemia. It can only be administered in elderly patients or those with social problems where maintaining A1c levels less than 7.0% is not of utmost priority. Even in them, it must be used cautiously.

Insulin Pen Devices

According to the consensus guidelines of diabetic management experts in India, insulin pen devices have considerable advantages over the conventional vial and syringe methods because of better patient compliance and higher accuracy of administration achieved through its use. FlexPen offers lower injection force and dose force and is thereby associated with fewer side effects such as pain. On the other hand, NovoPen offers higher treatment accuracy. Regardless of the insulin delivery system used, pen devices, overall, facilitated about 2.1% higher reduction of hypoglycemia when compared with vials and syringes.[17]

Conclusion

New insulin or analogue insulin including both rapid-acting and long-acting analogs are better than older insulin such as regular insulin or NPH. They correspond with better glycemic control (both HbA1c and fasting) and lower risk of hypoglycemic events, most particularly nocturnal or postprandial hypoglycemia. This concludes that insulin analogs have a higher safety and efficacy than old insulin and is also associated with better treatment compliance by the patient due to flexibility of treatment offered to them. Among insulin analogs, degludec is the most promising agent having a long duration of effect and no apparent peak. However, a combination of degludec and aspart is recommended in patients as a safer alternative.

CHAPTER

63 Insulin Regimens for Initiation in Type 2 Diabetes Mellitus

Sudhir Chandra Jha, Syed Yousuf Faisal, Gautam Kr Sandilya

Abstract

Type 2 diabetes mellitus (T2DM) has emerged as the global epidemic. It is a relentlessly progressive disease resulting in various dreadful complications. These complications, however, can be delayed/prevented by modifying risk factors and optimizing glycemic control. The optimization of glycemic control often requires using multiple pharmacological agents including oral antidiabetes drugs (OADs) and insulin. Insulin has the unmatched HbA1c lowering capacity. Therefore, in clinical situations where achieving HbA1c goal has not been possible despite using multiple OADs, insulin initiation seems logical. A basal regimen may be ideal to start with because of its simplicity and favorable impact on weight and lower risk of hypoglycemia. However, intensification of this regimen may be required later to maintain proper glycemic control.

Introduction

There is a tsunami of diabetes mellitus sweeping across the globe. In 2019, approximately 463 million adults (20–79 years) were living with diabetes. By 2045 this figure is likely to rise to 700 million.[1] Type 2 diabetes Mellitus (T2 DM) accounts for around 90% of cases. Nearly 1 million Indians die due to diabetes every year. T2DM has emerged as a major cause of blindness, stroke, heart attacks, kidney failure, and lower limb amputations. So T2DM is a chronic progressive disease associated with multiple complications that can be prevented or delayed by modifying risk factors and attaining proper glycemic control. UKPDS shows that at the time of diagnosis β-cell function is already markedly compromised by up to 50%, with β-cell function continuing to deteriorate in the years following diagnosis. So β-cell function progressively declines in T2DM, and there is increasing difficulty in maintaining glycemic control. In many patients, achieving HbA1c goal may not be possible despite using multiple OADs.[2]

Due to unprecedented explosion in the number of cases of T2DM globally, diabetes-related complications are posing a major challenge both at the individual and social level. Insulin initiation early in the course of disease may be an important measure to meet this challenge.[3] Unfortunately, clinical inertia exists and insulin is used quite late despite the benefits of timely glycemic control and guidelines encouraging earlier use of insulin. That is one important reason for increase in complications in T2DM. There are *several barriers* to initiation of insulin—both at the levels of the patient and the treating physician.[4] At the level of patients, important factors are—fear of injections, risk of hypoglycemia, difficulties in managing insulin therapy. Physicians also contribute to clinical inertia by their concerns about potential side effects (particularly hypoglycemia), difficulties in training patients and absence of clear-cut guidelines. However, early institution of insulin therapy has shown beneficial effects on β-cell function and may cause remission in various studies.

Ryan et al. demonstrated in a study that if insulin is used early in the course of disease even for a short period of 2–3 weeks to achieve intensive glucose control, it may cut down glucotoxicity drastically. This may lead to improvement in β-cell function and high-remission rates even at the end of 1 year.[5]

In a landmark multicentric randomized study, Weng et al. compared the effects of short-term intensive control of blood glucose by multi-dose injections of insulin or CSII (continuous subcutaneous infusion of insulin) versus effects of multiple OADs. The insulin group showed marked improvement in β-cell function. In addition the insulin group also showed significantly higher remission rates even at the end of 1 year.[6]

In another important metaanalysis, Krammer et al. demonstrated that intensive insulin therapy for even a short period of 2–3 weeks had a positive impact on glycemic control, insulin resistance, and remission rates.[7]

Most patients with T2DM have inadequate glycemic control on one or more oral antidiabetes drugs (OADs). In these circumstances, it may be a vital decision to add another OAD or initiate insulin.

It is well known that insulin has the greatest and unparalleled glucose lowering effect. While OADs have limited capacity to decrease HbA1c by around 1–1.5% only. So patients with HbA1c of 8.5% or higher are good candidates for insulin initiation. Indian (RSSDI-ESI) guidelines suggest that insulin should be considered in those T2DM patients who have failed to achieve normal glycemic control despite using three OADs. These guidelines also recommend insulin initiation in significant hyperglycemia (fasting plasma glucose more than 270 mg/dL or HbA1c more than 9%) and patients having symptoms of polyuria, polydipsia, polyphagia, and loss of weight. RSSDI-ESI guidelines also advocate use of insulin in unstable states, severe infections, and ketosis. Patients put on insulin need to be monitored and titrated. In selected cases intensification of insulin regimen maybe done.[8] One important thing to keep in mind is that OADs should not be suddenly stopped on initiating insulin therapy because of the risk of rebound hyperglycemia.[9]

Before discussing the different insulin regimens for T2DM, it may be worthwhile to know insulins, which are readily available in Indian market and their duration of action, onset, and peak of action **(Table 1)**.

Analogues may be preferred because of less risk of hypoglycemia particularly during night. However, cost consideration is also very important in poor country like ours. Education/counseling about timing and monitoring of different insulins to the patient is very important.

TABLE 1 Insulins available in Indian market

Type of insulin	*Preparation of insulin*
Rapid acting insulin	Lispro
	Aspart
	Glulisine
Short acting insulin	Regular/soluble insulin
Ultra-fast acting insulin	Aspart (Fiasp)
Intermediate acting insulin	NPH or isophane insulin
Long acting insulin	Glargine Detemir Degludec (longest acting) Toujeo (Glargine-300 U/mL)
Premixed human insulin	30% Regular plus 70% NPH 50% Regular plus 50% NPH
	25% Lispro plus 75% NPL 50% NLP 50% Lispro 30% aspart plus 70% protamine aspart

NPH, neutral protamine hagedorn; NPL, neutral protamine lispro

OADs During Initiation of Insulin

Continuing OADs should be considered during initiation of insulin. Combination of therapies not only lowers daily insulin requirement but results in effective HbA1c reductions. Combination of most of OAD with insulin is usually safe and effective. In analysis of different studies—no increased risk of adverse effects was evident on combining insulin with OADs with few exceptions. When insulin is used with pioglitazone, there are more chances of fluid and water retention, edema, and weight gain.[10] So one needs to be very careful and pioglitazone is better avoided. There is more chances of gastrointestinal disturbances if insulin is used with acarbose.[11] Combination of insulin with sulfonylureas/secretogogues are better avoided because of the increased risk of hypoglycemia.[12,13]

However, it is known that glycemic and metabolic control can improve morbidity and mortality in T2DM, the impact of insulin and different regimens on cardiovascular outcomes remains unknown.

Basal Insulin Regimen

Adding once a day, long acting basal insulin to the OADs will help achieve not only optimum glycemic control but

also may prove to be easy for early facilitation to insulin in T2DM. Once a day basal insulin regimen is effective and safe in patients with T2DM with HbA1c of 8.5%. For this purpose, NPH insulin (once or twice a day) may be used. Alternatively a long acting analogue insulin—detemir, glargine, or a newer insulin like degludec or toujeo (high strength insulin glargine 300 U/mL) may be used. It has been found useful for symptom relief if tight control is not a major issue. Potentially there is less weight gain and less frequency of hypoglycemia. The starting dose may be 10 units/day or 0.1–0.2 U/kg/day and is titrated by 10–15% or 2–4 units to optimize fasting plasma glucose level.[11]

The advantages of long acting analogue insulins particularly degludec over NPH insulin are longer half-life, lesser glycemic variability and lower incidence of nocturnal hypoglycemia.[14]

Due to its flatter curve and lesser day-to-day variability, degludec promises to reduce risk of hypoglycemia as compared to other basal insulins. DEVOTE study demonstrated non-inferiority of degludec over glargine as far as cardiovascular outcome is concerned. At the same time there were significant reductions in the episodes of hypoglycemia particularly nocturnal ones in patients taking degludec.[15]

Basal-plus Insulin Regime

When a rapid acting bolus insulin is added before the main meal of the patient who is already on basal insulin regimen it is known as "basal-plus" strategy.[15] This may be an effective step to insulin intensification before implementing the gold standard basal bolus regimen. Careful evaluation of the patient's life style, eating habits, and self-monitoring of glucose are important for adopting this regimen.[16]

Basal Bolus Regimen

Basal bolus regimen is invaluable in uncontrolled severe hyperglycemia, and in life threatening or organ/limb threatening clinical situations. This regimen comes closest to normal physiological pattern of insulin secretion from a healthy pancreas. In this, long acting basal insulin takes care of the metabolism in the fasting state, whereas the rapid acting insulin prior to meals takes care of postprandial surge of glucose.[17] Fifty percent of the total calculated insulin requirement is taken as basal insulin and rest 50% is distributed before major meals as bolus insulins. However, patients require education and counseling regarding self monitoring of blood glucose (SMBG), and carbohydrate insulin ratio and management of hypoglycemia.[18]

Insulin dose adjustment is done as shown in **Table 2**.

TABLE 2 Insulin dose adjustment according to SMBG during insulin therapy

Type of insulin	*Time of SMBG*
Basal insulin	Fasting blood glucose before breakfast
Pre-breakfast bolus insulin	Blood glucose 2 hours after breakfast or before lunch
Pre-lunch bolus insulin	Blood glucose 2 hours after lunch or pre-dinner
Pre-dinner bolus insulin	post-dinner or bedtime blood glucose

Premix Insulin Regimen

Premixed insulins are fixed premixed formulations of short-acting or rapid insulin and intermediate- or long-acting insulin for control of both fasting and postprandial glucose. These formulations may be a combination of short and long acting conventional human insulins or short and long acting insulin analogues. Premix insulin formulations are useful for those patients who have consistent lifestyle and find it difficult to count carbohydrates. They may be started as once or twice daily and intensified to three times a day in some cases. Premixed regimen has less complicated & less demanding glucose monitoring. Initiating with premix insulins offers improved efficacy and safety and offers the advantage of simplicity. Insulin analogues offer more predictable onset of action and lesser incidence of hypoglycemia. In some studies they have shown better glycemic control particularly postprandial glucose.[19]

Conclusion

T2DM is a chronic progressive disease associated with decline in β-cell function and multiple complications. Proper glycemic control is important to slow down or prevent the process. Insulin has shown maximum efficacy in reducing HbA1c and early insulin therapy can help reduce long-term complications. There are different insulin regimens to choose according to

Contd...

Contd...

the individual characteristics and factors of the patient. Basal insulin regimen is simple, effective, and easy as augmentation therapy with OADs. Later intensification may be required. Treatment needs to be individualized based on discussion with the patient and his family members on glucose control, cost, side effects, and QOL (quality of life) while choosing optimum insulins and regimens. Premix insulins have the advantage of simplicity in patients with routine life style and consistent eating pattern. Basal bolus regimen offers optimum flexibility in terms of diet and activity but it requires multiple insulin injections, is more complicated to support and teach and needs knowledge of carbohydrate counting. Problems of hypoglycemia and weight gain need to be kept in mind. So full patient motivation is required with regular monitoring of blood sugar.

CGM Guidelines in 2021

Amit Gupta, Saurabh Srivastava

Abstract

Until recently mainstay of blood glucose monitoring was mainly dependent on SMBG and HbA1c; however, both the modalities may not serve as measure for glycemic variability. Intensified diabetes management requires accurate determination of blood glucose concentrations. Continuous glucose monitoring helps to detect trends and tracking pattern of glucose values, aids in detection of hypo- and hyperglycaemia, and help in minimizing glucose excursions, thus help in acute and long-term therapy adjustments.

Introduction

Blood glucose monitoring has entered a new era. The traditional methods of measuring glycemic control with glycated haemoglobin-HbA1c has been used for years and till date glycemic goals are defined by HbA1c, however HbA1c has many limitations. HbA1c though provides an average of blood glucose over a period of 8 to 12 weeks, it doesn't provide an estimate of intraday and interday glycemic variations and excursions. Glycemic Excursions i.e hypoglycemia or hyperglycemia have been linked to both microvascular and macrovascular complications of diabetes. Continuous glucose monitoring (CGM) depends upon the measurement of the interstitial glucose levels and track glucose levels in real time.[1]

Limitations of HbA1c

Elevated HbA1c is associated with increased risk of microvascular and macrovascular complications of Diabetes Control and Complications Trial (DCCT). United Kingdom Prospective Diabetes Study (UKPDS) has emphasized the importance of good glycemic control in improving the health outcomes in patients living with diabetes. A target HbA1c of less than or equal to 7 is recommended by most of the global organizations; however, all the guidelines equivocally recommend that HbA1c goal should be individualized for every person living with diabetes according to age, duration of diabetes, comorbidities, and life expectancy. The HbA1c has several limitations like it only provides an average over 2–3 months and it does not provide any information on hypoglycemic or hyperglycemic events.[2] HbA1c measurement may be unreliable in certain clinical settings like anemia, pregnancy, hemoglobinopathies, and iron deficiency. It does not provide data that can facilitate the decision to choose one drug over another. Studies have also reported variable glycation rates in people with different ethnic and racial backgrounds. HbA1c should be measured by a method certified by National Glycohemoglobin Standardization Program (NGSP). However, in spite of all the limitations, HbA1c remains an indispensable marker of glycemic control, a reliable marker for population health and a validated marker linked to diabetes complications.

Continuous Glucose Monitoring

It is important to understand some of the terminology often used for CGM.[3] There are CGM devices, which provide real-time unblinded data (real-time continuous glucose monitoring—rtCGM) with alarms and alerts for hypoglycemia and hyperglycemia to the users.[4] Such CGMS devices are used in most of the published randomized controlled trials. Interstitial glucose, which is measured by the rtCGM correlates well with plasma glucose and provides near real-time data on blood glucose. The glucose data received in real time allows the patient or the caregiver to take a treatment decision and allows for the timely intervention to avert severe hypoglycemic episodes. Some devices have options of sharing the glucose values with family members and friends enabling the timely alert for hypoglycemia.

The other types of devices are the ones which provide data to the patients and their health-care providers retrospectively for the analysis—intermittently viewed CGM (iCGM). The CGM device has to be physically scanned by a health-care provider **(Fig. 1)**.

iCGM is also called flash CGM.[4] There are studies to show that there is an improvement in overall time spent in hypoglycemia with rtCGM when compared to iCGM. Some rtCGMs require calibration, and frequency of calibration is variable based on the type of the device. CGM systems for which self monitoring of blood glucose (SMBG) is required to guide treatment decisions are called adjunctive while the one that does not require SMBG is called non-adjunctive. SMBG alone improves glycemic control and quality of life; however, it cannot predict impending hypoglycemia.

CGM Devices Working

CGM measures interstitial glucose levels with a delay of 5–15 minutes with rapidly changing plasma glucose levels; however, it correlates well with the plasma glucose.[5] CGM devices can measure glucose levels every 5–15 minutes. An electrochemical enzyme sensor is placed subcutaneously by the applicator and glucose readings are transmitted automatically to a receiver, which can be a smartphone, smartwatch, or any other smart device. Some CGM devices use fluorescence based sensors implanted subcutaneously with a transmitter either placed on or worn over the skin for transmitting the receiver. The sensor can record interstitial glucose values for 90 days.[6]

Interpretation of CGM Data

Data from the CGM devices can be downloaded for analysis. The glucose data is displayed in the form of current glucose values as well as in the form of trends and the direction of glucose change.[7] The data is very helpful in titrating the doses and helps in fine tuning the treatment. The ambulatory glucose profile (AGP) represents a standardized glucose reporting format in the form of mean glucose, percent of time in rage (70–180 mg/dL), percent of time spent in hypoglycemia (<70 mg/dL) and percent of time spent in hyperglycemia, that is, more than 180 mg/dL.[8]

Variability in glucose levels is reported in the form of standard deviation and percent coefficient of variation. A minimum of 10 days of data is required to accurately predict or estimate the HbA1c levels as calculated from glucose management indicator (GMI). Estimated HbA1c calculated by GMI uses a conversion based formula.[9] The estimate is based on data from clinical trials and modern CGM devices and estimated HbA1c may be the same, low or more than the laboratory HbA1c. CGM devices are also used with insulin pump therapy and are helpful in identifying glycemic patterns and deciding the insulin dose and rate for continuous subcutaneous insulin infusion.

When blood glucose levels rise rapidly the interstitial glucose concentration takes time for equilibration between the venous and interstitial fluid compartments and because of this reason CGM may yield lower glucose readings. The CGM values are less accurate at the extremes of hypoglycemia (<40 mg/dL) and hyperglycemia (>400 mg/dL) with a mean absolute relative difference of less than 11%.[10] It is difficult to compare the variability between different devices due to different sample sizes, study designs, methodologies, etc.; however, the reliabilities of newer CGM devices are improving **(Fig. 2)**.

It has been found that patients on high-dose vitamin C and on paracetamol may show falsely elevated CGM glucose values (in some CGM devices acetaminophen is oxidized by CGM electrodes).

Glycemic Variability

Glycemic variability is an independent risk factor for diabetes complications.[11] It represents the amplitude, frequency, and duration of glycemic excursions. Glycemic variability also has an effect on quality of life and cognitive

(*Source:* Centre for Diabetes Care)

functions and is now a well-accepted clinical marker of glycemic control. Availability of CGM has made it easy to assess glycemic variability. CGM data reflects all the three components of variability. Standard Deviation (SD), mean amplitude and, coefficient of variation (CV – SD divided by mean) are used to quantify glycemic variability. Stable glucose levels are defined by a coefficient of variation less than 36% while CV more than 36% defined unstable glucose levels. Clinicians should look at glycemic variability also while interpreting CGM data as a key clinical marker of glycemic control **(Fig. 3)**.

Time in Range

As discussed earlier, time spent by an individual in the target glucose range is called Time in Range (TIR). TIR provides valuable information on current glycemic control, which cannot be derived from HbA1c.[12] TIR alone cannot be taken as a marker of good glycemic control; however, it effectively illustrates metrics for clinicians as well as researchers. The future studies must report TIR along with other parameters of glycemic control to better understand the glycemic variations and diabetes-related complications and outcome **(Fig. 4)**.

CGM in Clinical Practice

Patients with type 1 diabetes or type 2 diabetes on multiple daily insulin injections are required to frequently check their blood sugar levels as it is necessary for adjusting insulin regimens to optimize glycemic controls. A six- or seven-point SMBG often provides useful information on glucose patterns; however, there are still many limitations to the conventional SMBG. An rtCGM can be of great value in detecting and avoiding potentially dangerous hypoglycemia, in identifying unrecognized hypoglycemia. A CGM glucose rising or falling trend can alert the patient, and the patient can adjust the dose of insulin accordingly. CGM data when coupled with information on food intake, physical activity and insulin dose can help in discovering some glucose patterns, which will otherwise go unnoticed. The information can be used to make necessary changes in diet and insulin. However, use of CGM requires adequate training and education of the patient. Contact dermatitis may be a common side effect of CGM devices.

CGM Guidelines/Guidance

The most recent and updated guidance on use of CGM are given by American Diabetes Association (ADA).[13] ADA states that CGM devices are useful tools in adults with both type 1 and type 2 diabetes and should be considered in patients who are not meeting glycemic goals have hypoglycemic unawareness or had severe episodes of hypoglycemia. However, their proper use requires robust diabetes education, training, and support. ADA also recommends the use of CGM in all children and adolescents on insulin injection or insulin pumps to improve glycemic control. In pregnant women with diabetes ADA states that use of rtCGM can improve HbA1c, TIR, and neonatal outcomes. A position statement by EASD and ISPAD[14] have stated that use of CGM devices may be helpful in determining carbohydrate intake before, during, and after exercise as per the trends of the rate of rise and fall in glucose levels.

Conclusion

CGM is the future of diabetes monitoring. CGM data provides a lot of information on glycemia, including variability and rate of rise and fall of glucose levels. The data can help in improving glycemic control, reduce complications, and improve quality of life of a person living with diabetes. However, there are challenges like cost, standardization, reliability of data, ever changing technology. Nevertheless CGM finds a place in all the guidelines and recommendations, latest being provided by ADA. The year 2021 marks the centenary year for insulin, but at the same time it gives us an opportunity to realize that "How Diabetes Technology is assuming a greater role in diabetes care."

CHAPTER

65 Role of 3Bs in Diabetes

Arthur Joseph Asirvatham, Adlyne Reena Asirvatham

Abstract

Understanding the pathophysiology of type 2 diabetes seems to be never ending, despite a leap of knowledge in the last decade. In addition to the ominous octet, newer pathophysiologic defects and disturbances are described to contribute to the development as well as progression of diabetes. Although β-cell failure and insulin resistance are the critical components in diabetes, brain, fat, and muscle influence both these core defects. Brain, Brown and Brawn—the 3 'B's have a considerable role to play in obesity and type 2 diabetes. Their major function is not limited to improving insulin sensitivity, but also in food intake regulation, glucose homeostasis, and also β-cell preservation. This novel concept would pave way for more research in therapeutic aspect by directly addressing the pathophysiological defects in type 2 diabetes rather than a guideline-based management.

Introduction

Obesity and type 2 diabetes are rampantly increasing in the developed as well as developing world. Weight gain occurs as a result of deregulated balance between calorie intake and calorie output. In order to achieve weight reduction, the focus has always been on the ways and means to increase the calorie expenditure. However, newer understanding on the physiology of calorie intake and its modulation in the management of metabolic dysfunction like obesity and type 2 diabetes has gained a lot of attention. Calorie intake and energy homeostasis revolves around Agouti-Related Peptide (AgRP), Brown Adipose Tissue (BAT) and skeletal muscle (SM) that form a circuit where hormonal and nutrient feedback from the periphery is signaled to the CNS.[1] In this topic, the new and important role of these 3 'B's—Brain, Brown, and Brawn in diabetes will be discussed.

3 'B's and their Role in Glucose Homeostasis

The knowledge and understanding about glucose homeostasis is increasing steeply and steadily. The role of brain especially hypothalamus and the arcuate nucleus (ARC) has been recognized as a key regulator of energy homeostasis, thus supporting the center driven control in regulation of food intake. Nevertheless, the brain integrates metabolic signals from peripheral tissues like liver, pancreas, adipose tissue, gut and skeletal muscle. Adipocytes in the brown fat also utilize glucose by UCP1-mediated thermogenesis as well as independent mechanisms thus contributing to glucose homeostasis.[2] This has been postulated to be one of the reasons behind the increasing prevalence of type 2 diabetes due to global warming. Thus, brain, brown fat, and brawn have a major role in glucose homeostasis and dysregulation of which contribute to obesity and type 2 diabetes.

Role of Brain in Diabetes

The role of brain in glucose homeostasis has been demonstrated by physiologist Claude Bernard in 1854 when he found glycosuria in a rabbit after puncture of the fourth ventricle. Ever since then in the last few decades, tremendous experiments prove the precise role

of brain and glucose sensing neurons in the hypothalamus. Glucose sensing neurons are of two types: Glucose-excited neurons in the Ventromedial Hypothalamus (VMH), Paraventricular Nucleus (PVN) and ARC that are stimulated by rise in extracellular glucose levels; Glucose-inhibited neurons in Lateral Hypothalamus (LH), PVN, and ARC that are activated by fall in glucose concentrations.

Brain in Feeding Control and Glucose Homeostasis

Neural circuits including AgRP neurons control appetite as well as glucose homeostasis. As a response to hunger, AgRP neurons induce eating and on the other hand, inhibit insulin-stimulated glucose uptake by SM. This effect of insulin resistance (IR) in the SM occurs due to the expression of muscle related genes in BAT. The effect of AgRP on the BAT and SM is shown in **Figure 1**. Acute regulation of AgRP plays the major role in feeding control and mice studies have shown that ablation of these neurons have resulted in cessation of hunger.[3] In addition to AgRP, Neuropeptide Y (NPY) an orexigenic peptide co-released by ARC and the neurotransmitter gamma-aminobutyric acid (GABA) also contribute in the food intake regulation. AgRP also plays a crucial role in glucose homeostasis apart from the feeding control. It has been demonstrated that suppression of hepatic glucose output by insulin occurs partially by inhibiting AgRP neurons in mice.[4] IR in obesity is also presumed to be due to obesity associated hypothalamic inflammation and consequently alteration of AgRP neuronal activity.[5]

Brain Integrates Peripheral Signals

Brain also puts together peripheral signals to regulate glucose metabolism. Hormonal input signals include insulin through hypothalamic insulin signaling pathway, leptin by leptin mediated regulation of glucose metabolism, long chain fatty acids through hypothalamic lipid sensing and more importantly glucose through glucose sensing. Glucose sensing mechanism in hypothalamus is better understood and is very similar to that in pancreatic β-cell. The sequence of events that occur in glucose-excited neurons following elevated plasma glucose is shown in **Figure 2**. On the contrary, the mechanism of glucose-inhibited neurons is unclear.

Brain and Effector Pathways

Besides the neuronal role and integration of peripheral signals, brain also has effector pathways to ensure glucose

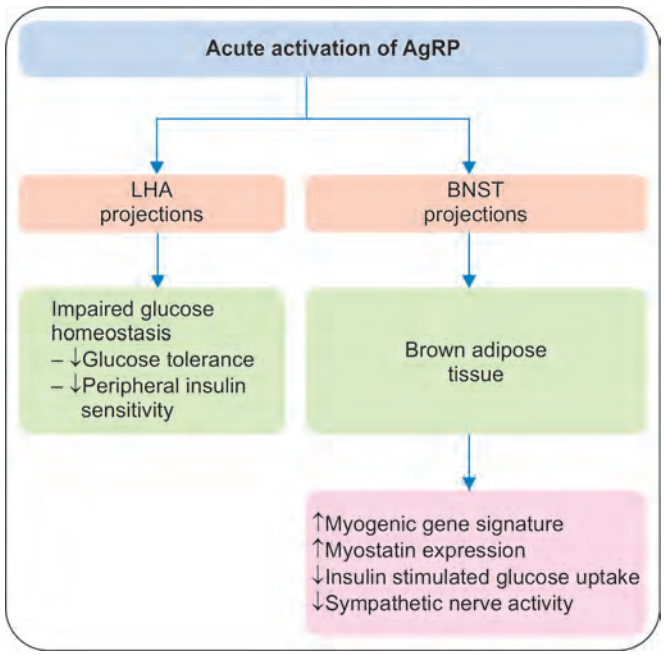

Fig. 1: Influence of AgRP on brain adipose tissue (BAT) and skeletal muscle (SM) during acute activation
LHA, lateral hypothalamus area; BNST, bed nucleus of the stria terminalis

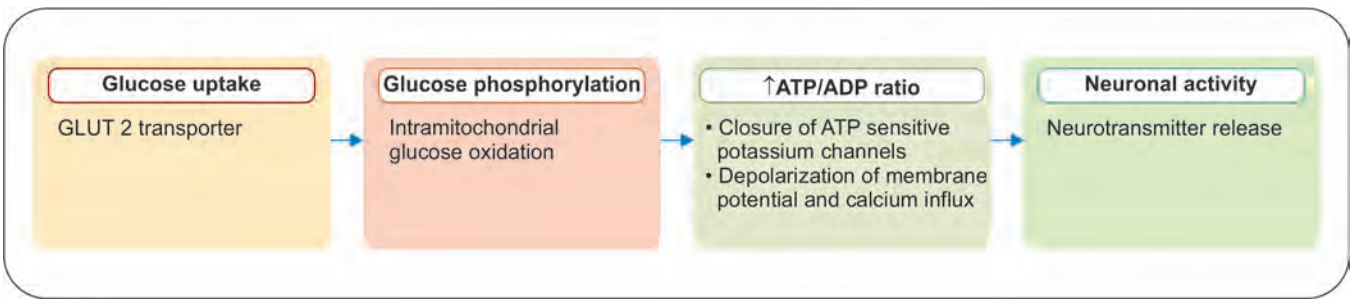

Fig. 2: Glucose sensing mechanism in hypothalamic glucose excited neurons

metabolism.[6] These pathways target organs as mentioned here.

- *Liver:* Insulin receptor in both liver and brain is required for the ability of insulin to effectively suppress hepatic glucose output. This has been proven in rodents where knockout of insulin receptor in brain sparing the liver did not completely produce hepatic glucose production (HGP) suppression.
- *Pancreas:* Autonomic nervous system controls the secretion of glucagon and insulin. Parasympathetic activity stimulates insulin and sympathetic nerves inhibit it while both stimulate glucagon secretion.
- *Skeletal muscle:* Leptin has shown to increase glucose uptake in skeletal muscle by translocation of GLUT4 glucose transporter. It also promotes glucose uptake via AMPK signaling pathway in SM through sympathetic nervous system.

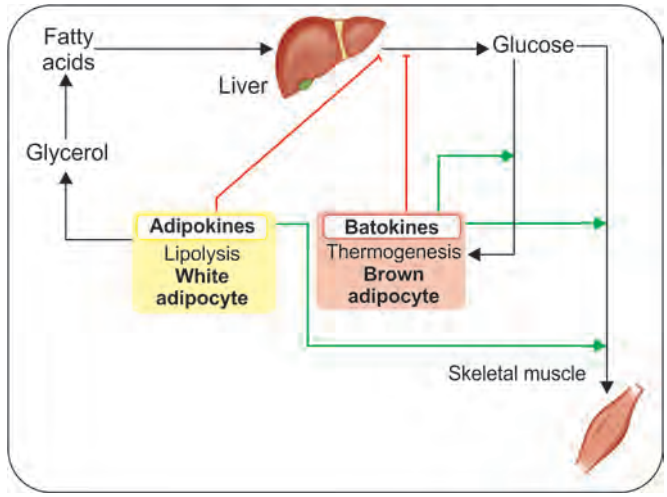

Fig. 3: Relationship between BAT and WAT and their role in systemic metabolic regulation

Role of Brown Fat in Diabetes

White adipose tissue (WAT) stores energy and is known for its association with metabolic disease. The role of BAT, which burns energy for thermogenesis, was unrecognized until few years ago due to underestimation of its existence in adults. Now, we know that the total amount of brown and/or beige fat is at least tenfold higher than previously calculated owing to studies with advanced PET scans.[7] Brown adipocytes regulate energy expenditure by their abundant and large mitochondria. Uncoupling Protein 1 (UCP1) is BAT specific protein located in the inner mitochondrial membrane, which when activated, generates heat instead of ATP and thus mediates BAT thermogenesis.

Glucose Uptake in BAT

Besides thermogenesis, BAT also plays a significant role in glucose homeostasis. At the cellular level, glucose uptake by BAT occurs through GLUT1 and GLUT4 contributing significantly to systemic glucose disposal. This glucose uptake and utilization is extremely responsive to β-adrenergic stimulation and insulin.[8] Cold induced stimulation of BAT has demonstrated improvement in glucose metabolism in type 2 diabetes.[9] Obesity attenuates GLUT1 translocation and thus glucose utilization in BAT. It has also been shown that 16.5% body weight reduction following chronic calorie restriction increased brown adipocytes in subcutaneous fat by 10%.[10] Furthermore, the fasting plasma glucose and fasting insulin levels improved.[9] The glucose uptake in BAT is also influenced by AgRP as discussed earlier.

Batokines and Glucose Metabolism

Batokines are the factors secreted exclusively by BAT in contrast to the adipokines secreted by WAT, which includes leptin, adiponectin, etc. These batokines regulate hepatic glucose output, hepatic lipogenesis in addition to glucose uptake and disposal by skeletal muscle.[11] The paracrine effect between BAT and WAT and the mechanisms by which they control systemic metabolic regulation are shown in **Figure 3**. Thus, brown and beige adipocytes have very good therapeutic potential in modulating glucose uptake, utilization, and glucose metabolism. Hence, several studies are on the way looking at increasing BAT size and function.

Role of Brawn in Diabetes

Function of skeletal muscle in glucose metabolism has been known for ages. IR has been the hallmark abnormality that is observed in SM. Several mechanisms have been hypothesized for IR including dysregulated GLUT4 translocation, insulin receptor downregulation, defective post-receptor signaling etc. Myokines are protein factors secreted by SM, which exerts its action on multiple tissues. Recently, suppression of adaptive glucose stimulated insulin secretion has also been found

to be an effect of these myokines on the pancreatic β-cell thus contributing even to the secretory defect of type 2 diabetes.[12]

Myostatin is another factor belonging to transforming growth factor-beta/bone morphogenetic protein (TGF-β/BMP) superfamily whose main role is inhibiting skeletal muscle growth. Myostatin inhibits skeletal muscle stem cell proliferation, differentiation and attenuates muscle fiber protein accretion and thereby result in decreased skeletal muscle mass. It also has a role in insulin stimulated glucose uptake as shown in animal studies. Myostatin knockout mice showed improved insulin sensitivity proving the impact of myostatin on liver and adipose tissue beyond SM. Myostatin mRNA levels were found to be increased in those with type 2 diabetes compared to controls.[13] Resistance training has shown to reduce myostatin levels by 20%.[14] This could possibly explain the benefit of inhibiting myostatin expression to achieve better lean body mass, enhanced insulin sensitivity, and improved glucose metabolism thus paving way for a potential beneficial target.

Recent studies prove the additional role of SM in improving β-cell mass and function that could also be regulated through myokines and protein factors. Exercise has shown to enhance β-cell viability to some extent through increased IL-6 release from SM that either act directly on β-cell[15,16] or indirectly by increasing GLP-1 secretion from L-cells and α-cells.[17] Other factors like Irisin are also released from SM that has been suggested to improve or protect β-cell mass and function.[18] On the contrary, muscle secretome could exert a negative effect on the β-cell mass and function. The myotubes and their secretory factors differ significantly between those with and without type 2 diabetes. Studies have proven that the myotubes in controls retained their ability to protect or augment glucose stimulated insulin secretion compared to those with type 2 diabetes.[12] This β-cell/SM communication and interaction remains to be understood further in type 2 diabetes.

Future Research

Despite several failures with BAT related therapies in the past, the future therapeutic targets seem promising. Pharmacological stimulation of BAT with BMP-7, FGF-21, protein regulator PGC-1α, etc. is being tried to produce favorable metabolic benefits. Even more interestingly, stimulation of precursor stem cells to differentiate into BAT is also being attempted. The ultimate challenge of BAT autotransplantation is currently under research. But whether increasing BAT mass be translated into augmented activity of BAT is questionable. Drugs to reduce myostatin activity like myostatin antagonist are in the pipeline.

Conclusion

The 3 'B's—Brain, Brown fat and Brawn play a significant role in food intake regulation, integrating metabolic cues from peripheral tissues, controlling glucose homeostasis, modulating IR, and protecting β-cell mass and function. Recent understanding of these circuits, the effectors and their cross talks, paves way for more research with possible therapeutic targets in metabolic diseases. Exercise, once thought to be an additional simple intervention to improve glucose uptake in SM, has been found to be more beneficial by reducing myostatin expression in SM and even preservation of β-cell mass and function. Novel therapies for diabetes and obesity are quite reassuring in the near future, until then easy modalities like exercise should be diligently practised for the more clearly proven benefits.

CHAPTER

66 Sleep Disorders and Type 2 Diabetes

Umashankar Mishra, Abinash Hota

Abstract

Sleep is an essential component of human life. Its disorders are gateway to metabolic syndromes. Sleep disorders and type 2 diabetes mellitus (T2DM) are closely associated and they enhance disease severity of each other and their complications as well. Sleep disturbances along with T2DM accelerate the cardiovascular, neurological, ocular, neuroendocrine, and sexual complications increasing morbidity and mortality significantly. Also sleep disorder is an important reason for inadequate glycemic control and vice versa despite of treatment. Its incidence in T2DM is well documented and its treatment improves quality of life significantly.

Introduction

Sleep is a complex, active, and physiologic event constituting more than 30% of human lifetime. It has its pivotal importance in maintaining metabolic homeostasis, memory consolidation, and in restoration of psychic structure and function. Sleep follows a particular rhythm comprising non-rapid eye movement (NREM) sleep (N1, N2, N3) and rapid eye movement (REM) sleep, derangement of which affects body functions. Association of quantity[1] and quality[2] of sleep with metabolic syndromes has been clearly established. So, deprivation of sleep, which is a part and parcel of modern lifestyle, may be responsible for booming of metabolic syndrome at present era.[3]

Type 2 diabetes mellitus (T2DM), being the most prevalent noncommunicable disease, constitutes a significant health-care burden. United Nations General Assembly in 2006 declared T2DM to be the first noncommunicable disease that threatens the world health to the same magnitude as communicable diseases such as HIV and TB.[4] Sleep disorders and T2DM are two events of a vicious cycle. Patients with T2DM report a higher rate of insomnia, sleep fragmentation, poor sleep quality, excessive day time sleepiness, and excessive use of sleep medications. The reason of the sleep disturbance in T2DM may be due to the disease itself or its complications.

India, being the diabetic capital of the world, there should be awareness among the physicians for the assessment of sleep disorders in T2DM.

Sleep Disorders in T2DM

Comparing with nondiabetics, sleep disorders constitute a higher health-care problem among diabetics. The higher incidence of sleep disorders in T2DM is likely due to painful diabetic neuropathy, sleep breaks due to nocturia, night hypoglycemic, and hyperglycemic episodes. Restless Leg Syndromes (RLS) & Periodic Leg Movement Syndrome (PLMS) were found to be more prevalent in T2DM.[5] There can be associated autonomic neuropathy causing central sleep apnea in other breathing disorders. Depression occupies a significant proportion of health-related problems in diabetes that severely

affects sleep.[6] Also T2DM itself affects sleep quality by directly affecting neurobehavioral, neurotransmitter, and autonomic functions.[7]

The sleep complaints in T2DM are difficulty in initiating sleep (21.1%), difficulty in maintaining sleep (21.9%), and excessive daytime sleepiness (12.2%).[8] Sleep disorders like obstructive sleep apnea (OSA), insomnia, sleep deprivation, excessive sleepiness, restless leg syndrome (RLS), periodic limb movements (PLMS) are associated with T2DM. Amongst them OSA has a strong association with T2DM.[9]

Sleep Disorders Leading to T2DM

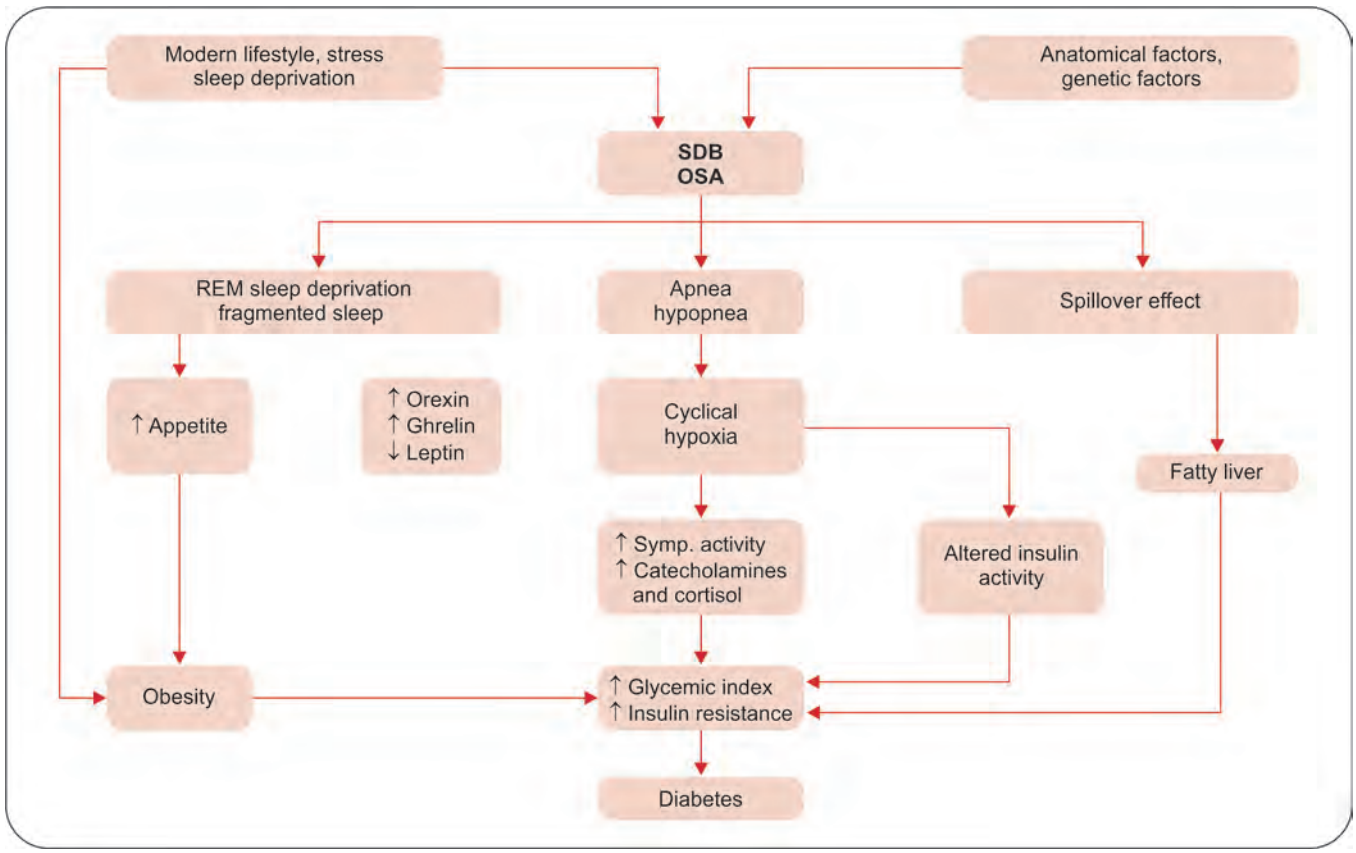
Among the sleep disorders, sleep disordered breathing (SDB), sleep deprivation, insomnia, excessive sleepiness, RLS dominantly affect glucose metabolism. A recent meta-analysis demonstrated that sleep disturbance is a significant risk factor for T2DM.[9] Difficulty in initiating sleep increased the risk of T2DM by 55%, while difficulty in maintaining sleep increased the risk by 74%. Likewise, the risk of development of T2DM in insufficient sleep (<6 hours) or excessive sleep (>9 hours) is comparably similar with the risk of T2DM in physical inactivity. This shows the importance of routine assessment of sleep disorder in T2DM.

The probable mechanisms of glycemic variability due to sleep disorders are summarized in the **Flowchart 1**.

Sleep Disorders and Neuroendocrine Control

REM sleep deprivation is common in OSA patients. Fragmented sleep and sleep deprivation decrease the neuroendocrine regulation over appetite. So, it leads to overfeeding causing hyperglycemia. The reason of overfeeding is thought to be associated with OREXIN hyperactivity in sleep deprived patient. Increased level of GHRELIN (hunger promoting hormone) and decreased level of leptin (satiety maintaining hormone) in the circulation of patients with sleep disorders were also found, which again supports the neuroendocrine theory.

Flowchart 1: Probable mechanisms of sleep disorders leading to development of type 2 DM



Sleep Deprivation Leading to Insulin Resistance

The presence of insulin resistance was demonstrated in sleep deprived patients.[10] Studies depicted that there is a clear association between sleep apnea and insulin resistance.[11] SDB and OSA are associated with cyclical hypoxia, which increases sympathetic and corticotropic effect. It increases level of catecholamines and cortisol in circulation causing "spill-over effect." It is thought to be the cause of increased visceral adiposity and insulin resistance in these patients.

Sympathetic Hyperactivity in Sleep Disorder

Repeated episodes of apnea and hypopnea during sleep in patients with OSA cause hypoxia, which increases sympathetic activity. Increased level of catecholamines itself cause dysregulation of glycemic status. So, if not associated with T2DM, these patients present with fasting hyperglycemia with normal postprandial oral glucose tolerance test (OGTT). So, only fasting hyperglycemia should raise a suspicion of sleep disorder.

Diabetes and Sleep Disordered Breathing

Prevalence

SDB is a spectrum of disorders consisting snoring, upper airway resistance syndrome and sleep apnea. Sleep apnea can be obstructive, central, or mixed. Higher incidence of SDB is clearly evident in T2DM and OSA is most common amongst them. The prevalence of SDB among T2DM can be as high as 58% and of OSA is 23%.[12] In Look AHEAD TRIAL (Action for Health In Diabetes), amongst the obese participants the prevalence of SDB reached up to 80%.[13] Though OSA is most common SDB among T2DM, but central type apnea are also reported, when associated with autonomic neuropathy.[14,15]

Clinical Features

OSA is characterized by collapse of the upper airway leading to deficient airflow despite of persistent respiratory effort. Though it usually occurs among obese, but nonobese, lean diabetics are also affected. Among the lean-diabetics anatomical factors of face and neck that promotes OSA include macroglossia, short neck, retruded chin or maxilla, neck circumference of more than 43 cm. So lean diabetics are to be screened for sleep disorders, as in India major proportion of diabetic patients are of low or normal body weight. Two prominent symptoms of OSA are habitual snoring and excessive day time sleepiness. Other symptoms are episodes of choking apnea, restlessness, diaphoresis, frequent change of posture during sleep, and difficulty in sleeping supine. Poor concentration, morning headache, mood swings, and irritability are commonly associated.

Complications

OSA independently increases the risk of developing insulin resistance, hypertension (HTN), and cardiovascular disease (CVD). Its causation can be defined by increased sympathetic activity, increased corticotropic action, altered lipid metabolism, hypoxia, oxidative stress, and systemic inflammation. Also T2DM has a clear association with CVD.

Hypothyroidism may be associated with OSA. Day time sleepiness and lethargy in obese patients with OSA can be confused with hypothyroid symptoms. So prescribing high doses of thyroxine without treating OSA can lead to higher mortality in CVD during sleep due to cardiac arrhythmia and cyclical hypoxemia.

Sexual dysfunction is a known consequence of OSA. In REM sleep, there occurs nocturnal penile and clitoral tumescence. So increased blood flow to these tissues possibly prevent excessive collagen formation maintaining their erectile function. So, REM sleep deprivation in OSA can be a possible explanation for it. Likewise, erectile dysfunction is a known complication of T2DM.

Cyclical hypoxemia during sleep in OSA has its deleterious effects on retina also. Sleep disorders in T2DM has been reported to play an etiological role in the development as well as progression of diabetic retinopathy.[16] Also there are repeated association of OSA with several eye disorders that is optic neuropathy, anterior ischemic optic neuropathy (AION), floppy eyelid syndrome, glaucoma, etc.[17] So, early treatment of OSA/SDB in T2DM may have a good retinal outcome.

Having above complications in common OSA/SDB can additively augment diabetic hazards. It can also be a cause of ineffective treatment of T2DM. Treatment of OSA with Continuous Positive Airway Pressure (CPAP) might correct the metabolic complications, but its effect over glycemic control is some-how mixed.[18] Treatment of OSA/SDB is of prime importance as it significantly improves quality of life and blood pressure control.[19]

Diagnosis and Management of Sleep Disorders

American Diabetes Association 2017 guideline recommends assessment of sleep pattern, sleep quality, duration, as part of comprehensive medical evaluation in persons with T2DM.[20] As reasons of sleep disruption in T2DM are multifactorial, so a detailed history and clinical evaluation is the primary tool toward diagnosis. Frequency of hypoglycemic and hyperglycemic episodes, frequency of nocturia, and associated causes are to be looked after. Proper neurological evaluation for peripheral neuropathy or associated autonomic neuropathy should be done. Association of depression should be given importance as its treatment is beneficial and diagnosis is easily overlooked. Keeping a sleep diary of past few weeks should be encouraged. However, when it's suspected for SDB/OSA, an overnight polysomnography should be done. Newer and more feasible technique like ACTIGRAPHY is also now widely available for detecting sleep disorders. Appropriate treatment of the sleep disorder requires finding out its cause and treating the same, some of which are enlisted in **Table 1**. A proper sleep discipline, sleep hygiene, sleep restrictions along with cognitive behavioural therapies, and relaxation therapies are required for primary insomnia and other refractory sleep disorders.

Recent Advances in Management of OSA

Looking into the progression of metabolic syndromes in untreated sleep disorders, there has been lots of studies for the treatment aspect, as well as the compliance of the patients toward it. As OSA is the most common SDB, there have been some new therapies specifically looking into the inconvenience of CPAP/BiPAP. In mild cases along with weight loss, positional therapy and oral appliances are advised. PROVENT therapy **(Fig. 1)** based

Fig. 1: PROVENT therapy

TABLE 1 Associated comorbidities for poor sleep in persons with diabetes and possible measures rectify them

Comorbidities	*Measures to rectify*
• Fluctuation in blood glucose • Restless legs syndrome & Periodic leg movement syndrome	• Optimum glycemic control avoiding hypoglycemia • Identifying and correcting iron deficiency, thyroid disease • Rule out RLS mimics • Dopamine agonists, dopamine precursors • Antiepileptics (gabapentin, pregabalin, carbamazepine) • Opiates in severe cases (oxycodone, methadone)
• Peripheral neuropathies	• Analgesics • Antidepressants (such as TCAs, SSRI) • GABAergic agents (gabapentin, pregabalin)
• Obstructive sleep apnea	• Weight loss, positional therapy • Oral appliances • Identification and treatment of upper airway obstruction • Nasal continuous positive airway pressure
• Depression	• Modafinil in res-OSA*[21] • Antidepressants and behavioral therapy

*Residual sleepiness in OSA despite of using CPAP; GABA, gamma-aminobutyric acid; SSRI, selective serotonin reuptake inhibitor; TCAs, tricyclic antidepressants

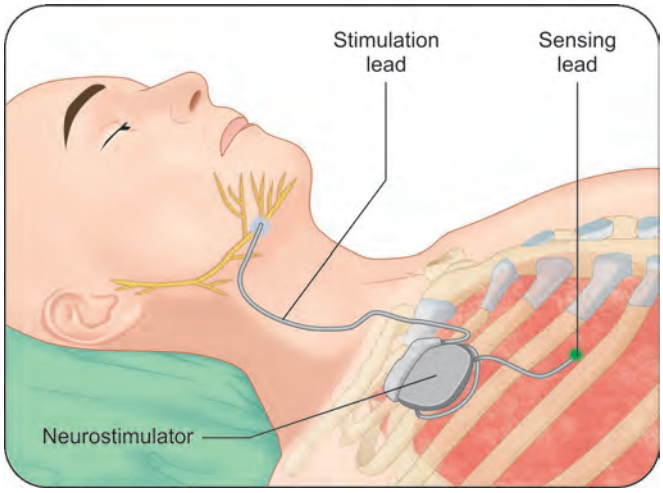


Fig. 2: Upper airway stimulation therapy

on nasal expiratory positive airway pressure (EPAP) is a new FDA approved therapy for mild to moderate OSA. Mini-CPAP consisting of battery powered micro-blowers, not requiring any hoses and masks, seems promising but still awaits FDA approval. Upper airway stimulation (UAS) therapy **(Fig. 2)** is an emerging option for refractory cases of moderate-severe OSA. Modafinil is found useful in OSA patients with residual sleepiness despite of using CPAP.[21]

Conclusion

Sleep disorders and T2DM are two events of a vicious cycle. So, ignoring sleep disorders not only leads to improper treatment of T2DM, but also helps in progression of its complications. OSA is no more considered to be a sleep disorder rather it's a gateway to metabolic syndrome. So, a routine assessment of sleep in T2DM should be done with a higher clinical suspicion in order to diagnose sleep disorders. Proper treatments of sleep disorder and its prevention by maintaining sleep hygiene should be enforced.

CHAPTER

67 Current Status of Oral Agents in Treatment of Gestational Diabetes

AK Chauhan

Abstract

Gestational diabetes mellitus (GDM) is a serious complication of pregnancy, in which women without prior overt diabetes develop chronic hyperglycemia during gestation. Risk factors for GDM include overweight and obesity, advanced maternal age, and a family history of any form of diabetes. GDM can have an impact, not only on normal fetal development, and lead to birth complications, but also raises the risk of development of type 2 diabetes later in life. The rising prevalence of GDM globally and in India, in recent years, has placed the spotlight on better management strategies. Glycemic control has traditionally been based on a combination of diet and insulin therapy. More recent data has focused on the role of oral hypoglycemic agents, specifically metformin and glyburide.

Introduction

Gestational diabetes mellitus (GDM), is defined as "the type of glucose intolerance that develops in the second and third trimester of pregnancy, resulting in hyperglycemia of variable severity."[1] It is a severe and neglected threat to maternal and child health, with women experiencing multiple adverse pregnancy outcomes.[2] Approximately half of women with a history of GDM develop type 2 diabetes mellitus (T2DM) within 5–10 years after delivery[2] and the offspring are at increased risk for the development of obesity and T2DM early in life.[1]

There has been a steady rise in the prevalence of GDM. According to the 2019 data of the International Diabetes Federation (IDF), an estimated 223 million women between 20 and 79 years of age are living with diabetes. Twenty million or 16% of live births had some form of hyperglycemia in pregnancy and an estimated 84% were due to gestational diabetes.[2] A vast majority of cases of hyperglycemia in pregnancy occurs in low- and middle-income countries.[2]

It is important for women with diabetes in pregnancy or GDM to carefully control and monitor their blood glucose levels to reduce the risk of adverse pregnancy outcomes with the support of their health-care provider.

Etiological Factors for GDM

The rise in number of women with GDM has been attributed to increasing obesity prevalence and advancing maternal age.[1] Several risk factors, attributed to the development of GDM, are listed in **Table 1**.[1]

Pathophysiology of GDM

Normal physiology in pregnancy raises the risk of insulin resistance due to physiological increases in homeostatic hormones including cortisol, growth hormone, human placental lactogen, progesterone, and prolactin.[3] While there is a compensatory increase in the release of insulin of up to 250% in normal women,[3] in beta cells in women with GDM, are unable to compensate with sufficient insulin secretion due to pre-existing beta cell failure.[4]

TABLE 1 Modifiable and non-modifiable risk factors for GDM

Modifiable factors	*Non-modifiable factors*
High pre-pregnant BMI	Advanced maternal age
Poor dietary quality	Personal history of GDM or prediabetes
Sedentary lifestyle	Family history of diabetes
Vitamin D deficiency	Ethnicity (Asian, Hispanic, Native American, and African American)
PCOS	Maternal history of low birth weight
High total bile acid in the first trimester	Low stature Twin pregnancy Genetic susceptibility

PCOS, polycystic ovary syndrome

When insulin secretion does not increase sufficiently to counterbalance the insulin-resistant state of the later trimesters, maternal glucose intolerance leading to GDM occurs. β-cell secretory impairment is an important aspect of GDM, which is probably a pre-existing one, and thereby confers a high risk of overt diabetes post-pregnancy.[4]

Insulin mediated suppression of lipolysis is reduced contributing to increases in free fatty acids and severe insulin resistance in late gestation. There is a reduction in glucose transporter type 4 (GLUT4) translocation and decreased insulin uptake. Adiponectin levels decline and excess lipolysis and inflammation precipitates severe insulin resistance in liver, muscle, and adipose tissue.[3]

Management of GDM

The primary goal of therapy is aimed at lowering the risk of adverse perinatal outcomes, by achieving euglycemia.[4] Plasma glucose threshold goals for fasting and postprandial plasma glucose have been provided in the guidelines of the American Congress of Obstetricians and Gynecologists and the American Diabetes Association.[5] Consensus evidence-based guidelines for management of GDM in India are also available.[6]

Initial treatment of GDM includes medical nutrition therapy and moderate physical activity.[7] However, half of the women may not achieve established glucose goals with diet modifications alone and will require pharmacologic therapy.[5]

Traditionally insulin has been the mainstay of therapy for GDM as it is not known to cross the placenta. However, use of insulin in GDM comes with many challenges, the need for patient education and poor compliance, being the most common.[6] Insulin is also required to be administered as multiple-daily injections, with up to 70% risk of hypoglycemia in women, sometime during their pregnancy.[5]

Oral Antidiabetic Agents

Oral antidiabetic agents are a suitable alternative due to the lower risk of hypoglycemia, and the ease of taking the medications, without need for self-injections,[5] In addition, the pathophysiology of GDM also indicates the use of oral antidiabetic agents. The use of oral agents in pregnancy, however, involves the balancing of risk of hyperglycemia with potential medication side effects, transplacental passage and teratogenicity, and the long-term effects of the medication on the child.[5]

Among the oral antidiabetic agents, the biguanide, metformin, and the sulfonylurea, glyburide are the two well-studied agents in pregnancy. There is significant data on pharmacokinetics in pregnancy, placental transfer, and maternal and neonatal outcomes when compared to insulin use in women with GDM.[8]

Metformin

Metformin is a biguanide, "insulin sensitizer" and its mechanism of action in controlling hyperglycemia is still a topic of research. Metformin is known to inhibit gluconeogenesis, suppress hepatic glucose output, and increase intestinal glucose absorption. It is also known to stimulate glucose uptake in the liver and peripheral tissues.[5] The most widely accepted model of the anti-hyperglycemic action of metformin is the suppression of hepatic gluconeogenesis as a result of mitochondrial inhibition, via 5' AMP-activated protein kinase (AMPK). AMPK is also believed to play a key role in long-term effects of metformin by improving lipid metabolism and mitochondrial function in the liver.[9]

Metformin-Pharmacokinetics

Metformin is absorbed from the duodenum and jejunum within about 6 hours of ingestion. It has an absolute oral bioavailability of 40–60%. The drug is rapidly distributed following absorption and does not bind to plasma protein. No metabolites or conjugates of metformin have been identified. The parent drug is excreted unchanged through

the kidneys and in bile, with a half-life of about 6 hours. About 30% of the drug is excreted directly through the feces.[3]

Placental Transfer of Metformin

Metformin freely and readily crosses the placenta. Metformin is rapidly transferred across the placenta with a simultaneous decline in maternal metformin levels and increases in fetal levels in pregnant women.[8] Placental concentrations of metformin can reach at least 50% of circulating maternal levels.[3] Metformin, however, does not cross through cell membranes by passive diffusion and metformin transfer was found to be dose dependent.[8]

Effectiveness of Metformin in GDM

Metformin has been used for decades in early pregnancy in women with polycystic ovarian syndrome (PCOS). Prepregnancy metformin helps in restoring normal ovulation and improving conception. Continuing to take it through the first trimester lowers the risk of spontaneous abortion.[5]

The Metformin in Gestational Diabetes Trial (MiG) by Rowan et al., published in the New England Journal of Medicine in 2008, was the first randomized trial comparing use of metformin and insulin for treatment of GDM.[10] A total of 751 women with GDM at 20–33 weeks of gestation were initiated treatment with metformin (with supplemental insulin if required) or insulin. Of the 363 women assigned to metformin, 92.6% continued to receive metformin until delivery and 46.3% received supplemental insulin. Metformin (alone or with supplemental insulin) was not associated with increased perinatal complications as compared with insulin. Metformin was preferred over insulin, with more women in the metformin group than in the insulin group stated that they would choose to receive their assigned treatment again (76.6% vs. 27.2%, $P<0.001$).[10]

Subsequent studies have found metformin to be an acceptable alternative to insulin, to effectively achieve glycemic control in normal or slightly overweight women or those with mildly elevated fasting glucose values.

In the 2-year follow-up of offspring in the MiG-TOFU study group, no adverse outcomes above baseline risk were seen in infants born of women randomized to metformin or insulin during pregnancy. No differences were observed in central fat measures, total fat mass or percentage body fat for the infants in the metformin group. However, compared with the insulin group, the metformin group had larger upper arm circumferences, bigger biceps and subscapular skin folds, and a more favorable pattern of fat distribution suggesting a potential protective effect against later development of insulin resistance in the offspring.[11] In 2018, the MiG-TOFU study group published the longest offspring follow-up study for metformin exposure at 7 and 9 years at two individual study sites. Metformin or insulin for GDM was associated with similar offspring total and abdominal body fat percent and metabolic measures at 7–9 years.[12]

Safety in Pregnancy and Lactation

Since metformin does not stimulate secretion of insulin, it does not cause maternal hypoglycemic episodes as seen with insulin. No congenital anomalies, or teratogenic effects have been reported in the over two decades of its use in the preconception and early pregnancy period.[13]

Gastrointestinal side effects, including diarrhea, flatulence, nausea, and vomiting, affect 5–15% of women. The potential side effect of lactic acidosis, can be avoided by gradually increasing dose. This side effect has not been reported in neonates. Metformin is classified as FDA Pregnancy Category B.[5]

It is safe to breastfeed if metformin is to be continued after delivery, as levels of metformin in maternal milk are low. There are no reports of developmental or growth problems in infants of mothers using metformin while breastfeeding.[5]

Metformin Dose

Metformin is available in 500, 850, and 1,000 mg regular and extended-release tablets. The currently recommended starting dose is 500–800 mg/day, with a maximum daily dose of 2,500 mg/day, in divided dosing.[5]

Glyburide

Glyburide (also known as glibenclamide) is a second-generation sulfonylurea, which increases insulin secretion and sensitivity in peripheral tissues and reduces hepatic insulin clearance by binding to pancreatic beta-cell ATP-calcium channel receptors.[5]

Glyburide-Pharmacokinetics

Glyburide is well-absorbed with oral administration and is metabolized by the liver. It reaches peak concentration

in approximately 3 hours and has a half-life of 8 hours. Glyburide decreases circulating glucose by approximately 20% and is most effective in patients who are normal weight or slightly overweight.[14]

Placental Transfer

Hebert et al. reported that there is significant placental transfer of glyburide with fetal cord blood levels that were 70% of maternal serum levels.[15]

Effectiveness of Glyburide in GDM

Glyburide was the first oral antidiabetic agent to be tested in GDM. Effectiveness of Glyburide in GDM versus standard-of-care insulin was tested and published by Langer et al. in the New England Journal of Medicine, in 2000.[16] A total of 404 women with singleton pregnancies and gestational diabetes that required treatment were randomly assigned between 11 and 33 weeks of gestation to receive glyburide or insulin according to an intensified treatment protocol. Glyburide was equivalent to insulin in achieving glycemic control. Important neonatal outcomes were similar between glyburide and insulin-treated women included large for gestational age, macrosomia more than 4,000 g, hypoglycemia, neonatal intensive care unit admission, and fetal anomalies.[16] Subsequent meta-analysis of 9 studies, including 745 glyburide-treated and 637 insulin-treated showed similar results.[15]

It has, however, been seen that 4–21% of women with GDM may not achieve adequate glycemic control with glyburide. The characteristics of women who failed glyburide therapy included older women, multiparous, and more likely to be diagnosed at less than 25 weeks of pregnancy, with higher fasting glucose values. It has been suggested that such women may represent a group with undiagnosed T2DM and should probably not to be treated with glyburide as primary therapy.[16]

Safety in Pregnancy and Lactation

Glyburide is known to cross the placenta, and umbilical cord concentration may reach as much as 70% of maternal

TABLE 2 Comparison of glyburide and metformin in GDM

	Glyburide	***Metformin***
Mechanism of action	Increase insulin secretion, reduce hepatic insulin clearance	Increase insulin sensitivity, stimulate insulin uptake
Peak concentration	3 h	4 h
Half-life	8 h	2–5 h
Action and hypoglycemia	Action can directly cause maternal hypoglycemia	Action does not directly cause maternal hypoglycemia
Proof of efficacy	Glyburide=insulin in achieving glycemic control Failure rate: 4–21%	Metformin=insulin in achieving glycemic control Failure rate up to 46%
	Metformin failure rate may be twice glyburide failure rate Neonatal hypoglycemia similar for each Metformin associated with lower maternal weight gain	
Maternal safety-hypoglycemia	Symptomatic hypoglycemia in 1–5%	Symptomatic hypoglycemia in 0–10%, despite mechanism of action
Maternal safety-other side effects	GI, dermatologic side effects, rare elevation in liver function tests	GI side effects, rare lactic acidosis avoided with gradual dose increase
Fetal safety	Placental transfer demonstrated No known congenital anomalies	Placental transfer demonstrated No known congenital anomalies
Lactation safety	Levels in breast milk likely negligible Do not recommend breastfeeding avoidance or discarding breastmilk if glyburide indicated postpartum	Maternal milk levels negligible, 0.5% of maternal dose Do not recommend breastfeeding avoidance or discarding breastmilk if metformin indicated postpartum

concentration.[17] No congenital anomalies have been found with the use of glyburide in pregnancy. It has been placed in FDA Pregnancy Category C.[5]

In a comparative study, women using insulin experienced 4.1 asymptomatic hypoglycemic episodes whereas those taking glyburide experienced 2.1. Further, insulin-related episodes were more frequently severe at less than 40 mg/dL and predominantly nocturnal, unlike the glyburide episodes which occurred equally between day and night.[18]

Gastrointestinal symptoms including mild nausea, heartburn, or feeling full, dermatologic effects including mild itching or skin rash, and elevated liver function tests were common, but more manageable.[5]

If glyburide is initiated to manage GDM, it should be discontinued after delivery. In case there is a need to continue, levels of glyburides in maternal breast milk are negligible and undetectable in infant blood with a 5-mg daily dose.[5]

Dosing

The currently recommend starting dose of glyburide is 2.5 or 5 mg daily or twice daily, with a maximum daily dose of 20 mg, in twice daily dosing.

Glyburide or Metformin?

Glyburide and metformin have been compared in GDM. In one study by Moore and colleagues' women randomized to metformin were more than twice as likely to fail oral hypoglycemic therapy, compared with glyburide,[19] while another study reported similar failure rates for metformin and glyburide.[20] **Table 2** details the differences between metformin and glyburide in GDM.

Conclusion

Glyburide and metformin have emerged as potential oral antidiabetic agents for GDM by virtue of their efficacy and safety, over insulin and can benefit women who prefer oral medication over multiple daily insulin injections. With increasing prevalence of GDM, oral antidiabetic agents may be treatments to be considered. However, there is a paucity of long-term offspring safety data, which could be the reason why most professional societies still recommend insulin as the sole first-line option for treatment of GDM.

Diabetes in Young: Challenges

GD Ramchandani, Rahul Ramchandani, Divyansh Mathur, KK Pareek, Girish Mathur

Abstract

Diabetes mellitus (DM) is one of the most prevalent non-communicable diseases that lead to a significant morbidity and mortality. Worldwide, the pandemic of DM was 9.3% of global population in 2019 and projected to increase to more than 10% by 2030. In India, the estimated number of people living with diabetes was 77 million in 2019 and will reach to 101 and 134 million by 2030 and 2045, respectively. The prevalence of diabetes in children and adolescents is increasing worldwide, with profound implications on the long-term health of individuals. Young-onset type 2 diabetes also affects more individuals of working age, accentuating the adverse societal effects of the disease. The diagnosis and management of diabetes in youth presents several unique challenges. Although type 1 diabetes is more common among children and adolescents, the incidence of type 2 diabetes in youth is also on the rise, particularly among certain ethnic groups. The management of diabetes in children and adolescents is challenging in some cases due to age-specific issues and the more aggressive nature of the disease.

Introduction

Type 2 diabetes mellitus (T2DM) is a global epidemic and its prevalence is continuously increasing. Initially it was considered as a disease of elderly population, but in current scenario it is equally seen in young population. Early appearance of this disease is associated with long-term major complications like microvascular and macrovascular complications. T2DM is most common type of diabetes and it is an estimation that by 2025, ~7.7% world's population will be affected with T2DM.[1] Under 40 years of age its prevalence is now increasing and early exposure will be having more complications in later part of life.[2-4] The development of T2DM at early age leads to serious health problem due to prolonged exposure to adverse risk factors like hyperglycemia and other components of the metabolic syndrome. And that is why it has become a major public health concern. Major concerns of T2DM in young adults are firstly it will be very aggressive as it develops at very young age and leads to various complications; secondly there is not long-term outcome studies are available to evaluate T2DM impact on young adults and lastly it certainly affects socioeconomic health of society.[5] This review article aims to explore the magnitude of the evolving problem and challenges physicians face in managing T2DM in younger adults.

Global Scenario of Diabetes Mellitus

Globally, 463 million population is living with diabetes mellitus, wherein china has the highest number of DM population, followed by India, which has 77 million diabetic population. From the current DM population, it is anticipated that by 2045, with the growth of 51%, globally total DM population will be 629 million; wherein currently 75% are from working-age between 30–55 years.[1,6] It is estimation that currently 5.8–6.4 years of life are lost in diabetes at the age of 50 years,[1] which can

TABLE 1 Prevalence estimates of Type 2 diabetes in adolescents and youth from the USA and UK studies

Study	*Prevalence of T2DM*	*Age group (years)*	*Year assessed*	*Source*
The SEARCH study (USA)	0.34/1000	<19	2001	Cross-sectional actie surveillance and case ascertainment

Royal College of Pediatrics and Child Health (UK)	3/100,000	<18	2009	Cross-sectional survey by secondary care clinicians in England

T2DM: Type 2 diabetes mellitus

lead to adverse social and economic complications.[6] For instance reported incidence varies from 0–330/100,000 person years depending on the age, gender, geography, and ethnicity of the study population and geographical region **(Table 1)**.[5] Globally many prevalence studies on T2DM are available but focusing on young T2DM patients is still waiting.

Challenges in Diagnosis of Diabetes in Young Patients

Insulin resistance is a pathological hallmark of T2DM and it is commonly associated with other conditions like obesity, polycystic ovarian disease (PCOD), and non alcoholic fatty liver disease (NALFD). These all metabolic conditions are overlapping with each other. In young people with T2DM is frequently associated with conditions like obesity and other cardiovascular risk factors such as hypertension, dyslipidemia, and nephropathy, which appear quite prevalent at the time of diagnosis and probably estimate abnormal glucose metabolism. Many times, patients will not have any symptoms of T2DM and it is detected incidentally, while in some case it may present with overt symptoms of T2DM like extreme weight loss, urinary tract infections, frequent urination, thirst or hunger, etc.[7,8] Differential diagnosis between T1DM and T2DM is very challenging as previous one is commonly associated with young age group of patients. And incorrect diagnosis of both diseases will cause adverse complications in patients. Incorrectly diagnosing T2DM in a young patient with T1DM could be life threatening if the situation is managed with oral diabetes medication rather than insulin. Likewise, misdiagnosing T1DM as T2DM can result in unnecessary life-long treatment with insulin, when alternative glucose lowering therapies may be more appropriate. Through biochemical test it can be differentiated, where in persistently high serum insulin and C peptide concentration is characteristic of T2DM and would be unusual in T1DM. However, at initial phase of diagnosis, these biochemical features are overlapping and may lead to misdiagnosis as well **(Table 2)**.[9,10]

Challenges in Management of Diabetes in Youngs

In T2DM, long-term evaluation and treatment is very challenging among many patients. Especially in young adults, to achieve target HbA1c and reduce blood sugar is difficult compared to adults. Even in 5 years of follow-up with therapy, young population find difficulties to achieve target with lesser complications. It is concerning to note that the proportion of young T2DM patients with suboptimal glycemic control was as high as 57% in the primary care setting in the UK.[5]

Proper Education

Appropriate education and life style modification certainly delay new onset of DM and also reduces severity of complications. But young T2DM patients have more depression and T2DM related stress, and they are failed to follow on regular guideline recommendations.

Glucose Lowering Therapy

In the management of T2DM along with glycemic control and HbA1c level <6.5% is an utmost important goal but along with that appropriate lifestyle modification, weight control is also required to get desired medication

TABLE 2 Differentiating features of different types of DM

	T1DM	*T2DM*	*MODY*
Prevalence (among young people with diabetes)	>90%	<10% (Japan 60–80%)	1–3%
Clinical features			
Onset	Usually acute onset	Usually insidious onset	Variable
Osmotic symptoms (polyuria, polydipsia, weight loss)	Prononounced	Often asymptomatic but can present with severe symptoms in some cases	Variable
Ketosis	Almost always present	Usually absent (except Afro-Caribbean origin)	Common in neonatal forms, rare in others
Body habitus	Usually not obese	Often osese	Usually not obsese
Signs of insulin resistance	Rare	Often present	Rare
Association with other autoimmune disorders	Yes	No	No
Family history in parents	2–4%	80%	90%
Diagnositic aid biomarkers			
Antibodies	ICA, Anti-GAD, ICA 512-positive	Negative	Negative
C-peptide	Negative	Positive	Noral range
C-peptide/reatinine ratio	Low	High	Normal
Treatment			
	Insulin	Oral hypoglycemic agents	Variable from diet to sulphonylurea to insulin

effect.[11] Physical exercise like aerobic activity, alone or in combination with diet, can reduce weight, body lipid level, elevated blood pressure and also helps to maintain healthy mental status as well.[12] For pharmacological management approach, metformin is the most appropriate starting point for any age group with T2DM. Results of the TODAY study suggest that monotherapy with metformin was associated with durable glycemic control in children and adolescents.[13] Apart from this in young age group patients, currently, many newer oral anti-diabetic agents are recommended which not only control sugar level but also reduce cardiovascular mortality as well like sodium-glucose cotransporter-2 (SGLT2) inhibitors, glucagon-like peptide 1 (GLP-1), dipeptidyl peptidase-4 (DPP-4) inhibitors. Metformin is always considered as first-line therapy until any contraindications, but after metformin or along with metformin if the patient has any marked CV risk factor then SGLT2 inhibitors, GLP-1 analogues are preferred agents. Treatment with these agents may increase the cost of therapy but proper counselling of patient may improve adherence to this therapy. In alternative cases, along with metformin other agents like sulfonylureas, meglitinides, thiazolidinediones, α-Glucosidase inhibitors, DPP-4 inhibitors are preferred options. In case of uncontrolled sugar level after dual oral antidiabetic drugs, or HbA1c level is more than 9% or T1DM; insulin injections and its analogues are preferred option to manage DM.[14] Bariatric surgery has emerged as a viable treatment option in young individuals with type 2 diabetes and evidence has shown that it is safe and effective in obese adolescents.[15]

Conclusion

Type 2 DM is going to be epidemic in younger adults and they are on high risk for development of diabetes-related complications such as nephropathy and CVD at early in the disease process with high mortality at a relatively young age. However, there are many gaps and lack of evidence for intervention to either optimize glycemic control or to address CV risk factors also results in non-standardized treatment and inevitable variations in standards of care in a young population. There is a need for sufficient scientific data and focused guideline-based approach for management of DM in young population for having a balanced socioeconomic condition in future.

CHAPTER

69 Management of Postprandial Hyperglycemia

Dinesh Sharma, Jugal Kishor Sharma

Abstract

Diabetes is increasing all over the world, so are its complications. There is much evidence that postprandial hyperglycemia is a major contributing factor for atherosclerosis development, causing cardiovascular morbidity and mortality in diabetic patients. There are rapid and high blood glucose levels after meals in diabetic patients known as hyperglycemic spikes responsible for cardiovascular complications. Hyperglycemia generates free radicals, which lead to atherosclerosis formation by multiple mechanisms. Early recognition and treatment of postprandial hyperglycemia by pharmacological and non-pharmacological means can prevent cardiovascular complications.

Introduction

Diabetes mellitus (DM) is a metabolic disorder due to defects in insulin secretion, insulin action, or both, thereby causing hyperglycemia. Chronic hyperglycemia is associated with long-term damage and dysfunction of different organs such as the eyes, kidney, nerves, heart, and blood vessels. Many studies have shown that increased plasma glucose in the body is an independent risk factor for morbidity and mortality in diabetic patients due to cardiovascular complications. Isolated postprandial hyperglycemia (PPHG) blood sugar >140 mg/dL (7.8 mmol/L), with normal fasting sugar <110 mg/dL and normal HbA1c (<6.1) is associated with a twofold increase in cardiovascular deaths. Management of PPHG becomes necessary as increased fasting glucose level alone is not a risk factor to cause cardiovascular complications.[1,2] This is a well-established fact that controlling blood sugar levels (HbA1c <7.0%) can reduce the progression of diabetic complications.[3-5] The risk of cardiovascular disease can be prevented by proper control of postprandial glucose. Management of PPHG is more difficult than FPG because there are no standard guidelines and treatment practices among diabetologists and physicians. However, treatment modalities are now available to treat PPHG, such as AGI, Glinides, Short-acting SU, Insulin analogs, DPP4 inhibitors, and GLP-1 derivatives.

