Contents

Foreword

This edition of *Ballenger's Otorhinolaryngology Head and Neck Surgery* continues in the tradition of being a comprehensive compendium of current knowledge in the fields of otology/neurotology, rhinology, facial plastic and reconstructive surgery, pediatric otorhinolaryngology, laryngology, head and neck surgery, and bronchoesophagology. The informational content for the 16th edition has been reorganized into 67 chapters with new sections on facial plastic and reconstructive surgery and pediatric otorhinolaryngology. More than half of the authors are new to the book, and another third of the chapters have been redesigned to address major developments in the topical areas. The content reflects the central responsibility of the otorhinolaryngologist in treating patients with diseases affecting the senses of smell, taste, and balance and with disorders of human communication affecting hearing, voice, speech, and language. The presentation of basic science underlying clinical otorhinolaryngology head and neck surgery has been expanded, and chapters on clinical topics have been structured to provide comprehensive coverage to meet the needs of practitioners in the twenty-first century.

The 64 senior authors have been chosen not only for their contribution to new knowledge to their topics through highly regarded research but also for their intellectual leadership of the specialty and, thereby, are truly authoritative in the subject matter of their chapters.

Both the basic science and clinical chapters stress the important role of molecular biology in understanding the pathogenesis of disease. Throughout the book, the genetic basis of disease is emphasized. This book provides students, residents, fellows, and practitioners with the understanding necessary to participate fully in the coming role of molecular biology in therapy.

James B. Snow, Jr, MD

Preface

Ballenger's Otorhinolaryngology Head and Neck Surgery is in its 94th year in this sixteenth edition. It has been in continuous use since 1908, when my great-uncle, William Lincoln Ballenger, brought out the first edition. My father, Howard Charles Ballenger, succeeded my great-uncle as editor, and in 1957, I succeeded my father. I am greatly pleased to have James B. Snow Jr. as coeditor. This reorganized and revitalized version is much to the credit of his leadership and forward-looking enthusiasm. We are delighted to have BC Decker Inc as the book's new publisher.

This new edition, as in the past, is enriched by the outstanding contributions of 118 distinguished scholars and practitioners, all of whom have written on their special interests. I extend my gratitude to each of them as well as their medical artists and illustrators, whose work clarifies the text. The contributors are drawn mainly from the United States but from several other countries as well.

The general format is to present an accurate picture of normal anatomy and physiology as a basis for the understanding of altered conditions that underlie diseases and their symptoms and signs. I believe that this book will be of great value to all studying this specialty and to other specialists seeking an authoritative reference.

CHAPTER 1

Anatomy of the Auditory and Vestibular Systems

Richard R. Gacek, MD, Mark R. Gacek, MD

The temporal bone is a complex portion of the skull base that contains the labyrinth with its nerve supply (cranial nerve VIII) but also other cranial nerves such as the facial, trigeminal, vagus, glossopharyngeal, spinal accessory, and hypoglossal nerves. A thorough knowledge of the gross and microscopic anatomy[1,2] of the temporal bone (TB) and the physiology of the labyrinthine sense organs is essential for the specialist who strives for accuracy in diagnosis and precision in surgery of the TB. This knowledge is gained first from dissection of cadaveric whole TB specimens but is greatly enhanced by study of prepared histologic sections from normal and pathologic TB.

OSTEOLOGY

Four major components of the temporal bone (TB) contribute to the skull base: the squamous, mastoid, tympanic, and petrous.

The *squamous* portion of the TB provides attachment for the temporalis muscle, which is bounded inferiorly by the temporal line (Figure 1–1). The temporal line provides an external landmark for the floor of the middle cranial fossa. The zygomatic process projects forward from the lower portion of this bone, and together they form the anterior border of the mandibular fossa, which receives the condyle of the mandible.

The *tympanic* portion of the TB is an incomplete cylindrical portion of the TB that, together with the squamosal portion, forms the medial part of the external auditory canal. This portion of the external auditory canal is 2 cm in length by 1 cm in diameter. Its anterior boundary is the posterior limit of the mandibular fossa; medially, its border is the tympanic membrane. The posterior part fuses with the mastoid component of the TB at the tympanomastoid suture. Failure in development of this part of the TB is responsible for congenital aural atresia, a form of conductive hearing loss correctable by surgery.

The major portion of the TB formed by the *mastoid* portion attributes its large size to extensive pneumatization. The mastoid process projects posteriorly and inferiorly behind the external auditory meatus and serves as the attachment for the sternocleidomastoid muscle. A deep groove in its inferior aspect houses the posterior belly of the digastric muscle, which is innervated by the facial nerve. The superior surface of the mastoid compartment is formed by a thin plate of bone known as the tegmen mastoidea. Posteriorly, it forms the anterior plate of the posterior cranial fossa and is indented by a groove for the sigmoid sinus. The superior and inferior petrosal sinuses travel medially along the superior and inferior aspects of this part of the TB.

The *petrous* portion of the TB forms its medial part inferior to the middle cranial fossa; posteriorly,

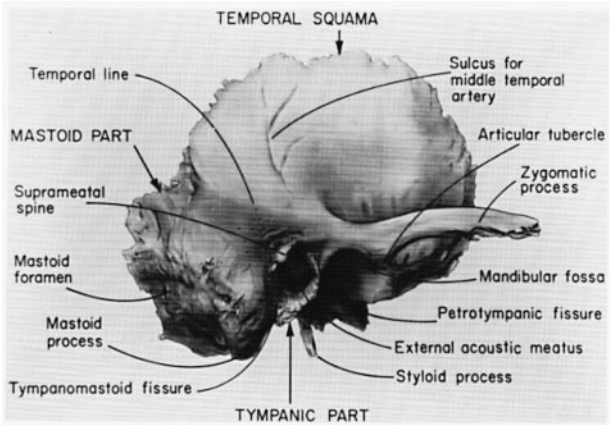

FIGURE 1–1. Right temporal bone, lateral view. Reproduced with permission from Anson BJ and Donaldson JA.[2]

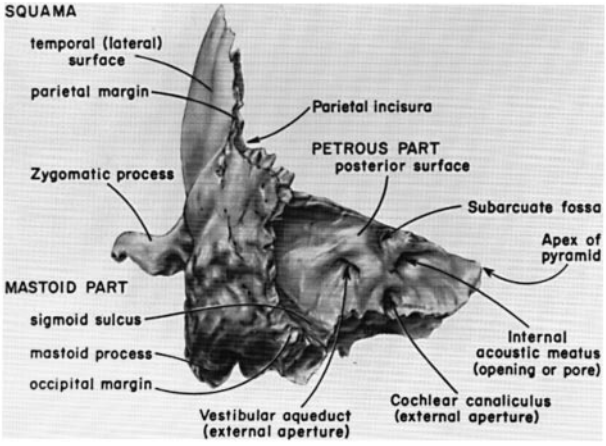

FIGURE 1–2. Left temporal bone, posterolateral view. Reproduced with permission from Anson BJ and Donaldson JA.[2]

it forms the anterior surface of the posterior cranial fossa (Figure 1–2). The superior surface of the petrous bone is highlighted by the prominence of the superior semicircular canal, a landmark in surgery within the middle cranial fossa. Anterior to this portion of the petrous bone is the hiatus for the greater superficial petrosal nerve, which joins with the geniculate ganglion of the facial nerve. In some temporal bones, this hiatus is enlarged, and the geniculate ganglion may be exposed in the middle cranial fossa. Anterior and medial to this region is a concave area for the semilunar ganglion of the trigeminal nerve. On the posterior surface of the petrous bone are several important landmarks. The most obvious aperture is the internal auditory meatus (canal) that transmits the seventh and eighth cranial nerves as well as the labyrinthine artery or loop of the anterior inferior cerebellar artery. The lateral end (fundus) of the internal auditory canal (IAC) is divided horizontally by the falciform crest.[1–3] The superior compartment contains the facial nerve anteriorly and the superior division of the vestibular nerve posteriorly. The inferior compartment transmits the cochlear nerve anteriorly and the inferior division of the vestibular nerve posteriorly. The endolymphatic sac may be found in a depression covered by a bony shelf (operculum) anterior to the sigmoid groove. It narrows down into the vestibular aqueduct as the endolymphatic duct. The depression for the semilunar ganglion and the fifth cranial nerve on the anterior surface of the petrous bone also carries the sixth cranial nerve through a dural canal referred to as Dorello's canal. These two nerves may be involved in inflammatory or neoplastic processes that occupy the petrous apex and are responsible for the clinical syndrome known as Gradenigo's syndrome (fifth cranial nerve pain, diplopia from lateral rectus muscle palsy, and otorrhea).

