CHAPTER

187 HIV and HBV Coinfection—Double Trouble

PK Agrawal

Abstract

Management of HIV/AIDS has undergone a revolution in recent years. Introduction of HAART lead to dramatic decrease in mortality associated with opportunistic infection that complicates advanced HIV infection. Incidence of chronic hepatitis has declined tremendously after introduction of vaccination of infants for Hepatitis B. But there is increased prevalence of HIV-HBV coinfection because both share common modes of transmission. HIV-HBV coinfection shows more rapid progression to end stage liver disease and liver fibrosis. Agents selected for the treatment of HIV-HBV coinfection should be active against both viruses.

Introduction

In recent years the management of HIV/AIDS has undergone a revolution. There was a rapid and dramatic decrease in mortality associated with opportunistic infection that complicate advanced HIV infection after the introduction of HAART. Since the emergence of vaccination of infants for Hepatitis B, the incidence of chronic hepatitis has declined tremendously. But as both Hepatitis B & HIV share common modes of transmission, there is increased prevalence of HIV-HBV coinfection. Hepatitis B infection is more frequent and more severe in HIV patients. The progression to cirrhosis and end stage liver disease is more rapid than in those not HIV infected. Coinfection of HIV may cause reactivation of Hepatitis B in HBsAG antibodies patient, especially in immunocompromised people. One of the most frequent causes of non-AIDS related death in HIV patients is liver disease caused by Hepatitis B.

Epidemiology

Since transmission routes of Hepatitis B and HIV are more or less similar (e.g., sexual contact, mother to child transmission at birth, parental (blood to blood), and through other infected bodily fluids. So there is high frequency of confection of HIV with hepatitis B. Worldwide nearly 10% of HIV infected population also infected with Hepatitis B. It is expected to be higher approximately 20% in Southeast Asia, 5% in North America and Western Europe. Higher rate of coinfection of HBV and HIV has been observed in MSM (men having sex with men) than heterosexuals or injecting drug users. Prevalence of HBsAg (2–14%) has been observed in HIV infected Indian population. Another studies indicated approximately 22% and 30% showing quite high frequency. These variations in study most probably due to small sample size data multicentre studies and unavailability of multirisk group data. Thus, in India, overall epidemiological trend remains obscure. According to NACO in 2017 National Adult (15–49 years), HIV prevalence in India is estimated at 0.22%. Total number of PLHIV is estimated at 21.40 lakhs. India is estimated to have 87.58 thousand new HIV infection in 2017. According to Journal of Clinical & Translational Hepatology (2017) it is estimated that about 200 crore of worldwide population have been exposed to the Hepatitis B Virus (HBV) of whom 350 million harbor

it chronically. India falls in the intermediate endemicity zone (prevalence of 2–7%, with average of 4%) with disease burden of about 50 million. Out of 36.7 million PLHIV globally, 2.7 million people also had HBV infection.

Pathogenesis

Hepatitis B is an immune mediated infection. Interaction of the virus and the host immune system leads to liver injury progressing to cirrhosis and hepatocellular carcinoma. HIV weakens the immune system by infecting and destroying CD4+ T Cells which leads to immunodeficiency. HIV attached to the CD4+ protein on the surface of these and other cells to gain entry. HBV is more or less 100 times more infectious than HIV. The risk of chronic Hepatitis B is greater in cases of HBV/HIV coinfection. It is demonstrated that in coinfection of HIV with HBV mortality due to liver disease is 19 times that of HBV infection alone and eight times more than in person with HIV infection alone. Mortality increase in individuals with CD4+ T-Cell counts. After initiation of highly active antiretroviral therapy (HAART), there is immune reconstitution leading to more liver damage. There are higher HBV DNA levels, lower serum ALT, more liver fibrosis, and more risk of end stage liver disease in the patient with HIV-HBV coinfection. Although healthy adults who are infected with HBV has less than 10% chance to develop into chronic hepatitis B, when an HIV positive adult is infected, the risk is up to 25%. CD4 restoration is less than satisfactory in response to HAART in these patients.

Treatment

For the treatment of HIV-HBV coinfection, agents selected should be active against both viruses. First goal of the clinician is to select the patient whether to treat for HIV alone, for HBV alone or for both the viruses. For patients having HIV or HIV with HBV the treatment endpoints remains the same although loss of HBeAg or HBsAg as well seroconversion to anti-HBeAg and anti-HBs is not common. The treatment must include agents active against both viruses in HIV-HBV coinfection. Not doing so will lead to emergence of HIV strains that are resistance to NRTI (nucleoside reverse transcriptase inhibitor). The recommendations from the recent the USA & Europe guidelines advocate the use of two anti-HBV drugs as part of HAART in HBV-HIV coinfection. The aim of this combination therapy is to decrease the development of resistance even though very little data exists on either mono- or coinfected patients with such therapy. The preferred treatment for dual HBV/HIV coinfection is the combination of tenofovir and lamivudine (emtricitabine). Removal of HBV therapy or change in HIV therapy for virologic failure may lead to rebound hepatitis. Hence, on changing ART always consider HIV therapy with activity against HBV. Latest studies suggest that despite faster decline of antigen level on addition of pegylated interferon for the treatment of HBV active ART in HBeAg positive coinfected person, HBeAg, or HBsAg clearance did not increased. Tenofovir alafenamide (TAF) is now available with comparable efficacy to Tenofovir but with reduced toxicity. Others—New antiviral agents like HBV entry inhibitors are currently in development. Even after HBsAg seroconversion, cessation of HBV active NRTI is safe or not remains unknown.

Vaccination

Vaccination against Hepatitis A and B should be given to all HIV patients who are not immune. In HIV positive patients the immunogenicity to HBV vaccination is decreased that is reflected by lower antibody titers, gradual waning immunity and seroconversion rates of 18–65%. Response to vaccination is poor in HIV patients especially in those with lower CD4 counts. These individuals poorly maintain the antibody titers after vaccination. May consider increase dose (double the dose of HBV vaccine) for adequate response. One month after completion of vaccine schedule anti-HBS titers should be checked. Patients with anti-HBS titer less than 10 IU/mL, a second vaccine cycle is recommended. Improved response may expect with higher CD4 counts and undetectable plasma HIV RNA on doubling the HBV vaccine dose.

Conclusion

The liver is frequently affected in patients with HIV. HIV/HBV coinfection shows more rapid progression to end stage liver disease and liver fibrosis. Since both HIV and HBV share common modes of transmission so the incidence is high with coinfection. Liver disease considered to be one of the leading causes of death in patients with HIV in post HAART era. Agents selected, for the treatment of HIV-HBV coinfection, should be active against both viruses. For better outcome in HIV-HBV coinfected patients there is increase need of close working relationships between primary care providers, infectious disease specialists, and hepatologists.

CHAPTER

188 Aging and HIV Infection: The Shape of Things to Come

Jaya Chakravarty, Aakash Rai

Abstract

The life expectancy of the PLHIV (People Living with HIV) has increased significantly because of increased availability of ART and "treat all" strategy, leading to increased proportion of patients with HIV are living longer. The challenges faced by aging PLHIV can be either associated with HIV related pathology (increased risk for chronic conditions), complications due to HIV treatment and age related pathology (cardiovascular diseases, diabetes, etc.).

Often older individuals are detected late as clinicians do not think that they are at risk for HIV infection. Early detection of HIV and prompt start of ART in older PLHIV should be done to decrease mortality. Aging PLHIV are at increased risk of malignancies. The risk of anal canal, colon, prostate, lung, hepatic, and oral cavity malignancies are increased in PLHIV as compared with age-matched general population, especially after 50 years of age. Screening for these malignancies should be done for early detection and effective management.

Long-term use of ART there is an increased risk of metabolic syndrome in the form of increase in centripetal fat, raised triglyceride & cholesterol levels, raised blood pressure and insulin resistance which are all risk factors for cardiovascular disease. Focus should be on drugs with excellent efficacy and minimal drug interaction and side effects when considering any ART for aging PLHIV. As this population is at increased risk for cardiovascular disease, counseling for lifestyle modifications like smoking cessation, regular exercise, and healthy diet would also decrease mortality and morbidity.

Introduction

With easy availability of antiretroviral therapy (ART), Treat All strategy by WHO, the life expectancy of the People Living with HIV (PLHIV) has increased significantly leading to increased proportion of patients with HIV a living longer. PLHIV are known to experience age-related comorbidities at relatively younger ages when compared with the general population. Thus many publications on HIV define older as ≥50 years of age. The challenges faced by these aging PLHIV are due to the disease itself, accelerated aging, and therapy-related toxicities and long-term side effects.

Burden of Disease

Approximately, there were 5.7 million individuals ≥50 years were living with HIV infection by the end of 2016 and it is estimated that by 2020, 21% of PLHIV will be in this older age group. Moreover, there were approximately 110,000 new infections occurring in persons of this age group in 2016.[1] This could be an underestimation as older individuals are frequently not perceived by their clinicians as being at risk for HIV infection and, consequently, are less likely to be tested for HIV compared with younger adults.[2,3]

In a study of 8,255 older adults who accessed HIV care in England, Wales, and Northern Ireland.[4] Almost half of older adults had CD4 cell count less than 200 cells/μL at the time of diagnosis. They were 14 times more likely to die within a year of diagnosis compared with older adults who were diagnosed at young age. Most studies have demonstrated that, despite successful ART and viral suppression, immune recovery is less robust with increasing age, highlighting the importance of early diagnosis and treatment.[5]

System-wise Non-AIDS Morbidity

The manifestations in older PLHIV could be due to HIV-related pathology, treatment-related complications, and age-associated pathology **(Table 1)**. Other manifestations that occur earlier or more commonly in this subset are bone-related pathologies like osteoporosis and fractures, neuropsychiatric manifestations, malignancies, and renal failure.[6]

Immune activation: HIV infection is a major source of inflammation in both treated and untreated individuals. ART that suppresses the viral load reduces these inflammatory markers but does not make it normal. This immune activation causes accelerated aging of T cells (immunosenescence) meaning that a PLHIV is physiologically older than his actual age. This causes increased incidence of age-associated conditions including cardiovascular, bone, metabolic, and neurocognitive diseases, which are generally seen at a later age in non HIV patients.[6-8]

Malignancies: PLHIV are at increased risk of malignancies.[9] The AIDS defining malignancies like Kaposi sarcoma, Non-Hodgkin lymphoma (NHL), and invasive cervical carcinoma are gradually decreasing. With increase survival of PLHIV, the incidences of non-AIDS-defining cancers are increasing. The risk of anal canal, colon, prostate, lung, hepatic, and oral cavity malignancies were excessively raised in PLHIV as compared with age-matched general population, especially after 50 years of age **(Fig. 1)**.[10]

This increased incidence of malignancy among PLHIV may be due to immunosuppression, direct effects of the HIV virus itself, coinfection with other oncogenic viruses, environmental factors, and possibly the use of antiretroviral drugs. Malignancies occur at an earlier age, have higher tumor grade, are more aggressive, and are at an advanced stage at presentation. Thus the focus should be on early screening, smoking cessation, HPV and HBV vaccination, treatment of Hepatitis C, and Hepatitis B.

Cardiovascular system: Long-term use of ART there is an increased risk of metabolic syndrome in the form of increase in centripetal fat, raised triglyceride & cholesterol levels, raised blood pressure, and insulin resistance, which are all risk factors for cardiovascular disease. The cardiovascular risk is also related to the duration of treatment with antiretroviral drugs and increases with uncontrolled disease, particularly in presence of other risk factors.[12]

The risk of acute myocardial infarction (MI) and advanced subclinical cardiovascular disease is increased in PLHIV when compared to age matched general population.[13] With increasing age, focus should be shifted on the treatment adherence and management of hypertension, dyslipidemia, obesity, and diabetes. Lifestyle modifications like smoking cessation, regular exercise, and healthy diet would also help in reducing cardiovascular mortality.

Central Nervous System

Neurocognitive disorders: It is estimated that the approximately 50% of the PLHIV on long-term ART have some amount of neurocognitive dysfunction. HIV-associated dementia is three times higher among patients ≥50 years than among patients aged 20–39 years. The most severe form of HIV-associated neurocognitive disorders is HIV-associated dementia (HAD), classically manifested as a subacute onset of impairments in subcortical function, such as decreased attention/concentration and psychomotor slowing. ART is known to have beneficial effect on the treatment and prevention of HAD. As HAD is associated with local replication of HIV in the CNS, it is

TABLE 1 Causes of morbidity in PLHIV

HIV-related pathology	*HIV treatment complications*	*Age-associated pathology*
• HIV-related increased risk for chronic conditions • HIV infection-related immunosenescence	• Lipodystrophy • Cardiac disease • Dyslipidemia • Diabetes • Metabolic syndrome	• Cardiovascular disease • Diabetes • Osteoarthritis/osteoporosis • Glaucoma/cataract • Sarcopenia • Neurocognitive diseases

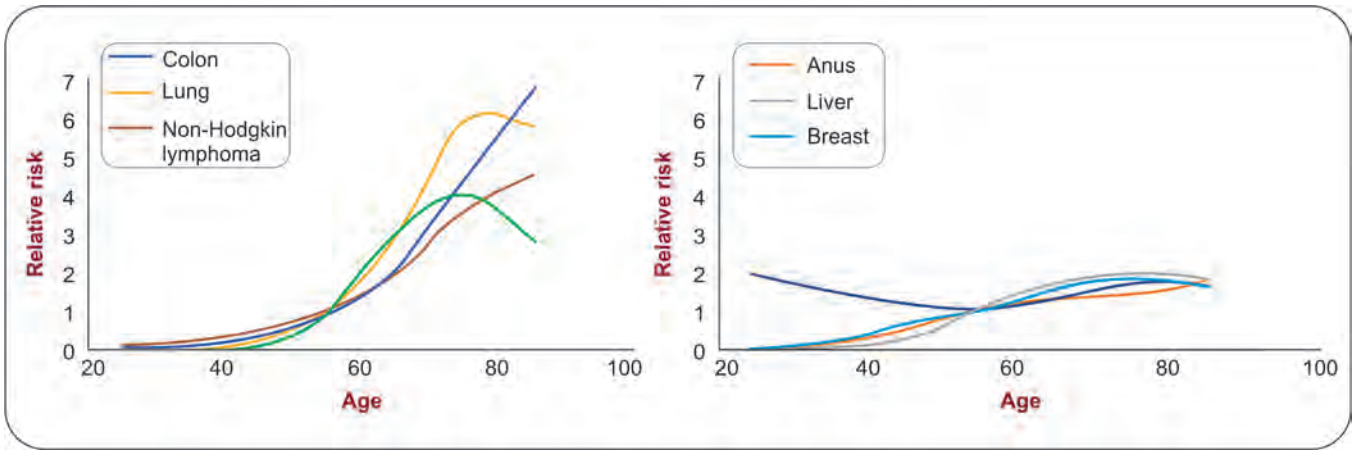

Fig. 1: Age-wise relative risk of malignancies in PLHIV compared to general US population. From Surveillance, Epidemiology and End Results (SEER) Study
Source: Justice AC et al. Journal of the International AIDS Society, 2019[11]

recommended that ART, which penetrates the CNS should be used. Some of the preferred regimens are Tenofovir-emtricitabine plus dolutegravir; Abacavir-lamivudine plus dolutegravir; or Tenofovir-emtricitabine plus ritonavir-boosted darunavir.

It is also important to distinguish between HIV-associated neurocognitive disorders and other neurodegenerative disorders, especially Alzheimer's disease. The incidence of neuropsychiatric manifestation especially depression is more in PLHIV as compared to the general population and it increases with age and should be recognized and treated early.[14]

Peripheral neuropathy: Ageing is a risk factor for peripheral neuropathy. In an observational study of 2,141 antiretroviral-naïve PLHIV who were seen annually between 2000 and 2007, ageing was associated with peripheral neuropathy despite virologic and immunologic control of HIV.[14] Almost 50% of the PLHIV are having some amount of HIV-associated sensory neuropathy (HIV-SN). This could be either be HIV-associated or as an adverse effect of ART. However, with the decrease in the use of antiretrovirals like stavudine, didanosine, etc. the incidence of ART induced neuropathy is decreasing.

Skeletal system: PLHIV are prone to a wide range of musculoskeletal problems including opportunistic bone infections, osteonecrosis, osteopenia, and osteoporosis, which could be either due to HIV itself or ART induced. The chronic inflammatory state, antiretroviral drugs like tenofovir, abnormal vitamin D metabolism, cigarette smoking, alcohol use, depression, opiate use, low testosterone levels, and premature menopause are the factors responsible for enhanced bone loss in PLHIV.[15] With increasing age, bone fractures (especially hip fracture) are responsible for very poor quality of life and a major physical and psychological impact on the patients and their family.[16]

Apart from the earlier mentioned problems, PLHIV also have sarcopenia, that is, loss of skeletal muscle mass. Many of the factors responsible for sarcopenia are already present in a PLHIV. Along with these factors, ART is also responsible for differential body fat distribution (already described earlier) and also sarcopenia.

Liver disease: Coinfection with hepatitis B and C viruses (HBV and HCV) is common among PLHIV and HIV coinfection increases the likelihood of chronic infection and a faster rate of liver fibrosis progression. Thus, chronic liver disease is a frequent finding in older adults with HIV. Thus, all efforts should be made to detect these chronic infections early and treat them. Vaccination for Hepatitis B should be done for all PLHIV at the time of diagnosis who are HBsAg negative.

Renal system: In general population, glomerular filtration rate (eGFR) decreases with increasing age normally. problems arising from age-associated diminished renal function may be compounded among older adults living with HIV. Kidneys are the reservoir for the virus, and

hence the risk of renal dysfunction is higher in PLHIV. Risk of acute renal failure is increased with Low CD-4 cell levels and long-term use of ART. HIV-associated nephropathy (HIVAN) has a high risk of developing end-stage renal disease (more often seen in African-Americans as compared to whites). Many ART drugs (tenofovir) are nephrotoxic, and hence may require dose modification in these patients or even require change in therapy.

Hypogonadism: Hypogonadism is common in men with HIV and has been associated with advanced disease and, in the ART era, persistent viremia. In one study of the Multicenter AIDS Cohort Study (MACS) cohort, the rate of decline in testosterone level decline over 10 years appeared similar between men with or without HIV, although HIV may be associated with greater loss of diurnal variation.[18]

Geriatric syndromes and functional impairment:[17] In addition to facing multimorbidity and polypharmacy, older adults with HIV may also be dealing with geriatric syndromes, such as falls, frailty, functional impairments, and disability. As with certain comorbidities, these geriatric syndromes may also occur at relatively younger age in adults with HIV compared with the general population.[18]

TABLE 2 Evaluation and monitoring of PLHIV

Cardiovascular risks	Blood pressure check	At baseline and annually
	Fasting sugar and/or HbA1C	• At baseline and every 6–12 months • 1–3 months after ART initiation
	Fasting lipid profile	• At baseline and every 6–12 months • 1–3 months after ART initiation
	Weight assessment	At baseline and follow-up visits
	Tobacco use assessment	At baseline and annually
Neuropsychiatric disorders	• Depression screening • Screening for cognitive deficits	• At baseline and annually • At baseline and annually
Medication toxicity	• Complete blood count with differential • BUN and creatinine • ALT, AST, and total bilirubin	At baseline, 2–8 weeks after ART initiation and every 3–6 months thereafter
	Urinalysis	• At baseline • At ART initiation or change • Annually
	Dilated fundoscopic examination	Every 6–12 months in patients with CD4 <50 cells/μL
Other metabolic complications	Bone densitometry	At baseline in postmenopausal women and men ≥50 years
Cancers	Colonoscopy	• At 50 years of age in asymptomatic person with average risk • Earlier screening in patients with strong family history • Subsequent testing based on baseline results
	Mammography	Annually in all patients of 50–74 year age
	Cervical pap smear	• At baseline and subsequent testing based on coinfection with HPV • Additional tests if abnormal results
	Anal pap smear	• Consider at baseline and annually • More frequent testing if abnormal results

Management of HIV Infection in Aging Population

Early diagnosis and prevention: Often older individuals are detected late as clinicians do not think that they are at risk for HIV infection. This mindset needs to be changed as early diagnosis and institution of therapy improves mortality in this group. Early screening of hypertension, diabetes, dyslipidemia, and counseling for weight loss, exercise, and tobacco cessation should be part of routine management. Screening for neurocognitive disorders, depression, bone health, and malignancies should be done routinely at baseline as well as part of follow-up **(Table 2)**. Vaccine against influenza, pneumococci, Hepatitis A and B should be given to older PLHIV.

Antiretroviral Therapy

Institution of early ART is recommended in this group so as to reduce the higher risk of non-AIDS-related complications. There are no preferred first-list ART regimens for older adults. However, while choosing the ART regimen focus should be given on concomitant medications and comorbidities, particularly liver and kidney disease. As this group patients are often on polypharmacy, that is, taking five or more medications it can lead to adverse drug events, drug-drug interactions, and inappropriate medication. This can also lead to poor adherence.

Age-associated physiologic changes like increased adiposity, increased gastric pH, decreased albumin levels, and changes in the cytochrome p450 enzyme system alter pharmacokinetics of drugs. Since both NNRTIs and PIs are metabolized by cytochrome p450, older patients with HIV may have significantly higher drug exposure when treated with antiretroviral agents and are thus prone to adverse effects. Moreover, cytochrome P450 interactions of PI and NNRTIs should be considered to minimize risk for drug-drug interactions.[19] Although integrase inhibitors have lesser interactions, interactions and timing of administration of polyvalent cations including calcium and iron supplements must be kept in mind as they can affect absorption of INSTI. Dolutegravir which is usually well tolerated causes increased neuropsychiatric problems in PLHIV more than 60 years of age and weight gain. Since both NNRTIs and PIs are metabolized by cytochrome p450, older patients with HIV may have significantly higher drug exposure when treated with antiretroviral agents and are thus prone to adverse effects. Moreover, cytochrome P450 interactions of PI and NNRTIs should be considered to minimize risk for drug-drug interactions.[19,20]

Conclusion

Health system is constantly working on enhancing the life expectancy of PLHIV. Early detection of HIV and prompt start of ART in older PLHIV should be done to decrease mortality. When considering any ART focus should be on drugs with excellent efficacy and minimal drug interaction and side effects. With the emergence of very effective ART the focus is now shifting on decreasing the functional and cognitive impairment, preventing cardiovascular mortality and morbidity, prevention and early detection of malignancy and decreasing the disability, and enhancing the quality of life in PLHIV. Screening and prompt detection of these comorbidities will go a long way in improving morbidity in these age groups. A public health approach that anticipates the needs of the ageing population with HIV will be best suited to prevent and manage these challenges.

Tuberculosis

CHAPTER

189 Newer Paradigms in the Management of Drug-resistant TB

D Behera, Ranjan K Behera

Abstract

Drug-resistant tuberculosis is an important impediment to successful TB control in any country. India has the highest number of MDR-TB cases in the world. Diagnosis and management of such cases are difficult; drugs are costly, of longer duration, and are associated side effects that are sometimes unacceptable. Further, treatment outcomes are not very encouraging. However, with availability of newer diagnostic opportunities, specifically CBNAAT, LPA for both the standard and second-line drugs and liquid culture and drug susceptibility testing have changed the approach. Further developments with availability of newer and efficacious drugs like bedaquiline, delamanid, and pretomanid have changed the paradigm of our approach for treating these cases with better outcomes. The duration of therapy has further come down with these new drugs and now we have the option of shorter courses of therapy to 6–9 months and the all oral longer duration of therapy for 18 months are now realities with success rates of more than 80%. Another important advantage is the no necessity of injectables so that patients accept these injection-free, all oral regimens with better compliance.

Introduction

The Revised National Tuberculosis Control Program (RNTCP), now known as the National Tuberculosis Elimination Program (NTEP) has notified around a total of 2.41 million TB patients of all types in 2019 according to the Nikshay dashboard.[1] More than a quarter of TB patients in India have drug resistance to one or the other anti-TB drug as per the 1st National Anti-TB Drug Resistance Survey (NDRS) of India (1914–1916).

A case of presumptive DR-TB includes the following:

- Positive sputum smear during any follow-up visit while on treatment with first line ATT;
- Pediatric TB non-responders;
- If the patient is a contact of a known DR-TB case;
- Earlier treated patient;
- TB-HIV coinfection;
- All notified new TB patients.

Results from a RNTCP (NTEP) accredited laboratory is taken as confirmed case of DR-TB. These patients are then classified according to the following definition:

Mono-resistance TB (MR): Biological sample—sputum or fluid or tissue shown to be resistant to any one anti-tubercular drug of the first-line only.

Polydrug resistance TB (PDR): When the biological sample shows resistance to more than 1 first-line anti-tubercular drug other than both INH (H) and rifampicin (R).

Rifampicin resistance (RR): When the sputum or the biological specimen shows resistance to rifampicin, when tested using phenotypic or genotypic methods and with or without resistance to other anti-TB drugs. It includes any resistance to rifampicin, in the form of mono-resistance, poly-resistance, MDR, or XDR. Most of the rifampicin resistant cases will also show H-resistance, hence the

RNTCP (NTEP) has taken a considered decision that all R-resistance cases will be treated as MDR-TB cases.

Multidrug resistance TB (MDR): In this form of tuberculosis, the biological specimen is resistant to both INH and rifampicin with or without resistance to other first-line anti-TB drugs. These patients may also have additional resistance to any/all fluoroquinolones or any/all second-line injectable (amikacin, kanamycin, and capreomycin) anti-TB drug.

Pre-XDR-TB: MDR TB with demonstrable resistance to any one of the second-line injectable anti-TB drugs like amikacin, kanamycin, or capreomycin OR to any one of the fluoroquinolones.

Extensive drug resistance (XDR): When there is additional resistance to at least any fluoroquinolone (like ofloxacin, levofloxacin, moxifloxacin, etc) and a second-line injectables (like amikacin, kanamycin, or capreomycin) in a case of MDR TB.

The following technologies are used nowadays (besides culture and DST methods):

- Line Probe Assay (LPA) for detection of MTB complex and detection of resistance to first-line drugs rifampicin, isoniazid, and second-line drugs (fluoroquinolones, second-line injectables);
- CBNAAT (Catridge Based Nucleic Acid Amplification Test) Xpert MTB/Rif testing by using the Gene X pert platform; and
- TrueNat TB test.[2]

Drug-resistant tuberculosis is a great impediment to the achievement of End TB strategy because of the complexity of drug regimes against this form of tuberculosis, treatment outcome, and cost involved. However, with availability of newer drugs particularly bedaquiline (BDQ), delamanid, and pretomanid and experience of success with shorter durations of therapy have raised hope to handle this form of the disease. An estimated 484,000 incident cases of MDR/RR-TB were reported in 2018 globally. MDR/RR-TB was reported in 3.4% of all new cases and 18% in all previously treated cases of TB. The three high burden countries for this form of TB were India (27%), China (14%), and the Russian Federation (9%). Around 123 countries of the world have reported the presence of XDR-TB (extensive drug-resistant TB) in their population. The proportion of XDR-TB among MDR-TB patients is 6.2% worldwide.[3] About 214,000 deaths occurred from MDR/RR-TB in the word in 2018. INH mono-resistance was reported in 7.2% of cases of new TB and 11.6% in previously treated cases of TB globally in 2018. India in collaboration with WHO carried out the first National Anti-TB Drug Resistance Survey (NDRS) between 2014–1916. The survey carried out drug susceptibility testing (DST) for 13 anti-TB drugs using the automated liquid culture system, (the mycobacteria growth indicator tube, MGIT 960). The main findings were: MDR-TB in 6.19% of cases (2.84% among new and 11.60% among previously treated TB patients). Additional resistance to any fluoroquinolones was observed in 21.82%, and 3.58% of cases to any second-line injectable drugs amongst all MDR-TB cases. XDR TB was present in 1.3% of cases.[4] During 2007–2018, India tested 2,798,599 patients using CB-NAAT and line-probe assays (LPAs). These tests detected 236,725 drug-resistant TB patients. In 2019, the program notified a total of 66,359 Multi Drug Resistant/Rifampicin Resistant (MDR/RR) TB cases and 56,500 (85%) of them put on treatment, which is an improvement of 7.6% over last year as reported by the India TB Report, 2020.

Approach to Treatment of DR-TB

Drug resistance emerges when anti-TB drugs are used inappropriately, poor TB control program, delayed diagnosis, inappropriate drug regimen, inadequate initial therapy, incomplete duration of therapy, inappropriate treatment modifications, addition of a single drug to an already failing regimen, improper use of chemoprophylaxis, poor adherence and incomplete follow up, failure to isolate MDR TB, failure to employ DOTS, availability of over the counter anti-TB drug, and faked drugs. Use of second-line drugs can cure MDR TB cases. However, second-line treatment options are limited and require long durations (up to 2 years of treatment). Besides the longer duration of therapy, other problems associated with these drugs are that they are expensive and toxic. More severe drug resistance can develop in some cases.

An independent expert panel of the WHO reviewed the latest evidence for treatment of drug-resistant TB in July 2018. The committee recommended certain key changes and issued a rapid communication.[5]

The programmatic management of drug-resistant TB (PMDT) was initiated in India in 2007 and the National Guideline scaled up the same which was achieved

Flowchart 1: Diagnostic algorithm for drug-resistant TB

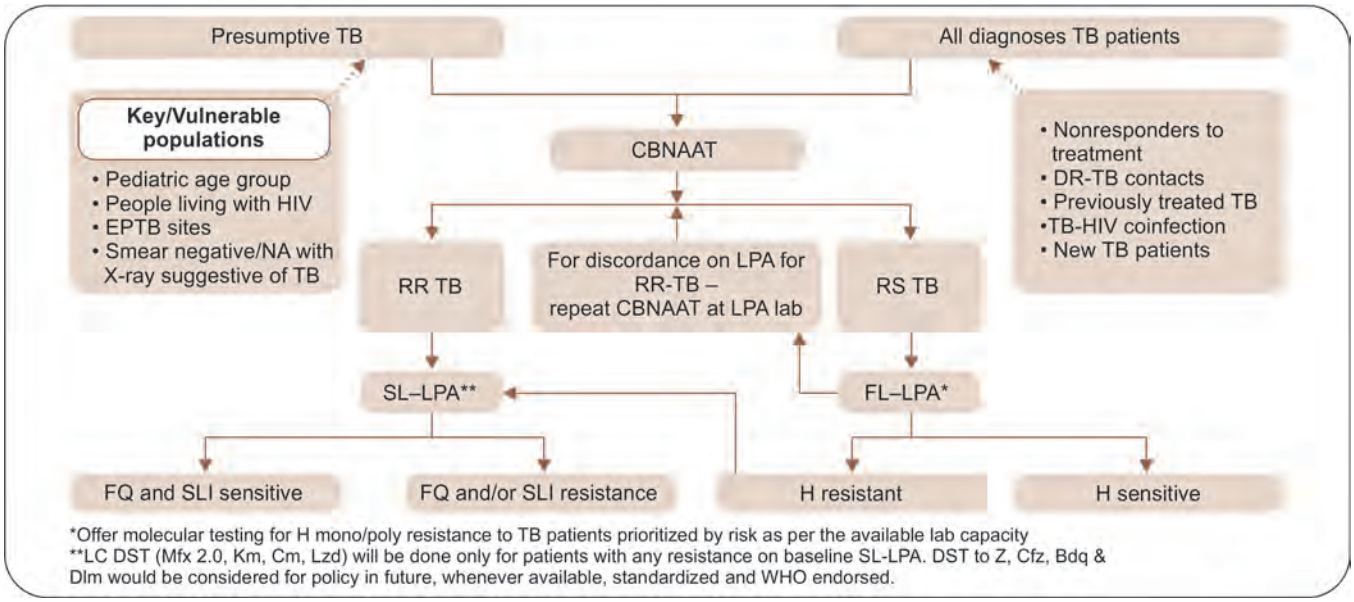

TABLE 1 Conventional drug regimen (previously used) for MDR/RR; and XDR-TB

Category of TB case	*Drug regimen (intensive phase)*	*Treatment regimen (continuation phase)*
MDR TB/RR-TB	(6–9 m) Kanamycin, Levofloxacin, Ethionamide, Cycloserine, Pyrazinamide, Ethambutol (duration 6–9 months)	(18 m) Levofloxacin, Ethionamide, Cycloserine, Ethambutol (duration 18 months)
XDR-TB	(6–12 m) Capreomycin; PAS-para Aminosalicylic Acid; Mfx-Moxifloxacin; High dose INH; Cfz-Clofazimine; Lzd-Linozolid; Amx/Clv-Amoxicillin-Clavulinic acid	(18 m) PAS-para aminosalicylic Acid; Mfx-Moxifloxacin; High dose INH; Cfz- Clofazimine; Lzd-Linezolid; Amx/Clv-Amoxicillin-Clavulinic acid

by March 2013. However, the success rate of MDR TB treatment has been around 46% consistently with a death rate of approximately 20% while the same figures at the global level has been 52% and 17%, respectively. Fluoroquinolone resistance in Indian patients was responsible for such high rates of treatment failure and death rates.[6]

The diagnostic algorithm for DR-TB is shown in **Flowchart 1**.

The conventional DR-TB regimens consisted of the following drugs, which many countries including India continued to use till recently. These are shown in **Table 1**. However, this regimen is no more used by the National program.

All MDR-TB isolates are subjected to liquid culture DST for kanamycin and levofloxacin at baseline to rule out pre-XDR and XDR-TB. Appropriate modifications have to be made if there is additional drug resistance. Pretreatment investigations are carried out and drugs are dispensed in patient-wise boxes on monthly basis. Follow-up is done with culture every month in intensive phase and every quarter in the continuation phase. However, the major issues with these regimens are the longer duration of therapy (24–27 months) resulting in poor compliance, side effects, and the overall success rate was below 50% with approximately 20% death rates. These regimens were continued till 2016 starting from 2007 when PMDT (Programmatic Management of Drug-resistant TB) was initiated in the country. With discovery and availability of BDQ (2012) and delamanid (2014) the situation changed.

Bedaquiline (BDQ) is a newly developed drug and is a diarylquinoline derivative. It targets the mycobacterial

ATP synthase.[7] It has strong bactericidal activity and tissue distribution is quite extensive and the distribution in the tissue can be there for up to 5.5 months after BDQ is stopped. The most significant benefit with the drug is that it shortens the time for culture conversion quite significantly. However, there was concern about cardiac toxicity with QTc prolongation, but subsequently it was found to be tolerated in most patients. The drug is given in the following doses:

- Week 0–2: BDQ in a dose of 400 mg (4 tablets of 100 mg) per day (all 7 days of the week) along with an optimized background regimen (OBR)
- Week 3–24: BDQ 200 mg (2 tablets of 100 mg) 3 times per week + optimized background regimen (OBR)
- After 24th week, and from Week 25 (start of month 7): Other drugs in OBR is to be continued

Delamanid (DLM) is a nitro-dihydro-imidazooxazole compound and acts by inhibiting the key mycolic acid synthesis of the *Mycobacterium tuberculosis*. The drug is administered orally as 100 mg twice daily (BID) for 2 months followed by 200 mg once daily (QD) for 4 months and is administered along with an optimized background regimen (OBR).

A number of societies, the WHO and the NTEP of India have recommended regimens for treating different forms of DR tuberculosis.[5,8-11] These recommendations are for the treatment of MDR-TB, XDR-TB, INH-resistant tuberculosis, or a mixed form of drug-resistant TB cases.

The WHO published the consolidated guidelines for DR TB in 2019 that include a set of comprehensive recommendations for the DR TB care and treatment.[5] It includes eight guideline documents developed by WHO over a period extending from 2011 till 2018. The document includes a consolidated policy recommendations for treatment regimens meant for INH-mono-resistant TB, (HrTB) and MDR/RR-TB. The treatment for the latter category includes both the longer and shorter regimens, monitoring guidelines using culture and the timing of starting antiretroviral therapy when this is associated. It also includes the recommendations for surgery for MDR-TB cases and an optimal model of care and treatment of such patients.

The recommended treatments of drug-resistant TB are in four groups:

- Treatment of INH-resistant cases
- Long duration (standardized) of therapy
- Shorter duration of therapy
- Treatment of mixed drug-resistant cases

The regimen may or may not include bedaquilline/delamanid and can be classified as treatment of:

- MDR/RR-TB
  - Shorter MDR-TB regimen
  - Conventional regimens for MDRTB
  - MDR or RR TB and additional resistance to any or all fluoroquinolones or second line injectable drugs
  - XDR-TB
- DR-TB (Mixed pattern)
  - with H mono + FQ/SLI/Lzd resistance
  - with MDR/RR-TB + FQ/SLI + Lzd resistance
- H-Mono/Poly Drug-Resistant TB

Treatment Regimens for INH-resistant Tuberculosis (HrTB)

The INH and other drug resistance produce significant problem in the success of TB treatment. **Table 2** shows the importance with various patterns of resistance that can ultimately lead to MDR/RR TB.

The World Health Organization (WHO) after reviewing many observational studies (–33 database, n-5418 INH mono-resistant cases) and individual patient data (IPD) came up with these specific guidelines for resistance to isoniazid in the absence of R-resistance. Rifampicin, levofloxacin, pyrazinamide, and ethambutol combination therapy is recommended for confirmed R-susceptible and H-resistant TB patients with confirmed rifampicin-susceptible and isoniazid-resistant tuberculosis. The treatment is for a period of 6 months. Streptomycin injection or other injectable drug is no more needed in this regimen. The duration can be extended up to 9 months. This will be true for extrapulmonary TB cases and TB with HIV also.

Conventional MDR-TB Regimen of MDR/RR-TB—Longer Duration Therapy

The regimen shown in Table 1 is recommended for R-resistant (RR) + H sensitive/unknown Or MDR–TB which was used till 2016. With the availability of new drugs, WHO has now grouped the anti-TB drugs used for DR-TB for longer MDR-TB regimens into three groups and has recommended how to include these drugs in

TABLE 2 Issues associated with H-mono- and polydrug-resistant TB (RNTCP data)

DST pattern *Total No. with DST available = 2,422 (%age out of 2,422)*	*Success (%)*	*Failure (%)*	*Progressed to Rif resistance (%)*
H-Mono (LJ/MGIT) n=819 (34%)	31	49	40
SH n=611 (25%)	25	54	52
SHE n=323 (13%)	16	67	53
S Mono n=442 (18%)	26	49	35
HE n=100 (4%)	31	54	64
SE n=68 (3%)	24	49	46
E Mono n=59 (2%)	29	56	59
H Mono (LPA) n=6426	53	24	41

TABLE 3 Grouping of drugs recommended for use in MDR-TB (longer regimens)

Group and steps	*Drugs*
Group A All the three drugs to be included	Levofloxacin, Moxifloxacin
	Bedaquiline
	Linezolid
Group B Add one or both drugs	Clofazimine
	Cycloserine, Terizidone
Group C Add to complete the regimen and when drugs from Group A and B cannot be used	Delamanid
	Pyrazinamide
	Imipenem-cilastatin OR Meropenem
	Amikacin (OR Streptomycin)
	Ethionamide or Prothionamide
	p-aminosalicylic acid

the regimen **(Table 3)**. This grouping is based on serious adverse events and relative risk for failure to treatment, or relapse and death compared to successful treatment.[5]

When a longer regimen is used for MDR/RR TB, all the three drugs in Group A and at least one agent from Group B must be included so that the treatment is ensured and is commenced with at least four anti-TB drugs which are likely to be effective, and at least three drugs should be included for the rest of the duration after BDQ is stopped after 6 months. If the regimen includes only one or two drugs belonging to Group A, then both the drugs listed in Group B are to be used. If it is not feasible and the regimen cannot include drugs from Group A or B, then Group C drugs are to be added so that the regimen is complete. Injectable agents like kanamycin and capreomycin are no more recommended in the longer regimen since BDQ is a part of the drug therapy. Levofloxacin or moxifloxacin are now a part of the longer treatment regimen for MDR/RR TB. BDQ can be and should be a part of the regimen for MDR/RR TB in patients above the age of 6 years. If susceptibility is demonstrated, amikacin can be used in adults above the age of 18 years with adequate measures for safety monitoring. Streptomycin may be considered if amikacin is not available.

The conventional regimen as indicated above (with BDQ for 6 months) is indicated in MDR/RR-TB with treatment duration of 24–27 months. If fluoroquinolone is used for more than 1 month or a second-line injectable drug like amikacin, kanamycin, or capreomycin, which is not a part of the shorter MDR-TB treatment regimen as described below, but that may cause cross resistance, then it should be excluded. However, if a reliable DST has excluded drug resistance to these two classes of drugs, the shorter regimen is a choice. BDQ is contraindicated (not administered) in pregnancy and extrapulmonary case. Drug susceptibility tests for pyrazinamide, isoniazid, ethambutol, ethionamide, and fluoroquinolones are not recommended to decide therapy because of unreliability of these tests.

Longer regimen for MDR/RR-TB is usually 18–20 months duration and can be used as a standardized one or in an individualized form. These regimens usually consist of at least five medicines that are considered to be effective. The following factors are taken into consideration to determine the choice of drugs:

- *Oral drugs are preferred over injectable drugs;*
- *drug-susceptibility test (DST results);*
- *reliability of the methods used for DST;*
- *drug resistance levels in the population;*
- *previous history of medicine used by the patient;*
- *tolerability of the drugs used; and*
- *issues pertaining to drug-drug interactions.*

NTEP Recommendations for Longer All Oral Regimen

This longer all oral regimen (there is no injectable now) is now recommended for *patients who are not suitable for receiving shorter MDR-TB regimen (see later) due to:*

- Exclusion criteria for the shorter regimen
- Adverse drugs reactions to any component of the shorter regimen
- If there is resistance to any of the drugs in the regimen (for inh A mutation ethionamide cannot be given, or pyrazinamide resistance obtained from a certified lab).

The all oral longer regimen consist of the following:
6–8 months of Bedaquiline (Bdq), Levofloxacin (Lfx), Linezolid (Lzd), Clofazimine (Cfz) Cycloserine (Cs)/12 Levofloxacin (Lfx), Linozolid (Lzd), Clofazimine (Cfz), Cycloserine (Cs).

All regimens under RNTCP (NTEP) of longer duration (conventional MDR/MDRFQ/SLI/XDR-TB) are to be replaced with this longer oral regimen in adults. The regimen can be used in children more than 6 years. If resistant to FQ class on SL-LPA, levofloxacin is to be replaced with high dose moxifloxacin.

This is the standard drug regimen now for all MDR/RR TH and XDR TB under the program.

Delamanid (Dlm) in DR-TB

WHO has given a conditional recommendation for the use of delamanid after reviewing all data and pending further review later. The recommendation states that delamanid should only be added to the longer regimen for MDR TB only when the said treatment regimen cannot be constituted according to the recommendations by the WHO. It further emphasizes that delamanid should not be added to an otherwise well tolerated and effective longer MDR regimen. WHO does not recommend delamanid to be a part of the shorter regimen for MDR TB as sufficient data for the same is not there.

The drug is indicated in patients who are 18 years of age or above and can be a part of the combination therapy for MDR TB.[12-14] Of course, now it is also recommended for children of 6 years age more.

The drug is recommended under RNTCP under the following conditions:

- Patients who are aged 6 years or above; and can also be used in patients with HIV, and who are not eligible for short course MDR TB treatment regimen due to resistance, other contraindications or inability to tolerate.
- Patients with MDR/RR TB and additional resistance to any or all fluoroquinolones and all second line injectable anti-TB drugs
- Extensively Drug Resistance TB (XDR TB)
- Patients with mixed pattern of Drug-Resistant TB and who are failing to any regimen for a drug-resistant TB regimen or who are not tolerating the drugs or there are other reasons of contraindication or those patients who come back after disruption or any new criteria of exclusion for shorter regimen or if the disease is extensive or advanced and when there is a possibility of poor outcome at the baseline risk **(Table 4)**.

Shorter MDR-TB Regimen

To reduce the duration of therapy, a shorter duration of therapy, and known as The Bangladesh regimen was first tried in Bangladesh.[15] The duration of therapy was for a minimum period of 9 months of treatment. The regimen consisted of gatifloxacin, clofazimine, ethambutol, and pyrazinamide all throughout the treatment period of 9 months and was supplemented by prothionamide, kanamycin injection, and high-dose isoniazid for a minimum of 4 months (intensive phase). The relapse-free cure was 87.9% (95% confidence interval, 82.7–91.6) observed among 206 patients. The regimen was well tolerated and infrequent major adverse drug reactions were observed and they could be manageable. The only issue with this regimen was that it was not a case control study, but an observational study. To establish the effectiveness further, a case control study was carried out subsequently.[16] This short regimen consisted of high dose moxifloxacin, clofazimine, ethambutol, and pyrazinamide administered over a 40-week period, with additional kanamycin, isoniazid, and prothionamide in the first 16 weeks.[16] There was provision of extension of the intensive

TABLE 4 Use of delamanid according to drug resistance

Resistance pattern	*DST-guided regimen class*	*Intensive phase*	*Continuation phase*	*Principle of regimen design*
Regimen with new drugs for MDR-TB + FQ/SLI resistance:				
MDR/RR + resistance to FQ class OR SLI class	MDR/RR + res to FQ class	(6–9) Km Eto Cs Z Lzd Cfz + (6) Dlm	(18) Eto Cs Lzd Cfz	0 GpA + 1GpB + 2 GpC + Z + add on 2 GpC + 1 GpD2
	MDR/RR + res to SLI calss	(6–9) Lfx Cm Eto Cs Z LzD Cfz + (6) Dlm	(18) Lfx Eto Cs Lzd	1 GpA + 1GpB + 2 GpC + Z + add on 2 GpC + 1 GpD2

phase to 20 or 24 weeks for those who did not have sputum conversion by 16 or 20 weeks, respectively. The regimen was similar to that of the Bangladesh Regimen except that moxifloxacin was substituted for gatifloxacin because quality-assured gatifloxacin was not available. A similar prospective observational study was carried out in nine African countries in 1,006 MDR-TB patients. The regimen similarly comprised of a standardized 9-month regimen (moxifloxacin, clofazimine, ethambutol) (EMB) and pyrazinamide (PZA) throughout and additional kanamycin, prothionamide, and high-dose isoniazid during the intensive phase of 4–6 months.[17] The cohort included 200 (19.9%) patients who were infected with the human immunodeficiency virus (HIV). Of these 1,006 patients, 728 (72.4%) were cured and 93 (9.2%) completed therapy; thus causing a success rate of 81.6%. Failure rate was 5.9%, 78 (7.8%) died, and 48 patients (4.8%) were lost to follow-up. Death among HIV positive cases was more (19.0% vs. 5.0%). The treatment success rate was not affected by HIV status. The main factor of failure was fluoroquinolone resistance. The bacteriological outcome was not affected by resistance to other drugs like pyrazinamide, ethambutol, or ethionamide. Hearing impairment of 11.4% was the most important adverse drug reaction with severe deterioration after 4 months. The observations of the trial supported the efficacy, and hence the use of shorter regimens.

The WHO recommends the use of short regimens of 9–12 months in place of long regimens in MDR/RR TB patients provided that the patient has not received second-line drugs for more than 1 month and there is no resistance to fluoroquinolones and second-line injectable anti-TB drugs.[4]

The National Technical Expert Group (NTEG) of the NTEP, India, has now recommended the use of shorter regimens in all cases of MDR TB except under the situations discussed in **Table 5**.

BPaL Regimen

Pretomanid, a new anti-TB drug was approved by the US FDA in August 2019 for use along with BDQ and linezolid (high dose); this regimen, referred to as the *BPaL regimen*, is administered for 6 months (extendable to 9 months) to treat adults with pulmonary form of the extremely drug-resistant TB (XDR-TB), or treatment-intolerant or non-responsive multidrug resistant TB (MDR-TB). It inhibits the biosynthesis of mycolic acid, thus blocking the production of cell wall by the

TABLE 5 Contraindications for shorter duration therapy

DST-based criteria	*Non-DST-based criteria*
• If DST/DRT result for FQ or SLI is resistant or • Presence of INH A mutation (for Eto) or • Resistance to Z (whenever available) • If result for DST (FQ, SLI, INH A mutation, Cfz & Z) is not available, history of use of high dose moxifloxacin (Mfx(h)), Kanamycin (Km), Ethionamide (Eto) or Clofazimine (Cfz) for >1 month	• Pregnancy • Any extrapulmonary disease in HIV positive cases • If the tuberculosis is disseminated, or TB meningitis, or tuberculosis of the central nervous system • If the patient does not tolerate any drug in the shorter MDR TB regimen or if there is a risk of toxicity to a drug in the regimen like drug-drug interactions

mycobacteria. It acts in non-replicating mycobacteria as a respiratory poison releasing nitric oxide under anaerobic situation. The regimen of the three drugs was investigated in three sites in South Africa. The drug regimen was as follows:

- BDQ in a dose of 400 mg once daily for 2 weeks that was to be reduced to 200 mg thrice weekly for a period of 24 weeks;
- Pretomanid—200 mg daily for a period of 26 weeks; and
- Linezolid of 1,200 mg daily for up to 26 weeks.

The dose was adjusted according to toxicity.[18] The study enrolled 109 patients (XDR TB and unresponsive MDR TB patients). After 6 months of the trial, an intention to treat analysis was done. Around 98 patients (90%; with CI of 83–95) showed favorable and 11 patients (10%) had unfavorable outcomes. There were 7 deaths. One patient withdrew consent during treatment, relapse occurred in two cases, and one patient was lost to follow-up. The linezolid toxicity included peripheral neuropathy (81%) and myelosuppression (48%). Although these were common toxicities, they were manageable. Very often reduction of dosages or in some cases interruption of linezolid resolved the toxicities. The trial is named as the *Nix-TB Trial*. This BPaL regimen consisting of BDQ, pretomanid and linezolid continued to show favorable outcome till 6 months after treatment completion in most cases even with high degrees of DR TB although some toxic effects were observed.

Salvage Regimen

In spite all the above approaches, some patients continue to have sputum-culture-positive despite therapy with second-line TB drugs. For them treatment options are limited, especially if there is no scope of resectional surgery because of advanced and bilateral disease. Salvage therapy may be an option. Salvage therapy refers to the design of a regimen that combines both new and previously used drugs in a final effort to attain sputum conversion before declaring treatment to have failed. A combination of BDQ and delamanid along with other drugs may sometimes help with good results.[19-22]

General

Surgery in very few cases will be required and whenever possible, should be offered. It is imperative that pretreatment evaluation including detailed drug history, confirmation of DR TB using molecular methods, or liquid culture is a must to ascertain the type of drug-resistant TB. Pretreatment evaluation will need complete blood count, liver, and kidney function tests including thyroid function test, audiometry, cardiac assessment (for BDQ and DLM) and psychosocial evaluation. Nutrition is also important. The Government of India is providing Rs. 500 every month to these patients through direct transfer (DBT). Provision of ancillary drugs, initial admission (not mandatory now), and prescribing appropriate drugs is very essential. Besides, adverse drug reactions monitoring is equally important. Whenever there are associated conditions like HIV, diabetes, COPD, or other ailments they need to be looked after with equal emphasis. Treatments of these cases are usually carried out at the DR-TB center or DR-TB nodal center.

Major Recommendations of NTEG (National Technical Expert Group) for the treatment of MDR/XDR TB are as follows: (held from 9-11 September 2020)

There will be only two types of regimens for treating MDR/XDR-TB –

- All oral Longer MDR-TB reagimen (12-18 months); and
- Shorter all oral bedaquiline (BDQ) containing regimen.

- Shorter all oral bedaquiline (BDQ) containing regimen, (4-6) Bdq (6 m) Lfx Cfz Z E Hh Eto/ (5) Lfx Cfz Z E ((recommended by WHO) in adults (>18 yrs) in individuals confirmed with pulmonary MDR/RR-TB, uncomplicated extra-pulmonary TB disease and in PLHIV to be introduced in a phased manner starting with an implementation pilot in selected states to gain programmatic experience to guide future expansion. This recommendation may be considered for children (6-17 years) given their special needs pan-India in consultation with NTEG for paediatric TB.
- Only those patients with mutations in both inhA and katG will not be eligible for shorter regimen. However, patients with only inhA or only katG mutations will be eligible for the shorter regimen provided other conditions are met.
- **Preventive treatment** among close contacts of MDR-TB index patients (in whom FQ resistance has been ruled out) using 6Lfx for all age groups to be introduced in a phased manner starting with an implementation pilot in selected states to gain programmatic experience to guide future expansion. This recommendation may be considered for children given their special needs pan-India in consultation with NTEG for paediatric TB.
- For all oral longer MDR-TB regimen, the revised replacement drugs sequence recommended would be Delamanid, Amikacin, Pyrazinamide, Ethionamide, PAS, Ethambutol, Carbapenems.
- Extension of BDQ beyond 6 months to be considered in patients in whom an effective regimen cannot be otherwise designed if only 2 of 5 drugs are available from Groups A & B and adequate number of Group C drugs are not available due to high background resistance, non-availability or unreliability of DST.
- Use of BDQ in pregnancy needs further discussion with the concerned experts before taking a policy decision for its use under the program setting.
- Combined use of BDQ and DLM in the regimen is recommended for those M/XDR-TB patients in whom an appropriate regimen cannot be designed using all 5 drugs from Group A and B.
- BPaL research proposal may be considered with flexibility to adapt with anticipated results of ZeNix trial and submitted to the National Operational Research Committee for approval and implementation. BPaL can be considered as a last resort by NTEP under prevailing ethical standards in individual patients for whom the design of an effective regimen not possible as per recommendations.
- Post-treatment completion follow-up of all successfully treated TB patients at 6th, 12th, 18th and 24th months to be initiated under NTEP. Plan and expedite introduction of Xpert-XDR test and drug susceptibility testing for the drugs Lzd, Z, Cfz, Bdq, Dlm
- Consider second line drugs procurement adjustments and forecasting (including child friendly formulations) and capacity building planning.
- Strengthen mechanisms for improved patient follow-up and implementation of aDSM (Active TB drug-safety monitoring and management) as per the PMDT guidelines.
- Expedite up-gradation of Nikshay for diagnostic module, DR-TB case finding report and aDSM module for improving monitoring of DR-TB patients.
- Build capacity of all providers (labs, DR-TBC, field staff) in optimally utilizing Nikshay (electronic data monitoring system) for real-time data entry as well as monitoring at state and district level in order to improve the quality of care and timely regimen change in DR TB patients.
- Programme to issue DO to all DRTB Centres to consider admitting children requiring in-patient care for management of DRTB as per PMDT guidelines and proactively engage the available paediatricians (in-house/honorary) for the management of paediatric DR-TB patients.
- Programme to issues Demi-Offcial letter for use of BDQ in children in the age-group 12-17 years for management of DR-TB
- National Task Force (NTF) mechanism to support the establishment and functioning of DR-TB centres in remaining Medical Colleges across India (also engaging Paediatric Dept. for management of paediatric DR-TB patients).
- Programme to establish the mechanism to ensure dissemination of any policy change to all stakeholders especially Nodal/District DR-TB sites including medical colleges. NTEP website to have all important communications sent to states periodically uploaded so that it can be easily accessed by all concerned.

Conclusion

The previously used longer but less effective drug regimen that contained an injectable drug has now been replaced with all oral, injection free short-course and longer duration (~18 months) therapy and is more effective. The National TB Elimination Program has quickly adopted these changes and has introduced these forms of therapy throughout the country so that DR-TB cases are treated more successfully. These are important developments that have been adopted by the program so that marching toward End TB will be a reality. However, prevention, early diagnosis, and completion of therapy are important keys to success.

CHAPTER

190 National DR-TB Guidelines in 2021

Vishwanath Upadhyay, Surendra K Sharma

Abstract

Drug resistant-tuberculosis (DR-TB) is relatively difficult to treat than drug-sensitive-TB. Nearly 27% of global multi-drug resistant/rifampicin resistant-TB (MDR/RR-TB) patients are in India. National guidelines for the treatment of DR-TB in India [programmatic management of drug resistant-TB (PMDT)] have been essentially adapted from 'WHO consolidated guidelines for DR-TB treatment (2020)'. These national guidelines emphasize access of universal DST to all TB patients and categorize DR-TB into rifampicin susceptible but isoniazid monoresistant-TB (Hr-TB), MDR/RR-TB, and extensively drug resistant-TB (XDR-TB). As per PMDT guidelines, patients should be examined for Hr-TB and should be treated with uniphasic rifampicin, ethambutol, pyrazinamide, and levofloxacin regimen for 6 months. Preferably, 7-drug injection-free, pan-oral shorter (9–11 months) or 5-drug pan-oral longer (18–20 months) DST-guided, bedaquiline-containing individualized MDR-TB treatment regimen should be constituted for intensive phases and 4-drug regimen for continuation phases, respectively. Monthly smear and culture should be done during follow-up. Active TB drug-safety monitoring and management (aDSM) is strongly recommended. Post-treatment, follow-up at 6th,12th,18th, and 24th months of all successfully treated DR-TB cases under national-TB elimination programme (NTEP) is recommended.

Introduction

National Guidelines on drug resistant-tuberculosis (DR-TB) in India [programmatic management of drug resistant-TB (PMDT)][1] have been adapted from WHO Consolidated Guidelines on DR-TB treatment (2020).[2] Recently, American Thoracic Society/Centers for Diseases Control and Prevention/European Respiratory Society/Infectious Diseases Society of America (ATS/CDC/ERS/IDSA) have jointly published comprehensive guidelines on treatment of DR-TB.[3] **Table 1** compares various differences between these three guidelines.[1-3]

DR-TB Definitions

The term DR-TB is a broader one encompassing several subentities, and is primarily a laboratory diagnosis confirming the presence of *Mycobacterium tuberculosis (Mtb)* and subsequently demonstrating its resistance to first-line and second-line anti-tuberculosis drugs on drug-susceptibility testing (DST). Various sub-entities of DR-TB are defined in **Box 1**.[1]

Epidemiology

DR-TB is highly prevalent[1,2] and continues to be a serious public health threat. According to the WHO Global TB report 2020,[4] worldwide there were 465,000 people (range 400,000–535,000) with new rifampicin resistant-TB (RR-TB) diagnosis and 78% of these had multidrug resistant-TB (MDR-TB). India (27%), China (14%), and Russian Federation (8%) contributed to almost half of these cases in 2019.[4] Globally, 3.3% of new and 17.7% of previously treated patients had MDR/RR-TB.[4]

TABLE 1 Comparison of WHO, ATS/CDC/ERS/IDSA and PMDT, India guidelines for the treatment of drug-resistant TB (DR-TB)

	WHO consolidated guidelines, 2020	***ATS/CDC/ERS/IDSA guidelines, 2019***	***PMDT, India, 2019-20***
Types of DR-TB	Deals with Hr-TB, MDR/RR-TB and MDR-TB with additional FQs resistance	Deals with Hr-TB, MDR-TB, pre-XDR-TB and XDR-TB Does not cover RR-TB	Deals with Hr-TB, MDR/RR-TB and XDR-TB
DST if *Mtb* isolated	Comprehensive DST if *Mtb* is isolated	Microbiological data are required to constitute an individualized treatment regimen based on DST of the *Mtb* strain isolated	Universal DST is strongly recommended to constitute treatment regimen for DR-TB
Hr-TB	Information on *katG* and *inhA* mutations on genotypic (molecular) DST is essential.	No specific recommendation for genotypic DST	Recommendation for genotypic DST is similar to WHO 2020 guidelines
	Hr-TB is treated with rifampicin, ethambutol, pyrazinamide and levofloxacin for 6 months [(6) R E Z Lfx]. If Lfx can't be used, R E Z treatment is recommended	For HR-TB patients should be treated with rifampicin, ethambutol, isoniazid and pyrazinamide for 6 months. Duration of pyrazinamide can be shortened to 2 months in selected situations such as non-cavitary disease, low- burden disease, or intolerance to pyrazinamide	About 10% of the Indian patients have *inhA* mutations where H^h can be administered and Eto can't be used because of cross-resistance About 90% have *katG* mutations and where Eto can be used. Addition of levofloxacin (Lfx) is done without a split for 6 months [(6) R E Z Lfx]
Classification of Drugs	Drugs are classified into ABC groups depending on safety and efficacy profiles. Treatment regimen is preferably constituted from Groups A and B and if it is not possible then from drugs can be added from Group C	**Recommendations:** **STRONG FOR:** Bdq, later generation fluoroquinolones (Lfx and Mfx) **CONDITIONAL FOR:** Lzd, Cfz Cs/Trd, E, Z (provided susceptibility to Z). **CONDITIONAL FOR:** Injectables Am and S, Imp-Cln and Mpm/Amx-Clv (if one of these is essential to constitute a regimen) **CONDITIONAL AGAINST:** Eto/Pto, Km and Cm, PAS **STRONG AGAINST**: macrolides (azithromycin and clarithromycin), Amx-Clv	*Grouping of drugs has been adapted from WHO guidelines 2020
Pan-oral Bdq- containing longer regimen (based on DST)	Intensive phase = at least 4 drugs Continuation phase= 3 drugs Pan-oral 5-drug longer regimen is constituted from Group A and B drugs and if it is not possible then Group C drugs are included from the replacement sequence depending upon drug susceptibility profile and tolerance	Intensive phase = 5 drugs Continuation phase= 4 drugs	Intensive phase =5 drugs Continuation phase =4 dugs Regimen: (6- 8) Bdq (6) Lzd Lfx Cfz Cs/12 Lfx Lzd^l Cfz Cs

Contd...

Contd...

	WHO consolidated guidelines, 2020	*ATS/CDC/ERS/IDSA guidelines, 2019*	*PMDT, India, 2019-20*
Pan-oral Bdq- containing shorter regimen	A shorter all-oral Bdq-containing 7-drug regimen of 9-12 months duration is recommended in eligible patients with confirmed MDR/RR-TB who have not been exposed to treatment with second-line TB medicines used in this regimen for > 1month, and in whom resistance to FQs has been excluded	Standardized 9- to 11-month shorter MDR-TB regimen is not preferred as it has injectables. A research recommendation has been given for the conduct of RCTs to evaluate the efficacy, safety and tolerability of newer oral drugs	9- to 11-month shorter pan-oral Bdq-containing 7-drug regimen comprising of (4-6) Bdq (6) Lfx Lfz Cfz Z E H^h Eto/ (5) Lfx, Cfz Z E to be administered if there are no contraindications
BPaL regimen	Bdq, Pa and Lzd (BPaL) for pre-XDR-TB (MDR-TB *plus* FQs) under operational research (OR) conditions who have no previous exposure or <2 weeks exposure to Bdq and Lzd	A total duration of treatment between 15 and 24 months after culture conversion is recommended in patients with pre-XDR- and XDR-TB	Combined use of Bdq and Dlm is recommended for M/XDR-TB patients in whom an appropriate regimen can't be made using all 5 drugs of groups A and B A 20-month treatment is recommended for XDR-TB patients BPaL regimen to be tried under OR conditions
Use of injectable	Amikacin may be included in patients aged ≥ 18 years on longer regimens to constitute a regimen. Use of injectables (especially Kanamycin and Capreomycin) is avoided as far as possible. Although, if all other options are exhausted, for the use of streptomycin *in vitro* drug sensitivity must be demonstrated	Use of injectables is not recommended. However, Am/S may be included if one is unable to constitute a 5-drug regimen and *Mtb* is drug-sensitive	Amikacin or streptomycin can be used to constitute a 5-drug regimen in patients with aged >18years, if it is essential and *Mtb* is susceptible to the drug depending upon tolerance of drugs and *in vitro* drug resistance
Duration of treatment for longer MDR-TB	Intensive phase=6-7 months Total duration=18-20 months After culture conversion= 15-17 months In MDR/RR-TB patients, on longer regimens containing amikacin or streptomycin an intensive phase of 6-7 months is suggested for most patients. However, the duration may be modified according to response to treatment	Intensive phase=5–7 months after culture conversion Total duration= 15–21 months	Intensive phase= 6–8 months (Bdq given for 6 months) Continuation phase= 12 months (fixed duration) Total duration = 18–20 months Extension of intensive phase will depend on culture conversion report at 4^{th} month or beyond

Contd...

Contd...

	WHO consolidated guidelines, 2020	*ATS/CDC/ERS/IDSA guidelines, 2019*	*PMDT, India, 2019-20*
Surgery for lung resection	In patients with RR-TB or MDR-TB, elective partial lung resection (lobectomy or wedge resection) may be done along a constituted drug regimen in a centre with a skilled and experienced thoracic surgeon and with careful selection of candidates	According to guidelines, an elective partial lung resection (e.g., lobectomy or wedge resection) with a DST-guided MDR-TB treatment regimen is more beneficial compared with medical therapy alone when clinical judgment, supported by bacteriological and radiographic data, suggests a strong risk of relapse or treatment failure Pneumonectomy is not recommended	Lung resection surgery is not done usually due to lack of infrastructure and well-trained and skilled thoracic surgeons
Preventive therapy	No specific recommendation for LTBI	For LTBI for MDR-TB patients' contacts, 6 to 12 months of treatment with a later-generation fluoroquinolone alone or with a second drug, on the basis of DST of the *Mtb* isolate of the source- case	No specific recommendation for LTBI

*Replacement drugs sequence consists of the following order: delmanid (Dlm), amikacin (Am), pyrazinamide (Z), ethionamide (Eto), *para*-aminosalicylic acid (PAS), ethambutol (E), penems. Use of Bdq during pregnancy is under consideration. Bdq may be used beyond 6 months if only 2 of 5 drugs from Groups A and B are available and adequate no. of Group C drugs are not available due to high background resistance non-availibility or unreliability of DST

Note: ATS/CDC/ERS/IDSA guidelines (2019) and WHO Consolidated DR-TB guidelines (2020) categorise following drugs, Am/S and E, H^h differently whereas in PMDT, 2019-20 PAS has been preferred over E and carbapnems

Source: WHO consolidated guidelines on tuberculosis. Module 4: treatment - drug-resistant tuberculosis treatment, 2020; Treatment of Drug-Resistant Tuberculosis-An Official ATS/CDC/ERS/IDSA Clinical Practice Guideline, 2019; Guidelines on programmatic management of drug-resistant tuberculosis in India, 2019-20.

BOX 1 DR-TB diagnosis methods and definitions

Laboratory methods for DR-TB diagnosis

- Genotypic (rapid molecular tests): provide early diagnosis
  - Nucleic acid amplification tests
    - ♦ Cartridge-based nucleic acid amplification test (CBNAAT): 1.5 hours
    - ♦ *TrueNat (chip based): 1 hour for *Mtb* detection + 1 hour for Rifampicin resistance testing
  - First-line and second-line line probe assays (FL-LPAs and SL-LPAs): 48 hours turn-around time
- Phenotypic methods (culture methods): time-consuming, used for confirmation and drug susceptibility testing (DST)†:
  - Liquid culture: 42 days
  - Solid culture: 56 days

DR-TB definitions

Monoresistance: refers to *Mtb* resistance to one of the first-line anti-TB drugs. Isoniazid monoresistance (Hr-TB) is commonly encountered

Polydrug resistance (PDR): resistance to more than one first-line anti-TB drugs other than both isoniazid and rifampicin

Multi-drug resistant TB (MDR-TB): *Mtb* resistance to both rifampicin and isoniazid

Pre-XDR-TB: includes MDR-TB and resistance to either of flouroquinolones (FQs) or second-line injectables (SLIs)

‡**Extensively drug resistant TB (XDR-TB):** a subset of MDR-TB that includes additional resistance to FQs and SLIs.

*TrueNat is a chip based battery operated nucleic acid amplification test system made in India.

In FL-LPA, mutations in *Mtb* for rifampicin and isoniazid resistance and in SL-LPA the mutations for FQs (Mfx and Lfx) and injectables (amikacin, kanamycin and capreomycin) are tested

†**DST definitions:** Critical concentration (CC), is the lowest concentration of an anti-TB drug in vitro that will inhibit the growth of 99% of phenotypically wild-type strain of *Mtb* complex. Minimal inhibitory concentration (MIC) is the lowest concentration of an antimicrobial agent that inhibits growth of > 99% of a microorganism in a solid or broth dilution susceptibility test. Critical breakpoint (CB) concentration(s) of an antimicrobial agent which defines an MIC above the critical concentration that separates strains that will likely respond to treatment. The CB is used in to guide individual clinical decisions in patient treatment

‡As SLIs will no longer be recommended in the revised DR-TB treatment guidelines, XDR-TB definition will require revision in future

Source: Guidelines on programmatic management of drug-resistant tuberculosis in India, 2019–20

BOX 2 Risk factors for drug-resistant tuberculosis

- Factors related to previous treatment
  Incomplete and inadequate treatment
  Inadequate treatment adherence
- Virulence of *Mtb* strain, e.g., W-Beijing genotype is well-known for multidrug resistance
- Presence of multidrug transporter proteins may lead to drug resistance in *Mtb* strain
- Lower anti-TB drugs levels due to either malabsorption of anti-TB drugs or drug-drug interactions like rifampicin and moxifloxacin
- Male gender
- Older age
- Low BMI
- Diabetes mellitus
- HIV/AIDS
- Factors such as psychiatric illness, alcoholism, drug addiction, and homelessness do predict non-adherence to treatment

BMI, body mass index; HIV/AIDS, human immunodeficiency virus/acquired immunodeficiency virus; Mtb, *Mycobacterium tuberculosis*

Source: Adapted from Sharma SK, Mohan A. Multidrug-resistant tuberculosis: a menace that threatens to destabilize tuberculosis control. Chest. 2006;130:261-72.

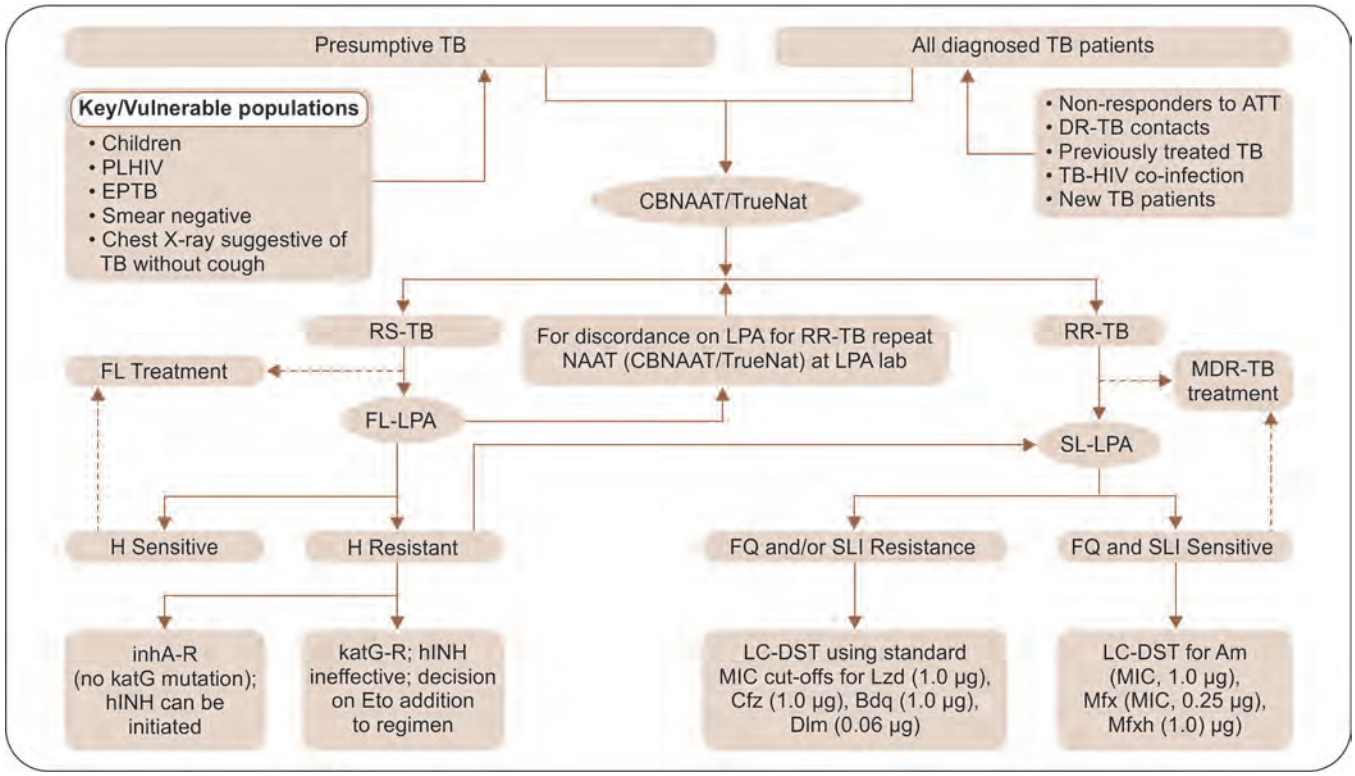
India had 66,255 laboratory-confirmed MDR/RR-TB in 2019, 55.5% of these were tested for second-line anti-TB drugs and 3.5% had extensively drug-resistant-TB (XDR-TB). MDR-TB developed among 2.8% of new and 14% of previously treated patients had MDR/RR-TB.[4] Globally, only one in three diagnosed MDR/RR-TB accessed DR-TB treatment, and in India 48% of laboratory confirmed MDR/RR-TB and 30% of XDR-TB cases were initiated on treatment. Various risk factors for DR-TB are described in the **Box 2**.[5]

According to National Anti-tuberculosis Drug Resistance Survey (NDRS) in India,[6] ~8% of Hr-TB patients are resistant to any fluoroquinolone (FQ) drug whereas resistance to linezolid (Lzd) is uncommon in MDR/RR-TB and minimal in isoniazid (H) mono/poly-DR-TB. In India, H resistant-TB (Hr-TB) occurs due to *kat*G gene mutations in ~90% patients and high dose H (H^h) may be ineffective in these patients whereas in the remaining (~10%) *inh*A gene mutation confers low-level resistance to H[7] and cross resistance to ethionamide (Eto). In this situation, H^h can be administered.[1]

Integrated Diagnosis of DR-TB

According to National Guidelines,[1] it is essential to rapidly characterize *Mtb* sensitivity or resistance to H, FQs, and second-line injectables (SLIs) with first line-line probe assay (FL-LPA) and second line-line probe assay (SL-LPAs) respectively after receiving nucleic acid amplification tests (NAAT) amplification report and treat according to DST report in order to avoid further amplification of DR-TB. Subsequently, although time-consuming, phenotypic culture with DST is required to establish the diagnosis. DST-guided treatment is strongly recommended in the

Flowchart 1: Integrated DR-TB diagnostic algorithm



Note: Vulnerable populations: As per WHO, children, pregnant women, elderly people, malnourished people, and people who are ill or immunocompromised, are particularly vulnerable when a disaster strikes, and take a relatively high share of the disease burden associated with emergencies. In H resistant Mtb ioslates, katG gene and inhA gene mutations can co-exist and it is considered as 'high-level' resistance only.
Am, amikacin; ATT, anti-tuberculosis treatment; Bdq, bedaquiline; CBNAAT, cartridge-based NAAT; Cfz, clofazimine; Dlm, delamanid; Eto, ethionamide; FL-LPA, first-line drug-line probe assay; FQ, fluoroquinolone; H, isoniazid; hINH, high dose isoniazid; inhA-R, inhA gene mutation resistance; katG-R, katG gene mutation resistance; LC-DST, liquid culture drug susceptibility test; Lzd, linezolid; Mfx, moxifloxacin; Mfxh, high dose moxifloxacin; MIC, minimum inhibition concentration of drugs; NAAT, nucleic acid amplification test; PLHIV, people living with HIV; RR, rifampicin resistant; RS, rifampicin sensitive; SLI, second line injectable agents; SL-LPA, second-line drug-line probe assay; TureNat, Chip based NAAT system made in India
Source: Guidelines on programmatic management of drug-resistant tuberculosis in India, 2019–20.

National TB Elimination Program (NTEP)[1-3] erstwhile known as Revised National TB Control Program (RNTCP) known to avoid further amplification of resistance and the integrated diagnostic algorithm **(Flowchart 1)** can be used for this. As mentioned previously, it is established that rapid molecular tests such as NAAT and LPAs provide early diagnosis of DR-TB and are helpful when used in tandem with phenotypic methods (solid and liquid cultures) as latter take longer for DST results.

The standard smear microscopy test has some inherent limitations as it is usually difficult to diagnose TB when the bacillary load in the sputum specimen is $<10^3$/mL.[8] The DST can be growth-based (phenotypic DST) on liquid culture (Bactec MGIT 960) or solid culture (Lowenstein-Jensen culture) or genotypic DST which employs rapid molecular tests for the diagnosis of DR-TB. Various molecular tests include NAAT (cartridge based NAAT or chip based TrueNat) and FL-LPAs (GenoType MTBDR*plus* V1, GenoType MTBDR*plus* V2) and Nipro (NTM *plus* MDRTB detection kit) and SL-LPAs (MTBDR*sl* V1 and MTBDR*sl* V2).[9] The NAAT test uses real time-polymerase chain reaction (RT-PCR) principle and the result is reported as *Mtb* detected/not detected with additional finding of *Mtb* rifampicin sensitive or resistant. Under programmatic conditions where the laboratory capacity is limited and facilities for FL-LPAs and SL-LPAs are not available, the report of NAAT as RR-TB is considered as a surrogate marker of MDR-TB and the patient is treated as MDR-TB as phenotypic tests with DST usually take from weeks to months. While the test report from FL-

LPAs provides additional information of *Mtb* sensitivity or resistance to H, SL-LPAs provide additional information on resistance to fluoroquinolones and SLIs.[9]

LPAs are a family of deoxyribonucleic acid (DNA) strip-based tests that determine the drug-resistance profile of an MTB[1] complex strain through the pattern of binding of amplicons (DNA amplification products) to probes targeting the most common resistance associated with the mutations to first- and second-line agents and to probes targeting the corresponding wild type (WT) DNA sequence.[9] LPAs are WHO-approved tests for rapidly detecting drug resistance to the first- and second-line agents. They can be used for testing of culture isolates (indirect testing) and direct testing of acid-fast bacilli (AFB) smear microscopy specimens (FL-LPA), and both smear positive and smear negative sputum specimens (SL-LPA). Mutations are detected by the binding of amplicons to probes targeting the most commonly occurring mutations (MUT probes) or inferred by the lack of hybridization (lack of binding) of the amplicons to the corresponding WT probes.[9] The post-hybridization reaction leads to the development of the colored bands on the test strip detecting probe binding. LPA results are reported as "Resistance not detected" instead of "Susceptible" to define the bacteria resistance profile.[9]

Given the limitations of LPA and in particular the fact that the resistance cannot be completely excluded even in the presence of all WT probes as not all mutations that confer resistance are covered by these tests or mutations that are covered may be below the limit of detection, it is more appropriate to report the result as "resistance detected" or "resistance not detected."[9] The term "resistance detected" is used whenever one or more MUT probes identifying specific mutations conferring resistance to the drugs are developed regardless of whether WT probes are developed or not.[9] The term "resistance inferred" is used whenever one or more WT probes in regions of the gene known to confer resistance to the drug are not developed and none of the MUT probes in the corresponding region is developed. In this case the precise mutation cannot be reported, only the region where the mutation lies is identified.[9]

FL-LPA showed sensitivity and specificity for the detection of rifampicin resistance 96.7% and 98.8%, respectively, and for the detection of H resistance, sensitivity and specificity 90.2% and 99.2%, respectively.[10] SL-LPA (GenoType MTBDR*sl* V1) showed pooled sensitivity and specificity for the detection of fluoroquinolone resistance by direct testing of 86.2% and 98.6% respectively, and a pooled sensitivity and specificity for the detection of second-line injectable drugs resistance of 87% and 99.5%, respectively.[9]

Treatment of DR-TB

Treatment of Isoniazid-resistant Tuberculosis (Hr-TB)

Substitution of H with levofloxacin (Lfx) is recommended for the treatment of Hr-TB. Drug regimen consisting of rifampicin, ethambutol, pyrazinamide, and levofloxacin (REZ-Lfx) is administered for 6 months without split of intensive and continuation phases.[2] Although, moxifloxacin (Mfx), arguably more potent than Lfx, has several limitations due to drug-drug interactions,[2] and QTc-prolonging ability when coadministered with drugs with similar properties. Further, Mfx peak plasma concentration and exposure declines when coadministered with rifampicin, however, unlike Lfx, does not require dose modifications in chronic kidney disease. Recent ATS/CDC/ERS/IDSA guidelines provide option of shortening the duration of pyrazinamide (Z) to 2 months in presence of non-cavitary and low-burden disease, intolerance, or toxicity to Z.[3]

Treatment can be extended to 9–12 months as per clinical, radiological, and microbiological responses, especially in extrapulmonary TB involving bone, central nervous system (CNS) and/or miliary TB. Use of injectable agents like streptomycin and others is not recommended in the guidelines.[1-3] In case of additional resistance, intolerance or toxicity to a drug, its substitution can be effected by, in order of preference with linezolid (Lzd), clofazimine (Cfz), or cycloserine (Cs).

Treatment of MDR/RR-TB

Two evidence-based guidelines on DR-TB treatment have been published in 2019. A propensity score-matched meta-analysis of an individual patient data meta-analysis (IPDMA) from 12,030 patients in 50 studies from 25 countries was used for making recommendations in these guidelines. Major differences between WHO Consolidated Guidelines, ATS/CDC/ERS/IDSA Guidelines, and current Indian Guidelines, 2019–20, are listed in **Table 1**. Current

BOX 3 Principles of drug-resistant TB management

- Drug susceptibility testing(DST)-guided treatment is recommended for DR-TB and universal DST should be available to all TB patients
- A bedaquiline based 5-drug regimen (3 drugs from Group A, two from Group B and if not possible from Group B then one or two drugs from Group C; refer Table 2) should be constructed for MDR/RR-TB
- A fully oral regimen is preferred and injectables like kanamycin and capreomycin are no longer recommended
- Long-term bedaquiline-based drug regimen should have at least 5 drugs for initial 6 months and afterwards 4 drugs should be continued for rest of the treatment duration
- The individualized, longer MDR-TB regimen is to be administered for the duration of 18–20 months, and the duration is primarily based on patient's response to treatment or 15–17 months after culture conversion
- In addition to smears, monthly follow-up cultures should be done from 1st month till the end of intensive phase. Decision on treatment extension should be based on culture reports at 4^{th}, 5^{th} and 6^{th} month
- If patient's culture is positive after 8 months from the specimen submitted at the end of 6^{th} month, treatment failure will be declared
- If drugs need to be discontinued due to intolerance or resistance on DST, then sequence of drug replacement should be according to the guidelines
- If fluoroquinolone (FQ) class resistance is detected on SL-LPA, replace Lfx with high dose moxifloxacin (Mfx^h)
- Fluoroquinolone should not to be used, if resistance to high dose moxifloxacin with LC-DST (MIC, 1.0 µg) is reported,
- In case of fluoroquinolone-resistant pre-extensively drug resistant (pre-XDR)-TB, a second line injectable drug (SLID) may be considered
- Duration of XDR-TB treatment should be longer than MDR/RR-TB
- Cascades of training are recommended for implementation and adoption of rapid changes in DR-TB management integrated with efficient mechanism of active drug-safety monitoring and management (aDSM).
- aDSM should focus on QTc monitoring (along with observation of serum K^+, $Mg^{2+}$and Ca^{2+} levels), myelosuppression, optic and peripheral neuropathy and lactic acidosis
- Ensure treatment adherence by different methods complemented with information and communication technology based adherence monitoring and reminder systems

Note: As per WHO consolidated guidelines on drug-resistant tuberculosis treatment, duration of standardized shorter MDR-TB regimen is 9-12 months which is one month more than the original standardised shorter MDR-TB regimen used in trial, given that some patients required slightly more than 11 months to complete a shorter regimen owing to brief interruptions.
LC-DST, liquid culture DST; Lfx, levofloxacin; MDR-TB, multi-drug resistant TB; Mfxh, high-dose moxifloxacin; MIC, minimum inhibitory concentration; SL-LPA, second-line-LPA
Source: WHO consolidated guidelines on tuberculosis. Module 4: treatment - drug-resistant tuberculosis treatment (2020).

Indian guidelines for MDR/RR-TB have been primarily adapted from WHO Consolidated Guidelines, 2020 **(Box 3)**.

A new feature of guidelines is regrouping of DR-TB drugs into A, B, and C categories and the ranking is based on the efficacy profiles of drugs **(Table 2)**.[1,2] Based on 6-month culture conversion results in the Delamanid (Dlm) Phase III trial, Dlm has been placed in group C.[11,12] Dosages of drugs for MDR/RR-TB treatment as per weight categories are detailed in **Table 3**.[1] Interim analysis of an Indian study on safety and efficacy of bedaquiline under conditional access program (CAP) for MDR-TB in India was recently published.[13] This feasibility study was conducted between June 2016 and August 2017 under programmatic conditions in the field settings at six sites of India. Of 620 MDR-TB patients, 57% patients had MDR-TB with additional drug resistance to fluoroquinolones (MDR_{FLQ}) and 5% with additional second-line injectable (MDR_{SLI}) and 16% had extensively drug-resistant TB (XDR-TB), 39% had severe malnutrition [body-mass index (BMI<16)]. After 6 months of treatment, the *Mtb* culture conversion was achieved in 83% of patients. The median time to culture conversion was 60 days, higher BMI was associated with faster culture conversion. Mortality was 12% and a majority of deaths (56%) occurred within the first 6 months of treatment. While Bdq was permanently discontinued in about 2%, its administration was temporarily interrupted in about 3% due to QTc interval prolongation and after correction of abnormalities of Mg^{2+}, Ca^{2+}, and K^+, it could be successfully reintroduced. Based on these results it was concluded that Bdq-based treatment for MDR/RR-TB is safe and can be scaled up with careful monitoring of QTc interval. According to WHO Guidelines, decisions to start the standardized shorter MDR-TB regimen should be made according to patient preference and clinical judgment **(Box 4)**. Since some geographical areas in India are still implementing standardized shorter MDR/RR-TB, a pan-oral, injection-free drug regimen is strongly recommended in the current National Guidelines of India.

TABLE 2 Grouping of anti-TB drugs for longer MDR regimen

Group and steps	*Drug*	*Standard abbreviations*
Group A Include all three drugs	• Levofloxacin *or* Moxifloxacin	Lfx/Mfx
	• Bedaquiline	Bdq
	• Linezolid	Lzd
Group B Add one or both drugs	• Clofazimine	Cfz
	• Cycloserine *or* Terizidone	Cs/Trd
Group C Add to complete the regimen and when drugs from Groups A and B can't be used because of drug intolerance, toxicity or some other contraindication	• Ethambutol	E
	• Delamanid	Dlm
	• Pyrazinamide	Z
	• Imipenem-cilastatin *or* Meropenem	Imp-Cln/Mpm
	• Amikacin (*or* Streptomycin)	Am (S)
	• Ethionamide *or* Prothionamide	Eto/Pto
	• *p*-aminosalicylic acid	PAS

- This table is intended to guide the design of individualized, longer MDR-TB regimens. Group C drugs are ranked by decreasing order of usual preference for use subject to other considerations. The 2018 Individual Patient Data-Meta-analysis (IPD-MA) for longer regimens included no patients on thioacetazone (T) and too few patients on gatifloxacin (Gfx) and high-dose isoniazid (H^h) for a meaningful analysis.
- Evidence on the safety and effectiveness of Bdq beyond 6 months and below the age of 6 years was insufficient for review.
- Evidence on the concurrent use of bedaquiline and delamanid was insufficient for review.
- Use of linezolid for at least 6 months was shown to increase efficacy, however, drug toxicity may limit use. The analysis suggested that using linezolid for the whole duration of treatment would optimise its effect (about 70% of patients on Lzd with data received it for >6 months and 30% for 18 months or the whole duration). From the IPD-sub-analysis no patient predictors for early cessation of Lzd could be identified.
- Evidence on the safety and efficacy of delamanid beyond 6 months, below the age of 3 years was insufficient for review.
- Pyrazinamide is to be used only if DST results confirm susceptibility.
- Every dose of Imp-Cln and meropenem is administered with clavulanic acid, which is only available in formulations combined with amoxicillin (Amx-Clv). Amx-Clv is not counted as an additional effective TB agent and should not be used without Imp-Cln or meropenem.
- Amikacin and streptomycin are only to be considered if DST results confirm susceptibility and high-quality audiometry monitoring for hearing loss can be ensured. Streptomycin is to be used only if amikacin cannot be used (unavailable or documented resistance) and if phenotypic DST results confirm susceptibility (streptomycin resistance is not detectable with second-line molecular line probe assays). Kanamycin and capreomycin are no longer recommended for use in MDR-TB regimens.
- These agents only showed effectiveness in regimens without bedaquiline, linezolid, clofazimine or delamanid, and therefore only proposed when other options to compose a regimen are not possible.

Source: WHO consolidated guidelines on tuberculosis. Module 4: treatment - drug-resistant tuberculosis treatment, 2020.

Current Indian guidelines recommend bedaquiline-based, preferably pan-oral 5-drug regimen as per DST in the Intensive Phase and 4-drugs in the Continuation Phase: 6–8 Bdq (6) Lfx, Lzd, Cfz, Cs/12 Lfx, Lzd[l], Cfz, Cs[14] **(Box 5)**. Similar regimens have been endorsed in the ATS/CDC/ERS/IDSA Guidelines **(Table 4)**. Bedaquiline should be stopped after 6 months and linezolid dose should be reduced to 300 mg once daily. Monthly sputum smear and cultures should be done. In case sputum culture positivity persists after 3 months then treatment failure should be strongly suspected and the DST should be repeated.

If SL-LPA detects FQ class resistance, then addition of two drugs is preferred in the previous regimen from class C drugs.[9] High dose Mfx (Mfx^h) is effective provided susceptibility is proven in LC-DST to Mfx^h (MIC,1.0µg)[15] [in many settings SL-LPA detects specific mutations such as A90V, S91P, D94A (*gyrA*) which contribute to low-level Mfx resistance]. In all MDR/RR-TB patients, SL-LPA is recommended which clarifies the additional FQ class resistance and second-line injectable drugs resistance. **Table 5** details the sequence of replacement drugs to modify the ongoing treatment in case of specific situations like drug toxicity or resistance.[1]

Management of extrapulmonary TB (EPTB) is similar to pulmonary MDR/RR-TB and patients are monitored for clinical, radiological, and microbiological outcomes

TABLE 3 Dosage of MDR/RR-TB drugs in adults

Drugs	*16–29 kg*	*30–45 kg*	*46–70 kg*	*>70 kg*
Rifampicin (R)*	300 mg	450 mg	600 mg	600 mg
High-dose H (H^h)	300 mg	600 mg	900 mg	900 mg
Ethambutol (E)	400 mg	800 mg	1200 mg	1600 mg
Pyrazinamide (Z)	750 mg	1250 mg	1750 mg	2000 mg
Levofloxacin (Lfx)	250 mg	750 mg	1000 mg	1000 mg
Moxifloxacin (Mfx)	200 mg	400 mg	400 mg	400 mg
High-dose Mfx (Mfx^h)	400 mg	600 mg	800 mg	800 mg
Bedaquiline (Bdq)	Week 0–2: Bdq 400 mg daily Week 3–24: Bdq 200 mg 3 times per week			
Linezolid (Lzd)	300 mg	600 mg	600 mg	600 mg
Clofazimine (Cfz)	50 mg	100 mg	100 mg	200 mg
Cycloserine (Cs)†	250 mg	500 mg	750 mg	1000 mg
Delamanid (Dlm)	50 mg twice daily (100 mg) for 24 weeks in 6–11 years of age 100 mg twice daily (200 mg) for 24 weeks for ≥12 years of age			
Imipenem/cilastatin (Imp/Cls)†	1000 mg imipenem/1000 mg cilastatin twice daily			
Meropenem (Mpm)†	1000 mg three times daily (alternative dosing is 2000 mg twice daily)			
Amikacin (Am)‡	500 mg	750 mg	750 mg	1000 mg
Capreomycin (Am)‡	500 mg	750 mg	750 mg	1000 mg
Kanamycin (Km)‡	500 mg	750 mg	750 mg	1000 mg
Ethionamide (Eto)	375 mg	500 mg	750 mg	1000 mg
Na-PAS (60% weight/vol)†‖	10 g	14 g	16 g	22 g
Amoxyclav (Amx-Clv) (In child: WHO 80 mg/kg in two divided doses)	875/125 mg BD	875/125 mg BD	875/12 mg (2 morning plus 1 evening)	875/125 mg BD (2 morning plus 1 evening)
Pyridoxine (Pdx)	50 mg	100 mg	100 mg	100 mg

*For H mono/poly resistant TB
†Drugs can be given in divided doses in a day in the event of intolerance
‡For adult more than 60 yrs of age, dose of SLI should be reduced to 10 mg/kg (max up to 750 mg)
‖In patient of PAS with 80% weight/volume the dose will be changed to 7.5 g (16–29 kg); 10 g (30–45 kg); 12 g (46–70 kg) and 16 g (>70 kg)
Source: Guidelines on programmatic management of drug-resistant tuberculosis in India, 2019–20.

BOX 4 Criteria to decide when the shorter MDR-TB regimen may be offered

A shorter all-oral Bdq-containing regimen (4–6) Bdq (6m) Lfx Cfz E H^h Eto/(5) Lfx Cfz Z E of 9–12 months duration is recommended in eligible patients with MDR/RR-TB in the following situations:

- Without resistance or suspected ineffectiveness of a medicine in the shorter regimen (except H resistance)*
- Without exposure to previous treatment with second-line medicines in the regimen for >1 month (unless DST confirms susceptibility to these medicines)†
- No pregnancy
- Age >6 years
- No extensive TB disease‡ and with no severe EPTB
- PLHIV

*H resistance determined by mutations in either *inhA* or *katG* genes (not both) or phenotypic DST. The presence of both mutations suggests that isoniazid at high dose and thioamides are not effective and therefore, in such patients, shorter regimen should not be used.
†Phenotypic DST for some medicines included in the regimen (ethambutol and ethionamide) is not considered reliable and reproducible.
‡Extensive TB disease: bilateral cavitary disease or extensive parenchymal damage on chest X-ray. In children under 15 years, advanced disease is usually defined by the presence of cavities or bilateral disease on chest X-ray.
Bdq, bedaquiline; Cfz, clofazimine; DST, drug susceptibility testing; E, ethambutol; EPTB, extrapulmonary TB H, isoniazid; H^h, high-dose isoniazid; Lfx, levofloxacin; MDR/RR-TB, multidrug-resistant/ Rifampicin resistant-tuberculosis; PLHIV= people living with HIV, Z, pyrazinamide
Source: WHO consolidated guidelines on tuberculosis. Module 4: treatment - drug-resistant tuberculosis treatment, 2020.

TABLE 4 ATS/CDC/ERS/IDSA criteria to build an individualized treatment regimen for MDR-TB

• Constitute a drug regimen consisting of five or more drugs to which the *Mtb* isolate is susceptible (or has low likelihood of resistance), preferably with drugs that have not been used to treat the patient previously • Choice of drugs is contingent on capacity to appropriately monitor for significant adverse effects, patient comorbidities, and preferences/values (choices therefore subject to program and patient safety limitations) • In children with TB disease who are contacts of infectious MDR-TB source cases, the source case's isolate DST result should be used if one is unable to obtain from the child • **TB expert medical consultation is recommended (ungraded good practice statement).**	
Step 1: Choose one of the later-generation fluoroquinolones	Lfx Mfx
Step 2: Choose both of these prioritized drugs	Bdq Lzd
Step 3: Choose both of these prioritized drugs	Cfz Cs/Trd
Step 4: If a regimen can't be assembled with five effective oral drugs, *and the isolate is susceptible*, use one of these injectable agents*	Am S
Step 5: If needed or if oral agents preferred over injectable agents in Step 4, use the following drugs‡	Dlm‡ Z E
Step 6: If limited options and cannot assemble a regimen of five effective drugs, consider use of the following drugs	Eto or Pto§ Imp–Cln or Mpm-Cln‖ PAS¶ H[h]**
The following drugs are no longer recommended for inclusion in MDR-TB regimens:	Cm and Km Amx/Clv (when used without a carbapenem) Azithromycin and clarithromycin

* Amikacin and streptomycin should be used only when the patient's isolate is susceptible to these drugs. Because of their toxicity, these drugs should be reserved for when more-effective or less-toxic therapies cannot be assembled to achieve a total of five effective drugs in the intensive phase.

† Patient preferences in terms of the harms and benefits associated with injectables (the use of which is no longer obligatory), the capacity to appropriately monitor for significant adverse effects, consideration of drug–drug interactions, and patient comorbidities should be considered in selecting Step 5 agents over injectables. Ethambutol and pyrazinamide had mixed/marginal performance on outcomes assessed in our PS-matched IPDMA; however, some experts may prefer these drugs over injectable agents to build a regimen of at least five effective oral drugs. Use pyrazinamide and ethambutol only when the isolate is documented as susceptible.

‡ Data on dosing and safety of delamanid are available in children ≥3 years of age.

§ Mutations in the *inh* A region of the *Mycobacterium tuberculosis* genome can confer resistance to ethionamide/prothionamide as well as to INH. In this situation, ethionamide/prothionamide may not be a good choice unless the isolate is shown to be susceptible with in vitro testing.

‖ Divided daily intravenous dosing limits feasibility. Optimal duration of use not defined.

¶ Fair/poor tolerability and low performance. Adverse effects reported to be less common in children.

** Data not reviewed in our PS-matched IPDMA (propensity score-matched individual patient data meta-analyses), but high-dose isoniazid can be considered despite low-level isoniazid resistance but not with high-level INH resistance.

Note: pepQ mutations were associated with low-level resistance to Bdq and cross-resistance to Cfz. These mutations reduced the efficacy of both drugs *in vivo* but did not lead to complete resistance to these drugs. The value of using loading doses and the optimal dosing for Cfz requires additional research.

Am, amikacin; Amx/Clv, amoxicillin -clavulanic acid; Bdq, bedaquiline; Cfz, clofazimine; Cln, cilastatin; Cm, capreomycin; Cs, cycloserine; Dlm, delamanid; DST, drug susceptibility testing; E, ethambutol; Hh , high-dose isoniazid; Imp, imipenem; INH, isoniazid; IPDMA, individual patient data meta-analyses; Km, kanamycin; Lfx, levofloxacin; Lzd, linezolid; MDR, multidrug-resistant, PS: propensity score; Mfx, moxifloxacin; PAS, p-aminosalicylic, acid; S, streptomycin; TB, tuberculosis; Trd, terizidone; Z, pyrazinamide

TABLE 5 Sequence of using replacement drugs to modify the regimen

Regimen	*Sequence of using replacement drug to modify the regimen*	
All oral H mono/poly	If SL LPA detects Lfx resistance; replace Lfx with Mfxh. LC DST should be used for detection of resistance to Mfx^h and Z If Mfx^h or Z can't be used; substitute with Lzd. If Lzd cannot be administered, replace with Cfz. If both Lzd and Cfz cannot be given, use Cs as replacement If both Mfx^h and Z can't be used; add two drugs of these Lzd, Cfz, Cs, in the order of preference Treat for 9 months in any of the above three situations; duration of the treatment can be extended to 12 months especially in CNS-TB, spinal, miliary, bone, and lymph node TB If R resistance; switch to appropriate regimen, i.e., MDR/RR-TB regimen	
Pan-oral Bdq-containing shorter MDR-TB regimen	If there is a need for stopping/replacing any drug, stop the regimen and switch to DST-guided all oral longer regimen	
Pan-oral Bdq-containing longer MDR-TB regimen	Replacement situations	Proposed composition of regimen after replacement
	Initial 6 months of treatment	
	Initiate treatment **If Lfx can't be used**, replace Lfx with Mfx^h if SL LPA pattern suggests **If Mfx^h can't be used**, replace it with Dlm **If Mfx^h & Dlm both can't be used**, add two drugs from replacement sequence†	**Lfx, Bdq, Lzd, Cfz, Cs** **Mfx^h*,** Bdq, Lzd, Cfz, Cs **Dlm*,** Bdq, Lzd, Cfz, Cs Bdq, Lzd, Cfz, Cs *plus* **two drugs** from replacement sequence†
	If Bdq can't be used, replace with Dlm If Dlm can't be used, replace with two drugs from replacement sequence†	Lfx, Dlm*, Lzd, Cfz, Cs Lfx, Lzd, Cfz, Cs *plus* two drugs from replacement sequence†
	If **one of Lzd, Cfz or Cs can't be used**, **no replacement** (if Bdq and Lfx/Mfx^h can be given) If **two or all three of Lzd, Cfz or Cs can't be used, replace with two or three drugs** respectively from replacement sequence† If **three out of five drugs from A & B group cannot be used, replaced with three drugs** from replacement sequence†	
	After 6 months of treatment	
	If **one of the drugs from Lfx, Lzd, Cfz, Cs can't be used**; no replacement is required If two drugs **from Lfx, Lzd, Cfz, Cs** cannot be used, replace with **two drugs** from Z*, Eto*, PAS, E in given order to complete the four drugs regimen	

*Use Dlm: if available, no history of prior use and no exclusion criteria for its use, Z: if resistance not detected, Eto: If inhA mutation not present, Am: if SL LPA pattern suggests. DST for Bdq, Dlm, Lzd, Cfz, and Z will be considered whenever it is available. DST for E and Eto is not reliable and reproducible

†Replacement sequence: Dlm, Am*, Z*, Eto*, PAS, E, Imp/Cln or Mpm *plus* Amx/Clv

Am, amikacin; Amx/Cln, amoxicillin-clavulanic acid; Bdq, bedaquiline; Cfz, clofazimine; Cln, cilastatin; Cm, capreomycin; Cs, cycloserine; Dlm, delamanid; DST, drug-susceptibility testing; E, ethambutol; H^h, high-dose isoniazid; Hr-TB, rifampicin sensitive but isoniazid resistant-TB; Imp, imipenem; Km, kanamycin; Lfx, levofloxacin; Lzd, linezolid; MDR/RR-TB, multidrug-resistant/Rifampicin resistant-tuberculosis; Mfx, moxifloxacin; Pa, pretomanid; PAS, p-aminosalicylic, acid; S, streptomycin; Z, pyrazinamide

Source: Guidelines on programmatic management of drug-resistant tuberculosis in India, 2019-20.

depending on EPTB site and the treatment duration is 18–20 months. Drug treatment preferably a regimen containing FQ, Bdq, Lzd, and Cs (injectables Am/S only if *Mtb* is susceptible); Cfz, Eto (provided *inh*A mutations are absent) may be used if required. Efavirenz may be replaced with nevirapine in patients with HIV/AIDS.[14,16] Treatment of MDR/RR-TB patients with pregnancy is done with a 4-drug regimen according to the DST and with drugs having a low-teratogenic potential. In children with seizures Mpm is preferred over Imp.

Nix-TB Trial: Bedaquiline, Pretomanid, and Linezolid (BPaL) Regimen for MDR-TB Treatment

Nix-TB is a clinical trial, conducted by TB alliance in three South African sites (April, 2015 to November, 2017) in which the 3-drug pan-oral BPaL regimen, consisting of

TABLE 6 Characteristics of drugs* used for DR-TB

Group	*Dosage*	*Adverse events*	*Special precautions*
Group A Include all three medicines (unless they cannot be used) Levofloxacin (Lfx) or Moxifloxacin (Mfx) Bedaquiline (Bdq)	500–1000 mg daily 400 mg daily 400 mg daily for initial 2 weeks and subsequently 200 mg thrice weekly for next 22 weeks (can be given longer)	In advanced CKD, class effect of fluoroquinolones may pose a higher risk of neuropsychiatric adverse events and tendinopathy; QTc prolongation on ECG more with Mfx than Lfx, a combination of Bdq, Cfz and Lfx (rather Mfx) preferred QTc prolongation, arthralgias, hepatitis, headache, anorexia, nausea	Dose adjustment required in CKD Cr cl 30–50 mL/min = 750–1000 mg daily <30 mL/min = 750–1000 mg thrice weekly No dose adjustment in CKD; predominantly hepatobiliary excretion; may increase hepatic enzymes; has good CNS penetration; avoid concomitant administration of antacids, phosphate binders, calcium, iron, or aluminum containing medications to avoid malabsorption; Administration with meal increases bio-availability; no dose adjustment with renal or liver disease; ECG should be done to monitor QTc prolongation at baseline, 2,12 and 24 weeks and stop the drug if QTc >500 ms, serum K^+, Mg^{2+} and Ca^{2+} monitoring required for QTc prolongation; QTc monitoring required when co-administered with clarithromycin, Cfz, Lfx/Mfx
Linezolid (Lzd)	600 mg once daily; the dose can be decreased to 300 mg after 3–6 months; linezolid should be discontinued in case toxicity occurs and can be re-introduced at a lower (300 mg daily) dose following recovery	Hematological toxicity, lactic acidosis, peripheral and optic neuropathy and serotonin syndrome. Drug toxicity is related to dose and duration of linezolid. Hematological toxicity and lactic acidosis occur early in few weeks to months while neurological toxicity occurs late after 3–4 months	Main route of excretion is hepatic with some renal clearance. No dose adjustment is required in CKD; careful monitoring of hematological toxicity, lactic acidosis, peripheral and optic neuropathy (often reversible) required. Pyridoxine 100 mg daily can be administered to prevent hematological toxicity. Avoid concomitant use of food items rich in tyramine and medications (SSRIs and other medicines) known to increase serotonin production to prevent development of serotonin syndrome
Group B Add both medicines (unless they cannot be used) Clofazimine (Cfz)	100 mg daily	Ichthyosis and dry skin, sun burn, pink-brownish-black discoloration of skin, cornea, retina and urine; acne flare	QTc monitoring on ECG is required when co-administered with Bdq, Lfx/Mfx and Cfz; serum potassium, magnesium and calcium monitoring required for QTc prolongation. Not to be used in pregnancy and severe hepatic insufficiency. Skin problems can be prevented by application of sunscreen and lubricants
Cycloserine (Cs) OR Terizidone (Trd)	10–15 mg/kg/day in divided dose or 250 mg morning 500 mg evening 300 mg morning 300 mg evening	Dizziness, slurred speech, convulsions, headache, tremor, insomnia, confusion, depression, and altered behavior, suicidal tendency, generalized hypersensitivity reaction or hepatitis	Cr cl ≥ 30 mL/min: no dose adjustment required; < 30 mL/min: 250 mg daily or 500 mg on alternate days; therapeutic drug monitoring is recommended if facility is available; avoid if possible in renal disease as the main route of excretion is renal. Cs (and Trd) should be avoided in patients with history of epilepsy, psychiatric illness or alcoholism, to prevent minor adverse reactions like insomnia administration of small dose of a tranquilizer is recommended or pyridoxine 50 mg/250 mg of administered cycloserine can be given to prevent neurotoxicity

Contd...

Contd...

Group	Dosage	Adverse events	Special precautions
Group C Add to complete the regimen and when medicines from Group A and B cannot be used Ethambutol (E)	15–25 mg/kg/day	Dose dependent optic (retrobulbar) neuropathy (> 30 mg/kg/day or 15-25 mg/kg in CKD); generally, reverses on prompt discontinuation; hyperuricemia Uncommon: interstitial nephritis, cholestatic jaundice, neutropenia and thrombocytopenia, reversible cutaneous hypersensitivity disappearing on desensitization	Cr cl ≥ 30 mL/min, no dose adjustment required; < 30 mL/min: 15–25 mg/kg thrice weekly. Patients should be monitored at baseline and regularly thereafter for visual acuity and red-green color discrimination
Delamanid (Dlm)	100 mg twice weekly for 6 months (can be administered longer)	QTc prolongation, nausea vomiting and abdominal pain, dizziness	QTc monitoring at baseline, 2, 12, and 24 weeks. Stop if > QTc 500 ms; monitor serum K^+, Mg^{2+} and Ca^{2+}
Pyrazinamide (Z)	25–30 mg/kg/day (1.5 g for 50 kg, 2 g for > 50 kg)	GI upset, hyperuricemia, arthralgia, hepatotoxicity (not dose related)	Cr cl ≥ 30 mL/min: no dose adjustment required; < 30 mL/min: 25–30 mg/kg three times/week
Imipenem - cilastatin (Imp-Cln) OR Meropenem Amoxycillin-Clavulanate (Mpm/Amx-Clv)	1g IV every 12 h 1g every 8–12 h IV administered with clavulanate (as amoxycillin clavulanate 250/125 mg every 8–12 h)	GI upset, transaminitis	Dose adjustment required in CKD Dose adjustment required in CKD
Amikacin (Am)	15 mg/kg-maximum 1 g; five to seven times weekly or 20–25 mg/kg 2–3 times/ week	Vestibular, auditory and renal toxicities	Baseline audiogram and renal functions. Dose adjustment required in CKD; *prefer to avoid if possible*. Periodic monitoring of audiogram and renal functions every 2-4 weeks
Ethionamide (Eto) Or Prothionamide (Pto)	15–20 mg/kg/day in divided doses. The usual dose is 250–1000 mg/day. Most patients should be started on 250 mg doses daily or twice daily and gradually increased over several days to 750 or 1000 mg total daily dose	Pto is generally considered to be less unpleasant and better tolerated than Eto. However, profile of adverse events is similar. GI disturbances, metallic taste and sulphurous belching; psychotic reactions, hypoglycemia (especially in diabetes mellitus patients); hepatitis; other rare side-effects include gynaecomastia, menstrual disturbance, impotence in males, acne, alopecia and peripheral neuropathy	Should not be administered in pregnancy (teratogenicity in animals). Careful monitoring is required if administered in patients with diabetes mellitus, liver disease, alcoholism or mental instability. No dose adjustment required in CKD. Serum TSH monitoring required periodically especially when co-administered with PAS
p-aminosalicyclic acid (PAS)	150 mg/kg or 10–12 g daily in 2–3 divided doses	GI disturbances (diarrhea is self-limiting), hypothyroidism (more chances if given along with ethionamide), hypokalemia, hepatitis, thrombocytopenia, aggravation of metabolic acidosis in patients with CKD	Although no dose adjustment required in CKD. However, caution should be exercised, since main route of excretion is renal. Periodic serum TSH monitoring required especially when co-administered with ethionamide

*All are bactericidal except Cs and PAS which are bacteriostatic; Cfz and Eto are weak bactericidal

Note: Creatinine clearance (CrCl) is best calculated with estimated glomerular filtration rate (eGFR) using CKD Epidemiology Collaboration (CKD-EPI) creatinine equation.

CKD, chronic kidney disease; CKD, chronic kidney disease; Cr Cl, creatinine clearance; ECG, electrocardiogram; GI, gastrointestinal; SSRIs, selective serotonin reuptake inhibitors; TB, tuberculosis; TSH, thyroid stimulating hormone

Source: Dheda K, Theron G, Calligaro G, Limberis J, Davids M, Esmail A et.al. Drug resistance tuberculosis. eds. Sharma and Mohan's Textbook of Tuberculosis and Nontuberculous Mycobacterial Diseases, 3rd ed. New Delhi. Jaypee Brothers Medical Publishers;2019. pp. 592-5.