Diagnosis

ADA in 2013 defined PPHG as a 2-h plasma glucose level of more than 200 mg/dL (11.1 mmol/L) for diabetes and 140–199 mg/dL for IGT by oral glucose tolerance test. The glucose load is 75 gm glucose dissolved in water as per the recommendation of WHO.[6]

IDF defines PPHG as a plasma glucose concentration of 140 mg (7.8 mmol/L) or more after 1–2 hours of food ingestion.[7]

Current guidelines recommend self-monitoring of blood glucose (SMBG) for assessing plasma glucose levels in diabetic patients. The timing and frequency are individualized according to the treatment regime and glycemic control.[7] Some emerging technologies for evaluating postprandial glucose levels are CGM and plasma 1.5-anhydroglucitol (1.5AG).[8] CGM measures plasma glucose every 1–10 minutes by a sensor; this is

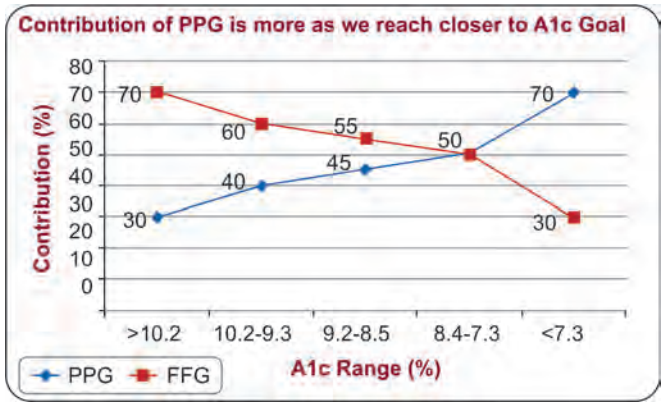

Fig. 1: As patients get closer to A1c goal, the need to manage PPG increases

transmitted to a storage device. 1.5AG is a natural dietary polyol that is the marker for postmeal hyperglycemia, but it is not readily available at this time.[9,10] HbA1c values can give many indications of PPG. Monnier et al. in 2003 demonstrated that contribution of PPG to glycemic load varies with the degree of glycemic control. In poorly controlled (HbA1c >10.2%), it was only 30% of the 24 hours. AUC, in better-controlled patients (HbA1c <7.3–8%), the contribution of PPG was 70–50%[11] **(Fig. 1)**. Flash glucose monitoring is a new noninvasive glucose monitoring launched by Abbott, using a sensor applied on the back of the arm, which measure and stores glucose values for 14 days. Compared to SMBG, which is painful and inconvenient, this is a safe, effective, and better alternative method.[12,13]

Epidemiology

PPHG is a frequent and under-diagnosed condition. Dickson et al. reported that Asian Indians had a marked increase in postprandial sugar after 75 gm of bread meal.[14] There is a direct relationship between CVDs and glycemic control in patients with type 2 DM (T2DM).[15] One study of 90 patients with T2DM demonstrated that isolated PPHG was seen in 24.4% of patients.[15] The mean HbA1c was a good indicator of IHD, as observed in the UKPDS study.[16] There was a ~10% increase in cardiovascular disease risk with each 1% increment in HbA1c. In the interventional version of UKPDS, intensive treatment with ~1% reduction in HbA1c leads to a 16% less MI incidence.[17] Many other studies such as Hoorn Study, Honolulu Heart study, Chicago Heart Study,[18] and DECODE study[19,20] have reported that postprandial glucose is a major CV risk indicator. This was confirmed by Coutinho et al.[21] and with pooled data of Whitehall Study, Paris Prospective Study, and Helsinki Policeman Study.[22] Diabetes Intervention Study favors PPHG as an independent risk factor for MI.[23] STOP-NIDDM data indicates acarbose for treatment for IGT can reduce 36% risk in progression to diabetes and 34% in the development of new hypertensive cases, and 49% in cardiovascular complications. A significant decrease in the progression of intima-media thickness was seen in a subgroup that is a surrogate for atherosclerosis.[24]

Pathophysiology

In nondiabetic individuals, the blood glucose levels begin to rise ~10 minutes after the start of a meal, with a peak at 60 minutes and returning to pre-prandial levels within 2–3 hours. Even after that, the absorption of ingested carbohydrates continues for 5–6 hours after a meal. PPHG depends on carbohydrate absorption, insulin, and glucagon secretion and their effect on glucose metabolism in peripheral tissue and the liver. In T2DM, peak insulin levels are delayed and insufficient to control PPG excursions, while in T1DM, peak insulin levels depend on the type of insulin injected as there is no endogenous insulin secretion. In diabetic patients, abnormalities in secretion of insulin and glucagon, hepatic glucose uptake, decreased hepatic glucose production, and peripheral glucose utilization lead to higher and prolonged PPG excursions than nondiabetics. Isolated PPHG doubles the risk of cardiovascular deaths,[16] and it is the earliest abnormality of glucose homeostasis in T2DM and further progress to fasting hyperglycemia.[25] During the meal, insulin is secreted in two phases. In the first phase, a small amount of insulin is secreted over approximately a 10-minute period, which controls postprandial glucose excursions. More sustained second phase insulin secretion occurs as plasma glucose levels increase and depend on the meal's glycemic load. The earliest manifestation of diabetes is the loss of first-phase insulin release, leading to increased PPG and free fatty acids, which delays second-phase insulin response **(Fig. 2)**. PPHG leads to increased lipid levels, triglycerides, and lipoprotein particles. This is known as postprandial dysmetabolism, which is a major risk factor for cardiovascular events.

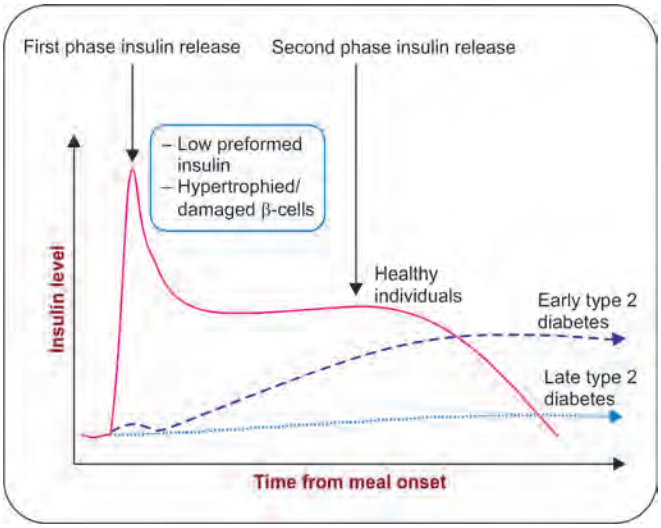

Fig. 2: Delay of first phase insulin in early type 2 DM

The main pathophysiological mechanism leading to cardiovascular damage is endothelial dysfunction, oxidative stress, and activation of inflammation, and coagulation mechanisms, thus facilitating lipoprotein particles' penetration into the arterial wall.[8] Hyperglycemia generates free radicals, promoting atherogenesis through peroxidation of LDL, fibrinogen oxidation leading to increased coagulation products, increased platelet activation by collagen,[26,27] and decreased production of nitric oxide.[23] Recent studies suggested that hyperglycemia causes an overproduction of superoxide by the mitochondrial electron-transport chain,[28] leading to an increase in NO generation due to endothelial NO synthase (eNOS) and inductively NO synthase (iNOS) uncoupled state, which leads to the formation of strong oxidant peroxynitrite, which damages DNA.[29] DNA damage stimulates activation of nuclear enzyme poly (ADP ribose) polymerase. This leads to depletion of the intracellular concentration of NAD+, decreases the rate of glycolysis, electron transport, ATP formation, and produces an ADP ribosylation of the GAPDH (glyceraldehyde-3-phosphate dehydrogenase).[29] All this results in acute endothelial dysfunction in diabetic blood vessels, which leads to the development of CVD[29] (**Flowchart 1**). Many direct and indirect evidence support this concept.

Management

Management of PPG includes non-pharmacological and pharmacological interventions. These are as follows.

Screening Tests

ADA recommendations for screening for PPG in all asymptotic patients who are overweight (BMI >25 kg/m^2) and have additional risk factors. Also, in other conditions such as IGT, high-risk CVD, GDM, Hypertension, Dyslipidemia, PCOD, Acanthosis nigricans, and first-degree relatives of people with diabetes. SMBG is important for detecting and treating PPHG, which is to be monitored in gestational diabetes and patients having high HbA1c and normal FBG.

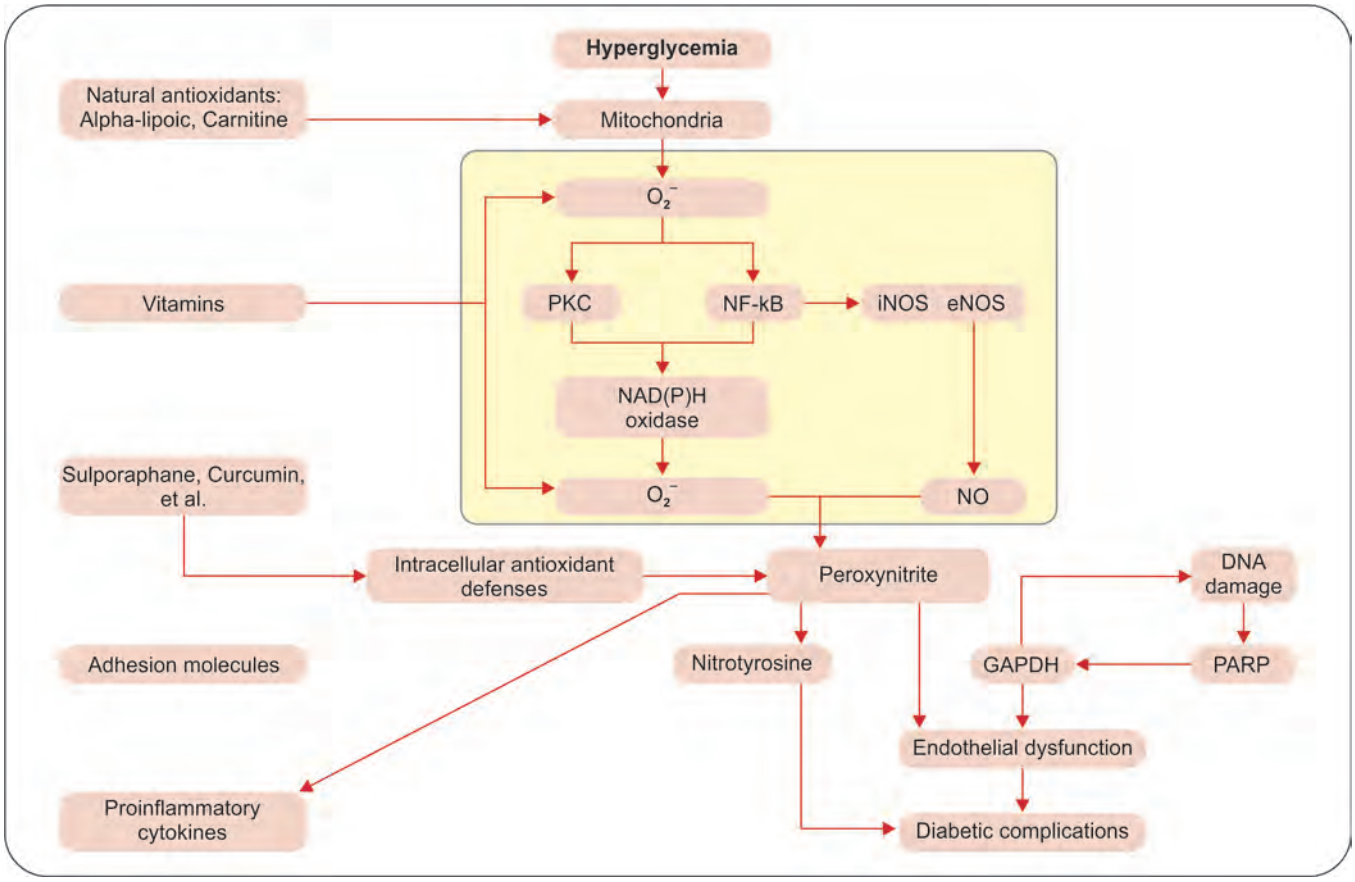
Non-pharmacological Therapy

In patients with IGT and T2DM with suboptimal glycemic control (HbA1c 7–8%), lifestyle modifications such as weight reduction, exercise, and dietary control can maintain normal glucose levels, thereby reducing the risk of development of diabetes.[30-32] Exercise helps in glycemic control by increasing insulin sensitization. Dietary modification for PPHG control depends on the type and quantity of carbohydrates taken. Foods with a high glycemic index (GI), such as rice, pasta, potatoes, white and brown bread, and breakfast cereals, have more glycemic load (GL), which is the product of carbohydrate content of the diet and its average GI. Low GI foods such as legumes, most of the fruits, which are slowly digested and absorbed, will cause less GL. The higher GL in the Indian diet causes more prandial glycemic excursions, increased incretin and glucosidase activity in the gut leading to high lipemic peaks resulting in CVS diseases. It is recommended that the diet should contain 45–65% carbohydrates of total calorie intake, food with a low GI, unsaturated fat, high fiber, fruits and vegetables, and pulses.

Pharmacotherapy

Pharmacotherapy is indicated when lifestyle modifications do not control the PPHG. Drugs that target PPHG may be given as monotherapy or in combination, which includes alpha-glucosidase inhibitors (AGI), Glinides, short-acting Sulfonylureas (SU), DPP-4 inhibitors, glucagon-like peptides (GLP-1) derivatives, and rapid-acting insulin.[33,34] SU and insulin sensitizers (metformin and thiazolidinediones) mainly affect fasting blood sugar; however, a combination of metformin and glyburide has shown a reduction in postprandial glucose excursion in some studies.[35]

Flowchart 1: Hyperglycemia



Meglitinides (Repaglinide and Nateglinide)

These are non-sulfonylurea insulin secretagogues that bind to islet beta cells at different sites than SU with different kinetics, which mainly affect early insulin release. They are recommended just before meals for early insulin release and a short half-life. Repaglinide is a new class of non-sulfonylurea secretagogues, which after oral administrations with meals, has rapid and short-lived insulinotropic action.[36] This is less hypoglycemic and weight neutral than SU. It is used as mono or combination therapy with metformin, insulins, and thiazolidinediones. Nateglinide is rapid-acting with a shorter duration of action than repaglinide.[37] It is less effective and causes less hypoglycemia than repaglinide.

Alpha-glucosidase Inhibitors (Acarbose, Miglitol, and Voglibose)

Inhibits glucosidase enzyme in the brush borders of the small intestine, which breaks down the disaccharides and more complex carbohydrates, thereby delaying the carbohydrate digestion, which reduces PPHG. Acarbose also increases the secretion of glucagon-like peptide (GLP-1). AGI causes abdominal pain, diarrhea, and flatulence.[38,39]

GLP-1 Analogs

It is an incretin hormone secreted by gut L cells into the circulation after meals, which lowers glucose by stimulating glucose dependent insulin secretion through activation of cyclic AMP dependent protein kinase in pancreatic Beta cells, inhibits glucagon secretion, delays gastric emptying, and induce satiety. Liraglutide and Exenatide are commercially available GLP-1 analogues. Subcutaneous injection of GLP-1 effectively reduces PPHG in people with T2DM with a low risk of hypoglycemia.

DPP-4 Inhibitors

Inhibits the DPP-4 enzyme causing degradation of GLP-1, which increases the active form of the hormone. This

stimulates glucose-dependent insulin secretion and suppresses glucagon release. DPP-4 inhibitors improve HbA1c by decreasing postprandial glucose without causing hypoglycemia. These are used as monotherapy or in combination with other oral hypoglycemia agents.

Insulin and Insulin Analogs

Injection of regular or long-acting insulin before meals will decrease postprandial glucose. Genetically engineered insulins are insulin analogues that are more beneficial than human insulin and cause less risk of hypoglycemia, improved physiological profile, and negligible weight gain. Rapidly acting insulin analogues effect is the same as normal insulin secretion, having faster absorption, shorter duration of action, and peaks about 1 hour after injection. These are insulin aspart, insulin lispro, and insulin glulisine.

Conclusion

PPHG alone can cause both microvascular and macrovascular complications in diabetic patients, thereby leading to cardiovascular morbidities and mortality. It is a better indicator of glycemic control than fasting blood glucose (FBS). Patients having normal fasting blood sugar and HbA1c, control on diet, exercise, and medical therapy may have uncontrolled PPHG. The main pathophysiology for PPHG is impaired early insulin secretion in diabetic patients. Early detection, optimal glycemic control, and treatment by effective medications can reduce diabetic complications. The emerging new treatment modalities such as meglitinides, AGI, GLP-1 agonists, insulin analogues, and DPP-4 inhibitors that target PPHG are now available to control PPHG, thereby preventing cardiovascular complications.

CHAPTER

70 Sexual Dysfunctions in Diabetes Mellitus

Jugal Kishor Sharma, Dinesh Sharma, Sunil Sharma

Abstract

Diabetes mellitus is reaching near to pandemic state and causes many psychological and sexual problems other than retinopathy, neuropathy, nephropathy, and other macrovascular complications. Sexual dysfunction is one of the most common complications and most under diagnosed complications of diabetes mellitus. This is common in both male and female because of end organ damage and psychological stress caused by diabetes mellitus. Sexual dysfunction maybe an early sign of diabetes mellitus and can occur in any phase of sexual process. Male sexual dysfunctions include disorders of libido, ejaculatory problem, and erectile dysfunction. All these can cause significant problems and affect the quality of life. Erectile dysfunction is three times more common in diabetic patients than in non-diabetic. There is multifactorial pathology but the common is endothelial dysfunction and autonomic neuropathy. Sexual dysfunction in females is difficult to identify and there are limited studies on it but there can be many problems such as arousal, lubrication, and orgasmic dysfunction. Diabetic patients do not volunteer their problems, hence the health-care professionals should routinely question about the sexual problems because it can cause deleterious effect on relationship and quality of life of both the partners. Many treatment options are now available to manage the sexual problem in time.

Introduction

Diabetes mellitus (DM) is one of the most common chronic diseases in almost all countries; its increase is near to pandemic assumptions. As per the 2015 reports of the International Diabetic Association (IDA), more than 371 million people had diabetes in 2012; by 2040, the number of people with diabetes is expected to be 642 million.[1] It is a well-known fact that DM causes different medical, psychological, and sexual complications.[2] Both macrovascular (including CVD) and microvascular (including retinopathy, nephropathy, and neuropathy) complications are associated with complications of diabetes.[3] Sexual dysfunction (SD) is a common occurrence in diabetic patients in both men and women due to diabetes-induced end-organ damage and psychological stress.[4-7] In some instances, SD can be an early sign of DM.[8] SD can occur in any of sexual function phases: desire, arousal, plateau, orgasm, and resolution.[9]

Sexual Dysfunction in Men

Diabetes is a known risk factor for SD in men. Most common SD in men with diabetes is erectile dysfunction (ED). ED is three times more common in people with diabetes compared to non-diabetic men.[5,10] Factors responsible for ED in diabetes varies from psychological, physical, and social. Anxiety is an essential factor responsible for erectile disorder and premature ejaculation in diabetes. Low sexual satisfaction, sadness, low self-esteem, distress, and depression can express in persons suffering from SD. ED may be defined as the perpetual inability to attain or maintain penile erection for successful sexual intercourse causing the compromised quality of life in men.[11,12]

TABLE 1 The sexual health inventory for men (SHIM)

How do you rate your confidence that you could get and keep an erection?		Very high	High	Moderate	Low	Very low
		1	2	3	4	5
When you had erections with sexual stimulation, how often were your erections hard enough for penetration (entering your partner)?	No. Sexual activity	Almost always or always	Most time (much more than half the time)	Sometime (about half the time)	A few times (much less than half the time)	Almost never or never
	0	1	2	3	4	5
During sexual intercourse, how often were you able to maintain your erection after you had penetrated (entered your partner?	Did not attempt intercourses	Almost always or always	Most time (much more than half the time)	Sometime (about half the time)	A few times (much less than half the time)	Almost never or never
	0	1	2	3	4	5
During sexual intercourses, how difficult was it to maintain your erection to completion of intercourse?	Did not attempt intercourses	Not difficult	Slightly difficult	Difficult	Very difficult	Extremely difficult
	0	1	2	3	4	5
When you attempted sexual intercourses, how often was it satisfactory for you?	Did not attempt intercourses	Almost always or always	Most time (much more than half the time)	Sometime (about half the time)	A few times (much less than half the time)	Almost never or never
	0	1	2	3	4	5

Incidence of ED is directly proportional to the age. By the year 2025, the worldwide prevalence of ED is expected to reach 322 million patients.[13]

Diagnosis of Male Sexual Dysfunction

Diagnosis of ED in a person can be made using standardized questionnaires involving his sexual activity. One such suitable questionnaire commonly used is the International Index of Erectile Function (IIEF)-5, which comprises items 5, 15, 4, 2, and 7 from the full-scale IIEF-15. A score of 21 or less suggests the possibility of ED.[14] Other scales used are the Sexual Functioning Questionnaire—male, Arizona Sexual Experience Questionnaire (ASEX), Male Sexual Health Questionnaire (MSHQ), and Premature Ejaculation Profile (PEP) **(Table 1)**. To work out your level of erectile function/dysfunction, add the numbers are corresponding to questions 1-5. The Sexual Health Inventory for Men further classifies erectile dysfunction as 1–7 severe, 8–11 moderate, 12–16 mild to moderate, and 17–21 mild ED.

Sexual Dysfunction in Women

The link between SD and diabetes is well established in men. However, among women, the data to support this association is lagging despite a significantly higher prevalence of female sexual dysfunction (FSD) in women who have diabetes as compared with women without diabetes.[15,16] As per the American Foundation of Urological Diseases (AFUD), female sexual dysfunction (FSD) comprises four components:

- Hypoactive sexual desire disorder (HSDD; reduced frequency of sexual intercourse, aversion to intercourse)
- Female arousal disorder (FAD; inability to achieve arousal)
- Female orgasmic disorder (FOD; inability to achieve orgasm)
- Sexual pain disorder (SPD; dyspareunia).

Also decreased sexual desire, lack of sexual satisfaction, decreased vaginal lubrication, and orgasmic dysfunction have been documented in a few studies conducted in women suffering from DM.[17] Anxiety and depression in women lead to difficulty in arousal, orgasm, and achieving pleasure.[18] Furthermore, SD interferes in cordial relationship with the partner. It increases emotional stress, and in the absence of regular communication, it may end up with divorce due to less marital satisfaction, difficulty in resolving problems and decreased self-care behavior, which may result in poor glycemic control.[19] FSD is caused

by disturbances in psychophysiological factors and alters the sexual response cycle in the female, which consist of disorders of sexual desire, arousal, pain, and orgasm.

Diagnosis of Female Sexual Dysfunction

In the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) combines sexual desire and arousal disorders into the "female sexual interest/arousal disorder" category, whereas vaginismus and dyspareunia together constitute "Genito-pelvic pain/penetration disorder" category. A woman suffering from these symptoms for a minimum of 6 months fits into the criteria for making a diagnosis. For distinguishing transient sexual difficulties from more persistent SD, severity criteria are used.

The Diagnostic tools used to diagnose SD in females are:

Female Sexual Functioning Index: It consists of 19 questions with six domains, desire (2 questions), arousal (4 questions), lubrication (4 questions), orgasm, satisfaction and pain (3 questions each). Sexual activity of the last 4 weeks is evaluated, and a score of less than 26.55 confirms SD.

Arizona Sexual Experience Questionnaire (ASEX): It consists of 5 components scale with five domains—sex drive, arousal, lubrication, orgasm, and satisfaction following orgasm. It evaluates the sexual activity of last week, including the consulting day. A total ASEX score of ≥19, anyone component with a score of ≥5, or any three components with a score of ≥4 suggests SD.

Sexual Functioning Questionnaire (SFQ): 28 items with six domains—Desire, Arousal, Orgasm, Pain, Enjoyment, and Partner relationship.

Female Sexual Distress Scale-Revised (FSDS-R): 13 items, and one domain included is distress about sexual life. Sexual Interest and Desire Inventory (SIDI)—15 items for Hypoactive Sexual Desire Disorder Domain.

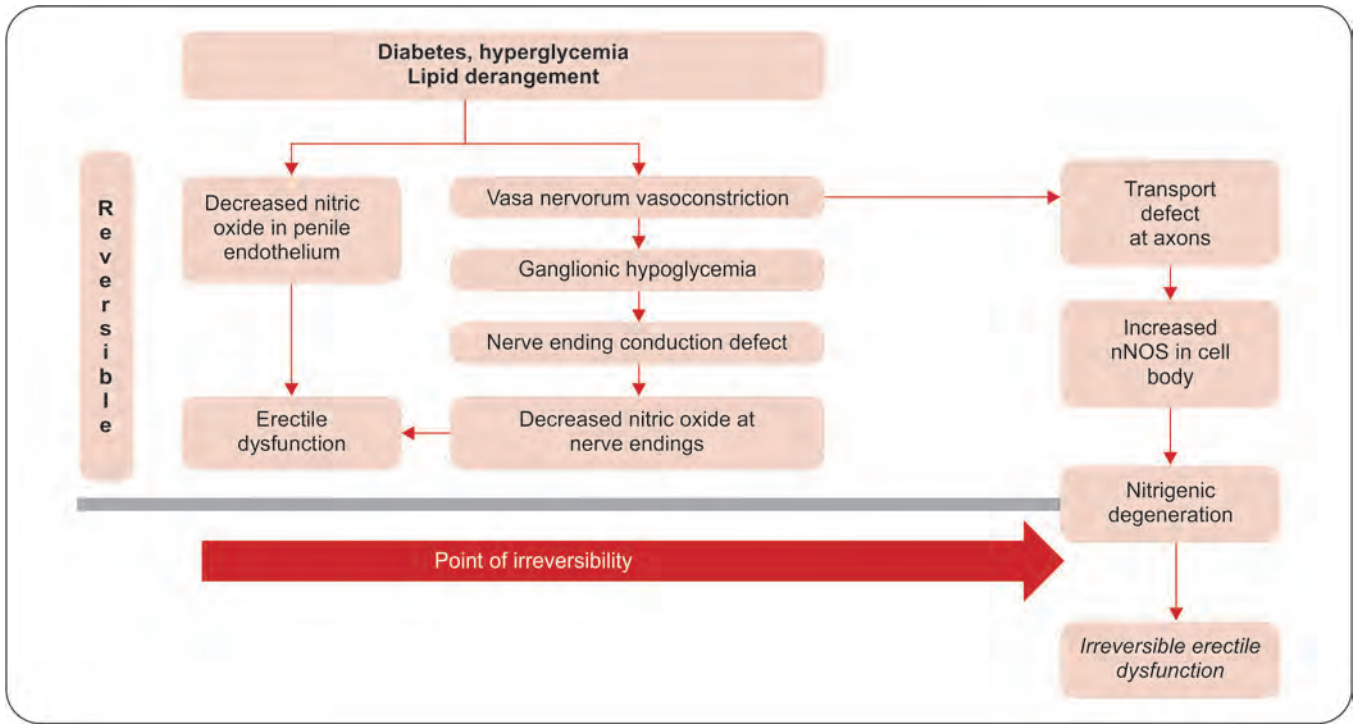
Pathophysiology

Pathophysiology of ED in diabetes is manifold which develops gradually. Usually, psychological and biological factors work together resulting in an erection.[20] In an average person, psychological arousal results in parasympathetic stimulation leading to nitric oxide (NO) release from local endothelial cells. NO release causes smooth muscle and vascular relaxation resulting in increased arterial flow in penile corpora cavernosa. This increased blood flow hampers venous return by causing compression of penile venules, which maintains the penile erection. The mechanism of ED in diabetic patients is the result of vasculopathy, neuropathy, insulin resistance, visceral adiposity, and hypogonadism. Vasculopathy is the result of endothelial dysfunction, macroangiopathy and microangiopathy. Macrovascular complications of diabetes lead to atherosclerotic damage in blood vessels causing decreased blood flow to the penis.[21] Microvascular complications impair distal circulation leading to ischemic damage, autonomic and peripheral neuropathy. This results in impairment of sensory impulse from the penis to reflex erectile center thereby inhibiting parasympathetic activity necessary for smooth muscle relaxation of corpus cavernosum. Norepinephrine and acetylcholine positive fibers in the corpus cavernosum are reduced in people with diabetes which impairs muscle relaxation. Endothelial dysfunction in diabetes is caused by decreased nitric oxide bioavailability, which impairs relaxation of the vascular smooth muscle of corpora cavernosa.[22] Accumulation of advanced glycation end products, increased free radicals levels, decreased bioavailability of NO are few causative factors in endothelial dysfunction, which leads to increased vasoconstriction due to imbalance between vasoconstriction and relaxation.[23]

Around 25% of diabetic males have low testosterone levels with low luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Testosterone is necessary for the erectile function. It regulates smooth muscle relaxation, the endothelial function of corpora cavernosa.[24] It regulates the timing of erection, sexual desire, and maintains the penile erection during sex. Overweight and obese diabetic males having insulin resistance and visceral adiposity have proinflammatory state leading to decrease the bioavailability of NO causing ED.

SD in diabetic female includes loss of sexual desire, arousal, lubrication difficulties, dyspareunia, and loss of orgasm.[25] Diabetes causes vascular and nerve dysfunctions, which impair sexual response by causing functional and structural changes in female genitalia. Vascular abnormalities causing atherosclerosis and endothelial dysfunctions are responsible for reduced clitoris engorgement and vaginal lubrication, which attenuates arousal and causes dyspareunia during coitus.

Flowchart 1: Flowchart of pathophysiology of erectile dysfunction



Diabetic neuropathy also alters normal transduction of sexual stimuli and initiating a sexual response.[26] FSD maybe because of imbalance in hormonal levels in diabetic females. Some epidemiological studies suggest an association between sexual problems in diabetic females and levels of estrogens, androgens, and sex hormone-binding globulin. Many endocrinal dysfunctions of thyroid, hypothalamic-pituitary, polycystic ovarian syndrome also contribute to this problem in such females[27] **(Flowchart 1 and Fig. 1)**.

Management

There are many treatment modalities for SDs in both males and females, which include:

Lifestyle modification: Regular exercise, weight reduction, blood glucose monitoring, thereby maintaining a reasonable glycemic control, control of hypertension, cessation of alcohol intake, smoking cigarette, and avoiding drugs which cause ED will help and lowers the risk of developing SD. The effect of lifestyle modification on ED in diabetic patients is modest.[28]

Phosphodiesterase type 5 inhibitors (PDE5I): PDE5I revolutionized the treatment of ED, this class of oral agents are the treatment of choice. FDA approved sildenafil, vardenafil, tadalafil, and avanafil for the treatment of ED. The action of PDE5I depends on the NO/cGMP pathway. Sexual stimulation causes the release of NO from cavernous nerves and endothelial cells. By multiple mechanisms, cGMP causes penile smooth muscle relaxation, which is deactivated by PDE5 found in the penis.[29] PDE5I prevents the deactivation of cGMP, resulting in persistently elevated levels of cGMP, which in turns maintain continued smooth muscle relaxation of the penis. The release of NO is mediated by neuronal and endothelial NO Synthase (NOS). Diabetic patients develop neuropathy and endothelial dysfunction, which blunts the efficacy of PDE5I. That is why the effect of PDE5I is better in non-diabetics than diabetic patients. These drugs are to be taken 1–2 hours before intercourse, and their effectiveness require sexual stimulation. Side effects are headaches, light-headedness, flushing and dizziness. These are contraindicated in patients taking nitrates IHD, CHF, HOCM, and hypertension. Another oral drug

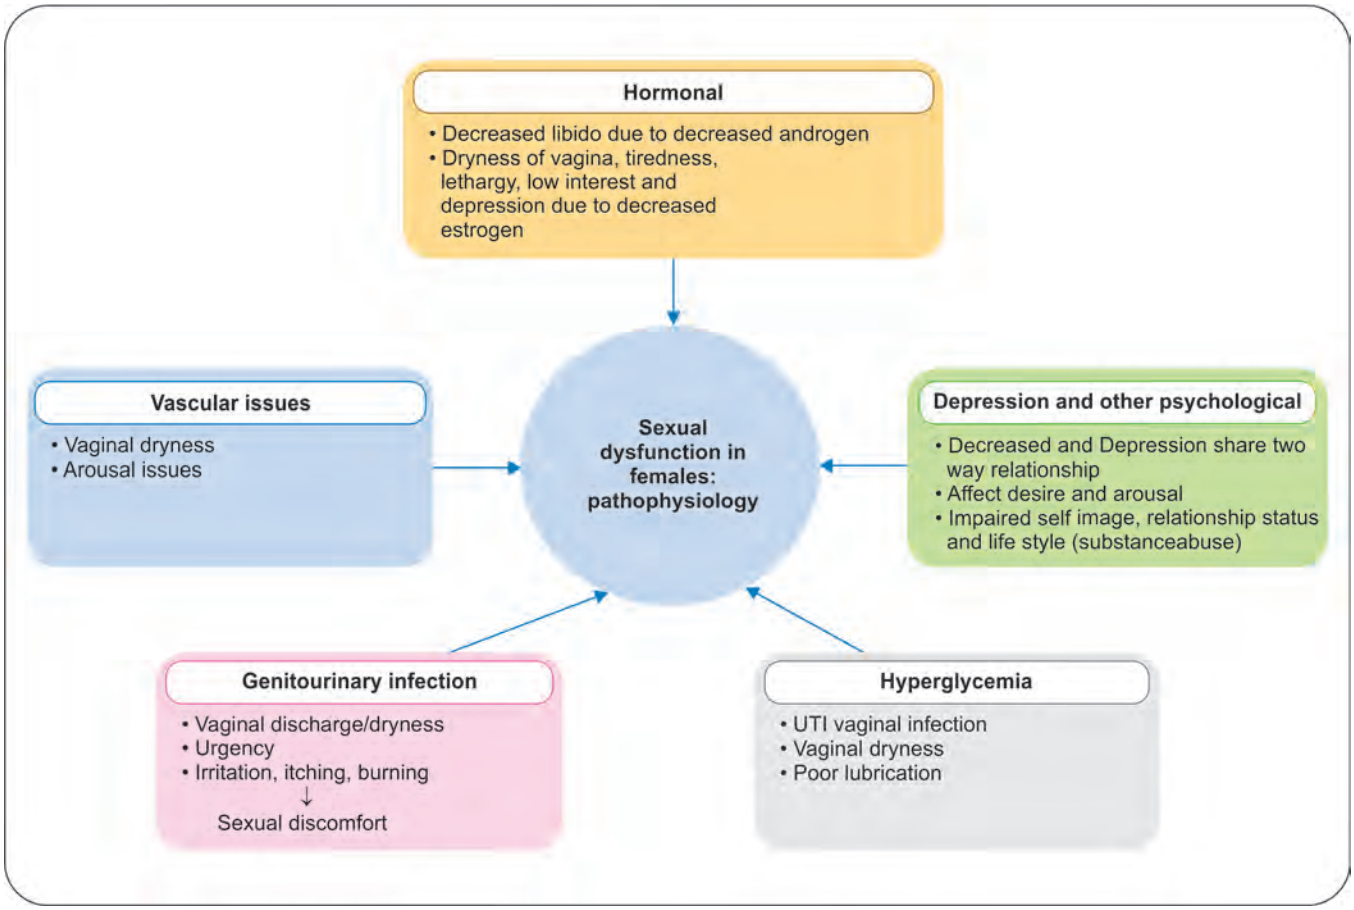


Fig. 1: Sexual dysfunction in females: Pathophysiology

is alpha2 adrenergic receptor blocker Yohimbine, which increases cholinergic and decreases adrenergic tone. It stimulates the midbrain and increases libido; this is more effective in psychogenic ED and less effective in diabetics.

Other treatment modalities (in those patients who are non-responders to oral treatment):

Vasodilators: Directly administered to the penile erectile tissue. These are papaverine, phentolamine and Prostaglandin E-1 (PgE1).[30] These are used in combinations; only PgE1 is approved by the FDA. PgE1 and papaverine may be injected Intracavernosal in the shaft of the penis with sterile techniques and under supervision of urologist 10–15 minutes before intercourse. Prostaglandins are also used as intraurethral suppository Medicated Urethral Suppository for Erections (MUSE). Side effects are pain, priapism, urethral burning, and irritation of partner's mucous membranes.

Mechanical therapy such as Vacuum Erection Devices (VED): It is used in non-responders of injections and urethral suppository. Vacuum pressure increases arterial inflow, and occlusive tension rings decrease venous outflow from penile corpus cavernosa. The penis is placed in a cylinder, a vacuum is created by a pump, which increases blood flow in the penis than a tension ring is applied at the base of the penis, and the erection lasts till the ring is removed.

Penile prostheses are the best substitutes for ED in persons who have diabetes if other modalities fail and give dissatisfaction. Prosthetic surgery is irreversible because it causes permanent alteration of corporal tissue, and thus, the physiological erection is not possible. Many materials, flaps, grafts have been tried, and most recent is hollow silicon cylinders inflated with saline or semi-rigid roads. The prosthesis has the highest satisfaction rate among all modalities for the management of ED, around 95% as

demonstrated by two large studies. A future version of prosthesis will be remote control devices similar to the garage door opener. The complication of surgical implant is the risk of infection.

Testosterone therapy: Persons having low testosterone and suffering from hypogonadism such as decreased libido, decreased energy, depression, fatigue, weight gain, anxiety may get benefitted with this therapy.

Future therapies can be gene therapy, penile low-intensity shock wave lithotripsy, which consists of 1,500 shocks twice weekly for 3–6 weeks to stimulate neovascularization to corporal bodies to improve penile blood flow and endothelial function. Some are NO-releasing polymers injected in cavernosa, which may improve ED.

Conclusion

SD in diabetes is an under-discussed, unrecognized, and usually untreated complication. It equally affects both the partners and is one of the treatable diabetic complications. This is due to vascular, neurological, and hormonal disturbances caused by diabetes. Sexual problems in diabetes include ED, sexual desire and ejaculatory dysfunction in males and many sexual problems in the female. Awareness about sexual problems is now increasing among diabetic patients. Many treatment options are now available such as oral medications, injectable drugs, vacuum devices, and inflatable prostheses. Controlling diabetes, discussing sexual problems, and management in time may improve sexual life in diabetic patients.

CHAPTER

71 CVOT Trials in T2D—What do they Mean for Clinical Practice?

V Palaniappen

Abstract

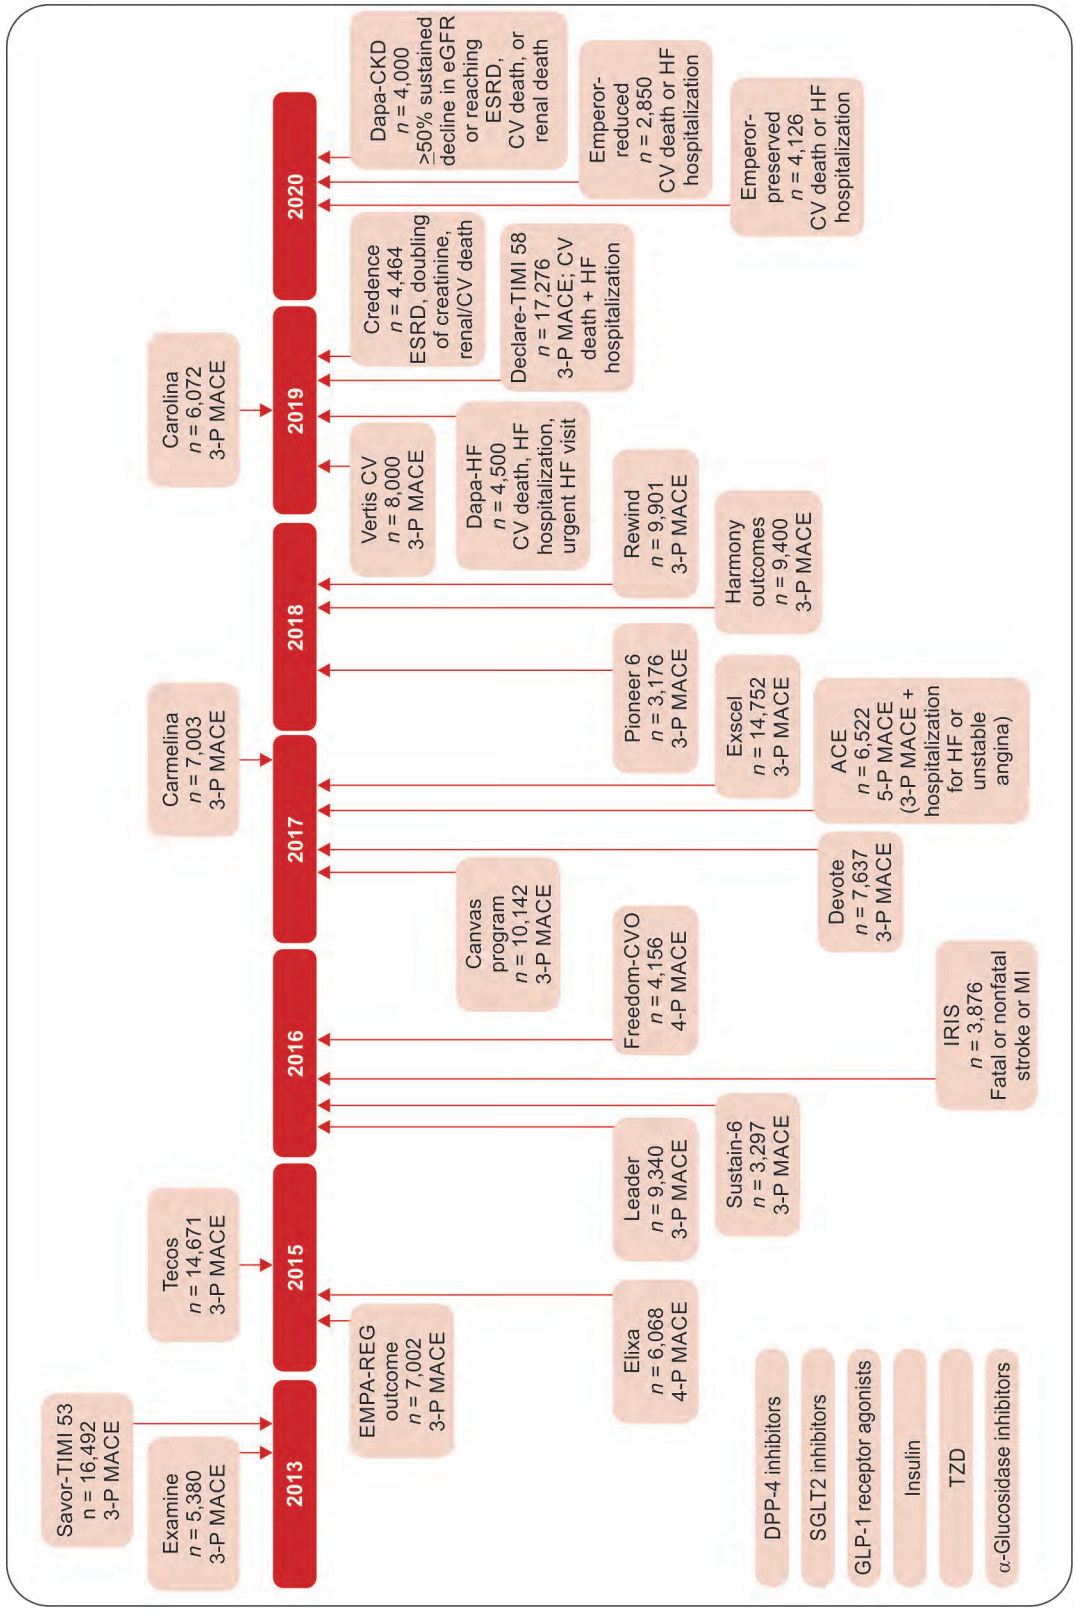
Nowadays good move is without CVOT trail and FDA approval no antihyperglycemic drugs can enter the market. EMPA REG outcome trail and LEADER trail had shown superiority and beneficial effects on CV safety in type 2 diabetics. SGLT2 inhibitors have shown to decrease the progression on renal dysfunction in long standing diabetics. All SGLT2i had shown significant reduction in hospitalization for heart failure.

Introduction

Patients with type 2 diabetes mellitus in general are more prone for atherosclerosis induced vascular disease like myocardial infarction and cerebrovascular accident with a tenfold increased risk. The is also increased risk of heart failure in diabetic patients. As diabetic patients are started on long-term oral hypoglycemic agents, the drugs should have a detrimental effect on cardiovascular safety. FDA imposed that "every newer antihyperglycemic agent have to undergo a CV safety trial" when there was a controversial results of rosiglitazone trial, which increased the risk of myocardial infarction and deaths due to CV disease. In cardiovascular outcome trial (CVOT) design, the newer glucose-lowering drug is added to standard of care (SoC) treatments in patients at high risk of CV events, and compared with SoC alone or added to an active comparator. The primary outcome is known as the 3-point MACE (major adverse cardiovascular events) which includes any CV death, nonfatal MI and nonfatal stroke and 4-point MACE which includes composite- or add hospitalization for unstable angina (HUA). Few of the studies has also included heart failure and renal protection effects. As per the guidance, CVOTs comparing an antihyperglycemic agent with a comparator must demonstrate that the upper bound of a two-sided 95% CI is <1.8. Few of the newer antihyperglycemic agents have also showed beneficial effects on CVD beyond glycemic control. The current chapter will elaborate on the various trials done in CV safety in type 2 diabetes mellitus. The first trial (SAVOUR-TIMI)was started in 2003 and many trials have been completed since then. It is done in DPP4 inhibitors, GLP-1 analogues, sodium-glucose cotransporter 2 (SGLT2) inhibitors, insulin analogues. **(Flowchart 1)**.

DPP4 Inhibitors

SAVOUR-TIMI involving Saxagliptin and EXAMINE trial that involved Alogliptin, Effect of Sitagliptin on Cardiovascular Outcomes in Type 2 Diabetes (TECOS), CARdiovascular Outcome Trial of LINAgliptin Versus Glimepiride in Type 2 Diabetes (CAROLINA), and CARdiovascular Safety & Clinical outcoME with LINAgliptin (CARMELINA). SAVOUR-TIMI showed a non-inferiority in CV safety compared to the placebo but there was an observation of increased hospitalization due to heart failure. EXAMINE trial also showed the rates of major composite events were not increased with alogliptin as compared with placebo in a follow-up to 40 months.



Flowchart 1: Approved CVOT trails between 2013 and 2020

Alogliptin neither increased CV morbidity or mortality, nor worsened preexisting heart failure, including in those patients with a very recent acute coronary syndrome, after a median duration treatment of 18 months. CAROLINA is first in kind head-to-head comparison between a SU and a gliptin (linagliptin) in high CV risk patients which showed a non-inferior risk of a composite CV outcome. CARMELINA trial showed that across all GFR, there is no increase in CV and renal events.

SGLT2 Inhibitors

There are four SGLT2 inhibitor trials with a composite 3-point MACE is the primary end point; in two, a composite renal outcome is the primary end point; and in three, a composite of HF outcomes and CV death is the primary end point in people with established HF. These include CANVAS, CREDENCE (ongoing), EMPA-REG outcome, EMPA-CKD, DAPA-HF, EMPEROR trials.

CANVAS

Canagliflozin compared with placebo was associated with a lower frequency of adverse cardiovascular events. Canagliflozin was also associated with a lower rate of progression of albuminuria; however, amputation occurred more frequently.

EMPA-REG Outcome

This trial was an event driven trial in CVOT trials that has shown a superiority in CV events by. Further it appears to have a salutary effects on renal outcome including the need for renal replacement therapy. It also reduced heart failures an hospitalizations for heart failure. The patients were receiving 10 and 25 mg of empagliflozin and the results include in the empagliflozin group there were significantly lower rates of death from cardiovascular causes (3.7%, vs. 5.9% in the placebo group; 38% relative risk reduction), hospitalization for heart failure (2.7% and 4.1%, respectively; 35% relative risk reduction), and death from any cause (5.7% and 8.3%, respectively; 32% relative risk reduction).

DAPA-HF

In patients with type 2 diabetes, inhibitors of SGLT2 reduce the risk of a first hospitalization for heart failure, possibly through glucose-independent mechanisms. This was shown by the DAPA-HF (dapagliflozin heart failure) trial among patients with heart failure and a reduced ejection fraction, the risk of worsening heart failure or death from cardiovascular causes was lower among those who received dapagliflozin than among those who received placebo.

With all these trials showing major CV benefits, ADA 2020 recommends in type 2 diabetes who have established atherosclerotic cardiovascular disease or indicators of high risk, established kidney disease, or heart failure, a sodium–glucose cotransporter 2 inhibitor can be added after metformin therapy.

GLP-1 Analogues

The CV safety is been studied in eight trial involving GLP-1 analogues out of which four trials have been completed.

ELIXIR

The first trial ELIXIR where lixisenatide was studied in patients with recent acute coronary syndrome (ACS) where it had a noninferiority in 4-point MACE, but showing no superiority in CV outcome.

LEADER Trial

Liraglutide was employed in this double blind trial where the rate of death from any cause was lower in the liraglutide group [381 patients (8.2%)] than in the placebo group [447 (9.6%)] (hazard ratio, 0.85; 95% CI, 0.74–0.97; P=0.02). The rates of nonfatal myocardial infarction, nonfatal stroke, and hospitalization for heart failure were nonsignificantly lower in the liraglutide group than in the placebo group. The most common adverse events leading to the discontinuation of liraglutide were gastrointestinal events.

SUSTAIN-6

This trial involved long acting semaglutide with weekly injection of 0.5–1 mg which has a favorable effect on 3-point MACE with a significant decrease in nonfatal stroke, nonsignificant decrease in nonfatal MI with no trend on CV deaths or all cause mortality.

EXSCEL Trial

This was performed in a usual-care setting among patients with type 2 diabetes with or without previous CVD. It was

shown to have noninferiority in 3-point MACE, but not superiority, of once-weekly treatment with 2 mg of the long-acting extended-release exenatide (HR 0.91 [95% CI 0.83–1.00], P=0.06).

REWIND Trial

Once-weekly dulaglutide administered via subcutaneous injection is superior to placebo in improving glycemic control and reducing CV events in patients with type 2 diabetes and higher CV risk. There was also a significant reduction in nonfatal strokes. In addition, the drug had a moderate effect on the composite renal outcome, and reduced new macroalbuminuria in this patient population.

Insulin

Two major trials were done with both the Basal insulin namely glargine and degludec. Increased fasting blood glucose is an independent risk factor for adverse cardiovascular outcome in patients with long-term diabetes. Control of fasting blood glucose less than 100 mg% by basal insulin has shown a clear cardiovascular benefit.

ORIGIN

This a 6.2-year study where glargine was used to control the fasting blood glucose, the therapy with basal insulin glargine had a neutral effect on cardiovascular outcomes and cancers. Limitations of the study are that metformin was ultimately used by 47% of the insulin-glargine group. Evidence that metformin is cardioprotective raises the possibility that any cardiovascular harm of insulin may have been mitigated by metformin.

DEVOTE

The risk of hypoglycemia was more with glargine compared with degludec insulin once daily. This trial was done comparing the CV outcome of glargine and degludec insulin which showed the noninferiority, if degludec on CV events compared to glargine with lesser hypoglycemic events.

The ADA guidelines have been revised regarding the second drug after metformin after CVOT trial outcomes individualizing the patients' associated CV risk factors. SGLT2 inhibitors and GLP-1 analogues have become the choice after metformin therapy with CV risk.

BOX 1 Changes to consensus recommendations

We previously recommended that, in the setting of type 2 diabetes, established CVD was a compelling indication for treatment with a GLP-1 receptor agonist or SGLT2 inhibitor. We now further suggest the following:

General consideration

- In appropriate high-risk individuals with established type 2 diabetes, the decisio to treat with a GLP-1 receptor agonist or SGLT2 inhibitor to reduce MACE, hHF, CV death or CKD progression should be considered independently of baseline HbA_{1c} or individualised HbA_{1c} target.
- Providers should engage in shared decision making around initial combination therapy in new-onset cases of type 2 diabetes

GLP-1 receptor agonist recommendations

- For patients with type 2 diabetes and established atherosclerotic CV disease (such as those with prior myocardial infarction, ischemic strok, unstable angina and ECG changes, myocardial ischemia on imaging or stress test, or revascularisation of coronary, carotid or peripheral arteries) where MACE is the gravest threat, the level of evidence for MACE benefit is greatest for GLP-1 receptor agonists
- To reduce risk of MACE, GLP-1 receptor agonists can also be considered in patients with type 2 diabetes without established CVD with indicators of high risk, specifically, patients aged 55 years or older with coronary, carotid or lower extremely artery stenosis >50%, left ventricular hypertrophy, eGFR < 60 mL/min $(173\ m)^2$ or albuminuria

SGLT2 inhbitor recommendations

- For patients with or without established atherosclerotic CVD, but with HFrEF (EF <45%) or CKD (eGFR) 30 to ≤60 mL/min $(1.73)^2$ or UACR >30 mg/g, particularly UACR >300 mg/g), the level of evidence for benefit is greatest for SGLT2 inhibitors
- SGLT2 inhibitors are recommended in patients with type 2 diabetes and HF, particularly those with HFrEF, to reduce hHF, MACE and CV death
- SGLT2 inhibitors are recommended to prevent the progression of CKD, hHF, MACE and CV death in patients with type 2 diabetes with CKD
- Patients with foot ulcers or at high risk for amputation should only be treated with SGLT2 inhibitors after careful shared decision making around risk and benefits with comprehensive education or foot care and amputation prevention

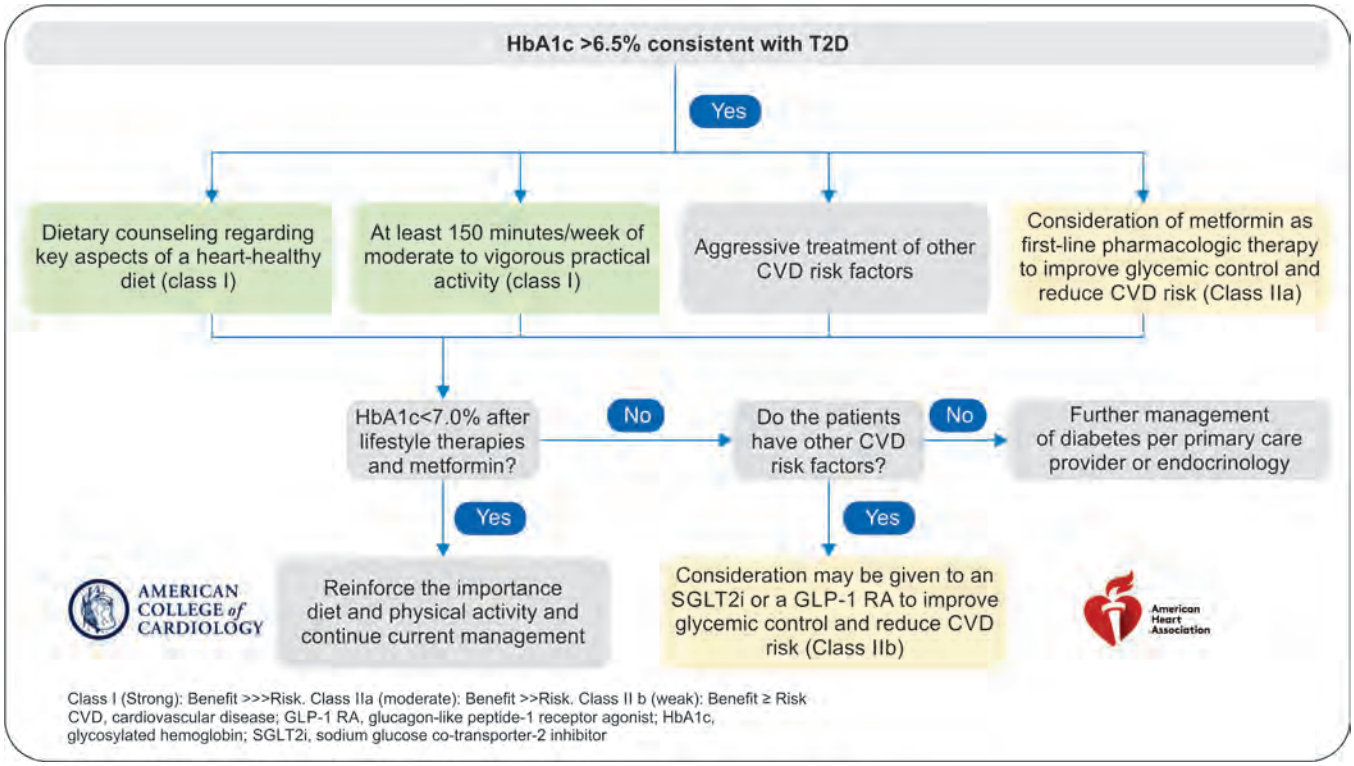


Fig. 1: Treatment of T2D for primary prevention of CVD

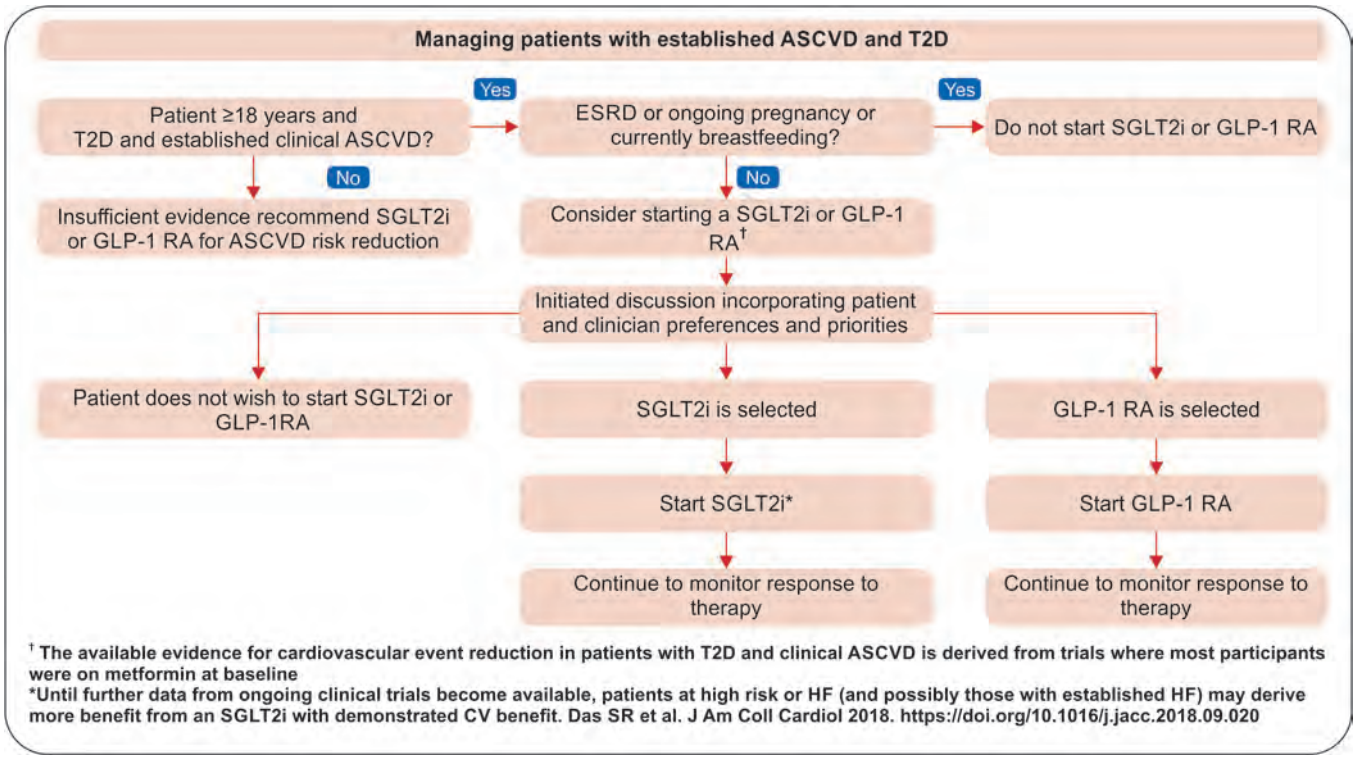
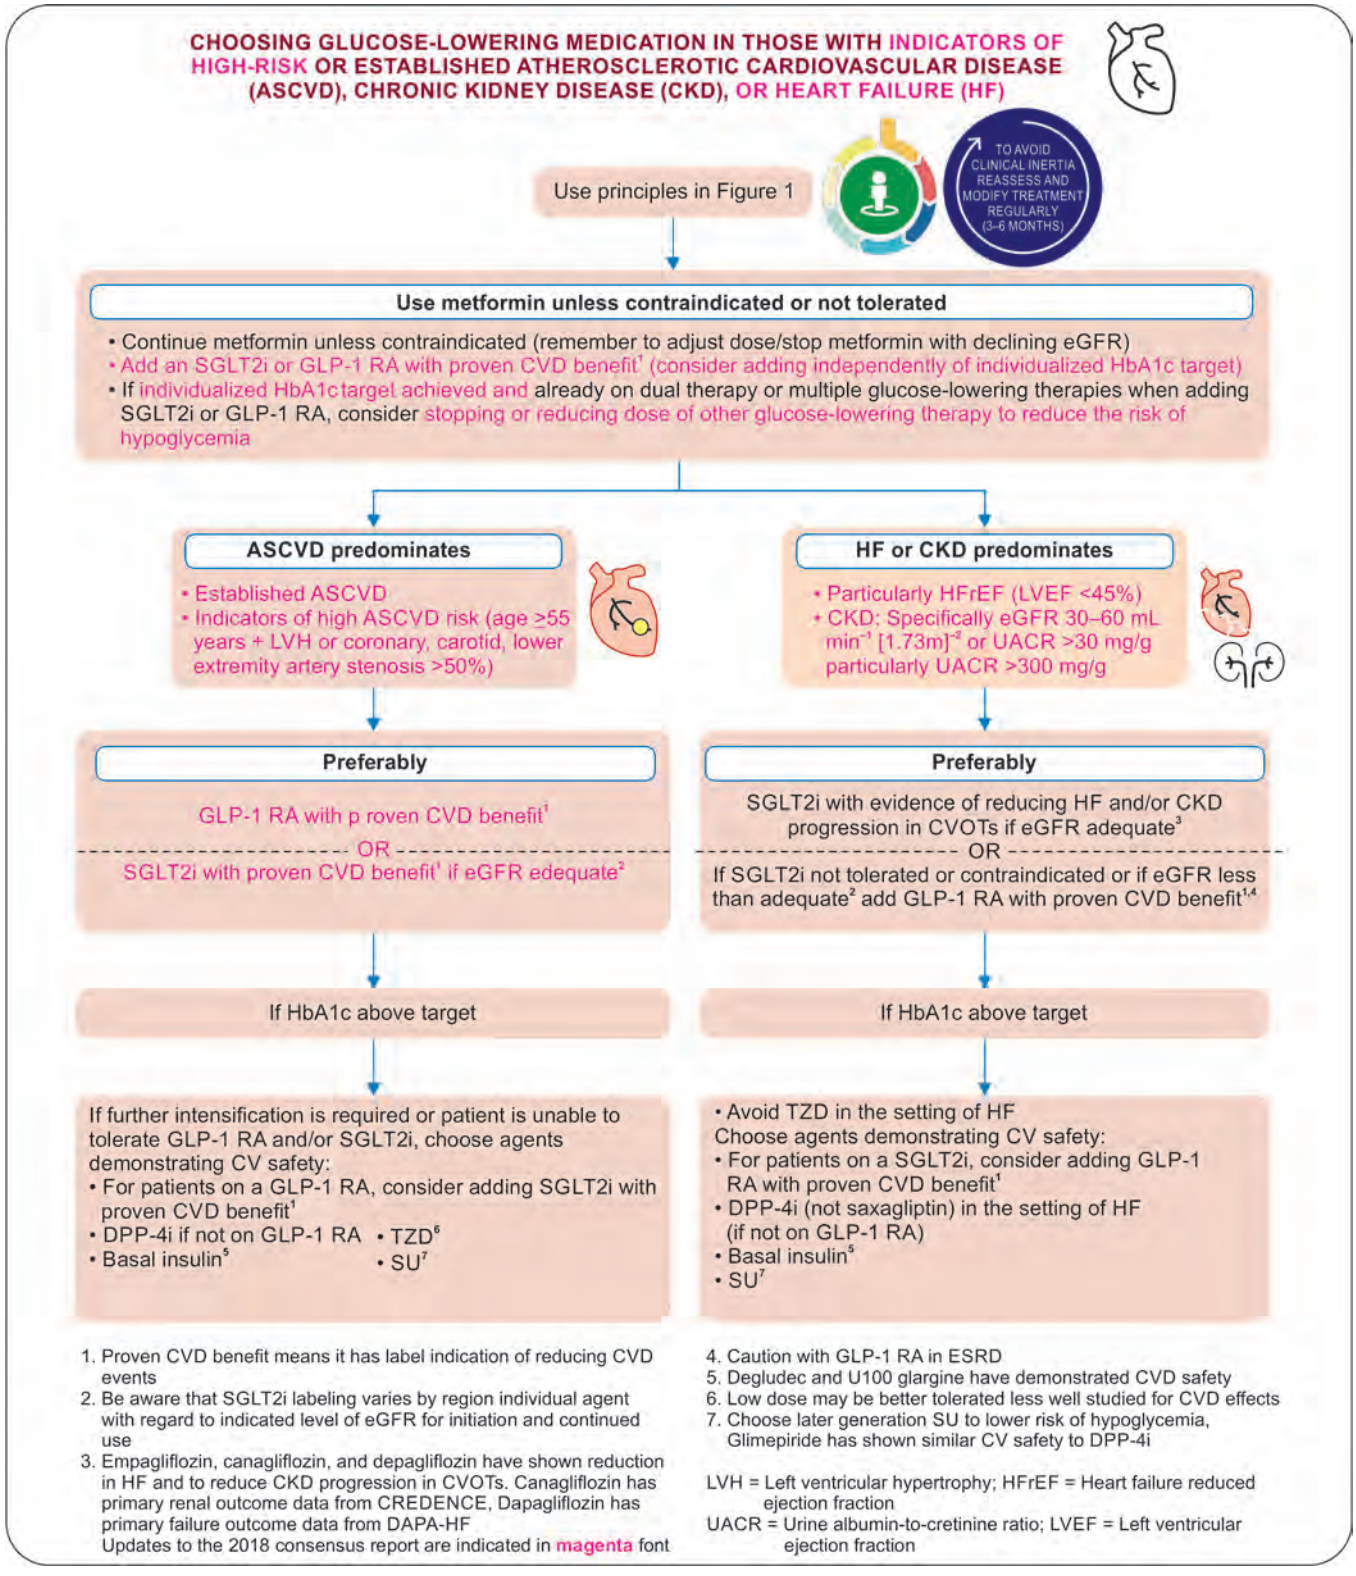
Flowchart 2: Managing patients with established ASCVD and T2D



† The available evidence for cardiovascular event reduction in patients with T2D and clinical ASCVD is derived from trials where most participants were on metformin at baseline
*Until further data from ongoing clinical trials become available, patients at high risk or HF (and possibly those with established HF) may derive more benefit from an SGLT2i with demonstrated CV benefit. Das SR et al. J Am Coll Cardiol 2018. https://doi.org/10.1016/j.jacc.2018.09.020

Flowchart 3: Choosing glucose lowering medication in those with indicators of high risk or established ASCVD, CKD, or HF



A consensus report by the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) has been shown in **Box 1**.

The treatment of diabetes for primary prevention of CVD is given in the **Figure 1**.

Managing patients with established ASCVD and T2D have been shown in the **Flowchart 2**.

Choosing glucose lowering medication in those with indicators of high risk or established ASCVD, CKD, or HF have been shown in the **Flowchart 3**.

Conclusion

- The CVOT trials, after the usage of rosiglitazone which had a detrimental effects on CV outcome.
- FDA has given a CV safety trial for all newer antihyperglycemic drug.
- Few of the studies showed a superiority in decreasing the deaths due to CV events and has a beneficial effects on CV outcome. These include EMPA-REG OUTCOME trial and LEADER trial which had shown clear beneficial effects on CV safety in type 2 diabetic adult patients and with this favorable outcome combined ADA and EASD has given clear guideline about the place after metformin therapy in diabetic population.
- SGLT2 inhibitors have shown to decrease the progression on renal dysfunction in long standing diabetes.
- DAPA-HF had shown that there is a significant decrease in hospitalization and deaths due to heart failure in long standing diabetes with heart failure with decreased ejection fraction when dapagliflozin is employed.

Diabetic Fatigue Syndrome

Puneet Saxena, Deepak Chadha, Rishika Goyal

Abstract

Fatigue occurring in diabetes is a multispectrum disorder with etiology touching many horizons ranging from glycemia related and endocrinal/iatrogenic to nutritional and lifestyle factors. In this article we tried to illustrate fatigue in general and from neurological standpoint alongside enumerating the etiology of fatigue in diabetes with further mentioning the pathogenesis behind causation of fatigue in diabetes and ways to diagnose and manage the problem. The recognition and timely management of fatigue in diabetes is of paramount importance as it hinders with the self management tasks of diabetes on part of the patient. The diabetes self management is the cornerstone in management guidelines of diabetes in current scenario. The major aim of this literature is to highlight the topic of diabetic fatigue syndrome and engrave the path for more focused studies on this subject in the near future.

Introduction

Diabetes mellitus is a major public health threat with a global prevalence that has expanded enormously over past decades and is affecting approximately 6% of total world's adult population.[1] Among those affected, there are frequent symptoms of fatigue including decrease ambulation, frailty, generalized muscle weakness, and loss of independence thereby regarding fatigue as one of the omnipresent but distressing complaint and is a strong predictor of functional limitations, disability, and increasing mortality. The fatigue in diabetes has a multifactorial causation and is not just only limited to poor glycemic control. Currently there is paucity of focused studies on diabetes fatigue syndrome describing the severity of problem thereby highlighting the need for further clarification over this neglected, but extremely important aspect of diabetes care.

What is Fatigue (In General)?

Fatigue is a subjective sensation with no measurable signs and is defined as physical or mental exhaustion leading to decrease the quality of life. There is no proper standardized quantification of measurement of fatigue thereby explaining the position of no proper defining criteria till now. Hence, fatigue is mainly identified on subjective grounds or decrement in physical performance.[2] The causation of fatigue touches multiple horizons that range from physiological to psychological and pathological disease states.[3,4] At the onset fatigue can occur in normal daily activities where it is regarded as the protective mechanism that signals the body's requirement of rest. This kind of fatigue is mainly acute in onset and relives off by taking adequate rest whereas on the other side of spectrum is chronic fatigue that is majorly associated with multiple disease states like diabetes, malignancies, fibromyalgias, and even chronic pulmonary obstructive disorders. It typically does not relieve on rest and is initiated by mild to moderate level of activity.[5,6]

The physiological mechanism behind fatigue broadly classifies fatigue into main types: peripheral and central fatigue. In peripheral fatigue, the underlying pathogenesis is attributed largely to the neuromuscular transmission

defect, muscular metabolic defects, or rarely to circulatory failure states.[7] In this type, patient complains of physical fatigue where he is unable to sustain adequate force during exertional activities. On the other side, in central fatigue there is failure of initiation of attentional tasks (mental fatigue) and physical activities requiring self motivation (physical fatigue) in the absence of any obvious motor weakness or neurological deficit.[8] The central fatigue can be of short duration as evident by normal individuals after loss of sleep, following stress, in females during menstruation and also after episodes of viral illness or persistence of central fatigue mainly seen in central disorders like Parkinsonism.

Fatigue can even be psychological in origin as is evident in clinical depression, stress, and burnout states.

Fatigue in Diabetes: Etiopathogenesis

The fatigue in diabetes is multifactorial in origin and is largely attributed to physiological, psychological, and lifestyle factors pertaining to diabetes as explained in **Flowchart 1**.

Physiological Factors

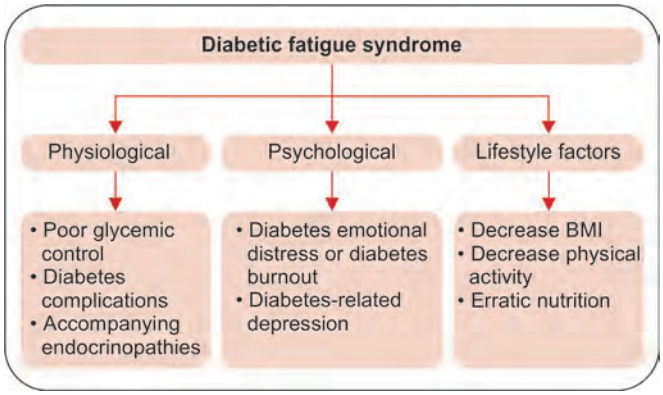
The physiological factors responsible for causation of diabetic fatigue syndrome (DFS) are mainly discussed under three subheadings like:

- Poor glycemic control
- Presence of diabetes-related complications
- Concomitant other endocrinopathies.

Poor Glycemic Control in Diabetes

- As evidenced by number of studies in the literature acute episodes of hyperglycemia are frequently associated with fatigue along with alteration in the mood states and decreased cognition.[9] This association is notably seen with fasting plasma glucose levels rather than HbA1c thereby corroborating the strong relation between fatigue and acute rather than chronic hyperglycemia.[10]
- Similarly acute episodes of hypoglycemia are also linked up with bouts of fatigue as evident by one of the controlled study conducted among type 1 diabetics.[11]
- There are fewer data available to establish linkage between chronic hyperglycemia and its contribution to fatigue, but still no association has been found between HbA1c and fatigue symptoms. The excursions of HbA1c are linked up with sleepiness, but not with fatigue.[12]
- There is also a strong association between symptoms of fatigue and glucose variability that is defined as fluctuations in glucose levels occurring over minutes to hours that are not revealed by single measurement of blood glucose or even by HbA1c. The frequency and magnitude of glucose variability is more marked in type 1 diabetics who are under the effects of exogenous insulin than in type 2 diabetics. The exogenous insulin is more responsible for alteration in the levels of counter regulatory hormones like glucagon or nor-epinephrine thereby responsible for more frequent episodes of hypoglycemia.[13] Among type 2 diabetics, the glucose fluctuations occurring during post prandial phase are frequently associated with bouts of fatigue.

Flowchart 1: Etiopathogenesis of fatigue in diabetic fatigue syndrome



Diabetes-related Complications

- There are many notable chronic complications of diabetes that are frequently associated with fatigue.
- Peripheral vascular diseases often present in diabetic patients and causes deep aching pain in the calves owing to perfusion defects in the lower extremities among diabetics and such patients frequently report fatigue.
- Similarly, neuropathic pain in hands and feet of diabetic patients with concomitant dysesthetic sensations also are linked up with onset of fatigue.[14]
- The leading cause of end stage renal disease is diabetes. This form of chronic kidney disease is largely linked with anemia that directly attributes to causation of increased fatigue.[15]

Other Accompanying Endocrinopathies

Patients with type 1 diabetes are prone to develop other concomitant endocrinopathies like hypothyroidism, hypogonadism, Cushing syndrome, and Addison's disease. These conditions if left untreated may further worsen DFS.

Psychological Factors

It encompasses two main states namely:

- Diabetes emotional distress
- Diabetes-related depressive symptom complex.

Diabetes Emotional Distress

- It also known as diabetes burnout phase is a state of psychological disturbances that arises while managing and living with diabetes.[16,17] There are many factors that directly or indirectly responsible for DFS in diabetes emotional distress.
- Stress of living with diabetes causes depletion of energy and fatigue with disruption of sense of well-being.
- The increase burden of self management of disease especially in type 1 diabetics with self adjustment of insulin dosages associated with sense of psychological or emotional fatigue apart from improve physiological blood levels.
- Also in diabetes burnout phase, the patient feels cynicism, emotional fatigue, and sense of detachment from recommendations of health-care providers when patient experience negative results during the course of self management of diabetes. The sense of ineffectiveness prevails during this phase.[18]

Diabetes-related Depression

- Diabetics are more likely to suffer from depression than general population.
- The elevated depressive symptoms further likely contribute to sense of physical and mental fatigueness.[19,20]

Lifestyle Factors

There are several factors linked up with DFS like the following:

Increased BMI

It has been found that type 2 diabetic patients are majorly overweight and obese that are two independent factors causing fatigue. There is increased level of proinflammatory cytokine production that plays a major role in the pathogenesis of fatigue.[21] This increased production of proinflammatory cytokines storm further causes oxidative stress and initiate apoptotic pathways in the central neural circuits that contribute to symptom complex of fatigue.[22]

Reduced Level of Physical Activity

- Regular physical activity especially vigorous exertion helps in building up of muscle mass, increases substrates usage for energy production, improves aerobic exercise capacity, decreases lactic acid production at the cellular level, and finally improves mood. Therefore, physical activity and exhibition of fatigue symptoms exhibit inverse relationship with increase activity; there occurs little or no fatigue at all.[23,24]
- Moreover physical activity helps in rejuvenation of mood and alleviation of multiple somatic symptoms like depression.

Erratic Nutritional Factors

Increase calorie consumption can precipitate excursions of glycemia that further play a role in fatigue. Even excessive dietary restriction causing very low calorie consumption leads to protein energy malnutrition and starvation ketosis that can precipitate DFS.

Miscellaneous Causes

Common medical conditions associated with DFS are:

- Multiple vitamin deficiencies, especially low vitamin D levels and vitamin D deficiencies are markedly notable in diabetic patients that are further associated with fatigue, depressive symptoms, and low quality of life. The prolonged muscle weakness associated with musculoskeltal pains is associated with vitamin D deficiency.
- Anemia in diabetes is also one of the medical conditions in causation of DFS as being described previously. Apart from being the stigmata of chronic kidney disease, anemia is also evident in patients with excessive blood loss or with worm infestations.

Approach to Patient with DFS

As the pathogenesis of DFS touches multiple horizons so the clinical approach in patients with DFS is not

TABLE 1 Common causes of fatigue in a person with diabetes

Disorders associated with endocrine dysfunction
• *Related to glycemic variations:* – High fasting plasma glucose – High postprandial surges with normal fasting – Recurrent episode of hypoglycemia – Glycemic variability
• *Presence of complications of diabetes:* – Nephropathy – Peripheral arterial disorders – Neuropathy
• *Presence of other endocrinopathies:* – Hypothyroidism – Hypogonadism – Polycystic ovarian syndrome – Cushing syndrome – Addison's disease
• *Association with drugs:* – Statins – Beta blockers – Corticosteroid use
Disorders associated with non-endocrine dysfunction
• *Lifestyle factors:* – Reduced BMI – Decreased level of physical activity – Erratic nutrition
• *Psychology-related to diabetes:* – Diabetes emotional distress – Diabetes depression syndrome

only centered on poor glycemic variability but should thoroughly follow hierarchy of responsible factors that need to be evaluated before labeling patient with DFS. All of the major causes are tabulated in **Table 1**.

- The initial assessment begins with lifestyle-related factors followed by endocrinal assessment. The evaluation of daily routine of patient with special emphasis on exercise habits, pattern, and quality of sleep, dietary habits. If the patient is having more sedentary lifestyle then motivation to be given for increase physical activities in the form of aerobic exercise or joining a game or simply doing cycling.
- For the assessment of glycemic control and presence of chronic diabetic complications, the search begins with thorough history and physical examination of the patient.
- When the symptoms of fatigue occur characteristically in the early morning and are associated with headache, sweating and relives on taking breakfast simply suggests hypoglycemia as the cause of fatigue.
- The appearance of pallor in patient with long standing diabetes accompanied by symptoms of breathlessness on exertion signifies prompt investigations for nephropathy and hypothyroidism. When symptoms of fatigue accompany breathlessness along with inability to do exercise suggest decrease cardiac reserve in the form of heart failure.
- The prominence of symptoms of pain in the calves while walking along with neuropathic symptoms suggests development of diabetic neuropathy responsible for DFS. When fatigue is accompanied by symptoms of weakness of proximal muscles then ruling out vitamin D deficiency is important, similarly if patient complains of bony pain and tenderness then osteomalacia or hypoparathyroidism are mare notable to exist.
- When fatigue occurs with symptoms of sexual dysfunction or loss of libido may suggest menopause, andropause, or even hypogonadism.
- Before labeling patient to be psychiatric, thorough evaluation for diabetes emotional distress and diabetes-related depression should be sought for.
- Drugs like centrally acting anti-hypertensives, diuretics, statins, and beta blockers also causes fatigue and are considered iatrogenic causes of fatigue.

Subjective Evaluation of Fatigue

There are multiple questionnaires for evaluation of fatigue as well like:

- Avlund Fatigue Scale
- The 36 Item Short Form Health Survey
- Sleep Quality Scales Like Pittsburg Sleeping Quality Index
- Multidimensional Sleep Inventory

What Fatigue does to Diabetic Patients?

The major drawback of fatigue is that it completely affects the self-rated health and quality of life in a very negative sense, and therefore is taking a huge toll over the diabetic patients.[25] The patient characteristically present with decreased physical functioning and inability to manage the daily routines of life. The most dreaded effect of fatigue in patients with diabetes is that fatigue acts as a strong barrier in patient's health promoting behaviors like

participation in self-care regimens of diabetes, following a regular exercise plan, and participation in healthy eating habits.[26] Thereby fatigue remains a challenging problem to manage on the part of health-care providers. The lack of standardized definition and paucity of diagnostic criteria makes the management part more difficult.[27]

Important Differentials of DFS

Differentiating DFS from Chronic Fatigue Syndrome

Chronic fatigue syndrome (CFS) is UNEXPLAINED and PERSISTENT fatigue that is not due to any exertional activity and not relieved by taking rest but leads to significant limitation of activity. There are few cardinal hallmarks of CFS that must be present for at least a period of 6 or more months like:

- Myalgias
- Multiple joint pains with no underlying inflammatory signs
- Impair attention span
- Headaches
- Unfresh even after sleep

The most important point differentiating CFS from DFS is that CFS is a diagnosis of exclusion and indeed requires a thorough evaluation of underlying mental status of the patient in terms of mood, personality, intellectual functions, and memory. Apart from psychological factors, there are also many biological factors responsible for causation of CFS like:

- Genetic factors.
- Immune etiologies like increase in number of natural killer cells CD16/CD3 causing abnormal cytotoxicity of natural killer cells and increase in immune activation markers.
- Infectious causes linked up with CFS are infectious mononucleosis, glandular fever, parvovirus B19, nipah virus human herpesvirus 4-6-7, and borna virus disease.