AUDITORY SYSTEM

External Ear

The external or outer ear is that portion of the ear that is lateral to the tympanic membrane (Figure 1–3). It consists of the external auditory canal as well as the auricle and cartilaginous portion of the ear. The auricle is a semicircular plate of elastic cartilage characterized by a number of ridges or grooves. The major ridges of the auricle are the helix and antihelix, the tragus and antitragus, which surround the concha, which is the scaphoid depression posterior to the external auditory meatus. The cartilage of the external auditory meatus is continuous with that of the outer portion of the ear canal and auricle.

The external auditory canal is made up of a cartilaginous extension of the auricle in its outer half and the mastoid and tympanic portion of the TB in its medial half. It is bounded medially by the tympanic membrane and is lined with skin that is thin with little subcutaneous tissue medially but laterally contains numerous hair follicles and ceruminous and sebaceous glands. The bony external auditory canal averages 3½ cm in length, with a diameter of 1 cm. The tympanic membrane is composed of three layers: the outer squamous cell epithelial layer, the medial mucosal layer facing the middle ear, and the fibrous layer or tunica propria, forming the substance of the tympanic membrane.[3] The fibrous layer gives the tympanic membrane its shape and consistency. Radial fibers of the tunica propria insert into the manubrium, circumferential fibers providing strength without interfering with vibration, whereas tangential fibers reinforce the architecture of the tympanic membrane. These physical characteristics are important for the vibratory characteristics necessary for sound transmission.

The tympanic membrane is identified by a prominent landmark, the manubrium of the malleus, which is limited superiorly by its lateral or short process and inferiorly by a rounded end

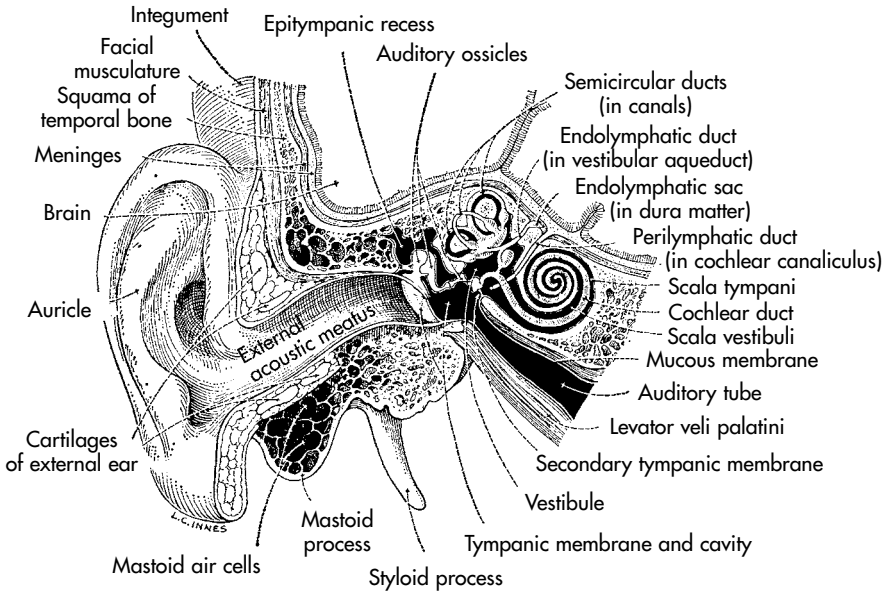

FIGURE 1–3. General relationships of parts of the ear (semidiagrammatic). Reproduced with permission from Anson BJ, McVay CB. Surgical anatomy. 5th ed. Philadelphia (PA): WB Saunders; 1981.

referred to as the umbo. The umbo forms the deep apex of the conical shape formed by the tympanic membrane. The tympanic membrane is incomplete superiorly, where it lacks a fibrous layer in the portion superior to the short process of the manubrium.[4] Since it lacks a fibrous layer, this portion is called the pars flaccida (Shrapnell's membrane). The major or inferior portion of the tympanic membrane is referred to as the pars tensa.

Middle Ear

The space between the tympanic membrane and the bony capsule of the labyrinth in the petrous portion of the TB contains the ossicular chain with its associated muscles, the aperture of the eustachian tube, and the vascular system. The tympanic cavity is divided into the epitympanic, mesotympanic, and hypotympanic regions. The *hypotympanic* portion is that portion of the middle ear that lies inferior to the aperture of the eustachian tube and the round window niche (RWN). This portion of the middle ear contains various bony trabeculae and the bony covering of the jugular bulb. This bony surface may be dehiscent, exposing the jugular bulb in the hypotympanic region. Inferiorly, a small channel (the inferior tympanic canaliculus) transmits Jacobson's nerve (a branch of cranial nerve IX).

The *mesotympanic* portion of the middle ear is limited superiorly by the horizontal portion of the facial canal and inferiorly by the RWN. This region contains the oval and round windows, the stapes bone, the stapedius muscle posteriorly, and the canal for the tensor tympani muscle anteriorly. The oval window is kidney bean shaped with a convex superior rim and a concave inferior rim. In the oval window, the footplate of the stapes bone is held in place by the annular ligament. The RWN forms a deep recess often covered with various mucous membrane configurations that obscure the round window membrane (RWM). The RWM is a fibrous membrane covered with a layer of mucosa that is roughly kidney bean shaped, with a major component anterior and inferior and a minor component located posteriorly and horizontally in the RWN. Posteriorly in the mesotympanum there are two bony recesses of clinical importance. The recess lateral to the vertical segment of the facial canal is called the facial recess. The space medial to the facial canal is called the sinus tympani (Figure 1–4). These two recesses are important clinically as they frequently harbor chronic middle ear infection and must be controlled in surgery. The facial recess also provides access to the middle ear space and RWN in those procedures in which the ear canal wall is preserved (ie, intact canal wall mastoidectomy, cochlear implantation). A bony projection from the facial canal (pyramidal eminence) contains the tendon of the stapedius muscle before its insertion into the neck of the stapes bone. The most anterior portion of the middle ear space is called the *protympanum* and is bordered superiorly by the orifice of the eustachian tube and anteriorly by the canal for the internal carotid artery (see Figure 1–4).