TABLE 7 Important rug cotoxicity and drug-drug interactions in patients with HIV/DR-TB coinfection

Description	*Responsible ARV drugs*	*Responsible anti-TB drugs*	*Considerations*
Renal toxicity	TDF	Aminoglycosides, Cm	• TDF causes renal failure with hypophosphatemia and proteinuria • Avoid TDF in patients receiving aminoglycosides and Cm • Serum creatinine should be checked before switching patients onto TDF after completion of aminoglycoside • Caution is advised when administering TDF or aminoglycosides in patients with underlying co-morbidities, such as, diabetes mellitus or in patients who are receiving concomitant nephrotoxic agents such as NSAIDs and amphotericin B • If TDF is necessary, close monitoring of serum creatinine is required
Electrolyte abnormality	TDF	Aminoglycosides, Cm	• Exclude exacerbating factors, such vomiting, diarrhoea, dehydration, diuretics, etc.
Hepatitis/hepatotoxi-city	NVP, EFV, PI (especially RTV), NRTI	Z, Bdq, PAS, FQ	• When severe stop both ARVs and anti-TB agents, restart TB drugs first • Assess for other contributing factors such as alcohol abuse, viral aetiologies and other drugs like co-trimoxazole • Avoid concomitant use of NVP and Z • The risk of NVP hepatotoxicity is highest in the first 3 months of starting therapy with higher risk in patients with CD4+ >250/mm^3, the risk of NVP hepatotoxicity is lower if VL is suppressed
Myelosuppression	AZT	Lzd, H	• Stop Lzd if myelosuppression occurs. Blood transfusion is indicated if haemoglobin falls below 8 g/dL • Avoid co-administration of AZT and Lzd • Adverse events should be managed with a combination of temporary suspension of linezolid, dose reduction and/or symptom management • Reduction dose of 300 mg daily may be associated with fewer neuropathic effects but is not supported by pharmacokinetic data • Consider stopping cotrimoxazole
Peripheral neuropathy	ddI, d4T	Lzd, Cs, H, Eto, E	• Avoid use of D4T or ddI in combination with Cs or Lzd • Use pyridoxine as prophylaxis in patients receiving Cs, H and Lzd
QTc prolongation		Bdq, Mfx, Cfz Lfx, Ofx	Close monitoring of QTc is recommended when using these agents in combination

Contd...

Description	*Responsible ARV drugs*	*Responsible anti-TB drugs*	*Considerations*
Central nervous system toxicity	EFV	Cs, H, Eto/Pto, FQ	• EFV toxicity occurs in first 2–3 weeks of treatment • Concurrent use of EFV with CS needs close monitoring
Headache	AZT, EFV	Cs, Bdq	• Headaches may be self-limited in case of AZT, EFV and Cs • Advice analgesia and hydration
Nausea and vomiting	RTV, d4T, NVP	Eto, PAS, H, Bdq, E, Z	• Most drugs will cause some degree of nausea • If persistent consider drug-induced pancreatitis, hepatitis
Lactic acidosis	d4T, ddI, AZT, 3TC	Lzd	• High index of suspicion needed to detect hyperlactatemia to prevent overt symptoms of lactic acidosis
Pancreatitis	d4T, ddI	Lzd	• Avoid co-administration where possible • If pancreatitis occurs discontinue the ARVs completely
Diarrhea	PI, ddI	PAS, FQ, Eto	• For mild diarrhea anti-motility drugs can be used • May be self-limited. Exclude opportunistic infections
Optic neuritis	ddI	E, Lzd, Eto	• Stop all suspected agents causing optic neuritis • Screen patients using the Snellen chart and Ishihara chart
Hypothyroidism	d4T	Eto, PAS	Monitor serum TSH for patients receiving these agents
Joint pain	PI (Indinavir)	Z, Bdq	Mild symptoms can be managed with simple analgesics

ARV, anti-retroviral drugs; ARVs, anti-retroviral drugs; AZT, zidovudine; Bdq, bedaquiline; Cfz, clofazimine; Cm, capreomycin; Cs, cycloserine; d4T, stavudine; ddI, didanosine; DR-TB, drug-resistant tuberculosis; E, ethambutol; EFV, efavirenz; Eto, ethionamide; FQ, fluoroquinolones; Gfx, gatifloxacin; H, isoniazid; HIV, human immunodeficiency virus; Lfx, levofloxacin; Lzd, linezolid; Mfx, moxifloxacin; NRTI, nucleoside reverse transcriptase inhibitors; NSAIDs, nonsteroidal anti-inflammatory drugs; NVP, nevirapine; Ofx, ofloxacin; PAS, para-amino salicylic acid; PI, protease inhibitor; Pto, prothionamide; RTV, ritonavir; TB, tuberculosis; TDF, tenofovir disoproxil fumarate; TSH, thyroid stimulating hormone; VL, viral load; Z, pyrazinamide

Source: Dheda K, Theron G, Calligaro G, et al. Drug resistance tuberculosis. Sharma and Mohan's Textbook of Tuberculosis and Nontuberculous Mycobacterial Diseases, 3rd ed. New Delhi: Jaypee Brothers Medical Publishers; 2019. pp. 592-5.

BOX 5 Composition of pan-oral longer MDR-TB treatment regimen

- 6–8 Bdq (6) Lfx Lzd Cfz Cs / 12 Lfx Lzd^{l} Cfz Cs
- Resistance to FQ likely to be high among RR/MDR-TB
- May need to stop Lzd due to ADRs
- Mfx^{h} fear of high cardiac ADRs with Bdq, Cfz, Mfx^{h}

Selection of fluoroquinolones:

- In presence of FQ class resistance by LPA, in-country data (BDQ CAP, NITRD, NIRT) show in ~80% patients Mfx^{h} may be sensitive. No such data are available for Lfx
- Lfx has been used in India for~8 years, while Mfx^{h} has not been used: concerns about efficacy of Lfx vs. Mfx^{h}. Both Lfx and Mfx have similar efficacy
- Lfx More likely to cause nephrotoxicity compared to Mfx
- Very limited data (SALVAGE regimen, BDQ CAP): combination of Bdq, Cfz, Mfx^{h} may be tolerated
- Systematic review (2018) also shows low incidence of cardiac ADRs with BDQ + other drugs

ADRs, adverse drug reactions; Am, amikacin; Bdq, bedaquiline; CAP, conditional access program; Cfz, clofazimine; Cs, cycloserine; E, ethambutol; FQ, fluoroquinolones; Lfx, levofloxacin; Lzd, Linezolid; Lzd^{l}, low dose linezolid; Mfx^{h}, high dose moxifloxacin; NIRT, National Institute for Research in Tuberculosis, Chennai, India; NITRD, National Institute of Tuberculosis and Respiratory Disease, New Delhi, India

Source: Guidelines on programmatic management of drug-resistant tuberculosis in India, 2019-20.

bedaquiline, pretomanid, and linezolid was administered in 109 XDR-TB patients.[17] Patients received bedaquiline 400 mg once daily for 2 weeks followed by 200 mg three times a week for 24 weeks, plus pretomanid 200 mg daily for 26 weeks and linezolid 1,200 mg daily for up to 26 weeks. Nix-TB data have demonstrated a successful outcome in 95 (89%) of the first 107 patients after 6 months of treatment with BPaL drug regimen and 6 months of post-treatment follow-up. With the advantages of pan-oral shorter treatment duration and very low rates of adverse drug reactions, in future BPaL regimen can be adopted as a standard DR-TB regimen.

Active TB Drug-safety Monitoring and Management

Several drugs used for the treatment of MDR-TB have additive toxicities and may cause adverse events (AEs) and serious adverse events (SAEs).[18] Active TB Drug-Safety Monitoring and Management (aDSM) has been strongly recommended for better adherence and successful treatment outcome. **Table 6** details serious adverse reactions of the drugs and special precautions required while treating MDR/RR-TB patients.[19] During treatment of HIV DR-TB patients, clinicians should be careful and need to carefully monitor additive drug cotoxicities and drug-drug interactions **(Table 7)**. Linezolid is a very potent anti-TB drug and its irrational use because of its free availability over-the-counter for other bacterial infections such as staphylococcus should be avoided. Its use in MDR-TB patients for the entire duration of treatment is desirable but its adverse events must be monitored carefully and the dosage may be decreased from 600 to 300 mg after 6 months. Lactic acidosis and hematological toxicity occurs early while peripheral and optic neuropathy occur late **(Table 6)**. Optic neuropathy is usually reversible if recognized early. Serotonin syndrome is known to occur with linezolid[20,21] and can be fatal at times **(Table 6)** and a heightened awareness is required. Cutaneous hyperpigmentation with clofazamine is usually reversible after stopping the drug **(Table 6)**. Similar to current Indian MDR/RR-TB guidelines, the ATS/CDC/ERS/IDSA guidelines[3] have emphasized health education regarding adverse events and serious adverse events of drugs in MDR/RR-TB patients. Post-treatment, follow-up at 6th,12th,18th and 24th months of all successfully treated DR-TB cases under national-TB elimination programme (NTEP) is recommended.

Conflicts of Interest

Prof. SK Sharma is a member of the National Technical Expert Group (NTEG) on treatment of TB, (National Tuberculosis Elimination Programme erstwhile known as Revised National Tuberculosis Control Programme) Central TB Division, Ministry of Health & Family Welfare, Government of India.

Conclusion

All efforts should be made to have quality laboratory network with regular accreditation. Universal DST is strongly recommended to enable individualized pan-oral long-term MDR/RR-TB regimens to prevent further amplification of drug resistance. Smear and mycobacterial cultures should be done monthly during follow-up, aDSM should be rigorously followed to have good adherence for better treatment outcome. All these concerted efforts will go a long way toward achieving the goal of TB-free world.

CHAPTER

191 Tuberculosis with Diabetes: How to Tackle?

Shailendra Kumar

Abstract

Diabetes is one of the largest causes of non-communicable morbidity and mortality worldwide and in India. Tuberculosis is the leading infectious disease in India and some other Asian countries including china. Tuberculosis and diabetes are frequently encountered together. About 10% of TB cases are globally linked to diabetes. Diabetes affects the presentation and treatment outcomes of tuberculosis. On the other hand tuberculosis also affects the treatment of diabetes due to significant drug interaction and some other factors. So, theoretically, treatment of both diseases needs to be modified. In this context many studies have been published which indicates that TB-diabetes need special considerations in treatment. It will help in improving the treatment outcome and preventing the emergence of drug resistance cases.

Introduction and Epidemiology

Globally tuberculosis is the leading cause of death from an infectious disease and in India the incidence of tuberculosis in 2018 has been estimated to be 27 lakhs, about 16% increase from previous year.[1,2]

Recent estimation of diabetic population worldwide is about 463 millions.[3] The proportion of people with diabetes are increasing in many countries. India has an estimated 77 million people with diabetes, which makes it second most affected country after China. India alone contributes to about 17% of world diabetic population.

TB and Diabetes Comorbidity

About 10% of TB cases globally are linked to diabetes. The precise biological mechanism is still not very clear but it has been observed that diabetes accounts for 20% of smear-positive pulmonary TB. Recent analysis have indicated that increase in diabetes prevalence in India has been an important obstacle in reducing TB incidence.[4] More recent studies suggest that DM increases the risk of active TB up to three- to fourfold. In an Indian study the prevalence of DM among TB patients was 13.1% (known diabetic 9.1% and new diabetic 4%).[5] TB and diabetes when present together affects each other in various ways:

- Diabetics have weaker immune system so they are at higher risk of progressing latent TB to active TB.
- Diabetes can lengthen the time for sputum culture conversion and thus may be potential cause for development of MDR-TB.
- People with TB and diabetes have four times higher risk of death during treatment and higher risk of relapse. Higher reported rate of mortality in TB patients with diabetes may be caused by cardiovascular complications rather than by TB itself.[6]
- Diabetes is complicated by the presence of infectious diseases, including TB. It is important that proper care for diabetes should be provided to patient suffering from TB-diabetes comorbidity.
- TB is associated with worsening of glycemic control in diabetics; good glycemic control can improve the outcome. Furthermore diabetics may have many other

comorbidities like hypertension, dyslipidemia, and needs to take many pills, so chances of developing complications due to other comorbidities and unwanted drug interaction are more.

How Diabetes Affects Clinical Spectrum of Tuberculosis?

Clinical Presentation

Major biochemical manifestation of diabetes is hyperglycemia which favors growth, viability, and pathogenicity of the tubercle bacilli.[7] Increased production of glycerol, and nitrogenous substance further aids to the growth of tubercle bacilli.[8] Tuberculosis runs more aggressive course in a diabetic. In diabetic subject increased prevalence of pulmonary TB and relatively infrequent extrapulmonary form of TB have been noticed. In a series of studies 82.6% of diabetics with TB were found to be above 45 years with male preponderance.[9] In another Indian study it has been observed 55% of TB-DM group were underweight and age group was above 45 years.[10] In DM-TB group prolonged duration of illness and more significant weight loss has been observed than in non-diabetic subjects.[9,11] Low grade fever and productive cough were observed with almost equal frequencies in both groups.[12]

Diagnosis

Sputum microscopy and X-ray chest are two most important investigations used for the diagnosis of pulmonary tuberculosis in RNTCP. Apart from that we have CBNAAT for detection of RR, LPA, and culture sensitivity test for individual DST. Now RNTCP has a well designed program structure from national level to PHI level. RNTCP was launched in 1997 and achieved full nationwide coverage by March 2006. DMC is the most peripheral laboratory under RNTCP. There are 13,000 DMCs across the country.[13] HIV screening of all patients undergoing sputum examination has also been included. In 2010, an integrated National Program for Prevention and Control of Cancer, Diabetes, Cardiovascular Disease, and Stroke,(NPCDCS) has been launched.

Effect of Diabetes on Sputum Examination

Sputum positivity indicates the infectivity of pulmonary tuberculosis and culture conversion the effectiveness of treatment. In a study it has been found that diabetics are five times more prone to develop sputum positive pulmonary tuberculosis than non-diabetics.[14] These factors were analyzed in a recent Turkish study containing 737 pulmonary tuberculosis patients hospitalized during 2000 to 2005.[14] They concluded that those who are diabetic, radiologically having extensive and cavitatory lesions, take longer sputum and culture conversion time than the other group. Another larger study concluded that pulmonary tuberculosis patients with diabetes had a higher bacillary load before initiation of treatment and DM was found to be an independent risk factor for more AFB on sputum smear examination.[15]

Effect on Chest X-ray

Comparative studies of radiological findings in TB-diabetes with tuberculosis alone group have yielded contrasting results. In a study by Perenez-Guzman et al. in Mexico, 192 diabetic patients were compared with radiological findings of tuberculosis alone.[16] They found that the TB-DM patients were older and have a decreased frequency of upper (17% vs. 56%), and an increased frequency of lower (19% vs. 7%) and increased frequency (64% vs. 36%) both upper and lower lung field lesions. In TB-DM group cavitatory lesions were more (82.5% vs. 59%) than control and that were more often in lower lung field (29% vs. 3%). Cavities were more often multiple in the TB-DM patients (25% vs. 2%).

Treatment Outcome and Complications

At the end of intensive phase treatment a slightly lower sputum conversion rates were observed in diabetics as compared to non-diabetic group. Regarding treatment outcome some reports suggest adverse effects of diabetes on treatment outcome of TB patients with increased rate of failure, death, defaults, and relapses.[17] Mortality rates in these patients are reported to be several times higher than the non diabetic TB patients.[7] However, in contrary recent study concludes that as far as tuberculosis is concerned, the survival rate and socioeconomic rehabilitation of adequately treated patients with diabetes and pulmonary TB are the same as that of TB patients without diabetes.[15]

How to Tackle?

Screening for Diabetes

Ideally WHO and International Union against Tuberculosis and Lung Disease recommend that all adult TB patients

TABLE 1 Recommended thresholds and cut-off points for diabetes and pre-DM

Blood test	*Diabetes mellitus*	*Pre-diabetes*
2 hrs plasma glucose after oral glucose tolerance test (OGTT)	≥11.1 mmol/L ≥200 mg/dL	7.8–11.0 mmol/L 140–199 mg/dL
Fasting plasma glucose (FPG)	≥7.0 mmol/L ≥126 mg/dL	6.1–6.9 mmol/L 110–125 mg/dL
Glycosylated hemoglobin (HbA1c)	≥6.5% ≥48 mmol/mol	6.0–6.4% 42–47 mmol/mol

should be screened for diabetes. But in country like India where resources are tight it may be more cost effective to go for the targeted screening policy for high risk patients; above 40 years of age, those who are overweight or obese, those with family history of diabetes, those who consume excess alcohol, those with a previous history of gestational DM or previous pre-DM.

When to screen a tuberculosis patient for diabetes is very important aspect for the ease of programmatic management and to alleviate fallacies like stress related diabetes. It has been recommended that TB patients should be screened for diabetes at the time of diagnosis and registration. The fasting blood glucose and HbA1c are the two most suitable tools in programmatic setting and in those patients who have symptoms of diabetes—polyuria, polydipsia, and polyphagia. In asymptomatic persons fasting after glucose both should be done **(Table 1)**.

Treating a diabetic-tuberculosis has many challenges with treatment of tuberculosis as well as treatment of diabetes. Both diseases alter each other management in many ways. Medications used for their management affect each other in terms of—efficacy, drug interaction, adverse reactions. More over TB adversely affects control of diabetes too. Diabetics have often cardiovascular complications and risk factors which may be worsened by tuberculosis. So there are some considerations which must be taken into account while dealing with this complex duel problem:

- Inflammation related with TB can lead to temporarily elevated blood suger—"stress induced hyperglycemia," sometimes quite pronounced but usually improve during TB treatment.
- Our initial priority should be successful initiation of TB treatment and with optimizing blood glucose control.
- Referral of TB patients to specialized DM treatment centre is not recommended in the early phase of treatment because of the risk of transmission of tuberculosis.

Treatment of Tuberculosis

For treating diabetic tuberculosis patients, under RNTCP a National framework for joint TB-diabetes collaborative activities has been launched in 2017 in co-ordination with NPCDCS (National Program for Cancer, Diabetes, Cardiovascular Diseases and Stroke). Currently recommended anti-tuberculosis treatment is similar for patients with combined TB and diabetes compared to those with TB only. This strategy needs proper evaluation because DM is associated with ATT drug resistance,[18] slower treatment response, higher rate of toxicity, treatment failure, and recurrent TB. Points to be considered for ATT in diabetics:

- The length of ATT might have to be adjusted. This is common practice in some countries including China. In a retrospective cohort study in Taiwan, a 9-months treatment regimen was associated with a lower rate of recurrent TB than the 6 months regimen.[19]
- Higher dose of ATT may be needed, especially rifampicin due to interaction with sulphonyl urea derivatives. In an observational study in the USA it has been found that therapeutic drug monitoring for INH and rifampicin, after 2 weeks of treatment was associated with significantly shorter time of sputum culture conversion among patients with combined TB and DM.[20]
- TB-DM should be prioritized for DST at least for RR by CBNAAT. Nowadays CBNAAT is recommended as initial DST for all patients with high MDR/TB burden

TABLE 2 Important drug interactions in TB-DM patients

Medication	*Refampicin*	*Isoniazid*	*Aminoglycosides*
Metformin	No clinically relevant Interaction Drug of choice in TB-DM	No important interaction May worsen neupatic symptoms	My worsen renal toxicity
Sulfonylurea (Glyburide, Glipizide, Glimepiride)	Decreased ↓ Glyburide level (39%), Glipazide (22%), Glimepiride (30%)	↑ Sr Conc. of Glimepiride and my cause Hypoglycemia	No significant interaction
DPP IV inhibitor (Sitagliptin, Saxagliptin)	May ↓ blood level of gliptines	Not significant	No significant interaction
Thiazolidinedione (Pioglitazone)	↓ Pioglitazone level (54%)	No interaction	No significant interaction
Insulin	None	None	None

Source: Adopted from www.heartlandntbc.org

but on ground level this is not happening due to resource issues.

- Close monitoring of ATT is needed due to risk of side effects and drug interaction particularly if more toxic second line drugs used for MDR-TB.
- Close monitoring for renal, hepatic function, and neuropathic sign and symptoms because OHA and ATT may have combined toxicity or diabetes may have impaired renal function. INH may aggravate neuropathic symptoms.
- Drug compliance needs more close observation because of high pill burden **(Table 2)**.

Treatment of Diabetes

Treatment of diabetes itself is a vast subject but here while treating a diabetic patient with tuberculosis following points to be considered:

- It should be noted that TB-diabetes form a heterogeneous group consisting of previously diagnosed (known) diabetic and "New" diabetic. In the TANDEM cohort, around 74% of TB-DM patients have previously diagnosed DM (74%), while 26% were newly detected as a result of screening.[21] The relationship between tuberculosis and diabetes is bidirectional. TB is a known cause of pancreatitis and tuberculosis pancreatitis might reveal itself only after the development of diabetes.[22]
- Management of diabetes should be aggressive and optimal glycemic control results in a better patient outcome. If tuberculosis is not extensive or severe there may not be much difference for treatment of diabetes alone, i.e., it may be treated as per general guideline for the treatment of diabetes. Some important drug interaction should be kept in mind while adjusting the dose of OHA.
- Refampicin, through enzyme induction, accelerates the metabolism of sulphonylureas and biguanides, reducing their plasma level and thereby leading to hyperglycemia.[23] Isoniazid antagonizes the action of sulphonylureas and worsen glycemic control. Isoniazid also inhibits the release of insulin even among none diabetics and causes hyperglycemia.[24] Metformin is the drug of choice having no clinically relevant drug interaction. It has some anti-tuberculous activity also.[25] DPPIV inhibitors causes immune paresis and probably worsen treatment outcome of tuberculosis. Thiazolidinediones efficacy may be decreased by enzyme inducing effect of refampicin.
- Insulin is the preferred agent for type 2 DM treatment with TB.[24] The rational for the choice of insulin includes:
  - Severe TB infection
  - Body tissue loss
  - The need for increased anabolism
  - Pancreatic hypofunction
  - Interaction between OHA and ATT
  - Possibility of associated liver disease which would preclude the use of oral agent

  So, usually in case of severe TB-DM with profound systemic sign and symptoms patient is switched over to insulin. After few weeks of treatment tuberculosis get controlled then dose requirement of insulin falls, patient may again be switched over to OHA. Choice of insulin should be based on safety, effectiveness, cost, and patient characteristics.

- Cardiovascular risk assessment is very important in patients with TB-DM. The higher reported rate of mortality in TB patients with diabetes may be caused by these cardiovascular complications rather than TB itself. Cohort study in Taiwan has shown that patients with newly diagnosed pulmonary TB have a 40% increased risk of ACS and a 50% higher risk of ischemic stroke.[26,27]

Conclusion

Our country India has very large number of tuberculosis cases as well as diabetics. Clinical presentation as well as treatment outcome of tuberculosis is largely affected by other comorbidities. Diabetes is an important comorbidity which affects all aspects of tuberculosis management and vise-versa. TB-DM is a commonly encountered situation which needs special attention in RNTCP (NTEP) to improve the treatment outcome and prevent complications.

CHAPTER

192 Molecular Assays as Initial Tests for the Diagnosis of Tuberculosis

DP Singh, SK Ghosh, Krishna Kumar

Abstract

Tuberculosis remains a major public health problem in developing countries like India due to undue diagnostic delay in diagnosis, and hence treatment of TB. While diagnosis of TB has entered into an era of molecular detection of tubercle bacilli which is faster and rapid, we are still sticking to sputum microscopy as initial test for diagnosing TB, which has comparatively less sensitivity.[1] WHO has recommended molecular assays (Gene X-pert MTB/RIF, Gene X-pert Ultra, and TrueNat) as initial tests for diagnosis of TB and rifampicin resistance in a recent communication, which will bring a paradigm shift in to End TB program.[2]

Introduction

A tribute to Robert Koch is the discovery of tubercle bacilli as a causative organism of tuberculosis (TB) on 24th March, 1882, but the mystery of TB continues even today. TB attacks lungs in 80% of cases called pulmonary tuberculosis (PTB), but it can also affect any extrapulmonary organ named extrapulmonary TB. Global burden of TB is still quite high. In 2018, 10 million people contracted TB and 1.5 million died. There are more than 0.5 million new cases of multidrug resistant TB.[3] Globally, diagnosis of TB and drug-resistant TB remains a challenge, because a third of people with TB and two-thirds of people with drug-resistant TB are not being detected. Accelerated efforts to diagnose TB and drug-resistance are crucial to end the global TB epidemic. India which accounts for 1/5 of global burden of TB needs adequate policy reforms and a high-quality laboratory system which utilizes modern diagnostics for early and rapid diagnosis of TB and rifampicin (RIF) resistance.

Diagnosis of TB

Standards of TB care in India (STCI)[4] have laid down clear diagnostic criteria for different types of TB:

- *Pulmonary TB:* Any adult patient complaining of cough more than 2 weeks, fever more than 2 weeks, significant weight loss, and any abnormality in chest X-ray must be evaluated for TB.
- *Pediatric TB:* Children with persistent fever and/or cough more than 2 weeks, loss of weight/or no weight gain, and/or contact with pulmonary TB cases must be investigated for TB.
- *Extrapulmonary TB:* For all patients with presumptive EPTB, appropriate specimens from the presumed site of involvement must be obtained for microscopy/culture and drug sensitivity/molecular assay to pathological examinations.

WHO urges countries to expand access to rapid molecular tests for detection of TB. Molecular assay (CBNAAT) is already the preferred first diagnostic tool for childhood TB and TB-HIV coinfection. A systemic review of 23 studies has shown that TB is diagnosed in India after a delay of about 2 months.[5] Molecular assay as initial test will lead to early diagnosis. It will also promote reduction in transmission and faster life-saving treatment of this deadly communicable disease.

Paradigm Shift[3]

There has to be a paradigm shift in the approach to TB diagnosis by using newer molecular tests in place of conventional sputum microscopy, if we want to achieve the ambitious goal of ending TB early and accurate diagnosis of TB and RIF resistance is a prime step in this direction.

- *Sputum microscopy:* It has been a diagnostic tool for TB for over a century and still most conventional method for diagnosing TB in India. It takes less than an hour during the examination. At least 5–10 thousand tubercle bacilli per mL of sputum (limit of detection LOD) are needed to demonstrate bacilli in the sample.[6] But this methodology lacks sensitivity and so misses many TB cases.
- *Mycobacterium culture:* Culture of mycobacterium TB is the gold standard for diagnosis of TB. In contrast to sputum microscopy only 10–100 tubercle bacilli are needed for culture positivity. Conventional L J Media takes longer time (4–8 weeks), but liquid culture media like BACTEC or non-radiometric MGIT (mycobacterium Growth Indicator Tube) takes 2–3 weeks times. But this process is cumbersome and time consuming. Hence, there is a dire need of a diagnostic tool which can provide a rapid and confirmed diagnosis of TB. Molecular assay is most suitable to perform this role.
- *Molecular assays:*[1,7] Science is moving from biology to microbiology and from microbiology to molecular biology. Molecular assay have ushered to a new era of rapid and early diagnosis of not only TB, but also RIF resistance.

Probe-based Methods/DNA Chip- based Methods:

- Cartridge Based Nucleic Acid Amplification Test (CBNAAT): Gene X-pert, Gene X-pert Ultra, and TrueNat are endorsed by WHO
- Line Probe Assay (LPA)
- Loop-mediated isothermal amplification (LAMP)

Rapid Molecular Tests:[2,8-10]

- Nucleic Acid Amplification Test (NAAT) is a molecular system that detects pathogenic DNA (deoxyribonucleic Acid) of *Mycobacterium tuberculosis* (MTB).

  Molecular assays have several advantages in their arms:
  - NAAT amplifies mycobacterium specific DNA sequences using a nucleic acid probe
  - It increases the rate of detection
  - It requires only 16–131 bacilli to give positive results in a given sample
  - It lessens the time of detection
  - It is more accurate diagnosis with sensitivity at least 80% in most studies and specificity 98–99%

  Disadvantage: It has one disadvantage that it is not able to differentiate active infections from old ones as DNA from a dead organism can be detected and amplified by PCR.

  X-pert MTB/RIF (USA) is an automated PCR test, which detects MTB and RIF resistance within 2 hours of starting the test.[7]

  X-pert Ultra is the new version of X-pert MTB/RIF, which is much more sensitive than X-pert. Its sensitivity is comparable to liquid TB culture. Gene Ultra is an advanced version of Gene X-pert with better TB detection capabilities and more definitive identification of RS and RR bacilli. Gene Ultra can be used as an alternative to Gene X-pert for initial testing in pts with s/s of TB. It is also planned to phase out Gene X-pert to be replaced by Gene Ultra.
- Line Probe Assays (LPAs) are active molecular tools. LPA of TB was endorsed by WHO in 2008. Meta analyses have shown that LPAs are highly accurate for the detection of first-line drug resistance of isoniazid (INH), RIF, and other first line drugs in sample positive specimens. By using LPA it is possible to diagnose MDR early and rapidly within 2 days.

  INH and RIF drug resistant strains are identified by detecting the most common single nucleotide polymorphism associated with resistance.
- *Loop-mediated isothermal amplification (LAMP):* LAMP is an isothermal nucleic acid amplification technique. It was recommended by WHO in 2016 for diagnosis of TB as a replacement of smear microscopy. Characteristics of TB-LAMP have been compared to those of Gene X-pert and LPA **(Table 1)**.

Evidences of Molecular Assays as Initial Test for TB Diagnosis[2,11,12]

- *X-pert TB/RIF:* WHO in 2010 has approved X-pert MTB/RIF machine, which utilizes molecular technique for

TABLE 1 Characteristics of rapid molecular assays[7,12,13]

Test specification	*TB LAMP*	*X-Pert MTB/RIF*	*X-Pert MTB/RIF Ultra*	*LPA*
Technology	LAMP	R-T PCR	R-T PCR	Multiplex PCR
Detects	MTB	MTB + RIF resistance	MTB + RIF resistance	MTB + resistance to RIF and INH
Targets	IS6110	rpoB gene	rpoB gene	rpoB, katG, inh genes
Time of detection	<1 hour	2 hours	<90 min	5 hours

LAMP, loop mediated isothermal amplification; LPA, line probe assay; R-T PCR, real-time polymerase chain reaction.

TABLE 2 Overall sensitivity and specificity of all samples sputum positive (SP) and sputum negative (SN) in Gene X-pert

	Sensitivity (%)	*Specificity (%)*
Non-HIV group	85	98
HIV group	81	98

rapid diagnosis of TB and RR.70 studies involving more than thirty thousand patients from 37 countries have shown high diagnostic accuracy of gene X-pert in pulmonary TB **(Table 2)**.

If a patient is rifampicin resistant (RR), can Gene X-pert give false rifampicin sensitive (RS) results? Answer is yes and this paradox is caused by silent mutation.

Data from JLNMCH, Bhagalpur, confirm clear-cut superiority of cartridge based NAAT (CBNAAT) over sputum microscopy.[14] Conventional approach using LED microscopy SP was 10.3% while CBNAAT detected 22% positivity. An addition advantage was 19% positivity in SN samples.[11,14]

- *Molecular assays are pillars in diagnosis of EPTB:* Difficulties were always encountered in confirming the diagnosis of EPTB because of its paucibacillary nature and obtaining tissues from unreachable sites. By using X-pert MTB increased numbers of bacteriologically confirmed EPTB cases were found.

  X-pert MTB/RIF ultra: X-pert MTB/RIF-ultra is much more sensitive than X-pert MTB/RIF.[13] **Table 3** shows the limit of detection (LOD) of different diagnostic tests of TB.

  In samples where MTB detected was very low false RMP resistance was seen in Gene X-pert, not in Gene Ultra. Such sample must be subjected to Gold Standard test of TB diagnosis-culture DST. For HIV-positive patients sensitivity of Ultra was 90% versus 77%, i.e., 13% more.

TABLE 3 Limit of detection (LOD)

Diagnostic tests for TB	*Limit of detection (bacilli per mL of sample)*
Sputum microscopy	5,000–10,000
Mycobacterium culture	10–100
Gene X-pert	131
Gene Ultra	16
TrueNat	29

It is as sensitive as mycobacterial culture. In other words Ultra will result in greater TB case detection rate in subjects with paucibacillary TB such as smear negative-culture-positive TB, those with HIV coinfection, pediatric TB, and those with extrapulmonary TB.

High diagnostic accuracy of Gene X-pert Ultra in adults with PTB: 5 studies from 12 countries (including high-burden TB countries) overall sensitivity was found to be 90%, which includes all specimens smear-positive and smear-negative ones. Overall specificity was 96% in both types of specimens.

- *Pediatric TB:* There are difficulties in obtaining sputum specimens in children and due to this limitation various non-pulmonary specimens (gastric, nasopharyngeal, and stool) are used for bacteriological confirmation. Data from 21 countries involving more than 6,000 patients show.

In pediatric TB these are variable sensitivity in different specimens (nasopharyngeal—46%, stool—61%, sputum—65%, and gastric—73%) and Specificity 98–100%.

X-Pert MTB/RIF to Detect RIF Resistance in Pediatric TB

Using Gene X-pert when RIF resistance was tested with reference to phenotypic drug sensitivity testing it was found to have high overall sensitivity (90%) and specificity

TABLE 4 Sensitivity and specificity of extrapulmonary samples by Gene X-pert[15]

Samples	*Sensitivity (%)*	*Specificity (%)*
Lymph nodes	84.9	92.5
CSF	79.5	98.6
Pleural fluid	43.7	98.1
Gastric lavage	83.8	98.8

(98%). Data from six studies which involved 200 patients from four high-burden countries supported the above findings.

EPTB: Similar to pediatric TB difficulties are faced in obtaining extrapulmonary specimens and in aiding bacteriologically confirmed diagnosis in EPTB.

Gene X-Pert as Initial Test for EPTB

Data was assessed from 59 studies from 26 countries, which used MTB/RIF in adults with extrapulmonary TB.[11] Sensitivity and specificity of extrapulmonary TB varied with specimen types **(Table 4)**.

Another studies group using X-pert Ultra showed high performance of detection of RIF resistance sensitivity 96–97% and specificity 99%.[8]

TrueNat as Initial Test for Diagnosis of TB[2,16]

TrueNat TB test is a new molecular assay, which is in fact a real time PCR system. It is simple and user friendly. It is a point of care (POC) tool and battery operated. Therefore, it is suitable for diagnosis of TB and RIF resistance for poor countries like India where it can be used in rural primary health centers (PHC).

WHO Endorses TrueNat Test

In December 2019, WHO considered the latest evidence on the use of Molbio TrueNat MTB/RIF test. Multicentric study of TrueNat assays done in India, Peru, Ethiopia, and Papua-New-Guinea involving 744 patients examined the performance of TrueNat MTB, MTB plus, and MTB RIF Dx assays, which showed comparable efficacy to X-pert MTB/RIF and X-pert Ultra in TB diagnosis and RIF resistance. Overall sensitivity of the TrueNat MTB assay was 83% and that of MTB plus 89% while specificity for MTB and MTB Plus assay was 99% and 98%, respectively. The endorsement of TrueNat by WHO will help the low and middle income countries to use TrueNat in elimination of the disease (TB).

To evaluate the performance of TrueNat assay in comparison with Gene X-pert, 274 samples were processed. The overall sensitivity of TrueNat and Gene X-pert was 94.7% and 96%, respectively.

Conclusion[3]

- There are robust data to support that molecular assays (X-pert MTB/RIF and X-pert Ultra) should be used as initial tests for diagnosis of pulmonary TB in adults.
- A large number of studies support the use of X-pert MTB/RIF and X-pert Ultra as initial diagnostic work-up of extrapulmonary TB.
- These molecular assays show clear superiority over conventional sputum microscopy in the diagnosis of pediatric TB.
- Both molecular assays X-pert and X-pert Ultra show high accuracy in the simultaneous detection of RIF resistance.
- Low cost and Indian molecular assay TrueNat MTB, MTB plus, and MTB-RIF Dx show comparable accuracy with both Gene X-pert and Gene X-pert Ultra in diagnosis of TB and RIF resistance.

CHAPTER

193 Association of Tuberculosis and COPD

SM Mishra

Abstract

COPD and Tuberculosis are common respiratory diseases in our country. Past history of Tuberculosis is considered an important risk factor for COPD. Chronic airflow obstruction in tuberculosis patients occurs due to tuberculosis-associated lung damage leading to COPD. A number of factors associated with COPD may increase the progression of Tuberculosis in these patients, most important factors are- use of inhaled/oral corticosteroids in the treatment of COPD and smoke related exposure related altered protective response to *M. tuberculosis*. There is bidirectional relationship between tuberculosis and COPD. Early diagnosis and standardized treatment of Tuberculosis and COPD is essential. Action to increase awareness regarding COPD is essential.

Introdution

Tuberculosis and chronic obstructive pulmonary disease (COPD) are major causes of morbidity and mortality worldwide. As per recent reports the prevalence of COPD is increasing worldwide. Past history of tuberculosis is an important risk factor of COPD. It is well known that COPD patients have an increased risk of developing tuberculosis. Thus, there is bidirectional relationship between COPD and tuberculosis. It is alarming for our country since both these diseases are prevalent in our country. These diseases have adverse impact on each other as far morbidity and mortality is concerned. We are committed to eliminate TB, if we have to fulfill our commitment, timely intervention and action for early diagnosis and institution of appropriate treatment of tuberculosis is essential. In addition to adequate steps for diagnosis and treatment of tuberculosis, common risk factors for tuberculosis and COPD must be addressed properly to prevent development of both these diseases in future, otherwise we cannot achieve the target of TB elimination.

COPD and pulmonary tuberculosis are two very important disease of respiratory system, worldwide. These diseases primarily affects lung, COPD is a non-communicable disease, and pulmonary tuberculosis is an infective disease caused by Mycobacterium tuberculosis. As per a number of studies conducted worldwide, there is bidirectional relationship between two diseases and effects each other adversely.

Due to recent advancement in medical field incidence of infective diseases are showing decreasing trend. Due to economic development epidemiological transition is going on globally, the incidence of infective diseases are decreasing, but there is increase in the incidence of non-communicable diseases like COPD. But due to rapid urbanization, overcrowding, lack of awareness, weak health-care system in our part of world (low and middle income countries), there is double burden of infective diseases like tuberculosis and non-communicable diseases like COPD.[1]

We are committed to eliminate tuberculosis, from India by 2025, 5 years ahead of global target, if we have to achieve the target we must take steps to control both COPD and tuberculosis simultaneously. Early diagnosis and proper and standardized treatment of tuberculosis

is mandatory to reduce the future burden of COPD and tuberculosis both. Similarly, steps must be taken to reduce air pollution and other common risk factors, which may help in prevention of these diseases. Fortunately a number of programs are going on in our country, so we can expect favorable results in near future.

Current Global Burden of Tuberculosis

As per global TB report (2019), this is one of the top 10 causes of death worldwide and the leading cause of death from a single infectious agent. About a quarter of the world's population is infected with *Mycobacterium tuberculosis* and thus at risk of developing TB disease.[2] Globally, an estimated 10 million people fell ill with TB in 2018, and there were about 1.5 million death due to this disease. With timely diagnosis and treatment, most people who develop TB can be cured and transmission of infection reduced in the society, thus decreasing mortality and morbidity.

Current Global Burden of COPD

COPD is a major public health problem worldwide, due to its high prevalence, morbidity and mortality.[3,4] Mortality due to COPD is showing an increasing trend. At present it is the third leading cause of death globally.[5] Chronic obstructive disease is a progressive disease, treatment can relieve symptoms and thus, improve quality of life and reduce the risk of death.[6] Air pollution and smoking both active and passive is very important risk factor. Use of conventional fuel is prevalent in our country, this is also an important risk factor. By risk reduction measures we can reduce the burden and socioeconomic consequences. Fortunately, a number of initiatives have been taken in our country, this may have a positive impact and reduce the burden of COPD in our country.

Tuberculosis and COPD Different Aspects of Association

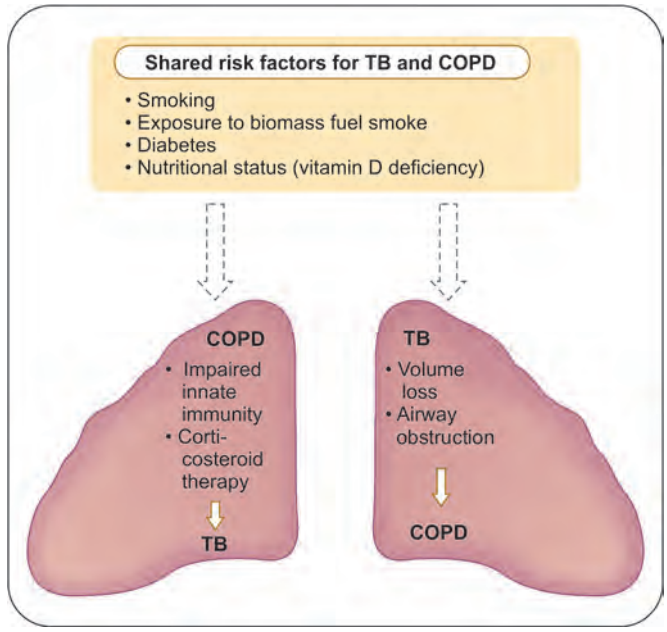
COPD and Tuberculosis Shared Risk Factors

There are some common risk factors for COPD and Tuberculosis, that is, they share some of the risk factors and these are shown in **Figure 1**.

Tuberculosis as the Risk Factor for COPD

Past history of tuberculosis is well recognized as risk factor for development of COPD, particularly in developing countries.[7,8] This relationship of TB and COPD is dangerous for our country since the prevalence of both diseases are high in our country. The pathological process due to tuberculosis leads structural changes in the lungs. These structural damage of the lungs increases with increasing number of episodes and they persists despite anti-tubercular chemotherapy.

Fig. 1: Common risk factors for COPD and tuberculosis



The structural damage leads to air flow obstruction and impairment of lung function. Impairment in airflow can occur during active phase of tuberculosis or may be detected after the treatment. Patients usually develop maximum loss of lung function within 6 months of diagnosis of tuberculosis and generally stabilize about 18 months after the completion of treatment.[9,10] Antitubercular treatment leads to improvement in lung function, but the residual lung function impairment depends on both pre- and post-treatment radiological extent of disease. Delay in initiation of treatment lead to more extensive disease and more structural damage leading to more impairment of lung function.

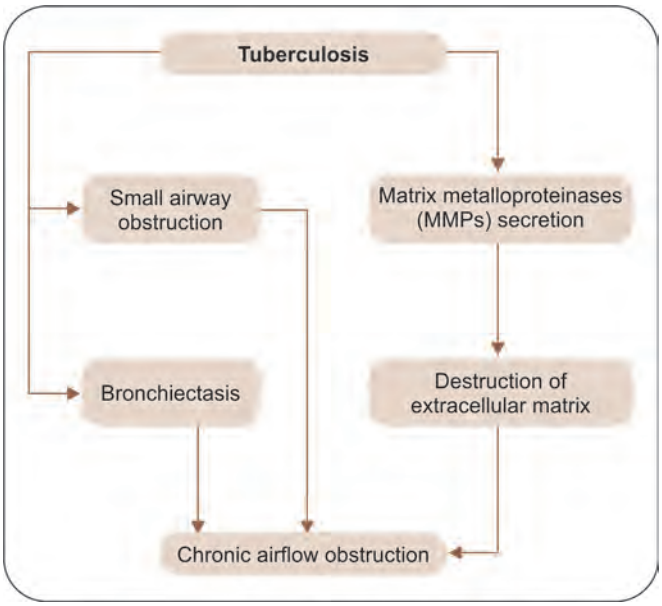
Mechanism of Airflow Obstruction Due to Tuberculosis

The sequence of pathological process leading to chronic airflow obstruction in post-tuberculosis patient is not clear, following mechanisms have been proposed:

- *Role of macrophages:* Macrophages are one of the key cells concerned in the pathological process of tuberculosis, these cells play an important role in wound healing and resolution, they may cause remodeling of airways, leading to chronic airflow obstruction.
- *Small airway involvement:* The pathological process undergoing in lungs in tuberculosis may involve the small airways leading to airflow obstruction. The observation of Allwood et al. during their study supports this concept, they observed that patients with chronic airflow obstruction with definite previous TB had higher gas trapping, fibrosis, and emphysema score than subjects with no previous tuberculosis. The diffusion capacity was also significantly lower in patients with definite previous TB.[11]
- *Bronchiectasis:* Post-tuberculosis bronchiectasis is very common finding and probably most common cause of Bronchiectasis in our country. Endobronchial obstruction or peribronchial fibrosis or obstruction by enlarged lymph nodes found in tuberculosis, may lead to bronchiectasis and chronic airflow obstruction.[12]
- *Accelerated parenchymal destruction:* Lung parenchymal inflammation occurs in tuberculosis, this leads to destruction of pulmonary extra-cellular matrix (ECM). As described earlier remodeling occurs in the lung due to ongoing pathological and healing process, Matrix metalloproteinases (MMP) are considered to mediate tissue remodeling in tuberculosis. MMPs are a family of calcium dependent zinc containing endopeptidases. There are different kinds of MMPs. Different MMPs plays different role in Mycobacterial infection. MMP-9 is concerned in the formation of stable granuloma, thus containing the infection. Reactivation of latent TB leads to MMP-1 secretion, which causes alveolar destruction and is responsible for cavitation in tuberculosis.[13] Type II pneumocyte makes MMP-1.[14] MMPs lead to degradation of ECM and thus involved in the pathogenesis of both tuberculosis and COPD, the scaffold of alveolar wall.

The pathological process in tuberculosis leading to chronic airflow obstruction maybe summarized in the **Flowchart 1**.

Flowchart 1: Pathological process leading to chronic airflow obstruction in post-TB patients



Impact of COPD on Tuberculosis

It is well known that patients suffering COPD have increased risk of developing tuberculosis. Lee et al. in his study observed that COPD is an independent risk factor for tuberculosis.[15]

Exact mechanism or the factors which leads to increased risk is not well known, inhaled and oral corticosteroids are used for the treatment of COPD. Corticosteroids are known to produce immune-suppression; this may increase the risk of tuberculosis.[16]

Use of corticosteroids is not the only factor responsible for immune impairment in COPD and tuberculosis, but other factors also involved in immune impairment in these cases are:

- *Cigarette smoke exposure:* According to study conducted by patients Shang et al., the cigarette smoke exposure alters the protective response to *M. tuberculosis*.[17]
- *High levels of cytokines:* High levels of some of cytokines like sIL-2R, IL-6, TNF-alpha, IFN-y are found in COPD patients. These cytokines by producing an exuberant inflammatory response may cause progression of tuberculosis in COPD patients.[18]
- *Dysfunction of alveolar macrophages:* In patients suffering from COPD, dysfunction of alveolar macrophages develops, which is considered independent of steroids, this leads to an additional risk of developing tuberculosis.[19,20]

Conclusion

COPD and tuberculosis are most common respiratory problem in our country. As per different studies conducted, past history of tuberculosis is considered an important risk factor for COPD. Chronic airflow obstruction in tuberculosis patients occurs due to tuberculosis associated lung damage leading to COPD. A number of factors related to COPD may increase the risk of progression of tuberculosis in these patients—use of inhaled and oral corticosteroids in the treatment of COPD, may increases the risk of progression of tuberculosis by causing immune suppression. Other factors are—smoke exposure related altered protective response to *M. tuberculosis*, high levels of some of the cytokines and dysfunction of alveolar macrophages observed in COPD patients, which is independent of steroids. Thus, above mentioned facts indicates that there is bidirectional relationship between two diseases.

Early diagnosis and timely initiation of standardized and complete of treatment of tuberculosis and COPD is essential. Government of India under 'National Tuberculosis Elimination' has increased facility for early diagnosis and proper treatment of tuberculosis, definitely this will have a positive impact. Diagnosis of COPD is based on clinical suspicion, confirmed by respiratory function tests , it is essential to increase general awareness regarding this disease and improvement in facility for diagnosis of COPD. Action to reduce shared risk factors for COPD and tuberculosis is the prerequisite to reduce the burden of both tuberculosis and COPD in our country. These steps may improve the quality of life, morbidity, and mortality due to these diseases.

CHAPTER

194 Exudative Pleural Effusion—Diagnostic Approach

Sanjay Kumar

Abstract

The exudative pleural effusion caused either by infections like tuberculosis or due to other diseases like cancer, is associated with a lot of complications and even mortality. The proper history and pleural fluid examination is the first step in differential diagnosis of exudative pleural effusion, but sometimes other investigation techniques like imaging, closed pleural biopsies, and pleuroscopy or video associated thoracoscopy are needed to clinch the diagnosis and proper management.

Introduction

Pleural effusion is a common condition in day to day practice. It develops when more fluid enters the pleural fluid than is removed. The first step in the evaluation of pleural effusion is to determine whether it is exudate or transudate. In cases of exudative effusion the stepwise approach to find out the etiology is needed. Thoracentesis and pleural fluid examination are useful in differential diagnosis of such cases. Other tests like CT scan, Pleuroscopy, etc. may help in reaching an etiological diagnosis.

Pleural effusion may be caused by variety of diseases. Traditionally to simplify the diagnostic approach the pleural effusion is first dichotomized as transudative or exudative. Exudative effusion usually develops due to inflammatory or malignant disorders. The basic pathophysiological mechanism of exudative pleural effusion is increased capillary permeability, which leads to accumulation of large molecular weight compounds in the pleural space.

There are numerous causes of exudative pleural effusion. The most common cause of this in areas where tuberculosis is endemic is secondary to pleural TB.[1] The other common causes are pneumonic, malignancy (primary or secondary) and pulmonary embolus with infarction. The less common causes are—rheumatoid arthritis, other connective tissue diseases, pancreatitis, esophageal rupture, post coronary artery bypass surgery, etc.

Initial Evaluation

The careful history, including the occupational history & history of past illness, symptoms, and signs on physical examination are the first vital measure in guiding the evaluation of pleural effusion.

Pleuritic chest pain, cough, and dyspnea are three basic symptoms of exudative pleural effusion besides other symptoms like fever may be present. Pleuritic chest pain is due to inflammation of parietal pleurae and it likely indicates some infectious cause, while dull aching chest pain is very much suggestive of pleural malignancy. Non-productive cough is also a common symptom. Although the exact mechanism of cough is not clear, but pleural inflammation is again implicated as possible cause.

The third symptom dyspnea is basically due to space occupying process in the thoracic cavity and reappearance

of fluid quickly after therapeutic thoracentesis is most likely due to malignant involvement of pleura.

Thoracentesis and Examination of Pleural Fluid

After the initial evaluation, the next step is diagnostic thoracentesis and examination of pleural fluid. It not only settles the issue of transudative versus exudative effusion, but also diagnoses the cause of exudative effusion in most cases.

The usual tests that should be performed on fluid obtained during diagnostic thoracentesis are—cell counts and differentials, glucose, adenosine deaminase (ADA) estimation, and cytologic analysis. The pH measurement and bacterial cultures should be done when acute infection is suspected. The routine pleural fluid tests are summarized in **Table 1**.

For proper total white blood cell count and differential cell count, it is necessary to send the pleural fluid in anti-coagulated tube. Otherwise the fluid is likely to clot leading to an inaccurate count.[3]

The main WBC cell type is determined by the mechanism of pleural injury and the time interval between the onset of pleural pathology and thoracentesis. So, the neutrophil-rich fluid is highly suggestive of an acute process like parapneumonic effusion, while lymphocyte predominant fluid profile is indicative of chronic process like tuberculosis or malignancy.

A low pH value of fluid has important therapeutic and prognostic implications with parapneumonic and malignant pleural effusion. Low pH value less than 7.20 in patients with parapneumonic effusion is indicative of drainage of the fluid.[4]

In the unavailability of pH value determination, a pleural fluid glucose concentration of less than 60 mg% helps in detecting complicated parapneumonic effusion.[4]

The enzyme ADA plays a very important role in lymphoid cell differentiation. Pleural fluid ADA level greater than 40 U/L is highly sensitive and specific marker for the diagnosis of tuberculous pleural effusion. The sensitivity varies between 90% and 100%, while specificity is as high as 85% and 95%.[5]

Pleural fluid culture for both aerobic and anaerobic bacteria may identify the culprit microorganism in almost 40% of parapneumonic effusion.[2]

Pleural fluid smears for mycobacterium are positive very rarely found in about 5% of cases[2] and about one third of patients with tuberculous pleural effusion have negative tuberculin skin test.[6]

Pleural fluid cytology is very important to diagnose malignant pleural effusion. Cytology positivity is almost 60% in malignant pleural effusion.[7]

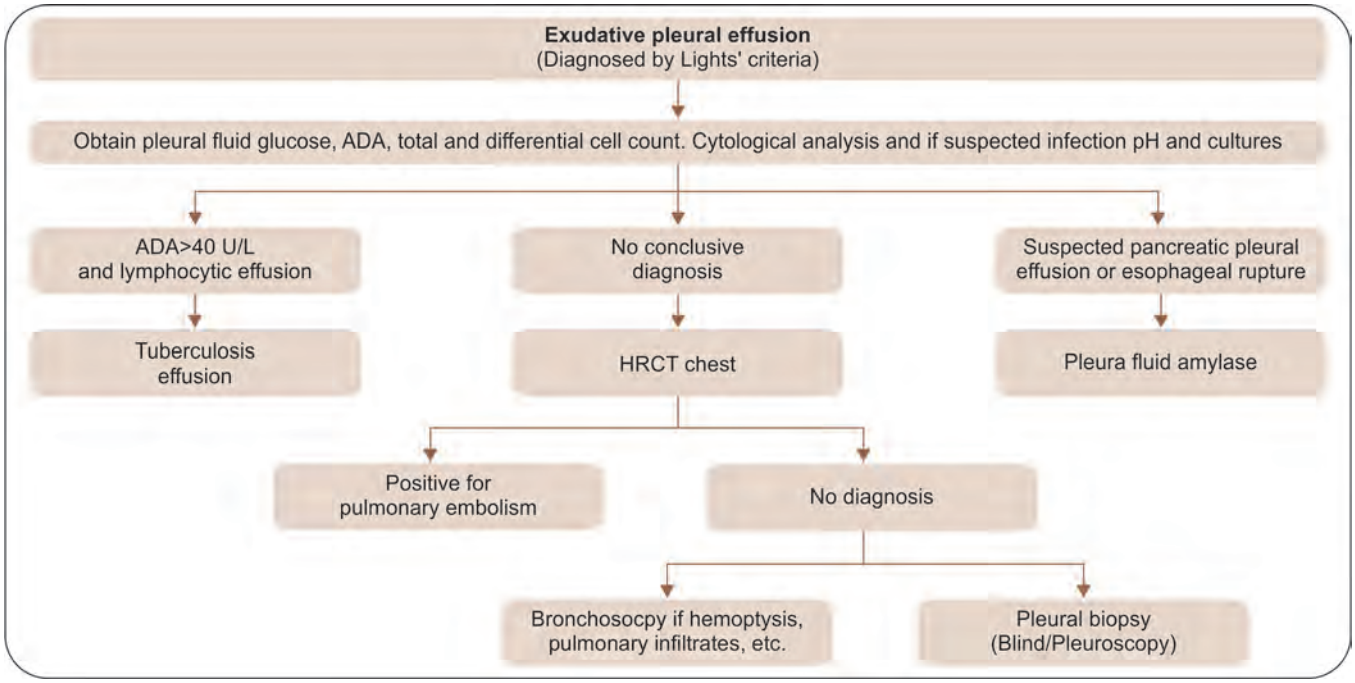
The test result negativity are related to different factors such as type of tumor (usually negative in mesothelioma, sarcoma, and lymphoma), the tumor burden in pleural space and the expertise of the person performing the job. An amount of 10 mL of pleural fluid is adequate for cytologic processing. Additional pleural taps increase the diagnostic yield further.

A second thoracentesis may be considered in suspected malignant effusion and the initial pleural fluid cytology examination is negative for malignancy.

TABLE 1 Routine pleural fluid tests for pleural effusion

Test	*Test value*	*Suggested diagnosis*
ADA	>40 U/L	Tuberculosis (>90%), Empyema (60%) complicated parapneumonic effusion (30%), malignancy (5%), Rheumatoid arthritis[2]
Cytology	Atypical cells/Malignant cells	Malignancy (primary or secondary)
Glucose	<60 mg/dL	Acute infection like parapneumonic effusion, tuberculosis, malignancy, rheumatoid arthritis[2]
RBC count	$>100\times10^6$/L	Malignancy, trauma, parapneumonic effusion, pulmonary embolism
WBC count & differential	10×10^9/L	Infection, empyema, etc.
Lymphocytes	>50%	Tuberculosis-most likely, malignancy, and post-CABG
Neutrophils	>50%	Parapneumonic effusion, pulmonary embolism, abdominal diseases

Flowchart 1: Exudative pleural effusion



Other Diagnostic Modalities

There are occasions when we need to further investigate the case in order to get a cause of exudative pleural effusion. The further work up includes:

- *Imaging techniques:* High resolution helical CT scan is the investigation that is used as first line modality for delineating pulmonary circulation in patients suspected to have pulmonary embolism. CT can distinguish malignant from benign pleural disease also as it detects nicely pleural nodules or nodular pleural thickening. The detection and differentiation of benign and malignant pleural disease is further enhanced using positron emission tomography scan.[8]
- *Bronchoscopy:* Endobronchial malignancy may lead to exudative pleural effusion also. Whenever this is suspected in chest radiography or CT scan images, or patient has symptoms of hemoptysis or there is massive pleural effusion or shift of mediastinum to the side of pleural effusion, bronchoscopy is useful.
- *Closed pleural biopsy:* In cases of undiagnosed exudative pleural effusion, percutaneous closed pleural biopsy (CPB) is recommended. Image guided biopsy is superior to blind closed biopsy. The sensitivity of image guided biopsy is much higher than closed biopsy. Histological examination associated with culture of pleural biopsy tissue confirms the diagnosis of tuberculosis in 90% of patients.[5]
- *Pleuroscopy:* Pleuroscopy, usually referred to as medical thoracoscopy, is gradually gaining importance and now recognized as procedure of choice both for diagnosing and treating exudative pleural effusion, which eludes diagnosis after thoracentesis. It is diagnostic in more than 90% of patients with pleural malignancy where cytology is negative.[9] Pleuroscopy offers the additional benefit of effective pleurodesis during the procedure.

Conclusion

The careful stepwise approaches starting from proper history taking, evaluation of symptoms & signs, and diagnostic tests help in finding out the exact cause of exudative pleural effusion in majority of cases. Despite the best of efforts, approximately 15% of patients of pleural effusion remain undiagnosed.[10]

The suggested algorithm for the investigation of exudative pleural effusion is shown in **Flowchart 1**.

CHAPTER

195 Tubercular Lymphadenitis—Challenges in Treatment

Deependra Kumar Rai

Abstract

Tubercular lymphadenitis is most common form of extrapulmonary tuberculosis. The most common Lymph node involved is cervical followed by Supraclavicular, Axillary, submandibular and, Inguinal region. Majority of patient presented as isolated chronic nontender lymphadenopathy. The regimen and duration of tuberculosis is same as pulmonary tuberculosis. Treatment is complicated by paradoxical reaction in almost 1/5th of patients, which does not require change in treatment and most of the patient subside by its own.

Introduction

We are living in the second-most populous country after China in the world and one-fourth of the global incident tuberculosis (TB) cases occur in India annually as per the WHO Global TB Report.[1] Extrapulmonary TB (EPTB) is defined as occurrence of TB other than lung is more common in immunocompromised individual with HIV infection. Lymph node TB was found as most common EPTB (37.14%) found in 517 EPTB cases.[2] Cervical lymphadenitis is also known as scrofula.[3] Tubercular lymphadenitis also caused mainly mycobacterium TB, rarely by nontuberculous mycobacteria (NTM), especially in children or patient who immunocompromised.

Pathogenesis

Tubercular lymphadenitis is considered as local manifestation of systemic disease while lymphadenopathy due to NTM is purely a localized disease. Tubercular bacilli generally enter the body via respiratory tract and undergo hematogenous and lymphatic dissemination. Hilar and mediastinal lymph node are first lymphoid organ involved when spread from lung parenchyma occur. This can occur during primary infection or may occur due reactivation of previous infection. In NTM lymphadenitis, the bacilli enter through oropharyngeal mucosa, salivary glands, tonsil, or conjunctiva.

There are five stages of lymph node TB described by Jones and Campbell:[4]

- *Stage 1:* Enlarged, firm mobile discrete lymph nodes showing non-specific reactive hyperplasia
- *Stage 2:* Large rubbery lymph nodes fixed to surrounding tissue due to periadenitis
- *Stage 3:* Central softening due to abscess formation
- *Stage 4:* Collar stud abscess formation
- *Stage 5:* Sinus tract formation

Clinical Presentation

Most common clinical presentation as slowly enlarging lymph node. Constitutional symptoms like fever, weight loss, anorexia, and fatigue rarely found. We found[5] almost one-fourth of study patients (25.38%) having a symptom for more than 1 year before getting diagnosed as tubercular lymphadenitis before putting on anti-tubercular treatment. Cervical lymph node is the most

commonly involved followed by axillary and inguinal lymph node. Fever has been reported in 20–50% of cases in HIV-negative patients and 60–80% in HIV-positive patients.[3] Our study[5] showed fever, anorexia, and weight loss in 72.30%, 50.76%, and 41.53%, respectively. More than half of study patients (55.38%) received homoeopathic or ayurvedic treatment before putting on anti-tubercular treatment that could be one of the causes of delayed presentation. Physical examination finding depends upon stage of disease. Enlarged lymph node may be firm, discrete mass or matted nodes fixed to surrounding structures; the overlying skin may be indurated.[6] The lymph nodes are usually non tender unless secondary bacterial infection has occurred. Sometimes, lymph node abscess ruptured leading to non-healing sinus formation. The typical TB sinus appears thin, bluish, undermined edges with watery discharge. There is various complication occur especially due to mediastinal TB. These include dysphagia due to pressure on esophagus, esophagomediastinal fistula and tracheoesophageal fistula. Node may cause thoracic duct obstruction presenting as chylothorax, chylous ascites, or chyluria.

We found[5] almost one-fourth of study patients (25.38%) having a symptom for more than 1 year before getting diagnosed as tubercular lymphadenitis before putting on anti-tubercular treatment.

Differential Diagnosis

- Hodgkin lymphoma and non-Hodgkin lymphoma
- Reactive lymphadenitis (secondary to bacterial or viral infections)
- NTM infection
- Cat scratch disease
- Fungal infection
- Sarcoidosis
- Kikuchi disease (idiopathic histiocytic necrotizing lymphadenitis)

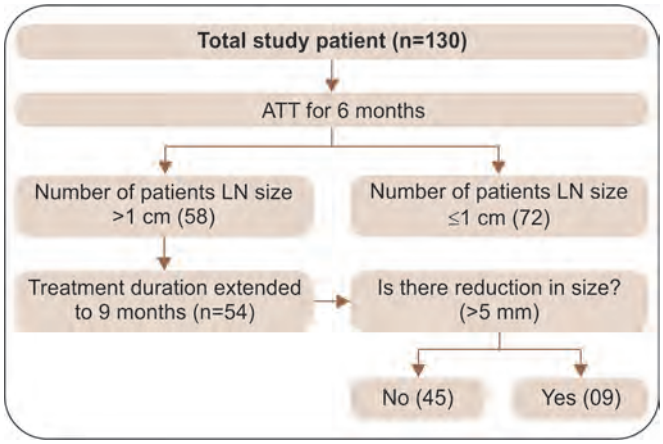
Diagnosis

Diagnosis of tuberculous lymphadenitis is confirmed by histopathology showing caseating granuloma and/or bacteriological evidence in form of smear positive for acid-fast bacilli (AFB), molecular test, or culture positivity. Fine needle aspiration (FNA) is appropriate for initial evaluation of cervical lymphadenopathy to evaluate for tuberculous lymphadenitis. The yield of FNA appears to be highest in the setting of HIV infection and in regions where the prevalence of TB is high. Specimens should be subjected for microscopy, culture, cytology, and polymerase chain reaction/GeneXpert testing. Excisional lymph node biopsy is indicated when FNA is not diagnostic. The finding of caseating granulomas on histopathology is highly suggestive of TB but it is not confirmatory because other disease like sarcoidosis and fungal infection may have granuloma. Multiplicity, matting and causation are three features which help in differentiating TB from other differential. In our study among 130 study patients, 62 (47.69%) were classified as having confirmed TB based on AFB positivity in FNAC sample. The remaining 68 (52.30%) patients had probable TB.

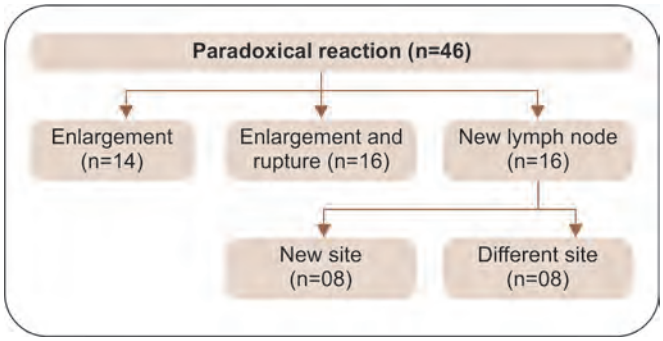
Treatment

Treatment options for tubercular lymphadenitis are surgical excision of involved node and/or anti-tubercular treatment. It is generally agreed that anti-tubercular treatment is sufficient for majority of cases and surgical treatment required in selected cases. INDEX TB guideline recommends 6-month therapy with first-line anti-tubercular drug of isoniazid, rifampicin, ethambutol, and pyrazinamide.[7] The studies evaluated 6–9 months regimen and found no difference as far as cure rates (89–94%) or relapse rates (3%) are concern.[8] Anti-tubercular treatment may be complicated by paradoxical reaction or increase in size of primary lymph node and/or appearance of new lymph nodes in up to 20% of patients during or even after cessation of treatment. These nodes may show histopathological features characteristics of TB but sterile on culture. These phenomena are transient and nodes ultimately regress in size. We did a study[5] to identify incidence of paradoxical reaction and residual lymph node at the end of 6 months of treatment. Forty-six (35.38%) patients out of 130 developed paradoxical reaction, and most of this occurred in the first 2 months of the initiation of anti-tubercular treatment. Fifty-eight patients (44.61%) had a residual lymph node of size more than 1 cm after 6 months of treatment. Only 9 patients out of 54 patients had significant reduction in the size of the lymph node with extended 9 months of treatment **(Flowcharts 1 and 2)**. So, presence of residual lymph node at the end of treatment does not require extended duration of treatment rather just close observation required but if there is increase in size of lymph node, send sample for histopathological examination, GeneXpert, and AFB culture.

Flowchart 1: Treatment outcome of standard 6 months and extended 9 months of lymph node tuberculosis patients



Flowchart 2: Characteristics of paradoxical reactions (number in bracket showing number of patients)



Conclusion

Lymph node TB is the most common forms of EPTB and is different from pulmonary TB in terms of diagnosis and treatment. Treatment regimen and duration is similar to pulmonary TB, but complicated by paradoxical reaction or residual lymph node at the end of treatment. So, patient might be given multidrug-resistant (MDR) treatment for paradoxical reaction and extended the duration of treatment for residual lymph node. Sample should always be processed for molecular test like GeneXpert and culture in all worsening lymph node with treatment to differentiate paradoxical reaction from drug resistance.

CHAPTER

196 Gastric Tuberculosis: An Often Unrecognized Entity

Piyush Manoria, Vishal Yadav

Abstract

Tuberculosis of stomach is a very rare manifestation of mycobacterium tuberculosis and presents as a diagnostic challenge to physicians. Gastrointestinal tuberculosis is the sixth most common cause of extrapulmonary tuberculosis, and stomach is the sixth most common site of it. It mostly occurs as a part of disseminated tuberculosis or in an immunocompromised state and presents as non-healing gastric ulcer or gastric outlet obstruction. It's mostly diagnosed after surgical intervention as yield of endoscopic biopsies is low due to submucosal location of granulomas. It's treated with conventional antitubercular therapy, and surgery is only needed when it presents with complications.

Introduction

Tuberculosis is endemic and a major health problem in India. Gastric tuberculosis is a rare manifestation of gastrointestinal tuberculosis and usually occurs in association with pulmonary tuberculosis or in immunocompromised states. It mostly presents as a diagnostic dilemma and often masquerades as peptic ulcer disease or gastric malignancy.

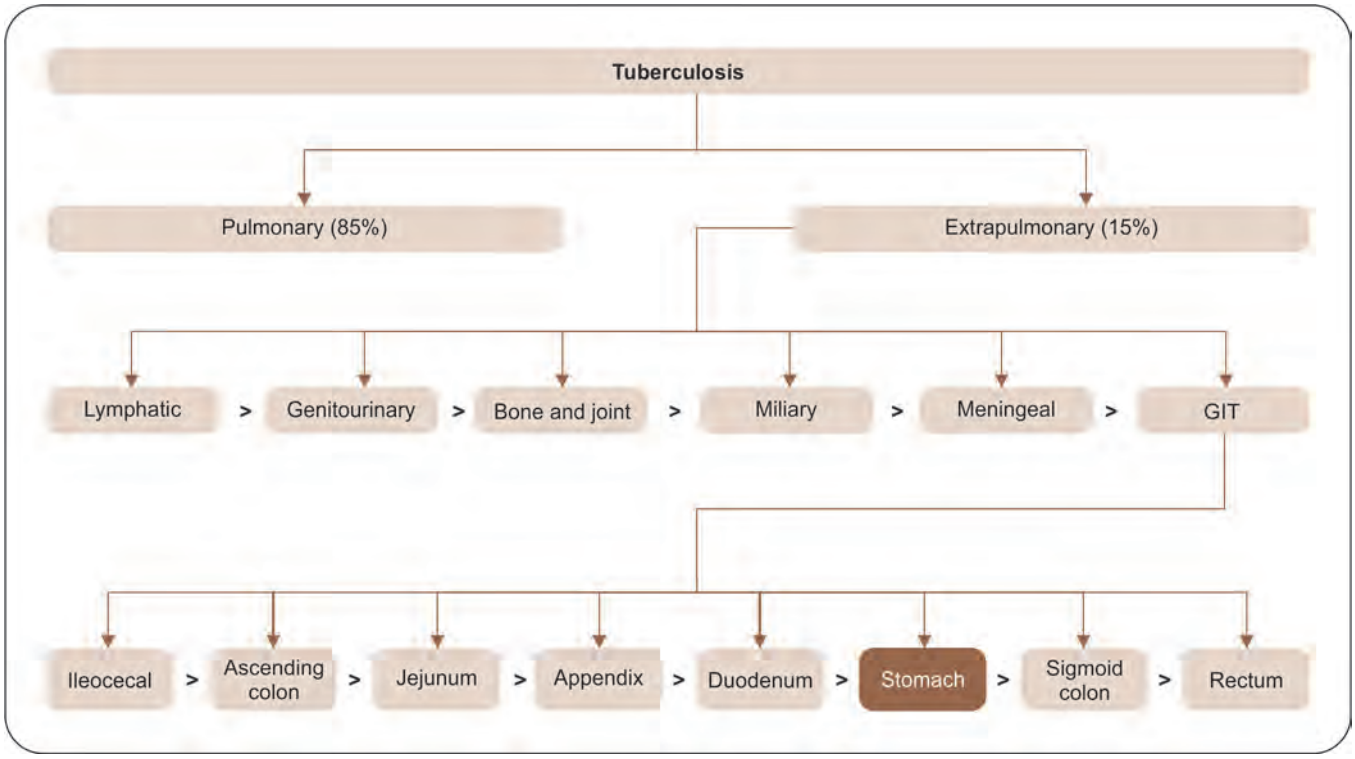
Epidemiology

Pulmonary tuberculosis accounts for 85% and extrapulmonary tuberculosis accounts for 15% of all cases of tuberculosis in an immunocompetent person. Gastrointestinal tuberculosis is the sixth most common cause of extrapulmonary tuberculosis after lymph node, genitourinary, bone and joints, miliary, and meningeal tuberculosis.[1] Tuberculosis can involve any part of gastrointestinal tract but it most commonly involves the ileocecal region followed by ascending colon, jejunum, appendix, duodenum, stomach sigmoid colon, and rectum.[2] The incidence of tuberculosis reduces as we move proximally and distally from ileocecal region. Stomach is the sixth most common cause of gastrointestinal tuberculosis and it accounts for 0.5–3% of its all cases.[3] The various sites of tuberculosis have been shown in **Flowchart 1**. It occurs mostly between ages of 15–62 years with a male preponderance.[4]

Pathogenesis

Gastric tuberculosis usually occurs as a part of disseminated disease or in immunocompromised states. Isolated gastric tuberculosis in immunocompetent person is very rare and only few case reports are published till date. We have published a case of isolated gastric tuberculosis in a healthy female presenting as non-healing gastric ulcer[5] **(Figs. 1A to C)**. Stomach as a site for tuberculosis is very rare due to bactericidal properties of gastric acid, absence of lymphoid tissue, and rapid transit of food in stomach due to its continuous motor activity.[6] The possible routes of infection in stomach are: direct infection of mucosa due to swallowing of sputum, direct infection from neighboring tubercular lesion, hematogenous spread or

Flowchart 1: Various sites of tuberculosis in an immunocompetent person



retrograde lymphatic spread.[7] Most commonly it occurs from neighboring celiac lymph nodes.[8]

Pathology

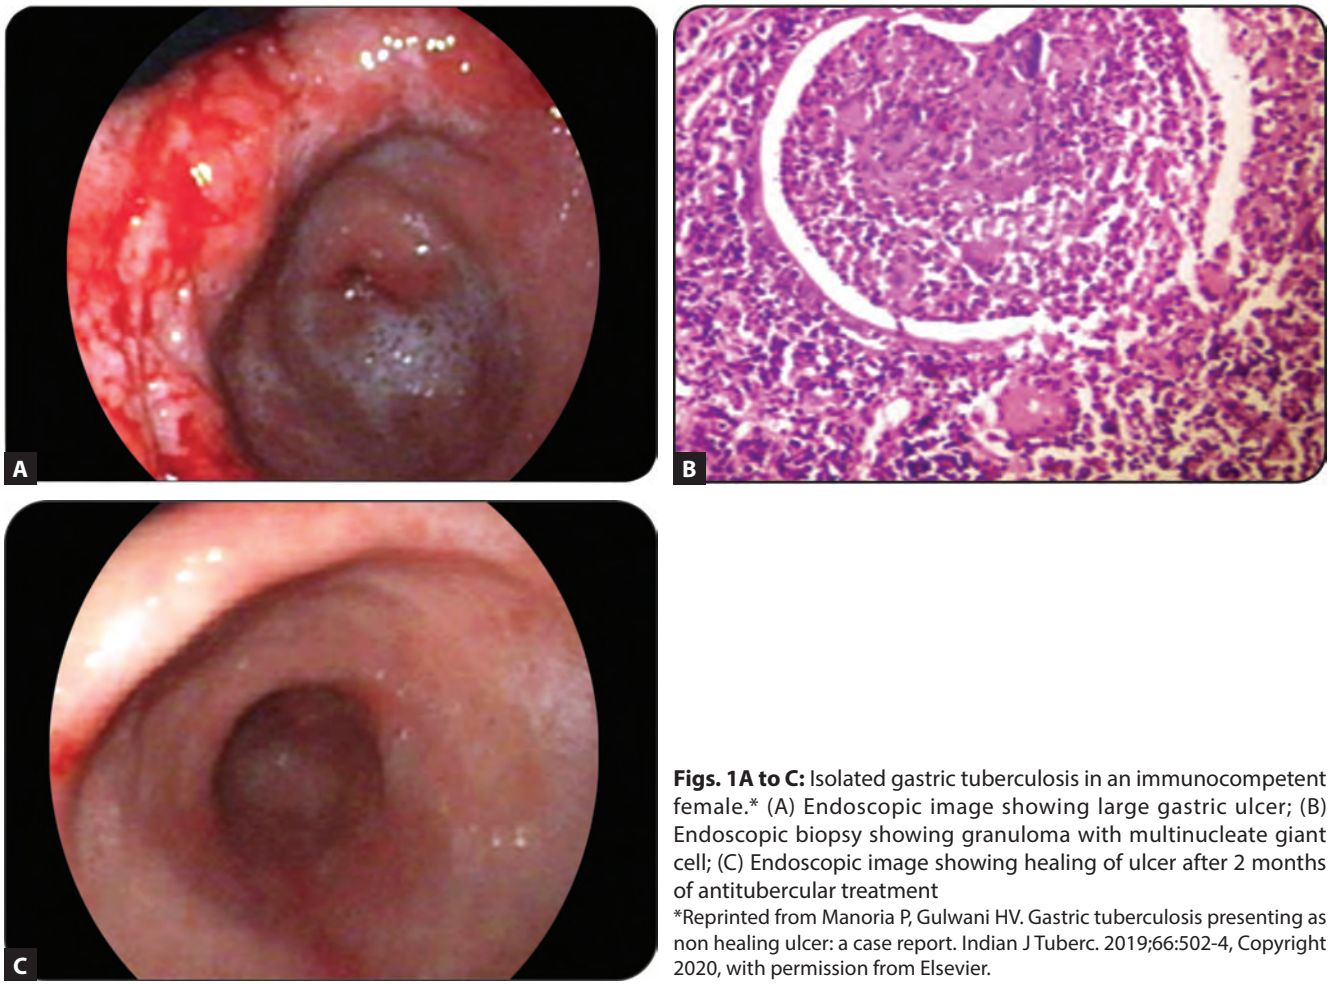
Gastric tuberculosis can present as an ulcer, hypertrophic mass, or ulcerohypertrophic lesion in the stomach.[9] It most commonly presents with non-healing gastric ulcer. Hypertrophic lesions mimic gastric carcinoma and present with gastric outlet obstruction. It mostly involves the antrum or prepyloric region in the lesser curvature.[10] The granulomatous lesions can involve the mucosa, submucosa, or serosa but most commonly it involves the submucosa. Granulomas in stomach can be caused by various disorders like tuberculosis, Crohn's disease, sarcoidosis, fungal and parasitic infection, Whipple's disease, xanthogranulomatous gastritis, lymphoma, Churg-Strauss syndrome, exposure to beryllium and silicates and syphilis, but most commonly it is caused by tuberculosis and Crohn's disease. Granulomas are more common in gastrointestinal tuberculosis compared to Crohn's disease. Caseation is present in around 40% cases. Granulomas in tuberculosis are more in number, larger in size, and confluent compared to Crohn's disease.[11]

Clinical Features

Clinical presentation of gastric tuberculosis is nonspecific. Its most common symptom is abdominal pain followed by vomiting. Constitutional symptoms of tuberculosis like fatigue, evening rise of temperature, loss of weight and appetite, etc. can also be present in some patients. Due to delay in its diagnosis it can also present with its sequelae like:

- Gastric outlet obstruction, which presents with postprandial vomiting, pain, and distension of abdomen
- Gastrointestinal bleed in the form of hematemesis and melena
- Perforation peritonitis and rarely
- Gastrocolic and gastrobronchial fistula.

Gastric tuberculosis most commonly presents as a case of non-healing gastric ulcer, which is resistant to proton pump inhibitor and negative for helicobacter pylori or as



Figs. 1A to C: Isolated gastric tuberculosis in an immunocompetent female.* (A) Endoscopic image showing large gastric ulcer; (B) Endoscopic biopsy showing granuloma with multinucleate giant cell; (C) Endoscopic image showing healing of ulcer after 2 months of antitubercular treatment

*Reprinted from Manoria P, Gulwani HV. Gastric tuberculosis presenting as non healing ulcer: a case report. Indian J Tuberc. 2019;66:502-4, Copyright 2020, with permission from Elsevier.

a case of a gastric outlet obstruction mimicking gastric malignancy but negative in histopathology. In both these clinical scenarios we should be highly suspicious of its diagnosis.

Diagnosis

Diagnosis of gastric tuberculosis is difficult and often delayed and it's mostly diagnosed after surgical intervention. The gold standard for its diagnosis is presence of acid fast bacilli in the histopathology specimen which is very rare.

Upper gastrointestinal endoscopy is the most important initial investigation. It can detect

- solitary or multiple ulcers in prepyloric region in lesser curvature
- ulceroproliferative mass in antrum causing gastric outlet obstruction, or
- submucosal lesion with normal overlying mucosa.

Endoscopic biopsies have a low yield for granuloma as majority of lesions are submucosal in location.[4] So it's advisable to take multiple deeper biopsies during endoscopy to increase the yield. *Helicobacter pylori* should always be ruled out in tissue biopsy and by doing rapid urease test. Colonoscopy should always be done in suspected cases as ileocecal tuberculosis can coexist with it.

Endoscopic ultrasonography (EUS) is very helpful and should be performed when it presents with submucosal mass or if there are associated adjacent lymph nodes. EUS guided fine needle aspiration cytology (FNAC) and biopsies should be taken from submucosal lesions and lymphnodes as it has a high yield for its diagnosis.

Imaging modalities like ultrasonography (USG) and contrast enhanced computed tomography (CECT) of

abdomen is not much useful in diagnosis as their findings are non-specific. They can show gastric wall thickening, hypodense lesion in antrum, multiple enlarge lymph nodes, peritoneal thickening, ascites, etc. CT or USG guided FNAC from enlarged lymph nodes should be done if they are accessible for making diagnosis. X-ray chest should always be done in any suspected patient as 25% of patients will have coexisting pulmonary tuberculosis.[12]

The yield of mycobacterial culture is from 0–69% in gastrointestinal tuberculosis in various studies. Bhargava et al. has suggested to do routine culture of biopsy specimen to increase the diagnostic yield.[13] The sensitivity and specificity of polymerase chain reaction (PCR) in endoscopic biopsies for gastrointestinal tuberculosis is 44% and 95%, respectively.[14] Kim et al. has suggested to do PCR testing as it also helps in ruling out Crohn's disease.[15] So, in any suspected cases of gastric tuberculosis, culture and PCR testing of biopsy should also be done to increase the yield of diagnosis.

Tuberculin test is non-specific test and is not done routinely for its diagnosis. There is no specific biochemical or hematological test for it.

Treatment

Treatment of gastric tuberculosis is conventional 6 months antitubercular therapy (ATT) with initial 2 months of intensive therapy with isoniazid, rifampicin, pyrazinamide, and ethambutol followed by 4 months of continuation phase with isoniazid and rifampicin. Few guidelines recommend longer duration of treatment of 1 year for it.[4] For uncomplicated cases ATT alone is sufficient for its treatment. Asia Pacific Association of Gastroenterology and Indian Society of Gastroenterology consensus on Crohn's disease have suggested a trial of ATT in cases where there is doubt in diagnosis.[16,17] Empirical ATT should always be given in any granulomatous lesion of stomach without a definitive diagnosis.

Surgery or endoscopic therapy is needed if it presents with complications.

- Surgery in the form of distal gastrectomy or primary closure is the main stay of treatment if it presents with perforation peritonitis.
- Gastric outlet obstruction secondary to tuberculosis can be dealt with endoscopic or surgical intervention. Endoscopic balloon dilatation followed by starting of antitubercular therapy should be the preferred initial treatment for it. For unresponsive cases surgery in the form of gastric resection with gastrojejunal anastomosis is usually done.
- Patient presenting with gastrointestinal bleeding should be initially managed with endoscopic hemostatic procedures like adrenaline spray, adrenaline injection, hemoclipping, etc. Non-responsive cases are treated surgically with partial gastrectomy.

Conclusion

Tuberculosis can involve any part of gut even in immunocompetent person. Gastric tuberculosis though rare should be kept as one of the differential diagnosis in any case of chronic infiltrative lesion of stomach like non-healing ulcers and gastric outlet obstruction. The yield of endoscopic biopsies is low for granuloma due to submucosal location of the lesion so deeper and repeated biopsies are advisable for making early diagnosis and avoiding surgical interventions. If diagnosed early, it responds very well to standard ATT.

CHAPTER

197 Interpretation of Thyroid Function Tests

Dheeraj Kapoor, Ruchi Kapoor, Abhishek Goyal

Abstract

Thyroid disorders have various etiologies and presentations. Pertinent treatment needs a conclusive diagnosis and is influenced by variety of coexisting medical conditions. This chapter delineates how to interpret thyroid hormones, referring to various evidence-based clinical guidelines for the management of thyroid disorders. In depth research of relevant literature and evidence-based approach has been taken to simplify interpretation of thyroid hormone levels. Topics addressed include thyroid hormone assays, thyroid antibodies levels, hyper- and hypothyroidism along with thyroid dysfunction in pregnancy.

Introduction

Thyroid is a small butterfly shaped endocrine organ located anteriorly in the lower part of neck. On an average it weighs around 25–30 g in an adult. It produces the thyroid hormones, which are released into the blood stream and then transported to different tissues in the body. They have an effect on each and every cell and organ of the body. Their main function is to maintain homeostasis in various functions ranging from controlling the metabolic rate, the muscle mass, digestive functions, development of brain, and bone maintenance.

Thyroid gland chiefly synthesizes the hormone thyroxine (T4) and small quantity of triiodothyronine (T3). T3 being the active form with a short half life is converted from T4 with removal of an iodine atom mainly in liver and in small quantities in heart, gut, muscle, and nerves. The gland is controlled by a feedback regulation from the pituitary, which releases thyroid-stimulating hormone (TSH), which in turn is controlled by the thyroid-releasing hormone (TRH) released from the hypothalamus.

Progress in technology over time has improved the sensitivity and specificity of thyroid function test available, and hence permitting an accurate diagnosis of thyroid condition to be made in majority of case. However, analytical inference still stands a major hurdle. The interpretation of thyroid function tests is generally straight forward; through sometimes the reports may seem fairly clear but are in fact misleading. This article aims to address the interpretation of thyroid functions test.

Thyroid-stimulating Hormone

TSH is secreted by anterior pituitary and is central to the negative feedback mechanism for secretion of thyroid hormones. It shows a diurnal variance, presenting a peak soon after midnight and a nadir by late noon, with peak values sometimes even twice the value seen in nadir. TSH may vary in between measurements to the extent of up to 20% without any change in thyroid state.[1,2]

TSH is now considered as the first diagnostic test for assessment of thyroid condition.[3] It presents as a foremost irregularity in case of thyroid disorders when the other test are normal. When TSH is used to confirm patients with suspected thyroid diseases in an Endocrine clinic it carries high sensitivity of up to 98% and a specificity of up to 92%. But in cases of mass screening the sensitivity and

BOX 1 Conditions associated with high risk for thyroid disease in which screening is recommended

- All new borns (neonatal screening)
- Those with strong family history of thyroid disease
- Those having an autoimmune disease, such as type 1 diabetes mellitus
- Genetic conditions (e.g., Down's syndrome, Turner's syndrome)
- Past history of neck irradiation
- Drug therapies such as lithium and amiodarone
- Elderly patients
- Women over age 35
- Pregnant women during the first trimester
- Women at 6 weeks to 6 months postpartum
- Dyslipidemia
- Atrial fibrillation
- Depression
- Reduced bone mineral density

positive predictive value is low due to underlying diseases or health of the individual screened, hence making the interpretation of test result problematic. As a routine now, value of TSH is considered low when less than 0.1 mU/L and high when more than 6.5 mU/L.

Using TSH as an ace standard does help to categorize patients in over 95% cases. But, TSH alone can be used only if the pituitary thyroid axis is intact. In case of pituitary diseases (hyperthyroidism secondary to TSH producing pituitary adenoma), non-thyroidal illness, HAMA antibody, drugs (glucocorticoids, tyrosine kinase inhibitor, octreotide, etc.), lab results can be misleading and difficult to interpret. Aberrant TSH levels may persist for up to few months even after initiation of thyroid treatment.

The American Thyroid Association recommends routine screening for thyroid disorders in all adults by measurement of serum TSH starting from the age of 35 years and then every 5 years, with more frequent screening in high risk or symptomatic person.[4] The American Association of Clinical Endocrinologists recommend routine measurement of serum TSH in all women of child bearing age before they conceive or during the first trimester of pregnancy **(Box 1)**.[5]

Conditions associated with abnormal TSH levels:

- Decreased TSH levels—
  - Primary hyperthyroidism
  - Pituitary or hypothalamic disease—secondary or tertiary hypothyroidism
  - Non-thyroidal illness
  - Drugs, e.g., glucocorticoids, dopamine
- Increased TSH levels—
  - Primary hypothyroidism
  - Pituitary adenoma (TSH producing)—secondary hyperthyroidism
  - Pituitary resistance to thyroid hormone (TSH unreliable)
  - Generalized thyroid hormone resistance
  - Old age
  - Drugs, e.g., amiodarone
  - Recovery phase after severe systemic illness

Thyroid Hormone Assays

Serum Thyroxine

T4 levels are elevated in patients of hyperthyroidism. Hence, in the course of treatment their levels are measured to ascertain the degree of thyroid dysfunction and titration of doses of anti-thyroid medication, because serum TSH values may remain suppressed for a continued duration during the course of therapy.[6]

Serum T4 values are also important in diagnosis of patients suffering from secondary hypothyroidism. Because a case of normal TSH and suppressed T4 should direct the clinical toward a possible diagnosis of secondary hypothyroidism, justifying the assessment of pituitary hormone levels for further investigations.

Serum Triiodothyronine

Evaluation of T3 levels is not suggested routinely because of its short half life and normal levels of it influenced by the endocrine homeostasis. Despite this it is of values in cases of T3 toxicosis, in which patients have low TSH, normal T4, and features of hyperthyroidism. This condition is observed in a small fraction of patients suffering from Graves' disease. A ratio of T3:T4 > 20 ng/mL is indicative of Graves'.[6]

Free Thyroxine and Free Triiodothyronine

Merely a meagre portion of thyroid hormones circulate in free form not bound to protein. These free form of thyroid hormones are physiologically more important. Their quantification is of value in conditions where levels of thyroid-binding globulin (TBG) are altered. Levels of TBG influence the levels of T3 and T4 in direct proportion

TABLE 1 Conditions associated with altered TBG[6]

Increased binding	*Decreased binding*
Oral contraceptives	Nephrotic syndrome
Pregnancy	Active acromegaly
Neonates	Major systemic illness
Acute intermittent porphyria	Genetic factors
Hepatitis, biliary cirrhosis	Asparaginase
HIV infection	Drugs—androgens, large dose glucocorticoids
Drugs—estrogen supplements, tamoxifen	

without any change in hormone activity, more TBG falsely more T3, T4, and low TBG presenting as falsely low T3 and T4 **(Table 1)**.

Free Thyroxine

fT4 is performed for optimizing thyroxine therapy in patients of newly diagnosed hyperthyroidism. It is also prescribed in diagnosis of secondary hypothyroidism and in cases of end organ thyroid hormone resistance.

Conditions associated with decreased fT4:
- Primary hypothyroidism (thyroid hypofunction)
- Secondary hypothyroidism (pituitary hypofunction)
- Tertiary hypothyroidism (hypothalamic hypofunction)

Conditions associated with increased fT4:
- Graves' disease
- Plummer's disease (toxic thyroid adenoma)
- Early phase of subacute thyroiditis
- Struma ovarii
- Thyrotroph hyper function—secondary hyperthyroidism

Free Triiodothyronine

fT3 levels are rarely required.

Conditions associated with decreased fT3:
- Critically ill patients
- Patients on high dose steroids
- Patients on beta blockers
- Severe hypothyroidism

Conditions associated with increased fT3:
- T3 toxicosis
- Hyperthyroidism

Thyroid Antibodies

Estimation of thyroid antibodies is advisable in altered thyroid functions. They help to determine if patient is having an autoimmune thyroid dysfunction. Various antibodies exist against thyroid antigens. The ones of importance include Anti Thyroperoxidase antibody (Anti-TPO Ab), antithyroglobulin antibody and TSH receptor antibody (TSH-RAb).

Anti-thyroperoxidase Antibody (Anti-TPO Ab)

Anti-TPO is also known as thyroid microsomal antibodies. They cause hypothyroidism by two distinctive mechanisms. First by blocking the thyroid peroxidase thereby hindering the synthesis of T3 and T4 and secondly by antibody dependent cell toxicity and inflammation of thyroid gland.[7] Anti-TPO Ab levels facilitate in the diagnosis of subclinical hypothyroidism and helps in evaluation of autoimmune thyroiditis.

TSH Receptor Antibody (TSH-RAb)

TSH-RAb may either stimulate of block the TSH receptor. If they stimulate they cause Grave's disease and associated ophthalmopathy. If they act as blocking anti-antibodies they may lead to hypothyroidism.[7]

Measurement of TSH-RAb is helpful in confirming the cause of hyperthyroidism and radioactive iodine therapy is not an option. This assay if of particular importance in managing pregnant patients with Grave's disease as high concentrations is a fair predictor of fetal and neonatal thyrotoxicosis.[8]

Thyroglobulin

It is a large glycoprotein, secreted along with the thyroid hormone. Raised thyroglobulin levels is not a reliable marker or a screening test for thyroid carcinoma; however, it gains importance as an important marker of remaining or recurrent malignancy in patients who undergo total thyroidectomy or radioactive thyroid ablation for papillary or follicular carcinoma.

Thyroid Function in Pregnancy

During pregnancy there is a paradigm shift in level of thyroid hormones leading to an increase in T4 levels and a reciprocal decrease in level of TSH. The reason for this physiological change is linked to—

- Human chorionic gonadotropin has an alpha subunit similar to TSH, which binds to TSH receptor. This leads to an increased production of T4, which gives a negative feedback to the pituitary resulting in reduction of TSH.[9]
- Estrogen produced by the placenta leads to increased secretion of sex hormone binding globulin (SHBG) by the liver. This SHBG increases secretion of T4 from thyroid.
- Pregnancy being a hypermetabolic state leads to increased glomerular filtration rate; hence, increased secretion of T4 by thyroid due to augmented elimination by the kidneys.

Detecting Thyroid Dysfunction

There exist an inverse log relationship between TSH and T4 levels. Elevated TSH levels indicate hypothyroidism and low TSH indicate hyperthyroidism.[10] Analysis of thyroid function test can be a challenge in case of hypothalamic pituitary disease (low TSH, low T4), systemic illness, starvation (low TSH, low T3).

Hyperthyroidism

An elevated fT4 and low TSH is indicative of thyrotoxicosis. Most of the young age group patients with these levels presents as Grave's disease while the elderly are more prone for nodular thyroid disease.

In cases of subclinical hyperthyroidism TSH levels may be borderline suppressed in the presence of normal fT3 and fT4. Treatment of subclinical hyperthyroidism is warranted in the presence of underlying condition like increased age, cardiac condition like atrial fibrillation, recent history of stroke, and osteoporosis.[7]

Temporary or short lived thyrotoxicosis can be presented in the form of viral thyroiditis. Most patients have a recent history of viral upper respiratory tract infection. This usually responds to anti-inflammatory medication. Prompt diagnosis of the condition stands as a key to treatment.

A small subset of patients may present with low TSH and normal fT4 thereby representing T3 toxicosis. In these cases measurement of T3 levels is of value. If in case fT3 is not raised then fT4 and TSH should be rechecked.

High fT4 with normal or raised TSH depicts a T4 to T3 conversion defect, or an analysis error.

During the course of treatment, TSH may remain suppressed for varied amount of time; in this case fT4 is measured every 6–8 weeks to monitor the treatment.

Hypothyroidism

Elevated TSH levels with low fT4 suggest a diagnosis of primary hypothyroidism, primarily autoimmune in nature but can also be a result of previous surgery or radio iodine ablation of thyroid gland. The prevalence of high TSH with raised antibody levels is more common in elderly women.[7]

Raised TSH in presence of normal fT4 indicates autoimmune thyroid condition. When TSH levels are more than 4 μIU/mL but less than 10 μIU/mL without any clinical sign, it represents subclinical hypothyroidism. Treatment is warranted in this condition in presence of thyroperoxidase antibody, pregnancy, goitre, or dyslipidemia. TSH levels more that 10 μIU/mL require treatment.

Low or normal TSH usually excludes the diagnosis of primary hypothyroidism. However, presence of low TSH and low fT4, low fT3 should indicate toward secondary hypothyroidism, most commonly seen in cases of Sick Euthyroid syndrome.

Thyroxine replacement in hypothyroid patient should be titrated to maintain a TSH of about 2 μIU/mL. Guidelines recommend that test for thyroid function and changes in dose of thyroxine should not be done before 6 weeks unless clinically indicated because it takes this much time for the body to accomplish reliable T4 levels. Patients who are less compliant to medication usually have tendency to replenish the dose before the scheduled visit. This presents as a raised TSH but normal fT4.

Patients suffering with differentiated thyroid cancers are given suppressive doses of thyroxine to maintain TSH levels below 0.1 μIU/mL to prevent flare ups. Those who initially had a high risk disease but are now disease free post-treatment are advised to maintain TSH levels between 0.1 and 0.5 μIU/mL for at least 5–10 years.[7,11]

Sick Euthyroid Syndrome

This is referred as a thyroid-related change that occurs during systemic illness in the absence of an intrinsic thyroid disease. The syndrome is acute, reversible, and occurs commonly after surgery, starvation and in many acute febrile illnesses. These changes may be observed in up to 75% of hospitalized patients. Any abnormality in hormone level is possible, but the most common observed abnormality is low fT3.

TABLE 2 Interpretation of thyroid function test[7]

	TSH	*fT4*	*fT3*	*Thyroid antibodies*
Normal	↔	↔	↔	↔
Primary hypothyroidism	↑	↓	↓	↑
Subclinical hypothyroidism	↑	↔	↔	↑
Hyperthyroidism	↓	↑	↑	↑
Subclinical hyperthyroidism	↓	↔	↔	↔
Pituitary diseases	↓	↓	↓	↔
T3 toxicosis	↔↓	↔	↑	Variable

↔ Normal, ↑ High, ↓ Low

Conclusion

Diseases of thyroid gland are common and initial test to be done for assessment of this condition is serum TSH. fT4 is indicated as a second line test, but the reference range for fT4 and TSH are not universal and reference interval provided by the lab should be acknowledged. Results of thyroid function test are interpreted in light of clinical status of patients: hypothyroid, euthyroid, or hyperthyroid. Subclinical thyroid diseases are commonly encountered and present with an abnormal TSH and normal fT4. Awareness of associated conditions can serve as a guide for further investigations and management. Confounding factors should be excluded before embarking upon further biochemical, radiological, or genetic testing **(Table 2)**.

CHAPTER

198 Cognitive Aspects of Hypothyroidism

Anubha Srivastava, Anurag Varma, Kachnar Varma

Abstract

Hypothyroidism is associated with myriad of neuropsychiatric manifestations in clinical practice. Due to its variable and wide clinical presentation it sometimes poses a dilemma for the treating physician and consultation—liaison should be considered when treating patients with neurocognitive symptoms.

Introduction

Disorders of Thyroid are one of the common endocrine problems encountered in clinical practice; the hypothalamic-pituitary-thyroidaxis is needed to maintain the normal functioning of various organs and systems, including the central nervous system.[1]

Thyroid dysfunction affects the nervous system and produces a wide and variable spectrum of clinical presentation due to alterations in cognition and emotions.[2] As early as 1888 Clinical Society of London had described myxoedema and its association with behavior and psychological disturbances.[3]

Pathophysiology

The hypometabolism of brain has been postulated to be associated with cognitive decline.[4] Thyroid hormones exert their influence on the central nervous system through a variety of mechanisms like modulation of gene expression of several groups of proteins and the influence on serotonin and noradrenergic neurotransmission. Antithyroid antibodies are also postulated to play a causativerole.[5] In autoimmune Hashimoto's thyroiditis link with Unipolar and Bipolar Depressive disorders is established; however, the exact pathophysiology, role of inflammatory markers or of second messengers is yet to be established and a direct correlation between the more specific marker of the disease, that is, thyroid peroxidase antibodies (TPOAb) or of thyroglobulin antibodies (TGAb) is still an ongoing research.

Epidemiology

Due to improvements in diagnosis and treatment of the hormonal disorders and universal iodine supplementation of common salt the most severe neuropsychiatric syndromes in endocrine diseases are not as frequent as in the past although psychiatric and subtle cognitive disturbances are still seen.[6] Data shows that 1–4% of patients diagnosed with affective disorders have overt hypothyroidism and 4–40% may have subclinical hypothyroidism (SCH). However, majority of patients diagnosed with major depression have normal thyroid function.[7]

Overt Hypothyroidism

Overt hypothyroidism by definition is an elevation of serum thyroid stimulating hormone (TSH) level with a low-free thyroxine (fT4) level.[2] Autoimmune thyroiditis (Hashimoto's) is the most common cause of

hypothyroidism which is commonly seen in middle age females.[8]

The most common presenting complaints are fatigue and impaired quality of life. Due to advances in interventional and functional imaging the subtle changes in cognition in specific domain like working memory and executive function are now more commonly diagnosed along with the more commonly seen anxiety and depression.

Neurocognitive Effects Seen in Overt Hypothyroidism

Cognition

Cognition is referred to as mental activities involved in the acquisition, storage, retrieval and use of information.

Memory is most commonly affected domain with specific deficits seen in verbal memory. Hypothyroid individuals have also shown deficits in visuospatial and executive functions.

The other cognitive domains affected include general intelligence, complex attention and concentration, language, learning and memory along with perceptual and visuospatial functions. The frontal lobe executive functions like reasoning, problem solving, decision-making may be affected. There are various psychological tests and measures available for evaluation of these individual cognitive domains.[4]

In congenital hypothyroidism irreversible cognitive deficits may happen if hypothyroidism is left untreated or intervention started belatedly after the critical window of brain development.

In adolescents who develop hypothyroidism again cognitive domains are affected and those who were treated with Thyroxine Replacement Therapy (TRT) were found to have improved performance on a battery of cognitive tests including reading performance and block design but the patterns of recovery are not definitive.

In adults with hypothyroidism again vocational and occupational pursuit may be affected whereas specific tests of cognitive domains are often seen to be not significantly impaired.

Dementia

In geriatric population there may be an overlap of symptoms seen in hypothyroidism and due to old age, itself. Hence, the diagnosis of hypothyroidism may be clinically missed.

Traditionally, Myxoedema used to be known as a reversible cause of dementia in the elderly. There occurs progressive neurocognitive decline leading to impaired social and cognitive functioning. Elderly patients tend to have problems with recent memory though remote memory and overall intelligence remains intact other common problems observed are lack of attention and emotional liability with easy fatigability leading also to a lot of family and caregiver burden.

There is decline in auditory acuity which might contribute indirectly to memory impairment due to sensory deprivation and poor registration usually seen in uncontrolled hypothyroidism which can partially be reversed with thyroxine. TSH levels and risk of developing Alzheimer's disease may also show some correlation.[9,12]

Other Neurological Complications[10]

Cerebellar dysfunction and motor coordination like ataxia, intention tremors are usually mild and more commonly seen in children and may result in poor outcomes in motor functions in later childhood if delayed treatment or inadequate hormone replacement is done.

Neuropathy: Hypothyroidism is associated with peripheral nerve demyelination and decreased nerve conduction velocity (NCV).

Entrapment neuropathy, like Carpal tunnel syndrome and polyneuropathy, is also seen but the bilateral and distal sensorimotor neuropathy is the most common.

With thyroxine replacement therapy the symptoms and signs of neuropathy along with changes in NCV usually normalize in adulthood but those who have symptoms of longer duration may show some residual symptoms of peripheral neuropathy.

Myopathy can occur when associated with symptoms or signs of hypothyroidism such as poor linear growth or global developmental delay with pain and muscle weakness along with elevation of creatine phosphokinase.

The delayed acquisition of early motor milestones may be a sign of missed congenital or early acquired hypothyroidism in young children and investigation of thyroid function should be performed in them.

Hashimoto's encephalopathy (HE) is a rare neuro-endocrine disorder to be associated with autoimmune thyroiditis (Hashimoto thyroiditis). Hashimoto's

encephalopathy is frequently seen in women and presents with symptoms of seizures, myoclonus, stroke, and also psychiatric manifestations mainly depressive disorders and even psychosis. These symptoms usually recover with treatment but relapses can also be seen.

Thyroid tests are usually normal. Neuroimaging is often normal. The diagnosis of Hashimoto's encephalopathy is made with classical clinical picture with positivity of antithyroid peroxidase antibodies. Treatment of Hashimoto's encephalopathy is corticosteroids.[11]

Anxiety disorders: These disorders present as restlessness, inability to concentrate, irritability, distraction, increased sweating, muscular tension, and insomnia. The most prevalent anxiety disorders are social anxiety disorder, generalized anxiety and panic disorder, the incidence of which is increased in hyperthyroidism and also in hypothyroidism.[2,7]

Mood disorders: Depression has a prevalence of 10–15% in the general population and may be more common in people with thyroid disorders. The normal circadian secretion of TSH peaks from 11 pm to 4 am. In depressive patients there is a dysregulation of Hypothalamic-Pituitary-Adrenal axis; hence, the nocturnal surge is absent which may point to functional central hypothyroidism in some depressed patients.

It has been seen that self-knowledge of mildly elevated TSH may be associated with poor quality of life or fatigue known as ("labeling effect").

Major depressive disorder can also happen in hyperthyroidism although more common in hypothyroidism, presence of antithyroid antibodies may have an etiopathological role and severity in causing depression. There are further complications as Lithium the gold standard medicine of Bipolar disorders leads to Hypothyroidism on prolonged use.

Depression is characterized with cognitive distortion in form of hopelessness, helplessness, and worthlessness this may lead to suicidal ideation and in few cases lead to self-harm and suicide.

Many cognitive symptoms like poorer memory, in attentiveness, slower thinking and speech, impaired concentration and apathy is seen in both the diseases. The common symptoms of being easily tired, lack of interest, and pleasure along with loss of appetite, decrease libido, and constipation may pose a difficulty in diagnosis though certain symptoms like weight gain, hypersomnolence or insomnia and impoverished quality of life may give a clue toward diagnosis of hypothyroidism but they are also common in mood disorders. An overlap of anxiety and mood disorders can be seen leading to variety of emotional disturbances.[2,7,15]

Psychotic disorders: Severe hypothyroidism in 5–15% may present as melancholic depression with mood congruent psychotic features, rarely frank psychosis, delusions, and hallucinations. These features are often seen in Myxedema madness.

Capgras syndrome a delusional disorder has also been associated with hypothyroidism where psychotic symptoms are preceded by symptoms of hypothyroidism even months to years of diagnosis.

Effects of Thyroxine Replacement Therapy on Hypothyroidism

After supplementation of thyroxine replacement therapy there may occur incomplete normalization of subjective neuropsychiatric symptoms even on reaching euthyroid state. There is no rationale of using combination of Levothyroxine (LT4) and Liothyronine (LT3) treatment for hypothyroidism who still complained of depressive symptoms. In these subsets of individual revaluation of other chronic medical condition and consultation liaison with psychiatrist should be sought.

Subclinical Hypothyroidism

"Subclinical" hypothyroidism (SCH) by definition is an elevation of TSH with a normal $fT4^2$. In young adults and middle age, the symptoms of depression are more frequent along with mild cognitive impairment, difficulty in learning and selective attention. Subclinical hypothyroidism is prevalent in as many as 20% of post-menopausal women and in older patients many of whom already have some cognitive decline.[14] The correction of the subclinical hypothyroid state with neuropsychiatric symptoms still remains elusive.[9]

There have been no improvements in symptoms of Subclinical hypothyroidism on thyroxine replacement therapy diagnosed with depression who are biochemically euthyroid. Various studies have shown no significant clinical improvement with coadministration of Levothyroxine (LT4) and Selective Serotonin Reuptake

Inhibitors (SSRI) in depressed patients when compared with SSRI alone.[9]

Congenital hypothyroidism (CH) is a common and treatable cause of preventable intellectual disability with a prevalence of approximately 1 in 2,000–4,000 new born. Thyroxine is an essential hormone during pregnancy especially during first trimester as it is required for fetal brain development at around 12 weeks postconception. Deficiency of thyroxine may lead to abnormal dendritegenesis and synaptogenesis leading to congenital hypothyroidism in neonates.

Congenital hypothyroidism can impair cognition but also cause arrange of other neurological sequelae including abnormal muscle tone, ataxia and strabismus and motor in coordination the most severe forms of congenital hypothyroidism may include alterations in domains of attention, memory, arithmetic, verbal skills, memory, and behavior.

In severe cases mental retardation, deafness, and spastic diplegia can be seen. There is also presence of other clinical features such as short stature, delayed puberty, and craniofacial abnormalities.

For prevention of neurobehavioral effects of congenital hypothyroidism supplementation of iodine preconceptually may be advised. The immediate goal of thyroxine replacement is to normalize T4 within 2 weeks and TSH within 1 month of birth to ensure growth and neurodevelopmental outcomes as close as possible to their genetic potential.[13]

Hypothyroidism has also been associated with attention deficit hyperactivity disorder (ADHD) and this may persist even in adults.

The preventive measures of congenital hypothyroidism may be early identification and early initiation of treatment, which has shown improvement in tests for formal intelligence. But certain domains of neurocognition may persist in late childhood and adolescence. Some domains like language, motor skills, attention, and visuospatial processing may be affected even after becoming euthyroid.[9,10]

Conclusion

Overt hypothyroidism is associated with myriad of symptoms ranging from fatigue affecting quality of life to mood and behavior changes along with cognition. Among the cognitive impairment seen in hypothyroidism is its effect on memory.

Though these changes may be subtle in patients of SCH and may not show major changes on mood and cognition, SCH have been seen to be associated with mild deficits in working memory and executive function especially in elderly.

The treatment with thyroxine replacement is the cornerstone and is always indicated in overt hypothyroidism. There have been improvements in physical symptoms along with resolution of deficits in mood or cognition though complete recovery may not be seen. The treatment of SCH is elusive and it depends upon the decision of treating physician.

The neuropsychiatric symptoms with mild hypothyroidism should be evaluated and treated as independent diagnosis with consultation liaison.

There appears significant merit in recommending universal thyroid screening for all pregnant females along with testing for any young infant or child with global neurocognitive or neuromuscular dysfunction.

Also, emphasis on thyroid testing for patients presenting with neuropsychiatric disorders and conversely assessment of mental health for all patients diagnosed with thyroid disorders can be instrumental for good clinical management as the timely intervention may improve quality of life among thyroid disorder patients with comorbidities.

Neuroplasticity more often favors infant rather than older individual. Thyroxine replacement therapy remains the main stay of treatment but the extent and duration of recovery especially neurocognitive domains is often incomplete and inconsistent. There is global decline in cognition if thyroxine replacement therapy is delayed or absent. Hence, universal screening of TSH in pregnant women should be emphasized.