Hence, diagnosis of CFS requires a holistic bio-psychological approach.

Fibromyalgia

Fibromyalgia syndrome denotes symptom complex of chronic pain, muscle fatigue, de arranged sleep, and many functional symptoms. The underlying mechanism for causation is based on oxidative stress and modified inflammatory response with baseline predisposition attributed to genetics as well. The diagnostic criteria defined by American College of Rheumatology states at least 3-month duration of pain both above and below the waist along with presence of 11 out of 18 possible tender points that are not explained by other disorders.

Management of DFS

There are many aspects of management scheme.

Improving Lifestyle Factors

Counseling and constant motivating the patient for:

- Initiating physical activity regimen in the form of playing outdoor games, aerobic activity like jogging, cycling and swimming. The patient should be motivated to do at least 150 minutes of moderate activity per week.
- Indulging in eating healthy diet.
- Participating in meditation for stress control.
- Good sleep pattern.

Maintenance of Euglycemia

The health-care providers should assess the condition of the patient in totality and initiate the drug regimens for complete and effective control of glycemia. There should also be optimization of other endocrinal and medical aspect of patient like correction of thyroid status if concomitant hypothyroidism ensues, correction of hormonal deficits in a patient with hypogonadism.

Mitigation of Diabetes Distress

As diabetes is a self-managing disease, so distress occurs when patient is unable to cope with the demands of life with diabetes that further makes the patient incapacitating in managing and monitoring the disease as well.

This psychological aspect can be overcome by:

- Utilization of external support
- Enhancing coping skills on the part of patient
- Enhancing self perception of the patient
- Making the patient to understand to minimize the discomfort of change.

Pharmacological Intervention

There are no practical prospective studies available for addressing fatigue in diabetes, but there is a list of drugs

TABLE 2 Drugs important in treatment of DFS

SSRI:
• Fluoxetine
• Paroxetine
• Sertraline
SNRI:
• Duloxetine
• Venlafaxine
• Desvenlafaxine
Atypical antidepressants:
• Milnacipran
Stimulants:
• Modafinil
• Methylphenidate

available based on experience of clinician in regards to treatment of depression and presence of fatigue in other conditions like CFS, fibromyalgia, or HIV as mentioned in **Table 2**.

Conclusion

Fatigue is very common and neglected problem for the people living with diabetes and its causation is indeed multifactorial interplay of physiological, psychological, and lifestyle-related factors. The poor self management of diabetes is both the causative factor and net result of DFS. Therefore, regular screening of fatigue along with other complications of diabetes is of paramount importance to prevent or retard the course of DFS. Lastly, to improve the quality of life and obtaining a good control of diabetes, early detection and management of DFS are very essential.

CHAPTER

73 Clinical Implications and Management of Glycemic Variability in Diabetes

Ashutosh Chaturvedi, Girish Mathur, Divyansh Mathur, Mihika Sinha

Abstract

Poor glycemic control is a major risk factor for long-term micro- and macrovascular complications of diabetes. In the day-to-day practice clinicians frequently encounter patients with high dysglycemic patterns. Measuring Glycated hemoglobin A1c (HbA1c) does not take into account the fluctuations in blood glucose levels. The intraday and interday swing in blood glucose levels including episodes of hyper- and hypoglycemia is known as glycemic variability (GV). GV can be due lifestyle related causes, pharmacological causes, biomedical related causes. It is now strongly suggested that diabetes management strategies should include minimizing GV and must focus on decreasing the postprandial glycemic excursions along with HbA1c levels to lower the risk for long-term complications.

Introduction

Diabetes mellitus (DM) is now a rapidly growing global epidemic with type 2 diabetes mellitus (T2DM) accounting for over 90% of cases. As per estimated by International Diabetes Federation (IDF), worldwide every 1 in 10 people or 592 million individuals will suffer from diabetes by the year 2035.[1] Poor glycemic control is a major risk factor for long-term micro- and macrovascular complications of diabetes. This poor blood glucose control in diabetes results due to both acute glucose fluctuations and chronic hyperglycemia over time. Thus, the main aim of diabetes management is to decrease the risk of diabetes complications by optimizing blood glucose levels and minimizing blood glucose variability and episodes of hypoglycemia. Glycated hemoglobin A1c (HbA1c) is considered the gold standard for assessment of glycemic control in diabetic patients, but it does not take into account the fluctuations in blood glucose levels This intraday and interday swing in blood glucose levels including episodes of hyper- and hypoglycemia is known as glycemic variability (GV). Studies suggest that GV contributes to diabetes-related complications[2] and also impacts patient's psychological well-being and quality of life (QoL).[3] Newer therapeutic strategies like glucagon like peptide-1 (GLP-1) analogs and dihydropeptidyl peptidase-IV (DPP-IV) inhibitors targeting multiple pathophysiological mechanisms are most promising in control of HbA1c and decreasing GV. It is important today to understand the clinical implications of GV and its management in diabetic patients.

Glycemic Variability: A Rising Concept

In the day-to-day practice clinicians frequently encounter patients with high dysglycemic patterns. Few individuals have extreme fluctuations in glucose levels during a particular day, while others present with variable blood sugar readings from day to day. GV may be associated with symptomatic hypoglycemia, impaired QoL, failure to titrate doses of anti-diabetic drugs, unwanted chronic complications and subsequently increased cost of treatment.[4] Thus, it has become a challenge for good diabetes care. Two important pathophysiologic

mechanisms proposed for the development of various micro- and macrovascular complications in diabetes are excessive advanced glycation end products (AGE's) and activation of oxidative stress. Lowering of hyperglycemic excursions that leads to reduction in GV also decreases the oxidative stress markers.[5] Studies also suggest that fluctuating glucose levels that produce harmful effects on endothelial function and oxidative stress may be more damaging for the cardiovascular system than is chronic sustained hyperglycemia.[6] Traditionally, diabetes management plans mainly targeted to decrease the triad of fasting and postprandial blood glucose and HbA1c. Nowadays GV and QoL have been added to the known components and these five elements are collectively termed as "glycemic pentad." The need was felt because even studies like DCCT, UKPDS, and ADVANCE trials failed to show any benefits of intensive treatment to retard the development of various chronic complications of diabetes.[7-9] In recent studies it was observed that HbA1c is not sufficient to justify all the uncertainties of diabetes complications and that GV might be a better indicator of glycemic control than HbA1c.[10]

Causes of Glycemic Variability

GV can be broadly classified under three main categories:

- lifestyle related causes
- pharmacological causes, and
- biomedical related causes **(Table 1)**.

Before evaluating the etiology of GV in a particular patient *Spurious or Fictitious GV* must be excluded, which can be due to wrong technique of self monitoring of blood glucose (SMBG) being used. It is important to assess the instrument and strips used, method of pricking the finger, how the instrument is being used and results are being read and recorded. Everything must be in order. Venous blood glucose estimation can be simultaneously ordered to check and confirm GV. It is now well known that continuous glucose monitoring systems (CGMS) and ambulatory glucose monitoring (flash) much more accurately confirm GV.[11]

TABLE 1 Causes of glycemic variability

Cause	*Type of variation*	*Example*
Lifestyle related	Diet	• Composition of diet • Diet pattern • Quality of diet
	Physical activity	• Exercise timing • Exercise duration • Intensity of exercise
	Management of stress	• Psychological stress • Sleep cycle issues • Social environment
Pharmacological	Type of preparation	• Long acting/ultra long acating insulin • Immediate release/ controlled or sustained release tablets
	Type of regimen	• Human insulin/ analong insulin • Premixed/bolus insullin
	Drug delivery related	• Site of injection • Injection at hypo-perfused or euperfused site • Gap between drug/ injection and meal
	Drug interactions related	• Rifampicin increases metabolism of sulfonylureas (SUs) • Azoles inhibit the metabolism of pioglitazone and SUs
Biomedical	Neuroendocrine causes	• Pancreatic exocrine deficiency • Glucagon deficiency • Hypoglycemia unawareness
	Gastrointestinal causes	• Malabsorption syndrome • Diabetic gastroparesis

Source: Kalra S, et al. Managing glycemic variability: clinical approach. JPMA. 2019;69(2):274-6.

Lifestyle-related GV

After confirmation of GV, first of all variability in lifestyle needs to be excluded. This can be due to either variation in diet, physical activity, or management of stress in life. Proper history taken from the patient reveals the variation in the composition, pattern, or quality of food taken, sleep pattern and timing, duration or intensity of physical activity/exercise, psychological or social stress. All these day-to-day variations in lifestyle can lead to fluctuations in glycemic levels.

Pharmacological GV

The GV can also arise due to variation in the selection of drug regimens, drug formulations, and manner and method of drug delivery. For a particular patient's glucophenotype the selected drug regimens, drug formulations, and manner and method of drug delivery may not be appropriate.[12] For example, for a person having severe hyperglycemia prescribing a basal insulin and using human insulins which have higher coefficients of variability as compared to analogue insulins which have lower. The physician, therefore, should be well-versed with the pharmacokinetics and pharmacodynamics of the each anti-diabetic drugs and various insulin regimes while prescribing them.

Biomedical Causes of GV

When the lifestyle related and pharmacological etiologies are ruled out, it is important to look for the biomedical causes of GV. Biomedical causes can be gastrointestinal, neuroendocrine or drug-drug interactions related. Disorders of absorption and motility result in a nutrient-insulin mismatch that leads to variable changes in the absorption of nutrients. Neuroendocrine reasons include endocrine and exocrine disorders of various glands of body and of the autonomic nervous system (resulting in hypoglycemia unawareness) that leads to GV through different mechanisms. Another type of biomedical cause is the drug-drug interaction occurring when new drugs are prescribed to treat the secondary illness like anti-fungal drugs (fluconazole and ketoconazole) to treat mycoses, anti-tubercular drugs (rifampin) for treating tuberculosis, and anti-seizure drugs (phenobarbital) for any neuropsychiatric illnesses.[13]

Measurement of GV

With the development of increasing interest in the clinical implications of GV in diabetes, a lot of methods and metrics has been described for assessment of GV which is at times really confusing for both physicians and patients. For those clinicians who want to apply GV in their routine clinical practice, unavailability of a uniformly accepted standard method of measurement of GV is a real challenging issue. Among all these methods the four most clinically relevant and commonly used methods are coefficient of variation (CV or % CV), standard deviation (SD), interquartile range (IQR), and mean amplitude of glycemic excursions (MAGE).

Most of the physicians commonly use SD to measure GV, but still it has been pointed out that SD is not regularly distributed around the mean glucose; therefore, the IQR, which is also strongly correlated with SD, can be used as a preferred method to measure GV. IQR is a part of the proposed international standard or uniform one-page glucose profile report [Ambulatory Glucose Profile (AGP)] and can be easily recognized on a standard day or 24-hour glucose profile plot and can be actually clinically relevant in decision-making for the clinician and patient.[14] For the purpose of research work, the coefficient of variation (CV or % CV) is still the preferred GV metric which is least influenced by fluctuations in mean glucose level or HbA1c. MAGE is an another long-used measure of GV which is defined as the average of all blood glucose excursions (up or down) that are of a magnitude greater than 1 SD of all glucose measures.[15] Different aspects of GV parameters which are commonly used in research and clinical practice are summarized in **Table 2**.

Timing of Glucose Excursions

It is the clinically most important metrics that give us the time which the patient spends within, above, and below the target blood glucose range. With the increasing availability of CGMS in recent years, such time-related GV metrics have become more well-known. Time in targeted blood glucose range (TIR) provides useful information on the level of glycemic control although it gives an incomplete picture of overall glycemic control. Clinically, assessment of TIR can help patients to know better than over the time how hypoglycemia or hyperglycemia improves with treatment.

Clinical Implications of GV

GV and Microvascular Complications of Diabetes

Due to the lack of consensus on the most reliable method of assessment of GV, ambivalent conclusions have been made from the studies examining the relationship between GV and development of complications of diabetes till now. In epidemiological studies while GV was an independent predictor of the prevalence of peripheral neuropathy,[16] while mean blood glucose (MBG) was significantly associated with the development of diabetic retinopathy but not with that of nephropathy.[17]

TABLE 2 Summary of GV metrics[15]

GV metric	*Definition*	*Advantages*	*Clinical implications of GV metric*
SD	The amount of variation or mean dispersion of all glucose readings in a set of data	Widely used, straight forward and easy to calculate	• Provides a measure of inter- or intraday GV depending on frequency of blood glucose measurements • Does not take into account the number of glycemic swings
% CV	It is the corrected measure of dispersion in relation to the mean blood glucose	It is useful in two or more gourps with different glucose tolerance	• Probably the best research metric to compare GV over time or between data stets • Does not consider the number of glycemic swings
IQR	It consists of values 25% above and 25% below the median	Likely the best method to visualize GV around the median glucose curve	It is easier to spot and give attention what time of day has the most GV by plotting the IQR around the median glucose curve
MAGE	It is the average amplitude of glucose excursions that are more than 1 SD	Most commonly used in literature and reflects both upward and downward glucose fluctuations	• Can be aplied to SMBG or CGMS data as well • Reflects intraday GV but it excludes minor fluctuations and is dependent on sampling frequency
CONGA (Continuous overall net glycemic action)	It is the standard deviation of the differences of glucose readings for a defined period of hours	It can capture smaller glycemic swings over shorter time intervals	• It measures intraday GC and is specifically developed for CGMS • Provides measures of short- or long-time intervals but requires software for calculation
MODD (Mean of dialy differences)	It is the mean absolute difference between blood glucose values derived from SMBG data at the same time on consecutive days	It shows the consistency and stability of day-to-day blood glucose patterns	It is measure of interday GV but it is affected by different daily lifestyle patterns

GV and Hypoglycemia

Cox et al. proposed GV as a better measure of predictor of future severe hypoglycemia than HbA1c.[18] The association of risk of hypoglycemia was found to be as much related to glucose variability as to the mean glucose value in the diabetes outcomes in veterans study (DOVES).[19] Limiting glycemic excursions along with maintaining the MBG and HbA1c in target range can be a key factor in achieving glycemic control.

GV and Cardiovascular Disease Risk

In patients with DMT2 and acute myocardial infarction, increased risk of mortality was observed in patients with increased visit-to-visit GV.[20]

Kilpatrick et al. showed that pre- and postprandial blood glucose, MBG were significantly related to cardiovascular disease risk but there was no association between HbA1c and glucose variability.[21]

GV and QoL

Increased frequency of fluctuations in blood glucose with hypoglycemia and hyperglycemic excursions can lead to mood changes, depression and poor QoL. High GV was shown to be associated with low QoL than HbA1c and 24-hour average blood glucose.[22]

Management of Glycemic Variability in Diabetes

Glycemic management of diabetes should focus on achieving near euglycemia without episodes of hypoglycemia; hence, reducing the risk for complications. It is now strongly suggested that diabetes management strategies should include minimizing GV and must focus on decreasing the postprandial glycemic excursions along with HbA1c levels to lower the risk for long-term complications.[10]

For improving the glycemic control management can be strategized into four possible categories of treatment which can be called as 4Ts:

- *Targets:* Setting the individualized glycemic goals carefully.
- *Team approach:* Use of team care along with self management training to patient and sharing the process of decision-making.
- *Therapeutics development:* Developing new oral and injectable anti-diabetic drugs.
- *Technology:* Application of new technologies in management like continuous glucose monitors, smartphone apps for tracking glucose, insulin pumps, tools for remote communication between the patient and team.

Lifestyle Measures

It is well known that weight loss through dietary restrictions and exercise are capable of decreasing blood glucose levels and improving the insulin sensitivity thus delaying the progression from impaired glucose tolerance (IGT) to diabetes. In a study it was shown that a diet based on whole cereals, legumes, vegetables, and fruits and rich in dietary fiber led to reduction in postprandial glycemic (PPG) excursions subsequently reducing GV.[23]

Oral Hypoglycemic Agents

Minimizing the PPG excursions is an important aspect of overall glycemic management, and a major barrier to optimal control of diabetes. Selection of diabetes medications and blood glucose goals must be beneficial for the individual, simultaneously reducing the risks of hypoglycemia. Sulfonylureas have been shown to be associated with significant GV, and can lead to an increase hypoglycemic episodes and mortality. Rationally glimepiride must cause less GV than glibenclamide because of the insulin-releasing activity which is high with glibenclamide and lowest with glimeperide.[24] In a study controlled-release glipizide combined with acarbose was found to be more effective in decreasing MAGE than controlled-release glipizide monotherapy.[25]

The DPP-4 inhibitors secrete insulin and suppress glucagon in a glucose-dependent manner, controlling postprandial glucose excursions as well as reducing the overall hyperglycemia without increasing the risk of hypoglycemic episodes. As compared to glimepiride and pioglitazone, sitagliptin, and vildagliptin significantly reduced GV in patients with type 2 diabetes not sufficiently controlled on metformin monotherapy.[26]

Prandial and Basal Insulins

Newer rapid prandial insulin analogs closely mimic the normal physiological insulin response to meals. Rapid acting insulin analogs such as insulin lispro, aspart, and glulisine better reduce the GV by reducing the periods of acute hyperglycemia, with lower rates of hypoglycemia than regular human insulin. In metformin-treated patients, as compared to insulin glargine alone, a premixed basal insulin glargine and rapid-acting insulin lispro was shown to result in reduced GV.[27] In type 1 diabetics, continuous subcutaneous insulin infusion (CSII) was considered as alternative when glycemic targets were not achieved with use of multiple dose insulin regimen in type 1 diabetic patients.

GLP-1 Analogs

When added to background therapy of oral antidiabetic drugs or high-dose basal-bolus insulin therapy, glucagon-like peptide-1 (GLP-1) receptor agonists like exenatide, liraglutide and lixisenatide have shown remarkable decrease in GV in the comparative studies. Heine et al.[28] compared the efficacy of insulin glargine (once-daily) or the GLP-1 agonist exenatide (twice daily) in suboptimally controlled type 2 diabetes. It was found that glargine lowered fasting glucose levels to a greater degree than exenatide, while exenatide decreased postprandial variability to a greater extent than glargine. HbA1c lowering was same in both groups but exenatide decreased glycemic excursions by almost 50% in the end when compared with baseline.

Conclusion

GV is a physiological phenomenon that contributes to increased mean blood glucose levels and also plays a key role in the development of chronic diabetes complications. Newer technologies in the field of diabetes education, monitoring, and therapy, especially in type 1 DM, have made it easier to identify GV as a promising target for betterment of overall diabetes management. By using CGMS, it is now possible to detect glucose fluctuations and relate their dynamics to relevant clinical implications. By carefully using SMBG and available

Contd...

Contd...

newer pharmacologic agents to avoid hyperglycemia and decrease hypoglycemic episodes, the burden of complications, disability, and mortality events associated with diabetes can be significantly reduced. However, due to lack of consensus for a standard metric and also difficulty in measuring GV, it remains a challenge for the clinicians to find out the most optimal approach for managing diabetes.

CHAPTER

74

Stem Cell Therapy in Diabetes

Sandeep K Mathur, Anshul Kumar

Abstract

Achievement of normoglycemia and a life free of insulin or oral anti-diabetic drugs has always been the goal of diabetes research and management. Stem cell therapy is the closest that we have ever got to the achievement of the above-mentioned goals. Here, in this chapter we aim to summarize the latest advancements in the use of stem cell therapy as a treatment modality in diabetes.

Introduction

Diabetes mellitus is a major pandemic that has been plaguing humanity since long and is growing tremendously with each passing year and is responsible for causing roughly four million deaths each year.[1] The trends for diabetes prevalence and incidence are particularly worrisome in developing countries.[2] Diabetes, which touched 230 million marks in 2008, is expected to affect over 300 million worldwide by the year 2025.[3]

Curative approach to diabetes that would make the administration of drugs such as insulin secretagogues, insulin sensitizers, or insulin itself redundant has long been sought. Pancreatic (whole organ) transplantation or islet transplantation following the Edmonton protocol has shown to be quite successful in achieving this "endeavor" of curing diabetes, primarily Type 1 Diabetes (T1D).[4] However, the main pitfall has been the lack of donors and the requirement of lifelong immunosuppression and thus, limits the application and benefit of this approach to only a few candidates.

Stem cell therapy heralds a promising new era in the management and possibly curative modality of advanced diabetes. Particular concerns regarding the type of stem cell, the transplantation procedure, and the long-term effects remain to be seen.[5-7] Several animal trials have shown the potential advantages of using stem cells for treating diabetes mellitus. However, given the numerous hurdles in the procedure and the ethical questions attached, human trials are still few and far between.

In this chapter, we briefly aim to review the treatment approach, the advances, the complexities, and the future directions in the treatment of both T1D and T2D using stem cell therapy as this might prove to be the one therapeutic approach that humanity has been searching.

What is a Stem Cell?

Stem cells are cells that can differentiate into a large number of cells; they are undifferentiated or partially differentiated cells. They are the first cells to form in the body and a particular cell lineage and tissue. They have the unique ability to proliferate without the loss of differentiation potential. They can broadly be classified into five different types:

- *Totipotent stem cells:* Also called omnipotent stem cells, they can differentiate into any embryonic or extraembryonic tissue, e.g., Totipotent cell from a zygote.

- *Pluripotent stem cells:* They can divide and differentiate into any of the three germ layers, i.e., ectoderm, mesoderm, or endoderm, e.g., Embryonic stem cells.
- *Multipotent stem cells:* These cells can multiply and give rise to a specific type of cells, e.g., Mesenchymal stem cells can differentiate into the osteoblastic lineage, myocyte lineage, adipocyte cell lineage, or chondrocyte lineage.
- *Oligopotent stem cells:* They are like the multipotent stem cells but are further limited in their capacity to differentiate, e.g., Hematopoietic stem cells are of mesodermal origin and can differentiate into all types of blood cells.
- *Unipotent stem cells:* These have the potential to differentiate into a single lineage of cells, e.g., Muscle stem cells.[8]

Pancreatic Islet Cell and Its Development

The human pancreas has dual functions: exocrine as well as endocrine. The exocrine part secretes various digestive enzymes. In contrast, the endocrine part is involved in the secretion of hormones that regulate body metabolism. The endocrine portion is organized into islets. These islets are composed of a variety of cells with each cell serving a different function; α cells, which secrete glucagon, β cells that secrete insulin, δ cells secrete somatostatin, ε cells secrete ghrelin while PP cells secrete pancreatic polypeptide. The chief action of all these various hormones is to maintain glucose homeostasis.[9] It is primarily the dysfunction of the β cells that leads to diabetes mellitus in T1D; there is autoimmune destruction of the β cell, and in T2D, there is β cell dysfunction combined with end-organ insulin resistance, but in both cases, the result is the same dysglycemia.

The development of stem cell-based therapy for diabetes requires the knowledge of underlying transcription factors that control the underlying islet cell differentiation process. However, this has been difficult owing to the relative unavailability of fetal endocrine tissue, and most of our knowledge of the development of endocrine pancreas comes from rodent experiments. Nevertheless, the development of islets in both rodents and humans is similar, and several generalizations can be made.

The human endodermal tissue becomes dedicated to pancreatic development before the evagination of dorsal and ventral pancreatic buds.[10] These buds contain multipotent pancreatic progenitor cells (MPCs), which under the influence of several transcription factors, get committed to endocrine or exocrine fates. After committing, these endocrine progenitors further differentiate and mature under the influence of lineage-specific transcription factors.

Here, we briefly discuss the transcription factors with involvement in β-cell development. The various stages in β-cell development and the different transcription factors expressed during that stage are shown in **Figure1**.

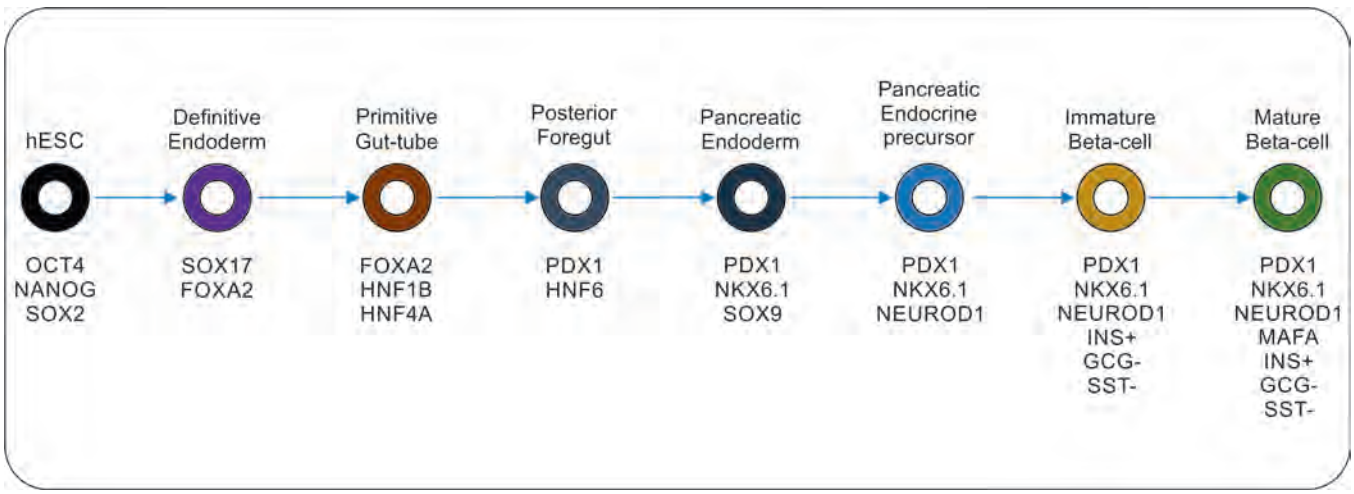

Fig. 1: Schematic representation of progression from hESC to mature beta-cell. The various stages and the different transcription factors expressed are shown

Transcription Factors Involved in Early Stages of Development

- *FOXA2:* This is an early transcription factor and is consistently expressed from week four onward,[11-14] as shown in several fetal pancreas studies.
- *SOX 17:* This high mobility group box gene is seen before 4 weeks but disappears within 1-week. Studies in mice have shown that its early expression is required for endoderm formation the continued expression represses pancreatic fate.[15]
- *Hepatocyte nuclear factor (HNF6):* This transcription factor is consistently found to be expressed from weeks 7–21 of the human pancreatic development.[12,13] INN rodents, it has been shown to have broad development until just before birth when it becomes restricted to alpha and acinar cells.
- *Hepatocyte nuclear factor 1 homeobox b (HNF1b):* In humans, it is expressed as early as 7 weeks and persists throughout pancreatic development.[16,17] Its heterozygous loss of function mutation leads to MODY 5.
- *PDX1:* It is also known as insulin promoter factor 1 (IPF1). It is present throughout the development, with high levels of expression limited to β cells only later in development and in adults.[11,12] Homozygous inactivating mutations of PDX1/IPF1 result in pancreatic agenesis (MODY4).
- *Pancreas transcription factor 1A (PTF1A):* It is barely detectable in the human pancreas until mid-gestation, perhaps owing to its enriched expression in the acinar cells at that time point. One study has identified a mutation in the PTF1a enhancer region leading to pancreatic agenesis.[18]
- *GATA binding protein 4 (GATA4):* These transcription factors are also expressed in the early development stages, and the late expression is limited to the mature acinar cells.[11]
- *SOX9:* It is found in PDX1+ cells in the early human pancreas by about 4 weeks and is then excluded from the pancreas development.[11,19]
- *Homeobox protein NK-6 homolog (NKX6.1):* This is expressed in the developing human pancreas after 4 weeks once SOX17 is excluded from the development.[11] Then by 14–16 weeks, its expression becomes restricted to β cells.[11,19] In adult pancreas, NKX6.1 is a key β cell identity factor and has severely reduced expression in human T2D islets.[20,21]
- *Motor neuron and pancreas homeobox 1 (MNX1):* In humans, its expression is found as early as 7 weeks and, then its expression decreases by 14–16 weeks of gestation.[12,13] Patient with a homozygous mutation in the DNA binding homeodomain of MNX1 presented with permanent neonatal diabetes.[22,23]

Multipotent pancreatic progenitor cells: These cells of developing pancreas are characterized by the continued expression of FOXA2, PDX1, SOX9, NKX6.1, and GATA4.[10] These cells are further destined to form the ductal endocrine and the exocrine components of the pancreas. The various transcription factors expressed at this stage include:

- *GATA6:* It is considered to be very important in the development of human pancreas with mutations in GATA 6 leading to pancreatic agenesis.[24,25]

Transcription Factors Involved in the Production of Islet Endocrine Cell Lineages

- *Neurogenin 3 (NGN3):* With the loss of SOX 9, as mentioned earlier, the expression of NGN3 initiates pancreatic endocrine commitment.[26] Its first expression is seen around 8 weeks, peaks around 11 weeks, and then declines to low levels by 19 weeks.[26] A case of permanent neonatal diabetes carrying a null mutation in NGN3 with low C-peptide levels has been reported.[27]
- *Regulatory factor X 6 (RFX6):* As demonstrated by quantitative real-time PCR, the expression of RFX6 is limited to the adult human pancreatic islets and autosomal recessive mutations have been found to result in rare cases of neonatal diabetes with the absence of insulin, somatostatin and glucagon secreting cells in the islets.
- *Paired box gene 4 (PAX4):* Its expression is evident by 9 weeks of gestational age,[13] and its mutation has been associated with MODY9.
- *GLIS family zinc finger 3 (GLIS3):* Patients with an autosomal recessive mutation at this locus have been associated with inherited forms of diabetes and congenital hypothyroidism.[28-30]
- *MAFB:* In humans, MAFB expression increases 7–21 weeks and after that continued expression is seen in adult α and β cells.[13,31]

Endocrine Cell Differentiation and Maturation

In humans, pancreatic hormone expression is first evident at about 8 weeks of gestation, with insulin being the first islet hormone to be formed; this is followed by the appearance of glucagon at around 9 weeks of gestation.[13,32,33]

Transcription Factors Involved in β-cell Differentiation

- *NKX2.2:* It is first seen around 8 weeks in the developing α and β cells with increased expression around 14–16 weeks.[11]
- *Insulin gene enhancer protein ISL-1 (ISL1):* It is also known as ISLET 1 and is thought to be essential for the development of the pancreas in humans.[33] A nonsense mutation in ISL1 seen in a Japanese diabetic patient points toward the potential role of ISL1 in pancreatic β cell development.[33]
- *NEUROD1:* It is first expressed at 15 weeks and is found in all islet cell types.[11-13] Heterozygous NEUROD1 mutation has been found associated with MODY 6 and neonatal diabetes as well (autosomal recessive).[34,35]
- *PAX6:* Its expression is seen around 14–16 weeks and persists in all cells throughout adulthood.[12] Single nucleotide polymorphism at PAX6 has been reported to result in decreased insulin sensitivity and response.[36]
- *MAFA:* In humans, MAFA is nearly undetectable in the human pancreas from 7–21 weeks, after which it is almost exclusively seen to express in human pancreatic β cells.[13,31] Decreased expression of MAFA in human pancreatic β cells has been proposed as a sign of dysfunctional cells.[21]

The sequence of development and expression of the various transcription factors is of immense importance in the proper development of the pancreas, and as noted above, any deviation resulting from mutation can result in pancreatic agenesis or diabetes mellitus.

Stem Cell-derived Treatment for Diabetes

The advances made in recent years in the field of stem cell research have opened up avenues toward newer approaches in treating both T1D and T2D. These advances have led us one step closer to finding the cure for diabetes and is now a real and achievable goal.

Significant progress in the generation of β cells from human stem cells has been made in the last decade, and the defining strategy is to emulate the development pathway closely from pluripotency to β cell.[21,37] Efforts have also been made to generate β cells that are capable of producing glucose stimulated Insulin secretion (GSIS).[38-42]

We shall review in brief the current state of generating human embryonic stem cell (hESC) derived pancreatic islet cells.

Stem Cell Niche Optimization for Islet Structure Generation

In vivo, the β cells do not occur in isolation. However, they are parts of intricate 3-dimensional islets composed of numerous cells, as noted earlier, whose products exert a variety of autocrine and paracrine effects on each other. As opposed to rodent islets where there is homologous cell-cell contact with a core of β cells surrounded the other types of islet cells,[43,44] the human islet has heterologous cell-cell contact with all the islet cell types found intermingled with one another.[45] This arrangement has several implications, for example, the homologous contact in rodents facilitates synchronous and simultaneous insulin secretion from islet β cells, while in humans, and there is an asynchronous release of insulin.[45] Recent data from cell sorting and sequencing also suggests the existence of distinct β cell types in human islet cells.[46]

Another critical interaction occurring in the islet cells is the interaction with non-endocrine cells, including mesenchymal, neuronal, perivascular, and endothelial cells.[47-49] The developing islet recruits several endothelial cells by the secretion of VEGF-A.[50] These endothelial cells help form the basement membrane, which a critical modulator of β-cell function, growth, and survival.[48,51-53] This intricate relationship between the β cells and the surrounding non-endocrine cells only strengthens the fact emulating the native β-cell niche will help improve the survival and function of hESC derived β cells in vitro.

Various efforts have been made to engineer the islet structure into "pseudo-islets" in vitro.[54] Several studies have shown enhanced functionality of these reaggregated "pseudo-islets" in vitro or in vivo after transplantation. Penko et al.[55] also showed improved GSIS with reaggregated "pseudo islets" with endothelial cells compared to pseudo-islets composed of β cells alone.

To summarize, more work is needed to determine the optimal islet microarchitecture that will attain the

maximum functionality and survival. One available option is the generation of niche cells themselves from the hESC or from induced pluripotent stem cells (iPSC). Another challenge is that pseudo-islets generation relies on the property of endocrine and non-endocrine to align themselves; this can perhaps be solved using 3-D printing techniques of islet tissue, allowing us to enforce the desired islet structure. The use of microfluidic devices, the so-called "organ on a chip" approach, may provide further sophistication and optimization of function.

Transplant Site

The site chose for the transplant also has a significant bearing on the survival as well as the functionality of the transplant, for example, in case of the engrafted islets stem-cell-derived or otherwise via infusion through the portal vein often require multiple infusions.[56] Another factor which is of significant importance is that the islets infused into the portal vein are not retrievable, and this is of concern for the clinical translation of trials using hESC-derived β cells until it has been indisputably proven that the cells have developed into mature human islet cells and all the possibility of neoplastic transformation has been ruled out completely. While, at the present stage of development, the risk of development of the transplant into a teratoma cannot be ignored, but the optimization and the generation of fully differentiated islet and β cells can negate this concern.

Learning from the information gained from solid organ and islet cell transplant, it is evident that a more optimal site for the transplant is required. Several investigators are evaluating subcutaneous and intramuscular sites for islet transplantation to increase engraftment and also allow for removal of the graft in case of tissue dysfunction or transformation.[57,58] Successful pancreatic transplant in T2D patients suggests that given an unlimited source of β cells and may provide a benefit in a vast majority of T2D patients.[59]

Immune Modulation in β-cell Replacement Therapy

Alloimmune and autoimmune systems remain significant barriers to the more widespread application of cell replacement therapies for curative treatment in T1D as well as T2D. Lifelong treatment with immunosuppressive drugs offers a solution to this problem but is riddled with its new problems like side effects and toxicities.

Engineered Stem Cell-derived β-cell to Protect against Immune Rejection

One of the major unresolved issues with the stem cell-derived islet cells is the task of evading the immune system and preventing rejection. Immune rejection is an even bigger issue in T1D where the immune cells are already primed to attack self β cells and, therefore, more likely to attack the stem cell-derived β cells. Furthermore, an allogeneic immune response to the stem cell-derived islets poses another obstacle in both T1D and T2D recipients.

Stem cell technology offers unique solutions to engineer the β cells to evade the immune system. The development of revolutionary gene-editing tools like CRISPR/Cas 9 system[60] provides the possibility to dismantle MHCs in the hESCs and thereby to prevent the presentation of alloantigens. This strategy would also work against autoimmune-mediated β-cell destruction in T1D patients. T cell-mediated recognition of the MHC molecules is the root cause behind alloimmunity. At the same time, in T1D patients, autoimmunity against transplanted β cells is dependent upon MHC class 1 expression on islet cells.[61] Thus, the strategy of using the CRISPR/Cas9 technique to dismantle MHC 1 and 2 can lead to a reduction of the immune rejection process of the transplanted β cells.

The abolition of HLA expression can abate the alloimmune as well as an autoimmune reaction. However, still, the islet autoantigens from the graft can be presented by the host antigen-presenting cells (APCs), thereby activating the autoreactive T cells leading to islet injury and rejection. Control of NFκB activation by overexpressing A20 and suppressing STAT1 activation by overexpressing SOCS 1 may prove effective in controlling inflammatory cascade against the β cells.[62-64] Additionally, using other immunomodulatory approaches like enhancing immune checkpoints via forced expression of PDL1, it may also be used for the protection of β cells against autoreactive T cells.

Also, to be considered are NK cells, which can be activated against the HLA ablated stem cell-derived β cells[65] Class1 HLA are major ligands for NK inhibitory receptors. So, complete ablation of Clas1 HLA expression

on stem cell-derived Islet cells may make them vulnerable to NK mediated killing. HLA-e and G are less Hla A, B, and C and can be expressed in islet endocrine cells;[66] these molecules have a strong inhibitory effect on NK cells. By retaining HLA-E and G alleles intact while deleting HLA-A, B, and C, it might be possible to inhibit NK cells while keeping a reduction in T cell responses.

Cell Encapsulation Strategies

Despite earnest efforts to develop immune tolerant β cells through genetic manipulations as discussed earlier or other methods, there is still a high likelihood of autoimmune and alloimmune reactions against the transplanted stem cell-derived islet cells.

We could also use another approach by utilizing a semi-permeable membrane/capsule to deliver the transplanted β cells, which would protect the cells against immune derived reactions while at the same time allowing the transfer of sufficient mass of insulin secretions. This encapsulation strategy would also serve to protect the patient against any stem cell-derived β-cell oncogenic transformation. This idea of encapsulation has been a pipe dream for many years. However, the development of an optimal device remains an elusive dream as the semi-permeable membranes that protect the cells against the immune reactions are not sufficiently permeable to the nutrients needed for the viability of the cells.

The use of a suitable device membrane as a physical barrier between the recipient and hESC-derived β cells could potentially enable the use of these therapies while eliminating the use of immunosuppressants. An idle encapsulation device would be one which provides blood supply for sustenance, biocompatible, immunoprotective, allow secreted insulin to pass, contain any tumorigenic transformation.

Encapsulation Strategies in Clinics

Microencapsulation based strategy is perhaps the only device that has made any headway in clinics; it uses microcapsules made from alginate, 300–400 microns in diameter, which are used to encapsulate allogeneic islets. These were delivered intraperitoneally and reduced insulin requirements.[67-71] One of the significant limitations to these devices has been the lack of oxygen one company Beta-O2 developed the bAir device, this device exogenous oxygen to the transplanted tissue. The device consists of a compartment, which contains islets that are encapsulated within an alginate hydrogel slab, which is adjacent to a gas chamber where cells obtain oxygen by diffusion through a gas-permeable membrane.[72] This device contains ports to allow for daily refilling of oxygen. A single case report on the device usage reported islet survival with a modest reduction in insulin requirement for 10 months.[73]

Two devices, the "theracyte" device and the "sernos" cell pouch,[74] aim to revascularize a subcutaneous site before implantation of the device, and this increased vascularization is aimed at improving the survival of the cells.

Microfabricated Devices

The use of microfabricated silicon membranes can lead to the achievement of high precision control over pore sizes, as shown by nanoporous biocapsules[75,76] and nanogland.[77-80] The resultant pore size control could potentially allow separating soluble inflammatory mediators and also provide immunoprotection while allowing insulin secretion. The surface of the silicon membranes can further be selectively grafted with biocompatible polymer thin films to ensure functional performance over extended periods.

Conclusion

We stand at the cusp of technology where history can be made; the use of hESC derived islet cells to cure diabetes is no longer a distant dream but a tangible reality. The use of cutting edge technology like CRISPR/Cas9 to modulate the immune response, the use of 3-D printers to design and fabricate islet cells, use of microencapsulation devices hopefully in the near future will bring forth the dream of humanity of finding a cure for diabetes.

CHAPTER

75 GLP Analogs versus SGLT2 Inhibitors in Diabetic Patients with Cardiovascular Disease

Udai Lal

Abstract

Complications of type 2 diabetes are broadly classified as macrovascular and microvascular. This spectrum usually encompasses conditions like chronic renal disease, heart failure, and atherosclerotic heart disease. While the older classes of anti-diabetic agents have demonstrated benefit in terms of microvascular outcomes, newer anti diabetic agents like SGLT2 inhibitors and GLP1RAs have gone one step ahead to demonstrate macrovascular benefits. Both these classes have demonstrated CV safety in CV outcome trials. GLP1RAs demonstrate CV benefits mainly due to reduced atherosclerosis. On the other hand, benefits of SGLT2i are derived due to reduction of heart failure. These benefits of both classes are attributed to mechanisms independent of glucose control. Based on the benefits demonstrated in the CV outcome trials, recent global guidelines like the ADA guidelines have favored the use of these drugs in diabetes patients with renal and cardiovascular risk.

Introduction

Type 2 diabetes is a metabolic disorder that affects nearly 10% of the global population. Its prevalence is predicted to increase in the coming years. It is now established that a long-standing diabetes patient would be at increased risk of macro- and microvascular complications. Cardiovascular (CV) disease is a leading cause of mortality in patients with diabetes. It is up to 2–4 times more common in patients with diabetes as compared to the ones without. The older agents that control hyperglycemia like the sulfonylurea, metformin, meglitinides, thiazolidinediones, and dipeptidyl peptidase inhibitors have shown improvements in microvascular outcomes. However, they fall short in reducing the morbidity and mortality associated with macrovascular disease. This vacuum is addressed by the newer antidiabetic classes, Sodium Glucose Cotransport-2 inhibitors (SGLT2i), and Glucagon like peptide 1 analogs (GLP analogs). These molecules have demonstrated cardioprotection and were associated with reduced CV outcomes in the cardiovascular outcome trials (CVOTs). The recent American Diabetes Association (ADA) guidelines recommend these newer classes in type 2 diabetes patients with chronic kidney disease (CKD) and CV disease after monotherapy with metformin, which remains the mainstay.[1]

This review dissects the data available with SGLT2i and GLP analogs in terms of CV protection and throws light on the proposed mechanism for these benefits.

CVOTs with SGLT2i

In the EMPA REG CVOT, 7020 subjects were treated for a duration of 3.1 years. The composite primary CV outcome was lower in subjects receiving empagliflozin. Death from CV causes, deaths from any cause and heart failure hospitalization was significantly lower in empagliflozin arm compared to placebo. There was no difference between groups in the rate of stroke and myocardial infarction (MI).[2]

In the CANVAS trial program (CANVAS plus CANVAS Renal) with canagliflozin, 10142 type 2 diabetes subjects at high risk for CV disease were followed up for a duration of 188.2 weeks. Subjects on canagliflozin had significantly low risk of non-fatal stroke, non-fatal MI and death from CV causes compared to those on placebo. However, there was an increased risk of amputations. CANVAS Renal was designed to detect the effects of canagliflozin on albuminuria. Subjects on canagliflozin had less frequent albuminuria progression. These effects of canagliflozin were more prominent in CANVAS Renal as compared to CANVAS.[3]

In the CREDENCE trial, type 2 diabetes patients with albuminuria and CKD with a GFR of 30–90 mL/min/1.73 sqm body surface area received either placebo or 100 mg of canagliflozin. At a follow-up of 2.6 years, CV events and risk of renal failure were lower in patients on Canagliflozin as compared to placebo.[4]

In the DECLARE TIMI CVOT with dapagliflozin, 17160 subjects were followed for a duration of 4.2 years. With respect to major adverse CV events, dapagliflozin met the criteria for non inferiority to placebo arm. Heart failure hospitalization rate or CV death rate was lower in dapagliflozin arm. This was due to the lower rate of heart failure hospitalizations.[5]

CV Benefits of SGLT2i

There are numerous mechanisms proposed to explain the beneficial effects of SGLT2i on heart. They may improve bioenergetics and cardiac metabolism due increased ketone production. Ketones are more efficient source of myocardial energy as compared to fatty acids. Ketones improve myocardial oxygen efficiency as it requires lesser oxygen for metabolism. Thus, it increases the efficiency of cardiac function.

Furthermore, SGLT2i causes hemoconcentration, thereby improving the oxygen delivery to tissues. Hemoconcentration and shift in the metabolic myocardial substrate have a synergistic effect. Natriuresis and osmotic diuresis reduce blood pressure (BP) and arterial stiffness resulting in favorable conditions for ventricular loading.

Investigations are underway to determine the effects of SGLT2i on cytokine production and modification of cardiac fibrosis.

SGLT2i in addition to CV diseases, reduce progression of albuminuria and nephropathy. The possible explanation of these benefits is due to reinstatement of the tubuloglomerular feedback. Reduction of intrarenal hypoxia has also been proposed as a mechanism for the beneficial effect on renal system.[6]

CV Outcome Trials with GLP Analogs

ELIXA CV outcome trial with lixisenatide was the first of the CVOT among GLP analogs. It was conducted in subjects with acute coronary syndrome (ACS) within 6 months of screening. 6068 subjects were followed up for 25 months. The study concluded that lixisenatide did not significantly change the rate of major CV outcomes in subjects with type 2 diabetes and recent ACS.[7]

Liraglutide in the LEADER CVOT was compared with placebo. The study had 9340 subjects with CV condition or CV risk factor who were followed up for 3.5 years. The primary composite outcome was significantly lower in the patients receiving liraglutide. In addition, secondary endpoints like death from CV causes and death from any cause were significantly lower in the liraglutide group.[8]

SUSTAIN 6 CVOT compared semaglutide versus placebo in type 2 diabetes subjects with CKD, CHF, pre-existing CV disease, or at least 1 risk factor for CV disease. 3297 subjects were enrolled and followed up for 2.1 years. Non-fatal stroke, non-fatal MI, and CV death rate were significantly lower in subjects receiving semaglutide versus placebo.[9]

The EXSCEL CVOT with once weekly exenatide showed no difference in major CV events incidence as compared to placebo.[10]

Albiglutide in HARMONY CVOT demonstrated its superiority over placebo in terms of major CV events.[11]

Composite CV outcome and non-fatal stroke were lower with dulaglutide in the REWIND CVOT when compared to placebo.[12]

CV risk profile of semaglutide (oral) was non inferior to placebo as shown in PIONEER 6 CVOT.[13]

To summarize, on one hand dulaglutide, albiglutide, subcutaneous semaglutide, and liraglutide demonstrated significant benefit in lowering the composite CV outcomes; oral semaglutide, weekly exenatide, and lixisenatide demonstrated non inferiority.[14]

GLP Analogs: Beneficial Effects on Cardiovascular System

Glycemic Control

GLP analogs are effective in reducing A1c. In addition to lowering A1c, they reduce glycemic variability (GV)

thereby reducing oxidative stress. This reduction of GV may explain its beneficial effects in CV disease.[15,16]

Hypertension

Dysglycemia and hypertension significantly raise the risk of stroke, heart failure, and MI. Data from trials have shown GLP analogs to reduce BP values. However, the mechanism behind the BP lowering is not clearly understood. Studies have shown that the fall in BP happens early (within 2 weeks of GLP analog initiation). Several potential mechanisms have been suggested. GLP1 receptor activation in renal system and arteries resulting in vasodilation and improved endothelial function might explain this effect. It is also hypothesized that the lowering of BP may be GLP receptor independent due to nitric oxide-mediated vasodilation.[16]

Dyslipidemia

Risks of CV episodes are much higher in patients with elevated low density lipoprotein (LDL) levels and diabetes. Even though the mechanisms are unclear, clinical trials have shown GLP analogs improve dyslipidemia. While, improvement of dysglycemia itself improves lipid profile due to reduction in hepatic synthesis of triglycerides and improved insulin sensitivity, reduction in triglycerides may also be due to reduced apolipoprotein B48 secretion mediated by intestinal mucosal GLP 1 receptors.[16]

Weight

It is a well-known fact that obesity is associated with both CV disease and type 2 diabetes. GLP analogs cause modest weight loss in addition to glycemic control thereby improving patient's quality of life and functional activity.[16]

Other Benefits

In a preclinical study, liraglutide, a GLP analog improved endothelial function by inhibiting expression of vascular adhesion molecule and plasminogen activator inhibitor 1.[17]

Studies have demonstrated cardioprotective effect of liraglutide. In patients who underwent coronary angioplasty, smaller infarct size along with lower levels of high sensitivity C reactive protein, and superior myocardial salvage index were seen in liraglutide arm compared to placebo.[18]

Effects of GLP Analogs/SGLT2i in Patients at Increased CV Risk

A network analysis published recently showed that as compared to patients on placebo, GLP analogs reduced incidence of stroke. Among the GLP analogs, odds were lower with dulaglutide and semaglutide administered subcutaneously.[19]

SGLT2i reduced heart failure related hospitalization. This was seen with all the 3 SGLT2i (dapagliflozin, canagliflozin and empagliflozin).[19]

The all cause mortality was reduced by extended release exenatide, liraglutide, dapagliflozin, and oral semaglutide. Liraglutide, empagliflozin, and oral semaglutide have lesser odds of death from CV cause compared to extended release exenatide, sulphonylureas, dulaglutide, pioglitazone, dapagliflozin, DPP4 inhibitors, and canagliflozin.[19]

Impact of CVOTs on Guidelines

In the 2017 guidelines, ADA recommended to begin with metformin monotherapy and add any one of the non-insulin agents for dual therapy.[20] However, these recommendations dramatically changed in the next 2 years to include GLP analogs/SGLT2i as add on to metformin in type 2 diabetes patients with atherosclerotic cardiovascular disease (ASCVD) or CKD.[21]

In addition, the European Society of Cardiology now recommends GLP analogs/SGLT2i should be considered as the first choice ahead of metformin in type 2 diabetes patients with high risk for CV disease or known CV disease.[22]

Exploring Uses/Potential Uses of SGLT2i

Obesity is an established risk factor for type 2 diabetes development. SGLT2i in addition to improving hyperglycemia, induces weight loss thereby targeting the pathogenesis of type 2 diabetes. Patients on SGLT2i excrete about 60–80 g of carbohydrates per day. As mentioned, the recent ADA/EASD guideline recommends these classes of drugs are for patients with type 2 diabetes with heart failure or CKD and those with established or high risk of ASCVD.

In addition, in patients without type 2 diabetes who have heart failure with reduced ejection fraction,

dapagliflozin has showed improved CV outcomes. This suggests that dapagliflozin may be used as a heart failure drug irrespective of whether the patient has diabetes or not. Furthermore, trials exploring its role in heart failure patients with preserved ejection fraction or CKD patients without type 2 diabetes are underway. SGLT2i are even being tried in type 1 diabetes concomitant to insulin therapy due to its insulin independent mode of action.[23]

Conclusion

Due to the results of CVOTs and the recommendations of international bodies,[24] SGLT2i and GLP analogs are preferred agents in diabetes patients with established CV disease and risk factor for CV disease. A physician can choose either of the therapies in case of atherosclerotic CV disease. However, in the presence of comorbid conditions like renal disease or heart failure, SGLT2i should be preferred over GLP analogs. The approach toward these patients should be personalized. In diabetes patients with very high CV risk, instead of choosing between these 2 groups, combining these 2 therapies has be speculated.[25]

CHAPTER

76 Challenges in Type 1 Diabetes in Adolescence

Akhil Krishna, Sujoy Ghosh

Abstract

The management of type 1 diabetes during adolescent period poses unique challenges. The period of adolescence has a great impact on type 1 diabetes and the disease per se puts huge demands on the adolescent boy or girl. Thus the disease and this critical phase of development influence each other. The glycemic control during this developmental phase is often suboptimal, mainly due to poor adherence to treatment and the hormonal changes of puberty, among other reasons. There is also higher risk for emergence of complications of type 1 diabetes during this phase, and hence it is recommended to begin screening for vascular complications at this period. Another challenge which emerge during this phase is the risk of indulging in the use of alcohol, smoking, and various illicit drugs, which can directly or indirectly impact the glycemic control and complications. Other issues to be addressed is with regard to sexual health with special emphasis on contraception and planned pregnancy. Finally, the transition from pediatric to adult care should be a planned process for optimal outcomes.

Introduction

According to WHO, adolescents are individuals in the age group 10–19 years. Individuals in 15–24 years age group are designated "youth." The term "young people" covers both adolescence and youth and includes 10–24 years.[1] Emerging adulthood usually refers to the developmental stage between 18 and 30 years.[2]

WHO emphasizes that adolescence should be considered as a phase of development rather than a fixed time frame in an individual's life. It should be viewed as an important developmental phase, which witness the appearance of secondary sexual characteristics (puberty) to sexual and reproductive maturity, the development of mental processes and adult identity and the transition from total socioeconomic and emotional dependence to relative independence.[1]

In this chapter, we shall be discussing the unique challenges in diabetes management during this phase of development.

What is the Effect of Adolescent Period on Type 1 Diabetes?

This will be discussed under following two headings:

- Effect of adolescence on Glycemic control
- Effect of adolescence on diabetes complications

Effect of Adolescence on Glycemic Control

Only about one-fifth of adolescents with type 1 diabetes meet the HbA1c goals set by American Diabetes Association (ADA) or International Society for Pediatric and Adolescent Diabetes (ISPAD).[3]

The suboptimal glycemic control during adolescence is due to varied reasons such as:

- Erratic meal and exercise patterns[4]
- Risk taking behaviors[5]
- Poor adherence[6]
- Hormonal changes during puberty

Studies have shown that females are more likely to have worsening of metabolic control during adolescence.[7]

Of the reasons listed above, poor adherence to treatment regimens and hormonal changes during puberty are discussed in more detail below.

Why Adolescents with Diabetes show Poor Adherence to Treatment Regimens?

Adolescence is a critical phase in the development when the individual's priorities changes and they try to cope up with the competing demands of social life.

Some of the intrinsic features of diabetes, like chronicity, need for frequent blood glucose measurements and dietary restrictions put more emotional stress on the adolescent. The negative emotions (like feeling frustrated, hopeless, guilty, angry, fearful), which arise from living with and managing diabetes is referred to as diabetes distress.[8] Diabetes distress is reported in about one-third of adolescents with diabetes and it negatively affects the self-management behaviors and glycemic control. Parents of type 1 diabetes are also at risk of developing diabetes distress.

Psychological comorbidities like depression, anxiety, and disordered eating behaviors are also prevalent in adolescents with diabetes. Elevated depressive disorders and depressive symptoms are reported in about 25% and anxiety disorders in about 20% of patients with type 1 diabetes. The most common disordered eating behavior seen in people with type 1 diabetes is omission of insulin in order to lose weight.

Several other factors like family dysfunction, difficult peer relationships, and poor school performance also act as hindrances to treatment adherence during adolescent period.

The consequences to poor adherence could be immediate in the form of hypoglycemia or ketoacidosis or medium to long term in the form of early appearance of microvascular complications, especially retinopathy and nephropathy. So ensuring adherence to medical and lifestyle measures should be part of the routine diabetes care in adolescents.

To improve the adherence, clinicians caring adolescents with diabetes should emphasize on:

- Maintaining a comfortable and mutually respectable relationship with the youth
- Negotiating treatment regimens with the adolescent, which are attainable and sustainable
- Building emotional strength
- Allowing adolescents to express their feelings
- Encouraging the successful activities or gains undertaken by the adolescent

Hormonal Changes during Puberty and Insulin Resistance

During puberty, insulin resistance occurs irrespective of the presence of diabetes. Insulin resistance is worse during all stages of puberty, but worst during mid puberty. Euglycemic insulin-clamp studies have shown that insulin sensitivity falls by around 30% during mid puberty (Tanner stages 2–4) in non-obese non-diabetic children when compared with prepubertal children or older adolescents (Tanner stage 5) and adults. This fall in insulin sensitivity is more marked during Tanner stage 3, in girls and in those with higher BMI.[9] Insulin resistance during this phase is due to higher growth hormone (GH) levels during puberty.[9]

Presence of diabetes cause a further dip in insulin sensitivity, mainly through alterations in GH-IGF-1 axis.

GH-IGF-1 axis in type 1 diabetes **(Fig. 1)***:*

- *Decreased upregulation of hepatic GH receptor:* In normal physiology, insulin has a permissive role in mediating GH action. Hepatic GH receptor (GHR) expression is upregulated by insulin in the portal circulation. Thus, insulin promotes the hepatic generation of insulin like growth factor-1 (IGF-1) by GH. In type 1 diabetes, where there is low insulin in portal circulation, there is decreased upregulation of hepatic GH receptor. This causes a decrease in hepatic IGF-1 generation.
- *Increase IGFBP-1:* Insulin causes a decrease in Insulin like growth factor binding protein-1 (IGFBP-1). IGFBP-1 binds to IGF-1 and causes a reduction in free bioactive form of IGF-1. Hypoinsulinemia causes upregulation of IGFBP-1 and therefore more IGFBP-1 binds to IGF-1 causing reduction in free IGF-1.
- *Chronic inflammation:* Presence of chronic inflammation in type 1 diabetes further decreases IGF-1.

In summary, decreased upregulation of hepatic GHR, elevated IGFBP-1, and chronic inflammation in type 1 diabetes causes low IGF-1, which leads to GH hypersecretion due to loss of negative feedback by IGF-1, which in turn leads to insulin resistance[10]

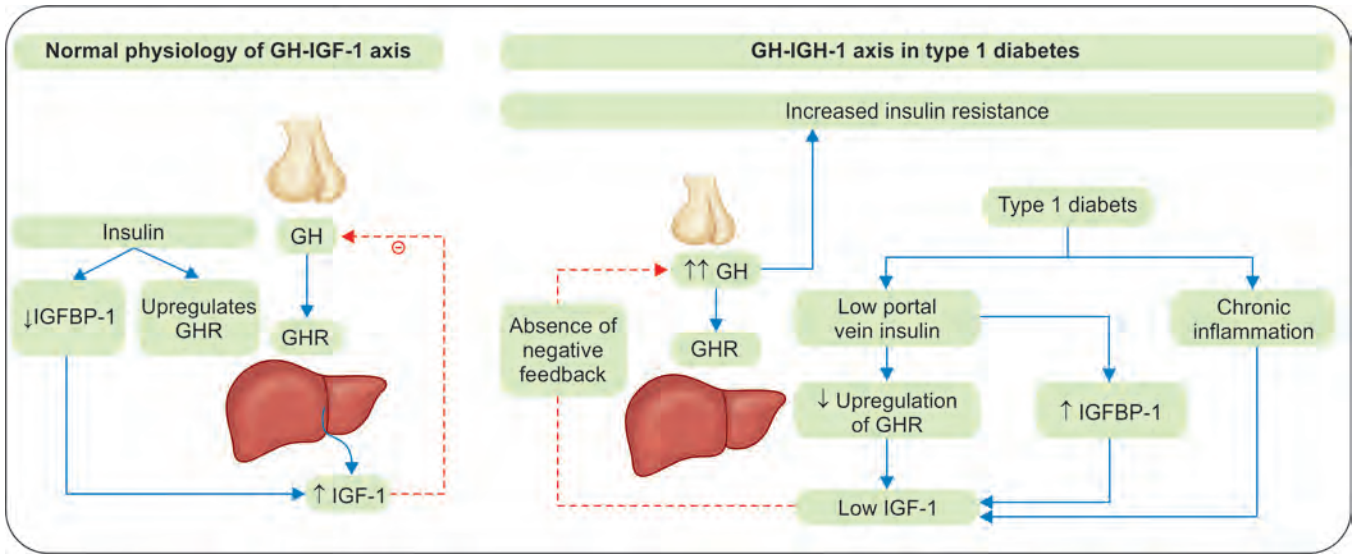

Fig. 1: GH-IGF-1 axis in normal physiology and in type 1 diabetes

- In normal physiology, Hepatic GH receptor expression is upregulated by insulin in the portal circulation. Thus insulin promotes the hepatic generation of IGF-1 by GH. IGFBP-1 normally binds to IGF-1 and causes a reduction in free bioactive form of IGF-1. By decreasing IGFBP-1, insulin causes an increase in the free form of IGF-1.
- In type 1 diabetes, where there is low portal insulin, there is decreased upregulation of hepatic GH receptor. This causes a decrease in hepatic IGF-1 generation. Hypoinsulinemia also causes upregulation of IGFBP-1 and thus a reduction in free IGF-1. Presence of chronic inflammation in type 1 diabetes further decreases IGF-1.
- Hence, decreased upregulation of hepatic GHR, elevated IGFBP-1 and chronic inflammation in type 1 diabetes causes low IGF-1, which leads to GH hypersecretion due to loss of negative feedback by IGF-1, which leads to insulin resistance.

Increased risk of Dawn phenomenon during puberty: Insulin requirements increase during early morning hours, generally between 5 a.m. and 8 a.m. causing prebreakfast hyperglycemia. This is known as "Dawn phenomenon." The reason for this is postulated to be due to increased nocturnal secretion of GH[11] and insulin clearance during early morning hours.[12] Since GH secretion is at its peak during mid to late puberty, risk for Dawn phenomenon is at its peak during this phase of development. This highlights the importance of increasing the availability of insulin during the dawn period.

Other factors contributing to insulin resistance: During adolescence, increase in BMI frequently occurs, especially in females.[13] Increase in BMI further increases insulin resistance.

Sexual dimorphism in insulin sensitivity during adolescence: Some studies have shown sexual dimorphism in insulin sensitivity during adolescence, where increase in insulin resistance is more marked in females compared to males.[9,14] This sexual dimorphism is seen during early adolescence and by the completion of puberty, both sexes have similar insulin requirement. This is thought to be due to earlier increase in adrenal androgens, estrogens, and GH in females.

Effect of Adolescence on Diabetes Complications

The period of adolescence is considered as high risk for the emergence of complications of type 1 diabetes due to various reasons like difficult to achieve optimum glycemic control and pubertal risk factors like alterations in GH-IGF-1 axis and insulin resistance.

The first signs of vascular complications of diabetes often appear during adolescence. Subclinical manifestations like early increases in urinary albumin excretion, retinal microvasculature changes, and subclinical changes in large blood vessels, like increased aortic and carotid intima media thickness and increased arterial stiffness, are common during this period.

Puberty Accelerates Diabetes Complications

The most important determinant of diabetic retinopathy and albuminuria is the duration of diabetes. But this

TABLE 1 Screening recommendations for vascular complications in type 1 diabetes (adapted from ISPAD 2018 and ADA 2020 guidelines)[22]

	When to commence screening		*Screening methods*
	ISPAD 2018	*ADA 2020*	
Nephropathy	11 years with 2–5 years diabetes duration	>10 years or at puberty (whichever is earlier), once the child has had diabetes for 5 years	Urinary albumin/creatinine ratio
Retinopathy	11 years with 2–5 years diabetes duration	≥11 years or at puberty (whichever is earlier), once the child has had diabetes for 3–5 years	Fundal photography or mydriatic ophthalmoscopy
Neuropathy	11 years with 2–5 years diabetes duration	>10 years or at puberty (whichever is earlier), once the child has had diabetes for 5 years	History Physical examination Clinical tests

ISPAD: International Society for Pediatric and Adolescent Diabetes; ADA: American Diabetes Association

becomes apparent only after puberty. Evidence suggests that risk for vascular complications is greater in those with diabetes during puberty than in those who develop diabetes after puberty.

Diabetic Retinopathy

The importance of age at diagnosis of diabetes and risk of complications is exemplified by the higher risk of developing retinopathy in those diagnosed with diabetes before 14 years compared to those diagnosed during adulthood.[15] Compared to adults with diabetes, adolescents are at greater risk of progression to more advanced stages like severe non-proliferative diabetic retinopathy (NPDR), proliferative diabetic retinopathy (PDR), and/or diabetic macular edema, which are vision threatening.[15] The progression may be more rapid in the background of poor glycemic control.[16] Retinopathy can regress with improvement in glycemic control.[17]

Diabetic Nephropathy

Increased albumin excretion ratio is seen in children after 11 years of age or after puberty compared to children less than 11 years or before puberty.[18] The adolescent type 1 diabetes cardiorenal intervention trial (AdDIT) showed increased cardiovascular risk (as suggested by higher lipid levels, arterial stiffness, increased aortic intima media thickness, and signs of impaired cardiac autonomic function) in adolescents aged 10–16 years with increased urinary albumin excretion levels.[19]

One interesting observation is that the risk of developing microalbuminuria or retinopathy during adolescence is higher for girls than boys.[20,21] But in adulthood, men carries a higher risk.

Based on the understanding of adolescence as a high-risk period for diabetes complications and puberty accelerating vascular complications in diabetes, International Society for Pediatric and Adolescent Diabetes (ISPAD) recommends screening for vascular complications starting at 11 years of age or at the onset of puberty, whichever is earlier, if duration of diabetes is 2–5 years **(Table 1)**.[22]

Alcohol, Smoking, and Illicit Drugs

Alcohol

Rates of alcohol and other illicit substance use among adolescents (15–18 years) and young adults (18–25 years) with type 1 diabetes seem similar or slightly lower than their non-diabetic counterparts.[23]

Alcohol intake typically causes delayed hypoglycemia, which occurs about 6–8 hours after intake. Alcohol also causes exacerbation of hypoglycemia unawareness. Initially hepatic glucose production is maintained by glycogenolysis, but once hepatic glycogen stores are depleted, delayed hypoglycemia occurs due to inhibition of gluconeogenesis. Alcohol is metabolized to acetaldehyde and then to acetone. This process increases NADH and decreases the availability of NAD+, which is a cofactor for

gluconeogenesis. Gluconeogenesis is further reduced by the inhibitory action of alcohol on GH release.

Adolescents with type 1 diabetes should be encouraged to refrain from binge drinking. For prevention of alcohol induced hypoglycemia, it is advisable only to drink alcohol with carbohydrates, maintain good hydration, check blood glucose levels before bedtime, and have snacks before sleep. Another issue with alcohol intake is that hypoglycemia might be confused with intoxication.

Smoking

Among adolescents and emerging adults with diabetes, smoking increases the risk of microalbuminuria and cardiovascular risk. It is also associated with very early onset of peripheral neuropathy.[24]

A smoking history should be elicited at initial and follow-up visits. Discourage cigarette smoking including e-cigarettes in those who do not smoke and smoking cessation should be encouraged in active smokers. Adolescents should be provided with specific interventions, which can help them to quit smoking like nicotine patches and cognitive behavioral therapy.

Illicit Drugs

Illicit drugs like cocaine, amphetamine, MDMA (ecstasy) can increase the risk of diabetic ketoacidosis. These drugs may also alter brain functions making diabetes management difficult.

Driving

The main factor that increases the rates of driving accidents in type 1 diabetes is hypoglycemia. To reduce this risk, ensure the following:

- To prevent hypoglycemia during driving, monitor blood glucose before driving and ensure appropriate food intake
- Encourage stable metabolic control
- Regular visual check ups

Sexual Health

Adolescent girls with diabetes should be counselled regarding following aspects of sexual health:

- Contraceptive practices
- Precautions to avoid STIs
- The importance of planned pregnancy
- The risks of congenital malformations, miscarriage, and fetal death associated with poor glycemic control

Contraception

Education about the risks associated with unplanned pregnancy should be part of the routine care of adolescents with type 1 diabetes.

Barrier Methods

- Male condoms are highly effective against unintended pregnancy and STIs when used consistently and correctly.[25]
- Female condoms and diaphragms are not recommended for adolescents.
- Coitus interruptus is associated with a high pregnancy rate and is not recommended.

Long Acting Reversible Contraceptions (LARCs)

- LARCs include intrauterine devices (IUDs) and implantable rods. They can be considered as first-line contraceptive choice for adolescents even if they are nulliparous.[26]
- The contraceptive effectiveness of implantable rods and hormonal IUDs are better than that of oral contraceptives.
- Non-hormonal IUDs may be considered if hormonal contraception is contraindicated.
- LARC methods neither protect nor increase the risk of STIs.

Combined Hormonal Oral Contraceptives

- Patients with duration of diabetes less than 20 years and without micro- or macrovascular complications may use any hormonal method.
- Combined oral contraceptives (COCs) should be avoided in patients with diabetes more than 20 years or having micro- or macrovascular complications. They may use IUDs, progestin only methods or barrier methods.
- No unfavorable effects on weight, metabolic control, or lipid profile have been seen with newer oral contraceptives containing lower dose of estrogen (≤35 mcg ethinyl estradiol) and newer progestins.
- Monitor blood pressure and side effects like headache, breast change, mood changes, and genital infections in young people taking oral contraceptives.

TABLE 2 WHO eligibility criteria of contraceptives in women with type 1 diabetes

	Combined contraceptives				*Progestin only*			*Intrauterine devices*		*Barrier methods*
	Oral	*Injectable*	*Patch*	*Vaginal ring*	*Oral*	*Deposit*	*Implant*	*Copper*	*LNG*	*Condom*
No micro- or macrovascular disease	2	2	2	2	2	2	2	1	2	1
Diabetes of >20 years duration	3/4	3/4	3/4	3/4	2	2	2	1	2	1
Nephropathy/ retinopathy/neuropathy	3/4	3/4	3/4	3/4	2	2	2	1	2	1
Macrovascular disease	3/4	3/4	3/4	3/4	2	2	2	1	2	1

1: Method may be used in any circumstances. 2: Method may be recommended. 3: Method is not usually recommended unless there are no appropriate, available, or acceptable alternatives. 4: Method should not be used.

Hormonal Injectables

- Depot medroxyprogesterone acetate injections are not recommended in adolescents with type 1 diabetes as it has been associated with reduction in bone mineral density.[27]
- For type 1 diabetes patients with erratic lifestyle and at high risk of pregnancy, monthly injections of combined hormonal contraceptives may be considered if they do not have access to LARC methods. But the safety data on type 1 diabetes patients is not available.

The WHO eligibility criteria of contraceptives in women with type 1 diabetes **(Table 2)** may be used as a guide to choose the right contraceptive for the right patient.

Transition from Pediatric to Adult Care

Society for Adolescent Health and Medicine defines transition as "the purposeful, planned movement of adolescents and young adults with chronic physical and medical conditions from child-centered to adult-oriented health-care systems."[28]

The transition period from pediatric to adult care is associated with deterioration of metabolic control, increased occurrence of acute complications, emergence of chronic complications, and psychosocial, behavioral, and emotional challenges.[2,29]

Pediatric health-care providers should ideally begin to prepare the teen for transition to adult health care during early adolescent years and no later than 1 year prior to the transfer.[2]

Preparation should focus on diabetes self-management skills for the adolescent/emerging adult and his/her parents. The transfer of responsibilities from the parent to the adolescent should be gradual. The adolescent should acquire adequate skills in self-monitoring of blood glucose, insulin delivery, ensuring proper supply of medications, identifying and treating symptoms of hypoglycemia, and scheduling appointments.

The pediatric care provider should provide a written summary including the medications, summary of past glycemic control, results of complication screening, diabetes-related comorbidities, any mental health problems, and referrals during pediatric care.

Transition tools developed by the Endocrine Society in association with ADA are available online for clinicians, adolescents, and families.[30]

Conclusion

Management of type 1 diabetes in adolescence poses unique challenges. Glycemic control during this developmental phase is difficult due to the complex interaction of various physiological, psychosocial, and psychological factors. Adolescence is also a high-risk phase for development of diabetes complications, so screening for the same should begin during this period. Adolescents should be counseled regarding the effects of alcohol, smoking, and other illicit drugs on the disease course. Advice on safe contraceptive practices should be part of routine diabetes care. Transition from pediatric to adult care should be gradual planned process with proper coordination between pediatric and adult health-care providers.

Evaluation, Causes, and Management of Hypoglycemia

Vineet Kumar Garg, Sneha Garg, Rahul Mathur

Abstract

Hypoglycemia is an important entity causing the morbidity and mortality in patients with or without diabetes. This chapter deals with the risk factor, pathogenesis, and causes of hypoglycemia. The urgent treatment and long-term management are also discussed in detail. This chapter also deals with psychiatric aspect of hypoglycemia mimic. Physicians should have an open mind in finding the cause as well as aim should be decreasing the recurrence of hypoglycemia episodes.

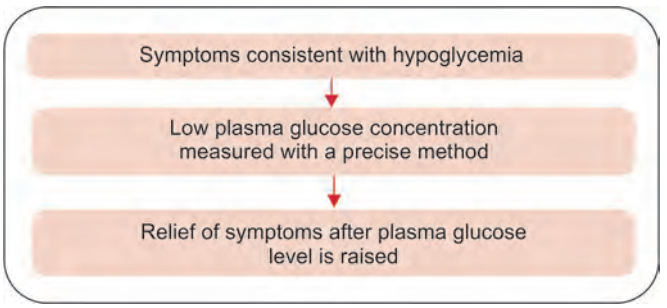
Introduction

Hypoglycemia is a state of glucose deficiency which presents with episodic symptoms. Dysregulation of glucose regulatory mechanisms leads to development of hypoglycemia. The most common cause is drugs that are used to treat diabetes. Whipple's triad is used to document hypoglycemia **(Flowchart 1)**. The lower limit of the fasting plasma glucose level is approximately 70 mg/dL. Normally, during pregnancy and during prolonged fasting (>24 hours), lower venous glucose levels occur. Hypoglycemia can be fatal if severe and should be suspected in a patient with confusion, altered sensorium or seizure.[1]

Etiology of Hypoglycemia

Hypoglycemia is caused by drugs (including anti-diabetic drugs), alcohol, sepsis, critical organ failure, inanition, non-β-cell tumors, hormone deficiencies, prior gastric surgery, and insulinoma. More elaborate causes are discussed in **Table 1**. Hypoglycemia can also be broadly classified into hypoglycemia in diabetes and in non-diabetes conditions. **Table 2** enlists causes of errors of metabolism which cause hypoglycemia.

Flowchart 1: Whipple's triad



Medications other than anti-diabetic drugs which commonly cause hypoglycemia are—Pentamidine (systemic), Trimethoprim-sulfamethoxazole, and renal failure, Propoxyphene and renal failure, Quinine, Quinidine, Salicylates, and renal failure.

Clinical Features

The symptoms are adrenergic symptoms and neurological symptoms. Adrenergic symptoms are shakiness, trembling, anxiety, nervousness, palpitations, tachycardia, calmness, sweating, dry mouth, hunger, pallor, and pupil dilation.

TABLE 1 Causes of hypoglycemia in adults[2]

Medicated or ill individual
• Drugs: Insulin/insulin secretagogue, alcohol, others • Critical illness: Hepatic, renal/cardiac failure, inanition, sepsis • Hormone deficiency: Cortisol, growth hormone, glucagon, epinephrine • Non-islet cell tumor (e.g., mesenchymal tumors)
Seemingly well individual
• Endogenous hyperinsulinism: Functional β-cell disorders (nesidioblastosis)—Non-insulinoma pancreatogenous hypoglycemia, Insulinoma, Insulin autoimmune hypoglycemia—Ab (antibody) to insulin, Post-gastric bypass, Ab to insulin receptor, Insulin secretagogue, other • Disorders of gluconeogenesis and fatty acid oxidation • Exercise • Accidental, malicious, or surreptitious hypoglycemia

TABLE 2 Hypoglycemia due to inborn errors of metabolism

Fasting hypoglycemia
• Glycogen storage disease (GSD) type 0 • GSD type I • GSD type III • GSD type IV • Fanconi-Bickel syndrome • Fatty acid oxidation defects • Gluconeogenesis defects (fructose-1, 6-bisphosphatase)
Postprandial hypoglycemia
• Glucokinase, SUR1, and Kir6.2 mutations • Congenital disorders of glycosylation • Inherited fructose intolerance
Exercise-induced hypoglycemia
• Increased β-cells monocarboxylate transporter 1 activity

Neurological presentations are irritability, paresthesia, headaches, difficulty in thinking/speaking, confusion, abnormal mentation, slurred speech, diplopia, ataxia, seizures, stupor/coma. Neuroglycopenic manifestations are direct result of CNS glucose deprivation. Cholinergic symptoms which are mediated by Ach such as hunger, sweating, and paresthesia are seen. These are from sympathetic postganglionic neurons. Heart rate and SBP are typically increased. These changes are blunted in a person who has suffered recent and repeated hypoglycemia episodes. Occasionally transient focal neurologic deficits occur. Permanent deficits are rare.

TABLE 3 Anti-diabetic drugs and hypoglycemia

Hypoglycemia causing	*Does not cause hypoglycemia*
• Insulin • Sulfonylureas • Glinides	• Metformin • Thiazolidinediones • α-glucosidase inhibitors • Glucagon-like peptide 1 (GLP-1) receptor agonists • Dipeptidyl peptidase IV (DPP-IV) inhibitors

Differential Diagnosis of Symptoms of Hypoglycemia

Many conditions are associated with episodes of symptoms similar to symptoms of hypoglycemia. These are Anxiety neurosis, Dumping syndrome, Thyrotoxicosis, Drugs (varencilline, decongestants, stimulants, and street drugs), Angina pectoris, autonomic neuropathy, renovascular hypertension, pheochromocytoma, withdrawal symptoms, hypogonadism, carcinoid syndrome, syncope and postural hypotension (including POTS), angina, cardiac arrhythmia, seizure disorders, atypical migraine, vertebral and ICA diseases, and psychiatric disorders.

Hypoglycemia in Diabetes

Recurrent morbidity is caused by hypoglycemia in most patients with type 1 diabetes and in many with advanced type 2 diabetes. It precludes the maintenance of euglycemia over a lifetime of diabetes and thus full realization of microvascular benefits of glycemic control. By producing hypoglycemia-associated autonomic failure, it also causes a vicious cycle of recurrent hypoglycemia—i.e., the clinical syndromes of defective glucose counter regulation and of hypoglycemia unawareness. Mortality rate of hypoglycemia is approximately 6–10% in T1DM. The hypoglycemia incidence is lower in T2DM than in T1DM **(Table 3)**.

The risk factors for hypoglycemia in diabetes are identified whether relative or absolute insulin excess is the sole determinant of risk **(Box 1)**.

Hypoglycemia-associated Autonomic Failure (HAAF)

In diabetes mellitus iatrogenic hypoglycemia is often a consequence of interaction between relative/absolute

BOX 1 Causes of relative/absolute insulin excess

- Insulin (insulin secretagogue) doses are ill-timed/excessive/of wrong type
- The influx of exogenous glucose is decreased (e.g., during an overnight fast, periods of temporary fasting, or after missed meals/snacks)
- Increased insulin-independent glucose utilization (e.g., during exercise)
- Increased sensitivity to insulin (e.g., with improved glycemic control, late after exercise, in the middle of the night, or with increased fitness/weight loss)
- Reduced endogenous glucose production (e.g., after alcohol ingestion)
- Reduced insulin clearance (e.g., in renal failure)

therapeutic insulin excess in addition to compromised physiologic and behavioral defenses against decreasing glucose levels. Dysfunctional counter-regulatory mechanisms compromise physiologic defense (especially decrements in insulin and increments in glucagon and epinephrine), and behavioral defense is compromised by hypoglycemia unawareness (ingestion of carbohydrate).