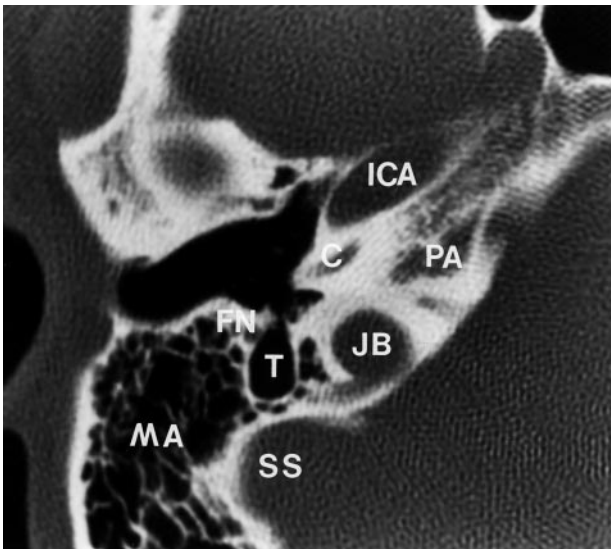

FIGURE 1–4. This axial computed tomographic scan of the temporal bone illustrates a normal mastoid cell system (MA), the horizontal segment of the internal carotid artery (ICA), the jugular bulb (JB), the sigmoid sinus (SS), and a nonpneumatized petrous apex (PA). C = basal turn of the cochlea; FN = facial nerve; T = sinus tympani.

The *epitympanum* is the portion of the middle ear that is limited superiorly by the bony roof of the middle ear called the tegmen tympani. This bony landmark is continuous posteriorly as the tegmen mastoidea. The medial wall of the epitympanum is formed by the bony prominence of the lateral and superior semicircular canal ampullae as well as the epitympanic portion of the facial (fallopian) canal. The head and neck of the malleus and its articulation with the body and short process and a portion of the long process of the incus occupy most of the space in the epitympanum. These two ossicular masses are held in place by ligaments anteriorly and posteriorly to provide an axis of rotation for the ossicular chain (Figure 1–5). The epitympanic space communicates posteriorly through a narrow opening called the aditus ad antrum to the central mastoid tract of the mastoid cavity. Anteriorly, the epitympanum is separated at the cochleariform process from an anterior epitympanic cell of variable size by a bony and mucous membrane barrier, which may completely or incompletely separate the two compartments. This anterior epitympanic space is formed by pneumatization from the protympanum (see Figure 1–5). The anterior epitympanic space is also important surgically as it may contain inflammatory tissue (ie, cholesteatoma) that has extended from the protympanum.

Auditory Ossicles Sound pressure energy is transmitted from the tympanic membrane across the middle ear space by the ossicular chain comprised of the malleus, incus, and stapes (Figure 1–6). The head of the malleus and body of the incus function as a unit suspended by ligaments in the epitympanum. The tip of the long process of the incus articulates at a right angle with the head of the stapes so that the sound energy transmission initiated by medial displacement of the tympanic membrane is carried by the parallel displacement of the elongate processes of the malleus and incus to the head, crura, and footplate of the stapes (see Figure 1–6). Since the surface area of the tympanic membrane is larger than that of the stapes footplate by a ratio of 25 to 1, the sound pressure density in the oval window and the inner ear fluids is similarly increased. Maintaining this ratio by various reconstructive methods constitutes

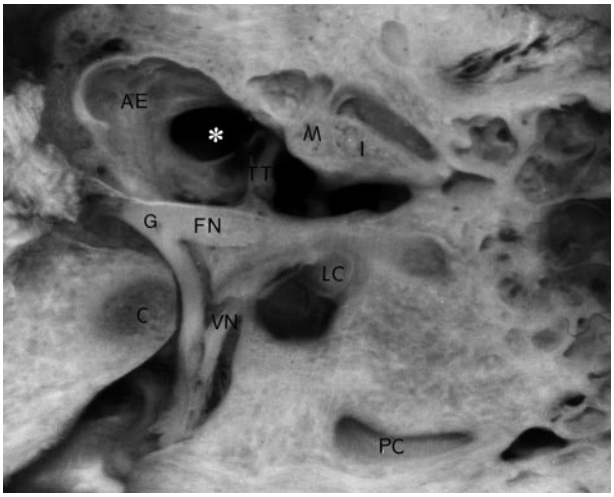

FIGURE 1–5. This horizontal cut through a celloidin-embedded temporal bone illustrates the relationship of the facial nerve (FN) to the superior division of the vestibular nerve (VN) in the internal auditory canal. The axis of rotation of the head of the malleus (M) and body of the incus (I) with their ligamentous attachments in the epitympanum is shown. AE = anterior epitympanic space ventilated into the protympanum (*); LC = lateral canal crista and ampulla; PC = posterior semicircular canal; C = endosteum of the cochlea (basal turn); TT = tensor tympani tendon; G = geniculate ganglion.

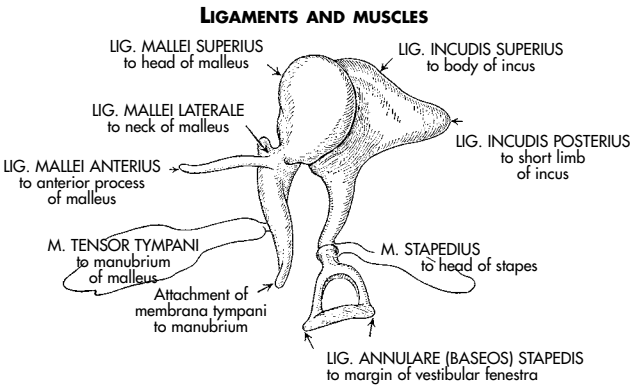

FIGURE 1–6. Auditory ossicles: their adult form and muscles and ligaments. Reproduced with permission from Anson BJ, editor. Morris' human anatomy. 12th ed. New York: McGraw-Hill; 1966.

an important principle in middle ear surgery. The stapes therefore acts in a piston-like fashion in the oval window. The stapes bone is shaped like a stirrup with a head, neck, and footplate or base. The crura are bowed, the posterior one more so than the anterior, and fused with the footplate, which is formed from both otic capsule and periosteal bone. These auditory ossicles are controlled to some degree by two middle ear muscles, the tensor tympani and the stapedius. The tensor tympani muscle is housed in a bony semicanal in the anterior mesotympanum just superior to the orifice of the eustachian tube (Figure 1–7). The muscle converges posteriorly into a tendinous segment that is anchored at the cochleariform process and turns abruptly lateralward to insert on the neck of the malleus. The tensor tympani is innervated by a branch of the fifth cranial nerve. Its motoneurons are located centrally in the parvocellular division of the trigeminal motor nucleus, and its action causes the drumhead to be pulled medially, thus raising the resonant frequency of the sound conduction system.

The stapedius muscle arises within either its own or the fallopian canal and is accompanied by the motor portion of the facial nerve. It converges superiorly and anteriorly to form the stapedius tendon, which emerges through the pyramidal eminence to insert at the neck of the stapes. The stapedius muscle is innervated by a branch of the seventh nerve, and its motoneurons are located in the brainstem in the interface between the facial nucleus and the lateral superior olivary nucleus. Contraction of the stapedius muscle displaces the stapes posteriorly and attenuates sound transmitted by the ossicular chain. Since reflex contraction of the stapedius muscle is activated by sound, it is regarded as a protective mechanism for the cochlea.