CHAPTER

199 Thyroid Myopathy—An Update

NS Neki

Abstract

Muscular complaints are common symptoms of thyroid disorder: hypothyroidism or hyperthyroidism. About 79% of hypothyroid patients and 67% of hyperthyroid patients develop neuromuscular symptoms. However, muscle stiffness is more common in hyperthyroidism while muscle weakness is observed commonly both in hypothyroidism and hyperthyroidism. The onset of weakness is usually insidious and proximal muscles are predominantly affected in both types of thyroid myopathy. Thyroid myopathy occurs as a result of either deficiency or overproduction of thyroid hormone, i.e., Thyroxine. Skeletal muscle is a major target of thyroid hormone. Patients with untreated or uncontrolled hypothyroidism and hyperthyroidism can develop severe myopathy resulting in severe functional limitations. These symptoms subside completely with proper diagnosis and appropriate treatment.

Introduction

Abnormal thyroid functions/disorder either too increased or too low can result in neuromuscular manifestations including hypothyroid myopathy, hyperthyroid (thyrotoxic) myopathy, thyrotoxic periodic paralysis, and thyroid associated ophthalmopathy because the skeletal muscle is a major target of thyroid hormone. Muscular complaints are common symptoms of thyroid dysfunction, especially muscle stiffness more so in hyperthyroidism and muscle weakness in both hypothyroidism and hyperthyroidism. The prevalence of neuromuscular manifestations varies between 20% and 50%. Most of these studies were retrospective and were done before FT4 and TSH assays were available.[1,2]

Types of Myopathy

Hypothyroid Myopathy

Various manifestations of hypothyroidism are observed in clinical practice. Hypothyroid myopathy (HM) occurs as a complication of uncontrolled or untreated hypothyroidism involving about 79% of patients. It is seen in both congenital and acquired hypothyroidism. Sometimes subclinical hypothyroidism manifests as HM. HM can occur at an age but most common age is 40–70 years and involves both sexes. However, females are predominantly affected than males.[3]

Pathogenesis: The exact pathogenesis of HM is not known. Thyroid hormones markedly influence the cellular metabolism and their deficiency results in cellular functional impairment. Thyroxine (T4) deficiency in hypothyroidism causes:

- Abnormal glycogenolysis
- Reduced mitochondrial oxidation
- Insulin resistant state of the cell

Ultimately this causes selective atrophy of Type 2 muscle fibers (fast twitching type) because these muscle fibers are dependent on glycolysis for energy. Finally, it results in slowing of muscle contraction which may be observed clinically. However, compensatory mechanism

occurs from accumulation of glycosaminoglycans in the muscle further causing muscle hypertrophy. Myopathy symptoms in HM result from low muscle carnitine. Various factors causing muscle involvement in hypothyroidism are due to

- Deposition of glycosaminoglycans
- Low myosin ATPase activity
- Changes in muscle fibers from fast twitching Type 2 to slow twitching Type 1 fibers
- Decrease in ATP turnover in skeletal muscle
- Structural muscle injury. A significant feature is that degree of muscle weakness does not always correlate with the severity of thyroid hormone deficiency. Rise in serum muscle enzymes in the absence of clinical manifestations or structural alterations results from changes in the muscle cell membrane permeability. Thyroid hormone may have a role in regulating gene expression of skeletal muscle proteins like myosin ATPase thus favoring the role of thyroid hormone deficiency in the pathogenesis of TM.[4]

Thyroid myopathy is of four types:

- *Myasthenic syndrome:* It is associated with Ptosis and marked weakness. It is commonly seen in children.
- *Atrophic type:* It is seen in severe muscle atrophy.
- *Kocher-Debre-Semelaigne syndrome:* It is commonly seen in children. Clinical features include myxedema, short stature, cretinism, and generalized muscle hypertrophy.
- *Hoffman syndrome (HS):* It occurs in adults. Clinical features include pseudohypertrophy of muscles, proximal muscle weakness, stiffness, and painful spasms. Commonly involved muscles are tongue, arm, and leg muscles. The pathogenesis of pseudohypertrophy is not exactly known but may be due to deposition of glycosaminoglycans and increased muscle fiber size.[5] Few cases of HS have been reported from India.[6,7] HS was first described by Hoffman in 1897 in an adult who developed muscle stiffness and difficulty in relaxation of muscles after thyroidectomy.[8] Usually the cause of HS is primary hypothyroidism (Hashimoto thyroiditis) but rarely secondary. Muscle biopsy is usually not required to confirm the diagnosis. Muscle MRI may be helpful. Prognosis is good in HS. Muscle enlargement usually regresses over time, but may persist in a few cases.

Clinical features of HM include cramps, muscle weakness, myalgia, stiffness, myxedema, and hyporeflexia. Muscle hypertrophy, wasting, and rhabdomyolysis are unusual features.[9] Rhabdomyolysis is a rare life threatening complication being precipitated by trauma, exercise, alcohol, and electrolyte disturbances. Rarely HM may present as acute compartment syndrome being precipitated by thrombosis, surgery, trauma, or IV drug abuse.

Differential diagnosis of calf muscle (gastrocnemius) hypertrophy include Duchenne and Becker muscular dystrophy, sarcoidosis granuloma, amyloid, and focal myositis.[10]

Myoedema is a classical sign of HM but is uncommon and hence is mostly missed by clinicians. It is demonstrated by percussion or applying pressure stimulus with thumb and index finger on the muscles of arm, especially biceps belly. This causes the muscle to form a visible palpable, nontender, firm, localized swelling around the site of stimulus. The swelling reaches its maximum size after 1–2 seconds and gradually subsides over 5–10 seconds so that the muscle regains its normal contour with no palpable localized hardening. The swelling does not spread elsewhere along the muscle. Myoedema is due to prolonged muscle contraction caused by delayed calcium reuptake by the sarcoplasmic reticulum after the stimulus causes release of local calcium. Differential diagnosis of myoedema is from malnutrition, hypoalbuminemia, hypovitaminosis, and hypothyroidism.[11]

Hyperthyroid Myopathy

Various names are Graves myopathy, thyrotoxic myopathy, Basedow myopathy, or Basedow paraplegia. It was described in early nineteenth century by Graves and Von Basedow documented in severe hyperthyroidism. There are two types of muscle fibers—Type 1 or Slow fibers are required for sustained effort like standing, while Type 2 fibers are fast fibers required for short rapid bursts like sprinting. In hyperthyroidism, there is increased production of ATP and reuptake of calcium. This results in very rapid contraction and relaxation. When this process occurs repeatedly, the structure and mechanics of slow fibers is changed to fast fibers so that muscles lose their endurance, become fatigued, weak, and wasted.

Hyperthyroid (thyrotoxic) myopathy occurs due to overproduction of thyroid hormone, that is, thyroxine.

Etiology includes mostly multinodular goiter and Graves' disease. Clinical features consist of muscle weakness, fatigue and heat intolerance, difficulty in climbing stairs, and proximal myopathy. If untreated, it can lead to marked debilitating condition and rarely death.[12]

Hyperthyroid myopathy can be acute or chronic. Acute hyperthyroid myopathy is rare than chronic hyperthyroid myopathy. It occurs due to rapid degradation of muscle fibers so that patients complain of severe muscle pain, muscle cramps, blurring of vision, and bulging eyes. It may present with more severe proximal and distal weakness and rarely quadriplegia with bulbar and respiratory involvement. Patients develop rhabdomyolysis and severe respiratory failure requiring artificial ventilation.

Chronic hyperthyroid myopathy develops after 6 months of onset so that symptoms appear slowly in the form of increased fatigue and difficulty in performing certain tasks. Some patients in thyrotoxic myopathy may have involvement of upper motor neurons related to pyramidal tract dysfunction as well as lower motor neuron symptoms related to peripheral neuropathy. This may overlap with those of amyotrophic lateral sclerosis (ALS).[13] However, there is no association found between hyperthyroidism and motor neuron disease.

Some patients of hyperthyroid myopathy may present with sensory polyneuropathy, carpal tunnel syndrome, headache, seizures, ischemic cardiovascular disease especially in patients of hyperthyroidism with atrial fibrillation, as well as cerebral venous thrombosis occurring as a result of hypercoagulable state, and auto immune mechanisms. Rarely, Guillain-Barré syndrome and chronic inflammatory demyelinating polyneuropathy have been associated with hyperthyroid patients.

Pathophysiology

Excess of thyroid hormone, that is, thyroxine, causes degradation of muscle fibers, especially at the motor end plates of neuromuscular junction. There occurs low level of acetylcholinesterase (AChE), which breaks down ACh in neuromuscular junction. Decrease in AChE blocks degradation of ACh causing Ach to overstimulate motor end plates of muscle fiber. Ultimately overstimulation of motor end plate leads to more sustained muscle contraction resulting in fatigue, muscle weakness and degradation occurring as a result of overproduction of thyroxine.[14]

Other theory of hyperthyroid myopathy is decrease in protein kinase affinity to cAMP within muscle fibers resulting in increase in cAMP within muscle fibers, which ultimately causes increased release of calcium from muscle fibers' sarcoplasmic reticulum. Finally, it results in more muscle contractions.[15]

Chronic hyperthyroid myopathy can be so severe that the patient may develop winging of scapula. If the myopathy progresses untreated, then patient may have involvement of muscles of face, swallowing, and respiration.

Ocular myopathy: It is also called dysthyroid ophthalmopathy, or exophthalmic ophthalmoplegia. It is more common in females. It may or may not be associated with chronic thyrotoxic myopathy. It may occur even after treatment for hyperthyroidism. In severe cases it may result in blindness and severe residual deficit.

Thyrotoxic periodic paralysis: It is a rare clinical entity mostly occurring in young adult Asian males in age group of 25–30 years. It manifests as sudden episodes of muscle weakness involving muscles of trunk and limbs, developing over a few minutes to hours, and lasting for hours to a few days. It is due to altered muscle membrane excitability secondary to hypokalemia. It reverses spontaneously or requires potassium. Patient may die due to cardiac arrhythmias. Many cases have been reported in the literature.[16]

Diagnosis: Laboratory investigations include CBC, FT3, FT4, TSH, serum sodium, serum potassium, serum calcium, serum phosphorus, blood glucose, blood urea, serum creatinine, serum vitamin B12, serum folic acid, ECG, auto antibodies against thyroid disease, CPK, CPK-MB levels (muscle enzymes), lipid studies, ultrasound of thyroid, hand-held dynamometry, EMG, nerve conduction study, and muscle biopsy, if needed. Normal levels of CPK may reveal early stages of progression while increased levels indicate late stages of progression.

EMG findings of thyroid myopathy include polyphasic action potential with early recruitment full interference pattern. Electromyography (EMG) findings in HM may show low/small amplitude potentials suggesting myopathic changes although it may be normal in half of the patients.

The distal muscles in thyrotoxic patients may show EMG findings of a rather neuropathic process. EMG is used

to diagnose myopathies by comparing muscle contraction responses to electrical stimulus. Response may be normal or myopathic. Muscle biopsy findings in case of HS include muscle fiber hypertrophy, increased nuclei, mucous deposits at places with increased inter fiber ground substance consistent with thyroid myopathy. Muscle biopsy in hyperthyroid myopathy is not specific but may show mild atrophic changes and type 2 fiber predominance. Management of HM consists of thyroid hormone administration and hyperthyroid myopathy treatment consists of antithyroid drugs (propylthiouracil, methimazole), radioactive iodine or surgery in the form of partial or total thyroidectomy. Treatment of thyroid myopathy is carried out by multidisciplinary team consisting of neurologist, endocrinologist, surgeon, ophthalmologist, and physical therapist. Aim in hyperthyroid myopathy is to reduce overproduction of thyroxine from the thyroid gland. While in HM aim is to correct thyroid hormone deficiency by administration of thyroid hormone. Thyroid replacement usually leads to resolution of laboratory abnormalities and symptoms over a few weeks. However, weakness may take months for recovery. Ultimate goal is to restore normal hormone homeostasis.

Conclusion

Neuromuscular symptoms and signs are common in 75% of hypothyroid patients and 67% of hyperthyroid patients because the skeletal muscle is a major target of thyroid hormone.[17] It is uncommon for a patient with hypothyroidism to present with muscle weakness as the chief complaint. Patients of hyperthyroid myopathy usually report after the age of 40 years unlike patients of hypothyroidism. Clinical suspicion supported by laboratory investigations is needed to diagnose patients of both hypo- and hyperthyroid myopathy. Weakness in hyperthyroid myopathy develops early but resolves completely during treatment, thus suggesting a functional muscular disorder.

CHAPTER

200 Impact of Altered Thyroid Status on Diabetes: Partners in Metabolic Malfunction

Swati Srivastava

Abstract

Diabetes and thyroid dysfunction have impact on each other and mutual interdependence has been a matter of interest since long. The prevalence of thyroid disorder in people with diabetes was found to be higher than in general population. Diabetic patients with hyperthyroidism experience a deterioration of glycemic control. Thyroid hormone excess can sometimes precipitate ketoacidosis in diabetic patients. About half of the patients with Grave's disease exhibit glucose intolerance of variable degree and about 2–3% may develop overt diabetes. Hypothyroidism is the most frequently encountered thyroid disease in patients with diabetes. Studies have found the occurrence of hypothyroidism in 5.7% patients suffering from diabetes. In individuals with T1DM, repetitive events of hypoglycemia hint toward hypothyroidism.

Introduction

The two most often seen endocrine disorders in medical experience are diabetes mellitus and thyroid abnormalities. Thyroid dysfunction is found to occur more frequently in patients with diabetes as compared to the general society.[1,2] Diabetes and thyroid dysfunction have impact on each other and mutual interdependence has been a matter of interest since long. Increasing body of evidence suggests a pattern of multiform combination of biochemical, inherited, and endocrinal defects leading to this pathophysiological interdependence. Epidemiologic data reveal that thyroid dysfunction is seen in 13.4% of diabetic population. Amongst the patients with diabetes, the subgroup having maximum prevalence of thyroid dysfunction were females with type 1 diabetes (31.4%) and minimum were males with type 2 diabetes (6.0%).[1] Thyroid hormones play role in metabolism, energy disbursement as well as insulin sensitivity. Vis-a-vis diabetes impacts TSH responsiveness to thyrotropin releasing hormone and causes low T3. The reciprocal interlinkage between thyroid hormone levels and diabetes mellitus has clinical connotation.

Epidemiological studies have shown similar genetic background for diabetes mellitus and thyroid disorders. However, the common genes identification is presently focused on the autoimmune etiology. The closest connection seen amongst type 1 diabetes and autoimmune thyroid diseases have relation with HLA class II sequences.[3] There is evidence to propose the likelihood of impact of intracellular T3 on insulin sensitivity.[4]

It is said that rectification of abnormal thyroid status in individuals with diabetes will enhance blood glucose levels, diminish cardiac and other complications chances, and improve overall health. However, there is dearth of unanimity concerning timing and periodicity about thyroid assessment to be conducted in standard approach to diabetes management.[5]

Hyperthyroidism and Glucose Metabolism

Thyroid hormones may affect glycemia secondary to their influence on glucose metabolism. Hyperthyroidism is known to increase blood sugar levels.[6]

Increase in thyroid hormones lead to enhanced intestinal absorption of glucose, insulin clearance,

glycogenolysis and gluconeogenesis.[7] The hepatic glucose output is increased with decreased insulin action and increased lipolysis.[7]

Hyperthyroid patients encounter decline in blood sugar control if they are also suffering from diabetes mellitus. Thyroid hormone excess can also sometimes precipitate diabetic ketoacidosis in diabetic patients.[8] Also, the clinical features of hypermetabolic state of thyrotoxicosis and those due to hyperglycemia may be confused among each other leading to missing the diagnosis.

About half the patients of Grave's disease exhibit glucose intolerance of variable degree and about 2–3% may develop overt diabetes.[6]

There is an escalated β-cells reaction to blood sugar levels/catecholamines perhaps secondary to expanded β-cell volume. Patients with elevated thyroid hormones may also have enhanced removal of insulin. Hyperthyroidism leads to increased glucose output from the liver and upregulates glycogenolysis producing glucose intolerance **(Flowchart 1)**.[9,10] It has been advocated that there is hypothalamic sympathetic impact on liver along with enhanced expression of hepatic GLUT 2 transporters with resultant increase of plasma-free fatty acids.[5] This situation accounts for magnification of elevated blood glucose levels in diabetics. Thyrotoxicosis can also result in state of ketoacidosis in patients with diabetes. This is secondary to the accelerated lipolytic activity and escalated liver β-oxidation.[7,11]

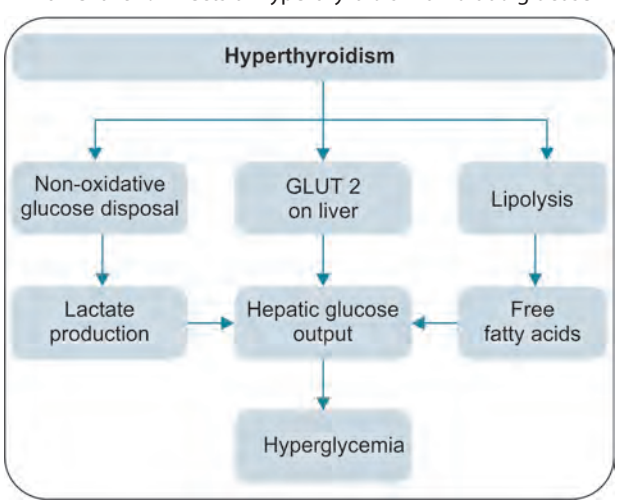
Hypothyroidism and Diabetes Mellitus

The most often thyroid disease that we come across in diabetes is hypothyroidism. Studies have found the occurrence of hypothyroidism in 5.7% patients suffering from diabetes.[1] The most common etiology in iodine sufficient regions being autoimmune thyroiditis.

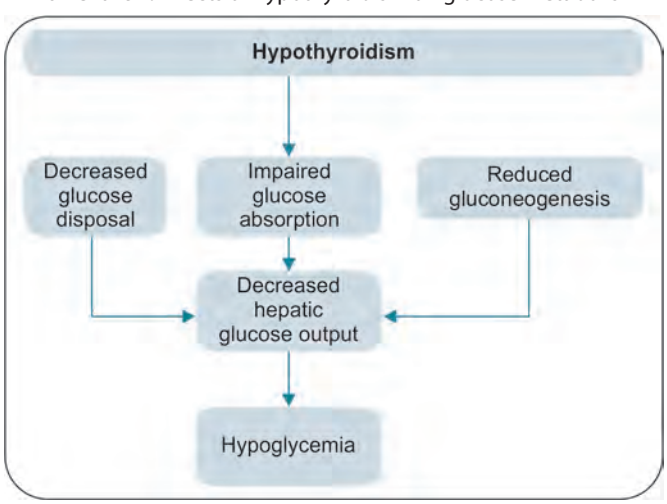
In individuals with T1DM, repetitive events of hypoglycemia hint toward hypothyroidism. It has been shown that treatment with thyroxine lowers the blood glucose variations.[12] It is documented that insulin resistant condition is seen in both overt as well subclinical hypothyroidism.[13]

The impact of reduced levels of thyroid hormone on metabolism in diabetic patients is contrary to that observed in hyperthyroidism.[5] Reduced thyroid hormones lead to reduced glucose absorption from gastrointestinal tract. Extended peripheral glucose accretion, lessened hepatic glucose yield, gluconeogenesis and lower peripheral glucose use is witnessed in hypothyroidism.[5] The insulin stimulated glucose transport and GLUT expression are lowered. Insulin clearance is reduced and less hunger further decreases insulin. A combination of all these metabolic alterations in patients with diabetes and coexistent hypothyroidism lead to reduction in blood sugar with increased frequency of hypoglycemia **(Flowchart 2)**.[14] Studies have also shown reduction and benefit in hypoglycemic episodes following treatment of hypothyroidism.[15] Studies have correlated hypothyroidism with lowered insulin sensitivity.

Flowchart 1: Effects of hyperthyroidism on blood glucose



Flowchart 2: Effects of hypothyroidism on glucose metabolism



Other factors:

- Role of thyroid hormones in lipid metabolism has been studied by many authors.
- They work along with controlling route for energy equilibrium and directly modify insulin equipoise and glucose disbursement by tissues.
- Triggering of melanocortin receptor type 4 (MC4R) brings about lowering of food ingestion and elevation in energy disbursement. Hypothalamic TRH neurons express these receptors which play role in central pathways of energy control.[16]
- Thyroxine relates to adipocytokines and gut hormones disturbing carbohydrate metabolism.
- Ghrelin hormone which impacts insulin sensitivity has been observed to have counter alliance with T3.
- The β-cell activity of insulin secretion mediated by glucose also is reduced in low thyroid hormone status.

Does Diabetes Mellitus Modify Dysfunctional Thyroid Status?

Diabetic patients have dampened diurnal TSH climax occurring at night. Also, there is weakened TSH response to TRH. Low T3 levels are witnessed in individuals with unchecked diabetes mellitus. It is seen that in diabetic individuals with unrestrained blood glucose, there may be blunted T4 to T3 conversion leading to low T3 state, which corrects with normalization of hyperglycemia.

Evidence suggests that reduced insulin sensitivity and hyperinsulinemia may cause multiplicative sequel on thyroid tissue resulting in thyromegaly and nodularity. Presence of concomitant diabetes also changes therapeutic response to thyroxine in hypothyroidism. Patients with Grave's orbitopathy have an increased prevalence of type 1 diabetes mellitus as compared to general population. Dysthyroid optic neuropathy has higher occurrence with patients with diabetes mellitus and Grave's orbitopathy as compared to those without diabetes mellitus.[17]

Does Thyroid Dysfunction Affect Diabetic Complications?

Diabetes is a well established individual predisposing cause for cardiac ailments. Hypothyroidism is known to have independent association with atherosclerotic cardiac diseases.[18] Coexistence of these disorders augment the cardiovascular risk of the patient.

Lipid profile disturbances are recognized in patients with hypothyroidism. Elevated total cholesterol, LDL cholesterol, apolipoprotein B, and decreased HDL are the typical findings.[19] Altered thyroid status has been correlated with dyslipidemia and insulin resistance in several studies. Literature also shows relation of hypothyroidism and obesity. Blood pressure changes in patients with hypothyroidism have also been studied by authors. Increase in systemic vascular resistance leading to high diastolic blood pressure has been documented in hypothyroidism.[20] Studies documenting higher intima media thickness in hypothyroid patients suggest endothelial dysfunction resulting in increased chances of CV risk.

The escalated peripheral vascular resistance and drop in cardiac output witnessed in subclinical and overt hypothyroidism put them to increased susceptibility to nephropathy. The diabetic patients with concurrent low thyroid hormones observed good renal response to therapeutic thyroid correction. Retinopathy seen in patients with diabetes was of greater intensity in subclinical and overt hypothyroid individuals than euthyroid people.[21] The above findings of high renal and eye complications documented in coexisting thyroid dysfunction in patients with type 2 diabetes provides rationale for assessing thyroid dysfunction in patients with type 2 diabetes mellitus.

Effect of Metformin on Thyroid Function

Studies document impact of metformin on thyroid function. Metformin given as therapeutic intervention for diabetes resulted in subduing of TSH in a study.[22] Another study conducted on thyroid nodules revealed a decrease in nodule size with use of metformin in patients with insulin resistance.[23] The studies show the effect to be without any changes in LT4 and LT3. Studies have also shown that following withdrawal of metformin there was some rebound rise in TSH levels.

Do Hypothyroid Individuals have Factitious Spike in HbA1c?

- Rising HbA1c in hypothyroid patients was witnessed in non-diabetic subjects also in a study.[24] The possibility of false spike probably owing to the lower hemoglobin levels in hypothyroid subjects was suggested.

- This questions the validity of using glycosylated hemoglobin for diagnosis of diabetes and management in cases with concomitant thyroid abnormalities.

Summarizing diabetes mellitus and thyroid cross-linking:

- Diabetes + Euthyroid — Reduced T3, reduced responsiveness to TRH
- Diabetes + Hyperthyroid — Glycemic control worsens
- Non-diabetic + Hyperthyroid — Proceeds to glucose intolerance in half cases
- Diabetes + Hypothyroidism — More events of hypoglycemia

Is there any Difference in Diagnosis of Hypothyroidism in Coexistent Diabetes?

- The elucidation of tests of thyroid function in individuals with unrestrained diabetes may be erroneous.
- Typical alterations include a low-serum T3, a low-serum T4 caused by decreased protein binding, and a low-serum TSH level.
- The similar symptoms of pallor, fatigue, edema, and increase in weight being common to renal disease related to diabetes and hypothyroidism may cause overlooking the diagnosis of the other disorder if one is suspected.

When should we screen diabetics for thyroid dysfunction:

- The significant interdependence seen between thyroid function and metabolic status in T1DM patients warrants timely and adequate monitoring of thyroid levels in these subset of patients.
- Regarding T2DM patients, the consensus regarding thyroid testing is less lucid. There are either no clear cut recommendations regarding once a year screening or in opposition to routine annual estimation of thyroid status in these patients.
- More often testing for thyroid abnormalities in diabetic individuals is approved.
- Similarly, some associations endorse analysis of thyroid status in pregnancy with diabetes. They propose TSH estimation along with palpation of the thyroid gland at identification of diabetes, with systematic observation thereof in individuals with positive results.
- On similar grounds, in those with abnormal lipid profile, age more than 50, TSH is proposed.
- A recent analysis by Kadiyala et al. suggested a comprehensible perspective to this matter. An initial TSH and TPO antibody assessment in patients with diabetes was advocated. Accordingly a high-risk group could be identified. This group would be consisting of T1DM patients, those with elevated TSH and those with TPO antibody positive. An annual TFT evaluation in this subset would be more likely to be cost effective and yielding desired results.[4]

Conclusion

There is a multifaceted linkage between thyroid defects and diabetes mellitus. In individuals with normal blood glucose status, high thyroid hormones bring about glucose intolerance whereas amongst those with established diabetes the metabolic control gets disturbed. On the other hand, hypothyroidism increases the susceptibility of hypoglycemic episodes in diabetic individuals. Increased insulin resistance is another important feature associated with hypothyroidism. Obscure thyroid defects would have unfavorable consequence not only on diabetes but also on its complications. Therapeutic interventions of subclinical hypothyroidism in patients with diabetes would be advantageous. A structured and well outlined approach to thyroid testing in diabetic subjects is suitable; nevertheless, there is a paucity of categorical specifications in this direction.

CHAPTER

201 Thyrotoxicosis: Evaluation and Management

Manoj Saluja

Abstract

Thyrotoxicosis, or inappropriately high circulating thyroid hormone concentration causing surplus action at the tissue level, may present as a constellation of clinical manifestations. Causes vary depending on various factors like iodine intake, age, and geography. Diagnosing the entity begins with detailed history and clinical examination aided by tests like thyroid hormone profile, radio and nuclear imaging, Doppler sonogram, serology for antibodies. While management differs according to cause and patient, the target is to control symptoms (beta blockers, glucocorticoids) and treating the cause (surgery, anti-thyroid drugs, radiotherapy). Latest researches on autoimmunity and molecular targets have opened new horizons in term of diagnosis and management as well.

Introduction

Thyrotoxicosis, characterized by inappropriately high circulating thyroid hormone concentration causing surplus action at the tissue level, may present as a constellation of clinical manifestations.[1,2] Hyperthyroidism, a clinical subset of thyrotoxicosis, indicates inappropriately high synthesis and secretion of hormone(s) by the thyroid.[1,2]

Effective management of the disease demands an intricate knowledge of the etiologies, pathophysiology, and treatment options. A basic understanding of approaching a patient, clinical, and lab parameters is important, as is the knowledge about various therapeutic regimens.

Etiology

A multitude of causes have been identified, differing in frequency—depending on iodine intake (Graves' disease predominates in iodine sufficient regions, nodular thyroid disease in iodine deficient regions), age (toxic nodular goiter increases with age; autoimmune thyrotoxicosis is common in young and middle aged), and geography (painless thyroiditis seen in 0.5% of cases in Denmark, 22% in Wisconsin)[1,2] **(Flowchart 1)**.

Approach to a Patient with Suspected Thyrotoxicosis

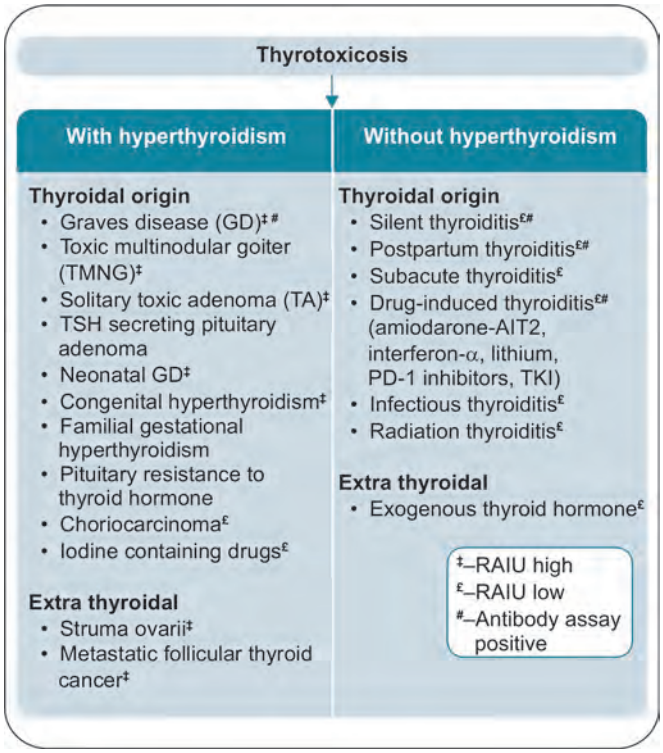
Combined and balanced assessment of history, clinical examination, and investigations guides the physician to diagnosis and management.

History

Clinical presentation, like medical and obstetric history, drug and diet intake, familial clustering of similar disease, is important. This provides an organized approach in less time, money, and resources.

Thyrotoxicosis has specific stigmata **(Flowchart 2)**[5] and may be suspected in presence of given signs and symptoms, concomitant type 1 diabetes/autoimmune diseases, new-onset atrial fibrillation, unexplained anxiety or change in behavior. Thyrotoxicosis typically presents with low thyroid stimulating hormone (TSH),

Flowchart 1: Causes of thyrotoxicosis[2-4]



AIT2, amiodarone-induced thyroiditis type 2; PD-1, programmed cell death 1; TKI, tyrosine kinase inhibitor; TSH, thyrotropin; TSHR, TSH receptor.

with (overt) or without (subclinical thyrotoxicosis) raised fT3 and fT4.

The **Flowchart 3** shows the approach to a patient with suspected thyrotoxicosis.[3]

Laboratory Investigations/Imaging

While thyroid profile (TSH, fT3, and fT4) is done to detect the disease, further workup assists in determining the underlying cause.

Radioactive iodine uptake (RAIU) using ^{123}I has become mainstay in diagnosing GD (diffuse uptake of radioactive iodine by the gland) and nodular thyroid disease (focal increased and decreased uptake in TMNG; uptake only in the nodule in TA). Anti-thyroid drugs (ATD) is given only in patients showing increased dye uptake, implying hyperthyroid state **(Fig. 1)**.

Color Flow Doppler Study (CFDS) is safe and efficient, particularly useful when RAIU is contraindicated (pregnancy/breastfeeding). It distinguishes between thyroid hyperactivity (increased flow) from destructive thyroiditis and between the two types of amiodarone-induced thyroiditis (AIT).[1]

Measurement of TRAb, especially in thyrotoxicosis without nodular signs/orbitopathy, distinguishes between GD and other etiologies. Young age, pre-existing autoimmune diseases, a positive family history are indications for antibody assays. Reduced cost and faster diagnosis have been proven in some studies when compared to RAIU.[1]

^{99m}Tc pertechnetate scan is used in nodular thyroid. Ratio of total T3 to T4 is useful in assessing hyperthyroidism. A hyperactive gland produces more T3 than T4, elevating T3 above the upper limit of normal more than T4. Vice versa is true in thyroiditis[1] and thyrotoxicosis factitia (exogenous levothyroxine). Acute phase reactants indicate active inflammation, as in subacute and infectious thyroiditis.

Management

We will discuss management of some of the common etiologies with a protocol for follow-up **(Flowchart 4)**.

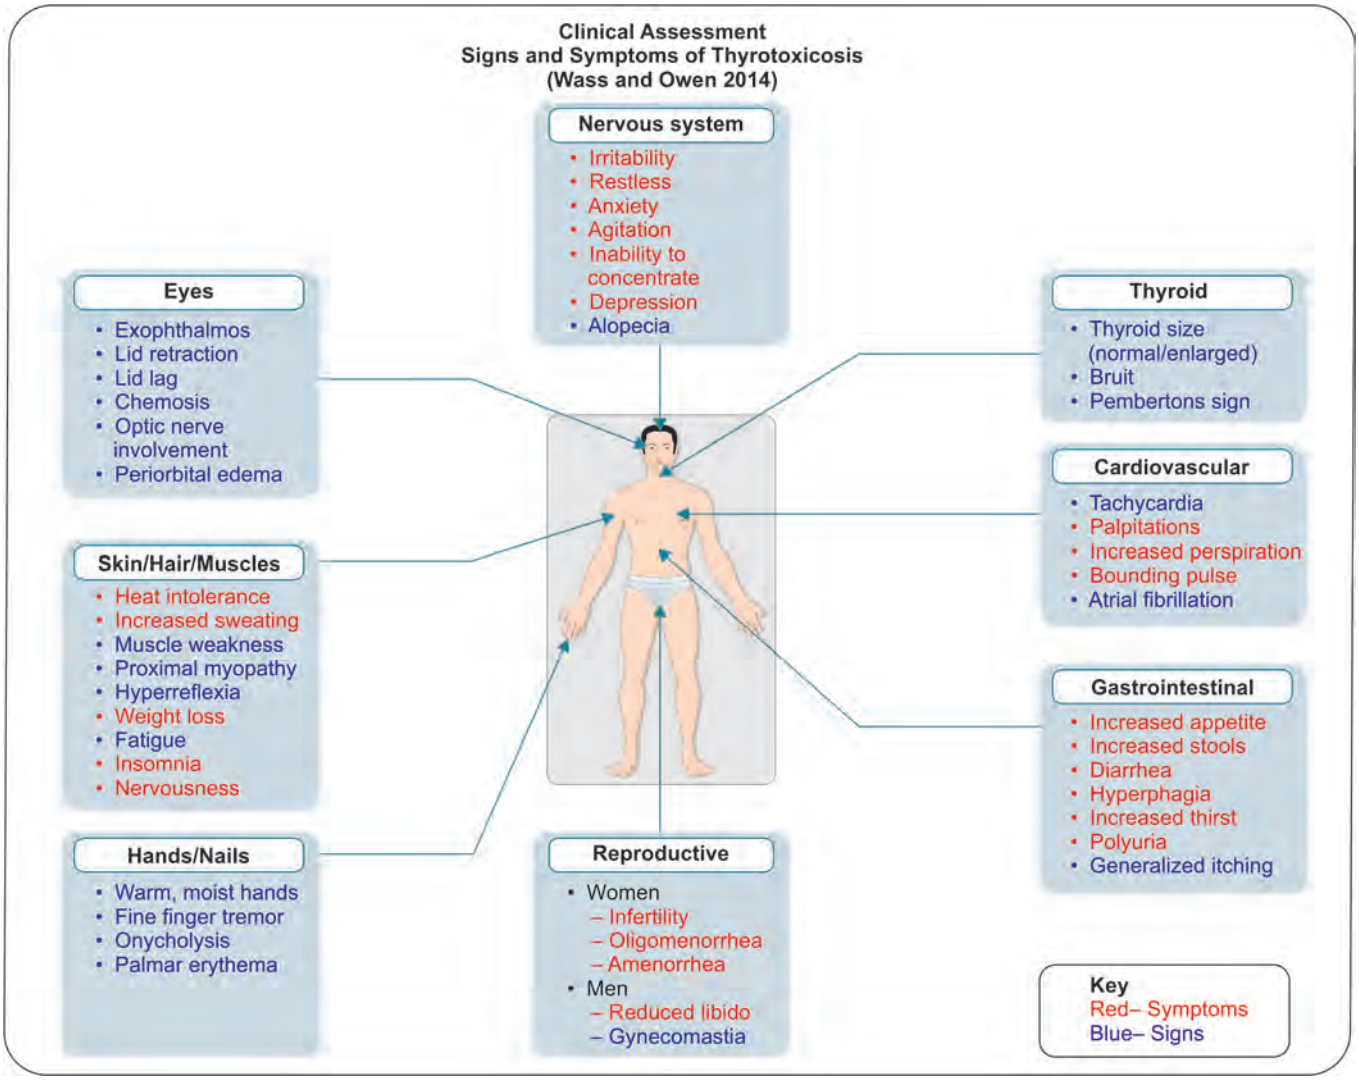
Graves' Disease

Follow two steps—one, symptom control and second, treat the underlying illness. Beta-blockers are used to abate symptoms (caused by overstimulation of beta adrenergic receptors). Propranolol (non-selective) additionally inhibits peripheral conversion of T4 to T3.[2] Glucocorticoids may be used in thyroid storm. For the underlying illness, radioactive iodine (RAI), ATD, and thyroidectomy are potential options. ATDs should be stopped 12–18 months after initiation to look for remission—defined as no recurrence of GD after 12 months without treatment **(Table 1)**.[2]

GD may be associated with ophthalmopathy, but only 5% develop severe symptoms (diplopia, visual field defects, and blurred vision). Mild symptoms like photophobia, irritation, and tearing can be solved using tight fitting sunglasses, saline drops/gel, and application of paper tape (at night) to avoid exposure keratitis. In case of corneal abrasion due to the tape, goggles are recommended. Medical emergency may ensue if orbital edema causes optic nerve compression. In such cases, high dose glucocorticoids and orbital decompression surgery are considered.

Dermopathy-nonpitting erythematous edema on anterior shin is due to glycosaminoglycan accumulation in dermis. High potency local steroid cream with nightly occlusive plastic wraps may be advised.[6]

Flowchart 2: Signs and symptoms (hyperthyroidism)



Young females may benefit from RAI and surgery more than ATD (better remission rates of former, high teratogenicity of latter), but comorbid condition/pregnancy or refusal to undergo RAI/surgery are indications to initiate ATDs.[2]

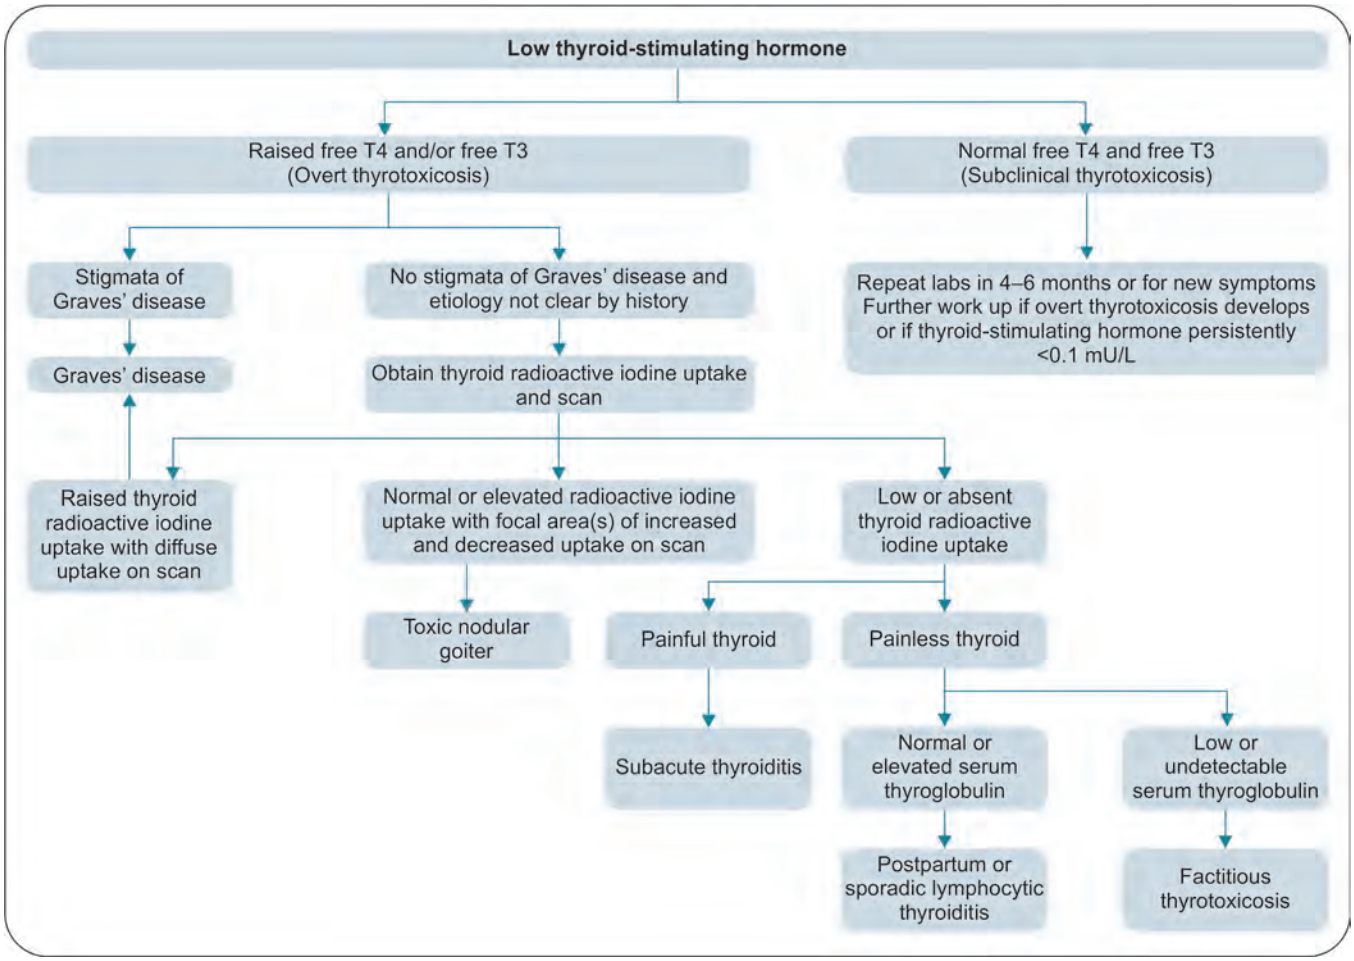
Toxic Adenoma and Toxic Multinodular Goiter

Toxic adenoma (TA) (benign monoclonal thyroid tumor) secretes excess thyroid hormones due to activating mutation in TSH receptor gene (increasing adenylyl cyclase independent of TSH). TMNG or Plummer's disease manifests as multiple autonomous nodules. Owing to this pathophysiology, ATDs show less satisfactory results and no remission despite long-term use. RAI and thyroidectomy are feasible and better management options. Selective uptake of the radioactive dye, as opposed to diffuse destruction as seen in GD, makes RAI first-line therapy unless contraindicated.[2] Risk of persistent hyperthyroidism is 11–20% with RAI and <1% with near-total/total thyroidectomy, but hypothyroidism at 5 years occurs in 16% and100%, respectively.[2]

Miscellaneous

Amiodarone-induced thyroiditis, caused by direct toxicity of amiodarone and its iodine content, is treated with

Flowchart 3: Approach to patient with thyrotoxicosis



long-term high dose ATDs and potassium perchlorate (type-1) or high dose prednisone (40–60 mg/day) for 1–3 months then tapered (type 2). Thyrotropin secreting pituitary adenoma is suspected if raised TSH with high T3, T4 is noted. Pituitary imaging (MRI) confirms the diagnosis. Apart from radiotherapy and/or radiosurgery, several new pharmacotherapies are being explored. Somatostatin receptors 2 and 5 on tumor cells have advocated somatostatin analogues as a possible cure or at least as a preoperative adjunct.[2,7] They also express dopamine receptors, but agonists have produced variable results.[2]

Hydatidiform mole, choriocarcinoma, testicular germ cell tumor, metastatic follicular thyroid cancer primarily require symptom control and multimodal approach to eradicate the root cause via surgery, radiation, or RAI. Detailed discussion is beyond the scope of this article.

Thyrotoxicosis without Hyperthyroidism

Subacute thyroiditis, seen post-viral infections due to antigenic mimicry, is painful but resolves spontaneously over a span of 2–3 months. It undergoes phases of hormonal changes: initially thyrotoxicosis caused by preformed hormone release followed by hypothyroidism due to the lack of new hormone synthesis during the disease period. Painless thyroiditis (seen in iodine sufficient areas), postpartum thyroiditis (seen after delivery/miscarriage) share an autoimmune etiology with a positive family history found more often than not. Supportive treatment is indicated beta-blockers, NSAIDs, and prednisone (for pain relief). During the latter part of disease, levothyroxine should be supplemented and tapered gradually while monitoring the hormone levels every 3–4 weeks. Selenium therapy has been tried in some

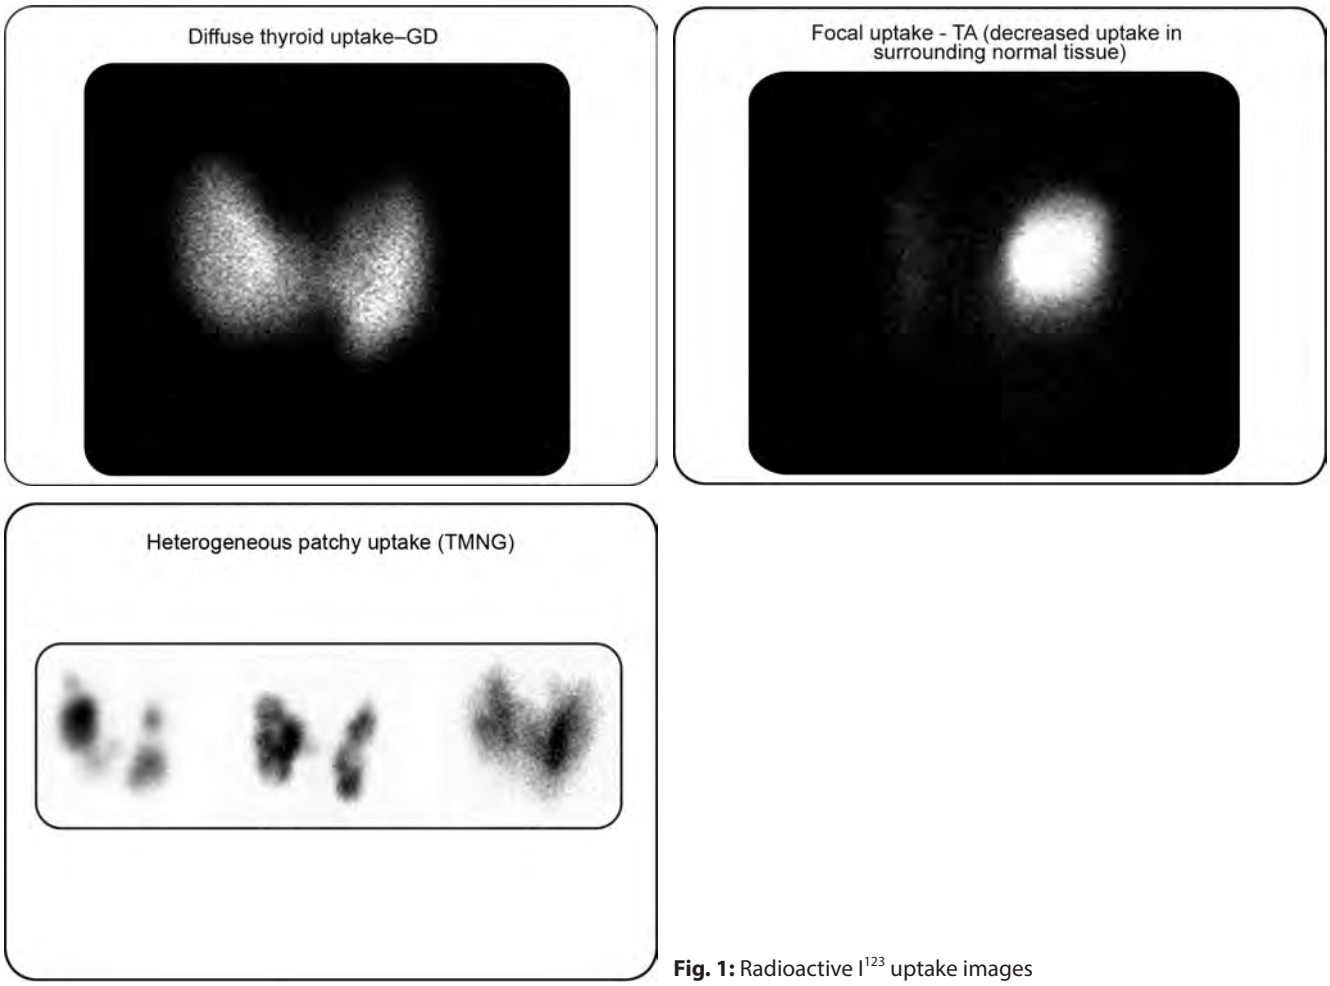


Fig. 1: Radioactive I^{123} uptake images

cases with inconsistent results.[2,8] Drug induced thyroiditis (sunitinib, sorafenib, ipilimumab, and pembrolizumab)[2,9] demands removal of offending agent and beta-blockers.

Exogenous Thyrotoxicosis

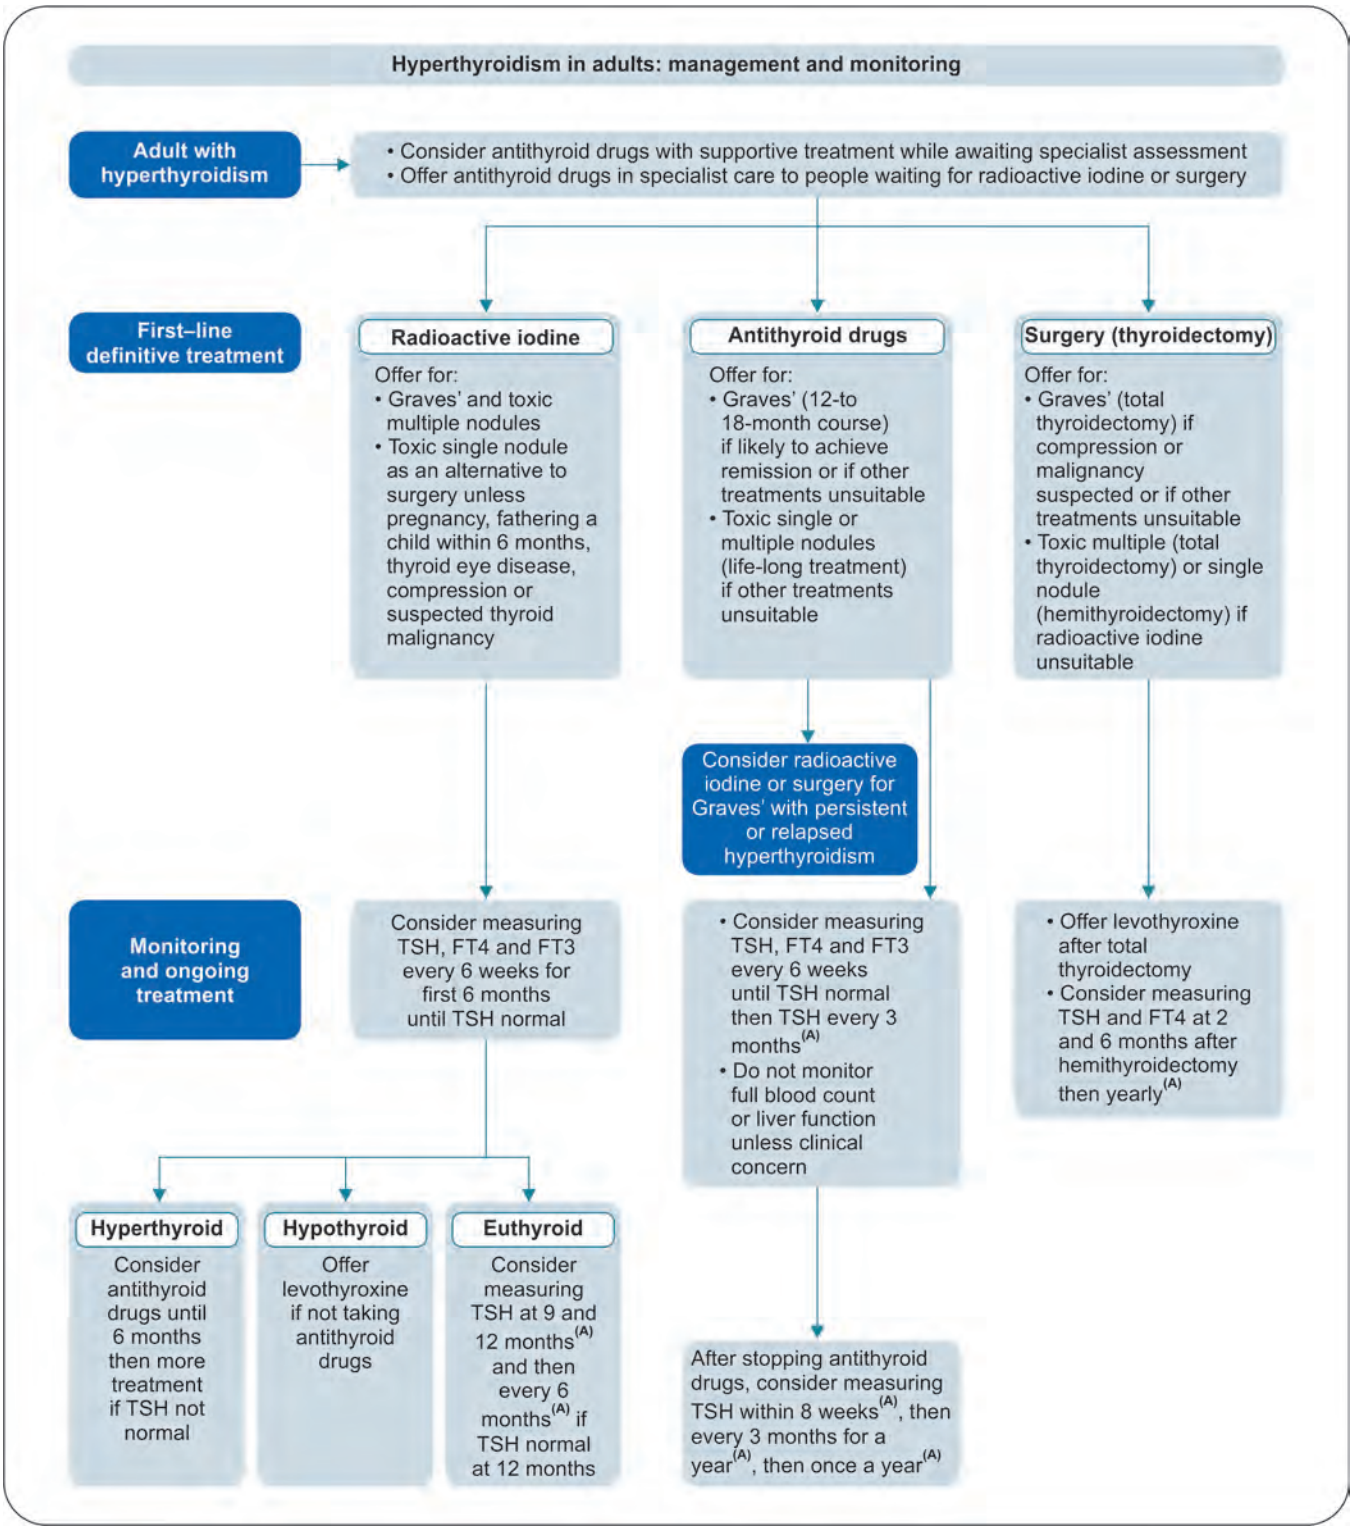
This may be accidental or intentional (thyrotoxicosis factitia). Intentional overdose needs appropriate counseling[2] along with beta-blockers, iopanoic acid and cholestyramine. In extreme cases, plasmapheresis may be required.[2,10]

Antithyroid Pharmacotherapy

ATD (methimazole, carbimazole, and propylthiouracil) inhibit formation of iodotyrosines in thyroglobulin (takes 2–8 weeks). PTU remains drug of choice in thyroid storm (due to its peripheral inhibition of T4 to T3) and in first trimester pregnancy. Methimazole and carbimazole have longer duration of action with once daily dosing, ensuring better compliance. Owing to teratogenicity (cutis aplasia), they are less preferred in first trimester of pregnancy, but may be restarted post 12 weeks gestation.[1,2,6]

ATDs should be titrated every 4 weeks. Adverse reactions are mild—include fever, rash, urticarial and arthralgia, usually seen within first week of treatment. Grave side effects include agranulocytosis, aplastic anemia, hepatic failure, lupus like vasculitis. Except agranulocytosis, all are more common with PTU. Granulocyte colony-stimulating factor (G-CSF) appears to accelerate recovery in patients with agranulocytosis. Dipping prevalence of these side effects from 30/1,000 to 1/1,000 at the end of 30 and 180 days, respectively, establishes safety in long-term therapy, especially in GD.[1,2]

Flowchart 4: Management and follow-up of thyrotoxicosis[4]



(A)With cascading--measuring FT4 in the same sample if TSH above reference range, and FT4 and FT3 in the same sample if TSH below reference range

TABLE 1 Treatment of Graves' disease

Treatment	*Mechanism*	*Dosing*	*Remission rate (%)*	*Adverse effects*	*Pregnancy*
ATDs[a] • MMI • PTU[b]	Block TPO	Initial dose proportional to degree of elevation of thyroid hormones, symptoms, and goiter size	30–60	Dose and duration dependent Rash, elevated liver enzymes, agranulocytosis (0.3%), vasculitis (<0.1%)	*MMI* ↑ Risk of congenital abnormalities; recommended in 2nd and 3rd trimester. *PTU* Lower teratogenic risk, ↑ risk of hepatotoxicity; recommended in 1st trimester All ATDs ↑ Risk of fetal hypothyroidism
Radioactive iodine I^{131}	Thyroid follicular cell necrosis	Fixed or calculated dose based on goiter size and uptake	80–90	Worsening thyrotoxicosis/ orbitopathy, Thyroiditis	Contraindicated
Thyroid surgery	Removal of thyroid tissue	Total thyroidectomy	100	Hypoparathyroidism, laryngeal nerve injury	Done in 2nd trimester

a ATDs, anti-thyroid drugs; MMI, methimazole; PTU, propylthiouracil; TPO, thyroid peroxidase; T3, triiodothyronine; T4, thyroxine; ↑, increased.
b Blocks TPO and peripheral T4 to T3 conversion.

Monitoring of liver function and explaining the possible reactions to the patients are quintessential. Up to 750 mg/day of PTU or 20 mg/day of methimazole in lactating mothers does not affect infants' thyroid function.[11]

Severe thyrotoxicosis calls for use of additive therapy with saturated solution of potassium iodide (SSKI) at a dosage of 10 drops twice daily, iopanoic acid at 1 g/day, cholestyramine (enhances enterohepatic clearance of thyroid hormone) up to 12 gm in three divided doses (for 4 weeks).[1,2]

Radioactive Iodine Therapy

RAI is effective, safe, avoids hospitalization with higher cure and lower recurrence rates. It causes thyroid specific fibrosis of the gland over weeks to months.[2] ^{131}I is administered at 75–200 μCi/g of estimated thyroid tissue divided by percent of ^{123}I uptake in 24 hours.[1]

It is absolutely contraindicated in children (<5 years), pregnancy (as it causes fetal hypothyroidism) and in lactating mothers. Patients are counseled to avoid conception for 3–6 months post RAI therapy. Severe ophthalmopathy could be exacerbated, so is either avoided or given with concomitant glucocorticoid therapy (prednisone 0.4 mg/kg for 1 month with subsequent taper).[2] To diminish the risk of worsened thyrotoxicosis, pretreatment with ATD (methimazole than PTU) may be considered for 3–5 days.

Thyroidectomy

Subtotal, near-total, total thyroidectomies are various options available. Severe hyperthyroidism in children, pregnant females noncompliant or intolerant to ATDs, patients with large goiters, severe ophthalmopathy, suspicious nodules, refractory AIT, and patients with unstable cardiac conditions are common indications.[6]

Prior to the surgery, euthyroid state should be achieved using beta-blockers (target heart rate <80/minute), ATDs (4–8 weeks) and stable (cold) iodine treatment. SSKI (1–2 drops twice daily for 10–14 days) is administered after ATDs and before the procedure. It reduces hormone secretion and decreasing gland vascularity (moderates intraoperative blood loss). Preoperative single dose dexamethasone (8 mg) is suggested avoid post-procedure nausea, vomiting, and pain.[1,2,6] Laryngeal nerve injury and hypoparathyroidism are possible complications. Hormone levels are checked every 4–8 weeks and T4 is titrated accordingly (started at 50–75 μg/day).

Endoscopic technique is a novel approach with better cosmetic satisfaction, lesser complications, and reduced time. Any surgical procedure, open, or endoscopic, yields better result if performed by a high-volume thyroid surgeon (>25 surgeries/year)[2,6,12]

Pitfalls, Controversies, and Unanswered Questions

Biotin has proven to cause spurious diagnosis of GD, especially at a dose of more than 10 mg/day, hence should be avoided for at least 12 hours prior to testing.[13] Second common pitfall is misdiagnosing iodine deficiency for thyrotoxicosis under the setting of increased radioiodine uptake by the gland. Amplified uptake but normal T3/T4/TSH implies iodine deficiency than endogenous hyperthyroidism.

Treatment of subclinical thyrotoxicosis has been a matter of debate for long. Current guidelines recommend treatment in case TSH is persistently <0.1 Mu/L.[12] Risk reduction of atrial fibrillation and low bone density in postmenopausal women is seen.

Questions concerning optimum dose and duration of ATD in GD, use of ATDs before and after RAI therapy, risk benefit ratio of block replacement regimen during RAI therapy, role of rituximab, lanreotide remain largely unanswered. Immunomodulatory therapy is being tested for GD.

Conclusion

The evaluation for cause should begin from the clinical picture itself to be supported by biochemical tests, nuclear medicine, and ultrasound imaging. Increased gland function remains an important aspect for therapy selection. GD and MNG remain the common causes. Long-term ATDs have replaced RAI and surgery for managing GD, except in special circumstances, while nodular goiter fare less well with ATDs. Thyroiditis constitutes major cause of thyrotoxicosis in absence of a hyperfunctioning gland. Thyroid autoimmunity has huge scope for developing novel therapies, particularly GD by addressing the pathophysiology itself. From redressal of less effective therapies to identifying newer targets at a molecular level, we have definitely come a long way with even better prospects in near future.

CHAPTER

202 Evaluation of Non-Diabetic Polyuria

Indira Maisnam, Soumita Mandal

Abstract

Polyuria is defined as urinary output more than 50 mL/kg/day or 3–3.5 L/day. It should be differentiated from increased urinary frequency by proper history and documentation of increased urinary volume. Polyuria can be due to solute diuresis or water diuresis. In most cases of solute diuresis the etiology is evident from history, physical examination and baseline laboratory investigations. For water diuresis a detailed history and physical examination and a number of tests consisting of serum sodium and other electrolytes, paired plasma and urine osmolality, water deprivation test, hypertonic saline infusion, and plasma copeptin levels help establish the diagnosis.

Introduction

Polyuria is defined as urinary output more than 50 mL/kg/day or 3–3.5 L/day.[1] It should be differentiated from increased urinary frequency. Polyuria can interrupt daily activities, disturb sleep, and cause bed-wetting in children. The two major types of polyuria are solute and water diuresis.

Water Homoeostasis

Extracellular fluid balance is under control of two factors: Antidiuretic hormone (ADH) also known as arginine vasopressin (AVP) and thirst. A rise in serum osmolality (most sensitive to serum sodium) and hypovolemia sensed by baroreceptors stimulate ADH secretion and thirst. ADH (V2) receptors are located at the luminal side of collecting duct of the kidney. On receptor binding, ADH leads to cAMP production with translocation of aquaporin 2 channels to luminal membrane, allowing reabsorption of water from lumen forming concentrated urine. Water moves out of the tubule along the concentration gradient created and maintained by reabsorption of solutes in thick ascending loop of Henle thereby producing hypertonic renal medullary interstitium. The sensation of thirst and ADH secretion is suppressed upon normalization of ECF volume and serum osmolality (280–295 mOsm/kg).

Determinants of Daily Urine Output

The daily urine output is dependent on solute load and concentrating ability of the nephron. Polyuria can therefore be solute diuresis, water dieresis, or both.

Solute diuresis due to excess saline/hypertonic saline infusion, protein excess with urea generation, glucose, and mannitol produces concentrated urine. Water diuresis (polyuria-polydipsia syndrome) producing dilute urine is of two types: diabetes insipidus (DI) and primary polydipsia (PP). In central diabetes insipidus (CDI), there is partial or complete ADH deficiency; in nephrogenic DI (NDI), there is resistance ADH action. Excessive water intake in absence of physiological stimulus, often in the background of psychiatric disorders is seen in PP. Sometimes solute and water diuresis coexist, for example, ADH deficiency/resistance with solute diuresis. Chronic

TABLE 1 Causes of polyuria

Osmotic diuresis	*Water diuresis (polyuria-polydipsia syndrome)*		
	Central diabetes insipidus (CDI)	*Nephrogenic diabetes insipidus (NDI)*	*Primary polydipsia (PP)*
Glucosuria **Urea diuresis** • Resolving phase of acute kidney injury • High protein diet • Glucocorticoid excess → protein breakdown → urea generation **Sodium diuresis** • Large volume of saline/ hypertonic saline • Post release of bilateral urinary tract obstruction **Mannitol**	**Tumors** • Craniopharyngioma • Pituitary tumor with suprasellar extension • Germinoma • Metastasis **Trauma** • Traumatic brain injury • Pituitary surgery • Pituitary apoplexy **Infiltrative/Autoimmune** • Lymphocytic hypophysitis • Langerhans cell histiocytosis • Sarcoidosis • IGF4 mediated • Immune check point inhibitors **Congenital/Genetic** • Familial CDI • Septo-optic dysplasia • Congenital hypopituitarism • Wolfram syndrome **Idiopathic** **Hypoxic encephalopathy**	**Congenital** • V2 receptor mutation • AQ2 channel mutation **Drugs** • Lithium • Amphotericin • Cidofovir • Foscarnet **Electrolyte imbalance** • Hypercalcemia • Hypokalemia **Renal disease** • Medullary cystic kidney • Adult polycystic kidney disease (ADPKD) **Obstructive uropathy** **Systemic diseases** • Sjogren's syndrome • Renal amyloidosis • Sickle cell disease	**Psychogenic** **Psychiatric illness** **Antipsychotics** • Causing dry mouth

renal failure, infiltrative renal parenchymal disease and relief of longstanding urinary obstruction sometimes have a mixed solute and water diuresis. Sometimes DI is seen in pregnancy due to placental vasopressinase increasing ADH breakdown and transient ADH resistance in second half of pregnancy **(Table 1)**.

Approach to a Patient with Polyuria

History

A detailed history regarding age and mode of onset, progression, and duration of polyuria and family history should be taken. Polyuria should be differentiated from increased urinary frequency. Hereditary NDI typically has a neonatal presentation; most craniopharyngiomas present in childhood and adolescence; infiltration, tumors, and metastasis present in any age. Polyuria with weight loss with family/personal history of diabetes mellitus suggests diabetes mellitus/uncontrolled hyperglycemia; polyuria after recent acute kidney injury, high protein diet/ supplement and after release of urinary tract obstruction suggests urea-induced diuresis. In glucocorticoid excess states, polyuria occurs due to hyperglycemia and protein breakdown with urea generation. A detailed medication history, history of head injury, or central nervous system surgery is important. Mannitol and hypertonic saline cause solute diuresis; many drugs cause NDI. Patients with DI prefer cold water; in CDI symptoms develop almost suddenly (as urine concentrating capacity is maintained until ADH synthesis decreases to 10–15% of normal); in PP symptoms develop gradually. Patients with PP may have coexisting psychiatric illness. These are not precise discriminating criteria and overlap exists in clinical features of CDI, NDI, and PP. The etiology of DI may be evident at presentation. Polyuria in a non-diabetic patient with breast cancer could be due to metastasis to posterior pituitary or hypercalcemia of malignancy. Metastasis to posterior pituitary is more common than to anterior pituitary as the systemic circulation supplies the posterior pituitary whereas the hypophyseal portal system supplies the anterior pituitary. DI due to craniopharyngioma may present with growth retardation and visual impairment.

Often the etiology is not obvious on presentation and unfolds as investigations progress, for example, infiltrative disorders, tumors, hypercalcemia, hypokalemia in Bartter syndrome, etc.

In most patients with DI, presence of intact thirst mechanism ensures that sodium levels are within normal. However, DI may present with hypernatremia in patients with limited access to water or unable to express thirst, for example, elderly people living alone, patients admitted in intensive care, infants, and in adipsic (impaired thirst) hypernatremia. Typically, patients with DI visiting a physician in out-patient setting complaining of polyuria have normal sodium levels; whereas those in intensive care setting, infants and elderly living alone may have hypernatremia.

Physical Examination

Clinical examination is unremarkable in most cases; however, one should look for wasting (diabetes, malignancy), evidence of glucocorticoid excess, and enlarged kidneys on abdominal palpation. Anthropometric evaluation in a child and confrontation perimetry is to be done when history or physical examination suggests sellar or suprasellar mass. Hypernatremic patients may have irritability, disorientation, unconsciousness, seizures, and focal neurologic deficits.

Investigations

Confirm Polyuria

While evaluating any case of polyuria, one must confirm it by advising patients to maintain a home fluid intake and output record. A 24-hour urine output and creatinine measurements help confirm polyuria and adequacy of urine collection, respectively.

Baseline Investigations

Baseline investigation include plasma glucose, HbA1c, urea, creatinine, complete hemogram, thyroid function tests, sodium, potassium, calcium, potassium, plasma and urine osmolality, urine routine examination including specific gravity (normal 1.010–1.025; low in DI); and other tests as history and physical examination suggest.

Paired Serum and Urine Osmolality

Baseline paired serum and urine osmolality gives valuable information. The hallmark of DI is production of large volume of dilute urine. Urine osmolality less than 300 mOsm/kg with normal, or slightly elevated serum, osmolality suggests DI. To ascertain DI type; confirmatory tests like water deprivation test and hypertonic saline infusion test are required. The water deprivation test is labor intensive and both tests entail some risk in susceptible individuals. Fortunately, the water deprivation and hypertonic saline tests are not indicated in every patient with polyuria.

Polyuria in Hypernatremic Patients

Hypernatremic patients with polyuria, with urine osmolality less than 300 mosmol/kg, have DI and water deprivation test is not required as ADH is already stimulated to maximally concentrate urine. The next step is differentiation between NDI and CDI by evaluating response to desmopressin **(Box 1)**.

Hypernatremic polyuric patients with urine osmolality more than 600 mosmol/kg have solute diuresis; however, mixed osmotic and water diuresis may be present. If on giving hypotonic fluids despite normalization of serum sodium, urine osmolality remains more than 600 msomol/kg, diagnosis is solute diuresis. If on giving hypotonic fluids, urine osmolality falls to 300–600 msomol/kg before sodium comes down to less than 145 mEq/L, diagnosis is mixed osmotic and water diuresis. If on giving hypotonic fluids, urine osmolality falls to less than 300 msomol/kg before sodium comes down

BOX 1 Assessing desmopressin response to differentiate between CDI, NDI, and PP

- Desmopressin is given at a dose of 10 µg by nasal insufflation or 2–4 µg subcutaneously or intravenously. Urine osmolality is measured every 30 minutes for the next 2 hours.
- **Complete NDI:** Urine osmolality rises <15% to a value <300 mOsmol/kg
- **Partial NDI:** Urine osmolality rises 15–45% to a value <300 mOsmol/kg
- **Complete CDI:** Urine osmolality rises >100% to a value >300 mOsmol/kg
- **Partial CDI:** Urine osmolality rises to 15–100% to a value >300 mOsmol/kg
- **Non-diagnostic:** Minimal or no rise in urine osmolality to a value >300 mOsmol/kg. In most cases non-diagnostic results are seen in partial CDI and PP
- **A baseline (without desmopressin) plasma copeptin >21.4 pmol/L suggest NDI**

to less than 145 mEq/L, diagnosis is DI. Desmopressin response will determine DI type **(Box 1)**.

Hypernatremic polyuric patients with urine osmolality 300–600 mosmol/kg may have solute or water diuresis. A total daily osmolar output (urinary osmolality × 24-hour urine output in litres) more than 1,000 mosmol indicates solute diuresis and less than 900 mosmol suggests water diuresis (DI). Desmopressin response will determine the DI type **(Box 1)**.

Polyuria in Normonatremic Patients

Normonatremic patients with urine osmolality more than 600 mosmol/kg have osmotic diuresis. The diagnosis is frequently obvious from history and laboratory investigations.

Normonatremic patients with urine osmolality 300–600 mosmol/kg may have solute diuresis, DI, or PP. A total daily osmolar output more than 1,000 mosmol indicates solute diuresis and lesser suggest water dieresis.

Normonatremic patients with urine osmolality of less than 300 mosmol/kg suggest water diuresis.

Determining the Cause of Water Diuresis in Normonatremic Patients

The next step in water diuresis is to determine the cause namely CDI, NDI, and PP.

If history and investigations suggest NDI, for example, bilateral urinary tract obstruction, hypercalcemia, long-term lithium use, and presenting in infancy with family history of DI; water deprivation test may not be done. A baseline plasma copeptin level or desmopressin response may be directly evaluated to confirm NDI **(Box 1)**.

In other cases of normonatremic polyuria [urine osmolality <300 mosmol/kg (and where NDI is not the obvious etiology) and total daily osmolar output <1,000 mosmol)]; water deprivation or thirsting test is done to raise the serum sodium more than 145 mEq/L and plasma osmolality more than 295 mosmol/kg to stimulate ADH to maximally concentrate urine.

The adequacy of ADH secretion and/or action can be assessed indirectly or directly. In indirect testing, at end water deprivation or hypertonic saline infusion, the urine osmolar response to exogenous AVP or desmopressin is assessed to classify the diuresis as CDI, NDI, and PP. In direct test, direct measurement of AVP or copeptin is done upon osmotic stimulation. Plasma AVP below, above, and at normal is diagnosed as CDI, NDI, and PP, respectively. However, AVP measurement provided a correct diagnosis in only 38% cases and was especially weak in differentiating partial CDI from PP.[2] AVP limitations include its platelets binding, instability in isolated plasma even at –20°C and insensitivity of commercially available assays.[3] Copeptin a 39-amino acid peptide is the C-terminal glycoprotein moiety of AVP prohormone pre-pro-vasopressin. It is cosecreted in equimolar amounts with AVP and neurophysin II. Copeptin is a surrogate marker for AVP secretion because of long half-life, insignificant diurnal variation, and absence of extraction step or pre-analytical procedures for testing.[4]

Water Deprivation Test

Before subjecting patient to the test, moderate fluid restriction for few days re-establishes medullary hypertonicity, which might have been lost (medullary washout) due to excessive water intake in psychogenic causes. This could have led to persistent serum hypoosmolality with wash out of solutes from medulla; hindering ADH mediated water reabsorption.

All fluids are withheld during the test to induce dehydration to stimulate maximal ADH secretion. It is important to ensure patients have no access to drinking water during the test (to avoid surreptitious drinking); avoid cigarette and caffeine in preceding 24 hours; and are free from non-osmotic stimuli for ADH release (e.g., nausea and vomiting). In patients with severe symptoms (e.g., complete forms of DI), few hours of fluid restriction cause sufficient dehydration. Thus, the test can be started in the morning. In mild disorders (e.g., PP), it can take several hours for sufficient dehydration, the test may need to begin the previous night. Duration of fluid deprivation may range 4–18 hours.

At the beginning of test, patient is asked to void urine and initial body weight measured. Hourly monitoring of body weight, serum sodium, urine volume, and urine osmolality is done. The test is terminated when dehydration is sufficient enough determined by body weight reduction of 3%, serum sodium more than 145 mEq/L or no further increase in urine osmolality (three consecutive urine samples with osmolality <30 mOsm/kg variability).[5] At test, termination plasma sodium, osmolality, and AVP/copeptin are measured. The patient is administered AVP or desmopressin and response

assessed. Giving exogenous AVP (or desmopressin) before serum sodium is more than 145 mEq/L cannot distinguish CDI from PP, since in both cases ADH levels are submaximal and will anyway respond to exogenous AVP or desmopressin. Therefore, maximum endogenous ADH secretion should be ensured by increasing serum sodium (>145 mEq/L) and osmolality (>295 mosmol/kg) before response to AVP or desmopressin is assessed.

Hypertonic Saline Infusion Test

Hypertonic saline infusion maybe used in place of water deprivation or may be used to supplement the water deprivation when it is insufficient to raise the serum osmolality to more than 295 mOsmol/kg and serum sodium more than 145 mEq/L (often in primary polydipsia or partial DI). 3% NaCl is infused @ 0.1 mL/kg/minute for 1–2 hours till serum osmolality and sodium are more than 295 mOsm/kg and more than 145 mEq/L, respectively. Hypertonic saline infusion should be avoided in high-risk individuals.

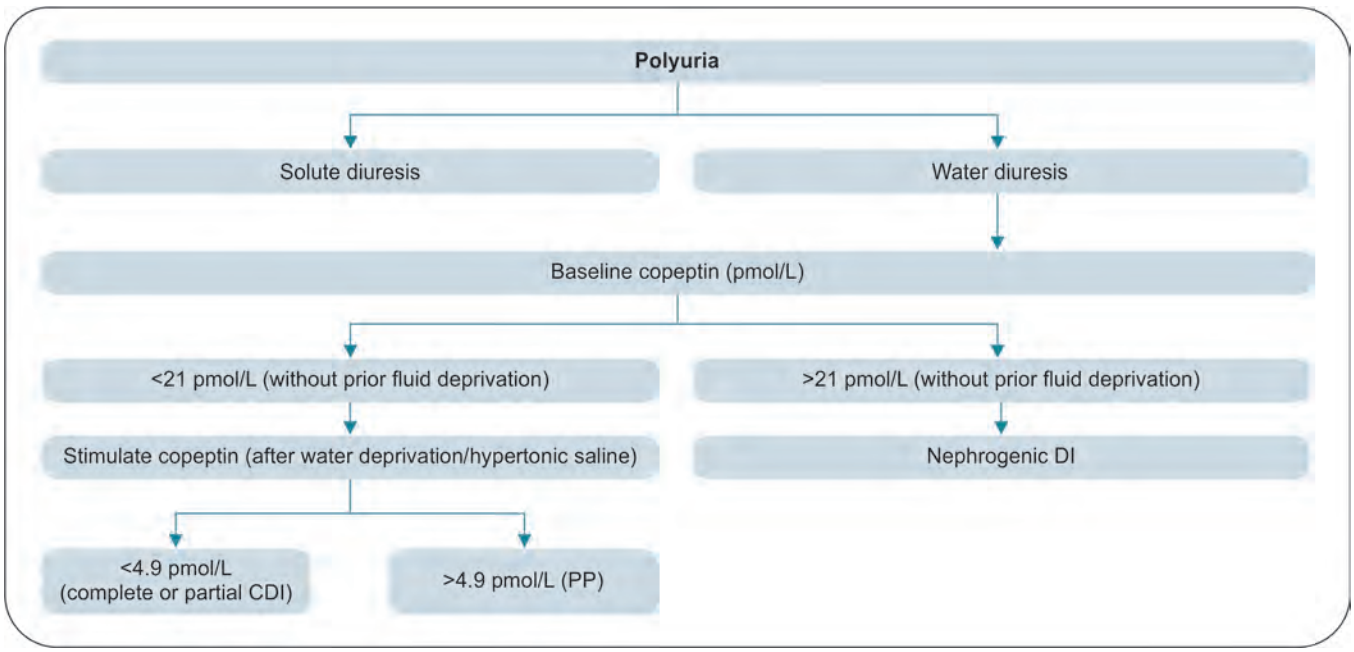
Interpretation[6,7]

- If at the end of water deprivation and/or hypertonic saline infusion test the urine osmolality more than 700 mosmol/kg, diagnosis is PP. If the urine osmolality less than 700 mosmol/kg it can be CDI, NDI, or PP.
- Assess desmopressin response, if urine osmolality of less than 700 mosmol/kg to differentiate CDI, NDI, or PP **(Box 1)**.
- Plasma copeptin more than 4.9 pmol/L at end of the test (when serum sodium was >145 mEq/L) suggests PP and lower value suggests partial CDI.
- Therapeutic trial of desmopressin help differentiates PP from partial CDI. Desmopressin 10 µg/day is given intranasally for 3 days. Patients are advised to limit fluid intake to 1.5–2 liters/day. Thirst and polyuria are assessed; and urine osmolality and plasma sodium measured twice daily. In partial CDI, there is resolution of symptoms of thirst and polyuria; whereas persistent thirst, non-adherence to fluid restriction, and development of hyponatremia suggest PP.

Polyuria in Hyponatremic Patients

Hyponatremia, low urine osmolality (less than half of plasma osmolality) in polyuric patients, suggests water overload due to PP. Hyponatremia, polyuria, and high urine osmolality suggests osmotic (solute) diuresis.

Flowchart 1: A simplified approach to polyuria



A Simplified Approach to Polyuria

Patients with polyuria should initially be classified as solute or water diuresis. In solute diuresis the cause is often obvious from history, physical examination, and baseline investigations. To further classify water diuresis, more tests are needed. Due to limitations of the indirect tests and increasing availability and reliability of copeptin measurements, a simplified approach to water diuresis is suggested **(Flowchart 1)**.[6]

Additional Testing

The polyuria type will determine additional testing. If history, physical examination, and laboratory evaluation suggest osmotic diuresis; the differential diagnosis are narrowed to diabetes mellitus, urea, saline/hypertonic saline, and mannitol. If evaluation suggests partial or central DI, MRI focusing on the hypothalamus and pituitary is required. It may show mass lesions; and loss of posterior pituitary bright spot in CDI. The bright spot results from T1-shortening effects of AVP stored in the neurosecretory granules. In PP the bright spot is usually seen. However, sometimes in NDI the bright spot maybe absent due to prolonged stimulus for vasopressin release. If evaluation suggest NDI; offending drugs, anatomic lesions of kidney and other systemic illness should be looked for. In PP no further testing other than counseling is required.

Conclusion

The diagnosis of polyuria can be challenging and needs to be differentiated from increased urinary frequency. A systematic approach, including detailed history, physical examination, and appropriate laboratory testing, helps in diagnosis in most cases.

CHAPTER

203 Postgraduate Clinic on Non-Thyroidal Illness Syndrome

Pankaj Kumar Agarwal

Abstract

Abnormalities in thyroid function test in a hospitalized patient are not always carried forward from the past; some do develop during the course of current systemic illness as well. Such abnormalities, where thyroid gland by itself is not at fault, are categorized under the heading, non-thyroidal illness syndrome. The commonest amongst such abnormalities is lowering of serum T3. Sometimes, serum T4 and TSH may also be reduced. These may develop because of alteration in synthesis, transportation, metabolism, or regulation of these hormones at different levels of hypothalamus-pituitary-thyroid axis. Most of these changes gradually return back to normal but the extent of correction and its exact course can't yet been defined very well. Therapeutic interventions in these cases have been found to be largely futile in most cases though T3 supplementation has been shown to be of partial help in some cardiac patients.

Introduction of the Clinical Case

Abnormalities in thyroid hormone tests (TFT) are a frequent finding in patients admitted in ICU or wards because of various systemic illnesses. Many of them have had normal TFT in the past and some are found with normal TFT in follow-up as well. This poses a question upon the genesis of these abnormalities in patients suffering from systemic illnesses. Today, in this Postgraduate Clinic, we will discuss about a similar patient and will try to understand the disorder in a thorough manner.

A 63-year-old female was admitted in near ICU for altered sensorium and right hemiplegia, two days back. Her TFT revealed low serum T3, low normal serum T4 and mid normal serum TSH. Her family members informed that her TFT was absolutely within normal limits, just 2 months back.

Question: Given this scenario, how would you interpret current low T3?

Answer: Normal TFT, and also normal T3, 2 months back suggests that the lady was not carrying any thyroid disorder in the past. Low T3 observed during cerebrovascular event can therefore suggest that it might have been produced by the effect of systemic non-thyroidal illness (NTI) on the thyroid hormones (TH) rather than being produced because of any organic disorder of the thyroid gland itself. Such abnormalities in TFT, which arise after any NTI and are not produced by the disorder of thyroid gland itself, are called non-thyroidal illness syndrome (NTIS). Considering TFT to be normal before and after the NTI, such abnormalities in the past were also known as *sick euthyroid syndrome*. The nomenclature has now been discarded because normalcy cannot be assured in future, always.[1,2]

Question: Name some disorders which can make a person prone for NTIS.

Answer: NTIS can be observed in as high as 70% patients admitted in the ICU.[3] Some common disorders associated with NTIS are as follows:

- *Severe critical illnesses*: Such as pneumonia, septicemia, MI, CHF, respiratory failure, IBD, cirrhosis, CRF, DKA, and malignancies.
- *Trauma and major surgeries:* Such as CABG
- *Deprivation of calories:* Such as starvation and anorexia nervosa[4]

Question: Does NTIS affect serum T3 only or it has any other clinical characteristics as well?
Answer: Clinical characteristics observed in NTIS are actually that of NTI and not because of abnormalities in TFT. Even total deficiency of TH may take as long as 2–3 weeks in producing its effects. So, even with the given abnormality of TFT, most patients appear to be clinically euthyroid. In the absence of any discernible clinical finding specific for the thryoid, NTIS is classified according to its laboratory characteristics only.

Low T3 syndrome—This is the commonest presentation of NTIS, which is seen in nearly 70% (40–100%) cases. It is often associated with elevated serum reverse T3 levels. Serum T4 and TSH levels are usually normal in the beginning.[3-5]

Low T4 syndrome—With the progression of systemic illness, serum T4 level also starts declining along with serum T3.[1]

Low TSH—Acute incident events such as major trauma, MI, or surgery are immediately associated with transient TSH elevation but progression of systemic illness may lead to fall in serum TSH levels in nearly 10% of such cases.[1]

Question: What could be the pathophysiology of abnormalities in TFTs in NTIS?
Answer: NTI may affect every aspect of TH including its secretion, peripheral metabolism, and action.

Low T3 syndrome (downregulation of T3 content in target tissues)—Low serum T3 is the initial feature of NTIS, which is associated with fall in tissue T3 concentration and its effects. It can be produced because of following factors.

Inhibition of conversion of T4 into T3—Approximately 80% of circulatory T3 is derived from the deionization of T4 by 5'-deiodinase type 1 (D1). NTIS leads to downregulation of D1 leading to reduced T4 to T3 conversion and therefore low serum T3.[6]

Inactivation of T3 and production of reverse T3—Another enzyme, 5'-deiodinase type 3 (D3), converts T4 into reverse T3. This is upregulated in NTIS leading to increased synthesis of reverse T3. In addition to converting T4 into T3, D1 is also responsible for metabolism of reverse T3. Downregulation of D1 in NTIS reduces its metabolism as well which is the main reason behind rise in reverse T3 in NTIS.[7] T4 metabolism in NTIS, thus is diverted toward the formation of bio-inactive reverse T3 in place of bioactive T3.

Inhibition of TH uptake into the cell and binding of T3 with its nuclear receptor—Numerous cytokines can be produced during systemic illnesses such as IFN-gamma and Nonesterified fatty acids (NEFA). These may interfere with the entry of TH into the target cell and their interaction with TH receptor. It creates a situation of tissue hypothyroidism in NTIS.[8]

Low T4 syndrome (downregulation of T4 content in circulation)—Fall in serum T4 is an indicator of rising severity of NTIS. This can be produced because of two main reasons.

Increased metabolism of T4—Systemic illnesses are often associated with fall in tissue perfusion. This may be associated with expression of D3 which converts T4 into reverse T3.[7] This leads to rise in serum reverse T3 level and fall in serum T4 level.

Inhibition of binding of T4 to TH binding proteins—Not only the metabolism, but the circulatory transportation of T4 is also affected in NTIS. As an acute phase reactant, serum albumin concentration falls in any acute illness. NEFA, which is otherwise bound to this albumin; therefore, increases in circulation. It displaces TH from TBG, which leads to fall in total T4 (and total T3) concentrations.[5] Free T4 and T3 hormone concentrations largely remain unaffected.[8,9]

Low TSH (central downregulation of hypothalamic TRH and pituitary TSH release)—NTIS may be associated with reduction in sensitivity of thyrotrophs toward TRH leading to fall in TSH secretion. This too may arise out of two reasons.

Cytokines induced direct suppression of TSH—Cytokines, especially interleukins (mainly IL6), tumor necrosis factor (TNF alpha) and interferons (IFN beta), can directly suppress thyrotrophs to reduce TSH secretion.[5]

Reduced stimulation of TSH secretion—Thyrotrophs possesses a different set of enzyme, deiodinase type 2 (D2), which converts intra-pituitary T4 into T3. T3 thus produced within the thyrotrophs is responsible for negative feedback and suppression of TSH secretion. This D2 is up regulated in NTIS, leading to rise in intra-pituittary T3 and suppression of TSH secretion.[6] NTIS,

thus is associated with exactly opposite effects on tissue T3 concentrations. Tissue T3 concentration falls in peripheral tissues but rises in thyrotrophs.

Reduced T3 concentration in target tissues and its reduced binding with TH receptors favors the hypothesis that NTIS is not merely an adaptive response to the systemic illness but is an actual state of "tissue hypothyroidism." Initial changes could be the compensatory responses toward a systemic illness but prolongation of this adaptation definitely becomes harmful in the long term.[8]

Question: What are the differential diagnoses for various abnormalities found in TFT in NTIS?
Answer: In fact, abnormalities in TFT, seen in NTIS, may mimic any organic disorder of the thyroid gland.

Low or low normal serum T3, T4, and elevated serum TSH level, sometimes found in the initial course of the disease may mimic Hashimoto thyroiditis and subclinical or overt hypothyroidism.

Midnormal or low normal serum T3, T4, and low TSH level, often seen in advanced NTIS may mimic subclinical thyrotoxicosis or central hypothyroidism.

NTIS may not only produce new changes in TFT, which may mimic organic disorders of thyroid gland, but may also interfere with the detection of its preexisting organic disorders as well. Chronic severe NTIS and use of dopamine or glucocorticoid therapy may lead to marked suppression of TSH secretion. This may interfere with the diagnosis of untreated or partially treated thyroprivic hypothyroidism. Similarly, low serum T3 in NTIS will change the reflection of T3+T4 thyrotoxicosis into T4 toxicosis alone.[1,8]

Raised serum T3, low serum reverse T3, markedly disturbed serum TSH (>20 mIU/L or <0.1 mIU/L) and presence of antithyroid antibodies may be the indicators of organic thyroid disorders along with systemic illnesses.[5,8]

Above mentioned facts preclude the policy of routine screening of critically ill patients for thyroid dysfunctions. In fact, during any critical systemic illness, only those patients should be screened for thyroid dysfunctions in whom there is a high degree of clinical suspicion of any organic disorder of thyroid gland.

Question: Does NTIS carry any prognostic significance as well?
Answer: Serum T3 levels have been found to be inversely proportional to the severity of NTI. Low serum T3 levels observed during coronary angiography are not only associated with significant morbidities but have been found to carry 1.8× higher risk of total mortality and 2.5× higher risk of cardiac mortality as well.[10]

Low T4 level with NTI actually points toward a much grave prognosis. Serum T4 <4 mcg/dL may increase mortality by 50% and level <2 mcg/dL may increase it up to 80%.[1,5,8,10-13]

Question: If low T3, T4, and TSH are so clearly linked with poorer clinical outcomes then should these patients be offered TH supplementation?
Answer: NTIS was earlier thought to be just compensatory adaptation of acute systemic illnesses only but the view is gradually changing. Now we know that this adaptation is not always beneficial for the patient. Many clinical studies have been performed in recent past to look for the effects of TH supplementation in such cases.

Intravenous T4 therapy—Intravenous T4 therapy (1.5 mcg/kg/d IV) has been tried in some critically ill patients with low serum T4 concentration. Contrary to the presumptions, it could not reduce total mortality rate.[14,15] Inability to normalize serum T3 level was opined to be the reason for its inefficacy.[8]

T3 Therapy—In an attempt to normalize serum T3 levels, T3 supplementation was also tried but this too could not reduce mortality.[16]

Till date, clinical benefits of TH supplementation have been observed in cardiac patients only.[17] Its hypothesized that IV T3 supplementation should at least be tried in patients with NTIS in whom serum T4 level is less than 4 mcg/dL. With clinical recovery in NTI, it can be switched to oral T4 supplementation.[8]

TRH therapy—Knowing that the hypothalamo-pituitary set point is low in patients with NTIS, TRH therapy has also been tried in it. It could successfully normalize serum TSH, T4, T3, and reverse T3 levels. Considering the catabolic state of these ill patients, addition of growth hormone to TRH has been found to be more effective in raising anabolic activities in these patients.[13,18]

Conclusion

It can clearly be understood that systemic illnesses can affect TFT in variety of manners. Many of these affections have been recognized well and there pathogenesis have also been deciphered up to some extent. Yet, there are still many unseen facets of this disorder which are restricting us from offering any meaningful therapy to our patients.

CHAPTER

204 Common Mistakes in Thyroid Disorders

Y Bhasker

Abstract

The knowledge on practical management of thyroid disorders with precision is ever expanding as a huge number of cases are detected because of easy availability of investigation facility. However, all the cases with abnormal results of thyroid function do not require treatment immediately, or nor ever. In this chapter, brief analysis of relevant investigation and modalities of treatment on such entities of thyroid disorders is presented.

Introduction

For long time, the diagnosis of hypothyroidism was only clinical. It used to be suspected only after manifestation of myxedema (spotters in undergraduate examination) and hyperthyroidism on development of features of Graves or hypermetabolic state. Later indirect tests like effective thyroxine ratio was available, but not within reach. Hence, clinical parameters were only the guidance to manage the cases until availability of triiodo thyroxine (T3), tetraiodo thyroxine (T4), and thyroid stimulating hormone (TSH).[1]

Ever since direct hormone assay (T3, T4, TSH) is widely available for past three decades, there is great leap in detection of number of thyroid disorders and management precision. In the last decade, diagnosis of thyroid disorders clinically has become a rarity and physician is encountered with abnormal reports of thyroid function tests for opinion. This is because the thyroid function tests are done as routine in non-thyroid illness and sometimes on self motivation. Potentially misleading reports may result in mistakes of management. In such a scenario, physician is expected to guide the patient for further appropriate investigations, final diagnosis, plan of long-term treatment, and management. This article focuses on discussed issues of thyroid functional disorders to guide the physician approach.

Common Mistakes

- Proceeding further without recheck of the laboratory results
- Not ordering further investigations
- Starting on medicines on certain thyroid disorders, which spontaneously remit
- Use and abuse of iodine
- Under utilization of radioisotope scanning of thyroid
- Hurry to start on medicines in subclinical hypo- and hyperthyroidism
- Monitoring of treatment of hyperthyroidism by TSH levels
- Selection of modalities of treatment (anti-thyroid drugs, radioiodine ablation, surgery) in hyperthyroidism
- Pregnancy versus thyroid disorders
- Diet restriction

Common Abnormalities in Thyroid Function Test (TFT)

- Increased TSH, normal/abnormal T3, T4
- Decreased TSH, normal/abnormal T3, T4
- Goiter or swelling of thyroid with normal TSH, T3, T4

Further investigations:

- Confirm the abnormality by repeating first line investigation TFT, since the treatment is prolonged and/or destructive
- Estimation of thyroid antibodies
  - Thyroid peroxidase antibodies (TPO)
  - Thyroglobulin antibodies (Tg-Ab)
  - TSH receptor antibodies (Tr-Ab), assay form of thyroid receptor stimulating immunoglobulin (TSI) used to predict neonatal thyrotoxicosis[2]

The above antibodies tests are neither 100% sensitive nor specific.[2,3] TPO assay is commonly done to assess the immune status of the disease, rest of the tests are not routinely done and expensive. TPO and Tg-Ab present in normal population, auto immune hypothyroidism, Grave's disease, multinodular goiter (MNG), transient thyroiditis. Where as Tr-b is absent in normal population, MNG, transient thyroiditis, and present in Grave, autoimmune hypothyroidism. Goiter and TPO-Ab are absent in secondary hypothyroidism.

- Ultrasound neck—It is done to know the size of thyroid, nodules in the thyroid gland, and for the presence of increased vascularity seen in Grave's disease.
- Fine needle aspiration cytology (FNAC) usually ultrasound guided is done to differentiate benign and malignant lesions and also to note lymphocytic infiltration suggestive of autoimmune thyroiditis.
- Radioisotope scanning of thyroid—It is very specific investigation in differentiation of hyperthyroidism etiologically. Transient thyroiditis like sub-acute, viral, postpartum thyroiditis shows low uptake of tracer because of follicular damage. In Grave's disease, gland is enlarged with homogenous increased uptake of tracer. Toxic adenoma shows focal areas of increased uptake of tracer and suppressed uptake in the remainder of the gland. Toxic multi-nodular gland is enlarged with increased and decreased uptake of tracer. Cold nodule (absence of uptake of tracer) suggestive of neoplastic lesion.[2]

Disorders with Increased TSH, Normal/Abnormal T3, and T4

- Hashimoto's/autoimmune thyroiditis, atrophic thyroiditis (end stage). It can present as hyper/hypothyroidism/normal. Investigations—TPO antibodies positive, Ultrasound, FNAC-lymphocytic infiltration suggestive of autoimmune thyroiditis.
- Iodine deficiency/endemic goiter—Not seen nowadays, diagnosed epidemiologically. Urine iodine levels are less than 50 ng/L. Treat by iodine supplementation. Iodine has complex effects on thyroid. Chronic administration of iodine causes hypothyroidism due to increased iodine content in thyroid. Paradoxically it can also precipitate thyrotoxicosis.[2,3] Hence, there is hardly any necessity to recommend iodine for healthy persons.
- Goitrogens—Intake of cassava root, cabbage, cauliflower—due to presence of thiocyanate, causes hypothyroidism, diagnosed epidemiologically.[3] Treat by thyroxine supplementation. There is no evidence based study to recommend routine restriction of cabbage, cauliflower, in all cases of hypothyroidism.
- Miscallaneous causes are—Iaotrogenic, infiltrative disorders like amyloidosis, sarcoidosis.

Disorders with Low/Undetectable TSH, Normal/Abnormal T3, and T4

- Subacute thyroiditis/De quervain's—due to viral etiology. There is release of stored hormones due to inflammation.[3] Spontaneous remission in 6 weeks. If thyroid antibodies are positive, suggests risk of ultimate progression to hypothyroidism. When prolonged abnormal levels of TFT, isotope scan—a low uptake confirms transient thyroiditis. Symptomatic treatment with NSAID/prednisolone.
- Silent/postpartum thyroiditis—Presence of TPO antibodies follow for autoimmune thyroiditis. Isotope scanning—negligible uptake. No role for glucocorticoids. Recovery is rule. Sometimes, pregnancy may be masking autoimmune thyroiditis. No role for anti-thyroid drugs. Symptomatic treatment with propranolol.[3]
- Grave's disease—Autoimmune disorder. Monitoring for life long. Ultrasound—increased vascularity. Thyroid antibodies—TPO, Tr-Ab, Tg-Ab all are positive.

Isotope scanning—homogenous and diffuse high uptake confirms the diagnosis. Ideal management by anti-thyroid drugs, sometimes with remission after 12–18 months of treatment.[2-4]

- Toxic adenoma/solitary nodule—Ultrasound and FNAC to confirm the nodule. Isotope scan is the choice of investigation—focal uptake with hyper-functioning nodule and diminished uptake in the rest of the gland. Treatment of choice is radioiodine ablation.[2,4]
- Toxic multinodular goiter—Ultrasound and FNAC, isotope scanning ideal investigation—heterogenous uptake with multiple regions of increased and decreased uptake of tracer. Radioiodine ablation is the treatment of choice. Alternate treatment is surgical if compressive symptoms are present.

Goiter or Swelling of Thyroid with Normal TSH, T3, and T4

- Simple goiter—unknown stimulus[2]
- Juvenile goiter—teenagers[3]
- Non-toxic adenoma
- Non-toxic multinodular goiter

If ultrasound, FNAC, and thyroid antibodies are negative, these conditions require follow-up with monitoring of TFT periodically. No medical treatment is necessary. Surgical treatment if compressive signs develop.

Sick Euthyroidism or Non-thyroid Illness or Low T3 Syndrome

Thyroid gland is normal, Abnormal TFT (Low T3, Low or normal T4, Low or normal TSH) due to acute systemic illness, causing failure of peripheral conversation of T4 to T3. Needs to be re-evaluated after recovery from acute illness for thyroid disorder.[3]

Subclinical Thyroid Disease

Subclinical hypothyroidism with high TSH, normal T3, T4, and Subclinical hyperthyroidism with low TSH, normal T3, and T4 are milder forms of the disease. No universally accepted guidelines for treatment and case to be managed depending on symptoms, age, and comorbidities. Excessive treatment to be avoided.[3,5]

Monitoring of Therapy

Treatment of hypothyroidism is monitored based on the levels of TSH. Treatment of hyperthyroidism is monitored based on the levels of T4, since TSH levels take longer time to reach normal.

Pregnancy—Thyroid Disorders

There is altered metabolism of thyroid hormones and thyroid–pituitary axis stability. Hence trimester specific normal ranges of TSH, T3, and T4, to be followed.[2,6]

Case Reports—Author's Own Experience

Case 1

- Female 35 years; Engineer in Govt. Service
- Incidental finding of low TSH, high T4, and normal T3
- Ultra sound neck FNAC—Cystic colloid nodule
- One month later—Persistent low TSH, TPO positive
- Isotope scanning of thyroid showed normal uptake of tracer. Not started on any treatment because of normal uptake of tracer. Two months later repeat TFT showed raised TSH—26.02 μIU/mL.
- Started on thyroxine. What started as hyperthyroidism turned to be autoimmune hypothyroidism over a period of 2 months.

Case 2

- Male 40 years general check-up before leaving for Gulf. Decrease TSH and increased T4 and T3.
- Ultrasound neck diffuse enlargement of both lobes, increased vascularity. FNAC suggestive of autoimmune thyroid. TPO positive. Isotope scanning—intense homogenous uptake of tracer 11.28% (normal is 0.5–4%).
- Diagnosis—Graves disease under management with antithyroid drugs.

Case 3

- Male 58 years presented with increased appetite, palpitations, tremors.
- Decreased TSH and increased T4 and T3.
- Ultrasound small colloid cyst left lobe of thyroid. Isotope scanning—diffuse increased tracer uptake—28.1%. Diagnosis Graves disease.
- Clinically this case suggestive of hyperthyroidism, ultrasound showed colloid cyst but isotope scanning is in favor of Graves disease. For the above three cases of hyperthyroidism isotope scanning is the clinching investigation.

Conclusion

It is obvious TFT reports suggestive of hypothyroidism irrespective of etiology, the treatment is thyroxine replacement except in iodine deficiency hypothyroidism. Whereas TFT reports suggestive of hyperthyroidism, the treatment differs.

Transient thyroiditis—No treatment, spontaneous recovery mostly.

Grave's disease—Antithyroid drugs or Radioiodine ablation.

Toxic adenoma/solitary nodule and Toxic multinodular goiter—Radioiodine ablation is the treatment of choice. To differentiate above disorders of hyperthyroidism, isotope scan is the investigation of choice.

CHAPTER

205 Glucocorticoids-induced Osteoporosis

Saurabh Jain

Abstract

Prolonged use of Glucocorticoids is associated with several adverse effects including Osteoporosis. High daily dose of GC (>7.5 mg), cumulative dose >5 gm both lead to increased risk of fractures. Vertebral fractures are most common. Often asymptomatic, these are found as incidental findings on routine chest X-rays. The fracture risk assessment tool – FRAX considers several risk factors for osteoporosis (including GC use) with the bone mineral density and gives us an estimate of the 10-year risk of major osteoporotic fracture and hip fracture in patients who are more than 40 years old. Prevention of GC-induced fractures requires identifying the high risk patient, and initiating them on preventive strategies like weight-bearing exercises, maintenance of normal weight, smoking cessation, and limitation of alcohol consumption. Bisphosphonates are considered as first-line agents for the management of Glucocorticoid induced osteoporosis. Treatment with an anabolic agent such as teriparatide or abaloparatide and Denosumab (human IgG2 monoclonal antibody specific to RANKL) should be followed by an antiresorptive agent. Patients experiencing treatment failure or having contraindications to conventional medications are considered of third line agents like raloxifene or with calcitonin. Raloxifene (a selective estrogen-receptor modulator) is approved by the FDA for the prevention and treatment of GC-induced osteoporosis in postmenopausal women. Pharmacologic treatment to prevent fractures are not recommended in pregnant ladies.

Introduction

Glucocorticoids (GC) are used in many inflammatory and autoimmune conditions. While being used to treat an underlying disease, GC are associated with appreciable risk of bone loss and increase the risk of fractures, which is actually more pronounced during the initial few months of use.

Epidemiology

The association of GC and osteoporosis was first described 80 years ago. The US data suggests that approximately 3% of adults older than 50 years and almost 1% of all adults receive GC either for allergic conditions or various inflammatory or neoplastic conditions.[1] GC use over long term is associated with various adverse effects. Amongst them fracture is the most common preventable side effect which is often serious.[2-4] Increase in the dose and duration of GC increases the risk of fracture.[5-7]

Risk Factors for Fractures

Related to Glucocorticoid Use

- High daily dose of GC (e.g., >7.5 mg of prednisone daily)
- Cumulative dose of GC >5 g
- Current or recent (<3 month) use of GC
- GC-associated myopathy (increases the risk of falls)
- GC-induced hypogonadism

Related to Underlying Condition

Rheumatoid arthritis, ankylosing spondylitis, etc. are independent risk factors.

Related to Risk of Osteoporosis

Advance age; white race; female sex; menopause; smoking; alcohol use (>2 units per day); bone mineral density T-score less than –1.5; previous fracture.

Vertebral fractures are the most common GC induced fractures and are often asymptomatic. These are diagnosed as incidental finding on chest or abdominal radiograph. In patients who have asymptomatic vertebral fracture there is often no history of preceding trauma. The typical symptomatic patient presents with acute back pain after sudden bending, coughing, or lifting. The risk of vertebral fracture increases within 3 months of starting the treatment and is maximum at 12 months.[7,8]

Studies, having a follow-up of 6 months to 10 years, have shown that with high dose of GC, risk of vertebral fractures is increased significantly. But, high doses if used intermittently (total cumulative dose of ≤1 g) had less fracture risk.[8] High-dose inhaled GC (dose equivalent to ≥1 mg fluticasone) when used for more than 4 years showed a marginal increase in the risk of fracture.[9]

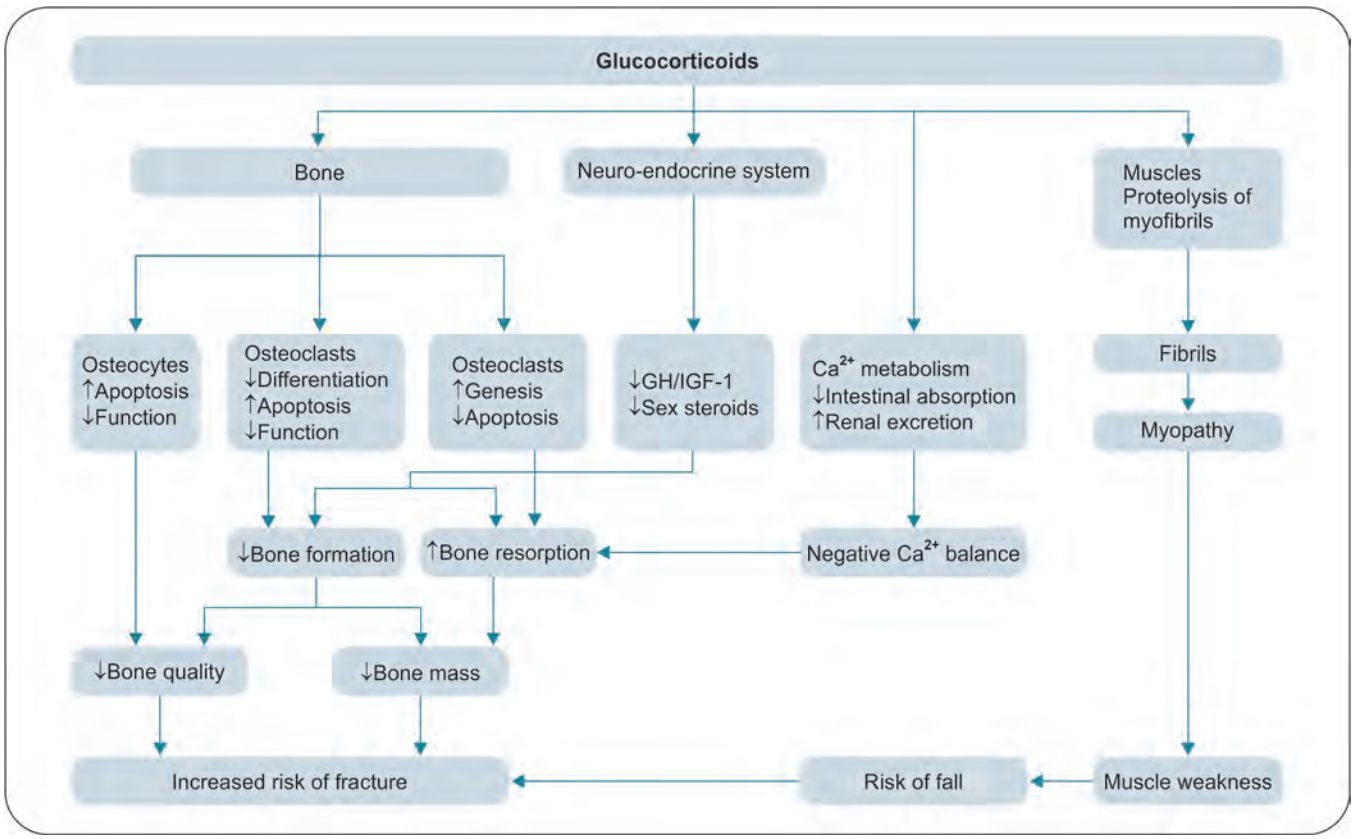
Also worth remembering is that GC can cause avascular necrosis.

Pathophysiology (Flowchart 1)

Specifically related to bone, GC receptors are found on all cells except osteoclast. GC use sends negative feedback effect on the hypothalamus and pituitary gland. It acts as an exogenous cortisol, so elevated GC levels reduce the secretion of ACTH, along with FSH and LH. Reduction in ACTH results in reduced endogenous steroid hormone production from the adrenal glands including cortisol and androgens.