Hypoglycemia Unawareness

Hypoglycemia unawareness is caused by the diminished sympathoadrenal response, that is, majorly the decreased sympathetic neural response to hypoglycemia—i.e., loss of the warning autonomic symptoms that earlier allowed the patient to acknowledge developing hypoglycemia and thus to end the episode by eating carbohydrates. These patients are at sixfold higher risk of severe hypoglycemia by the intensive diabetes therapy.[3]

Evaluation of Hypoglycemia

Hypoglycemia Evaluation in DM Patients

Hypoglycemia is worrisome in a diabetic patient when the plasma glucose concentration on self monitoring is falling rapidly or ≤70 mg/dL (3.9 mmol/L). Glycemic control is advised to have long-term microvascular benefit in a diabetic patient but strict monitoring to be adhered to prevent hypoglycemia. Adjustment in treatment regimens are recommended for prevention of hypoglycemia in diabetes **(Box 2)**.[2]

The typical risk factors and compromised defenses should be evaluated in recurrent treatment-induced hypoglycemia **(Table 4)**.

BOX 2 Hypoglycemia prevention in diabetes

- Diabetes self-management (supported by education and empowerment)
- Frequent self-monitoring of blood glucose
- Flexible and appropriate insulin/insulin secretagogue regimens
- Individualized glycemic goals
- Ongoing professional guidance and support
- Consideration of each of the known risk factors for hypoglycemia

TABLE 4 Conventional risk factors and compromised defenses against hypoglycemia

Conventional risk factors	*Compromised defenses against hypoglycemia*
• Excessive/ill-timed dosing of insulin/secretagogue • Wrong type of insulin/insulin secretagogue • Conditions which reduce exogenous glucose delivery or endogenous glucose production • Increased glucose utilization • Increased sensitivity to insulin • Decreased insulin clearance	• Endogenous insulin deficiency degree • Severe hypoglycemia history • Hypoglycemia unawareness • Recent antecedent hypoglycemia • Prior exercise or sleep • Lower glycemic goals *per se*

Two/three weeks of meticulous avoidance of hypoglycemia is advised in patients with known hypoglycemia unawareness with the probability that awareness of hypoglycemia will be back in most of them.

Hypoglycemia Evaluation in Patients without DM

The history, physical examination, and all relevant laboratory data inferring to specific disorders like drugs, hormone deficiencies, critical illnesses, non-islet cell tumors must be reviewed. To ascertain the cause of hypoglycemia in an apparently well individual—plasma glucose, insulin levels, C-peptide levels, proinsulin levels, insulin antibodies, and β-hydroxybutyrate levels should be measured. Screen for intake of oral hypoglycemic agent (OHA) during spontaneous hypoglycemia episode and observe the response to glucagon 1.0 mg intravenously. These will differentiate endogenous versus exogenous causes.[4,5]

In cases where a spontaneous hypoglycemic episode is not observed, the circumstances which will lead to symptomatic hypoglycemia are recreated. One such method is a fast of up to 72 hours after a mixed meal. The findings of this test is—

- symptoms, signs, or both; with
- glucose plasma concentrations <55 mg/dL (3.0 mmol/L)
- insulin of 3.0 μU/mL (18 pmol/L) at least
- C-peptide of 0.6 ng/mL (0.2 nmol/L) at least
- proinsulin of 5.0 pmol/L document endogenous hyperinsulinism at least
- β-hydroxybutyrate levels of ≤2.7 mmol/L and rise in plasma glucose of 25 mg/dL (1.4 mmol/L) at least after IV glucagon indicate mediation of the hypoglycemia by insulin (or by an IGF)

In cases of documented fasting/PP endogenous hyperinsulinemic hypoglycemia, no circulating insulin antibodies, and negative screening for OHA suspect insulinoma. Imaging techniques used are CT or MRI, transabdominal and endoscopic ultrasonography, and selective pancreatic arterial calcium injections with insulin levels in hepatic vein measurement **(Table 5)**.

TABLE 5 Urgent hypoglycemia bundle card

Laboratory service instructions:
• This patient is having symptoms of low blood sugar • Do not give the patient anything to eat or drink, or administer any IV medication or solution until the blood sample(s) have been drawn, unless it is determined that the patient's life is at risk • Immediately see this patient and draw the urgent hypoglycemia bundle: – Medical record number – Patient's name (first, middle, last) – Ordering provider name – Ordering provider pager

Anxiety and Hypoglycemia

Anxiety associated with depression is quite commonly studied in those with diabetes mellitus. Specific phobias, in particular needle injection and fear of hypoglycemic episode, are commonly seen in those patients who are on insulin therapy.[6] Hypoglycemic phobia is a very important aspect of treatment in diabetes as these group of patients are more likely to miss glucose monitoring or insulin administration. They might also maintain chronic hyperglycemic state because of the fear of hypoglycemic episode. Clinical features shared by both hypoglycemia and anxiety are sweating, tremor, anxiety, confusion, and tachycardia. This could lead to a diagnostic challenge. Those with long standing anxiety disorder the likelihood of missing warning signs of hypoglycemia are more. Medications for management of anxiety disorders—SSRIs, benzodiazepines, and beta-adrenergic blockers could interfere with glycemic control and physiological warnings of an hypoglycemic episode.

Alcohol Use and Hypoglycemia

Prevalence of alcohol use is around 50% in diabetics.[7] Most common and a serious concern associated with alcohol use in diabetes is hypoglycemia. It includes a spectrum of alcohol-induced fasting hypoglycemia, potentiation of drug-induced hypoglycemia/reactive hypoglycemia in susceptible patients **(Box 3)**.

BOX 3 Recommendations of alcohol use among diabetics

- Assess all patients for alcohol use
- Questionnaire like CAGE should be used
- Advise nonusers to not to start and users to abstain/use in moderation
- Education on harmful effects of alcohol use
- People using insulin/insulin secretagogues should be given knowledge of delayed hypoglycemia occurring up to 24 hours after alcohol intake
- Increased awareness in T1DM patients of hypoglycemia associated with alcohol used
- Limit alcohol (for men <14 standard drinks/week and women <9 standard drinks/week)

Management of Hypoglycemia

Urgent Treatment

When patient is conscious and is able to take orally, glucose tablets/glucose-containing fluids, candy/food is appropriate in an initial dose is 15–20 g of glucose. When the patient is unable to take carbohydrates orally, because of parenteral therapy is necessary. IV administration of 25 g glucose followed by a glucose infusion guided by serial plasma glucose monitoring. If IV therapy is not practical, subcutaneous/IM glucagon (1.0 mg in adults) can be used, particularly in T1DM. Glucagon is less useful in T2DM as

it stimulates insulin secretion. Octreotide (somatostatin analogue) can be used in SU-induced hypoglycemia to suppress insulin secretion. These treatments raise plasma glucose and patients should eat soon to replete glycogen stores.

Prevention of Recurrent Hypoglycemia

This approach requires identification of cause of hypoglycemia. Discontinuation of offending drugs or reduction of their doses. Hypoglycemia caused by SUs can persist for hours or days. Treatment of underlying critical illnesses should be prompt. Replacement of deficient cortisol and growth hormone. If the tumor cannot be cured surgical, chemotherapeutic, or radiotherapeutic reduction of a non-islet cell tumor can provide relief from hypoglycemia. In such patients glucocorticoid or growth hormone administration also may decease hypoglycemic episodes. Surgical resection of an insulinoma is curative. Diazoxide/octreotide medical therapy can be used if resection is not advised. Also useful in people with a non-tumor β-cell disorder along with partial pancreatectomy. Autoimmune hypoglycemia treatment is difficult but these disorders are self limited sometimes. Treatment with glucocorticoid or immunosuppressive drugs is tried. Frequent feedings and avoidance of fasting should be followed if these treatments fail. In some patients administration of uncooked cornstarch at bedtime or an overnight intragastric infusion of glucose may be required.

Conclusion

Diagnosis of hypoglycemia by Whipple's triad is well established. Broadly approach to evaluate hypoglycemia is based on the patient's diabetes status and exogenous/endogenous factors. Prompt diagnosis and prompt treatment are the key to save permanent neurological damage in a patient with severe hypoglycemia. Avoidance of precipitating factors and patient counseling are very important aspects of reduced morbidity and mortality.

Metabolism, Lipids, and Obesity

CHAPTER

78 Current Concepts in Etiopathogenesis of Obesity

CL Nawal, Abhishek Yadav

Abstract

Obesity is one of the most common chronic communicable diseases in the world. It is not only accumulation of adipose tissue in the body, but also a defect in homeostasis of our energy. Many factors contribute to etiology of obesity, but a complex interface between hormones, environment, and genetics play a major role. For a better understanding of pathogenesis of obesity, it can be grouped into energy consumption, energy utilization, and role of genetics. Serotonin, Dopamine, and some gut hormones influence homeostatic and hedonic pathways that control intake of energy. Reduction in resting energy expenditure, activity energy expenditure, and diet induced thermogenesis contribute to obesity via low energy utilization. Leptin gene discovery was a big breakthrough in molecular genetics research on obesity. Obesity can be a result of polygenic factors, or single gene disorders apart from various syndromes which have obesity as their predominant manifestation. Being a modern epidemic, obesity incurs significant cost to world economy and targeted therapies as per genetic profiling of individuals are the need of future.

Introduction

Obesity is a pandemic of the 20th century. It is among the one of the most common chronic non-communicable diseases throughout the world. Obesity is not only the accumulation of adipose tissue leading to weight gain; it is rather a defect in our energy homeostasis. Obesity is increasing at an alarming rate both in developed and developing countries. The etiology of obesity is multifactorial, which involves a composite interface among hormones, the environment, and genetics.[1] The aim of this article is to review the etiopathogenesis and the role of genetics in obesity.

Etiology and Pathogenesis of Obesity

Human beings consume food as energy, which is stored as well as utilized in maintaining the basal metabolism of the body. Reduction in physical activities due to sedentary lifestyles leads to excessive storage of energy of which 60–80% is as fat or adipose tissue. It leads to obesity, the fifth most common cause of non-communicable disease.[2] In the pathogenesis of obesity, multiple factors play a role, which include lifestyle affecting reduced energy expenditure, hormones affecting energy intake and the part of genetics. Gastrointestinal hormones, adipokines, and various genes including beta-3-adrenergic receptor gene peroxisome-proliferator-activated receptor gamma 2 (PPAR-γ) gene and other genetic polymorphism majorly regulates the pathophysiology of obesity.[3-5]

Pathogenesis of obesity can be divided into three ways:

- Energy consumption
- Energy utilization
- Role of genetics

Energy Consumption

Homeostatic and hedonic are the two pathways that control intake of energy. When the body is deficient in

energy, the homeostatic mechanisms stimulates the appetite, the hypothalamus as well as brainstem acts as central regulators and senses the signals including leptin, insulin, hormones, and vagal afferents. Hedonic pathway is a mediator of rewarding aspects for food intake. When both pathways and systems are uncontrolled, it leads to obesity. Two neurotransmitters serotonin and dopamine play a vital role in the energy intake.[6]

Serotonin and dopamine: Serotonin is a neurotransmitter of homeostatic pathways. Reduction in signaling by serotonin in the hypothalamus contributes to the origin of obesity as it affects the negative feedback from the food intake, which leads to over consumption. Various studies explain a strong link between hypo-serotonin environment and development of obesity.[7,8] As far as dopamine is concerned, decrease in the dopaminergic signaling also promotes overconsumption. As dopamine is a reward hormone, thus lower reward sensations lead to its effects.[9]

Gastrointestinal hormones: Gut-brain axis or feedback system plays an important role to maintain hunger and satiety. Several gut hormones: ghrelin, cholecystokinin, peptide YY, glucagon like peptide-1, oxyntomodulin are involved as messengers in this axis. Along with the function related to food digestion, these hormones equally affect specific brain areas modulating food or energy intake.

Ghrelin, the only hormone that stimulates hunger is produced by the endocrine cells of gastric fundus.[10] Ghrelin binds to the growth hormone receptor which is highly expressed in the hypothalamus. In obese subjects, the fasting levels of ghrelin are low as compared to normal weight controls. Diet induced obesity mainly occurs due to ghrelin resistance, which arises as there is reduction in the NPY/AgRP responsiveness to plasma ghrelin leading to suppression of neuroendocrine ghrelin axis.[11] Other intestinal hormones are anorexigenic which includes glucagon-like peptide 1 (GLP1), peptide YY (PYY), and cholecystokinin (CCK).[12] The over consumption of meals in obese humans is strongly associated with the reduction of activity of these anorexigenic hormones.[13]

Leptin: The revolutionary discovery of leptin occurred in 1994. It is synthesized in white adipose tissues. The level of leptin in the body correlates with the fat mass. The leptin levels in plasma and CSF will be higher in a person with excess body fat.[14] Leptin acts as an informant to the brain about the reserved adipose energy. It crosses the blood brain barrier and inhibits orexigenic NPY/AgRP neurons and stimulates POMN-expressing anorexigenic neurons in the hypothalamus. Responsiveness to leptin decreases in obesity. Leptin resistance not only affects the energy consumption but also decreases insulin sensitivity and cognition. Leptin levels are higher in obese individual due to increased production by adipocytes to compensate the low responsiveness. Inability or defect in crossing the blood brain barrier is also associated with reduced feedback by leptin.[15] Low levels of leptin or resistance of leptin impairs its ability to counterbalance the effect of ghrelin.[16]

Insulin: Sedentary lifestyle leads to increased risk of diabetes. It is associated with raised insulin levels due to insulin resistance. Hyperinsulinemia lead to weight gain and obesity because of a physiological property of insulin. Beside the effect of lifestyle factors, the pathway to obesity needs hyperinsulinemia as an important moderator in translating an unworthy lifestyle turning into gain of weight.[17] The insulin resistance, which causes hyperinsulinemia and later obesity, occurs mainly due to defect in insulin signaling in adipocytes as well as downregulation of GLUT4.[18]

As a pleiotropic effect, raised insulin levels lead to more synthesis of adipocytes from preadipocytes. It also promotes lipogenesis by stimulating ADD-1/SREBP-1c which plays the role of regulating fatty acid synthesis and lipogenesis in hepatocytes and adipocytes.[19] With the recognition of insulin resistance and hyperinsulinemia as the potential mechanism of obesity has come increases investigation and research aimed at elucidating potential insulin sensitizing agents. Thus, it's established that insulin receptor function is vital for energy homeostasis.

Circadian rhythms: Nature is always dominant. Biological rhythms play an important role in virtually all aspects of life. These rhythms are controlled in large part by circadian clocks, a molecular mechanism which is intrinsically maintained to control these biological rhythms and adapt or condition the human beings to its changing environment. Two types of clocks exist, the central and the peripheral clock. Suprachiasmatic nucleus (SCN) of the brain possesses the central clock, which responds with light. Other than SCN (including those clocks found

in other cells of the central nervous system) all other cells possess peripheral clocks which work under the influence of neurohormonal changes.

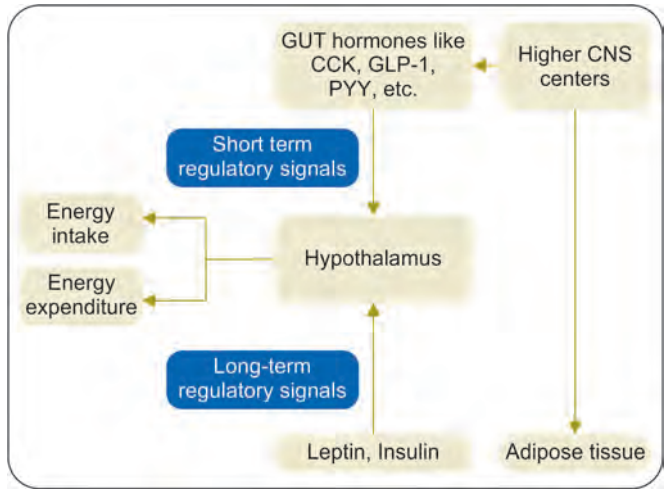
Changing lifestyles, late night working shifts alters the functioning of these clocks leading to poor anticipation of diurnal variations in the environment of the body. It could be circulating levels of glucose, fatty acids, or hormones including insulin and triglycerides. Altered molecular mechanism in the adipocytes leads to accumulation of fat and finally obesity.[20]

Gut bacteria: Our gut consists of numerous bacteria. These play an important role in digestion of food. Recent research indicates that gut microbiota also plays a part in pathogenesis of obesity. Low fecal diversity markedly leads to overall adiposity and dyslipidemia along with low-grade inflammation.[21] In obese individuals, *Firmicutes strain of bacteria are increased and Bacteroidetes* strain is markedly low in fecal samples, in comparison to lean individuals.[22] It suggests, overweight/obesity are preceded by differences in the gut microbiota. Several other studies too found change in gut bacteria composition in obese individuals but high ratio of Firmicutes:Bacteroidetes in obese individuals with excess Bacteroidetes during weight loss is not consistent.[23,24]

Energy Utilization

Low energy expenditure (LEE) contributes to development of obesity is always suggested. Reduction in resting energy expenditure (REE), activity energy expenditure (AEE), and diet induced thermogenesis (DIT) all lead to storage of energy leading to weight gain and obesity.[25] A review was done Carneiro et al. to see the comparison between energy expenditures measures and its components, namely REE, AEE, and diet-induced thermogenesis (DIT), playing role in obese and non-obese adults. Results clearly shown the obese individuals require higher absolute REE and total EE. Although no difference is seen when fat free mass and metabolically active components are involved. However, AEE and DIT can be low obese individuals, because of sedentary habits, poor physical activity, and high intake of fat.[26] Reduction in exercise associated thermogenesis and non-exercise associated thermogenesis significantly contributes weight gain in obesity. Nowadays various phenotypes of obesity like sarcopenic obesity and normal weight obesity are associated with energy expenditure in comparison to lean and thin individuals.[27]

Flowchart 1: A schematic diagram showing integration of long-term and short-term regulatory signals influencing energy intake and expenditure



Weight gain is also associated with drugs as anti-psychotics, tricyclic antidepressants, lithium, steroids, antiepileptics and insulin. Smoking cessation, due to nicotine withdrawal also causes weight gain **(Flowchart 1)**.

There is also a role of endocrine disruption chemicals (EDCs) in obesity as their exposure is associated with stimulation of adipogenesis and changes in insulin secretion, sensitivity, and metabolism of liver. EDCs like perfluorinated chemicals (PFCs) and bisphenol-A (BPA) are linked with accumulation and maintenance of excess body fat in many studies.

Role of Genetics in Obesity

For long it was proposed that obesity may also be caused due to innate biological mechanisms under influence of genetic factors. In 1977, Feinleib et al. established the fact through their study that familial aggregation for obesity results from genetic influence.[28] Stunkard and colleagues performed two studies in 1986 and 1990 amongst twins offering compelling evidence that one's weight could be determined by one's parentage. The leptin gene discovery in 1994 was a big breakthrough in molecular genetics research on obesity. Twin study suggests that heritable factors are responsible for 40–85% variation in body fat. Risk of obesity in children is 2.5–4 times high in single parent obesity, whereas it was 10 times for both parents being obese.[29,30]

The influence of genetic variables can be significantly reduced by high level of physical activity and environmental modifications.[31] Mutations in various other molecules responsible for energy balance via the hypothalamus/melanocortin pathway have been described, which contribute to obesity.[32]

Polygenic obesity: Genetic factors play a permissive role and interact with environmental factors to produce obesity. Genome wide association studies (GWAS) in European population focused on 70–80% common variations using single nucleotide polymorphism (SNP). Variation in intron-1 of Fat Mass and Obesity associated (FTO) gene has been identified as contributor to polygenic obesity.[33] MC4R gene was associated with hyperphagia and early onset diabetes. SH2B1 (Src-Homology-2 [SH2] domain containing putative adaptor protein-1) is associated with increased serum leptin. Other genes, which are highly expressed in hypothalamus and associated with obesity are KCTD15 (potassium channel tetramerization domain-containing 15), GNPDA2 (glucosamine-6-phosphate deaminase-2), MTCH2 (mitochondrial carrier homolog 2), SDCCAG8 (serologically defined colon cancer antigen 8), FAIM2 (Fas Apoptotic Inhibitory Molecule 2) and PRL (prolactin).[34,35]

One peripheral acting gene TFAP2B (transcription factor activating enhancer-binding protein 2β) is preferentially expressed in adipose tissue, which is involved in glucose transport, lipid accumulation, and adiponectin expression. New GWAS have started to appear in East Asian population promising discovery of further more loci related to genetic forms of obesity.

Syndromic obesity: A variety of syndromes with obesity as their primary manifestation have been identified. Some of the important ones with their main features have been described in **Table 1**.

Monogenic obesity: These are single gene disorders causing a highly penetrant form of disease. These genes affect the leptin/melanocortin pathway in central nervous system and have been described in **Table 2**.

Even after discovery of these numerous genetic factors, only a small fraction of obesity cases could be attributed to them. Variations in FTO and MC4R are two most important genes that are strongly linked to obesity, but still account for less than 2% of variance in adult BMI.[1] It is assumed that there must be a missing link in the heritability of obesity, and more GWAS are underway to search for them. Discovery of these factors would open up new possibilities for novel drugs, diagnosis, treatment, and prevention of obesity.

TABLE 1 Syndromes having obesity as their predominant manifestations[36,37]

Syndrome	*Gene*	*Obesity onset (type)*	*Clinical features*
Albright hereditary osteodystrophy (pseudohypoparathyroidism type 1a)	GNAS1	Early (generalized)	Short stature, round face, cognitive delay, skeletal abnormalities along with obesity
Alström	ALMS1	Age 2–5 years (central)	Obesity with acanthosis nigricans, normal cognition, blindness, deafness, chronic nephropathy, type 2 diabetes, and cirrhosis
Bardet-Biedl syndrome	BBS1, 2, 3…	Age 1–2 years (central)	Obesity with cognitive delay, polydactyly, retinitis pigmentosa, hypogonadism and renal dysfunction
Beckwith-Wiedemann	Multiple		Obesity with intolerance of fasting, hyperinsulinemic hypoglycemia
Carpenter	RAB23	(Central)	Short stature with obesity, brachycephaly, polydactyly, umbilical hernia, mental retardation high-arched palate, cryptorchidism, male hypogonadism
Cohen	COH1	Mild-childhood (central)	Hypotonia and failure to thrive in infancy, mental retardation, microcephaly, prominent central incisors; long, thin fingers, and toes
Prader-Willi	NDN, SNRPN	Age 1–3 years (generalized)	Hypotonia, upslanting eyes, cognitive delay and behavioral abnormalities along with obesity

TABLE 2 Single gene disorders causing obesity[37]

Disorder (Gene)	*Gene*	*Clinical feature*
Leptin deficiency (various mutations interfering with synthesis or secretion of leptin)	LEP	Severe early-onset obesity, hypometabolic rate, hyperphagia, pubertal delay, impaired glucose tolerance, hypothalamic hypogonadism, frequent infections. Very low or undetectable leptin levels. Obesity and hyperphagia respond to replacement with exogenous recombinant leptin
Leptin receptor deficiency	LEPR	Severe early-onset obesity, hypometabolic rate, hyperphagia, pubertal delay, hypothalamic hypogonadism. Leptin levels are high but are proportional to the degree of obesity, so they are not a useful marker for this defect. No response to treatment with exogenous leptin
Leptin dysfunction (biologically inactive leptin)	LEP (LEP p.D100Y)	Severe early-onset obesity, hyperphagia. Leptin level are high (consistent with degree of obesity) but biologically inactive. Obesity and hyperphagia respond to treatment with exogenous recombinant leptin
Pro-opiomelanocortin deficiency	POMC	Adrenal insufficiency (typically presenting in the neonatal period), severe early-onset obesity, hyperphagia, and red hair in Caucasians
Pro-protein convertase 1/3 deficiency	PCSK1, also known as prohormone convertase 1	Early-onset obesity, diarrhea, abnormal glucose homeostasis, hypogonadotropic hypogonadism, hypocortisolism, elevated plasma proinsulin and POMC
Melanocortin receptor 4 haploinsufficiency	MC4R	Early-onset moderate to severe obesity, early-onset hyperphagia, increased bone density, accelerated linear growth, severe hyperinsulinemia, mild central hypothyroidism
Melanocortin 2 receptor accessory protein 2	MRAP2	Severe nonsyndromic early-onset obesity (probably very rare)

Conclusion

A complex interaction between genetic factors, environmental factors, and human behavior influences pathogenesis of obesity. Obesity is a modern epidemic and incurs massive health-care cost to world economy. Even with all recent advances, less than 2% of interindividual variations in BMI can be attributed to discover established gene loci. Along with well-known principles of prevention and control of obesity, targeted therapies as per genetic profile of the individual are of the need in future.

CHAPTER

79 Dilemma in the Management of Hyperuricemia

Brijesh Kumar, Mohammad Aquiqe

Abstract

Introduction: Hyperuricemia is a condition which is due to excess accumulation of uric acid in the blood either due to overproduction or under excretion or both.

Clinical Manifestations: Four stages asymptomatic, acute gout, inter-critical, and advanced gout.

Management: Asymptomatic individual usually does not require treatment but symptomatic patient may require pharmacological and non-pharmacological treatment.

Conclusion: Symptomatic patient with or without complications may require treatment.

Introduction

Hyperuricemia is a disorder of purine metabolism in which last product of metabolism, that is, uric acid is increased either due to overproduction or under excretion or both of the process. Hyperuricemia is defined as serum urate concentration 405 μmol/L (6.8 mg/dL) [serum urate level of 7.0 mg/ dL (415 μmol/L) and in men 5.7 mg/dL (340 μmol/L) for women].[1]

Causes

- Urate under excretion Primary hyperuricemiais—or idiopathic; Secondary hyperuricemia, due to—inhibition of urate secretion, abnormally decrease in renal function.

  Drugs which causing under excreation—ethumbutol salicylate and laed etc.
- Urate overproduction—
  - Primary hyperuricemia due to enzyme defect.
  - Secondary hyperuricemia due to
    - purine rich diet,
    - increase nucleotide turnover,
    - ATP degradation
      - Glucose-6-phosphatase deficiency,
      - Tissue hypoperfusion
  - Over alcohol intake.[2]

Hyperuricemia is related with cardiovascular conditions, obesity, and metabolic syndrome etc.[3]

Clinical Manifestation

Stage 1: Asymptomatic hyperuricemia: this condition is most common but does not constitute disease, if urate deposited then damage the organ directly but not found in all and evidence suggests that no need of treatment in this stage.[4]

Stage 2: Acute gout-in this stage patient develop local deposition of urate particles and any minor trauma can produce release of urate crystals in joint space and condition of acute gout.[5]

Stage 3: Intercritical period.

Stage 4: Advanced gout. Chronically deposition of urate crystals and patient develop stiff joint. This progression is variable from person to person.[6-9]

Complications

Most common is gouty arthritis and other complications are nephrolithiasis, urate nephropathy, and uric acid nephropathy.[10-12]

Investigations

- Twenty-four hours uric acid excretion: Normal uric acid excretion is 600 mg/day in a purine-free diet individual if this value exceeds then it suggests that hyperuricemia is due to overproduction and if this value decreases then it means hyperuricemia is due to under excretion of uric acid, but if patient on regular diet then normal uric acid excretion value up to 800 mg/dL.
- Complete blood count (CBC), lipid profile, calcium, and phosphate levels. These laboratory studies assess for underlying disease leading to elevated uric acid.
- Joint radiographs for joint swelling or deformity etc.[13]
- Renal ultrasound is done for uric acid stones.
- Consider joint aspiration to evaluate for uric acid crystals, look for negatively birefringent less polarized microscopy.[13]

Treatment

Hyperuricemia does not constitute a disease condition. Treatment depends on cause and potential consequences and complications in every patient.[18]

- Asymptomatic hyperuricemia is mainly treated by non-pharmacological interventions like lifestyle modifications, purine free diet, weight reduction, decrease in the quantity of alcohol soft drink consumption.[18] As mentioned earlier metabolic syndrome is a risk factor for hyperuricemia so treat the accompanying diabetes mellitus, hyperlipidemia, high blood pressure and morbid obesity.
  - *Body Weight and Exercise:* In a cross-section analysis it is found that with increase in body weight serum level of uric acid increases and also positive correlation with metabolic syndrome. So weight reduction done via dietary modification and exercise can decrease the serum uric acid level also reducing the risk of gout. Gradual decrease in body weight is more valuable than drastic reduction. Because abrupt fall in weight can lead to ketosis and in turn this will lead to increase absorption of uric acid and ultimately increase in level of uric acid in serum.[14-17]
  - *Dehydration and Rehydration:* Uric acid excretion is directly proportional to urine flow so one of the risk factor for gout is dehydration and thus gout patients are advised to take lots of fluid. If taking adequate amount of fluid 24 hours before gouty flare then there is definite decrease in gout attacks.[18,19]
  - *Dietary Factors:* An open labeled study suggest that there is some role of dietary factors in prevention of hyperuricemia and gout. But some also have ability to increase the level of uric acid. It is also found that those patient who are having hyperuricemia have a poor diet.[20]
  - *Purine-Rich Foods:* Those foods which are rich in purine, on ingestion can increase the serum uric acid level. But not all purine rich foods lead to increase serum uric acid level.

    Duration of food ingestion is also important. For example, if taking diet which is rich in purine for 7–10 days then only slight change level of serum uric acid and for some duration only, and also if we are taking diet which is low in purine content for 1–2 weeks then only 1–2 mg/dL decrease in serum uric acid. So this menas strict restriction of purine derivative foods in diet has not much role in uric acid control.[21]
  - *Fructose:* Fructose is the only sugar in fruits, which can increase the level of serum uric acid. Thus, fructose consumption is one of the factors in recent, which increases the prevalence of gout nowadays.[22]
  - *Dairy Products:* Dairy product reduces the risk of development of gout because the can decrease the serum uric acid level, which is suggested by some studies also.[23,24]
  - *Cherries:* Cherry from many decades used as alternative therapy for gout. Gout ingestion lead to decrease pain of gout. First study done in 1950.[25]
  - *Mediterranean Diet:* This diet is very helpful in patients of diabetes and coronary disease etc. It contains legume, cherry, olive oil, moderate fish consumption, etc.[26]
  - *Alcohol:* Alcohol promotes hyperuricemia it increases urate level by increased production by

the accelerating the hepatic breakdown of ATP and also led to decrease excretion of uric acid via kidney. Alcohol consumption also induces hyperlactacidemia, which inhibit uric acid secretion, consumption of bear confers a greater risk of gout than liquor and moderate wine intake does not increase gout risk.[27]

Pharmacological treatment: Earlier there is a relation found in between hyperuricemia and cardiovascular disease and renal disease so this lead to the evidence that treatment of asymptomatic hyperuricemia started with urate lowering drugs.[28]

Nowadays asymptomatic hyperuricemia is not treated by pharmacological therapy, that is, with antihyperuricemic agents.

Pharmacological treatment is given when—

- Two or more acute gout attacks per year,
- Presence of tophi,
- Stone formation, and
- Those individuals who were taking cytolytic drugs for malignancy in the past.[29]

Most common drug used for lowering of serum uric acid is allopurinol by blocking uric acid production.

Side effects: Diarrhea, headache, skin rash with itching.

Other toxicities are pyrexia, increase in leukocyte and eosinophils, hypersensitivity syndrome, etc.[30,31]

Oxypurinol is a metabolite of allopurinol, which is used as an alternative for allopurinol. It is used when severe adverse effects of allopurinol occurs.[32]

Uricosuric drugs: These drugs are named as probenecid and sulfinpyrazone. They have less side effects stilt use is very limited.[33] These drugs decrease the serum uric acid level by uricosuric effect so also increase uric acid in urine and increase the chance of development of uric acid stones.[34]

Thus, for better effect of these uricosuric drugs, kidney function should be normal, that is, creatinine clearance should be more than 55–60 mL/min and also patient should take at least 2 liters of fluid everyday with no history of nephrolithiasis.

- Symptomatic Hyperuricemia is treated with antihyperuricemic drugs. Basic aim of giving urate lowering agent is to decrease the total uric acid pool and serum uric acid should be below 6.5 mg/dL. Symptomatic hyperuricemia can present as—
  - Acute gouty arthritis
  - Nephrolithiasis
  - Uric acid nephropathy

A. Acute gouty arthritis: Risk of gouty arthritisis in those who are hyperuricemic individuals with high level of urate. Usually hyperuricemic person does not develop gout, and there is no need of prophylactic treatment. Also there is no structural kidney damage and no tophi are identifiable before first attack of gout.

Urate lowering agents should be started in those who are not managed by low purine diet, high fluid intake, moderation of alcohol intake, decrease in body weight and not on diuretics, etc.

Hypouricemic therapy started or not decision depends on—

- The number of acute attacks of gout
- More than 9.0 mg/dL of serum uric acid
- Nephrolithiasis

- Uricosuric agents like—
  - Probenecid are used when kidney function is normal, that is, when 24-hour urine sample contains uric acid less than 600 mg (underexcrete) and also need large amount of fluid intake, that is, about 1.5 liter of water intake per day. Starting dose of probenecid is 250 mg bid daily and maximum can be given up to 3 gm/day.
  - Other uricosuric agent like benzbromarone is more effective in CKD patients.
  - Some other agents which are not a hypouricemic drug but have little uricosuric effect are losartan, fenofibrate, and amlodipine are also use.
- Dose of xanthine oxidase inhibitor, allopurinol, is usually start with 100 mg once daily in morning and if required then can be reach maximum up to 800 mg daily morning.

  Dose reduction is required for allopurinol in chronic kidney disease patients on the basis of serum creatinine level.

Allopurinol toxicity is more when—
- Patient on thiazide diuretic
- Patient allergic to penicillin and ampicillin
- In Asian who expressing HLA-B 5801

- Febuxostat is approved in the United States and dose is 40 or 80 mg once a day and this drug also needs adjustment in mild to moderate renal disease.
- If patients cannot tolerate or fail to take full dose of above mentioned treatment then another drug is available named as pegloticase, which is a pegylated uricase. This drug is very potent given as 8 mg in every 2 weeks via intravenous route and reduces serum uric acid level very fast.
- Along with hypouricemic drugs an anti-inflamatory drug, that is, colchicine is also given.

  The prophylactic dose of colchicine is 0.6 mg once daily or bid and stops when—
  - Patients serum uric acid level is normal
  - No gout attack up to 6 months
  - As long as tophi present[35]

B. Nephrolithiasis: Antihyperuricemic therapy is recommended for the individual who has both gouty arthritis and either uric acid or calcium-containing stones, both of which may occur in association with hyperuric aciduria. Regardless of the nature of the calculi, fluid ingestion should be sufficient to produce a daily urine volume 2 L.

Active metabolite of allopurinol, that is, oxypurinol has a long half-life (18 hours) so given as single daily dose. Allopurinol is also useful in patients of gout and those with hyperuricemia or hyperuric aciduria without gout having recurrent calcium oxalate stones.

Potassium citrate (30–80 mmol/day orally in divided doses) is an alternative therapy for patients with uric acid stones alone or mixed calcium/uric acid stones.

Allopurinol is also used when 2,8-dihydroxyadenine kidney stones are present.[35]

C. Uric acid nephropathy: This condition is a rapidly worsening of kidney function seen when hyperuric aciduria occurs. In this condition deposition of uric acid crystals occurs in the renal interstitium and tubules leading to partial or complete obstruction of collecting ducts, etc.

For prevention of this condition, allopurinol or rasburicase is given prior to treatment with cytotoxic drugs.

For prevention of deposition of uric acid crystals, iv hydration and diuretics like furosemide given and maintain flow of urine above 100 mL/hour.

Acetazolamide and sodium bicarbonate for urine alkalanization and solubilization of uric acid in urine. During this ensure that pH remains 7.0 and no volume overload.

In addition to this hemodialysis may be required.

Urate oxidase (rasburicase) can also be administered IV to prevent or to treat tumorlysis syndrome.[35]

Conclusion

Hyperuricemia is a purine metabolism disorder, asymptomatic condition usually does not require treatment while symptomatic individuals with or without complications may require urate lowering agent therapy.

CHAPTER

80 Risk Factors for Gout Flare

Udas Chandra Ghosh, Asish Mondal

Abstract

Gout, the most common form of crystal induced inflammatory arthritis, has developed flares due to some modifiable and non-modifiable risk factors. Male sex, increasing age, specific race, and ethnicity with some genetic preponderance are the non-modifiable risk factors. Alcohol, mutton, seafish with other purine rich foods in diet, diuretics, antitubercular medicines, etc. in drugs, chronic kidney disease, diabetes mellitus, hypertension, obesity, dyslipidemia, cardiovascular disease etc in comorbidities are modifiable risk factors. Lifestyle modification, dietary habits, and urate lowering therapy with patient education are important to prevent gout flare.

Introduction

Gout is the most common form of crystal induced inflammatory arthritis, mostly affecting the men. The clinical stages of gout are asymptomatic hyperuricemia, recurrent flares of inflammatory arthritis (gout flare), intercritical gout, chronic gouty arthritis, and tophus formation.

When there is super-saturation of serum uric acid concentration (i.e., ≥6.8 mg/dL in physiological pH and temperature), the monosodium urate (MSU) crystals are deposited in joints and subcutaneous tissues, which lead to acute inflammation and pain. Upon deposition of MSU in human fibroblast-like synoviocytes (FLS), it releases reactive oxygen species (ROS) and reactive nitrogen species (RNS), which lead to FLS necroapoptosis. MSU also can directly cause cytotoxicity and inflammation resulting necroapoptosis of synovium and is mediated by the receptor-interacting protein RIPK-1, RIPK-3, and the pseudokinase mixed-lineage kinase domain-like (MLKL)-driven necroapoptosis pathways. It is said that this necrosis is the primary event of crystal-induced necroinflammation. On the other side, MSU also involve caspase-1-activating NALP3 inflammasome, and produce active interleukin (IL)-1β and IL-18, the proinflammatory cytokines, which lead to influx and activation of neutrophils.[1] Activated neutrophils recruit and activate macrophages to release proinflammatory cytokines like IL-1, IL-6, IL-8, TNF-α, (COX)-2, and LTB-4 at the same time degranulation or lysis of cell membrane of the activated nutrophils results release of inflammatory mediators. The resolution of gout flare occurs due to increase concentration of negative regulatory factors of the inflammation which is initiated by aggregation of neutrophil extracellular trap structures (NETs) and also there is dissolution of MSU or protein coating of MSU crystals, which leads to turning off the ongoing inflammatory process.[2]

In the pathogenesis of gout there have a number of key regulatory points **(Flowchart 1)**. *At some of these points therapeutic interventions or risk factors elimination may retard the development of gout or prevent flare* **(Fig. 1)**.

Risk Factors

Risk factors for gout flares can be subdivided by non-modifiable and modifiable risk factors **(Table 1)**.

Flowchart 1: Key points of pathogenesis of gout

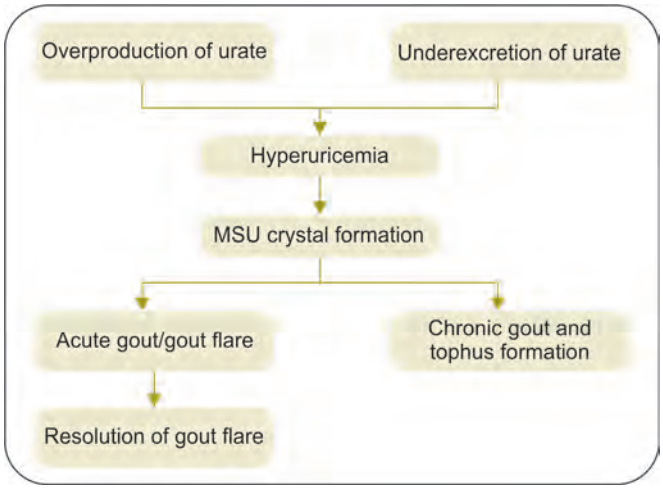

Fig. 1: Gout flare in first MCP joint

TABLE 1 Risk factors for gout flares

Non modifiable risk factors	*Modifiable risk factors*
• **Sex** • **Age** • **Race/ethnicity** • **Genetics**	• **Dietary factors** – Alcohol – Purine-rich foods: like meats, seafoods – Soft drinks, fructose consumption – Dairy product (protective effect) – Vitamin C (protective effect) – Cherry (protective effect) • **Drugs** – Diuretics – Anti tubercular drugs : Pyrazinamide, Ethambutol – Aspirin – Immunosuppressive agents Cyclosporine, Tacrolimus • **Comorbidities** – CKD – Hypertension – DM – Obesity – Cardiovascular disease – Hypertriglyceridemia & hypercholesterolemia • **Others** – Immunization – Post surgical periods – Urate lowering therapy (ULT) – Coffee

Non-modifiable Risk Factors

Sex

In below 65 age group people, male to female prevalence ratio is 4:1, but above 65 age group people this ratio reduced to 3:1. Mean age of onset in males is about 10 years younger than the females. This may be attributed to enhancement of renal tubular urate clearance in premenopausal women partly due to decrease post-translational expression of urate transporter 1 (URAT1), glucose transporter 9 (GLUT9), sodium-coupled monocarboxylate transporter 1(Smct1), and urate efflux transporter ATP-binding cassette sub- family G member 2(ABCG2) by the estrogen and progesterone resulting decreased reabsorption of urate from renal tubules. Male gender has higher numbers of gout flare than females.[3] The risk of incident gout was seen to be higher among the postmenopausal women but the women with surgical menopause or premature menopause (age <45 years) have higher incidence than to those with natural and average age of menopause. In postmenopausal women there is increased incidence of insulin resistance, which can reduce the urate excretion, and therefore hyperuricemia is more common in them than the premenopausal.

Age

The risk of hyperuricemia is strongly associated with increasing age. The chronic illness like diabetes, hypertension, cardiac diseases, renal diseases, etc. are more common in older age and also increases use of

diuretics are the another reasons for increased prevalence of hyperuricemia. The incidence of first flare is constant across the all age group and in female the incidence of first flare is more in older age group. Over all lower number of flare has been seen in older age group in a large population-based study in the UK.[4]

Race/Ethnicity

Study revealed African Americans had increased risk of gout than the Caucasian and the incidence rate were 3.11 and 1.82 respectively per 1,000 person-years, may be attributed to genetic predisposition with increased incidence of hypertension and use of diuretics in African Americans. In another study over the 20 years of follow-up, African American and Caucasian males had equal risk of incident hyperuricemia (HR 1.12, 95% CI, 0.88-1.40), whereas African American females had 2.3 times higher risk of hyperuricemia (95% CI, 1.34-3.99) than the Caucasian females.[5] Prevalence of hyperuricemia is more in the Māori population than the Europeans (27.1% vs. 9.4% in males and 26.6% vs. 10.5% in females, respectively) in New Zealand. This high prevalence is due to genetic predisposition with high prevalence of comorbidities like obesity, diabetes, hypertension in the background of genetic predisposition. In Southern China, higher prevalence of gout seen in the Minnesota Hmong males (6.1%) than the non Hmong males (2.5%). Age of onset of gout in Hmong males also have significantly younger than the Caucasians (37.4 vs. 55 years).[6]

Genetics

A study involving twins has found that gout is strongly heritable where 90% of the variation in gout concordance attributable to genetic factors. A similar approach revealed that 60% heritability of renal urate clearance and 87% heritability of the fractional excretion of urate. Recently the genome-wide association scanning (GWAS), a human genome project has enabled us to find out the genetic basis of hyperuricemia and gout to some extent. It is evident that the primary cause of gout in 90% of patients is renal under-excretion while renal excretion of uric acid is heritable. So the genetic variation in urate transporter plays a significant role to control serum urate level. The first reported association of the *SLC2A9* gene with serum urate concentrations in Italian cohorts was utilized in the Framingham and Rotterdam Heart Studies. Up to 5% variation of serum urate concentration in Caucasians has been explained by genetic variation of the *SLC2A9* gene. This variation also influences the risk of gout in Caucasians with odds ratio between 1.3 and 2.2. The said variants also become an extremely significant risk for gout in Māori of New Zealand and Pacific Island with a 500% increased risk (OR=5), and >98% of Māori and Pacific Island patients homozygous for the risk allele compared with 79% of NZ Caucasian patients.

SLC2A9 gene encodes glucose transporter type 9 (GLUT9), which is responsible for reabsorption of a large portion of urate. So mutation of *SLC2A9* can be suspected in patient of hypouricemia without mutation of other genes like *SLC22A12*. There are number of studies which have correlated polymorphisms in *SLC2A9* with uric acid levels and gout.

SLC22A12 encodes urate anion transporter 1 (URAT1), which is seen in the brush border of proximal tubules and also have significant role for reabsorption of urate. It was first identified in a Japanese patient having hypouricemia and the said gene was found to be mutated. Polymorphism has also been seen in *SLC22A12*.

ABCG2 encodes the adenosine triphosphate (ATP)-binding cassette transporter 2 (ABCG2), which mediates utrate secretion across the apical membrane of proximal tubules. The variants were indentified through GWAS and mutation of it can cause hyperuricemia.[6,7]

Modifiable Risk Factors

Dietary Factors

Alcohol: We all know that consumption of ethanol beverages, especially beer, is significantly associated with higher risk of incident gout. In few study, wine appears to protective against gout flare but Tuhina Neogi et al. (2014), concluded that the episodic alcohol consumption, regardless of type of alcoholic beverage, was associated with higher risk of gout flares.[8] Beer contains significant amount of guanosine, which is most readily absorbed purine, responsible for high urate production. A study to compare increase of serum uric acid level between alcoholic beer to nonalcoholic beer revealed that plasma uric acid levels had increased 6.5% and 4.4% ($p<0.05$), respectively points out that purine load alone had a significant effect on uric acid level. Ethanol increases uric acid production by increasing ATP degradation to uric acid precursors. It also causes lactic academia, which results in decrease urate excretion.

Purine-rich foods: Uric acid is the end product of purine degradation. Intake of purine rich foods such as meat or sea food is associated with hyperuricemia and incident gout.[9] Choi et al. found in their study that the differences in uric acid levels between the extreme quintiles of intake were 0.48 mg/dL for total meat (95% confidence interval [95% CI] 0.34, 0.61; P < 0.001 for trend), 0.16 mg/dL for seafood (95% CI 0.06, 0.27; P = 0.005 for trend), after adjusting for age.[10] Yuqing Zhang and his colleagues proved that 2 days intake of highest quintile of purine, mainly from animal source increases the risk of flare almost five times than the lowest quintile of purine and the association was independent of other risk factors like sex, alcohol consumption, diuretics or allopurinol use. Long-term moderate amount of purine rich vegetables (like—lentils, spinach, mushrooms, peas, and cauliflower) intake are not associated with gout flare.[10] Although soy has moderate purine content, it also not been shown to be associated with gout rather it may be inversely associated with hyperuricemia.

Soft drinks, fructose consumption: In first step of fructose metabolism there is phosphorylation by ATP, which accelerates purine catabolism and de-novo purine synthesis. Fructose may increase the risk of insulin resistance which can cause reduction of renal excretion of urate and leads to hyperuricemia. Sugar sweetened soft drinks and fruit juices contain high concentration of fructose, the intake of which is associated with high level of serum urate and may be an important risk factor for frequent gout flare. NHANES, a cross-sectional study showed increased in urate of 0.33 mg/dL (95% CI, 0.11-0.73) in participants drinking 1-3.9 sugar-sweetened servings per day than those drinking none after adjustment for diet including total energy intake, age, sex, medications, hypertension, and glomerular filtration rate. Men who ingested the highest 5th of fructose incurred double the risk of gout than those in the lowest (RR 2.02, 95% CI, 1.49-2.75) after adjustment for intake of total carbohydrate.[11]

Dairy products: Increased amount of dairy products intake is associated with decreased level of urate and incident gout. It has been shown in a study that the glycomacropeptide (GMP), a milk fragment and G600 milk fat extract have anti-inflammatory effects and they acts by decreasing interleukin-1β (IL-1β) expression, which may be the second protective role of dairy product.

Vitamin C: Vitamin C has a protective role against gout. It increases renal clearance of urate by increasing fractional excretion of uric acid. Vitamin C competitively inhibits the urate reabsorption in proximal tubules. In an RCT where significant reduction of serum uric acid levels was seen with supplementation of 500 mg/day of vitamin C and the mean uric acid reduction was 0.5 mg/dL (95% CI, -0.6 to -0.3).[12]

Cherry: In a case-cross over study, consumption of cherry was found to lower recurrent gout attacks by 35%. This beneficial effect of cherry may be due to its effects on glomerular filtration and probable inhibition of xanthine oxidase along with having its antioxidant properties.

Drugs

Diuretics: Diuretics can cause hyperuricemia by increasing uric acid reabsorption in the proximal tubules, increasing secretion of uric acid and contraction of plasma volume. Increased level of urate usually seen few days after initiation of diuretics and the association is dose dependent, and the concentration persists for prolonged period of administration. Hunter et al. (2006) pointed out that recent use of diuretics is associated with a significantly higher risk for gout flare.

Anti-tubercular drugs: Pyrazinamide can cause more than 80% reduction in renal excretion of uric acid at 300 mg therapeutic daily dose and precipitate gouty attack. The active metabolite of pyrazinamide has a trans-stimulatory effect on URAT1, a member of the organic anion transporter (OAT) family, resulting reabsorption of urate from renal tubules. So patient having first attack of gout should monitor the uric acid level and needs prompt discontinuation of the drug on recurrent gout flare. Another drug, *Ethambutol*, can also increase SUA and precipitate the attack.

Immunosuppressive agents: Cyclosporine use in an organ transplant recipient is most important predictors of incident gout and gout flare. Recently *Tacrolimus* also to be seen associated with hyperuricemia and gout flare but relatively less in frequency may be due to impairment of renal functions which is seen more frequently in cyclosporine use.

Aspirin: Studies shows that low dose *aspirin* can cause hyperuricemia but in contrast high dose aspirin is shown to have uricosuric effect. This paradoxical effect is due to fact that low dose of aspirin acts as facilitator of urate reabsorption and high dose acts as inhibitor of urate reabsorption through Renal Urate Transporter (URAT1).[13]

So intake of low dose aspirin can causes acute or recurrent gout flare and acts as an important risk factor.

Comorbidities

Hyperuricemia is commonly seen in chronic kidney disease (CKD) and is frequently associated with incident gout and recurrent gout flare, which requires adequate ULT. Hyperuricemia in CKD is due to decrease urinary clearance of uric acid. Approximately two-thirds of uric acid is excreted through kidney and is severely impaired in depressed renal function. Obesity shows to a strong risk factor for incident gout and flare in those having previous attack. Hypertension is consistently seems to be another risk factor for flare up especially with diuretic use. It is concluded in various studies that in hypertension and cardiovascular disease there is increased xanthine oxidase activity and high serum urate level. Diabetes is an independent risk factor. Suppiah et al. (2008) demonstrated that gout is highly prevalent in patients with type 2 diabetes and highest (41%) in men over the age of 65 years and requires early recognition and management. Hypertriglyceridemia and hypercholesterolemia both are associated with gout flare.

Other Risk Factors

Immunization is a pro-inflammatory trigger, which can also acts as a trigger for gout flare. An internet-based case-crossover study showed that immunization doubled the risk of a gout flare within the ensuing 48 hours of vaccination compared with periods in not vaccinated people (odds ratio [OR] 1.99, 95% CI 1.01-3.89).[9]

There is an increased incidence of gout flare in *post-surgical periods*. Study shows patient having a previous history of gout who undergoes laparoscopic gastric bypass surgery can frequently develop gout flare. Increase release of fat, starvation, volume contraction may all responsible for high serum urate levels in post-surgical periods.

Initiation of *urate lowering therapy (ULT)* may precipitate a gout flare, especially in early months but in long-term use it can prevent or reduce the frequency of flare. So adequate anti-inflammatory prophylaxis overlap for some duration may sometimes be needed while initiating ULT.

Intake of *coffee* is protective for gout flare. It increases renal blood flow, and hence increases urate excretion. Again it may increases the insulin sensitivity, which has a positive role for urate clearance.

Conclusion

Gout flare is very much common and a large number of patients of incident gout develop at least one flare in their lifetime. The predisposing factors for gout flares act on various points of its pathogenesis. Few factors have protective effect also. For prevention of gout flares daily consumption of alcohol must be reduced or stopped, composition of diet is to be changed, dietary supplementation like Vit. C, cherries is to be given, ideal body weight must be maintained, comorbidities should adequately be managed and anti-inflammatory prophylaxis may be needed in early months of initiation of ULT in an incident gout patient. Moreover, patient's education is important for proper lifestyle modification and pharmacological therapy other than ULT in gout patients with comorbidities.

CHAPTER

81 Vitamin D—A Hope or Hype?

Sanjay Dash

Abstract

Healthy bone is dependent on interplay between vitamin D, calcium, and phosphates. In addition to its important role in maintaining bone health, a new area of vitamin D's role in pleiotropic activities unrelated to skeletal metabolism is now recognized and it is now increasingly being clear that optimum levels of vitamin D is also important in preventing several other dreaded chronic diseases including DM, CVD, and malignant diseases. Osteoporosis and fractures are common in elderly population and one of the most important causative agents is hypovitaminosis D. Hypovitaminosis D prevalence in India is widespread. Correction of vitamin D deficiency improves skeletal health and prevents rickets in younger population, osteoporosis, and fractures in elderly population. There are plethora of research suggesting the extra-skeletal benefits of vitamin D.

Introduction

Healthy bone is dependent on interplay between vitamin D, calcium, and phosphates. Vitamin D facilitates absorption of calcium from gut and plays a major role in calcium and phosphate balance in the body.

The major source (90%) of its availability is through dermal synthesis in the presence of Sunlight. Vitamin D is also ingested in the diet as vitamin D_2 (ergocalciferol), mainly from some plants and UV irradiated yeast & mushroom and vitamin D_3 (cholecalciferol) from animals (oily fish and fish liver oils).

Its deficiency accelerates bone turnover and bone loss leading to rickets in children, where the cartilage is not formed, osteomalacia, where the newly formed bone matrix (osteoid) is not mineralized and osteoporosis, the latter causing falls and fractures in elderly people. In addition to its important role in bone health, it also has some role in preventing several other dreaded chronic diseases including diabetes mellitus (DM), cardiovascular disease (CVD), and malignant diseases.

Metabolism

The precursor of vitamin D, 7-dehydrocholesterol, present in the epidermis and dermis, is converted nonenzymatically to pre-vitamin D_3 during exposure to solar rays (UV-B radiation of wavelength 290–320 nm). At body temperature this undergoes rearrangement of its structure and gets converted to vitamin D_3. Vitamin D_3 from the skin or vitamin D_2 from plant sources is biologically inactive. They enter the circulation bound to vitamin D binding protein (DBP) and reach liver and get converted enzymatically to 25(OH) vitamin D. It reaches kidneys bound again to DBP. The crucial active vitamin D1, 25-dihydroxyvitamin D or calcitriol is synthesized here. Both serum calcium and phosphorous as well as serum parathormone (PTH) have important role in regulating its synthesis in kidneys.[1] As serum calcium and phosphate levels rise the production of $1,25(OH)_2D$ falls. Vitamin D level in turn regulates its own synthesis. As its level becomes optimal the synthesis of PTH decreases. From the kidneys $1,25(OH)_2D$ reaches intestine and bone

where its major action in increasing calcium absorption from the gut happens. Also, through osteoclastic activity in bone, calcium and phosphorous are drawn out. All these help in maintaining serum calcium and phosphorous levels. Vitamin D receptor (VDR) presents in these tissues helps in this action. VDR acts in the nuclei of vitamin D target cells to regulate the expression of genes whose products control diverse, cell type–specific biological functions. $1,25(OH)_2D$ stimulates the absorption of calcium in the duodenum and increases calcium influx in distal tubules of kidney through nuclear VDR; latter action is specifically regulated by PTH level. It also stimulates intestinal phosphate absorption, directly suppresses PTH release from the parathyroid gland, regulate osteoblast function. It allows PTH-induced osteoclast activation and bone resorption.

Normal Value of Vitamin D and Defining Hypovitaminosis

Though brief casual solar exposure is equivalent to ingestion of 200 IU/day, this depends on variables like the skin type, latitude, season, time of day, atmospheric pollution, solar zenith angle, and melanin pigmentation. The solar zenith angle is more oblique in winter season and during early morning and late afternoon. Before 10 am and after 3 pm the UV-B rays penetrating the earth is at minimum levels and Vitamin D synthesis through skin layers is negligible during this time period. Prolonged UV-B radiation converts pre-D3 to lumisterol and tachysterol, its inactive metabolites, protecting the body from vitamin D toxicity.

As 25(OH)D levels rise serum PTH falls. Once vitamin D level reaches 40 ng/mL PTH level stops rising further.[2] Intestinal absorption of calcium increases from 45% to 65% when vitamin D level increases from 20 ng/mL to 32 ng/mL in women.[3]

Currently serum total (25[OH]D) concentration (sum of 25-hydroxyvitamin D_3 and D_2) is considered the best biomarker to define vitamin D status.[4] It has a long half-life of 2–3 weeks. Its deficiency leads to rickets and osteomalacia and with adequate intake of vitamin D both these diseases disappear with increase in vitamin D levels. A level below 12 ng/mL usually causes rickets and osteomalacia. For a healthy bone, levels between 20 ng/mL and 50 ng/mL is required.[5]

A minimum level of 20 ng/mL of serum 25(OH) D is enough for roughly an entire population (97.5%) requirement. A level above 50 ng/mL may cause undesirable effects.[6]

Biochemically, a deficient state is defined when 25(OH)D levels are less than 20 ng/mL and an insufficient state when levels hover between 20 ng/mL and 29 ng/mL.[7]

ICMR/FSSAI's recommendation on RDA of vitamin D is 400 IU—all age groups. Other scientific organizations have developed RDA basing upon age to 400–800 IU.[7,8]

Magnitude of Hypovitaminosis D in India

Hypovitaminosis D prevalence in India is widespread. Community-based studies[9-12] report a prevalence varying from 56% to 93% indicating widespread prevalence in both sexes and all age groups. Most of these studies have taken a cut off value of 25(OH)D as less than 20 ng/mL.

Vitamin D Deficiency and Its Effects on Skeletal Health

A vitamin D deficient patient is able to absorb only 10–15% of dietary calcium and about 60% of dietary phosphorus. Hypophosphatemia and hypocalcemia are a consequence. Persistent vitamin D deficiency leads to secondary hyperparathyroidism. This in turn causes increased synthesis and secretion of PTH. By increasing calcium absorption from kidneys PTH keeps calcium levels at near normal levels. It also stimulates osteoclastic activity. The net result is, though the serum calcium level increases but the casualty is bone matrix which becomes weak and osteopenia and osteoporosis sets in. Hip fracture is an unfortunate consequence of secondary hyperparathyroidism. Chronic severe vitamin D deficiency results in bone demineralization causing osteomalacia in adults and rickets in children. This also leads to increased bone pain. So, Vitamin D is a bridge between a healthy bone and calcium-phosphorus balance in the body.

Non-calcemic Functions of Vitamin D

For the last several decades scientists are trying to ascertain if there is a role of vitamin D in preventing various chronic metabolic, cardiovascular, autoimmune, and neoplastic diseases. They have detected the presence of VDR in almost all cells and tissues in the body including

neurons in the brain, gut, breast tissue, immune cells and several other cells. It has been shown that the conversion of 25(OH)D to $1,25(OH)_2D$ is possible in many tissues and cells besides kidneys. This realization has opened a new area of vitamin D's role in pleiotropic activities unrelated to skeletal metabolism. This active form of vitamin D gets metabolized into calcitroic acid and become inert locally and does not reach the circulation to act on skeletal metabolism. Only $1,25(OH)_2$ D, which is produced in kidneys can be exported to the blood stream. This locally produced active form of vitamin D influences several genes which prevent proliferation of cells and can cause apoptosis too.

Cancer

Studies have shown at least 14 cancers, including colorectal, breast, and prostate are related to vitamin D deficiency.[13-15]

Serum vitamin D level ≥33 ng/mL, compared to ≤12 ng/mL was associated with 50% lower risk of colorectal cancer.[16]

WHO working group has found link between increased risk of colorectal cancer with low serum vitamin D levels.[17]

A meta-analysis of prospective studies has shown that the risk of cancer breast decreased with vitamin D levels between 27 and <35 ng/mL with flattening of effects above 35 ng/mL in postmenopausal women.[18]

Several studies have underlined the fact that countries which are at a distance far away from equator have more risks of suffering from certain cancers. This may be because of less sun exposure and decreased UV radiation causing less vitamin D synthesis in higher altitudes.[19-22]

Several observational studies and a few RCTs[23-25] have shown that high normal vitamin D levels are linked to decreased incidence of several malignancies including colorectal, breast, prostate, etc. Some have also shown decreased mortality rates due to cancer.[25]

Immune System

VDR and vitamin D metabolic enzymes are present in almost all cells of innate and adaptive arms of immune system including dendritic cells, B and T cells, and macrophages. Researchers have found that all these cells produce active vitamin D without calcium homeostatic regulation.[26]

Researchers have found that vitamin D reduces activation of acquired immune system whereas it activates the innate immune system particularly monocytes and macrophages.

Multiple sclerosis in north and south hemisphere, T1DM and RA in north hemisphere are found in increasing numbers at higher altitudes where UVR is less. Studies have shown that UVR downregulates cellular immunity by attenuating T helper T cell mediated immune responses. UVR thus might be beneficial in MS, T1DM, and RA. One of the possible mechanisms for downregulation involves UVR induced vitamin D synthesis. Thus, vitamin D may have a protective role in preventing T1DM.[27]

Observational studies have found a strong link between prevalence of MS and less than normal vitamin D levels.[28,29]

Risk for developing active TB and its link to low levels of vitamin D has been found in one meta-analysis,[30] whereas vitamin D supplementation can enhance rapid clearance of sputum in active TB;[31] it can also protect against respiratory infections.[32]

In conclusion, a link between vitamin D endocrine system and immune system is highly plausible, but whether its deficiency has real implications for infections or autoimmune diseases is yet to be confirmed by large scale RCTs.[33]

Cardiovascular Diseases

Several genes playing important roles in CV system are targets of vitamin D signaling, including those encoding renin, PAI, and thrombomodulin.

Conclusion from a meta-analysis of 19 prospective studies is that risk of CVD is inversely associated with vitamin D levels of 8–24 ng/mL.[34] Similar conclusion is derived from another meta-analysis of 34 publications related to vitamin D levels and CVD events and mortality.[35] In contrast, VIDA trial did not support such an association.[36]

In northern hemisphere as one goes from south to north the incidence of hypertension increases. One reason could be reduction of solar induced vitamin D synthesis. Animal studies have shown VDR null mice develop high renin hypertension.[37] Some studies support inverse relationship of BP and vitamin D levels[38] whereas others do not.[39]

Vitamin D and Skin

Keratinocytes express all enzymes of vitamin D metabolic pathway and skin can synthesize its active form in presence of solar UV-B rays. Active vitamin D produced locally controls keratinocyte proliferation and differentiation as well as epidermal barrier integrity. Topical application of vitamin D analogues reduces the symptoms of psoriasis, probably due to its anti-inflammatory properties and effects on epidermal cell proliferation.

The same wave lengths of UV-B solar rays, which are required for dermal synthesis of vitamin D, are also oncogenic. It is therefore a difficult choice to make how much of solar rays one must be exposed to while avoiding long-term risk of developing skin cancer.[33]

Vitamin D and Muscle Weakness

Muscle strength correlates positively with vitamin D levels in elderly male patients.[40]

Proximal muscle strength may modestly improve with vitamin D supplementation given to elderly subjects with vitamin D levels <12 ng/mL.[41]

Some studies[42] have found no effect on reducing risk of falls with vitamin D supplementation.

Overall, the data suggests vitamin D supplementation in elderly vitamin D deficient subjects may modestly improve muscle function, improve balance, and decrease the risk of falling.[33]

Type 2 DM

The risk of developing T2DM is reduced with higher vitamin D levels.[43]

Mortality

A recent meta-analysis of observational studies and RCTs which reported associations between vitamin D and cause specific mortality outcomes has concluded that there is inverse relationship between vitamin D levels and risk of death due to CV disease, cancer, and other causes and also vitamin D supplementation significantly reduces overall mortality among older adults.[44]

Treatment of Vitamin D Deficiency

The usual adult dose for treatment of vitamin D deficiency is 60 K IU of vitamin D_3/week given for 8–12 weeks followed by maintenance dose of 60 K IU once every month.

Conclusion

Vitamin D deficiency is quite prevalent in India. It is now recognized as an important health problem, which needs to be addressed by stakeholders. Vitamin D deficiency and skeletal consequences are well known. There is significant improvement in rickets when treated with vitamin D supplements. Though several researchers have pointed out the relationship between vitamin D status and non-skeletal diseases, more research is required to conclusively prove the link.

CHAPTER

82 Hyponatremia—An Update on Diagnosis and Treatment

Samir Sahu

Abstract

Hyponatremia, defined as serum sodium concentration of less than 135 mEq/L, is a common electrolyte disorder that often poses a diagnostic and a therapeutic challenge. The primary aim of the diagnosis is to differentiate between acute (<48 hours) versus chronic (>48 hours), symptomatic versus asymptomatic and hypotonic versus non-hypotonic hyponatremia. Further, hypotonic hyponatremia is differentiated on the basis of volume status, urine sodium, and urine osmolality. The treatment for hyponatremia is decided on the basis of duration and symptoms. For acute symptomatic hyponatremia and severe chronic hyponatremia, bolus of 3% hypertonic saline is the initial treatment of choice. Though the first-line therapy for most forms of chronic hyponatremia is fluid restriction, therapy to increase renal-free water excretion like vasopressin receptor antagonists, loop diuretics, and urea are often necessary.

Introduction

Hyponatremia is a common electrolyte disorder, defined as sodium concentration below 135 mEq/L.[1] It is a state of relative water excess to sodium. With the expanding use of various medications and the growing elderly population, the incidence is on a rising trend. Among the inpatients, especially in ICUs, the incidence is up-geared to 15–30%.[2] Consequences will be catastrophic, if not treated with prompt measures. Hence, a well-directed investigation from the gamut of tests available helps in quick and accurate diagnosis. Incorporating the recent concepts in the management reduces the morbidity and mortality.

Definition and Background

Plasma Osmolality (P_{osm}): It's the ratio between plasma solutes and water. The major contribution of plasma solutes is provided by sodium salts while rest by other ions (e.g., potassium), glucose, and urea.

$$\text{Plasma osmolality} = 2 \times [\text{Na}] + [\text{glucose}]/18 + \text{blood urea nitrogen}/2.8$$

Urine Sodium (U_{Na}): Urine sodium is a measurement of the concentration of sodium in the urine. On spot estimation, the values are normally more than 20 mEq/L.

Urine Osmolality (U_{osm}): Urine osmolality is the measure of number of dissolved particles per unit of water in the urine. Urine osmolality in an individual with a normal diet and normal fluid intake ranges 500–850 mosm/kg water.

Osmotic Demyelination Syndrome (ODS): A dreaded disorder characterized by the wide spread development of demyelination in the pontine as well as the extrapontine regions usually because of rapid correction of hyponatremia.

Classification and Symptoms of Hyponatremia

See **Table 1**.

TABLE 1 Classification of hyponatremia based on duration, serum sodium, and symptoms

Severity	*Serum sodium*	*Duration*	*Neurological symptoms*
Severe	<120 mEq/L	Acute (<48 hours)	Vomiting, seizures, coma, cardiorespiratory distress
Moderate	120–129 mEq/L		Nausea without vomiting, confusion, headache
Mild	130–134 mEq/L	Chronic (>48 hours) or duration unknown	Altered mood, concentration and cognitive deficits, gait disturbances, falls

Evaluation

History

A history of electrolyte-rich fluid loss (vomiting, diarrhea, or diuretic therapy) may indicate hypovolemia. Past history of CNS disease, malignancy, HIV infection, and plasma cell dyscrasia may add important clue to the diagnosis.[3] History of common drugs causing hyponatremia (thiazide diuretics, mannitol, antidepressants, antiepileptics, antipsychotics, and ecstasy (methylenedioxymethamphetamine) should not be missed.

Physical Examination

Peripheral edema and/or ascites may be a manifestation of renal failure, cirrhosis, or heart failure. Look for signs of extracellular volume depletion such as decreased skin turgor, tachycardia, orthostatic or persistent hypotension.[3] Sometimes patient may present with only signs of adrenal insufficiency or hypothyroidism.

Investigations

Laboratory testing is almost always essential to establish the diagnosis. Investigations helpful in the initial evaluation of hyponatremia include: complete blood count, serum glucose, urea, creatinine, sodium, potassium, chloride bicarbonate, calcium, lipid profile, and liver function test. U_{osm} and U_{Na} play an inevitable role in the evaluation of hyponatremia **(Flowchart 1)**.

Differential Diagnosis

Hyponatremia may be divided into:

- Pseudohyponatremia
- Isotonic or hypertonic hyponatremia
- Hypotonic hyponatremia

In the first two situations, hyponatremia and hypoosmolality are discordant; these are important to recognize, as they represent situations where hyponatremia need not be treated.

Pseudohyponatremia

Hyperlipidemia, hyperproteinemia, plasma cell dyscrasia.[4]

Isotonic or Hypertonic Hyponatremia

Sodium concentration falls by approximately 2 mEq/L for each 100 mg/100 mL rise in glucose concentration. Other causes include mannitol, IVIG, and absorption of glycine or sorbitol, the irrigation solutions during transurethral resection of prostate.[1]

Hypotonic Hyponatremia

Most have hypotonic hyponatremia, as serum sodium concentration remains one of the major determinant of tonicity. Evaluation of hypotonic hyponatremia has to be done meticulously **(Flowchart 1)**. Severely reduced glomerular filtration rate (GFR) and intake of thiazide diuretics are important causes of hypotonic hyponatremia.

Severely Reduced GFR: Free water excretion is significantly reduced in advanced renal impairment (e.g., GFR <15 mL/min) leading to hyponatremia.

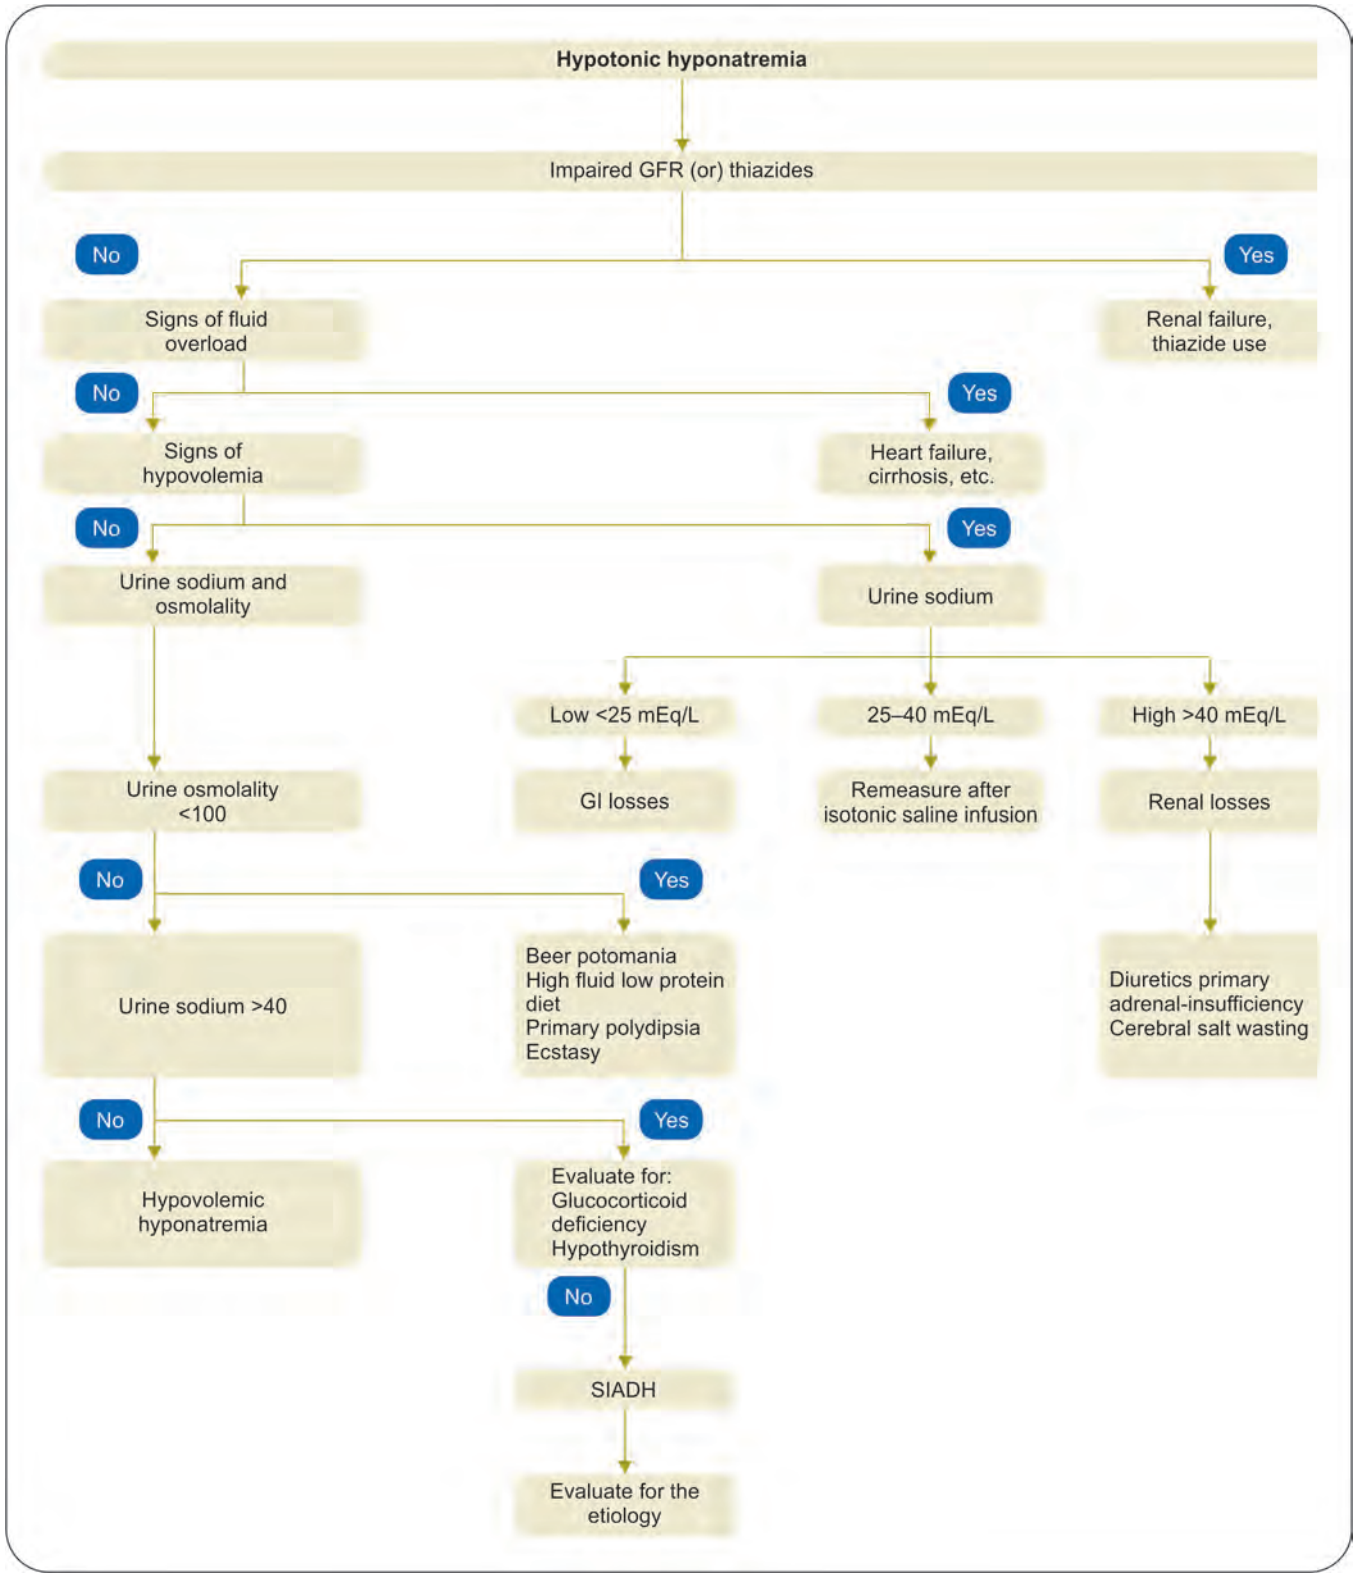
Thiazides: An occasional but a severe complication of thiazide typically begins soon after onset of therapy; but at times occur on long-term therapy. Improvement on discontinuation helps to distinguish from syndrome of inappropriate antidiuretic hormone (SIADH), which also shares similar features.[3]

Those patients, who do not have either of the above, should be evaluated for the evidences of fluid overload. They can be classified as hypervolemia, euvolemia and hypovolemia.

Hypervolemia

The major causes of hyponatremia in fluid overload conditions include heart failure (HF) and cirrhosis, typically in advanced stages. In spite of excess plasma and extracellular volumes in the above, the carotid sinus baroreceptors sense a reduced pressure, because

Flowchart 1: Approach to determine the cause of hypotonic hyponatremia



of a fall in cardiac output in heart failure and arterial vasodilatation in cirrhosis.

Hypovolemia

Clinical features of hypovolemia are not always diagnostic. It may be either due to a renal fluid loss or an extrarenal fluid loss. Measurements of U_{Na} and Urine chloride (U_{Cl}) concentrations distinguishes both.[5]

- *Low U_{Na} (<25 mEq/L):* Seen in patients of gastrointestinal fluid losses (e.g., diarrhea) and in renal fluid loss due to diuretics, if measured after the diuretic effect has abated.
- *High U_{Na} (>40 mEq/L) with low U_{Cl} (<25 mEq/L):* Seen among hypovolemic hyponatremic patients with metabolic alkalosis caused secondary to vomiting.
- *High U_{Na} and U_{Cl} concentration (>40 mEq/L):* Commonly seen during diuretic therapy with its effect still on. Other causes of renal fluid loss with hyponatremia are primary adrenal insufficiency and cerebral salt wasting syndrome (CSW). Clinical features of hypovolemia differentiates CSW from SIADH.[6]

Euvolemia

- *Low U_{Na} (<25 mEq/L) with Low U_{osm} (<100 mosmol/kg):*
  - *Primary polydipsia:* It is usually seen in psychiatric patients. It may cause hyponatremia when water intake is so high that it exceeds the normal excretory capacity in spite of it being normal. Once water intake stops, the serum sodium concentration will increase spontaneously.
  - *Malnutrition:* It occurs in beer drinkers (beer potomania) or in those on a low-protein, high-water diet, in which dietary solute intake (sodium, potassium, protein), and therefore solute excretion is so low that the rate of water excretion is markedly diminished even though urinary dilution is intact.
- *High U_{Na} (>40 mEq/L) and U_{osm} (>300 mosmol/kg):*
  - *SIADH:* The most common cause of hyponatremia in euvolemic patients is a diagnosis of exclusion. The patient may also have other corroborative features like hypouricemia (<4 mg/dL), and low blood urea nitrogen (<5 mg/dL). The underlying mechanism is presumed to be due to increased clearance of uric acid and urea respectively, as a result of water retention and volume expansion in the SIADH and stimulation of V1a receptor via an uncertain mechanism.[7] Administration of normal saline worsens the hyponatremia.
  - *Reset osmostat:* They present similar to SIADH, with a moderately reduced plasma sodium concentration (usually between 125 and 135 mEq/L), that is stable on multiple measurements.
  - *Severe hypothyroidism:* Causes hyponatremia via uncertain mechanisms.
  - *Cortisol deficiency:* Secondary adrenal insufficiency (hypopituitarism), in contrast to primary adrenal insufficiency, presents with euvolemic hyponatremia and biochemical features similar to SIADH. The mechanism is found to be due to the interruption of negative feedback loop of cortisol on antidiuretic hormone (ADH) secretion and hypersecretion of ADH as a result of reductions in systemic blood pressure and cardiac output.[1]

Treatment

Aims of Therapy

- *Prevention of further fall in serum sodium:* The patients prone to develop are self-induced water intoxication and parenteral fluid administration.
- *Prevent brain herniation:* The vulnerable are, patients with acute hyponatremia and associated intracranial pathology.
- *Relieve symptoms of hyponatremia:* Even the most severe symptoms can be relieved by a correction of sodium levels by 4–6 mEq/L during the first 24 hours.
- *Avoid over correction:* Rapid correction of chronic hyponatremia may lead to ODS.[1] To avoid this, the **maximum rate of correction** should be 8 mEq/L in any 24-hour period. The risk factor of ODS are mentioned in **Table 2**.