Eustachian Tube The eustachian tube is an essential communication between the nasopharynx and the middle ear (Figure 1–8). It is responsible for pneumatization of the middle ear and the mastoid and for maintaining normal pressure between the middle ear and the atmosphere. It represents the pharyngeal extension of the first branchial arch and extends from the lateral wall of the nasopharynx. The skeleton of the medial three-fourths of the eustachian tube is cartilage that is surrounded by soft tissue, adipose tissue, and respiratory epithelium. The cartilage of the eustachian tube, which is hook shaped on cross-section, is stabilized and displaced

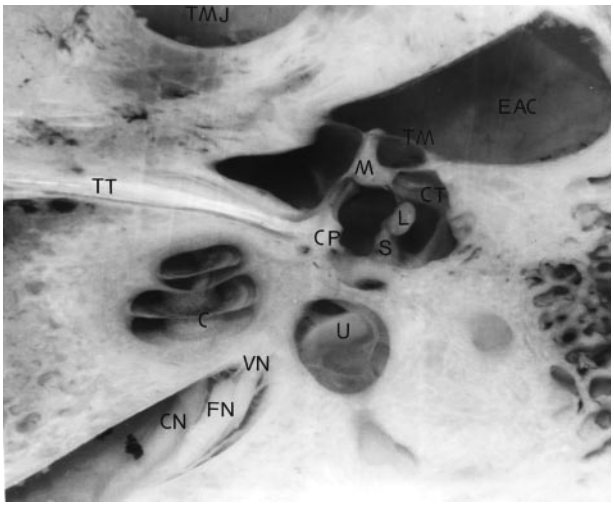

FIGURE 1–7. A more inferior cut through the same temporal bone as in Figure 1–5 demonstrates the cochlea (C), the utricular macula and its nerve (U), the cochlear nerve (CN), the facial nerve (FN), and vestibular nerves (VN) in the internal auditory canal. The muscle and tendon of the tensor tympani muscle (TT) overlie the cochlea as it turns laterally in the cochleariform process (CP) to attach near the neck of the malleus (M). The articulation of the long process (L) of the incus with the stapes head (S) can be seen in the mesotympanum. The chorda tympani nerve (CT) passes between the malleus and incus. TM = tympanic membrane; EAC = external auditory canal; TMJ = temporomandibular joint space.

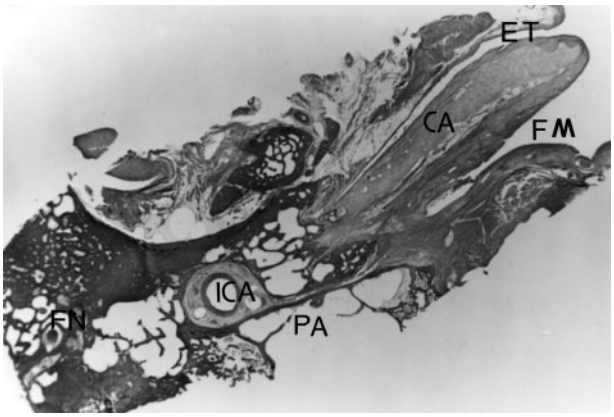

FIGURE 1–8. Low-power horizontal section through the eustachian tube (ET) as it passes into the protympanum. CA = cartilage of the ET; FM = fossa of Rosenmüller; ICA = internal carotid artery; FN = facial nerve; PA = petrous apex air cells.

by contraction of the tensor veli palatini and levator veli palatini muscles on swallowing or yawning. The eustachian tube is thereby opened, allowing for pressure equalization. The lining epithelium of the cartilaginous portion is similar to that of the pharynx with pseudostratified columnar cell epithelium and many mucous glands. Posterior to the union of the cartilaginous and osseous portion of the eustachian tube where the isthmus is located, the mucosa undergoes transition to cuboidal or low columnar cell epithelium similar to the tympanic cavity epithelium. Neoplastic compression of the eustachian tube lumen near its pharyngeal orifice (Rosenmüller's fossa) will cause fluid to fill the middle ear space (serous otitis media), usually in an adult patient (see Figure 1–8). Investigation of this occult region by endoscopy, radiologic imaging, and biopsy is necessary in such instances.

Nerve Supply of the External and Middle Ear The auricle and the external auditory canal receive the sensory nerve branches from the fifth nerve via the auriculotemporal nerve and the greater and lesser auricular nerves. Branches from the glossopharyngeal and vagus nerves also contribute to this innervation. The branch of the vagus nerve is referred to as Arnold's nerve, which travels in the posterior part of the ear canal in the posterior part of the tympanomastoid suture. When this nerve is stimulated, it produces a cough reflex as when the external auditory canal is being cleaned with an instrument. It may also participate in heralding a neoplastic or infectious process in distant regions of the aerodigestive tract also innervated by the vagus nerve (ie, larynx, hypopharynx) when pain is referred to the ear.

The main innervation to the middle ear space is through the tympanic plexus and Jacobson's nerve, which receives a major contribution from the glossopharyngeal nerve through the inferior tympanic canaliculus. This nerve travels in a bony sulcus or canal over the promontory along with the inferior tympanic artery anterior to the oval window and finally anteriorly to become the lesser superficial petrosal nerve. This nerve ultimately carries the fibers of the preganglionic neurons of the ninth nerve to the otic ganglion, where they synapse with postganglionic neurons and are carried over the auriculotemporal nerve to the parotid gland. Sympathetic fibers from the carotid plexus also contribute to the tympanic plexus. The chorda tympani nerve, which is a sensory branch of the facial nerve, will be discussed in the section on the facial nerve.

Mastoid Compartment The air cell system of the mastoid bone represents an extension of the air compartment in the middle ear from the first pharyngeal pouch. This process occurs in development of the TB and may result in a variable degree of pneumatization in the mastoid compartment (see Figure 1–4). Recurrent infection in the middle ear and mastoid has been identified as a factor that may limit the extent of pneumatization of the mastoid air cell system, whereas absence of such infection may favor full development of the air cell system. The air cells in the mastoid compartment extend from the aditus ad antrum in the epitympanum to the central mastoid tract (antrum) from which further extension in several directions may occur.[5] The *posterior superior* cell tract extends medially at the level of the superior semicircular canal toward the petrous apex (PA), and the *posterior medial* cell tract extends toward the PA at the level of the posterior semicircular canal. The *supralabyrinthine* cell system extends medially superior to the labyrinth, whereas the *retrofacial* cell system extends posteriorly and inferiorly along the bony ear canal to pneumatize the mastoid tip. These cell tracts may vary considerably and are important for the surgeon to know as a

guide in tracing infection into deep recesses of the mastoid compartment, particularly the PA.

Cell tracts arising from the middle ear space also are important for the surgeon. These cell tracts, particularly those that may lead to air cell development in the PA, are those that course inferior to the labyrinth or those that extend around the canal of the internal carotid artery (see Figure 1–8). Extensive pneumatization in the development of the PA may create air cells that can become isolated when the cell tract is obliterated by bone or fibrous tissue leading to the formation of cholesterol cysts over a period of many years. Over time, these cysts erode the surrounding bone and may reach considerable size in early or late adulthood. Compression of the trigeminal nerve and the sixth nerve near the PA may present a clinical picture similar to Gradenigo's syndrome, which is the clinical manifestation of petrous apicitis.

The PA is of special interest because of a variety of lesions that may involve this region. The clinical manifestation may be subtle and requires a high index of suspicion to pursue the diagnosis.[6] Imaging (both computed tomography and magnetic resonance imaging) is especially sensitive to the identification of pathology in the PA. Since the composition of the PA can include air cells (see Figure 1–8), bone marrow (Figure 1–4), the internal carotid artery (Figure 1–4), and the cartilage of the foramen lacerum, the list of lesions that occur here is lengthy. Cholesterol cysts and congenital cholesteatomas are the most common; however, infection, bone marrow neoplasms, cartilage tumors, metastatic malignancies, neurogenic tumors, and aneurysms of the internal carotid artery have been reported. Clinical signs of a progressive lesion in the PA relate to nearby structures: eustachian tube obstruction, facial pain or anesthesia, and lateral rectus muscle palsy.