Low FSH and LH reduce production of androgens and estrogen from the gonads. Low androgens and estrogens increase the risk of osteoporosis.

Flowchart 1: Pathophysiology of glucocorticoid-induced osteoporosis



Bones contain three main types of cells. Osteocytes—the mature bone cells formed by osteoblasts, Osteoblasts—the bone building cells, and Osteoclasts—bone eating cells. And in our case, immature osteoclast termed pre-osteoclasts. GC stimulates osteocyte apoptosis, with long-term use. The predominant effect of GC on the skeleton is actually reduction in bone formation. The decline in bone formation is mediated by direct inhibition of osteoblast proliferation and differentiation, and by an increase in the apoptotic rate of mature osteoblasts and osteocytes. High GC levels stimulate RANKL synthesis by osteoblasts thus supporting osteoclast differentiation and net bone resorption. In normal condition there is this molecule called osteoprotegerin, which regulates this osteoblast-osteoclast interaction, by binding to the RANKL and preventing osteoclast stimulation. However, GC increases osteoclastic activity by suppressing synthesis of osteoprotegerin and also by increasing production of RANKL, which is required for osteoclastogenesis. So RANKL binds onto osteoclasts stimulating osteoclastic activity, it becomes active osteoclast, which will breakdown bone minerals and this is termed bone resumption. In addition GC increases bone resorption by decreasing secretion of androgens and estrogens. The net bone resorption by osteoclast reduces bone mineral density and bone remodeling, thereby increasing the risk of fractures. Bone resorption leads to an increase in serum calcium and phosphate levels due to the breakdown of bone minerals. Now when you have a high serum calcium the body does not want to keep it. High serum calcium reduces intestinal absorption of calcium and also increases urinary calcium excretion because you want to get rid of all the calcium in your body, now this will cause hypocalcemia. Hypocalcemia stimulates the parathyroid gland to release parathyroid hormone. Parathyroid hormone works by binding onto parathyroid hormone receptors on osteoblasts, which stimulates expression of RANKL, which will further promote osteoclastgenesis and so increase bone resorption further. Indirect GC effects that also predispose patients to an increased risk of fractures include reduced muscle mass and weakness, both leading to an increase in the risk of fall.

After discontinuation of GC treatment, the risk of fracture also downtrends. It was also reaffirmed in a prospective study where within 6 months after discontinuation of GC, lumbar spine showed significant recovery in bone mineral density.[10]

Clinical Evaluation

The fracture risk assessment tool—FRAX considers several risk factors for osteoporosis (including GC use) with the bone mineral density and gives us an estimate of the 10-year risk of major osteoporotic fracture and hip fracture in patients who are more than 40 years old.[11]

One of the limitation of the FRAX score calculation is that it uses bone mineral density at the hip joint, which can give false values as GC have the greatest detrimental effect on the vertebrae. Also in patients, receiving very high doses of prednisone may underestimate the risk of fracture.

Treatment

Prevention of GC-induced fractures requires identifying the high-risk patient, and initiating them on preventive strategies.

Nonpharmacologic Options

- Weight-bearing exercise
- Maintenance of normal weight
- Smoking cessation
- Limitation of alcohol consumption
- Assessment and management of fall risks
- Minimizing GC use

Calcium and Vitamin D

Because GC increases the excretion of urinary calcium, dietary intake of calcium (1,000 mg per day) and vitamin D (600–800 IU) is commonly suggested to patients receiving GC.

A Cochrane meta-analysis suggested that the bone mineral density at the lumbar spine was significantly better in patients receiving calcium and vitamin D supplementation in comparison with the placebo group.[12]

Pharmacologic Treatment

Bisphosphonates

Multiple randomized trials have suggested that in patients receiving GC, the use of bisphosphonates is associated with an increase in the bone mineral density.[13] A 2016 Cochrane review involving 12 RCTs showed that in the group receiving bisphosphonates the risk of new vertebral fractures was lower by 43% in comparison to those who received either calcium or vitamin D, or both. In patients

receiving bisphosphonate treatment over a period of 3–5 years, there was less incidence of serious adverse events (like osteonecrosis of the jaw and atypical femoral fractures).[14] Due to their good safety profile and affordable cost, oral bisphosphonates are recommended as first-line agents to prevent GC induced fractures unless they are contraindicated or have undesirable adverse effects.

Patients who are not able to tolerate the oral formulation, or who for some reasons are not adherent to oral bisphosphonate regime, are offered intravenous bisphosphonates.

Other Recommended Agents

Teriparatide and abaloparatide are anabolic molecules and increases bone formation.[15] In a study of 428 patients on GC, receiving either teriparatide or alendronate were followed for 36 months. Patients receiving teriparatide showed better improvement in bone mineral density at the spine, than alendronate. They also had lesser rate of radiographic vertebral fractures. However, no significant difference was noted in the rates of nonvertebral fracture in the two groups.[16] In the teriparatide group, 21% of patients had hypercalcemia, as compared to 7% in the alendronate group. In a smaller study, effects of teriparatide and risedronate were noted on middle-aged men receiving GC. Teriparatide group showed higher bone mineral density and lower rate of fractures.[17] However, after discontinuation of teriparatide, bone loss and fractures occurred at a rapid rate. Hence, after discontinuation of teriparatide, it is prudent to initiate an antiresorptive agent such as bisphosphonate or denosumab. In severe osteoporosis where bone mineral density T score is less than –2.5 in patients with a past history of fracture, initial treatment with an anabolic agent such as teriparatide or abaloparatide should be followed by an antiresorptive agent.

Denosumab is human IgG2 monoclonal antibody specific to RANKL. By binding to RANKL, it suppresses the development of osteoclasts. In a trial involving patients on GC, denosumab was compared with risedronate. Denosumab group showed superiority with respect to increase in spinal bone mineral density at 12 months and noninferiority in terms of rates of fracture.[18] Few studies have reported higher risk of infection with denosumab in comparison to bisphosphonates which may be attributed to its immunomodulatory effects.[19] Hence in patients on immunosuppressive medicines or biologicals, denosumab is generally not recommended. Denosumab, in dosages that is used to treat osteoporosis, is associated with minimal risk of osteonecrosis of the jaw and atypical fractures.[13] However, similar to anabolic agents, after its discontinuation there is a rapid increase in the rates of vertebral fracture, especially in patients with a previous history of vertebral fracture. Here also an alternative antiresorptive therapy should be initiated after its discontinuation.[19]

Third-line Agents

Patients experiencing treatment failure or having contraindications to conventional medications are considered of third-line agents like raloxifene or with calcitonin. Raloxifene (a selective estrogen-receptor modulator) is approved by the FDA for the prevention and treatment of GC-induced osteoporosis in postmenopausal women. A study done in postmenopausal women receiving GC showed that raloxifene significantly increased absolute bone mineral density at the lumbar spine by 1.3%, in comparison to Calcium and Vit D supplementation.[20] However, no difference in bone mineral density was noted at the femoral neck between the treatment groups. Studies have shown that raloxifene use is associated with decreased risk of estrogen-receptor–positive breast cancer;[21] however, it can cause serious complications like venous thromboembolism, and fatal stroke.[22]

Calcitonin-Salmon is a man-made form of the hormone. A meta-analysis of nine trials with 500 patients on GC, compared the effects of calcitonin with calcium and Vit D supplementation, concluded that calcitonin improved the bone mineral density at the lumbar spine (but not hip); however, there was no difference in the risk of vertebral fracture in both the groups.[23] Calcitonin is available as injectables which can be administered subcutaneously and also as a nasal spray. Hypocalcemia and Vit D deficiency must be corrected before initiating the treatment. In clinical trials among calcitonin treated patients, overall incidence of malignancies are reported to be higher in comparison with placebo.

Treatment in Women of Childbearing Age

Pharmacologic treatment to prevent fractures is not recommended in pregnant ladies. A summary of case study involving 65 women receiving bisphosphonate

before or in the first trimester of pregnancy showed no clinically significant adverse effects in the fetus.[24] However, there is a reluctance to treat women in child bearing age with bisphosphonates as it may cause long-term retention of these agents in bone and may have affect on the fetal skeleton later when these ladies conceive. If treatment has to be offered owing to their risks, agents having a shorter half-life and lesser retention in bone are generally recommended such as risedronate and teriparatide. Animal's studies have shown that denosumab has teratogenic effects and should be used with caution in women of childbearing age.[25]

Guidelines/Recommendations

The 2017 Guidelines of the American College of Rheumatology[26] recommend the following:

Which patient requires intervention?

- All adults taking ≥2.5 mg of prednisone daily for >3 months

Whom to test and monitor for changes in BMD?

- All adults ≥40 years of age and adults <40 years with a history of fragility fracture or other risk factors;
- Test within 6 months after initiation of GC;
- Repeat testing every 2–3 years and every 1–3 years in adults ≥40 years receiving GC without treatment for osteoporosis.

Correction used with the FRAX tool to adjust risk estimate for prednisone dose >7.5 mg:

- Risk of major osteoporotic fracture is increased by 15% and risk of hip fracture is increased by 20%

Calcium and Vit D supplementation:

- 800–1,000 mg of calcium daily and 600–800 IU of vitamin D daily

Threshold for pharmacologic treatment:

- All adults with a previous fragility fracture
- Adults ≥40 years with BMD T score of –2.5 or less or FRAX risk ≥20% for major osteoporotic fracture or ≥3% for hip fracture
- Consider in adults ≥40 years with FRAX risk 10–19% for major osteoporotic fracture or >1–2.9% for hip fracture
- Adults <40 years with BMD T score below –3 and >7.5 mg of prednisone daily
- Adults with >10%/year bone loss at hip or spine
- Adults ≥30 years taking very-high-dose GC (≥30 mg daily)
- High cumulative use (>5 g in 1 year)

Pharmacologic interventions:

- First-line therapy: oral bisphosphonates
- Second-line therapies (in order of preference): intravenous bisphosphonates, teriparatide, denosumab, raloxifene (only in postmenopausal women when other listed second-line medications are not appropriate)

Duration of pharmacologic intervention:

- If continuing to receive GC >5 years, continue treatment if having moderate to high risk
- If GC is discontinued before 5 years, continue treatment for osteoporosis for 5 years if moderate to high risk
- Discontinue treatment for osteoporosis when GC are discontinued if low risk.

Conclusion

Long-term use of Glucocorticoids is known to cause many adverse effects and it is essential to identify the high risk individuals. After lifestyle change and correction of calcium and vitamin D, initiation of appropriate anti-resorptive medicines can prevent long-term debilitation and morbidity associated with osteoporosis.

Refractory Rheumatoid Arthritis

Rohini Handa

Abstract

A sizeable number of patients with rheumatoid arthritis (RA) are unable to attain low disease activity or remission despite treatment. These difficult to treat (D2T) patients are labeled as refractory RA. The troika of D2T RA, as outlined by the European League against Rheumatism, comprises of treatment failure history, presence of active/symptomatic disease, and clinical perception. The approach to refractory RA is evolving.

Introduction

Rheumatoid arthritis (RA) is the commonest inflammatory polyarthritis seen in clinical practice. Current management paradigms use a "treat to target" stratagem to achieve tight disease control. The conventional synthetic disease modifying anti-rheumatic drugs (csDMARDs) led by methotrexate form the initial treatment. A better understanding of the disease, pathobiology has led to the development of several targeted treatments, which are broadly divided into two categories: biologic DMARDs (bDMARDs) and targeted synthetic DMARDs (tsDMARDs). Despite tremendous advances in disease assessment, and an ever expanding treatment armamentarium, a significant proportion of patients are unable to achieve optimal disease control. This group of "refractory" patients poses a challenge to the immunologists from a mechanistic angle, to rheumatologists from the perspective of disease definition, and to all clinicians from a treatment viewpoint. This chapter outlines the approach to refractory RA from a clinical standpoint.

Definition of Refractory RA

The definition of refractory RA is imprecise as different authors, in absence of a consensus, have defined it differently. The analogy that I often use is "pyrexia or fever of unknown origin" (PUO/FUO) that was initially defined as a condition in which the core body temperature is >38.3°C for a period of three weeks or more, with no diagnosis reached after 1 week of "*inpatient investigation*." The quantum and extent of investigations were not spelt out. Also, modern day health care has moved away from hospitalization for investigations. The revised definition of PUO-"persistent fever that remains undiagnosed despite 1 week of hospital evaluation or three outpatient visits" also suffers from lack of specificity. Much in the same way, the definition of refractory RA continues to elude consensus.

Simply put, refractory RA is disease that continues to be active despite adequate treatment for sufficient time. The lack of uniformity stems from the fact that refractory RA has three dimensions: disease activity, adequacy of treatment, and time. The concept of disease activity is a quantitative target with reasonably well defined variables. Validated indices like simplified disease activity index (SDAI) and clinical disease activity index (CDAI) are available and widely used in rheumatology clinics. Their use is overtaking the use of DAS 28 (disease activity score 28). A detailed exposition of various disease activity measures is beyond the scope of this chapter. Briefly, SDAI

TABLE 1 Instruments to measure disease activity in RA

	Score range	*Remission*	*Low*	*Moderate*	*High*
DAS28	0–9.4	≤2.6	≤3.2	>3.2 and ≤5.1	>5.1
SDAI	0.1–86	≤3.3	≤11	>11 and ≤26	>26
CDAI	0–76	≤2.8	≤10	>10 and ≤22	>22

CDAI, clinical disease activity index; DAS, disease activity score; SDAI, simplified disease activity index

TABLE 2 American College of Rheumatology/European League Against Rheumatism definitions of remission in RA

For clinical trials	*For clinical practice*
Boolean-based definition At any time point, patient must satisfy all of the following: • Tender joint count ≤1 • Swollen joint count ≤1 • C reactive protein ≤1 mg/dL • Patient global assessment ≤1 (on a 0–10 scale)	*Boolean-based definition* At any time point, patient must satisfy all of the following: • Tender joint count ≤1 • Swollen joint count ≤1 • Patient global assessment ≤1 (on a 0–10 scale)
Index-based definition At any time point, patient must have a Simplified Disease Activity Index score of ≤3.3	*Index-based definition* At any time point, patient must have a Clinical Disease Activity Index score of ≤2.8

is simple numerical summation of swollen joint count (SJC)-28 joints, tender joint count (TJC)-28 joints, CRP in mg/dL (range 0.1–10), patient's global disease activity on a 10-cm visual analogue scale (VAS) and physician's global assessment on a 10-cm VAS. The CDAI excludes CRP. DAS 28 requires four simple inputs: 28 TJC, 28 SJC, ESR, and general health (GH) assessment by the patient on a VAS from 0 to 100. The formula used is: DAS 28 = $0.56\sqrt{TJC} + 0.28\sqrt{SJC} + 0.7 \ln ESR + 0.014$ GH. Online calculators and apps are available for calculation. The cut offs are mentioned in **Table 1**. The goal of treatment is remission **(Table 2)**,[1] failing which low disease activity (LDA) is an acceptable alternative.

The second operational component—time taken to achieve LDA/remission—has undergone a sea change. Older publications talk about early disease as a disease duration of 2 years. Current recommendations like European League against Rheumatism (EULAR) and American College of Rheumatology talk about early RA as a disease duration less than 6 months.[2,3] They also emphasize that clinicians should aim for clinical remission (ACR-EULAR criteria) or at least low disease activity within 6 months (of which about 80% improvement of disease activity should be within 3 months of starting treatment).[4] It is recommended that if there is no improvement by at most 3 months after the start of treatment, or the target has not been reached by 6 months, therapy should be adjusted.

It is the third component of the definition—adequate treatment—that is a matter of debate. Recent clinical trials define refractory RA as "moderately to severely active RA (≥6 tender joints of 68 joints examined, ≥6 swollen joints of 66 joints examined, and a serum CRP level ≥3 mg per liter) and patients must have previously received one or more TNF inhibitors and discontinued treatment because of an insufficient response after 3 months or more or because of unacceptable side effects."[5] Other authors define refractory RA as patients who have experienced three treatment courses (with at least one biological) over a minimum of 18 months since diagnosis without reaching the treatment goal of low disease activity or remission.[6]

To make matters complex, some authors have proposed that non-responders be classified into "primary" and "secondary" non-responders. The latter, after the initial response to the drug, stop responding after a variable period of time. In some of these, anti-drug antibodies (ADA) to the biologics may be responsible for the secondary non-response. This has been termed "pharmacokinetic refractoriness" to differentiate it from intrinsic refractoriness in the primary non-responders.[7]

It is to be noted that not all secondary non-response are due to ADA. Also, ADA are seen with biologics, which are foreign proteins and not with csDMARDs or tsDMARDs like JAK inhibitors. This group proposes that refractory RA be defined by resistance to multiple therapeutic drugs with different structures and mechanisms of action—inefficacy of optimal dose methotrexate and at least two biologics with different mechanism of action.[7] They suggest that multiple within-class bDMARD resistance (as with TNFi cycling) be excluded from the ambit of refractory RA and a patient failing MTX and one TNFi needs to fail another non-TNF before being labeled as refractory.[7] The time period of 6 months incorporated in most guidelines for achieving LDA with treatment would translate into a period of at least 18–24 months for a patient to fail a minimum of two classes of bDMARDs.[7] It is pertinent to point out that *not* incorporated in this working definition is the place of JAKi.

Can the Same Definition of Refractory RA be Applied to Low Resource Settings?

The uptake of targeted treatments in resource constrained countries is very low. This is especially true of bDMARDs. With little insurance or government support, the bulk of treatment cost is borne by the patients themselves. The average duration of biologic use is less than a year.[8] The indirect implication of this is that definitions of refractory RA, as applicable in the west, cannot be extrapolated to countries like India. Biologic use, to begin with, is quite less and switching or swapping of biologics even lesser. From a practical standpoint, refractory RA in India can be defined as patients who continue to have active disease despite a combination of csDMARDs plus low dose steroids (prednisolone <7.5 mg daily). Implicit in this statement is optimal dosing of drugs: subcutaneous methotrexate (15–25 mg weekly) along with hydroxychloroquine (200–400 mg daily) and leflunomide (20 mg daily). In clinical settings like women of child bearing age, sulfasalazine (2–3 gm daily) can be used in place of leflunomide.

The availability of low cost, generic JAK inhibitors in the near future is likely to change the whole equation. Biologic DMARDs and biosimilars are expensive, given the complexities of manufacture. However, tsDMARDs like tofacitinib and baricitinib are not as difficult or expensive to produce. Their availability would necessitate a change in the definition of refractory RA in India.

How Common is Refractory RA?

Biologics, contrary to the popular perception of many internists, do not work for all patients. As many as one-third of patients treated with TNF inhibitors exhibits inadequate response or intolerance. In general, the efficacy of biologics in patients failing methotrexate is given by the broad thumb rule of ACR-20/-50/-70 of 60/40/20%. That is, ACR 20 response is seen in 60% of such patients, ACR 50 response in 40% patients while ACR 70 response is seen in 20% patients. In patients failing anti-TNFs, the ACR-20/-50/-70 drop further to 50/25/12% respectively.

The prevalence estimates of refractory RA vary between 6% and 21% depending on threshold and study population.[9] Obviously, referral centers would be expected to encounter more refractory patients. Risk factors for refractory RA include treatment delay, baseline disease activity and function, female gender, smoking, obesity, and lower socioeconomic status.[9]

How should Overdiagnosis of Refractory RA be Avoided?

A label of refractory RA should be applied after careful consideration **(Fig. 1)**. Overclassification and misclassification may result in inappropriate therapy escalation. Coexistence of fibromyalgia may lead to disproportionate increase in patient reported symptoms and distort disease assessment. Secondary damage and osteoarthritis can also lead to higher disease activity scores and apparent refractoriness.

Treatment of Refractory RA

The treatment of refractory RA revolves around the use of targeted treatments—bDMARDs or tsDMARDs. Patients failing one drug are switched to another agent. Switching to an alternate agent with same MOA (intra-class switching) has been called "cycling" and switching to agents with a different MOA has been termed "swapping."[10] These terms are by no means universally accepted. There is no consensus on sequence of switching. Physician familiarity, patient preference, and drug characteristics like availability, cost, safety, and efficacy are some of the factors to be considered. Of the ten bDMARDs available worldwide, six are available in India **(Table 3)**. The tsDMARDs in RA are the JAK inhibitors. Two of the four JAKi are available for use in India **(Table 4)**.

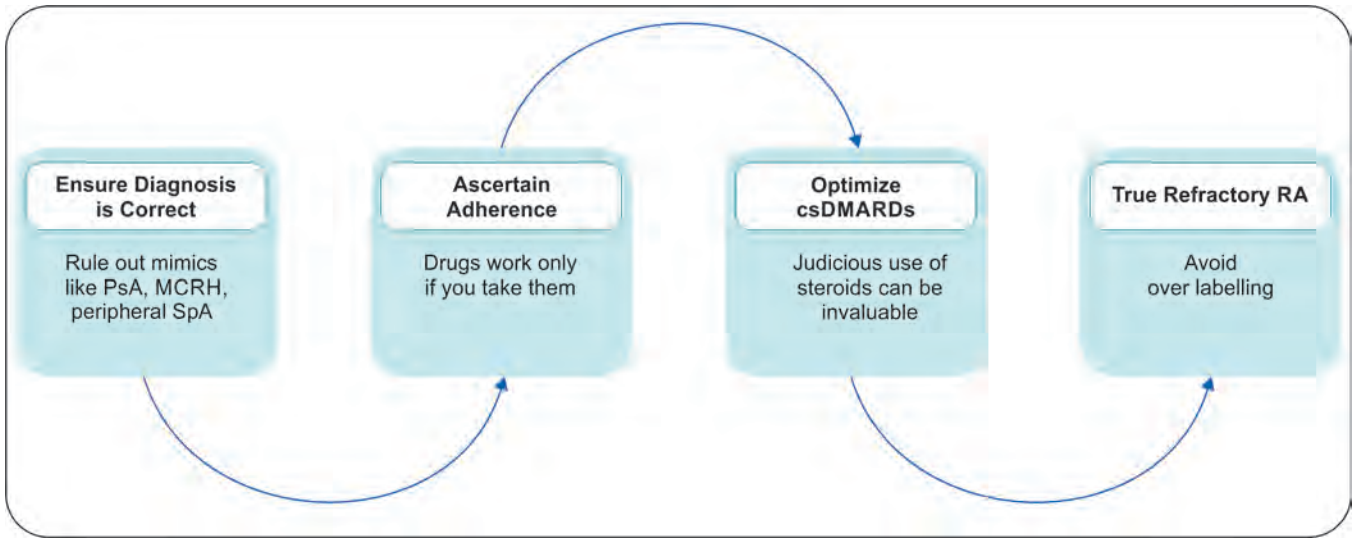

Fig. 1: Pathway to labeling refractory RA
csDMARDS, conventional synthetic DMARDs like methotrexate, hydroxychloroquine, leflunomide and sulfasalazine; MCRH, multicentric reticulohistiocytosis; PsA, psoriatic arthritis; SpA, spondyloarthritis

TABLE 3 Biologics available in India

Biologic	*Target*	*Route of administration*	*Usual adult dose*
Infliximab	TNF	Intravenous	In conjunction with methotrexate, 3 mg/kg at 0, 2, and 6 weeks, then every 8 weeks
Etanercept	TNF	Subcutaneous	50 mg weekly
Adalimumab	TNF	Subcutaneous	40 mg every other week
Golimumab	TNF	Subcutaneous	50 mg once a month
Tocilizumab	IL-6R	Intravenous and subcutaneous	Intravenous: Recommended starting dose is 4 mg/kg every 4 weeks followed by an increase to 8 mg/kg every 4 weeks based on clinical response. Subcutaneous: 162 mg administered subcutaneously every other week, followed by an increase to every week based on clinical response
Rituximab	CD 20 on B cells	Intravenous	The dose for RA in combination with methotrexate is two-1,000 mg intravenous infusions separated by 2 weeks (one course) every 24 weeks or based on clinical evaluation, but not sooner than every 16 weeks

IL-6R, interleukin 6 receptor; TNF, tumor necrosis factor
N.B.: Abatacept, Anakinra, Sarilumab, and Certolizumab are not available in India.

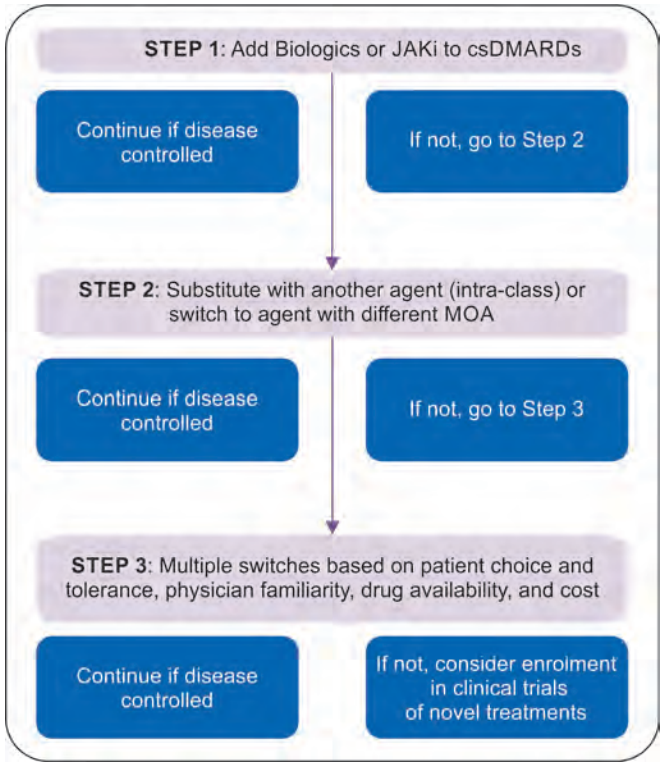
TABLE 4 Targeted synthetic (ts) DMARDs available in India

Agent	*JAKs targeted*	*Oral dose*
Tofacitinib	JAK1, JAK2, JAK3	5 mg BD
Baricitinib	JAK1, JAK2	2–4 mg OD

JAK, Janus kinas
N.B.: Upadacitinib and Peficitinib are not available in India

Recommendations from professional bodies like APLAR and EULAR do not spell out any particular sequence to follow.[2,11] It is to be pointed out that csDMARDs can be combined. However, combinations of biologics or JAKi or biologic-JAKi combination are not recommended for fear of intense immunosuppression **(Flowchart 1)**.

Flowchart 1: Treatment of refractory RA



Conclusion

Refractory RA represents an area of unmet need in the arena of rheumatology. The definition itself continues to evolve with the expansion of DMARD classes—from csDMARDs through bDMARDs to, now, tsDMARDs. Ensuring adherence to treatment and excluding the contribution of damage/degeneration to disease activity assessment are important to avoid misclassification as refractory RA. Biologics and tsDMARDs are used to treat refractory disease. In absence of biomarkers, the sequencing of bDMARDs and tsDMARDs at present is empirical. Hopefully, the advent of precision medicine in future would permit clinicians to move away from "generic" protocols to "individualized" protocols in the disease segment that is refractory RA!

CHAPTER

207 Difficulties in Rheumatoid Arthritis

Rajan Kumar

Abstract

Rheumatoid arthritis is not an uncommon arthritis. There is overlap in the markers and clinical features. One should try to decipher the diagnosis with their markers and this will help in deciding treatment. By identifying the signs of flare ups and treatment failure we can plan treatment with algorithm.

Introduction

Rheumatoid arthritis marked by synovitis in small joints, acute phase reactants, and biomarkers. Sometimes biomarkers are absent but small joints and acute phase reactants are present diagnosis depend on clinical judgment and wait for others markers to evolve but if treated early, then long-term complications of join deformities and disabilities can be decreased. In presence of other biomarkers along with specific for Rheumatoid arthritis, subtle judgment will help in classifying disease syndrome. It is also pertinent to identify flare ups of disease and failure of treatment so that we can achieve remission. Finally treat to target will help in prolonging life.

Rheumatoid arthritis is one of the most common arthritis. Every clinician might have got an opportunity to treat it. They might have encountered some difficulties in the management, particularly in:

- Diagnosis
- Treatment

To diagnose rheumatoid arthritis when all clinical sings and markers are present is not a difficult task. Patients classically come with the complains of pain and early morning stiffness lasting for more than an hour and for more than 6 weeks with systemic symptoms or no systemic symptoms. There is an involvement of smaller joints in hand symmetrically, particularly involving proximal interphalangeal (PIP) joints, metacarpophalangeal (MCP) joints with positive squeeze sign and loss of guttering in between MCP joints, wrist, elbow, shoulder, knee, and feet with small joints. You can diagnose it easily if there is more than three symmetrical joints involvement in hand of PIP, MCP along acute phase reactants and autoimmune markers in the form of rheumatoid factor (RF) and anti-cyclic citrullinated (ACC) antibodies. When this is the situation, things are very easy. But the problem starts when:

- You have autoimmune markers but no clinical features or synovitis or joint pain.
- Clinical features of synovitis and evidence of symmetrical small joint arthritis with no autoimmune markers.

How to predict the diagnosis of rheumatoid arthritis in these two conditions.

Firstly, with autoimmune markers without evidence of synovitis:

- RF only
- Both RF and anti-cyclic citrullinated protein (ACCP) antibody

TABLE 1 There different studies which shows the predictive value

Nielen et al (2004)	RF-IgM, anti-CCP2	PPV of up to 100% for RA diagnosis within 5 years
Deane et al. (2010)	RF isotypes, anti-CCP2	Anti-CCP and/or two or RF isotypes positive with >96% PPV for RA compared to two control groups
Ramos-Remus et al. (2015)	RF, anti-CCP2	RF and anti-CCP positivity at baseline with PPV 64% for RA within 5 years; anti-CCP alone with PPV of 58%
Sokolove et al. (2012)	RF, ACPA array, variety of cytokines and chemokines	A set of ACPAs and cytokines was 58% sensitive and 87% specific for identifying a sample ≤2 years before diagnosis

ACPA, anti-citrullinated protein antibody; CCP, cyclic citrullinated protein/peptide; PPV, positive predictive value; RA, rheumatoid arthritis; RF, rheumatoid factor.

We have to take the account that genetic factors (e.g., the shared epitopes) are environmental factors (smoking and high body mass index) and RF isotypes particularly high-titter IgM-RF and IgA-RF presence will favor the future development of rheumatoid arthritis.

ACCP are of three types on the basis of method of antigen used anti-CCP1 (ELISA), anti-CCP2 (tested with synthetic peptides), anti-CCP3 (tested with synthetic peptides), of theses, presence of anti-CCP2 has more predictive value for the future development of RA.

With only presence of autoimmune markers, it takes 3–5 years to develop from the stage of autoimmunity to autoimmune disease. But it depends on:

- Levels of autoantibodies
- Number of ACCPAs
- Presence of both ACCPAs and RF
- Additional biomarkers such as cytokines and chemokines
- Other factors such as environmental exposures and symptoms

There different studies which show the predictive values have been discussed in the **Table 1**.

We need to develop an effective tools to measure the response of successful preventive interventions in preclinical RA (window of opportunity), when challenged with disease-modifying anti-rheumatic drug (DMARD) or other effective treatment in this window of opportunity.

Rituximab and other pharmacologic agents, including hydroxychloroquine, abatacept, and atorvastatin were tried in various trials for prevention in various trials without much success.

The best time to treat is when patients having arthralgia and synovitis. Treatment within first 3 months of onset of the disease can lead to long-term remission, the so-called window of opportunity period.

Now second situation is that when there is a synovitis with typical joint involvement but no autoimmune markers, then how we can diagnose RA. We need;

History of more than 6 weeks of morning stiffness, symmetric arthritis involving PIP, MCP joints, subcutaneous nodules, and the deformities characteristic of RA.

There are other disorders but having similar presentation but with presence of rashes, dry mouth and dry eyes, Raynaud's phenomenon, myositis, or nephritis, involvement typical organs and by various autoantibodies not seen in RA may clinch the diagnosis, for example. Systemic lupus erythematosus (SLE), Sjögren's syndrome, Dermatomyositis (DM), Sarcoidosis, Psoriatic arthritis, Overlap syndromes such as mixed connective tissue disease.

Some of inflammatory arthritis (IA) which do not fit in any of the classical syndrome, then we mark them as unclassified arthritis. Now even in these situations we can work up diagnosis in the favor of RA with anti-CCP presence, unconventional serologic findings (e.g., IgA type rheumatoid factor, pyridinoline), and MRI-proven early joint damage, synovial thickening, marrow edema, and erosions.

There are situations in which inflammatory arthritis is present with:

- RF with ANA (anti-nuclear antibodies) with erosions, the diagnosis goes the favors RA.
- Without erosions and clinical features suggestive of SLE or but with ANA and ACCP antibody clinch the diagnosis of rheumatoid arthritis.
- But patients having features of both RA and SLE with presence of RF and ANA will favor the diagnosis of overlap syndrome.

- With RF, ANA, and Un RNP and IA, the diagnosis will go in favor of mixed connective tissue disease.

Two of clinical variants of RA poses some difficulty. The first one is the presentation with monoarthritis.

Mono arthritis with involvement a large joint, such as the wrist, knee, shoulder, hip, or ankle, may be the sole manifestation of RA, but how to predict RA in these patients. One should investigate the patients, for the presence of the RF and ACCP antibodies.

If they are there, then wait for typical disease features to evolve. Usually it takes days to several weeks to develop polyarthritis from monoarthritis till then we should treat them as monoarthritis with NSAIDs and local steroid injection if required.

To rule out that monoarthritis of large joints are due to spondyloarthritis, MRI will help to find out more destructive change (synovial thickening, marrow edema, and erosions) in the patients with RA and but enthesopathy in the patients with spondyloarthropathy than in the patients with undifferentiated arthritis.

Second one is the presentation with *Palindromic rheumatism* in this condition, episodes of joint inflammation sequentially affecting one to several joint areas for hours to days, with the symptom-free periods that may last from days to months. Patients with anti-CCP antibodies appear more likely to progress to definite RA later on. It has to be differentiated from the migratory arthritis.

So the key points for predicting RA we will need to focus on sex, age, morning stiffness, localization of symptoms, tender and swollen joint counts, C-reactive protein, rheumatoid factor positivity, and presence of ACCP antibodies. There are scoring systems to predict the development of RA.

We face some difficulties in treatment also.

Firstly, in the choice of treatment, secondly detecting the failure of DMARD and lastly managing the flare ups.

We usually start treating with NSAIDs (nonsteroidal anti-inflammatory drugs), steroid and CsDMARDs (conventional synthetic DMARD). But sometimes it does not give the desired results. Treat to the target is the rule of thumb.

Failure can be defined as:

- Not able to remission with the target achievement within 3–6 months of continuous use of DMARDS irrespective of nonbiologic (conventional synthetic [cs]), biologic (b), or targeted synthetic (ts) DMARD in maximally tolerated doses within the usual therapeutic range.
- Continued erosion despite patient on treatment even with no pain.
- Requirement of 5–7.5 mg prednisone or larger doses to maintain achievement after 3 months of DMARD use.
- Multiple courses of treatment with glucocorticoids for the treatment of recurrent disease flares in patients whose DMARD doses have been increased to the maximally tolerated.

Flares may be with:

- Single or few affected joints treated them with NSAIDs for few days and local steroid injection in joint if required.
- Widespread flares with multiple joints with need low doses of steroid.
- Severe flares, particularly those associated with systemic manifestations and life-threatening conditions, such as rheumatoid vasculitis will need intravenous pulse methylprednisolone in high doses with long use of steroid.
- Flaring frequently or severely will need escalation of doses of continued DMARD and/or addition of another DMARD of same group of different groups.

DMARDS are selected in step ladder approach:

- MTX (methotrexate)
- HCQ/SSZ (hydroxychloroquine/sulfasalazine)
- HCQ + SSZ + MTX, i.e., triple therapy

  Patients resistant to triple therapy can be treated with MTX plus leflunomide (LEF) please note that this may require closer monitoring (e.g., monthly with aminotransferase testing) for hepatotoxicity, given the increased risk of hepatotoxicity in some but not in the most studies, including reports of fatal liver failure.
- MTX + TNF blocker (tumor necrosis factor) ETN (Etanercept) or ADA (Adalimumab)
- Methotrexate plus Rituximab equivalent to TNF blocker combination
- Rituximab is effective alone in the patient intolerant with MTX
- MTX + tsDMARD (tofacitinib)
- LEF (leflunomide) alternative to MTX
- In pregnancy TNF blocker can be used alone
- LEF if there is moderate renal dysfunction/nontolerant to MTX

- MTX + Abatacept
- MTX + IL 6 inhibitors tocilizumab and sarilumab

Patient needs months and years of continued therapy for adequate response.

Downregulating the DMARDs only after 1 year of sustained response otherwise flare ups are very much common.

Some patients remain in remission on reduced doses but decision to discontinue treat remain debatable and controversial.

The best candidates for achieving a drug-free remission appear to be the patients who have a short duration of symptoms when treatment is started, are of the male sex, have an absence of RF and ACPAs, have received early intensive therapy, and have achieved a deep remission based upon composite scores of disease activity.

Conclusion

Autoimmune biomarker testing and clinical features allow us to rightly interpret the diagnosis. And knowing the failure, remission, and flare up sign and symptoms will lead to proper use of different demands in algorithm.

CHAPTER

208 Monoarthritis—A Clinical Dilemma to Internists

Arup Kumar Kundu, Abhishek Kundu

Abstract

The monoarthritis can either be acute or chronic, and may be either inflammatory or non-inflammatory. A detailed history and meticulous physical examination are essential in determining the etiology of arthritis. Diagnosis of monoarthritis is always a challenge to the internist. The common causes of acute monoarthritis are gout (crystal-induced arthritis), trauma, and infection, while that of chronic monoarthritis are osteoarthritis, tuberculous arthritis, gout, or spondyloarthropathy. So-called polyarticular diseases like systemic lupus erythematosus, rheumatoid arthritis may start as monoarthritis. If one investigation has to be done, it is synovial fluid examination, while synovial biopsy specimen is often examined for etiological agents in Lyme disease, gonococci, tuberculosis, or chlamydia infection. Light microscopy may identify gout crystals, but polarized microscopy is always preferred. Review of systemic diseases like sarcoidosis, malignancy, etc. is important because they may be complicated by monoarthritis.

Introduction

Monoarthritis is defined as inflammation of one joint at a time, while acute monoarthritis is acute inflammation of a single previously healthy joint, typically developing within a few days. Chronic monoarthritis is the inflammatory arthritis of a single joint that persists for more than 6 weeks. Acute monoarthritis may be the initial manifestation of many of the rheumatological disorders or systemic connective tissue diseases. *The most common causes of acute monoarthritis are crystal arthropathy (i.e., gout and pseudogout), trauma, and infection.*[1] The patient of monoarthritis should undergo careful and meticulous history, rational physical examination, and selected laboratory tests. Acute monoarthritis (red-hot joint) represents a rheumatologic emergency and requires rapid assessment, diagnosis, and aggressive treatment, since an untreated septic arthritis may lead to irreversible joint damage and resultant disability. In spite of the intensive investigations, at times, no clear diagnosis can be made. Complete blood count, bleeding and clotting time, ESR, C-reactive protein (CRP), serum uric acid, rheumatoid factor and antinuclear factor, urine analysis, and blood or urine culture should be performed, as and when necessary. Blood culture should be done if clinical suspicion of septic arthritis is very high. Many a time, examination of joint fluid is essential in making a definitive diagnosis. Leukocyte counts may vary widely in septic and sterile synovial fluids, and should be interpreted cautiously in an open mind. The joints, such as hip or sacroiliac joints, are difficult to aspirate and very often computed tomography or ultrasound-guided arthrocentesis helps to draw synovial fluid from these types of deep-seated joints. When an infection is suspected, culture and Gram staining of the synovial fluid should be performed and antibiotics should be started empirically. Light microscopy may identify gout crystals, but polarized microscopy is always preferred. If, however, the diagnosis is yet to be reached, radiographic studies (such as technetium bone scan,

computed tomographic scanning or magnetic resonance imaging) are performed in selected cases (such as internal derangement or osteonecrosis), and even, invasive procedures such as arthroscopy and synovial biopsy may be necessary to clinch the final diagnosis in undiagnosed chronic monoarthritis. The other systems should be evaluated because, many a time, thalassemia, sarcoidosis, sickle cell anemia, or hemophilia may be a cause for monoarthritis.

Monoarthritis: An Overview

Monoarthritis represents a diagnostic challenge to every physician. The doctor first decides the anatomical basis of pain (i.e., articular vs. non-articular). Joint pain can be the result of abnormalities in the joint itself, adjacent bone, surrounding ligaments, tendons, bursa, or soft tissues. Articular structures consist of synovium, synovial fluid, articular cartilage, joint capsule and juxta-articular bone. Non-articular (periarticular) structures include ligaments, bone, tendons, bursa, muscle, fascia, nerve, and overlying skin. "Arthritis" results in stiffness, reduced range of motion, and pain of the involved joint during normal use, which is most noticeable in the morning, improves with motion, and may be associated with systemic symptoms (i.e., malaise or fever). Joint pain due to mechanical factors (non-articular) usually improves with rest, deteriorates with activities and is not associated with systemic symptoms. In differential diagnosis (D/D) of musculoskeletal pain diffuse bone diseases like multiple myeloma, metabolic bone disease or multifocal osteomyelitis should be considered.

Possible causes of acute and chronic monoarthritis have been elaborated in **Table 1**.[2,3] Arthritis may be monoarthritis (single joint), oligo- or pauciarthritis (2–4

TABLE 1 Etiology of monoarthritis[2,3]

Common causes	• Trauma • Crystals—monosodium urate (MSU), calcium pyrophosphate dehydrate (CPPD), hydroxyapatite, calcium oxalate • Septic arthritis (non-gonococcal, gonococcal) • Hemarthrosis (trauma and/or coagulation disorder) • Avascular necrosis of bone (i.e., osteonecrosis) • Internal derangement (e.g., meniscus tear, cartilage debris) • Osteoarthritis • Osteomyelitis • Overuse (e.g., in a pre-existing osteoarthritic joint) • Monoarticular flare of oligoarthritis or polyarthritis
Less frequent causes	• Malignancy of bone • Hemoglobinopathies (i.e., sickle cell anemia) • Enteropathic arthritis (e.g., Crohn's disease, ulcerative colitis) • Sarcoidosis • Loose bodies within joint • Infections—mycobacteria, fungi • Leukemia • Rheumatoid arthritis (RA—palindromic), reactive arthritis (ReA), psoriatic arthropathy (PsA), juvenile idiopathic arthritis (JIA) • Vasculitis
Rare causes	• Hypertrophic pulmonary osteoarthropathy (developing from bronchogenic carcinoma) • Foreign body (e.g., plant thorn) • Pigmented villonodular synovitis • Amyloidosis • Lyme disease • Familial Mediterranean fever • Relapsing polychondritis • Charcot joint • Behçet's syndrome • Synovial chondromatosis/sarcoma/synovial metastasis

TABLE 2 Working classification according to onset and duration[2,3]

Acute (duration <6 weeks)	*Chronic (duration >6 weeks)*
• Infection (bacterial, mycobacterial, fungal, or viral; Lyme disease)	• Infection (tuberculosis, brucellosis, fungal)
• Crystals (MSU, CPPD, calcium hydroxyapatite, calcium oxalate)	• Crystals (MSU, CPPD, etc.)
• Trauma (fracture or internal derangement)	• Osteoarthritis (commonly knee joint)
• Monoarticular presentation of a polyarticular disease (i.e., immunoinflammatory—RA, SpA, PsA, IBD, or SLE)	• Sarcoidosis (e.g., ankle joint)
• Osteoarthritis (knee, hip, or 1st MCP)	• Seronegative SpA and chronic ReA
• Hemarthrosis (trauma, coagulation abnormality)	• Pigmented villonodular synovitis (PVNS)
• Ischemic (avascular) necrosis—of hip from SLE or corticosteroid therapy	• Synovial chondromatosis/sarcoma
• Tumor (metastasis, PVNS)	• Foreign body (plant thorn) synovitis
• Foreign body synovitis (wood fragments, plant thorn)	• Charcot (neuropathic) joint (e.g., leprosy, syringomyelia)
• Systemic diseases presenting as monoarthritis (e.g., acromegaly producing pseudogout)	• Monoarticular presentation of a polyarticular disease (i.e., RA, SpA, PsA)
Summary of working classification: Acute monoarthritis—Septic, crystals, traumatic, SpA (especially, ReA) Chronic monoarthritis—Osteoarthritis, crystals, SpA (especially chronic ReA), tuberculous	

IBD, inflammatory bowel disease; MCP, metacarpophalangeal; PsA, psoriatic arthropathy; RA, rheumatoid arthritis; ReA, reactive arthritis; SLE, systemic lupus erythematosus; SpA, spondyloarthropathy

joints) and polyarthritis (≥5 joints). Monoarthritis can either be acute (duration <6 weeks) or chronic (duration >6 weeks), and may be either inflammatory or non-inflammatory **(Table 2)**.[2,3]

Approach to Evaluation of Monoarthritis

The first and most important steps in evaluation are thorough *history taking*. Onset of symptoms, history of fever, recent travel, IV drug or alcohol abuse, sexual exposure, tick or insect bite, diarrhea, urinary tract infection, trauma, gardening (e.g., plant thorn synovitis), or pre-existing systemic disease should be enquired. History of drug therapy (e.g., diuretics in gout), skin rash, oral or genital ulcers, and prolonged bleeding should be taken into account **(Table 3)**. Next task is to start thorough *physical examination* where a physician has to differentiate articular from non-articular disease (see previous paragraph). Deep-seated joints like hip and sacroiliac joints are difficult to evaluate. Consider the D/D of single "red-hot joint" **(Table 4)**.

Clue for initial clinical observation (ideal examples):

- Middle-aged male with red, hot, tender, and swollen 1st metatarsophalangeal joint points toward gout.
- Elderly diabetic lady having knee replacement 1 year back where the knee is presently acutely swollen, hot, tender with high pyrexia, and toxicity indicates septic arthritis.
- Young male with acute knee pain, plus history of neck and back pain will have a probable diagnosis of ankylosing spondylitis (SpA).

Investigations—If one investigation has to be done, it is synovial fluid examination, and the fluid should be examined for

- Gram stain
- Routine culture
- Total and differential WBC count
- Crystals under polarized light microscope.

It is simple, safe, and a very easy bedside procedure without any complication, if performed aseptically. Synovial biopsy is done in selective cases (e.g., tuberculous synovitis) by needle aspiration or arthroscopy. Recently, by polymerase chain reaction and immunoelectron microscopy, synovial biopsy specimen is examined for etiological agents in Lyme disease, gonococci, or chlamydia infection. Other common tests done are blood for total and differential count, blood and urine culture,

TABLE 3 Clinical clues in the history and physical examination

History and clinical findings	*Probable diagnosis*
Sudden onset of pain developing within seconds or minutes	Trauma, fracture, internal derangement
Onset of pain arising over several hours or within days	Infection, crystal arthropathy, any inflammatory arthritis
Onset of pain developing over days to weeks	Indolent infection, osteoarthritis, infiltrative disease, tumor (synovium/bone)
Young adult with history of promiscuous sex and migratory arthritis	Gonococcal arthritis
History of diabetes mellitus, immunosuppression, bacterial endocarditis, or IV drug abusers	Septic arthritis
Previous history of acute attack in the joint with spontaneous resolution	Gout, any inflammatory arthritis
History of sustained bleeding (coagulopathy) or use of anticoagulants	Hemarthrosis
Positive family history	Gout, IBD-induced spondyloarthropathy, psoriasis, ankylosing spondylitis, osteoarthritis
Prolonged use of corticosteroid in the recent past	Infection, avascular necrosis
Urethritis (chlamydiae), conjunctivitis, skin or penile rash, diarrhea (campylobacter, salmonella, shigella)	Reactive arthritis (ReA)
Arthritis precipitated after binge alcohol intake or consumption of diuretics	Gout
Low back pain, uveitis (red eye), heel pain, or Achilles tendonitis	Ankylosing spondylitis
Hilar adenopathy, erythema nodosum (Lofgren syndrome)	Sarcoidosis
Bedside clinics: • Oral ulcers • Pyrexia • Lymphadenopathy • Tophi over olecranon process, or helix • Erythematous rash in face • Bronzing (darkening) of skin • Pyoderma gangrenosum • Erythema nodosum • Psoriatic skin patches or pitting nails • Circinate balanitis or keratoderma blenorrhagicum	 • Behçet's disease, SLE, ReA • Infection, crystals, immunoinflammatory • Tuberculosis, malignancy • Gout • SLE (butterfly-like), lupus pernio (sarcoidosis) • Pseudogout (hemochromatosis) • IBD, RA • IBD, SLE, sarcoidosis, tuberculosis • Psoriatic arthritis • ReA

TABLE 4 Acute monoarthritis presenting as 'red-hot joint'[4]

Infectious	Bacterial (Staphylococci, Streptococci, Gonococci, gram-negative organisms), viral
Crystal-induced	Gout, pseudogout (i.e., from hemochromatosis, acromegaly, hypoparathyroidism)
Acute exacerbation of:	RA, ReA, PsA, palindromic rheumatism

serum uric acid, and rheumatoid factor. Radiology is not much helpful except in sacroiliitis, osteoarthritis, and chondrocalcinosis (e.g., pseudogout). MRI may be helpful in deep-seated arthritis.

Pitfalls and Reality in Monoarthritis (Table 5)

Management

Management of acute monoarthritis depends on the actual diagnosis though the general principles of management include rest to the joint, application of ice, and physiotherapy to help maintain range of motion in joints and minimize subsequent muscle atrophy. Specific therapy includes antibacterial agents for septic arthritis, non-steroidal anti-inflammatory drugs (NSAIDs) and/or intra-articular corticosteroid injections for non-infectious inflammatory monoarthritis; arthroscopy is performed for internal derangement. *Presence of infection*

TABLE 5 Pitfalls versus reality in diagnosing monoarthritis[5]

Pitfalls	*Reality*
A normal serum uric acid level excludes gout	Serum uric acid may be normal or low up to 30% cases of gout as stress-induced liberation of ACTH and TNF-α may act uricosuric. Moreover, there may be unrelated asymptomatic hyperuricemia associated with other monoarticular arthritis
Presence of fever distinguishes infective from non-infective arthritis	Presence of fever is not a reliable indicator of septic arthritis, and moreover acute attack of gout or pseudogout may be associated with pyrexia. Similarly, absence of leukocytosis, raised ESR, raised CRP, or absence of organisms does not exclude septic arthritis
Presence of crystals (MSU or CPPD) in the joint fluid rules out infection	Crystal may be present in septic arthritis
The problem is always in the 'joint' as the patient complains of joint pain	Many a time, soft tissue rheumatism due to adjacent soft tissue inflammation (such as olecranon bursitis of the elbow) may be the source of pain
Diseases manifested as polyarthritis cannot have monoarthritis-like presentation	Monoarticular flare of rheumatoid arthritis or reactive arthritis is not uncommon
A negative Gram staining and culture of synovial fluid virtually excludes infection	Results of culture may be negative in early infection, and thus culture of blood/urine should be performed repeatedly in strong clinical suspicion of infection
In synovial fluid analysis, presence of WBC >2,000/mm^3 clinches the diagnosis of septic arthritis	Synovial fluid WBC >2,000/mm^3 is very often found in RA, SpA, SLE, or gout

should always be ruled out before giving intra-articular corticosteroid injection. Acute gout should be treated with colchicine, NSAIDs, or prednisolone. Joint aspiration is necessary in hemarthrosis. Osteoarthritis patients are advised to save their cartilage by practical demonstration, and treated with intra-articular corticosteroid and/or hyaluron injection. Pain in reactive arthritis is relieved by NSAIDs and ultimately the patients are advised to take disease-modifying anti-rheumatic drugs (DMARDs).

If the clinical suspicion of septic arthritis is very strong, empiric antibiotic therapy should be started, pending the reports of synovial fluid analysis. Modifications of antibiotics and its dosage may be done as soon as Gram staining and culture reports of synovial fluid are available. Septic arthritis should be treated in a hospital under the supervision of an orthopedic surgeon. Many a time, surgical drainage of a septic arthritis is required.

Practical Recommendations for Acute Monoarthritis[1,6]

- Acute monoarthritis is a medical emergency. With a short history of red-hot swollen joint, one should always suspect infection and unless otherwise indicated, it should be treated as septic arthritis. Other D/D are acute gout, trauma, and acute onset of inflammatory polyarthritis.
- The most significant point of clinical examination is to differentiate true synovitis (i.e., arthritis) from periarticular disease (e.g., cellulitis, bursitis, etc.).
- Septic arthritis can destroy a joint very rapidly, if not treated promptly. Septic arthritis is often superimposed on gout or pseudogout. Gonococcal arthritis is commonly a disease of sexually active young women.
- RA, ReA, IBD-associated arthritis, SLE, PsA, Behçet's disease can begin as acute monoarthritis, while systemic diseases like sarcoidosis, sickle cell anemia, or hemophilia may be complicated by monoarthritis. Tuberculosis and other indolent infections should be considered in chronic monoarthritis, and synovial biopsy may be needed to pin-point the diagnosis.
- The synovial fluid should be aspirated and sent for Gram staining and cultures (apart from total analysis) in acute and chronic monoarthritis. Synovial fluid analysis is the most important investigation.
- Absence of leukocytosis/high ESR/high CRP, negative Gram stain, or negative synovial fluid cultures does not exclude infection.

- In gout, synovial fluid samples must be sent for polarized microcopy for demonstration of intracellular MSU crystals as serum uric acid may be normal in acute attack of gout; in its absence, ordinary microscopy often gives a clue for crystals.
- Plain X-ray of the affected joint is usually of no benefit.
- In septic arthritis, start relevant antibiotics as early as possible pending culture reports. Usual pathogens are *Staphylococcus aureus* or streptococci but Gram-negative organisms are commoner in the elderly and immunocompromised patients. Conventionally, IV antibiotics are given for 2 weeks, followed by oral antibiotics for 4 weeks or more till local/systemic manifestations resolve and acute phase reactants (e.g., CRP) return to normal.
- Septic arthritis should be treated by orthopedic surgeon, crystal arthropathy, and inflammatory arthritis by rheumatologist, and osteoarthritis by orthopedic surgeon and physiatrist jointly.

Conclusion

Acute monoarthritis is a rheumatologic emergency and demands prompt diagnosis. So far as diagnosis and treatment of chronic monoarthritis are concerned, it needs patience, sound clinical background, and experience. Prompt diagnosis of joint infection is crucial as it rapidly results in joint destruction. Before putting the needle within a joint to inject corticosteroid, it is the duty of orthopedic surgeon or rheumatologist to exclude infective arthritis. The diagnostic and therapeutic dilemma in monoarticular arthropathy can be solved easily if the attending doctor examines the patient meticulously, and analyze the clinical findings and investigation reports logically.

CHAPTER

209 Oral Targeted Treatments in RA—Update 2021

Ramakrishna Rao Uppuluri, Sripurna Deepti Challa

Abstract

The current concept in the management of rheumatoid arthritis (RA) and other immune-inflammatory arthritis is "treat to target", the target being low disease activity or remission. The standard of care in RA involves pharmacotherapy initiating conventional synthetic disease modifying anti-rheumatoid drugs. However, some patients do not respond to the conventional therapy. Advanced target therapy for RA involves biologic agents or oral small molecules. JAK inhibitors, a form of oral targeted treatment, are convenient, orally administered which do not produce drug antibodies. Robust clinical trials demonstrated their efficacy and safety.

Introduction

Among the inflammatory polyarthritis, rheumatoid arthritis (RA) is the most common. Over the past few decades, significant advances were made in understanding the pathogenesis of RA. The role of several important proinflammatory cytokines, such as tumor necrosis factors (TNF), interleukins (e.g., IL-6), and cell-associated targets (e.g., CD20) have been validated by the use of targeted biologic therapies in last two decades. Standard of care in RA involves initiation of the treatment with conventional synthetic disease modifying anti-rheumatoid drugs (csDMARDs) such as methotrexate (MTX). Biologic therapies (bDMARDs) have led to further reduction of the signs and symptoms of RA resulting in low disease activity (LDA) or remission of the disease. However, they have limitations—they have to be given parenterally and stored at lower temperatures. They can induce immunogenicity developing tolerance. Small molecules with low molecular mass that inhibit intracellular inflammatory signaling pathways are developed during the last decade. They are an important alternative to biologics for RA. These are called oral targeting treatments of RA.

Advances in the Treatment of RA

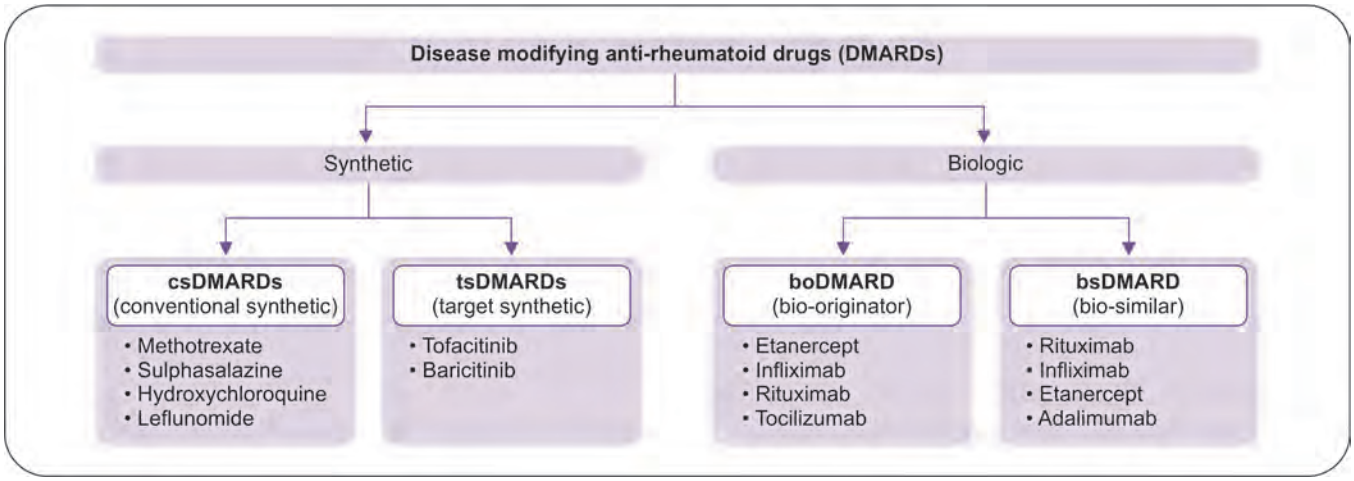
In the treatment of RA, csDMARDs occupy a central role **(Flowchart 1)**. MTX is still a baseline therapy unless contraindicated. Most of the rheumatologists use combination therapy with csDMARDs.[1]

However, significant number of the patients of RA do continue to progress with erosive arthritis. Biologic era in the past few years had seen remarkable advancement in the therapy of RA. In view of persistent unmet needs in the management of RA, oral targeted therapy inhibiting intracellular signaling pathways is developed in the last decade **(Fig. 1)**.[2]

Oral Targeted Therapy: Janus Kinase Inhibitors

Intracellular signaling pathways involved in signal transduction from the cell surface to the nucleus after ligand receptor binding have been identified. Small molecular therapies target these intracellular pathways. Protein kinases that phosphorylate intracellular proteins are major players in signal transduction. Tyrosine kinases,

Flowchart 1: Classification of DMARDs



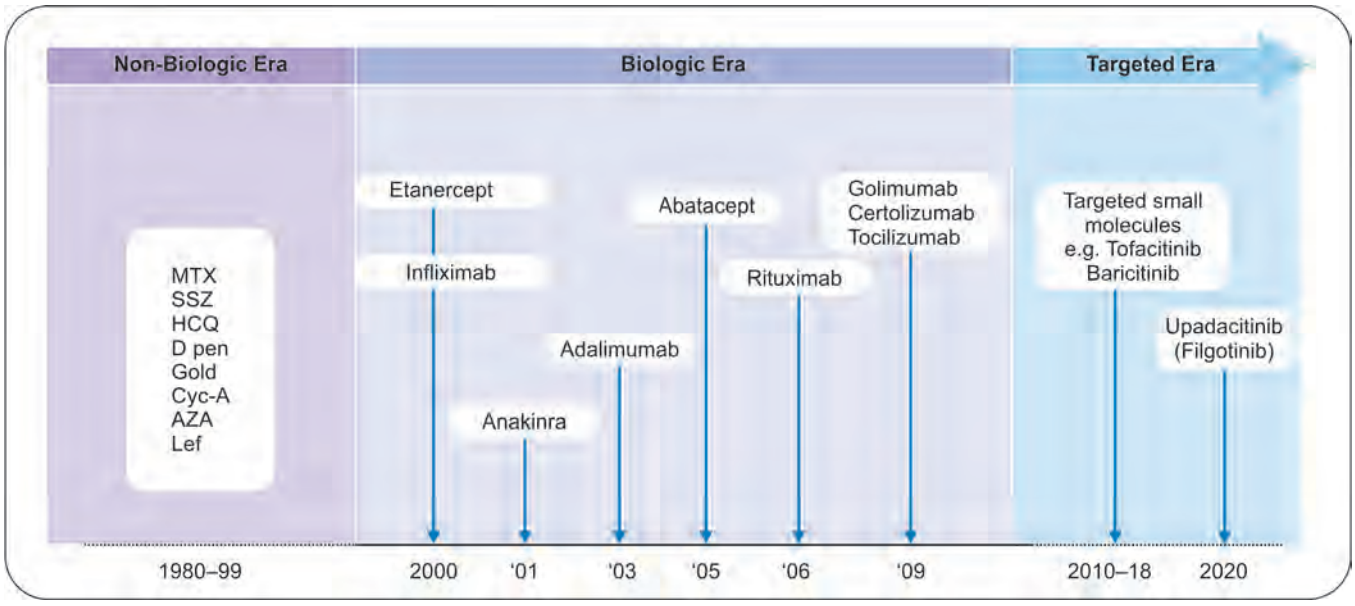


Fig. 1: Timeline in RA therapy (FDA approvals)
Arrival of oral targeted treatment—JAKinibs

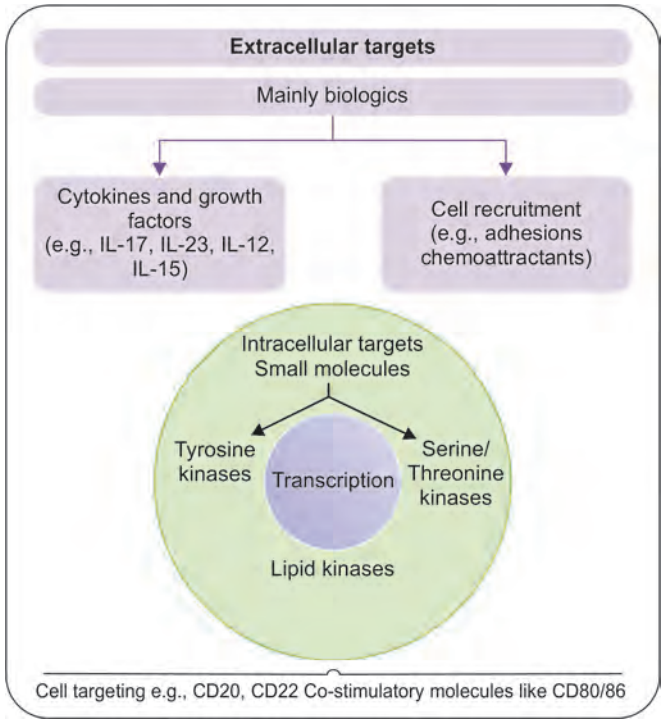
Janus kinases (JAKs), and Serine kinases are some of the protein kinases **(Flowchart 2)**.

Receptor polymerization and activation of associated JAKs occur once the cytokine binds to its cell surface receptor. JAKs, named after the two-faced Roman God Janus, consist of four types—JAK1, JAK2, JAK3, and TYK2. Phosphorylation of the receptors activated by JAKs dock the STATs (Signal Transduction Activator Transcription) **(Figs. 2A and B)**. They dimerize, translocate to the nucleus, and activate new gene transcription generating further cytokines **(Figs. 2C and D)**.[3]

JAK inhibitors (Jakinibs) have been successfully developed as oral targeted therapy in RA. Autophosphorylation and further activation of JAKs is inhibited by Jakinibs, for example, Tofacitinib. JAKs cannot phosphorylate the receptors and cannot dock the STATs. Phosphorylation of STATs, dimerization, and translocation are inhibited. Hence, gene transcription and further

production of cytokines do not take place **(Fig. 3)**. There are seven STATs: STAT1, STAT2, STAT3, STAT4, STAT5A, STAT5B, and STAT6. Different cytokines have the ability to preferentially recruit different STATs by virtue of selective binding to cytokine receptors.[4] The JAK/STAT pathways exert their function through type I and type II receptors. Type I receptors are used by several interleukins (ILs), colony-stimulating factors, and hormones, while type II receptors are used by interferons (IFNs) and IL-10 related cytokines **(Fig. 4)**.[5]

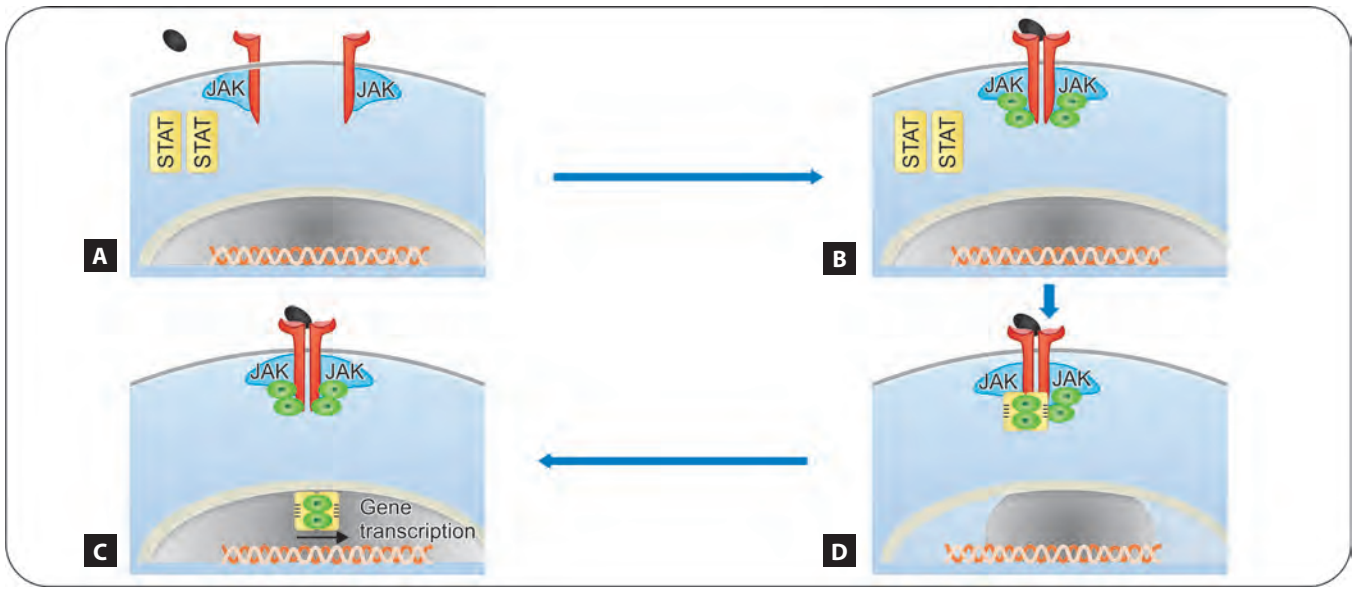
Flowchart 2: Small molecules—intracellular targets



Tofacitinib, one of the early Jakinibs, was approved in the USA in 2012 for the treatment of moderately severe RA not responding to conventional therapy and was approved in India by 2016. Baricitinib, another Jakinib, is also approved in India for the treatment of RA more than a year ago. Upadacitinib and Filgotinib are other Jakinibs yet to enter Indian market. All these molecules have undergone robust clinical trials for efficacy in RA[6] **(Tables 1 and 2)**. Randomized controlled trials (RCT) and long-term extension (LTE) studies have shown that Jakinibs are as efficacious as biologics. Safety profiles of these Jakinibs have also been carefully monitored long term.[7] Tofacitinib in Indian patients with RA had confirmed its efficacy and safety by a post hoc analysis in Phase 3 and LTE studies over 7 years.[8]

The Place of Jakinibs in Contemporary RA Management

Tofacitinib and baricitinib are currently available Jakinibs for the treatment of patients with moderately severe RA



Figs. 2A to D: JAK signaling pathways

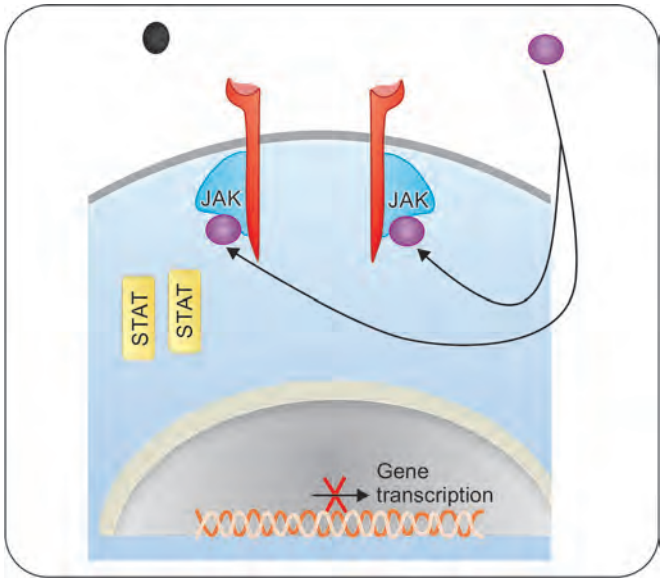


Fig. 3: Mode of action of JAK inhibitor (see text for the explanation)

not responding to conventional DMARDs. Tofacitinib targets mainly JAK1, JAK3 and Baricitinib JAK1, JAK2. Tofacitinib is also approved in other disorders such as psoriatic arthritis (PsA) and ulcerative colitis (UC). Many more Jakinibs are in the process of randomized clinical trials[9] **(Table 3)**.

Drug Target Indications

American College of Rheumatology (ACR) guidelines and European League against Rheumatism (EULAR) recommendations for the management of RA advise use of MTX to begin with.[10,11]

However, only a third of patients with early RA benefit from MTX monotherapy in controlling disease activity, improving patient reported outcome measures (PROMs) and slowing radiographic progression.[12] The ACR guidelines recommend combination of csDMARDs or

addition of a bDMARD or a Jakinib, when the patients fail to achieve a satisfactory response to MTX monotherapy and a short period of glucocorticoids. Jakinibs with or without MTX are also considered in bDMARD inadequate responders. EULAR recommendations also advise similar management for RA, especially with poor prognostic factors such as high titers of RF/ACPA (anti cyclic citrullinated protein antibodies), high disease activity, early joint damage and/or failure of two or more csDMARDs **(Fig. 5)**.

Real world evidence for safety and efficacy of Jakinibs is also necessary to bridge the gap between RCTs and rheumatology clinics.[13] Usually there is little difference in the screening and monitoring of infections between Jakinibs and biologics. Increased risk of Herpes zoster may be common to all Jakinibs. In real world practice,

TABLE 4 Some of the ongoing clinical trials with JAKINIBS other than RA

accumulation of cases to evaluate risks of relatively rare serious adverse events (SAEs) is needed. Some of the SAEs are thromboembolic events, gastrointestinal (GI) perforation, and interstitial lung disease. Pharmacovigilance activity is required to establish the efficacy and safety of Jakinibs in patients with RA and other rheumatic diseases **(Table 4)**.

Advantages of Jakinibs

Jakinibs are orally administered small molecules unlike biologics, which are large proteins and given only by subcutaneous or intravenous.[14] Jakinibs act fast showing their benefits within 1–2 weeks. Small molecules can be synthesized easily, carried easily, and do not require cold chain. They do not have immunogenicity seen in some biologics; hence do not generate drug antibodies. Since their half-life is short for a few hours, they can be stopped in situation where infection is suspected with a rapid reversal of drug-related side effects. Blockade of a wide spectrum of cytokines may cover many inflammatory pathways. Tofacitinib and Baricitinib with background MTX proved to be non inferior and superior respectively over standard of care biologic Adalimumab in active RA.[15] PROMs, such as pain, function and fatigue are improved very well with Jakinibs.[16,17]

Jakinibs are proved to be beneficial and convenient even as monotherapy in RA. Tofacitinib in ORAL-Start study, Baricitinib in RA-Begin study, and Upadacitinib in SELECT-Early study have shown superiority over MTX on clinical, functional, and radiographic measures.[18]

Side Effects of Jakinibs

Infections

Usage of Jakinibs may increase serious and opportunistic infections. However, the rate of infections is not more than biologics except Herpes zoster.[19] The risk of reactivation of varicella zoster virus is increased by the use of Jakinibs with the combination of steroids and MTX. Before starting therapy with Jakinibs, vaccination against Herpes zoster is considered. Treatment with Jakinibs can cause anemia and decreased cell counts including lymphocytes, neutrophils, and platelets.[20] There is no particular association of these changes with serious infections or malignancy.

Tuberculosis

RA itself can increase the susceptibility to tuberculosis (TB). Biologics especially the TNF inhibitors increase the risk of TB, mostly in an endemic area. The incidence is less with Jakinibs. Among 5,671 subjects enrolled in Phase 2 and 3 and LTE studies of Tofacitinib, 26 cases of TB were reported. The median time between the start of Tofacitinib and diagnosis of TB was 64 weeks (15–161). Extrapulmonary infection occurred in fifteen (58%) cases. Most cases (20/26, 77%) were reported in those taking Tofacitinib 10 mg twice a day. However, globally Tofacitinib dosage is only 5 mg BID in RA. TB rate with Jakinibs was also associated with endemicity.[21]

Thromboembolic Events

Possibility of increased risk of thromboembolic events is noted with the use of Baricitinib. RA itself has a tendency to develop the risk of deep venous thrombosis and pulmonary embolism. Relating this complication to the action of a specific or a group of cytokines is difficult. JAK2 inhibition disturbs thrombopoietin signaling and platelet homeostasis, but its relation to thrombosis is ill-defined.[22]

Malignancy

Patients with RA have an increased incidence of malignancy including lymphoma. The rate of cancer in patients on Jakinibs is similar to those on biologics[23] **(Table 5)**.

Other Problems

Jakinibs are associated with an increase in total cholesterol, low-density lipoprotein (LDL), and high-density lipoprotein (HDL) particles. Jakinibs may limit vascular damage by decreasing inflammation in spite of increased cholesterol.[24] Minimal increases in creatine phosphokinase levels are observed without overt muscle disease. The use of Jakinibs may be associated with increased liver enzymes and GI perforation. Jakinibs are

TABLE 5 Incidence rates of adverse events of special interest of JAKINIBS in RA

Adverse events	*Tofacitinib*	*Baricitinib*
Serious infection	2.7 (2.5, 3.0)	2.9 (2.5, 3.4)
Herpes zoster	3.9 (3.6, 4.2)	3.2 (2.8, 3.7)
Tuberculosis	0.2 (0.1, 0.3)	0.15 (0.07, 0.27)
Malignancy excluding NMSC	0.9 (0.8, 1.0)	0.8 (0.6, 1.0)
NMSC	0.6 (0.5, 0.7)	0.4 (0.2, 0.5)

MACE	0.58 (0.39, 0.88)	0.5 (0.4, 0.7)
DVT/PE	DVT: 0 in PBO-controlled cohort and 0.1 (0, 0.3) in dose-comparison cohort PE: 0 in PBO-controlled cohort and 0.1 (0, 0.4) for 5 mg bid	DVT/PE: 0.5 (0.3, 0.7)
GI perforation	0.11 (0.07, 0.17)a	0.05 (0.01, 0.13)

Incidence rates (95% CIs) in RA patients treated with each JAK inhibitor were shown.
DVT, deep vein thrombosis; GI, gastrointestinal; MACE, major adverse cardiovascular event; NMSC, non-melanoma skin cancer; PBO, placebo; PE, pulmonary embolism.

contraindicated at the time of pregnancy. Women of childbearing age should use effective contraception while on treatment. During breastfeeding, Jakinibs should not be used.

Conclusion

- JAK inhibitors are the latest addition of the treatment of RA in the last decade.
- They act by blocking intracellular JAK/STAT signaling pathways inhibiting the production of inflammatory cytokines.
- They are rapidly acting, oral targeting anti-rheumatoid drugs with convenience.
- They showed sustained efficacy and established safety by robust clinical drug trials and real world experience.
- Recommended as a second line therapy for csDMARDs inadequate responders or Biologic inadequate responders by several guidelines.

CHAPTER

210 Biosimilars: Bane or Boon for India

Durga Prasanna Misra, Pallavi Patro, Vikas Agarwal

Abstract

Biosimilars are structural analogues of innovator biological drugs which have undergone rigorous development and testing. In this chapter, we overview definitions of biosimilars, biomimics, and biocopies; review regulatory processes for biosimilar approval; and discuss the concepts of extrapolation, switch, substitution, re-switch, and nocebo effect as assess perspectives for biosimilar use (including cost) from an Indian perspective.

Introduction

Better understanding of pathophysiological process driving disease has given rise to targeted therapies for the treatment of these diseases. Biologic drugs are drugs administered parenterally, which target specific molecular pathways resulting in disease phenotypes. Biologic drugs are now used in many medical specialties such as Rheumatology, Hematology, Oncology, and Nephrology.[1-3]

The classical example of a biologic drug that has revolutionized patient management in drugs targeting the proinflammatory cytokine tumor necrosis factor alpha (TNF-α) in disease settings like rheumatoid arthritis (RA) and ankylosing spondylitis (AS). Such anti-TNF therapies have become frontline agents for the management of these lifelong inflammatory diseases, and markedly improved disease control in those refractory to conventional disease-modifying antirheumatic drugs. However, despite their use being described in RA and AS since the late 1990s, anti-TNF agents remained out of reach for a majority of the Indian populace until recently, in no small part due to prohibitive costs.[2] A major reason for increased accessibility has been the advent of biosimilar drugs, which are copies of the innovator biologic drug, however, are amenable to manufacture locally as well as not covered by any existing patents. Therefore, biosimilars are cheaper and more accessible. The recent past has seen a flooding of the local market for such biosimilar drugs. In this chapter, we discuss the impact of biosimilar agents (benefits as well as costs) and their comparability in terms of effectiveness and adverse effects, as well as issues such as nocebo effect, which potentially limit their use in patients.[4] We also discuss certain peculiar adverse effects occasionally described with biosimilars.

Biosimilars and Biomimics/Biocopies

Biologic drug synthesis is complex, in that it relies on recombinant deoxyribonucleic acid (DNA) technology for synthesis of these molecules. Biosimilars are similarly synthesized using recombinant DNA technology,[5] so also are biomimics or biocopies with similar molecular structure (primary, secondary, and tertiary). However, biosimilars differ from biomimics or biocopies in that they also have been demonstrated to have equivalent effect on disease states in preclinical and clinical trials, as well as demonstrate similar pharmacokinetic and pharmacodynamic properties (including immunogenicity) to the innovator biologic drugs.[6]

Regulatory Processes for Approval of Biosimilar Drugs

The two major agencies regulating drug approval in the world, the European Medicines Agency (EMA) and the United States Food and Drug Administration (US FDA) have laid down guidelines for the approval of biosimilar drugs. Broadly, the similar protein structure of the innovator biologic drug and the biosimilar should be demonstrable, followed by studies that demonstrate equivalence in pharmacokinetic and pharmacodynamic properties with innovators. Thereafter, efficacy and safety of biosimilar drugs with innovator biologic drugs should be demonstrated before consideration for approval. Ideally, equivalence with innovator (i.e. neither a clinically significant detriment nor benefit when compared with innovator biologic) should be demonstrated rather than non-inferiority (i.e. simply the lack of a clinically significant detriment). Furthermore, since these are foreign proteins, the lack of significant difference in immunogenicity when compared with innovator biologic drugs should also be demonstrable. Mere identity in protein structure without demonstrating the other steps mentioned simply results in a biomimic. Such biomimics have been noted to have a greater propensity to develop adverse effects than innovators, and are often in vogue in regions of the world with poor regulatory policies.[7-9] The approval processes for biosimilars in India are broadly in line with the EMA and US FDA standards. This requires approvals from the Central Drugs Standards Control Organization (CDSCO).

Are Biosimilars the Same as Generic Drugs?

A common source of confusion is generic drugs and biosimilars. It is important to understand that generic drugs are mere chemicals with identical structure to the original molecules. The generation of biologic drugs has the added complexity that they require biologic systems for the generation of their recombinant protein structure; hence, they are thematically more complex to generate and attain equivalence to innovators when compared with chemical generic drugs.[7]

The Need for Post-marketing Surveillance for Long-term Safety of Biosimilars

An often-quoted tale of caution regarding biosimilar use has been the example of recombinant erythropoietin biosimilar, which was introduced in South America as a cheaper alternative to innovator erythropoietin analogue. This drug was primarily intended for use in patients with chronic kidney disease with anemia (which often results due to erythropoietin deficiency). Unusually, some patients treated with erythropoietin biosimilar developed pure red cell aplasia, resulting in refractory transfusion-dependent anemia.[10] This was a consequence of antibodies that neutralized the effect of erythropoietin due to differences in immunogenicity of the biosimilar molecule.[10] Such issues were later rectified in future erythropoietin biosimilars by modifying the protein structure to ameliorate such abnormal immunogenicity.[7] This is a case in point, which reiterates the need to seek long-term safety of biosimilars that are eventually approved and marketed by means of continual post-marketing surveillance.[11]

Extrapolation

Another term often used in the context of biosimilars is extrapolation. Many a times, the same biologic drug is used for a number of disease states. For example, anti-TNF agents are used in RA, AS, psoriatic arthritis (PsA), inflammatory bowel diseases (IBD), and sarcoidosis. Should a biosimilar be shown to be equivalently efficacious to the innovator in RA, this is often extrapolated to assume its effectiveness to a similar degree in the other disease states it is indicated for, such as AS, PsA, and IBD. This is a common practice with biosimilars; however, due caution and careful post-marketing surveillance should accompany any such extrapolation of indication for the use of biosimilars.[12]

Switch, Substitution, and Re-switch

Switch refers to the decision of the treating clinician to change a biologic drug from innovator to biosimilar, or vice versa. If such a decision is taken by somebody who is not the treating physician, say, a regulatory authority or the hospital administration (due to costs or other concerns), this is instead referred to as a substitution (also known as a non-medical switch). After an initial switch, it is possible to re-switch back and forth between the two products, depending on feasibility issues such as availability, ability to afford, etc.[1]

Switching offers an opportunity to provide head-to-head comparisons between innovators and biosimilars. Analysis of more than 300 patients with IBD from Sweden

switched from innovator infliximab to biosimilar infliximab CT-P13 revealed similar disease activity state at 12 months of observation.[13] In another study from the Netherlands, 625 patients switched to biosimilar etanercept were compared with a historical cohort of 600 patients treated with innovator etanercept at the same region. Indications for etanercept use in these patients were inflammatory arthritides (RA, AS, and PsA). At 6 months, retention rates of the biosimilar (in the switched cohort) or innovator (in the historical cohort) were nearly 90%, although patients switched to etanercept biosimilar had a slightly higher risk of discontinuation.[14] A Scandinavian biologic registry spanning five countries compared retention rates for infliximab (innovator 320, biosimilar 999 patients) and etanercept (innovator 493, biosimilar 522) in patients with spondyloarthritis. At 1-year follow-up, 66% treated with etanercept biosimilar continued the same compared with 73% treated with etanercept innovator; corresponding figures for infliximab at 2-years were 44% for biosimilar and 46% for innovator, suggesting similar rates of retention irrespective of biosimilar or innovator molecule.[15] A comparison of more than 1,600 etanercept biosimilar switchers with more than 400 non-switchers (continuing on innovator etanercept) from Denmark for RA, AS, and PsA revealed numerically higher retention rates at 1 year for switchers than non-switchers (although of little difference in magnitude and not significant statistically).[16] A long-term follow-up of patients for 52 weeks switched to biosimilar infliximab compared with innovator infliximab in a randomized trial (NOR-SWITCH trial) for a variety of multisystem inflammatory diseases revealed similar rates of efficacy and safety.[17] An expected benefit of switching is lesser health-care costs; however, a recent analysis of 1620 recipients of etanercept biosimilar from Denmark did not reveal a significant cost-saving in the year following the switch compared to the year preceding it.[18] Hence, the cost-effectiveness of switching biosimilars needs further evaluation.

Nocebo Effect

A perceived lesser degree of response to a drug owing to psychological or contextual factors might be described as a nocebo effect. This is thematically the antithesis of a placebo effect (i.e. perceived positive effect of a placebo, when no active drug is being administered). Biosimilar drug use in real life might be affected by the nocebo effect. In the setting of rheumatic diseases, biosimilar drugs have not shown significant differences compared to innovator drugs in blinded randomized controlled trials. However, open-label clinical trials and real-life registry data have often demonstrated lower retention rates (and higher rates of switch back to innovator drug) with biosimilars. This might be due to the perceived ineffectiveness of these drugs by the patients, which is supported by the fact that many such switches are based on subjective (rather than objective) measures of ineffectiveness. Such a nocebo effect has the potential to limit the cost-saving effect of biosimilars at an aggregated level by limiting their utilization.[4] However, the authors perceive that nocebo effect might be a particular problem in societies where health care is nationalized. In countries like India, where a majority of the time patients pay out-of-pocket to afford biologic drugs, the lower cost of biosimilar agents is likely to reduce the likelihood of nocebo effect (since affordability now becomes the major concern rather than perceived effectiveness).

Perspectives from India Regarding Biosimilars

Overall published literature regarding the effectiveness of biosimilars from India is scarce. A significant chunk of the available literature relates to a biosimilar of adalimumab (ZRC-3197). Regulatory approval was obtained after proving efficacy of this adalimumab biosimilar in patients with RA when compared with innovator adalimumab.[2] Thereafter, real life data regarding ZRC 3197 use in 51 patients with spondyloarthritis and 39 patients with RA was published. At an observation period of 1 year after treatment, more than 90% patients with spondyloarthritis had attained clinical remission. Nearly 60% of the cohort with RA also attained control of disease activity.[19] Post-marketing surveillance under the Adalimumab Biosimilar Patient Registry (ASPIRE) further recently reported data in relation to RA and spondyloarthritis. In 73 patients with RA, significant reductions in disease activity were noted by 24 weeks; nearly one-half patients attained good control of disease activity.[20] For 100 patients with AS treated with adalimumab biosimilar in this same ASPIRE registry, adequate control of disease activity with attainment of Bath Ankylosing Spondylitis Disease Activity Score (BASDAI) below 4 at 24 weeks of observation was possible

BOX 1 Recommendations of the EULAR, GRS, and PANLAR regarding the use of biosimilars in rheumatology practice[22-24]

- Biosimilars should have lesser cost than the reference/innovator product
- Biosimilars should undergo strict regulatory processes to demonstrate equivalence in safety, efficacy, and immunogenicity with innovator molecules
- In the absence of having undergone strict regulatory processes, such drugs shall only remain as biomimics and should not be referred to as biosimilars
- Biosimilars should be preferably prescribed by their brand name to differentiate them from innovator biologics (also prescribed preferably by their brand name)
- Biosimilars should not be substituted for innovator products, or vice versa, without the knowledge of the prescribing physicians
- All patients receiving biologic drugs, whether innovator or biosimilar, should preferably be enrolled in registries
- Ongoing surveillance should be done to assess any unexpected adverse effects of biosimilars, which might be evident only after marketing

EULAR, European League against Rheumatism; GRS, Greek Rheumatology Society; PANLAR, Pan American League of Associations for Rheumatology

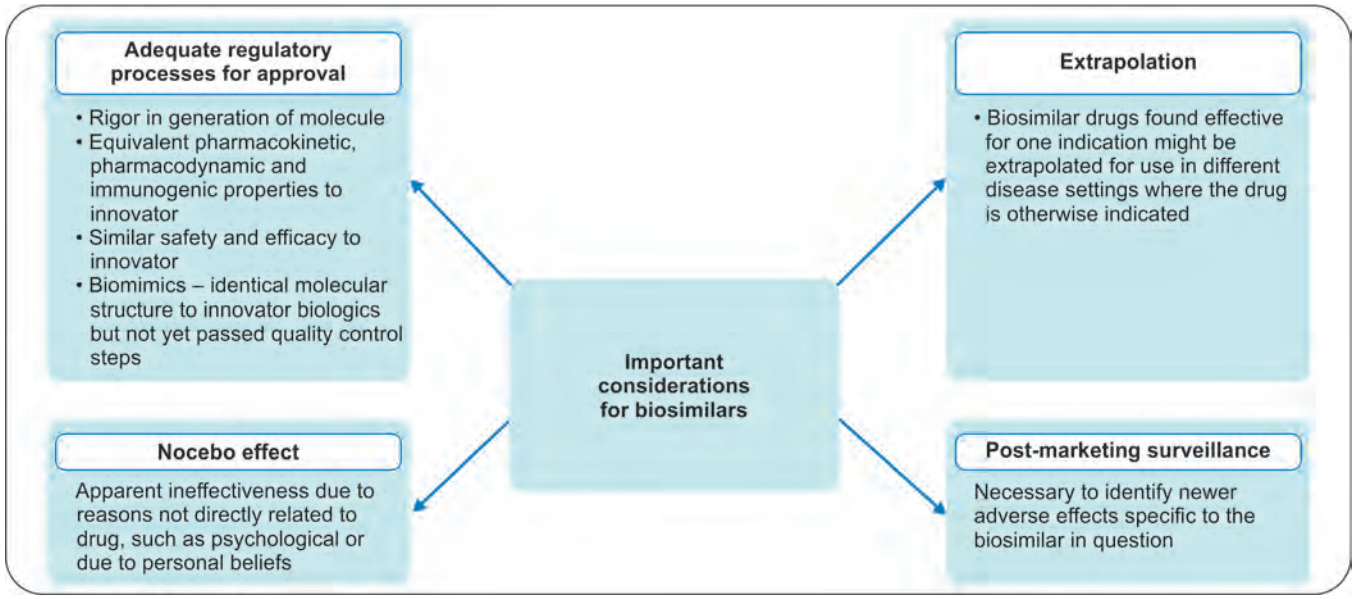

Fig. 1: Issues related to biosimilars and their approval processes

in more than 90% patients.[21] Neither of these two studies identified any adverse safety signals with adalimumab biosimilar during post-marketing surveillance.[20,21] There remains an unmet need to generate and publish such real-world data in a larger number of patients for biosimilar drugs used for different indications in India.[22]

Recommendations for Biosimilar Use in Rheumatic Diseases

Considering the proliferation of available biosimilar drugs worldwide for the management of rheumatic diseases, as of now various international societies have provided guidelines for the prescription of biosimilar drugs. **Box 1** summarizes the relevant information from the guidelines for biosimilar use provided by the European League against Rheumatism, the Greek Rheumatology Society, and the Pan American League of Associations for Rheumatology.[23-25] Briefly, these recommendations suggest that biosimilars should be cheaper than reference biologics, share similar safety and efficacy profile, undergo suitable regulatory approvals before marketing, and be subject to post-marketing surveillance.

Conclusion and Future Perspectives

Figure 1 summarizes the various issues associated with biosimilar approval and use. Despite potential advantages of biosimilar drugs in terms of cost savings and greater accessibility with similar efficacy/effectiveness and safety to innovator biologic drugs (provided they have passed through rigorous regulatory processes), the uptake of biosimilars has not been uniform. An analysis of a database from the United States of America reviewed prescriptions of innovator and biosimilar infliximab amongst patients visiting rheumatology practices. Only 3.5% patients took up infliximab biosimilar, despite this retention rates were similar to innovator infliximab.[26] As discussed earlier, one of the barriers toward uptake or retention of biosimilars could be a nocebo effect.[4] It is important to evaluate such factors and attempt to reduce factors, which limit their uptake despite adequate efficacy and safety. This could be facilitated by conducting qualitative research in this area. Furthermore, despite some studies showing no definitive cost-saving with biosimilars, it is reasonable to hypothesize that in a country, like India, where a majority of health-care settings where biosimilars are used is out-of-pocket expenditure,[27] use of biosimilars shall result in saving of significant costs. Literature suggests that a significant proportion of physicians might not be adequately aware about the nature and utility of biosimilars; hence, better education in this regard might help improve the appropriate utilization of biosimilars in the proper setting.[3]

To conclude, biosimilars are a boon for India, particularly since they are cheaper and equally efficacious and safe alternatives (after appropriate regulatory approvals) and can potentially improve the sustainability of biologic use when used appropriately. At the same time, it is necessary to caution about biomimics until they have undergone appropriate regulatory approvals to prove their equivalence in safety and efficacy.

CHAPTER

211 An Approach to Vasculitis

Packiamary Jerome

Abstract

Vasculitis is an immunological disorder leading to inflammation of the vessel wall. The clinical symptoms range from a mild self limiting illness to severe life threatening complication. Vasculitis affects blood vessels of all types and all organs. It may happens as a de novo phenomenon or secondary to other causes like infection, drugs, malignancy, and so on. Vasculitis affects all organs in the body including skin, eye, ear, nose, throat, lungs, heart, joints, etc. The clinical manifestations mimics like that of a viral illness. There will be an elevation of acute phase reactants. Biopsy of the involved organ can give a clue to the diagnosis of vasculitis. Treatment includes supportive care, followed by steroids and immunosuppressants. A comprehensive approach is needed for an accurate diagnosis of vasculitis.

Introduction

Vasculitis is a group of disorder characterized by the inflammation of the vessel wall. The clinical manifestations of vasculitis range from a mild self limiting cutaneous involvement to severe life threatening multiorgan involvement. The diagnosis of vasculitis is difficult as the clinical presentations mimic many other illnesses and the diagnosis of vasculitis often gets delayed. A high degree of suspicion, detailed history and systematic physical examination may help in arriving at the diagnosis of vasculitis.

Epidemiology

The incidence of vasculitis in western population is 20 per million per year. The exact incidence and prevalence in India is not available. Among the various types of vasculitis, the most common is Takayasu's arteritis and the most uncommon is Temporal arteritis. Wegener's granulomatosis is more common in north India than south India.

Classification

Vasculitis affects blood vessels of all the types and all the organs. Vasculitis should be suspected in any patient with unexplained ischemia in the absence of atherosclerosis. Because of the increased vasculature skin is more prone for vasculitis. The vasculitis is primarily classified into two types:

- *Primary vasculitis:* It is presumed to be immune origin.
- *Secondary vasculitis:* It is mainly secondary to other causes like infection, drugs, malignancy, or idiopathic.

Chapel Hill Classification (1993)

This classification is currently considered as "Gold Standard." *See* **Table 1**.

LIE Classification (1994)

Primary Vasculitis

- Vasculitis of Large, Medium, and Small Vessels:
  - Giant cell arteritis

TABLE 1 Classification based on vessel size

Large vessel vasculitis	• Giant cell arteritis • Takayasu disease
Medium vessel vasculitis	• Polyarteritis nodosa • Kawasaki disease
Small vessel vasculitis	• Microscopic polyangiitis • Wegener's granulomatosis • Churg strauss syndrome • Henoch schonlein purpura • Essential mixed cryoglobulinemia • Cutaneous leukocytoclastic vasculitis

TABLE 2 Granulomatous and non granulomatous vasculitis

	Granulomatous	***Non-granulomatous***
Large	• Temporal arteritis • Takayasu arteritis	–
Medium	–	• Classic PAN • Kawasaki disease
Small	• Wegener's granulomatosis • Churgstrauss syndrome	• Microscopic polyangiitis • Henoch schonlein purpura • Essential mixed cryoglobulinemia

  - Takayasu disease
  - Isolated angiitis of CNS
- Vasculitis of Medium and Small Vessels:
  - Polyarteritis nodosa
  - Churg strauss syndrome
  - Wegener's granulomatosis
- Vasculitis of Small Vessels:
  - Microscopic polyangiitis
  - Henoch schonlein purpura
  - Cutaneous leukocytoclastic vasculitis
- Miscellaneous:
  - Burger's disease
  - Behcet's disease
  - Cogan's syndrome
  - Good pasteure's syndrome
  - Kawasaki's syndrome

Secondary Vasculitis

- Infection
- Connective tissue disease
- Drug hypersensitivity
- Essential mixed cryoglobulinemia
- Malignancy
- Hypocomplementemia
- Post organ transplant

Savage Classification (1997)

See **Table 2**.

Causes of Vasculitis

- Immune (idiopathic)
- Infection (Bacteria, Fungus, Viral, Rickettsia)
- Drugs
- Tumors
- Radiation
- Extremes of temperature

Approach to Vasculitis

Vasculitis has multiple presentations. There are no definite guidelines or approach to the diagnosis of vasculitis. To diagnose vasculitis systematic approach is essential with proper history taking, clinical examination, and laboratory parameters.

- Clinical Findings
- Laboratory Findings
- Radiology
- Histology

Clinical Manifestations

Vasculitis may present with isolated cutaneous involvement or with a diffuse systemic involvement. Systemic vasculitis presents usually around 2nd to 5th decade except that Henoch schonlein purpura and Kawasaki disease in pediatric age group. Takayasu arteritis is common in young females.

General Manifestations

The clinical manifestations of vasculitis mimic like that of a normal viral illness. It includes fever, weight loss, malaise, fatigue, night sweats, generalized ache and a feel of physical unwell. These manifestations are due to the systemic inflammatory response which is produced by the release of chemical mediators from the inflamed blood vessels. These findings may not occur in patients with localized form of vasculitis.

TABLE 3 Systemic manifestations of vasculitis

Organs involved	*Manifestations*
Skin	Pupura, Nodules, Plaques, Infarcts, Ulcers, Pyoderma gangrenosum, Widespread skin necrosis, Gangrene, Urticarial wheels
Muscles & joints	Arthralgia, Arthritis, Myalgia, Weakness
Eyes	Scleritis (prelimbic area), Ring ulceration, Scleromalacia, Globe perforation, Uveitis and Retinal vasculitis, Loss of vision
Ear	Recurrent otitis media unresponsive to grommet insertion, Hearing loss, Recurrent ear drum perforation
Nose	Recalcitrant sinusitis, Nasal septal perforation, Collapsed bridge of the nose
Throat	Recurrent oral ulcers
Airways	Tracheal and bronchial stenosis
Lungs	Infiltrates, Nodules, Cavities, Mass lesions, Abscess, Areas of hemorrhage
Heart	Coronary arteritis—Kawasaki Pericardial and myocardial involvement at necropsy
GI tract	Mild abdominal angina, Perforation, Peritonitis, Hemobilia, Hepatic/splenic infarction, Pancreatitis
Kidneys	Renovascular hypertension, Hematoma around the kidney, Glomerulonephritis, Renal failure, Proteinuria, Microscopic hematuria
Reproductive system	Testicular infarction, Penile ulcers on glans & shaft, Scrotal ulcers
Central nervous system	Mononeuritis multiplex, Polyneuritis cranialis, Diffuse brain dysfunction

Systemic Manifestations

See **Table 3**.

Symptoms of Individual Vasculitis

See **Flowchart 1**.

Red Flag Signs in Vasculitis

- Polymyalgiarheumatica—classical of Temporal arteritis
- Jaw claudication during mastication—Temporal arteritis
- Stridor—Wegener's granulomatosis
- Abdominal pain, vomiting, intestinal obstruction, bleeding
- Proteinuria, microscopic hematuria, active urinary sediment in the absence of infection
- Mononeuritis multiplex, Polyneuritis cranialis
- Acutely progressing skin lesion

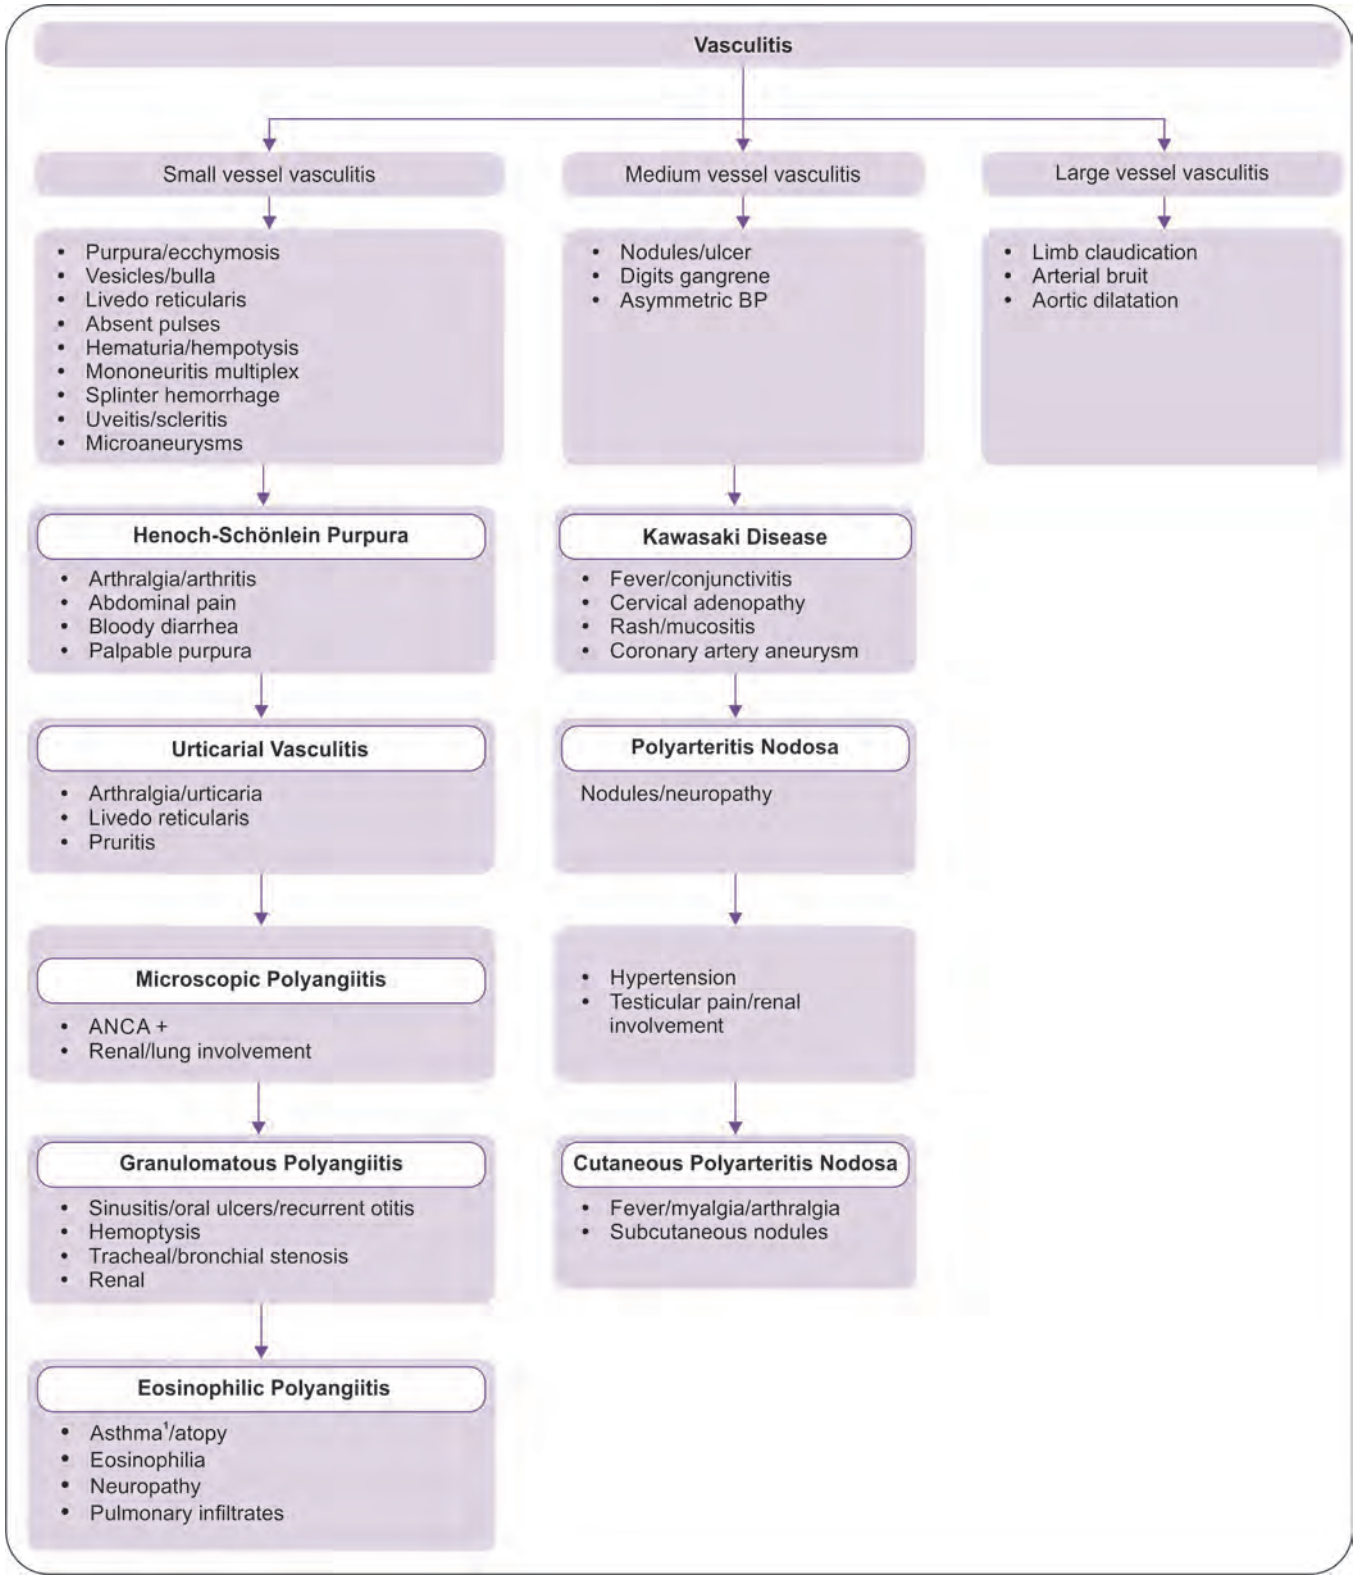
Drug-iduced Vasculitis

Drug-induced vasculitis should never be missed as the withdrawal of the offending drug is the main treatment. The same picture like that of isolated cutaneous involvement to diffuse organ involvement can happen with certain drugs. Some common drugs causing vasculitis are propylthiouracil, antiepileptics like phenytoin, carbamazepine, valproate, antibiotics including macrolides, quinolones, aminoglycosides, penicillins, antitubercular drugs like rifampicin and isoniazid. Several antihypertensives like hydralazine, methyldopa, nifedipine, atenolol, frusemide, diltiazem can cause vasculitis. Other drugs include heparin, warfarin, streptokinase, allopurinol, methotrexate, antidepressants. Drugs which cause ANCA positive vasculitis include hydralazine, propylthiouracil, ciprofloxacin, minocycline, phenytoin, clozapine, allopurinol, sulfasalazine, D-penicillamine.

Vasculitis Mimics

- Infections—infective endocarditis,[2] tuberculosis, syphilis, invasive fungal infections, viral/rickettsial infections.
- Drug induced vasculitis
- Cholesterol embolus disease, antiphospholipid syndrome, sarcoidosis, amyloidosis
- Malignancy, atrial myxoma

Flowchart 1: Vasculitis



Investigations

Hematology

The laboratory picture of vasculitis mimic like that of an infection. ESR will be elevated. Hematology shows normocytic normochromic anemia, leukocytosis, and thrombocytosis. Eosinophilia is most common in Churgh strauss syndrome.[3] CRP will be increased.

Biochemistry

Renal function and liver function tests are helpful in determining the extent of the disease, organ damage, and therapeutic intervention. Elevated serum creatinine and decreased creatinine clearance occurs in PAN, GPA, MPA.

There will be hypoalbuminemia with hyperglobulinemia. Gammaglobulinemia is predominantly of IgG type but in WG, HSP it is of IgA type. IgE levels are increased in CSS.

Urine Analysis

Urine investigations should be a must to rule out infection. Urine may show proteinuria, hematuria, and cylindruria. ANCA associated vasculitis may show active urinary sediment with red cell casts.

As the treatment of vasculitis involves the use of immunosuppressants, infections should be ruled out as it can lead to disastrous complications. Procalcitonin is a good diagnostic tool to rule out vasculitic mimic like infection. It will be elevated in infections rather than non-infective inflammatory etiology. But the cost and availability hinders its usage. Apart from the basic workup, specific autoimmune workup has to be done for further evaluation.

Serology

Rheumatoid factor is frequently positive in vasculitis. Very high titre of rheumatoid factor is a hallmark of systemic rheumatoid vasculitis. ANA will be positive in high titres in SLE, Systemic sclerosis, Sjogrens syndrome, and Overlap syndrome. hepatitis B, hepatitis C is a must to rule out classical PAN, cryoglobulinemia vasculitis. Anti GBM antibody will be positive in Good Pasteur's syndrome.

Antineutrophil Cytoplasmic Antibodies (ANCA)

ANCA is specific diagnostic tool for diagnosing vasculitis. ANCA is done by indirect immunofluorescence/ELISA.

TABLE 4 ANCA and its specificity

Pattern		***Antibodies directed against***	
C–ANCA	Central, coarse, dense, granular, cytoplasmic fluorescence	Anti-serine protease 3(PR3)	Wegner's (>90%) MPA (100%) CSS (50–60%)
P–ANCA	Perinuclear fluorescence	Anti-myeloperoxidase (MPO)	MPA (70–90%) WG(<10%)
Atypical ANCA	Mixed pattern	Lactoferrin, cathepsin G, elastase, lysozyme	

During the acute phase of vasculitis, ANCA will be positive in very high titres.[4] But, ANCA has a poor correlation between tires and clinical disease activity. There are three different patterns of ANCA shown in **Table 4**.

Imaging

X-ray Chest

Nodular, cavitating infiltrates is characteristic of Wegner's granulomatosis. Vasculitis must be included in the differential diagnosis, when there is unresolving, rapidly progressive consolidation during adequate antibiotic/ATT. Rapidly enlarging parenchymal lesion suggestive of pulmonary hemorrhage is characteristic of Wegner's granulomatosis, microscopic polyangiitis.

CT/MRI/PET Scan

The above imaging modalities are used in the diagnosis, delineation of disease extent, identification of biopsy site, and monitoring response to therapy.

FDG PET scan will help in detection of aortic wall inflammation.[5]

Angiography

Angiography defines the extent of disease involvement. It is also useful in classifying the type of vasculitis, identifying the areas for intervention like angioplasty and stent insertion. It is important in large and medium vessel vasculitis. It shows the pathognomonic visceral aneurysms in Polyarteritis nodosa.