Indications for Hospitalization

- Acute hyponatremia
- Symptomatic hyponatremia
- Severe hyponatremia

Acute Symptomatic Hyponatremia (or Chronic with Severe Symptoms)

Severe symptoms are reflective of brain edema, small increase in serum sodium concentration may be sufficient

TABLE 2 Risk factors for ODS

Risk factors
• Serum sodium ≤105
• Hypokalemia
• Alcoholism
• Malnutrition
• Liver disease

enough to improve edema and prevent herniation;[7] failing, death may follow rapidly. Since there is no brain adaption with acute hyponatremia, chances of ODS is little.

Intravenous (IV) infusion of 150 mL, 3% saline over 20 minutes to achieve a target of 4–6 mEq/L increase in serum sodium. The same dose shall be repeated with serum sodium monitoring after every infusion. In non-responders, continue infusion with 3% saline aiming at 1 mEq/L/hr increase in serum sodium concentration.[8] Adrogué–Madias equation [Change in Serum Na = (infusate Na – serum Na)/(tbw+1)] may be used for estimating the correction rate, while serum sodium being monitored 4 hourly. Etiology specific treatment is preferred once the desired levels are attained.

Acute Asymptomatic Hyponatremia

Even though the symptoms are not much pronounced, an acute drop in serum sodium to a level more than 10 mEq/L, may worsen the clinical condition. Hence, patients at risk are to be treated with a single IV infusion of 150 mL 3% saline, so as to prevent further drop.[8] Serum sodium to be monitored every 4 hourly, till the cause specific treatment is initiated.

Chronic Asymptomatic Hyponatremia

These patients are particularly predisposed to develop ODS from rapid correction. If the hyponatremia is severe (<120 mEq/L), initiate IV infusion of 3% saline at 15–30 mL/hr targeting a maximum correction of 8 mEq/L. After sodium correction in these patients and also in cases of mild to moderate hyponatremia, provide a cause specific treatment.[8]

Treatment of Specific Hyponatremia

- *Hypovolemic hyponatremia:* Gastrointestinal losses, vomiting, and diarrhea and renal loss secondary to diuretics are accompanied by hypokalemia, where measures should be taken to correct hypokalemia first rather than hyponatremia.[8] Sodium and potassium being the exchangeable ions, with correction of potassium, sodium levels are restored; however, correcting sodium levels first, risks ODS, due to the rapid correction. Extracellular volume must be restored with IV infusion of 0.9% saline or a balanced crystalloid solution at 0.5–1.0 mL/kg/hr[9] to achieve the desired sodium levels. In primary adrenal insufficiency after the initial measures, fludrocortisone may be added along with hydrocortisone.
- *Euvolemic hyponatremia:* This area remains a challenge in clinical practice. The clinical presentation varies and often has some underlying disease.
  - *SIADH:* Fluid restriction is conventionally considered as the first line of treatment. However, the response to therapy depends on the levels of AVP. Oral salt may be added among patients with serum sodium above 120 mEq/L and very mild or absent symptoms. Loop diuretics shall be used as a concurrent therapy in patients with urine osmolality above 500 mosmol/kg. Urea is considered as an alternative to the combination of loop diuretics and oral salt.[10] It has the advantage over any, as it corrects hyponatremia gradually without risk of over correction.[9] However, poor palatability and azotemia had made its use limited in clinical practice. Vasopressin (V2) receptor antagonists (Vaptans) can be added if adequate response is not noticed. Tolvaptan, an oral V2 receptor antagonist initiated at 15 mg/day, can be gradually titrated by 15 mg/day to a maximum dose of 60 mg/day. The commonly noticed side effects are dry mouth, thirst, increased urinary frequency, dizziness, nausea, and orthostatic hypotension.[11] Although hepatotoxicity was not noticed in the recent studies, early trials had shown elevation of alanine aminotransferase (ALT). Hence, its use should be restricted to 30 days and not to be used in patients with underlying liver diseases. Of utmost importance is liberal fluid intake, especially during first 24–48 hours, since Vaptans clear free water and there are high chances for rapid correction with fluid restriction.[1] Monitor serum sodium concentration 6–8 hourly till 48 hours.

- *Hypothyroidism:* Thyroxine replacement along with fluid restriction suffice.
- *Glucocorticoid deficiency:* Nearly always responds to glucocorticoid replacement. Prompt water diuresis following initiation of glucocorticoid treatment supports the diagnosis.
- *Primary polydipsia:* Counseling for fluid restriction and alternative methods such as wetting the mouth with ice chips, ameliorates sensation of thirst and helps to reduce fluid intake. Studies had shown favorable role of antipsychotic drugs in reduction of polydipsia and prevention of recurrent hyponatremia.[1]

- *Hypervolemic hyponatremia:* Hyponatremia in hypervolemic conditions such as liver cirrhosis, HF, and end stage renal failure heralds a poor prognosis. Notwithstanding the cause, the primary treatment rests on sodium and water restriction. Fluid restriction to 50–60% of daily fluid requirement or a gross restriction to daily input of less than 800 mL/day is generally followed. Loop diuretics interferes the counter current mechanism in the thick ascending loop of Henle, giving rise to a state of ADH resistance, resulting in less concentrated urine. Vaptans can be added in HF and liver cirrhosis.

Treatment of Sodium Overcorrection

In situation where there is over correction of hyponatremia, electrolyte-free water is infused at 10 mL/kg over 1 hour while urine output and fluid balance are strictly monitored. In addition, IV desmopressin 2 µg, not more than 8 hourly, may be considered after expert opinion.[8]

Conclusion

The laboratory investigations plays a key role in diagnosis of specific causes of hyponatremia, besides the goal directed history and physical examination. Amongst them, the widely and cheaply available U_{Na} and U_{osm} are the crucial decision-makers. The recent evidence supports bolus infusion of hypertonic saline, for certain serious conditions of hyponatremia. Correction rate should not exceed 8 mEq/L in any 24 hours, irrespective of the duration and severity.

CHAPTER

83 Osteoporosis "The Battle Still to Overcome"

Niraj Lodha, Divyansh Mathur, Naman Lodha

Abstract

Osteoporosis is common silent disease. Its prevalence increasing due to increase in geriatric population. It is associated with increase in morbidity and mortality in elderly population. Prevention of first fracture and targeting young population for primary prevention is key in successful management of this chronic problem.

Introduction

With the increase in the life expectancy, the geriatric population is rising worldwide; therein increasing the cascade of "Non-infectious chronic diseases". Amongst them, osteoporosis being a silent killer is one of the important causes of mortality and disability.

Osteoporosis is defined as low bone mineral density (BMD) caused by altered bone strength ultimately predisposing patients to low impact fragility fractures. Strength of bone is assessed by its mass and quality. Osteoporosis is a process that develops gradually over many years as we age.[1]

Incidence

Decrease bone strength and fragility fractures are common worldwide. It is estimated that around 13–18% of women above 50 years of age are osteoporotic. Fracture risk in these women is around 40% in the remaining life. In a longitudinal study in USA on 200,000 asymptomatic women above 50 years without known osteoporosis, BMD test was performed.[2] In this study 40% had osteopenia or low bone mass and 7% had osteoporosis. About 93% of women above 80 years are either osteoporotic or having low bone mass.[2]

Morbidity and Mortality

Both spine and hip fractures are associated with increased disability and mortality. Impact of fragility fracture is equivalent to stroke and myocardial infarction in geriatric population. Hip fractures have 34% excess mortality in first year in men. In female excess mortality is 20–24%.[3] Death rate for hip fracture in elderly woman has now exceeded from stroke in certain European countries. Likelihood of death after 50 years of age in women is equal with breast cancer and hip fracture.[4]

Most patients after hip fracture are not able to live independently. About 40% patients are not able to return to previous functional status.

Institutionalization/death rate is 39.2% within 2 years in female (>60 years) after hip fracture while it is 19.7% in control population. In male it is 52.1% while in normal population it is 12.4%.[5]

Hospital bed occupancy days are much higher with hip fracture (568,000) in comparison to other chronic disease. In stroke it is 352,000 days while in chronic obstructive pulmonary disease it is 35,300 days.[5]

Osteoporosis is not limited to female gender as 20% cases occur in male. In the United States, 2 million males are osteoporotic while many more are osteopenic.[6]

Fragility fracture is the most drastic complication of low BMD that occur following minimal trauma.[7]

Risk factors for fragility fracture:

- Low BMD (twofold increased risk for one SD decrease of BMD)
- Age (after 60 years with each decade risks increases by twofold)
- Previous fragility fracture (fivefold increased risk)

Economic Effect

In the USA, annual cost of fracture-related expenses secondary to osteoporosis was 13.8 billion in 1995 in comparison to asthma, which was 7.5 billion and congestive heart failure 20.3 billion.[8] As baby boomers hit retirement age the cost by year 2050 will reach around 130 billion. In 2010, the cost of fragility fracture in the European Union was 37 billion and based on demographic changes it is predicted to double by 2050.

Investigations

BMD is measured by Dual-Energy X-Ray Absorptiometry (DXA). It is most commonly used test because of its accuracy and ease of using.[9]

Bone densitometry report includes:

- *T Score:* Patient value is compared with young normal subject (peak bone mass) and expressed as number of SD above or below.
- *Z Score:* Patient value is compared with mean value of age matched normal subject and expressed as number of SD above or below.

Absolute BMD—It is the measured BMD (unit GM/CM^2)[8]

Limitation of DXA

It measure bone density, that is, hydroxyl apatite per bone area. But it is altered by atherosclerosis (Aorta) and other degenerative changes due to calcification.[10]

As two dimensional images in DXA, it does not identify minor details of the bone and its poor fracture prediction ability led to the development of new technique like TBS, HR PQCT.[10]

BMD of spine and hip can predict fracture risk but there is a paradox, as most patients with fracture are osteopenic because of high population of this group.[11]

Indications of BMD Measurement

- Age ≥65 (women) and ≥70 (men)
- Female with menopause and one risk factor
- Deformity, fracture, and osteopeniea of vertebrae
- For analysis of response to therapy for osteoporosis
- Glucocorticoid therapy for more than 3 months
- Primary hyperparathyroidism
- Fracture in adults after age of 50[12]

Risk Factors for Osteoporosis

Non-modifiable

- Age
- Race (Asian, Caucasian)
- Gender (female)
- Menopause (early)
- Built (slender)
- Family history[5]

Modifiable

- Diet low in calcium and vitamin D
- Lack of estrogen
- Lifestyle (sedentary)
- Smoking
- Alcohol (more than two drinks/day)
- Caffeine (more than two serving/day)[5]

About 70% of men with Osteoporosis have secondary cause. Among it alcohol abuse, glucocorticoid use, hypogonadism, and treatment with gonadotropin-releasing hormone (GnRH) analog are common causes.[13]

Diagnosis of Osteoporosis

- T Score ≥1 (Normal)
- T Score between –1 and –2.5 (Osteopenia)
- T Score ≤–2.5 (Osteoporosis)[8]

Common Associated Conditions with Osteoporosis/Osteopeniea

Diseases

- *Endocrine disorder:* Thyroid disorder (hypo- and hyperthyroidism), hyperparathyroidism, hyperprolactinemiea
- *Deficiency disorder:* Osteomalacia[14]

- *GI disorder:* Inflammatory bowel disease
- *Connective tissue disorder:* Rheumatoid arthritis[5]
- *Renal failure*

Drugs

- Steroids
- Excess thyroid hormone
- Anti-epileptics
- Proton pump inhibitors[15]

Treatment and Prevention

Non-pharmacological measures:

- Regular resistance and aerobic exercises
- Adequate calcium—1,000–1,200 mg/day for premenopausal women, men. For postmenopausal women and men 65 years or older it is 1,200–1,500 mg/day
- Adequate vitamin D (800–1,200 U/day)
- Limitation of alcohol and caffeine consumption, smoking cessations
- Fall prevention in elderly (risk for frequent falls are sedative, cognitive and visual impairment, disability, and obstacle to ambulation)[16]

Pharmacological Therapy for Osteoporosis

Indications:

- Anyone with vertebral or hip fracture (fragility fracture) BMD not required
- T Score <2.5
- For osteopenia follow FRAX tool. Treatment is recommended for those having 10-year risk of 3% or more for hip fracture or 20% or more for other osteoporotic fracture[1]

Types of medications:

- Antiresorptive agents:
  - Bisphosphonates
  - Raloxifene
  - Calcitonin
  - Estrogen
  - Denosumab (monoclonal antibody against RANKL)[17]
- Anabolic agents:[12,18]
  - Teriparatide (34 amino acid fragment of intact PTH)
  - Abaloparatide
  - Romosozumab

There is 30–70% reduction of vertebral fracture by these drugs. Osteoanabolic drugs reduces incidence of nonvertebral fracture 40–50% while antiresorbtive drugs reduce it by 20–25%.

To determine efficacy of treatment BMD is repeated after 2 years. To determine serial changes, least significant change for particular instrument must be known.[10,14]

There is a definitive treatment gap. As 40–95% of high-risk fracture patients do not receive treatment. In spite of benefit of treatment there is 50% reduction in the use of bisphosphonate in the USA. It is documented from 2008 to 2012 (crisis in osteoporosis).[16]

Prevention of Fragility Fracture

- Prevention of first fracture is the most important step. There is five times high incidence of another fragility fracture after first fracture. Fracture liaison services (FLS) have been started in many countries to close the care gap. It is further evolved to identify the high risk groups to prevent the first fracture. In it dedicated coordinators work with endocrinologist and rheumatologist. They take care of all the aspects (identification, investigation, and intervention) of the disease.[16]
- Frequent fall can be prevented by discontinuation of sedatives, correcting visual impairment, prescribing ambulatory aids, and hip protectors.[4]

Conclusion

- Targeting young population for primary prevention will ultimately lead to decrease in health-care cost, disability, and death in geriatric population. So ultimate aim will be adequate bone mass in youth and policy for this is urgently needed.
- Most of the patients are not well informed about osteoporosis and its long-term impact and most patients believe that there is low to no increase in fragility fracture after first, despite contrary evidences.
- Like other chronic medical problems, osteoporosis also needs successful strategies for identification and treatment. As the population ages, number of patients will increase and there will be acute need for screening and prevention.
- Weak bone in elderly is a significant concern because it is associated with low quality of life and disability. Like in stroke, cancer, and myocardial infarction, fragility fracture is also linked with increased deaths, hospital admission, and impairment of health in elderly.

CHAPTER

84 Intermittent Fasting in Obesity—Hope or Hype?

Soumitra Ghosh

Abstract

Intermittent fasting is a form of calorie restriction that allows calorie intake on few days of the week (e.g., 2:5) or specific hours of the day (e.g., 8:16 or 10:14) and restricting the calorie intake at other times. It may be divided into alternate day fasting (ADF), modified ADF (MADF), and time restricted eating (TRE). In TRE food intake is limited to 8–10 hours in a day or lesser in sync with the external light-dark cycle and internal circadian clock. It has been seen that night shift workers are at increased risk of obesity, other metabolic diseases, and cancers. Short-term studies in humans have shown that TRE results in modest weight loss, fat loss, with improvements in insulin sensitivity, inflammatory markers, and triglyceride level. Intermittent fasting may offer greater improvements in body composition, metabolic, and inflammatory markers. Intermittent fasting may be advised to motivated individuals as one of the options of Calorie Restriction, keeping in mind that we have insufficient evidence on its beneficial effects on long-term obesity and chronic metabolic outcomes. Though it has been hyped by the press and the lay public, the scientific community has the hope and the wisdom to accept its promises as well as its limitations.

Introduction

Obesity is the result of an interplay of genetic, epigenetic, and environmental factors that impair the neurohormonal signaling that controls the satiety and hunger, and the calorie storage and expenditure. Despite the burgeoning problem, the treatment options of obesity are limited. Pharmacotherapeutic agents are limited by their insufficient targeting of obesity pathogenesis and significant adverse effects. Metabolic surgery, though currently the most effective means to treat obesity and its complications, has its share of short-term and long-term complications. Lifestyle modification in the form of appropriate diet, physical activity, and behavioral change forms the cornerstone of therapy.

Daily Energy Restriction: Challenges

An important component of lifestyle modification is restriction of energy intake to promote weight loss. Daily energy restriction (DER) where daily calorie intake is restricted is often not sustainable in the long run due to increased hunger, reduced energy expenditure, defense of body weight and other unknown factors. Research and advancements in intermittent energy restriction (IER) also known as intermittent fasting (IF) has raised from the quest for an alternative, more effective, and sustainable forms of energy restriction.

Intermittent Fasting/Intermittent Energy Restriction

Intermittent fasting is a form of calorie restriction (CR) that allows calorie intake on few days of the week or specific hours of the day and restricting the calorie intake at other times. There is no consensus on the exact definition of IF and different studies used different definitions. Broadly it may be divided into alternate day fasting (ADF), modified ADF (MADF), and time restricted eating (TRE). In ADF,

patient fasts on alternate days. In MADF, patients fast on few days in a week, for example, 5:2. In TRE food intake is restricted to few hours of the day, 8–10 hours or less, for example, 8:16 or 10:14. There is no consensus on the amount of energy intake on fasting days, with energy intake ranging from 0% to 50% of non-fasting days in different studies.

Potential Mechanisms of Benefit of Intermittent Fasting

One basic idea of IF is that individuals do not fully compensate on non-fasting days for the reduced/absent calorie intake on fasting days thereby decreasing total calorie consumption. Proponents of intermittent fasting claim that it improves body composition and other obesity comorbidities.

"Fasting physiology" are adaptations developed by organisms during evolution to promote good health and to prolong survival by allowing repair and regeneration. In one very basic life-form yeast, addition of nutrients like glucose and amino acids blocks survival response and removal of these improves survival,[1] while addition of water protects against DNA oxidative damage and use of alternative fuels by yeast as sources of energy.[2]

In studies in both animals and humans, fasting has been found to reduce oxidative stress and promote autophagy. Autophagy is an evolutionary programmed cell repair process that recycles damaged organelles and misfolded proteins so as to prolong the lifespan of the cell. Autophagy is impaired in obesity, diabetes mellitus, and ageing. Fasting was also found to reprogram age-related pathways and hormones like Sirtuin 1, mTOR pathway, and IGF-1.[3,4]

Another form of intermittent fasting (IF or IER) is TRE. In TRE food intake is limited to 8–10 hours in a day or lesser. Every organism has an internal circadian clock that is programmed to work in sync with the external light-dark cycle. The circadian system consists of a master clock in the suprachiasmatic nucleus of the hypothalamus and peripheral clock situated in other brain areas and the periphery. The entrainment factor (zeitgeber) for the master clock is light. The cellular oscillator is composed of a positive limb (CLOCK and BMAL-1) and a negative limb (CRYs and PERs). CLOCK and BMAL-1 dimerize in the cytoplasm and translocate to the nucleus. Transcriptional activators CLOCK and BMAL-1 promote the transcription of target genes period (PER) and cryptochrome (CRY) among others. The product of the target genes then forms a repressor complex which inhibits transcription of CLOCK and BMAL-1. Through this transcriptional-translational feed-back loop the master clock modulates rhythmic physiology of metabolism and other body rhythms. In normal circumstances cross-talk between the master and peripheral clocks synchronizes circadian rhythm with feeding behavior so that food intake occurs during the light period. From the metabolic perspective the circadian clock and circadian physiologic and biochemical rhythms partition metabolic processes according to the time of the day. Peripheral clocks are entrained by food too. Thus, when food intake occurs in the dark period, there is a desynchrony between the master and peripheral clocks, resulting in misalignment of metabolic processes resulting in obesity and its downstream complications.

The character of the gut microbiota is altered in obesity. A healthy gut microbiota is vast, complex, diverse, and have cyclical fluctuations in response to diet. The diurnal fluctuations in the gut microbiota in response to feeding and fasting modulate the activity of the gut microbiota, which in turn modulates metabolism. Therefore, fasting and eating in sync with the circadian rhythm would promote good metabolic health.

Evidences in Animal Models

TRF in rats in line with the circadian timing system (i.e., feeding during the active phase) improved glucose tolerance during the active phase,[5] while TRF desynchronized with the circadian timing system (i.e., feeding during the inactive phase) worsened glucose tolerance. TRF increased bile acid synthesis, enhanced cholesterol excretion, and protected from inflammation.[6,7]

A study in rats found that IF compared to daily CR protected the myocardium against ischemia-induced cellular damage and inflammation.[8] IF was found to improve cognitive performance.[9] CR and IF was found to improve longevity and resistance to age-related diseases in animal models.[10]

In a study three groups of mice were subjected to either daily CR, ADF (with ad libitum food on every alternate day), or ad libitum food intake daily for a period of 20 weeks. It was seen that ADF mice compensated for periods of fasting by almost doubling the food intake on fed days. Therefore, the weight gain in ADF group was similar to

daily ad libitum feeding group. But the daily CR mice had significantly lesser weight. However, despite weight gain in the ADF, fasting glucose and insulin concentrations were similarly improved in ADF and daily CR groups, but such benefit was not seen in the daily ad libitum fed group.[11] The findings suggest that the "fasting physiology" could have played a favorable effect on the improved metabolic profile and CR on fed days is equally essential for weight loss in ADF.

Evidences in Humans

Night shift workers are at higher risk for obesity, other metabolic diseases, and cancers.[12] The increased risk of obesity is independent of calorie intake.[13] Circadian misalignment for 10 days was associated with increased postprandial glucose, serum insulin, and increased mean arterial pressure.[14]

Short-term studies in humans lasting from 4 days to 16 weeks have shown that TRE results in modest weight loss and fat loss.[15,16] Improvements in insulin sensitivity, inflammatory markers, and triglycerides were seen.[17]

In humans, restriction of food intake to lesser hours in TRE was associated with a reduction in total calorie intake by 20%. This resulted in weight loss of ~4% at 16 weeks and was sustained for up to a year.[18] However, the timing of TRE is very important. It may be early TRE (eTRE), that is, eating in the morning or delayed TRE (dTRE), that is, eating in the evening. In two weight loss intervention studies greater weight loss was seen in eTRE compared to dTRE, highlighting the importance of not only restricting the eating duration and prolonging the fasting duration; but also eating in sync with the circadian clock.[19,20] In another 4-day randomized cross-over study, 11 overweight adults ate between 8 am and 2 pm (eTRE) and between 8 am and 8 pm (control schedule). Compared to control schedule, eTRE significantly decreased mean 24-hour glucose levels as well as glycemic variability. In eTRE group, a rise in ketones, cholesterol, expression of the stress response, anti-aging gene SIRT1 and the autophagy gene LC3A were seen before breakfast. It was thus concluded that eTRE improved 24-hour glucose levels, favorable lipid metabolism, circadian clock gene expression and autophagy, and may have anti-aging effects in humans.[17]

Overweight subjects who consumed a low calorie (500 Kcal) but relatively high protein diet for 2 days in a week for 6 months (MADF) had lower abdominal fat, blood pressure, and improved insulin sensitivity.[21] However, a review by Barnosky et al. found that daily CR was better than IF for weight loss, though both regimens improved insulin sensitivity and decreased visceral fat.[22] A recent meta-analysis found that both IER and CER produced equivalent weight loss.[23]

Another RCT comparing ADF, daily CR, and no-intervention found weight loss was similar between ADF and CR at 6 or 12 months. However, there was greater dropout in the ADF group.[24] DEXA and MRI at week 24 found no difference between fat mass, lean mass, visceral, and adipose tissue mass between ADF and CR groups.[25] In another small study of 11 patients, ADF participants had higher muscle expression of the SIRT1 gene.[26] SIRT1 is known to be associated with longevity in humans. Unlike rodent studies most evidences suggest that calorie intake in ADF is not markedly increased on eating days in humans.

Limitations of Current Evidences

Most of the studies in animal and humans were small in size and of short duration. Therefore, effect of IER on long-term weight maintenance is unknown. There was no unanimity on the definition of IF across studies. Most studies did not study the effect of IF (IER) on other important parameters like appetite, mood, behavior, sleep, and physical activity. However, one reassuring fact of ADF in humans is that humans tended to not compensate (overeat on fed days) for the reduced calorie on fast days unlike rodents exposed to ADF with ad libitum food intake on fed days. Most evidences in humans suggest equivalent weight loss in DER and IER; proposing that CR is responsible for the weight loss. However, few studies reported improvements in metabolic and inflammatory parameters in IER highlighting the importance of "fasting physiology" and "circadian synchrony" that improves health and survival outcomes in humans. However, the optimal eating window in TRE is not clearly defined.

There are concerns about the applicability and the durability of IF in real world settings, where family and social factors, appetite, mood, and behavior pose challenges. Larger and longer studies in real world settings are needed to answer these questions. This will help answer the questions raised and also identify the individuals who would benefit from such a fasting regimen. There is an urgent need to have standardized definitions for the different forms of IER (IF); uniform methods

for monitoring food intake; and optimal timing of food intake in TRE. The fasting regimens are not applicable in patients of diabetes mellitus on hypoglycemic agents. The long-term effect of IF on chronic diseases like diabetes, cardiovascular disease, cancers, and other degenerative disease is currently unclear.

Conclusion

Currently available evidence is insufficient for health-care professionals to recommend IF as standard practice. It is apparent that IF may benefit those who are motivated to lose weight. Any other energy restriction regimen would benefit only the motivated individuals and thus IF is no exception. Evidences in humans suggest that IF may offer greater improvements in body composition, metabolic and inflammatory markers despite similar weight benefits compared to DER. Therefore, currently IF may be advised to motivated individuals as one of the options for CR, bearing in mind that the benefits on weight loss may be similar to DER with possibly better improvement in other metabolic parameters with IF, and also accepting that we have insufficient evidence on its long-term applicability in real world settings or its beneficial effects on long-term chronic obesity outcomes. We may thus conclude that IF is another form of CR. Though it has been hyped by the press and the lay public, the scientific community has the hope and the wisdom to accept its promises and limitations.

Neurology

CHAPTER

85 Advances in Epilepsy Management and Current Perspectives

Man Mohan Mehndiratta, Natasha Singh Gulati, Vasundhara Aggarwal

Abstract

Epilepsy is common neurological disorder attended in Neurology clinics accounting for ~1% of the global disease burden across all ages. Neurologists worldwide now aim at seizure remission in patients with epilepsy because recurrent seizures lead to significant morbidity and mortality and also affect the quality of life (increased health-care use, unemployment, or even sudden death) of the patient and the caregiver. The first step toward accurate diagnosis, therapy, and prognostication of epilepsy is adequate knowledge of its definition and classification. After the appropriate diagnosis is made the two key questions are what and when to start pharmacological treatment and when is non-pharmacological treatment required. Activity modification and restrictions also play an important role in customized treatment. This chapter provides a useful insight into the current perspectives and recent advances in management of epilepsy.

Introduction

Major advances in epilepsy management have surfaced in recent years. In recent years there have been many improving definitions, guidelines, diagnostic, and treatment protocols that have come to the fore. The causes and consequences of epilepsy have been more deeply explored. It is very important to fine tune our knowledge and keep updated. It's rightly said "Staying Updated Is Our Commitment to Our Patients."

Definition and Classification—Recent Changes

The first step toward accurate diagnosis, therapy, and prognostication of epilepsy is adequate knowledge of its definition and classification. One of the most eminent international organizations dedicated to epilepsy care, education, and research is the International League Against Epilepsy (ILAE). **Table 1** describes the 2014 ILAE Epilepsy Operational (practical) definition.

Seizure is defined as "occurrence of transient signs and/or symptoms due to abnormal excessive or synchronous neuronal activity within the brain."

ILAE published "position papers" on the latest classification of epilepsies and seizures,[2] as well as an "instruction manual" for use of seizures operational classification[3] in 2017. Position paper of the "ILAE Commission for classification and terminology 2017" states a new multilevel Classification **(Fig. 1)**, which requires a diagnosis at all three levels. First of all it is assumed that the patient is having epileptic seizures as defined by the latest 2017 ILAE Seizure Classification. It starts with Level 1: Seizure type diagnosis. The next step is Level 2: Epilepsy type diagnosis, including focal epilepsy, generalized epilepsy, combined generalized, and focal epilepsy, and also an unknown epilepsy group. The next is Level 3: Epilepsy syndrome diagnosis.

It also incorporates and emphasizing the requirement to considering etiology at each step of diagnosis. The *etiology* is broken into six subgroups **(Fig. 2)**, keeping in

TABLE 1 2014 ILAE operational (practical) definition of epilepsy[1]

Epilepsy: A disease of the brain defined by any of the three following conditions			
At least two unprovoked (or reflex) seizures which occur >24 h apart	One unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (i.e., at least 60%) after two unprovoked seizures, which can occur over the next 10 years	An epilepsy syndrome diagnos	Epilepsy is considered to be resolved for individuals who have past the applicable age and had age-dependent epilepsy syndrome or individuals who have remained seizure-free for the last 10 years, with no seizure medicines for the last 5 years

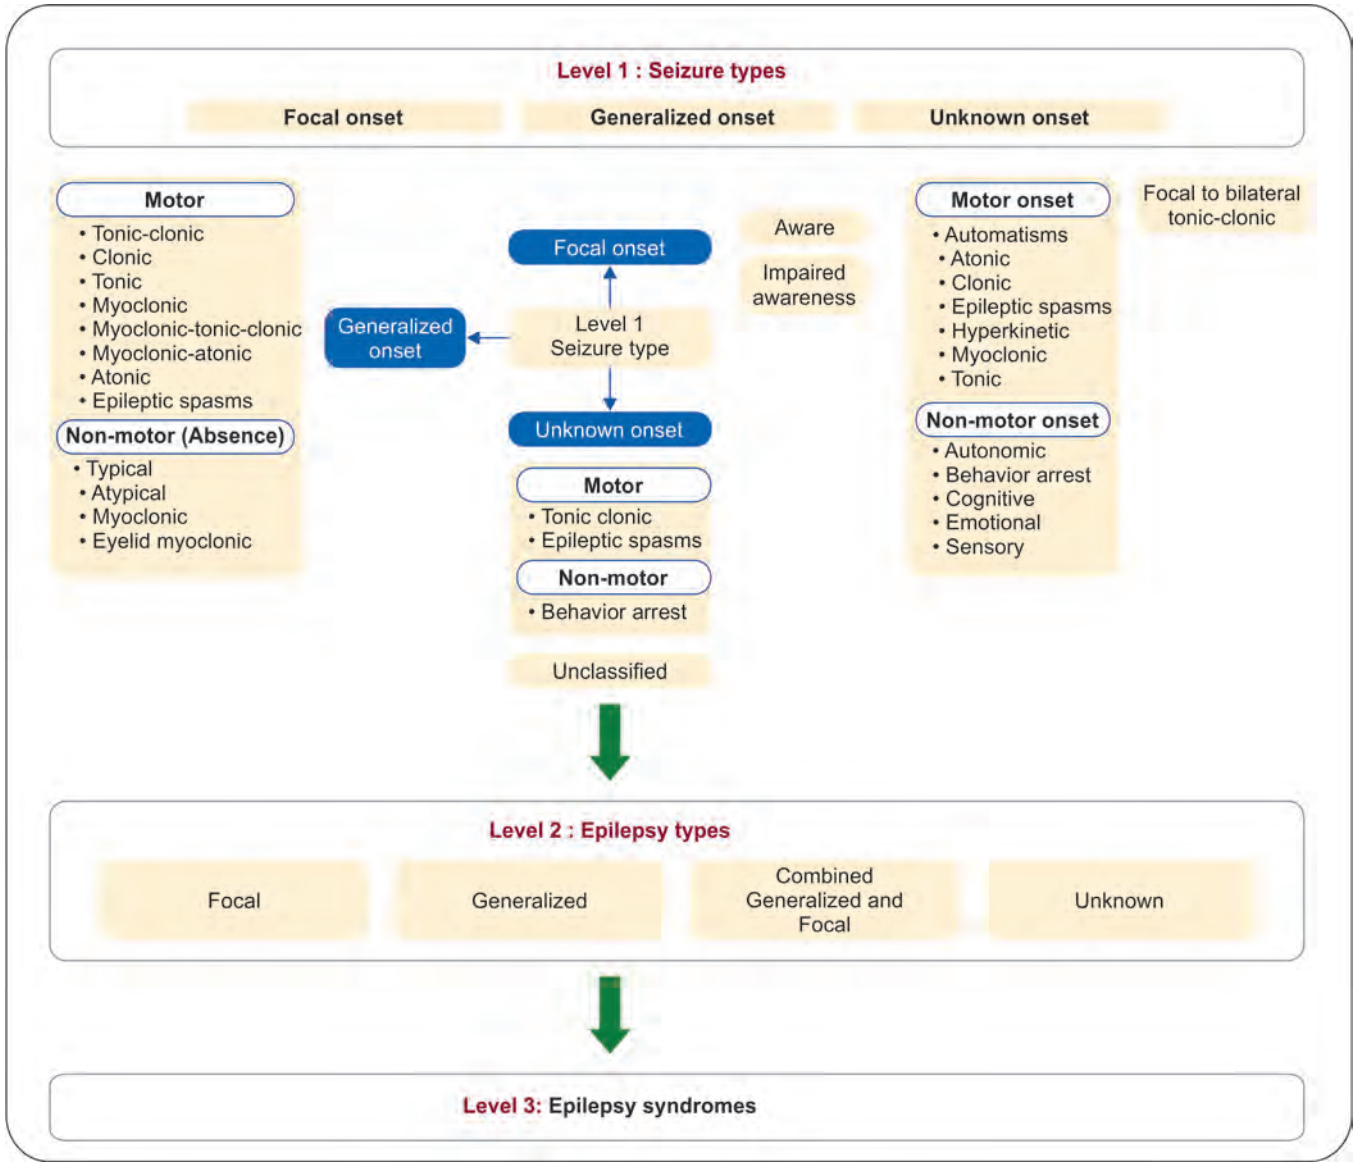

Fig. 1: New multilevel classification of approach to diagnosis of epilepsy

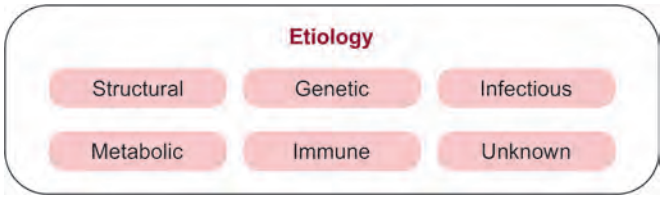

Fig. 2: Six broad subgroups of etiology of epilepsy

mind the possible therapeutic consequences. It lays special emphasis on diagnosing a genetic cause of epilepsy. It also emphasizes to consider *comorbidities* including depression, anxiety, migraine, cognitive impairment, etc., which can affect the progression and management. There are certain drugs to be preferred and avoided in epilepsy with comorbidity. The understanding of etiology and comorbidities will help targeted therapies to the specific type of disease and etiology.[2,4]

New Regarding the Classification of Epilepsy[4]

- Combined generalized and focal epilepsy type added (it cannot be just focal or generalized)
- "Benign" are now termed "self-limiting" or "pharmaco-responsive" (where therapy can spontaneously resolve it)
- New term added epileptic encephalopathy and developmental and epileptic encephalopathy
- Psychosocial and other comorbidities included

New Regarding the Classification of Seizures[3-5]

- Newly added types and terms in ILAE 2017 classification:
  - New focal seizure types include automatisms, autonomic, cognitive, behavior arrest, emotional, sensory, hyperkinetic, and focal to bilateral tonic–clonic seizures. Atonic, clonic, myoclonic, epileptic spasms, and tonic seizures, which can be either generalized or focal.
  - New generalized seizure types include epileptic spasms, absence with eyelid myoclonia, myoclonic–tonic–clonic, myoclonic–atonic, and myoclonic absence.
- The discontinued terms are:
  - Simple/complex partial
  - Convulsions
  - Dyscognitive
  - Psychic
  - Secondarily generalized
- Changed terms:
  - Simple to aware
  - Complex to impaired awareness
  - Partial seizure to focal (onset) seizure
  - Secondarily generalized clonic to focal to bilateral tonic–clonic
  - Hypermotor to hyperkinetic
  - Psychic/experiential to cognitive
- Seizures of unknown onset can still be provisionally classified
- Bilateral versus generalized: The term "bilateral" for tonic–clonic seizures is used when it propagates to both hemispheres and "generalized" for seizures that seemingly originate in both hemispheres simultaneously
- Classifiers used in the classification:
  - Onset:
    - Decides focal/generalized if there is 80% confidence level
    - The first prominent sign/symptom is used to classify seizure type
  - Awareness:
    - Used as classifier of focal seizures
  - Motor/nonmotor
  - Additional descriptors: After classifying seizure type based on initial signs and symptoms, additional descriptions of other signs and symptoms, called as descriptors can be added. However, these do not alter the seizure type.[2-4]

Approach to Management of Epilepsy

Pharmacological Management[6-8]

The mainstays of treatment are anti-epileptic drugs (AEDs). Two key questions "When and What to Start"??

When to Start Antiepileptic Drugs: Treatment Indicated??

Definitions[7]

- Unprovoked seizure can have an unknown etiology or can occur in relation to a preexisting brain lesion or progressive nervous system disorder. In the later cases, it is often referred to as a remote symptomatic seizure.
- Provoked seizures has an acute condition, which provokes seizure such as a head trauma, toxic, or metabolic disturbance or acute stroke (also called acute symptomatic seizures).

First Unprovoked Seizure

- Decision must be individualized and guided by following factors:
  - High seizure recurrence risk of to meet criteria for epilepsy according to ILAE
  - High risk clinical variables
  - Remote symptomatic cause revealed by clinical history or neuroimaging, e.g., brain tumor, head injury with loss of consciousness brain malformation, prior infection of central nervous system, or prior brain injury or brain surgery scar
  - Prior brain insult
  - Epileptiform abnormalities on electroencephalogram (EEG)
  - Significant abnormality on brain imaging
  - Nocturnal seizure
  - Abnormal focal findings and intellectual disability on neurologic examination
  - Significant side effect profiles in individual patient comorbidities and age
  - Social consequences

What to Start: Which and How Many Antiepileptic Drugs

Start with a single AED introduced at a small dose (except status epilepticus or frequent seizures). Monotherapy advantages being:

- avoids drug interactions
- decreases the likelihood of adverse effects
- less cost than polytherapy

The dose is then gradually increased to the lowest effective maintenance dose.

The drug is to be tailored to *factors such as disease related factors, drug related factors and individual person characteristics*—No single AED that is ideal for all patients.

First generation AEDs remain valuable first-line therapies, which are discussed in **Table 2**.

Second generation AEDs **(Table 3)** offer advantages in terms of drug resistance, fewer drug interactions, and improved tolerability and tailoring treatment **(Table 3)**.

AEDs can also be divided based on their mechanisms as given in **Table 4**.

Example: If first generation AED carbamazepine fails to control the seizures then second generation AED like lamotrigine, topiramate, tiagabine, gabapentin, levetiracetam, oxcarbazepine, pregabalin, and zonisamide can be considered (new anticonvulsants are generally considered second-line therapy, however, can be used as first-line therapy in some patients).

TABLE 2 First generation AEDs[6]

First generation AEDs	• Valproic acid
	• Benzodiazepines
	• Phenobarbital
	• Primidone
	• Carbamazepine
	• Phenytoin
	• Ethosuximide

TABLE 3 Second generation AEDs[6]

Second generation AEDs	• Lamotrigine
	• Levetiracetam
	• Topiramate
	• Zonisamide
	• Oxcarbazepine
	• Perampanel
	• Vigabatrin
	• Rufinamide
	• Felbamate
	• Eslicarbazepine acetate
	• Lacosamide
	• Pregabalin
	• Gabapentin
	• Tiagabine
	• Brivaracetam
	• Everolimus
	• Stiripentol

If seizures persist on the first AED despite optimal up-titration to the maximally tolerated dose, exclude non-compliance and reappraise the diagnosis and treatment.

If an AED change is required switch to an alternative monotherapy.

Polytherapy is usually offered after failure of two or three sequential monotherapies (except in a difficult to treat form of epilepsy unlikely to respond fully to monotherapy).

Drug Resistant Epilepsy: ILAE defines drug-resistant epilepsy as "failure of adequate trials of two tolerated,

TABLE 4 AEDs based on mechanism of action[8]

Mechanism	*Name*
Drugs Blocking repetitive activation of the sodium channel	Phenytoin, oxcarbazepine, carbamazepine, eslicarbazepine, topiramate, lamotrigine, cenobamate
Drugs Enhancing slow inactivation of the sodium channel	Lacosamide, rufinamide
Drugs blocking N-methyl-D-aspartic acid (NMDA) receptor	Felbamate
Drugs enhancing Gamma-aminobutyric acid (GABA)–A receptor	Phenobarbital, clobazam, and benzodiazepines
Drugs blocking T-calcium channel	Ethosuximide, valproate
Drugs blocking Alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor	Perampanel and topiramate
Drugs modulating H-current	Gabapentin and lamotrigine
Drugs blocking N- and L-calcium channel	Lamotrigine, zonisamide, topiramate, and valproate
Drugs Blocking unique binding sites	Gabapentin, perampanel and levetiracetam
Neuronal potassium channel (KCNQ [Kv7]) opener drugs	Ezogabine
Carbonic anhydrase inhibitors drugs	Topiramate, zonisamide
Other anticonvulsants	Cannabidiol, stiripentol

appropriately chosen and used AED schedules (whether as monotherapies or in combination) to achieve sustained freedom from seizures."

Factors Influencing Choice of AEDs

Disease-related Factors: Anticonvulsants for Specific Seizure Types[8]

- Ethosuximide—For absence seizures alone
- Valproic acid or lamotrigine, or topiramate—If other seizure types along with absence seizures (e.g., generalized tonic–clonic seizures, myoclonic seizures)
  (Caution: Drugs may exacerbate absence seizures—carbamazepine, gabapentin, or tiagabine)
- Broad-spectrum AEDs—Lennox-Gastaut syndrome with seizures
- Adjunctive therapy with rufinamide, clobazam, extended-release topiramate, cannabidiol and stiripentol—Seizures associated with Lennox-Gastaut syndrome, Dravet syndrome, or tuberous sclerosis complex
- Valproic acid, lamotrigine, and topiramate—Juvenile myoclonic epilepsy JME and myoclonic seizures—(JME has a high recurrence rate)
- Levetiracetam—As adjunctive therapy of JME
- Valproic acid, topiramate, or lamotrigine and adjunctive therapy with Levetiracetam, perampanel—Primary generalized tonic–clonic seizures
- Valproate should remain the drug of first choice for generalized and unclassified epilepsies except in women of childbearing age
- Monotherapy with carbamazepine, cenobamate, lacosamide, lamotrigine, oxcarbazepine, and topiramate adjunctive therapy with levetiracetam, tiagabine, gabapentin, pregabalin, lacosamide, cenobamate, or ezogabine—Focal-onset seizures
- Lamotrigine—First line in elderly subjects (patients aged ≥60 years)

Standard and New Antiepileptic Drugs (SANAD) Trial

The largest individual randomized trial examining different antiseizure drugs as monotherapy for the initial management of epilepsy **(Fig. 3)**.

Drug-related Factors[7]

See **Box 1**.

Individual-related Factors[8]

Specific patient populations and conditions-related considerations

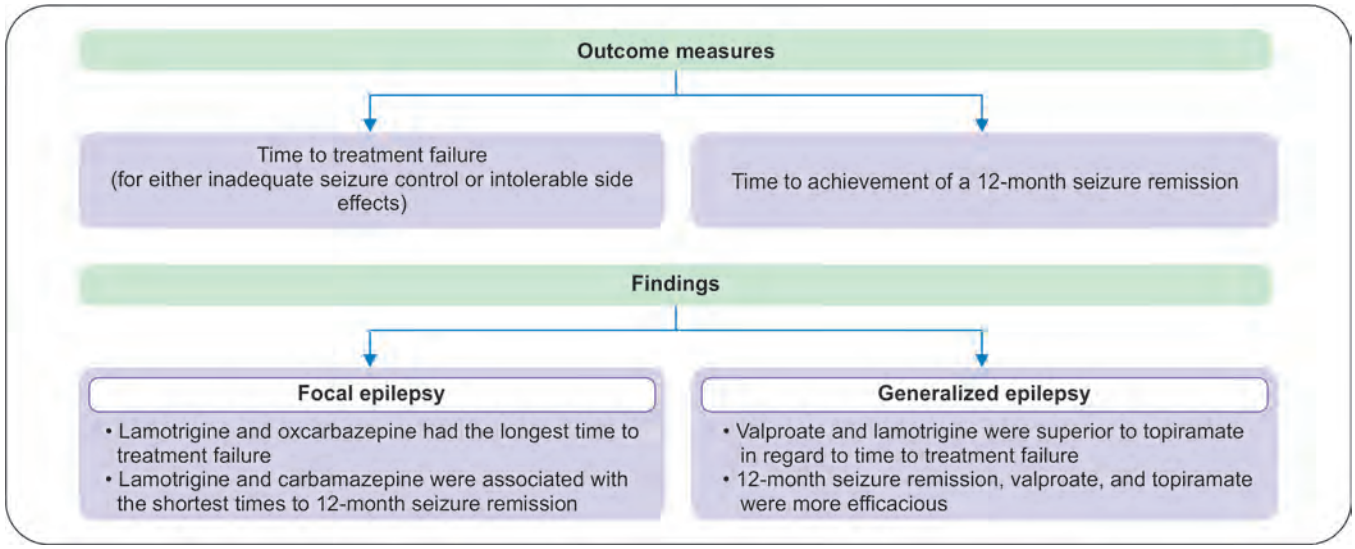

Fig. 3: SANAD trail

BOX 1 Drug-related factors influencing choice of AEDs

- Comparative efficacy
- Dosing frequency
- Drug interactions
- Aging
- Neuro-cognitive side effects
- Hypersensitivity reactions; Stevens-Johnson Syndrome (SJS) and Toxic Epidermal Necrolysis (TEN)
- Suicidality
- Weight loss or gain
- FDA indications
- Cost of medications

- Neonates and children:
- Adjust doses per kg body weight
- Tend to metabolize the drugs quicker
- Rapid rise in the total volume of distribution

Elderly patients: Need less initial dose and maintenance doses because of slow hepatic metabolism, decreased renal clearance and decreased volumes of distribution.

Women on oral contraceptive pills:

- AEDs that induce hepatic enzyme decrease the efficacy of oral contraceptive pills—carbamazepine, phenytoin, primidone, felbamate, phenobarbital, lamotrigine, topiramate, and oxcarbazepine.
- High-dose estrogen-progesterone contraceptive can be administered to counteract this effect.
- Can use alternative method of contraception.

Women of childbearing age and pregnant women:

- Obstetric complications, changes in seizure frequency, teratogenesis, vitamin K, folic acid, blood levels of AEDs, and breastfeeding are nicely covered in 2009 new guidelines for the management of antiepileptic drugs (AEDs) during pregnancy by the American Academy of Neurology and the American Epilepsy Society.
- Not recommended: Switching medications during pregnancy and polypharmacy.
- Drug serum levels should be obtained frequently.

Renal insufficiency:

- Gabapentin, zonisamide, oxcarbazepine, levetiracetam, lacosamide, and pregabalin doses should be altered as they are excreted mostly by means of renal clearance.
- Nephrolithiasis could be associated with topiramate and zonisamide.

Hepatic disease:

- In patients with chronic liver disease, levetiracetam, pregabalin, gabapentin, and vigabatrin as they do not undergo hepatic metabolism.

- Phenytoin, valproic acid, carbamazepine, and felbamate should be used with caution as they have been associated with acute hepatic injury.[7,8]

Post-stroke epilepsy: Consider impact of the antiseizure drug on post-stroke functional recovery and the potential for drug interactions with warfarin and salicylates.

Brain tumors: Consider possible drug interactions with chemotherapeutic agents and increased possibility for allergic cutaneous reactions during radiotherapy.

Psychiatric disorders:
- Depression correlates more strongly with a poor quality of life than the frequency of the seizures.
- Some AEDs also appear to have mood stabilizing properties while some AEDs cause or exacerbate a depressed mood.

Migraine: Valproate, gabapentin, and topiramate are antiseizure drugs that have demonstrated efficacy for migraine prevention in placebo-controlled trials.

Osteoporosis risk: AEDs in chronic use have been associated with bone loss. Moreover seizures are also associated with falls and associated bone fractures. Monitor bone density, routinely supplement vitamin D, and calcium. A consistent exercise regimen is also required.[7]

Discontinuing AEDs

After an individual has been seizure free for typically 2–5 years, many consider discontinuing AEDs. Patients with juvenile myoclonic epilepsy (JME) have high recurrence rate (of about 80–90%) during adulthood.

Risks of Seizure Recurrence

After drug discontinuation, risk of relapse increase if there are:
- Abnormalities on imaging such as on brain MRI scan and epileptiform or focal abnormalities on an EEG
- Higher number and frequency of seizures
- Longer duration of epilepsy before the seizures-free period
- Specific seizure type, e.g., tonic or atonic seizures
- Shorter duration of freedom from seizure

During tapering AEDs and for at least for first 3 months after discontinuation of AEDs, advise patients to observe strict activity and lifestyle precautions (e.g., not to drive, etc.)

Non-pharmacological Therapy

There have been rapid advances in surgical technology and neuroimaging and parallel understanding of developments in epilepsy neurobiology.

Surgical Procedures

The types of surgery performed in patients for refractory epilepsy include:

Anterior temporal lobectomy (ATL): Most common surgical procedures performed in temporal lobe epilepsy in adolescents and adults.

Extratemporal resection: In early childhood, this is the most common type of surgery performed with etiologies being cortical development malformations, vascular malformations, and tumors.

Lesionectomy: Lesionectomy involves the resection of circumscribed epileptogenic lesions, including tumors, vascular malformations, and well-delineated malformations of cortical development.

Hemispherectomy: When little or no functional cortex remains and the entire hemisphere is considered epileptogenic. For example, in Rasmussen's encephalitis, Sturge-Weber syndrome or large hemispheric infarction.

Corpus callosotomy (CC): The procedure is performed in patients with symptomatic generalized epilepsy who are poor candidates for resective surgery. Occasionally done in frequent secondary generalized tonic–clonic, tonic and atonic seizure leading to falls and injuries.

Multiple subpial transection (MST): Occasionally used in focal epilepsy arising in or around eloquent areas.

Thermal ablation: Minimally invasive type of laser surgery. Laser destroys the small well-defined focal point of seizure in brain tissue without damaging the surrounding tissue.

Devices for Brain Stimulation

Intracranial systems (implant device): Deep brain stimulation (DBS) and Responsive neurostimulation (RNS)

Extracranial systems:
- Focal cooling and uncaging
- RTM—Repetitive Transcranial Magnetic Stimulation

- TDC—Transcranial Direct Current Stimulation
- TNS—Trigeminal Nerve Stimulation
- VNS—Vagus Nerve Stimulation

Devices Detecting Seizures

Helps in alerting the individual and their care givers and thus helps in monitoring and managing the seizure behavior. However, these devices also have their own limitations:

- Wearable device—Accelerometer, Medpage ST-2, SeizAlert, Protective Headwears
- Sensor implant device—BrainGate™ Neural Interface System
- Mobile-phone-based device—Epdetect and Epilert
- Watch-based device—SmartWatch Alert
- Software-based multichannel sensor device—NeuroPort System
- Cortical stimulators and mapping—Rehabilicare
- Working mats—Safety Place Mat®

Devices for Surgery

Include Cyber knife®, Functional MRI, Gamma knife®, High-resolution brain Single-photon emission computed tomography (SPECT), Magnetoencephalography, Near-Infrared Spectroscopy (NIRS), Signal Modeling For Real-Time Identification And Event Detection (SIGFRIED), and Tractography and diffusion tensor imaging.

Responsive neurostimulation (RNS) **(Fig. 4)** is the first generation "closed loop" device using Brain Computer interface (BCI). The device is set to particular EEG (depending on the patients individual EEG) and whenever there is a seizure the implant helps to detect and record the EEG pattern. It then sends an electrical signal to disrupt that pattern of seizure activity. The FDA in November 2013, approved the NeuroPace RNS System for the controlling seizures in patients with drug-resistant epilepsy particularly partial-onset epilepsy.

Transcranial magnetic stimulation (TMS) is another method for brain stimulation magnetic field induced brain currents were introduced with the help of magnetic stimulator coil from a safe distance to stimulate focally and deeply in the brain tissues.

Vagal Nerve Stimulation (VNS) is FDA approved in patients above 12 years of age to treat medically refractory focal-onset epilepsy. Candidates for VNS should meet the following criteria:

- Medically refractory seizures.

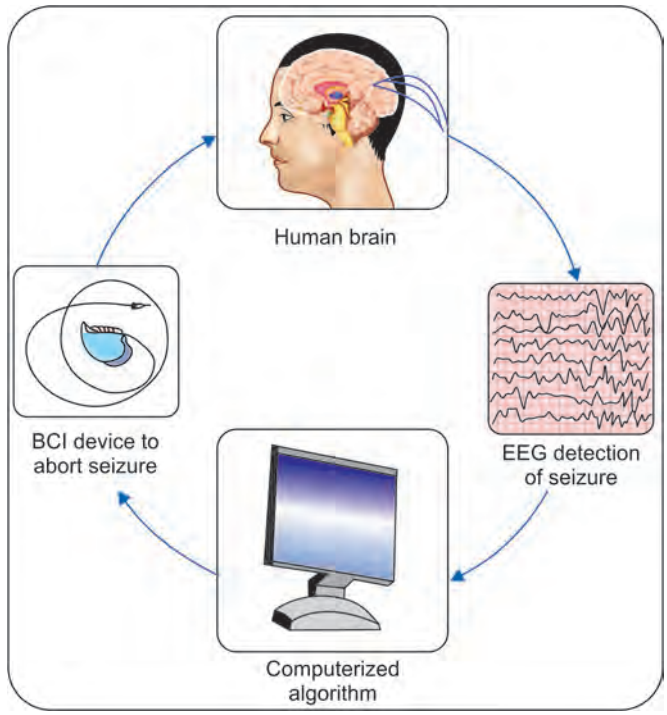

Fig. 4: Responsive neurostimulation (RNS)

- Adequate trials of at least 2 or 3 AEDs (preferably with different mechanism of action).
- Exclusion of nonepileptic events.
- Not a good candidate for epilepsy surgery.

If the patient is a good candidate for focal resective surgery, then it should be preferred over VNS, as this procedure has a superior seizure free rate.

The noninvasive brain stimulation technique of VNS is transcutaneous vagus nerve stimulation (tVNS). It uses a bipolar electrode (external device) to stimulate the left auricular branch of the vagus nerve at the ear conch. It is a newly developed CE (Cerbomed GmbH, Erlangen, Germany) certified tVNS (NEMOS®) device.

Radiosurgery

Radiosurgery is also an alternative to drug resistant epilepsy and other epilepsy surgeries. For example, CyberKnife® and Gamma Knife®. However, due to the radiosensitivity, the safety of the normal tissues around the lesion is at risk.

Diet Therapy

Ketogenic diet (KD): In patients with drug-resistant epilepsy and where surgery is not feasible, Ketogenic diet

consisting of high fat and low carbohydrates and proteins, i.e., 3:1 or 4:1 (fat:carbohydrate and protein) ratio by weight can be given.

Modified atkins diet (MAD): It is a modified traditional KD. Here diet consists of approximately 1:1 (fat:carbohydrate and protein) weight ratio. It is preferred as it is more palatable and less complex compared to KD. Efficacy in children with drug resistant epilepsy is similar to KD.

Software

Analysis of user defined seizure events logged in a database over a given time period and converting it into reports and graphs leading to high-tech seizure pattern analysis. Many software tools are presently available. For example, include EpiTrax, eemagine EEG, Epivista, Epilexia, iPlan® Net, IdentEvent™, Leonardo Brainmap, Neuroport Software System, NeuroScore NeuroGuide Deluxe QEEG 2.5.5, Net Station 4.3 and many more.[9]

Activity Modification and Restrictions

Seizure Lifestyle Precautions

Driving Motorized Vehicles

Driving laws vary from country to country. Generally it is not advisable for persons with epilepsy to drive during the first 2 years of treatment. The USA permits a person to drive if she/he is seizure free between 3 and 18 months. In the UK, a driving license can be granted if a person is seizure free for 1 year. In Australia, driving licenses are issued to those who've been seizure-free for a period of 6 months to 2 years. As of today, the Government of India has no provision to issue special driving licenses to People with Epilepsy (PWE), no matter how long they have been seizure free.[10]

Water Precautions

PWE should not swim alone, have adult lifeguard while swimming, and wear a lifejacket on a boat. Even a simple task of taking bath may be risky.

Heights, Fire, and Power Tools

Use of safety devices for example. Having automatic shut-off switch in operating these tools is recommended.[8]

Epilepsy and Law

A book was published jointly by the Indian Epilepsy Association and the Indian Epilepsy Society in 2017.[10]

Conclusion

Epilepsy is a complex neurological disorder with complex pathogenesis. Understanding the updated definitions and classifications and the advanced pharmacological and non-pharmacological approach for its treatment will definitely improve the patient care. Introducing activity modification and restrictions in the treatment protocol will help in customized care of clinical condition of the patient. What we know till date is just the tip of the iceberg. Despite all the ongoing researches, any definitive curative treatment is still a remote possibility. We have miles to go before we relax.

CHAPTER

86 Emerging Concepts in Anti-MOG Syndrome

MK Roy, Hema Krishna P

Abstract

Myelin oligodendrocyte glycoprotein (MOG) is a glycoprotein present on the surface of myelin sheath. It accounts to only 0.5% of the central nervous system (CNS) myelin sheath and is present only in the CNS. It is considered to have a role in regulating microtubule stability of oligodendrocytes, mediate complement cascade and also help in adhesion of myelin fibers. In spite of its very low concentration, its highly immunogenic nature and presence on surface of myelin sheath make it an easy target to antibodies in CNS autoimmune responses.

MOG antibodies were a topic of interest for past three decades and their role in CNS inflammatory diseases has been supported by their detection in sera and cerebrospinal fluid (CSF) of multiple sclerosis (MS) patients using ELISA and Western blot. Thus, these were thought to be involved mainly in MS pathophysiology. These techniques used denatured MOG peptides as antigens. However, recent techniques using cell based assays showed strong association of antibodies to intact, full length human MOG protein with recurrent optic neuritis, myelitis and brainstem encephalitis like presentations than with classic MS. This has led to the recognition of a new entity, MOG antibody disease (MOG-AD) in patients who have clinical phenotype not fitting into either classic MS or Neuromyelitis optica (NMO), but testing positive for MOG-IgG antibodies. While NMOSD is an astrocytopathy, MOG-AD is a disorder of oligodendrocytes wherein astrocytes are typically spared. Though there is significant clinical and radiological overlap between (MOG-AD) and other related CNS demyelinating disorders like MS and Aquaporin 4 positive NMO, it is important to distinguish these in view of different therapeutic and prognostic implications.

Introduction

We, as treating physicians, are well acquainted with acquired inflammatory demyelinating disease called multiple sclerosis (MS). However, there has been a sea change in our present understanding of demyelinating disorders due to emergence of newer entities, especially Myelin oligodendrocyte glycoprotein associated disease (MOG-AD).[1] It is important to identify this as a distinct clinical entity in view of its different therapeutic and prognostic implications.[2]

Clinical Significance

MS and MOG-AD have considerable features in common like relapsing course,[3] certain radiological features, and in fact in adults with MOG-AD, about 33% meet McDonald's criteria for MS at least once during disease course,[4] leading to misdiagnosis and thus have serious therapeutic consequences as many drugs used for MS are ineffective and at times leads to clinical worsening in a case of MOG-AD. Thus, patients with suspected MS with worsening on treatment need to be screened for MOG-IgG. Early identification of MOG-AD is important because:

- Few drugs approved in MS (interferon beta, natalizumab, fingolimod) can actually be harmful in MOG-AD.[3,5]
- Immunopathogenesis for MOG-AD is different from MS.
- MOG-AD requires high dose steroids and careful and slow steroid taper (high risk of flare up).[6]

- In MOG-AD, for:
  - *Acute attacks:* antibody depleting treatments are very effective (plasma exchange;[3] IVIG in children).
  - *Long term:* B-cell targeted therapy (Rituximab).

Evolving Spectrum of Demyelinating Disorders of CNS (Fig. 1)

Based on site of involvement, clinical, radiological and serological findings, central nervous system (CNS) demyelinating disorders are classified as:[2]

Types of acquired demyelinating diseases are depicted in **Flowchart 1**.

MOG-AD: Pathophysiology

MOG is a glycoprotein of immunoglobulin superfamily presents exclusively in CNS and many of its epitopes are highly immunogenic. Several studies revealed that T cell/B cell cooperation is an important factor in pathogenesis of CNS autoimmunity. During ongoing inflammation, immune cells enter CNS and recognize CNS MOG and export antigen recognition and expose these antigens to peripheral immune system while draining to cervical lymph nodes. This results in MOG antibody production by peripheral B cells, which further trigger new waves of CNS infiltration.[8] Pathologically, there is inflammation and myelin destruction with astrocytes being spared (unlike in NMOSD), as evidenced by CSF analysis (elevated MBP, absence of GFAP). Brain biopsy showed demyelinating lesions with marked infiltration of T cells and macrophages (with myelin degradation products) with preserved astrocytes and axons along with B-cell infiltration and IgG and complement deposition consistent with pattern II MS lesions.[9]

Prevalence

The exact incidence and prevalence of MOG-AD is yet to be elucidated. However, studies showed that it constituted 7.4% of all NMOSD, 6.3% of inflammatory demyelinating diseases of CNS.[10] Among AQP4-IgG negative patients with bilateral and recurrent ON, 40% were MOG-IgG positive

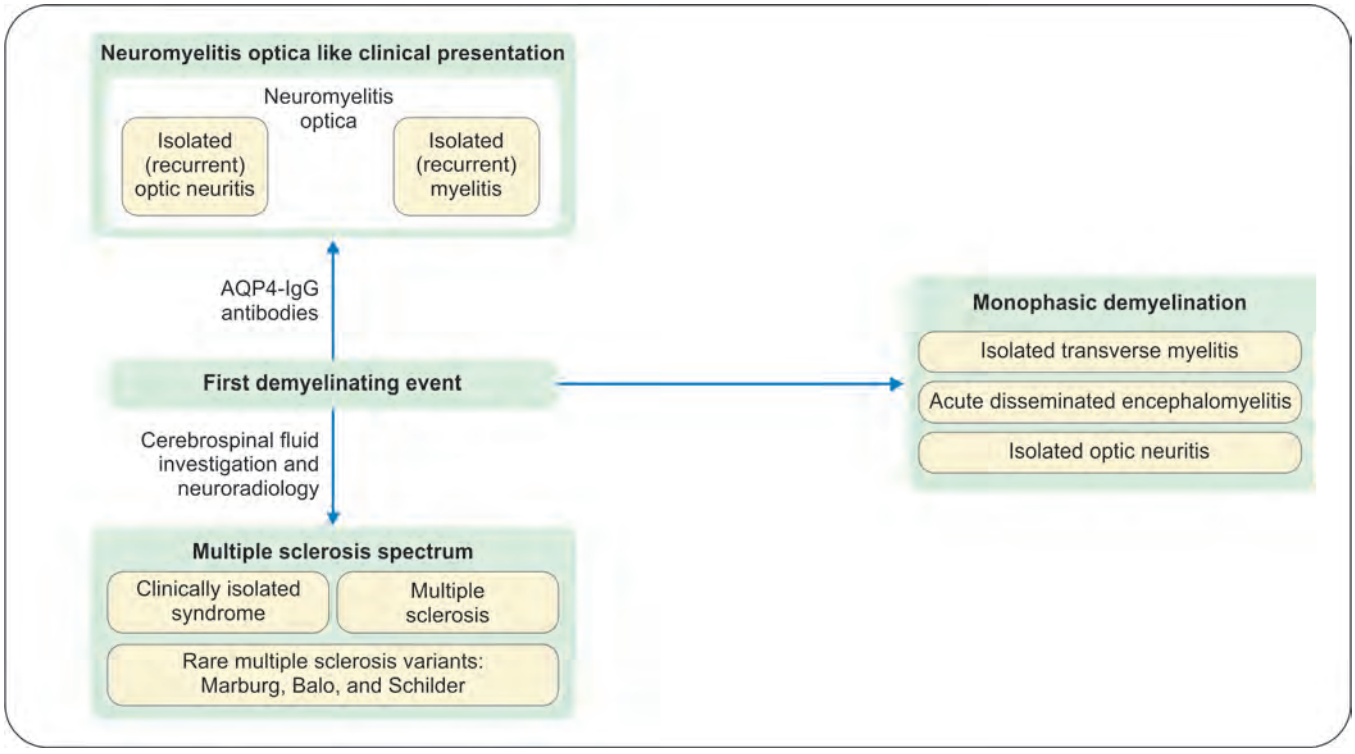

Fig. 1: Spectrum of acquired CNS inflammatory demyelinating diseases[3,7]

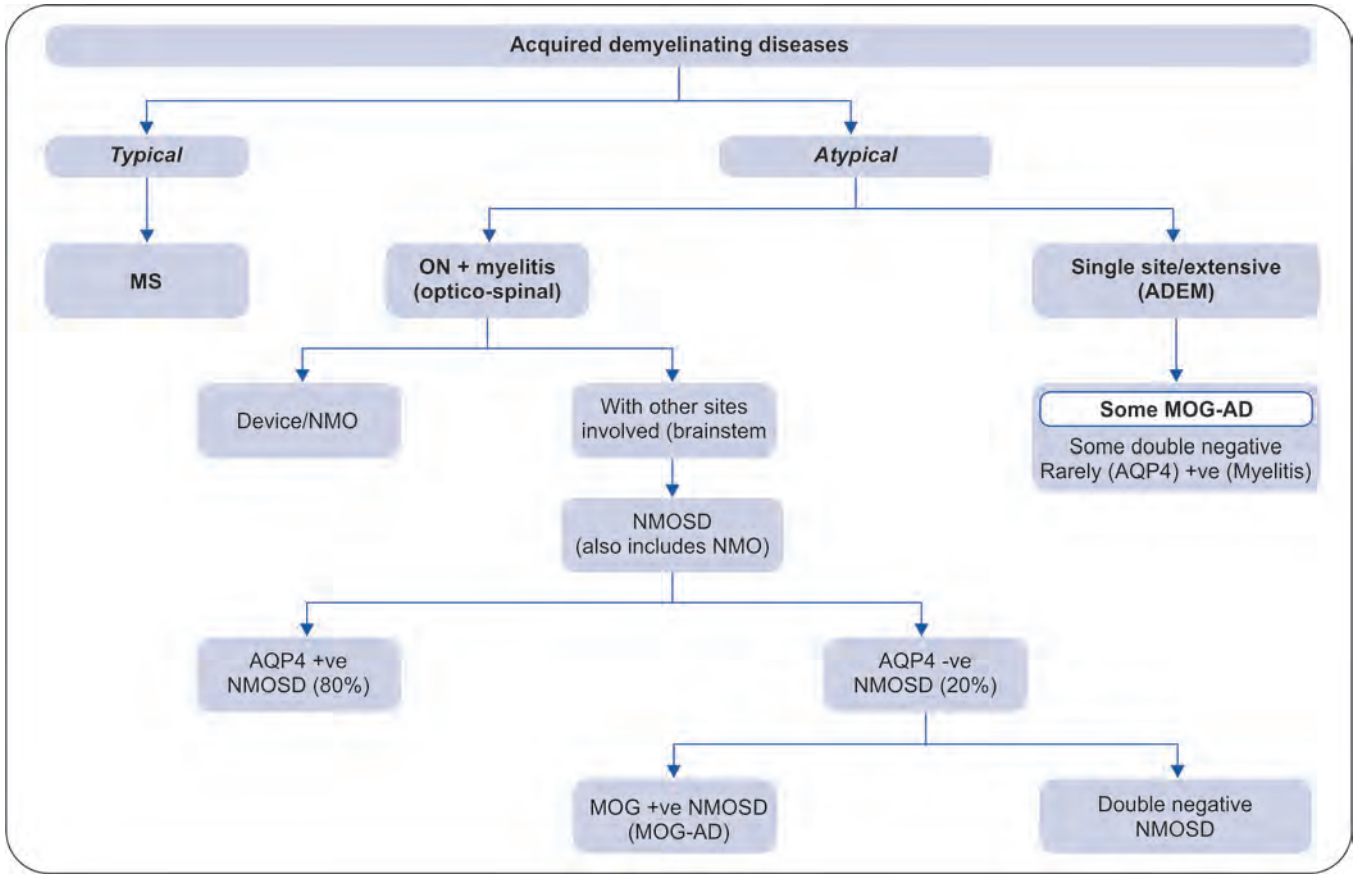
Flowchart 1: Types of acquired demyelinating diseases



and with respect to LETM, 7.4–23.2% had MOG antibody.[2] The prevalence among children was higher constituting 50% of definite NMO cases and 80% of recurrent optic neuritis.[11]

Demographics

MOG-AD is relatively more common in males compared to NMOSD with a female to male ratio of 2.8:1 vs. 9:1 in NMOSD.[1] It has no predilection to specific ethnic groups; however, few studies showed higher occurrence among Caucasians. It is more common among children and young adults (third decade), although any age can be affected.

Clinical Phenotype

Most of MOG antibody positive patients have optic neuritis, encephalitis with brain demyelinating lesions and/or myelitis, which lead to a new term MOG-IgG-associated ON, encephalitis, and myelitis (MONEM).[12] ON is the most common phenotype (41–63%),[3] followed by LETM (29–31%), NMO (6–24%), and encephalomyelitis (2–6%).[2] Also, concomitant occurrence of both ON and transverse myelitis is more common in MOG-AD than AQP4-IgG patients. Overall, MOG-AD patients have a favorable prognosis compared to MS and AQP4-NMOSD patients **(Fig. 2)**.

ADEM, Acute disseminated encephalomyelitis; AQP4-NMOSD, Aquaporin 4 positive neuromyelitis optica spectrum disorder; LETM, Longitudinally extensive transverse myelitis; MY, Myelitis; ON, Optic neuritis

Clinical Features

A preceeding infectious prodrome occurs in many cases in the form of fever, malaise, cough, and rhinorrhea. Though most of cases occur without any predisposing events, post-infectious demyelination after HSV, Borrelia,

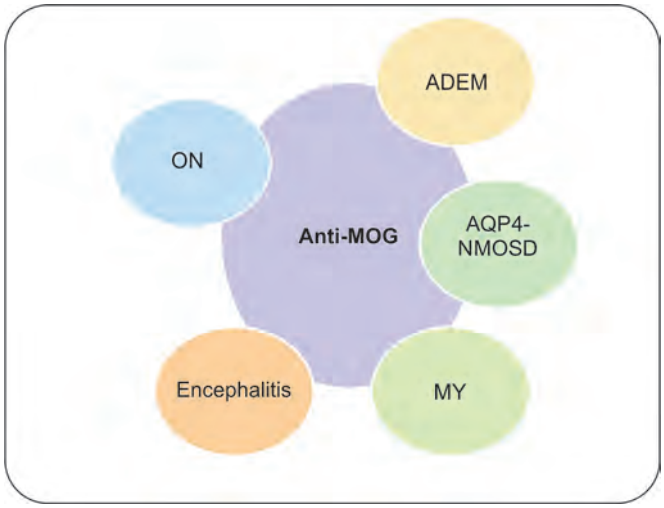


Fig. 2: Clinical phenotypes of MONEM[12]

and EBV have been seen. Studies have described cases of LETM after influenza infection, vaccination, and ADEM after infectious mononucleosis. However, whether these are causative or silent bystanders are yet to be established.

Some patients have a monophasic illness while others may have a relapsing course. Relapse occurs in 44–83% of patients and is mostly optic neuritis. Studies have shown that MOG-AD has higher percentage of single attacks and few relapses compared to AQP4-NMOSD.[2] Also, median time for second attack was longer in MOG-AD (11.3 years vs. 3.2 years in AQP4-NMOSD).[13] Common clinical manifestations of MOG-AD include:

- Optic neuritis:
  - Though unilateral ON is a more common presentation, 30–50% of MOG-AD patients have bilateral ON (bilateral ON is less common in AQP4-NMOSD, rare in MS).
  - Characterstic feature is significant optic disc edema in almost 86% of cases with more than 50% optic nerve affection (anterior part) and relative sparing of optic chiasma.[14]
  - It has better visual outcomes compared to AQP4-NMOSD, though recurrence of ON is more frequent in MOD-AD.
  - Some patients may develop steroid dependent optic nerve involvement called chronic relapsing inflammatory optic neuropathy.
- Myelitis:
  - Typically causes LETM (involving >3 vertebral segments) in almost two-thirds of cases. Short segment involvement is seen in one third of cases especially in elderly. Usually, motor symptoms predominate. Severity of myelitis is more than MS but less than AQP4-NMOSD.
  - Preferential involvement of thoracolumbar and Conus[2] (explains disproportionate sphincter and erectile dysfunction) region occurs.
  - Central/lateral cord lesion.
  - Clinically may resemble enterovirus associated acute flaccid myelitis.
  - Recurrent LETM is rare (<2%).[2]
  - TM at onset is the most important predictor of long term disability.
- ADEM/ADEM like:
  - More common in children. Can occur at onset in up to 18% of patients.
  - MOG antibodies are present in almost 50% of all multiphasic ADEM patients.[1]
- Brainstem syndrome:
  - Area postrema syndrome presenting as intractable nausea and vomiting is less common than in AQP4-NMOSD.
  - Can be seen in 6–15% of cases.[2]
- Cortical encephalitis:
  - It is a less common presentation and is usually due to unilateral mild edematous cortical lesion best seen on FLAIR sequences.
  - Patient may present with seizures, abnormal behavior or focal symptoms and it has a very good prognosis **(Fig. 3)**.[1]

Diagnosis

Imaging: MRI

Optic nerve:

- During ON, orbital MRI with coronal T2 fat suppressed images shows extensive anterior optic nerve segment T2 hyperintensity (sparing optic chiasma and retrochiasmatic parts) with evidence of optic disc edema.[15]
- Inflammation and enhancement of perioptic nerve sheath is seen in one third of cases **(Figs. 4A and B)**.

Spinal cord:

- During myelitis, may show evidence of LETM (T2 hyperintensity involving ≥3 vertebral segments lengthwise and >50% of the axial section of the medullary cord). Cloud like heterogeneous enhancement may be noted.