Inner Ear

The petrous portion of the TB houses the labyrinth with its attendant sensory structures responsible for auditory and balance function. Within the bony labyrinth is contained the membranous labyrinth, which represents a continuous series of epithelial lined tubes and spaces of the inner ear containing endolymph and the sense organs of hearing and balance. The membranous labyrinth can be divided into three regions that are interconnected: the pars superior or the vestibular labyrinth with the exception of the saccule, the pars inferior (cochlea and the saccule), and the endolymphatic duct and sac. All of the sense organs of the labyrinth have in common that they contain hair cells with rigid cilia and are innervated by afferent and efferent neurons.[7,8] Displacement of the cilia of the hair cells is responsible for opening potassium and calcium channels that initiate the electrical potential within the hair cell that is then leaked into the afferent neuron and carried to the brainstem.

Cochlea The cochlear duct, the auditory portion of the labyrinth, extends approximately 35 mm.[9] The cochlear duct and associated sensory and supportive structures assume the form of a spiral similar to a snail shell of 2½ to 2¾ turns (Figure 1–9). This allows the long cochlear duct to be contained in a small space. A cross-section of a cochlear turn (Figure 1–10) demonstrates the essential structures in this sense organ. The scala media or cochlear duct con-

taining endolymph is triangular in shape in cross-section. The basilar membrane forms the horizontal limb of the triangle, Reissner's membrane, the superior limb, and the stria vascularis with spiral ligament on the vertical side. The cochlear duct is filled with a fluid referred to as endolymph, whereas the fluid in the scala vestibuli and scala tympani is perilymph. Perilymph of the two scalae communicates through the helicotrema at the apex of the cochlea. All of the structures of the cochlear duct and, particularly, the basilar membrane have a morphologic gradient whereby the width of the basilar membrane is narrowest at the basal end and widest at the apex. The spiral ligament and epithelial elements in the organ of Corti also have a morphologic gradient from base to apex (see Figure 1–9). This morphologic gradient, to a large degree, determines the location of maximal stimulation of the basilar membrane and inner hair cells by a given tone or frequency that is introduced to the inner ear. In this way, high frequencies are located at the base and low frequencies at the apex, with the frequency scale laid out in an orderly fashion over the remainder of the basilar membrane. The cochlear duct ends in a blind pouch (cecum) that is located near the RWM.

Perilymph of the scala vestibuli fills the vestibule under the stapes footplate. This perilymphatic compartment extends up the scala vestibuli of the cochlea and communicates with the perilymph in the scala tympani, which extends down the cochlea to terminate at the RWM. The perilymphatic compartment also communicates with the subarachnoid space through the periotic duct by way of the cochlear aqueduct that is filled with a trabecular meshwork of connective tissue capable of allowing some exchange of cerebrospinal fluid and perilymph. However, perilymph is primarily formed by filtration from the vascular network in the spiral ligament.

The organ of Corti is a complex sense organ that contains inner and outer hair cells and supporting cells resting on the basilar membrane, with the ciliated ends of the hair cells protruding into or near a covering structure, the tectorial membrane (Figure 1–11). The apical portions of the hair cells are anchored in the cuticular plate, with the stereocilia (usually 100 to 150 per cell) protruding through the cuticular plate.[7] The stereocilia of the outer hair cells make contact with the tectorial membrane, whereas the stereocilia of the inner hair cells lie free in the endolymphatic space inferior to the tectorial membrane. There are a single row of inner hair cells and three to five rows of outer hair cells. These cells differ morphologically in that the inner hair cells are more flask shaped and tightly surrounded by supporting cells and have stereocilia that are arranged in a linear fashion, whereas the outer hair cells are columnar and incompletely surrounded by phalangeal or supporting cells lying free in the perilymph of the organ of Corti.[10] The stereocilia of the outer hair cells form an inverted "W,"

and a basal body representing a rudimentary kinocilium is located on the spiral ligament side of the ciliary tuft. The inner hair cells are supported by interphalangeal cells, whereas the outer hair cells are supported by Deiters' cells inferiorly and laterally by Hensen's cells. The tectorial membrane is anchored medially at the limbus and attached to the Hensen's cells laterally by a fibrous net. The basilar membrane and tectorial membrane are displaced vertically by the traveling wave created by sound energy delivered to the oval window. Since the fulcrum of these two structures is separate, they will slide horizontally when stimulated, resulting in a shearing action between the tectorial membrane and the cuticular plate. The resultant displacement of stereocilia initiates an electrical event in the hair cell. The organ of Corti contains approximately 15,500 hair cells, with about 3,500 of them being inner hair cells and 12,000 being outer hair cells. These hair cells are innervated by afferent and efferent neurons in a complex but orderly manner. The afferent neurons to the auditory sense organ are bipolar neurons referred to as spiral ganglion cells that are located in Rosenthal's canal of the bony modiolus. Approximately 30,000 spiral ganglion cells innervate the human organ of Corti (see Figure 1–11). The spiral ganglion takes the form of clusters of ganglion cells throughout the extent of the length of the cochlea. Ninety to 95% of the spiral ganglion neurons are type I neurons, which are large and myelinated and project a single dendrite directly to an inner hair cell.[10] Approximately 10 to 20 type I spiral ganglion cells innervate one inner hair cell. These form the major afferent input from stimulation of the organ of Corti. Type I ganglion cells degenerate readily following injury to the dendrite. The remaining 5% of afferent neurons in the spiral ganglion are type II ganglion cells, which are smaller and unmyelinated and have very thin distal processes. The dendrites of these type II neurons cross the tunnel space along its floor enveloped by pillar cell processes and form spiral bundles between Deiters' cells. These dendrites then course apically between Deiters' cells to innervate several to many outer hair cells per type II dendrite.[9] A type II ganglion survives following injury to its dendrite. The axons of the spiral ganglion cells project to the cochlear nucleus complex, which has anteroventral and posteroventral divisions of the ventral cochlear nucleus and the dorsal cochlear nucleus. Each type I afferent neuron bifurcates and also sends a trifurcating branch to the dorsal cochlear nucleus in an orderly fashion according to frequency.[9] Apical turn neurons terminate in the most medial portion of the nuclear complex, whereas the basal turn neurons terminate laterally. Remaining frequency projections are ordered between these two regions of the cochlear nucleus. The central termination of the type II ganglion cells is not known largely because the small caliber axons are difficult to trace for long distances.

This frequency organization of the auditory pathway characterizes the remainder of the afferent pathway from end-organ to cortex. Another feature of the afferent auditory pathway is that the numbers of neurons involved at the various nuclear way stations undergo a progressive increase from cochlear nucleus to the cortex.[11] Although there are 30,000 spiral ganglion cells in the monkey auditory nerve, 88,000 neurons are found in one cochlear nucleus in the primate. One superior olivary complex contains 34,000 neurons, whereas the nucleus of the lateral lemniscus has 38,000 neurons, and at the inferior colliculus level there are almost 400,000 neurons on each side and at the medial geniculate body 500,000. The auditory cortex has approximately 10 million neurons.