2D Echo

Done to rule out left ventricular dysfunction, myxoma.

Histology

Skin Biopsy

Skin biopsy may show features suggestive of inflammation. The same histology may be seen in patients with benign cutaneous vasculitis and SNV. For ideal histopathological examination, sample should be taken less than 48 hours of onset of symptoms.[6] Nodular skin lesions and involved muscles are preferred sites for PAN.

Renal Biopsy

Granulomatous inflammation in tissue biopsy is suggestive of Wegner's granulomatosis.

Nerve Biopsy

Vasculitis of the vasa vasorum is characteristic of mononeuritis multiplex. Sural nerve biopsy is indicated if peroneal neuropathy is seen on electromyography. In giant cell arteritis, Temporal artery biopsy is done. Biopsy of subclavian artery is done in Temporal arteritis.

Mucosa of Sinus and Nose

As vasculitis is a patchy process, it may be easily missed in a small biopsy.

Open Lung Biopsy

It is a highly rewarding procedure. Pulmonary tissue biopsy is highly specific for Wegener's granulomatosis.

Treatment

General Measures

Avoid stress, bed rest, and keep extremities warm. Avoid smoking in case of severe pulmonary involvement. Antihistaminics to reduce itching and NSAIDs to decrease pain.

Specific Therapy

- *Antibiotics*: To control infections according to culture and clinical profile.
- *Drug*: Stop the offending drug in case of drug induced vasculitis.
- *Dapsone:*[7] It can be used as the initial agent for CSVV in the absence of systemic involvement (Dose: 50–200 mg/day in divided doses). The response can be observed within 2 weeks. In urticarial vasculitis dapsone can be combined with indomethacin or hydroxychloroquine.
- *Hydroxychloroquine* (200–400 mg/day): It can be used in HUV but not in other small vessel vasculitis.
- *Corticosteroids:* Low dose steroids (<10 mg on alternate days) are used to reduce the inflammation in patients not responding to steroids in small vessel vasculitis. High dose systemic steroids are indicated in severe necrotic/ulcerative cutaneous lesion, acute glomerulonephritis, peripheral neuropathy with impending palsy and gastrointestinal bleeding.

  Steroid has a good response in HSP in preventing nephritis as well as improves the outcome of existing nephritis. In classic PAN disease control can be achieved with steroids. In HCV associated cutaneous vasculitis, short-term systemic steroids are beneficial in controlling renal and CNS manifestations.[8] Steroids should be short term in virus associated vasculitis in order to prevent the risk of viral replication.

  Steroids show a good remission. It helps in decreasing the infection rate, cumulative dose of cyclophosphamide to achieve remission and decrease rate of secondary malignancy. Temporal arteritis shows a very good response to steroids. After remission it can be maintained with immunosuppressants like azathioprine or methotrexate. Systemic steroids are contraindicated in Kawasaki disease to avoid coronary aneurysm formation.

  Intravenous pulse steroid (methylprednisolone 1 gm/day for 3 days) therapy is indicated in life threatening organ involvement in diseases like WG, MPA, CSS.
- *Cyclophosphamide:* Between 2–3 mg/kg/day. It can be continued for a year after remission was attained. The side effects are hemorrhagic cystitis, bladder cancer, marrow toxicity. There is an increased occurrence of relapse after withdrawal of the drug.

  Alternative regimen is intermittent "pulse" Cyclophosphamide therapy (750 mg/m^2) every 2–3 weeks initially for 2–3 doses every 4 weeks till 6 pulses.
- *Azathioprine:* It prevents recurrence in CSSV either used alone or in combination with steroids.
- *Rituximab:* Used in frontline drug in patients with HSP. Two doses 1 gm each with an interval of 2 weeks. It gives prolonged remission.

- *Antivirals:* Interferon α is the preferred drug in hepatitis C virus associated CV. Significant improvement has been documented with decrease in cryoglobulin levels. Ribavirin may be used for treatment as well as in prevention of relapse in hepatitis C induced vasculitis.
- *Immunoglobulins:* It may be of use in Kawasaki disease. Dose: 2 g/kg single dose in combination with aspirin. Early administration prevents the risk of aneurysm formation. c-PAN was treated successfully with IVIg (2 g/kg over 2–5 days), but relapse rate is common.
- *Plasmapheresis:* It is helpful in cryoglobulinemia and hepatitis B related classical polyarteritis nodosa in severe cases refractory to other treatments.
- *Mycophenolate Mofetil:* Used in steroid dependent, steroid resistant cases of HSP, especially with renal complications.
- *Deoxyspergualin:* Monoclonal antibodies have a variable success rate.
- *Infliximab:* Used in steroid non-responsive necrotizing CSSV.

Conclusion

The mortality and morbidity related to vasculitis is mainly due to late diagnosis. As the symptoms are very subtle at the initial stage, there is a delay in the suspicion and diagnosis of vasculitis. Treatment is individualized. A comprehensive approach is needed for successful management of vasculitis.

CHAPTER

212 How to Manage DMARDs Failure in RA?

N Subramanian

Abstract

Rheumatoid arthritis is the most common disease affecting the musculoskeletal system and the immune-inflammatory cascade causes avalanche of detrimental effects to the human systems. Incidence appears to be increasing worldwide and treat to target after early identification of the condition remains the current approach to tackle RA. DMARDs have been the conventional drugs of choice for years together and with the advent of cytokine inhibitors since 2000, prognosis and outlook of immune mediated diseases have improved remarkably. Biologics and Biosimilars have revolutionized the management of RA; however, DMARDs remain the gold standard care for these patients. This article focuses on the management of patients with RA who fail to respond to DMARDs.

Introduction

Rheumatoid arthritis (RA) is the most common of all arthrides and current incidence in India is increasing. The prevalence of RA was available from only four studies, ranging from 0.28% to 0.7%.[1] Literature review suggests the RA prevalence, based on the ACR criteria, ranged from 2.8 per 1,000 to 7 per 1,000, varying throughout India. Patients with RA taking disease-modifying antirheumatic drugs (DMARDs) ranged from 11% to 100%, with the majority of the studies reporting proportions more than 75%.[1]

Various studies report that the DMARDs available to the patients in India include the methotrexate (1990), leflunomide (2001), and sulfasalazine (1998).[2,3] Shankar et al. reported that on comparing the characteristics among erosive and non-erosive RA patients in northern India, the median DMARD-naive time period was recorded as 3 years among patients with erosive disease and 2 years among those without erosive disease.[4] Shankar and colleagues reported again in a study focused on only female RA patients, the median DMARD-naive time period was 3 years.[5]

RA occurs frequently in females and around 30 new patients per Lac population each year are diagnosed with RA. Stress and environmental triggers may trigger the disease onset. About 5% of first degree relatives are at risk of developing RA.[6] Cigarette smoking, coffee, and oral contraceptive pills appear to increase the risk of development of RA.[7] In developing countries due to various factors in accessing medical help, delayed diagnosis occurs thereby causes functional disability and reduced quality of life.[8]

Diagnosis and Current Management

Rheumatoid arthritis, most common form of inflammatory arthritis is usually diagnosed by the presence of joint swelling, raised inflammatory markers, positive anti CCP and imaging evidence of erosions, if required. Ultrasonogram and MRI have been beneficial in identifying the early changes in the synovium and marrow.[9]

Currently RA is managed using multimodality treatment. Diet, counseling, physiotherapy, and occupational therapy compliment drug treatment.

Drug management aims to relieve symptoms as soon as possible followed by disease modification that slows or stops radiological progression, which is closely correlated with progressive functional impairment.

Disease modifying conventional drugs included methotrexate (10–15 mg) given weekly once, sulfasalazine (1–2 gm), leflunomide (10–20 mg) and iguratimod (25–50 mg). Monitoring of bloods for patients while on DMARDs will have to be done every 4 weeks for 2 months and then once in 3 months.

Poor prognostic factors:[10]

- Persistently moderate or high disease activity despite DMARDs
- High ESR < CRP
- Presence of high titers of RF and/or ACPA
- Presence of early erosions

Evidence points to reduced compliance to oral DMARDs and also effective in two-thirds of patients with RA while achieving remission.[11] Hence, there is unmet need to improve the patients health, quality of life, and induce remission for the remainder of population with RA.

Causes for DMARDs Failure in RA

- Compliance issues
- Cost factors
- DMARD intolerance issues
- Comorbidities
- Fear of toxicities and long-term side effects

As RA is chronic and long-term drug treatment is necessary, it is important for the physicians to explore the patients understanding and family support in daily life. Compliance can be a problem due to fear of side effects driven by the society or cost issues or intolerance to DMARDs. Few patients may have comorbidities that might preclude to effective DMARD therapy. Hence, it is imperative to explore all these factors before we call as DMARD failure.

Clinical disease activity should be measured using DAS 28 ESR score—including swollen joint, tender joint, VAS scale, and ESR.

How to Manage the Resistant RA?

International guidelines including American College of Rheumatology (ACR),[12] British Society of Rheumatology and NICE guidance (BSR),[13] European League of Association of Rheumatologists (EULAR)[10] have supported the use of various biologics in patients with resistant rheumatoid arthritis and evidence has shown time and again that Biologics have achieved remission and improved the quality of life.

Before starting on biologics, we must ensure adequate optimization of oral DMARDs with regards to dose, compliance, and side effects. Many occasions, patients do not share the compliance issues, and hence it is important to explore the problems in taking DMARDs and address those issues.

Biologics are expensive to most patients in India as developing nation; therefore, biosimilars tend to be preferred in patients who can afford. Evidence shows approved biosimilars are equally efficacious in the management of various inflammatory rheumatic diseases.

Biologics and Biosimilars

We have seen tremendous developments in the use of biologics and biosimilars during the last decade and monoclonal antibodies are used in various rheumatic diseases with Treat to Target approach.

Biologic therapies have been used in various inflammatory rheumatic diseases like RA, spondyloarthritis (SpA), psoriatic arthritis, ANCA associated vasculitis, and osteoporosis.[14-17]

Biosimilars are similar to biologics intended to offer comparable safety and efficacy to the reference molecule. They are often manufactured in cell lines and subject to modification like glycosylation. Biosimilars must be shown to be identical to innovator biologics based on data from clinical and analytical studies.[18]

Methotrexate remains the anchor drug for RA, which has been proven to reduce anti-drug antibodies and also retains radiological remission.[19]

The list of currently licensed biologics for use in RA in shown in **Table 1**.

Pretreatment Screening[20]

Although biologics and biosimilars can be used in various indications in rheumatology, patients need to be screened for TB, Hepatitis, and HIV. They also need to be vaccinated against hepatitis, chickenpox, influenza, and pneumonia.

Screening tests include blood count, CRP, LFT, renal function tests, hepatitis B, C screening, mantoux, and immunoglobulins for rituximab. ECG and ECHO when appropriate.

TABLE 1 NICE UK approved Biologics for RA

Drugs	*Mechanism of action*	*Route of administration*	*Frequency*
Infliximab	Chimeric anti TNF	IV and Sc	After loading, every 8 weeks
Etanercept	Fusion protein receptor blocker	Sc	Once weekly
Adalimumab	TNF blocker	Sc	Once fortnightly
Tocilizumab	IL-6 blocker	IV and Sc	Once a month
Sarilumab	IL-6 blocker	Sc	Fortnightly
Rituximab	CD20 blocker	IV	Once in 6–12 months
Tofacitinib	JAk inhibitor	Oral	Daily
Golimumab	Human Mab to TNF alpha	Sc	Once in 4 weeks
Certolizumab	Pegylated anti TNF	SC	Once in 4 weeks

Contraindications for use of biologics:

- Uncontrolled heart failure, multiple sclerosis, active infections, Hep B, and Hep C positive and untreated cancers.
- Previous septic arthritis, pregnancy, and lactation.
- Risk of TB has been found to be more in Asian countries.[21]

Nearly a decade of experience in using biologics and biosimilars has given a wide range of choices for patients with RA and those drugs are used in India and gaining acceptance too.[22]

What do we do if not Affordable to Biologics or Biosimilars?

Recently RA affects women and men of both socioeconomic groups and being a chronic disease it's understandable for patients with low income to default on DMARDs. Hence, it would be prudent to consider low dose long-term steroids and NSAIDs along with monotherapy like methotrexate for disease remission,[23] after having explained the risk for diabetes and stomach upset.

Conclusion

DMARDs are effective in RA, but resistant rheumatoid needs careful approach to devise the management program tailor made to the patient and holistic intervention is required that includes biologics/biosimilars, physiotherapy, and yoga. Apart from disease remission and improved quality of life, we also need to achieve cardiovascular risk reduction and healthy family life.

CHAPTER

213 IgG4-related Disease

Harpreet Singh, Somdatta Giri, Anju Arya

Abstract

IgG4-related disease is a chronic inflammatory condition characterized by tissue infiltration with igG4-secreting plasma cells. It manifests as organomegaly, fibrosis, and organ dysfunction. Elevated IgG4 level in blood gives an important clue to the diagnosis. CD4+ cytotoxic T cells and plasmablasts are central to the pathogenesis, and IgG4 antibody may be a bystander. Biopsy is essential for diagnosis whereas CT, MRI, and PET scan help in defining the extent of the disease. Response to steroid is excellent. Steroid resistant cases are treated with Rituximab.

Introduction

Immunoglobulin G4 (IgG4)-related disease (IgG4-RD) is a multiorgan immune mediated fibroinflammatory condition of unknown etiology. It was in 2013 in an international symposium that term IgG4RD was adopted.[1]

Epidemiology

Due to the low awareness of disease, there is difficulty in ascertaining the epidemiology of the disease. IgG4-RD has an elderly and male preponderance (Male:Female 3:2).[2] It tends to involve pediatric age group less commonly. Presently, there are not much epidemiological studies on IgG4-RD in India.

Pathogenesis

The pathogenesis of IgG4-RD suggests about disease to be autoimmune in nature though incompletely understood. In the past it was suggested that IgG4-RD to be T helper cell-2 (Th-2) mediated condition. But the concept of Th-2 memory cells circulating in IgG4-RD presently has been rejected since only a small subset of patient of IgG4-RD having atopy had this feature. Recently, researchers noticed that $CD4^+$ cytotoxic T lymphocytes, which are clonally expanded, are found in both peripheral and fibrotic lesion of IgG4-RD.[3] The cytotoxic T cells release interleukin-1 (IL-1), transforming growth factor-beta (TGF-beta) and Interferon gamma and these cytokines/chemokines are responsible for increased fibrosis, which is the dominant part of IgG4-RD.

Further, the disease has a sustained $CD4^+$ cytotoxic T cells effect due to continuous antigen presentation by B cells and plasmablast. In addition to $CD4^+$ cytotoxic T lymphocyte effect, there is also a follicular helper T(Tfh) response that is responsible for development of germinal centers (within the lymph node/involved organ) and production of cytokines (esp IL-4). The germinal center/cytokine drives the IgG4 class switch, producing IgG4 plasmablast and long lived plasma cells.[4] The IgG4 antibodies positivity in IgG4-RD is due to the downregulating response to another primary process.

So IgG4 antibodies are not pathogenic of IgG4-RD, rather $CD4^+$ cytotoxic T lymphocytes and plasmablasts play central role in the pathogenesis.

Clinical Features

The symptomatology in IgG4-RD is based on organ/s affected. It is subacute in onset. Clinical presentation in IgG4-RD is due to the resultant inflammatory infiltration/fibrosis, which cause the tissue or organ dysfunction. Additionally, tumor like effect may cause obstructive/compressive complications. Despite the multiorgan involvement, four clinical types can be more commonly identified. These are:

- Group 1: Pancreato-hepatobiliary disease
- Group 2: Retroperitoneal fibrosis and/or aortitis
- Group 3: Head and neck limited disease
- Group 4: Classic Mikulicz syndrome with systemic involvement

Symptoms of asthma or atopy may be present but fever is rare. Salivary and lacrimal glands, pancreas, biliary tract, and kidney are commonly involved.

Auto immune pancreatitis (AIP) is of two types. In the context of IgG4-RD, type 1 AIP is generally a pancreatic disease and biliary tract involvement (mimicking Primary Sclerosing Cholangitis) in combination.[5]

IgG4-RD commonly involves retroperitoneal tissue often resulting into fibrosis. This fibrosis may result in obliteration of adjoining structures (aorta and ureter).

Eye involvement (25–50%) in IgG4-RD usually presents as a mass (orbital pseudotumor) due to dacryoadenitis or MALT lymphoma.

Major salivary gland (parotid/submandibular) involvement mimics Sjögren syndrome, although in IgG4-RD the symptoms of dryness of eyes and mouth are milder along with seronegativity for anti Ro/La antibody.

Lung involvements are often asymptomatic or may present with respiratory-related symptoms. These symptoms may be due to the alveola/interstitial involvement or due to opacities (ground glass/nodular). The pulmonary manifestations of IgG4-RD may mimic sarcoidosis.

Kidney involvements related to IgG4 are tubulo-interstitial nephritis (TIN). Membranous nephropathy is much less common. IgG4-related TIN presents with profoundly hypocomplementemia (due to the complement activation by other IgG subclasses—IgG1 or IgG3).

Riedels thyroiditis is IgG4-RD of the thyroid gland disorder.

Cutaneous pseudolymphoma, hepatopathy, gastritis, sclerosing mastitis, central nervous system involvement (esp. patchy meningitis) with or without hypopituitarism, prostatitis, IgG4-related disease of the ovary, constrictive pericarditis, generalized lymphadenopathy are other organ presentation described.

Laboratory Tests

If there is a suspicion of IgG4-RD one should start work up with routine blood investigations, IgG4 level, imaging studies and finally tissue biopsy, if possible.

Blood Tests

Blood investigations usually reveal hypergammaglobulinemia. Peripheral blood shows eosinophilia with elevation of serum IgE (especially in presence of atopy) and IgG4 level. Serum IgG4 levels can also be elevated in other conditions, which may mimic IgG4-RD.[6] Plasmablast concentration is a better marker than IgG4 level, as it predicts response to treatment and also relapse.[7] Hypocomplementemia is particularly common in IgG4-related kidney disease as well as with mild proteinuria. Serum amylase and lipase may be planned if pancreatitis is suspected.

Imaging

On contrast enhanced CT, lesions look homogeneous with well-defined margins.

MRI (T2-weighted) shows hypointense to isointense images depending upon fibrosis/cellularity.

Increased metabolic activity on FDG-PET/CT helps in locating the extent of involvement.

Histology

Findings include lymphoplasmacytic infiltrate, storiform fibrosis (cartwheel appearance of the arranged fibroblasts and inflammatory cells) and obliterative phlebitis.[8] In addition, an increased number of IgG4-positive plasma cells greater than the cut-off point and elevated IgG4/IgG cell ratio more than 40% needs to be proven. There may be modest tissue eosinophilia.

Diagnosis

IgG4-RD is diagnosed by a combination of clinical (organomegaly), serologic (increased IgG4 level), radiologic (masses on CT, MRI), and pathologic findings (as described above). Biopsy of the involved organ is

crucial for diagnosis. Japanese comprehensive clinical diagnostic criteria (CCD) 2011,[9] are used for diagnosis. Organ-specific diagnostic criteria is used when CCD criteria does not properly fit in for the diagnosis of IgG4RD.

Differential Diagnosis

The major disorders that should be distinguished from IgG4-RD are cancers (pancreatic cancer, cholangiocarcinoma), primary sclerosing cholangitis, connective tissue disease like (Sjögren syndrome, granulomatosis with polyangiitis), Castleman disease, idiopathic RPF, and infectious aortitis.

Treatment

Treatment should be initiated early to impede the progress from the inflammatory to fibrotic stage (treatment nonresponsive). There is no international consensus on treatment guideline at present. The approach to treatment in IgG4-RD is discussed here.

Pretreatment Evaluation

Evaluation of the extent of disease after establishing the diagnosis is desired before initiating treatment, so baseline investigations are desired pretreatment. These are:

- Complete blood count, RFT, LFT, serum amylase and lipase, IgG subclass levels—esp IgG4, IgE concentration, serum C3 and C4 concentration, HbA1c.
- Fecal elastase in pancreatic involvement.
- Urinalysis to document asymptomatic proteinuria related to TIN.
- Imaging—CECT/PET scanning to determine the extent of disease.

Initial Therapy

All symptomatic or those with progressive disease should be started on therapy. The others—asymptomatic, non-progressive and limited disease need serial watchful waiting approach.

Steroid

Glucocorticoids are the drug of choice for initiation, unless contraindicated. The initial recommended oral dose of prednisolone for remission induction is 0.6 mg/kg/day for 2–4 weeks followed by tapering to 2.5–5.0 mg/day over a period of 2–3 months. Steroid pulse therapy is considered for acutely ill patients.

In the early stage of disease majority responds to glucocorticoids (decrease in size of mass, betterment of organ function, decrease in IgG4 value), though duration of response remains variable. But disease flare is seen during or after tapering of glucocorticoids. Also, patients with fibrotic changes respond poorly.

Rituximab

Patients with multiorgan disease (≥3 organs) or extremely high serum IgG4 concentration (>5 times UNL) are very likely to require an agent other than glucocorticoid alone for induction of remission. Rituximab (anti-CD20 antibody) is effective for both induction and maintenance in a dose: 1 g IV for a total of 2 doses 2 weeks apart.[10]

Rituximab do not directly kill plasma cells as they lack the CD-20 receptor. It acts by depleting the pool of CD20+ progenitors—either naïve B cells or memory B cells. Thus, it wipes out plasmablasts, which have a short lifespan. This loss of plasmablast results in decrease in IgG4 production.

Maintenance Therapy

High relapse rate is reported with multiorgan disease or extremely elevated IgG4 level. An IgG4-RD responder index (RI) has been developed to predict relapse. Low-dose prednisolone (2.5–5 mg/day) needs to be continued as maintenance therapy to avoid relapse for a period of at least 3 years, but keeping watch on steroid related complications. However, in case of relapse initial dose of steroid is recommended.

Mycophenolate (up to 2.5 g/day) and azathioprine (2 g/kg/day) are the other options for maintenance therapy.

Rituximab is very effective as maintenance therapy especially where steroid and other immunomodulator fails. It has a very low relapse rate. The reason being memory B-cell count appeared to be unaffected by steroid treatment, therefore partly explaining why the maintenance of remission in IgG4-RD often fails during glucocorticoid withdrawal.

Surgery

Selected patients may require surgery like—hydronephrosis due to ureteral obstruction in retroperitoneal fibrosis/obstructive jaundice due to sclerosing cholangitis requires biliary stenting and drainage/aortic aneurysm in aortitis/

compressive symptoms in Riedell's thyroiditis/vascular and organ compression from sclerosing mesenteritis requires debulking surgery.

Prognosis

IgG4-RD has a variable course. Some treatment naïve patients are reported to have spontaneous remission though short lasting. Whereas, most of them have relapse/chronic progression at variable rate. Baseline levels of serum IgG4, IgE, and eosinophil serve as markers for relapse prediction. Non-treatment results in a significant morbidity and mortality due to irreversible damage of organs and its sequalae because of the associated fibrosis. There is a divided opinion regarding increased risk of malignancy with IgG4-RD.

Conclusion

So to conclude, IgG4-RD results in a subacute multiorgan dysfunction/enlargement. The diagnosis is made in a background of clinical features which shares specific serological and pathlogical findings. Measurement of plasmablast concentration correlates better than IgG4 level with disease activity and is a promising tool to be used in future. A good initial response to steroid is a characteristic behavior of the disease, steroid needs to be tapered over a period of 2 months and any relapse or failure to the initial response, Rituximab holds a good promise.

CHAPTER

214 Treatment of SLE beyond Steroids

Rathindra Nath Sarkar, Rudrajit Paul

Abstract

Systemic lupus erythematosus (SLE) is a multi-system connective tissue disorder where immunosuppression is the mainstay of therapy. Steroids, although effective immunosuppressant, have a lot of side effects in the long run. Thus, there is a need of steroid sparing immunosuppressive agents for long-term therapy in SLE. In the first part of this chapter, the conventional steroid sparing drugs like Methotrexate, Cyclosporine, and Mycophenolate, which have been mentioned in the 2019 EULAR guidelines, have been discussed in details. In the second part of this chapter, newer therapies like Voclosporin, anifrolumab, Belimumab, and Baricitinib have been discussed along with the recent clinical trial results. Lastly, newer frontiers of therapy like Glucocorticoid induced leucine zipper (GLIZ) and other experimental drugs have been explained. Discussion of each drug is also associated with mention of the dose and side effects.

Introduction

Systemic lupus erythematosus (SLE) is a multisystem connective tissue disorder with considerable mortality and morbidity. Since it mainly affects the young adult, economically productive, age group, the financial burden of this disease is also significant. Treatment of this disease continues for a long time, sometimes even lifelong. With developments in immunology and medical genetics, our understanding of the pathogenesis of this disease is also evolving. This is opening up newer avenues for therapeutic target.

SLE is a disorder of autoimmunity. Thus, immunosuppression or immunomodulation in various forms is the mainstay of therapy. In the early days, the main drug used for this purpose was steroids. While steroid is an effective immunosuppressant and quite effective in saving lives (especially in acute flares), it also has a lot of side effects in the long run[1] **(Table 1)**.

Thus, for long-term treatment, steroids are not an ideal choice. The current SLE guidelines also advice quick tapering of oral steroids to avoid these side effects.

The mainstays of SLE therapy, especially in acute flares, are cyclophosphamide and steroids with steroid sparing drugs like Azathioprine and MMF for maintenance. But in spite of quick diagnosis and early treatment, mortality from SLE is still very high. In 2017, Jorge et al. from the Harvard Medical School published an article, which showed that over 15 years, between 1999 and 2014, the mortality from SLE has not been decreased appreciably.[2] As early as in 2000, researchers from Baltimore, USA, had also shown that long-term steroid therapy in SLE is associated with significant organ damage.[3] Thus, it is evident that the current therapies including steroids are not adequate and there is a large *unmet need* in SLE management.

Conventional Agents

There are many drugs, besides steroids, which are used in SLE. They include hydroxychloroquine (HCQ), mycophenolate mofetil (MMF), azathioprine (AZT), cyclophosphamide, methotrexate (MTX), cyclosporine (CYC), and tacrolimus (TAC). But they are all not equally effective. HCQ is used as a background therapy but it is

TABLE 1 The different systemic effects of long-term steroid use

Musculoskeletal	*Endocrine*	*Cardiovascular*
• Osteoporosis • Myopathy • Osteonecrosis	• Dysglycemia • Cushingoid features • Adrenal suppression • Growth failure in children	• Edema • Hypertension • Premature atherosclerosis • Arrhythmia
Ophthalmologic	***Psychiatric***	***Dermatologic***
• Cataract • Glaucoma • Central serous chorioretinopathy	• Depression • Hypomania • Sleep disturbance • Akathisia	• Acne • Hirsutism • Skin thinning • Recurrent infections

TABLE 2 2019 EULAR recommendations for non-steroid drugs in SLE

Main target of treatment	• Complete remission • Low disease activity status (if remission is not obtained) • Prevention of flares
HCQ	To be used in all patients (5 mg/kg), long term; if HCQ intolerant, quinacrine
MTX	To be added when symptoms not controlled with HCQ+GC; once weekly dose; 10–25 mg/week
AZT	To be added when symptoms not controlled with HCQ+GC; safe in pregnancy; 2–3 mg/kg/day
MMF	Can be used for both induction and maintenance; *not effective* in neuropsychiatric lupus; costly; discontinue 6 weeks before planned pregnancy Induction: 3 g/day Maintenance: 1–2 g/day
CYC	Used in moderate to severe disease activity; avoid in severe renal disease; 1–3 mg/kg/day
Cyclophosphamide	Mainly used as rescue therapy; gonadotoxic Use either Euro-Lpus or the NIH regimen; avoid after induction dose; oral therapy not recommended
IV Ig	1 g/kg/day (1–2 days); mainly used for hemolytic anemia
Rituximab	RCTs negative; still used off-label; only after failure of above drugs 1000 mg on days 1 and 15; may be repeated after 6 months

AZT, azathioprine; CYC, cyclosporine; GC, glucocorticoids; HCQ, hydroxychloroquine; MMF, mycophenolate mofetil; MTX, methotrexate.

not effective in acute flares or life threatening conditions. A French study (PLUS) in 2013 found that HCQ is unable to prevent life threatening flares.[4] But this does not mean that HCQ is a non-essential drug in SLE. Continuous HCQ is effective in preventing flares of skin rashes or arthritis and this drug should be given to all lupus patients **(Table 2)**.[5] AZT and MMF are both steroid sparing agents. In the MAINTAIN trial, both of them were found to be equivalent in preventing relapse of nephritis in SLE.[6] In the ALMS study, MMF was found to be equivalent to IV Cyclophosphamide in inducing remission in renal flares.[7] Thus, although cyclophosphamide (in NIH or Euro-Lupus protocol) remains the mainstay of rescue therapy in renal flares, MMF may be tried as an alternative. AZT is mainly used to help reduce the dose of oral steroids. It is safe in pregnancy (in contrast to MMF that must be stopped at least 6 weeks before conception) but neutropenia may be a rare, yet serious, adverse reaction.

There have been very few studies of MTX in SLE. A 2014 systematic review concluded that MTX is effective in treating arthritis and mucocutaneous manifestations of SLE and it also helps to reduce the dose of oral steroids.[8] Another study from Germany also depicted that SLE patients, who had not improved despite 6 months of oral steroids, did respond to oral MTX 15 mg/week.[9] There was not much side effect of MTX in this regimen. However, the efficacy of MTX in lupus nephritis is still debatable.[10]

Cyclosporine, a calcineurin inhibitor (CNI), is another drug, which has been tried in SLE. Although this is a good immunosuppressant, it has common side effects like hypertension and nephrotoxicity, which makes it unsuitable for high-dose therapy. But low-dose maintenance therapy can always be used in SLE. There are very few RCTs with CYC in SLE. These have shown that CYC is effective in decreasing proteinuria and improving renal function.[11] Also, the doses of other immunosuppressants and steroids could be reduced when CYC is used long term. Some studies have also shown that CYC may improve the renal histology in lupus patients.[11] However, the serological markers like anti-ds-DNA or complements do not change appreciably with CYC. One reason may be that CYC mainly acts on T-cell subset with very little effect on the humoral immunity. But despite persistence of serological abnormalities, clinical improvement occurs after CYC use.

Tacrolimus, another CNI, till now used in organ transplant recipients, is now being used in combination with steroid as well as MMF in refractory proteinuria. Several small studies have looked into the use of TAC in Class III, IV, and V lupus nephritis, both as induction and as maintenance therapy in patients refractory to other treatment. Majority were Asian patients.[12] Another study by Szeto et al. in 18 patients with biopsy proven Class V lupus nephritis treated with TAC 0.1 to 0.2 mg/kg/day with tapering doses of prednisolone showed 76.2% decrease in proteinuria compared to historical control group treated with cyclophosphamide or azathioprine.[13] Side effect profiles are same as CYC with glucose intolerance.

IV Ig use is still considered experimental in SLE. A 2014 meta-analysis found that IV Ig is effective in reducing disease activity.[14] In some studies, it has also been shown to be effective as a steroid sparing agent. But till now, only a few studies have assessed IV Ig for lupus nephritis. The results have been mixed. Thus, it is an uncommon choice in acute renal flares.

Table 2 gives a summary of the 2019 EULAR recommendations for the use of non-steroid drugs, as discussed earlier, in SLE.[15]

Newer Agents

The drugs discussed above are effective in controlling disease activity in many cases but still a large percentage of SLE patients continue to have flares and worsening of organ failure. However, there are newer therapies in the horizon for SLE. These will be discussed next.

A newer analog of CYC, which is in development, is *Voclosporin*. This drug was first developed in the 1990s, but its potential uses are being investigated only recently. In January 2019, Rovin et al. published the results of the AURA-LV study, where Voclosporin was used in addition to MMF and rapidly tapering oral steroids for induction therapy in lupus nephritis.[16] The dose of Voclosporin used was 23.7 mg (low dose) or 39.5 mg (high dose) BD.[16] It was found that there was significantly high complete renal remission (CRR) rate in the Voclosporin group (both low and high dose) and this advantage was sustained at 48 weeks. Very recently, in March 2020, Aurinia Pharmaceuticals, the company promoting Voclosporin, announced the results of the *AURORA* study.[17] This was a Phase 3 Global RCT, which assessed the efficacy of Voclosporin in addition to MMF and rapidly tapering oral steroids for induction phase. The results showed that Voclosporin was effective in inducing a superior and faster renal response. The side effect profile in the AURORA trial was similar to standard therapy. There was no excess mortality. In this trial, the dose of Voclosporin was 23.7 mg BD. Thus, if this new drug is approved, it may be a valuable addition in SLE treatment strategy.

Type I interferon (INF) is known to be an important mediator in the pathophysiology of SLE. Recently, an inhibitor of the type 1 IFN receptor, *Anifrolumab*, has been developed. In January 2020, Morand et al. published the results of a trial of Anifrolumab in active SLE (*TULIP-2* trial).[18] Anifrolumab (300 mg) was given i.v. every 4 week for 48 weeks. At 52 weeks, there was significantly more response (assessed by BILAG) in Anifrolumab group compared to placebo.[18] Anifrolumab mainly helped in reduction of the glucocorticoid dose and decreasing severity of skin disease. But there was not much difference in tender joint count. This was the first successful trial of a biological drug in SLE since Belimumab almost a decade ago. The first trial with Anifrolumab was the *TULIP-1* trial, published in the Lancet, in 2019.[19] In this trial, the primary end point was SLE responder index (SRI-4) at 52 weeks. But this first trial was, however, a failure as there was no difference in SRI-4 between the groups.[19] But secondary end-points like reduction in corticosteroid dose and BILAG response were achieved. The researchers then quickly published the results of the second trial (as

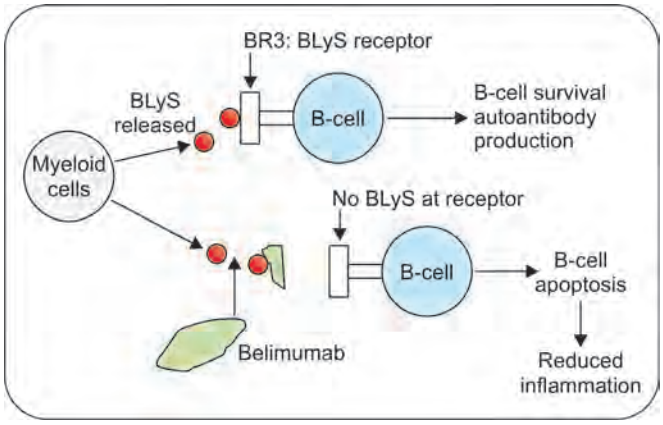

Fig. 1: The pathway of action of Belimumab ©RP

mentioned earlier) where favorable results were shown. Anifrolumab is generally safe for human use. But in 2017, a Phase IIb trial with the drug found some excess incidence of Herpes Zoster and influenza, compared to placebo.[20] The maker of the drug, AstraZeneca, plans to move ahead with application for approval although expert opinion is still divided about potential efficacy of the drug.

Belimumab, which was approved by the FDA in March 2011, is the first targeted biological therapy for active SLE.[21] B lymphocyte stimulator (BLyS) is a costimulator for B-cell survival and function **(Fig. 1)**. It is expressed by a variety of cells like macrophages and is also found in soluble form in tissues. BLyS receptor is present on B-cells, the most important receptor being BR3. Interaction of BLyS with BR3 prevents apoptosis of B-cells and promotes autoantibody production. Overexpression of BLyS increases activity of autoreactive B-cells and this is important in the pathogenesis of autoimmune conditions like SLE. Belimumab is a human monoclonal antibody against BLyS. Binding of belimumab with BLyS prevents its interaction with BR3 and thus, reduces B-cell survival and antibody production.[21] There have been two Phase III trials of Belimumab in SLE: *BLISS-52* and *BLISS-76*. The numbers (52 and 76) indicate the number of weeks for which the study subjects were followed up. While both the studies demonstrated efficacy of the drug, it was also seen that the effects were not sustained at 76 weeks.[22] *The dose of the drug is 10 mg/kg, given i.v. at weeks 0, 2, 4, and then monthly*. It is used with standard therapies like MMF. But one problem of the drug is that, in the trials, it was not studied in active lupus nephritis or active CNS lupus. *Thus, use of the drug in these conditions is not approved.* However, as more data becomes available, the recommendations will change. Adverse effect profile of belimumab is also favorable.[22] In December 2019, GSK, the maker of belimumab, announced results of the *BLISS-LN* trial where belimumab was shown to be effective in reducing nephritis. However, the approval of belimumab for treatment of lupus nephritis is still pending.

Rituximab is an anti-CD20 antibody, which is an important drug in the treatment of rheumatoid arthritis, some malignancies, and some dermatological conditions. There have been many trials of rituximab in SLE also.[23] The first few published studies were open, uncontrolled studies. For example, the data published by Leandro et al. in 2002 shows that there were improvements in both clinical and laboratory features of SLE after treatment with rituximab (500 mg: 2 doses, 2 weeks apart).[24] This therapy was used along with oral steroids and i.v. cyclophosphamide. In 2006, Ng et al. published results of a trial using rituximab for refractory SLE.[23] They showed that repeated cycles of rituximab may be helpful in difficult-to-treat lupus. However, most of these were clinical open studies. Later, two RCTs were undertaken to assess the efficacy of rituximab in lupus: *LUNAR* (renal lupus) and *EXPLORER* (non-renal). Both trials studied rituximab as an add-on therapy to the standard regimen of immunosuppressants like steroids. Overall, the EXPLORER trial did not reveal any extra benefit of rituximab when added to standard therapy.[25] But subgroup analysis revealed significant effect on the primary end point in African-American and Hispanic patients. Also, there were significant fall in anti-ds-DNA levels and rise in complement levels. The dose of rituximab used was 1000 mg, 2 doses, 14 days apart. Oral steroid was also used in tapering doses. In the LUNAR trial, patients with Class III or IV lupus nephritis were randomized to receive rituximab as two 1000 mg doses, 14 days apart, to be repeated after 6 months.[26] The primary end point of renal response at week 52 was not met. The only significant findings were, like EXPLORER trial, decrease in anti-ds-DNA and increases in complement levels. However, further analysis revealed that patients of African ancestry were more likely to respond to rituximab. Also, there was more reduction in proteinuria in the long term in the rituximab group. So, overall, both these trials were negative. So, although clinical results were encouraging, the randomized trial data did not support

the use of rituximab. This made the use of rituximab for SLE controversial. In 2019, a meta-analysis was published on this topic.[27] Twenty-four studies were analyzed. It was seen that, overall, in controlled trials with rituximab, there was more probability of total remission (OR=2.02, 95% CI: 1.23–3.32, P<0.01). Also rituximab is associated with more decrease of proteinuria compared to controls. So, based on this meta-analysis, rituximab may be considered as a viable option in lupus nephritis. The ideal dose is still debated because some of these trials used four 375 mg/m^2 weekly doses and some used two 1000 mg fortnightly doses.[28]

Another anti-CD20 therapy tried in clinical trials for SLE was *Ocrelizumab* (OZM) (humanized antibody).[28] There were two trials: BEGIN (non-renal) and BELONG (Renal). The BEGIN study was stopped early. In the *BELONG* trial, OZM was used at doses 400 mg or 1000 mg on days 1 and 15, and then 4 monthly.[28] This trial was also stopped early due to increased risk of infections in the group receiving OZM+MMF. The intention-to-treat analysis at 32 weeks showed that there was some improvement in renal response in the OZM group, although it did not reach statistical significance. But the data also showed that there was more probability of response when OZM was combined with the *Euro-Lupus* protocol. But as of now, OZM is not a priority candidate drug for lupus trials. The drug is only approved for some forms of multiple sclerosis.

Ustekinumab (UKB) is an IL-12/23 antagonist.[29] IL-12 is involved in activation of various T-cell subsets involved in autoimmune response. IL-23 is involved in expansion and survival of pathogenic Th-17 cells. These two pathways are closely related **(Fig. 2)**. In September 2018, Vollenhoven et al. published a study of UKB in active SLE in the Lancet.[29] In this study, UKB was given intravenously at the beginning, followed by 90 mg subcutaneously every 8 weeks. Like other biologics, this was also given along with standard therapy. At 24 weeks, there was significantly more response with UKB, compared to placebo. The same group of researchers published a follow-up study in 2019.[30] In this, it was shown that the benefits of UKB were maintained at 48 weeks. There were no excess malignancies or opportunistic infections. Presently, UKB is approved for Psoriasis, Ulcerative colitis, and Crohn's disease. But in the future, this may be a promising therapy for active SLE.

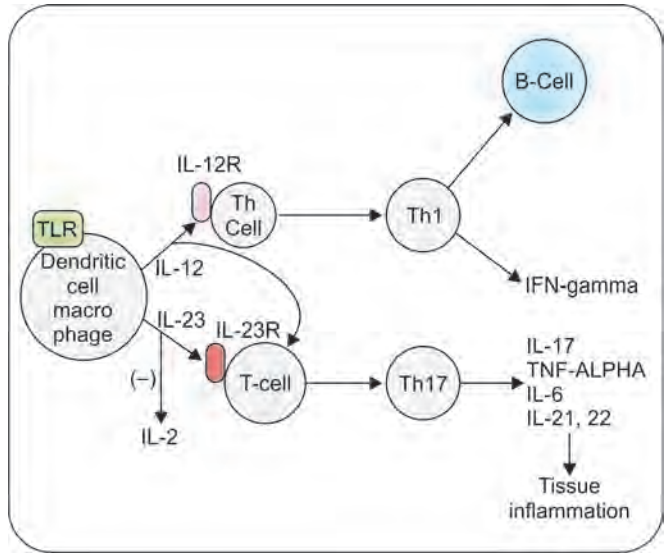

Fig. 2: Schematic representation of the IL-12/23 pathway in tissue inflammation ©RP

Baricitinib is an oral Jak1 and Jak2 inhibitor, which has been approved for use in rheumatoid arthritis. Recently, there have been trials of baricitinib in SLE. In 2018, Wallace et al. published the results of a Phase II trial of baricitinib in SLE patients with arthritis or dermatological manifestations.[31] Here, it was found that baricitinib significantly improved these manifestations at 24 weeks. Thus, this was a proof of concept that baricitinib can be a viable option for SLE patients in addition to standard therapy. However, the dose of baricitinib used (4 mg) has raised some concerns about the potential for serious side effects like neutropenia.[32] A Phase 3 trial (*SLE-BRAVE-X*) is underway to test the efficacy of baricitinib in SLE. This and similar other studies can clarify the role of this drug in the future.

New Frontiers

The most promising new target in controlling inflammation is the glucocorticoid pathway **(Fig. 3)**.

Glucocorticoid-induced leucine zipper (GILZ) is one of the GREs in the cell nucleus and it is one of the earliest areas in the DNA activated by the hormone.[33] GILZ is one of the principal mediators of anti-inflammatory activity of GCs. The most robust evidence of the anti-inflammatory activity of GILZ is its effect on the NF-κB/MAPK pathway.[33] It directly inhibits NF-κB and prevents induction of the

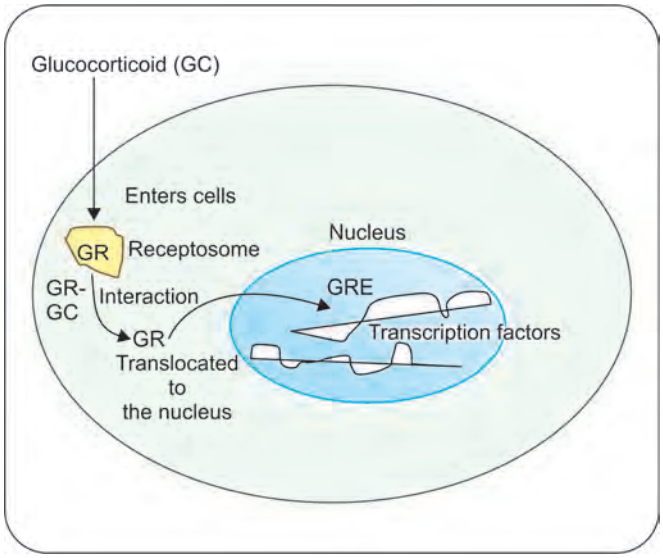

Fig. 3: Glucocorticoid cellular pathway
GR, GC receptor; GRE, GC recognition element

proinflammatory genes. Overall, it shifts the inflammatory milieu from Th1 to Th2 response. This molecule is encoded by the *Tsc22d3* gene located on the X chromosome.

In autoimmune diseases like SLE, it has been shown that active disease is associated with lower intracellular GILZ levels. This raises the possibility that GILZ deficiency is one of the factors in the pathogenesis of this disease and conversely, *GILZ augmentation may be a potential therapeutic target.* GILZ has effect on Th1, 17 cells and also B-cells.[34] Deletion of GILZ in mouse models is associated with an increase in B-cells in blood.[34] And increased B-cells means increased autoantibodies.

As discussed in the introduction section, glucocorticoids are associated with a lot of side effects and this raises a lot of problems in long-term treatment. So, it may seem like a paradox that the same glucocorticoid pathway is now the focus of research. But this new research is aimed at other intermediary compounds in that pathway which can *maintain the immunosuppressive effects without giving rise to the side effects*. So, there is a lot of research to find glucocorticoid receptor agonists and modulators, also called Selective Glucocorticoid Receptor Agonist & Modulator (SEGRAMs).[35] GILZ is one such target to bypass the glucocorticoid receptor.[35] It has good immunosuppressive activity and also, it lacks significant metabolic effects. It has neutral or even positive effect on bone density. However, all metabolic effects are still not known like its effect on glycemic status, skin thinning, or cataracts. So, although this is an exciting prospect, its potential for human use is still unknown. Research on GILZ till now is mostly animal model-based.[35] Some studies have used truncated regions of the protein while others have used virus vectors with transcription factors to induce GILZ expression in laboratory animals. Presently, two SEGRAM compounds under investigation, RU24858 and ORG 214007-0, are based on targeting GILZ.[36]

Other newer therapeutic options, which are in various stages of trial, are mentioned here:

- *Tabalumab:* Anti-BAFF monoclonal antibody; trials: *ILLUMINATE-1 and 2*
- Epratuzumab: Anti-CD22 antibody; trials: *EMBODY 1 and 2*
- *Atacicept:* Anti-TACI, tumor necrosis factor transmembrane activator and calcium modulator and cyclophilin ligand interactor; trials: *ADDRESS-II; APRIL-SLE*
- *Blisibimod:* Anti-BLyS antibody; trials: *PEARL-SC*
- *Rigerimod:* Peptide derived from a region of U1-70k snRNP protein; immunomodulator binding to MHC-II; can restore immune tolerance; Phase IIb trial encouraging; further trials in progress
- *Others:* IL-2 therapy, anti CD40 antibody etc.

Conclusion

As the earlier discussion makes clear, there are a lot of options in SLE management. Steroids are needed in the beginning and during life threatening flares. But once the patient is stabilized, we should try to shift to the steroid sparing therapies in order to avoid the long-term side effects. Choice of steroid-sparing agents or biologicals should be based on patient profile, affordability, and organ involvement.

CHAPTER

215 Gout Is the Only Enemy That I Do Not Wish to Have at My Feet

Anjana Pandey, Ajay Maurya, PK Maheshwari

Abstract

Gout or monosodium urate (MSU) crystal arthropathy is a disorder caused by hyperuricemia (serum urate >6.8 mg/dL [>0.4 mmol/L]) that results in the precipitation of monosodium urate crystals in and around joints, resulting into recurrent acute or chronic arthritis. Acute gouty arthritis is characteristically monoarticular and often involves the 1st metatarsophalangeal joint or ankle. Symptoms of gout include acute, severe pain, tenderness, warmth, redness, and swelling. Definite diagnosis requires demonstration of monosodium urate crystals in synovial fluid. This chapter deals with practical approach to diagnosis and management of patients with gouty arthritis.

"Gout is the Only Enemy That I Do Not Wish to Have at My Feet"
–Reverend Sydney Smith (1841)

Introduction

Gout is one of the oldest joint diseases known to humanity. The term gout originated from the word 'gutta' meaning a drop (in Latin), as the ancient belief was that the devil is causing the disease by instilling the poisonous humor into the joint of the victim drop by drop.

Gout is a crystal-deposition disease that results from chronic elevation of uric acid levels above the saturation point for monosodium urate (MSU) crystal formation. Normal level of serum uric acid (sUA) is 7 mg/dL in males and 6 mg/dL in females. Initial presentation is mainly severely painful episodes of peripheral joint synovitis (acute self-limiting "attacks") but joint damage and deformity, chronic usage-related pain, and subcutaneous tophus deposition can eventually develop. Chronic recurrent gouty arthritis leads to development of tophi in the cartilage, tendon, or other soft tissues.

Epidemiology

The global burden of gout is substantial and seems to be increasing in many parts of the world over the past 50 years. Gout is most common inflammatory arthritis in men aged more than 50 years. Overall prevalence of gout in adult male is 1–2%. Prevalence in India is 0.1%, but incidence and prevalence have been doubled over past two decades probably because of adoption of western life styles.[1] Gout is rarely seen in premenopausal females and children. After menopause, due to lack of estrogens, females are at equal risk of developing gout.

Pathogenesis

The disease often runs in families, but the genetic basis of gout is not well understood. Uric acid is the end product of purine degradation in humans. Purines are derived either from the diet or by de novo synthesis. Normal metabolism includes conversion of purine first into hypoxanthine in presence of enzyme xanthine oxidase, then hypoxanthine into xanthine again in presence of enzyme xanthine

oxidase, and finally xanthine is converted into uric acid which is a trioxypurine. Most of the uric acid is eliminated through urine or intestine, the kidney excretes two-thirds, and rest one-third is excreted via intestine.

Classification

Primary Gout

- Unknown cause
- Genetic defects in renal handling of urate
- Under secretors (90%) and overproducers (10%)

Secondary Gout

- Increased urate production:
  - Inherited enzyme defects (HGPRTase deficiency, glucose-6-phosphatase deficiency)
  - Myeloproliferative disorder
  - Psoriasis
  - Hemolytic diseases
  - Malignancies
  - High purine diet, alcohol
- Decreased renal clearance:
  - *Renal:* Chronic kidney disease, polycystic kidney disease, lead nephropathy
  - *Endocrine:* Hyperparathyroidism, hypothyroidism, diabetes insipidus
  - *Metabolic syndrome:* Obesity, hypertension, dyslipidemia
  - *Drugs:* Diuretics, low dose aspirin, pyrazinamide, ethambutol, cyclosporine
  - *Others:* Down syndrome, sarcoidosis, toxaemia of pregnancy

Stages

These are the following four stages of gout:

- Asymptomatic hyperuricemia
- Acute gouty arthritis
- Intercritical periods (asymptomatic)
- Advanced/chronic gout (frequent or constant joint pain, tophi)

Asymptomatic Hyperuricemia

Asymptomatic hyperuricemia is accidental finding and does not warrant urate lowering therapy. Whenever patient comes at this stage, meticulous search for other comorbidities must be done and it's rewarding. Treatment of asymptomatic hyperuricemia should be done only in those patients who have history of kidney stones and asymptomatic patients with very high sUA, that is, more than 12 mg/dL in men and more than 10 mg/dL in women.

Acute Gouty Arthritis

In an acute presentation, patients will notice severe pain, redness, swelling, warmth, and severe tenderness in one or more joints. Symptoms worsen within first 24 hours. Joint involvement (in order of decreasing frequency) includes the metatarsophalangeal joint (podagra), forefoot, the ankle, the knee, the wrist, and the fingers.[2] In elderly women, an initial presentation may be acute arthritis of fingers, having inflamed Heberden's and Bouchard's nodes.[3] Untreated acute gout usually resolves within 1–3 weeks.

Intercritical Gout

This is the period between two attacks of gout. Approximately 60% of patients have a second attack within the first year, and 78% have a second attack within 2 years. Only 7% of patients do not have a recurrence within a 10-year period.[4]

Chronic Tophaceous Gout

Tophaceous disease is more likely to occur in patients with the following: a polyarticular presentation, a serum urate level higher than 9.0 mg/dL, and a younger age at disease onset (i.e., 40.5 years or younger).[5] The rate of tophi formation correlates with the duration and severity of hyperuricemia. The most common sites include the joints of the hands and feet. The helix of the ear, the olecranon bursa, and the Achilles tendon are classic, though less common, locations for tophi. Additionally, urate deposition in kidneys could lead to nephrolithiasis.

Diagnosis

- Clinical picture
- Crystal examination
- Serum uric acid
- Imaging

Clinical Pictures

Clinical features helpful in establishing provisional diagnosis of gout:

- Rapidity (12–24 hours) with which inflammation reaches maximal
- *Location:* 1st MTP (most common), intertarsal areas, ankle, knee, insertion of tendoachillis, olecranon
- Monoarticular, intermittent arthritis
- Spontaneous and complete resolution with or without treatment
- Presence of visible or palpable lesion, which by location, texture, or appearance is likely to be tophus
- History of similar episodes in past
- A recent history of trauma, surgery, intercurrent medical illness, or initiation of urate lowering medication or other culprit medicines
- Presence of hyperuricemia

Joint Aspiration and Synovial Fluid Analysis

Identifying urate crystals in fluid aspirated from an affected joint is the only definitive way to diagnose gout. MSU crystals are needle-shaped and negatively birefringent on simple polarized light microscopy.[6] In an acutely inflamed joint, these crystals are seen in polymorphonuclear cells.[7]

Hyperuricemia

Hyperuricemia should never constitute a sole criterion for the diagnosis of gout as hyperuricemia is not present in 40% episodes at the time of acute attack.

Imaging

Joint X-ray: X-ray in gout shows typical punched out lesions with scalloping margins/rat bite erosions (Martel's sign or G sign). These are asymmetrical, eccentric, and away from joint margins.

High resolution ultrasound: Detect subclinical Microtophi and MSU deposit within cartilage of 1st MTP Joint.

MRI: It shows bone "edema," soft tissue pannus, and swelling.[8]

Management

Aims in the Management of Gout

Maintain serum urate in non-tophus gouty arthritis patients less than 6.0 mg/dL and if chronic tophaceous gout then target serum urate level is less than 5 mg/dL to prevent future attacks and reverse prior damage (urate-lowering therapies).

Non-pharmacological Management[9,10]

Life style modifications that are important in reducing risk for gout and/or reducing urate levels **(Table 1)**.

Pharmacological Treatment of Acute Gout

Guidelines

- Affected joints should rest, fomentation should be done.
- Analgesic and anti-inflammatory drug therapy: commenced immediately and continued for 1–2 weeks.
- *Colchicine:* Effective alternative (preferably low-dose colchicine)

TABLE 1 Life style modifications important for reducing the risk of Gout

Risk factor	*Management modality*	*Result*
Diet	Reduction in meat, sea food	Decreased risk
	Increase in low fat dairy intake	Decreased risk
	Increase in protein/complex carbohydrate	Decreased risk
	Reduced fat	Decreased risk
	Reduced beverages beer > distilled spirits > fruit juices > and high fructose corn syrup containing soft drinks	Decreased risk
Obesity	Weight reduction	Decreased risk
Hypertension (HTN)	Reduce BP	Decreased risk
Culprit drugs	Substitute	Decreased risk

- Urate-lowering drugs (Allopurinol/Febuxostat) should not be started during an acute attack.
- In patients already on Allopurinol/Febuxostat, it should be continued with simultaneous treatment for acute attack.

Terminating the Acute Gout Flare

Options: Virtually all anti-inflammatory agents have been used effectively in terminating acute gouty flare.[11]

NSAIDs

- Most useful agent is indomethacin in a dose of 50 mg 6 hourly for 2 days followed by 50 mg 8 hourly. Once pain settles, it can be reduced further to 25 mg 8 hourly. Other nonsteroidal anti-inflammatory drugs (NSAIDs) that can be used are naproxen (750 mg/day), etoricoxib (120 mg/day), and diclofenac (50 mg 8 hourly).
- NSAIDs are relatively contraindicated in patients suffering from renal diseases, peptic ulcer disease, congestive heart failure, and hypertension.
- Aspirin used for cardiovascular prophylaxis can be continued during acute attack under cover of anti-inflammatory agents.

Colchicine

Colchicine is the ideal drug where diagnosis of gout is not confirmed, the latest recommendation is to start 2 tablets of 0.5 mg colchicine as loading dose then 0.5 mg, 1 hour later, if needed, one more tablet of 0.5 mg after 12 hours, then continue colchicine in a dose of 0.5 mg twice or thrice a day after meals until acute attack resolves.[12,13]

Corticosteroids

Preferred only when NSAIDs or colchicine are contraindicating or ineffective especially useful in polyarticular gout following surgery, renal or hepatic insufficiency, or congestive heart failure.

Intraarticular: 40 mg of triamcinolone acetonide or 80 mg of depot steroid (methylprednisolone).

Parenteral (intramuscular or intravenous): Methyl-prednisolone (100–150 mg), the dose can be repeated 12 hourly for 1–3 days in incomplete responders.

Oral: 20 mg of prednisone BD, taper to stop within 7–10 days.

ACTH (Adrenocorticotropic Hormone)

Dose: Between 25 and 50 IU IM/SC; the dose can be repeated 12 hourly for 1–3 days in incomplete responders.

IL-1β Inhibitors (Anakinra, Canakinumab, and Rilonacept)

Highly effective but cost is the constrain.

Gout Flare Prevention (Prophylaxis)

Aim: To decrease frequency and severity of acute gout flares, especially when starting urate lowering therapy.
Options:

- Oral colchicine (in dose of ≤0.6 mg twice daily after meals)
- NSAIDs-benefit not established but can be used in a patient who is intolerant or in whom colchicine is ineffective
- IL-1β inhibitors? (Rilonacept; canakinumab)

Prophylaxis is initiated when urate-lowering therapy is started and stopped when sUA is in goal range for more than or equal to 6 months.

Management of Recurrent, Intercritical, and Chronic Gout[11]

Goal of therapy: sUA < 6 mg/dL

Candidates for chronic therapy

- Patients with two or more attacks per year
- Patients with tophi
- Patients with renal insufficiency
- Patients with uric acid stones

Co-prescribe: Colchicine or NSAIDs for 6 months

Avoid use of medications that can increase sUA. Example: diuretics, ethambutol, pyrazinamide, etc.

Options: Agents that promote uric acid excretion (uricosuric agents):

- Probenecid
- Sulfinpyrazone
- Benzbromarone
- Losartan
- Fenofibrate
- Vitamin C

Agents that inhibit uric acid formation (xanthine oxidase inhibitors):

- Allopurinol
- Febuxostat

Agents that convert uric acid to allantoin (uricase preparations):

- *Rasburicase:* Recombinant fungal uricase (*Aspergillus flavus* and *Candida utilis*)
- *Pegloticase:* Pegylated, recombinant, porcine-baboon uricase

Biologic Agents

- Anakinra
- Canakinumab
- Rilonacept
- Start uric acid lowering therapy 1–2 weeks after inflammation has settled
- Initial long-term treatment of recurrent uncomplicated gout (Allopurinol or febuxostat)

Uricosuric Agents[14]

Promote uric acid excretion

- Hyperuricemia results from impaired renal uric acid clearance in 90% of gout patients (under-excretors of uric acid).
- Candidate patients for uricosurics are fewer than with xanthine oxidase inhibitors.

Limitations of uricosurics:

- Ineffective in renal insufficiency (CrCl < 50–60 mL/min)
- Results in modest decrease in sUA
- Risk of uric acid stone formation
- Cannot be used in presence of renal calculi

Probenecid: Achieve satisfactory control in 60–85% of patients and dose is 1–2 gm/day.

Sulfinpyrazone: It is uricosuric agent and related to phenylbutazone. It also acts as antiplatelet agent. Therefore, should be used cautiously in patients, who are anticoagulated, have bleeding problem and peptic ulcer disease.

The dosage is 100–200 mg twice a day and increase up to 800 mg/day.

Patients on uricosuric drugs are advised to maintain high urine flow (plenty of water intake) to avoid crystallization of uric acid in renal tubules.

Benzbromarone: Potent uricosuric drug used in patients with no improvement with allopurinol and in renal transplant patient. It is safe in mild to moderate renal impairment and rarely cause hepatotoxicity. Therefore SGOT/SGPT level should be monitored before starting and after continuation of therapy.

Dosage is 50–200 mg daily.

Angiotensin receptor blocker: Particularly losartan is also uricosuric drug and acts by inhibiting renal tubular reabsorption of urate.

Fenofibrate: It is a lipid lowering agent and has uricosuric effect.

Vitamin C: It can be given in a dose of 8 gm/day in divided dosage.

Urate-lowering Strategies

Inhibit uric acid formation by inhibiting xanthine oxidase inhibitors:

- Allopurinol
- Febuxostat

Allopurinol: Approved at daily doses of 100–800 mg/day but 95% of dosing is at less than or equal to 300 mg/day and at this dose it sub-optimally controls the sUA levels (only 21–55% patients achieve target sUA of 6 mg/dL).

Factors contributing to low dosing of allopurinol:[15,16]

- Intolerance (~10%) including rare but life-threatening rashes and hypersensitivity syndrome.
- Dosage reduction recommended with impaired renal function.
- Minimal RCT evidence for safety and efficacy of allopurinol at doses more than 300 mg/day.

Unmet needs with Allopurinol therapy:[14]

- *Under-dosing:* Only 53% patients achieve target sUA with the commonly used dose of 300 mg/dL
- *Intolerance and allergies:* Drug rash with Eosinophilia and Systemic symptoms (DRESS)
- *Dosing adjustment required in comorbid conditions:* Kidney impairment
- *Drug:* Drug interactions (Azathioprine, Mercaptopurine)

The above factors result into non-compliance (50%) and treatment failure.

Febuxostat: Non-purine, selective xanthine oxidase/xanthine dehydrogenase inhibitor, which completely inhibits activity of XO enzyme by obstructing substrate binding.[17-19]

Indications

- Chronic management of hyperuricemia in patients with gout
- Allopurinol hypersensitivity/intolerance/failure
- CKD, where the reduced allopurinol dose sub-optimally controls the sUA levels

Initiate dose is 40 mg OD. Monitor the sUA after 2 weeks. If target (<6 mg/dL) not achieved, shift to the higher dose (80 mg or 120 mg).

Adverse effects: Transaminitis, acute gouty flares, myocardial infarction, immune hypersensitivity reaction, renal failure, angioedema.

Uricase

- Apes and human beings lack uricase
- Uricase converts insoluble uric acid into soluble allantoin

Recombinant Uricase

Rasburicase: Short-term use in tumor lysis syndrome but unsuitable in gout due to short half-life and immunogenicity.

Pegloticase: It is useful in treatment failure cases and tophi. Dose 8 mg IV every 2 weeks. Limitation is infusion reactions, attenuation of clinical response due to development of inhibitory antibodies.

Conclusion

Hyperuricemia and gout are not synonymous. Do not treat asymptomatic hyperuricemia. At least half of patients who present with an initial attack of gout take a diuretic or other medication predisposing to hyperuricemia or gout. Do not start a urate-lowering agent during an acute attack of gout; however, do not stop one if the patient is already taking it and experiences a recurrence. Limiting allopurinol to 300 mg/day is insufficient to control gout in many cases; aim should be "dose to target." Febuxostat represents an effective treatment option to allopurinol may be considered as first-line treatment. Biologics are very effective option, but cost is the maim constraint.

CHAPTER

216 Liver Dysfunction and NAFLD in RA: Is MTX Really a Culprit?

Kartik Nikhil Balankhe, Rishabh Ramu Nayak, Pulin Kumar Gupta

Abstract

There is an increased risk of nonalcoholic fatty liver disease (NAFLD) in patients with rheumatoid arthritis (RA) as they share a lot of risk factors. Methotrexate (MTX), which used in the treatment of RA, further increases the risk as it is a potentially hepatotoxic drug. NAFLD related to MTX is believed to be related to folate antagonism and genetic (C677T) polymorphism. However, there is an absence of significant clinical and histological hepatic worsening seen. Possible options for monitoring include LFT, USG, Fibroscan, and scoring systems (like NAFLD-LFS). Transaminase elevations more than three times the normal values are rarely seen. If at all seen, then the first step should be to evaluate for other confounding causes. If MTX is the likely culprit, it should be withheld and restarted after normalization of values. As a last resort, other DMARDs can be tried; however, it should always be the priority to keep the patient on MTX for as long as possible as it is the sheet anchor drug in RA. Also, MTX is associated with a possible reduction in serious outcomes and has a possible protective effect from the development of metabolic syndrome.

Introduction

Rheumatoid arthritis (RA) is the most common autoimmune inflammatory arthritis. It is an autoimmune disorder that can also affect other parts of the body including the liver. There is an increased risk of nonalcoholic fatty liver disease (NAFLD) in patients with RA as they share a lot of risk factors including obesity, and hence metabolic syndrome (MS) (which is worsened with decreased physical activity in these individuals). Additionally, a known hepatotoxic drug, methotrexate (MTX), which is commonly used and is the sheet anchor drug in the treatment of RA is associated with transaminitis as a common side-effect. NAFLD represents a spectrum of liver disorders ranging from steatosis, steatohepatitis (NASH), cirrhosis to primary liver cancer. In the United States, about 29% of patients with RA have mild to moderate NAFLD and about 1.4% have advanced disease.[1] The prevalence of NAFLD in general population of India ranges from 9% in rural to 32% in urban.[2] Asians have been found to have increased body fat as compared to the Europeans even at the same BMI, and hence Indians are at a greater risk for NAFLD even if having a normal BMI.[3] Reasons for this may be environmental factors and lifestyle related factors like high-fat diets and reduced physical activity. Having said that, still most of the Indian patients with NAFLD are overweight or obese instead of having a normal BMI as per the Asian-Pacific criteria even though they do not have the typical morbid obesity that is seen among the Western patients.[4] However, in the Indian patients with NAFLD, a lower prevalence of full-blown MS is found, which may be related to the lower frequency of hypertension and diabetes in patients presenting with raised transaminases.[5] In Indian patients with RA, the prevalence of MTX-associated NAFLD with transaminitis is found to be 4.7%. This is somewhat lower than expected and the methodological, ethnic, and genetic variations may

be a reason for this discrepancy in the actual prevalence. However, the simultaneous use of other disease-modifying antirheumatic drugs (DMARDs), viz. hydroxychloroquine and sulfasalazine, does not influence the development of NAFLD with transaminitis.[6] In another Indian study involving patients with RA on low-dose weekly MTX, only 7.5% were reported to have significant hepatic fibrosis as assessed by transient elastography.[7] There is a paucity of Indian studies regarding the exact prevalence of NAFLD (by USG) in patients with RA and on MTX.

Role of MTX in Pathogenesis

As per the studies conducted in the past, the duration of MTX therapy and especially its cumulative dose seems to be significantly related to the occurrence of transaminitis.[6,8] However, some also suggest that these factors are not significant in causing transaminitis in patients with RA.[9]

NAFLD associated with MTX therapy is believed to be related to folate antagonism in the hepatic tissues which have high cellular turnover. The probable mechanism involves inhibition of purine metabolism, polyamine synthesis, and homocysteine metabolism.[10] The liver biopsy specimens taken from the patients with RA have demonstrated hepatic folate deficiency and accumulation of MTX-polyglutamates in the liver.[11] The other culprit mechanism is related to the genetic polymorphism in metabolic pathways of MTX that resulted in the development of NAFLD. It is also been reported that C677T polymorphism increases the likelihood of MTX toxicity.[12,13] However, studies with new grading systems and electron microscopy now have confirmed an absence of significant changes in liver histology in patients with RA on long-term MTX. There is also an absence of clinical meaningful hepatic worsening. Hence, it is safe to use MTX for a long duration with proper monitoring in patients with RA.[14] In fact, many of the serious adverse effects of MTX are linked with the daily dosing or very higher doses (e.g., 100 mg/week) that was used in the past but with the introduction of lower and less frequent dosing regimens, these toxicities are hardly seen nowadays.

Does MTX have a Protective Role?

It is seen that the patients with RA on MTX, despite having minor or major transaminitis, do not have an increased risk of liver cell failure, cirrhosis, or death. There is a strong trend toward less of these serious outcomes in them although not reaching the statistical significance. However, the reason for this possible decrease in serious outcomes is not completely apparent.[15] Similarly, a negative association between MTX use and the presence of the MS is noted, which suggests that MTX may protect against its development. This protective effect of MTX is not a result of generic anti-inflammatory effect, but is likely to be drug-specific. This is not observed with any of the other DMARDs.[16] A similar association was also observed in another study where it was assumed to be purely due to the anti-inflammatory effect of MTX, although no data was presented to support it.[17] The lower incidence of MS in patients on MTX may be seen because of the increased physical activity in these individuals as the disease activity reduces with appropriate treatment; however, further studies are needed to confirm this postulate.

Clinical Features

Patients with RA and NAFLD are structurally obese with clinical evidence of insulin resistance in the form of acanthosis nigricans. They are usually asymptomatic but may have occasional pain in the right upper quadrant of abdomen due to underlying hepatomegaly. Clinical features due to enzyme derangements in the form of loss of appetite, nausea, or vomiting are minimal because the degree of transaminitis is generally minimal despite the usage of MTX. Peripheral stigmata of chronic liver disease and portal hypertension may be rarely seen in advanced cases (especially those with cirrhosis).

Diagnosis

Since the diagnosis of NAFLD does not require any invasive testing, it is always to be done by history, physical examination, liver imaging, and few blood tests (to exclude other liver diseases). History of ethanol consumption of more than 20 g/day in men and more than 10 g/day in women exceed the diagnostic cut-off for NAFLD. Intake of medications causing hepatic steatosis and other causes of liver injury like viral hepatitis, autoimmune diseases must be excluded.[18] Suspicious drugs including other co-prescribed hepatotoxic drugs in the treatment of RA like leflunomide and NSAIDs[19,20] and other risk factors for NAFLD like obesity, diabetes, dyslipidemia, insulin resistance, and MS may also increase the likelihood of NAFLD and they always need careful evaluation.[21] Hence,

it is not easy to simply mark the liver dysfunction to MTX in patients with RA.

Liver biopsy is the gold standard to confirm NAFLD, but it is an invasive procedure and is very rarely advocated for the confirmation of MTX related liver disease. It is rather indicated for the evaluation of other potential causes of transaminase elevations when the diagnosis is unclear.[15] A pretreatment liver ultrasound for patients at a high risk of NAFLD is recommended. Some centers even advocate a pretreatment liver biopsy for high-risk patients but is not recommended as a blanket practice in current guidelines.[22] Amongst the imaging modalities, ultrasonography of the liver is the imaging modality of choice for screening of fatty liver.[23] This has almost replaced the liver biopsy for the diagnosis of NAFLD.[21] Another imaging technique is the Transient Elastography or Fibroscan, which measures liver fibrosis by measuring liver stiffness. The other newer imaging modalities like Shear-Wave Elastography (SWE), Proton Magnetic Resonance Spectroscopy (^{1}H-MRS), MRI using Proton Density Fat Fraction (MRI-PDFF), and MRE (MR Elastography) are also useful in diagnosis.

Biochemical tests include estimation of alanine transaminase (ALT) and aspartate transaminase (AST) levels in serum. Elevation of ALT and AST is very modest and usually less than twice normal. As the hepatic fibrosis increases, the ALT levels fall further downward. The characteristic AST to ALT ratio of less than 1 seen in NASH patients reverses as the disease progresses toward cirrhosis.[24] Another biochemical test is the detection of Cytokeratin/Keratin (CK/K) 8 and 18 fragments in blood, which can help to differentiate NASH from simple steatosis or normal liver more reliably than serum aminotransferase levels.[18]

Many other noninvasive scoring systems can also be very useful. The FIB-4 score, for instance, is a valuable tool to diagnose liver disease in patients with RA treated with long-term MTX therapy.[25] Hepatic indices like NAFLD-Liver Fat Score (NAFLD-LFS), Hepatic Steatosis Index (HSI), Fatty Liver Index (FLI), and Aspartate aminotransferase-to-Platelet Ratio Index (APRI) are handy and easy tools and can also reliably predict NAFLD.[26,27] The Lipid Accumulation Product (LAP) is also useful to identify people with hepatic steatosis.[28] Out of the four NAFLD prediction scores—FLI, HSI, LAP, and NAFLD-LFS; it is found that the NAFLD-LFS score has the best noninvasive prediction value for NAFLD.[29]

Treatment

The treatment of patients on MTX having abnormal liver functions is always debatable. The first step in the treatment of such patients is to confirm the diagnosis. Evaluation for other potential causes, viz. NSAIDs, alcohol intake, obesity, and viral infections (hepatitis B and C), should be done. If no other cause is identifiable, then look at the degree of transaminitis. Though transaminase elevations do not necessarily correlate with the stage of NAFLD, most of the guidelines have used this to monitor hepatotoxicity with MTX. The estimation of baseline transaminase levels before MTX initiation is important. A person who previously had elevated transaminase levels which has not changed after starting MTX should not be subjected to further evaluation. Transaminase elevation more than three times the upper limit of normal is often an indication to withdraw the drug. In case of persistent low-grade elevations particularly if the trend is for a progressive increase in the levels, the dose of MTX is reduced and further investigations are carried out simultaneously.[15] Some also advise stopping MTX when transaminases rise to more than two times the upper normal limit.[22] However, irrespective of the cut-off used, it may be restarted at a lower dose after normalization of these levels. Some other modalities like USG of the liver, Fibroscan, and Scoring Systems (FIB-4 Score) can also be used to identify NAFLD and adjust the MTX dose accordingly.[25] Now, the question that still remains unanswered is—"What if significant transaminitis reappears even with lower doses of MTX and other causes being ruled out?". Here, we would like to suggest switching to other DMARDs or biologicals after considering the patient's disease severity, accessibility, and affordability. However, we need to remember that MTX is still the sheet anchor drug in RA with probably being the most efficacious, cheapest, easy for compliance, and with minimal side effects (especially at a dose less than 25 mg/week, which is far lower than the doses used in oncology) and its substitution should only be done if we are left with no options to continue with it.

Conclusion

MTX is a proven culprit causing liver dysfunction in patients with RA, although with the current data and studies available, it is seen in very few patients. It is mostly transient and not always

Contd...

Contd...

clinically significant enough to warrant its discontinuation. To exclude the other causes of NAFLD should be the first rule. Pharmacogenetic approaches may help to optimize the treatment with MTX but this may not be feasible in all parts of the world before starting this drug. Fibroscan is not available at all the diagnostic centers and the poor people of developing countries like India cannot go for repeat evaluations. At the most, what we can use for serial monitoring are LFTs, noninvasive scores (NAFLD-LFS), and occasional USGs of the liver for serial evaluation of such patients. MTX is and will always remain the gold standard backbone therapy in RA, and hence we recommend continuing therapy and keeping such patients on a regular follow-up to pick up liver dysfunction early. Careful small dose adjustments should be done as per the laboratory parameters and prompt reintroduction of the drug should be done as soon as the picture normalizes. To summarize the protective effect of MTX, it is associated with a possible reduction in serious outcomes and also has a possible protective effect from the development of MS.

CHAPTER

217 Sexual Dysfunction in Rheumatic Diseases

Vinod Ravindran

Abstract

Normal sexual function is an important component of both physical and mental well being. Sexual dysfunction, therefore can negatively impact an individual's quality of life. Sexual dysfunction, though not uncommon, remains an under-explored area in Rheumatology. There are several unique factors contributing to the burden of sexual dysfunction in patients with rheumatic diseases. This review discusses pertinent areas which need specific exploration and offers some thoughts on how to effect the therapeutic aspects of management of this challenging comorbidity in day-to-day rheumatology practice.

Introduction

Sexual health has been defined by the World Health Organization (WHO) as a state of physical, mental, and social well-being in relation to sexuality and it has been recognized as an important factor having positive or negative effects on an individual's quality of life.[1] The WHO has recognized sexual health as extremely important necessitating well thought out plans to pick them up, start preventive measures and appropriate management.[1] Sexual functioning is a neglected area of quality of life in patients with rheumatic diseases and is not routinely addressed.[2] In a study assessing the impact of an outpatient based intervention to improve rheumatologists' identification of sexual health aspects in younger individuals with chronic rheumatological diseases found that only few rheumatologists ever screen their patients for sexual activity.[3] Existing health assessment questionnaire and other quality of life tools for rheumatological conditions do not assess sexual function.[4] **Box 1** lists some of the barriers in effective exploration of the sexual dysfunction.

Female preponderance of several rheumatic diseases is an additional factor which may negatively impact effective communication between not only female patient-male clinician but also between female patient-female clinician.[5] In addition, generally, cultural, religious and social barriers in India make the due assessment of sexual dysfunction difficult, irrespective of the gender. Shame and frustration prevent patients to volunteer the information on issues with sexual function. In addition, lack of specific exploration of this area by clinicians leads to under diagnosis of sexual dysfunction in such patients.

BOX 1 Barriers in exploring/assessing sexual dysfunction in rheumatic diseases

- I am too busy! (time constraints)
- Discomforting subject (uneasiness)
- Why should I screen? (ambivalence in role)
- How should I do it? (competence)
- Not a part of standard assessment, so not important! (perceived lack of applicability)
- Gender of the patient (barrier in communication)

The Sexual Response Cycle

Sexual function and the amount of satisfaction derived from it have the potential to positively or negatively impact on the individual's quality of life. Sexuality encompasses the sexual act itself, self-image and the valorization of self and the relationship with the partner. The sexual response cycle is comprised[6-8] of four distinct stages namely, desire, excitation, orgasm, and resolution. In either gender it leads to simultaneous and often reciprocal physiological changes allowing and facilitating the sexual act and its desirable outcomes. Any disturbances in sexual desire and physiological aspects of the sexual response cycle may cause distress and inter-personal difficulties and are labeled as sexual dysfunction.[8]

Mechanisms of Sexual Dysfunction in Rheumatic Diseases

Sexual dysfunction in rheumatic diseases is fairly common ranging from 36% to 70%.[9-11] The factors responsible for aberration in the sexual function in rheumatic diseases can be categorized into physical and physiological domains **(Table 1)**. In chronic rheumatic diseases both these domains are likely to play a part. Conditions such as osteoarthritis, ankylosing spondylitis and rheumatoid arthritis may prevent attaining relevant sexual positions. Both primary and secondary Sjogren's syndrome can lead to vaginal dryness, which may cause dyspareunia. Pain and fatigue which are a part and parcel of many rheumatic diseases also contribute. Altered body image and apprehension about partner's interest (for example, due to skin involvement in systemic sclerosis, psoriatic arthritis, and lupus or deformities of rheumatoid arthritis) may compound the problems. In some conditions such as ankylosing spondylitis erectile dysfunction has not only been reported to be common but appears linked to high disease activity.[12]

TABLE 1 Contributors to sexual dysfunction in rheumatic diseases

Physical domains	*Psychological domains*
• Heightened tactile sensitivity	• Diminished sense of sexual attractiveness
• Reduced endurance	• Reduced sexual desire
• Impaired motion	• Reduced satisfaction
• Vaginal dryness	• Issues with sexual arousal
• Inability to have an orgasm	• Impaired sensation of penile turgidity
• Inability to have erection	• Inability to achieve orgasm

Drugs and Sexual Dysfunction

Pharmacological treatment of the rheumatic diseases fortunately does not cause major issues as far as the sexual function is concerned. There are reports though of reversible erectile impotence caused by methotrexate, sulfasalazine, and hydroxychloroquine. Commonly used non-steroidal anti-inflammatory agents such as diclofenac, misoprostol, and naproxen may cause interference with libido. Antidepressant medications used in the management of fibromyalgia can lead to loss of desire and difficulty with orgasm. Steroids can contribute to sexual dysfunction in multiple ways including weight gain, abnormal hair growth, altered body image, psychosis, and striae.[13]

Determinants of Sexual Dysfunction

Factors such as severity of the disease, levels of fatigue, amount of pain, physical limitations, act of weight bearing leading to discomfort, perception of self, self-esteem and emotional status, adverse effects of pharmacologic agents, effects of surgery, and fatigue either alone or in combination can determine the sexual function in an individual with rheumatic disease.[14] Generally speaking, irrespective of the gender of the patient, sexuality is adversely impacted by level of pain, depression, and physical limitations. A recent study looking into sexual functioning and its correlates in premenopausal married Indian women with SLE found that dose of glucocorticoids, active lupus, presence of depression and anxiety, and marital satisfaction were all important determinants.[15]

Strategies to Manage Sexual Dysfunction

General Measures

Irrespective of the type of rheumatic diseases, some practical tips to patients and partners are useful and easily adoptable **(Box 2)**. They are generally aimed at relaxation, relieving pain and improving function. A useful resource in this regard is a booklet entitled "Sex and Arthritis" by the

UK based charity Arthritis Research UK.[16] This booklet has information on sexual positions which most couples can try and improve with a little experimentation and open discussion, and adopt positions that are comfortable and enjoyable for both partners.[16]

Specific Approaches

Panush and colleagues have proposed a specific multidisciplinary approach to manage sexual dysfunction entitled "PLISSIT" (for *P*ermission, *L*imited *I*nformation, *S*pecific *S*trategies and *I*ntensive *T*herapy).[17] Details of this approach have been provided in **Table 2**.[17] It is envisaged that an ideal team would have psychologist, physiotherapist, occupational therapists, sex therapist, rheumatologist, and gynecologist.[8]

It is also important to consider hip or knee arthoplasty as per the clinical needs. Both knee and hip arthroplasty have been shown benefit in improving sexual function mainly by allowing the liberty to choose a greater variety of sexual positions.[18,19]

BOX 2 Measures for patients and their partners

- Resting before sexual activity
- To ease stiffness of joints and muscles use of warm shower or hot bath, use of electric blanket
- Taking analgesics and anti-inflammatory drugs as required well before sexual act
- Massage during the act of foreplay to help relax muscles and joints
- Supporting joints appropriately by rolled up blankets or pillows
- Use pacing as a strategy to avoid fatigue
- Use specific positions to reduce discomfit

TABLE 2 PLISSIT approach to managing sexual dysfunction in rheumatic diseases*

Step	*Actions*
Permission	• Demonstrating readiness for the dialogue and exploration of patients' issues related to sexual function • Conveying that patient's issues related to sexual function are manageable • Exploring the issues related to sexual function by involving the patient and his/her partner
Limited information	• Seeking and furnishing information about sexual dysfunction • Trying to establish the cause of sexual dysfunction
Specific strategies	• Considering specific interventions to address the cause/reason of sexual dysfunction, e.g. considering hormonal replacement, review of exiting pharmacological treatment, stress management, measures to reduce vaginal dryness, and approaches listed in **Box 2**
Intensive therapy	• Involving a sex therapist as required

*Table created based on information available from Panush et al.[17]

Conclusion

Sexual dysfunction in rheumatic diseases is though common, remains either under or undiagnosed and affect men as well as women.[20] It is important for the clinicians to be aware of this important aspect of their patients' well-being and be prepared to explore it further and offer appropriate management with the help of a multidisciplinary team.

CHAPTER

218 Interpretation of Common Investigations in Rheumatology

Renu Saigal, Amit Kansal, Vikram Raj Jain

Abstract

Autoimmune rheumatic diseases (ARDs) are multiple; diagnosis of these diseases depends on meticulous history, physical examination, and investigations. These diseases are characterized by inflammation, autoimmunity, and the presence of autoantibodies. Inflammation is assessed by acute phase reactants, viz. high leukocyte count, erythrocyte sedimentation rate, C-reactive protein, ferritin, alkaline phosphatase, and by low albumin levels. Various antibody tests are done to support the clinical diagnosis of ARDs, e.g., rheumatoid factor (RF), antinuclear antibodies (ANA), anti-neutrophil cytoplasmic antibodies (ANCA), etc. Positivity does not always confirm the diagnosis as false positivity may be seen in normal persons, in non-rheumatic diseases and other ARDs, e.g., ANA may be positive in rheumatoid arthritis (RA) patients and RF may be present in systemic lupus erythematosus (SLE); therefore, clinical setting and pre-test probability have to be considered before ordering or interpreting positive tests. Few patients may be suffering from ARD, but the tests may be negative. Therefore, a good correlation between clinical features and laboratory tests has to be done before the final diagnosis.

Introduction

Rheumatic diseases are multiple and are characterized by inflammation, autoantibodies and damage to the organs. To evaluate autoimmune rheumatic diseases (ARDs) it is very important to elicit a good detailed history and perform meticulous examination of patient before getting tests done. Ordering an "Arthritis Panel" should be avoided as tests of inflammation are non-specific and may be elevated in other conditions also. Similarly autoantibodies may be falsely positive in normal persons and in patients with non-rheumatic diseases. One antibody may be present in other ARDs too, for example, rheumatoid factor (RF) and antinuclear antibody (ANA).

Tests to Assess Inflammation

In response to inflammation there is increase in serum concentrations of acute phase reactants (APRs) **(Table 1)**, for example, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), ferritin, and alkaline phosphatase. Negative APRs are also there, which decrease with inflammation, for example, albumin.

ESR—ESR increases with age, upper limit for males is half the age while in females half of sum of age plus 10 (so for 70 year male it is 35 while in female will be 40).[1] ESR is also high in anemia, infections, cancer, pregnancy, trauma, kidney disease, obesity, and with high fibrinogen levels. Its rise and fall may be delayed with the onset and remission of inflammatory disease, respectively.

CRP—It is more consistent than ESR as it rises and falls quickly. It gets elevated within 4 hours of inflammation or infections and peaks at 24–72 hours. In systemic lupus erythematosus (SLE) CRP is usually normal except in presence of infection, severe serositis, or synovitis.

Autoantibodies

Rheumatoid Factor (RF)

It is an autoantibody directed against the Fc (constant) region of the IgG molecule. Antibody may be of various

TABLE 1 Acute phase reactants

Laboratory test	*Abnormality*	*Autoimmune rheumatic disease (ARD)*
CBC	• Anemia • Leukocytosis • Leucopenia • Thrombocytosis	• NCNC, IDA • Active inflammation • SLE, MAS • Active inflammation
ESR	• Increased • Low	• In most ARD • MAS
CRP	• Increased (>6 mg/L)	• In most ARDs except in SLE • Infections
S. Alkaline phosphatase	• Increased	Indicates active inflammation
S. Ferritin	• Increased • Very high	• Active inflammation • SoJIA, ASD, MAS
S. Albumin	Decreased	In inflammation

ASD, Adult onset still disease; CBC, Complete blood count; CRP, C-reactive protein; ESR, Erythrocyte sedimentation rate; IDA, Iron deficiency Anemia; MAS, Macrophage activation syndrome; NCNC, Normocytic normochromic; SoJIA, Systemic onset juvenile idiopathic arthritis.

isotypes, IgM, IgG, and IgA. IgM RF is routinely measured using latex agglutination while all the three isotypes are measured using nephelometry and enzyme linked immunosorbent assay (ELISA). RF is present in 70–80% patients of RA. Titer usually correlates with the severity of rheumatoid arthritis. RF may be present in normal persons and in various other rheumatic diseases (Sjögren syndrome 75–95%, Mixed cryoglobulinemia type II 100%, SLE 15–35%, mixed connective tissue disease 50–60%, Systemic sclerosis 20–30% ANCA associated vasculitis, Dermato-/polymyositis 20%, Systemic vasculitides 5–20%, etc. and in non-rheumatic conditions as well **(Table 2)**.[2]

Anti-citrullinated Peptide Antibody (ACPA)

It is an antibody against citrullinated peptide (post-translationally modified citrulline). It is better test for RA as compared to RF as it is 98% specific for RA but its sensitivity is equal to RF, that is, 70–80% and it is costly.

Seroprevalence of ACPA was found in 10% of other rheumatic diseases[3] and in non-rheumatic diseases. Presence of ACPA may antedate RA by several years and is indicative of severe erosive disease.

TABLE 2 RF positivity in non-rheumatic diseases

Condition	*Frequency of RF (%)*
Aging (>50 years)	5–25
Infection	
Bacterial endocarditis*	40
Hepatitis C*	40–76
Tuberculosis	15
Syphilis*	8–37
Parasitic diseases	10–25
Leprosy*	70–80
Other viral infections*	15–20
Pulmonary disease	
Sarcoidosis*	5–30
Interstitial pulmonary fibrosis	10–50
Silicosis	30–50
Asbestosis	30
Miscellaneous diseases	
Primary biliary cirrhosis*	45–70
Malignancy*	5–25
After multiple immunizations	10–15

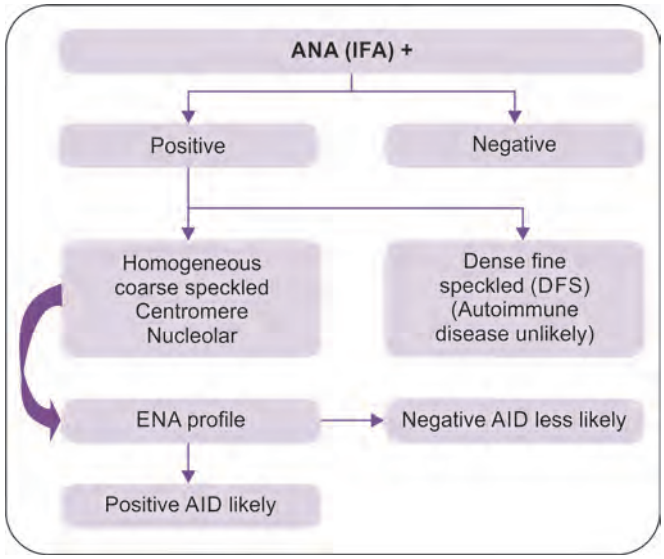
*May cause polyarthritis resembling RA. The best-documented examples of viral infection (in addition to hepatitis B and C) are rubella, mumps, influenza, HIV, dengue, coxsackie virus, EBV and CMV infections, Herpes virus, and parvovirus. Major parasitic diseases are Chagas' disease, Leishmaniasis, onchocerciasis, and schistosomiasis. B cell neoplasms are the most common malignancies.

Antinuclear Antibody (ANA)

The term antinuclear antibody describes a variety of autoantibodies that react with multiple intracellular antigens such as nuclear antigens (DNA, histone, nucleosomes, centromere, topoisomerase, etc.) and in some patients against cytoplasmic antigens (e.g., Jo1 or histidyl tRNA synthetase, mitochondria, smooth muscle cell, etc.).

ANA should be done by indirect immunofluorescent assay (IIFA) using human epithelial cells (HEP2) derived from human laryngeal carcinoma cell line as substrate. It is reported positive in 1: 80 or more dilution, depending on the kit manufacturer's recommendations. ANA may be positive in 20% of normal sera, majority of which are against dense fine speckled 70 antigen (DFS-70). Anti-DFS antibody may be diagnosed by immunoadsorption

Flowchart 1: ANA (IFA) algorithm



ANA, antinuclear antibody; ENA, extractable nuclear antigen; AID, autoimmune disease

method, which is seen in normal persons with false-positive ANA **(Flowchart 1)**.[4]

ANA should always be ordered when there are clinical features of connective tissue disease like fever, photosensitivity, alopecia, mucosal lesions, serositis, nephritis, Raynaud's phenomenon, inflammatory polyarthritis, skin ulcers, skin rashes, sicca symptoms, and proximal muscle weakness. It should never be repeated once it is positive in significant titers.

ANA detection by ELISA: It is of low sensitivity so is not a preferred method for detection of ANA.

The titer of ANA is more important than the pattern **(Figs. 1A to C)**.

It may be positive in many autoimmune diseases and in diseases other than systemic rheumatic disease **(Table 3)**.

Extractable Nuclear Antigen (ENA) Profile (Table 4)

If features of connective tissue disease (CTD) are present and ANA by IIFA is positive then the ENA profile should be ordered by Immunoblot or Line immunoassay (LIA) or by ELISA. ENA profile may be done in suspected Sjogren syndrome and inflammatory myositis even if ANA is negative.

- *Anti-dsDNA:* There are three methods of assessment:
  - IIF using crithidia Luciliae—It uses unicellular hemoflagellate, staining of its kinetoplast is seen with serial dilutions of plasma by IIF technique.
  - ELISA—Since titers are available by this method, so it is good for monitoring disease activity. Specificity for SLE by this method is 70%.[5] It also correlates moderately well with active nephritis.
  - Radioimmunoassay assay (Farr Assay)—Seldom used because of difficulty in disposing of radioactive material.
- *Anti-Sm and Anti-U1 RNP:* Both antibodies produce coarse speckled pattern **(Fig. 1B)** in IIF assay and corresponding antigens (Sm and U1 Ribonucleoprotein) colocalize in small nuclear ribonucleoprotein particles (sn RNP). Anti-Sm Ab is found in 20–30% patients of SLE and is specific for SLE unlike anti-dsDNA, it may remain positive in remission also. Anti-U1 RNP is present in all patients of mixed connective tissue disease (MCTD) and few patients of SLE **(Table 4)**.
- *Anti-Ro (SSA) & Anti-La (SSB):* Autoantigen Ro60 is localized to nucleus and nucleolus, while Ro52 is localized to cytoplasm. So, if Anti-Ro52 (in cytoplasm) is present ANA may be reported negative by HEP2 IIF method. Anti-Ro52, if present in juvenile idiopathic inflammatory myositis (IIM) it denotes severe disease. In adults IIM Anti-Ro52 may be associated with ILD.

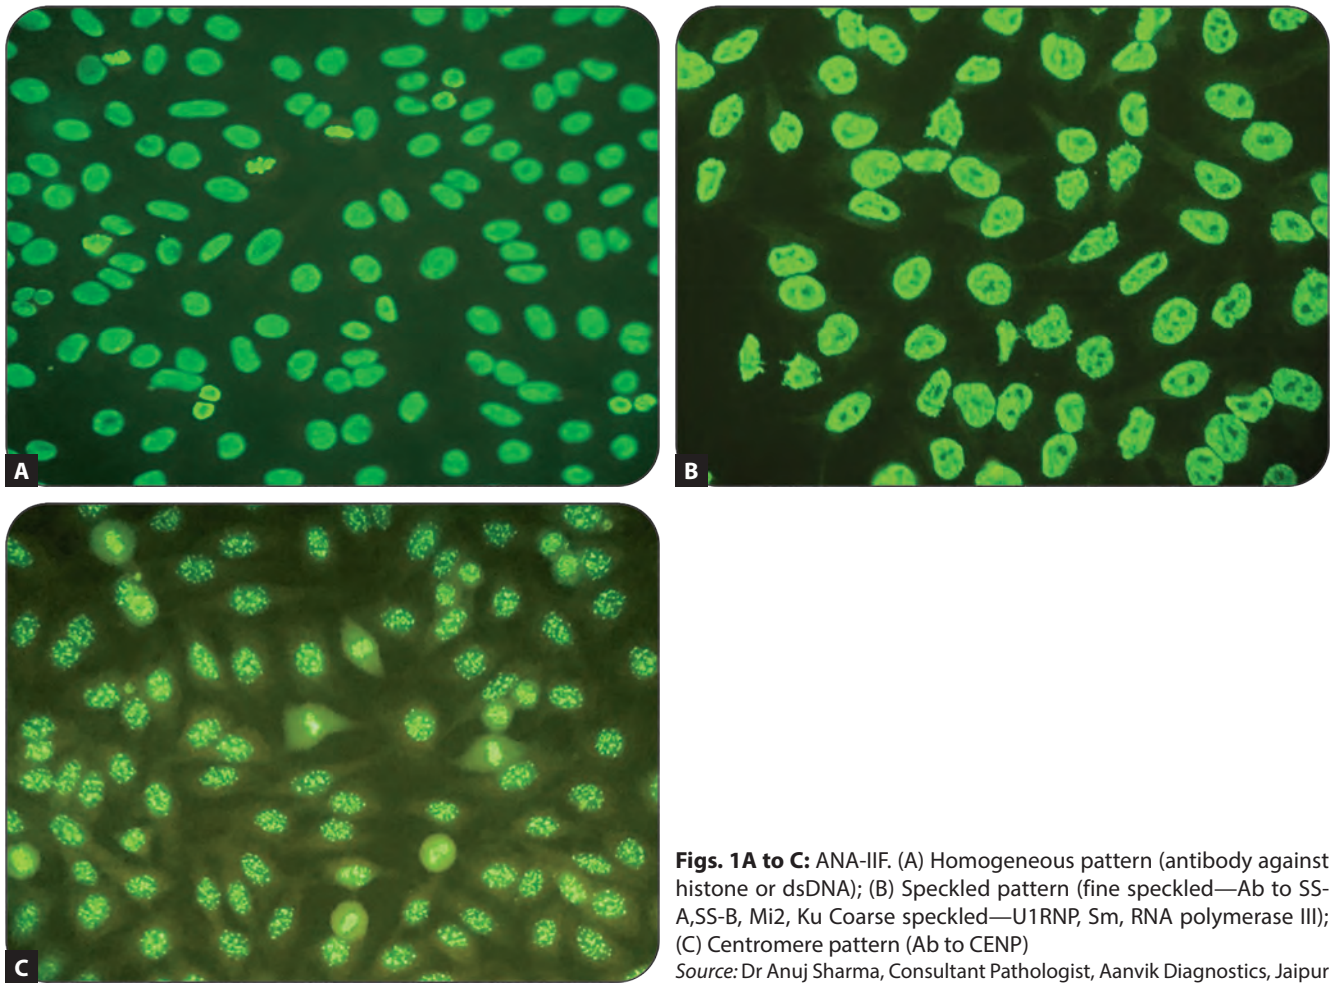
The presence of Anti-Ro antibody in pregnant lupus patient may lead to congenital heart block, neonatal lupus syndrome in fetus and may be present in ANA negative lupus patients and may antedate SLE by 4 years.[6] It may also be positive in subacute cutaneous lupus erythematosus.

Anti-La/SSB autoantigen is present in both nucleus and cytoplasm but it is predominantly found in the nucleus. Anti-Ro and Anti-la Ab should be ordered when sicca symptoms or salivary gland enlargement is present and in SLE patients who wish to become pregnant.

Anti-Neutrophil Cytoplasmic Antibody (ANCA)

This is done by high-quality ELISA (more specific) or IIF (more sensitive but subjective).

ELISA: Current consensus is that in suspected ANCA associated vasculitis (AAV) first high-quality antigen



Figs. 1A to C: ANA-IIF. (A) Homogeneous pattern (antibody against histone or dsDNA); (B) Speckled pattern (fine speckled—Ab to SS-A,SS-B, Mi2, Ku Coarse speckled—U1RNP, Sm, RNA polymerase III); (C) Centromere pattern (Ab to CENP)
Source: Dr Anuj Sharma, Consultant Pathologist, Aanvik Diagnostics, Jaipur

specific ELISA test should be done if it is negative and clinical suspicion is strong, then repeat testing may be done by ELISA or IIF.[7]

Specific ELISA tests for antibodies using purified specific antigens proteinase 3 (PR3) and myeloperoxidase (MPO) are associated with higher specificities and positive predictive value than IIF assays. Anti-PR3 ANCA is present in granulomatosis with polyangiitis (GPA) and Anti-MPO ANCA is present in microscopic polyangiitis (MPA). ANCA against both PR3 and MPO is seen in levamisole adulterated cocaine users.

ANCA by IIFA (Figs. 2A and B)

Using alcohol-fixed buffy coat leukocytes, there are two patterns.

- *Cytoplasmic ANCA (c-ANCA)* **(Figs. 2)***:* There is coarse granular staining of the cytoplasm. The main antigen is PR3, c-ANCA is seen in 90% cases of GPA (10% cases of GPA have ANCA against MPO antigen) and has greater specificity than p-ANCA. In limited GPA c-ANCA may be absent.
- *Perinuclear ANCA (p-ANCA)* **(Figs. 2A and B)***:* ANCA is directed against MPO antigen (occasionally against PR3). There is staining of the perinuclear area leaving cytoplasm clear. ANA positive patients may be falsely labeled as p-ANCA positive, this can be avoided if IIFA tests are done with both formalin and ethanol fixed substrates. p-ANCA is associated with MPA (90%), renal limited vasculitis (75–80%), eosinophilic granulomatosis with polyangiitis with renal involvement, drug induced AAV and ulcerative colitis.
- *Atypical ANCA:* The atypical patterns are usually confused with p-ANCA patterns and may be seen in

TABLE 3 Diseases associated with a positive ANA[12]

Systemic autoimmune diseases	
SLE	
Active	98–100%
Remission	90%
Scleroderma	95%
Rheumatoid arthritis	45%
Sjögren's syndrome	60%
Mixed connective tissue disease	100%
Drug-induced LE	80–95%
Raynaud's phenomenon	40%
Polymyositis/dermatomyositis	35%
Juvenile idiopathic arthritis	15–40%
Organ-specific autoimmune diseases	
Hashimoto's thyroiditis	50%
Graves' disease	50%
Autoimmune hepatitis	70%
Primary biliary cirrhosis	50–70%
Infectious diseases*	
Viral: EBV, HIV, HCV, Parvovirus B19	
Bacterial: Subacute Bacterial Endocarditis, Syphilis	
Malignancies:* Lymphoproliferative diseases, Paraneoplastic syndromes	
Miscellaneous diseases:* Inflammatory bowel disease, Idiopathic pulmonary fibrosis	

SLE, systemic lupus erythematosus; EBV, Epstein-Barr virus; HCV, hepatitis C virus; *Although positive tests of ANA are reported in these diseases more often than in healthy controls, precise estimates vary.
Source: Reproduced with permission from Reference 12.

immune-mediated diseases such as CTD, inflammatory bowel disease, and autoimmune hepatitis. ELISA test for PR3 or MPO is negative.

Indications for getting ANCA done:[7]

- Glomerulonephritis, especially rapidly progressive glomerulonephritis
- Pulmonary hemorrhage, especially pulmonary-renal syndrome
- Cutaneous vasculitis with systemic features
- Multiple lung nodules
- Chronic destructive disease of the upper airways
- Long-standing sinusitis or otitis
- Subglottic tracheal stenoses
- Mononeuritis multiplex or other peripheral neuropathy
- Retro-orbital mass
- Scleritis

Facts about ANCA:

- Negative test does not exclude the diagnosis of AAV, sometimes biopsy is required to confirm the diagnosis.
- Positive test does not establish the diagnosis of AAV as false positive may be seen in other diseases.
- Titers do not correlate with severity so disease should be assessed clinically.

Anti-phospholipid Ab (APLA)

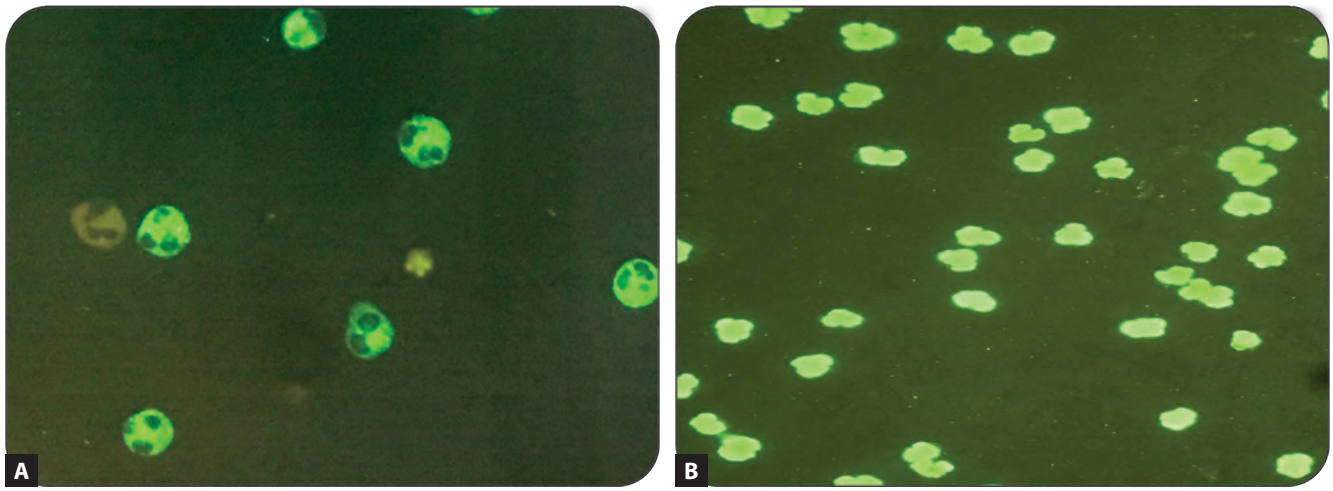
Commonly three APLA are being done.

1. Lupus anticoagulant (LAC):
   Screening tests:
   - dilute Russell viper venom time (dRVVT)
   - activated Partial Thromboplastin Time (aPTT) is prolonged and fails to get corrected when the patient's plasma is mixed with normal plasma excluding coagulation factor deficiency.

TABLE 4 ENA profile

ENA antigen	*Antibody*	*Clinical significance*
• Double stranded DNA • Smith Ag • Histones (proteins of nucleosomes) • Ribosomal P protein	• Anti-dsDNA • Anti-Sm Ab • Anti-Histone Ab • Anti-Ribosomal Ab	• 95% Specific for SLE + in active disease & with nephritis • Present in 10–20% SLE • + in drug induced lupus • Specific for SLE esp. neuropsychiatric lupus
• Ro/SSA-Ro60 (protein of cytoplasmic RNA) & Ro52 (ubiquitin ligase in cytoplasm) • La/SSB (present in nucleus & cytoplasm)	• Anti-Ro/SSA (Anti-Ro60 & anti-Ro52) • Anti-La/SSB	• + in Sjögren syndrome 40–95% and in ANA negative SLE • + in 25–40% Sjögren syndrome *(Both anti-Ro & anti-La associated with extraglandular manifestations*& glandular lymphocytic infiltration)*
Ribonucleoprotein (RNP)—RNA + Proteins	Anti-U1 RNP	• MCTD • 40–60% SLE (not specific)
Topoisomerase-I (Scl70)	• Anti-Topoisomerase-I/ • Anti-Scl70	+ in 30% cases of diffuse Cutaneous SSc, may be associated with ILD
Centromere	Anti-centromere Ab	• Limited cutaneous SSc • Pulmonary hypertension
Cytoplasmic • Histidyl tRNA synthetases • Ku Ag (also present in nucleus) • Mitochondria • Smooth muscle	 • Anti Histidyl tRNA synthetase (Anti-Jo1) • Anti Ku Ab • Anti-mitochondrial Ab • Anti-smooth muscle cell Ab	 • Polymyositis/Dermatomyositis, Strongly associated with ILD • With overlap syndromes, e.g., myositis + SSc or SLE, UCTD • Primary biliary cirrhosis • Autoimmune hepatitis
RNA Polymerase III	Anti RNA Polymerase III	DcSSc with renal involvement
PM-Scl	Anti PM-Scl	Systemic sclerosis

*Extraglandular manifestations – Purpura, vasculitis, lymphadenopathy, leukopenia & thrombocytopenia. DcSSc, diffuse cutaneous systemic sclerosis; ILD, interstitial lung disease; UCTD, undifferentiated connective tissue disease



Figs. 2A and B: Antineutrophilic cytoplasmic antibody (ANCA), c-ANCA, and pANCA. IIF Staining—c-ANCA, p-ANCA

TABLE 5 APLA positivity in diseases other than primary APS

ARD[13]	*Infections (usually IgM aCL positive)*	*Drugs (usually transient IgM aCL)*
• SLE—25–50% • Sjögren syndrome—42% • Rheumatoid arthritis—33% • Autoimmune thrombocytopenic purpura—30% • Autoimmune hemolytic anemia – (Unknown) • Psoriatic arthritis28% • Systemic sclerosis—25% • Mixed connective-tissue disease—22% • Polymyalgia rheumatica or giant cell arteritis—20% • Behçet syndrome—20%	• Syphilis • Hepatitis C infection • HIV infection • Human T-cell lymphotropic virus type 1 infection • Malaria • Bacterial septicemia • Leptospirosis	• **Cardiac—**Procainamide, quinidine, propranolol, hydralazine • **Neuroleptic or psychiatric—**Phenytoin, chlorpromazine • **Other—**Interferon alfa, quinine, amoxicillin

– Kaolin clotting time

aPTT and dRVVT may sometimes be normal if there is acute large thrombus and it may be falsely prolonged if the patient is on anticoagulants.

2. Anticardiolipin Ab—IgG, IgM, & IgA*
   Most sensitive test for APS
3. Anti-beta-2 Glycoprotein Ab—IgG, IgM, & IgA*

Done by ELISA, not affected by thrombosis or oral anticoagulants

(*IgA isotype is included in the SLICC criteria of SLE but these are not routinely available in laboratories)

Significant APLA titers:

1. aCL IgG antibody more than 40 IgG phospholipid (GPL) units or aCL IgM more than 40 IgM phospholipid (MPL) units, or more than 99th percentile (measured by ELISA) are significant.[8] Titers are low (<40 GPL or MPL), moderate (40–80 GPL or MPL) or high (>80 GPL or MPL).[9]
2. Anti-beta-2 glycoprotein 1 antibody of IgG and/or IgM isotype in serum or plasma in titer more than 99th percentile (measured by ELISA).[8]

These tests are usually done at the time of acute thrombotic event and must be repeated after 12 weeks to exclude false positive tests secondary to infections or drugs **(Table 5)**.

Complement C3 and C4

These are measured by nephelometric immunoassay. Normal C3 levels range from approximately 80–160 mg/dL. Normal C4 levels range from 16–48 mg/dL.

Decreased C3 or low C3, C4 may be seen in immune complex-mediated diseases, viz. SLE, APS, Sjögren's syndrome, MCTD, hypocomplementemic urticarial vasculitis, mixed cryoglobulinemia, serum sickness, some glomerulonephritides including post-streptococcal nephritis. With the treatment of these diseases, C3 or C4 may normalize. Low C4 with normal C3 may be seen in hereditary angioedema and acquired C1 inhibitor deficiency.

HLA B27

This test is done by flow cytometry and polymerase chain reaction (PCR). PCR is preferred as it gives accurate results. This test should be ordered when there are clinical features of spondyloarthritis (SpA), viz. inflammatory backache, as in general population 8% population is positive for HLA B27, so if ordered injudiciously a person with mechanical backache may be wrongly diagnosed as a patient of SpA. Ankylosing spondylitis, a subtype of SpA, 85–95% are positive for this gene remaining 5–15% may be negative, while in SpA secondary to psoriasis or inflammatory bowel disease and in reactive arthritis, up to 50% may be positive for HLA B27.[10] False positive and false negative do occur so judicious ordering for this test is the need.

Serum Uric Acid (SUA)

It is lower in females (≤6 mg%) than males (≤7 mg%). SUA is usually assessed in the diagnosis of gout but during acute gout flare, the levels may be normal or low in up to 40% because of release of cytokines and ACTH during flare, which can lower the uric acid levels. High uric levels lend support to the clinically suspected case of gout but its estimation is neither diagnostic nor mandatory for confirmation of the diagnosis of gout.