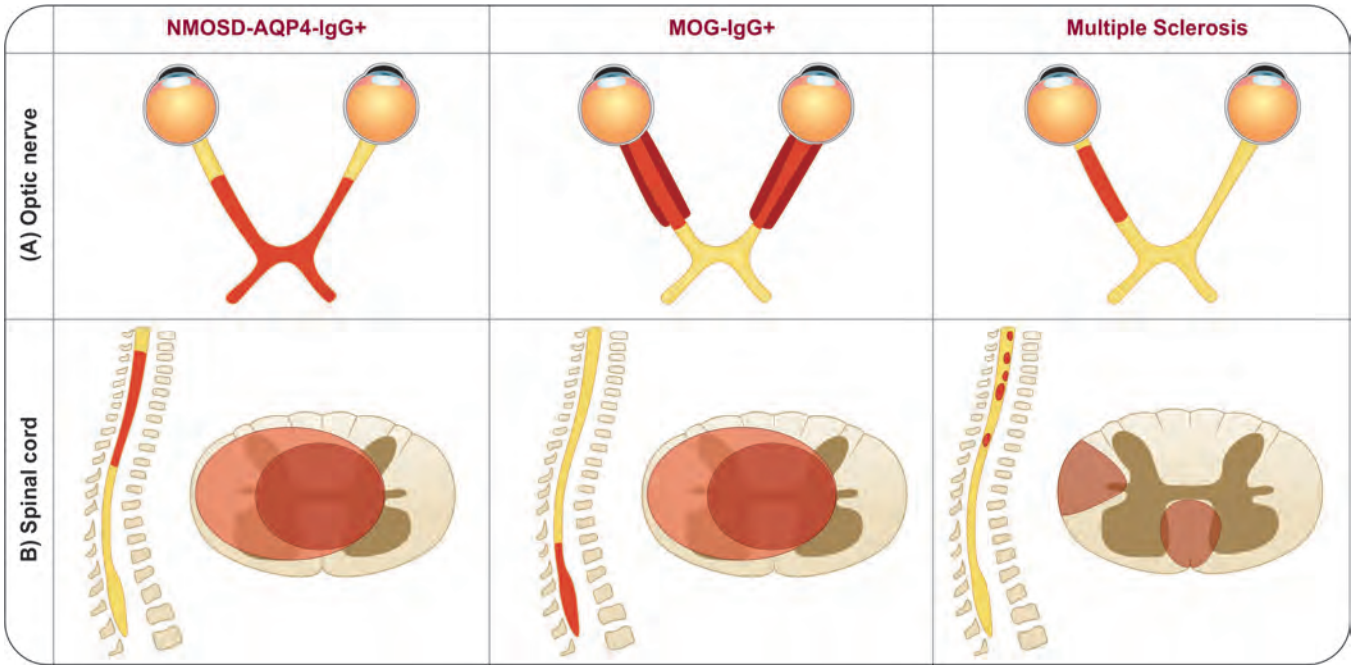

Fig. 3: Comparitive patterns and sites of involvement. AQP4-NMOSD: Bilateral, long segment, posterior optic nerve involvement involving optic chiasma; central/gray mater, complete, LETM, thoracolumbar cord involvement. MOG-AD: Bilateral, long segment, anterior optic nerve involvement including optic nerve head, sparing optic chiasma; central/lateral, complete, LETM, consu involvement is characteristic. MS: Unilateral, short segment optic nerve involvement, frequent chiasmal involvement; peripheral, short, partial, multiple cordlesions

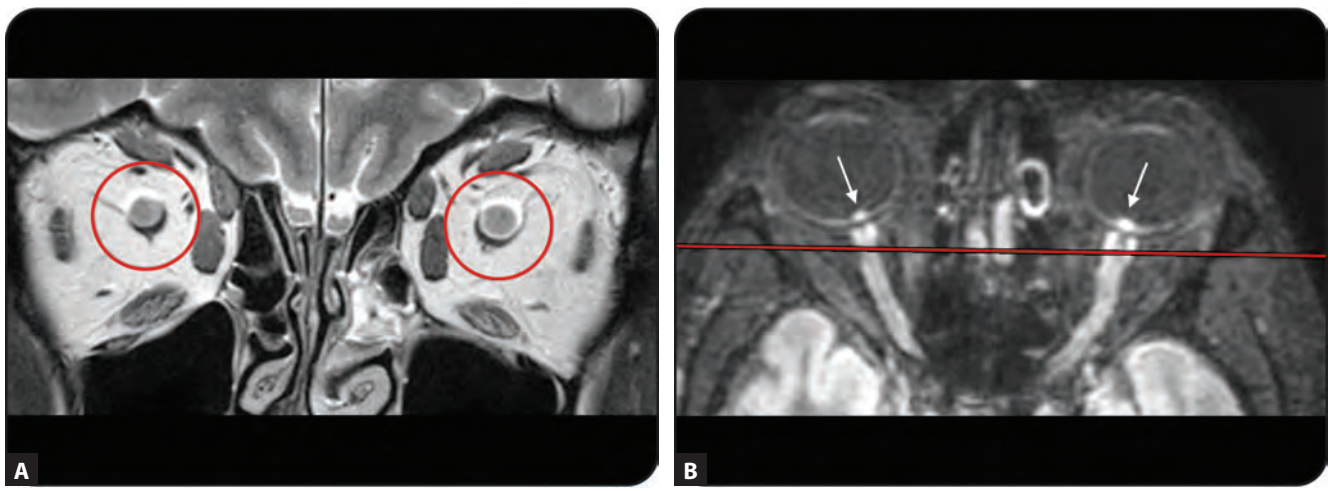
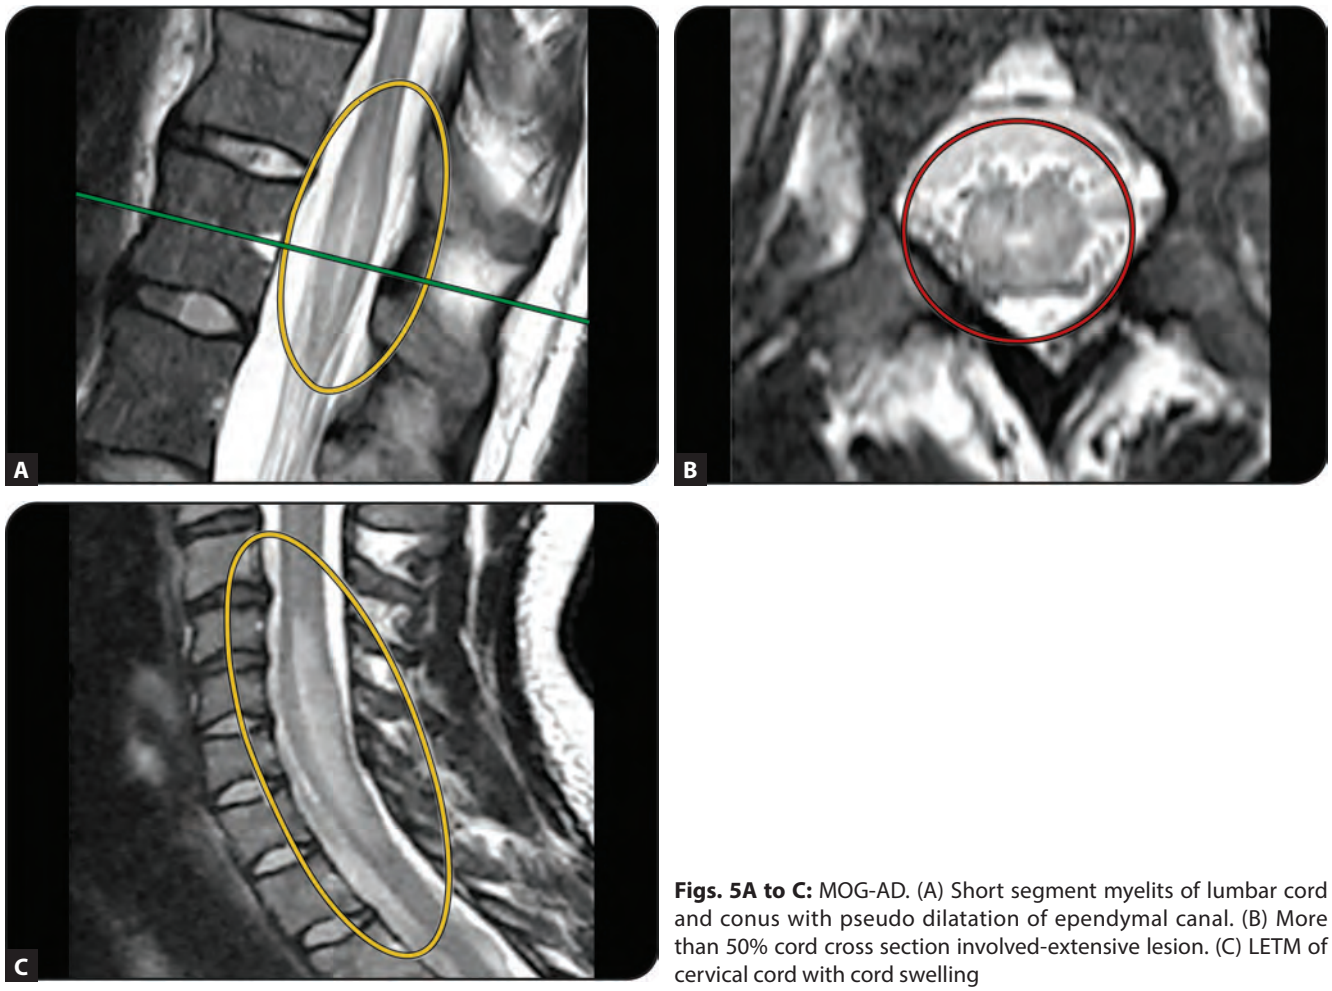


Figs. 4A and B: MOG-AD patient with bilateral optic neuritis. (A) Bilateral optic nerve swelling, (B) Longitudinaly extensive ON withoptic nerve head swelling (arrows)

- Short lesions involving less than 2 vertebral segments can be seen especially in elderly. Conus involvement is highly specific for MOG-AD.[16]
- Lesions are usually central and associated with cord swelling.

Brain:

- It is abnormal in 45% of cases at onset of disease.[16] Lesions are usually bilateral and fluffy.
- Thalamic and pontine lesions are common, subtentorial (brainstem) in one third of cases.



Figs. 5A to C: MOG-AD. (A) Short segment myelits of lumbar cord and conus with pseudo dilatation of ependymal canal. (B) More than 50% cord cross section involved-extensive lesion. (C) LETM of cervical cord with cord swelling

- Dawson's fingers, U shaped ovoid lesions close to body of lateral ventricle are less common **(Figs. 5A to C)**.

CSF

CSF findings during an acute attack are variable:

- 50% of the patients have elevated white cell counts (in 5–10%, lymphocyte count can be 100–300 cells/μL) and an elevated CSF protein (>1 g/L in 10%).
- 10% of patients have an elevated protein with normal white cell count.
- Oligoclonal bands are less common (6–17% of patients).[1]

Serum

- IgG MOG antibody tests should be done only in selected patients with clinical and paraclinical features of MOG-AD, in view of chance of false positivity.
- A cell based assay using full length human MOG as target antigen is preferred.

Biposy

Biopsy findings suggestive of pattern II MS lesions can be noted, but not commonly performed.

Diagnostic Criteria (International Panel of Experts—Jarius et al.)[17,18]

MOG-related disorders should be diagnosed in patients who meet all of the following criteria:

- Monophasic or relapsing acute ON, myelitis, brainstem encephalitis, or any combination of these symptoms.
- MRI or electrophysiological (visual evoked potentials in patients with isolated ON) findings compatible with CNS demyelination.

TABLE 1 When to test for MOG antibody[19]

Test if	• Clinical/paraclinical feartures are suggestive of MOG-AD (2018 International Recommendations) • Diagnosis of MS is made, interferon beta or natalizumab has been started, but efficacy is unexpectedly poor and clinical/paraclinical features are compatible with MOG-AD
Retest if	• MOG antibody positive, but clinical/paraclinical features not suggestive of MOG-AD (red flags) • Clinical/paraclinical features continue to be suggestive of MOG-AD, but MOG antibody is negative • Likelihood of further events is sought, after diagnosis of MOG-AD

TABLE 2 'Red flags'—conditions that suggest probable false positive result and thus should be retested with a different cell-based assay[3]

Disease course
• Chronic progessive disease (rare in MOG-AD), including SPMS (especially SPMS without relapses) and PPMS • Sudden symptom onset e.g., <4 h from onset to maximum (ischemic cause), or continuous worsening over weeks (tumor, sarcoidosis, etc.)
MRI
• Lesion adjacent to lateral ventricle that is ovoid/round or associated with an inferior temporal lobe lesion, or Dawson's fingers • Active brain MRI over time with silent increase in lesion burden between relapses
CSF
• Bi or trispecif MRZ reactions (MS)
Serology
• MOG-IgG levels at or just barely above the assay-specific cut-off, especially if clinical picture is atypical • Positive MOG-IgM and/or MOG-IgA result with negative MOG-IgG (? significance) • MOG-IgG positivity in the CSF but not in the serum (MOG-IgG is produced extrathecally) • AQP-4 IgG/MOG-Ifg "double-positive" test results (extremly rare; should retest for both antibodies)
Others
• Clinical or paraclinical findings suggesting diagnoses other than MOG-EM, NMOSD, or MS (e.g., neurotuberculosis, neuroborreliosis, neurosyphilis, neurosarcoidosis, Behcet syndrome, SACD, Leber's hereditary optic neuropathy, vasculitis, CNS lymphomoa, gliomatosis cerebri, paraneoplasmic neurological disorders, PRES, PML, and evidence for CNS infection) • Combined central and peripheral demyellination (MOG is not expressed in the PNS)

MRZ, Measles, Rubella, Zoster virus

- Seropositivity for MOG-IgG as detected by means of a cell-based assay employing full length human MOG as target antigen.

Treatment-related indications for testing: Particularly good response to antibody depleting therapies (PEX), immunoadsorption (IA), and B-cell depleting therapies (rituximab, ocrelizumab, and ofatumumab), but relapse immediately after reoccurrence of B cells.

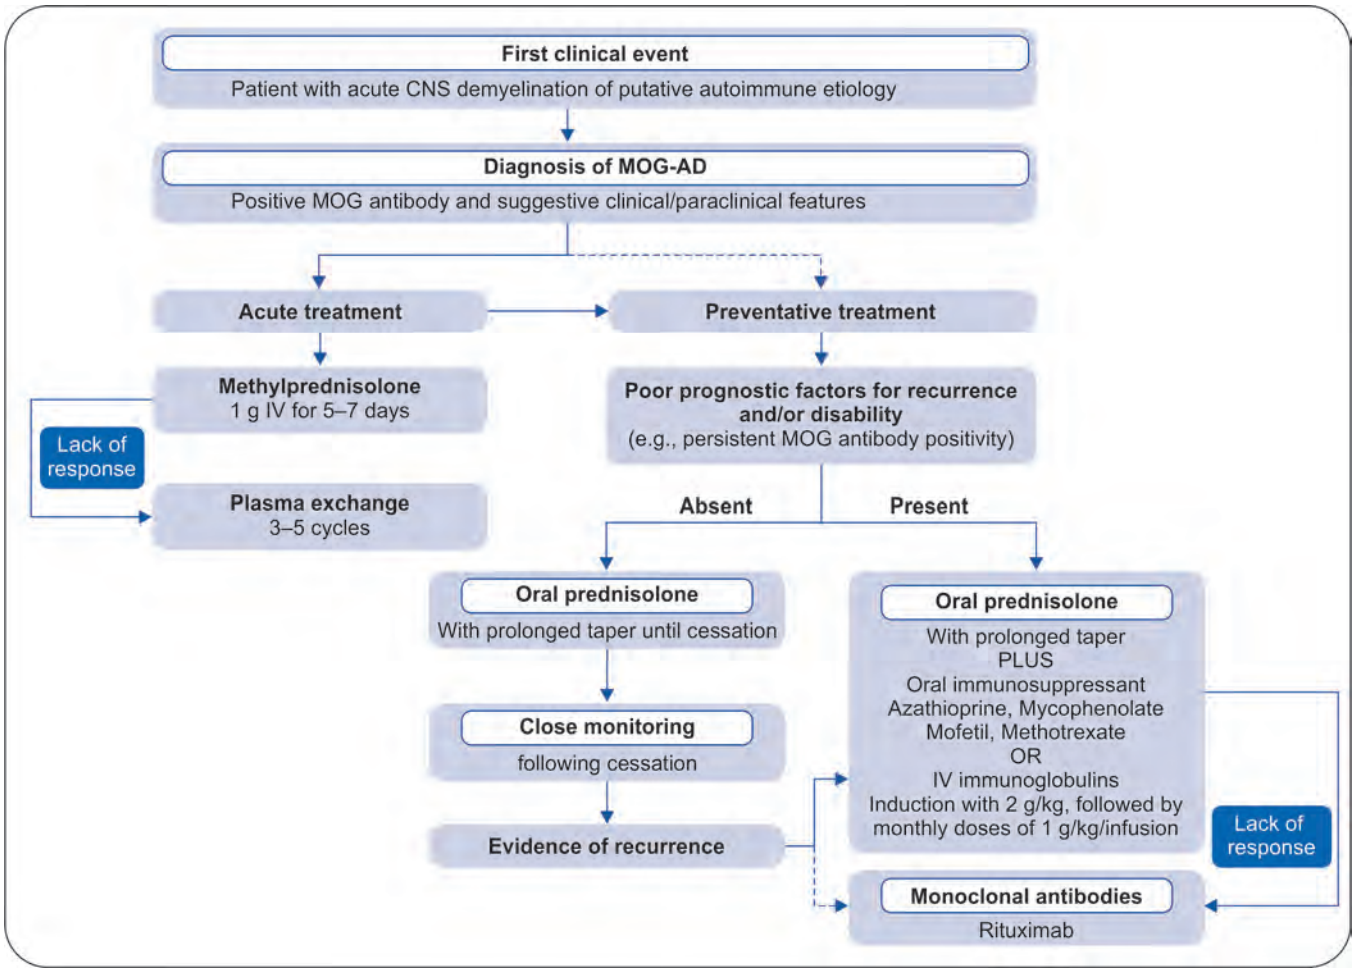
Tables 1 and 2 depict the conditions when MOG antibody should be tested and the Red flags should be considered respectively for avoiding the wrong diagnosis in appropriate clinical scenario.

Special Features

MOG-AD has some differences compared to AQP4-NMOSD:

- Optic nerve involvement more than spinal cord. Optic nerve involvement is bilateral commonly and caudal spinal cord (conus) affection is characteristic.[16]
- Mostly monophasic or may have few relapses. Has a relatively less female preponderance.
- More brainstem and cerebellar involvement with few supratentorial lesions.
- Has a wider spectrum and is less commonly associated with other autoimmune disorders.

Flowchart 2: Algorithm for management of MOG-AD[3,16]



- Responds to B-cell depleting agents and has a better prognosis with good recovery after attacks and minimal disability.[16]

Treatment

Currently, there are no controlled treatment trials in MOG-AD and consensus regarding preferred drug, candidates for immunosuppression and duration of therapy is still uncertain.

Acute Treatment

During acute phase, high dose IV methylprednisolone (1–2 gm/day for 3–5 days), is usually effective with partial or no response in 50%. In steroid resistant cases, plasma exchange (3–5 cycles) results in improvement in around 40% of cases.[3]

Disease Modifying Treatment

Several studies have shown that long-term immunosuppression reduces annual relapse rate in MOG-AD patients. The optimal duration of initial immunosuppression after first attack is not clear. However, since relapse risk is maximum early after disease onset, it is reasonable to continue low dose prednisolone (10 mg) for 6 months after 1st attack (change to steroid sparing agent if side effects occur). MOG antibody should be retested after 6 months and if negative, prednisolone should be gradually withdrawn since disappearance of MOG antibody indicates remission. If antibodies are persistently present, since relapses usually occur only in these patients, immunosuppression may be continued up to 12 months.[16]

However, not all patients with persistent antibodies relapse. Possible risk factors for relapse include: initial

severe attack and persistent MOG antibody. If relapse occurs, steroid sparing agents like azathioprine, methotrexate, mycophenolate mofetil, maintenance IVIG, and rituximab may be started with gradual tapering of steroids.[16] Rituximab however may cause a temporary rise in B-cell activating factor and autoantibody levels resulting in new attacks within 1st few weeks of infusion **(Flowchart 2)**.[3]

Conclusion

MOG-AD constitute a group of acquired inflammatory demyelinating disorders of CNS, which share clinical and radiological features with MS and AQP4-NMOSD, but their distinct pathophysiology and certain specific features delineate them from their counterparts, and hence considered a separate disease entity by themselves with distinct therapeutic and prognostic implications. The diagnosis of MOG-AD relies on presence of suggestive clinical and paraclinical features with positive MOG-IgG antibody. It is important to identify them early because few conventional therapies used in MS can be harmful in MOG-AD and their early diagnosis and treatment aids in improving recovery and minimizing disability.

CHAPTER

87

Rapidly Progressive Dementia

K Mugundhan

Abstract

Rapidly progressive dementia (RPD) is a rapid decline in one or more cognitive functions which interfere with independent daily living within a period of 1–2 years from symptoms onset. Most of the causes of RPD are treatable and early diagnosis is essential to prevent irreversible neurological injury. Serum vitamin B12, thyroid function test, and MRI brain are the investigations recommended by American Academy of Neurology in any patients with typical dementia apart from routine blood investigations. But the diagnostic workup in RPD needs additional investigations based on clinical profile and stepwise diagnostic approach should be followed including invasive biopsy.

Introduction

Rapidly progressive dementia (RPD) is a group of neurological disorders, which behave quite differently from the slowly progressive neurodegenerative dementias requiring an appropriate diagnostic workup and management. There is no classical definition for the time frame for the onset of dementia; however, these constitute a group of conditions in which first onset symptom to dementia progress in less than 1–2 years, but commonly over weeks to months.[1,2] RPDs often cause distress to the patients and caretakers but presents a real challenge to the clinicians as an array of investigations and nimble decisions on management has to be made to protect as much as viable neural tissue. As many of these conditions can be treated and cured, a prompt and accurate diagnosis of the disease causing the dementia is mandatory. Various etiologies have been contributing to this entity are listed in **Table 1**.[3]

The differential diagnoses of RPD are numerous; nevertheless, a meticulous approach is required to arrive at the accurate diagnosis. A precise history entailing the time course of progression of events is very important.

TABLE 1 Etiologies of rapidly progressive dementia

Etiologies of RPD
• CJD and other spongiform encephalopathies
• Vascular disorders
• Autoimmune and paraneoplastic encephalopathies
• Malignancies
• Metabolic, endocrine, and toxic disorders
• Subacute central nervous system infections

The use of the mnemonic VITAMINS (Vascular, Infectious, Toxic-Metabolic, Autoimmune, Malignancy, Iatrogenic, Neurodegenerative, and Systemic) will help us consider the manifold etiologies, evaluating a case of RPD.[2] The prototype is the prion disease, Creutzfeldt-Jakob disease (CJD).

Diagnostic Approach

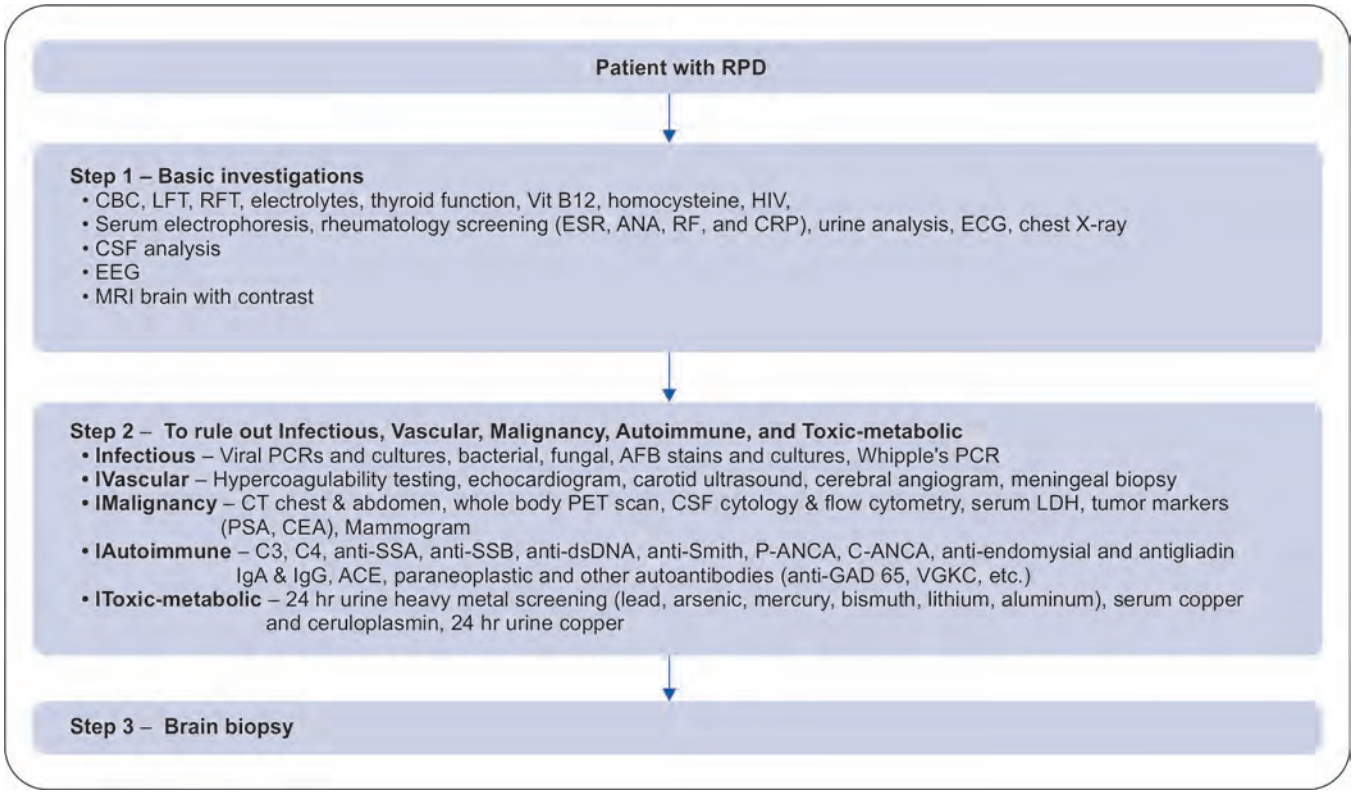
Diagnostic workup of a case of RPD should primarily involve ruling out delirium and its causes. A complete blood count with differential, basic metabolic screening

(calcium, sodium, magnesium, phosphorus), liver function tests, rapid plasma reagin, rheumatologic screening (ANA, ESR, CRP), thyroid function tests, vitamin B12 level, HIV, medication levels according to treatment history (e.g., lithium, phenytoin levels), urine analysis should be done as a part of initial evaluation. Cerebrospinal fluid (CSF) analysis for cell count, protein, glucose, IgG index, oligoclonal bands, VDRL, neuron specific enolase ELISA, 14-3-3 protein western blot, total tau enzyme linked immunosorbent assay, real-time quaking induced conversion test, cryptococcal antigen, viral antibodies, cultures and PCR, bacterial, fungal, acid fast bacilli cultures, and stains are the recommended screening for diagnostic evaluation of a case of RPD. MRI with or without contrast is the initial imaging modality of choice. It should include T1, T2, fluid-attenuated inversion recovery (FLAIR), diffusion weighted imaging, apparent diffusion coefficient map, and hemosiderin sequences. EEG should also be done, as epilepsy, nonconvulsive status, transient epileptic amnesia should be contemplated when working up a case of dementia. Screening for mood disorders, assessment of hearing loss, sleep dysfunction, and medication overuse should be always kept in mind and ruled out, as these conditions are potentially reversible. The stepwise investigations in approaching RPD are described in **Flowchart 1**.

Neurodegenerative Disease with Rapid Course

Most of the neurodegenerative diseases presenting as dementia is marked by their tardy course of progression, however, can present as RPDs occasionally. Alzheimer's disease (AD) has a median survival rate of 12 years can present occasionally as RPDs, especially in association with amyloid angiopathy. Although the CJD is the commonest cause of RPD, AD represented one among frequent non CJD causes of RPD.[3] Frontotemporal lobar degeneration (FTLD) was yet another common cause for RPD, which presents earlier in life than AD and an overlapping FTLD–motor neuron disease and FTLD–parkinsonism syndromes often predispose a faster

Flowchart 1: Stepwise investigations in rapidly progressive dementia



progression of the disorder. The tau-related pathologies like corticobasal degeneration and progressive supranuclear palsy (PSP), was reported as cause of RPD by multiple studies.[1,3,4] Dementia with Lewy bodies mimics CJD, and progress as RPD, although it lacks its classical MRI imaging properties and single photon emission computed tomography with 123 I-ioflupane can aid the diagnosis.[3]

Creutzfeldt-Jakob Disease

CJD can present with rapid cognitive decline (in weeks or months) associated with gait disturbances, visual hallucinations and behavioral disturbances, myoclonus and extrapyramidal symptoms.[5] It is caused by the transformation of the normal neuronal prion protein, resulting in its abnormal accumulation within the neurons. The disease presents as a sporadic form (sCJD), a familial/genetic form and a variant form (vCJD) of which the sCJD is the commonest, accounting for approximately 85% of cases. sCJD usually has late presentation at 50–70 years of age and affecting both sexes identically. Prognosis is often worse with survival rate of 15% at end of 1st year. Mutations of the prion protein gene are accountable for the genetic forms of CJD and include familial CJD, Gerstmann–Sträussler–Scheinker and fatal familial insomnia. Even though they have a similar clinical presentation, the progression is often slower. The EEG is often characterized by focal or diffuse slowing in the initial period but as with the disease progression, pseudo-periodic and, eventually, periodic 1–2 Hz triphasic sharp waves characterize the picture which is highly pathognomonic, even though late in appearance. Normocytic CSF with elevated protein is often seen with 14-3-3, tau proteins and neuron specific enolase having specific diagnostic values.[6] Hyperintensities involving the striatum (caudate and Putamen) and thalamus in the FLAIR and DWI sequences are seen earlier in the disease with "cortical ribboning" (hypersignal delineating the cortex) in the parietal, temporal, and frontal cortices is of statistical importance (sensitivity and specificity of 92% and 94%, respectively) in diagnosing the disease and can be seen even before the EEG findings. However, a definitive diagnosis requires demonstration of prions in the brain. The clinical criteria for probable sCJD require progressive dementia with at least two of the following: pyramidal and/or extrapyramidal symptoms, visual or cerebellar symptoms, myoclonus, akinetic mutism, and positivity in at least one out of three tests (EEG, 14-3-3protein, and MRI). No effective treatment is found for delaying this fatal condition and only palliative treatment for controlling seizures and myoclonus seems to be beneficial.[3]

Toxic-Metabolic

Complete treatment history, occupational, and home environmental exposure history are important in analyzing the toxic causes of encephalopathy. Lithium (iatrogenic) can cause encephalopathy. Inorganic lead causes peripheral neuropathy and organic lead is more noxious and can cause cognitive and behavioral symptoms. Mercury (organic and inorganic forms) can cause psychological disturbances. Bismuth toxicity, due to inappropriate use for gastrointestinal disorders, can cause RPD and is reversible if detected early.[1] A few reversible causes like vitamin deficiencies, and endocrinological disorders should also be definitely ruled out. Niacin deficiency (vitamin B3) can cause subacute cognitive impairment and is encountered mostly in nutritionally deprived and in association with systemic disorders like diabetes mellitus, chronic malignancies, and chronic gastrointestinal disorders. Thiamine (vitamin B1) deficiency causes Wernicke encephalopathy and needs urgent thiamine replacement. Vitamin B12 deficiency, folate deficiency, etc. are other potentially reversible causes. Endocrine abnormalities involving thyroid, parathyroid, and adrenal should be screened in any case of rapid progression of dementia. Serum electrolyte levels including sodium, potassium, calcium, and magnesium should also be included in the diagnostic evaluation. Uremic encephalopathy, portosystemic shunt encephalopathy, acquired hepatocerebral degeneration, hypoxia or hypercarbia, hyperglycemia, or hypoglycemia are some other etiologies for RPD. Screening for porphyria and mitochondrial diseases should also be done.

Vascular

Vascular conditions like strokes, especially thalamic or callosal infarcts, multi infarcts, cerebral amyloid angiopathy, venous sinus thrombosis, dural arteriovenous fistulas, posterior reversible encephalopathy syndrome (PRES), CNS vasculitis, hypertensive encephalopathy account for other primary causes of RPD.[1,3] Diffusion-weighted imaging, and gradient echo MRI, vascular

imaging like CT angiography, magnetic resonance venography (MRV), magnetic resonance angiography (MRA) aid in the diagnostic workup of dementia.

Infections

Infectious causes for a rapid cognitive decline include herpes simplex encephalitis, AIDS, and its associated CNS conditions like (toxoplasmosis, primary CNS lymphoma, and progressive multifocal leukoencephalopathy), Lyme disease, Whipple's disease, fungal infections like CNS aspergillosis and rare local infections like Balamuthia mandrillaris and neuroleptospirosis. In endemic regions, neurosyphilis should also be considered as a close differential. Infectious causes usually present with specific symptoms like fever, pleocytosis, and meningeal signs and have relatively acute onset.

Malignancy

Neoplastic causes like primary CNS lymphoma and intravascular lymphoma may present with a sudden deterioration of cognition and may present a challenge for the physician. The clinical presentation may mimic Creutzfeldt-Jakob disease and imaging with MRI may not be yielding, as it may not always present with a space occupying lesion or mass lesion. Other metastases/neoplasm related causes that should be considered in the differentials include lymphomatosis granulomatosis, lymphomatosis cerebri, gliomatosis cerebri, metastatic encephalopathy, carcinomatous meningitis, etc.

Autoimmune Dementia

At present autoimmune encephalopathies are thought to be the cause for a relatively fair amount of RPDs.[3] A good number of these encephalopathies are treatable, and hence the importance of prompt diagnosis. The pathognomonic features include rapid and fluctuating course, presence of autoantibodies in the peripheral blood and inflammatory markers in CSF. Clinical presentation may be in the form of limbic encephalopathy with disorders of short-term memory behavioral alterations, depression, and temporal lobe seizures. Limbic encephalopathy may be often paraneoplastic, even preceding the diagnosis of the underlying malignancy, in many cases the neurological disorder is non-paraneoplastic. Anti-Hu antibody is the most common cause of limbic encephalopathy, associated with small-cell lung carcinoma, whereas Anti-CV2 antibodies can be associated with small cell lung carcinoma and thymoma. N-methyl D-aspartate receptor (NMDA) antibodies are usually associated with paraneoplastic encephalitis, occurring in young women with ovarian teratoma.[7] Autoantibodies against neuronal VGKC may be related to lung cancer or thymoma, but most cases are not paraneoplastic, especially in the absence of other paraneoplastic autoantibodies. The former has even shown association with acquired neuromyotonia (Isaacs' syndrome). The clinical spectrum may be of limbic encephalitis combined with neuromuscular hyperexcitability.

Antiglutamic acid decarboxylase (anti-GAD) antibodies are seen associated with conditions like type 1 diabetes and stiff person syndrome and occasionally, cause subacute encephalitis with RDP, ataxia, autonomic instability, and myoclonus, which responds well to immunosuppressive therapy.[8] Autoimmune RPDs can even mimic CJD, both clinically and radiologically, especially limbic encephalopathy with anti VGKC antibodies (LGI1 antibody subtype) exhibiting cortical ribboning in MRI scans. Hyponatremia due to SIADH is more common in VGKC antibody complex encephalopathy.

A steroid responsive encephalopathy with high-serum titers of antithyroid (anti-thyroglobulin antibodies [anti-TG] and anti-thyroid peroxidase antibodies [anti-TPO antibodies) brings into the picture of Hashimoto's encephalopathy. The disorder usually affects middle aged women and the presentation may be of stroke like relapsing and remitting episodes or of an RPD. There are reports of systemic autoimmune disorders like SLE and Sjogren's syndrome presenting as RPDs rarely in the literature.[3] The later may be due to antibody mediated vasculitis or direct antibody attack to the CNS parenchyma as in case of SLE. Despite its propensity for affecting the peripheral nervous system Sjogren's can present as RPDs with cognitive decline and mood disorders often mimicking multiple sclerosis with recurrent attacks and focal symptoms. The presence of antiphospholipid antibody can aid as a clue to the situation. Neurobechet's, neurosarcoidosis, and celiac disease worth mention as they present as RPDs rarely with cognitive decline, behavioral alteration, and spinal cord lesions. Primary or secondary vasculitis due to Wegener's granulomatosis and polyarteritis nodosa can cause encephalopathy resembling RPDs. These

conditions often prompt the requirement of extensive workup with inclusion of serum ACE levels, perinuclear and cytoplasmic antineutrophil cytoplasmic antibodies, antigliadin, antitissue transglutaminase, and anti-endomysial antibodies and even a cerebral angiogram in the armory of evaluation panel, depending on appropriate clinical picture.[3]

Secondary Causes of RPDs

Normal pressure hydrocephalus also rarely presents as RPD. The complete clinical gamut of memory loss, gait ataxia, and urinary incontinence may not always manifest. High-resolution structural MRI with orthogonal reconstructions will delineate the cause. Diagnosis can be confirmed by means of CSF pressure measurement and improvement following a drainage lumbar puncture. These patients benefit from a ventriculoperitoneal shunt.

Systemic disorders like sarcoidosis, mitochondrial disorders can clinically present with rapid cognitive impairment. Drugs also may precipitate a steep decline of cognitive function. Narcotics, anticholinergic medications, and benzodiazepines are commonly implicated.

Pseudodementia is a diagnostic possibility of exclusion. Patients with history of major depression may present with rapid decline of cognitive functions and often get misdiagnosed as RPDs. A thorough evaluation and ruling out of the neurological and systemic causes will aid in considering the possibility.

Conclusion

Considering the wide range of clinical conditions, which can present as RPDs, the clinician should always give emphasis on enquiring on the natural progression of the disease with particular attention in eliciting the relevant clinical signs. The exact pattern of the cognitive decline and association of psychiatric and neurological symptoms should be enquired in detail with an interrogation into the association of inherited familial conditions, systemic diseases, and causes including metabolic, drugs, and toxins.

The investigation armory should not be restricted to the routine panel of hemogram, electrolytes, liver, renal, and thyroid function testing, a screening for rheumatological disease and malignancy, CSF analysis including a search for oligoclonal bands and MRI, and rather it should be structured and staged. The use of a systematic approach in diagnosis like "VITAMINS" is often rewarding and aid in rapid diagnosis of reversible conditions. However, if the first stage of interrogation is absurd, one should always open eyes to wide array of differentials and impetuous enough to consider a second stage of investigation including a paraneoplastic workup, CT thorax and abdomen, whole body PET, or immunoassays for specific pathogens if required. A blind alley should prompt to consider even brain biopsy.

CHAPTER

88 Approach to a Patient with Acute Muscular Weakness

Lakshmi Narasimhan Ranganathan, Namrata Jayaharan,
Rini George, Guhan Ramamurthy, Shrivarthan R

Abstract

The approach to a patient with acute muscular weakness chapter deals with the discussion of various causes of muscular weakness, its clinical features, recommended diagnostic testing, and management. Advancements in genetic testing,imaging studies and laboratory diagnostics offers better understanding about the disease pathogenesis and its course. New molecular markers developed in myopathy help in clinical prognostication and guide treatment. The care of the patients with acute muscular weakness can be challenging. Treatment must be individualized and effective patient participation is necessary for effective management.

Introduction

Acute onset paralysis of the limbs and bulbar musculature is a neurological emergency. It may be caused by a wide variety of disorders. Some of these conditions may have associated respiratory muscle involvement requiring mechanical ventilation. A detailed history, general physical and neurological examination demonstrating the pattern of involvement can help in narrowing the differential diagnosis. Salient features to be noted in history, physical and neurological examination are summarized in **Table 1**.

When evaluating a patient presenting with acute onset weakness of limbs, it is imperative that the following factors be considered. The **Flowchart 1** helps in providing a structured approach to a patient presenting with acute muscular weakness.

- The mental status of the patient should be ascertained—a depressed sensorium suggests central nervous system (CNS) pathology.
- The history of the temporal course and progression of the illness is noted—whether it is acute, subacute, chronic, progressive, relapsing, and remitting. Acute onset weakness occurs in Guillain-Barré Syndrome (GBS), porphyria, diphtheria, tick paralysis, inflammatory myopathy, periodic paralysis, to name a few. Fluctuating weakness is seen in myasthenia gravis and Lambert Eaton myasthenic syndrome. Episodic weakness occurs in periodic paralysis.
- On examination of the motor system we can determine the limbs involved—whether the weakness is symmetrical or asymmetrical. The involvement of all four limbs with a definite sensory level on the torso indicates the presence of a high-cord lesion.
- The presence of sensory symptoms or sensory level helps in diagnosis. The sensory symptoms can be attributed to early polyneuropathy. A definite sensory level on the torso is seen in myelopathy.
- The history of bowel, bladder involvement, and other autonomic signs should be enquired. Early bladder involvement occurs in myelopathy.
- It should be examined whether the weakness is proximal or distal: A proximal weakness occurs in myopathy. In polyradiculoneuropathy the weakness

TABLE 1 Assessment of a patient with acute muscle weakness

Assessment of a patient with acute muscle weakness
History
• Onset and progression and duration • Distribution of weakness • Presence of sensory symptoms • Recent history of fever and diarrhea • Exposure to drugs / toxins • Similar history of weakness in the past • Positive family history
Physical examination
• Look for the presence of skin findings of dermatomyositis (Gottron papules, heliotrope rash, shawl sign, holster sign) • Thyromegaly and thyroid eye disease • Eye signs in myasthenia - Curtain sign, see saw ptosis, peek sign, Cogan's lid twitch • Bulbar involvement • Evaluation of respiratory reserve—coughing ability, single breath count of 30, Forced vital capacity, negative inspiratory force
High yield - Neurological examination
• Pattern of weakness • Bulk, Tone, reflexes • Sensory examination

is initially proximal followed by distal weakness. The involvement of both proximal and distal muscles occurs in polyradiculoneuropathy.

- Early wasting points toward an axonal rather than a demyelinating etiology.
- Bulbar symptoms can occur in GBS, myasthenia gravis, inflammatory myopathy.
- The hereditary nature of illness is determined by associated family history.
- History of associated medical illness like thyroid disease, connective tissue disease.
- H/o drug/toxin exposure should be looked into. Arsenic poisoning, barium carbonate poisoning mimic GBS with systemic symptoms.

It is essential to localize to the most probable site in the motor unit and the possible etiology that has caused the acute muscle weakness. The various causes of acute muscle weakness are summarized in **Table 2**. The discussion of all the disorders presenting with bilateral muscular weakness is beyond the scope of this chapter. A few common conditions are elaborated below.

Guillain-Barré Syndrome

It is an immune-mediated, rapidly progressive, ascending, predominantly motor polyneuropathy leading to bulbar and respiratory compromise. It has a monophasic course. All age groups can be affected. Antecedent respiratory/gastrointestinal illness is found in 60% of cases. Campylobacter jejuni is the most common infection associated with the AMAN variant. Assisted ventilation may be required in up to 25% of cases.[1]

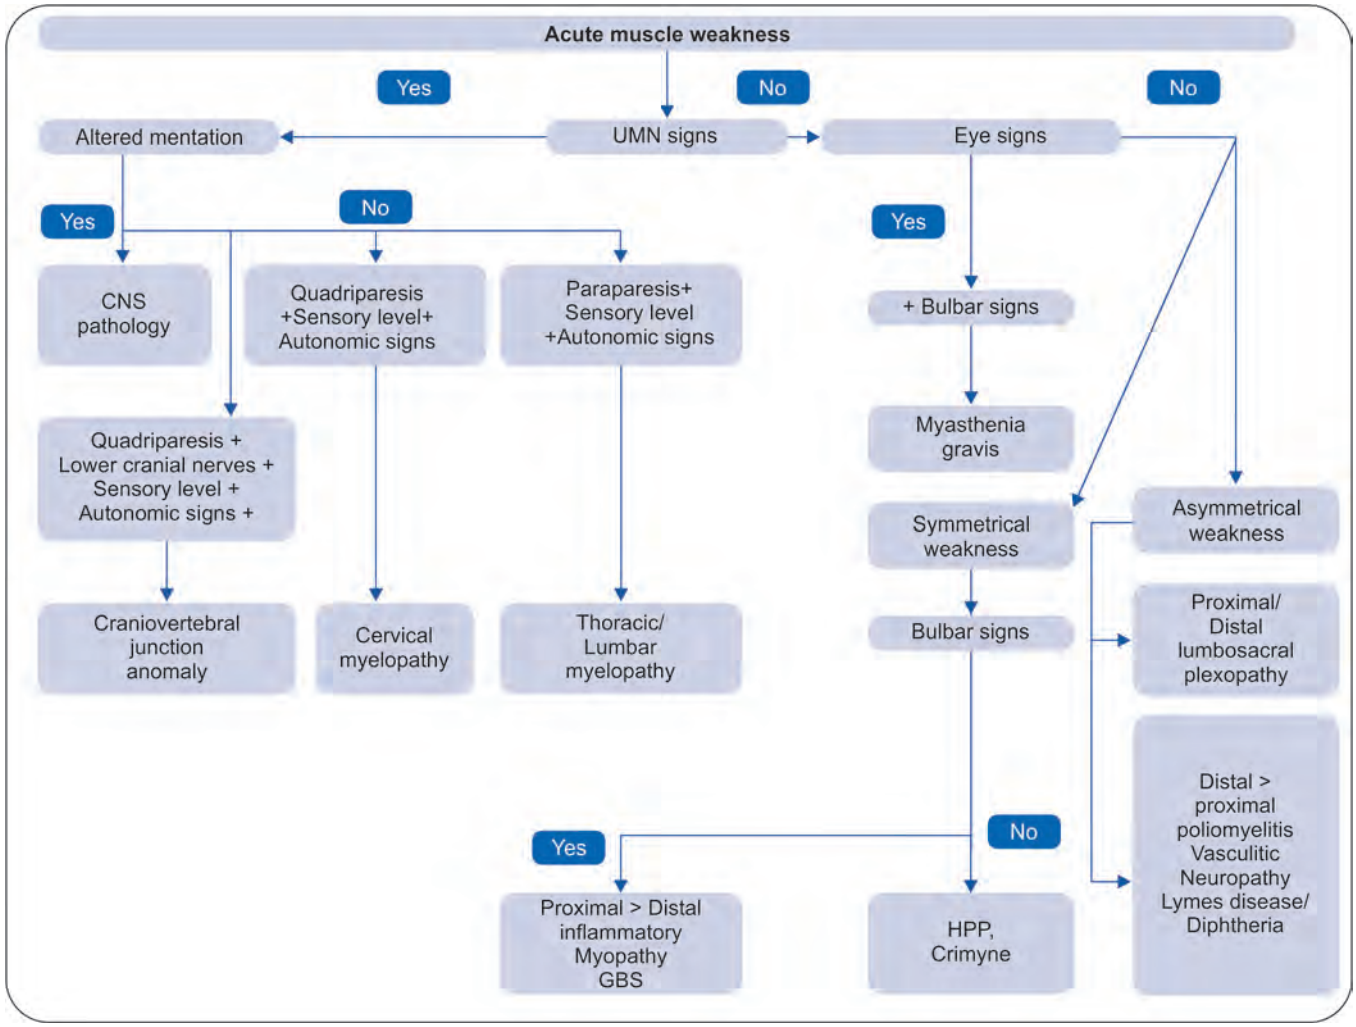
Clinical Features

- Acute flaccid symmetrical quadriparesis. Around one third of patients remain ambulant throughout the course of the illness.
- Early areflexia.
- Distal paresthesia involves the toes and fingers simultaneously (unusual in other causes of polyneuropathy).
- Bifacial weakness occurs in 50% of cases.
- Bulbar weakness with dysphagia and dysarthria are common.
- Back pain and radicular pain are seen in 25% of patients.
- Autonomic dysfunction can occur. It does not progress beyond 4 weeks. Most individuals have a peak deficit by the first week of illness.

The subtypes of GBS include:

- Acute demyelinating polyneuropathy (AIDP). Most common in North America and Europe (90%).
- Acute motor axonal polyneuropathy (AMAN)—Accounts for 30–47% of cases. It is now classified as a nodopathy.[2] It reaches nadir quickly. It is strongly associated with antibodies to GM1, GD1a. The binding of antibodies to the nodal axolemma leads to activation of complement and formation of membrane attack complex. The binding of antibodies alone leads to a functional disruption in conduction, whereas axonal degeneration occurs with the destruction of the nodal protein by the membrane attack complex. Recovery can occur at rates compatible with AIDP depending on the stage in pathogenesis, with functional disruption being associated with a better prognosis.
- Acute motor and sensory axonal polyneuropathy (AMSAN)—It is essential to screen these patients for porphyria. It is the most severe phenotype with rapid

Flowchart 1: Approach to a patient with muscle weakness



HPP, hypokalemic periodic paralysis; Crimyne, critical illness myopathy and neuropathy

TABLE 2 Causes of acute muscle weakness

Causes of acute muscle weakness
Acute conditions affecting the spinal cord – Infections (HIV, TB, Syphilis, CMV, EBV), Acute transverse myelitis, Vascular (Ischemia, hemorrhage)
• Anterior Horn cell—Poliomyelitis**,** West nile virus infection
• Polyradiculoneuropathy—GBS, HIV infection, Zika virus, COVID-19
• Polyradiculopathy—Disc disease, Cytomegalovirus infection, neoplasm, hematoma
• Plexus—Acute Brachial Plexopathy, Acute Lumbosacral Plexopathy
• Nerve—Mononeuritis multiplex, Diphtheria, Lyme disease, Acute intermittent porphyria, critical illness neuropathy, Paralytic seafood poisoning
• Neuromuscular Junction—Organophosphate poisoning, botulism, tick paralysis, myasthenia gravis
• Muscle—Inflammatory myopathy, infectious myopathy, acute periodic paralysis, toxic myopathy, critical illness myopathy

onset and complete paralysis. It is strongly associated with antiganglioside antibodies GM1 and GD1a.

Other variants and their associated antiganglioside antibodies.

- Miller Fischer Syndrome: GQ1b, GD1b, GT1a
- Acute sensory ataxic neuropathy: GD1b
- Pharyngo-cervical brachial variant: GD1a, GT1a, GD1b
- Multiple cranial neuropathies
- Facial diplegia with a parasthesias
- Paraplegic variant
- Acute pandysautonomia

Diagnosis

Lumbar puncture showing albuminocytological dissociation is the hallmark of Guillain-Barré syndrome. This is an elevated CSF protein with a normal cell count. This occurs mainly in the second week of illness.

Nerve Conduction Study

- It is normal early in the course of the illness.
- Abnormalities depend on the variant.
- AIDP: Prolonged distal latencies, reduced conduction velocity, prolonged F-wave latency, conduction block, temporal dispersion.
- AMAN/AMSAN: decreased motor and/or sensory amplitudes in the absence of demyelinating features.

The electrophysiological findings in AMAN can at times show a conduction block, which leads to misdiagnosis with AIDP. Conduction block occurs with functional disruption due to antibody binding to the nodal axolemma which is termed as reversible conduction failure. Serial electrophysiology is therefore required to differentiate between the variants.

Antiganglioside antibodies: Their role in diagnosis has not yet been established.

Serum potassium levels: Hypokalemia can mimic GBS.

Other blood tests: Sodium, potassium, phosphate, magnesium, CPK, white cell count, CRP.

MRI spine with contrast: Nerve root enhancement is visualized.

Treatment

- It requires a multidisciplinary approach.
- Intravenous immunoglobulin (IVIg) and plasmapheresis are FDA approved for the treatment of GBS.
- IVIg is administered at a dose of 2 g/kg over 5 days in patients with severe illness and presentation within 2 weeks of disease onset.
- Plasma exchange: From 5–6 cycles at 1–1.5 times the plasma volume.
- Regular monitoring is required for respiratory dysfunction, autonomic dysfunction.
- Prevention of complications like deep vein thrombosis, decubitus ulcers is important.

Inflammatory/Autoimmune Myopathy

It a heterogeneous group of disorders which include:

- Dermatomyositis
- Immune-mediated necrotizing myopathy
- Anti tRNA synthetase syndromes
- Polymyositis

They can be differentiated by characteristic clinical features, serological tests, and findings on muscle biopsy.[3]

Clinical Features

- Proximal muscle weakness of the upper and lower limb manifested clinically as difficulty in getting up from squatting position and difficulty in raising the arms overhead
- Distal muscles are relatively spared
- Truncal weakness
- Neck muscle weakness
- Dysphagia due to pharyngeal weakness

Dermatomyositis:

- *Gottrons papules:* Scaly erythematous lesions on the extensor surfaces of the fingers
- *Shawl sign:* Erythematous rash over the shoulders
- *Heliotrope rash:* Periorbital violaceous eruption
- *Holsters sign:* Poikiloderma of the upper outer thigh
- *Calcinosis:* Painful lumps on the skin surface
- There may be the development of malignancy like adenocarcinoma either before or after the onset of weakness.

Immune-mediated necrotizing myopathy:

- H/o statin exposure
- Progressive symptoms are noted despite stopping statins, thus differentiating it from statin-induced myopathy
- It is not associated with extramuscular features

Antisynthetase syndrome: Is associated with: Raynauds phenomenon, arthritis, mechanics hands (hyperkeratotic lesions on the radial and palmar surfaces), interstitial lung disease, myositis.

Polymyositis: These patients present with proximal muscle weakness without associated dermatological manifestations. Prior to biopsy, there is a probability for misdiagnosis with conditions like dermatomyositis sine dermatitis, inclusion body myositis, limb-girdle muscular dystrophy.

Extramuscular involvement:
- Interstitial lung disease
- Joint disease
- Cardiac involvement

Diagnosis
- Creatinine kinase, LDH, AST, ALT, aldolase are elevated
- *EMG:* Small polyphasic motor unit potentials are seen
- Spontaneous activity may reveal complex repetitive discharges in dermatomyositis

Muscle Biopsy
- *Dermatomyositis:* Perifascicular atrophy, perivascular infiltrate with B cells, plasmacytoid cells, dendritic cells.
- *Immune-mediated necrotizing myopathy:* Muscle fiber necrosis
- *Antisynthetase syndrome:* Perifascicular necrosis
- *Polymyositis:* Inflammatory infiltrates in the non-necrotic muscle fibers

Serological Tests
See **Table 3**.

TABLE 3 Serological markers in inflammatory myopathy

Type of myopathy	*Serological tests*
Dermatomyositis	Anti TIF1, anti MDA5, anti Mi-2, anti NXP2
Immune-mediated necrotizing myopathy	Anti SRP, anti HMG-CoA reductase
Antisynthetase syndromes	Anti tRNA synthetase anti jo 1 (histidyl)1, anti-threonyl, anti-alanyl, anti-alanyl, anti-glycyl, anti-phenylalanyl, anti-tyrosyl, anti-isoleucyl tRNA synthetase syndromes

HMG-CoA, 3-Hydroxy-3-methylglutaryl CoA; MDA, melanoma differentiation associated protein; NXP, nuclear matrix protein; SRP, signal recognition peptide; TIF, transcription intermediary factor.

Treatment
- IV/oral steroids are useful depending on the severity.
- Immunosuppressants: azathioprine, mycophenolate mofetil, cyclophosphamide, cyclosporine, tacrolimus as maintenance therapy.
- Refractory cases: IV immunoglobulin, Rituximab

Critical Illness Polyneuropathy
It is an acute axonal sensorimotor polyneuropathy leading to muscle weakness with difficulty weaning from the ventilator.[4] It is often associated with critical illness myopathy represented by the acronym CRIMYNE (critical illness myopathy and neuropathy). It is considered that both entities have a common pathophysiological mechanism. Around 70–80% of the patients admitted to ICU develop CIP. Difficulty in weaning the patient from the ventilator despite normal mental, pulmonary, and cardiovascular function, and correction of the metabolic, infectious causes of respiratory failure.

Risk Factors for Critical Illness Polyneuropathy
Sepsis/SIRS, multiorgan failure, female sex, prolonged illness, renal failure and renal replacement therapy, TPN, hypoalbuminemia, vasopressor use, hyperglycemia, hyperosmolarity.

Clinical Features
- It leads to symmetrical flaccid weakness.
- Proximal and distal weakness with hypotonia and areflexia.
- Muscle atrophy can occur.
- Cranial nerve involvement is very rare. Ophthalmoplegia has been reported in a few instances. If there is cranial nerve involvement, other causes of acquired muscle weakness like Guillain-Barré syndrome should be ruled out.

Treatment
Treatment is not effective.

Prevention

Nutritional intervention, antioxidants, testosterone derivatives, growth hormones, immunoglobulins, treatment of sepsis, intensive insulin therapy (maintaining blood glucose between 80–110 mg/dL; risk of hypoglycemia).[5]

Periodic Paralysis

They are a group of autosomal dominant disorders involving muscle ion channels. They are characterized by episodic muscle weakness and areflexia. These are triggered by changes in behavior and diet. Primary periodic paralysis includes hypokalemic periodic paralysis, hyperkalemic periodic paralysis, Andersen-Tawil syndrome. There is an overlap with other disorders causing myotonia and episodic weakness like paramyotonia congenita. Differences between hypokalemic and hyperkalemic periodic paralysis is given in **Table 4**.

Hypokalemic Periodic Paralysis

It is associated with mutations in the calcium channel (CACNA1S) in 60–80% or mutations involving the sodium channel (SCN4A) in 20%.[6]

Clinical Features

Symptoms occur at weekly/monthly intervals. There may be sensory symptoms prior to the onset of weakness—fatigue, myalgia. Usually, there are no cranial nerves or respiratory symptoms. Initial attacks are associated with complete recovery. With time, progressive muscle weakness develops.

Diagnosis

- It may be made clinically from the clinical history and associated features.
- The serum potassium levels are reduced, but never below 2 mM. With lower potassium levels, gastrointestinal, renal, adrenal causes should be ruled out.
- ECG: Features of hypokalemia such as prolonged PR interval, absent T waves and prominent U waves may be present.
- Thyroid function tests should be done in all cases to rule out thyrotoxic periodic paralysis.
- A glucose challenge test with 2–5 mg/kg of glucose may precipitate an attack.
- EMG during an attack reveals short polyphasic motor unit potentials.
- Genetic testing for calcium channel mutations has now largely replaced the need for biopsy.

Treatment

Acute attacks are treated with oral/IV potassium depending on the severity.

Prophylaxis

- Carbonic anhydrase inhibitors like acetazolamide can reduce the frequency and duration attacks. Dichlorphenamide can be used in cases not responding to acetazolamide.
- Other drugs like potassium-sparing diuretics, ACE inhibitors can also be used to prevent attacks.

Myasthenia Gravis

It is an autoimmune disorder with antibodies directed against the nicotinic acetylcholine receptor (AChR). The amount of acetylcholine released is normal, but the availability of acetylcholine receptors is reduced leading to smaller endplate potential.

Clinical Features

The patient presents with extraocular, bulbar, respiratory, and proximal limb weakness. Extraocular weakness may mimic III, IV, VI nerve palsy with sparing of the pupils.[7] Bulbar weakness may present with difficulty

TABLE 4 Distinguishing features of hypokalemic periodic paralysis and hyperkalemic periodic paralysis

	Hypokalemic periodic paralysis	*Hyperkalemic periodic paralysis*
Duration of symptoms	Hours to days	Minutes to hours
Precipitating factors	Rest after exercise, carbohydrate load	Post-exercise, fasting
Severity	Moderate to severe	Mild to moderate
Associated myotonia	Absent	Present

in swallowing, speaking, and nasal regurgitation. Limb weakness is proximal, resembling myopathy. These patients characteristically have diurnal variations with fatigue. Anti-MUSK (muscle specific kinase) myasthenia presents with ocular, bulbar, neck, and respiratory muscle weakness. Myasthenic crisis is when a respiratory failure occurs as a result of weakness. A precipitating event like an infection, surgery, and change in medications is often present.

Diagnosis

Repetitive nerve stimulation is abnormal in 50–70% of patients with myasthenia graves. In MG, there is a decremental response of 10% in the CMAP with slow RNS, which is not seen in normal subjects. The decremental response is the electrophysiological correlate of fatigable weakness.

Tensilon test: Edrophonium is short-acting acetylcholinesterase injected intravenously under cardiac monitoring. The patient is observed for improvement in symptoms, particularly of the extraocular muscles and ptosis.

Ice pack test: It is a nonpharmacological test. It can be used in patients in whom edrophonium is contraindicated. The placement of an ice pack over the ptotic lid leads to improvement.

Serological tests: Anti-acetylcholine receptor antibody

Anti MUSK antibody: Anti titin, actin, myosin, ryanodine receptor, and other striated muscle antibodies are positive in patients in early-onset thymomatous myasthenia gravis.

CT/MRI chest: To rule out the presence of a thymoma.

Treatment

- Symptomatic treatment with acetylcholinesterase inhibitors
- Rapid-acting immunomodulation with IVIG or plasmapheresis.
- Long-lasting immunosuppression with steroids and immunosuppressants.
- Surgical treatment in cases with thymoma.

Conclusion

Acute muscular weakness may be caused by a wide variety of etiologies. The pattern of weakness may vary depending on the etiology. The weakness may be proximal or distal, symmetrical, or asymmetrical. There are characteristic features that help in arriving at a diagnosis. Careful attention should be given to the presence of respiratory, bulbar weakness, which warrants intensive care since acute onset weakness is a neurological emergency.

CHAPTER

89 The Art and Science of Thrombolysis in Acute Ischemic Stroke

MV Padma Srivastava, Ayush Agarwal

Abstract

Opening a blocked artery remains the prerequisite to ensure reperfusion of the critically perfused brain. The "science of thrombolysis" in acute ischemic stroke is built on robust twin pillars of good clinical practice and sound science. It is imperative that patients are immediately triaged, imaged, and judged whether they have viable tissue, which could recover with reperfusion. Thereafter, through the evidence gathered over time, it is identified whether the patients meet the strict criteria for thrombolysis. Patients often fall in grey areas, outside these strict established guidelines, who, however, may be salvaged with thrombolysis with expert clinical acumen. The "art of thrombolysis" is to identify these patients. Thrombolysis is the most validated and valuable tool for physicians in their arsenal against acute ischemic stroke and only smart patient selection can expand its repertoire further, providing best chances of a positive functional outcome.

Introduction

Acute ischemic stroke (AIS) is a heterogeneous disorder with varied etiology and complex pathology. Major trials have confirmed the benefit of thrombolysis in the acute stage, irrespective of the stroke subtype. Based on a very simple algorithm that "time is brain" and "unblocking" a "blocked" artery remains the quintessential prerequisite to ensure reperfusion of the critically perfused brain, the "science" of "thrombolysis" in AIS is built on robust twin pillars of good clinical practice and sound science. It is imperative that patients are immediately triaged, imaged, and judged whether they have viable tissue, which could recover with reperfusion.

The evidence gathered over several decades is used to identify patients who fulfill the current guidelines and inclusion criteria for thrombolysis. However, in clinical practice, patients are often encountered who fall "outside" established guidelines, those in whom thrombolysis is "absolutely" contraindicated, those who do not benefit with thrombolysis (failed thrombolysis) and those who lie within "grey areas" but may nonetheless be salvaged with thrombolysis with expert clinical acumen.

The "art" of thrombolysis is to identify patients in the above categories.

Approach

Precise history taking and proper structured evaluation are imperative for decision-making with regards to acute stroke management. The points that have to be noted include the time of symptom onset, age, baseline vitals and blood sugar and stroke severity (graded by NIHSS[1]) **(Table 1)**.

Neuroimaging is undertaken after clinical assessment, with the aim of establishing a clinical diagnosis as promptly as possible. The choices for the same include NCCT or MRI.[2] The former is frequently used because it distinguishes a hemorrhagic from an ischemic stroke and may reveal early ischemic changes. These are graded on the ASPECTS scale **(Fig. 1)** (Scores >7).

TABLE 1 NIHSS scoring

Tested item	*Title*	*Responses and scores*
1A	Level of consciousness	1-Alert 2-Drowsy 3-Obtunded 4-Coma/Unresponsive
1B	Orientation questions (2)	0-Answers both correctly 1-Answers one correctly 2-Answers neither correctly
1C	Response to commands (2)	0-Performs both tasks correctly 1-Performs one task correctly 2-Performs neither
2	Gaze	0-Normal horizontal movements 1-Partial gaze palsy 2-Complete gaze palsy
3	Visual fields	0-No visual field defect 1-Partial hemianopia 2-Complete hemianopia 3-Bilateral hemianopia
4	Facial movement	0-Normal 1-Minor facial weakness 2-Partial facial weakness 3-Complete unilateral facial palsy
5	Motor function (arm) • Left • Right	0-No drift 1-Drift before 10 seconds 2-Falls before 10 seconds 3-No effort against gravity 4-No movement
6	Motor function (leg) • Left • Right	0-No drift 1-Drift before 5 seconds 2-Falls before 5 seconds 3-No effort against gravity 4-No movement
7	Limb ataxia	0-No ataxia 1-Ataxia in one limb 2-Ataxia in two limbs
8	Sensory loss	0-No sensory loss 1-Mild sensory loss 2-Severe sensory loss
9	Language	0-Normal 1-Mild aphasia 2-Severe aphasia 3-Mute or global aphasia
10	Articulation	0-Normal 1-Mild dysarthria 2-Severe dysarthria
11	Extinction or inattention	0-Absent 1-Mild loss (1 sensory modality lost) 2-Severe loss (2 sensory modalities lost)

Total score- 42. Higher score corresponds to higher stroke severity.

Multimodal imaging (CT/MRI) **(Table 2)** provides added information about the vascular status (primary and collaterals), perfusion status, and extent of ischemic insult.[4,5] These take between 10–15 minutes to perform and are required in guiding thrombolysis decisions in special situations like unknown time of onset and wake-up strokes. Small infarct core with higher salvageable penumbra or DWI hyperintensities without corresponding ones seen on T2-FLAIR are usually taken as markers to thrombolyse patients in these situations.[5]

Treatment

The primary therapeutic goal of acute stroke treatment is the prompt restoration of blood flow in the occluded vessel. The following factors must be considered to guide patient selection for the same:

- Age
- Time of symptom onset
- Baseline:
  - NIHSS
  - ASPECTS

Within the Standard Guidelines

Intravenous alteplase (0.9 mg/kg body weight; 10% dose given as an intravenous bolus, with the remaining infused over 1 hour; maximum dose—90 mg) and tenecteplase (0.25 mg/kg body weight; given as a bolus dose) are the thrombolytics approved for use. They can be used up to 4.5 hours of stroke onset, the greatest benefit found with earlier treatment [The NNT increases from 2 (treatment 0–1.5 hours) to 7 (treatment 1.5–3 hours) to 14 (3–4.5 hours)].[6] The standard guidelines[7] for the same are discussed as follows.

Inclusion criteria:

- Diagnosis of ischemic stroke causing measurable neurological deficit
- Onset of symptoms <4.5 hours since treatment initiation
- Age ≥18 years

Exclusion criteria:

- Significant head trauma or prior stroke in the past 3 months
- Symptoms suggestive of subarachnoid hemorrhage
- Arterial puncture at a non-compressible site in the past 1 week

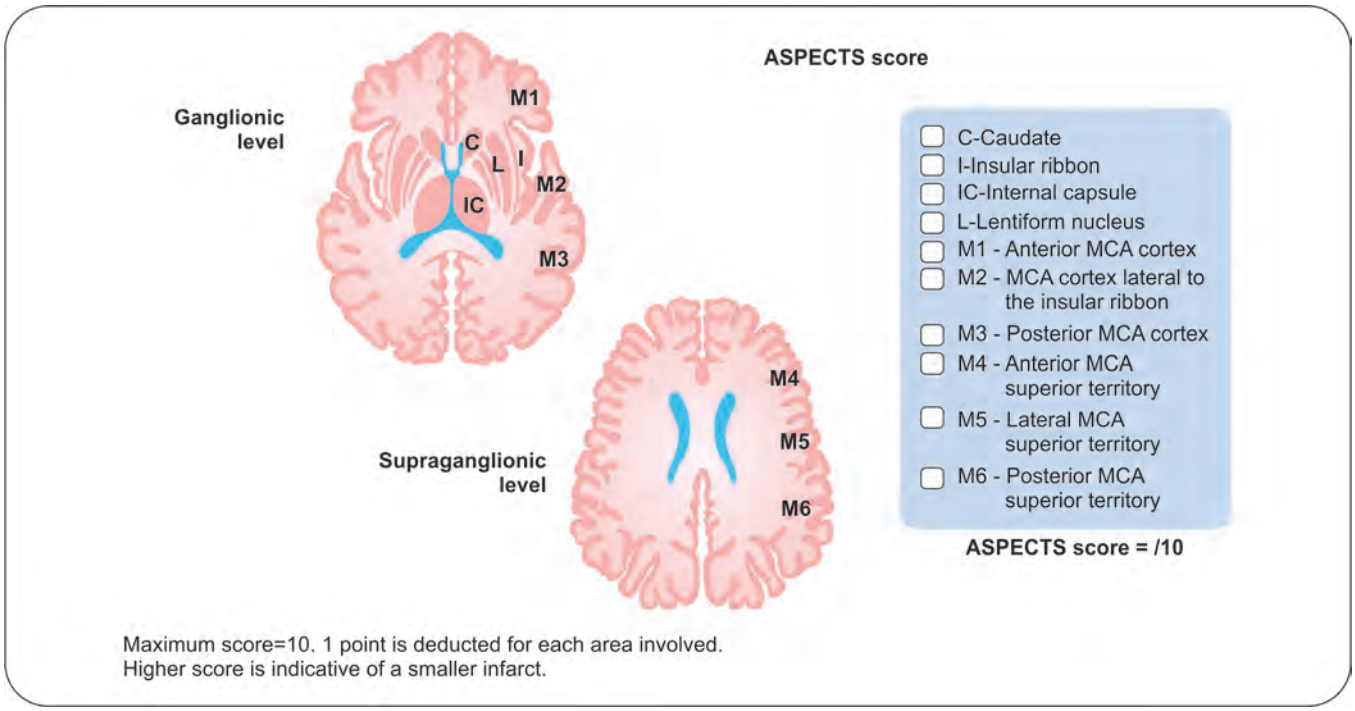

Fig. 1: ASPECTS score[3]

TABLE 2 Multimodal imaging

Imaging	*Functions*	*Advantages*	*Disadvantages*
CTP	Information about infarct core and penumbra	Quicker than multimodal MRI	Additional exposure to radiation and contrast agents
CTA	Extent and location of arterial occlusion/stenosis/dissection		
CTV	Detection of CVT		
Multimodal MRI • DWI • PWI • T2-FLAIR • MRA • MRV	• Location, age, and extent of ischemia • Location and extent of hypoperfused area • Exclusion of stroke mimics • Location and extent of arterial occlusion/stenosis/dissection • Detection of cerebral venous thrombosis	More accurate in determining posterior circulation stroke	Longer time to perform, not widely available, expensive, cannot be used in cases with ferromagnetic implants

- History of previous intracranial hemorrhage
- Intracranial neoplasm, arteriovenous malformation or aneurysm
- Recent intracranial or intraspinal surgery
- Active internal bleeding
- Elevated blood pressure (systolic >185 mm Hg, diastolic >110 mm Hg)
- Acute bleeding diathesis, including but not limited to:
  - Platelet count <100,000/mm^3
  - Heparin received in the past 48 hours resulting in abnormally elevated aPTT above the upper limit of normal
  - Current use of anticoagulant with INR >1.7 or PT >15 seconds
  - Current use of direct thrombin or direct factor Xa inhibitors

- Blood glucose <50 mg/dL
- CT demonstrates multilobar infarction (hypodensity in >1/3 of cerebral hemisphere)

Relative exclusion criteria:

- Minor or rapidly improving stroke symptoms
- Pregnancy
- Seizure at onset with post-ictal residual neurological impairments
- Major surgery or serious trauma within the previous 2 weeks
- Recent gastrointestinal or urinary tract hemorrhage in the past 3 weeks
- Recent myocardial infarction in the past 3 months

*Relative contraindications for thrombolysis between 3–4.5 hours:

- Age >80 years
- Diabetes mellitus
- NIHSS >25
- History of oral anticoagulant intake irrespective of INR

Outside the Standard Guidelines

The standard guidelines for thrombolysis were set based on the findings of the pivotal trials (NINDS, ECAS III, and ATLANTIS).[8] These trials excluded many patients to limit complications, who could potentially benefit from thrombolysis. These include patients mentioned under the relative contraindications section.

Delayed Thrombolysis

The patient selection for this subgroup is largely dependent on the multimodal imaging techniques mentioned previously. With the advent of these, the era of exclusively time-based thrombolysis may finally be over.

The WAKE UP trial[9] enrolled patients with wake-up strokes or strokes whose time of stroke onset was not known, but were last seen normal more than 4.5 hours ago. This was based on the premise that stroke in these patients usually occurs closer to waking up/found not to normal unlike traditional teaching where it was taken from when they were last seen to be normal. Inclusion criteria required the presence of ischemic lesion visible on DWI but no parenchymal hyperintensity on FLAIR (indicating that the stroke had probably occurred in the past 4.5 hours). They found that this approach was associated with a significantly better functional outcome as compared to placebo.

The EXTEND trial[10] enrolled ischemic stroke patients for thrombolysis in the extended window period (4.5–9 hours after stroke onset or wake-up stroke between 4.5–9 hours of sleep), guided by perfusion based imaging. Those patients who were found to have hypoperfused, yet salvageable brain regions by the same were randomly assigned either to receive intravenous alteplase or placebo. Patients were eligible if they had a mismatch between the core of infarction and potentially salvageable brain tissue in the penumbra. They found a higher likelihood of better functional outcome in thrombolysed patients as compared to placebo.

Minor Nondisabling/Recovering Strokes

The AHA/ASA recommend the administration of intravenous alteplase for patients with mild disabling strokes but are indecisive about mild strokes with nondisabling symptoms.[7] This has posed a therapeutic dilemma: treat because they might worsen or do not treat because of risk of sICH? The PRISMS trial[11] helped define the role of intravenous rTPA in this setting. Apart from the excellent outcome in the aspirin group, the overall similar outcomes between the two groups make it unlikely that thrombolysis in patients with NIHSS scores ≤5 with nondisabling deficits would significantly improve their functional outcome. However, the trial does not address the issue of what constitutes a "non-disabling" deficit in its entirety. Ambiguity and lack of consensus in this regard will continue to raise concerns regarding "missing" eligible patients for thrombolysis on the grounds of the deficits being "nondisabling."

Patients with Seizure at Onset

Post-stroke seizures are classified as early (within 1 week of stroke) and late (>7 days post-stroke).[12] Occasionally, these early seizures occur at stroke onset. The inherent difficulty in differentiating Todd's palsy from ischemic stroke associated weakness makes this situation a relative contraindication for thrombolysis.[13] However, with the advent of multimodal imaging techniques described previously, the decision for thrombolysis can be made with more certainty if there is an ischemic penumbra that can be salvaged.[14] Both AHA/ASA and ESO recommend thrombolysis, if it can be ascertained with confidence that the focal deficit is due to ischemic stroke, and not a post-ictal phenomenon.[2]

Patients on Anticoagulation

All patients on vitamin K activity based anticoagulation (warfarin/acitrom) need to undergo INR testing prior to anticoagulation, and can be safely thrombolysed if INR <1.7. All patients with an INR above that range cannot be thrombolysed as the risk of bleeding negates the benefit of thrombolysis.[7]

Ideally, patients on novel non-vitamin K based anticoagulants (direct thrombin inhibitors/factor Xa inhibitors) should not be thrombolysed if the last dose has been taken within the past 48 hours. However, it can be considered if all appropriate laboratory tests: aPTT, PT, clotting time, thrombin time, and factor Xa assay are normal.[7]

Pregnancy

Ischemic strokes in pregnancy and puerperium are rare and usually of cardioembolic origin (secondary to rheumatic heart disease) in our country. Treatment is challenging because of the potential risks to the mother and teratogenicity to the fetus. The former include antepartum hemorrhage due to abruption placentae, peri-, or postpartum hemorrhage and premature labor.[15]

No RCTs on thrombolysis have been conducted in this patient population both due to ethical reasons and paucity in numbers. Some case reports/case series have shown beneficial results. The afflicted patient is thrombolysed based on the inclusion and exclusion criteria mentioned previously as the maternal health takes precedence over the fetal health. Also, rTPA does not cross the blood-placental barrier and animal studies till date have not shown any evidence of teratogenicity.

Therefore, the decision regarding thrombolysis should be taken on a case-to-case basis balancing the benefits against potentially unknown harms.

Dementia

Thrombolysis in individuals with dementia remains unaddressed and does not find mention in either inclusion or exclusion criteria for thrombolysis. The higher burden of small vessel disease and/or amyloid angiopathy in this patient population makes most physicians reluctant toward thrombolysis due to the presumed added risk of post-thrombolysis hemorrhage.[16,17] However, studies revealed that white matter disease was associated with increased risk of post-thrombolysis hemorrhage but not for poorer outcome at 3 months.[18] Another study found no difference in the rates of mortality and intracranial hemorrhage in this patient population compared to those without dementia.[19]

Caution may be exercised in individuals who are no longer independent for activities in daily living (mRS >3) as not much might be gained from thrombolysis, but should be actively contemplated in the remainder.

Malignancy

There is limited data available on the safety and efficacy of thrombolysis in patients with a malignancy. The presumed risk of symptomatic intracranial hemorrhage makes it a relative contraindication for the same.[20] However, a few case series found that it was not a significant independent risk factor for post-thrombolysis morbidity or mortality. Therefore, thrombolysis may be safely considered in patients with malignancies, provided an absence of an intracranial neoplasm or brain metastasis.

Conclusion

Thrombolysis with rTPA and tenecteplase has dramatically revolutionized acute stroke treatment due to their availability as an effective means of treatment. There is mounting evidence of their benefit not only within but also beyond the standard treatment guidelines. The benefit of thrombolysis can be further extended through smart selection of patients based on a clinico-imaging criterion, which improves response rates and decreases the complication risk. Evidence-based exclusion criteria are invaluable but should be adaptable in the acute setting as stringent additional testing will be counter-productive wasting precious time.

The selection of patients for thrombolysis is both an art and a science. The "art" is dependent on the clinical acumen and experience of the treating physician. This art reassures him that a benefit is expected from the treatment and is not being done for the lack of other better alternatives. The "science" part arises from the analysis of predictive markers determining the response to therapy.[21]

Thrombolysis is the most validated and valuable tool for physicians in their arsenal against ASI and only smart patient selection can expand its repertoire further, providing best chances of a positive functional outcome.

CHAPTER

90 Imaging in Stroke

Justin C

Abstract

Stroke imaging is growing by leaps and bounds with every passing year.Since mechanical thrombectomy has become the standard of care in large vessel occlusions. Its imperative that every physician is equipped with the knowledge of stroke imaging to keep up with the latest trends. This chapter briefly outlines the important signs of stroke in imaging starting from non contrast ct brain to advanced imaging evaluations done before a patient is undertaken for mechanical thrombectomy.

Introduction

A clinical diagnosis of stroke even when it is largely accurate by an experienced clinician warrants mandatory neuroimaging. Imaging in stroke patients is the quintessential step before any step in the management of these patients. Furthermore, in stroke there is a rapid shift from time-based approach to tissue-based approach during interventions. Before doing MR imaging, a non contrast CT brain in stroke window will be a cost effective, time saving, and logical first step and in many cases the only investigation that will ever be needed in stroke patients. With the advent of extended stroke interventions with endovascular techniques, CT angio, and CT perfusion imaging will be needed to assess the risk benefit ratio before intervening.

Acute Stroke

Ischemic strokes contribute to almost 85% of stroke cases with hemorrhagic strokes contributing to 10% of cases and the rest by subarachnoid hemorrhage (SAH). Transient ischemic attack is a transient neurological deficit due to focal brain, spinal cord or retinal ischemia that rapidly recovers usually within 1 hour with no infarction or tissue injury.

Intracerebral Hemorrhage (ICH)

Even though MRI brain is the most specific investigation for identifying bleeds in brain, non-contrast CT is the gold standard investigation for ICH. The density of bleed declines by 1.5 HU/day. The location of the bleed may offer some clue to the etiology of the bleed **(Table 1)**.

Hematoma clot expansion in hypertensive patients can be halted by effective blood pressure management and if necessary by rFactor VII administration.[1] Hemorrhage extending into ventricles worsens the clinical outcome in all patients (except in thalamic hemorrhage). Hence, early CT brain helps charter the course in ICH patients and not merely excludes hemorrhage for acute ischemic stroke patients. Some of the important signs of ICH in both NCCT and CT brain are listed in **Table 2** and depicted in **Figures 1A to C**.

Vascular Imaging

Vascular imaging may be necessary in patients with suspected arteriovenous malformation (AVM) induced superficial bleed that can be surgically evacuated or in aneurysmal SAH.

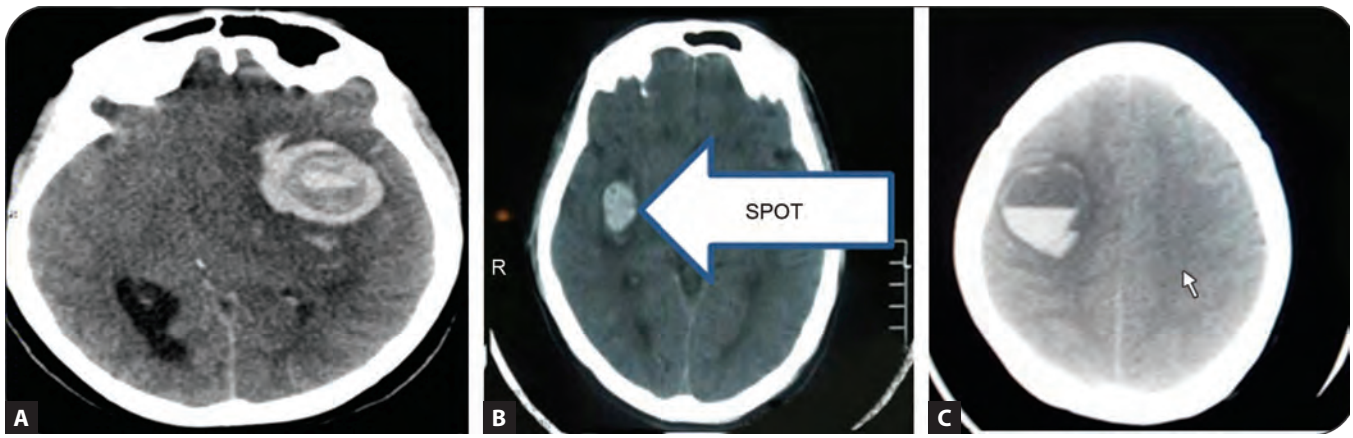
TABLE 1 Location of bleed and its etiology

Location	*Etiology*
Striatocapsular & striatothalamic	Hypertension
Lobar—(more in occipital)	CAA
Lobar—(large irregular shaped from cortex to ventricles)	AVM
Lobar—with blood fluid level	Coagulopathy
Lobar—parietal or temporal	Vein of Trolard or Labbe thrombus
Lobar -Frontal with SAH (dissecting Jet of bleeding aneurysm)	Aneurysms
Cisternal bleed/sulcal bleed	Aneurysms
Parasagittal bleeds/Meningeal based bleed with edema	Dural venous thrombosis/CVT
Subdural bleed	Coagulopathy or trauma
EDH	Trauma
Primary IVH	Cavernoma, AVM, coagulopathy, HT, tumors
Convexity SAH/ICH	RCVS

AVM, arteriovenous malformation; CAA, cerebral amyloid angiopathy; CVT, cerebral venous thrombosis; EDH, epidural hemorrhage; HT, hemorrhagic transformation; ICH, intracerebral hemorrhage; IVH, intraventricular hemorrhage; SAH, subarachnoid hemorrhage.