A brief description of the afferent auditory pathway follows (Figure 1–12). The cells of the dorsal cochlear nucleus project axons to the dorsal acoustic striae, which crosses the midline and ascends in the contralateral lateral lemniscus to terminate in the dorsal nucleus of the lateral lemniscus and the inferior colliculus, particularly its inferior half. The cell bodies of the ventral cochlear nucleus project axons to the ipsilateral accessory and main superior olivary nuclei and to the medial dendrites of the contralateral accessory olive. The neurons of the accessory olive have bipolar dendrites arranged horizontally. This arrangement is favorable to receive input from projections of both cochlear nuclei. As such, it is an important nuclear way station for determining sound localizaton. Some fibers of the intermediate and ventral cochlear striae travel beyond the superior olivary complex and enter the contralateral lateral lemniscus to terminate in the inferior colliculus. The superior olive is thought to function as both a relay station for the auditory pathway and as a reflex center. The best-known reflex mediated through the superior olive is the stapedius reflex. Stapedius muscle motoneurons are

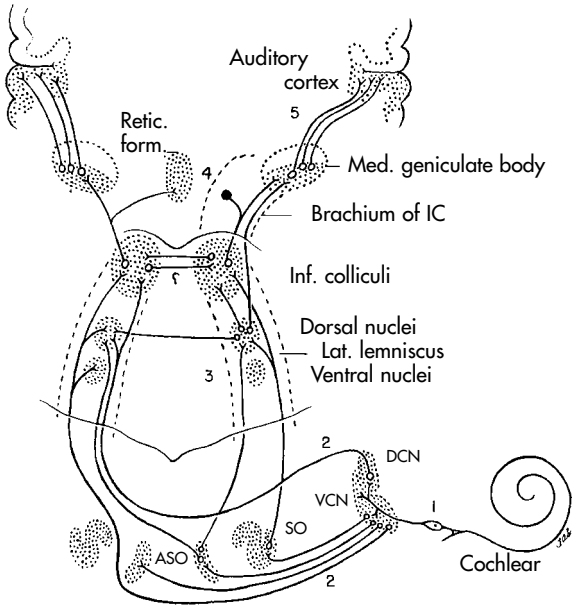

FIGURE 1–12. Diagram of the neuronal linkage that serves the afferent auditory pathway from one cochlea. Numerals indicate order of neuron units in the pathway. VCN = ventral cochlear nucleus; DCN = dorsal cochlear nucleus; SO = lateral superior olivary nucleus; ASO = accessory superior olivary nucleus; IC = inferior colliculus; Retic. form. = reticular formation. located in the interface between the superior olivary and the facial nerve nuclei. The accessory superior olive projects bilaterally in the lateral lemnisci to terminate in the dorsal nuclei of the lateral lemnisci and the inferior colliculi. The lateral superior olive projects homolaterally in the lateral lemniscus to terminate in the dorsal nucleus of the lateral lemniscus and also in the inferior colliculus. No neurons from the superior olivary nuclei project beyond the inferior colliculus.

Projections from the inferior colliculus are primarily to the medial geniculate body. However, some projections to the medial geniculate body are received from the nuclei of the lateral lemniscus. All ascending neurons terminate in the medial geniculate body so that the final projection pathway to the auditory cortex, which is a major one, is from the medial geniculate body to the auditory cortex. Furthermore, the only commissural or interconnections between the two sides of the auditory pathway are at the superior olivary level, the level of the nuclei of the lateral lemniscus, and the inferior colliculus. No commissural projections are present superior to the inferior colliculus.

The ascending auditory pathway, although comprised of four to five neurons in the linkage from end-organ to auditory cortex and having an increasing volume of neural units active at each level, nevertheless is precisely organized according to the frequency scale and project bilaterally but predominantly in a contralateral pathway to the auditory cortex.

Efferent Auditory Pathways Paralleling the afferent auditory pathway is a descending pathway originating in the auditory cortex and terminating in the end-organ (Figure 1–13). This pathway does not involve as many neurons as the ascending or afferent pathway but has the feature of extensive ramification and formation of many terminals, which contact a large number of neurons. Nevertheless, the efferent

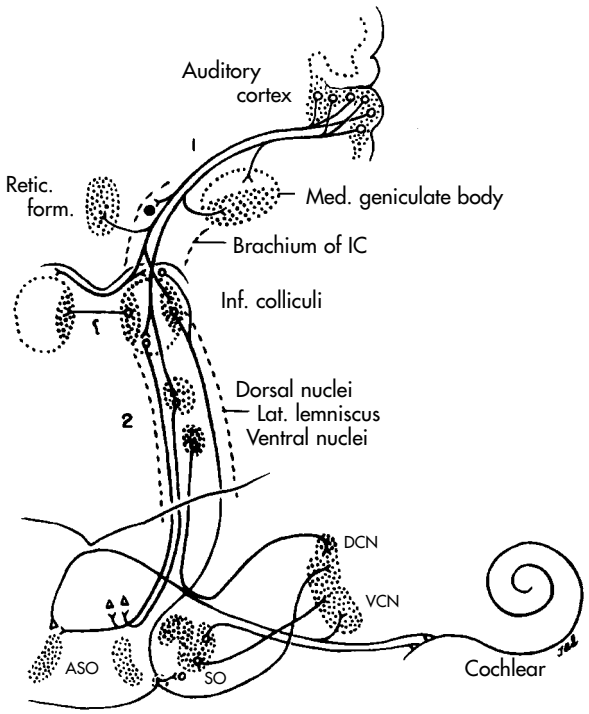

FIGURE 1–13. Diagram of the descending (efferent) auditory pathway. IC = inferior colliculus; DCN = dorsal cochlear nucleus; VCN = ventral cochlear nucleus; ASO = accessory superior olivary nucleus; SO = lateral superior olivary nucleus. Reproduced with permission from Gacek RR. Neuroanatomy of the auditory system. In: Tobias JV, editor. Foundations of modern auditory theory. Vol 2. New York: Academic Press; 1972. p. 253.

pathway does not make as many neural contacts in the auditory nuclei as the ascending pathway. The descending auditory pathway originates in the auditory cortex and initially projects to the inferior colliculus and the dorsal nucleus of the lateral lemniscus, with some termination in the medial geniculate body and the reticular formation.

The next neuron in the descending chain is located in peripheral regions of the inferior colliculus and the nuclei of the lateral lemniscus. These projections terminate in brainstem neurons that give rise to efferent neurons projecting to divisions of the cochlear nucleus and to neurons that give rise to the third and final neuron in the descending auditory pathway, the olivocochlear bundle, which innervates the organ of Corti.[12,13]

The olivocochlear bundle has both an ipsilateral and a contralateral limb or component (Figure 1–14). The neurons, which number approximately 1,000 to 3,000, arise from neurons located within and near the superior olivary complex. The contralateral limb of the olivocochlear bundle forms a major part of the efferent bundle, accounting for approximately three-fourths of the number of efferent neurons projecting to the organ of Corti in one ear. These axons arise from small neurons located near the accessory olivary nucleus,[14] ascend in the brainstem, and cross the midline at the level of the facial genu below the floor of the fourth ventricle. They are joined by the smaller ipsilateral component, which arises from similar olivary and periolivary neurons of the ipsilateral superior olivary nucleus before joining the contralateral limb as it enters the vestibular nerve root. As it leaves the brainstem in the vestibular nerve, the bundle gives off collateral branches to the ventral cochlear nucleus and exits the vestibular nerve within the IAC just distal to the saccular ganglion. It then enters Rosenthal's canal, where it travels perpendicular to the spiral ganglion cells and their dendrites, forming the intraganglionic or juxtaganglionic spiral bundle. The fibers from the efferent bundle are then given off regularly as they ascend the cochlea. These fibers penetrate the habenulae perforatae in the osseous spiral lamina along with afferent dendrites to enter the organ of Corti. The differential termination of the efferent neurons from the ipsilateral and the contralateral limbs is as follows: the fibers from the ipsilateral efferent component terminate on type I afferent dendrites and their terminals below the inner hair cell. The contralateral limb of the efferent

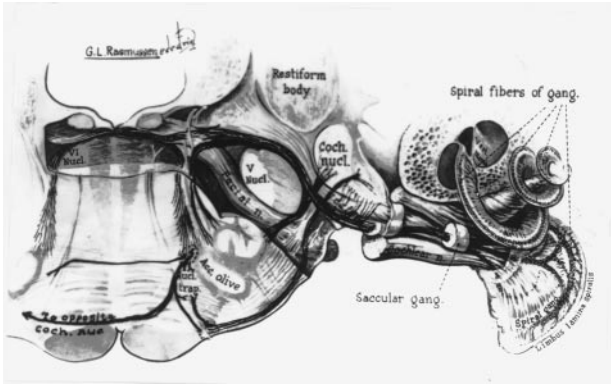

FIGURE 1–14. Drawing of the olivocochlear efferent pathway (from Rasmussen). See text for a description.