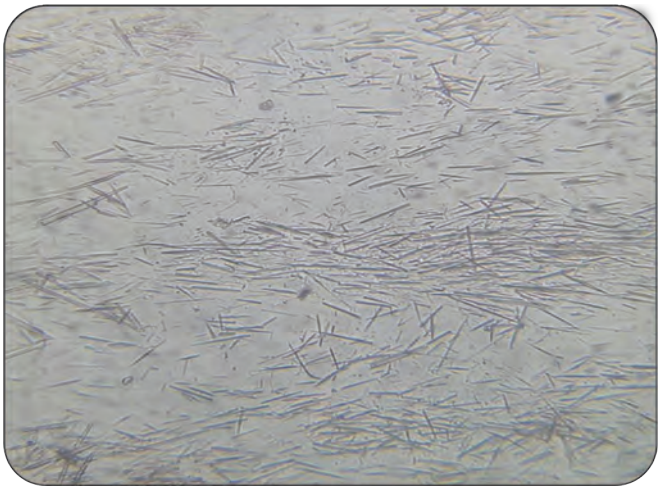

Fig. 3: Needle-shaped urate crystals as seen under low power microscope[11]

Synovial Fluid (SF)

In monoarticular involvement, SF may be examined for bacteria (tubercle bacilli or non-tubercle bacilli), fungus, and crystals. In the suspected case of gout, SF should be aspirated may be seen under light microscope **(Fig. 3)**[11] as polarizing microscope, which is ideal for the demonstration of urate crystals, is not routinely available.

Conclusion

In treating ARD, it is of utmost importance that a very good history and physical examination have been done before ordering investigations. False positives and false negatives do occur so one should be cautious in interpreting these investigations. "Arthritis panel" is to be avoided and should never be ordered.

Balance Gait and Fall in Elderly

Kauser Usman, Azher Rizvi, Suraj Singh Yadav, Abhishek Singh

Abstract

Gait and balance disorders in the elderly act as harbingers of underlying serious medical disorders and are the major cause of one of the classic geriatric syndromes, fall. The decline in cognitive function, sensory processes, and muscle strength that occur with aging aggravated by a number of neurological, musculoskeletal, sensory, cardiovascular disorders along with environmental factors increase the susceptibility to fall in elderly. Elderly patients presenting with falls should be thoroughly evaluated in order to identify the underlying risk factors along with complete neurological, musculoskeletal, and cardiovascular examination. Various clinical trials have concluded that a comprehensive multifactorial evaluation for identifying risk factors followed by targeted interventions can reduce the risk of fall by about one-third.

Introduction

Impaired mobility is one of the major concerns for physicians attending to the elderly patients. Gait and balance abnormalities are often considered to be a common phenomenon of aging. However, this is an erroneous assumption as studies have shown that up to 20% of adults have normal gait patterns even in advanced age. Gait and balance abnormalities act as harbingers of underlying serious medical disorders and are the major cause of one of the classic geriatric syndromes, fall.[1] The annual prevalence of falls among adults aged 65 and above is 28% and it progressively increases with age with a higher incidence among women in contrast to men.[2] Falls in the elderly have devastating consequences with significant morbidity and mortality. Falls leading to serious injuries are the fifth most common cause of death among the elderly. Other serious consequences include increased hospitalization, reduced functional ability, social isolation, depression, and fear of falling.[3] Multiple factors are involved in the causation of falls and a multidisciplinary approach is required to identify and tackle them. With the expanding elderly population, globally and in our country, it becomes important to acknowledge the impact of this problem and develop an effective approach to manage it.

Physiology of Balance and Gait Disturbance in the Elderly

Balance is regulated through the complex integration of sensory input, central processing, and motor output. With aging, there occurs a gradual functional decline in all of these systems. Sensory information is relayed through vision, vestibular system, and proprioception. Diseases of the aging eye lead to dysfunction of acuity, depth perception, and dark adaptation. Vestibular impairment is a usual process of aging or can be seen in ischemia and head trauma. Peripheral proprioception may be weakened in older adults due to diabetes, peripheral vascular disease or any neuropathy. Studies have reported that visual decline contributes more to instability in elderly as compared to decreased proprioception.[4]

The central nervous system structures like the motor cortex, basal ganglia, cerebellum, and spinal cord are involved in planning motor sequences and regulating balance. Damage to these structures from hypoperfusion, neurodegenerative diseases, trauma, or sedative drugs contributes to balance disorders and falls. The righting reflex which produces correcting movements when there is imbalance is impaired in extrapyramidal lesions increasing the risk of falls. Cognitive decline seen in various forms of dementia is also an important risk factor for falls.

Muscle and joints are effector organs of the motor system. Disorders of the peripheral nerves and neuromuscular junction contribute to muscle weakness. This combined with the progressive decline in muscle mass called sarcopenia leads to decreased muscle strength. Arthritis causes pain, restriction of motion, and joint deformities leading to altered gait, balance and increased risk of falls. Musculoskeletal disorders have a strong association with reduced physical activity further aggravating functional decline, frailty, and increased risk of falls.[2]

Risk Factors Associated with Gait and Balance Disorders

Gait and balance disorders were found to be multifactorial in 75% of elderly patients. The most common associated underlying conditions were reported to be arthritis (37%) and orthostatic hypotension (9%).[1] Acute medical conditions such as infections, electrolyte imbalances may precipitate falls in elderly with underlying subclinical balance disorders. Chronic conditions which increase fatigue such as congestive heart failure or anemia also increase the risk of falls.

Musculoskeletal Diseases

Osteoarthritis reduces joint movement and alters gait due to joint deformities and pain. Osteoporosis is also associated with increased risk of fall and fractures in elderly. Lumbar canal stenosis, radiculopathies cause leg and back pain with reduced activity. Hypothyroidism is often associated with proximal muscle weakness, increasing the risk of falls.[1,3]

Cardiovascular Diseases

Any condition which reduces cerebral perfusion due to hypoxia, hypotension can present as unsteadiness and falls. These conditions include arrythmias, congestive heart failure, orthostatic hypotension, or thromboembolic disease.[1,3]

Neurologic Disorders

Parkinson's disease, cerebellar degeneration, multiple sclerosis, myelopathy, and stroke affect the vulnerable brain areas involved in maintaining gait and balance, increasing the risk of falls. Cognitive impairment seen in dementia is also associated with reduced attention, psychomotor slowing and increased susceptibility to falls. This is particularly apparent when cognitive stress is given along with performing a motor activity in an assessment called "dual tasking."[1,3]

Sensory System

Involvement can occur in the form of peripheral neuropathy due to diabetes and vitamin B12 deficiency. Vision can be impaired in age-related eye diseases like macular degeneration, glaucoma, cataracts, and presbyopia. Vestibular apparatus damage can occur in Meniere's disease and benign positional vertigo.[1,3]

Affective Disorders

Depression and sleep disorders increase the risk of falling. Fear of falling can further aggravate the risk of falls. Patients who fall limit their physical activity starting a vicious cycle which leads to functional decline, increased muscle weakness, and disability further amplifying the risk of falls.[1,3]

Medications

Among pharmaceutical agents, psychoactive and sedative drugs such as benzodiazepines, barbiturates, opioids, haloperidol, and risperidone are often the culprit drugs associated with falls. Cardiovascular drugs leading to arrhythmias, electrolyte imbalances, and postural hypotension are also linked to increased risk of falls. This category includes antiarrhythmics, diuretics, and alpha antagonists. Polypharmacy by itself proportionally

increases the risk of falls. Antiplatelet and anticoagulation drugs further increase complexity as they can lead to grave consequences in case of fall.[1,2]

Environmental Factors

An often underestimated risk factor for fall is the interaction of the person with the external environment. Elderly people tend to fall at lower levels of challenge provided by the environment as compared to young, healthy adults. Commonly associated environmental factors include poor lighting, slippery floors, uneven surfaces, and absence of stairway railings.[1,3]

Clinical Assessment

It is important for clinicians to meticulously obtain history of fall from elderly patients as well as family members because patients may fail to remember due to dementia or intentionally hide history of fall for fear of relocation or restriction of activity. It is also important to identify patients at high risk for future falls. Patients at high risk of falls often have other geriatric syndromes such as incontinence, depression, delirium, or frailty.[3]

- While eliciting history of previous falls, it is crucial to inquire about the circumstances that led to the fall such as time of day, location, frequency, injuries, and associated symptoms such as dizziness, vertigo, palpitations, musculoskeletal pain, instability. An abrupt onset is usually associated with cerebral hypoperfusion, toxic, or metabolic abnormalities.
- The physicians should also question about the extrinsic factors such as lighting, uneven surfaces, absence of railing, etc. in the residential environment, which increase the risk of falls.
- Patients should be asked about their previous medical history of underlying neurologic, cardiovascular, musculoskeletal, and visual/sensory impairment.
- A careful drug history to identify offending drugs such as sedatives, antiarrhythmics, diuretics, and alpha antagonists is essential. Associating the falls with the dosing schedule of the medications is also helpful.
- Symptoms of depression and sleep disturbance should be identified.
- The functional status of the patient should be evaluated not only to indicate disability but also to monitor the response to treatment. This can be determined by documenting the instrumental activities of daily living (activities for independent living such as housekeeping, cooking, shopping, use of transportation, management of finances) and activities of daily living (ability to care for oneself such as dressing, toileting, continence, bathing, and mobility).[5]

A thorough physical examination is fundamental for identifying the risk factors and distinguishing the patients at increased risk of falls.

- Gait should be carefully observed from the time the patient enters the examination room. Points to be noted include posture, stance, difficulty in initiation, step length, cadence (steps per unit time), instability, and need for assistance.
- Vitals signs with blood pressure measurement in the supine and standing position should be assessed. Pallor, signs of any diseases of the heart should be examined for recognizing underlying chronic illnesses that may cause fatigue.
- Cognitive impairment can be assessed using the Mini Mental State Examination (MMSE) and the Montreal Cognitive Assessment (MOCA).
- A complete neurological examination should be carried out with focus on sensory and motor examination. Testing for visual acuity, visual field, dark adaptation, and depth perception should be performed. Testing for vibration sense, light touch should be done to detect peripheral neuropathy. Romberg's test can be performed to identify impairments in vestibular function and proprioception clinicians should look for focal neurological deficits, spasticity, hyperreflexia for identifying cerebrovascular diseases. Pattern of gait can give an insight into the underlying neurological condition such as frontal lobe involvement, cerebellar involvement, sensory impairment, or Parkinsonism. Signs of extrapyramidal dysfunction such as rigidity, tremors, hypokinesia should be identified. Cerebellar signs such as psychomotor slowing (finger to nose test, dysdiadochokinesia), scanning speech, ataxic gait should be looked for.
- Testing of muscle strength and joint mobility, deformity, and swelling should be carried out to characterize underlying musculoskeletal conditions like myopathy or arthritis.[1,5]

Special Clinical Tests in Evaluation of Fall

No studies are available to indicate a specific clinical test for gait and balance assessment, till date. The "Get Up and Go" test is easy to perform and can identify older adults prone to fall. Patients are scored on their time taken to get up from a chair, walk 3 meters, turn around, and get back to their original position. A score of 14 seconds or more is considered abnormal and associated with an increased risk of falls.

Other tests of mobility include the Berg balance test for predicting risk of falls and the performance oriented mobility assessment (POMA) test for dynamic and static balance. Nowadays balance testing is combined with a cognitive task in order to unmask underlying cognitive defects. Patients who fail to perform such dual tasks are at increased risk for falls.[6]

Laboratory Evaluation

Laboratory evaluation can be carried out based on the findings of history and physical examination. A 12-lead electrocardiography should be obtained, if arrythmias or cardiac causes are suspected. A complete metabolic panel can be considered for electrolytes and renal function. A complete blood and differential count to rule out anemia or any underlying infection. Serum vitamin B12, thyroid function test, and vitamin D levels should be measured as they are associated with peripheral neuropathy, proximal myopathy, and increased propensity to fall respectively.

Interventions

Lack of effective outcome measures make the assessment of interventions for gait and balance disorders inadequate. However, medical therapies for underlying chronic conditions may produce modest improvement in gait and balance. It is evident by various clinical trials that a comprehensive multifactorial evaluation for identifying risk factors followed by targeted interventions leads to 30–40% reduction in the evidence of fall.[7]

The focus of therapy to reduce falls should be on the reduction of risk factors. Use of visual and hearing aids for increasing sensory input, antiarrhythmic medications and pacemaker insertion for cardiac rhythm disorders, correcting acute metabolic defects that may precipitate falls, appropriate management of arthritis, osteoporosis, correction of vitamin deficiencies such as Vitamin B12 and Vitamin D have resulted in a reduction in the risk of falls. Surgical intervention may be needed for cervical myelopathy, arthritis of knee or hip and lumbar canal stenosis. It is more important to recognize the sedative/psychotropic medications in elderly that precipitate falls and gradually taper their dose appropriately in patients at high risk. All of the prescribed medications should be reviewed and the goal should be to minimize as much as possible the doses and the absolute number of drugs.

Physical activity should be encouraged among the elderly to maintain strength, balance, and flexibility. Tai chi has proven to be an effective intervention in elderly patients for improving balance and reducing risk of falls. The combination of exercise along with visual evaluation and treatment has shown to considerably reduce the risk of falls.[8] Exercise plans should progressively increase physical activity over time with special focus on muscle strengthening and weight bearing. Physical therapists have an important role to play in management of patients with gait and balance disorders. Patients suffering from cerebrovascular diseases or Parkinson's disease should preferably be enrolled in rehabilitation programs.

All efforts should be made to ensure safety of the elderly in their homes by eliminating the extrinsic risk factors. Adequate lighting, strong stairwell railings, switching to safer footwear, avoiding loose rugs, and slippery floors should be ensured to provide a secure and protected environment to the elderly.

In selected patients, assisted devices like canes, walkers, or wheelchairs improve mobility and stability by increasing the base of support and unloading of the painful joints. It is also important to ensure the appropriate size of such devices as incorrectly measured devices may actually increase the risk for falls.[2,3]

Conclusion

The major aim for clinicians treating the elderly is to ensure an independent lifestyle for as long as possible. Gait and balance disorders leading to falls deprive them of such a lifestyle by adversely impacting the day-to-day activities of the elderly. It is vital for clinicians to identify patients at risk of falls, start prevention strategies by individualized multicomponent interventions in order to reduce the morbidity and mortality that result from fall. Recent researches have strongly suggested that interventions to reduce falls are effective. With the growing elderly population the world over, there is an urgent need for implementing fall prevention strategies on a larger scale.

CHAPTER

220 Anemia in Elderly

Alpana Raizada, Ashish Goel

Abstract

Anemia in elderly is a common problem seen in out-patient as well as in-patient general and specialty medical care. The term, anemia of elderly has largely been replaced by anemia in elderly in current times to promote better understanding of the pathophysiology. Anemia in older persons has been found to be associated with increased hospitalization, longer hospital stay, and a higher mortality.

The present article presents an overview of the definition and epidemiology of anemia in older persons and discusses a broad etiological approach to the problem. Success of preventive medicine and infection control have resulted in an increase in the share of older persons in the Indian population. A wide variation has been noticed in the prevalence of anemia across different study groups in the Indian population owing to the variations not only in the definition employed but also in the cultural practices, nutrition and socioeconomic structure. Further, the chapter presents established therapeutic options such as iron and erythropoiesis stimulating agents. It revisits the role of blood transfusions and associated complications in older persons and provides a brief overview of newer therapies under development.

Introduction

The world population has witnessed a remarkable increase in the share of the older people owing to the success of public health measures over the last few decades resulting in an increase in life expectancy. Declining rates of fertility have also contributed to the changing demographic structure of the world population. As per World Health Organization (WHO), the 900 million population of elderly (>60 years of age) in 2015 is projected to increase to 2 billion by the year 2050, accounting for 22% of the world's population and outnumbering those under 15 years of age.[1] Parallel to these global projections, the population of elderly in India by 2050 is expected to be around 300 million accounting for 20% of the total population against 8% in 2015.[2] This demographic transition is likely to bring unprecedented challenges of disease and disability associated with longevity. Falls, frailty, incontinence, dementia, and nutritional deficiency are few recognized *geriatric giants* that have been recognized in recent times.

In addition to the traditionally described *geriatric giants*, anemia has been increasingly recognized in older persons, and it often goes undiagnosed. The previously used term *'anemia of elderly' signified the acceptance of fall of hemoglobin to be a natural accompaniment of aging against the currently used term 'anemia in elderly'* which considers declining hemoglobin with age as a disease entity. This change in terminology and thought has been evidence based as anemia has been found to be independently associated with multiple adverse outcomes like loss of muscle power, increased risk of falls, cognitive decline and dementia. Culleton et al. in a longitudinal study conducted on patients more than 66 years of age observed that anemia was associated with increased risk of hospitalization, longer hospital stay as well as increased risk of death.[3]

The present chapter presents a review of literature to provide an etiological approach to diagnose anemia in elderly and offers a broad management plan for physicians involved in the care of older people.

Definition

The definition of anemia has been a subject of debate among geriatricians, and hemoglobin cut-offs to use have often been discussed. To address this issue WHO has launched a novel ambitious program to revise hemoglobin thresholds for different populations including the elderly.[4] Until then, in most epidemiologic studies on anemia in elderly, the original WHO cut-offs of hemoglobin less than 12 g/dL for women and 13 g/dL for men are being used.[5] However, in place of absolute hemoglobin cut-offs, it might be more relevant if the definition of anemia in elderly is based upon clinical outcomes. This is exemplified by the Cardiovascular Health Study (CHS) study wherein hemoglobin concentrations above 13.7 g/dL for men and 12.6 g/dL for women gave survival advantage against those with lower hemoglobin levels.[6]

Epidemiology

Anemia in elderly (AE) is common, relevant, and rapidly increasing owing to an aging population round the globe. The overall prevalence of anemia in elderly ranges from 10% to 24% around the globe and is likely to depend on the level of hemoglobin used to define it.[7] The prevalence of anemia is higher among older people who are hospitalized (40%) or those residing in nursing homes (47%). The prevalence of anemia rises rapidly with age, approaching nearly 50% in men older than 80 years.[8]

The prevalence of anemia in elderly in India varies from 17.7% to 89%.[9] The prevalence of anemia in elderly men and women residing in old age homes in India was 65.1% and 70.9%, respectively, with an overall prevalence of 68.7%.[10] In a community-based cross sectional study 92.1% of the elderly subjects were anemic in high-altitude regions[11] whereas anemia was documented in 38.2% elderly population of rural India.[12]

Characterization

NHANES III study performed a laboratory evaluation of over 5,000 community dwelling elderly subjects. They reported that about 10% of men and women above 65 years of age had anemia according to the WHO criteria and that with increasing age beyond 65 years there was substantial increase in prevalence of anemia.[13] According to NHANES III, anemia can be characterized on the basis of underlying etiology into the following subtypes:

- Nutritional deficiency anemia
- Anemia of chronic inflammation (ACI)
- Unexplained anemia of elderly (UAE)

It has been established that anemia in elderly should be evaluated promptly because even mild anemia is associated with adverse clinical outcomes and may often be the first visible pointer towards an occult or subclinical disease.

Etiology

The myriad of causes of anemia in elderly are mentioned in **Table 1**. More often than not, anemia in older individuals is the result of interplay of multiple factors.[24,25] However, the underlying causes may be classified into the following three groups on the basis of pathophysiology.

TABLE 1 Etiology of anemia in elderly

Nutritional	*Chronic inflammation*	*Unexplained/Undifferentiated*
• Poor intake • Malabsorption • Iron deficiency anemia • Deficiency of vitamins such as B12 or folate • Deficiency of trace elements such as copper	• Rheumatic disorders • Chronic infections such as tuberculosis, osteomyelitis • Geriatric syndromes such as frailty • Inflammaging • Neoplasms	An important category of anemia in older persons that remains unexplained after evaluation. Most of the unexplained anemia can be classified into one or the other defined causes after appropriate follow-up. Neoplasms and hematological malignancies are important among them

This table presents the common etiologies of anemia in elderly. However, it is not a comprehensive list of causes and does not discuss some of the important causes that should be considered in detailed evaluation including blood loss (often in stools), drugs, and endocrine causes.

Nutritional Deficiency Anemia

The leading cause of nutritional deficiency anemia is iron deficiency anemia (IDA). In the older individuals, iron deficiency is common due to occult blood loss from the gastrointestinal tract, which in turn may be chronic or acute as per the underlying etiology. It may be the result of nonsteroidal anti-inflammatory drugs (NSAIDs) use, a gastric ulcer, colon cancer, diverticulosis, or angiodysplasia. Killip et al. noted that gastrointestinal malignancy was present in 6% of patients with iron-deficiency anemia.[14] Malnutrition is also responsible for IDA in elderly. Thus, iron replacement therapy should always be accompanied by a thorough gastrointestinal diagnostic workup in the elderly.

Folate deficiency may be present due to malnutrition as frequently seen in chronic alcoholics or can be secondary to medications like methotrexate or phenytoin. Pernicious anemia is another albeit a rare one. Malabsorption syndrome caused by *Helicobacter pylori* infections, anti-acidity drugs, or atrophic gastritis can also lead to cobalamin deficiency. Laboratory screening for Vitamin B12 and folate followed by prompt supplementation can correct both anemia and neurological manifestations associated with deficiency.

Anemia of Chronic Inflammation (ACI)

ACI, also known as anemia of chronic diseases, is the most prevalent anemia in older patients. It is a normocytic normochromic anemia found secondary to infections, which lead to activation of immune system, autoimmune disorders, various malignancies, chronic kidney disease, or to isolated age-associated inflammation. Underlying pathophysiological mechanisms in ACI are manifold and are overlapping **(Fig. 1)**.

Franceschi et al. in year 2000 introduced the term "*inflammaging*," a low-grade, chronic inflammatory state associated with ageing and having potential for tissue damage and degeneration. Inflammaging has been reported as a putative mechanism for some of the age-associated disorders like unintentional weight loss, frailty, anemia, and asthenia.[15]

Unknown/Undifferentiated Anemia of Elderly (UAE)

Anemia, which cannot be classified into a specific etiology and is considered a diagnosis of exclusion, which is

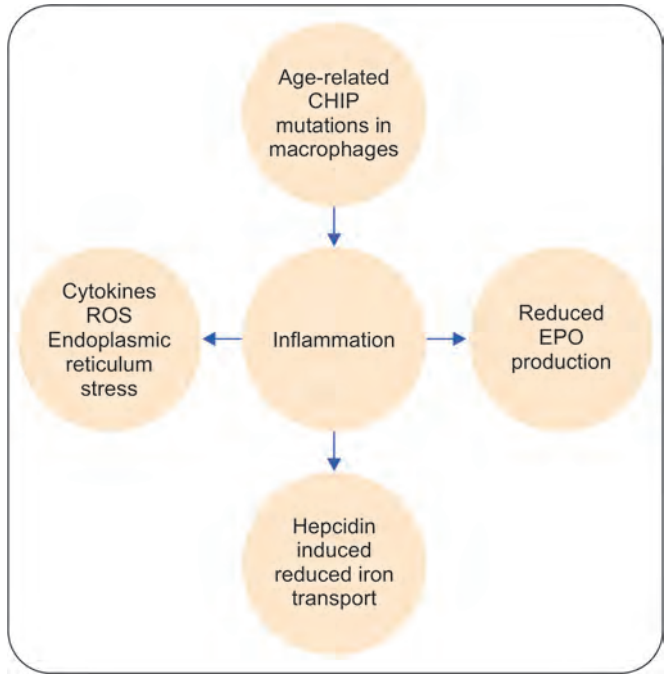

Fig. 1: Potential mechanisms for anemia of chronic inflammation
CHIP, clonal hematopoiesis of indeterminate potential; EPO, erythropoietin; ROS, reactive oxygen species

termed *unknown anemia*, *undifferentiated anemia,* or *anemia of unknown etiology*. This entity accounts for almost one third of all cases of anemia and is compounded by the fact that anemia in geriatric age group is often a result of multiple comorbidities. The various causes which underlie UAE are age-related renal insufficiency, decreased levels of testosterone, vitamin D insufficiency or deficiency, occult deficiency of iron, stem cell aging, and myelodysplasia (MDS).[16] The diagnosis of UAE is largely a diagnosis of exclusion and is complicated as the classical cut-offs of laboratory parameters like mean corpuscular volume (MCV) and ferritin used in younger individuals do not perform well in elderly. However, hypoproliferative anemia, that is, one with a low-reticulocyte index coupled with inadequate erythropoietin level for the degree of anemia should raise the probability of UAE after excluding other common causes.

MDS is more common in older adults, and more than 75% of patients with MDS are older than 60 years of age at diagnosis. Patients are either asymptomatic or have fatigue, pallor, frequent infections, easy bruisability, and petechiae. More often the disease is detected during routine blood tests due to presence of one or more

peripheral blood cytopenias. An estimated 30% of MDS progress to acute leukemia.

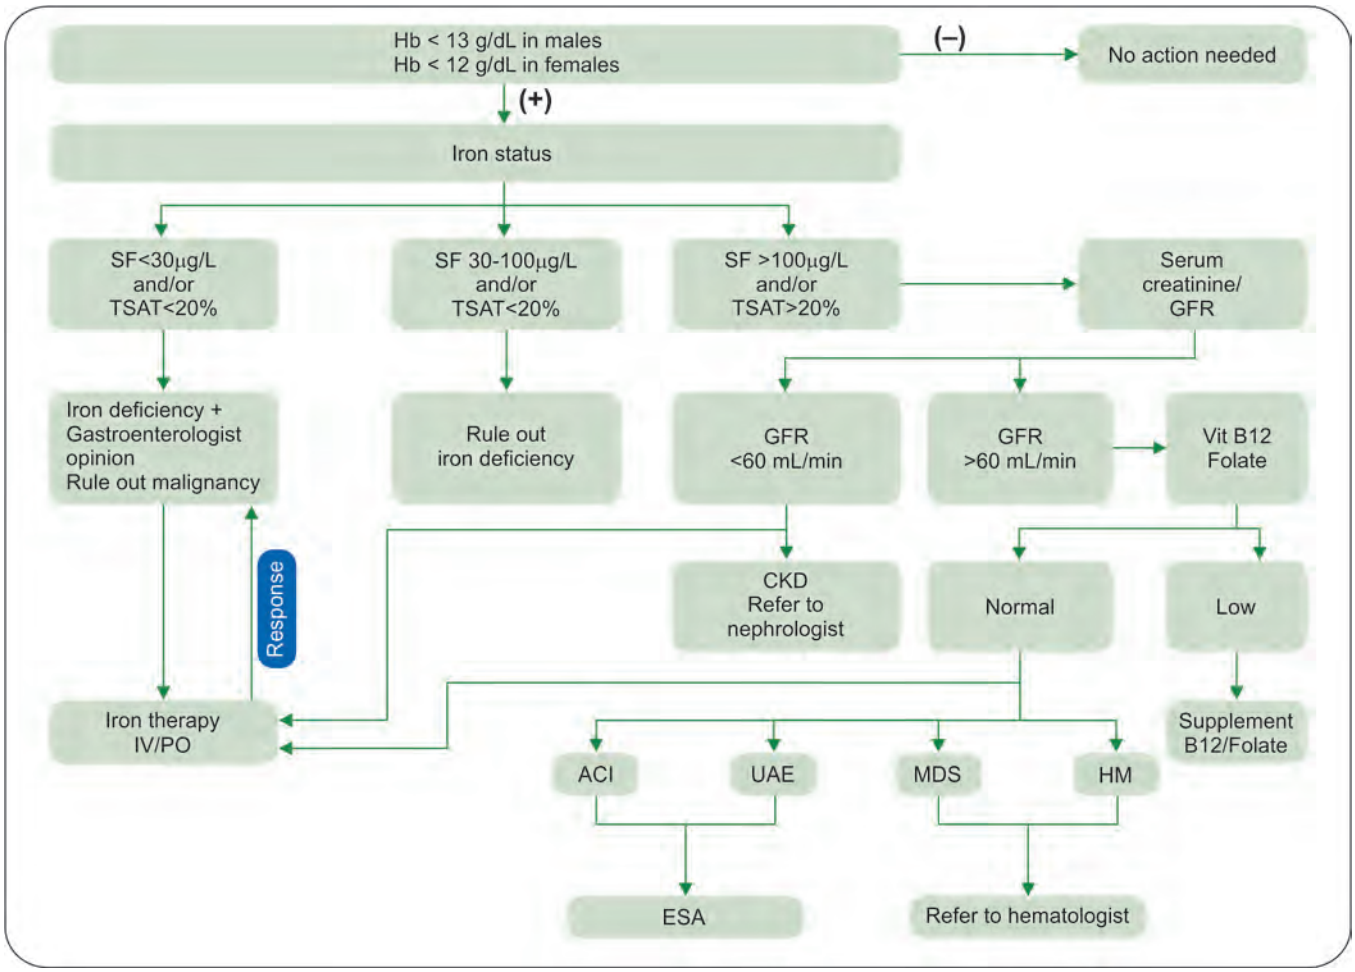
The management of UAE is a continuous process often requiring regular interactions between the patient and the physician, since in the absence of an etiology there is no definite treatment.

Diagnostic Evaluation

The initial evaluation of AE should include laboratory parameters like hemoglobin, total and differential blood count, red blood cell indices, reticulocyte count, reticulocyte hemoglobin, serum iron studies, C-reactive protein, fibrinogen, vitamin B12, serum folate, lactate dehydrogenase, haptoglobin, liver enzymes, kidney function tests, erythropoietin level, and serum electrophoresis. This basic workup is helpful in identifying nutritional deficiency anemia, ACI, and CKD **(Flowchart 1)**.

Due to higher possibility of underlying malignancies additional radiological investigations like ultrasound of the abdomen and kidney and gastrointestinal endoscopic procedures may be warranted as guided by clinical evaluation. The presence of anomalous blood counts or signs of clonal hematologic disease coupled with increased frequency of MDS in elderly may require performance of invasive procedures like bone marrow aspiration and biopsy. The invasiveness of such procedures makes it obligatory to weigh the benefits of establishing a diagnosis

Flowchart 1: Initial evaluation and treatment of AE



SF: serum ferritin; TSAT: transferrin saturation; GFR: glomerular filtration rate; CKD: chronic kidney disease; ACI: anemia of chronic inflammation; UAE: unexplained anemia of elderly; MDS: myelodysplastic syndromes; HM: hematological malignancy; ESA: erythropoiesis stimulating agent

followed by therapeutic intervention against its impact on life expectancy and functional improvement in the elderly. More specialized investigations like flow cytometry and cytogenetics may be required depending upon the findings of bone marrow aspiration and/or biopsy.

Treatment Options

Treatment plans need to be tailored according to the primary diagnosis and accompanying diseases. Anemia in the elderly is often complex and multifactorial necessitating more than one strategy for diagnosis and treatment. As no therapy is without the potential for adverse effects; therefore, it is important to introduce optimal age adjusted therapy, which can positively impact the quality of life of geriatric age group of patients.

Iron Therapy

Deficiency of iron either absolute as in IDA; or functional as in ACI is very commonly present as a factor in anemia in elderly and is complex due to multiple factors contributing to anemia in older individuals. Therefore, iron substitution is still the most recommended symptomatic treatment in IDA and ACI[17] as well as in iron-deficient UAE.[18]

Oral iron substitution is the cornerstone of treatment of anemia across all age groups. However, their use in geriatric patients may be relatively limited due to poor absorption of oral iron.[19] The quest for an oral iron substitute with good efficacy and reliable absorption was over with the FDA approval of ferric maltol for treatment of IDA in adults in 2019. The safety and efficacy of ferric maltol was established by three placebo-controlled trials [AEGIS 1 and 2 (IBD), AEGIS 3 (nondialysis CKD)], and led to its approval by FDA. Oral ferric maltol was found to be effective in raising hemoglobin without significant gastrointestinal side effects in patients with IBD.[20] Thus, ferric maltol is an efficacious and safe alternative to intravenous iron for patients, especially geriatric patients who cannot tolerate salt-based oral iron therapies and wish to avoid parenteral treatment.

As much as oral iron substitution is the gold standard for patients with absolute iron deficiency, it is ineffective for functional iron deficiency as seen in anemia associated with chronic inflammation and inflammation-associated increase of hepcidin. Also in situations with ongoing blood loss, oral iron is insufficient. In such cases intravenous iron substitution is recommended.[17] Complete or near-complete replacement of iron in a single setting using intravenous iron preparations is now the norm. Bygone are the fears of anaphylactic reactions with high molecular weight dextran preparations. The new and safer formulations like ferric carboxymaltose and iron isomaltoside are well tolerated though they too may rarely lead to severe hypophosphatemia with subsequent osteomalacia and bone fractures.[21] These bone mineral metabolic disorders are associated with recurrent and high doses needed in patients with severe IDA. This can be occasionally of concern in geriatric patients.

Erythropoiesis Stimulating Agents (ESAs)

ESAs are so far registered for the treatment of anemia in CKD and in patients with low risk MDS as per recommendations of the American Society of Hematology/American Society of Clinical Oncology Clinical Practice guideline update.[22] Data on efficacy of ESAs in other types of anemia are limited. The effect of epoietin alfa on hemoglobin and quality of life was studied in community dwelling older individuals aged 65 years or more. Erythropoietin was found to be safe and beneficial in chronic anemia.[23] However, there is lack of clear evidence to support the use of ESA in undifferentiated anemia of elderly.

It is important to recognize the potential of ESAs to cause increased risks of death and thromboembolic events and these should be considered while prescribing these drugs.

Blood Transfusion

Blood transfusion is the mainstay of treatment of severe and symptomatic anemia across all age groups including that in elderly patients. No specific cut-off level of hemoglobin is available to guide blood transfusions in geriatric patients. However, these patients should be transfused after due consideration to comorbidities, especially cardiovascular disease. The number and frequency of transfusions should be tailored according to clinical condition. The level of hemoglobin to be achieved in the elderly with chronic anemia following transfusion is also not well defined. Overall, liberal transfusion practices are not advocated and patient outcomes with restrictive transfusions maintaining hemoglobin levels closer to 10 g/dL were similar to those targeting higher hemoglobin levels. In general, transfusions in elderly should be slower and on a unit to unit basis after close monitoring of clinical condition.

Therapeutics on the Horizon

New drugs are currently being developed mainly for anemia in chronic kidney disease and anemia in cancer patients, but may serve as future therapeutic agents for a well-defined group of elderly patients with anemia. The major groups of these investigational drugs are:

- Hepcidin inhibitors
- Hypoxia inducible factor (HIF)—prolyl hydroxylase inhibitors
- Activin type II receptor agonists

These drugs are awaiting approval for dearth of sufficient clinical data.

Conclusion

Anemia in elderly is a significant health issue. The etiology of anemia despite extensive workup may still be elusive in a substantial number of older persons. Several pathophysiological mechanisms, which decrease erythropoiesis are under study and a better understanding of these should provide critical entry points for intervention, which can improve survival and quality of life older people. Patient-specific management strategies for anemia in elderly must be employed after thorough evaluation for the underlying cause.

CHAPTER

221 Comprehensive Approach in Providing Geriatric Care in India

OP Sharma, AP Ambali

Abstract

The population of elderly (>60 years) is steadily rising in India, and health-care system is not yet ready to provide comprehensive geriatric health care. The more important issue is the elderly shall be living 17 added years after retirement age. The health and social issues in elderly people are challenging issues for the treating clinician. The presence of communicable disease, non-communicable diseases and their complications, degenerative diseases, and disabilities in elderly make them special group and requires multidisciplinary team to provide the comprehensive assessment and care. The role of preventive geriatrics like immunization, falls prevention should be emphasized before there is outbreak of health catastrophe in this segment of population.

The year 2021 will witness rise in number of medical colleges opting to start MD in Geriatric Medicine. As evident in any specialty, there is bound to be shortage in trained manpower. Hence, there is need to sensitize existing undergraduate and postgraduate students regarding geriatric medicine. The National Medical Council has already included geriatric medicine in undergraduate curriculum.

The majority of elderly are living in rural areas and seek health services from primary health centers. There is also need to sensitize medical officers of primary health centers regarding geriatric care. The National Program for Health Care of Elderly (NPHCE) is conducting training program for medical officers in few districts which needs to be across our country.

The clinician must restrain Ageism in all possible ways. We need to develop care system that meets the needs of elderly of India and not to copy western style. This chapter has reviewed the issues and possible solutions in providing comprehensive geriatric care.

Introduction

Ageing is progressive, generalized impairment of function resulting in loss of adaptive response to stress and in increasing risk of age-related diseases.[1]

The elderly constitutes the fastest growing age segment all over the world. Providing healthcare for the older people (>60 years) is a biggest challenge, the medical fraternity is facing today all over the world. The older people are blended with multiple diseases and are also associated with psychological, financial, and social issues. The approach toward healthcare in this set of population is holistic and multidisciplinary with a strong team coordination.

The majority of the older people reside in rural India. Hence, the healthcare services should concentrate more for older people residing in rural area. Now the scenario of family physician is slowly vanishing and there are specialist and super specialist to treat diseases of each organ in the body. This comes with riders for older people as this leads to multiple consultations and polypharmacy, which again need to be corrected by a geriatric physician or family physician.

The 542 medical colleges in India can become a role model for providing low cost, and quality healthcare for older people by initiating geriatric clinic in each college hospital.

The National Program of Health Care Elderly (NPHCE) has been launched in 100 district hospitals by Government of India from the year 2010-2011 with huge budgetary allocation.

Though the medical council of India had made it mandatory for all medical colleges to have geriatric clinic in their teaching hospital, unfortunately it has not been followed, citing shortage of doctors qualified in geriatric medicine.

The availability of palliative care, physiotherapy, and rehabilitation units should be ensured in all medical college hospitals, which will help provide comprehensive healthcare for older people of all walks of life.

Aging Situation and Projections around the World and in India

The elderly (>60 years) population in the world has been rising rapidly and the longevity is due to many factors, which include increasing health awareness and developments in medical field. In the year 1980, elderly population was 382 million, which by the year 2017 became 962 million and it is expected to be 2.1 billion by the year 2050. The 320 million people aged 60 years or over in upper-middle-income countries in 2015 represented a 64% increase over 2000 when older persons in those countries numbered 195 million. Between 2015 and 2030, upper middle-income countries are anticipated to continue to experience rapid growth in the number of older persons: the projected 545 million people aged 60 years or over in 2030 marks a 70% increase over the number in 2015[2] **(Fig. 1)**.

The age division of Indian population (0–14) is 30.8%, (15–59) is 60.3%, (60+) is 8.6%. According to Population Census 2011, there are nearly 104 million elderly persons in India. It has increased from 5.5% in 1951 to 8.6% in 2011 and projected a rise up to 19% in 2050.[3]

As regards rural and urban areas, 71% of elderly population resides in rural areas while 29% of elderly population resides in urban area. Among the challenges which India faces, UNFPA report says the feminization of ageing remained a key one.[4]

At age 60, average remaining length of life was found to be about 18 years (16.7 for males and 18.9 for females) and that at age 70 was less than 12 years (10.9 for males and 12.4 for females). About 65% of the aged had to depend on others for their day-to-day maintenance. Less than 20% of elderly women and majority of elderly men were economically independent.[4]

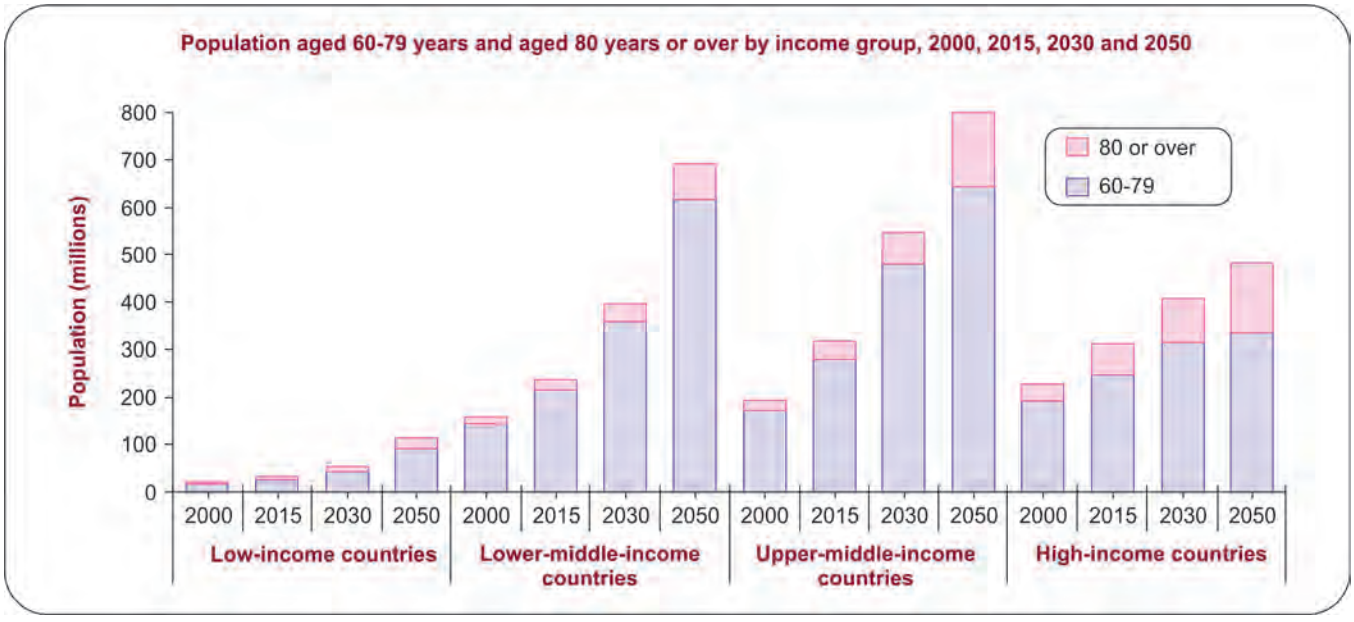

Fig. 1: United Nations (2015). World Population Prospects. The 2015 Revision

In rural areas 55% of the aged with sickness and 77% of those without sickness felt that they were in a good or fair condition of health. In urban areas the respective proportions were 63% and 78%.

The population of 80-plus people is on rise "with a predominance of widowed and highly dependent very old women" and so the special needs of such old women would need significant focus of policy and programs.[5]

Comprehensive Approach

The older people in India are diverse spread over 28 states. Their cultural background, economic status, lifestyle, behavior, nutrition, beliefs, family status, and disease pattern differ, hence 'there is no one solution to all the problems' for the older people in India.

The broad measures that can contribute toward comprehensive care to the older people are discussed here. Let us look at the health, financial, and social issues of the older people in India.

Health

The factors related to health of older people are:

- Multiple disabilities like blindness, locomotor disabilities, and deafness are most prevalent
- Multiple comorbidities, polypharmacy, and iatrogenic diseases
- Mental illness arising from senility and neurosis
- Complications of the chronic non-communicable disease
- Communicable diseases
- Absence of geriatric care facilities at hospitals in rural area.

Financial[4]

- Retirement and dependence of elderly on their children for basic necessity
- Sudden increase in out of pocket expenses on treatment.

Social[4]

The common social issues that are detrimental for the health status of the older people are:

- Elder Abuse and Neglect by the family members toward their old parents
- Disillusionment due to retirement
- Feeling of powerlessness, loneliness, uselessness and isolation, and widowhood

The geriatric care involves taking care of all the four aspects of the health, that is, physical, mental, social, and spiritual wellbeing. The challenge is during post discharge, as our social network and home services are still in nascent stage.

Apart from these four aspects, the care should continue to ensure quality of life, end of life care, and dignified death.

The most important issue in providing geriatric care is to prevent a disability. Because the older people fear disability more than death, it hampers the quality of life and makes them more dependent on family members. All these factors contribute of mental illness and social isolation. So, the main goal in providing the comprehensive care is to prevent a disability!

Services Available in Geriatric Care in India

The various medical colleges and district hospitals in India listed here are having geriatric care wards in their respective hospital. This has added special wards for senior citizens. The colleges are:

- Government Medical College, Chennai
- AIIMS, Delhi
- AIMS, Cochin
- CMC, Vellore
- St John's Health Sciences, Bengaluru
- KMC, Mangalore
- MGM, Navi Mumbai
- Yenepoya University, Mangalore
- JSS Medical College Mysuru
- Shri B M Patil Medical College Hospital, Vijayapura

Apart from inpatient services, the outpatient care for senior citizen is provided through Geriatric Clinics at:

- M S Ramaiah Medical College, Bengaluru
- Apollo Hospital, New Delhi
- Bangalore Medical College, Bengaluru
- BLDE DU, Shri B M Patil Medical College Hospital and RC, Vijayapura
- AIIMS, Bhubaneshwar
- JSS Medical College, Mysuru
- Deccan Medical College, Hyderabad
- KLEU Prabhakar Kore Hospital, Belagavi
- Bharati Vidyapeeth Medical College, Pune

- GMCH, Miraj
- BJGMC, Pune
- Osmania Medical College, Hyderabad
- SVS Medical College, Mahabubnagar, Telangana
- St John's Health Sciences, Bengaluru
- Baptist Hospital, Bengaluru
- Manipal Hospital, Bengaluru
- Yenapoya Medical College, Mangalore.
- S N Medical College, Bagalkot, Karnataka
- J J Hospital, Mumbai
- MGM, Aurangabad
- SMS Medical College, Jaipur
- AFMC, Pune
- Geriatric Psychiatry, NIMHANS, Bengaluru
- Jubilee Mission Medical College and Research Institute, Thrissur
- JLNM Hospital, Srinagar
- District Hospital, Lakhimpur Kheri, UP
- Kasturba Medical College, Mangalore

Doctors who are trained in geriatric care and are not attached to medical college are also contributing in health care for senior citizens through private clinics. The important aspect of these services is that these clinics are in rural areas. To mention a few clinics:

- Dr. P. R. Patgiri Elderly Care Clinic, Guwahati
- Dr Pathak Geriatric Clinic, Gokak, Karnataka
- Anand Hospital, Vijayapura
- Masters Medical and Geriatric Centre, Thirssur, Kerala
- Gericare, Chennai
- Neo Geriatric Care Hospital, Haridwar

The academic contribution is also picking up slowly. There is creation of consultants in geriatric medicine through Diploma/MD Geriatrics courses and DM in Geriatric Psychiatry in following colleges. A total of 45 consultants and 400 diploma degree holders pass out through these colleges or University every year and are available for geriatric care.[6]

- Madras Medical College, Chennai
- AIIMS, Delhi
- Christian Medical College, Vellore
- Mahatma Gandhi Missions Medical College, Kamothe, Navi Mumbai
- Amrita School of Medicine, Ponekkara, Kochi
- Government Medical College, Aurangabad, Maharashtra
- Netaji Subash Chandra Bose Medical College, Jabalpur
- DM - Geriatric Psychiatry – NIMHANS, Bengaluru
- Institute of Medical Sciences, BHU, Varanasi
- All India Institute of Medical Sciences, Rishikesh, Uttarakhand
- Indira Gandhi National Open University

The *Indira Gandhi National Open University (IGNOU)* is providing postgraduate diploma courses in geriatric medicine all over India for MBBS and above degree holders. The duration of the course is 1 year. The exam conducted is at par of MD degree standards. It is recognized by Government of India. The IGNOU has been creating 400 qualified geriatricians every year in India for last 15 years.[7] The need of the hour is to give due recognition for this huge cadre of geriatricians and utilize their services in primary health care centers across India with handsome salary.

Diseases Pattern among Elderly in India

The main presenting symptoms in one hundred older people presenting to geriatric clinic when analyzed by Ambali et al,[8] it was found that the 30% of elderly presented with breathlessness as the main symptom, followed by pain abdomen (17%), fever, and loose stools (10%) each, chest pain and giddiness (4%) each. The other symptoms were seizures, hemiparesis, cough, joint pain, headache, and lack of sleep.

The common comorbid conditions either in single or multiple were noted in all the patients. The commonest comorbid was hypertension in 21%, followed by chronic obstructive pulmonary disease (17%), anemia (12%), coronary artery disease (10%), diabetes mellitus (9%), epilepsy (11%), frailty (1%), obesity (1%), benign prostatic hypertrophy, fractured spine, hypothyroidism (5%), and human immunodeficiency virus infection (1%).[8]

In a study by Eram,[9] the most common complaints in elderly were generalized bodyache (53%), diminished vision due to refractive error (60%), joint pain (30%), chronic cough (25%), Asthma and impaired hearing (21%), Gastrointestinal upset symptoms (11%), and urinary symptoms (10%).

The common comorbidities were hypertension in 22%, diabetes in 8%, dental problems in 27%, and cardiac illness in 5%.[9]

The mental health issues like depression, loneliness, and attempted suicide are also on rise in Indian elderly and need to be addressed. The prevalence of depression in older people with chronic disease was highest among the

stroke patients (56.5%), coronary artery disease (47.8%), chronic obstructive airway disease (39.1%), diabetes mellitus (34.7%), and hypertension (26.1%).[10]

The older people attempting suicide too is matter of concern. In a study by Ambali et al.,[11] organophosphorus compounds were commonly used by 70% of participants to end their life and factors like depression and abuse were common precipitating factors to attempt suicide. These need to be addressed are primary care level as well as tertiary care.

The Government of India has passed stringent law to curtail elder abuse. The act "Maintenance and Welfare of Parents and Senior Citizens Act, 2007" has been passed and is been implemented in few districts of India.[12]

Approach

From healthcare point of view this group can be divided in three subgroups. Young old (60–74 years), who are independent and gainfully employed. Their Medical and Health needs are like young people and they may be looked after by physicians/geriatricians. Old old (75–84 years) need more of assistance and nursing care rather than medical help. Very old (>85 years) and above are mostly dependent requiring domiciliary Care or Hospital Care.

All the above three categories may be managed by a good general practitioner with an extra briefing on ageing, the clinical differences between adults and elderly, Geriatric syndromes, geriopharmacy and drug interaction, physiotherapy, diet, preventive aspects, and social issues like elder abuse needs to be carried out. **Figure 2** describes that the briefing can be by short courses, telemedicine, bulletins and Mass Mailing Service in regional languages. Help centers established in five areas of the country managed by Central Government/State Government/ NGOs/Pharma industry.

For the Population who is Approaching 60 Years

Regarding second category, that is, the people who are approaching old age; one can attempt to herald the process of ageing and prevent the diseases by:

- Lifestyle changes, which include a healthy lifestyle comprising of nutritious food, restrictions of calories to maintain proper body weight, regular exercises, adequate sleep, avoidance of alcohol, tobacco and other narcotics, and positive thinking.

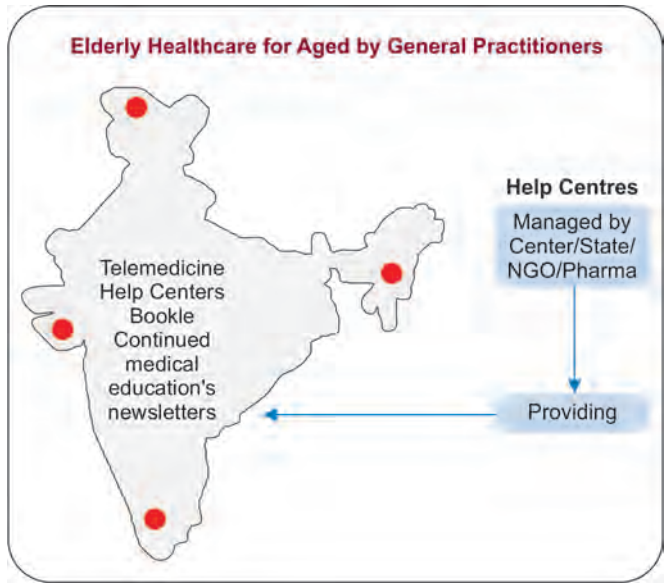

Fig. 2: Planning for the aged

- Appropriate management of comorbidities like diabetes, hypertension, etc.
- Prevention of diseases and risk factors by medicines (lipid lowering, antiplatelet drugs, etc.) and vaccinations.

For those who are getting aged, the planning may be done by adding geriatrics in the medical curriculum as shown in **Figure 3**. We may sensitize budding doctors about special aspects of geriatrics in their teaching and training.

General Measures

- Ageing will continue and number of elderly populations will rise. Number of comorbidities will also rise, due to changes in lifestyle. Accidents and falls will also increase. Due to change in social setups and migrations, the family support will dip and the cost of living as well as treatment will continue to rise.
- We have to have improvements in nutrition by making diet a balanced one, improving cooking, minimizing the effects of insecticides and pesticides, check the adulteration and improve the process of storage. Use of local foods should be encouraged.
- Housing for elderly need provisions for sunlight, adequate ventilation, water, sewage, and non-skid flooring.
- The transport system should be elderly friendly.

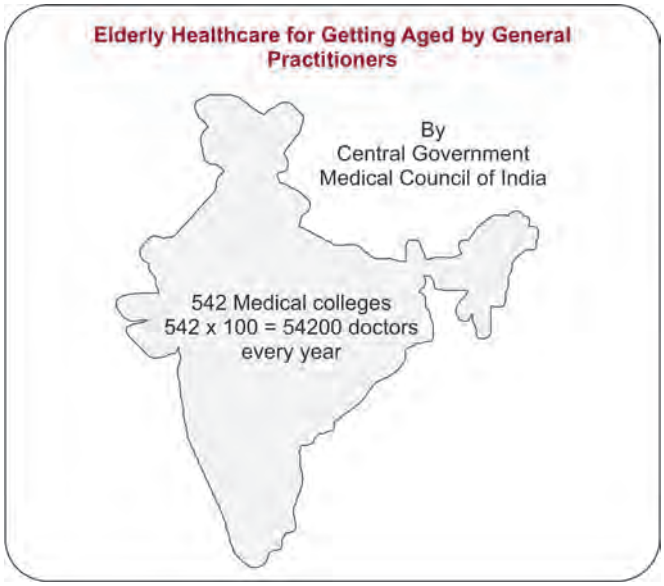

Fig. 3: Planning for the health care of getting aged

- People should be educated about the Misuse of over the counter drugs like analgesics, painkillers, and antibiotics. The polypharmacy should be minimized/avoided in elderly as it causes increased incidents of drug interactions.
- The use of vaccines like Hepatitis B, Influenza, Pneumococcal, T-dap, and Zoster, which are advised in elderly, should be encouraged.[13]
- Reach the unreached—healthcare services should reach the older people in villages with special attention to those who are bed-ridden, and differently abled.
- Yearly they should undergo consultation with ENT, ophthalmology, and dental surgeon.

National Program for Healthcare of Elderly

The NPHCE provides free, specialized healthcare facilities exclusively for the elderly people through the state health delivery system. It also provides training services in geriatric care to the medical officer of primary health centers.

The main objectives of NPHCE[14] are to provide comprehensive healthcare to the elderly by preventive, curative, and rehabilitative services and build capacity of the medical and paramedical professionals as well as the care-takers within the family for providing healthcare to the elderly.

Role of Caregiver and Training

The caregivers in our country are either a family member or relative or member of society without formal training. It is now recognized as very important service.

There is need to train the nurses in geriatric care. In fact, the trained nurses in geriatric care are in huge demand in urban areas.

The family members can be trained to a specific disease pattern like care of person with dementia, stroke, or person who is bed ridden. The larger aspects are rendered by nurse. The main goal is to assist in activities of daily living.

The caregiver should uphold the dignity of the elderly receiving the care.

Conclusion

The western countries became rich first and then their population grayed, while in India, its population is graying fast while we are yet to be a rich country.

We are still not prepared to face the so-called tsunami of older population and related problems. We need to provide services to the elderly who are above 80 years, bed ridden, and living with disabilities, dementia, and Parkinson's disease.

The Government of India has priority for health issues related to infants, pregnant mothers, immunization in children, communicable diseases like tuberculosis to mention a few. The projects for older people are in process of implementation through regional research center across India.

The various programs for the benefit of older people have been launched a decade ago, but yet to reach the rural elderly population.

The new curriculum has included geriatric medicine in MBBS course. The postgraduate students in clinical subjects must undergo short course training in geriatric care.

The overall care should be promotive, protective, and preventive so that, active ageing is achieved.

The caregiver plays a vital role in providing care.

A holistic approach is need of the hour in providing comprehensive care for the elderly in India.

CHAPTER

222 Severe Acute Respiratory Infections in Elderly

YS Raju, Y Rahul, Y Sairam

Abstract

Estimates suggest that elderly (above 60 years of age) globally will increase from 12.5% in 2015 to 16.5% in 2030, suggesting need for greater emphasis on health care for elderly population globally. Lower respiratory tract infections (LRTIs) are the most common causes of death among infectious diseases in adults and are among the top ten causes of death in the elderly (aged more than 60 years). Severe acute respiratory infections (SARIs) by definition include a respiratory tract infection with history of fever more than or equal to 38°C and cough; with its onset within 10 days and requiring hospitalization. As the global burden of elderly population is estimated to increase, and older age is an important risk factor associated with increased mortality, there is a need for greater emphasis on health care for elderly population globally. In patients with influenza associated SARI, cough was the most common symptom and the low pulse oximetry (less than 90% on room air) was the most common sign. In elderly, getting admitted with COVID-19 most common symptom was fever followed by cough, fatigue, shortness of breath, and headache. In elderly patients presenting with SARI, empirical antimicrobial treatment should initiated awaiting culture and sensitivity reports; if there is respiratory distress, supplemental oxygen therapy should be initiated immediately. Recognition of severe hypoxemic respiratory failure even with supplementary oxygen mandates institution of ventilatory support. In case of non-invasive ventilation (NIV) failure or in patients with contraindications for NIV, endotracheal intubation and mechanical ventilation should be initiated. In the current situation of COVID-19 pandemic, with no available specific antimicrobial drugs for the treatment, universal hand hygiene precautions, avoiding touching mouth, eyes, and nose, maintaining social distancing likewise preventive measures are the need of the hour.

Introduction

Even after a century following Spanish flu pandemic, with the recent pandemic of coronavirus disease (COVID-19), respiratory tract infections continued to be one of the leading causes of morbidity and mortality among all diseases globally. Lower respiratory tract infections are the most common causes of death among infectious diseases accounting for 3 million deaths in 2016.[1] Severe acute respiratory infections (SARIs) by definition include a respiratory tract infection with history of fever more than or equal to 38°C and cough; with its onset within 10 days and requiring hospitalization.[2] Despite recent advances in the development of antiviral drugs and vaccines, seasonal epidemics of influenza contribute to significantly to workload for practioners, emergency hospital admissions, and deaths as with the case of recent COVID-19 pandemic. Elderly (age ≥60 years)[3] population compared to the young, suffer with several chronic illnesses, and comorbid conditions. In addition to that immune decline with aging makes them more vulnerable to infectious diseases.

Epidemiology

The pace of global population is accelerating and projections indicate that people above 60 years globally will increase from 12.5% in 2015 to 16.5% in 2030 compared to 2.3% increase from 2000 to 2015. By 2030, people above

60 years are expected to account for 25% in Europe and North America, 20% in Oceanica, 17% in Asia, Latin America, and the Caribbean, and 6% in Africa.[4] These projections indicate need for greater emphasis on health care for elderly population globally. Lower respiratory tract infections are among the top ten causes of death in both men and women aged more than 60 years.[4] In a study conducted in United States over 12 years from 1997 to 2009, an annual average of 19,100 deaths were attributed to influenza and 11,300 deaths to respiratory syncytial virus (RSV) taking in to consideration of respiratory broad definition of any respiratory illness with symptoms of cough, breathlessness, and fever, with mortality rates of 6.61 (standard deviation: 2.66) and 3.91 (standard deviation: 0.65) per 1,00,000 population annually for influenza and RSV, respectively. When cardiorespiratory outcome for influenza death was considered, 9%, 14%, and 73% were found in the age groups of 50–64, 65–74, and 75 or more, respectively, indicating increased percentage of deaths associated with respiratory illness as the age advances.[5] India, having the history of highest mortality with nearly 18 million deaths during the second wave of Spanish flu pandemic in 1918, has higher incidence of under five mortality compared to elderly being affected as in high-income countries.[6,7] In the 2009 H_1N_1 pandemic, in a study from 2009 to 2017, revealed most commonly affected age group was 46–60 years accounting for 29.7% of total cases.[8] With the recent COVID-19 pandemic, its strain variability, mutation rate, genetic selection during its interaction with the host population, and transmission across the nations creates a challenging scenario in both diagnosis and management.[9]

Etiology

Etiology of SARI varies with seasonality, region being affected and active infection with virulent organism associated. In a study conducted in Georgia from 2015 to 2017, Influenza was the most common etiology followed by RSV, Coronavirus, and Rhinovirus for SARI in people more than or equal to 65 years.[10] In a study from Lisbon which was conducted on respiratory infections in elderly in 2013–2014, Rhinovirus was the most common etiology followed by influenza and human bocavirus.[11] Viral and bacterial agents can occur as concurrent etiology with viral infections such as RSV, influenza, and rhinovirus along with bacterial causes like *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Klebsiella* species. RSV was the most common viral etiology and *S. pneumoniae* was the common bacterial etiology in those with concurrent etiology **(Table 1)**.[12] In India apart from influenza virus and RSV, human coronavirus was found to be an important cause of SARI in southwestern part, in a study conducted in 2011–2012.[13]

Parainfluenza virus
Bacterial etiology
Streptococcus pneumoniae
Haemophilus influenzae type b
Klebsiella species
Staphylococcus aureus
Escherichia coli

Risk Factors

Risk factors associated with increased mortality were age more than or equal to 65 years, comorbid conditions, virulence of etiological agent, being bedridden, admission to critical care unit, low PaO_2/FiO_2 ratio (<250), low platelet count (<1,50,000/μL), and increased creatinine concentration (>1 mg/dL). Seasonal vaccination has been observed to significantly reduce need for hospitalization in vulnerable population; and lack of seasonal vaccination appear to be one of the important factors in increased morbidity and mortality patients with SARI.[14] In elderly affected with COVID-19, older age and decreased lymphocyte count at admission were found to be the most important factors associated with mortality along with others like presence of hypertension and previous respiratory problems.[15]

Clinical Features

In patients with influenza associated SARI, cough was the most common symptom and the low pulse oximetry (<90% on room air) was the most common sign.[14] In elderly, getting admitted with COVID-19 most common symptom was fever followed by cough, fatigue, shortness of breath, and headache.[16] Anorexia, weight loss, asthenia, and headache were observed in older age group. Running nose and intercostals recession were less common in elderly population.[12] Along with low pulse oximetry, other signs include tachypnea, tachycardia, and those of lobar and bronchopneumonia. Median incubation period was 6.7 days.[16]

Management

Laboratory Investigations

In adults with SARI, laboratory investigations revealed lymphopenia (<1000/μL), low platelet count (<1,50,000), hypoalbuminemia (<3.5 g/L), hyponatremaia (<135 mEq/L), increased plasma lactate dehydrogenase (>250 UI/L), increased blood urea nitrogen concentration (>20 mg/L), increased serum creatinine concentration (>1 mg/dL), and increased serum C-reactive protein (>100 mg/L, 10 times the upper normal value) were evident.[14]

In elderly with COVID-19, lymphocyte count, amino-terminal pro-brain natriuretic peptide, aspartate transaminase, alanine transaminase, cardiac troponin-I, C-reactive protein, D-dimer, and serum creatinine levels were significantly different in survivors compared to non-survivors.[15]

Treatment

Early Supportive Therapy and Monitoring

For the patients presenting with SARI and respiratory distress, supplemental oxygen therapy should be initiated immediately at 5 L/min to maintain percentage saturation of oxygen (SpO_2) ≥ 90%.[17] Conservative fluid management is indicated when there is no evidence of shock with caution to avoid fluid overload as aggressive fluid management may worsen oxygenation. Empirical antimicrobial treatment should be initiated for SARI patients with shock within 1 hour of presentation. Likely choice of empiric antimicrobial treatment is based on the clinical diagnosis, local epidemiology, and susceptibility data. In case of suspected influenza infection neuraminidase inhibitors are to be given based on the travel history or exposure to persons with active infection. Invasive pneumococcal disease following influenza infection is much more common in elderly.[18] Prophylactic broad spectrum antibacterial agents like third generation cephalosporins are considered in suspected cases of influenza to treat secondary bacterial infections, later can be changed according to culture and sensitivity reports.

Comorbid conditions must be appropriately managed along with tailoring the management plan of critical illness for better care of the patient. Signs of clinical deterioration such as rapidly progressive respiratory failure and sepsis must be carefully monitored and timely active interventional supportive therapies are to be considered, which forms the cornerstone of management.

Management of Hypoxemic Respiratory Failure and ARDS

Recognition of severe hypoxemic respiratory failure even with supplementary oxygen is essential in patients with SARI. Hypoxemic respiratory failure may lead to acute respiratory distress syndrome (ARDS) either from intrapulmonary ventilation-perfusion mismatch or shunt and usually requires mechanical ventilation.

Patients receiving a trial of noninvasive ventilation (NIV) should be carefully monitored and tracheal intubation is indicated in case the patient does not improve after a short trial or acutely deteriorates. Patients with altered mental status, hemodynamic instability, and multi-organ failure should not receive NIV.

In case of NIV failure or in patients with contra-indications for NIV, endotracheal intubation and mechanical ventilation should be initiated with airborne precautions. In patients with sepsis induced respiratory failure who do not meet ARDS criteria, implementation of mechanical ventilation with lower tidal volumes (4–8 mL/kg predicted body weight) and lower inspiratory pressures (plateau pressure <30 cm H_2O) was recommended.[17] In patients with moderate or severe ARDS, higher positive end expiratory pressure (PEEP) is suggested. PEEP has to be titrated considering the benefits like reducing atelectrauma and improving alveolar recruitment and the associated risks, such a, end-inspiratory overdistension leading to lung injury and higher pulmonary vascular resistance. Ventilation in prone position for a period of

more than 12 hours/day is recommended for patients in severe ARDS. Use of conservative fluid management strategy for patients with ARDS is to be considered without tissue hypoperfusion.[17]

Prevention of Complications

As the patients with SARI are getting treated in intensive care units (ICUs), with requirement of mechanical ventilation in some of them, it is of paramount important to prevent the predictable complications of prolonged ICU care.

Reduction of days of Mechanical Ventilator Support

Use of weaning protocols for readiness of spontaneous breathing trials daily have overall favorable outcome in patients on mechanical ventilator support. Weaning off from continuous to intermittent sedation and minimize the dose of sedation gradually till the point when sedation no longer required is mandatory for early weaning off from ventilator support in patients who have recovery from primary illness.

Reduction of Incidence of Ventilator-associated Pneumonia

Maintaining semi-recumbent position (head of bed elevation 30–45°), using closed suctioning system, periodically draining the condensate in tubing, changing ventilator circuit if it is soiled and changing heat moisture exchanger if it is soiled or once in 5–7 days aids in reducing the incidence of ventilator associated pneumonia.

Reduction of Incidence of Venous Thromboembolism

Pharmacological prophylaxis with low molecular weight heparin in patients without contraindications prevents deep venous thrombosis. Additional factors like intermittent pneumatic compression devices, compressive stockings, and early mobilization of patients prevent deep venous thrombosis.

Reduction of Incidence of Catheter-associated Blood Stream Infections

Using a checklist while inserting a catheter with sterile precautions, regular care of the catheter and daily assessing for the removal of the catheter if no longer needed helps in preventing catheter associated blood stream infections. Following a bundle care serves as a daily reminder for the care of the patients with central venous catheters.

Reduction of Incidence of Stress Ulcers, Gastrointestinal Bleeding, and Pressure Ulcers

Administering proton pump inhibitors or histamine-2 receptor blockers for patients at risk of gastrointestinal bleeding like mechanical ventilation, coagulopathy, renal replacement therapy, liver disease, multiple comorbidities prevents stress ulcers and gastrointestinal bleeding. In addition early initiation of enteral feeding avoids stress ulcers. Frequent change of position of the patient prevents pressure ulcers and their related complications.

Reduction of Incidence of ICU-related Weakness and Psychosis

Active limb physiotherapy and early mobilization of the patient prevent muscle weakness and atrophy in elderly patients. Allowing patients to interact with the family members while following sterile precautions helps in mood elevation and avoids ICU-related psychological problems.[17]

Prophylaxis

In the current situation of COVID-19 pandemic, with no available specific antimicrobial drugs for the treatment, universal hand hygiene precautions, avoiding touching mouth, eyes, and nose, maintaining safe distancing likewise preventive measures are the need of the hour.

In a study from United States over a period of six influenza seasons from 2010 to 2016, vaccination has prevented between 1.6 and 6.7 million illnesses, 39,000–87,000 hospitalizations and 3,000–10,000 deaths related to influenza each season, emphasizing the role of vaccination in influenza related illnesses.[19]

Concept of a universal influenza vaccine with features of being effective against symptomatic influenza virus infection, protective against group I and II influenza A viruses, having durable protection that lasts at least 1 year and through multiple seasons and being suitable for all age groups is yet a farfetched reality.[20]

Conclusion

A century later following Spanish flu, yet with another pandemic of respiratory illness in the form of COVID-19 still poses a greater challenge to humanity affecting both developed and underdeveloped nations alike. With expected increase in elderly population, in developing countries like India where tertiary health care and ICU care facilities are not widely available, preventive measures play a major role in the management of such pandemics. Even with effective preventive measures, the challenge to face such pandemics likely poses the question "Are we yet ready?"

Poisoning and Toxicology

CHAPTER

223 Management of Organophosphorus Poisoning

Bhupen Barman

Abstract

Poisoning both accidental and intentional is a single contributor to mortality and morbidity throughout the world. The commonest cause of poisoning in developing countries including India is pesticide, the reason being agriculture based economics and organophosphorus (OP) constitute the largest bulk of pesticides. Clinical manifestations result from inhibition of acetylcholinesterase and stimulation of muscarinic and nicotinic receptors and characterized by pinpoint pupil, excessive salivation and sweating, bronchospasm leading to respiratory distress, CNS, and neuromuscular dysfunction. After initial stabilization, atropine should be used in appropriate doses and ventilator support may be required for those who developed respiratory failure due to neuromuscular dysfunction.

Introduction

Poisoning both accidental and intentional is a single contributor to mortality and morbidity throughout the world. The most common cause of poisoning in developing countries including India is pesticide; the reason being agriculture based economics and organophosphorus (OP) constitute the largest bulk of pesticides. According to recent WHO data, it is estimated that deliberate ingestion of pesticides causes 370,000 deaths every year (https://www.who.int/ipcs/poisons/en/). However, these figures are probably an underestimate, especially in developing countries because of insufficient regulatory and surveillance systems, shortage of trained medical manpower, and ineffective utilization of existing facilities. India is a country with about 60–70% rural population, and agriculture is a major component of the economy. Every year, there are about 10,000 reported cases of pesticide poisoning in India with a mortality rate varies between 15% and 30% and is the fourth most common cause of mortality, especially in rural areas.[1] The National Poisons Information Center (NPIC) was established at All India Institute of Medical Sciences, New Delhi, in 1995 to provide toxicological information and advice on the management of poisoned patients across the country. A survey done by NPIC from 1999 to 2002 reported a total of 2,719 poisoning, of which agricultural pesticides represent 12.8% of total cases. On further analysis of the main data, it was found that OP poisoning represents 18.75% cases of all agricultural products.[2]

Pathophysiology

Organophosphorus compounds (OPCs) inhibit the function of acetylcholinesterase (AChE) by binding into the acyl pocket at the active site of AChE. The binding of a phosphate group to the serine amino acid at the active site of AChE changes the configuration of the enzyme molecule and make it dysfunctional. Normally the cholinesterase rapidly hydrolyzes the neurotransmitter acetylcholine into inactive fragments of choline and acetic acid. The neurotransmitter acetylcholine is present in the terminal endings of all postganglionic parasympathetic nerves, at myoneural junction, and at both parasympathetic and

TABLE 1 Clinical manifestations of organophosphorus (OP) poisoning

Muscarinic effects	*Nicotinic effects*	*CNS effects*
• Miosis • Blurred vision • Nausea • Vomiting • Diarrhea • Salivation • Lacrimation • Bradycardia • Abdominal pain • Diaphoresis • Wheezing • Urinary incontinence • Fecal incontinence	• Muscle fasciculations • Paralysis • Pallor • Muscle weakness • Hypertension • Tachycardia • Mydriasis (rare)	• Unconsciousness • Confusion • Toxic psychosis • Seizures • Fatigue • Respiratory depression • Dysarthria • Ataxia • Anxiety

sympathetic ganglia. The inhibition of cholinesterase leads to accumulation of acetylcholine at synapses, causing overstimulation and subsequent disruption of transmission in both central and peripheral nervous system.

Clinical Features

Patients with OP poisoning can become symptomatic within minutes depending on the route and degree of exposure. Most victims become symptomatic within 8 hours of exposure and virtually all within 24 hours. The clinical manifestations can be classified into: cholinergic crisis (muscarinic or nicotinic receptors) **(Table 1)**, CNS effects, and sequelae (Intermediate syndrome).

Intermediate Syndrome

Approximately 10–40% of OP poisoning develop intermediate syndrome which typically manifests after 24–96 hours of exposure. It was first described as type II paralysis. It reflects excessive cholinergic stimulation of nicotinic receptors and is characterized by respiratory and bulbar symptoms as well as proximal muscle weakness, diminished deep tendon reflexes, and respiratory failure. The sensory system remains intake and full recovery is evident in 4–18 days. This syndrome almost never found with carbamate poisoning.

Diagnosis

Diagnosis of OP poisoning is based on the history of exposure to a known OP compound and classic clinical feature like miosis. Two mnemonics which help to remember the clinical manifestations are: **DUMBELS:** *D*iarrhea, *U*rinary frequency, *M*iosis, *B*ronchospasm, *E*mesis, *L*acrimation, *S*alivation; **SLUDGE** and the Killer *B*ees: *S*alivation, *L*acrimation, *U*rinary frequency, *D*iarrhea, *G*astric distress, *E*mesis and *B*ronchospasm, *B*ronchorrhea, and *B*radycardia. For nicotinic effects, think of the days of the week: *M*onday = *M*ydriasis, *T*uesday = *T*achycardia, *W*ednesday = *W*eakness, T*h*ursday = *H*ypertension, *F*riday = *F*asciculation.

Estimation of butyrylcholinesterase activity in plasma (or AChE in whole blood) helps in confirming the diagnosis. However, their importance is limited only for clinical research due to unavailability issues and drawback (use and interpretation). Studies showed that RBC-AChE is a good marker of neuronal function, severity of poisoning, and the need for atropine in patients with OP poisoning, especially initial low plasma/RBC-AChE and high glucose level are good marker for predicting OP induced intermediate syndrome.[3] However, one should not wait for the report to come before starting treatment as normal value of the enzyme does not exclude the diagnosis of OP poisoning.

An atropine challenge test may sometime help in diagnosing OP or carbamate poisoning where history is insufficient to suggest exposure but patients present with findings suggestive of cholinergic poisoning. A test dose of 1–5 mg of atropine (0.05 mg/kg in children) should produce classic antimuscarinic effects like mydriasis, tachycardia, and dry mucus membrane. In contrast, the persistence of cholinergic findings after an atropine challenge strongly suggests OP or carbamate poisoning.

Other ancillary investigations that may help in diagnosis are: leukocytosis, high hematocrit, hyper- or hypoglycemia, anion gap acidosis, and increased serum creatine kinase.

Management

Treatment goals include support of vital signs, preventing the further absorption of the poison (decontamination), administration of specific antidotes, and prevention of re-exposure.

Supportive Measures

- *Check ABC:* Make sure that patient has a patent airway and adequate breathing and circulation. Provide high-flow oxygen with mask. Intubate the patient in compromised airway or breathing.
- *Position of the patient:* Patient should be kept in the left lateral position, preferably with head down position, to reduce risk of aspiration of stomach contents.
- Frequent suctioning is essential as excessive oropharyngeal and respiratory secretion may occlude the airways.
- Obtain intravenous (IV) access and give IV fluid (0.9% NS) to replace loss. Aim is to keep the systolic blood pressure above 80 mm Hg and urine output above 0.5 mL/kg/hr.
- Record pulse rate, blood pressure, size of pupil, presence of sweat, and findings of chest on auscultation at the time of first atropine dose. Prepare atropine chart.
- Continuous monitoring of respiratory function. If tidal volume is less than 5 mL/kg or vital capacity is less than 15 mL/kg, or if they have apneic spells, or PaO_2 < 60 mm Hg on FiO_2 > 60% immediately intubate and ventilate the patient.
- It is important to assess flexor neck strength regularly in conscious patients by asking them to lift their head off the bed and hold it in that position while pressure is applied to their forehead. Any sign of weakness is a sign that the patient is at risk of developing intermediate syndrome.
- The following drugs are contraindicated: Parasympethomimetic, phenothiazine, antihistamine, and opiates. One should not administer Succinylcholine to ventilated patient.
- Treat agitation by reviewing the dose of atropine being given and provide adequate sedation with diazepam. Physical restraint of agitated patients in warm conditions risks severe hyperthermia, which is exacerbated by atropine because it inhibits normal thermoregulatory responses, including sweating. Adequate sedation is therefore important.
- If metabolic acidosis persists despite correction of hypoxia and adequate fluid resuscitation, consider correction with IV bicarbonate guided with arterial blood gas analysis.
- Broad spectrum antibiotics may be required to prevent secondary infection.

External and Gastric Decontamination

Decontamination may be done by removing the contaminated clothes and washing with soap and water. Although there are no evidence based studies; however, this seems to be cost effective and an easy to perform practice by which we can reduce further absorption of the poison into the system. Gastric lavage is a widely used decontamination procedure globally despite the absence of confirmed benefit by randomized controlled trials (RCTs).[4] OP compounds are easily absorbed through mucus membrane and gastric lavage may play a role in the first hour of poisoning. It may be performed, in a patient who is awake, preferably in the left lateral position with tap water (5–10 mL/kg). However, the duration for which the OP compounds remain in the stomach is still unknown and there are concerns for increased risk for aspiration pneumonia and respiratory distress. Activated charcoal has been widely used for absorbing pesticide poisons. The two commonly used regimens of activated charcoal are:

- Single dose of 50 mg
- Multiple doses of 25 mg.

However, no RCT has addressed this issue, especially in OP poisoning.[5]

Antidotes

The three most commonly used classes of antidotes are: Atropine, Oxime (Pralidoxime), and Benzodiazepine.

Atropine: Atropine is an antagonist to muscarinic receptors of Acetylcholine and is the mainstay of treatment of acute OP poisoning. It is used to reverse the cholinergic effect and has no role in neuromuscular junction and

muscular weakness. The five markers indicating atropine requirements are:

- Miosis
- Excessive sweating
- Bronchorrhea and bronchospasm causing difficulty in air entry
- Bradycardia
- Hypotension.

The two commonly used regimens are:

- Bolus dose administration
- Incremental dose administration with rapid escalation.

The aim of therapy is to prevent bradycardia, maintain blood pressure, clear lungs, and dry skin. Bolus dose is defined as 2–5 mg of atropine every 10–15 minutes followed by maintenance using reduced dose or increasing the time interval between the doses. Incremental dose is defined as 1.8–3 mg of atropine by intravenous infusion, repeating the doses every 5 minutes interval, then doubling the doses each time until atropinization occurs, followed by 10–20% of atropine required for atropinization to be given every hour by intravenous infusion. The end points of atropinization are:

- Clear chest on auscultation with resolution of bronchorrhea
- Heart rate of more than 80/minute
- Systolic blood pressure of more than 80 mm Hg
- Dry axillae
- Pupils of more than 2 mm.

Once atroponized, these five parameters should be monitored every 15 minutes initially which can be gradually increased to 1-2-3 hours depending on the state of atropinization **(Table 2)**. Atropine is associated with toxic effects like confusion, agitation, various arrhythmias like multiple ventricular ectopics, atrial arrhythmia, A-V dissociation, raised intraocular pressure, hyperthermia, hallucination, and delirium and ileus. Once atropine toxicity starts, it should be immediately stopped. It may be restarted at 70–80% of the previous rate once the patient settles down. Duration of atropine therapy depends on the severity and response to therapy; usually it is maintained for 24–48 hours and gradually withdrawn over 3–5 days.

Oximes: Oximes reactivate acetylcholinesterase by removing the phosphate moiety from the acetyl pocket. In addition, they also slow the ageing of the phosphorylated enzyme complex and have a direct action in converting OP to a harmless compound. They are effective in counteracting both the muscarinic and nicotinic effects. Pralidoxime (2-PAM) is the only oxime available in India. Despite clear reactivation of red cell AChE, current evidence is insufficient to indicate whether oximes are harmful or beneficial in the management of acute OP poisoning. The WHO recommends a regimen of 30 mg/kg body weight bolus infusion followed by 8 mg/kg body weight/hour intravenous infusion of PAM to all symptomatic patients who need atropine.[6] Pralidoxime is expensive and not free from toxicities. In a recent RCT from India which included 200 patients with moderate OP poisoning stated that high-dose pralidoxime iodide (2 g loading dose, followed by 1 g either every hour or every 4 hours for 48 hours, then 1 g every 4 hours until recovery) associated with reduced case fatality, fewer cases of pneumonia, and reduced time on mechanical ventilation.[7] A Cochrane review including two RCTs reported no clear evidence of benefit or harm from pralidoxime in

TABLE 2 Organophosphorus (OP) observation sheet

OP poisoning.[8] Few other meta-analyses combined non-randomized or historically controlled observational studies with RCTs concluded that oximes are harmful.[9,10]

Benzodiazepine: Patients with OP poisoning are often developed agitated delirium due to multiple reasons, viz. atropine toxicity, pesticide itself, brain hypoxia, alcohol ingested along with the poison, and medical complications. Diazepam (5–10 mg IV slowly, every 15 minutes, up to a maximum of 30 mg and for children 0.25 mg/kg IV slowly, every 5–10 minutes, up to a maximum 10 mg) is easily available and best drug to control agitation.[11] It also helps in sedation in ventilated patient and used as first-line drug for convulsion which although rare but may occur especially with organophosphorus nerve agents (such as sarin, soman, and tabun). However, there are no trials evaluating the efficacy of benzodiazepine as a primary treatment for OP poisoning.

Newer Therapies

Magnesium sulfate: Intravenous magnesium sulfate ($MgSO_4$) has a role in the management of acute OP poisoning as it blocks the voltage gated calcium channel, thereby reducing the release of acetylcholine from synapses.[12] It also reduces the NMDA receptors mediated CNS activation. Intravenous $MgSO_4$ (4 g) on first day has shown to decrease hospitalization period and improve outcome.

Clonidine: Clonidine, an alpha-2 receptor agonist, inhibits the release of presynaptic acetylcholine and thereby decreases the cholinergic symptoms.[13] Optimum dose of clonidine regimen is bolus injection of 0.15–0.30 mg followed by infusion rates of 0.5 mg/24 hours.

Alkalization: Alkalization by sodium bicarbonate (blood pH between 7.45 and 7.55) may help in OP poisoning as shown by some studies.[13]

Fresh frozen plasma (FFP): FFP is a cellular component of blood containing clotting factors, proteins, and many enzymes. It is hypothesized that the enzyme butyrylcholinesterase presents in FFP will sequester the free poison present in blood and remove them from circulation.[14]

Removal of OP from blood by using hemodialysis, hemofiltration, or hemoperfusion is not yet clear. However, in a recent report, it was claimed that hemofiltration after dichlorvos poisoning had revealed beneficial therapeutic effect.[15]

Prevention of Re-exposure

Once the patient is fully recovered, he should not be re-exposed again to OPCs for at least few weeks. It has been said that risk for serious harm can happened on re-exposure to a previously harmless product because of alteration in body chemistry of the host due to previous poisoning. In ideal condition and if facility available, following acute poisoning patient should be precluded from further exposure to OPCs until sequential cholinesterase level is available and confirm that cholinesterase level reached a plateau phase. Plateau phase is defined when sequential determination does not differ by more than 10% and it normally takes 3–4 months following acute poisoning. It is important to note that optimization of health education system amongst the agricultural workers regarding procedure of pesticide handling, strictly following the operative and well-maintained spraying equipment and using necessary precautions at all stages of pesticide handling are essential for reducing their exposure to pesticides.

Conclusion

Being cheap and easily available over the counter, OP poisoning is becoming a major health problem, especially in a developing country like India. Acute OP poisoning is a medical emergency leading to severe toxicity and death. It can be diagnosed on the basis of history of exposure to OP compounds and clinical examination. The estimation of RBC AChE can have a role for confirmation of diagnosis. Early initiation of selective decontamination and antidote therapy (particularly atropine) with close monitoring for complications are important in preventing death due to OP poisoning.

CHAPTER

224 Snakebite

Sanjib Kumar Sharma

Abstract

Snakebite is the second deadliest neglected tropical disease. Southeast Asia is the most affected region in the world. Manifestation of envenomation can be either neurotoxic and/or hematotoxic depending upon biting species. Local manifestation can be severe depending upon the species involved in envenomation. In absence of specific definitive diagnostic test, clinical features along with circumstance of bite may help identifying biting species of snake. Snakebite with systemic envenomation is life threatening medical condition and timely administration of antivenom along with supportive therapy can save life. Administration of antivenom can be associated with antivenom reactions including life threatening anaphylaxis. Prophylaxis administration of subcutaneous adrenalin can reduce the incidence of severe adverse reaction related to antivenom.

Introduction

Snake bite is a public health issue with acute and chronic consequences. It mostly affects economically disadvantage population of rural communities in the tropics. South Asia, due to its high human and snake population and agricultural activities, is the world's most affected region. Most of the victims of snakebite die (97% in India and 80% in Nepal) before reaching treatment centers leading to serious misreporting. Community based study has shown that the snakebite figures are alarming.

Snakebite is a life threatening medical emergency. Survival of the victims depends much on immediate transportation of the victim to the nearest health-care center where antivenom can be administered and supportive therapy is available.

Burden and Characteristics of Snakebite

Around the globe snakebite occurs in approximately 5 million people. It is estimated that snakebite causes up to 138,000 deaths and 400,000 disabilities. The Southeast Asia Region has one of the highest snakebite burdens in the world and 70% of all global snakebite deaths occur in South Asia. In India, the direct estimate of deaths attributable to snakebite in 2005 was 46,000 (99% CI 41,000–51,000), or 1 snakebite death for every 2 HIV/AIDS deaths.

The characteristics of snakebite in South Asia are shown in **Table 1**.

Medically Important Venomous Snake of India and Nepal

There are around 300 species of snake found south of the Himalayas. Among them approximately 67 are front fanged venomous species. Medically the most important venomous snakes, also known as "BIG FOUR" are Russell's viper (*Daboia russelii*), Common cobra (*Naja naja*), Common krait (*Bungarus caeruleus*), and Saw scaled viper (*Echis carinatus*). The pit viper species; Malabar (*Trimeresurus malabaricus*), Green pit viper (*Trimeresurus albolabris*), Hump-nosed viper (*Hypnale*

TABLE 1 Characteristics of snakebite in South Asia

Characteristic	*Details*
Age	About three-quarters of the victims belong to 10–40 year age group, with mean age of 30 years.
Gender	Male predominates with 2:1 male female ratio.
Occupation	Farmers account for more than 50%. Students and housewives are also commonly affected.
Time of bite	Krait bites are generally nocturnal. Viper and cobra mostly strike during the daytime.
Bite to treatment delay	Time between bite and treatment delay varies greatly. Very few victims reaches hospital in less than an hour.
First aid methods	Mostly harmful and inappropriate methods are used. Tourniquets use is ubiquities and it is applied by up to 98% of patients.
Mortality	Highly variable (0.5–58%) they are. Most deaths occur before reaching hospital.

hypnale), Bamboo pit viper (Trimeresurus stejnegeri); Sea snakes (*Hydrophiinae*) and others like the King cobra (*Ophiophagus hannah*), Monocle cobra (*Naja kaouthia*), Banded krait (*Bungarus fasciatus*), Sind krait (*Bungarus sindanus*), and *Echis sochureki* are important causes in certain geographical areas.

Clinical Manifestation

Snakebite is a life-threatening medical emergency. Prompt identification of early signs of systemic envenoming is crucial for the optimal management of the victims. Snakebite may have one of the following consequences:

- Dry bite—It may be due to bite from non-venomous snake or bite by venomous snake without envenoming. Fang mark (bite mark) may be present.
- Local effects of venom in parts of bitten site like swelling, bullae formation, necrosis, etc. This may extend to whole limb in viper bite. Secondary infection may lead to abscess formation.
- Absorption of the venom in systemic circulation leading to systemic manifestation. Depending on the biting species the systemic manifestations are neurotoxicity or hematotoxicity.
- Effects of traditional treatment, for example, local gangrene due to tight tourniquet, pain abdomen, vomiting, etc. due to congestion of chilies, herbal medicine, etc. Tight tourniquet/s may cause manifestations that may be confused with local envenoming.
- General manifestation with or without snake envenoming may result in excessive fear, nausea, vomiting, malaise, pain abdomen, weakness, prostration, excessive salivation, etc.

Elapidae Groups of Snakes (Neurotoxic Features)

Elapidae groups of snakes envenoming produce descending paralysis due to neuromuscular blockade. The important neurotoxic features are: Ptosis, diplopia, ophthalmoplegia, pupillary dilatation, inability (or limitation) to open mouth and/or tongue extrusion, inability to swallow, broken neck sign (patients cannot hold his/her neck straight when sitting up from supine position), skeletal muscle weakness, loss of gag reflex, paradoxical breathing (outward protrusion of abdomen during deep inspiration), and respiratory failure. Paralysis of tongue and muscle of deglutition may lead to upper airway obstruction. This may lead to asphyxia due to aspiration of pooled secretions. Hypoxia-associated manifestation like cyanosis and hypoxic brain injury may be secondary to respiratory failure. Abdominal pain may suggest krait envenoming in appropriate circumstance and is likely due to venom induced submucosal hemorrhages in the stomach.

Viperidae Group of Snakes (Hematotoxic and Cytotoxic Features)

Venom of Russell's viper and saw scaled viper manifest as systemic bleeding. Feature of neurotoxicity may also present as added manifestation. Systemic manifestation of coagulopathy can also present in green pit viper envenoming. Malabar pit viper is attributed to cause significant morbidity in India.

Spontaneous bleeding from various orifices and mucosal surface is the major manifestation of viper envenoming. The bleeding is common from venipuncture

site, gums, nose (epistaxis), respiratory system (hemoptysis), gastrointestinal system (melaena, rectal bleeding), genitourinary system (hematuria, bleeding from vagina), bleeding into the mucosae (subconjunctival hemorrhage), skin (petechiae, purpura, ecchymosis), retina (bleeding into tears), bleeding from inflicted wound, if any, bleeding into internal organs like brain and intracranium, lungs or abdomen, acute kidney injury and other organ dysfunction may occur secondary to hypotension following bleeding. Laboratory evaluation reveals prolonged bleeding time (BT) and clotting time (CT), increased prothrombin time and INR. Twenty-minute whole blood clotting test (20 WBCT) is useful bedside test to see incoagulability of the blood and can detect venom induced coagulopathy.

Rhabdomyolysis

Rhabdomyolysis is characterized by muscle pain, and muscle necrosis that releases intracellular muscle constituents into the circulation. Creatine kinase level is highly elevated. Myoglobinuria may be present. All myotoxic snake venoms contain phospholipase A2, which is responsible for the rhabdomyolysis. Russell's viper, saw scaled viper, hump-nosed pit viper, green pit viper, and sea-snake can produce rhabdomyolysis **(Table 2)**.

Long-term sequalae of snakebite: Long-term effects of snake bite may occur. Some known sequelae are as follows:

- Chronic ulceration, bone infection (osteomyelitis) or arthritis
- Physical disability
- Chronic kidney disease due to bilateral renal cortical necrosis and chronic panhypopituitarism may occur in Russell's viper envenoming
- Sequelae of intracranial bleeding in hematotoxic envenoming
- Delayed psychological morbidity like depression and anxiety, impaired functioning, post-traumatic stress disorder, and unexplained residual physical disability as reported from Sri Lanka.

Diagnostic Test for Snakebite Envenoming

Neurotoxic Envenoming

Neurotoxic envenoming is clinical diagnosis and laboratory investigations is rarely of help.

Hematotoxic Envenoming Due to Vipers

- Prolonged BT and CT
- Increased INR
- Incoagulable blood as demonstrated by 20 WBCT (positive 20 WBCT)
- Raised urea and creatinine, if AKI develops
- Leukocytosis indicates systemic envenoming. Hemoconcentration may occur due to systemic bleeding and platelet count may decrease in case of viper envenoming.

Management of snakebite: Management of snakebite involves the following steps:

- First aid and transportation to the hospital
- Immediate clinical assessment and resuscitation

TABLE 2 Summary of the clinical feature of snakebite

Feature	*Cobra*	*Krait*	*Russell's viper*	*Saw-scaled viper*	*Humped nose viper*
Local pain/Tissue damage	Yes	No	Yes	Yes	Yes
Neurological signs	Yes	Yes	No*	No	No
Coagulation abnormality	No	No**	Yes	Yes	Yes
Acute kidney injury	No	No	Yes	No	Yes
Response to neostigmine	Yes	No	No	No	No
Response to antivenom	Yes	Yes#	Yes	Yes	No

* May be seen as added feature to hemostatic abnormality
** May be seen in envenoming with *Bungarus niger* (Greater black krait)
# Response to antivenom in krait envenoming may not be seen. Antivenom currently available is unlikely to neutralized venom of krait species other than common krait (*Bungarus caeruleus*)

- Antivenom treatment
- Supportive/Ancillary treatment
- Treatment of the bitten part

- *First aid and transport to the hospital:* The most of the envenomed patient of our region die before reaching hospital and this is likely due to delay in transport of victim in snakebite causing neuroparalysis. So all means should be applied to transport the patients, as soon as possible, to the hospital or snakebite treatment center, where facilities to administer antivenom exist. The recommended first aid methods are:
  - Reassurance.
  - Immobilization of the bitten limb using a splint or sling. Time should not, however, wasted searching for this materials and delay transport of the patient.
  - Tight fitting ornaments and clothing should be removed. Do not inflict cutting, sucking, electrocautery, etc. of the bite wound.
  - Rapid transport: Transportation of the victims to the nearest health center with facility to treat snake envenoming at soonest possible. Transport using motorcycle is found to save life in snakebite envenoming. The victim is seated and held between driver and pillion rider.
  - Tight (arterial) tourniquet must be discouraged.
- *Rapid clinical assessment and resuscitation:* Snakebite is a medical emergency. A quick clinical assessment to decide whether patient needs antivenom therapy and/or resuscitation should be done upon arrival of the victim. Clinical conditions when snakebite victim may require urgent resuscitation are:
  - Hypotension and shock
  - Respiratory distress and respiratory failure
  - Cardiac arrest
  - Rapid deterioration or development of features of severe envenoming
- *Antivenom therapy:* Antivenom is the only specific treatment from snakebite envenoming. Effective against the four common species of snakes found in India; Russell's viper (*Daboia russelii*), Common cobra (*Naja naja*), Common krait (*Bungarus caeruleus*), and Saw scaled viper (*Echis carinatus*). Antivenom currently is unlikely to be effective against similar sounding species of snakes.

Indications for Antivenom

- Presence of definite evidence of neurotoxicity. Ptosis is the earliest reliable sign of neurotoxicity.
- Evidence of coagulopathy: Abnormal (positive) 20WBT, spontaneous systemic bleeding (gums, hemoglobinuria, myoglobinuria, and mucosa, bleeding).
- Rapid extension of local swelling (more than half of limb) which is not due to pit viper bite or tight tourniquet application.
- Cardiovascular collapse, i.e., shock and hypotension.

Dose of Antivenom

Amount of injected venom during snakebite is similar for children and adults. Therefore, the dose of antivenom for children is same as adult dose.

Initial dose: Neurotoxic/hematotoxic envenoming: 10 vials (100 mL) is further diluted or mixed with dextrose water or saline (100–400 mL). Then it is administered with intravenous infusion at the rate of 2 mL/min (40–60 min at 60–70 drops/min).

When to repeat the dose of antivenom?

Neurotoxic envenoming: If neurological sign/s deteriorates an IV push of 5 vials of antivenom (50 mL reconstituted antivenom) should be administer at 2 mL/min.

Hematotoxic envenoming: Repeat 20WBCT (or other test for coagulation) after 6 hours. If 20WBCT is abnormal (uncoagulable blood) or other coagulation test are abnormal repeat 5 vials of antivenom (50 mL reconstituted antivenom) IV push at 2 mL/min. This can be repeated every 6 hours till coagulation profile is corrected.

Note: Do not use antivenom more than 20 vials or so. Administration of higher dose antivenom is unlikely to be useful, if patient has not responded to initial bolus or around 20 vials of antivenom.

Prevention of ASV Reaction

Prophylactic subcutaneous adrenalin (epinephrine) should be routinely administered before initiation of antivenom treatment to prevent antivenom reaction. However, it should be avoided in older patients with evidence or suspicion of underlying ischemic heart

TABLE 3 Dose of adrenalin

Age (years)	Dose (μg)	Volume (mL)
>13	250	0.25
>10–12	250	0.20
>5–10	125	0.12

disease or cerebrovascular disease. The dose of adrenalin (0.1%) is shown in **Table 3**.

Antivenom reaction: Three types of antivenom reaction can occur.

- *Anaphylaxis:* It usually develops within 3 hours of antivenom initiation. Common features are itching, which may be intense, urticaria, fever, angioedema, dyspnea due to bronchospasm, laryngeal edema, hypotension, etc. Intramuscular adrenalin must be given at first sight of sign of anaphylaxis. Details of treatment of anaphylaxis related to snakebite can be found in national guideline of snakebite management of Nepal and India.
- *Pyrogenic reaction:* Usually develops 1–2 hours after treatment initiation. Features include, chills, rigors, fever, fall of blood pressure, and febrile convulsion may develop in children.
- *Late reaction (serum sickness type):* It can developed 1–12 (mean 7) days after receiving antivenom. Features include fever, itching recurrent urticaria, arthralgia, myalgia, lymphadenopathy, proteinuria, etc.

Supportive therapy: Antivenom treatment alone cannot always prevent respiratory paralysis. Patients with impending respiratory failure artificially ventilated to avoid asphyxiation and hypoxia. Similarly, appropriate measure to be taken to treat hypotension and shock. Patients with acute kidney injury may need dialysis therapy, if indicated. All snakebite patients should receive tetanus toxoid injection at the time of discharge. Neostigmine or may be administer along with atropine, if antivenom is not available for weakness or paralysis secondary to envenomation by a snake capable of causing postsynaptic neurotoxicity. Local wound should be care as like other wound and secondary infection should be treated accordingly.

Conclusion

Snakebite is a true neglected tropical disease that mostly affects the most impoverished people of remote rural area. Immediate transport to health center and timely administration of antivenom, when indicated, along with supportive therapy are key to survival. Local envenomation may need prolonged wound care. Reaction to antivenom, which can be severe, can be reduced by subcutaneous adrenalin prior to antivenom infusion.

CHAPTER

225 Snakebite in Indian Scenario and Its Management

Vinay Rampal

Abstract

We Indians take pride in Worshipping Vasuki Naag, who being instrumental in Churning of sea for Nectar between the gods and the demons, and, Bhujang who adorns the head of lord Shiva still, the mere imagination of a bite by the smallest of kraits causes perspiration in strongest of human beings. We also take pride in calling ourselves the biggest democracy in the world offering free medical aid to all. Today, when we are thinking of landing at Mars, every year, hundreds of thousands of poor farmers, construction workers, forest employees, trekkers, and migrant laborers lose their precious lives, which can be easily saved by proper timely intervention. Snakes rightly called the sons of soil are as much part of the universe as human beings and created to rid the universe of smaller nuances like rodents and other creepers should be properly taken care of by taking proper precautions with dwellings, footwear, gloves use of stick and light while going to old ruins, fields, forests, and night roaming, especially during summer and monsoons, when the snakes move freely around in tall grass and during floods. Even if bitten, all types of venomous snakebites are amenable to treatment and the hub of treatment the polyvalent anti venin serum (AVS) is available free of cost in all the dispensaries/health centers but what is needed is education and awareness of the populace and the relief givers. In the following pages an effort is being made to bring forth the lessons learnt during last 35 years of treating more than 8,000 snakebite cases, especially the deadliest ones from Kandi area (dry belt of Shivalik Hills).

Introduction

Although snakes constitute an alma-mater of all medical emblems the staff of Aesculapius **(Fig. 1)** and the staff of Appolo, the Cadeceus **(Fig. 2)** still they continue to remain an enigma for not only the human society but the medical profession as well, when it comes to the management of snakebite poisoning. They (snakes) not only find a mention in the Hindu religious books, wherein they are worshipped for attainment of love, health, procreation, wisdom & virtue as "Bhujang" adorning the head of Lord Shiva and "Vasuki" being credited with churning of Ocean for Nectar (Amrit). On the contrary in the Christian mythology, they are treated as backbiters needing pithing. In the developing world most snakebites occur in those who work or sleep outside, such as foresters, farmers, hunters, fishermen, herdsmen, the Army personnel, the trekkers, and the migrant laborers, while in the United States & the Europe, those keeping them as pets are bitten[1] as the famous Aspi of Cloepetra **(Fig. 3)**. Snakes bite both as a method of hunting and a means of protection. The WHO once again lists snakebite as a neglected disease.[2] Out of an average of 5 million snakebites annually, worldwide with around 2.5 million envenomations and 30,000–125,000 deaths, Indian Subcontinent constitutes more than 50% of the share,[3] partly because of the ignorance, prevalence of old practices (Ojha & mantras), and the lack of proper medical facility in far flung areas. There are about 216 species of snakes in India out of which

Fig. 1: Staff of Aesculapius

Fig. 2: Staff of Apollo, Our Emblem

Fig. 3: Cloepetra's famous Aspi

52 are venomous. Broadly speaking there are four major families of venomous snakes:

- Viperidae, with sub class
  - viperinae the old world vipers and
  - crotaline new world and Asian pit vipers
- Elapidae the cobras, kraits, coral snakes, sea snakes, and all venomous Australian snakes
- Lamprophiidae (subfamily Atractaspididae the burrowing asps)
- Colubridae (a large family in which most of species are non-venomous with only a few being dangerously toxic to mankind)[4]

The vipers are mostly hemotoxic and cardiotoxic but occasionally may also be neurotoxic. The Elapidae are mostly neurotoxic but may affect the cardiac as well as the vascular system causing sudden deaths or coagulopathy. Most snake venoms contain multiple toxins ranging from cytotoxins, hemotoxins, neurotoxins, bungarotoxins, cardiotoxins, and myotoxins, which comprise of different types of peptides and proteolytic enzymes, glycoproteins, metal ions and hyaluronidases, phospholipases, etc. The most commonly found examples of viperidae are Russel viper, pit viper, the commonly found elapids are Cobra (Naja naja) and common krait (Bungarus caeruleus).

Poisoning by most viperids and some elapids with necrotizing venoms causes progressive local swelling, pain, ecchymosis, and hemorrhagic bullae or serum filled vesicles. In serious bites tissue loss can be significant. Systemic finding may include change in taste, mouth numbness, persistent severe vomiting and/or abdominal pain, muscle fasciculations, arrhythmias, for example, tachycardia or bradycardia, torsades-de-pointes, ventricular fibrillation, hypotension, shock, pulmonary edema,[5] hemorrhage from any site and renal dysfunction. Poisoning by neurotoxic elapids such as kraits, many Australian elapids (Atractaspis spp.) and tiger snakes (Notechis spp.), cobras and some viperids cause neurologic dysfunction, starting with cranial nerve involvement like ptosis, external ophthalmoplegia, altered mental status progressing to bulbar paralysis, and/or general paralysis involving the muscles of respiration leading to death. Most

often the patient has been brought to us in an unconscious state without any history of snakebite in the absence of any fang marks but a history of having slept on the floor.[6] After elapid bites, the time of onset of envenomation varies from minutes to hours depending upon the species involved, the anatomic location of the bite, and the amount of venom injected.

Management

Basic management at the location of bite: It involves retardation of absorption of venom and neutralization of venom as quickly as possible. The most important management of snakebite of any type remains as ever reassurance, the mere fact of a snakebite frightens the boldest of the persons at times to fainting attacks, so assuring a person that nothing lethal has happened will not only prevent him from collapsing but will also prevent the adrenaline secretion resulting in increased heart rate, and enhanced dissipation of the venom in circulation and its immediate effects. The person should be made comfortable by lying down and placing the part bitten below the level of heart and stabilizing it with a splint so as to cause minimum movement, and hence prevent absorption of the poison. Even if there are no visible fang marks and the snake is apparently non-poisonous the basic management should remain the same, because most of neurotoxic snakebites (common krait) cause minimum pain and little or no visible fang marks. No tourniquets (tight ligatures) to be applied in any case which will result in complication than help, rather remove any rings, watches, bracelets or anything around the bitten part, which may act as a tourniquet once the part swells-up. The person should be made to be fully aware given plenty of fluids and talked to incessantly. If there are minimal fang marks and no ecchymosis or swelling a soft elastic bandage should be applied proximal to the bite through which the little finger can be easily passed (neurotoxic bite, vide-supra). Incising of the wound, applying electric current or suction should be avoided because they can enhance local tissue damage. Similarly, the application of poultices and ice packs should be strongly discouraged. In case of hemorrhagic symptoms the best plan is to stabilize the part with a splint and keep it below the level of heart and wash it with soap and water no pressure or incision to be given in any case. Watch for bleeding from any site and as mentioned above if there are chances of hemorrhagic shock then fluids orally need to be increased and the patient carried on a cot or stretcher to the nearest hospital/dispensary which has the polyvalent anti-venin serum (AVS) available.

Hospital management: The patient should be closely monitored at least for 24 hours even if there are no fang marks and the snake was apparently non poisonous (vide-supra). A care should be taken of airway, blood pressure, respiration, heart rate, and neurological status/deficit, while taking the history and performing a preliminary clinical examination. In case of viper bites the level of swelling of the bitten extremity should be noticed and diameter measured half hourly and the part placed below the heart level till AVS is instituted. The bands or tourniquet if applied should be very slowly removed after a large bore Intravenous access so as to prevent the sudden release of acidotic blood collected in the distal part to the central circulation which may result in bradycardia or hypotension leading to shock and sudden death. A sample of 3–5 mL of venous blood should be immediately drawn and poured in to a dry test tube which should be placed vertically so as to see for 20 minute whole blood clotting time (20 WBCT) and tilted to 45° at 4–6 hours intervals so as to assess for coagulopathy and further institution of AVS.[7] In addition other blood chemistry and measurements like thrombocyte count, renal and hepatic functions, coagulation studies, and urine for fibrin degradation products to diagnose consumptive coagulopathy and for blood and myoglobin should be carried out. If the bitten part is swollen due to intra-compartmental bleed the part should be raised above the heart level after starting AVS and if it does not respond to conservative measurements then Mannitol (1 gm/kg fast) should be infused to release the pressure. Arterial blood gas (ABG) studies, electrocardiography, and chest radiography may be carried out in severe envenomation when there is no active bleeding going on. In case of neurotoxic poisoning a care should be taken about ptosis, drooling of saliva, respiratory insufficiency, or other types of neurodeficiency.

The hub of treatment of venomous snakebite, resulting in significant envenomation is the administration of specific AVS. These sera are obtained from the sera of animals after, either by the injection of the venom of common varieties of snakes obtained by milching them **(Fig. 4)** or by giving them a direct bite. The AVS

Fig. 4: Russell's viper snake

available in our country is a polyvalent one, which acts as an antidote to the most of the types of snake venoms involved in our country. Produced either at Haffkine's Institute, Mumbai, or National Serum Institute Kassauli (Himachal Pradesh). The goal of AVS administration is to allow antibodies (or antibody fragments) to bind up circulating venom components before they can attach to target tissues and cause deleterious effects. Because the hemotoxic snake venom due to its procoagulants and anti-coagulants causes venum induced consumptive coagulopathy[8,9] through its toxins exerting effect on the platelets, coagulation factors, coagulation products and blood vessels, the administration of AVS should be strictly according to the nature of the clot, that is, if no clot forms within 20 minutes full dose of AVS to be instituted (100 units stat) and firmer the clot lesser the dose of AVS. Some studies have also mentioned the role of liver gene regulation in hemostasis.[10]

Since the heterologous sera, obtained from any source, being a foreign body carry their own risks like acute, non-allergic/allergic anaphylaxis and delayed type hypersensitivity reactions (serum sickness) skin testing for potential allergy is a must although our practice has been to administer 100 mg of hydrocortisone IV before starting AVS even if the intradermal test was ambiguous or in the alternative 0.01 mg/kg, up to 0.3 mg of epinephrine subcutaneous or intramuscularly. The indications for administration of AVS to victims of bites by viperids or elapids depend upon:

- Presence of systemic symptoms or signs (vide-supra), persistent and severe vomiting and/or abdominal pain and/or laboratory abnormalities and significant progressive local findings (massive local necrosis, soft tissue swelling crossing a joint or involving more than half the bitten limb or continuous bleeding from any site, internal or external). In case of neurotoxic poisoning the administration of AVS is indicated at the first sign of any neurotoxicity (ptosis, difficulty in swallowing or signs of peripheral neuropathy).
- Modest expansion of patients' intravascular volume with crystalloids also may blunt acute adverse reactions, hence their administration should be concomitant with IV administration of AVS, which should be started in the presence of a doctor and closely monitored by him for any adverse reactions like acute bronchospasm or cardiovascular collapse.