TABLE 2 Signs in CT brain indicating active bleed

ICH signs in CT	*Comments*
CTA Spot *sign*—contrast extravasation into hematoma	Active bleed with poor outcome
Swirl sign (in NCCT) akin to CTA Spot sign	Acute extravasation of blood into hematoma
Island sign—multifocal bleed around main bleed	Active hematoma expansion
Blend sign—blending of hypodense and hyperdense area	Active hematoma expansion
Black hole sign (hypoattenuating within hyperdense)	Active hematoma expansion



Figs. 1A to C: Some important ICH signs in Plain CT Brain. (A) Plain CT brain Showing central Swirl sign and peripheral island sign. (B) CT brain demonstrating central spot sign. (C) Plain CT brain demonstrating blood fluid level

MR Imaging

MR imaging remains as the most accurate investigation for detecting very small hemorrhages. The transition of oxyhemoglobin (diamagnetic) in blood to later derivatives starting from deoxyhemoglobin (paramagnetic) causes local T2 dephasing of the protons from its precessional path and induces rapid signal loss in GRE and susceptible weighted imaging, manifesting as blooming. Whether thrombolysis can be safely done in patients with microbleeds due to hypertensive vasculopathy is a topic of controversy with many deferring thrombolysis when there is more than 10 microbleeds.

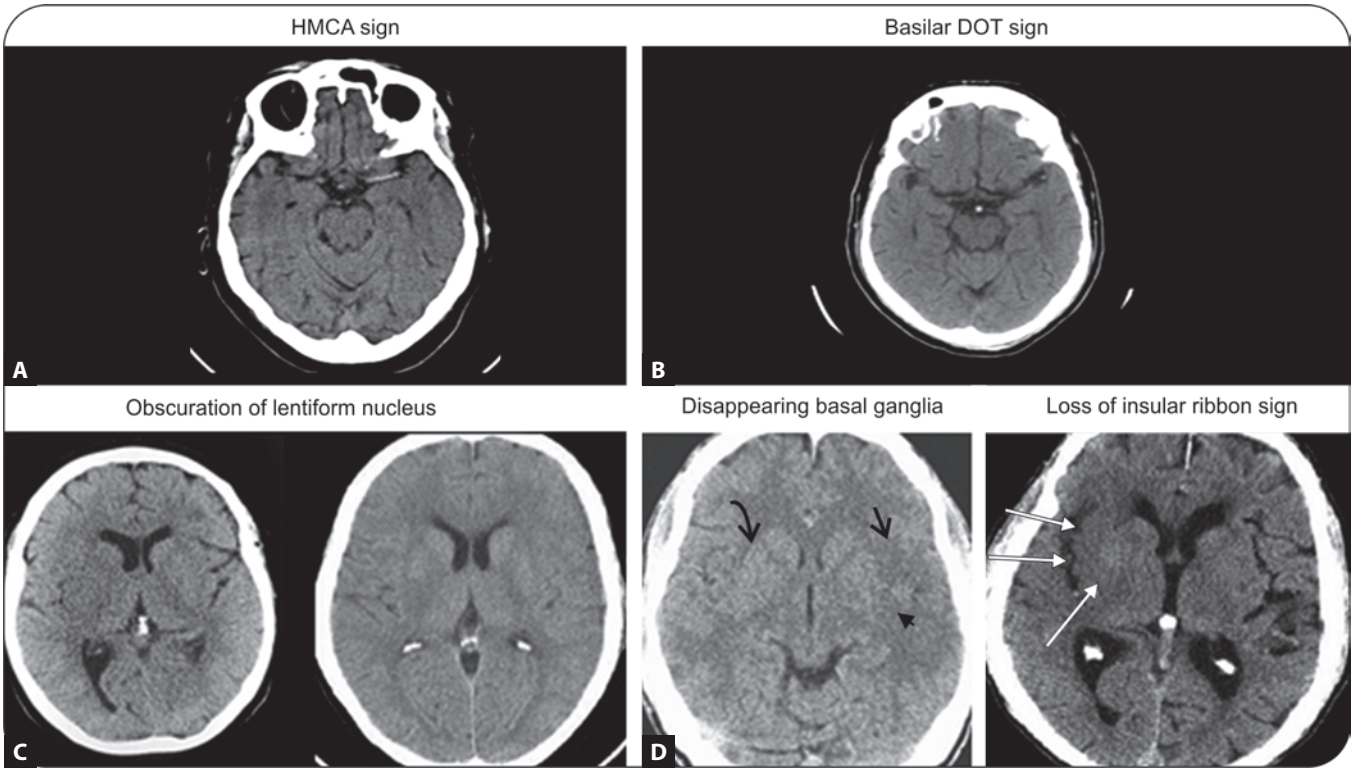
Acute Ischemic Stroke (AIS)

Aided with an accurate history, an NCCT is the ideal emergency investigation in AIS patients. It conveniently rules out hemorrhage and many of the stroke mimics. Ischemic tissue due to cytotoxic edema appears hypodense on NCCT. Reversible ischemic tissue may appear hypodense and swollen in CT. Very large hypodense lesion portends poorer outcome and high risk of hemorrhagic transformation.

Even in an acute setting almost half the patients with AIS have a normal CT brain. A well trained eyes can pick out some of the early ischemic signs **(*see* Figs. 2A to D)** in plain CT **(Table 3)** so that thrombolysis can be undertaken without delay.

TABLE 3 Signs of early ischemia in NCCT

Early ischemic changes in NCCT	***Comments***
Hyperdense arteries (MCA, PCA, ACA)	Highly sensitive, less specific
M2 Dot sign	Highly specific, less sensitive
Basilar artery Dot sign	Very high mortality
Striatal and lentiform hypodensity	
Loss of insular ribbon sign	One of the earliest changes
Cortical gray-white differentiation loss	
Hemispherical sulcal effacement	
Focal compression of lateral ventricles	



Figs. 2A to D: Early Ischaemic signs in Plain CT brain. (A) Showing hyperdense left MCA in the sylvian cistern (HMCA sign). (B) Showing Hyperdense Basilar artery in suprasellar cistern (Basilar Dot sign). (C and D) Showing blurring of margins of basal ganglia & Right insular ribbon sign respectively

ASPECTS Scoring

The *Alberta stroke programme early CT score (Anterior ASPECTS)* is a 10-point scoring system with CT imaging done in patients with MCA strokes **(*see* Fig. 3)**.

Anterior ASPECTS

- Two slices are chosen for the analysis—thalamic level (M1 to M3) and just above basal ganglia (M4 to M6) **(*see* Fig. 3)**.
- Ten segments located within mca distribution. Caudate head, insula, lentiform nucleus, internal capsule, and M1–M6.
- Normal segments—0 point. Ischemic region—1 point. Points are deducted from an initial score of 10 for every region involved
- Maximum is 10 points. Lower scores denotes larger regions of mca infarct. A score of 7 or less indicates 1/3 of mca territory infarct and increased chance of poor clinical outcome.
- Score 7 = 1/3 mca infarct. Score 0 = full mca

Posterior ASPECTS

The posterior ASPECTS just like anterior aspects is the 10-point scoring system where points are lost for each region affected. The pons and the midbrain are worth 2 points each (unilateral or bilateral) **(*see* Fig. 4)**.[2]

- Thalamus (1 point each)
- Occipital lobes (1 point each)
- Midbrain (2 points)
- Pons (2 points)
- Cerebellar hemispheres (1 point each)

Many accredited stroke centers follow an individualized stroke image algorithm. One such highly recommended algorithm adopted by Massachusetts General Hospital, USA is shown in the **Flowchart 1**.

Massachusetts General Hospital acute stroke imaging algorithm for triage of patients with severe ischemic

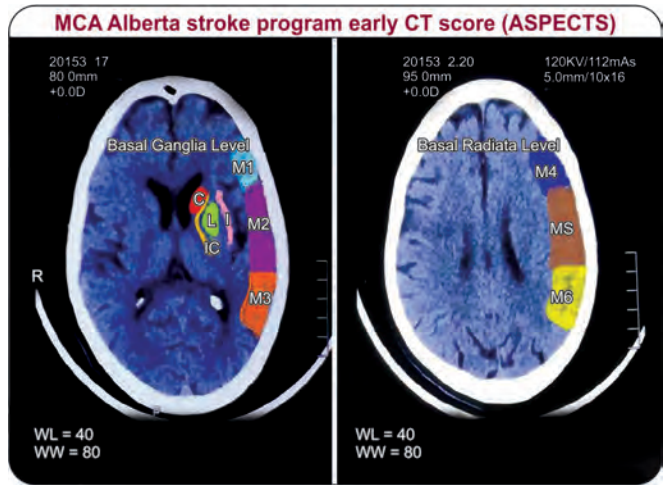


Fig. 3: Plain CT brain demonstrating MCA segments (Thalamic Level-M1 to M3 and level above basal ganglia-M4 to M6) used to calculate ASPECTS Score
C: caudate; IC: internal capsule; L: lentiform nucleus; I: insular Cortex.

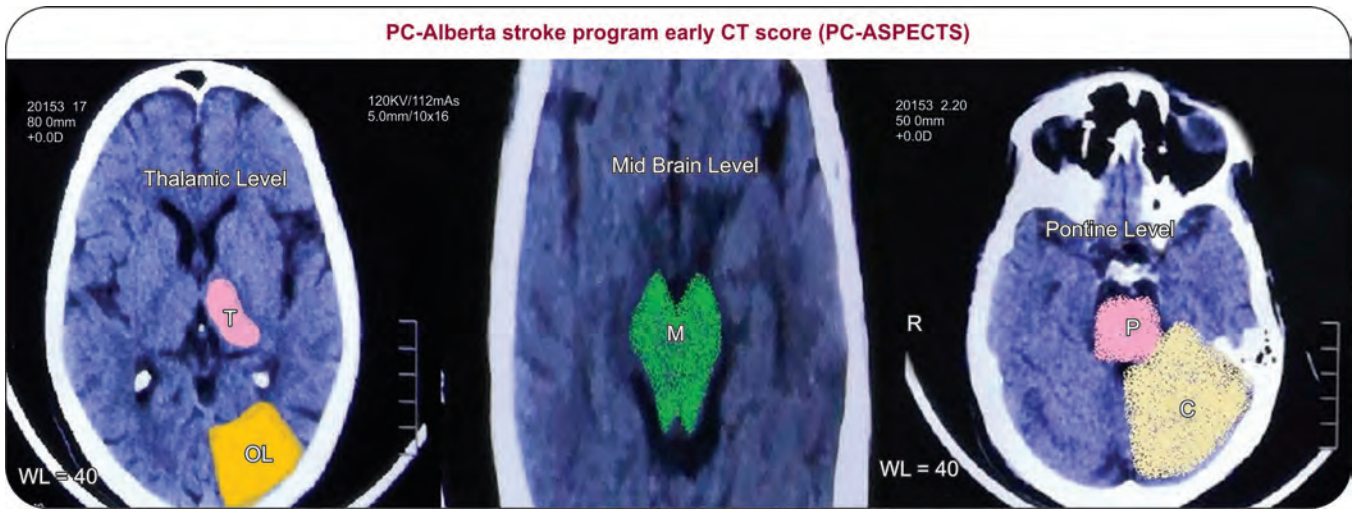

Fig. 4: Plain CT brain demonstrating posterior circulation. Segments used to calculate posterior ASPECTS
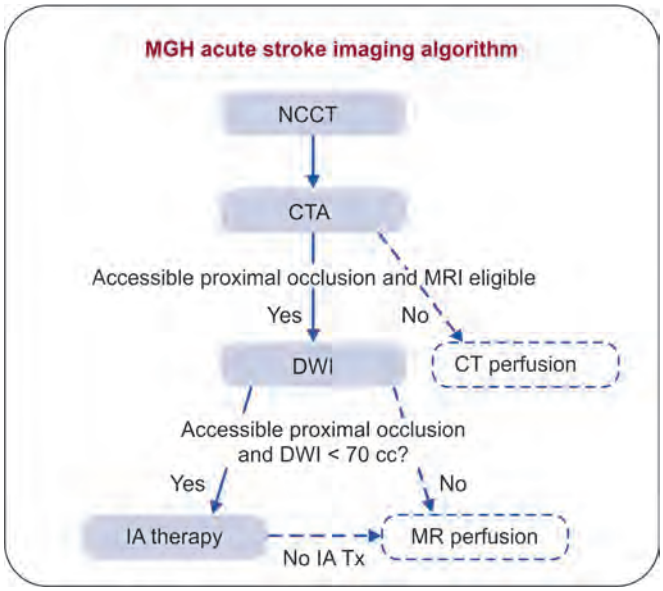
T, thalamus; OL, occipital lobe; M, any part of the midbrain; P, any part of the pons; C, cerebellar hemispher.

Flowchart 1: Flowchart depicting stroke imaging algorithm adopted in Massachusetts General Hospital, USA



strokes caused by anterior circulation occlusions dictates a Plain CT Brain for all patients followed by CT angiography. The patient is further evaluated with DWI if the patient has an NIHSS score of 10 or above with an occlusion identified at distal ICA and Proximal MCA with accessibility to microcatheter. If the size of core infarct is less than 70 mL in DWI the patient is taken up for endovascular therapy. If the patient is unfit for endovascular therapy, perfusion studies can be done for further guidance of therapy.

Goals of Acute Stroke Imaging-4Ps

- Parenchyma—assess early signs of acute stroke, rule out hemorrhage
- Pipes—assess extracranial and intracranial arteries
- Perfusion—assess CBV, CBF, MTT
- Penumbra—assess tissue that can be salvaged

CT Angiography

Contrast enhanced CT offers substantial additional value in assessment of cerebral blood volume, CT perfusion studies and in CTA. One of the most important objectives is location of the clot in the distal ICA or proximal MCA so as to undertake intra-arterial therapy. Volume of infarct is an important parameter deciding the use of IAT, with

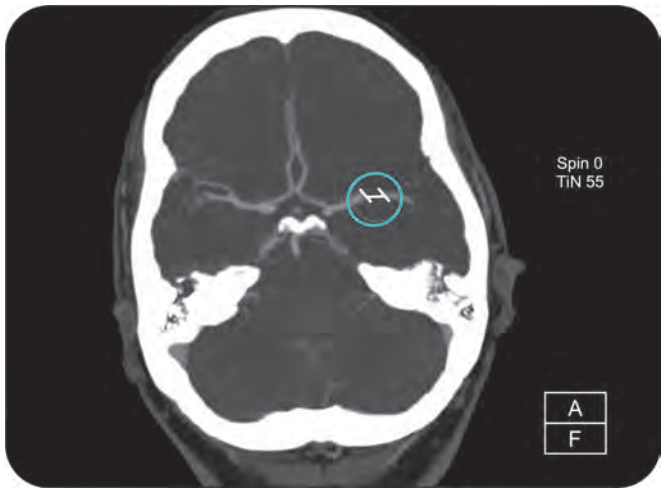


Fig. 5: CT brain angio showing flow a void due to a clot in MCA. The entire length of the flow void from distal to proximal (blue circle) is taken as clot length

volume greater than 70–100 mL having high chances of hemorrhage.

CT angiography may offer great insights into the nature of the thrombus by following assessments.

- *Length of clot:* In MCA strokes, studies have shown that the IVT has no potential to recanalize if the clot length exceeds 8 mm **(*see* Fig. 5)**. Such patients may greatly benefit from endovascular interventions (Provided with good collaterals). Surprisingly many basilar artery occlusions (BAO) even with high NIHSS scores obtain very good recanalization with IVT even comparable to intra-arterial thrombolysis.
- *CTA source image ASPECTS:* For ASPECTS scoring and collateral assessments. CTA SI being more sensitive offers a distinct advantage in early ischemic strokes when compared to NCCT **(*see* Fig. 6)**.
- *Residual flow assessment:* Succesful thrombolysis and outcome depends upon the ability of the thrombolytic agent to permeate the entire length of the clot . This can be assessed in CTA by means of residual flow grade with residual grade 1 and 2 offering greater chances of opening up of vessels by means of either allowing thrombolytic agent to permeate the clot or by means of good collaterals **(*see* Fig. 7)**. Another way of analysing residual flow includes calculating proximal and distal clot interface HU ratio. With ratio greater than 2 having poor chances of recanalization.

- *Terminal Internal carotid artery occlusions:* Carotid T and L shaped occlusions theoretically may have less chance of recanalization when compared to Terminal I shaped occlusion because of collateral MCA flow,higher density of the clot and increased lepto meningeal collaterals in the later. Shape of the thrombus also helps interventionalists to plan and decide approach to thrombectomy. **(*see* Fig. 8)**.
- *Clot burden score:* It is a scoring system to determine the extent of thrombus in proximal anterior circulation by location with scores ranging from 0–10. A score of 10 is normal and a score of 0 indicate multi segment occlusion with a score greater than 6 having greater recanalization rates **(*see* Fig. 9)**:
  - 10-total patency. 0-occulsion of major vessel
  - 2-absence of contrast opacification m1
  - 2-distal m1/supra clinoid ica
  - 1-each m2
  - 1-a1 segment
  - 1—infra clinoid ica
  - lower cbs—larger, proximal thrombus, large infarct, worse collaterals
  - >6 higher recanalization. <6 less rate of recanalization **(*see* Fig. 9)**
- *Collateral score:* collaterals that supports the penumbral tissue during ischemia includes convexity leptomeningeal vessels and circle of willis. Decreased flow leads to increased progression of ischemia and absent collaterals is associated with worse clinical outcome.

A modified Tan **(*see* Fig. 10)** or Miteff scoring systems is used for angiographic collateral assessment determining the course of AIS.

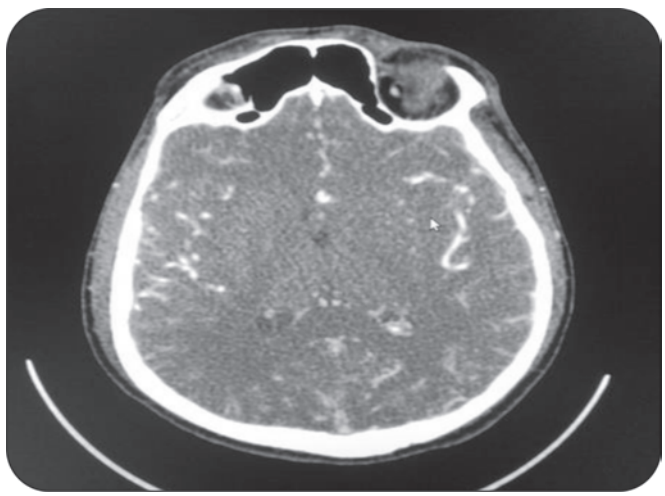

Fig. 6: A normal CTA source image

CT Perfusion (CTP) Imaging

CTP is sensitive to capillary and tissue level blood flow and provides insight into delivery of blood to brain parenchyma. Typical parameters assessed are the following:

cbv: total volume of blood in a given unit volume of brain (mL/100 g)

cbf: volume of blood moving through a given unit volume of brain/unit time (mL/100 g/mt)

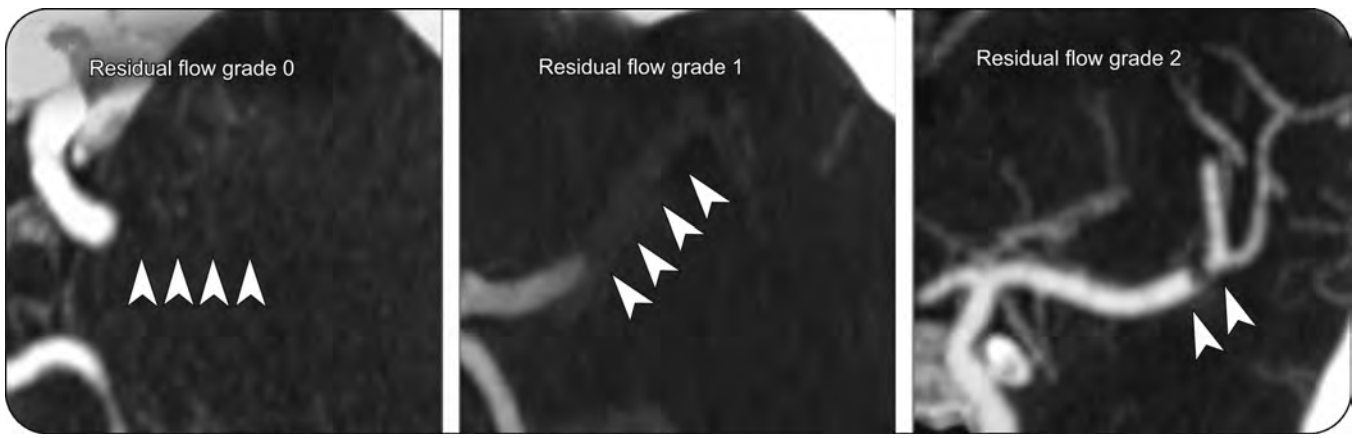

Fig. 7: CTA showing different grades of residual flow in MCA

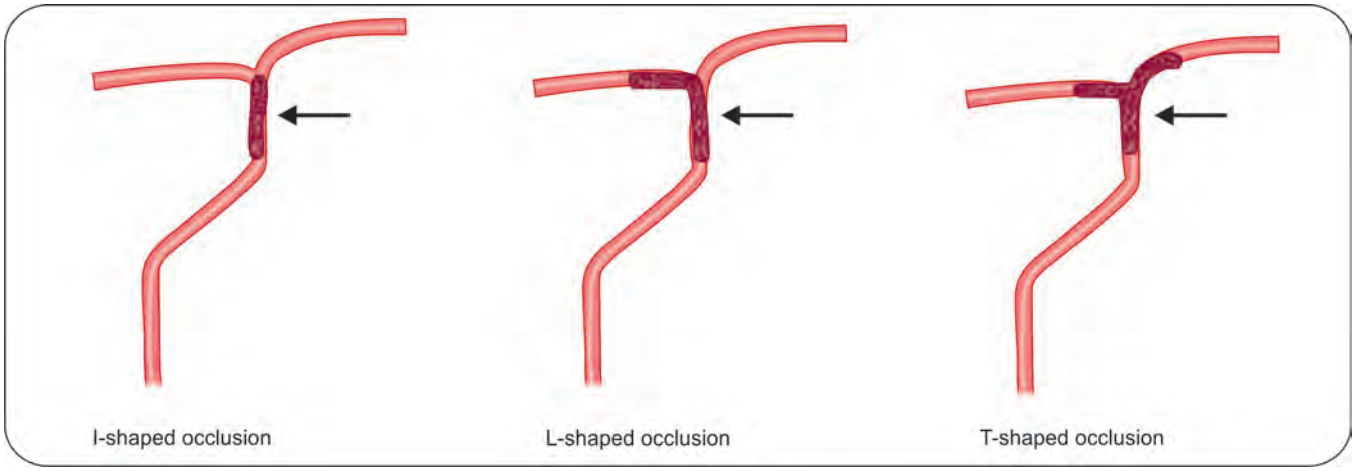

Fig. 8: Illustration of right ICA showing different shapes of carotid occlusions (depicted through black arrows)

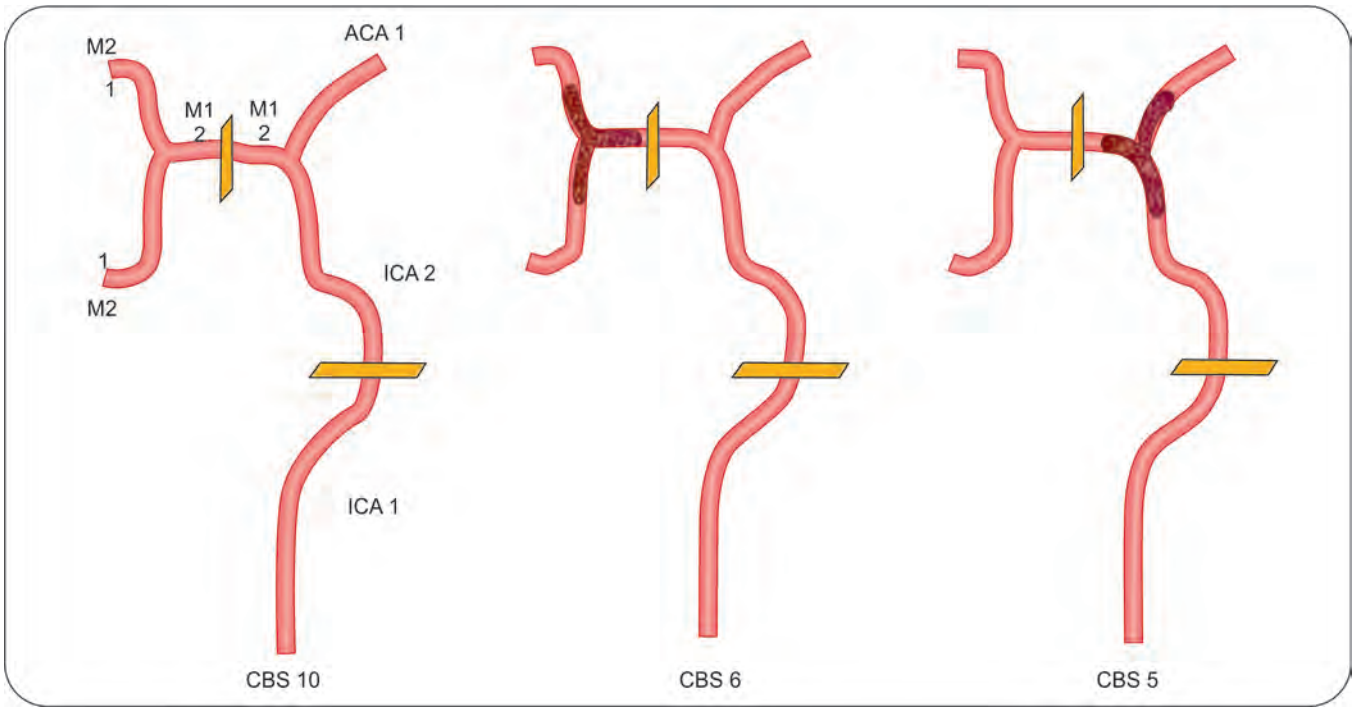

Fig. 9: Illustration of right ICA showing values of vessel segments to calculate clot burden score (values of involved segments are subtracted from the total score)

mtt: average of transit time of blood through a given brain region

$$mtt = cbv/cbf$$

In the first few hours after stroke, the final infarct volume in absence of reperfusion is predicted by MTT and TTP. Tissue infarction is represented by reduced CBV due to failure of autoregulatory responses. Ischemic penumbra is then the difference between CBV and MTT and TTP, which in turn denotes viable tissue at risk for infarction.

All three perfusion CT parameters can be depicted either visually—on a color scale—or numerically, using selected regions of interest.

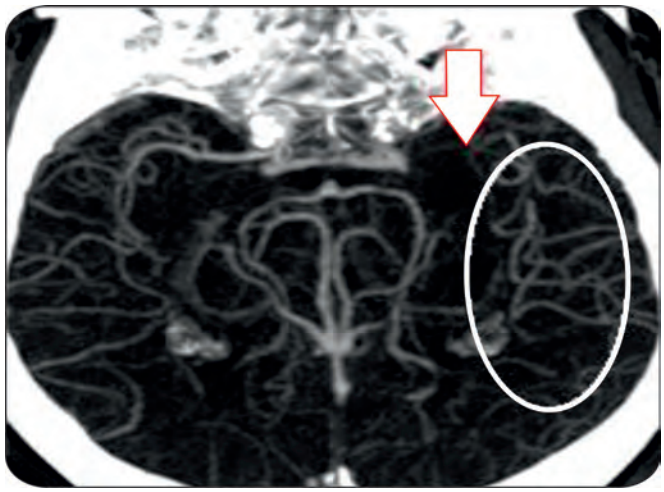

Fig. 10: CTA showing left MCA occlusion (arrow) with good collaterals

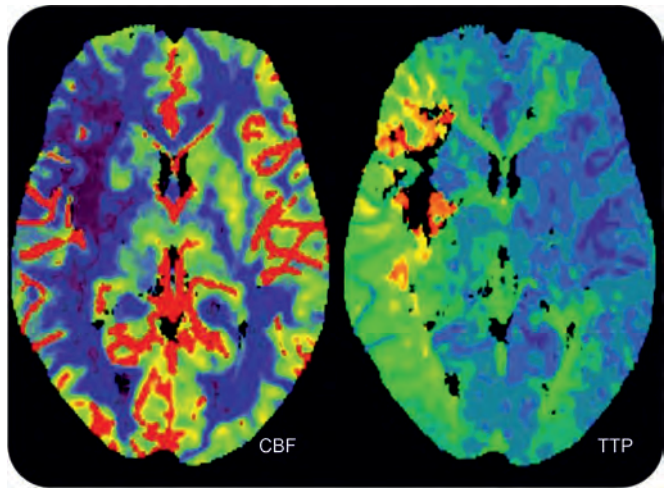

Fig. 11: CT perfusion imaging showing right MCA territory abnormal perfusion with increased T max

The standard color scale is graded from shades of red and yellow to blue and violet.

With CBV and CBF, perfusion is portrayed in red/yellow/green (highest) to blue/purple/black (lowest).

Normally there is equal symmetric perfusion in the cerebral hemispheres with higher CBF and CBV in gray matter (cortex, basal ganglia) compared to white matter.

MTT shows the most prominent regional abnormalities. Color scales are reversed to emphasize the abnormally prolonged transit time in the ischemic brain. The slower the transit time, the closer to the red end of the scale. Brain with normal transit time appears blue ***(see* Fig. 11)**.

Important ancillary finding like Luxury perfusion and crossed cerebellar diaschisis may be seen.

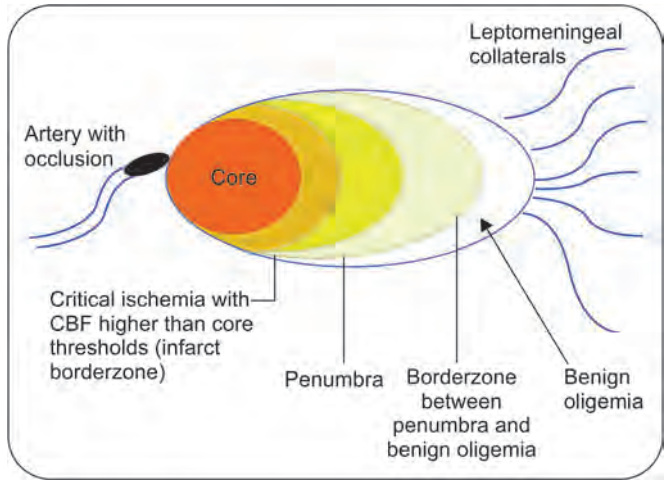

Fig. 12: Illustration demonstrating core, penumbra and Zone of benign oligemia in AIS

MR Imaging

Diffusion weighted imaging is one of the most sensitive technique for ischemic core estimation. Studies have shown that a DWI abnormality volume of more than 70 mL is highly specific for a poor outcome.

Diffusion and perfusion weighted imaging offers vast information regarding tissue viability in stroke. Perfusion MRI is applied as a bolus tracking during gadolinium administration (same as CTP) or instead of using an intravascular contrast agent, CASL magnetically labels the blood entering the brain allowing measurement of TTP, MTT, CBV, and CBF. CASL imaging within 24 hours of stroke symptom onset can depict perfusion defects and diffusion-perfusion mismatches.

DWI/PWI Mismatch

Ischemic penumbra is depicted as DWI/PWI mismatch in MR imaging. The errors in calculation of core infarct size is because diffusion imaging overestimates core volume by causing restriction in regions of penumbra whereas perfusion imaging overestimates penumbra by including regions with benign oligemia **(*see* Fig. 12)**.

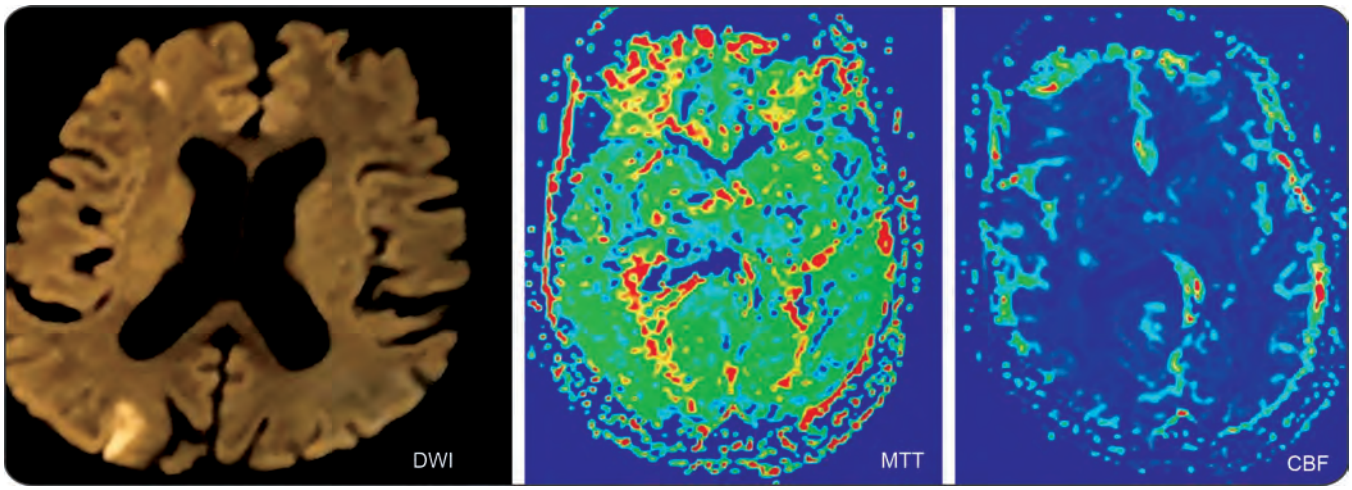

Fig. 13: MRI brain showing right occipital diffusion restriction with right temparo-occipital perfusion mismatch (raised MTT and reduced CBF)

"Classic" mismatch pattern is where the ischemic core on DWI is embedded within a hypoperfused penumbral brain region on PWI ***(see* Fig. 13)**.

"Nonclassic" fragmented mismatch pattern is where part or all of the ischemic regions on DWI are dissociated from the hypoperfused region on PWI.

It is very clear that proximal MCA and distal ICA has to have a small core infarct with a disproportionately large penumbra, nearing a DWI/PWI mismatch of 100%. This is also confirmed clinically with the clinical/diffusion mismatch, for example, NIHSS score (≥8) with a small core infarct (≤25 mL).

DWI Negative Stroke

- Lacunar infarcts
- Brainstem infarcts
- Clot lysis with recanalization
- Moderately reduced or fluctuating hypoperfusion that is not severe enough to restrict water movement

MR Angiography

There are three types of MR angio techniques:

- Time of flight
- Phase contrast
- Gadolinium contrast

Only CE MRI has any use much like CTA in acute ischemic stroke patients.

MRS

The use of MRS in AIS patients apart from showing reduced NAA peak and a raised lactate peak does not offer much information and remains to be validated.

PET/SPECT Imaging

SPECT has application only in presurgical epileptogenic foci mapping and has negligible role in neuroimaging much less in strokes and is largely superseded by the superior PET imaging in every possible way. PET imaging has research application in strokes patient and is currently out of focus in strokes because of the complexities in metabolic activity of the ischemic tissue.

Xenon Inhalation CT

Xenon is inhaled and based on the tissue concentration the CBF data is obtained. The anesthetic properties and difficulty in administration has precluded its routine use.

Transcranial Doppler Ultrasound/TCCD

TCD and TCCD are rapidly evolving as auxiliary investigations in stroke patients. Operator dependence and high expertise are the major limiting factor for its routine use.

TCD and TCCD have a role in stroke following settings:

- Continuous monitoring and identify recanalization during or after thrombolysis

- Detection of right to left shunt
- Monitor flow velocities in sickle cell patients to prevent stroke
- Cerebral VMR measurement
- Vasospasm in SAH

Conclusion

Imaging in stroke has grown by leaps and bounds and much exciting developments await in the horizon. Both CT and MRI are complementary in stroke imaging and in many patients a detailed evaluation will require both these investigations.

CHAPTER

91 Movement Disorders: Can We Apply Break to It?

Pradeep K Maheshwari, Anjana Pandey, Akanshi Agarwal

Abstract

Movement disorder encompasses large number of neurological disorders that share the common clinical feature of involuntary movements of either hypo- or hyperkinetic character. Movement disorders are classified first phenomenologically and then etiologically. In terms of phenomenology, hypokinetic movement disorders include Parkinson's disease, several other conditions with Parkinsonian features, and rare disorders like stiff-person syndrome. A large number of hyperkinetic movement disorders are divided in several categories including tremors, chorea, dystonia, tics, stereotypies, and myoclonus. The ataxias and movement abnormalities associated with cerebellar system disorders and the large category of gait disorders also fall within this category. This chapter deals with the clinical approach and management of common movements disorders.

Introduction

The term "movement disorder" denotes an abnormality of the form and velocity of movements of the body and is often equated with disorders of basal ganglia. Although some movement disorders are present in pure isolation, many clinical syndromes take form of "mixed movement disorder." Thorough clinical examination should take front seat in diagnosis rather than adopting a scattergun approach to investigations is critical which in turn is time consuming and costly.

Movement disorders are defined as neurologic syndromes that cause interruption of motor activities by either production of excessive, unwanted and involuntary movements or paucity of normal free flowing movements.

Classification

Broadly, movement disorders can be classified into:

- *Hypokinetic Disorders*
  - Parkinsonism
- *Hyperkinetic disorders*
  - Tremors
  - Myoclonus
  - Chorea
  - Ballism
  - Dystonia
  - Tics
  - Athetosis

Parkinsonism

Parkinson's disorder results from dopaminergic neuronal degeneration in the nigrostriatal pathway. It affects about 1% of population over the age of 50 and is the second most common movement disorder.[1]

Differential Diagnosis of Parkinson's Disease

- PD
- Parkinsonian syndromes
  - Progressive supranuclear palsy
  - Multisystem atrophy (MSA)

  - Diffuse Lewy body disease
  - Corticobasal degeneration
  - Drug induced
- Other Non-Parkinson's akinetic-rigid syndromes
- Wilson's disease
- Depression
- Arthritis, polymyalgia, fibromyalgia

Cardinal Features

- *Tremors:* The commonest presentation is rest tremor in one hand which is often accompanied by decreased arm swing and shoulder pain. The tremor is a coarse "pill rolling" movement, fairly rhythmic, from 2–6 Hz.
- *Bradykinesia and rigidity:* More commonly visible on symptomatic side, and midline signs such as reduced facial expression or mild contralateral bradykinesia may already be present. Patients typically develop stooped posture. Poor balance, tendency to fall, and difficulty in walking is seen in patients with Parkinson's disease.

Other Motor Features:

- Micrographia
- Masked facies
- Reduced eye blinking
- Soft voice
- Dysphagia
- Freezing
- Bradylalia

Non-Motor Features:

- Sensory disturbances
- Mood disorders
- Sleep disturbances
- Autonomic disturbances—orthostatic hypotension, gastrointestinal disturbances, sexual dysfunction
- Cognitive impairment (dementia)

Treatment

Drugs commonly used:

- Management of motor complications **(Table 1)**
- Management of non-motor complications **(Table 2)**:
- Neuroprotective therapies: *See* **Table 3**
- Deep brain stimulation (DBS): DBS is functional neurosurgical approach used to treat motor fluctuations. Indications are:
  - Levodopa responsive Parkinson's disease
  - Motor fluctuations
  - Age < 70–75 years
  - Adequate trial of dopaminergic medications given

TABLE 1 Management of motor complications[2]

Medication	*Starting dose*	*Target dose*	*Adverse effects*	*Main benefit*
Carbidopa-L-Dopa	25/100 mg tid	Up to 50/250 mg	Dyskinesia, hallucination, nausea, confusion	Bradykinesia and tremors controlled
Anticholinergics				
Trihexyphenidyl	0.5 bid	Up to 2 mg tid	Atropinic effects	Tremor reduction
MAO- inhibitors				Potential neuroprotection
Selegiline	5 mg	5 mg bid	Cheese effect	Reduced off time
Rasagiline	0.5 mg	1 mg daily	"	"
Dopamine agonists				
Ropinirole	0.25 mg tid	9–24 mg/day	Orthostatic hypotension, confusion, sleepiness	Reduced motor fluctuations
Pramipexole	0.125 mg tid	0.75–3 mg/day	"	"
COMT inhibitors				
Entacapone	200 mg		Diarrhea, dyskinesia	Prolonged effect of L-Dopa
Also- Tolcapone and newer acting Opicapone				
Glutamate antagonists				
Amantadine	100 mg/day	100 mg bid-tid	Confusion, hallucination, congestive heart failure	Smoothing of motor fluctuations

TABLE 2 Management of non-motor complications

Symptom	*Medication*
Depression	SSRIs—Mirtazapine, TCAs
Psychosis	Anti-psychotics like quetiapine
Dementia	Cholinesterase inhibitors like donepezil, rivastigmine
Sleep disturbances	Low dose clonazepam
Bladder disturbances	Oxybutynin, tolterodine
Orthostatic Hypotension	Low dose fludrocortisone, midodrine[3]

TABLE 3 Neuroprotective approaches and their mechanism of action

Mechanism	*Potential neuroprotective approach*[4]
Oxidative stress and mitochondrial dysfunction	Antioxidants (monoamine oxidase inhibitors, coenzyme Q10), glutathione promoters, inhibitors of α synuclein aggregation[5]
Excitotoxicity	Glutamate antagonists (e.g., riluzole)
Apoptosis	Antiapoptotic agents (e.g., mixed lineage kinase inhibitors)
Trophin deficiency	Neurotrophins
Caspase activation	Caspase inhibitors as minocycline

- Ablative surgeries:
  - Thalamotomy
  - Pallidotomy
- Newer drugs in development:
  - *Istradefylline*: Adenosine A2a antagonists which improve motor fluctuations as an add-on drug
  - *Remacemide:* NMDA channel antagonist delays the absorption of L-dopa

Hyperkinetic Disorders (Table 4)

Overview of examination of hyperkinetic disorders:

- The site or location of the movements
- The distribution or extent of the movement
- The rhythmicity, regularity, uniformity, multiformity pattern, and recurrence of movements
- The speed, frequency, and course of particular movement
- The movement's force and amplitude
- What is the relationship of movement to rest, activity, posture, exertion, or temperature?

TABLE 4 Classification of hyperkinetic disorders

Regular/predictable	*Intermediate*	*Fleeting/unpredictable*
• Tremor • Hemiballismus • Palatal myoclonus	• Dystonias • Myokymia • Athetosis • Tic • Stereotypy • Myorhythmia	• Fasciculations • Myoclonus • Chorea • Dyskinesias

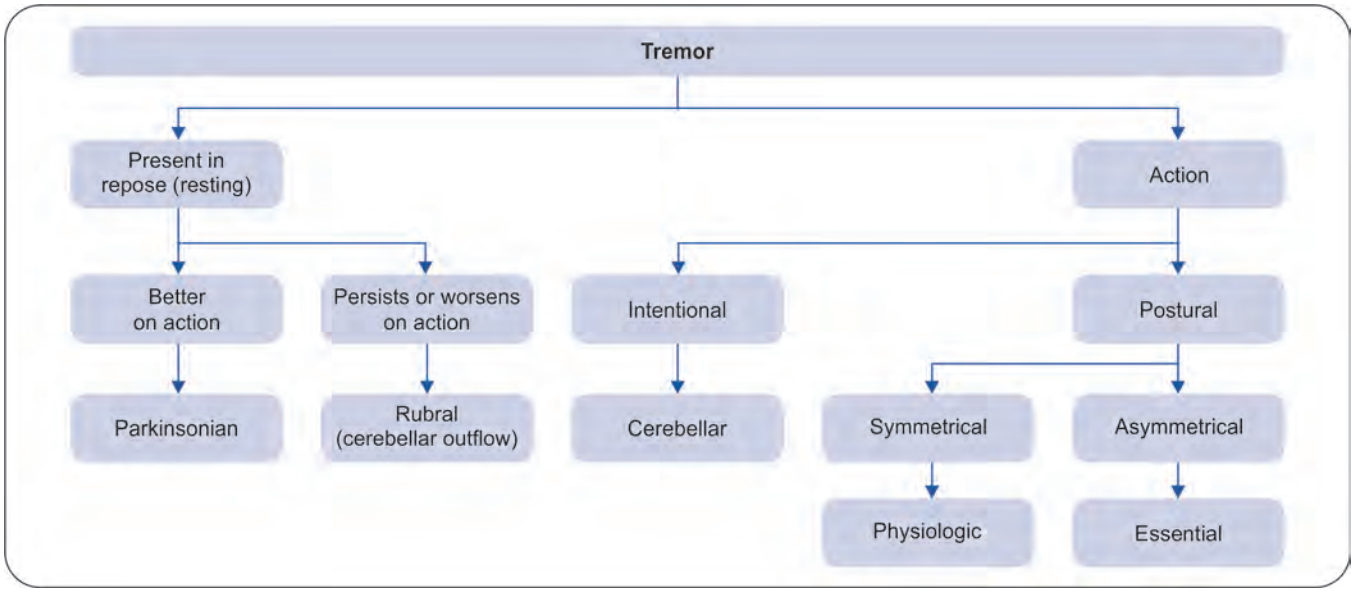
- Whether the movement is suppressible by attention or sensory tricks?
- Whether the movement is present or absent during sleep?

Tremors

Rhythmic, oscillatory, and involuntary movement produced by alternating, synchronous contractions of reciprocally innervated muscles **(Flowchart 1)**.

- *Essential tremors (ET):* It is commonest of all movement disorders. ET is often familial. It is an action tremor that affects head, hands, and voice, worsened by anxiety. The neurological examination is otherwise normal.
- *Parkinsonian tremors:* The tremor is slow, coarse, and compound, rate averaging 4–5 Hz. Causes include idiopathic Parkinson's disease, drugs induced like antipsychotic agents, HIV/AIDS, neurosyphilis, toxoplasmosis, PML or chronic head trauma.
- *Orthostatic tremors:* Orthostatic tremor consists of a high-frequency (14–18 Hz) tremor in the legs during standing. Unaware of the tremor, the patient may complain of unsteadiness or discomfort in the legs that are relieved by leaning against a stationary object, by walking, or by sitting down.
- *Cerebellar tremors:* Cerebellar tremors are slow, absent at rest, and progressively increase with amplitude of movement. A variant known as Holmes tremor is typically present during rest, posture holding, and movement.
- *Hereditary geniospasm:* It is characterized by involuntary vertical movement of the tip of the chin with quivering and mouth movements.
- *Neuropathic tremor:* These are associated with neuropathy diagnosed when other tremorgenic neurologic disorders have been rules out. The neuropathic tremors are kinetic, usually postural 4–7 Hz in frequency.

Flowchart 1: Main types of tremors[6]



Management of Tremor

See **Table 5**.

Chorea

Chorea is swift, graceful, semi-purposeful, dance-like non-patterned, involuntary movements involving proximal or distal muscle groups. They are present at rest but are increased by emotional stress, tension, activity, and self-consciousness.

Huntington's disease: It is an autosomal disorder which is progressive and fatal. It is characterized by:

- Involuntary choreiform movements which advances to dystonia, rigidity, myoclonus.
- Cognitive dysfunction: depression with suicidal tendencies, psychosis, and aggression.
- Gait abnormality.
- Oculomotor involvement: Characterized by slowness of both pursuit and saccadic movements and patient is unable inability to make a volitional saccade without movement of the head.

Management: Dopamine blocking agents like Tetrabenazine have been approved. More recently, deuterated tetrabenazine has also been approved. Recently, an experimental anti-sense drug successfully lowered the level of mutant huntingtin protein in spinal fluid of affected patients.[9]

TABLE 5 Medical management of tremors[7,8]

Tremor syndrome	*Medication*
Essential Tremor	First line: Propranolol (up to 320 mg) and Primidone Second line: Topiramate, Gabapentin Third line: Clonazepam, Botulinum toxin
Parkinson's Disease	Levodopa and/or Dopamine agonists
Orthostatic tremor	Clonazepam, Gabapentin
Dystonic tremor	Clonazepam, Baclofen
Palatal tremor	Phenytoin, Carbamazepine
Cerebellar tremor	Propranolol, Clonazepam
Neuropathic tremor	Propranolol, Primidone

Sydenham's chorea (aka Saint Vitus Dance): It is acute in onset, self-limited choreiform movements seen mostly in patients with rheumatic fever.

Paroxysmal chorea is seen in hyperglycemia and hypoglycemia, infections, and vascular diseases.

Athetosis

In athetosis (Hammond's disease), the movements are involuntary, coarse, rhythmic and writhing in character. Movements are slower but more sustained and have larger in amplitude than those in chorea. Any combination of flexion, extension, pronation, supination, and abduction in variable degrees can be seen. The movements are

intensified by voluntary activity (overflow phenomenon) and disappear in sleep. Athetosis is usually congenital following perinatal injury but can also be acquired following disease, trauma, or drug toxicity. Treatment is exactly like chorea.

Dystonias

Dystonia is defined as involuntary, sustained patterned, or repeated muscle contractions often associated with twisting movements and abnormal posture. Voluntary actions worsen dystonia and it is because of overflow muscle activation.[10] Factors that aggravate dystonia are stress and fatigue and relieving factors are relaxation and sensory tricks (geste antagoniste). Classification of Dystonia is given by European Federation of Neurological Sciences (EFNS-2011)[11] **(Table 6)**.

Management

- Anticholinergic is the most successful oral medication for the treatment of dystonias, particularly trihexyphenidyl.
- Baclofen: This drug has good response in young patients less than 20 years of age and with mild to moderate dystonia.[12]
- Benzodiazepines: Mainly used for blepharospasm and cervical dystonia with predominant head tremor.

TABLE 6 Classification of dystonia by European Federation of Neurological Sciences (EFNS-2011)[11]

Classification by	*EFNS Guidelines*
Age of onset	• Early onset • Late onset
Distribution	• Focal- – Blepharospasm – Laryngeal – Cervical torticollis – Oromandibular – Limb—writer's cramp, foot dystonias • Segmental • Multifocal • Generalized hemidystonia
Aetiology	• Primary – Primary Pure (DYT 1,6) – Primary Paroxysmal (DYT8,10,18) – Primary Plus (Dystonia Plus syndromes) • Secondary (stroke, trauma, demyelinating, degenerative disease) • Herodegenerative

- Botulinum toxin: Treatment of choice for patients with focal or segmental dystonia, like spasmodic dysphonia, blepharospasm, oromandibular, cervical, and lingual dystonia. It can also be used to treat occupational dystonias, like writer's cramp.
- Physical and occupational therapy.

Hemiballismus

Here the movements are wide, flinging, incessant that occur unilaterally. It classically occurs due to hemorrhage or infarction in contralateral subthalamic nuclei. The movements occur incessantly during awake state and disappear only with deep sleep. It is difficult to treat situation, extremely disabling and occasionally fatal too.

Myoclonus

It can be defined as single or repetitive, sudden, brief, jerky, arrhythmic, lightning-like, involuntary movement involving part of muscles, entire muscles, or groups of muscles. It appears symmetrically on both sides. Such synchrony is unique to myoclonus. The distribution of myoclonus can be localized, diffuse, segmental, or generalized. On the basis of etiology, myoclonus can be classified into physiological myoclonus (e.g., hypnic jerks), epileptic myoclonus, essential myoclonus (idiopathic or hereditary), myoclonus is secondary to an underlying disorder or psychogenic or symptomatic myoclonus.[13]

It arises in the CNS from cortical, subcortical, and spinal cord levels. Can be provoked by various stimuli like noise or touch but disappears during sleep.

Clonazepam may be helpful in all types of myoclonus. Other drugs that can be used for cortical myoclonus are antiepileptic drugs such as valproate, levetiracetam, and piracetam, but ineffective in other forms of myoclonus.

Tourette's Syndrome

Neurobehavioral disorder which predominately affects males and characterized by multiple motor tics and vocalizations. Such tics may be suppressed for short periods of time or even totally abolish for days to weeks. Onset occurs before the age of 15 years and incidence decreases or even nil during adulthood. Tourette's syndromes are associated with anxiety, attention deficit hyperkinetic disorder (ADHD), depression, and obsessive compulsive disorder (OCD). Onset in adults is

associated with Parkinson's disease, dystonia, drugs (e.g., neuroleptics, levodopa), and trauma.

Tics

It is a brief stereotyped irresistible repetitive purposeful movement. It can be voluntarily suppressed for a short period.

Drug-induced Movement Disorders

Acute

They include akathisia, acute dystonic reactions, serotonin syndrome, tremor, neuroleptic malignant syndrome. It occur within minutes to days of drug ingestion.[14]

Subacute

It occurs within days to weeks of drug ingestion.

Tardive syndromes: These are drug induced and occur either during exposure or within weeks of stopping a drug and these are present for at least 1 month.[15]

- *Tardive dyskinesia (TD):* It develops months to years after ingestion of antipsychotic treatment. Characterized by choreiform movements of the mouth, tongue, and lips.
  - Lower risk of TD is conferred by youth and use of atypical antipsychotics. Increased risk is conferred by advanced age, toothlessness, and organic cerebral dysfunction.
  - Roughly one third of TD cases resolve within 3 months of discontinuing the offending drug. Most other patients slowly improve over a course of years.
- *Tardive dystonia:* Chronic neuroleptic exposure leads to this condition and is characterized by rocking motion and axial muscle involvement. Tardive dystonia often persists even after offending medication is weaned off and is often refractory to treatment.
- *Tardive akathisia* and *Tardive Tourette's syndrome* are much less common but still associated with chronic antipsychotic exposure.

Neuroleptic malignant syndrome is characterized by hyperthermia, rigidity, tachycardia, and renal failure. It usually occurs days to weeks after exposure to medication. It might also be precipitated by discontinuation of antiparkinsonian medications.

Conclusion

Movement disorders can manifest in numerous ways, with symptoms ranging from subtle to disabling. In recent years, there has been tremendous increase in new diagnostic information, pharmacological, and neurosurgical treatments for movement disorders, as well as a greater understanding of impaired motor control function. The most important for anyone affected by movement disorder is a dedicated team of specialists who can monitor the progress and support optimal health with the latest therapeutic options available.

CHAPTER

92 Migraine—Difficulties in Diagnosis

Basavaraj GT, Malingaraya N

Abstract

Headache poses diagnostic challenges to the physicians for many reasons. It is an extremely common complaint which may be associated with acute illness or serious pathology such as brain tumor or cerebral aneurysm. The majority of patients experiencing recurrent headache in the population suffer either from a variant of tension type headache or migraine. Migraine is more likely to be disabling and becomes the most likely diagnosis for any patient presenting with recurrent headache interfering with function. It is the surround of migraine—the aura, prodrome, and postdrome that can be most challenging and confused with other pathologies.

A basic working knowledge of the common primary headaches and a rationale manner of approaching the patient with these conditions allow a specific diagnosis of migraine to be made quickly and safely. This article discusses about the approach for diagnosis of migraine.

Introduction

Migraine is the most incapacitating disorder of brain, which presents as more severe form of headache with recurrent attacks. The incidence of migraine in women is 15% and whereas in men it is 6%. Approximately 20% of the population experience migraine during their lifetime.[1] Migraine is highly prevalent and is the 7th leading cause of time spent disabled worldwide, yet it has received relatively little attention as a major public health issue. According to "waiting room" survey, 29% of patients encountered at least one migraine headache in a primary care setting within the preceding year.[2] Unfortunately, only 48% of individuals with migraine have received the appropriate diagnosis.

There are many barriers to the diagnosis of migraine, approximately one third of the migraineurs fail to consult the medical care, relaying largely on treatment with over the counter analgesics.[3] This may reflect inadequate access to medical care, ignorance of the availability of the excellent treatment of headache, or reluctance to present with a symptom that society often labels as "benign or nuisance." Even with the evidence of neurological basis of migraine, the stigma of a psychiatric element persists widely in society. Under appreciation by the physician's acts as a barrier for effective diagnosis in clinical settings, magnified by undue emphasis on the serious, but much more uncommon, causes of headache.

Definition

Migraine is defined as intermittent attacks of headache lasting 4–72 hours, with the pain exhibiting two of four specific characteristics (unilateral, throbbing, moderate-severe, worse with activity) and requiring either nausea or photophonophobia.[4]

Migraine may begin early in childhood, but its prevalence increases at 10–14 years of age and continues to increase until 35–39 years of age, after which it gradually decreases, particularly women after menopause. Migraine affects three times more commonly in women than men.

Classification of Migraine

See **Box 1**.

Clinical Features

Migraine, which often begins in childhood, adolescent, or early adulthood, can progress through four stages, not everyone who has migraines goes through all stages.

- Premonitory (Prodromal) Phase (50–80%)—A day or two before the onset of migraine, the changes that alert upcoming migraine attack includes mood changes, neck stiffness, frequent yawning, food cravings, increased thirst, micturation, and constipation.
- Aura (15–20%)—Some people experience aura before or during migraines, which are reversible symptoms of the nervous system, that includes visual symptoms such as flashes of light, scintillations, bright spots, hemianopsia, scotoma, vision loss, auditory phenomena, like hearing noises, pins, and needle sensation of arm or leg, numbness in the face or one side of the body. Each symptom usually begins gradually and progress with time, lasting over 20–60 minutes.
- Headache—If untreated, this phase usually lasts from 4 to 72 hours. Headache characterized by unilateral throbbing/pulsatile headache occasionally affecting both sides, associated with nausea, vomiting, sensitivity to light and sound.
- Post Drome (80%)—This phase lies between resolution of headache and normalization of patient symptoms, during which the patient experiences non-headache symptoms such as limitation of normal functions, which includes easy tiredness, difficulty in concentration, neck stiffness, and irritability.

BOX 1 International Classification of Headache Disorders, Third Edition BETA (ICHD-3 BETA)[5]

- Migraine without aura
- Migraine with aura:
  - Migraine with typical aura
  - Migraine with brainstem aura
  - Hemiplegic migraine
  - Retinal migraine
- Chronic migraine
- Complications of migraine:
  - Status migrainosus
  - Persistent aura without infarction
  - Migrainous infarction
  - Migraine aura-triggered seizure
- Probable migraine:
  - Probable migraine without aura
  - Probable migraine with aura
- Episodic syndromes that may be associated with migraine:
  - Recurrent gastrointestinal disturbance
  - Benign paroxysmal vertigo
  - Benign paroxysmal torticollis

Triggers of Migraine

Glare, bright light, sound, hunger, physical exertion, hormonal fluctuations during menses, lack or excess of sleep, alcohol intake, barometric pressure changes.

Diagnosis

Why Diagnosis of Migraine is Difficult?

Migraine headaches can be easily diagnosed, but aura may mislead the diagnosis, migraine aura is positive phenomenon, hallucinations associated with migraine are usually elementary instead of complex, but the most common one is unformed visual aura and is characteristic feature of the disease. Investigations in these patients turns out to be normal, even if abnormalities are detected they may be incidental.

Migraine can be differentiated from autonomic cephalgias, but overlap syndromes such as cluster headache also seen, and diseases simulating migraine such as headache from hypertension, giant cell arteritis, reversible cerebral vasospastic syndrome, carotid artery disease, acute glaucoma, intracranial mass lesions, raised intracranial pressure, meningitis and reversible cerebral vasospastic syndrome must not be missed.

Borderline conditions include mitochondrial cytopathies, migralepsy, and migrainous stroke. Importantly migraine is often misdiagnosed for other paroxysmal events mainly cerebrovascular disease and seizures, but also peripheral nervous system disorders, syncope, multiple sclerosis, vestibular disorders, gastrointestinal and cardiac disease, functional and psychiatric illness.

The diagnosis becomes even more difficult when the patient is in transitional or intermediate or having mixed

features of both tension type headache and migraine, in such patients a headache diary or headache notebook is useful to get necessary information in diagnosing the migraine.

Diagnostic Evaluation

When to Suspect a Migraine?

It will be most accurate and most efficient, to consider migraine simply as the most common episodic headache presenting to clinician. Acute sinusitis is an easily recognized source of headache, but chronic sinus dysfunction rarely acts as independent source of recurrent headache.[6] Migraine should be the first thought for those patients describing episodic headache that is severe, disabling, or interfering with normal function. A stable pattern, an absence of daily headache or daily analgesic use and a normal neurologic examination will help in diagnosis of migraine. Typical symptoms and signs can be used to provide additional support to the diagnosis. Fundamentally we should "think migraine first" with any clinical presentation of episodic headache, particularly when it is disabling.

Patients with a stable pattern, normal general physical and neurological examinations and a typical migraine presentation do not require further diagnostic evaluation. However, progressive patterns, abnormal examination findings, or atypical presentations including those with daily headaches will need further evaluation.

The "Nasty Nine" (listed in **Box 2**) outlines the nine specific situations necessitating neuroimaging, electroencephalography, lumbar puncture, or serum studies.[7]

The IHS criteria are helpful in diagnosis of the migraine, and it has made migraine a positive diagnosis rather than a diagnosis of exclusion. Careful questioning of the patient and application of the diagnostic criteria and to carry out a brief, but sensitive and highly focused neurological examination is very helpful.

An abbreviated version of IHS diagnostic criteria is shown in **Box 3**.

There are two main types of migraine:

- migraine without aura
- migraine with aura.

Migraine without aura is three times common than migraine with aura.

BOX 2 Indications for diagnostic evaluation of headache: "Nasty Nine"

- First/worst severe headache
- Abrupt-onset headache
- Progressive or changing headache pattern
- Headache with neurologic symptoms >1 hour
- Abnormal examination findings in headache patient
- Headaches associated with syncope or seizure
- Headaches in children <5, adults >50 years of age
- Headaches in immunocompromised patients
- Headaches that increase on Valsalva, exertion, and sexual activity

BOX 3 IHS diagnostic criteria for migraine from Headache Classification Committee of The International Headache Society[8]

- Migraine without aura—lasts 4–72 hours
- Has at least two of the following characteristics:
  - unilateral
  - pulsating
  - moderate or severe intensity
  - aggravated by exertion
- Associated with one or more of the following:
  - nausea, vomiting, phonophobia, photophobia

- Migraine with aura—Two or more headache preceded by aura:
  - Aura symptoms usually involving:
    - blurred vision
    - flashing lights
    - missing area of visual field
  - Aura symptoms fully reversible, lasting less than 1 hour. Headache follows aura within 1 hour

Migraine without Aura

Migraine without aura previously known as common migraine, where patient complains of episodic headache lasting from hours to days, disabling type accompanied by gastrointestinal symptoms or by increased sensitivity of special senses. With exercise or hard work, tension type headache can be easily distracted but same is not possible in migraine without aura. The duration and frequency of migraine plays vital role in differentiating headache due to medication overuse (MOH) or tension type headache (TTH) where the frequency is more than twice a week, but the same frequency is unlikely seen in migraine without aura (MO).

Migraine with Aura

Migraine with aura previously known as focal or classic migraine, aura progress over time and lasts for several minutes, improves at one aspect and at other it worsens. It is difficult to distinguish between migraine with aura from thromboembolism and epilepsy because here aura sometimes affects sensation, movement, cognition, vestibular function, or consciousness. Sometimes in migraine with aura of recent onset is usually preceded by long standing history of MO, which should be differentiated from "bilious attacks," "sinusitis" or "normal headaches."

In middle age group migraine with aura without headache is most common, sudden onset of MA episodes without headache is mistaken as transient ischemic attacks (TIA). In contrast, sudden episodes of MA with headache need to be distinguished from thromboembolism as it is associated with headache of abrupt onset with non-evolving impairment, which is restricted to single vascular territory.

Take a Detailed History

From diagnosis point of view, history taking remains the most important aspect. It is important to allow patients for proper description regarding their attacks and also for clarifying the history by proper questioning with the aim to fill the gaps in the history that the patient has told you spontaneously. The mainstay of diagnosis of migraine depends completely on history, thorough examination of a patient helps to identify other associated problems, which may exacerbate an underlying tendency to migraine.

The questionnaire should begin by asking about the pattern of the pain, including when, and how headaches begin, duration and frequency of episodes with associated exacerbating or triggering factors. The questionnaire should also include nature of pain, its location, character, and severity, and the symptoms, which accompany pain suggesting other primary or secondary headache disorders such as epiphora, nasal and conjunctival hyperemia, ptosis, edema of eyelids, fever, neck stiffness, and sweating.

It is important to know about present and previous treatments that have been tried and on what basis these treatments are taken and the reason for their discontinuation if any and regarding patient's previous medical history (anxiety, depression, and sleep disorders), current treatment for non-headache diseases, family history (of headache), and social history (regarding occupation, smoking, alcohol, and caffeine consumption).

If structured approach to history taking is strictly followed and proper headache diary is maintained then necessary information that is needed for most probable diagnosis can easily be gathered and gaps in patient's history can be easily filled without specifically asking patient.

Examination

The main aim of examination is to consider regarding organic brain disease and to screen for accompanying comorbid diseases such as hypertension, depression, etc., and also to reassure the patient and their family regarding disease. A thorough neurological examination assessing cognitive, sensory, motor system along with the fundoscopy for the pappilledema is must.

Investigate Appropriately

Decision about investigation done on migraine patients are driven by two most common cultural myths. The first myth being the brain tumor common cause of headache followed by abnormal blood tests or scan results based diagnosis of migraine. The goal of investigation is to

TABLE 1 Investigations to rule out other pathologies of headache

Tests	*Reason*
CBC with ESR	Temporal arteritis
CSF analysis	For fever with headache patients
X-ray PNS	For sinusitis
X-ray chest	Consider in smokers or with metastatic cancers
X-ray cervical spine	Cervical spondylosis
Brain MRI	Due to its greater sensitivity and capability of visualizing intracranial structures it is preferred for all subacute and chronic presentations of headache
CT	Useful in patients presenting with abrupt onset of headache and to find rare brain tumors, subarachnoid hemorrhage, and chronic subdural hematomas
EEG	Useful in evaluation of patients with headache, loss of consciousness and to diagnose basilar migraine in addition to differentiation of organic headache

exclude other causes of migraine like symptoms not to confirm migraine. The following are the investigations required for those headache patients with unusual signs and symptoms are CBC with ESR, Chest X-ray, X-ray PNS, X-ray C spine, CSF fluid analysis, CT/MRI brain, and EEG **(Table 1)**.

Differential Diagnosis

- Tension type headache
- Cluster headache
- Idiopathic stabbing headache
- Medication overuse headache

Conclusion

Migraine presents a major diagnostic and therapeutic challenge to general physicians and neurologists. Patients with unstable or progressive pattern headache, an abnormal examination or an association with features unusual for migraine should trigger further evaluation. According to studies there is a general disenchantment of migraine patients with their physician[9] and a widespread problem of analgesic overuse.[10]

These problems may be overcome by programs of education for the public, physicians, and neurologists, patient should be made aware of the dangers of the analgesic abuse and of the availability of appropriate and more effective migraine treatments.

CHAPTER

93 Vascular Dementia—Current Concepts

V Nagaraajan

Abstract

Vascular dementia is a disease, carrying a great history of understanding, dates back to 19th century, when pathologists identified arteriosclerotic changes in the brain vessels, supplying the gray and white matter of the brain, was contemplated as senile dementia. The main problem was the identification of vascular dementia was submerged in the wide understanding of Alzheimer's disease (AD), which was dominating the understanding of dementia, along with identification of frontotemporal dementia. In the elderly citizens, who are prone for atherosclerotic changes in the vessels offer great contribution to the development of dementia. Vascular dementia (VAD) is now understood along with vascular cognitive impairment (VCI) not only includes VAD, but also AD with ischemic cerebral lesions and VCI without dementia. The identification of VAD is essential, in the concept of management of dementia, which in other conditions are progressive. The therapeutic amenability of VAD makes it as a distinctive entity in the early stage of the disease. Subcortical vascular ischemia with dementia (SIVD) is identified by the severe degree of occlusion of small vessels that ramify into the white matter, causing occlusion, resulting in multiple lacunar infarctions in the subcortical structures. The differentiating issues with AD and SIVD may by difficult by assessing the cholinergic deficits, but the recent progress of in vivo amyloid imaging studies could relatively identify the separate entity of SIVD, from AD, where in the amyloid plaques are absent in SIVD. The upcoming concepts between VAD/VCI and their clinical concepts give wonderful idea about the management of the SIVD.

Introduction

SIVD is widely identified disease of slowly progressive dementia, in contrast to the classical Alzheimer's disease and frontotemporal dementia, which are due to development of degeneration and infiltration of amyloidal plaques into the gray matter of the brain, causing shrinkage of the brain matter. There are some distinct identifiable clinical observations between these diseases, and the main benefit of understating the SIVD is its amenability to the treatment. Hence, identification of SIVD become mandatory, and excluding it from other forms of dementia, since other forms of dementia are difficult for management. The identification of subcortical white matter lacunes becomes one of the major components of identification of SIVD, which depending on its location makes the clinical manifestations, as well its volume of affected brain matter. Vascular dementia (VAD), due to CVD, that directly or indirectly damages the neurons associated with cognitive activity.[1] It is also identified that in majority of AD cases, vascular lesions becomes a coexisting factor, contributes heavily in the pathogenesis of dementia, with the existing degenerative brain parenchyma.[2,3] The recent postulation of vascular cognitive impairment (VCI), which embraces both VAD, AD with CVD—sometimes labeled as mixed dementia. More so, another entity also identified as VCI with no dementia (VCIND). VCI becomes a larger term that would include all the stages of cognitive impairment associated with CVD.

Indian Scenario of Vascular Dementia

VAD is a complex presentation in clinical practice. Varied presentations are observed in clinical practice. Its symptoms are not homogenous, but highly variable. The incidence of VAD is ubiquitous in India, but still now exact incidence is not clearly available, even though quite an amount of data is available in the literature. In a cohort study, where in NINDS-AIREN criteria were used to diagnose VAD. Patients were subtyped into subcortical, cortical, cortical-subcortical, and infarct may be quite tiny, but in a strategic location, may present as dementia. In a study by Suvarna Alladi et al., dementia in developing countries: Does education play the same role in India as in the West? over 42 patients with VAD, subcortical dementia was the most common type (52.4%), followed by cortical-subcortical (26.2%), strategic infarcts (14.3%), and cortical dementia (7.1%). Stroke (81%), hypertension (71.4%), and diabetes (35.7%) were principal risk factors. Small artery disease was the elementary vascular mechanism in 42.9%; intracranial large artery disease, in 16.7%; extracranial disease, in 2.3%; cardioembolism, in 2.3%; multiple mechanisms, in 19%; and unknown, in 16.7%. Subtypes were similar in associated risk factors and neuropsychological features but differed in clinical corelates and vascular mechanisms. The results and clinical presentations is highly dependent on the underlying mechanism, pathology, extent and location of the infarct, which may differ in different ethnic groups.[4,5]

Pathophysiology

The main issue involving VAD is generated from vascular lesions. These lesions may be large like a major artery occlusion or tiny perforators, causing lacunar infarcts. These lacunar infarcts, even though they are tiny, when happens in multiple areas, and constitute a major brain volume affection, the dementia evolves. More so, tiny infarcts in strategic locations like frontal lobe, temporal lobe, or brain stem do affect the higher mental function critically. Hence, the deciding factors are volume of infarction, or location of the infarction. Once the ischemic process begins, axonal degeneration results, from the neuronal damage, Wallerian degeneration results, especially more in the white matter subcortical lesions. Neuronal interconnections become a gross impediment in the thought process, ranging from minimal cognitive impairment to a progressive dementing illness.

Recent Concepts in VAD and VCI

The following classification is widely adopted among neurologists across the world:

- Multi-infarction dementia,
- Strategic infraction dementia,
- Hemorrhagic dementia,
- Mixed dementia,
- SIVD, and
- Other forms of vascular dementia.[6,7]

Strategic infarction dementia, hemorrhagic dementia, does develop in a rapid fashion clinically due to acute cerebrovascular diseases. A stepwise progression, inherent fluctuation of clinical presentation of symptoms, and focal neurological signs are suggesting the development of acute VAD. With SIVD, cognitive impairments are often sneaky in its onset, while later decline progressively, like in classical AD.[8]

Classical motor symptoms is not most often demonstrable clinically, sometimes unnoticeable, further confusing clinicians. Existence of pure SIVD has been reported in studies related to amyloid imaging, where significant subcortical white matter ischemic changes were evident with no trace of deposition of amyloid plaques. Pure SIVD is distinct from AD or mixed dementia, which demonstrate fibrillar forms of amyloid deposition in the brain.[9]

Various other types of VAD include dementia where in the etiologies are heterogeneous, for example, cerebral amyloid angiopathy, hereditary diseases (such as cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) [CADASIL]) and vasculitis.[10-12]

On the issues of mild cognitive impairment (MCI) due to AD or early phase of AD, it is observed that accumulation of amyloid beta (Aβ) plaques and neurofibrillary tangles (NFT) in the brain. These deposits and NFT do hinder the neuronal transmission, interfering with the thought process of the patients suffering from AD. But, the understanding of VCI identifies potentially treatable and preventable components of dementia. It is worth observing that after the establishment of cognitive impairment, the vascular potential risk factors, can be clinically intervened, and there is a chance of rectification of clinical symptoms, and mostly it prevents secondarily in the newly occurring ischemic zones, toward worsening of symptoms in contrast to AD.[13]

It is also observed that small vessels which are deeper in the brain do have multiple changes due to atherosclerosis,

and also due to various small vessel diseases, causing SIVD, in senior citizens, very commonly which is a finding recently observed, by many workers.[14]

Pathophysiology of SIVD

- Marked ischemic change in the brain, due to discrete and incomplete infarctions which may be tiny in character.
- Hypo or diminished perfusion of blood into the white matter, due to critical occlusion of the perforators and medullary branches of the cerebral vasculature.
- There is a typical white matter lesions resulting in ischemia of neurons, oligodendrocytes, Wallerian degeneration of the myelin sheath and axons. The lacunar infarctions (étatlacunaire) are a result of perforating arteriolar occlusions within the subcortical structures, including basal ganglia, thalamus and external and internal capsules. It is observed that there are decreased auto regulation, BBB disruption, endothelial dysfunction, resistance to blood flow, and dilatation of perivascular spaces.[15]
- Consequent these vessel changes and subclinical infarctions there is gross disruption of the prefronto-subcortical circuits and thalamocortical circuits due to white matter ischemic lesions and lacunar infarctions.
- These disruptions are the causative factors for the ongoing dementia and cognitive impairment in SIVD. There are some evidences that A-beta plaques, neurofibrillary tangles are visualized in the SIVD, which is also thought to be a consequent issue due to ischemia of the brain structures.[16]

Clinical Manifestations of SIVD and Its Associations with Structural and Functional Brain Images

The mainstay in the SIVD is the cognitive impairment of varying degree, its stepwise development along with the neurological deficits is common. Abnormal behavior disorders like disinhibition and akinetic mutism are common if the prefronto subcortical circuits are damaged directly or as a secondary effect of ischemia.[17]

Other findings are uncommonly hemiparesis, peripheral speech disorders, pseudobulbar palsy, urinary incontinence, and features of extrapyramidal involvement when the ischemia is in basal ganglia especially in putamen. Impairment of attention, poor verbal fluency may manifests in early phase of SIVD **(Table 1)**.[18,19]

Still there are studies in progress which can differentiate SIVD from mixed dementia by establishing the clinical, imaging studies, especially from studies available with amyloid PET imaging.

SIVD Biomarkers

So far various studies have been observed, without any conclusive evidence of any biomarkers. Many of the recent longitudinal studies have met with results that they proceed ultimately to AD. In VAD, the novel genetic variants discovered could be presumably used as potential biomarker for diagnosis and treatment.

The field of pharmacogenetics is a beacon of hope in VAD for improving drug efficacy and safety. Causal gene identification is highly limited to monogenic form of VAD, while by evidence VAD of sporadic form is less probable. For future research, more homogenous subgroups with a larger and heavier sample sizes are essential. For further genetic investigations in VAD, endophenotypes look as a promising research tool. Apart from genome wide association studies (GWAS) and gene analysis studies, focus on epigenetic modifications and microRNAs are also increasing. The therapeutic implications of the same have to be evaluated in future, depending on the evidences available time of time. BBB (blood brain barrier) disruption is one of the beneficial situations for future analysis. Significant, biodegradation products are

TABLE 1 Differential diagnosis clinical features between SIVD and AD

Higher cognitive functions	*Vascular dementia (SIVD)*	*AD*
• Attention	• Grossly impaired	• Mildly impaired
• Language and understanding	• Decreased output and fluency	• Poor recalling and naming
• Visuospatial orientation	• Fair and mild affection	• Gross affection
• Memory functions all types	• Moderate loss	• Gross and severe loss
• Frontal lobe executive functions	• Severe loss	• Moderate loss

identified, which include increased albumin leakage in CSF. It is also observed that certain metalloproteinases are observed to be available as markers of neuroinflammation, as they disrupt the basal lamina, tight junctions of blood vessels, with disruption of myelin. The levels of metalloproteinases-9, in CSF, are observed to be increased in VAD. The concentration of the neurofilament cytoskeleton, which may give hall mark for white matter disruption of large meylinated axons, observed to be higher in patients with SIVD.[20]

Several different results have been reported with biomarker studies on VAD/VCI patients. A recent study compared the biomarkers from CSF of four groups, namely MCI group that remained stable as MCI (MCI-MCI); SIVD (MCI-SIVD); mixed dementia (MCI-MD); and MCI group that finally progressed to AD (MCI-AD). It was reported that the levels of phosphorylated and total tau (T-tau) were lower, while that of Aβ were higher in the MCI-SIVD than the MCI-AD group. In the MCI-MD group, biomarker levels in the CSF were between those levels of MCI-SIVD and MCI-AD group. CSF levels of MDI-SIVD were closer to the levels of control group and the MCI-MCI group. The intermediate levels of CSF biomarker levels of tau and Aβ in the SIVD group as compared to MCI-MD and control groups indicate a common pathology of SIVD with AD. The biomarker levels in the CSF of VAD and AD patients when compared, it is observed that Aβ levels are lower, while tau levels are higher in AD patients as compared to VAD patients. However, overlaps have been observed between the two. No such differences were observed between the biomarker levels in non-elderly individuals, who had mild, moderate, or severe white matter hyperintensities.