pathway crosses the tunnel space and ramifies extensively to terminate on several outer hair cells in the first and second rows in a wider area than the inner hair cells at that region. The efferent innervation to outer hair cells is most extensive in the basal turn and decreases as the apex is reached.[15] This decrease is most noticeable in the outermost rows of outer hair cells of the organ of Corti. Whereas the inner hair cell type I neuron innervation provides the major afferent input to the cochlear nucleus, the efferent innervation of the outer hair cells is thought to alter mechanically the resistance at the outer hair cell level by contractile changes in the length of the outer hair cells. In this way, the sensitivity to sound stimulation of type I–innervated hair cells is modified. The predominant effect on auditory nerve transmission by stimulation of the efferent pathway has been to suppress the action potential in the auditory nerve.[16] It is thought that the outer hair cells with their type II afferent innervation and the efferent innervation sharpen the characteristic frequency discrimination of the organ of Corti. It is also probable that the hair cells, with their spontaneous and induced transition in length, may be responsible for otoacoustic emissions, which are small electrical potentials recorded from the ear.[17] In some patients in whom the inhibitory effect of the efferent system is lost (ie, surgery, infection), the facilitated otoacoustic emissions may be perceived as ringing in the ear (tinnitus).

VESTIBULAR SYSTEM

The sense organs of the vestibular system are of two types, the cristae and the maculae (Figures 1–15 and 1–16). These sense organs have two types of hair

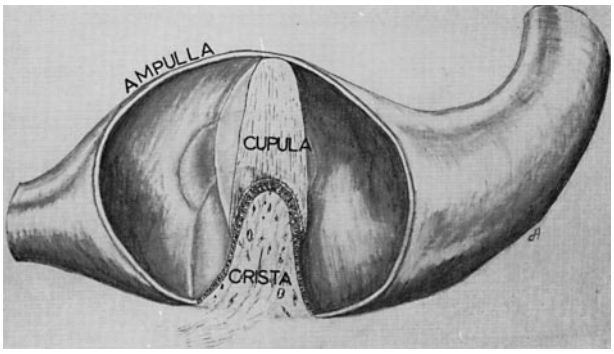

FIGURE 1–15. Section (diagrammatic) through the ampulla of a semicircular duct.

cells,[8,18] type I and type II, which are secured in the neural epithelium by supporting cells (see Figure 1–16). The type I hair cells are flask shaped and are enclosed in a large calyx-type ending by one or two large-diameter afferent neurons. Type II hair cells are cylindrical in shape and contacted by bouton-shaped endings from both the afferent and efferent systems. These afferent neurons are myelinated but small compared with those that innervate type I hair cells. The crista is a ridge of neuroepithelial cells that traverse the ampullated end of each membranous duct. The ampulla contains the sense organ for the detection of angular acceleration and deceleration[19] (see Figure 1–15). The hair cells in the crista ampullaris are arranged with the type I hair cells near the crest of the crista and type II hair cells near the slopes.[7,18] It is noteworthy that the hair cells in cristae of the semicircular ducts are oriented in a single direction based on the alignment of their ciliary bundle.[7,18] The ciliary bundle of each vestibular hair cell consists of 100 to 150 stereocilia and a single kinocilium, which is located to one side of the stereocilia (see Figure 1–16). In the case of the horizontal duct, the kinocilium of each hair cell is located on the utricular side of the crista. In the vertical cristae, the kinocilia are located toward the nonampullated ends or away from the utricle (Figure 1–17). Sitting on top of the crista and reaching to the roof of the ampullary wall, even attached to it, is a gelatinous partition called the cupula, composed of mucopolysaccharides possessing an equal density to the endolymph, which surrounds it (see Figure 1–15). It is the displacement of the cupula that initiates through the hair cells an action potential in the neurons contacting the hair cells.[19,20] When the deflection of the cupula is toward the kinocilium, there is a depolarization of the hair cell neuron unit with an increase in the resting vestibular nerve action potential, whereas a deflection away from the kinocilium produces hyperpolarization or a decrease in the resting discharge of the vestibular neuron.[7] The semicircular ducts in each labyrinth are oriented to each of three planes in space, with the lateral ducts recording angular acceleration in a horizontal plane, whereas the two vertical ducts record movement in the two vertical planes of space. To induce

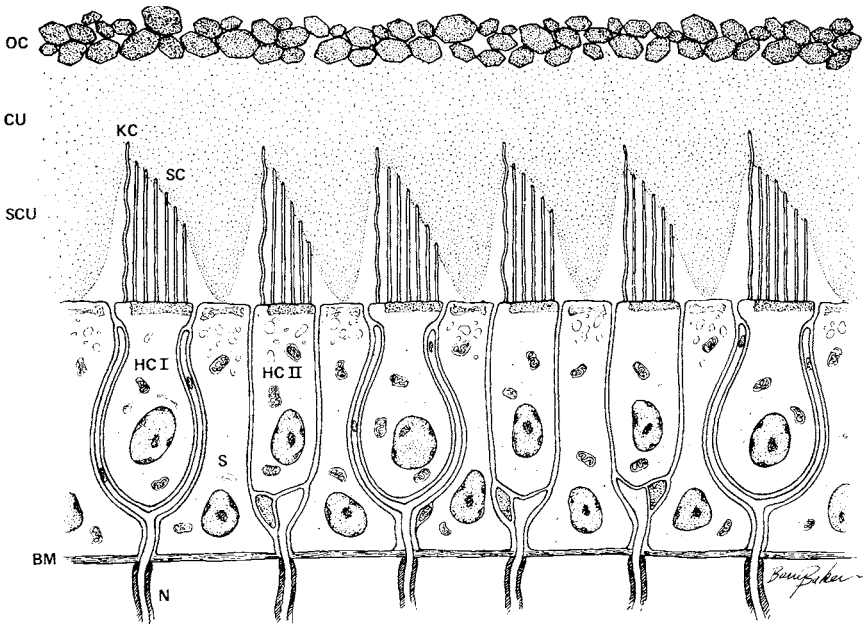

FIGURE 1–16. Schematic drawing of a cross-section of a macula. The gelatinous substance is divided into cupular (CU) and subcupular (SCU) layers. There are two types of hairs: kinocilia, labeled KC (one per hair cell), and stereocilia, labeled SC (many per hair cell). OC = otoconia; HC I = type I hair cell; HC II = type II hair cell; N = nerve fiber; BM = basement membrane; S = supporting cell.