Specific Treatment

- *Hemotoxic/Cardiotoxic bite:* The patient presenting with a local swelling or bleed or ecchymosis or signs of bleeding from any part (mouth, gums, hematemesis/melaena) signs of cardiovascular failure and apprehension.
  - Reassurance.
  - Administration of tetanus toxoid.
  - Establish two large bore IV lines with normal saline/crystalloid starting with a bolus 20–40 mL/kg body weight if the patient is hypotensive, if in shock treat it.
  - Maintenance of proper airway, breathing, blood pressure, and raise the swollen part above the level of heart once AVS is started.
  - Urgent clotting time estimation (CT) vide-supra 4–6 hours (Reid criteria).
  - Intradermal test of AVS and thereafter 100 mL (ten vials of lyophilized/liquid polyvalent AVS) in 500 mL of normal saline over a period of 4–6 hours to be preceded by 100 mg of hydrocortisone (in case of doubtful test).
  - The above dose to be repeated after 6 hours if the blood remains non-clotting (>20 minutes depending upon the quality of clot) (Reid criteria).
  - If the swelling in the bitten extremity points toward subfascial muscle edema impeding tissue perfusion (muscle compartment syndrome) IV

mannitol (1 gm/kg) may be administered in a hemodynamically stable patient. However, if the response is not proper, fasciotomy of the limb may be needed after orthopedic consultation.[11] AVS must be administered in all cases presenting in an acute form with active bleeding even if presenting after 3–4 weeks of bite.
  - Antibiotics effective against staph like cloxacillin/cephalexin 500 mg 8 hourly. In case of massive necrosis and skin and muscle damage metrogyl should be added.
  - The amount of AVS administered depends upon the clinical response and is inversely proportional to the quality of the clot (i.e., poor clot, more AVS and good clot less AVS. Watch the clot for 4 hours because at times the clot may redissolve). No fixed dose of AVS has been calculated so far.
- *Neurotoxic bites:*
  - Reassurance
  - Maintenance of proper airway, breathing, blood pressure, and watch for signs of neurodeficiency like altered mental status, ptosis, drooling of saliva, difficulty in swallowing, diplopia, difficulty in breathing or signs of peripheral neuropathy, paralysis, or unconsciousness.
  - Intradermal test of AVS and thereafter 100 mL (ten vials of lyophilized/liquid polyvalent AVS) in 500 mL of normal saline over a period of 4–6 hours to be preceded by 100 mg of hydrocortisone (in case of doubtful test).
  - Atropine 0.6 mg IV (children, 0.02 mg/kg; minimum of 0.1 mg) follow with:

Edrophonium: 10 mg IV (children, 0.25 mg/kg)
Or
Neostigmine 1.5–2 mg IM (children, 0.025–0.08 mg/kg)

Continue neostigmine at a dose of 0.5 mg (children, 0.01 mg/kg) IV or S/C every 30 minutes as needed, with continued administration of atropine by continued infusion of 0.6 mg over 8 hours (children 0.02 mg/kg over 8 hours). Stop this regimen if no relief is evident after three doses because in that case the bite is that of a krait.

Maintain vigilance regarding aspiration risk and secure the airway with endotracheal intubation as needed and put on ventilator if still not responding.
  - Continue to repeat the AVS dose till substantial relief or death of the patient.
- In case of an acute reaction to AVS the infusion should be temporarily stopped and the reaction immediately treated with intramuscular epinephrine 0.01 mg/kg up to 0.03 mg, antihistamines (diphenhydramine, 1 mg/kg to a maximum of 100 mg and cimetidine, 5–10 mg/kg to a maximum of 300 mg and glucocorticoids (200 mg IV). Once the reaction is controlled if the severity of poisoning warrants additional AVS, the dose should be diluted further in isotonic saline and restarted as soon as possible. Rarely in recalcitrant cases desensitization needs to be done with hydrocortisone (starting from 400 mg hourly and tapering till normalization or a concomitant IV infusion of epinephrine may be required to hold allergic sequelae at bay while further AVS is administered). The patient must be monitored very closely, preferably in an intensive care setting, during such therapy.
- Blood and blood products are rarely necessary in the management of a hemotoxic bite, although these bites can cause a drop in platelet count or hematocrit and depletion of coagulation factors these usually rebound within hours after administration of adequate amount of AVS. Even if there is a great need for these products they should be given only after adequate AVS administration to *avoid adding fuel to the fire of ongoing coagulopathy*.[4,8,9]
- Patients who develop acute renal failure due to rhabdomyolysis or hemolysis should be managed in a conventional fashion, as the insult is one of acute tubular necrosis and is frequently reversible and if not responding should be referred to a nephrologists for hemodialysis or peritoneal dialysis.
- A dry, sterile dressing should be applied to the wound while splinting with padding between the digits. Pain control should be achieved with paracetamol or codeine. Salicylates and other non-steroidal anti-inflammatory agents should not be used because of their effect in prolonging clotting of blood.
- After full care of the wound and normal clotting of blood, physiotherapy should be instituted for return to a functional state. The victim should keep contact with the treating physician even after discharge and be made aware about signs and symptom of wound infection, AVS related serum sickness and long-term sequelae like pituitary insufficiency, with central diabetes insipidus[12] in Russel viper bites and the late onset of coagulopathy after 2–3 weeks of bite and to

avoid elective surgery or activities involving high risk of trauma. The serum sickness should be treated with prednisone (1–2 mg/kg daily) until all findings resolve and then tapered over 1–2 weeks, besides oral antihistamines and analgesics.

Morbidity and Mortality

The mortality in India is high because of religious beliefs (witchcrafts and mantras) lack of connectivity and ignorance in both, the treater and the treated (vide-supra). Similarly, the incidence of morbidity (permanent functional loss in a bitten extremity) is also substantial due to muscle, nerve, or vascular injury or to a scar contracture with resulting inability to work and earn a proper living.

Future Aspects

In the biggest democracy of the world which boasts of free-medical care for all and when we are planning to land at Mars, a substantial portion of the population either losses life or is mauled permanently due to a preventable cause. The following main points which need to be addressed are:

- Education of the masses about the prevalence of the types of snakes and their proliferation at a particular time of the year (summer and monsoon) and at specific places (farmland, mudhouses, ruins, forests) and use of proper gear (covering the lower limbs up to knees and the upper limbs up to elbows with long boots and thick gloves or in the alternative with thick wrappings like jute, etc. and use of a lathi and torch/lamp when going to fields/forests or working at extremes of times makes it easily preventable). Digging of a shallow ditch around the Jhuggis as the defense personnel do around their tents. Special care needs to be taken during floods, which not only bring the snakes out of their burrows but also from far off places.[13]
- Availability of proper amount of AVS (which is available) and qualified persons at subcenters of the health department which already exist to orientate them and to make them more conscious about envenomation and its management because the ultimate treatment of any type of snakebite poisoning is only timely administration of AVS besides other remedial measures.
- Since this is mainly a problem of developing countries only, a combined research should be oriented toward production of a snake venom vaccine/venom toxoid for those people who are prone to snakebite poisoning like the farmers, the foresters, the trackers, and the migrant laborers who sleep on the ground.
- Some trials are being given to the use of PLA2 inhibitor Varespladib[14] as an alternative to AVS because of its effective inhibition of snake phospholipase. Some local people have also used Citrus peels locally but again it is firmly stressed to follow only the above standard guidelines because human life is invaluable and does not need to be experimented with.

Conclusion

Snakes, an essence of the Universe, have been created by the almighty, like human beings to take care of the rodents and other insects, which otherwise would cause immense loss to the mankind. Worshipped in some civilizations and hated in others, the Snakes find an important place in our Medical emblems. In the West they are being nurtured as pets as well since the Roman Empire. Still a word of caution is essential when dealing with them, especially in certain seasons like rains and floods which cause a surge in their population and activity. For the defense personnel, forest employees, trackers, and explorers like archaeologists a proper gear needs to be worn and a lathi and torch for the house holder are a must and only antidote of snake bite poisoning the AVS though available liberally needs to be used judiciously. Similarly, a lot of old remedies like laceration, tourniquet, and application of electric current need to be discarded. Neurotoxic snake bite should be ruled out in all unconscious patients in the planes, especially during rainy sessions. New drugs are in the pipeline but till their confirmed benefit AVS should be the hallmark of treatment.

Since a neglected problem, especially of the developing countries a combined effort to develop an anti-toxin or vaccine of universal usage is the need of the hour and may be the answer as has been very fortunately carried out in the case of COVID-19 in less than a year.

CHAPTER

226 Hemolytic Anemias: Diagnostic Approach

Shubha Laxmi Margekar, Ashok Kumar, Purnima Margekar, Venu Gopal Margekar

Abstract

Hemolytic anemias are an important type of anemia in which destruction of RBCs occurs. Manifestations occur in the form of development of anemia along with sign and symptoms of hemolysis. Usually the diagnosis is made by good clinical history relating the cause of anemia and evidence of hemolysis in laboratory evaluation. Therefore, a general approach for making etiological diagnosis of the hemolytic anemia is always needed for classification and management of anemia. In this chapter an effort has been made to provide a relevant approach for the evaluation of hemolytic anemia.

Introduction

Anemia is defined as decrease in hemoglobin (Hb) level, according to reference ranges specific for age, gender, and race. For men Hb <13 g/dL and for women Hb <12 g/dL is considered as anemia as per World Health Organization (WHO).

The mean life span of Red Blood Cells (RBCs) is 120 days. Taking a good history followed by proper clinical examination along with laboratory investigations is still considered as the best approach for any case of anemia.

In hemolytic anemias, there is premature destruction of RBC, that is, in less than 120 days (which defines the hemolytic disorder) which in turn to compensate, there is increase in the production capacity of RBCs by bone marrow. When the rate of destruction of red blood cell exceeds the capacity of producing more red cells by bone marrow, the hemolytic disorder will manifest as hemolytic anemias.

Usually the diagnoses of hemolytic anemia are made through the laboratory investigations but a clinical history along with physical examination is also helpful for providing useful information about presence of hemolysis and its probable etiology.

Causes of anemia that can be treated (anemia due to nutritional deficiencies, gastrointestinal bleed, anemia of renal origin, and hemolysis) should be looked for carefully, so that it is not missed.

Classification

- On the basis of etiology, hemolytic anemia can be classified as:
  - Inherited or
  - Acquired.
- According to the site of hemolysis **(Table 1)**, it is divided into:
  - Intravascular, where RBCs destruction is in the circulation or
  - Extravascular, where destruction occurs in the spleen or liver (within macrophages).
- From the clinical perspective, hemolytic anemia can be
  - acute or
  - chronic.
- According to mechanism (location of the abnormality) **(Table 2)**, there may be
  - intrinsic (intracorpuscular) defect or
  - extrinsic (extracorpuscular) defects.

TABLE 1 Classification according to site of hemolysis

Intracorpuscular factors (Red cell abnormality)	*Extracorpuscular factors*
Hereditary • Membrane defect (spherocytosis, elliptocytosis) • Metabolic defect (Glucose-6-Phosphate-Dehydrogenase (G6PD) deficiency, Pyruvate kinase (PK) deficiency) • Hemoglobinopathies (unstable hemoglobins, thalassemias, sickle cell anemia) **Acquired** Membrane abnormality-paroxysmal nocturnal hemoglobinuria (PNH)	**Immune hemolytic anemias** • utoimmune hemolytic anemia – caused by warm-reactive antibodies – caused by cold-reactive antibodies • Transfusion of incompatible blood **Nonimmune hemolytic anemias** • Chemicals • Bacterial infections, parasitic infections (malaria), venons • Hemolysis due to physical trauma – hemolytic-uremic syndrome (HUS) – thrombotic thrombocytopenic purpura (TTP) – prosthetic heart valve – Hypersplenism

TABLE 2 Classification according to the location of the abnormality

	Intracorpuscular defects	*Extracorpuscular factors*
Hereditary	• Hemoglobinopathies • Enzymopathies • Membrane-Cytoskeletal defects	• Familial (atypical) hemolytic uremic Syndrome
Acquired	• Paroxysmal nocturnal hemoglobinuria (PNH)	• Mechanical destruction (microangiopathic) • Infectious • Autoimmune • Toxic agents • Drugs

Mechanisms involved in anemia include:

- *Inadequate production:* Stem cell damage or defective red cell maturation.
- *Excessive destruction (hemolysis):* Intrinsic defect in red cell leading to shortened lifespan or external factors in blood or blood vessels destroy red cells.
- *Blood loss (bleeding)*

Causes of hemolytic anemia include:

- *Inherited red blood cell membrane abnormalities:* There is change in the shape of cell due to membrane defects and this change in shape is identified as abnormal by spleen and destroyed it.
- *Inherited enzyme deficiencies in red blood cells:* Abnormalities in enzyme levels makes the red blood cell fragile, which makes red blood cell prone to get destroyed easily.
- *Hemoglobin disorders:* Abnormal hemoglobin is because of inherited gene in some people. Abnormal hemoglobin can lead to easy destruction of red blood cells. Disorder includes sickle cell anemia and the thalassemias.
- *Physical damage to RBCs:*
  - During heart-lung surgery
  - In patients with artificial heart valves (as blood flows near devices)
  - In a patients with severe burn (exposure to extreme heat)
- *Physical damage to RBCs:*
  - During heart-lung surgery
  - In patients of artificial heart valves
  - In patients with severe burn due to exposure to extreme heat
  - *Autoimmune hemolytic anemia:* It can occur in autoimmune conditions like lupus, certain types

of infections, and use of some drugs. This happens when the red blood cells of the body gets destroyed by immune mechanism of its own body.

– *Hypersplenism:* The spleen is enlarged and becomes overactive. It traps the circulating red blood cells and destroys it.

General Features of Hemolytic Disorders

Hemolytic anemias can be differentiated from other anemias by presence of signs and symptoms arising because of hemolysis.

General examination: Jaundice, Pallor, Bossing of Skull

Physical findings:

- Enlarged spleen (as a preferential site of hemolysis) leading to neutropenia and/or thrombocytopenia
- Enlarged liver (in some cases)
- Skeletal changes, because of bone marrow over activity (seen in severe congenital forms)
- Hemoglobin—From normal to severely reduced
- MCV—Usually increased
- Reticulocytes—Increased (sign of the erythropoietic response by the bone marrow)
- Bilirubin—Increased (mostly unconjugated)
- LDH—Increased
- Haptogloin—Reduced to absent

Two main principles for diagnosis:

- First is to confirm the diagnosis of hemolysis
- Second is to determine its etiology

The etiology of hemolytic anemia can be determined by:

- A good clinical history
- The peripheral blood film

Clinical Presentation

- New onset pallor or anemia
- Hemolytic faces—Chipmunk facies
- Jaundice
- Splenomegaly, bossing of skull (in severe congenital cases)
- Gall stones
- Dark colored urine
- Leg ulcers

Features of Hemolysis

- Hemoglobin—Normal to severely reduced
- MCV, MCH—Usually increased
- Bilirubin is raised (mostly unconjugated)
- LDH is raised (up to 10 times of normal with intravascular hemolysis
- Reticulocytes, n-RBC—Raised
- Haptoglobins are reduced to absent
- Urinary hemosiderin, Urobilinogen are +ve

↓

Blood Smear

↓

- Spherocytes—
  - DCT +ve (Autoimmune hemolysis)
  - DCT –ve (*H. Sherocytosis*, malaria, clostridium)
- No spherocytes—Hereditery enzymopathies
- Fragmentation—Microangiopathic, Traumatic

Laboratory Evaluation of Hemolysis

See **Table 3**.

Metabolic Manifestations of Increased Red Cell Turnover

There is significant iron loss (requiring treatment), due to persistent hemoglobinuria because of chronic intravascular hemolysis. If frequent blood transfusions are needed or if erythropoiesis is massively increased then iron overload is very common. This iron overload leads to hemochromatosis affecting liver and heart muscles eventually leading to cirrhosis and heart failure respectively.

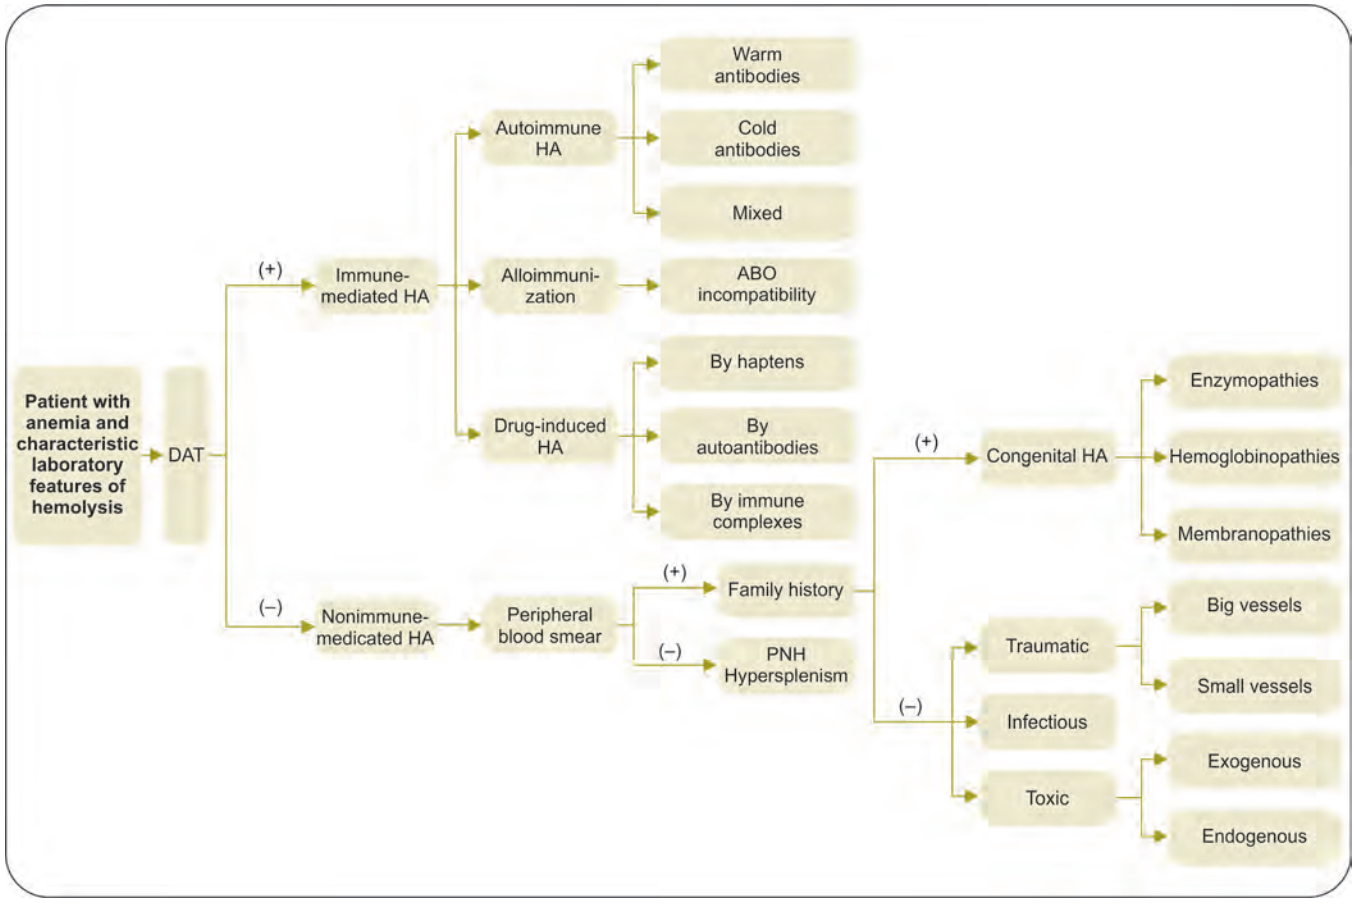
Morphological Abnormalities of RBCs in Hemoltyic Anemias

- Schistocytes—thrombotic microangiopathies or cardiac prosthetic valves
- Spherocytes—hereditary spherocytosis, immune hem. anemia, burns, chemical injury to RBC
- Sickled cells—sickle cell disease
- Elliptocytes—hereditary elliptocytosis
- Echinocytes—pyruvate kinase deficiency
- Heinz bodies—G6PD deficiency
- Basophilic stipplings—thalassemia, Wilson's disease, and lead poisoning

TABLE 3 Laboratory evaluation of hemolysis

	Extravascular	*Intravascular*
Hematologic		
• Peripheral blood film • Reticulocyte count • Bone marrow examination	• Polychromatophilia • Raised • Erythroid hyperplasia	• Polychromatophilia • Raised • Erythroid hyperplasia
Plasma or serum		
• Bilirubin • Haptoglobin • Free hemoglobin • Lactate dehydrogenase	• Unconjugated decreased • Absent • N/increased (Variable)	• Unconjugated • Absent • Increased • Increased (Variable)
Urine		
• Bilirubin • Hemosiderin • Hemoglobin	0 0 0	0 + + → severe cases

Flowchart 1: Approach to identify and classify hemolytic anemias



Red Cell Survival Study

To prove that the life span of RBC is reduced than normal (about 120 days), then the study labeling the red cells with 51Cr can be done and fall in radioactivity over days to weeks can be measured. Nonradioactive isotope 15N can also be used now in place of radioactive substance.

Algorithm for the Evaluation and Diagnosis of Hemolytic Anemia

Anemia—present
Indirect hyperbilirubinemia—present
Reticulocytosis—present

↓

Then look for hemolysis: CBC, reticulocyte count, LDH, indirect bilirubin, haptoglobin, and peripheral blood smear

↓

- *If negative:* Consider alternative diagnosis (other causes of normocytic anemia like chronic kidney disease, hemorrhage, chronic disease)
- *If positive:*
  - Spherocytes, positive DAT **(Flowchart 1)**—Immune hemolysis: lymphoproliferative disorder/malignancy, autoimmune diseases, drugs, infections, transfusion.
  - Spherocytes, negative DAT, family history—Hereditary spherocytosis.
  - Schistocytes—Microangiopathic hemolytic anemia PT/PTT, LFT, KFT, Blood Pressure TTP, HUS, DIC, Eclampsia, Preeclampsia, malignant hypertension, prosthetic valve.
  - Hypochromic microcytic anemia Thalassemia-Hemoglobin electrophoresis.
  - Sickle cells-Sickel cell anemia—Hemoglobin electrophoresis.
  - Infection/drug exposure—G6PD activity.
  - Fever/recent travel—Thick and thin smears, Babesia serology, bacterial cultures.

Conclusion

Hemolytic anemias can be diagnosed on the basis of detailed history, general and physical examination. Laboratory investigations and peripheral smear are helpful to confirm the hemolysis and to guide further tests to look for etiology.

CHAPTER

227 Thalassemia in Adults—Management Issues

Ramesh Aggarwal, Anupam Prakash

Abstract

Beta-Thalassemia can be broadly classified into transfusion-dependent thalassemia (TDT) and non-transfusion-dependent thalassemia (NTDT). The primary management in these patients is regular blood transfusion and adequate iron chelation. Some patients may require splenectomy and hematopoietic stem cell transplantation (HSCT). Majority of the complications arise because of transfusion related iron overload and include cardiac failure, arrhythmias, endocrine complications like hypogonadism, hypoparathyroidism, diabetes, hypothyroidism, delayed growth, osteoporosis, renal complications, and infections. Early initiation of chelation therapy can reverse the process of iron deposition in tissues and salvage or prolong the development of complications. This chapter highlights the challenges which arise in managing patients of beta-thalassemia and summaries the clinical approach in preventing various complications which arise out of iron load in these patients.

Introduction

The disease β-Thalassemia includes many different conditions like β-thalassemia major, β-thalassemia intermedia, and HbE/β-thalassemia. They can be broadly classified into transfusion-dependent thalassemia (TDT), which includes severe forms of HbE/β-thalassemia and β-thalassemia major and non-transfusion-dependent thalassemia (NTDT), which includes thalassemia intermedia and milder forms of HbE/β-thalassemia **(Fig. 1)**. TDT are patients who require regular transfusion of blood to survive whereas NTDT will require blood transfusions in certain conditions like pregnancy, surgery, and infections.[1]

Management

The management of TDT requires regular blood transfusion and adequate iron chelation. In some patients, splenectomy and hematopoietic stem cell transplantation (HSCT) are required. **Table 1** summarizes the current therapies available for TDT.

Complications and Management Issues

Majority of the complications in TDT arise because of transfusion related iron overload and include cardiac failure, arrhythmias, endocrine complications like hypogonadism, hypoparathyroidism, diabetes, hypothyroidism, delayed growth, osteoporosis, renal complications, and infections. Some complications like silent cerebral infarction and pulmonary hypertension are more common in patients with NTDT.

Cardiac Complications

They include cardiomyopathy congestive heart failure, arrhythmias, peripheral vascular disease, and pulmonary hypertension. Persistent hypoxia, high levels of abnormal hemoglobin, and high iron levels in tissues along with

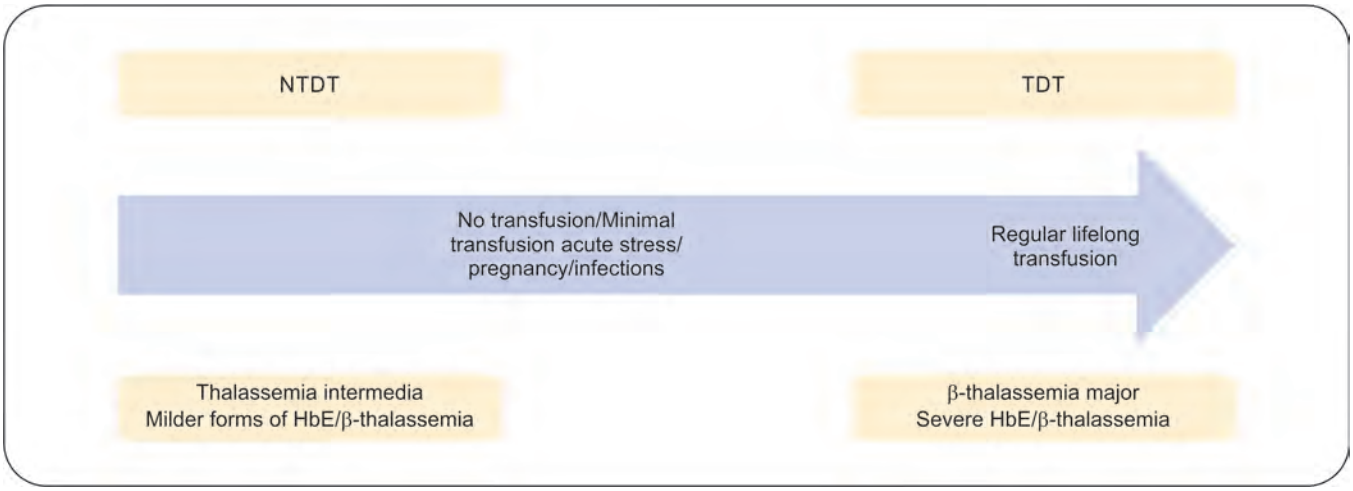

Fig. 1: Classification of thalassemia based on transfusion dependence

TABLE 1 Treatment options for beta thalassemia[2]

Treatment modality	***Merit***	***Demerit***
Blood transfusion	Helps by suppressing ineffective erythropoiesis, prevents bone marrow expansion	• Every 2–4 weeks' transfusion required for life long • Transfusion associated complications like infections, iron overload, and alloimmunization
• Iron chelation • Deferoxamine: Parenteral • Deferasirox: Oral • Deferiprone: Oral	• Decreases iron overload in myocardium, liver, pituitary, etc. • Improves endocrine functions and cardiac health	• May not be effective in every patient • Side effects are common • Parenteral formulation often lead to non-compliance • Cost of therapy is high
Hydroxyurea (It is a cytotoxic antimetabolite that helps to increase fetal hemoglobin levels)	• Some hematological parameters may improve in NTDT patients • Cost of therapy is low	• Lack of clear evidence of its use in TDT
Splenectomy	• The quality of life and growth may improve • It may improve hemoglobin concentration • The frequency of transfusions may decrease	• Risk of infection and sepsis increases • The risk of venous thrombosis and pulmonary hypertension increases • It also reduces the ability to scavenge toxic-free iron species
HSCT	• Treatment of choice for patients younger than 14 years • Others may benefit depending on donor availability and iron load after this age • The survival rate is up to 90% and the disease-free survival rates reaches up to 80% • The quality of life is improved • Long-term cost-effective	• May not be useful for all patients, only a subset of patients qualify for this treatment • Young age • Donor should be a compatible sibling • Risk of 5–10% mortality • Preparation for this treatment requires myeloablative conditioning and can cause impairment of fertility • Highly trained centers are required • Very high cost

HSCT, hematopoietic stem cell transplantation; NTDT, non-transfusion-dependent thalassemia; TDT, transfusion-dependent thalassemia

infection with cardiotropic viruses contribute to initiation and progression of cardiomyopathy in these patients. Presenting features are dyspnea, fatigue, or palpitations.

Cardiomyopathy in thalassemia presents with two different phenotypes:

- Dilated cardiomyopathy where the left ventricle is dilated and contractility is reduced. This progresses to congestive heart failure.
- Restrictive cardiomyopathy where the left ventricle filling is restrictive. This phenotype can lead to pulmonary hypertension, dilatation of right ventricle, and subsequent heart failure.

Measurement of amino-terminal pro-B-type natriuretic peptide is more reliable in early diagnosis than Doppler echocardiography.[3] Cardiac MRI provides better estimate of iron burden than serum ferritin and it has been found to be a better predictor of heart failure and arrhythmia in different studies.[4]

Rhythm Disturbances

They are atrial fibrillation, atrial flutter, intra-atrial re-entrant tachycardia, ectopic atrial tachycardia, and ventricular arrhythmias. Prolonged QT interval and repolarization abnormalities occur because of iron overload leading to torsades de pointes and sudden cardiac death (SCD).[5]

Management

As aggressive iron chelation therapy can restore the functions of myocardium, it should be the goal:

- Asymptomatic patients with no cardiac dysfunction and no deposition of iron in heart: healthy lifestyle and adequate chelation therapy
- Iron deposition in heart but no cardiac dysfunction: healthy lifestyle and intensification of chelation therapy including use of combination therapy
- Cardiac dysfunction with or without symptoms:
  - Healthy lifestyle and intensification of chelation therapy including use of combination therapy
  - Slower transfusion of blood with use of diuretics
  - Use of ACE inhibitors, or ARII blockers
  - Cardioselective beta-blockers like bisoprolol and carvedilol
  - Digitalis if atrial fibrillation is present along with anticoagulation

Endocrine Complications

They include hypogonadism, growth retardation, diabetes mellitus, hypoparathyroidism, and hypothyroidism.[6]

Gonadal Axis

Hypogonadism can be primary (hypergonadotropic hypogonadism) due to iron deposition in gonads or secondary (hypogonadotropic hypogonadism) due to iron affecting the gonadotrophs in anterior pituitary. Secondary hypogonadism is more common in patients with TM. Primary amenorrhea precedes secondary amenorrhea in most women with thalassaemia major. Screening for hypogonadism should be done annually. Careful history should be taken which includes erectile function, libido, spontaneous erections in males and libido, vasomotor symptoms, and menstrual history in females. The patient's genitalia should be examined and loss of secondary sexual characters should be noted.

Investigations:

- Serum fasting testosterone, SHBG, LH, FSH, and hCG in males and estradiol, LH, and FSH in females.

Management:

- *Females:* Treatment is given to relieve from symptoms of estrogen deficiency like sweats, hot flushes, mood changes and vaginal atrophy. Hormone replacement therapy (HRT) is helpful to overcome them and prevent osteoporosis.
- *Males:* Testosterone replacement in the form of transdermal gel or intramuscular injections every 2 weekly helps to improve libido, erectile dysfunction, and may improve bone mineral density and muscle mass.

Growth Hormone Axis

Many factors contribute to delayed growth in patients, which are iron overload, chronic anemia, hypersplenism, hypothyroidism, hypogonadism, chronic liver disease, malnutrition, stress, and growth hormone (GH) deficiency. GH deficiency is common in patients with TM and results in short stature and delayed growth. GH deficiency can have varied presentations like classic GHD, GH resistance or a combination of both.[7] Clinical Assessment should

be done preferably at regular interval of 6 monthly. It includes:

- Patient's height (standing and sitting) and weight
- Measurement of upper/lower segment ratio and calculation of BMI and annual growth velocity (GV)
- Recording of parental heights at the first visit (calculate mid-parental height)
- Accurate measurement of standing and sitting heights, weight, and head at each visit; measurement of the head circumference especially during the first 2 years of life
- Plotting growth data on ethnically adjusted charts or international (WHO) adjusted charts
- Calculating annual growth velocity (GV), body mass index (BMI), and upper/lower segment ratio at every visit
- Assessment of pubertal status as per Tanner stage (development of breast in girls and testicular volume in boys)
- Assessment of bone age

Investigations:

- Serum IGF-1, Serum TSH, and free T4, LH, FSH, and sex steroids along with X-ray of wrist and hand for bone age.

Treatment:

- Children who are short with low IGF-1 levels and normal GH secretion to stimulation tests may benefit from IGF-1 or GH-IGF-1 treatment.
- If the bone age is 10 years or greater, then priming with sex steroids is done before initiating any treatment for GH deficiency.
- Treatment of other diseases like diabetes and hypothyroidism has to be done simultaneously.
- There must be psychological evaluation and support for conditions that are non-treatable like constitutional delay of puberty and growth, familial short stature, etc.
- Treatment with rhGH should start with low doses and then titrated according to IGF-1 levels and growth rate.

Adrenal

Patients with thalassemia are often asymptomatic for adrenal insufficiency and may have only biochemical evidence. A study of 56 children suffering from thalassemia had shown presence of adrenal insufficiency in about 37.5% asymptomatic patients.[8] Acute stress can precipitate adrenal insufficiency and symptoms can be feeling of lack of energy, fatigue, decreased appetite, and muscular weakness. Adrenal androgen deficiency can sometimes lead to decreased pubic and axillary hairs.

Investigations:

- Serum cortisol level, adrenocorticotropic hormone (ACTH) stimulation test or rarely insulin stimulation test (ITT) can be done to assess adrenal insufficiency.

Treatment:

- Acute adrenal crisis is not common in these patients, and hence steroids should not be used routinely to cover asymptomatic individuals. Glucocorticoids can be used in acute stressful conditions.[9]

Thyroid

Primary hypothyroidism is present in 4–29% of patients with TDT and is much common than central or secondary hypothyroidism.[10] Prevalence of hypothyroidism is directly proportional to iron load. With the increase in serum ferritin the prevalence of hypothyroidism increases. Also hypothyroidism is more frequent in splenectomized patients than non-splenectomized patients. The reason may be because of the fact that intact spleen acts as reservoir of excess iron and functions as a scavenger for free iron fraction.

Classification of hypothyroidism:

- *Sub-biochemical hypothyroidism:* The response to TRH test is exaggerated and TSH and FT4 are normal.
- *Subclinical hypothyroidism:* The TSH is high (>4.2 mIU/L and <10 mIU/L) and FT4 levels is normal.
- *Overt (clinical) hypothyroidism:* The TSH is high (TSH >10 mIU/L) and FT4 is low.

Investigations:

- Assessment of serum-free T4 and TSH should be done annually from the age of 9 or earlier if hypothyroidism is suspected. For early diagnosis, TRH stimulation test can be used. In patients with iron overload, there is exaggerated TSH response to TRH, which may evolve into subclinical or clinical hypothyroidism. In clinical hypothyroidism, there are the FT4 and basal TSH gradually decrease over time.

Treatment:

- Early detection and adequate chelation therapy may reverse the thyroid dysfunction. Patients with overt hypothyroidism are treated with L-thyroxine.

Hypoparathyroidism

It is an uncommon and a late complication in TM patients. Deposition of iron in parathyroid glands results in hypoparathyroidism. Hypocalcemia and paraesthesia occur in mild cases and severe cases may present with tetany and seizures.

Investigations:

- Measurement of calcium, phosphate and parathyroid hormone (PTH) levels should be done. In hypoparathyroidism there is low serum calcium, high phosphate, and low PTH levels.

Treatment:

- Supplementation with calcium and vitamin D is done. Calcitriol 0.25 μg twice daily brings the calcium and phosphate levels to normal. In some patients with high phosphate levels, phosphate binders may be used. In severe hypocalcemia, tetany, and cardiac failure, intravenous calcium has to be given.

Thalassemia Bone Disease

Patients with thalassemia can suffer from bone diseases, which include osteopenia, osteoporosis, bone deformity and fractures.[11] Risk factor for bone disease in these patients includes concurrent presence of hypogonadism and deficient growth hormone. Other contributory factors include chronic anemia and marrow expansion, chelator toxicity, hypercalciuria, and renal dysfunction from deferasirox, liver disease, and advancing age.

Investigations:

- Serum calcium, serum phosphorus, alkaline phosphatase, and 25-hydroxy vitamin D
- PTH, LH, FSH, testosterone levels
- Osteocalcin
- C-terminal telopeptide
- 24-h urinary calcium
- X-ray of spine (AP and lateral views)
- MRI spine: to exclude an intervertebral disc degeneration
- Dual-energy X-ray absorptiometry (DEXA) scan for assessing bone mineral density (BMD)

Treatment:

- Treatment with calcium and vitamin D can be started although there is not much evidence of improvement in BMD.
- Bisphosphonates like zoledronic acid have the advantage of intravenous administration and longer duration of action lasting more than 12 months and should be initiated earlier.
- Other drugs helpful in bone disease include teriparatide, denosumab, and zinc.

Glucose Intolerance and Diabetes Mellitus

Patients with thalassemia are susceptible to develop diabetes. The etiology is multifactorial including genetic predisposition, β-cell destruction because of iron overload, insulin resistance, insulin deficiency, chronic liver disease, and viral infections. Initially patients may present with impaired glucose tolerance because of insulin resistance and later develop insulin deficiency. Some characteristics of insulin dependent diabetes in thalassemics are:

- Ketoacidosis is an uncommon presentation
- Islet cell antibodies are usually negative
- HLA haplotypes like DR4, B8-DR3, and BW15 have no association

Investigations:

- Fasting blood sugar levels, 2-h oral glucose tolerance testing (OGTT) and measurement of insulin levels should be started at the age of 10 years. HbA1c is altered in hemoglobinopathy and cannot be used as a reliable marker for monitoring. Instead serum fructosamine levels may be used for monitoring long term glycemic control.

Treatment:

- Dietary counseling and weight reduction in metabolically obese patients.
- Chelation therapy should be more intensive. There is increase in insulin secretion and decrease in insulin resistance with intensive chelation therapy.
- Data on use of oral antidiabetic drugs is limited. Insulin is needed in late presentation and complications.

Conclusion

The management in thalassemia requires a team effort and a multidisciplinary involvement. Management of TDT mainly depends on lifelong transfusion therapy. The complications arise because of the iron deposition in various organs and infections from frequent blood transfusions. It has been proven in studies that early initiation of chelation therapy can reverse

Contd...

Contd...

the process of iron deposition in tissues and salvage or prolong the development of complications. Pregnancy, fertility, and psychosomatic stress are other associated issues in managing patients of thalassemia and require treatment for enhancing quality of life in these patients.

Approach to Thrombocytopenia

Avinash Kumar Singh, Divya Krishna, Gautam Kumar Rakesh, Bhupendra Kumar

Abstract

Thrombocytopenia is a common medical problem encountered by physicians in their day-to-day OPD as well as IPD practice. Anxiety is at peak for patients as well as young physicians when dealing with case of severe thrombocytopenia. Thorough history, physical examination, and directed investigations lead to correct cause and resolution of thrombocytopenia. Causes range from benign disease like ITP and megaloblastic anemia to serious diseases like leukemia, lymphoma, and TTP. Drugs are culprit in many cases and sometimes misleading drug history leads to unnecessary battery of tests. Once properly diagnosed, correct and timely treatment can resolve thrombocytopenia. Platelet transfusion is not always required and should be reserved for severe thrombocytopenia or with bleeding patients.

Introduction

By the time you shall be reading this chapter, we hope that world will be on the path of recovery from COVID pandemic crisis and message like "stay safe" will be less frequently used.

Thrombocytopenia is a common medical problem encountered by physicians in day-to-day practice. It creates panic among general people as well as practicing physicians, which is not always justified.

We will describe how to approach a case of thrombocytopenia with brief about treatment options of common diseases.

Thrombocytopenia is defined as a platelet count below the 2.5th lower percentile of the normal platelet count distribution. Results of the third US National Health and Nutrition Examination support the traditional value of 150×10^9/L as the lower limit of normal; however, counts between 100×10^9/L and 150×10^9/L do not necessarily indicate disease if they have been stable for more than 6 months, and the adoption of a cut-off value of 100×10^9/L may be more appropriate to identify a pathologic condition.[1-3]

Low Platelets—How Serious It is?

Platelets play an important role in vessel wall integrity and so low platelet leads to primary hemostatic defects. Its relevance in an individual patient is variable and depends upon the clinical presentation.

Clinically significant bleeding does not occur unless platelets are less than $10–20,000 \times 10^9$/L, while mild to moderate thrombocytopenia becomes significant when there is additional bleeding risk like surgery, trauma or when higher cut-off to be met as when treatment for hepatitis C or chemotherapy is indicated.

In some situation, finding of thrombocytopenia points toward serious disease like HIV or Myelodysplastic syndrome and also sometimes it indicates disease activity like in thrombotic thrombocytopenic purpura (TTP).

How Important is Setting of Thrombocytopenia?

In OPD settings, mostly thrombocytopenia is isolated and asymptomatic and diagnosis is straight forward while in inpatient, or in ICU settings, multisystem

TABLE 1 Clinical scenario and most common causes of thrombocytopenia

Outpatient	*Inpatient*		
ITP	***Multisystem illness/ICU***	***Cardiac***	***Pregnancy/Postpartum***
DITP	Infections	HIT	GT
Infections: HIV, Hep C, CMV, H. Pylori, Dengue, and other recent viral infection	DITP	Cardiac bypass	ITP
Connective tissue disorder	TTP/HUS	GP IIB/IIIA inhibitors	HELPP syndrome
Vaccinations	DIC	DITP	Pre-eclampsia
Congenital thrombocytopenia	Liver disease/BM disorders	Dilutional	TTP/HUS
Common variable immunodeficiency disease	HIT		
MDS	MAS		
	CIT		

CIT, chemotherapy-induced thrombocytopenia; DITP, drug-induced ITP; MAS, macrophage activation syndrome; MDS, myelodysplastic syndrome.

involvement leads to thrombocytopenia and diagnosis and management is sometimes challenging **(Table 1)**. Pregnancy with thrombocytopenia has to be approached differently as it has significance in the care for mother as well as the newborn.

A structured approach involves clinical details and support of lab along with other medical disciplines.

Mechanism of Thrombocytopenia

Major mechanism of thrombocytopenia is reduced production as in aplastic anemia, Myelodysplastic syndrome (MDS), or chemotherapy induced thrombocytopenia and platelet destruction as in disseminated intravascular coagulation (DIC) or TTP.

Less common mechanism is platelet sequestration as in congestive splenomegaly and hemodilution as in excessive fluid or platelet poor component transfusion.

There are conditions like ITP and hepatitis C, where multiple mechanisms play role.

History and Physical Examination—How does it Help in Evaluation?

As for any medical disorder history is very important for thrombocytopenia evaluation and question should be directed toward bleeding history, associated symptoms like fever, jaundice, joint pain, medication history, dietary habits, addiction and history to rule out autoimmune disease and malignancy.

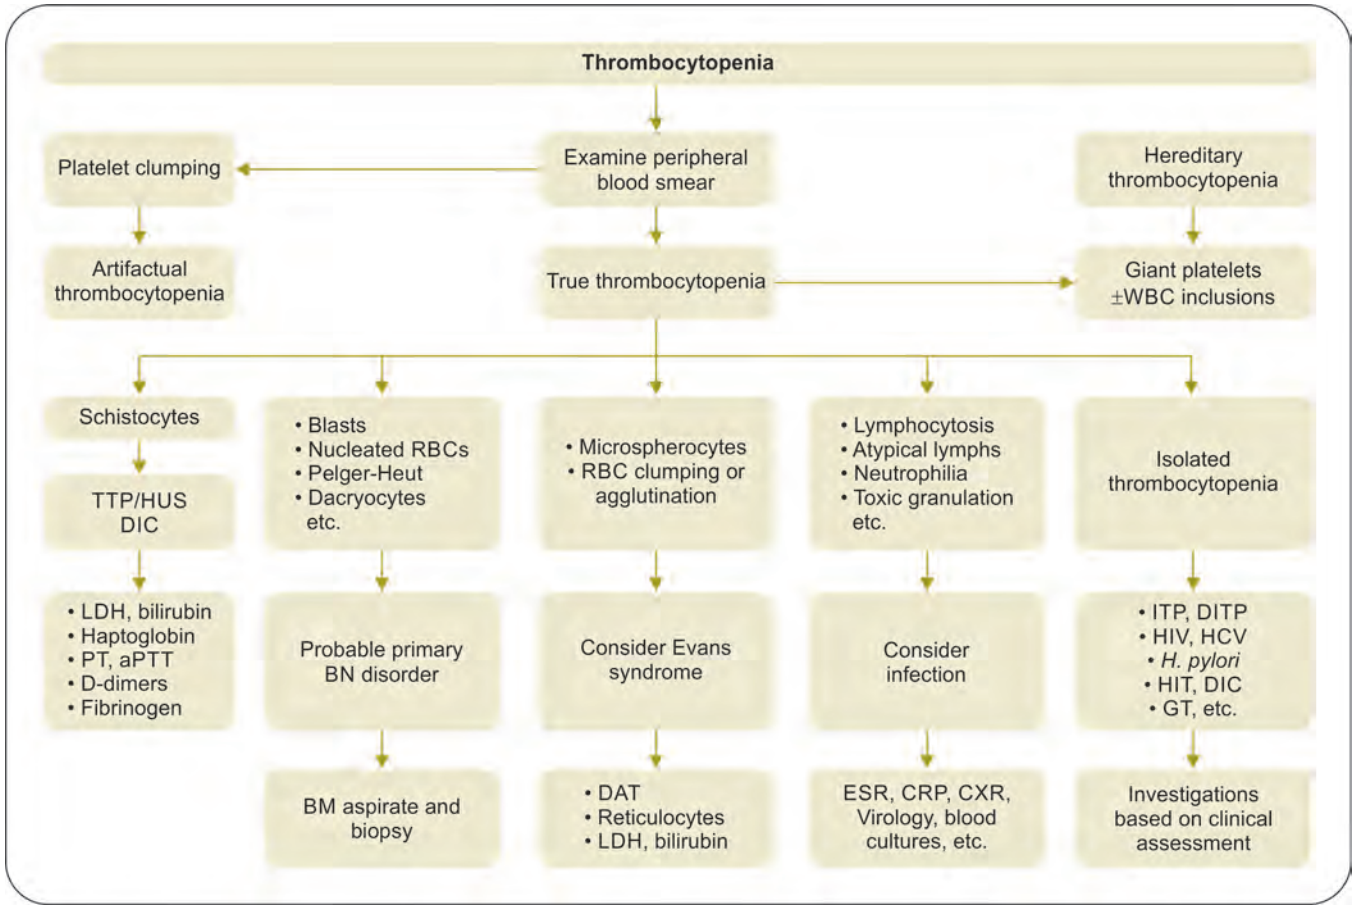
Physical examination should be directed to look for bleeding, organomegaly, or skeletal abnormality.

Lab Investigations—What Battery of Tests Required?

Even today, initial and basic investigation for thrombocytopenia evaluation is complete blood count (CBC) and peripheral smear. Routine tests, like liver function and renal function test, are always required. Chest X-ray is required to look for focus of infection and mediastinal mass and USG abdomen is done to look for any evidence of chronic liver disease or lymphadenopathy. Autoimmune workup is required in suspected cases to rule out SLE/APLA syndrome. Infective workup is required in patients who present with classical features. Immature platelet fraction or reticulated platelets help in differentiation from bone marrow failure (low percentage) and hyper-destructive thrombocytopenia (higher percentage).[5,6] **Flowchart 1** shows algorithm for thrombocytopenia on the basis of peripheral blood smear findings.[7]

Artefactual thrombocytopenia and conditions like Harris platelet syndrome are not so rare problem encountered in our clinical practice and it has huge psychological impact on the patient, their immediate care giver, and physicians.[8] They need only counseling that they should not worry and need no intervention. We will discuss common conditions leading to thrombocytopenia in our practice.

Flowchart 1: Algorithm for the workup of thrombocytopenia based on peripheral blood smear finding



Isolated Thrombocytopenia

It is defined as thrombocytopenia in the absence of RBC or WBC abnormality and without signs or symptoms of systemic illness. Common examples are ITP and D-ITP.

Immune Thrombocytopenia (ITP)

(terms idiopathic and pupura have been removed)

Even being the commonest cause of isolated thrombocytopenia, there is no single test, which confirms ITP as diagnosis and it remains a diagnosis of exclusion. **Box 1** lists all blood investigations in a suspected case of ITP. Antiplatelet antibody assay is not very sensitive, but specificity approaches 90%. **Table 2** enumerates morphologic features and pointers towards different causes of thrombocytopenia. Bone marrow is not required unless patients are more than 60 years or with atypical features.

BOX 1 List of basic tests required as per international consensus report[4]

- Complete blood count
- Peripheral blood smear
- Reticulocyte count
- Quantitative Ig level measurement
- BM examination (in patients >60 years)
- Blood group (Rh)
- Direct antiglobulin test
- *H. pylori*
- HIV
- HCV

ITP patients are divided into newly diagnosed (thrombocytopenia is of less than 3 months duration), persistent (thrombocytopenia extends from 3 months to

TABLE 2 Showing morphological findings on PBS in different causes of thrombocytopenia

Platelets
• Platelet clumping – Platelet clumping caused by EDTA-dependent platelet autoantibodies is a common cause of artifactual thrombocytopenia. It occurs in about 1 in 1000 nomral adults and is not associated with bleeding or thrombosis
• Platelet size and granularity – Consistently large platelets suggest hereditary macrothrombocytopenia. Large platelets with a gray color on Wright-Giemsa stain define the gray platelet syndrome, an autosomal-dominant macrothrombocytopenia associated with bleeding tendency due to absent or greatly reduced α-granules – In thrombocytopenia due to peripheral destruction, large platelets or giant platelets are often seen in addition to platelets of normal size – When thrombocytopenia is due to reduced platelet production (e.g., after chemotherapy), platelets are of normal size. In myelodysplasitc syndromes, platelets have variable size (giant platelets may be seen) and are frequently hypogranular. In Wiskott-Aldrish syndrome, and X-linked thrombocytopenia, both cuased by mutations of the WAS gene, platelets are smale
WBCs
• Leukemic cells – Malignant hematological disorders (leukemias and lymphomas) are often associated with thrombocytopenia, which is almost never an isolated finding – Other abnormalities of WBCs, including leukocyte inclusions ♦ A constellation of nonspecific abnormalities of WBCs are common to many conditions (e.g., neutrophilia, lymphocytosis, leukopenia, etc.) and may be associated with thrombocytopenia. The presence of hypolobulated neutrophilis (Pelger-Huet anomaly) suggests a myelodysplastic syndrome. Dark coarse granules (toxic granulations) found in neutrophils suggest sepsis. Atypical lymphocytes suggest viral infection. The presence of WBC inclusion (Dohle-like bodies) should be investigated carefully when platelets are mostly large (MYH9-related congenital macrothrombocytopenia)
RBCs
• Schistocytes – The presence of RBC fragments known as schistocytes is indicative of a thrombotic microangiopathy (TTP/HUS) or DIC
• Size and other morphological features. – Microspherocytes may suggest Evans syndrome, but may also be present along with chistocytes in thrombotic microangiopathies. Macrocytosis (and hypersegmentation of neutrophils) suggest vitamin B12 or folate deficiency. Dacryocytes (teardrop-shaped cells) suggest myelofibrosis. Nucleated RBSc suggest hemolytic anemia, myelofibrosis, or an inflitrative process of the BM
• Parasites – The presence of intracellular parasites (e.g., in malaria) is diagnostic of infection

12 months), and chronic when thrombocytopenia is for more than 1 year.

In ITP patients with emergency (intracranial bleed, massive GI bleed) IVIG, High dose methylprednisolone, and anti D (in Rh positive patients) are options.

For asymptomatic or patients with minor bleeding, observation and local bleeding control are best options, as most of the morbidity in ITP patients are due to treatment than due to low platelet count. Good counseling can reduce need of drugs and give better quality of life to patients. It is important to explain to patients that even with very low platelets, severe or life threatening bleeding is rare in ITP.

Options in symptomatic patients are steroid (short course), immunosuppressants (azathioprine, MMF), Dapsone, MAB (rituximab), Thrombopoietin mimetic (wltrombopag, romiplostim), and splenectomy. Other less commonly used options are danogen, vincristine, cyclosporine, and cyclophosphamide.

Drug-induced Immune Thrombocytopenia (D-ITP)

The list of drugs leading to thrombocytopenia is ever increasing one. The pathophysiological mechanism of D-ITP is due to formation drug dependent antibody against epitope of platelet glycoprotein created by their interaction with the drug.

Sometimes D-ITP can be confused with ITP, and only good history can help to differentiate.

Diagnosis often is difficult as sometimes not only drug but even food and beverages can lead to thrombocytopenia.

Diagnosis is mostly empirical with recovery of platelet count after discontinuation of drug. Lab diagnosis is by demonstration of drug dependent antibody by various methods.

An overall score of 5 or more is compatible with overt DIC. A score less than 5 is suggestive of non-overt/low-grade DIC.

Thrombocytopenia in Hospitalized Settings

Approximately 1% of admitted patients in acute care hospital are thrombocytopenia but only 30% of them have bleeding manifestation.[9] As expected it is more common in ICU, where 8–68% are thrombocytopenic on admission and 13–44% during stay in the unit.[10] Many potential etiologies like sepsis, DIC, drugs, CABG coexist and it is often difficult to elucidate cause of thrombocytopenia ITP should always be considered as it is seen in about 20% of these and antibiotics are the major culprit.[11,12] Discontinuation of such drug should always be based on clinical criteria.[13]

Disseminated Intravascular Coagulation

DIC is a consumptive coagulopathy characterized by activation of intravascular coagulation with microvascular thrombi formation, thrombocytopenia, depletion of clotting factors, bleeding complications, and end organ damage. It can be acute or chronic. International society on thrombosis and hemostasis divides DIC into overt (decompensated hemostatic system) or non-overt (compensated coagulopathy).[14]

Acute DIC is seen in sepsis, septic shock, after trauma (neurotrauma), after surgery, after obstetric complications and in APML. Chronic DIC is seen in solid tumors and large aortic aneurysm. **Table 3** enumerates factors and scoring to diagnose overt or non-overt DIC.

Thrombocytopenia in Cardiac Patients

Open heart surgery is an important cause of thrombocytopenia in cardiac patients. Nadir is typically seen on days 2–3 and recovery starts rapidly thereafter. Causes of low platelet after surgery are multiple.

Severe thrombocytopenia has been observed in 0.1–2% of patients after exposure to gp IIb/IIIa inhibitors (abciximab, tirofiban, eptifibatide). Peculiarity is sudden onset, usually within hours after surgery, and used to resolve by day 10. This has been attributed to presence of naturally occurring antibody to neoepitopes exposed by gp IIb/IIIa inhibitors.[15]

HIT—It occurs in 1–3% of patients receiving heparin beyond the first postoperative week and in 10% of patients after ventricular assist device implantation.[16,17] 4T described in **Table 4** helps in diagnosis of heparin induced thrombocytopenia.[18]

Pregnancy with Thrombocytopenia

About 6–15% of women develop thrombocytopenia (<1.5 lakhs/mm^3) at the end of pregnancy but platelets less than 1 lakh/mm^3 are seen in only 1% of patients. Most common cause of thrombocytopenia is gestational thrombocytopenia (GT) (70%), preeclampsia (21%) ITP (3%).[19,20]

Gestational Thrombocytopenia (GT)

GT is seen in mid second to third trimester of pregnancy and it is extreme variation of normal physiological fall of platelet count. Platelet count usually remains above 70 k/mm^3 and if falls to lower than 70 k, then alternative diagnosis should be considered. Diagnosis is

TABLE 3 Diagnostic score of DIC

Parameters	*0*	*1*	*2*	*3*
Platelet count	>100 × 10^9	50–100 ×10^9	<50 × 10^9	
Elevated fibrin degradation products	No increase		Moderately increase	Strong increase
PT more than ULN	<3S	>3S	>6S	
Fibrinogen	>1 gm/L	<1 gm/L		

TABLE 4 The 4Ts pretest probability of heparin-induced thrombocytopenia

	*Points**		
4Ts	***2***	***1***	***0***
Thrombocytopenia	Platelet count decrease >50% and platelet nadir >20 × 10^9/L	Platelet count decrease 30–50% or platelet nadir >10–19 × 10^9/L	Platelet count decrease <30% or platelet nadir <10–19 × 10^9/L
Timing of platelet count decrease	Clear onset between d 5 and 10 or platelet decreases ≤1 d (prior heparin exposure within 30 d)	Consistent with d 5–10 decrease, but not clear (e.g., missing platelet counts); onset after d 10; or decreases ≤1 d (prior heparin exposure 30–100 d ago)	Platelet count decrease <4 d without recent exposure
Thrombosis or other sequelae	New thrombosis (confirmed); skin necrosis; acute systemic reaction post intravenous	Progressive or recurrent thrombosis; non-necrotizing erythematous) skin lesion; Suspected thrombosis (not proven)	None
Other causes for thrombocytopenia	None apparent	Possible	Definite

Pretest probability socre: 6–8, high; 4–5, intermediate; 0–3 low.
*0, 1, or 2 for each category with a maximum possible score of 8.

by excluding other causes and there may similar history of thrombocytopenia in previous pregnancy and fetus/newborn remains unaffected (normal platelet) and recovery takes 1–2 months after delivery.

ITP in Pregnancy

ITP in pregnancy is seen in about 1–2 of 1,000 pregnancies. It is the most common cause of thrombocytopenia in first and early second trimester. One third of patients are diagnosed first time during pregnancies and rest has history of ITP.

Differentiating GT from ITP is difficult and it is more important for neonatal management as 9–15% of neonates of ITP mother can have thrombocytopenia and 1–2% can have intracranial hemorrhage.[21]

Whenever platelet is less than 50 k/mm^3, diagnosis is ITP by default, though as in medicine always it should be correlated in clinical context.

COVID-19 and Thrombocytopenia

SARS-CoV-2 leading to present COVID-19 pandemic present commonly with fever, cough, and breathlessness. Common abnormality in hematological parameters includes leukopenia, lymphocytopenia, and thrombocytopenia. Thrombocytopenia is seen in about 5% of patients at admission and overall about 36% of patients showed thrombocytopenia, most of which are significant in severe cases. The proposed mechanism is multifactorial due to cytokine storm, direct hematopoietic stem cell injury, increased autoimmune destruction and lung injury.[22-25]

Bleeding due to thrombocytopenia is rarely seen.

What are the Indications, Dosing of Platelet Transfusion?

- Any patient with bleeding due to thrombocytopenia or severe thrombocytopenia (less than 30 k/mm^3 even without bleeding) or patient with moderate thrombocytopenia (30 k to 1 lakh/mm^3) and due for surgery or has other associated bleeding risk need platelet transfusion.
- Higher threshold (more than 1 lakh/mm^3) is required for patients with life threatening bleeding (ICH) or planned for neurosurgery or ophthalmic surgery.
- Exact cut-off depends upon primary disease leading to thrombocytopenia.
- In aplastic anemia and acute leukemia, platelet transfusion should be done when platelet count is less than 10 k/mm^3 without fever and less than 20 k with fever, for APML threshold is higher due to excess bleeding risk.
- Disease like TTP and HIT are conditions where platelet transfusion is always avoided and common disease like ITP rarely needs platelet transfusion.
- Physicians should think twice before ordering for platelet transfusion in asymptomatic thrombocytopenia patients.

- Dose for adult patient is single donor platelet or 6 unit random donor platelet (1 RDP per 10 kg). One SDP leads to increase of platelet by 40–50 k and RDP increase platelet by 5–10 k unless reasons for platelet refractoriness are absent.

Conclusion

Thrombocytopenia is a common problem encountered by physicians in day-to-day in IPD as well as OPD practice. Common causes are ITP, D-ITP, and infections. Good history, physical examination, and directed investigations can lead to correct diagnosis of thrombocytopenia.

Delay in diagnosis and blind treatment leads to unnecessary intervention in many patients, which should always be discouraged. Platelet transfusion is required in emergency cases and should not be misused, just to overcome fear and anxiety of low platelet.

We thank our patients for having faith on us and giving us opportunity to understand "thrombocytopenia" and all supporting staff including nurses who help us in patient management.

CHAPTER

229 Management of CML in Resource-limited Settings

Hemant Malhotra, Naveen Gupta, Ajay Yadav

Abstract

After the development, testing and global availability of BCR/ABL targeted tyrosine kinase inhibitors (TKIs), the prognosis of patients with CML in the chronic phase has improved to point that the majority of patients can expect a multi-decade survival which is now close to that of age and sex matched subjects without the disease, at least in the developed world. However, the situation in the low- and middle-income countries (LMIC), like India, may not be as encouraging. Many hematological cancers in developing countries, including CML, have subtle and not so subtle differences in incidence, age of onset, stage at presentation, phenotype, stage-for-stage response rates, and prognosis as compared to their counterparts in the developed world. Several reasons have been postulated for this and these include; socioeconomic factors, genetic differences, environmental factors (infections, particularly, viral infections, exposure to pesticides, etc.), nutritional factors and factors related to availability of drugs, means for monitoring the disease and option for the use of second generation agents. Generic first generation TKIs (imatinib) and also second generation ones are available in many parts of the world but several challenges still remain in providing optimal treatment to the patients with CML in resource-poor countries. These include availability of optimal and high-quality BCR/ABL testing, availability and cost of second and third generation TKIs (nilotinib, dasatinib, bosutinib, and ponatinib) and hematopoietic stem cell transplantation, compliance and toxicities of drugs and ensuring minimal standard-of-care treatment and monitoring for each and every patient diagnosed with CML. Some of these issues will be reviewed and highlighted in this article.

Introduction

Chronic myeloid leukemia (CML) is a clonal hematopoietic disorder of a pluripotent stem cell that leads to increased proliferation of cells of the myeloid lineage. Its hallmark is the presence of reciprocal translocation between the long arms of chromosomes 9 and 22, t(9;22)(q34;q11), which brings the BCR (breakpoint cluster region) gene into proximity to the ABL1 (Abelson murine leukemia viral oncogene homolog 1) gene, forming a new fusion chimeric gene—BCR-ABL1—which is the oncogene responsible for the pathogenesis of the disease.[1] The truncated chromosome so formed is termed the Philadelphia chromosome, owing its name to the city where it was first described.[2]

Our understanding of the pathophysiology of this disease led to the development of targeted therapies in the form of tyrosine kinase inhibitors, which have a specific action to inhibit the BCR-ABL1 fusion oncogene. The agents were rightly dubbed "magic bullets" and revolutionized the practice of oncology. They have led to a paradigm shift in the management of CML, and now most patients with newly diagnosed disease can look forward to a multi-decade survival as opposed to the 4–5 years survival in old times.

In this chapter we have discussed the practical aspects of usage of these agents with special focus on optimum use in a setting of resource constraints.

Clinical Features, Diagnosis, and Risk Stratification

A significant proportion of patients are nowadays detected in asymptomatic stage with incidentally detected leukocytosis. Patients in more advanced stages of the disease present with signs and symptoms of gross splenomegaly (abdominal fullness and discomfort with feeling of early satiety), symptomatic anemia, and constitutional symptoms like fever, fatigue, or weight loss. Hemogram shows leukocytosis, which may be accompanied with thrombocytosis and/or anemia. The differential leukocyte count shows prominence of immature precursors of the granulocytic series, like myelocytes and metamyelocytes. Circulating blasts are also seen. Basophilia is a consistent feature. The absolute eosinophil and monocyte counts are usually increased, although the percentages are not elevated. Small numbers of nucleated red blood cells and mild reticulocytosis may be seen. Clinical chemistry may reveal hyperuricemia and hyperuricosuria, elevated serum lactate dehydrogenase (LDH), increased serum vitamin B12-binding capacity, and increased serum B12 levels. Low or absent neutrophil alkaline phosphatase activity is seen in 90% of patients.

Bone marrow (BM) examination usually shows marrow hypercellularity up to 75–90% with marked increase in myeloid precursors. Blasts usually represent less than 5% of cells in CP CML. Presence of more than 10% blasts indicate transformation to AP. Megakaryocytes may be hypolobated and typically dwarf forms are seen.

The definitive diagnosis of CML is established by demonstrating the presence of the characteristic translocation and its resultant transcript. This can be done by conventional cytogenetics, fluorescence in situ hybridization (FISH) or by polymerase chain reaction (PCR).

The disease has a triphasic clinical course through chronic phase (CP), accelerated phase (AP), and blast phase (BP).[1] Without treatment, the disease inevitably progresses from CP to AP/BP, which have high morbidity and mortality. Risk stratification helps in predicting survival and it can be done using the Sokal score[2] or ELTS score.[3]

Treatment

The standard goals of therapy were relief of symptoms and prevention of progression of the disease. The classical understanding was that treatment has to be continued lifelong for continued suppression of the BCR-ABL1 transcript. But with tyrosine kinase inhibitors (TKIs), we have managed to achieve such deep suppression of the disease activity that it is possible in a certain cohort of patients to discontinue TKI after a few years and attain a state of treatment-free remission (TFR) and in fact, TFR has now become one of the standard goals of therapy.[4,5]

Tyrosine Kinase Inhibitors

TKIs are orally administered agents, which act by binding to the ATP binding site in the BCR-ABL1 protein and inhibit its kinase activity. These agents are able to provide much deeper and sustained responses and can provide near normal life expectancy in a large proportion of patients. Imatinib was the first TKI approved for the use in CML after showing markedly better results than the previous standard therapy of interferon plus low dose cytarabine in the pivotal IRIS trial.[6] Acquired mutations in the kinase domain can render imatinib ineffective in certain proportion of cases. Second generation TKIs, which include nilotinib, dasatinib, and bosutinib, can be effective in such a setting. These agents are also approved as first line agents where they have demonstrated superior activity than imatinib with respect to rapidity and depth of response, although survival outcomes are similar (ENESTnd,[7] DASISION,[8] and BFORE[9] trials). The T315I is a unique mutation that renders the disease resistant to all four of these TKIs. The 3rd generation TKI ponatinib is effective in such cases.[10] These TKIs are summarized in **Table 1**.

Monitoring Response to Therapy

Initiation of therapy leads to resolution of symptoms, splenomegaly, and normalization of blood counts. Complete blood count (CBC) needs to be monitored every 2 weeks till a state of complete hematological response is noted. Subsequent depth of response is monitored using techniques that detect the characteristic chromosomal translocation using karyotyping or FISH or by detecting the BCR-ABL1 transcript using PCR. Monitoring using PCR based assays is the current gold standard as it allows for detection of minute quantities of the transcript, and hence responses can be monitored to a degree of depth, which is not possible by any of the other techniques.

There can be dramatic variations in the absolute transcript value across laboratories and standardization

TABLE 1 Tyrosine kinase inhibitors for CML

Generation	***Imatinib***	***Nilotinib***	***Dasatinib***	***Bosutinib***	***Ponatinib****
	1st	***2nd***	***2nd***	***2nd***	***3rd***
Dose (1st line/ 2nd line)	400 mg OD	300 mg BD/400 mg BD	100 mg OD/70 mg BD	400 mg OD/500 mg OD	45 mg OD (May initiate at lower dose)
Adverse effects	• Myelosuppression • GI intolerance • Fatigue • Edema • Skin changes • Muscle cramps	• Myelosuppression • Hyperglycemia • Hepatotoxicity • Cardiotoxicity • Pancreatitis	• Myelosuppression • Pleural effusion • Pulmonary hypertension	• Diarrhea • Myelosuppression • Raised ALT	• Thrombotic events • Hypertension • Arrhythmias
Sensitive kinase domain mutations	None	F317L/V/I/C, T315A, V299L	Y253H, E255V/K, F359V/I/C	F317L/V/I/C, T315A, Y253H, F359V/I/C	All mutations including T315I

*Not available in India at the time of writing.

TABLE 2 Response definitions

Test	***Frequency of monitoring***	***Definition of response***
Clinical examination and complete blood counts	Every 15 days until CHR, then every 3 monthly unless otherwise required	Complete hematological response: • Platelets ≤450 × 10^9/L • WBC count ≤10 × 10^9/L • Differential without immature granulocytes and with ≤5% basophils and • Non-palpable spleen
BCR-ABL1 quantitative PCR (ratio of transcript/ housekeeping gene expressed on IS)	Three monthly	• Major Molecular Response (MMR): ≤0.1% • MR^4: ≤0.01% • $MR^{4.5}$: ≤0.0032% • MR^5: ≤0.001% • Deep molecular response (DMR)—MR^4 or deeper • Molecularly undetectable leukemia—Undetectable BCR-ABL1 mRNA transcripts
Cytogenetics (chromosome banding analysis of bone marrow metaphase cells)	Alone not sufficient for monitoring To be done in patients with atypical translocations, atypical transcripts of BCR-ABL1 not quantifiable by PCR, at failure or progression to document ACA	• Complete (CCyR): No Ph^+ chromosome • Partial (PCyR): 1–35% Ph^+ metaphase • Minor (mCyR): 36–65% Ph^+ metaphase

techniques are employed in order to homogenize the results. The BCR-ABL1 transcript value is described as a ratio of the transcript value to that of a housekeeping gene like ABL1 or GUSB. This ratio is further converted to the International scale (IS). The baseline 100% was defined as the median transcript value measured in 30 pooled samples of patients of newly diagnosed CML CP enrolled in the IRIS trial. Reference materials were generated using this pool of samples and laboratories can use this to generate specific conversion factors to convert their results into IS values.[11] The results are defined on a log scale; 1%, 0.1%, 0.001%, 0.0032%, and 0.0001% correspond to 2, 3, 4, 4.5, and 5 log reductions respectively from the baseline value of the IRIS trial. BCR-ABL1 quantitative PCR is recommended to be performed every 3 months.[5] The standard response definitions are described in **Table 2**.

Effective therapy leads to progressive decline in the BCR-ABL1 IS and target values at different timepoints are defined in order to ascertain the efficacy of treatment. The

TABLE 3 Molecular targets of treatment (BCR-ABL1 IS values)

	Optimal	*Warning*	*Failure*
Baseline	NA	High risk ACA, high risk ELTS score	NA
3 months	≤10%	>10%	>10% if confirmed within 1–3 months
6 months	≤1%	>1–10%	>10%
12 months	≤0.1%	>0.1–1%	>1%
Anytime	≤0.1%	>0.1–1% Loss of MMR	>1%, resistance mutations, high risk ACA

molecular timepoints as per the European LeukemiaNet 2020 guidelines are described in **Table 3**.[5] In case of suboptimal response or failure of therapy there is a need to determine if any mutations are present in the kinase domain. Detection of these mutations serves as a guide for choosing the most optimum second line therapy. Mutation analysis was conventionally done using Sanger sequencing but Next-generation sequencing has proved to be more sensitive and has become the recommended technique.[12]

Imatinib was the first TKI to be approved for use in CML based on the results of the IRIS trial. The starting dose is 400 mg once a day but higher doses of 600 mg and 800 mg have also been tried. The second generation TKIs were compared with imatinib as the frontline agent in newly diagnosed CML CP in various trials and were found to induce faster and deeper responses as compared to imatinib, but there was no significant superiority in progression-free and overall survivals in any of these studies. No head-to-head comparison is available for any of the 2G-TKIs. Hence, the choice of frontline TKI depends on a combination of various factors including risk stratification, cost, availability, adverse effect profile, comorbidities, and individual preferences of the physician and the patient. The choice of agent for second line use also depends on similar factors but also take into account mutation status.

Treatment of patients with failure of two previous TKIs is not so straightforward. Allogeneic stem cell transplant should be considered in this setting. TKIs (2G and 3G) can be used but responses are seldom durable. If effective, TKIs can be used as an effective bridge to transplant.

Advanced phase CML (AP and BP) can present either de novo or as progression from CP. TKIs are effective in TKI-naïve patients with de novo AP. Imatinib at higher dose of 600 mg or any of the 2G TKIs may be considered in this setting. Patients with AP who have additional cytogenetic abnormalities or who have progressed after TKI failure respond poorly with second line TKIs and allogeneic stem cell transplant should be considered. CML BP can be either myeloid-type or lymphoblastic-type and this should be determined by immunophenotyping. The outcomes of CML BP remain poor and the only modality that can provide long-term cure in setting of BP is allogeneic stem cell transplant. Patients are usually treated with TKI along with acute myeloid leukemia (AML)-like or acute lymphocytic leukemia (ALL)-like chemotherapy to bring the disease into chronic phase or hematological remission prior to proceeding with transplant.

When TKIs were first introduced two decades ago it was thought that they have converted CML into a chronic disease with near normal life expectancy and lifelong treatment. But long-term experience with TKIs showed that it is possible to go even a step further. These drugs are able to achieve sustained deep molecular responses when used over a period of few years and it is possible to discontinue the drug in selected patients, providing them with the equivalent of a "cure." This concept of TFR was initially explored with the use of the older agent interferon.[13] The STIM1[14] and TWISTER[15] trials demonstrated that TFR can be achieved in patients on long-term imatinib. Subsequently a large number of trials have been done with both first line and second line TKIs demonstrating the utility and feasibility of TFR.[16] Although all studies have used different criteria for patient selection, a few common criteria have emerged. Ideally the patient should be in first CP, on first line TKI for prolonged duration (5 years or more), having achieved optimal response at all milestones and having achieved a sustained deep molecular response (DMR) for 2 years or more. Patients on TFR should be motivated and have access to regular monitoring (monthly for initial 6 months, 2 monthly for next 6 months, and subsequently 3 monthly for life).[5] The success rates of TFR in almost all trials have been in the range of 40–50%.[16] Failure of TFR is considered when there is a loss of MMR. Most failures occur in the initial 6 months but thankfully nearly all patient regain MMR following reinitiation of TKI. The success of TFR has led to its incorporation as one of the standard goals of therapy.

Managing CML in Resource Poor Settings

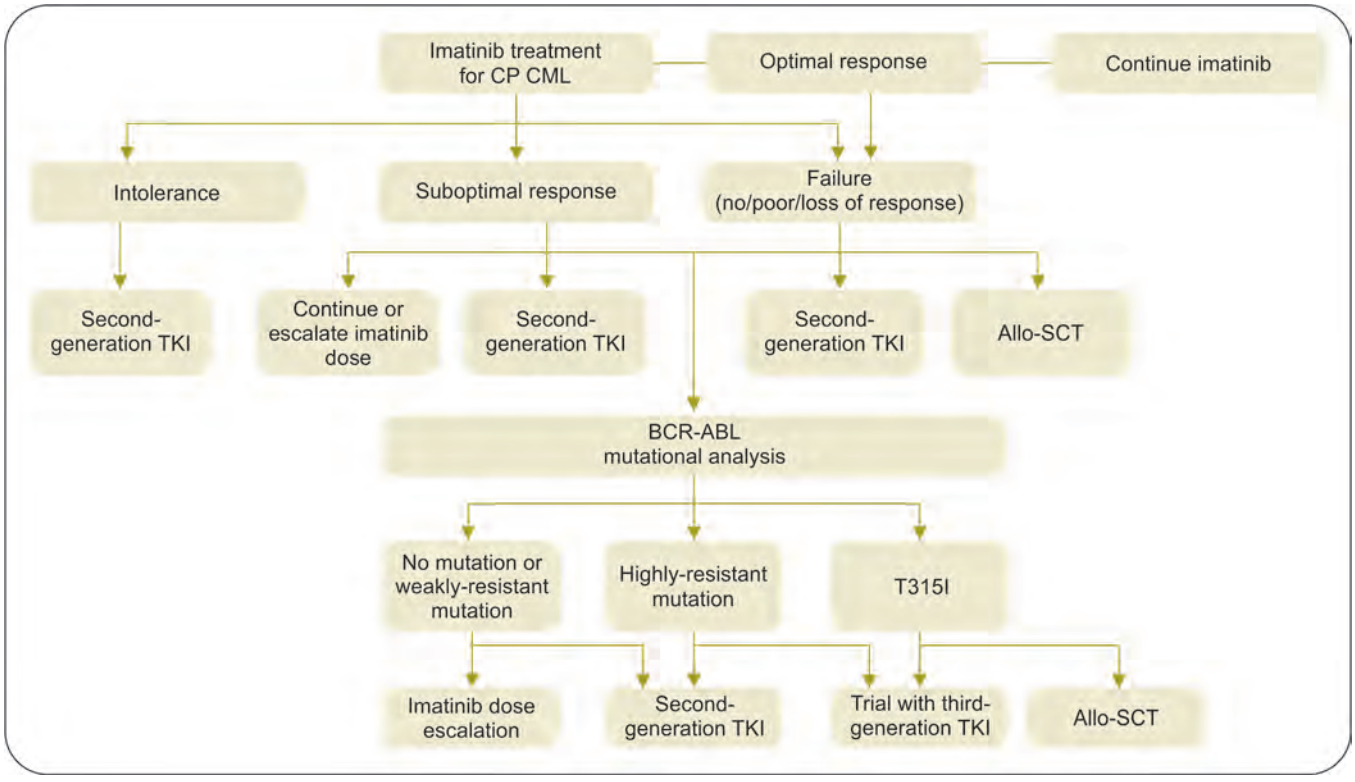
Although major advances have been made in our understanding, treatment, and monitoring of CML, these advances have not universally permeated into clinical practice, and this is particularly true for low and middle income countries. Patients and physicians in these regions of the world face unique challenges at every step of disease management. Efforts are needed to ensure that our patients are able to obtain similar benefits of treatment as those in developed nations.[17]

An algorithm for guidance in resource-limited setting is provided in **Flowchart 1**.

Specific Issues Related to CML Treatment in Resource-limited Settings

- *Delays in diagnosis:* A majority of CML patients in India are diagnosed late and have a higher disease burden and higher risk score at the time of diagnosis.[18,19] This is related to poor awareness of the disease and inadequate access to diagnostic modalities in peripheral centers. Presentation with a higher risk score leads to inferior survival outcomes.
- *Age at diagnosis:* Patients of CML in Asian countries present a decade earlier than those in the west.[20] This translates to a longer course of the disease and subsequently a longer need for TKIs and monitoring, which adds to the overall financial burden.
- *Investigations:* Molecular and cytogenetic methods for diagnosis and monitoring are not readily available in smaller cities. Even with availability, the cost of these investigations ends up posing a hindrance to their usage. The standard recommendations on the monitoring frequency (once in 3 months) are seldom, if ever, followed in India. Clinicians have to devise their own modifications to these guidelines in order to ensure that the patient remains well monitored yet not be overburdened by the cost.
- *Drugs:* The cost of imatinib at the time of launching was prohibitively expensive, but three major developments have ensured that today they are within the reach of nearly every patient who needs it. In this regard,

Flowchart 1: Algorithm for CML-CP treatment in resource-limited settings



Allo SCT, allogenic stem cell transplantation; CP CML, chronic phase CML; TKI, tyrosine kinase inhibitor

massive strides have been made in the last two decades. Firstly, the Glivec International Patient Assistance Program (GIPAP), in association with the Max Foundation, which sought to make imatinib available free of cost to patients particularly in low and middle income countries.[21] India has been the largest beneficiary of this program, and GIPAP has provided free of cost imatinib to more than 12,000 patients (25% of all GIPAP beneficiaries) from 2002 onward. The program stopped enrolling new patients in 2016. Secondly, a large number of Indian pharmaceutical companies started production of generic imatinib, which is available to patients at a much cheaper rate. Thirdly, several public funded institutions provide generic imatinib free of cost. These benefits are not restricted to imatinib alone. Nilotinib is available at a concessional cost as a part of a patient assistance program. Generic formulations of Dasatinib and Bosutinib were launched in early 2020. These have ensured that even the 2G TKIs are much more accessible to patients than what they were previously and have led to increased use of these agents both as first line and second line.

- *Adherence to treatment:* Poor adherence to treatment is a major barrier to obtaining favorable long-term outcomes.[22] Various factors non-adherence relevant to the Indian context are financial constraints, lack of social support, and poor patient awareness about the disease and treatment. Treating clinicians must pay adequate attention to addressing these issues. Adequate counseling at diagnosis and reinforcement of the same at each hospital visit is essential. Various government and non-government aid regarding provision of TKIs go a long way in ensuring uninterrupted treatment.

Conclusion

CML is a chronic myeloproliferative neoplasm characterized by t(9;22)(q34;q11) and the resultant chimeric BCR-ABL1 oncogene. Effective targeted therapy is now available in the form of TKIs, which can induce deep and prolonged molecular responses in a large number of patients. TFR has shown moderate success and has become one of the major goals of treatment. Challenges remain in low and middle income countries related to accessibility and affordability of investigations and treatment. Various governmental and non-governmental schemes along with availability of generic medications have gone a long way in ensuring our goal of providing treatment for all.

CHAPTER

230 Disability-free Hemophilia in India—Myth or Reality

Sunita Aggarwal, Ranvijay Singh, Sandeep Garg

Abstract

Hemophilia is a rare X-linked genetic disorder where a patient bleeds because of lack of clotting factors essential for coagulation. Based on the type of clotting factor deficiency, hemophilia is classified into hemophilia A, which is deficiency of factor VIII and deficiency of a clotting factor IX is called hemophilia B. Currently, replacing the deficient clotting factors with plasma derived and recombinant clotting factor is the widely accepted treatment modality for hemophilia. In many countries, advanced treatment prophylaxis is the accepted modality of treatment, which allows persons living with hemophilia (PWH) to lead a disability-free life. According to recent survey, India has 10% of all the PWH in the world.[1] Yet most of the patients have not been adequately treated because of various factors. A void in awareness, unavailability of clotting factors, high treatment costs, poor economic status, and lack of home therapy along with low frequency of physiotherapy exercises are causing big dent in the Indian PWH's aspiration in achieving a disability-free life. In India, access to prophylaxis and optimal dosages of CFCs is still not up to the established standards of care. This review describes the current scenario of hemophilia care and the challenges faced by PWH in India.

Introduction

Hemophilia is a mostly inherited genetic bleeding disorder, first found in the literatures of 2nd century's Jewish-Talmud (Jewish religious script). A more detailed explanation was given by the 11th century physician Albucasis. The word "hemophilia" is derived from the Greek word "haima" which means "blood" and "philia" which means "love or attraction." In the late 18th and early 19th century, the understanding of hemophilia evolved and conceptualized. The European royal families suffered during the same period, and it led the world to recognize the disease and brought it into prominence. The two types of hemophilia, that is, Hemophilia A and Hemophilia B (Christmas disease) were recognized in the mid-20th century. Hemophilia is transmitted as X-linked recessive pattern where males are usually affected and females remain as asymptomatic carriers. The lack of heterogeneous transformations of the coagulating factor qualities because of the mutation *F8C* gene and *F9* gene causes Hemophilia A and B, respectively. Hemophilia A constitutes to about 80–85% of the hemophilia patients **(Table 1)**.[1]

Clinical Features

Hemophilia is X-linked recessive disease where male is clinically affected and women are almost asymptomatic. Family history is absent in ~30% of the cases, attributing to de novo mutation. Severe the hemophilia earlier the presentation of first bleeding episode, which can present as early as at birth and majority of them are spontaneous bleeds. New born can present as cephalohematoma, central nervous system (CNS) bleed, or excessive bleeding during medical intervention like venipunctures and circumcision. As child starts walking, joint bleed, bruising

TABLE 1 Hemophilia clinical classification[2]

Hemophilia type	*FVIII/FIX activity (% of normal)*	*Pattern of bleeding episodes*	*Clinical manifestation*
Mild	6–40	Uncommon	Major trauma, Surgery
Moderate	1–5	4–6 per year	Minor trauma
Severe	<1	24–48 per year	Spontaneous

and musculoskeletal bleed becomes more common. In older children and adult, presentation is mainly joint and muscle bleed. Hemarthrosis can affect every joint but commonly involves knee, elbow, ankle, shoulder, and hips. However CNS, oropharyngeal, and retroperitoneal bleed are life threatening and require immediate therapy.

Complications

Hemophilic arthropathy: Most common and develops in ~50% of patients with severe hemophilia. Mechanism of arthropathy is multifactorial including chronic or episodic synovitis, loss of cartilage, subchondral cyst formation, bone cysts, erosion and joint space narrowing leading to contractures, pain, and limitation of motion.

Infection: Found relatively more in plasma-derived products compare to recombinant factor products and elimination of Parvovirus B19, hepatitis A and prion diseases like Creutzfeldt-Jakob disease is still a challenge.

Pseudotumor: Unique to hemophilia, pseudotumor is a potentially disabling condition that results from inadequately treated soft tissue bleeds usually in muscle adjacent to bone, which can be secondarily involved.

Inhibitors: The cumulative incidence (i.e., lifetime risk) of inhibitor development in severe hemophilia A is in the range of 20–30%, approximately 5–10% in moderate or mild disease and hemophilia B has 1–5% lifetime risk of inhibitor development.[3,4]

Inhibitors are neutralizing alloantibodies developed following the host immune response to the infusion of clotting factor concentrate, seen by host immune system as foreign protein. Inhibitors development is highest during the first 20 exposure days (ED) to factors. Frequent screening is required during initial exposure days, screening every 5ED until 20ED are reached and after 150ED frequency of screening can be reduced. Inhibitors are detected either during routine screening or it is suspected when patient fails to respond to replacement of CFC. High titer inhibitor (HTI) and low titer inhibitor (LIT) are inhibitor classes quantified by Bethesda units (BU).

High titer inhibitor (≥5BU) and low titer inhibitor (<5BU) behave differently and consequently are managed differently. LTI may be transient and disappear spontaneously without specific treatment but significant proportion of it gets converted into HTI; hence, demands close monitoring. Treatment of bleed in LTI include factor infusion at higher dose, porcine rFVIII, which is not quickly inactivated unlike human FVIII and Desmopressin (DDAVP) in mild hemophilia A, which releases endogenous FVIII.[5]

HTI are persistent and completely resistant to factor concentrates; hence, their management requires avoidance of further FVIII exposure until immune tolerance induction (ITI) is commenced where infusions of variable doses of FVIII and FIX given over a period of time to tolerize the immune response. Use of bypassing agents (rFVIIa and aPCC) and monoclonal antibody emicizumab can be opted.[1,5] Emicizumab (Hemlibra) is registered in over 50 countries around the world for prophylactic use for hemorrhagic episodes in adult and pediatric hemophilia A patients with inhibitors.[6] In addition, this drug has recently been approved by FDA for prophylaxis in patients with hemophilia A without FVIII inhibitors.[6]

Treatment Modalities

Hemophilia is treated by replacing the deficient clotting factors. Based on source, there are plasma derived clotting factors concentrates (PDCFCs) and recombinant clotting factors (rFVIII/rIX). Recombinant clotting factors are inherently safer as the risk of transfusion transmitted diseases is much less compared to plasma derived CFCs. There are two modalities in treatment based on timing of the therapy, i.e., episodic/on demand therapy and prophylaxis therapy.[7]

TABLE 2 Dose required in hemophilia[2]

Type	*1 unit/kg factor VIII/IX*	*Dose required (in units)*
Hemophilia A	Raise the plasma FVIII level approximately 2%	[Body weight × Desired level]/2
Hemophilia B	Raise the plasma FIX level approximately 1%	[Body weight × Desired level]

TABLE 3 Desired level of factors in different sites of bleed in hemophilia A & B[4]

Site of bleed	*Desired level (IU/dL)*
Muscle/joint	40
Iliopsoas bleed	60
Throat	50–80
Neck	
GI bleed	
Genitourinary bleed	
Surgery (Postoperative)	
Surgery (Preoperative)	100
Intracranial bleed	

On Demand Therapy

Assuming the baseline factor of persons living with hemophilia (PWH) as 0%, the therapy should raise the clotting factor to a certain minimum level in order to stop the bleeding. Although on demand, treatment can stop bleeding, reduce the pain to an extent and restore joint movement. It will not protect the PWH from arthropathy. The target dose of CFC is calculated with the help of bleeding site specific desired levels and approximate raise of plasma factor levels **(Tables 2 and 3)**.

Prophylaxis Therapy[7]

Here the treatment is given by intravenous injection of factor concentrate to prevent anticipated bleeding. It prevents life threatening bleeding, joint destruction and preserves normal musculoskeletal function. Prophylaxis has been a standard of care in developed countries. Two well-studied and documented clinical protocols for prophylaxis are being followed across the world:

- *Malmo protocol:* (high dose: 25–40 IU/kg/dose)[1]
- *Utrecht protocol:* (intermediate dose: 15–30 IU/kg/dose)[1]

For hemophilia A, the factors are administered thrice a week and for hemophilia B, the factors are administered twice weekly. In countries with resource constraints lower dose of prophylaxis maybe given as an interim measure.

On Demand versus Prophylaxis Therapy

Manco-Johnson et al. conducted a randomized controlled study and found prophylaxis is more effective in preventing hemarthrosis and is also efficacious in decreasing bleeding and joint damage compared to on demand therapy.[8] Another randomized controlled study, ESPRIT study, concluded by saying prophylaxis was more effective when started at age 36 months or less with PWH having fewer joint bleeds and no radiologic signs of arthropathy versus patients treated on demand.[9] The MUSFIH study concluded, on demand therapy failed to preserve musculoskeletal functions in PWH.[10] All these studies are stressing the importance of prophylactic replacement of clotting factors over the on-demand therapy. Even in India, several pilot studies conducted across India have shown the evidence of the advantage of prophylaxis over on-demand.[11,12]

Hemophilia Scenario in India

India has currently 20,321 registered PWH. 17,606 with hemophilia A and 2,715 with hemophilia B.[1] Majority of Indian PWH fall into 19–44 years of age. However, as per the incidence and prevalence estimates, India should have had approximately 100,000 PWH. Many of the patients go undiagnosed or unregistered because of lack of awareness and lack of diagnostic facilities.

Among the registered patients, a significant percentage of them suffer from joint disease due to recurrent joint bleed. In a study of 148 severe hemophilia A patients from 5 centers across India, Kar et al. found that about 94% had some form of disability. Patients from the age group 25+ were the most affected with 0% of them being free from disability.[13] This pervasive disability has turned hemophilia from a mere bleeding disorder to a chronic musculoskeletal disorder. Many of these patients in India do not complete education, are not gainfully employed and become a burden to their families and the society. In

contrast, in most developed countries, PWH enjoy good joint health, are not burdened with disability and lead a normal and productive life.

This stark contrast among the quality of life led by PWH in India and other countries may be ascribed to several factors:

- *Lack of optimum management of bleeds:* Bleeds are not treated with optimum dosages in many cases. In India, mean per capita factor VIII and IX usage is 0.230 and 0.063 IU/population while global mean is 2.40 and 0.37 IU/population.[1] Also the time from onset of bleed to factor administration is rarely less than 2 hours. This leads to increased blood in the joint space, increased inflammation and increased time to recovery and in the long-term results in joint arthropathy.
- *Lack of prophylaxis:* Only about 13% of Indian PWH have access to prophylaxis.[1] Some of the reasons could be lack of awareness, difficulty in venous access in young children, training the parents of PWH and in some cases inadequate supply of clotting factors. Moreover, psychosocial barriers like handling the myths, misconception, apprehensions about prophylaxis and willingness to endure repeated venipunctures play a vital role.
- *Lack of home therapy:* Self-administration at home setting demands skills and expertise with proper training of the family members. Lack of motivation among patients and administrative hurdles reduce the efficiency of home therapy.
- *Lack of diagnostic facilities:* Only a few laboratories across the country can perform factor and inhibitor assays. This may be one of the reasons why only small portion of the PWH are identified.

However, there has been a significant improvement in the hemophilia care in India in the recent years. Out of all the genetic disorders and hemoglobinopathies hemophilia have attracted a fair share of support and funding from the government. Over the last few years treatment of hemophilia in India has evolved from whole blood transfusion, fresh frozen plasma and cryoprecipitates to plasma derived and recombinant clotting factor concentrates. It is also encouraging to note that hemophilia is now listed in "The Rights of Persons with Disabilities Act, 2016". The government is allocating funds, purchasing good quality clotting factors and bypassing agents. Many hemophilia treatment centers (HTCs) are opening across the country to help PWHs. Most HTC have well qualified treating physicians, nurses, lab technicians and physiotherapists with adequate experience of handling PWH.[14] HTCs are mainly supported by respective State Governments and in some cases by Central Government as well.[14] Some hospitals also serve as tertiary care centers for hemophilia care where advanced management for inhibitors and even surgeries are provided. However, the number of such surgeries is abysmally low. Some of the tertiary centers have started prophylaxis and home therapy as pilot projects, albeit at smaller scale.

The Hemophilia Federation of India (HFI) is a patient support group, working to help PWH in India in various ways. It also performs a vital task of maintaining a national hemophilia registry for all PWH.

Conclusion

Persons living with hemophilia (PWH) in India still face many issues in terms of comprehensive care, inhibitor management, optimum dosage in acute bleeds and optimum prophylaxis regimen. Paving our way toward WFH's vision of "Treatment for All". *Awareness*, *access* to *safe factors*, *prophylaxis* and *home therapy* should be the focus areas for all the concerned stakeholders to work in a coordinated fashion and make the treatment accessible to all the PWH. With such an approach of comprehensive hemophilia care and tireless efforts of medical experts, government, health administrators, and even patients, we can aspire for a disability-free hemophilia in India.

CHAPTER

231 Immunotherapy in Clinical Practice

Vineet Talwar, Amrith BP

Abstract

Cancer immunotherapy is rapidly evolving and is gaining a major role in current oncological practice. Advances in understanding of immune surveillance and tumor biology have opened up new therapeutic strategies that can be used for the treatment of many cancers. Immune evasion is a hallmark of property of cancer and cancer immunotherapy uses strategies to augment body's immunity against cancer. A subset of cancer patients dramatically benefit from this approach and identifying a right patients through a biomarker is need of the hour. In addition, knowledge on tumor response to immunotherapy and toxicity profile of these agents are important as they differ from traditional cytotoxic chemotherapies by virtue of its unique mechanism of action.

Introduction

Advances in understanding of the interlink between immune surveillance and tumor biology have opened up new therapeutic strategies that can be used for treatment of many cancers.[1] Nobel prize for physiology/medicine in 2018 was awarded to James P. Allison for the discovery of cytotoxic T-lymphocyte associated protein (CTLA-4) and to Tasuku Honjo for programmed cell death protein 1/programmed cell death protein ligand 1 (PD-1/PD-L1), a landmark discoveries in the field of immunotherapy.[2] Cancer immunotherapy is based on the principle of strengthening the host immune system to combat against the cancer.

Evasion of Immune Surveillance

Evasion of the immune surveillance is one of the hall marks of cancer.[3] Adaptive immunity directed at the cancer antigens is one of the defense mechanism which helps to fight against the cancer. There are several mechanisms by which the cancer cells escape this natural defense known as "immune evasion."[4] Immune evasion helps in tumor growth despite having a normally functioning host immune system. Various mechanisms for immune escape include:

- Up regulation of immune checkpoints such as PD-1 and PD-ligand 1 (PD-L1)
- Alteration of antigen presentation mechanism by loss of MHC class 1 expression or cellular mechanisms that help in transportation of tumor antigens for T cell recognition
- Promotion of immune tolerance by alteration of cytokines like IL-6, IL-10, and TGF-beta

Proper understandings of these mechanisms have been exploited as the basis of immunotherapy in current clinical practice.

Approaches to Cancer Immunotherapy

A number of therapeutic approaches are in practice or under investigation to strengthen the body's immune system fight against cancer. Various immunotherapy approaches in current practice are enumerated in the **Box 1**.

BOX 1 Immunotherapy approaches in current practice

Modalities of immunotherapy
Check point inhibitors • PD-1 and PD legend (PD-L1) inhibitors • CTLA-4 inhibitors
Manipulation of T cells • Chimeric antigen receptors • Bispecific T cell engagers
Cancer vaccines
Cytokines
Oncolytic viruses

Checkpoint Inhibitors

Programmed Cell Death 1 (PD-1) and PD-Ligand 1/2

Programmed cell death-1 (PD-1), a transmembrane protein expressed on immune cells like T cells, B cells, and NK cells. Ligand of PD-1 (PD-L1) is usually expressed on many tissues including tumor cells. Interaction of the PD-1 with its ligand acts as check point and resists the cell death by inhibition of apoptosis.[5] Up regulation of PD-L1 expression is seen in many tumor cells and drugs targeting PD-1/PD-L1 pathway known as check point inhibitors are an important class of immunotherapy in current oncological practice. The interaction of the PD-1 with its ligand is depicted in the schematic **Figure 1**.

Cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) is another immune check point, which helps in down regulation of the immune responses against tumor cells.[6] Monoclonal antibodies targeting CTLA-4 can also clear these "breaks" in immune surveillance. Ipilimumab, an anti-CTLA-4 antibody was the first immune checkpoint inhibitor to be approved in patients with malignant melanoma.[7]

The various check point inhibitors currently in use are listed in **Table 1** with the approved indications and doses.

Immunotherapy Response Criteria

The pattern of response to immunotherapies mainly checks point inhibitors that can differ from that of classical cytotoxic chemotherapeutic agents by the virtue of difference in mechanism of action of these agents.[8] Unlike chemotherapy the responses may take longer time to become apparent. The immune infiltration of the tumors can lead to an apparent increase in the size of the lesion

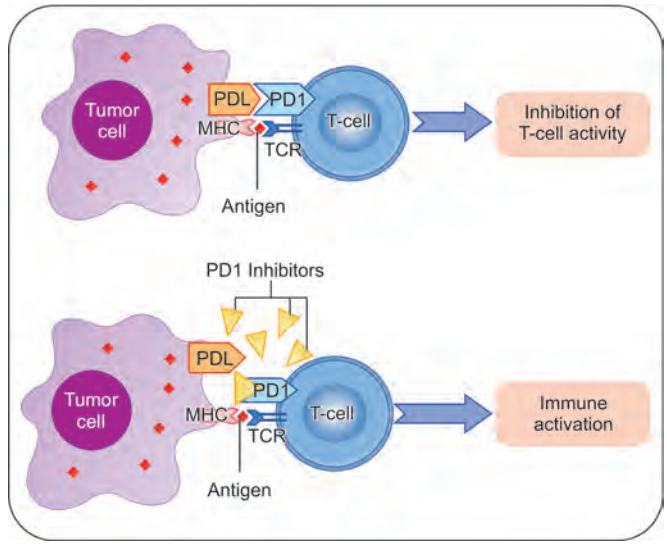

Fig. 1: PD-1/PD-L1 pathway and check point inhibitors

initially known as immune confirmed progressive disease (IUPD) commonly known as pseudoprogrssion.[9] In such situations the clinical status of the patient should be taken into consideration in deciding the further course of action.

To address these issues many response criteria have been developed like immune-related response criteria (irRC), immune response evaluation criteria in solid tumors (iRECIST),[10] immune-modified response evaluation criteria in solid tumors (imRECIST).[11] Detailed description of these criteria is beyond the scope of this chapter.

Toxicities Associated with Checkpoint Inhibitor Immunotherapy Immune-related Adverse Events (IRAEs)

The toxicities depend on the class of immunotherapeutic agents. Check point inhibitors are the most commonly used class of immunotherapy in clinical practice. Though these drugs are well tolerated in most of the cases they are known for unique side effects related to their mechanism of action. These are known as immune-related adverse events (irAEs).[12] Virtually these can affect any organs. However, the important organs affected and the manifestations are depicted in the **Figure 2**. The usual timeline of appearance of these side effects are shown in the **Figure 3**.

The management of irAEs depends on the severity of manifestations. It varies from close monitoring,

TABLE 1 Check point inhibitors with approved indications

Drug	*Target*	*Dose*	*Approved indications*
Nivolumab	PD-1	240 mg once every weeks Or 480 mg once every 4 weeks	• Head and neck squamous cell carcinoma • Hepatocellular carcinoma • Hodgkin lymphoma • Melanoma • Lung cancer • Renal cell cancer • Urothelial cancer
Pembrolizumab	PD-1	200 mg once every 3 weeks	• Cervical cancer (recurrent or metastatic) • Esophageal cancer (recurrent locally advanced or metastatic) • Gastric cancer (recurrent locally advanced or metastatic) • Head and neck cancer, squamous cell • Hepatocellular carcinoma • Hodgkin lymphoma, classical (relapsed or refractory) • Melanoma • Microsatellite instability-high cancer • Non-small cell lung cancer • Renal cell carcinoma • Urothelial carcinoma
Cemiplimab	PD-1	350 mg once every 3 weeks	• Cutaneous squamous cell carcinoma, metastatic or locally advanced
Atezolizumab	PD-L1	Breast cancer: 840 mg Day 1 and Day 15 every 4 weeks Others: 1200 mg every 3 weeks	• Breast cancer (triple-negative) • Lung cancer • Urothelial carcinoma
Durvalumab	PD-L1	10 mg/kg every 2 weeks	• Lung cancer • Urothelial carcinoma
Avelumab	PD-L1	800 mg once in every 2 weeks	• Merkel cell carcinoma • Renal cell carcinoma • Urothelial carcinoma
Ipilimumab	CTLA-4	1–10 mg/kg (depending on the indication)	• Melanoma • HCC • RCC

interruptions in treatment, dose reductions, and other pharmacological management. The pharmacological agents like steroids, infliximab, may be used in the management of irAEs.[13]

Other Forms of Immunotherapy

Manipulating T Cells

Immune enhancement by manipulating the T cells is another emerging mode of immunotherapy.

Chimeric Antigen Receptors (CAR) T Cells

CAR-T cell therapy involves the modification of the patient's own T cells to recognize the cancer cells more effectively and to destroy them. Chimeric antigen receptors (CARs) are the engineered proteins that give T cells this new acquired ability. These proteins are chimeric as they are engineered by combining antigen-binding and T cell activating functions into a single receptor.[14] So CAR-T cell therapy utilizes these T cells engineered with CARs as a therapeutic strategy.

CAR-T cells are studied in various solid and hematological malignancies and have shown a great result in B-cell acute lymphoblastic leukemia (B-ALL). Tisagenlecleucel and axicabtagene-ciloleucel were the first two CAR-T cell therapy receiving FDA and EMA approval for ALL (tisagenlecleucel) and diffuse-large B-cell lymphoma – DLBCL (tisagenlecleucel and axicabtagene ciloleucel).[15]

CD3-Directed Therapies—Bispecific T-cell Engagers

Bispecific T-cell engager antibodies (BiTEs) act as linker between T cells and specific target antigens. These consist of a protein, which contains two separate variable regions,

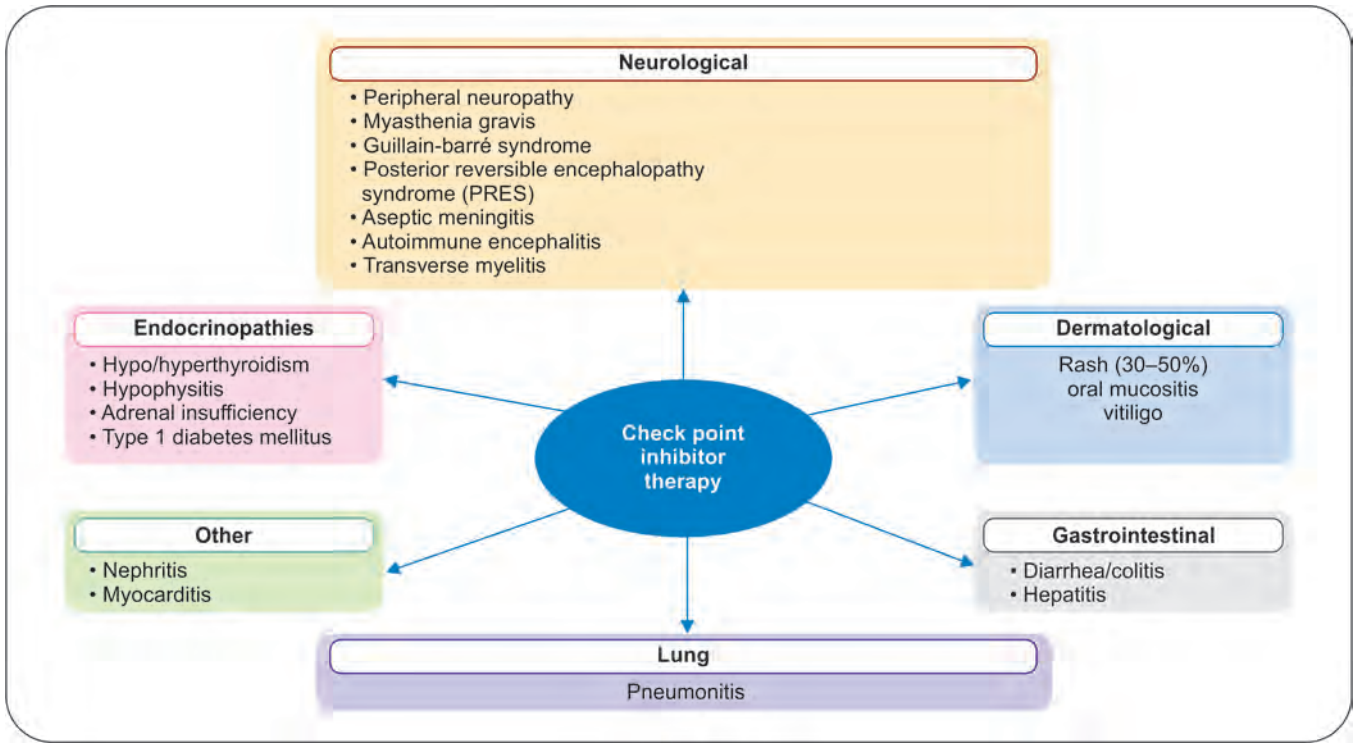

Fig. 2: Immune-related adverse events (irAEs)

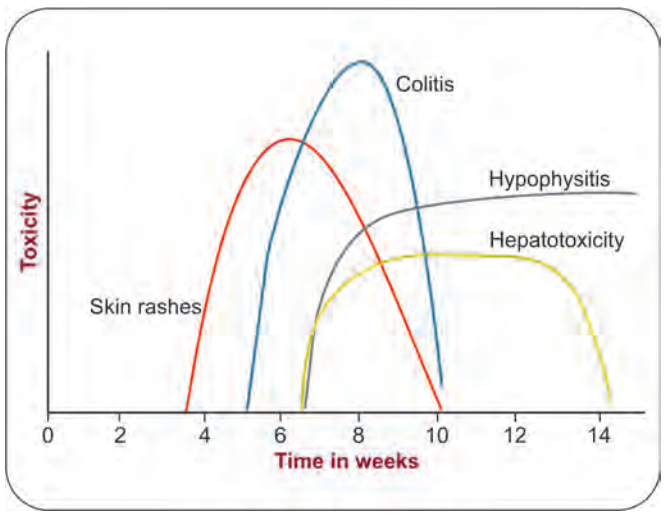

Fig. 3: Timeline of immune-related adverse events (irAEs)

one recognizing CD3 on T cells and the other recognizing target antigen. Thus, activating cytotoxic T cell-mediated tumor damage. BiTEs functioning in an MHC independent manner and don't require patient specific processing enabling it to administer to all the patients irrespective of human leukocyte antigen (HLA) type.[16]

Blinatumomab is a BiTE having specificity for CD19 found on B cells and the Fc region of the CD3 receptor on T lymphocytes and is approved for Philadelphia-chromosome negative B-ALL.[17]

Oncolytic Viruses

Several viruses are genetically engineered to infect the cancer cells preferentially and to present the tumor associated antigens to immune system. Many virus backbone like attenuated herpes simplex virus 1, adenovirus, reovirus have been studied in clinical trials. talimogene laherparepvec (T-VEC) uses an attenuated HSV-1 to over express granulocyte macrophage colony-stimulating factor (GM-CSF) and mediates the antigen presentation through dendritic cells. Intratumoral injections of T-VEC have shown durable responses in Melanomas.[18]

Therapeutic Cancer Vaccine

Therapeutic cancer vaccines are a form of immunotherapy, which educates the immune system about how cancer cells look like so that it can fight against it. Vaccine antigen is the most important component of a cancer vaccine,

which can be tumor-associated antigen or tumor-specific antigen. There are mainly three types of vaccine platforms that are being investigated for cancer therapy. These includes cellular vaccines (autologous or allogeneic), virus vector vaccines, and molecular vaccines comprised of either peptides, DNA, or RNA.

The first US Food and Drug Administration approved therapeutic cancer vaccine is sipuleucel-T (Provenge).[19] It was used for metastatic castration-resistant prostate cancer (mCRPC). Sipuleucel-T was developed by enriching the patient derived DCs and their activation ex vivo with a chimeric protein, GM-CSF fused to the antigen PAP.

Cytokines

The initial approaches of immunotherapy were mainly based on alteration of cytokines that influence the immune system.

- Interleukin-2(IL-2):
  - IL-2 plays an important role in activation of immune system and is an approved treatment for renal cell carcinoma and melanoma.[20]
  - Immunomodulators like lenalidomide and pomalidomide are an established therapy in multiple myeloma act by destruction of Ikaros family proteins, which results in inhibition of IL-2 secretion.[21]
- Interferon (IFN) alfa-2b has also been used in malignant melanoma.

Conclusion

The immune-oncology has transformed the care of cancer patients. These act in a targeted manner minimizing the side effects. Checkpoint inhibitors are the mainstay of current immunotherapy practice in oncology. CAR-T cell therapies and personalized cancer vaccine have limited utility at present, which will be added to the immune-oncology armamentarium for wider use in near future.

CHAPTER

232 PNH—A Great Masquerader: When to Suspect?

Asish Rath, Jasmita

Abstract

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired clonal disorder characterized by partial or complete deficiency of glycophosphatidylinositol anchored proteins (GPI-AP). PNH can present with varied clinical manifestations. PNH can masquerade as an intravascular hemolysis or thrombosis. It can be associated with acquired bone marrow failure. Early diagnosis of PNH is crucial for appropriate clinical management. However, the rarity and diverse clinical manifestations complicate an early diagnosis. Though various tests are available, flow cytometric PNH analysis is considered the gold standard because of its rapidity and high sensitivity. A high index of suspicion and choice of appropriate high sensitivity assay helps in timely diagnosis and prevention of fatal complication in patients.

Introduction

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired disorder of hematopoietic stem cells caused by a somatic mutation in X-linked PIGA gene resulting in partial or absolute deficiency of all glycophosphatidylinositol (GPI) linked proteins.[1,2] The GPI anchored proteins (GPI-AP) have different functions as enzymes, receptors, adhesion molecules, or complement regulators.[3] Examples of GPI-AP, which inhibit the complement are CD55 (decay accelerating factor-DAF) and CD59 (membrane inhibitor of reactive lysis-MIRL). PNH can cause myriad manifestations ranging from the expected intravascular hemolysis to presentation with thromboses or bicytopenia/ pancytopenia due to bone marrow failure.[4] In addition, some patients of PNH present with abdominal pains and leg cramps with compensated hemolysis.

Clinical Manifestations and Pathogenesis[2,5]

Complement-mediated Intravascular Hemolysis

PNH red cells are vulnerable to complement mediated lysis due to reduction or absence of CD59 and CD55. CD55 (DAF) accelerates destruction of membrane bound C3 convertase where as CD59 (MIRL) inhibits membrane attack complex (MAC) induced lysis. In PNH there is low-level continuous activation alternate complement pathway, which in association with GPI-AP causes chronic intravascular hemolysis. Classically patients have paroxysms of hemolysis at night, a morning dark colored urine and gradual resolution over the day. It is primarily the CD59 molecule that is responsible for inhibiting complement mediated lysis.

Thromboses

- NO (nitric oxide scavenging)—Free hemoglobin released into plasma following intravascular hemolysis scavenges NO. This leads to endothelial dysfunction and platelet activation. NO depletion can manifest in abdominal pain, dysphagia, erectile dysfunction, and thrombosis.
- Platelet activation by procoagulant microparticles released from GPI-AP deficient cells.
- Deficiency of GPI-AP like u-PAR (urokinase like plasminogen activator receptor) and TFPI (tissue factor

pathway inhibitor) that lead to reduced inactivation of the thrombotic pathway.