Alternative biomarkers associated with SIVD include those related to BBB breakdown. Albumin leakage can result following BBB breakdown, increasing the protein concentration in the CSF as a result. In view of this, increased albumin levels are supportive as evidence of SIVD. MMPs are attributed as neuroinflammatory markers, as they attack the blood vessel tight junctions and basal lamina, apart from disrupting the myelin. MMP-9 levels were increased in CSF of VCI patients as compared to AD patients. Neurofilament is another important white matter disruption marker. Neurofilament acts as a cytoskeleton in large myelinated axons. In individuals with higher neurofilament levels, SIVD is prominent. In non-demented individuals with severe white matter lesions, similar findings were reported. As described previously, advanced imaging techniques can help serve as potential biomarkers, enabling understanding of underlying pathophysiology of SIVD.

Imaging in SIVD

One of the promising diagnostic identification of SIVD is done in imaging studies. MRI imaging appears to be a superb identification tool, than CT of higher resolution, along with the MR angiography to identify the affected territory. Tiny infarcts in common locations like cortical, subcortical, exceeding a volume of more than 50 cc, or any small tiny insignificant volume of infarct in a strategic location, results in high degree of clinical manifestations (***Refer* Figs. 1 and 2**). Hence, it is observed by MRI studies, that it is not the multiplicity, but its location and total volume of gray matter involvement or white matter connect ions, manifests in clinical syndromes. PET scan also observed to be quite useful in identifying ongoing infarct, or preimaging status of the infarcts, which would be useful in assessment of management of the disease. It is almost emphasized as on current state of affairs, more than bio markers, imaging studies are highly efficient in identifying the diseases at an early state.

- Large areas of infarction or hemorrhage post stage with severe brain substance damage, both gray and white matter.
- Decreased diffusion anisotropy in the places of white matter hyperintensities, amyloid PET imaging for routine diagnosis of AD, myloid PET imaging can be clinically useful for differentiating pure SIVD and mixed dementia, which sometime can be challenging to distinguish and would give rise to diagnostic dilemmas.

Role of Neurophysiological Studies

It is not the issue that neurophysiological studies like cortical evoked potentials, EEG, and BAER also play an important role in identifying the interrupting pathways well in advance to imaging studies. But it needs heavy and careful scrutiny to identify such subtle changes, to inform the clinicians about the development of SIVD.

Strategies for Treatment of SIVD

- Major treatment strategies include improving the obvious clinical symptoms at the same time mitigating the underlying small vessel disease progression.

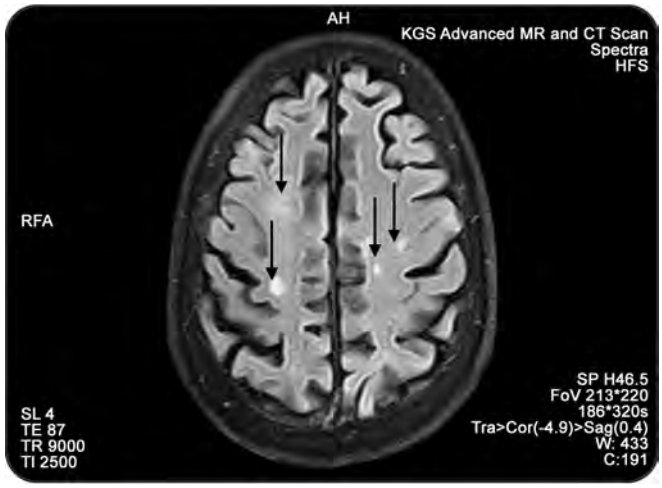

Fig. 1: Multiple tiny infarcts, constituting more volume of infarct and also multiple hyperintese areas in the strategic location of the brain

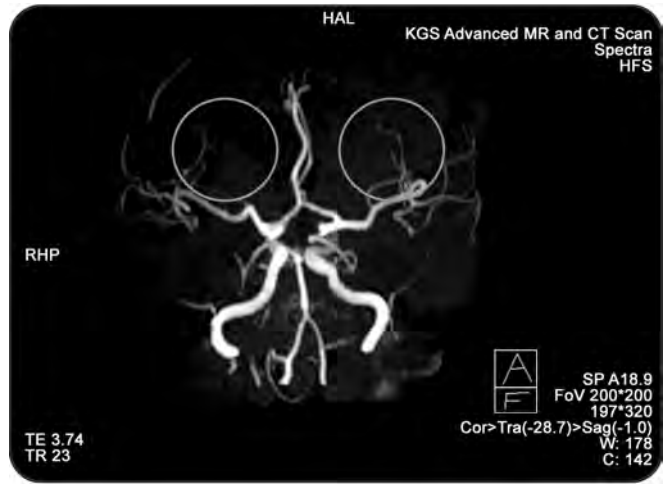

Fig. 2: Left side denotes fair vascularity of penetrating arteries, right side shows avascular component, MR angiogram

- An important significant factor contributing to cognitive impairment and brain atrophy is microinfarct pathology. By regulating small vessel disease, once can administer antiplatelets agents as a means of secondary stroke prevention.
- For the primary prevention of VCI, antiplatelet agents as a means of therapy are not established yet. Due to its vasodilatory effect, nimodipine, a calcium channel blocker, has been found as a potential agent for SIVD treatment. In early clinical trials for VAD, nimodipine was found to be successful, following which an "intention to treat" trial with 230 patients was conducted. The set primary end point was not achieved in the trial, although, positive results were obtained in the mini mental state examination and global deterioration scale, along with improvement in language production.
- For managing cognitive symptoms, the uses of cholinesterase inhibitors have been implicated. SIVD associated cholinergic deficits are well defined from the findings that perforating arterioles supply the basal forebrain cholinergic nuclei and that hippocampal CA1 region is highly vulnerable to ischemia.
- Deficits in the cholinergic fibers have been identified in CADASIL patients. In view of which, cholinesterase inhibitors have brought in for the treatment of cognitive impairments of VAD, which are linked with deficits of the cholinergic fibers. Beneficial effects on cognitive functioning of cholinesterase inhibitors were observed in a randomized controlled drug trial on CADASIL patients. In another CADASIL study, donepezil, a cholinesterase inhibitor did not show improvement in the primary endpoints. A subgroup analysis on the other hand indicated improvement in the treatment group in executive functions. Associated behavioral changes can be managed by use of atypical neuroleptics while depression can be managed by the use of antidepressants such as selective serotonin reuptake inhibitors (SSRIs). For preventing AD and VCI, modification of cardiovascular risk factors has been suggested. The risk factors include diabetes, hypercholesterolemia, and hypertension. Associated lifestyles changes in diet, physical activity, smoking, obesity, alcohol consumption, etc. may also help manage VCI.
- Nimodipine 30 mg once daily, donepezil 10 mg, maintain till the higher cognitive functions become stable.

Abbreviations

AD, Alzheimer's disease
SIVD, subcortical ischemic vascular disease
VAD, vascular dementia
VCI, vascular cognitive impairment

Conclusion

VAD is a diverse condition encompassing various conditions. SIVD can imitate AD, and as like AD, SIVD also demonstrates a slow progression in cognitive decline. Changes in mood and behavior, along with impairments in frontal executive symptoms can be revealed by carrying out neuropsychological tests and extensive medical histories. Dementia from other causes can be differentiated from SIVD by the help of neuroimaging studies and identifying specific CSF biomarkers. Proper management and early treatment of SIVD along with secondary stroke prevention can be accomplished effectively by clinicians by reviewing carefully a patient's medical history, his test reports obtained following neurological examinations, structural/functional neuroimaging, biomarker analysis, etc. Means of making the treatment and diagnosis of SIVD more effective and efficient include development of diverse experimental SIVD model for thorough understanding of the pathology. Identifying and corroborating the specific biomarkers will also assist in improving treatment strategies. Maintaining a database of extensively collected details from longitudinal studies, data from imaging and biomarker studies for subcortical vascular MCI and SIVD is required, which can be shared with fellow scientists and researchers for ensuring better management of the disease condition. Standardization methods for vascular lesions in neuroimaging and neuropathologies are underway. However, miles are to be covered before the concept of SIVD can be incorporated in clinical practice and be accepted widely.

CHAPTER

94 Chronic Inflammatory Demyelinating Polyradiculoneuropathy

Sindhu S, Pawan Dhull, Salil Gupta, Ravi K Anadure

Abstract

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is an acquired, immune-mediated disorder of peripheral nerves and radicles. It is usually a symmetrical, non-length-dependent hyporeflexic neuropathy, involving both proximal and distal limbs, with motor and sensory deficits, progressing over at least 08 weeks. Although a rare entity, it is thought to represent about one-fifth of all initially undiagnosed neuropathies, and is one of the commonest treatable neuropathies worldwide. Pathophysiologically, it is characterized by immune-mediated loss of myelin, resulting in slowed/blocked nerve conduction. Many new paranodal proteins, which may be specific targets of immune attack in some subsets of CIDP, have been described. Clinically, it differs from Guillain-Barre syndrome (GBS) with respect to the onset and duration of symptoms, as well as prominent involvement of sensory nerves. In contrast to GBS, which is monophasic, CIDP is a chronic, relapsing-remitting illness, and requires long-term immunosuppression. Corticosteroids, plasmapheresis, and intravenous immunoglobulin (IVIg) are the recommended first-line therapies, and 50–90% patients respond to one of these. Apart from this, many atypical variants of CIDP have also been described. The EFNS/PNS Criteria 2010 are used to diagnose CIDP on the basis of clinical and electrophysiological data. After the first-line treatment, long-term immunosuppression is usually given in the form of either oral drugs such as azathioprine, methotrexate, mycophenolate, or biologicals such as rituximab. Subcutaneous IVIg has been recently approved as a maintenance therapy for CIDP. Few validated scoring systems are available for objectively documenting the response to therapy. The aim, in the long term, is to balance risk of early relapse with the need to avoid overtreatment and immunosuppression. Overall, CIDP remains one of the few chronic neuropathies that are readily treatable, and early diagnosis and appropriate treatment are crucial to improve the patient's quality of life.

Introduction

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is an acquired, immune-mediated disorder of peripheral nerves and radicles. It is a symmetrical, non-length-dependent hyporeflexic neuropathy, involving both proximal and distal limbs, with motor and sensory deficits, progressing over at least 8 weeks. It was first described by Austin in 1958, and later identified as a separate entity—"Chronic Inflammatory Polyradiculoneuropathy," by Dyck in 1975.[1,2] It has an estimated incidence of 0.7–1.6 cases per 100,000 per year, and prevalence varying 1.2–8.9 per 100,000 persons.[3] Although a rare entity, it is thought to represent about one-fifth of all initially undiagnosed neuropathies, and is one of the commonest treatable neuropathies worldwide.[4] Corticosteroids, plasmapheresis and intravenous immunoglobulin (IVIg) are the recommended first-line therapies,[4] and 50–90% patients respond to one of these.[5]

Epidemiology

CIDP is a disease of adulthood, and its prevalence increases with increasing age. In patients less than 19 years of age, the prevalence is 0.23–1.26 per 100,000; while it increases up to 5.74–14.37 per 100,000 in ages above 60 years.[3] It is 1.6–2.9 times more common in males.[3] It is also more common among diabetics, though exact figures are debatable.[6]

Pathophysiology

CIDP is characterized by immune-mediated loss of myelin, predominantly in the spinal roots, proximal nerve trunks, and major plexuses, but it can also be disseminated throughout the peripheral nerves. This causes slowing of nerve conduction and/or conduction block.[7]

Myelinated axons only allow action potentials at the nodes of Ranvier between the myelinated internodes (saltatory conduction), and they propagate the action potential at rates significantly higher (70–150 m/sec) than in unmyelinated neurons (0.5–10 m/s) **(Fig. 1)**.

Both cell-mediated and humoral mechanisms are involved in pathogenesis of CIDP. It is considered an autoimmune response against some unidentified Schwann cell/myelin antigen. The trigger for this autoimmune response is also unknown.[7]

Cellular mechanisms are implicated on the basis of inflammatory infiltrates in nerve biopsies, changes in the frequencies/function of T-cell subsets, altered expression of cytokines in blood and CSF of patients, and the role of T-cells in experimental autoimmune neuritis (EAN) model.[7,8]

Deposition of immunoglobulins and complement on the surface of Schwann cells and myelin in sural nerve biopsies, and rapid response to plasmapheresis indicate the role of humoral immune-system.[7]

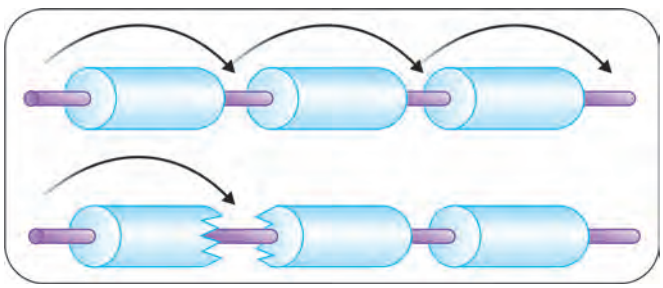

Fig. 1: Upper panel: Normal saltatory conduction along myelinated nerves; Lower panel: Breakdown of saltatory conduction due to demyelination

Proteins in and around the node of Ranvier are also involved. The paranode consists of contactin-1/CASPR-1(contactin associated protein-1) complexes, which bind to Schwann cell neurofascin-155 (NF155). They are vital for the initial clustering of sodium (Na^+) channels, and maintenance of clustering at the node,[9] acting as a membrane barrier to limit diffusion of ion channels essential for saltatory conduction. They undergo immune-attack in several anti-ganglioside-mediated "nodoparanodopathies."[9] Antibodies against NF155 have been identified in 4% of CIDP cases.[10] An additional subset of CIDP has been identified with autoantibodies against contactin-1/CASPR-1 complex.[11]

Clinical Features

Typically, patients have relatively symmetric proximal and distal weakness (non-length dependent), along with sensory dysfunction in the form of paresthesias, numbness, sensory ataxia, and uncommonly pain. By definition, these symptoms must progress for at least 8 weeks. On examination, profound hyporeflexia/areflexia is characteristic.[4,8]

Though motor weakness is often more prominent and disabling, sensory loss occurs in up to 90% of patients, and is greater for vibration and proprioception than pain and temperature. Pain is rare initially, but is present in up to 70% of patients in the long term.[8]

Uncommon features:

- Cranial neuropathy—up to 20% cases: facial nerve (10–15%) or oculomotor nerve (5%)[8]
- Back pain—lumbar canal stenosis or cauda equina syndrome can occur rarely if there is marked nerve root swelling or hypertrophy[12,13]
- Distal neuropathic tremors—up to 50% of patients[13]
- Dysautonomia—mild, limited distribution[13]
- Respiratory failure—extremely rare (<5%), must prompt search for alternate diagnosis[13]

There are also variations in onset and course of CIDP **(Table 1)**.[14]

Acute onset and relapsing forms are difficult to distinguish from Guillain-Barré syndrome (GBS) **(Table 2)**. Patients with GBS-like presentation who progress beyond 8 weeks, or relapse beyond 2 months or more than twice, are considered to have CIDP.[15]

TABLE 1 Variations in onset and course of CIDP

Onset (duration between onset to worst weakness)		*Course*	
Acute (<4 weeks)	2–16% cases	Chronic progressive	Around 2/3rd
Subacute (4–8 weeks)	17–35%	Relapsing-remitting	Between 18–33% (more common in younger patients)
Gradual (>8 weeks)	>50%	Monophasic	Between 10–25% (more common in children)

TABLE 2 Differences between GBS and CIDP

Features	*GBS*	*CIDP*
Onset	Acute	Insidious
Nadir of weakness (from onset)	<4 weeks	>8 weeks
Antecedent events (infections, vaccination, etc.)	>70% cases	<30%
Sensory features	Less prominent	More prominent
Dysautonomia	65%, may be severe	25%, may be mild
Respiratory failure	Common	Rare
Response to steroids	Absent	Present

Apart from this, there are many other clinical variants of CIDP, which are syndromically distinct **(Table 3)**.

Some clinical conditions may predispose a patient to CIDP. They should be investigated in all patients, because treatment of the primary underlying disease may sometimes lead to improvement of neuropathy **(Box 1)**.[17]

Diagnosis

Currently, EFNS/PNS criteria-2010 are the most widely accepted diagnostic criteria **(Table 4)**.[18] Maximum emphasis is placed on clinical and electrophysiological evidence of demyelination. All other investigations are supportive. The second revision of these criteria has just started, and further changes are expected.[19]

Differential Diagnosis

Immune mediated: GBS, MMN, drug-induced demyelinating neuropathy [TNF-alpha inhibitors-(infliximab, etanercept, adalimumab), tacrolimus, checkpoint inhibitors, bortezomib].

Metabolic: Diabetic and rarely, uremic neuropathies.

Systemic diseases: Amyloidosis, sarcoidosis, lymphoma, paraproteinemia-associated neuropathy, POEMS.

Infections: Neuroborreliosis, diphtheria, leprosy, HIV-associated neuropathy or radiculopathy, CMV-radiculopathy.

Hereditary: Hereditary neuropathy with pressure palsy, Charcot Marie Tooth disease, Fabry disease, Refsum disease, mitochondrial neuropathies.

Treatment

Corticosteroids, plasmapheresis and IVIg are approved first-line therapies for the treatment of CIDP.[4,5]

Steroids: Treatment is initiated with high dose/pulse of oral or injectable steroids. Regimens proven in trials include daily prednisolone (1–1.5 mg/kg), dexamethasone pulses, methylprednisolone intravenous or oral pulses. High dose should be maintained for at least 3–6 months, when the disease plateaus, after which gradual taper may be attempted. Relapse rates are unacceptably high; so, a steroid-sparing agent should be added with the initial regimen, so that by the time steroid taper is started, the other immunosuppressant is effective.[4,20]

IVIg: The ICE study established the role of IVIg as a first-line therapy.[21] Dose—2 gm/kg divided over 5 days. Maintenance doses may be required every 4–8 weeks.[22]

TABLE 3 Clinical variants of CIDP

Lewis-Sumner syndrome *[Also called multifocal acquired demyelinating sensory and motor neuropathy (MADSAM)]*	Strikingly asymmetrical sensory and/or motor deficits in individual nerve distributions, clinical and electrophysiological motor and sensory involvement, (distinguishing it from multifocal motor neuropathy), steroid responsive[13,16]
Chronic Immune Sensory Polyradiculopathy (CISP)	Sensory ataxia due to inflammation restricted to dorsal roots—progressive numbness, ataxia, hyporeflexia, normal power. Nerve conduction studies (NCS) usually normal, but somatosensory evoked potentials (SSEP) shows prolongation. MRI may show enhancing radicles[13,16]
Sensory-Predominant CIDP (*Chronic sensory demyelinating neuropathy)*	Prominent sensory ataxia, pain, and paresthesias. Despite the lack of weakness, NCS shows significant motor conduction slowing 10% of CIDP, responds well to IVIg[13,16]
Distal Acquired Demyelinating Symmetric Neuropathy (DADS)	Symmetric, sensory, or sensorimotor starting distally in the lower limbs, without proximal involvement (length-dependent). Slowly progressive, frequently (nearly 2/3rd) associated with IgM paraprotein. Approximately 50% DADS with IgM also have anti-MAG antibodies. Tends to be resistant to standard therapies for CIDP[4,16]
Pure Motor CIDP	Rare (2–5%)—involvement of motor and sparing of sensory fibers. Non-segmental pattern of weakness, lack of bulbar involvement, demyelinating electrophysiologic abnormalities, and response to immunotherapy distinguish it from motor neuron disease[16]
Neurofascin antibody-mediated CIDP	IgG4 autoantibodies to neurofascin-155(NF155). Younger age at onset, more common sensory ataxia and tremor. Often responsive to B cell depletion therapy (e.g., rituximab), less response with IVIg[10]
Contactin-1 antibody-mediated CIDP	Clinical phenotype not well established, often characterized by advanced age, rapid onset and severe, predominantly motor, and early axonal involvement. May also be responsive to B cell depletion, and refractory to IVIg[11]
CANOMAD (Chronic ataxic neuropathy with ophthalmoplegia, IgM paraprotein, cold agglutinins, and disialosyl antibodies)	Similar to the Miller Fisher variant of GBS, though chronic in nature (disialosyl ganglioside is GQ1b). Other associated IgM antibodies include GD1a and GD1b, which cause a sensory-predominant disorder
Localized variants	Limited chronic focal upper limb variant and chronic inflammatory lumbosacral polyradiculopathy (considered a regional lower extremity variant of CIDP), responsive to IVIg[12]

BOX 1 Conditions associated with CIDP

- Hepatitis C
- Lymphoma
- Monoclonal gammopathy of undetermined significance (MGUS)
- HIV/AIDS
- Organ transplant recipients
- Connective tissue disorders (notably SLE and Sjogren's syndrome)
- Inflammatory bowel disease
- Melanoma
- Diabetes mellitus

Plasmapheresis (PLEX): In a rapidly deteriorating patient, PLEX is the best treatment.[4,5] Usually, 5–7 cycles are performed over 2–4 weeks. Improvement begins within days, but relapse rates after stopping are very high (70%, 14 days after stopping PLEX). Therefore, additional immunosuppressive medication must be used. It is preferred, if patients are very weak, rapidly deteriorating, or unresponsive or intolerant to steroid or IVIg.[4,8,12,13,18]

Subcutaneous immunoglobulin (SCIG): PATH study (2018) comparing low-dose SCIG (0.2 g/kg), high-dose SCIG (0.4 g/kg), and placebo, showed absolute risk reduction (for relapse) of 25% for low-dose, and 30% for high-dose SCIG compared to placebo.[23] Therefore, SCIG seems to be a promising agent, but requires further large-scale studies to establish dosing protocols.

Biological agents: Rituximab was shown to be effective in a small retrospective Italian study.[4,5] In refractory CIDP, and patients with NF-155 or CASPR-1 associated disease, it has been stated to be an effective drug.[10,11] The RECIPE trial, started recently, hopes to shed more light on its role in CIDP.[24]

TABLE 4 EFNS/PNS 2010 criteria for CIDP

Clinical criteria

- **Inclusion criteria**
  - ***Typical CIDP***
    - Chronically progressive, stepwise, or recurrent symmetric proximal and distal weakness and sensory dysfunction of all extremities
    - Duration ≥2 months
    - Absent/reduced DTRs in all extremities
  - ***Atypical CIDP***
    - Predominantly distal (DADS)
    - Asymmetric (MADSAM)
    - Focal (e.g., involvement of the brachial or lumbosacral plexus, or of one upper or lower limb)
    - Pure motor
    - Pure sensory (including CISP)
- **Exclusion criteria**
  - Neuroborreliosis, diphtheria, drug, or toxin exposure probable to have caused neuropathy
  - Hereditary neuropathy
  - Prominent sphincter disturbance
  - Multifocal motor neuropathy (MMN)
  - Other causes—POEMS, osteosclerotic myeloma, diabetic and non-diabetic lumbosacral radiculoplexus neuropathy, peripheral nervous system (PNS) lymphoma, amyloidosis
- **Supportive criteria**
  - Elevated CSF protein with leukocyte count <10/mm^3
  - MRI: Gd-enhancement and/or hypertrophy of cauda equina, nerve roots, or brachial or lumbosacral plexuses
  - Abnormal sensory electrophysiology in at least 1 nerve:
    - Normal sural with abnormal median or radial sensory nerve action potentials (SNAP)
    - Conduction velocity <80% of lower limit of normal (LLN) (<70%, if SNAP amplitude <80% of LLN)
    - Delayed SSEP without CNS disease
  - Objective clinical improvement following immunomodulation
  - Nerve biopsy showing unequivocal evidence of demyelination and/or remyelination by electron microscopy or teased fiber analysis

Electrophysiological criteria

- **Definite:** At least one of the following:
  - Motor distal latency ≥50% above upper limit of normal (ULN) in two nerves (excluding median neuropathy at the wrist), or
  - Reduced motor conduction velocity ≥30% below LLN in two nerves, or
  - Prolonged F-wave latency ≥30% above ULN in two nerves (≥50%, if motor amplitude <80% LLN), or
  - Absent F-waves in two nerves if these nerves have distal motor amplitudes ≥20% of LLN + ≥1 other demyelinating parameter in ≥1 other nerve, or
  - Partial motor conduction block: ≥50% proximal motor amplitude reduction relative to distal, if distal amplitude ≥20% LLN, in two nerves, or in one nerve + ≥1 other demyelinating parameter in ≥1 other nerve, or
  - Abnormal temporal dispersion (>30% duration increase between the proximal and distal CMAP) in ≥2 nerves, or
  - Distal CMAP duration increase in ≥1 nerve (median ≥ 6.6 ms, ulnar ≥ 6.7 ms, peroneal ≥ 7.6 ms, tibial ≥ 8.8 ms) + ≥1 other demyelinating parameter in ≥1 other nerve
- **Probable:** ≥30% amplitude reduction of the proximal CMAP relative to distal, excluding posterior tibial nerve, if distal negative peak CMAP ≥ 20% of LLN, in two nerves, or in one nerve + ≥1 other demyelinating parameter in ≥1 other nerve
- **Possible:** As in "definite" but in only one nerve

TABLE 5 Overall disability sum score

Arm disability scale – function checklist	***Not affected***	***Affected but not prevented***	***Prevented***
Dressing upper part of body (excluding buttons/zips)	○	○	○
Washing and brushing hair	○	○	○
Turning a key in a lock	○	○	○
Using knife and fork (/spoon—applicable if the patient never uses knife and fork)	○	○	○
Doing/undoing buttons and zips	○	○	○
Arm grade 0 = Normal 1 = Minor symptoms or signs in one or both arms but not affecting any of the functions listed 2 = Moderate symptoms or signs in one or both arms affecting but not preventing any of the functions listed 3 = Severe symptoms or signs in one or both arms preventing at least one but not all functions listed 4 = Severe symptoms or signs in both arms preventing all functions listed but some purposeful movements still possible 5 = Severe symptoms and signs in both arms preventing all purposeful movements			
Leg disability scale – function checklist	***No***	***Yes***	***Not applicable***
Do you have any problem with your walking?	○	○	○
Do you use a walking aid?	○	○	○
How do you usually get around for about 10 metres?			
Without aid	○	○	○
With one stick or crutch or holding to someone's arm	○	○	○
With two sticks or crutches or one stick or crutch and holding to someone's arm	○	○	○
With a wheelchair	○	○	○
If you use a wheelchair, can you stand and walk a few steps with help?	○	○	○
If you are restricted to bed most of the time, are you able to make some purposeful movements?	○	○	○
Leg grade 0 = Walking is not affected 1 = Walking is affected but does not look abnormal 2 = Walks independently but gait looks abnormal 3 = Usually uses unilateral support to walk 10 metres (25 feet) (stick, single crutch, one arm) 4 = Usually uses bilateral support to walk 10 metres (25 feet) (sticks, crutches, two arms) 5 = Usually uses wheelchair to travel 10 metres (25 feet) 6 = Restricted to wheelchair, unable to stand and walk few steps with help but able to make some purposeful leg movements 7 = Restricted to wheelchair or bed most of the day, preventing all purposeful movements of the legs (e.g., unable to reposition legs in bed)			
Overall disability sum score = arm disability scale (range 0–5) + leg disability scale (range 0–7); overall range: 0 (no signs of disability) to 12 (maximum disability). For the arm disability scale: Allocate one arm grade only by completing the function checklist. Indicate whether each function is "affected," "affected but not prevented," or "prevented." For the leg disability scale: Allocate one leg grade only by completing the functional questions.			

TABLE 6 CDAS classification scheme for disease activity

Cute: > 5 years off treatment	• Normal examination • Abnormal examination, stable/improving
Remission: < 5 years off treatment	• Normal examination • Abnormal examination, stable/improving
Stable active disease: > 1 year, on treatment	• Normal examination • Abnormal examination, stable/improving
Improvemet: > 3 months < 1 year, on treatment	• Normal examination • Abnormal examination, stable/improving
Unstable active disease: abnormal examiation with progressive or relapsing course	• Treatment naïve or < 3 months • Off treatment • On treatment

Other immunosuppressive agents: Methotrexate, azathioprine, and mycophenolate mofetil are common steroid-sparing agents. Cyclosporine and cyclophosphamide are also used as second-line agents.

Strength-training exercises and gradual weight bearing, along with orthotics (when required) are also extremely important for recovery. Symptomatic treatment for neuropathic pain, dysesthesias, tremors, and dysautonomia is given as clinically indicated.

Most patients show maximum benefit from IVIg or steroids by 3rd month. If a clear treatment response is not documented by 3–6 months, the drug, dosage, or diagnosis should be reconsidered.[8] Once maximum benefit is achieved, structured dose reduction or optimization may be attempted.[19] However, the strategy to best taper treatment is unknown. Objective documentation of treatment response may help in such decision-making. INCAT-ODSS (Inflammatory Neuropathy Cause and Treatment-Overall Disability Sum Score) scale for disability assessment,[25] and CDAS (CIDP Disease Activity Status)[26] scheme for disease activity are two such scoring systems **(Tables 5 and 6)**. The aim is to balance risk of early relapse with the need to avoid overtreatment and immunosuppression.

Prognosis

Overall, CIDP is a treatment-responsive neuropathy, and 50–90% patients respond to one of the first-line therapies.[4,5] Lack of response must prompt search for alternative etiology. Poor prognostic factors are rapidly progressive disease, early axonal changes on NCS, advanced age, delayed initiation of therapy, and high proportion of fibers showing demyelination on biopsy.[27] A recent study also identified certain patterns on nerve ultrasound at the time of diagnosis, which may predict good response to treatment.[28] In the original series by Dyck et al. (1975), 60% were ambulatory, 25% wheelchair or bed-bound, and 10% died.[2] This figure has significantly improved with advances in diagnosis and treatment, and in a recent 14-year study of Danish patients, 53% could discontinue treatment, only 6% had severe morbidity, and 1% died.[29] However, CIDP is a lifelong disease that invariably results in some residual disability even with effective therapies.[5]

Conclusion

CIDP is a treatable immune-neuropathy with variable clinical presentation. Diagnosis is based on clinical phenotype and electrophysiological features. Early and effective immunotherapy can prevent long-term disability accumulation. Regular follow-up with objective monitoring can help in therapeutic decision-making.

CHAPTER

95 Autoimmune Encephalitis

Gurinder Mohan, Arvinderpal Singh, Sidhant Sachdeva

Abstract

Autoimmune encephalitis is an upcoming cause of altered mental status with a subacute onset. The most common presentation is limbic dysfunction in patients of autoimmune encephalitis. However, other areas like hindbrain, spine, neocortex, striatum, and peripheral nervous system can also be variably involved depending upon the antibody involved. Paraneoplastic and non-paraneoplastic are the two broad categories of antibody dependent CNS disorders. Anti-NMDA Receptor Encephalitis is the most well defined autoimmune encephalitis syndrome. Detection of specific autoantibodies helps in establishing a definitive diagnosis of autoimmune encephalitis. Treatment is aimed at removal of the antibodies and suppression of the immune system. first line therapy includes intravenous methylprednisolone along with IVIG/plasma exchange. Second line therapy includes rituximab, cyclophosphamide, azathioprine, MMF.

Introduction

Autoimmune encephalitis is an upcoming cause of altered mental status with a subacute onset. It is only a recent addition to the medical literature. However, it is still not considered in the differential diagnosis outside of large tertiary care hospitals.

The term "autoimmune encephalitis" includes a group of disorders that present with closely related clinical features and MRI findings, but can be differentiated by the specific antibody.

The most common presentation is limbic dysfunction in patients of autoimmune encephalitis. However, other areas like hindbrain, spine, neocortex, striatum, and peripheral nervous system can also be variably involved depending upon the antibody involved. Prominent extralimbic involvement can also be seen in a few subtypes.

Subacute onset of impaired memory and cognition is generally seen.[1-5]

Pathophysiology

Paraneoplastic and non-paraneoplastic are the two broad categories of antibody dependent CNS disorders.

Paraneoplastic disorders are associated with antibodies acting against intracellular antigens. They are associated with cancer and involve T-cell mediated attack against the neurons. This leads to an irreversible neuronal damage. These antibodies act as useful tumor markers.

The other group involves antibodies against extracellular antigens of ion channels and the receptors. The association with cancer tends to be variable. The prognosis in this group is much better. The antibodies are directly pathogenic and cause reversible damage to the neurons without neuronal death.

Clinical Features

Autoimmune encephalitis can have varying manifestations. The typical presentation is altered cognition along with

TABLE 1 Autoimmune encephalitis syndromes

Antigen	*Clinical features*	*Tumor association*
NMDAR	Psychosis, insomnia, memory impairment, seizures, dyskinesias, autonomic disturbances	Ovarian teratoma
LGI1	Myoclonus, hyponatremia, dystonic seizures	Thymoma in 5% cases
Contactin-associated protein-like 2	Limbic encephalitis, neuromyotonia, memory loss and confusion, sleep disturbances, autonomic instability, neuropathic pain	Thymoma
AMPAR	Psychiatric disturbances	70% (various solid tumors)
GABA-A receptor	Rapidly deteriorating encephalopathy, status epilepticus, epilepsia partial continua	Thymoma (40%)
GABA-B receptor	Seizures, limbic encephalitis	SCLC
IgLON5	REM and non-REM sleep disturbances, obstructive sleep apnea	No association with cancer
DPPX	Encephalopathy, CNS hyperexcitability, hyperekplexia	Rarely B cell neoplasms
GlyR	Encephalomyelitis, muscle spasms, rigidity, myoclonus, hyperekplexia	H/O carcinoma
Metabotropic glutamate receptor 5	Encephalitis	Hodgkin's lymphoma* or no tumor
Metabotropic glutamate receptor 1	Ataxia	Hodgkin's lymphoma or no tumor
Neurexin 3-alpha	Confusion, seizures, encephalitis, dyskinesias	No cancer association
D-2 receptor	Involvement of basal ganglia	No cancer association

*Limbic encephalitis and Hodgkin's lymphoma are together known as Ophelia syndrome.
AMPAR, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor; Caspr2, contactin-associated protein-like 2; CNS, central nervous system; DPPX, dipeptidyl-peptidase-like protein 6; FLAIR, fluid-attenuated inversion recovery; GABA, gamma-aminobutyric acid; GlyR, glycine receptor; LGI1, leucine glioma inactivated 1; mGluR, metabotropic glutamate receptor; MRI, magnetic resonance imaging; NMDAR, N-methyl-D-aspartate receptor; REM, rapid eye movement.

subacute progressive decrease in consciousness. Memory involvement occurs early in the disease **(Table 1)**.

Anti-NMDA Receptor Encephalitis

It is the most well defined autoimmune encephalitis syndrome. The pathogenesis involves IgG autoantibodies acting against the GluN1 portion of the NMDAr. The neuronal dysfunction is reversible initially but may become permanent if untreated due to persistent inflammation and glutamate excitotoxicity mediated by NMDA.

Clinical features:

- Prodromal symptoms like headache, fever, malaise
- Psychiatric symptoms such as bizarre, agitated, anxious behavior, hallucinations[6]
- Insomnia, seizures, memory deficits, decreased consciousness, stupor with catatonic features
- Dyskinesias, autonomic dysfunction

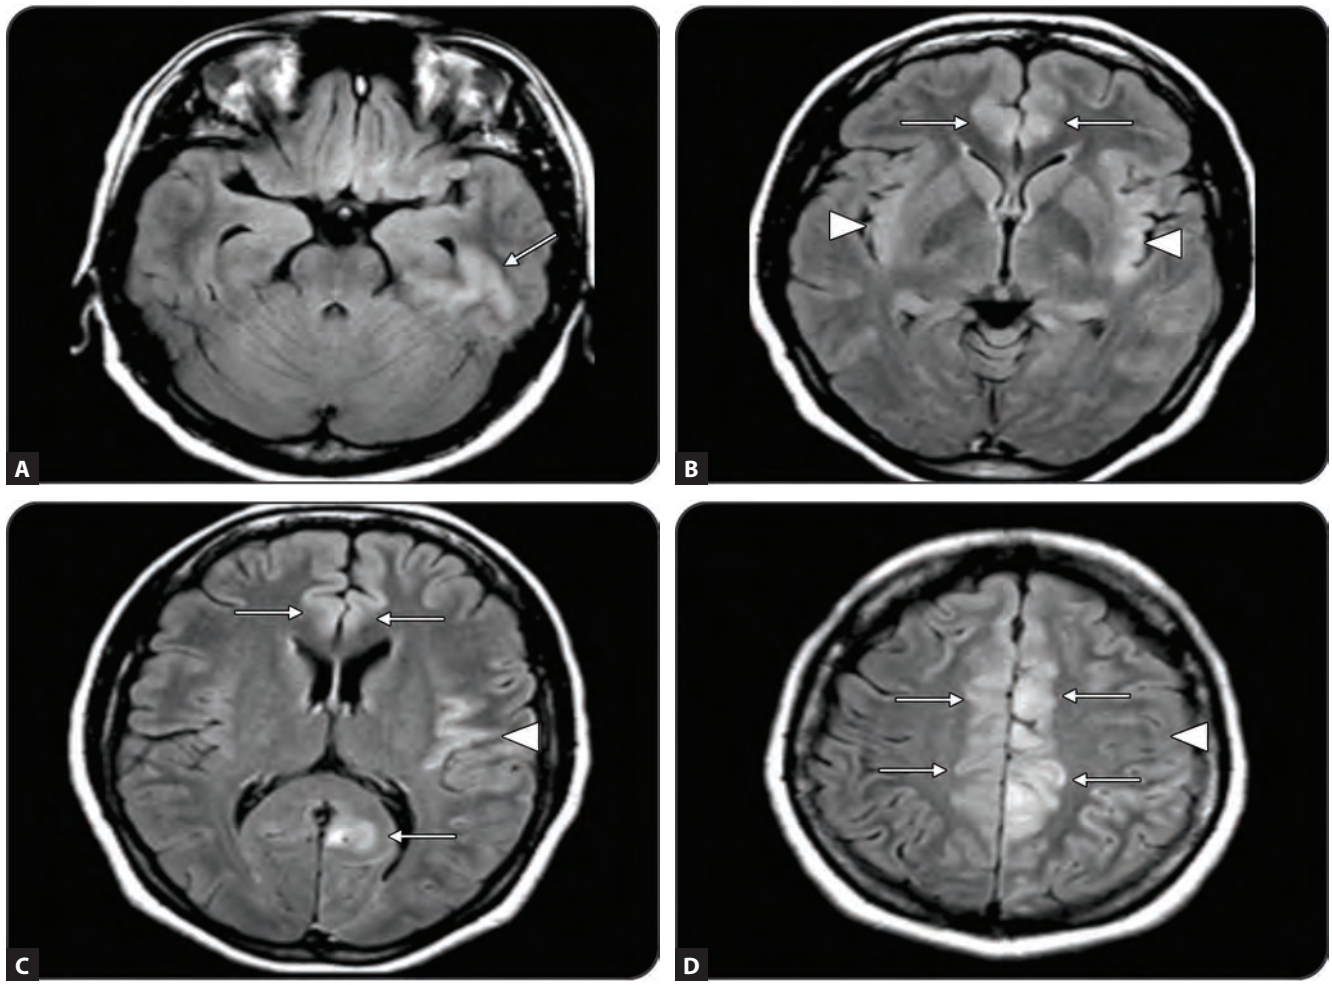
Diagnosis and differential diagnosis **(Table 2)**:

- Cerebrospinal fluid (CSF) analysis shows:
  - lymphocytic pleocytosis or
  - oligoclonal bands
- Electroencephalography (EEG) shows infrequent epileptic activity and frequent slow, disorganized activity
- MRI is usually normal or may show transient abnormalities in cortical or subcortical regions. Medial temporal symmetric hyperintensities are most frequent findings **(Figs. 1A to D)**
- PET scan demonstrates an increased gradient of cerebral glucose metabolism in the frontal-occipital region
- The detection of IgG antibodies against the GluN1 portion of the NMDA receptor is confirmatory of anti-NMDA encephalitis[7]

TABLE 2 Anti-NMDA receptor encephalitis diagnostic criteria

Probable anti-NMDA receptor encephalitis
All three criteria must be present: • Subacute onset (<3 months) of 4 out of 6 major groups of symptoms:* – Psychiatric manifestations or cognitive decline – Speech involvement – Involvement of the autonomic system – Seizures – Movement disorder – Depressed level of consciousness • One of the following: – Abnormal EEG (epileptic activity, slow/disorganized activity, extreme delta brush) – Oligoclonal bands or pleocytosis on CSF examination • Exclusion of other differentials
Definite anti-NMDA receptor encephalitis
• Positive IgG antibodies against GluN1 with 1 or more of the 6 major groups of symptoms, along with exclusion of other differentials

*Diagnosis can be made by presence of three groups of symptoms in the presence of ovarian teratoma



Figs. 1A to D: MRI showing T2 hyperintensity in the left inferior temporal lobe (A), cingulate gyrus (B–D), insular cortex (B and C)

Association with tumors: The occurrence of ovarian teratoma is dependent upon the age at which the patient presents. Female patients who are older than 18 years have ovarian teratomas in 50% of the cases, while girls who are younger than 14 years have a teratoma in 9% of the cases. Detection of a tumor is rare in male patients.

Association with HSVE: Herpes simplex viral encephalitis (HSVE) is associated with Anti-NMDA receptor encephalitis. MRI features like asymmetry of temporal lobe hyperintensities may be subtle findings, which may differentiate between the two diseases.

Treatment and prognosis: Treatment options include:

- *Immunosuppression:* Immunosuppression in form of IV methylprednisolone (1 g/day for 5 days) and either IVIG (400 mg/kg per day × 5 days) or PEX (plasma exchange)
- Tumor resection

Second-line therapies: Rituximab (375 mg/m^2 once a week × 4 weeks, or 1 g twice given two weeks apart) and cyclophosphamide (750 mg/m^2 once a month × 4–6 months). Other agents include Azathioprine and MMF.[8]

Anti-LGI1 Encephalitis

Hyponatremia, myoclonus and fasciobrachial dystonic seizures are most common presentations.[9-12]

This is a usual cause of rapidly progressive dementia in elderly. Recurrent hyponatremia is also common.

MRI shows features typical of limbic encephalitis. CSF is often normal or only shows oligoclonal bands.

Around 5–10% of cases are associated with thymoma.

Treatment includes glucocorticoids, IVIG, *mycophenolate* mofetil, and/or plasma exchange.

Anti-Caspr2-Associated Encephalitis

Anti-Caspr2 (contactin-associated protein-like 2) associated encephalitis commonly presents as limbic encephalitis, as Morvan syndrome (neuromyotonia, memory involvement and confusion, sleep disturbance, autonomic disturbance), or it can even present as isolated neuromyotonia referred to as Isaacs syndrome.[13] The progression of the disease is slower than other autoimmune encephalitis syndromes. It is usually not associated with cancer.

The target antigen, Caspr2, is involved in the normal functioning of voltage-gated potassium channels (VGKC).

Patients with thymoma are more likely to develop Morvan syndrome.

Immunotherapy remains the mainstay of treatment.

Anti-AMPA Receptor Encephalitis

Alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAr) encephalitis presents with purely psychiatric symptoms.

It has a high association with cancer, more commonly in lung, breast, or thymic tumors.

Treatment consists of management of underlying tumor and/or immunotherapy.

Anti-GABA-A Receptor Encephalitis

It is characterized by a rapidly progressive encephalitis along with seizures which are refractory to the usual treatment, status epilepticus, or may even present with epilepsia partialis continua.

Tumors, most commonly thymoma, occur in 40% of patients.

Immunotherapy is the mainstay of treatment. Pharmacologic-induced coma may be required for prolonged seizures.

Anti-GABA-B Receptor Encephalitis

It is characterized by antibodies against the B1 subunit of the gamma-aminobutyric acid B (GABA-B) receptor. The patients commonly present with limbic encephalitis. Approximately 50% of the cases are associated with small cell carcinoma of lung.

Treatment includes immunotherapy and tumor treatment.

Anti-IgLON5 Encephalopathy

Patients present with sleep disorders (REM and non-REM) along with abnormal movements during sleep and features of obstructive sleep apnea.[14]

Video-polysomnography is essential to define the complex sleep disorder. CSF and imaging studies are normal aside from the presence of IgLON5 antibodies in CSF and serum. Response to immunotherapy is poor.

Anti-DPPX Encephalitis

Patients with antibodies against dipeptidyl-peptidase-like protein-6 (DPPX) present with prodromal symptoms of

weight loss and diarrhea, followed by encephalitis with features of central hyperexcitability (agitation, myoclonic seizures, tremors, hyperekplexia).

Treatment consists of immunotherapy.

Anti-GlyR Encephalopathy

Antibodies to the α-1 subunit of the glycine receptor (GlyR) have been associated with a syndrome of PERM, acquired hyperekplexia, and stiff-person syndrome.

Most patients respond to immunotherapy.

Anti-mGluR5 Encephalitis

Antibodies against the metabotropic glutamate receptor 5 (mGluR5) are associated with features suggestive of limbic encephalitis.

Hodgkin lymphoma (Ophelia syndrome) and SCLC are the tumors most commonly associated with this syndrome.

Treatment consists of immunotherapy and management of the underlying tumor.

Anti-mGluR1 Encephalitis

Anti-metabotropic glutamate receptor 1 (mGluR1) encephalitis presents commonly with ataxia (cerebellar).

There is usually no association with cancer. The patients improve with early immunotherapy.

Anti-Neurexin-3 Alpha Encephalitis

The common presenting features are severe encephalitis, progressively worsening consciousness, dyskinesias, and hypoventilation.

Treatment consists of immunotherapy.

Diagnostic Approach

Detection of specific autoantibodies helps in establishing a definitive diagnosis of autoimmune encephalitis.

Characteristic MRI findings in such patients include hyperintensities on FLAIR or T2-weighted images in affected brain regions commonly medial temporal lobes and/or brainstem.

Nonspecific EEG abnormalities are common and include focal/generalized slowing, epileptiform activity, and periodic lateralized epileptiform discharges (PLEDs). Patients with N-Methyl-D-aspartate (NMDA) receptor encephalitis have a characteristic EEG pattern called extreme delta brush.

CSF findings include modest elevation of protein usually less than 100 mg/dL, lymphocytic pleocytosis, elevated immunoglobulin G, and/or oligoclonal bands.

The patient should also be evaluated for occult malignancy, with the tumor location being guided by the presenting syndrome.

Antibody testing: Paraneoplastic and autoimmune antibody testing should be performed on both serum and CSF.[15]

General principles to be followed are:

- Test for antibodies in serum and CSF. Testing serum and then, if negative, testing CSF delays diagnosis and can lead to false positive results and is therefore not recommended.
- If the CSF is negative but the serum antibody is positive, the serum result should be considered as a false-positive diagnosis.
- If the clinical findings do not correlate with the antibody identified, the antibody identified may be a false-positive, particularly if the antibodies were identified only in serum.

Diagnostic Criteria[16]

See **Table 3**.

Treatment Approach (Flowchart 1)[17]

Treatment for autoimmune encephalitis when suspected clinically should be started prior to results of antibody testing after infectious etiology has been ruled out. The results of antibody testing can then be used to refine treatment strategy.

Treatment is aimed at removal of the antibodies and suppression of the immune system.

First-line therapy includes intravenous *methylprednisolone*, for example, 1 gm daily for 5 days in an adult and either intravenous immunoglobulin G, for example, 400 mg/kg per day × 5 days or PEX (plasma exchange) and tumor removal as and when indicated.

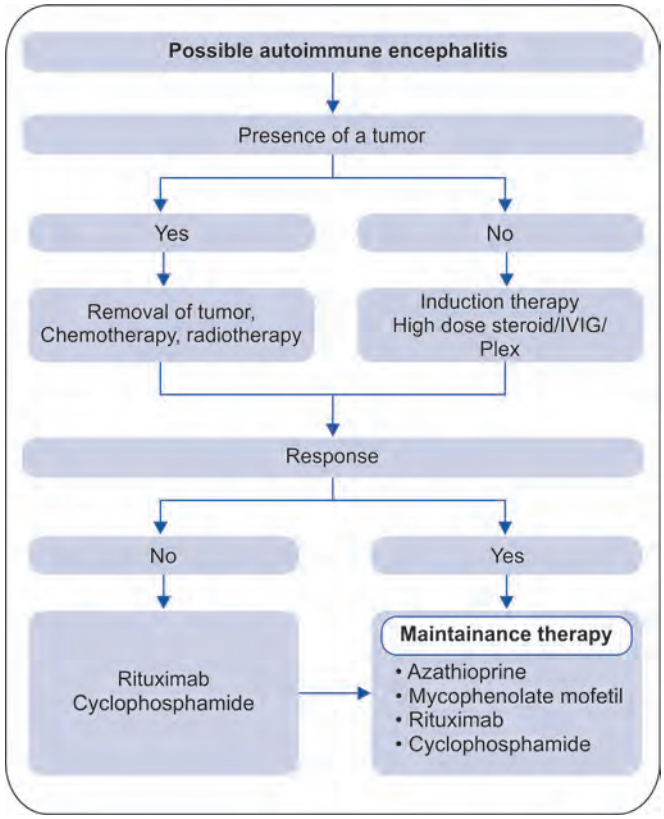
Second-line therapies include *rituximab* (either 375 mg/m^2 weekly × 4 weeks, or 1 gm given twice 2 weeks apart) and *cyclophosphamide* (750 mg/m^2 once a month × 4–6 months depending on results). Other agents include Azathioprine and MMF.

Seizures should be treated aggressively with antiepileptic drugs.

TABLE 3 Autoimmune encephalitis diagnostic criteria

Possible autoimmune encephalitis
All three following criteria should be met: • Subacute onset (<3 months) of memory disturbances, alteration in sensorium, or psychiatric signs and symptoms • At least one of the following features: – New onset focal neurological deficit – Seizures unexplained by a previous seizure disorder – Raised CSF cell count (>5 white blood cells per mm^3) – MRI showing features suggestive of encephalitis • Exclusion of other differentials
Definite autoimmune limbic encephalitis
All four following criteria must be met: • Subacute onset (<3 months) of features suggestive of limbic system involvement (memory disturbances, seizures, or psychiatric signs and symptoms) • MRI showing bilateral brain involvement of medial temporal lobes • At least one of the following: – Raised CSF cell count (>5 white blood cells per mm^3) – EEG showing epileptic/slow-wave activity restricted to temporal lobes • Exclusion of other differentials

Flowchart 1: Approach to autoimmune encephalitis



Conclusion

Autoimmune encephalitis is an important differential in patients presenting with altered sensorium of a subacute onset. The two main groups (intracellular directed antibodies and cell-surface directed antibodies) have a considerable overlap. Limbic structures are most commonly involved on neuroimaging. A small percentage of patients have no findings on neuroimaging in spite of profound neurological dysfunction, but antibody testing can ultimately lead to the diagnosis of autoimmune encephalitis in such patients.

Benign Paroxysmal Positional Vertigo: Diagnosis and Management by Physical Therapy and Repositioning Maneuvers

Ajay Kumar Vats, Atulabh Vajpeyee, GD Ramchandani, Jugal Kishor Sharma

Abstract

Benign paroxysmal positional vertigo (BPPV) is the most common peripheral vestibular disorder worldwide. It is of paramount importance to understand the pathophysiology of this purely mechanical vestibular disorder. This is because the treatment involves physical therapy and/or repositioning maneuvers, which are dependent on the elicited positional nystagmus that localizes as well as lateralizes the involved semicircular canal. The chapter discusses the pathophysiology, clinical subtypes, diagnostic oculomotor patterns (positional nystagmus), and therapeutic repositioning maneuvers, and physical therapy for the treatment of different subtypes of the BPPV. The YouTube link of videos of diagnostic positional tests and the therapeutic repositioning maneuvers are presented in a tabular form.

Introduction

Benign paroxysmal positional vertigo (BPPV) is a mechanical disorder of the membranous labyrinth and is the most frequent cause of vertigo worldwide. It is caused by vestibular lithiasis, which exists in two forms:

- *Canalolithiasis:* The degenerative otoconial debris gets detached from the utricular matrix and inappropriately enters one of the three semicircular canals namely posterior, horizontal, and anterior in that order of frequency.[1]
- *Cupulolithiasis:* The otoconial debris becomes inappropriately adherent to the cupula, making it heavy and gravity sensitive.[2] Cupulolithiasis exists in two forms, with the otoconial debris getting attached to either canal (Cup-C) or utricular (Cup-U) side of the cupula.[3]

The chief symptom of BPPV is severe rotational vertigo triggered by changes in the position of head relative to the gravity. The typical situations during which attacks occur are lying on the bed, getting up from supine to sitting, assuming lateral recumbent positions, bending forward (e.g., to tie shoelaces), and pitching the head up (e.g., keeping an object on a high shelf). The associated autonomic symptoms like perspiration, nausea, and vomiting are more common in the horizontal semicircular canal benign paroxysmal positional vertigo (HSC-BPPV).[4] The head motion normally moves endolymph in the appropriate semicircular canal, bending the cupula to generate the nerve impulse in the vestibular nerve: the latter apprises the brain (via the vestibulo-ocular reflex) in which plane and at what angle the head has moved. Consequently, the brain reflexely generates the corrective eye movements equal in angle but in the opposite direction so that the point of fixation falls on the fovea centralis. If otoconial particles inappropriately enter any of the semicircular canals, they continue to drag endolymph for few seconds (maximum 30 seconds in canalolithiasis[5] and longer in cupulolithiasis[6]) even after the head movement has ceased, thus causing a sudden severe asymmetry in the resting vestibular tone and a transient severe vertigo. By a similar mechanism, a sudden severe asymmetry of the resting vestibular tone results from a cupula that has been rendered abnormally heavy and gravity-sensitive by the adherent otoconial debris and the consequent positionally triggered vertigo.

PSC-BPPV, Posterior Semicircular Canal Benign Paroxysmal Positional Vertigo; HSC-BPPV, Horizontal Semicircular Canal Benign Paroxysmal Positional Vertigo; ASC-BPPV, Anterior Semicircular Canal Benign Paroxysmal Positional Vertigo

Table 1 shows the relative frequency of all patients diagnosed with BPPV at any specialty clinic.[7-17] Due to its peculiar anatomy, which facilitates the sequestrated degenerative otoconial debris to gravitate into the canal, the posterior semicircular canal BPPV (PSC-BPPV) is the most prevalent variant of the disorder. The relatively higher location of the anterior semicircular canal (ASC) within the bony labyrinth restricts the upward movement of the otoconial debris as well as facilitates self-clearance of any debris' through its non-ampullary arm, that inadvertently enters it. Therefore, the anterior semicircular canal BPPV (ASC-BPPV) is the least prevalent variant of the disorder.[17] In the upright positions, the horizontal semicircular canal (HSC) is inclined 30-degrees relative to the horizontal plane, its cupular barrier is at a higher location, and it becomes vertical in the supine position. Therefore, any free-floating debris that enters the HSC tends to leave the canal through the utricular exit in its non-ampullary long posterior arm during lateral recumbent positions. The spontaneous remissions of HSC-BPPV reported in a few studies are perhaps responsible for its modest frequency.[11,18]

Classification of BPPV

BPPV can be classified as under:

Monocanalicular

- *Posterior Semicircular Canal BPPV (PSC-BPPV):*
  - Geotropic variant (*geo*-PSC-BPPV)—Otoconia either free-floating in the ampullary arm in the juxtacupular location or adherent to the cupula.
  - Apogeotropic (*apo*-PSC-BPPV)—Due to free-floating otoconia in the non-ampullary arm.
- *Horizontal Semicircular Canal BPPV (HSC-BPPV):*
  - Geotropic variant (*geo*-HSC-BPPV)—Due to free-floating otoconia in the long non-ampullary posterior arm (long posterior arm horizontal semicircular canalolithiasis).
  - Apogeotropic Variant (*apo*-HSC-BPPV)—Either due to free-floating otoconia in the short ampullary anterior arm of the HSC (short anterior arm horizontal semicircular canalolithiasis) or due to cupulolithiasis. The latter exists in two forms with otoconial debris getting adherent to either canal (Cup-C) or utricular side (Cup-U) of the cupula.
- *Anterior Semicircular Canal BPPV (ASC-BPPV):* The ASC-BPPV is due to canalolithiasis, as per the consensus statement of the committee for the classification of vestibular disorders of the Bárány Society.[19] The otoconial debris in the ampullary arm of ASC results in positional downbeating nystagmus during the provocative positional tests. The cupulolithiasis of the ASC and the non-ampullary arm ASC canalolithiasis are not convincingly known to exist.

Multicanalicular

- *Single-canal bilateral* involving the same semicircular canal in either of the labyrinths.

- *Multicanal unilateral* involving at least two different semicircular canals (posterior, lateral, or anterior) in one of the labyrinths.
- *Multicanal bilateral* involving two or more different semicircular canals in both labyrinths.

Diagnosis

The clinical features of the BPPV are enumerated in the introduction section of the chapter and it is impossible to localize and lateralize the involved semicircular canals based on the symptomatology alone. Two additional important points about the symptomatology of BPPV are:

- Vertigo in the HSC-BPPV occurs during the lateral movement of the patient's head in the supine position and is less frequent during extension or flexion of the head.[20]
- A prominent sense of continuous dizziness rather than true rotational vertigo still enhanced with the change of position but, overall, continuous is the hallmark of *apo*-PSC-BPPV.[4]

The experiments of Julius Ewald (1855–1921) in pigeons framed the three laws that bear his name, and these laws are fundamental for understanding the pathophysiology of the diagnostic positional tests namely Dix-Hallpike test (DHT), supine roll test (SRT), and straight head hanging test (SHHT), which generate the diagnostic oculomotor patterns for semicircular canals affected by the vestibular lithiasis.[21] Ewald (1892) cannulated each of the three semicircular canals and applied negative and positive pressures to observe the intensity and direction of the generated nystagmus. The two main outcomes of his experiments are:

- The generated nystagmus is always directed parallel to the plane of the stimulated canal (Ewald's 1st law).
- The generated nystagmus is stronger when the endolymph moves toward the ampulla (ampullopetal) in the case of the HSC (Ewald's 2nd law), and away from the ampulla (ampullofugal) in case of vertical semicircular canals (PSC and ASC) (Ewald's 3rd law). With this background knowledge of physiology of semicircular canals, the positional tests are discussed below.

Dix-Hallpike Test[22]

The positional nystagmus generated during DHT is always directed parallel to the plane of the stimulated canal as per the Ewald's 1st law. Lowering the 45-degrees rotated head in the yaw plane to the 20-degrees head hanging position during the DHT aligns the PSC with the sagittal plane and places its ampullary end to the superior most position. Consequently, there is an ampullofugal shift of the otoconial debris in the ampullary arm of the PSC, leading to an excitatory cupular deflection (Ewald's 3rd law) and this generates the oculomotor patterns characterized by an upbeating ipsitorsional positional nystagmus.

The patient is placed on the examination table in long-sitting, such that the distance between his bottoms and the head end of the table allows his head to hang during Dix-Hallpike positioning. The patient's head is held with both hands and is rotated 45-degrees to one side (for example left) in the yaw plane. Thereupon he is positioned supine such that his 45-degrees left rotated head extends 20-degrees on the support of the author's hands representing the left Dix-Hallpike position **(Fig. 1)**. Left Dix-Hallpike positioning is maintained for at least 60 seconds or until elicited nystagmus lasts. A similar sequence of positioning is done in the right head hanging position if no nystagmus is elicited on the initially tested side. The DHT results can be interpreted as:

- An upbeating ipsitorsional positional nystagmus suggests the most prevalent geotropic variant of the PSC-BPPV (*geo*-PSC-BPPV). The lateralization is to the side eliciting positional nystagmus in the 20-degrees head hanging position during the DHT (https://youtu.be/MBsbJeYRF7s).
- A downbeating torsional nystagmus suggests either ASC-BPPV or the *apo*-PSC-BPPV. The lateralization of the ASC-BPPV is suggested by the direction of the torsional component, which is too often little or inconspicuous. The DHT elicits positional downbeating nystagmus in the head hanging position to either side as well as in the deep or enhanced straight head hanging positions in the ASC-BPPV. The positional downbeating nystagmus of *apo*-PSC-BPPV is not typically crescendo-decrescendo, often lasts longer, and is contratorsional. However, initially, too often it is impossible to differentiate between an ASC-BPPV and *apo*-PSC-BPPV based on findings of the DHT alone (https://youtu.be/wlb-iYZThzU).

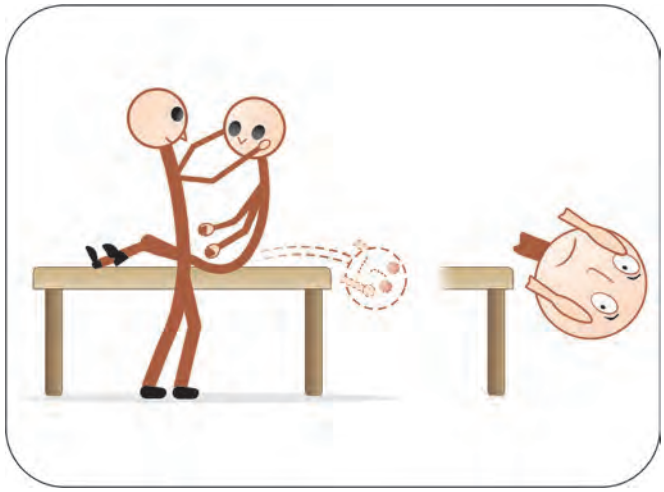

Fig. 1: ***Dix-Hallpike Test:*** The Dix-Hallpike test (DHT) involves moving the patient from a long sitting position on the examination table with the head rotated 45-degrees to a side (left in the figure) to 20-degree below horizontal head-hanging supine position. After a latency of few seconds it produces an upbeating ipsitorsional nystagmus in the PSC-BPPV, and downbeating ipsitorsional nystagmus in the ASC-BPPV. The torsional component is either little or inconspicuous in ASC-BPPV. If positional nystagmus is not elicited on one side even after 60 seconds, the patient is positioned to upright sitting, and an identical sequence is repeated with the head rotated 45-degrees to the opposite side

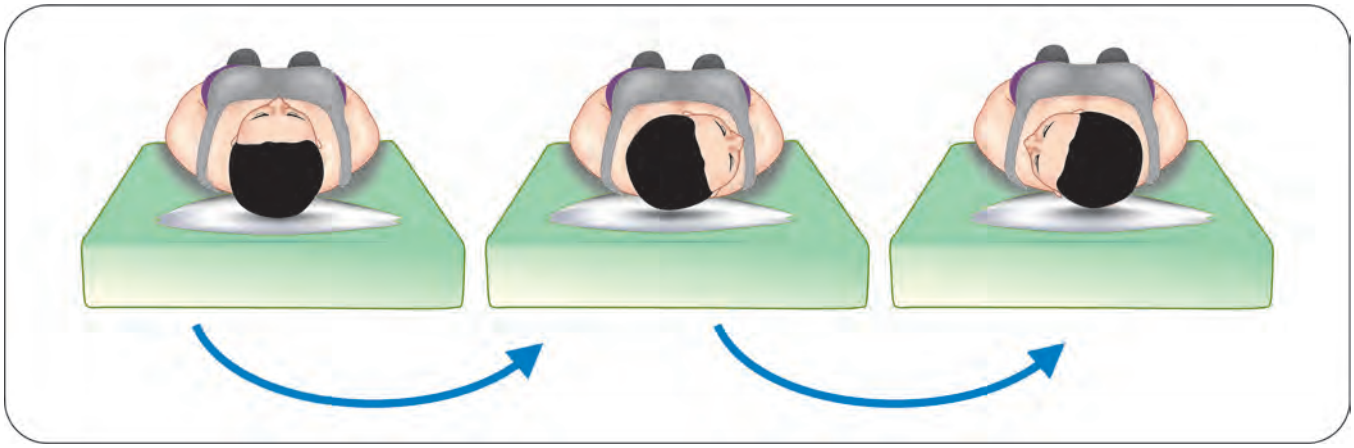

Fig. 2: ***Supine Roll Test:*** A pillow of about 4-inch thickness is placed at the head end of the examination table. The supine roll test is performed with the patient in long-sitting on the examination table. From long-sitting, the patient is shifted to a supine position so that the head is flexed to 30-degrees as the occiput lands on the pillow. The patient's head is rolled from neutral to one side while the patient is supine. After waiting for any nystagmus or vertigo to subside, the test is performed to the opposite side

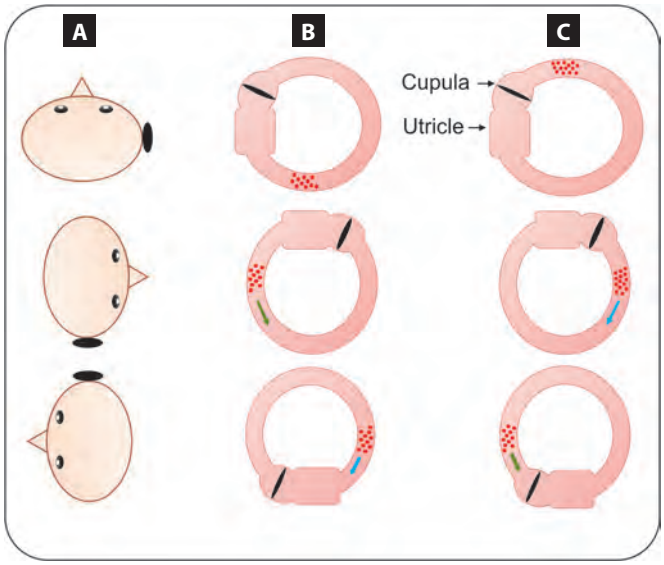
Supine Roll Test (Head Yaw Test or Pagnini McClure Maneuver)[22]

A pillow of about 4-inch thickness is placed at the head end of the examination table. The SRT is performed with the patient in long-sitting on the examination table. From long-sitting, the patient is shifted to supine position so that the head is flexed 30-degrees as the occiput lands on the pillow. The patient's head is rolled from neutral to one side while the patient is supine. After waiting for any nystagmus or vertigo to subside, the test is performed to the opposite side **(Fig. 2)**. The positive test elicits horizontal positional nystagmus, which may be:

- *Geotropic:* Implying that the fast component of the nystagmus is directed toward the lowermost ear. The geotropic positional nystagmus is elicited on the lateral head roll to either side and is attributed to the long posterior non-ampullary arm horizontal semicircular canalolithiasis. The side to which the lateral head roll elicits stronger geotropic nystagmus is the affected side as per the Ewald's 2nd law (https://youtu.be/jwRgSZ71Ux8Or).
- *Apogeotropic:* Implying that the fast component of the nystagmus is directed away from the lowermost ear. The apogeotropic positional nystagmus is elicited on the lateral head roll to either side and is attributed to the



Figs. 3A to C: ***The location of otoconial debris in the supine neutral position and during lateral head rolls executed in the supine roll test.*** (A) Top to bottom—supine neutral position, lateral head roll to right and to left. (B) Otoconia in the posterior arm of right horizontal semicircular canal (geotropic variant) shifts ampullopetal (green arrow) on the lateral head roll to right and ampullofugal (blue arrow) on the lateral head roll to left. (C) Otoconia in the anterior arm of right horizontal semicircular canal (apogeotropic variant) shifts ampullofugal (blue arrow) on the lateral head roll to right and ampullopetal (green arrow) on the lateral head roll to left

short anterior ampullary arm horizontal semicircular canalolithiasis or cupulolithiasis. The side to which the lateral head roll elicits weaker apogeotropic nystagmus is the affected side as per the Ewald's 2nd law. (https://youtu.be/t_Ie7LGcCXQ).

In the geotropic variant of the HSC-BPPV (*geo*-HSC-BPPV), in which otoconial debris is free-floating in the long posterior non-ampullary arm of the HSC, an ipsilesional lateral head roll in the yaw-axis, during the SRT, produces an excitatory hydrodynamic drag of the endolymph toward the ampulla. This very reason in the variant, during SRT, elicits stronger geotropic nystagmus to the side of lesion than to the opposite side **(Figs. 3A and B)** (https://youtu.be/-gp7Dol6_jk). In the apogeotropic variant of HSC-BPPV (*apo*-HSC-BPPV), where otoconial debris is either free-floating in the short anterior ampullary arm of the HSC or is adherent to the cupula, thus making it heavier, the excitatory hydrodynamic drag of the endolymph toward the ampulla occurs when there is contralesional lateral head roll in the yaw axis during SRT. Accordingly, in the *apo*-HSC-BPPV during the SRT, stronger apogeotropic nystagmus is elicited when the head is yawed to the contralesional side **(Figs. 3A and C)** (https://youtu.be/v6vmGAJaRDs).

The duration of the positional nystagmus is up to 1 minute in the canalolithiasis and more than 1 minute in the cupulolithiasis. The HSC-BPPV caused by short anterior ampullary arm canalolithiasis presents with apogeotropic positional nystagmus that may last longer than 1 minute. However, if the SRT elicits persistent apogeotropic positional nystagmus lasting more than 1 minute and there are no changes in the direction of nystagmus even after repetitive head roll tests, it is explicable by the horizontal canal cupulolithiasis either on canal-side (Cup-C) or on the utricular-side (Cup-U)[19] (https://youtu.be/glT9HtAwaFc).

Straight Head Hanging Test[23]

The straight head hanging test (SHHT) is carried out with the patient in long-sitting on the examination table such that the distance of the patient's bottoms from the head end of the table allows the head to hang during supine positioning. The patient's head is firmly held and is positioned to the supine neutral position with the head 30-degrees or maximally extended (beyond the short edge of the examination table). The patient is held in the enhanced straight head hanging position till positional nystagmus is elicited and lasts or for at least 60 seconds if no positional nystagmus is elicited. The patient is instructed to keep their eyes open even when experiencing vertigo in the head hanging position to observe the pattern of induced positional nystagmus. A SHHT is positive if a downbeating nystagmus is elicited with or without a torsional component (https://youtu.be/Ubwsqx9J75c).

Table 2 summarizes the currently known variants of BPPV, the anatomico-physiological correlation between otoconial location and oculomotor patterns generated on the diagnostic positional tests in terms of the direction, latency, and duration of the elicited positional nystagmus. Column 7 of **Table 2** shows the YouTube links to access the videos of the oculomotor patterns of the generated nystagmi during the positional tests in different variants of BPPV. Because the management of BPPV exclusively depends on the repositioning maneuvers and/or physical therapy, it is imperative to localize as well as lateralize the involved semicircular canal by a meticulous execution of

TABLE 2 Synopsis of otoconial location, diagnostic positional test, elicited nystagmus characteristics, and YouTube links in different BPPV subtypes

BPPV variant	*Otoconial location in upright position*	*Positional test*	*Nystagmus direction*	*Nystagmus latency*	*Nystagmus duration*	*You Tube link*
geo-PSC-BPPV	Juxta-cupular in the ampullary arm of PSC	DHT	Upbeating & ipsitorsional	Brief latency (rarely up to 40 s)	<1 min	https://youtu.be/MBsbJeYRF7s
apo-PSC-BPPV	Non-ampullary arm of PSC near common crus	DHT & SHHT	Downbeating & contratorsional	Brief or no latency	>2 min	https://youtu.be/Ubwsqx9J75c
PSC-BPPV cupulolithiasis	Adherent to cupula of PSC	Half-DHT*	Upbeating & ipsitorsional	Brief or no latency	>1 min	-
ASC-BPPV	Juxta-cupular in ampullary arm of ASC	DHT & SHHT	Downbeating & ipsitorsional; torsion often too little or absent	Brief or no latency (rarely up to 30 s)	<1 min	https://youtu.be/wlb-iYZThzU
Long posterior-arm HSC-canalolithiasis	Long non-ampullary posterior-arm of HSC	SRT	Horizontal geotropic	Brief or no latency	<1 min (rarely up to 2 min)	https://youtu.be/-gp7Dol6_jk
Short anterior arm HSC-canalolithiasis	Short ampullary anterior arm of HSC	SRT	Horizontal apogeotropic	Brief or no latency	<1 min (rarely up to 2 min)	https://youtu.be/v6vmGAJaRDs
HSC cupulolithiasis	Adherent to cupula of HSC (Cup-C or Cup-U)	SRT	Horizontal apogeotropic	Brief or no latency	>1 min	https://youtu.be/glT9HtAwaFc

*The patient's head is turned 45° toward the side to be tested: the patient is then inclined 60° backward to one side, instead of 110° so that the cupula of PSC is earth horizontal. Rolling the head 180° to the other side (release position) should reveal a less intense nystagmus beating in the opposite direction, due to ampullopetal deflection of the cupula.

PSC-BPPV, Posterior Semicircular Canal Benign Paroxysmal Positional Vertigo; HSC-BPPV, Horizontal Semicircular Canal Benign Paroxysmal Positional Vertigo; ASC-BPPV, Anterior Semicircular Canal Benign Paroxysmal Positional Vertigo; geo, Geotropic; apo, Apogeotropic; Cup-C, Cupulolithiasis canal side; Cup-U, Cupulolithiasis utricular side; DHT, Dix-Hallpike Test; SHHT, Straight Head Hanging Test; SRT, Supine Roll Test

the provocative positional tests and observing the patterns of the elicited positional nystagmus thereon.

Management

The treatment of BPPV with drugs is neither indicated nor successful. In selected patients who develop severe nausea and/or vomiting during the repositioning maneuvers and/or physical therapy, promethazine may be used. Once accurate lateralization of the side and localization of the involved canal is known, an appropriate repositioning maneuver and/or physical therapy is carried out. In general, canalolithiasis is more amenable to treatment with repositioning maneuvers compared to cupulolithiasis. It is important to review the patient at short intervals at least twice, at 1 hour and 24 hours after the repositioning maneuver and/or physical therapy. The improvement is evaluated in terms of extirpation of the positional nystagmus and associated vertigo. The treatment of different BPPV variants with repositioning maneuvers and/or physical therapy is summarized in the **Table 3**. **Figures 4 to 8** illustrate the different maneuvers used in the treatment of the common variants of BPPV. Column four of the **Table 3** shows YouTube links to access the videos of the therapeutic repositioning maneuvers and/or physical therapy. After the repositioning maneuver, otoconial debris occasionally refluxes into a canal different from the one originally affected. This phenomenon is known as canal-switch and occurs in 6–8% of patients.[34-36] The appearance of a different oculomotor pattern on a verifying positional test than the one initially observed, after the patient has been subjected to a seemingly successful repositioning maneuver, is a harbinger of canal-switch. Patients undergoing canal-switch require treatment according to the protocol of the canal involved with the switch phenomenon. The appearance of persistent spontaneous nystagmus following a repositioning maneuver in HSC-BPPV may result from jamming of the otoconia within a canal or between the cupula and the adjacent ampulla wall. The canal jam results in partial or complete obstruction within the canal, resulting in spontaneous nystagmus that persists irrespective of a change in head position.[37] The physicians involved in the physical treatment of patients with BPPV should be aware of these two potential complications of physical therapy, namely the canal-switch and canal jam.

The author is grateful to Professor Thomas Lempert, Professor of Neurology, Chief Physician of the Neurology Department at the Schlosspark Clinic, Berlin, Germany, for his kindness in providing his illustration **(Fig. 4)** for this chapter. To Mr. Renith Kurian, who video recorded the diagnostic and therapeutic maneuvers (shown in the YouTube links) and precisely captured the nystagmus during the entire diagnostic and treatment period and to Mr. Ashraf for drawing the **Figures 6 and 7** on CorelDraw graphics suite 2019.

Conclusion

Successful treatment of BPPV with repositioning maneuvers and physical therapy has been one of the greatest accomplishments in the field of Otoneurology. This has been possible due to several factors like *in vivo* demonstration of otoconia in the SCC, application of physical laws to precisely lateralize as well as localize the otoconial debris within the SCC, and conceptualizing the movement of otoconia in the SCC during head movements in the physical models of the labyrinth to develop specific canal clearing maneuvers. A trained vestibular physician's role in the medical fraternity is to obviate the unnecessary and often expensive neuroimaging studies, which patients of BPPV often undergo due to ignorance of physicians at large to identify and treat this truly benign peripheral vestibular disorder by repositioning maneuvers and physical therapy.

CHAPTER

97 Tachyarrhythmias in ICU

Nikhileshwar Prasad Verma

Abstract

Tachyarrhythmia in ICU is very common. Their recognition and management are of paramount importance.

Introduction

It is not uncommon to see patients admitted in ICU to develop various tachyarrhythmias (HR >100 bpm) as they are on multiple drugs and in a state of stress. Tachyarrhthmias are more common than bradyarrhythmias and are well tolerated by some patients. But some may become unstable and manifestations in these patients could be:

- Dyspnea
- Hypotension
- Ischemic chest pain
- Altered sensorium

Tachyarrhythmias have profound effect on morbidity and mortality of the patient. Tachycardias result from enhanced automaticity, triggered activity or reentry and could be supraventricular or ventricular. There are various types of tachycardias, but the most common forms with whom an intensivist is confronted with a:

- Sinus tachycardia
- Supraventricular tachycardia (AT, AVNRT, AVRT)
- Atrial fibrillation
- Atrial flutter
- Multifocal atrial tachycardia (MAT)
- Ventricular tachycardia (monomorphic and polymorphic)

Assessment of Patient

An intensivist should first evaluate whether the patient is stable or not. Unstable patients must be urgently cardioverted. One should look for precipitating factors like electrolyte imbalance, hypovolemia, abnormal temperature, sepsis, abnormalities in gases, and drugs. When QRS complex is less than 0.12 second, it is termed as narrow complex tachycardia (NCT) and when QRS is more than 0.12 second, it is termed as wide complex tachycardia (WCT). The rhythm may be regular or irregular. A 12-lead ECG is mandatory to evaluate the arrhythmia. Response to vagal maneuvers as carotid sinus massage (CSM), valsalva maneuver and response to adenosine help in differentiating supraventricular tachycardia from ventricular tachycardia. Adenosine (6 mg) is given rapidly and 12 mg may be repeated after 2 minutes as second dose. Adenosine may cause severe bronchospasm and sometimes atrial fibrillation (AF). After giving adenosine it should rapidly be flushed with normal saline. Bedsides, echo will tell us about the status of heart.

NCT with Regular Rhythm

Sinus Tachycardia

It is the most common tachycardia seen in the ICU and the HR is between 100–180 bpm. It rarely requires

treatment. In ICU, most of the time it is an appropriate response to underlying causes like fever, hyopovolemia, pain, and hypotension. There could be iatrogenic causes too. Over enthusiastic treatment may sometimes backfire. Ischemia induced sinus tachycardia may be treated with beta blockers. It is difficult to differentiate from atrial tachycardia. The morphology of non sinus p wave of AT is the clue, which is different from sinus p wave in differentiating it from AT. The maximum sinus HR for a person is 220 – Age.

Atrial Tachycardia

Three continuous non-sinus APBs originating from the same focus make AT. If arrhythmia lasts for more than 30 second, it is called sustained. Mostly in ICU AT is non-sustained. The atrial rates range 100–260 bpm. Unstable patients are treated with synchronized DC shock. In stable patients AV nodal blocking agents are used to control the ventricular rate.

Atrioventricular Nodal Reentrant Tachycardia (AVNRT)

More than 60% of SVT is due to AVNRT. Here AV node has a dual conducting pathway. Since atria and ventricles are stimulated simultaneously p wave is usually submerged in QRS or sometimes appear just after QRS. It may also be seen as pseudo R' in V1. The HR is usually between 140–220 bpm. Patients complain of palpitation and lightheadedness. Majority of the patients tolerate it well and arrhythmia can be terminated by vagal maneuvers or AV nodal blocking agents. Long-term preventive therapy is catheter ablation or use of AV nodal blocking agents.

Atrioventricular Tachycardia (AVRT)