Bone Marrow Failure

Approximately 30–45% of PNH patients have associated aplastic anemia or myelodysplastic syndrome (MDS). A second hit following PIGA mutation causing immune destruction of normal stem cells and clonal selection of PNH stem cell may explain coexistence of PNH clones in acquired aplastic anemia.

PNH has been subclassified by *International PNH interest group*[1] into three categories:

- The classical PNH—clinical and laboratory signs of intravascular hemolysis without evidence of other diseases of bone marrow failure
- PNH associated with AA/MDS
- Subclinical PNH with a minor PNH clone usually less than 1%

We will discuss three case scenarios **(Table 1)** to elucidate the manifestations of the disease and identify patients who should be tested for PNH.

TABLE 1 Details of the three clinical cases

Case details	*Case 1*	*Case 2*	*Case 3*
Age/Sex	21/Male	28/Female	31/Male
Primary complaints	symptomatic anemia, intermittent jaundice, leg cramps	Jaundice Abdominal pain	Petechiae Anemia requiring transfusions
Duration of illness	2 years	1 month	2 months
Hb (g/dL)	8.1	10.2	5.1
TLC ($\times 10^9$/L)	5.08	8.2	1.2
Platelets ($\times 10^9$/L)	150	99	18
MCV (fL)	115.3	96.5	91.5
Reticulocyte (%)	13.4	3.2	0.9
Additional information	-	-	ANC-120/µL
Bilirubin total/Indirect (mg/dL)	5.2/4.8	2.2/1.9	0.8/0.2
LDH (U/L; Normal reference 220–420)	890	550	230
Peripheral blood smear	Macrocytes, polychromasia, hypersegmented neutrophils	Normocytic normochromic; mild polychromasia; Normal platelets	Pancytopenia with normocytic normochromic red cells
Bone marrow aspirate	Megaloblastic erythroid hyperplasia; giant myeloid forms	Normoblastic erythroid hyperplasia with adequate megakaryocytes	Paucicellular with predominantly lymphocytes and plasma cells
Perl's stain	Absent iron stores	1+	4+
Bone marrow biopsy	Hypercellular; megaloblastic erythroid hyperplasia	Normocellular with normoblastic erythroid hyperplasia	Cellularity 10% consistent with hypoplastic anemia
Other lab tests	Negative G6PD, incubated osmotic fragility test, Direct Coombs test	AST>ALT, Negative Direct Coombs test; Thrombophilia workup normal including Antiphospholipid antibody syndrome and JAK2V617F mutation	Chromosomal fragility test negative
Radiology	-	Hepatic vein thrombosis, mild hepatomegaly and mild ascites	-
Summary	Unexplained hemolytic anemia with secondary folate deficiency	Hepatic vein thrombosis with evidence of hemolysis	Aplastic anemia

When to Suspect PNH?[5-10]

The rarity and diversity of clinical manifestations complicates the early diagnosis of PNH. Patients may present with anemia, fatigue, dyspnea, chronic kidney disease, abdominal pain, pulmonary hypertension, erectile dysfunction, dysphagia, thrombosis or hemoglobinuria. Many of these signs and symptoms are so common that every patient with anemia or thrombosis cannot be screened for PNH. Thus, PNH testing should be advised when some clinical or laboratory findings raise a suspicion.

A PNH test should be ordered in any patient who presents with:

- Intravascular hemolysis (~25% patients present with hemoglobinuria) as evidenced by hemoglobinuria, elevated LDH, reticulocytosis, and elevated plasma hemoglobin.

  Significant hemoglobinuria is usually present in classical PNH, whereas in cases associated with AA or MDS it may be absent due to a small PNH clone.
- Evidence of unexplained hemolysis with accompanying iron-deficiency, or abdominal pain or esophageal spasm, or thrombosis, or neutropenia and/or thrombocytopenia.
- Other acquired Coombs' negative, non-schistocytic, non-infectious hemolytic anemia.
- Thrombosis with unusual features:
  - Unusual sites—Hepatic veins (Budd-Chiari syndrome)/Other intra-abdominal veins (portal, splenic, splanchnic)/Cerebral sinuses/Dermal veins
  - With signs of accompanying hemolytic anemia
  - With unexplained cytopenia
  - Young patients

  PNH is the second most common cause of intra-abdominal vein thrombosis after myeloproliferative neoplasms. Thrombosis is the leading cause of mortality in PNH. About 29–44% of PNH cases experience at least one thromboembolic event during course of the disease. An early diagnosis and management of PNH associated thrombosis is paramount.
- Evidence of bone marrow failure:
  - Suspected or proven aplastic or hypoplastic anemia: Up to 70% patients with acquired AA have a PNH clone and 40% PNH evolves from AA. Mahapatra et al. in their extensive study at AIIMS New Delhi of 1501 AA patients, detected PNH clone in 39.7% cases at diagnosis.[9]

    Various studies have mentioned an excellent response of AA to immunosuppressive therapies in presence of minor PNH clones. Emergence of PNH clones and expansion of pre-existing PNH clones post ATG is known. However, clinically relevant PNH clones are seen in less than 5% cases of AA post ATG causing significant hemolysis.
  - Refractory cytopenia with unilineage dysplasia, hypoplastic MDS: Up to 50% patients with MDS test positive for a PNH clone. Testing for PNH in MDS is recommended in cases with refractory anemia subtype, MDS with evidence of hemolysis, or evidence of bone marrow failure such as hypoplastic MDS.
  - Other cytopenias of unknown etiology after adequate workup.

Diagnosis

Diagnosis of PNH is done by detection of the PNH clones. Different methods can be adapted.

Complement-based Test—Modified Ham's Test, Sucrose Lysis Test[5,11,12]

These tests are based on the sensitivity of PNH cells to activated complement proteins. Though inexpensive, these tests are laborious, technically challenging, and not accurate quantitatively. As these tests are RBC based, spurious results may be obtained during hemolytic episodes and post-blood transfusion. Also, autoimmune hemolytic anemia and congenital dyserythropoietic anemia may give false positive reports. Hence, these tests are no longer recommended as tests of choice for the diagnosis of PNH.

Gel Card-based Tests[5,11,13]

Gel card-based test is based on antigen-antibody reaction. If GPI linked proteins, like CD55 and CD59, are not present on RBCs there will be no reaction with anti-CD55 and anti-CD59. Minor clones and subclinical clones cannot be identified using this technique. This test is non-quantitative. Just like complement-based tests, this test also has limited ability to detect PNH clone during hemolytic episodes and in post-transfusion samples.

Flow Cytometric (FCM) Detection of PNH Clones[5,13-15]

This is a rapid, highly sensitive assay. FCM for PNH is the gold standard test for detection of PNH clones. FCM can pick up subclinical clones and can delineate type I, type II, type III RBCs with normal expression, partial deficiency, and complete deficiency of GPI linked protein, respectively. Patients with more than 20% type III red cells are likely to manifest as hemolysis whereas patients with majority type II clone without significant type III cells usually do not show hemolysis. Unlike previous tests, PNH can detect PNH clones in RBCs and neutrophils. As in multiparametric FCM one can acquire more events/cells and analyze multiple antigen characteristics of a cell, it can help detecting clones as low as 0.01%. More importantly monitoring of patients can be done by highly sensitive technique like FCM.

However, a proper knowledge of monoclonal antibodies to be used, their expression, sample requirement, gating strategy, and sensitivity of the assay is required.

Sample Requirement[14,16]

Most preferred specimen is peripheral blood in EDTA. Bone marrow sample is not recommended as immature myeloid cells may have changes in GPI-linked protein expression and in MDS patients there may be altered expression of some GPI-linked proteins in neutrophils and monocytes.

A minimum of 1 mL sample is required. But in cases with pancytopenia sample as much as 3 mL is required for higher cell acquisition to detect small subclinical PNH clones.

Though sample can be stored for 7 days at 4°C for RBC analysis, it is preferable to process sample within 48 hours as alteration in scatter and antigen expression in neutrophils over time is known.

Any commercial lysing agent with fixative can be used for WBC analysis (ammonium chloride with fixative may be used).

RBC or WBC[5,14,16]

Goal of RBC analysis is to diagnose and quantify cells lacking GPI-linked protein (type I/II/III cells). However, testing only RBCs may not be adequate in cases having active hemolysis or in case of transfusion where it underestimates clone size. So, determining WBC clones is more important for appropriate quantification of PNH clones.

Choice of Antibodies[5,14,16,17] (Table 2)

GPI-linked protein—simultaneous two GPI-linked proteins for two lineages are recommended.

CD55 and CD59 analyses in neutrophils are not recommended as they give a higher false positivity rate for PNH.

FLAER directly binds to GPI anchors and detects wide range of GPI-linked structures in different WBCs.

CD157 is brightly expressed on both neutrophils and monocytes and can replace two different antibodies for neutrophils and monocytes and is cost effective.

Testing for lymphocytes is not recommended because of their longer life span, which may give erroneous results in new onset PNH.

TABLE 2 Antibodies and panels used for the diagnosis of PNH by flow cytometry

Lineage of cells		*Gating marker*	*Lineage marker*	*GPI-AP*
RBC		CD235a		CD55, CD59
WBC	Neutrophils	CD45	CD15	CD24, CD157, FLAER
	Monocytes	CD45	CD64	CD14, CD157, FLAER
PANELS	RBC	3-color CD235a/CD55/CD59		
	WBC	6-color CD45/CD15/CD64/CD24/CD14/FLAER 5-color CD45/CD15/CD64/CD157/FLAER		

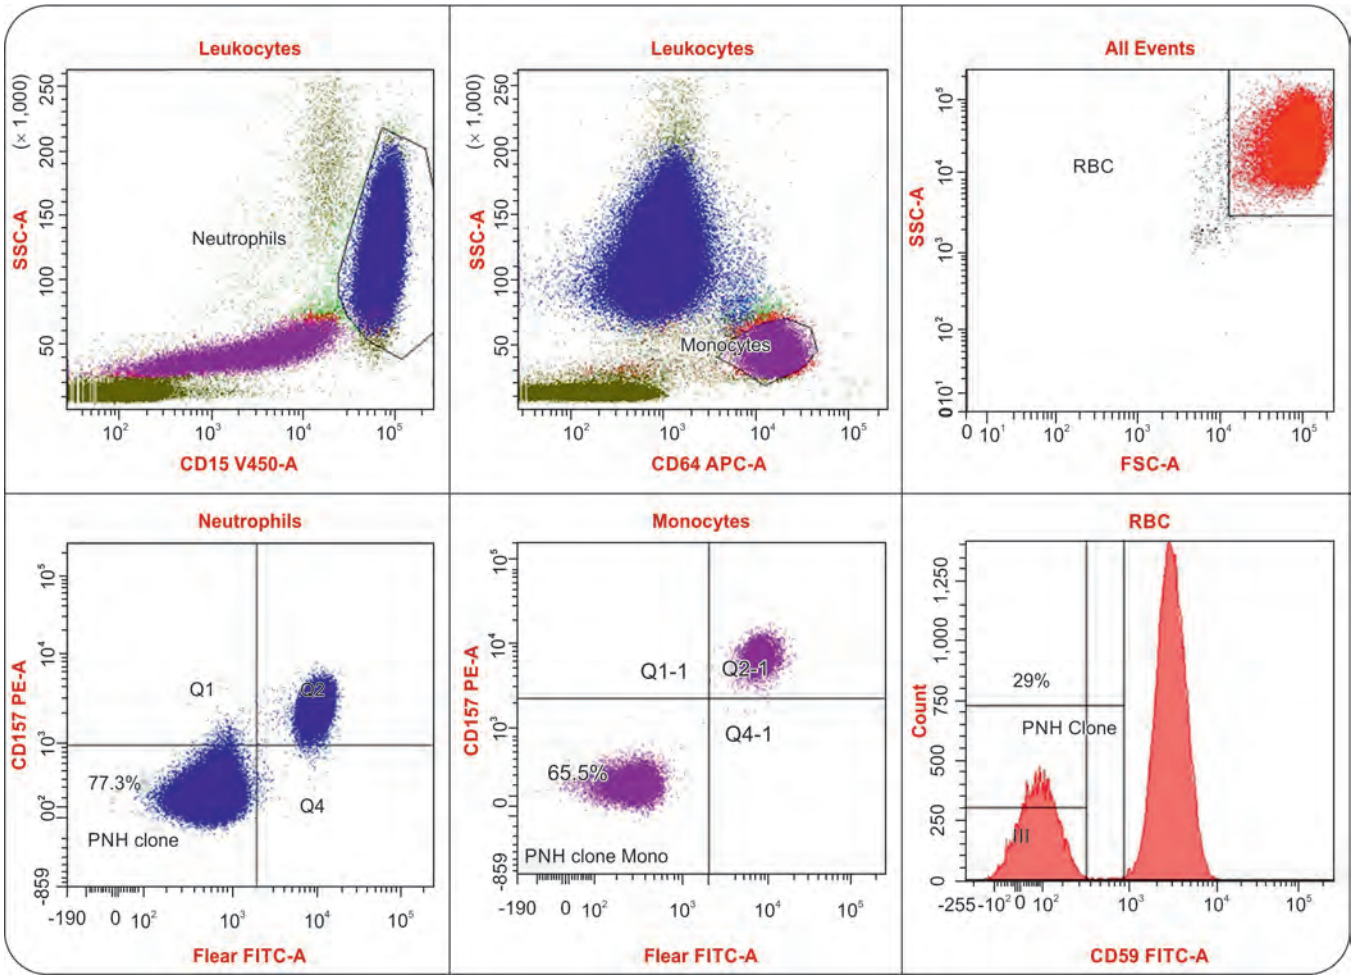

Fig. 1: Case 1. Neutrophils gated on the CD15-SSC plot after refinement of initial gate on CD45-SSC plot show a 77.3% PNH clone while monocytes gated on CD64 vs. SSC plot show a 65.5% PNH clone at diagnosis using a high-sensitivity assay. Red cells had a 29% PNH clone primarily type III with complete absence of GPI linked proteins. The clone size was smaller in red cells due to brisk hemolysis

- *Quantification*[14,16]—A laboratory specific lower limit of detection and lower limit of quantification should be established. In a high-sensitive FCM-PNH assay, minimum 50 PNH cells should be obtained to appropriately quantify. A minimum of 1,00,000 RBCs, 50,000 CD15 positive cells, and 10,000 CD64 positive cells are recommended to be acquired for sensitivity of 0.05%, 0.1%, and 0.5%, respectively in high sensitive assays. High sensitivity assays are not required for classical PNH but small clones in AA/MDS.
- *Interpretation*[14]—
  - >1% clone—PNH clone
  - 0.1–1%—Minor PNH clone
  - <0.1%—Rare cells with PNH phenotype
- *Monitoring/Retesting*[7,18]—Monitoring of PNH clones may be done annually or more frequently if there is worsening of symptoms. Frequent monitoring may also be needed in eculizumab therapy.

Patients with aplastic anemia need serial monitoring as minor clone can progress to a hemolytic PNH. Patients with no detectable clone should be screened every 6 months, decreasing to yearly if no clone appears in the first 2 years. If a clone is present or appears, patients should be screened every 3 months until the clone size is shown to be stable for 2 years.

Outcome of the three Cases

See **Table 3**.

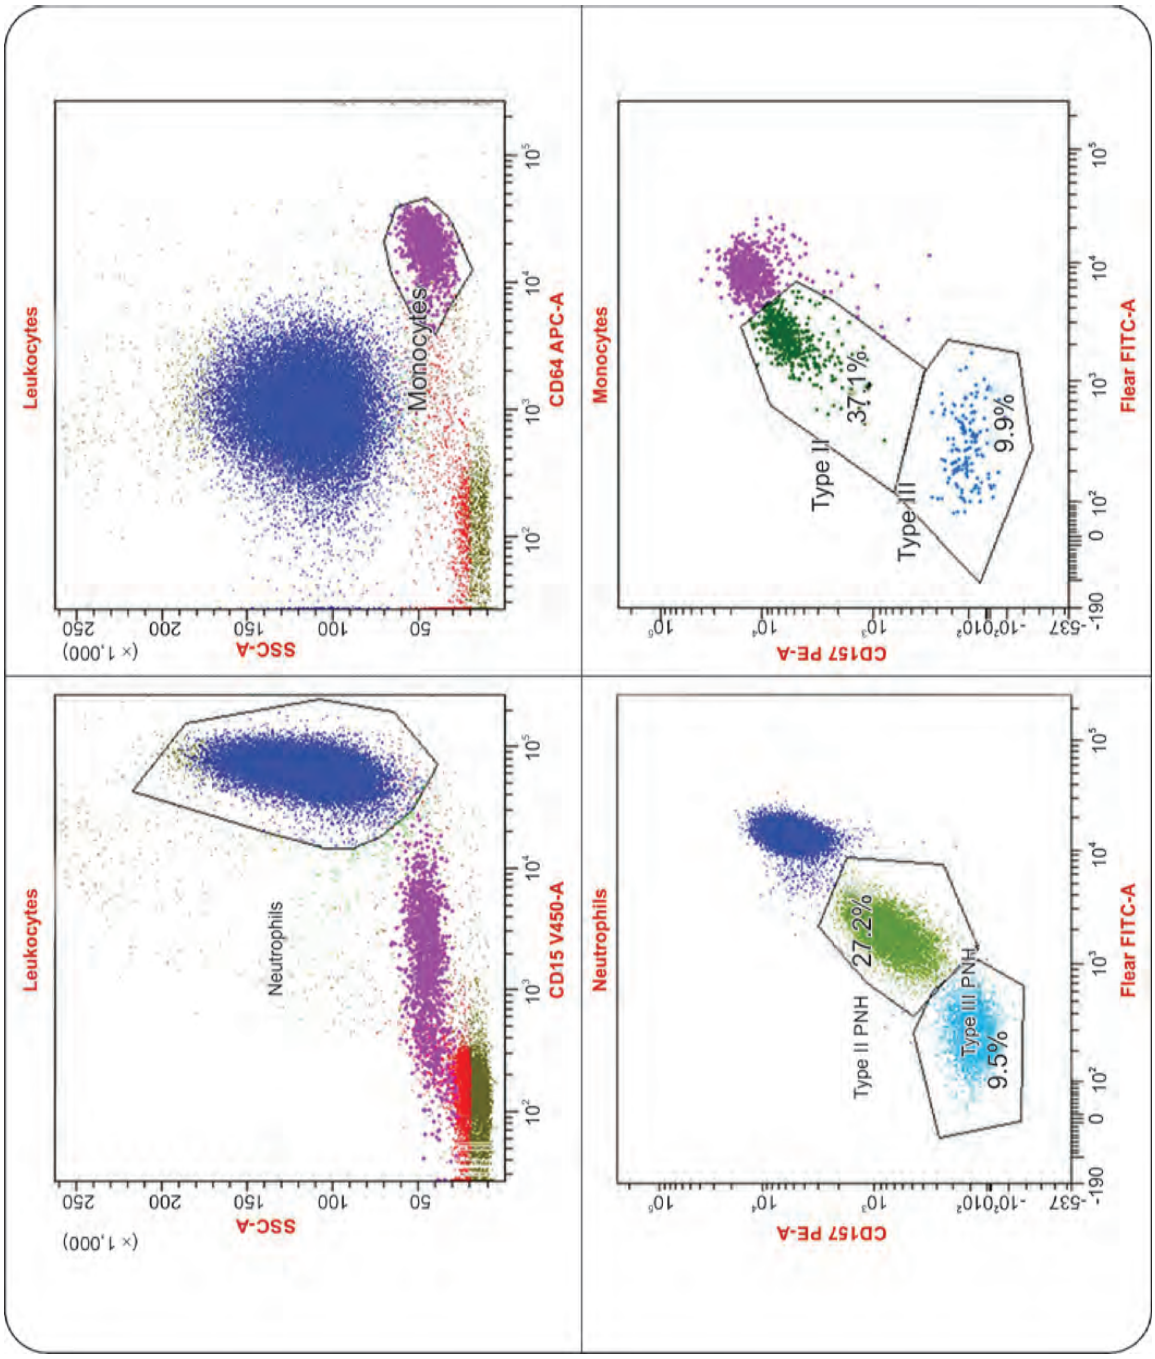

Fig. 2: Case 2. Both neutrophils and monocytes exhibit predominant type II PNH clones with reduced expression of GPI anchor and related proteins. Type II clones are sometimes clearly apparent on the CD157-FLAER plots in neutrophils and monocytes

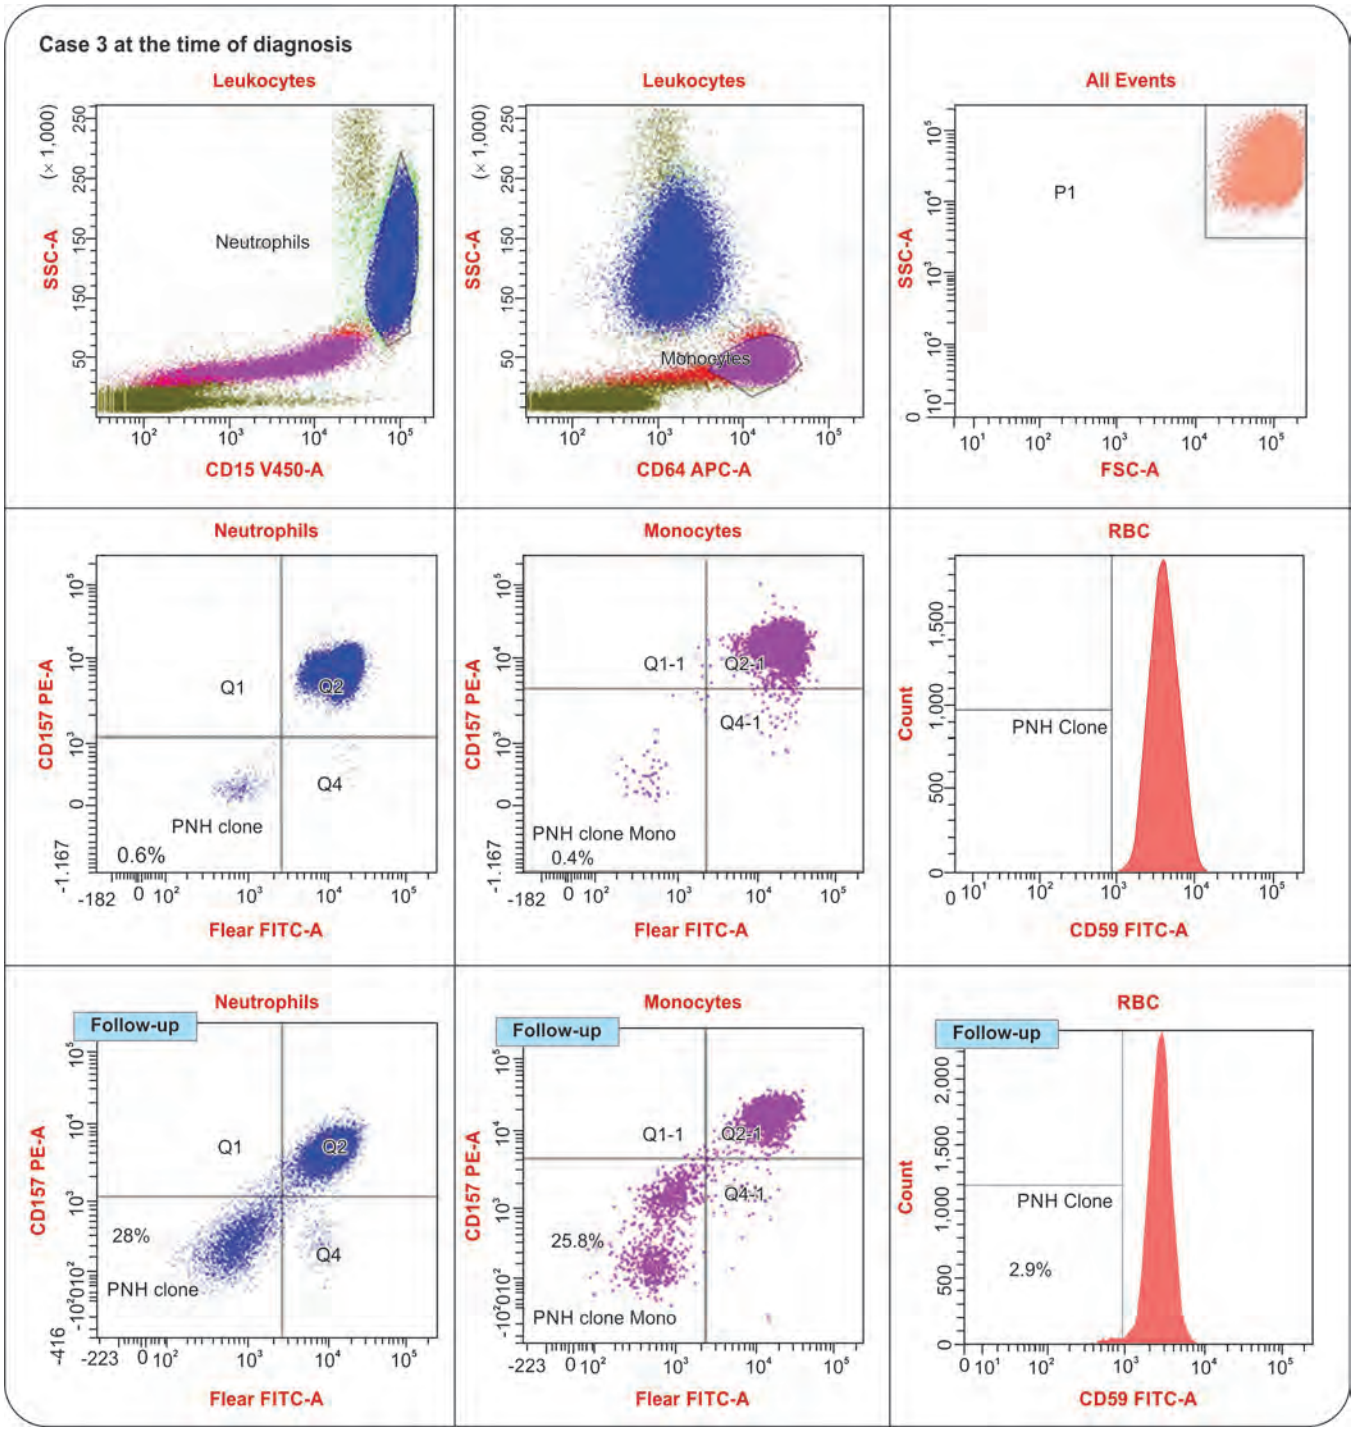

Fig. 3: Case 3 at the time of diagnosis and follow up. Neutrophils gated on the CD15-SSC plot after refinement of initial gate on CD45-SSC plot show a 0.6% PNH clone while monocytes gated on CD64 vs. SSC plot show a 0.4% PNH clone at diagnosis using a high-sensitivity assay. Red cells do not show any PNH clone on a routine sensitivity assay. After 5 years, PNH immunophenotyping was repeated when cytopenias recurred. PNH clone in neutrophils and monocytes had increased to 28% and 25.8%, respectively while a small clone of 2.9% was seen in red cells, mostly type II. The reason for lower red cell clone was attributed to ongoing packed cell transfusions and mild hemolysis

TABLE 3 PNH clones and clinical course in the three cases

	Case 1	*Case 2*	*Case 3*
Summary	Unexplained hemolytic anemia with secondary folate deficiency	Hepatic vein thrombosis with evidence of hemolysis	Aplastic anemia
PNH flow cytometry Neutrophil clone Monocyte clone Red cell clone	**(Fig. 1)** 77.3% 65.5% 29%, Type III: 28%	**(Fig. 2)** 36.7%, type II: 27.2% 47%, Type II: 37.1% Not done	**(Fig. 3)** 0.6% 0.4% 0.1%
Clinical course	Due to unavailability of eculizumab in India and lack of response to steroids, the patient underwent matched sibling donor transplant; remains asymptomatic 2 years post-transplant	Patient was treated with full anticoagulation but succumbed to death due to a second thrombotic episode	Patient responded to immunosuppressive therapy (ATG + cyclosporine) and attained hematological recovery. However, the patient relapsed with cytopenias 5 years later. Repeat bone marrow revealed hypoplasia with Monosomy 7. PNH-FCM showed increasing PNH clones

Conclusion

PNH is a rare and life-threatening disorder, has varied presentation like hemolysis, thrombosis at abnormal locations or bone marrow failure. Knowledge of different presenting symptoms and high index of suspicion is needed for an early diagnosis. Reliable testing and reporting procedures matter. Laboratory testing for high sensitivity PNH analysis by FCM in WBCs and RBCs should be preferred.

CHAPTER

233 JAK2 Mutation—What Physicians Should Know?

Tulika Seth

Abstract

Myeloproliferative disorders include polycythemia vera, primary myelofibrosis, and essential thrombocytosis. These disorders have an increased risk of thromboembolic complications and may progress post fibrotic state or transform into acute myeloid leukemia. Understanding of the molecular pathogenesis has resulted in newer targeted therapies and better risk stratification of patients.

Introduction

We are entering an era of molecular medicine. All of us were earlier taught about the variability of disease presentation, severity, and varied responses to treatment. We are now aware that variability even in infectious diseases and much more so in non-infectious diseases has a genetic basis. We know that different mutations, polymorphisms of genes, and even the allele burden are implicated in diseases. Knowledge about JAK2 mutation associated diseases is increasing. The classic JAK2 diseases are myeloproliferative conditions—polycythemia vera (PV), essential thrombocytosis (thrombocythemia) (ET) and primary myelofibrosis (PMF).[1] But the JAK2 mutation has been found in many other conditions and to make things more complicated the classic conditions of PV, ET, and PMF may also occur without JAK2.[2]

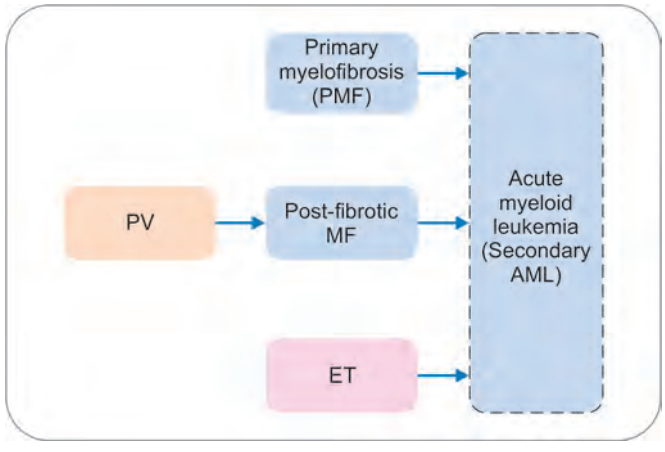

Fig. 1: Different myeloproliferative disorders and their risk of transformation

JAK2 Mutation

When we speak of JAK2 mutation we commonly refer to JAK2 (V617F) mutation **(Fig. 1)**. This mutation is acquired, and is present in the myeloid lineage of the hematopoietic cells. JAK2 mutation has been associated with a wide variety of myeloproliferative/myeloid disorders—such as PV, PMF, chronic myelomonocytic leukemia (CMML), myelodysplastic syndrome (MDS),[3] etc. **(Table 1)**. The presence of the mutation is not diagnostic of any disorders; it has to be taken in context with other clinical and laboratory abnormalities. To make a diagnosis we need to evaluate the clinical presentation and hematological parameters. Many of the conditions typically associated with JAK2 can also arise without JAK2 mutation.

TABLE 1 Conditions associated with JAK2 V617F mutation

Conditions associated with JAK2 V617F	*Frequency of JAK2*
• Polycythemia vera (PV)	PV: >90% JAK2 exon 12 = PV: 2–3%
• Essential thrombocytosis/ thrombocythemia (ET)	ET: 60%
• Primary myelofibrosis (PMF)	PMF: 60%
• Systmemic mastocytosis (SM)	25%
• Chronic neutrophilic leukemia (CNL)	17–33%
• Hypereosinophilic syndrome (HES)	0–2%
• Myelodysplastic syndrome (MDS)	1.5–5%
• Chronic myelomonocytic leukemia (CMML)	3–13%
• Unclassified MPD (UN)	20%
• HVOTO/ Budd-Chiari Syndrome (BCS)	Varied

Blood. 2005;106(6):2162-8; Blood. 2005;106(10):3370-3; Blood. 2005;106(4):1207-9.

Abbreviations: CMML, chronic myelomonocytic leukemia; CNL, chronic neutrophilic leukemia; ET, essential thrombocythemia/thrombocytosis (ET); HES, hypereosinophilic syndrome; MDS, myelodysplastic syndrome; PMF, primary myelofibrosis; PV, polycythemia vera; SM, systemic mastocytosis; UN, unclassified MPD.

What are the Implications of JAK2?

JAK2 associated diseases are a wide variety of chronic diseases in the myeloproliferative neoplasms (MPN) or MDS group of diseases. They are characterized in MPN by increased production of red blood cells, platelets, or one type of white blood cell; or in MDS by increased production of dysplastic hematopoietic cells, resulting in cytopenias.[3,4] They are associated with constitutional symptoms, high symptom burden, poor quality of life, and decreased life expectancy and risk of transformation to acute myeloid or other leukemia **(Fig. 1)**.

Why Do Various Conditions Evolve from the Same Mutation?

The JAK2 gene is a signaling molecule for many cytokines including: INF-γ, erythropoietin (EPO), prolactin, thrombopoietin, G-CSF, GM-CSF, and IL-3 via activating many signaling pathways like: MAPK, PI3, ERK20, and importantly STAT. JAK2 abnormalities present with different genetic alterations **(Table 2)**, the interplay of various genetic and cytokine abnormalities results in the clinical disease state and its severity.[3-5]

TABLE 2 Types of JAK2 abnormalities and pathogenesis

Rearrangements
JAK2 can be rearranged with other genes: • TEL/ETV6: t(9;12) (p24;p13) reported in myeloproliferative neoplasm (MPN), also in T-cell ALL • BCR: t (9;22) (p24;q11.2) reported in few MPN • PCM1: t (8;9) (p22;p24) reported in MPN, also in AML and ALL • NF-E2: der (9) t(9;12) (p24;q13) reported in MDS
Point mutations
V617F G >T at nucleotide 1849 on exon14, the classical MPNs T875N reported in AML (M7)
Deletions/Insertions
Exon12: In 4% PV patients there are >8 reported mutations including deletions and insertions in codon 538 to 543
Numerical
It can present as trisomy (+9) or be overexpressed due to amplification.

What is JAK2?

The JAK2 gene is a member of a family of genes that includes four Janus kinases 1, 2, 3, and tyrosine kinase 2. The protein group was named Janus kinases after the Roman God Janus with two faces, as the non-receptor kinases have two similar "active" and "inactive" domains.

The JAK gene has domains, which binds to type 1 cytokine receptor, it plays a role in trafficking of the (erythropoietin) EPO receptor (EPOR).

The JAK2 protein in contact with the cytoplasmic domain of the receptor catalyses tyrosine phosphorylation and leads to activation of signal transducer and activator of transcription (STAT) molecules that act as transcription factors and modifies other key regulatory pathways and cytokine signaling[3-5] (diagram illustrating functional JAK STAT pathway—**Fig. 2**).

The V617F mutated JAK2 spontaneously activates downstream STAT mediated transcription, and activation of ERK/MAP kinase and P13K/AKT pathways. The wildtype JAK2 has an autoinhibitory activity, and does not mediate such events. The hematopoietic stem cells in patients of myeloproliferative/myeloid disorders are extremely sensitive to growth factors; proliferation is

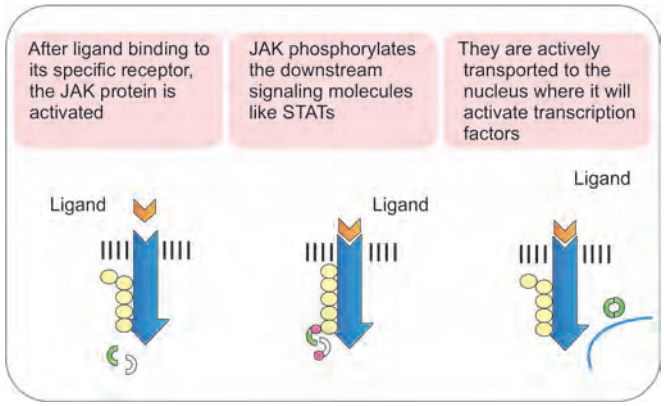

Fig. 2: Steps of JAK-STAT pathway

triggered by JAK2 signaling. Patients who are homozygous for JAK2 mutation have advanced disease and increased risk of progression to secondary myelofibrosis compared to heterozygous patients.[3-6]

Types of JAK2

JAK2 V617F occurs more frequently in a specific JAK2 haplotype, named JAK2 46/1 or GGCC, which is tagged by rs10974944 (C/G), rs12343867 (T/C), and rs4495487 (T/C). Other JAK2 mutations are more commonly associated with Budd Chiari and other disorders.[6-9]

Allele Burden and Disease

Allele burden has different implications in different diseases, a high V617F allele burden in PV is associated with a more aggressive phenotype, but a low allele burden in myelofibrosis is associated with reduced survival.[10]

JAK2 as a Target for Therapy

We now have agents, which are targeted inhibitors JAK2, and also has inhibits JAK1. This is approved for therapy of patients with intermediate- or high-risk MF, including primary MF (PMF), post-polycythemia vera MF (PPV-MF), and post-essential thrombocythemia MF (PET-MF), and PV patients with hydroxyurea (HU) failure or intolerance. Newer more specific JAK2 inhibitors are in phase 3 trials—fedratinib.

Clinical Features of MPN

The MPN are characterized by increased counts and constitutional symptoms **(Table 3)**. These may occur secondary to other conditions, so exclusion of renal, pulmonary causes of increased hemoglobin, or causes of reactive thrombocytosis etc. are necessary. Myelofibrosis is often missed or under diagnosed as the huge splenomegaly may be confused with other medical conditions. The bone marrow fibrosis results in massive splenomegaly, hepatomegaly, and extramedullary hematopoiesis as a compensatory mechanism. In India, patients with lower hemoglobin levels than standard criteria may be recognized; the other molecular tests and bone marrow evaluation are useful to identify them so that they can receive appropriate therapy. MPN patients particularly PV may show iron deficiency, this may be due to many reasons, but one important factor is disorder of iron metabolism, with the inflammation caused by PV counteracting Hepcidin suppression.[11] Iron therapy is controversial as the HU used in cytoreductive therapy in high-risk PV patients is more effective in iron-deficient than in iron-replete patients.

The diagnosis of MPNs is made in a symptomatic patient and requires a combination of parameters and tests.[12,13]

Diagnostic Criteria

The diagnosis of MPNs is made in a symptomatic patient and requires a combination of parameters and tests. The usual criteria followed are the WHO 2016 diagnostic criteria.

The diagnosis of MPN should be based on the 2016 WHO diagnostic criteria.[12] Criteria include specific findings from the CBC, blood smear, bone marrow analysis, correlated with clinical history, as well as the presence of certain molecular markers and the exclusion of other disorders.

Laboratory Tests

All patients should have a CBC, differential count test; this should be repeated to ensure no fallacy. Tests to fulfill diagnostic criteria of WHO criteria[12] should be done. In PV serum erythropoietin levels and evaluation to exclude causes of secondary polycythemia are required. In all patients, a detailed peripheral smear with evaluation for blasts, base line tests for RFT, LFT, evaluation for comorbidity, history of smoking, medications, etc., should be performed. Cardiovascular risk assessment is essential.

TABLE 3 Clinical features of JAK2 positive myeloproliferative diseases

MPN	*Clinical presentation*	*Features*
PV	• Median age 60 years, rare before 40 years. Male to female ratio 1.2:1. Median survival 14 years • Facial plethora, headaches • Heaviness of head, fatigue, weight loss, congestion of eyes, blurring vision or diplopia, and burning (erythromelalgia) sensation or itching in hands and feet, often worse after water (aquagenic pruritus). Increased risk of thrombosis—venous and arterial	• High number of RBCs (high hemoglobin, high hematocrit, red cell mass), bone marrow fibrosis, risk of thrombosis • Risk of post-PV myelofibrosis (MF) ET with poor outcome
ET	• Median age 65 years, but can be seen at any age. Female to male ratio 2:1 • Median survival 20 years • Headache, dizziness, fainting, chest pain, temporary vision changes • Numbness and tingling of hands and feet • Redness, throbbing, and burning pain in hands and feet (erythromelalgia) • Increased risk of thrombosis	• High platelet number, and risk of thrombosis. Bone marrow shows increased numbers of large, atypical megakaryocytes • Post ET myelofibrosis is rare, need to rule out if previous diagnosis of ET was actually early-phase of PMF
PMF	• Mean age 60 years. Male to female ration 1.5:1. Median survival 6 years. Increased constitutional symptoms in comparison to the blood count abnormality. Fatigue, weakness, shortness of breath, pain or fullness of abdomen (due to massive splenomegaly, hepatomegaly), early satiety, unintentional weightloss. • Fever, excessive sweating, fever, easy bruising, itching, bleeding, or bone pain	• De novo/primary MF (PMF) (rather than from the transformation of PV to MF) • Leukoerythroblastic blood smear with dacryocytes if marrow is fibrotic • Bone marrow fibrosis might be absent or minimal in early-stage/prefibrotic PMF • Reticulin or collagen fibrosis is considerable in overt PMF
CNL	Fatigue, weight loss, night sweats, bone pain, easy bruising, pruritus, or symptoms of gout	• Sustained neutrophilia in peripheral blood (cells are not immature), hepatosplenomegaly. Bone marrow is hypercellular with predominance of myeloid proliferation • CSF3R mutations may be present but not specific
CEL, NOS	Fatigue, fever, cough, muscle pain, itching, diarrhea, periorbital swelling, angioedema	• Eosinophilia due to clonal proliferation • Evidence of clonality; and abnormal bone marrow morphology
MPN-U	Same as other classic MPN	• Cases with features of an MPN but do not meet diagnostic criteria, either because features are not fully fulfill subtype or if not clear due to advanced stage or another diseases

MF, myelofibrosis; MPN-U, myeloproliferative neoplasm unclassifiable; NOS, not otherwise specified.

Diagnostic Molecular Testing

Testing for BCR-ABL1 mutation is required as by definition these conditions are BCR-ABL negative. Then evaluation for other MPN mutations should be performed. Molecular testing is used to assess clonality and to detect MPN-specific mutations. First testing for JAK2 V617F mutation should be performed in all MPN suspected patients; it is the most common mutation and occurs more than 95% patients with PV.

If the JAK2 V617F mutation is not detected, testing for CALR and then MPL mutations should follow for patients with ET or PMF.[12,13] If PV is still suspected in those with negative JAK2 V617F mutation results, testing should be performed for JAK2 exon 12 mutations. In those with ET or PMF but without JAK2, MPL, or CALR mutations (triple-negative MPNs), testing for mutations in ASXL1, CBL, CSF3R, DNM3TA, EZH2, IDH1, IDH2, LINK/SH2B3, SF3B1, SRSF2, TET2, TP53, and U2AF1 genes should then be considered. A comprehensive next generation sequencing (NGS) myeloid panel can be useful for this, instead of single-gene tests and provides details of additional prognostic genes.[13]

Bone Marrow

Bone marrow examination is very important and a bone marrow aspiration and biopsy is necessary confirm a diagnosis of MPN, and for prognosis by assessment of blast percentage and evidence of fibrosis.[12,13]

Cytogenetics

Cytogenetic analysis is important in distinguishing MPN subtypes. The chromosome analysis also serves to provide evidence of clonality and clonal evolution, it may be repeated if concerns of progression exist.

Prognosis

The overall survival of patients with MPNs is variable depending on the subtype. Several scoring systems and prognostic models have been developed for the risk stratification of patients with MPN. The dynamic international prognostic scoring system (DIPSS) is commonly used for its ease and ability to stratify patients into risk groups.[14] Treatment decisions are made per the risk stratification of the patient, higher risk patients are more likely to develop progression from their baseline MPN this can mean transformation to acute myeloid leukemia or post-fibrotic myelofibrosis. These secondary cases are more difficult to treat and have poorer prognosis.

Therapy

These patients must get a hematology consultation periodically due to their risk of thrombosis, progression, and symptom load. Shared care with primary care physicians is possible and desirable for low-risk patients. Therapy of MPN depends on the diagnosis, age, risk classification, and whether complications of thrombosis have occurred or not.[15-18]

Patients of PV and ET require low-dose aspirin to decrease the risk of thrombosis. Younger PV patients can be well managed by phlebotomy, and/or interferon alpha, but older patients or those with history of thrombosis require hydroxyurea (HU). HU is titrated to response; those who fail or are intolerant to HU can be given ruxolitinib (a JAK2 inhibitor). In ET along with low-dose aspirin, additional medications to reduce the platelet counts like hydroxyurea, anagrelide, and interferon alpha are used.[17,18]

Myelofibrosis low-risk patients may be given HU, thalidomide-prednisone or ruxolitinib. High-risk patients should be offered allo-hematopoietic stem cell transplant as a curative option. Patients with low-risk disease will have a longer life and supportive treatments like hydroxyurea and ruxolitinib are acceptable.[15,16] All of these treatments are palliative. For high-risk patients curative options of allogeneic hematopoietic stem cell transplant (bone marrow transplant, BMT) should be discussed and planned.

Glossary

- A gene is polymorphic if more than one allele occupies the gene's locus within a population. A polymorphic variant of a gene can lead to the abnormal expression or abnormal form of protein. These may cause or be associated with diseases.
- An allele is any of the possible forms in which a gene for a specific trait can occur. In humans, two alleles for each gene are inherited, one from each parent. The variant alleles arise by mutation and are found at the same place as the original gene on the chromosome.
- Wildtype gene is in its normal state, mutated gene has acquired or inherited alterations.
- Allele burden One, called the gene-dosage hypothesis, postulates a correlation between disease phenotype and the proportion of JAK2 (V617F) mutant alleles introducing the concept of allele burden, that is, the ratio between mutant and wildtype JAK2 in hematopoietic cells.
- Haplotype—A haplotype is a group of genes, which is inherited together by an organism from a single parent.

Conclusion

JAK2 associated conditions of PV, ET, and PMF may be underrecognized and underdiagnosed. The rare conditions associated with JAK2 are also often missed. High index of suspicion, appropriate tests, and timely referral can change the scenario. Correct diagnosis and treatment can prevent serous thrombotic complications and allow access to recommended treatment will help the patient.

CHAPTER

234 Approach to a Case of Polycythemia: More Blood May Be Bad....

Tuphan Kanti Dolai, Prakash Singh Shekhawat, Malini Garg

Abstract

A 59-year-old male teacher reported with painful erythematous finger swelling and excessive itching without any rash of 3-week duration. Physical examination shows multiple excoriations, splenomegaly, and erythematous swelling of hands. Vitals were normal. Complete blood count shows Hb 17 g/dL, MCV 87 fL, TLC 14 × 10^9/L, and platelet 780 × 10^9/L. Biochemistry shows normal LFT and urea, creatinine while serum EPO was 2.4 U/L (range 7–20 U/L). He had JAK2V617F mutation and was started on regular phlebotomy and Tab Aspirin 75 mg PO OD. His hand swelling and pruritus improved.

Introduction

Polycythemia means an abnormal increase in hemoglobin or hematocrit. It is categorized as absolute and relative. Absolute polycythemia has an increased red blood cell mass (RCM), the classical example being polycythemia vera (PV). There is a mild rise in hematocrit without raised RCM in cases of relative polycythemia like severe dengue fever, severe diarrhea, or other conditions with a moderate increase of hematocrit secondary to reduced plasma volume. Absolute polycythemia is categorized into primary and secondary.[1,2] PV is the standard example for primary absolute polycythemia. Secondary absolute polycythemia has hypoxia, because of chronic lung disease, carboxyhemoglobinemia due to smoking and renal cell carcinoma producing erythropoietin. PV is a clonal malignant disorder arising from a mutation in multipotent hematopoietic stem cells with an increase in blood cell production independent of cytokine. It is the commonest myeloproliferative neoplasm (MPN) in the United States and has a male preponderance with median age of diagnosis in the seventh decade.[3] Annual incidence ranges from 1–2.5 per 100,000 persons in different countries.

Etiology and Pathogenesis

Primary polycythemia is caused by dysregulation in erythropoietin sensing mechanism and is mainly associated with low erythropoietin levels. Primary familial and congenital polycythemia has an EPOR gene mutation, which disrupts down regulation of JAK2 pathways. PV is due to an acquired, somatic mutation of multipotent hematopoietic stem cell triggering clonal proliferation plus suppression of normal polyclonal hematopoiesis. Most common mutation is JAK2V617F found in 95–98% of cases.[4] It causes persistent activation of EPO receptor signaling. In vitro development of erythroid colonies in absence of EPO is characteristic of PV.[3] PV can occur at any age because JAK2V617F expression is age-independent.[5]

Secondary polycythemia has increased erythropoietin production because of hypoxia. Secondary familial and congenital polycythemia may have mutations that exist in genes encoding hypoxia inducible factor (HIF), von Hippel-Lindau (VHL) proteins, or prolyl-hydroxylase domain (PHD) enzymes, which regulate renal oxygen sensing and EPO production. Secondary acquired causes have increased EPO levels either secondary to tissue hypoxia (pulmonary illness, CO poisoning, high

altitude, high-affinity binding hemoglobinopathy) or due to overproduction (stenosis of renal artery, kidney cyst, tumors with ectopic EPO production). Smoking history or occupational exposure to hydrocarbon may lead to increased carboxyhemoglobin and increased EPO levels.[4] Separation of primary and secondary polycythemia is important as primary polycythemia has risk of leukemic/fibrotic transformation. Phlebotomy is rarely needed in secondary polycythemia unlike primary polycythemia.[3]

Diagnosis

Polycythemic patients are often diagnosed incidentally having elevated hemoglobin or hematocrit found in CBC during baseline evaluation of other complaints. History of smoking, high altitude stay, congenital heart disease, alcohol, and drug abuse along with clinical examination becomes very important to distinguish secondary from primary causes.

Clinical spectrum varies from no symptoms to life threatening thrombosis. Genesis of these symptoms could be related to increased RCM or the underlying disease process. Increased RCM may cause hyperviscosity resulting in symptoms like vertigo, tinnitus, headache, visual disturbance, and hypertension. Both usual and unusual types of arterial and venous thrombosis can be seen. Thrombotic symptoms depend upon the site and the extent of thrombus. Polycythemic patients may have characteristic ruddy complexion.

Although aquagenic pruritus and peptic ulcer disease are common associates of polycythemia, commonly they may have signs and symptoms of the underlying disease like chronic obstructive airway disease (COAD) or cyanotic heart disease. Apart from the signs of the underlying disease patient may have splenomegaly, which is rarely seen in early phase of the disease.[4]

Pretreatment correct diagnosis is essential. Overt PV is easily revealed by clinical findings.[6] Splenomegaly is seen in 75% of the cases and is rare in other varieties.[6] Around 30% cases have hepatomegaly. Pruritus occurs in 40% of PV cases and is rare in other varieties of polycythemia. Associated thrombocytosis, leucocytosis, or basophilia indicates the diagnosis of polycythemia vera. Panmyelosis is seen in bone marrow.[6] Diagnostic marrow studies commonly show reticulin fibrosis and absent iron stores. Bone marrow cytogenetics shows clonal markers in 13–31% of untreated patients.[6] In patients lacking definite evidence of PV the differential diagnosis includes early or mild polycythemia vera, primary pure erythrocytosis or secondary erythrocytosis.[6] The history and physical examination may give clues to the presence of a cause for secondary erythrocytosis. Additional laboratory testing is often helpful. An oxygen saturation < 92% indicates hypoxemia as the cause for polycythemia.[6] HPLC and oxygen dissociation curve can pick high oxygen affinity hemoglobins which usually has a family history. Renal ultrasound, intravenous pyelography, or computed tomography is essential to rule out suspected renal lesion. In selected patients hepatic lesion is diagnosed by ultrasound, CT scan, or radionuclide scan. Similarly, for cerebellar hemangioblastoma a CT brain with stress on the posterior fossa is helpful and can determine the source of ectopic EPO production. Commercially available serum erythropoietin radioimmunoassay is helpful in differential diagnosis. Overall, increased erythropoietin suggests secondary erythrocytosis, whereas a normal value is uncertain as occasionally erythropoietin may be increased in secondary erythrocytosis. Erythropoietin assay may be most useful in those lacking obvious clinical sign of PV and no apparent cause for secondary erythrocytosis.[6] In PV patients endogenous colony formation occurs without added erythropoietin, whereas for other causes of polycythemia exogenous erythropoietin should be added.[6] **Flowchart 1** shows the approach to polycythemia.

WHO defines polycythemia vera as a myeloproliferative neoplasm with hemoglobin level >165 g/L (16.5 g/dL) for males and >160 g/L (16 g/dL) for females or hematocrit levels >49% in men or >48% in women or increased red cell mass (RCM) >25% from baseline **(Table 1)**.

Treatment of Polycythemia Vera

Age, sex, initial presenting symptoms along with blood picture must be considered for individualized therapy. Goal of therapy is to decrease symptoms, reduce likelihood of thrombus, and prevent/delay transformation.

Phlebotomy: Initially phlebotomy is needed in all patients to keep hematocrit <45% to reduce the risk of thrombotic and cardiovascular complications.[8,9] In young fit, a 450 mL phlebotomy is safely done on alternate days till this goal is reached. In older, unfit patients smaller phlebotomies approximately 200–300 mL twice weekly can be considered.[6] A standard unit of phlebotomy

Flowchart 1: The approach to polycythemia

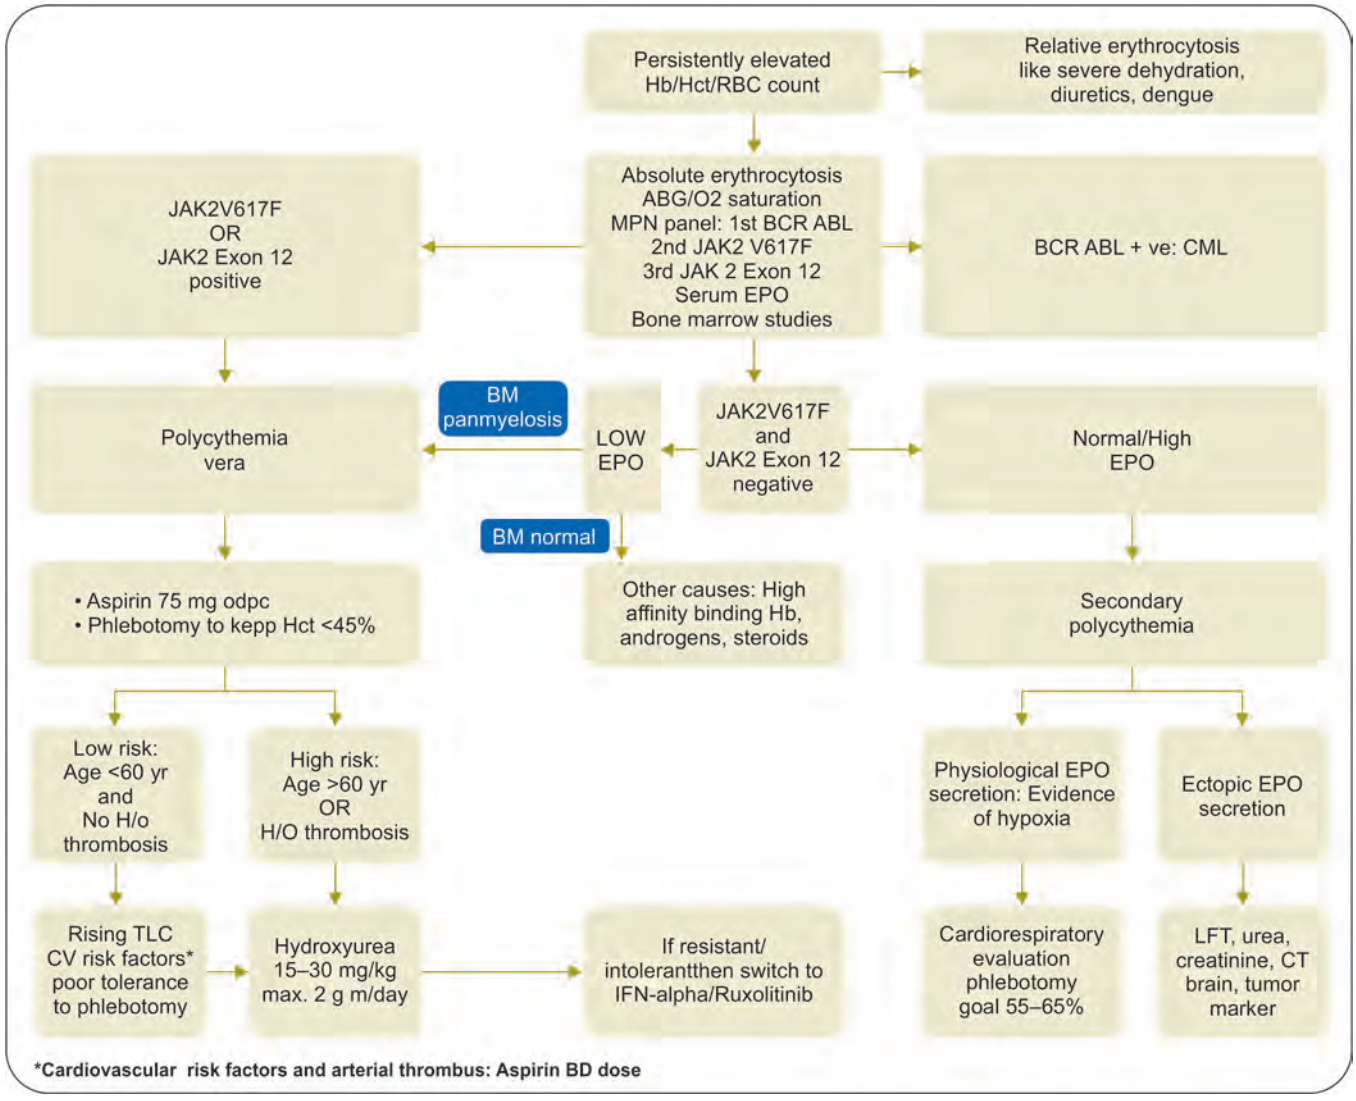

TABLE 1 WHO 2016 PV diagnostic criteria[7]

Major criteria	• Hb >16.5 g/dL in men (or Hct > 49%), Hb >16 g/dL in fematles (or Hct >48%), or >25% increase in red cell mass • Bone marrow biopsy showing characteristic panmyelosis and pleomorphic megakaryocytes • Mutation in JAK2V617F or JAK2 exon
Minor criteria	Serum EPO level below the normal reference range
Diagnosis	• All three major criteria or • First two major criteria and the minor criterion

TABLE 2 Polycythemia vera risk stratification[7]

PV risk stratification	*Age ≤60 years*	*Age >60 years*
No history of thrombosis	Low risk	High risk
History of thrombosis	High risk	High risk

decreases Hct by 3%. Polycythemia Vera Study Group (PVSG) recommends use of myelosuppressive treatment. Cytoreduction is usually not needed in low risk group whereas it is used in high risk group **(Table 2)**.

Hydroxyurea (HU): HU, a ribonucleotide reductase inhibitor, is effective and first-line recommendation for cytoreduction in high risk group. Need of cytoreduction or other therapy should be individualized, and this reminds us of Dameshek. "There is a tendency in medical practice—by no means limited to hematologists—to treat almost any condition as vigorously as possible. In hematology, this consists in attempting to change an abnormal number—whether this number is the hematocrit, white cell count, or platelet count to get normal values, whether the patient needs it or not!"[10] Overall hydroxyurea is the commonest cytoreductive drug used for ET and PV cases, based on the results of the PT-1 randomized controlled trial in 809 high-risk patients with ET, in which HU proved superiority to anagrelide in the rates of serious hemorrhage, arterial thrombosis, and myelofibrosis progression[11,12]

Interferons: Interferon-α is an important drug if HU is no longer suitable for a patient. Newer longer acting pegylated-α-2a is available and can allow less frequent administration. IFN-α has anti-clonal activity and also helps in histological improvement.[13,14]

Although it does not have leukemogenic effect and is safe for long-term use but flu-like symptoms and mood changes often limit its use.

Ruxolitinib: The JAK1/2 inhibitor ruxolitinib is approved therapy for PV cases where HU is intolerant or refractory, based on RESPONSE and RESPONSE-2 studies in patients with or without splenomegaly, respectively.[15-17] It is given in 15–20 mg BD doses for symptom control.

Treatment of Secondary Polycythemia

Cause and underlying mechanism will help in deciding treatment for polycythemia, especially secondary causes. Aggravating factors like smoking and dehydration must be rectified. Smokers must be encouraged to refrain from tobacco usage. Diuretics can reduce plasma volume, increase hyperviscosity, and thus are avoided where possible. Drugs like Androgens must be carefully discontinued or lower doses used if feasible. Smoking cessation helps in reversal of polycythemia related to carboxyhemoglobinemia and it can improve chronic obstructive pulmonary disease associated polycythemia.[6] Continuous low flow oxygen therapy may reduce hematocrit and it improves status of hypoxemic patients due to sleep apnea and chronic obstructive pulmonary disease.[18] Reducing weight may be helpful in obesity-hypoventilation syndrome. Surgical removal of EPO producing lesions usually causes improvement and resolution of the polycythemia. Likewise, polycythemia reversal may be seen after correcting underlying benign renal lesion. Some secondary polycythemics require phlebotomy. Preoperative elective phlebotomy should be considered in these cases.[6] The ideal hematocrit level in these patients is a tough call, to maximize the oxygen carrying capacity, and minimize the deleterious side effects of hyperviscosity.[6] The ideal hematocrit differs with the main disorder and usually differ amongst patients with the same illness. Usually hematocrit >60% is expected to be harmful and they must undergo phlebotomy, especially when sign/symptoms of poor oxygenation are seen.[6] There is decreased arteriovenous oxygen difference, improvement in pulmonary artery resistance, better right ventricular function along with improved hemodynamics and exercise tolerance.[6] Maintaining hematocrit between 50–55% is likely to help hypoxic lung patients. Acute hemodynamic effects of phlebotomy can be managed by isovolumic phlebotomy. Myelosuppressive treatment is best avoided in cases of secondary erythrocytosis.

Treatment of Relative Polycythemia

Numerous factors are responsible for the relatively increased hematocrit. Abstaining from alcohol intake and smoking may be helpful. Strict hypertension management is essential. Hydration status should be well supported. Phlebotomy is not recommended in cases of relative polycythemia.

Conclusion

Polycythemia included variety of causes from smoking, high altitude, dehydration, congenital heart disease to the clonal polycythemia vera, which has a risk of leukemic progression. They have an increased likelihood of vascular manifestation and risk of thrombosis. Goal is to keep Hct <45% and a cardiovascular risk factor modification. Phlebotomy and aspirin forms important part of treatment along with hydroxyurea or interferons in selected cases. Ruxolitinib is approved for HU resistant or intolerant cases.

Technology and Medicine

CHAPTER

235 Artificial Intelligence: The Space-X of Diabetology!

Hem Shanker Sharma

Abstract

The age of pestilence and famine was muddled with malnutrition and infectious diseases. Metaphorically we are already sitting on the top of a volcano, the number of diabetics have already affected almost half a billion people. The artificial intelligence (AI) has revolutionized all spheres of life. The discussions on the application of AI in health-care system is omnipresent, this underlies the huge hidden potential of this unique technology in dethroning the enormous burden of several chronic medical conditions. This is an era of Industry 4.0, which is a refabricated concept of smart production and application, that is identified with the 4th industrial revolution and the emergence of cyber-physical systems and this shall govern the future of medicine. The most flabbergasting advances in the application of AI techniques come from data-driven methodologies that learn from large datasets. With AI at hand the diabetes management is headed for an elegant, personalized, custom-made management of therapies, at the level of most minuscule stratum of medical care!

Introduction (from Pestilence to Diabetes)

The age of *pestilence and famine* was flooded with malnutrition and infectious diseases. The high-fertility rates seeking to explode the living population were dismantled by an equated killing competence of these infirmities. This gradually paved way for the mechanized world with cozy couches and watches devoid of time to engage in any sort of physical activity. This again led to malnutrition, but this time featuring the other end of the spectrum. The resulting epidemic of obesity, hypertension, and diabetes signaled the new age of indolence and metabolic syndrome. Metaphorically we are already sitting on the top of a volcano, the number of diabetics have already affected almost half a billion people.

Cracking Ominous Octet with Artificial Intelligence

The complex interaction of the ominous octet for the causation and feasible interjections, which has to be intervened to diagnose and treat the diabetes has to be envisaged with something equally intelligent. The smart machines that are being made to *think and behave* in humane manner are transforming the way we manage these complexities. Way back in the 1950s, the fathers of the field Minsky and McCarthy, described artificial intelligence (AI) as any task performed by a program or a machine, which uses human intelligence to accomplish it. The AI has revolutionized all spheres of life. The discussions on the application of AI in health-care system is omnipresent, this underlies the huge potential of this unique technology in deforesting the enormous burden of several chronic medical conditions. At present diabetes appears to be the brand ambassador for its application in health care for a number of reasons.[1] This is an era of Industry 4.0, which is a restructured concept of smart production and application, that is identified with the fourth industrial revolution and the emergence of cyber-physical systems and this shall govern the future of medicine. Intelligent algorithms are utilized extensively in

the data driven methods to sustain sophisticated analysis and provide specific medical aid. This is being harnessed by a number of healthcare-related companies.[2]

Information: The Key to Intelligence

Acquirement of information is the key input required for exhibition of intelligent behavior. Because learning is an effectual way to instigate such knowledge, most AI applies such learning techniques. The chief aim of learning from knowledge is to let computers become skilled robotically without human interference or aid. The unearthing of knowledge revolves around the investigation and conception of algorithms for retrieving potential information from databases; this is commonly known as knowledge discovery in databases. Its prime purpose is to identify valid, potentially useful, and comprehensible information. The AI has already begun to revitalize the strategies to control blood glucose, the timely and correct prediction of blood glucose level, the detection of severe glycemic events, the life style support, the meal detection, and calculation of the confusing insulin boluses.

The Long Held Dream of an Artificial Pancreas

Creation of an artificial pancreas has been frantically attempted over the past decade. It consists of a mechanized system that has been made to mimics the physiology of islet cells, which include a sensor for glucose, a closed-loop management algorithm, and an infusion device for introduction of insulin. The eventual objective of this system is to perk up overall diabetes management and to trim down the frequency of life-threatening events associated with insulin dependent diabetes. The algorithms used by the artificial pancreas to compute the dosage of insulin have been thoroughly investigated, either by means of data from patients or processor created *virtual patients*. The foremost candidate algorithms are obtained from conventional control engineering theory; however, AI has become more time-honored over the past few years and could, in due course, provide better candidates to congregate the challenges of an artificial pancreas.[3,4] In a recently concluded trial which involved the evaluation of the remote patient monitoring of the fuzzy logic controller, the artificial pancreas was tested on 75 patients with insulin dependent diabetes for four successive nights. The results verified safe and competent glycemic control.[5] The fuzzy logic uses a method of reasoning that mimics human intelligence.

Conducive Insulin-Glucose Dynamics!

Harmonizing with the advances in control algorithms, efforts are being applied to progress with the models that can crack the insulin-glucose dynamics. Focus in applying neural networks for identification and control of nonlinear systems has garnered great attention. Zarkogianni et al, developed a neural network skilled with a synchronized learning algorithm that models the blood glucose kinetics of diabetic patients and foretells the glucose levels using information obtained from meal, glucose measurements, and the amount of insulin infused.[6-8] The aptitude to predict the blood glucose fluctuations would be a blessing, because it shall provide the early warnings concerning futile or poor treatments being given to the patient. Although the real-time anticipation of the glucose levels is quite challenging, pertaining to the number of physiological factors involving in the tug of war to maintain it, such as delays allied with assimilation of food and insulin, the wider variations in food intake and inadvertent stress situations which can dismantle the hemostat, but AI can take many of these variables into account to cut down the possible fallacies associated with the measurements.[9] As with blood glucose anticipation, AI has been put to use for real-time prediction of adverse glycemic episode and this involves a set of tools that deal with the convolutions of effective glucose control. These paraphernalia facilitate to spot the incidence of adverse glycemic events and give ample time to respond swiftly to their effects. This analysis takes into account the continuous glucose monitoring, self reported glucose monitoring, the EEG using the neural-fuzzy interference system to interpret and analyze the data.[10-12]

The Tedious Task for Glycemic Harmony

The most widespread insulin therapies for diabetics, the dosing computation for subcutaneous insulin and multiple daily insulin injections run based on similar doctrine.[13] The estimation of desirable insulin doses and the evaluation of the amount of calories gulped in a diet is a regular hurdle in the life of many patients dependent on insulin for their sugar management. Bolus dose advisors base their calculations on

- Insulin doses being already used
- Measurement of blood glucose level
- Premeditated carbohydrate estimates
- Insulin-to-carbohydrate ratio
- Insulin sensitivity

Manual calculation of bolus doses and counting calories can be multifarious and exigent because individuals must mull over multiple parameters to attain pleasing glucose control, and blunder of these values, if any, might very well turn the tide against harmony. To bear caloric assessment and determination of insulin doses, tools for providing bolus recommendations and carbohydrate estimates are being adopted progressively. These tools seek to boost the precision of insulin doses. Researchers at the Imperial College of London carried out an all-embracing study of an insulin doses calculation by means of case-based reasoning methodology.[14-18] The approach that they applied, which takes into account an assortment of enthusiastically optimized diabetes scenarios, was verified to be a secure decision-making algorithm. At the University of Bern, The Center for Biomedical Engineering Research carried out more than a few imperative and all-embracing studies[15-19] to explore the GoCARB system, which puts forth dietetic counsel to diabetic patients based on mechanical carbohydrate counting. Pilot studies identify it to be a brilliant assistive tool.

One Touch Personalized Care

Treatment of diabetes is influenced by bundle of inexorable factors, incorporating high intra- and interpatient inconsistencies that can spectacularly impact quality of life and undercut the medication adherence even when patients follow their treatment regime austerely. Such unpredictability sternly confines the use of universal models, which cannot incarcerate the specific physiologies. Thus, an imperative step en route for better risk recognition and intrusion is personalization of the system. Over the past decade, foremost investigative efforts have been loyal to developing administrative tools capable of stratifying patients in different segments of the population. Algorithms proficient in early uncovering of grave events affecting glycemic control, such as an infusion set failure, are critical for systematic automation. Physical activities offer multitude of benefits for diabetic patients, but these can also set hurdles in the management of diabetes. Systems and tools focused on programmed detection of exercise could develop the precision of treatments. Jacobs et al. anticipated a regression model to mechanically detect exercise in patients who carry an accelerometer and a heart rate sensor.[24] Turksoy et al. have worked on the development of a meal recognition structure based on scrutiny of continuous glucose monitoring signals using a fuzzy system to approximate the calorie content,[20-24] it revealed a sensitivity of 91.3% and an error of 23.1% in carbohydrate inference. Recently, Everett et al. offered a data system using a machine learning to endorse submission to physical activity and weight reduction. Insulin pump malfunction may upshot a protracted hyperglycemia or diabetic ketoacidosis. Detection in the early hours of failure could curtail the connected risk. Cescon et al. projected the exploitation of autoregressive model to develop a patient vigilance system. Miller et al. used a machine learning modus operandi to haul out information from drug prescriptions from electronic health record data and categorize factors tied with patient care flaws. Moreover, tools have been developed to scrutinize clinical schedules, prescriptions, and therapy adherence.

Conclusion

Transition from intelligent caretaker to intelligent care!
Beginning with the time of diagnosis, patients are obligated to optimize their lives to deal with complications and other comorbid state of affairs, with the overall goal of enhancing their own care. Time tested technologies and data warehouses bring-in-hand the solutions that replicate the data system and make eminent decisions based upon them. The most awe-inspiring advances in the application of AI techniques come from data-driven methodologies that learn from large datasets. With AI at hand the diabetes management is headed for an elegant, personalized, custom-made management of therapies, at the level of most minuscule stratum of patients or even individuals.

Technology and Medicine

CHAPTER

235 Artificial Intelligence: The Space-X of Diabetology!

Hem Shanker Sharma

Abstract

The age of pestilence and famine was muddled with malnutrition and infectious diseases. Metaphorically we are already sitting on the top of a volcano, the number of diabetics have already affected almost half a billion people. The artificial intelligence (AI) has revolutionized all spheres of life. The discussions on the application of AI in health-care system is omnipresent, this underlies the huge hidden potential of this unique technology in dethroning the enormous burden of several chronic medical conditions. This is an era of Industry 4.0, which is a refabricated concept of smart production and application, that is identified with the 4th industrial revolution and the emergence of cyber-physical systems and this shall govern the future of medicine. The most flabbergasting advances in the application of AI techniques come from data-driven methodologies that learn from large datasets. With AI at hand the diabetes management is headed for an elegant, personalized, custom-made management of therapies, at the level of most minuscule stratum of medical care!

Introduction (from Pestilence to Diabetes)

The age of *pestilence and famine* was flooded with malnutrition and infectious diseases. The high-fertility rates seeking to explode the living population were dismantled by an equated killing competence of these infirmities. This gradually paved way for the mechanized world with cozy couches and watches devoid of time to engage in any sort of physical activity. This again led to malnutrition, but this time featuring the other end of the spectrum. The resulting epidemic of obesity, hypertension, and diabetes signaled the new age of indolence and metabolic syndrome. Metaphorically we are already sitting on the top of a volcano, the number of diabetics have already affected almost half a billion people.

Cracking Ominous Octet with Artificial Intelligence

The complex interaction of the ominous octet for the causation and feasible interjections, which has to be intervened to diagnose and treat the diabetes has to be envisaged with something equally intelligent. The smart machines that are being made to *think and behave* in humane manner are transforming the way we manage these complexities. Way back in the 1950s, the fathers of the field Minsky and McCarthy, described artificial intelligence (AI) as any task performed by a program or a machine, which uses human intelligence to accomplish it. The AI has revolutionized all spheres of life. The discussions on the application of AI in health-care system is omnipresent, this underlies the huge potential of this unique technology in deforesting the enormous burden of several chronic medical conditions. At present diabetes appears to be the brand ambassador for its application in health care for a number of reasons.[1] This is an era of Industry 4.0, which is a restructured concept of smart production and application, that is identified with the fourth industrial revolution and the emergence of cyber-physical systems and this shall govern the future of medicine. Intelligent algorithms are utilized extensively in

the data driven methods to sustain sophisticated analysis and provide specific medical aid. This is being harnessed by a number of healthcare-related companies.[2]

Information: The Key to Intelligence

Acquirement of information is the key input required for exhibition of intelligent behavior. Because learning is an effectual way to instigate such knowledge, most AI applies such learning techniques. The chief aim of learning from knowledge is to let computers become skilled robotically without human interference or aid. The unearthing of knowledge revolves around the investigation and conception of algorithms for retrieving potential information from databases; this is commonly known as knowledge discovery in databases. Its prime purpose is to identify valid, potentially useful, and comprehensible information. The AI has already begun to revitalize the strategies to control blood glucose, the timely and correct prediction of blood glucose level, the detection of severe glycemic events, the life style support, the meal detection, and calculation of the confusing insulin boluses.

The Long Held Dream of an Artificial Pancreas

Creation of an artificial pancreas has been frantically attempted over the past decade. It consists of a mechanized system that has been made to mimics the physiology of islet cells, which include a sensor for glucose, a closed-loop management algorithm, and an infusion device for introduction of insulin. The eventual objective of this system is to perk up overall diabetes management and to trim down the frequency of life-threatening events associated with insulin dependent diabetes. The algorithms used by the artificial pancreas to compute the dosage of insulin have been thoroughly investigated, either by means of data from patients or processor created *virtual patients*. The foremost candidate algorithms are obtained from conventional control engineering theory; however, AI has become more time-honored over the past few years and could, in due course, provide better candidates to congregate the challenges of an artificial pancreas.[3,4] In a recently concluded trial which involved the evaluation of the remote patient monitoring of the fuzzy logic controller, the artificial pancreas was tested on 75 patients with insulin dependent diabetes for four successive nights. The results verified safe and competent glycemic control.[5] The fuzzy logic uses a method of reasoning that mimics human intelligence.

Conducive Insulin-Glucose Dynamics!

Harmonizing with the advances in control algorithms, efforts are being applied to progress with the models that can crack the insulin-glucose dynamics. Focus in applying neural networks for identification and control of nonlinear systems has garnered great attention. Zarkogianni et al, developed a neural network skilled with a synchronized learning algorithm that models the blood glucose kinetics of diabetic patients and foretells the glucose levels using information obtained from meal, glucose measurements, and the amount of insulin infused.[6-8] The aptitude to predict the blood glucose fluctuations would be a blessing, because it shall provide the early warnings concerning futile or poor treatments being given to the patient. Although the real-time anticipation of the glucose levels is quite challenging, pertaining to the number of physiological factors involving in the tug of war to maintain it, such as delays allied with assimilation of food and insulin, the wider variations in food intake and inadvertent stress situations which can dismantle the hemostat, but AI can take many of these variables into account to cut down the possible fallacies associated with the measurements.[9] As with blood glucose anticipation, AI has been put to use for real-time prediction of adverse glycemic episode and this involves a set of tools that deal with the convolutions of effective glucose control. These paraphernalia facilitate to spot the incidence of adverse glycemic events and give ample time to respond swiftly to their effects. This analysis takes into account the continuous glucose monitoring, self reported glucose monitoring, the EEG using the neural-fuzzy interference system to interpret and analyze the data.[10-12]

The Tedious Task for Glycemic Harmony

The most widespread insulin therapies for diabetics, the dosing computation for subcutaneous insulin and multiple daily insulin injections run based on similar doctrine.[13] The estimation of desirable insulin doses and the evaluation of the amount of calories gulped in a diet is a regular hurdle in the life of many patients dependent on insulin for their sugar management. Bolus dose advisors base their calculations on

- Insulin doses being already used
- Measurement of blood glucose level
- Premeditated carbohydrate estimates
- Insulin-to-carbohydrate ratio
- Insulin sensitivity

Manual calculation of bolus doses and counting calories can be multifarious and exigent because individuals must mull over multiple parameters to attain pleasing glucose control, and blunder of these values, if any, might very well turn the tide against harmony. To bear caloric assessment and determination of insulin doses, tools for providing bolus recommendations and carbohydrate estimates are being adopted progressively. These tools seek to boost the precision of insulin doses. Researchers at the Imperial College of London carried out an all-embracing study of an insulin doses calculation by means of case-based reasoning methodology.[14-18] The approach that they applied, which takes into account an assortment of enthusiastically optimized diabetes scenarios, was verified to be a secure decision-making algorithm. At the University of Bern, The Center for Biomedical Engineering Research carried out more than a few imperative and all-embracing studies[15-19] to explore the GoCARB system, which puts forth dietetic counsel to diabetic patients based on mechanical carbohydrate counting. Pilot studies identify it to be a brilliant assistive tool.

One Touch Personalized Care

Treatment of diabetes is influenced by bundle of inexorable factors, incorporating high intra- and interpatient inconsistencies that can spectacularly impact quality of life and undercut the medication adherence even when patients follow their treatment regime austerely. Such unpredictability sternly confines the use of universal models, which cannot incarcerate the specific physiologies. Thus, an imperative step en route for better risk recognition and intrusion is personalization of the system. Over the past decade, foremost investigative efforts have been loyal to developing administrative tools capable of stratifying patients in different segments of the population. Algorithms proficient in early uncovering of grave events affecting glycemic control, such as an infusion set failure, are critical for systematic automation. Physical activities offer multitude of benefits for diabetic patients, but these can also set hurdles in the management of diabetes. Systems and tools focused on programmed detection of exercise could develop the precision of treatments. Jacobs et al. anticipated a regression model to mechanically detect exercise in patients who carry an accelerometer and a heart rate sensor.[24] Turksoy et al. have worked on the development of a meal recognition structure based on scrutiny of continuous glucose monitoring signals using a fuzzy system to approximate the calorie content,[20-24] it revealed a sensitivity of 91.3% and an error of 23.1% in carbohydrate inference. Recently, Everett et al. offered a data system using a machine learning to endorse submission to physical activity and weight reduction. Insulin pump malfunction may upshot a protracted hyperglycemia or diabetic ketoacidosis. Detection in the early hours of failure could curtail the connected risk. Cescon et al. projected the exploitation of autoregressive model to develop a patient vigilance system. Miller et al. used a machine learning modus operandi to haul out information from drug prescriptions from electronic health record data and categorize factors tied with patient care flaws. Moreover, tools have been developed to scrutinize clinical schedules, prescriptions, and therapy adherence.

Conclusion

Transition from intelligent caretaker to intelligent care!
Beginning with the time of diagnosis, patients are obligated to optimize their lives to deal with complications and other comorbid state of affairs, with the overall goal of enhancing their own care. Time tested technologies and data warehouses bring-in-hand the solutions that replicate the data system and make eminent decisions based upon them. The most awe-inspiring advances in the application of AI techniques come from data-driven methodologies that learn from large datasets. With AI at hand the diabetes management is headed for an elegant, personalized, custom-made management of therapies, at the level of most minuscule stratum of patients or even individuals.

CHAPTER

236 Utilities of Smartphone Applications in Medical Practice

Ashish Gautam, Prabhat Agrawal, Nikhil Pursnani,
Ajeet Singh Chahar, Vijay Singhal, Jitendra Doneria

Abstract

Smartphones have gained the position of personal assistant and full time companions for us. They are featured with numerous properties that can be used in various ways in our personal and professional life. Smartphone applications have several utility features that can be used to manage patients at clinics, hospital, and even from home. Applications can also be used for patient appointments, tracking medical records, diagnosing disease, planning treatment, follow-up care, real time treatment monitoring, risk calculation, and training and education. Using applications not only saves time at clinic but also accuracy of treatment plan improves significantly. Treatment and management methods are changing rapidly in the modern world, due to which a clinician must be aware of these technologies. A judicious use of these applications can effectively change the way of our clinical practice.

Introduction

Smartphone is greatest invention of this decade which has transformed our life both in good and bad ways. Their judicious use not only gives a better way of living but also have favorable effects on our physical and mental health. Utility applications in smartphones are the key of their success and worldwide acceptance in every professional field. In different ways, these applications have changed the tradition of clinical practice both at basic and advance level. But actually, these applications are not used in their full strength and their awareness among medical fraternity is minimal. Ignorance, lack of confidence for their use, and firm belief over traditional methods of practice are the main reasons for their under use. These applications can assist health care professionals (HCPs) for clinical judgment making, maintaining severity score, and follow-up on records, medical education and research, e-consultations and e-clinics, ready references and drug dose calculations, and legal consultations. Smartphone can never be a replacement of clinician. They are just clinicians assistant which help them to deliver better health care.

What are "Apps"?

Smartphone Applications are simple software programs designed to run on them to accomplish a specific and targeted task. Smartphone applications are of three types:

Native mobile apps: These apps are developed for one platform and are "native" to smartphone. They are preinstalled in your phone when purchased.

Hybrid mobile apps: They are downloaded from application marked and after installation they work like native apps, but they need internet and run on web browsers.

Web apps: New technology in app developed makes website to change its shape size and design according to screen size. These responsive websites thus can be accessed from different devices with extreme ease to use. Similarly, latest self adaptive web applications scale themselves to fit the different screen sizes of smartphone and similar devices.

Utility of Smartphone Devices for Health-Care System and Professionals

Features of Smartphones

Smartphone devices are featured with both different modes of communication and are useful for computing also. Because of handy size and ease of use they can be used as point of care (POC) anywhere and anytime. Besides voice calling and texting new generation devices are also having several hi-tech functions, such as browsing, GPS, ultra high quality/megapixel cameras with high definition modes, and voice/sound recorders.

Need for all Purpose Use of Smartphone Applications at POC

Broad categories of uses of smartphone applications at a POC under which we can utilize them are listed below:

- *Communication:* Voice calling, text messages & social media chatting/video calling applications, video conferencing, e-mail.
- *Hospital information system (HIS):* E-medical record (EMR), clinical decision support system (CDSS), picture archiving & communication system (PA&CS), laboratory information system (LIS), and e-health record (EHR).[1]
- *Informational resources:* e-journals, textbooks, guidelines, medical literature, drug references.
- *Clinical software applications:* Disease diagnosis aids, medical calculators, risk assessment calculators, drug dose calculators, etc.[2]

Apps for Data Management and Education

HCPs use smartphone apps for several purposes. A few of popular applications are mentioned in **Table 1**.

Recording and Sharing Data and Daily Schedules

Applications are often used for gathering and recording information, time management, and planning daily schedule. *Evernote, Notability,* and *Gboard*, assists user to dictate and/or write text and prepare notes, audio files recording, store and store photographs, and systematize different files into category contained by a searchable e-database.[3] Few apps develop modify the text from literature in such a way that it looks like a book. Most preferred E-book reader apps are *GoodReader, iAnnotate,* and *Kindle*. They make possible users to underline and highlight text as we do in books. Text and pictures can be enlarged also. Cloud enabled storage and file-sharing services such as *Dropbox,* and *Google Drive*, are used to store, update, and share documents or photographs with others without physically exchanging a flash drive or compact discs.[4]

Communication and Consulting

While working in existing health-care systems HCPs often have to visit different places in a day like clinics, wards, emergency department, operation theaters, laboratories, ICU, etc. Our health-care system is very diverse and without moving to these places giving adequate care is not possible. So, HCPs not only need to be keep themselves mobile but also need to be able to communicate and collaborate with people in these different locations.[5] Social networking apps like *whatsapp, telegram,* etc. are utility tools for enabling consultations while they are on move.

Medical Search Engines

PubMed/MEDLINE apps are equipped with powerful search engines facilitate searches of medical literature databases to identify published medical information. Smartphone medical literature search apps useful for HCPs are: *PubSearch, Medscape,* and *MEDLINE Database on Tap.*[5] Articles on *NEJM*, *The Lancet*, and *BMJ* apps can be viewed on smartphone devices.

Drug References

These groups of applications are used to get drug information like drug name, indication, dosage, side effect and interactions, contraindications, cost, and dose calculators. The most frequently used smartphone drug reference apps include: *Epocrates, Micromedex,* and *RxDrugs.*

News and Updates

MedPage Today provides breaking medical news with facility to organize news by significance, and obtaining CME credit hours.[6]

Apps Dedicated for Patient Management

Clinical Decision-Making

Smartphone are easy way to access the diagnostic clues for any disease and also let you know the differential

TABLE 1 Popular applications and their utilities

Basic purpose of application	*Examples*	*Utility*
Data collection, Data storage, and sharing	Evernote	Taking notes, vocal typing, and organization
	Notability	
	iAnnotate	PDF editing and viewer, highlighting and making notes and annotation on PDF
	GoodReader	
	dropBox	Storage in Cloud space and sharing different file formats. Limited space, which can be expanded on purchase
	box	
	Google Drive	
Communication and Consulting	Clinked	Social communication/networking site for HCPs
	Idloom-wall	
Ready reference and Information seeking	Epocrate	Medical reference and drug detailing
	Dynamed	
	Skyscape/Omnio	
	Micromedex	Drug and pharmaceutical reference
	Medscape	Clinical reference
	Dynamed	
	Medpage-Today	News and updates in medical research and practice
Tracking patient care and management and Monitoring health	Diagnosaurus	Diagnostic clues and differential diagnosis
	Pocket Lab	Laboratory reference values
	Archimedes	Biomedical Stat and clinical calculators
	Med-Calc	
	Mediquation	
	Calculate	
	AHRQ ePSS	Screening for disease and prevention by regular health parameter monitoring
Training and Education	MedPage Today	CME
	QuantiaMD	

diagnose. All the details available about a particular disease are updated and are evidenced based. Printed medical references previously used for disease diagnosis are now available at smartphone device apps that provide information on diagnosis, treatment, differential diagnosis, risk calculators, severity assessment, evidence development, and guiding flowcharts. Such apps include: *Dynamed, 5-Minute Clinical Consult (5MCC),* and *UpToDate.*[3] On the spot accurate decision to order disease specific tests and procedures reducing cost of care. Pathology and biochemistry laboratory test apps are used for reference values and interpretation. Few advance apps provide causes for abnormal values also, for example, *Pocket Lab Values* and *LabProValues.* Few apps are useful for visual acuity or color blindness, as well as blood pressure or glucose level determination.[4] *iSeismometer* gives analysis of electromyogram produced by measured tremor frequency by this app. *iMurmur* is a collection of 20 types of heart murmurs sounds, to learn and compare the physician's observations. *Perfect OB Wheel* app determines pregnancy due dates very accurately by using an ultrasonographic observations and date of last period. In our day-to-day practice there are several indices need to be calculated for treatment decisions and follow-up purposes. This requires several data to be put into complex formulas which actually is very tedious job and takes toll of time.[5] Medical calculators facilitate HCPs to determine easy calculation of various and indices. BMI, BSA, e-GFR, maddrey's discriminate function, MELD and PELD scores, and several other such applications are available at app

market which can be downloaded free of charges. Thus, HCPs only need to enter the parameters in applications to quickly produce a reliable result. Popular medical calculators are *MedCalc, Mediquations,* and *Calculate.*

Patient Tracking and Monitoring

Smartphone apps play a wonderful role to monitor vital stats, general health, and location of patients with chronic diseases or conditions even from remote places. *iWander* monitors and tracks patients with Alzheimer's disease who are prone to lost the way to or fro from home using the smartphone device GPS. Highly sensitive microphone of smartphone is used as sensor to record and analyze cardiac sounds by app *iStethoscope.* Few app in smartphone devices have also been used to track heart rate and rhythm by precision.

Medical Education and Training

Technology enabled medical studies is a real need of future. Development of mammoth sized data from various researches and studies is not possible to carry in books and hard copies of journals. Also quick ease of availability of any small information from sea of literature can be easily accessed using simple applications. Thus, smartphone devices are used by medical students to log their experiences, to access information about drugs and diseases, to perform calculations, and to make basic notes. Several smartphone apps for medical students can be used for knowledge assessment, such as case study quizzes.

Benefits Provided by Smartphone Devices and Apps for Health-care Professionals

Advanced smartphone gadgets and applications have given numerous advantages to HCPs, permitting them to settle on more fast choices with a lower mistake rate, expanding the nature of information the executives and availability, and improving practice proficiency and information. These and different advantages advanced smartphone gadgets are.

Convenience

Medical care experts get various comforts with utilizing a smartphone and PDA gadget in clinical practice, for example, transportability, and fast admittance to data and sight and sound assets, adaptable correspondences. Despite the fact that there will never be an option in contrast to conventional books; however, now clinical understudies no longer need to convey thick reference books.[1]

Better Clinical Decision-Making

Numerous clinical applications make advanced mobile phone gadgets priceless instruments that help clinical dynamic at the purpose of care. This quality is significant when rehearsing proof based medication, since clinicians may not generally look for answers to every clinical inquiry while doing assessment a case.

Improved Accuracy

More precise diagnostic coding, more successive documentation of symptoms, and expanded prescription wellbeing through diminished clinical blunders is conceivable with advanced mobile phone applications. Convenient correspondence inside emergency clinics has additionally been resolved to lessen clinical mistakes, particularly in basic consideration conditions.

Increased Efficiency

The utilization of smartphones has been appeared to give HCPs various upgraded efficiencies, including: expanded nature of patient documentation through less mistakes and more complete records, more fast admittance to new data, and improved work process designs. Physicians have reported that the use of a smartphone device for retrieving information from a drug database led to more efficient decision-making and patient care.[2]

Enhanced Productivity

Work process speed is likewise a significant part of treatment while thinking about the colossal populace in line for treatment. This requires expansion of efficiency with more exactness of medical care framework. For example, advanced mobile phone applications help increment pharmacist profitability by permitting significant medication data like contraindications and interactions, to be checked rapidly, bringing about fast handling of prescriptions.[6]

Future Trends for Smartphone Devices and Apps in Health Care

As it is happening in various different fields identified with way of life, routine works, and diversion, advanced

smartphone applications are assuming a significant function in medical care framework too. Positive and game changing patterns with respect to the utilization of advanced smartphone gadgets and applications in medical services have been anticipated for what's to come. As better physical and emotional wellness upkeep become the possible objective of the medical services framework, applications will be expected to satisfy that reason. The prevention and management of chronic health conditions, such as diabetes, obesity, and heart disease, is biggest challenge for HCPs and health-care governance system. Patient care management and compliance are other difficult challenges, especially in Indian scenario where doctor-patient ratio is far below the target. Smartphone/PDA and its applications, which can illuminate a few comparative purposes and effectively address these issues are required and anxiously anticipated. Accessibility of monetary and moderate advanced mobile phones builds its possession in each financial class of licenses, which is beyond the realm of imagination with PC Future applications will likewise have capacity to synchronize with medical clinic information base so HCPs can get to any patient record. These applications will likewise assist HCPs with observing the indoor patients continuously. Such measures will enable HCPs to use smartphone apps in a more meaningful way that hopefully leads to improved patient care. Medical services instruction as on when required is additionally a significant field to advance in future. As the utilization of clinical gadgets and applications grows, more instructive medical care programs are required to incorporate them into clinical educational plan. With the rapidly changing world, a need of full time companion who can assist in clinical practice is a need of future. Smartphone and mobile applications could serve this purpose of HCPs and effectively and easily. Some HCPs are still turn down to adopt their use in clinical practice probably due to fear of errors and lack of confidence. Medical devices and apps inarguably provide the HCP with many advantages still they are used without a methodical understanding of their associated risks. Among the worries raised with respect to advanced smartphone gadgets are: their trustworthiness for settling on clinical choices; quiet information security and protection; sway on the specialist persistent relationship; and appropriate mix into the work environment. HCPs, unexposed or uninterested in new advancements, might be off guard if the utilization of PDA gadgets turns into a necessity inside the medical care fields. Guidelines for best-practice techniques for clinical application engineers and clients additionally should be set up to keep up culture ethnical practice. Barely any applications are accessible from just about 10 years yet due to under use they are not creating information. Make sure to have a compelling and touchy application we need vigorous information, which can be utilized to create calculations and create and update them. As more information becomes accessible, this will prompt a more valuable determination of approved PDA clinical applications for HCPs. Consequently increasingly more application uses will grow better applications in future.

Conclusion

With the quickly evolving world, a need of full time buddy who can aid clinical practice is a need of future. PDA and portable applications could fill this need of HCPs and successfully and without any problem. Some HCPs are still go down to receive their utilization in clinical practice likely because of dread of blunders and absence of certainty. Clinical gadgets and applications inarguably give the HCP numerous points of interest still they are utilized without a deliberate comprehension of their related dangers. For all legitimate purposes broad assessment, confirmation, and the improvement of best-practice guidelines for clinical applications are compulsory to guarantee a degree of value and security when these apparatuses are utilized. These measures will satisfy the motivation behind improvement of these applications to give noteworthy, exact, and reasonable data and direction to the HCPs to serve the sacred expectation of accomplishing persistent results.

CHAPTER 237

Basic Computer and Smartphone—Technology for Practicing Physicians in COVID-19 Era

SV Kulkarni, Priyanka Jadhav, Ajay Kukreja, Sagar Sinha, Laxman G Jessani, Manasi Kulkarni, Aditya Kulkarni

Abstract

Technology has made a great impact on the health-care outcomes in the recent years. Starting with simple apps or peripherals which can be attached to a smartphone or basic clinical evaluation equipment. The research process has advanced due to faster access to the literature and resech papers. Many new concepts like augmented, virtual, mixed, and immersive reality will be changing the spectrum of health care. Same applies for augmented artificial intelligence, big data, cloud computing, data mining, and retrieval. Telemedicine, Electronic health records, and virtual visits have made a sea change in patient management in the COVID-19 era. Many unexplored vistas of the new modality need to explored and utilized.

Introduction

The influenza pandemic a century ago was in a very different era but caused a catastrophic loss. With the onset of the COVID pandemic, the world has faced its greatest health crisis in the 21st century. There could not be a more opportune time for us to realize the value and implications of technology and there is a golden moment to radically transform health care via the use of basic smartphones and computers.

This working group has been advocating the same since the last 10 years. The basics of technology including hardware/software, world of apps, including challenges and issues not covered as quoted in our earlier publications.[1]

Specific approaches to smartphone applications include:[2]

- *For Doctors:* Developer, Content, Accessibility, Purpose, Cost
- *For Patients:* Integration, Electronic presence, Patient-doctor relationship, Outcome, Cost

Non-communicable diseases like diabetes have always been a focus of most developers and care of these patients has now been adapted and integrated via interventions at community level and social media. Besides blood glucose monitoring, data recording, control and tracking, futuristic parameters like electronic fall detectors and remote vitals monitoring are now in our reach. Exercise and fitness promotion with specific apps targeted for diabetic patients are now being absorbed for good holistic patient management.[3,4]

Medical calculators, bundled apps like *Medscape* and *UpToDate*, and specialty-specific apps are the essentials to have on a physician's smartphone. As we embrace technology especially for electronic health records, data safety, and privacy too are real concerns but must be addressed thoroughly with a simple approach of audit trails, password protection and data encryption.[5]

Artificial Intelligence (AI) is not science fiction anymore and evidence-based medicine is now taking evolutionary steps with fundamentals rooted in pattern recognition, deep learning, cloud computing, and big data. From the

decade old story of IBM's Watson, now Internet of the Things (IoT) is actually here.[6]

The future of medicine will be founded on 'The Big Five':[7]

- Artificial Intelligence
- Big Data
- Cloud Computing
- Data Mining, Retrieval, and Analysis
- Electronic Medical Records

Technology and the Primary Physician

While emphasizing that the physician's touch and clinical acumen can never be replaced, technology when used aptly can transform one's practice significantly... and, it is here to stay; and evolve, at the same pace as medicine itself!

Teleconsultations/Virtual Visits

The west was rapidly able to evolve quickly due its past adaptation to modern technology but the COVID-19 pandemic has proven and given a boost to Tele-Health in India too.[8] Inculcating it in our regular practice will become the new normal, with guidelines and regulations made for its practice and use. International response was swift to promote telesolutions.[9] MoHFW, India, already released guidelines for the practice of Telemedicine on March 25, 2020.[10]

Clinic software management companies have quickly adapted to it to include it as one of the *essential features* in their software besides

- Ease of access
- Lesser wastage of time
- Cost-effectiveness

The goal is for the patients despite being far away still get the best out of the physician.[11] Additional principles must be adapted to avoid repeated flaws we face.

- Distinguishing between need of virtual and physical visit
- Good documentation
- Observing guidelines (laid down by that country's legislation/rules)
- Well-communicated session

Clinic Management Software

Challenges:

- Difficulty for a traditional physician to shift to technology-assisted practice
- More than 50 software options available online **(Table 1)**
- Confusion, viz. cost vs. features vs. "the latest one"

Essential features and how to choose"

- Cloud-based system for easy accessibility
- Better data security and storage
- Appointment management, billing, and invoice generation
- Multiple online payment options
- Printed prescription
- Easy EHR (Electronic Health Record) management system

All these also provide smartphone-based app extension for their software which helps manage things "on the go." The physician has to choose according to individual needs. There are also specialty-specific software solutions available, which are further fine-tuned according to the specific specialty requirements (e.g., *Crystal pm*, *Ehnote*, *NETRA clinics* for Ophthalmology).

TABLE 1 Comparison of three common EHR platform providers

Examples	*Practo*	*Docon*	*Doxper*
Strengths	• Digital presence • Good appointment management • Patient feedback rating linked	• Easy & fast prescription system • Quick turnover time • Helpful for 'not-so-tech-savvy' physicians	• Good old 'pen & paper technique', digitized EHR of what is written on notes • Good prescriptions, option of additional customized audio/video advice
Challenges	• Complicated billing • Weak prescription system • Risk of commercialization?	• Minimal online presence	• Limited presence

But is that enough? We actually need a SINGLE clinic management software, which integrates and accepts readings from various clinic equipment like a Bluetooth stethoscope, a Bluetooth pulse oximeter, an ECG machine, a Bluetooth weighing machine, a BP monitor, wirelessly transmitting the patient's data to this desktop software; and the physician can use this not only for better patient management but also for extrapolating, analyzing and doing research from this data in the long run. An IDEAL software will be the one having all the features mentioned above; yet simple enough to finish the physician's work with a minimal "click count."

What's the future? The future is newer software with voice recognition and recording system, having predictive investigation and treatment algorithms, and much more beyond it. And all this is already happening today (e.g., *Augmedix*) and the same is an inevitable future, and the faster a physician adapts to it and uses it, the better.

Teleconferencing Solutions

Telehealth, teleconsultation, and telemedicine are also deeply connected with the original simple communication platforms, which have now made remote networking very easy. Besides its role in essential conferencing, these tools are now being increasingly adapted for tele-education, teleconferencing, and continues professional development.[12-14]

Various platforms are available:
Big players/professional ones:

- *Zoom*, Microsoft *Teams*, Google *Meet*, *Skype*, CISCO *Webex*
- *UberConference*, *TrueConf Online*, *FreeConference*, *Appear*.in, *Slack Video Calls*, *Facebook Live*, *YouTube Live*

Zoom, originally created for businesses is the world leader today with >200 million daily users, the best current product in the market as it was designed as a dedicated conferencing product through easy adoption with WebRTC technology.

Features which must be considered are—All device access (phone/PC, etc.), it is encrypted at both ends & secure, must have an easy to operate screen share feature, accessible via audio/(HD) video calls, flexible number from 10-1,000 participants via video can join, legal permissions for users role-based, easy to remember quick Google/Outlook calendar integration, recording/transcripts is very simple & at multiple locations Cloud or Local disk options (important for medico-legal purposes), Team chat is a boon, extra features as per our demands are available with paid versions which are not that costly. However, few lacunae like inability to display the live captions on screen as in Google meet, or tracking by word as in Ted talks, with an underline to it.

The Fourth Dimension of Evaluation in Clinical Medicine

Future of clinical medicine is going to be exponentially explored by these four technologies:

- Virtual Reality (VR)
- Augmented Reality (AR)
- Immersive Reality (IR)
- Mixed Reality (MR)

VR is the computer-generated simulation-re-organization of a three-dimensional image or environment that can be interacted with in a seemingly real or physical way by a person using special electronic equipment, called as Head Mount Unit (HMD) like a helmet with a screen inside or gloves fitted with sensors or other accessories VR head-mounted displays (HMDs), costly as HTC Vive or Oculus Rift, experience a high degree of immersion.

On low end HMDs for mobile devices, such as Samsung Gear VR and Google Cardboard, enable everyone to experience immersive virtual environments. The HMD market is expected to be valued at USD 25 billion by 2022.

It has applications exist in order to offer a higher quality of care and efficiency to patients and medical professionals alike.

VR is used in surgical preparation—check lists to patient illness, education, and therapy.

Examples:

- Embodied labs using VR simulations for attendants of Alzheimer's disease to understand the disease better, even the consequences visualized softly to understand the need of care
- *Floreo* technique—virtual reality to teach multifactorial social and communication skills to patients of autism, contexts include games and activities that explore social connections, situational training preparedness and calming-pacifying or even awarding techniques, meditation training for pain relief, writers cramps and

cognitive behavioral therapy for perimenopausal hot flashes & many varied symptoms difficult to manage.

- *SyncThink* has VR goggles with eye-tracking abilities to test for optic deficiencies and *Eye-Sync platform* (a breakthrough device designation awarded by FDA) helps test for concussions soon after a person sustains a bad blow to the head. Useful in unrecognized head injuries like hypoglycemia, alcoholism, mass gatherings, or high intensity sports.

  AR technology that superimposes a computer-generated image on a user's view component, the real world around him, thus providing a composite-interactive view in medical teaching training.
- *Augmedix* (*AR-BASED MEDICAL RECORDS)* uses *Google Glass* allows access to a patient's electronic health records. EMR relays information, like previous personal or video visits and current medications. An addition of Google Glass also acts as a scribe that records, vital information, eases in to a more natural doctor-patient interaction, saving time, money, and displays no errors on the side of past medical records, procedures, or drug history.

The new powerful, next generation, interactive headsets & AI based software AR-VR will be the new normal of clinical evaluation. Accepted by health-care professionals to provide them with hands-free working environment, greater flexibility with overlaying information, and data processed by the camera. ID Tech Ex, an investment consultant organization predicts this market to be over $20 billion.

MR is the future of real and virtual worlds to have a unique new environments and visualizations, here physical and digital objects coexist simultaneously interact in real time.

Many educative, training, & operative possibilities exist here. This happens not in either the physical or virtual world, but is a hybrid of reality and virtual reality, encompassing both augmented reality and augmented virtuality via immersive technology. A technology concept that is difficult to imagine right now.

We users experience a virtual three-dimensional representation of real objects embedded into the physical surroundings. *Microsoft HoloLens* and *Google Glass* are examples of MR devices with different technologies that demonstrate the most prominent emerging technologies.[15] India will soon have Jio Glasses as their competitors.

Around INR 14,000, Snap Spectacles 3 was launched in India at a price point of around INR 30,000. Microsoft HoloLens retails at a sky-high price of INR 2,63,000.

As the number of consumers grows, the cost will be still more affordable.

All this will make a sea change in medical education systems and learning right from our formative years in anatomy without the smell of formalin in the dissection halls.[16]

It has been proved even in training of paramedics and volunteers for life saving procedures hands on training like pediatric cardiopulmonary resuscitation.[17]

Utility of the same in psychiatry is recently been evaluated in this meta-analysis with immense practical positive outcomes.[18]

In the present dreadful COVID era, it has been very usefully in protection of HCW, in minimizing exposure to nosocomial infection, optimizing the use of PPE, and enhancing aspects of care. Deploying such *holo-lens augmented technologies* at pace requires context-specific information security, infection control, user experience, and workflow integration led by clinical end-users setting up an entirely new field for exploration.[19]

Immersivevirtualreality(*IVR*)hasendlesspermutations combinations, which exist for application in health care. We can now immerse their patients in environments to achieve exposure to a specific clinical situation like Hypoglycemia, Bowel movement irregularities as in IBS, whether constipation type,diorrhea type or mixed pattern & patients correlation with feeling of bloating, blocked or urge as his experience. After the evoked targeted physical & emotional responses, in therapy we can inspire, acclimatize, or distract from an experience occurring in reality. Best example being a patient of Agoraphobia or Claustrophobia gives instructions or commands from HMD special goggles-lenses.

IVR is a future in health care, research, practice, education, and profitable components with many studies exploring its feasibility for acute treatment of health conditions; however, evidence of its effectiveness needs further research.[20]

AI in Health Care—The Rising Horizons

AI makes medicine more *pre-emptive, predictive, & personalized.*

Today, AI and related technologies in health care are rather much more advanced and developing rapidly with the help of Big Data. These technologies have the potential to transform many aspects of patient care, administrative processes within the provider, health-care insurance and pharmaceutical organizations.[21]

The most tried AI tools in health care so far are AI-driven diagnostic tools that are helping physicians in clinical decision-making and helping with disease diagnostics. The spectrum of AI solutions like natural language processing (NLP), image analysis, and predictive analytics based on machine learning-neural networks and deep learning are widely used for diagnostics in clinical medicine.

AI-led telemedicine services are disrupting the entire value chain practice and patient care. AI is empowering telemedicine making a better diagnosis, assisting eldercare, and remote patient monitoring. As health care becomes more technology-driven, IoT and Telemedicine could offer quality service options at a reasonable cost, just by increasing the number and frequency of consumers components of IoT or IoMT has several component sensor conducted bio signals, Gyrocsope mediated motion linked data as in fall detectors or exercise Apps, contextual data components like locations, supermarket visits humidity or temperatures.

Ethical, legal, and social implications will need to be considered for use of AI in health care. The use of smart machines to make or assist health-care decisions raises issues of privacy, permission, transparency, and accountability.[21] Also, ensuring the use of capable and useful AI technologies in the health-care domain in daily clinical practices remains a challenge.

Undoubtedly, AI has a great future in health care. With the help of smart devices and health-care apps, they can act as a personal health assistant for common people. Apart from early diagnosis, fast and accurate clinical decision-making, cost reduction in health care, AI techniques like machine learning have the capability behind the development of precision medicine.

Technology and India during COVID-19

We as Indians are less jubilant as far as use of technology is concerned compared, to either eastern or western users. But there was tremendous surge in uses of smartphones and its applications during this initial COVID-19 pandemic time. Some sources report to have increased by 120% within initial couple of months of lockdown. Some sources which have collected data, line Cybermedia Reserch Surveys that more emphasis was on different content creation which was spread out by users to others. Also there was significant increase usage of video calling applications.

Gradually as the lockdown curbs were eased and online sales platform started activities for non-essential goods. People had obviously picked up the activities on these applications for ease and to maintain restrictions. Most people had upgraded their devices like smartphones and laptops. People tried different applications and processes that were supported by faster internet connections and such devices. But the usage of such processes although was very significant was limited to knowledge of government schemes and other information like epidemic progression and whether forecasting. Although usage of Aarogya Setu app was increased overall usage for health-care benefit was not that significant.[22]

There is a resolute demonstration by the people of India to accept technology. The health-care sector must embrace this opportunity to radically adapt technology.

Simple starting steps would be use of the basic apps, which would assist greatly with health care during the pandemic:

- Web-tools for symptoms like *https://www.mayoclinic.org/covid-19-self-assessment-tool* and *diy.health/help-yourself*
- Apps like *Calculate by QxMD* for risk-stratification and management, which can be used for COVID including CURB-65, qSOFA, NEWS, ROX-index.
- Specific infectious diseases apps like *John Hopkins Guide, Sanford Guide, Micromedex, Sepsis Guide,* and *Infectious Disease Compendium*.
- Apps for infusion management of vasopressors and glycemic control like *IV Infusion calc* and *InsPro* are extremely helpful in these manpower-resource-limited times
- Drug-drug interactions especially when COVID-cocktail therapy is being practiced can be evaluated by simple apps like *Epocrates*
- Peripheral smartphones add-ons like pulse-oximeters and digi-stethoscopes are already commercially available now
- *Medscape* and *UpToDate* still remain the best bundled apps with continuous rolling updates about the pandemic from verified sources.

Conclusion

The pandemic has brought the world to its knees but given all of us a chance to rise up to this once-in-generation challenge. The government too has set off a pace of reforms for enhancing the use of technology in medicine with significant resolve in areas of telemedicine and concept of Unique-health-ID with a promise of complete horizontal and vertical cross-integration. The future has arrived for technology in health care.

While understanding its tremendous power and scope for exponential promises in thrust areas of AI and the four realities (AR/MR/VR/IR); the physician needs to start with the simple steps of using telemedicine and basic apps in their practice for a simple reason… The best interest of the patient!