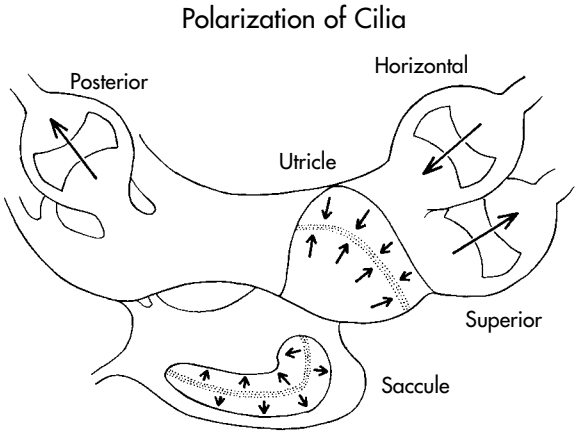

FIGURE 1–17. Diagram summarizing the orientation of hair cells in the vestibular sense organs based on the location of the kinocilium in the ciliary bundle.

complementary input to the vestibular nuclei, the ducts of each labyrinth are coplanar; in other words, the posterior duct of one labyrinth is coplanar with the anterior duct of the contralateral labyrinth. Because of the opposite polarization of hair cells in coplanar ducts, following rotation in a given plane, one coplanar duct will be facilitated and its contralateral partner will be inhibited.[21]

The maculae are flat sense organs that are divided approximately in half by a line called the striola. The striola divides the macula into two halves, in which the hair cell ciliary polarization is in opposite directions (see Figure 1–17). In the macula of the utricle, the hair cells are oriented toward the striola, whereas in the saccule, hair cells are oriented away from the striola. Since the maculae project centrally to the vestibulospinal pathways primarily, but to a lesser extent to the vestibulo-ocular pathways, it is possible that the opposite polarization of regions in the maculae allows excitation and inhibition to antagonistic muscle groups. Type I hair cells seem to predominate near the striola, with type II hair cells furthermost from the striola. The cilia of the hair cells in the macular sense organs are covered by an otolithic membrane, gelatinous in makeup with otoconia composed of calcium carbonate crystals with a specific gravity of 2.71 embedded in the gelatinous blanket. The movement of the otoconial membrane by gravitational forces or inertial forces displaces the hairs of the hair cells, thus bringing about activity in their afferent nerve input.

The innervation of hair cells in the vestibular sense organs is by both afferent and efferent neurons (see Figure 1–16). The afferent neurons can be divided into two types, the large afferent neurons belonging to the large bipolar ganglion cells in Scarpa's ganglia, which innervate type I hair cells with large calyx-like endings,[8,18] and the smaller afferent bipolar neurons in Scarpa's ganglia, which innervate type II hair cells with bouton-type terminals. Vestibular neurons have a high spontaneous activity with a higher range (90 to 100 spikes per second [sps]) in canal afferents than in macular afferents (60 to 70 sps). The large vestibular afferents characteristically show an irregular discharge pattern, whereas the smaller afferents have a regular pattern of discharge.[21] The significance of such different afferent units is not known but implies a functional difference. The efferent neurons are also small in diameter and consist of both myelinated and unmyelinated axons. They penetrate the basement membrane of the neuroepithelium and ramify extensively to form bouton-like terminals filled with many synaptic vesicles on both type II hair cells and the calyces of type I hair cells.

The afferent neurons to the vestibular sense organs are bipolar neurons of Scarpa's ganglion. There are approximately 18,000 to 19,000 ganglion cells in the human vestibular ganglion. The organization of the afferent neurons in the vestibular nerve has been elucidated.[22] The vestibular nerve has superior and inferior divisions, with the superior division innervating the cristae of the lateral and superior semicircular ducts and the utricle as well as a small portion of the saccule (Figure 1–18). The inferior division innervates the macula of the saccule and the posterior duct crista. The bipolar neurons innervating the lateral and the superior duct crista travel in the most rostral (toward the facial nerve) portion of the vestibular ganglion. As they course centrally, they are joined by axons of the bipolar neurons innervating the posterior duct crista to form the rostral portion of the vestibular nerve containing all semicircular duct afferents. The afferent neurons innervating the utricle then bend caudally to join those of the saccule and form the caudal portion of the vestibular nerve as it reaches the brainstem. Between these two groups of neurons is located the parent efferent bundle for both the cochlear and vestibular efferent axons. Consistent with the innervation pattern in the cristae ampullaris, the large afferents travel up the center of the ampullary nerve to innervate type I hair cells at the crests of the crista,[18,22] whereas the smaller fibers

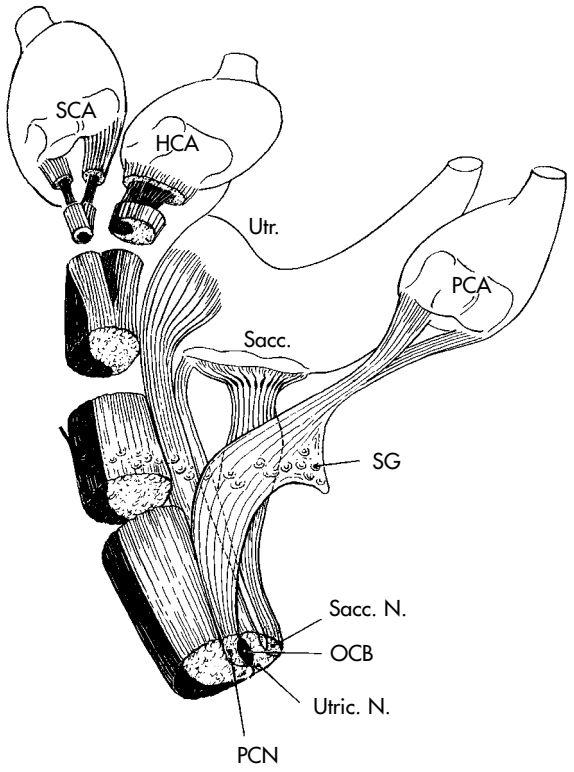

FIGURE 1–18. Drawing of the organization of bipolar neurons of the vestibular nerve. Ganglion cells in Scarpa's ganglion (SG) that innervate the cristae converge into the rostral two-thirds of the nerve trunk as it approaches the brainstem. The ganglion cells that supply the utricular and saccular maculae occupy the caudal third of the vestibular nerve trunk. The cochlear and vestibular efferent axons are located at the interface of these two divisions. The dark portion of the vestibular nerve signifies the location of large neurons that supply type I hair cells in the superior and lateral duct cristae. SCA = superior canal ampulla; HCA = horizontal canal ampulla; PCA = posterior canal ampulla; Utr. = utricle; Sacc. = saccule; Sacc N. = saccular nerve; Utric N. = utricular nerve; PCN = posterior canal nerve; OCB = efferent bundle (cochlear and vestibular). innervate the slopes and therefore surround the larger fibers in each ampullary nerve (see Figure 1–18). On the other hand, the distribution of the large and small afferents in the saccular and the utricular nerves is more dispersed since the division between the location of type I and type II hair cells in the maculae is not so precise as in the cristae.

Central Vestibular Pathways

The division of duct afferents in the rostral one half to two-thirds in the vestibular nerve and utricular afferents in the caudal portion of the vestibular nerve is related to their termination in the major vestibular nuclei in the brainstem.[22] The duct afferents after bifurcating send an ascending branch to the superior vestibular nucleus and a descending branch with many collaterals to the rostral portion of the medial vestibular nucleus, with some collaterals to the ventral division of the lateral vestibular nucleus (Figure 1–19). This projection is organized in that the duct innervated by the inferior division terminates most medially in the superior nucleus and most ventrally in the medial nucleus, whereas the two ducts supplied by the superior division of the vestibular nerve terminate dorsolaterally in the superior nucleus and dorsally in the medial nucleus.[22] Short collaterals from

the incoming axons of duct afferents also terminate on the intravestibular nerve nucleus, a small nucleus within the vestibular nerve root. The afferents from the utricular and saccular maculae also bifurcate, with their ascending ramus terminating in the lateral and medial nuclei and the descending branch to the descending and group Y vestibular nuclei (Figures 1–20 and 1–21). The projection to the lateral nucleus is on neurons in the ventral division of the lateral vestibular nucleus and on large neurons in the rostral extension of the medial vestibular nucleus. The large neurons in the medial nucleus represent afferents to the abducens nucleus and to the subnucleus in the oculomotor nucleus, which innervates the medial rectus muscle. The latter projection pathway travels over the ascending tract of Deiters.[23] The saccular afferents also send terminations to the group Y nucleus, a minor nucleus that is located between the restiform body and the dorsal acoustic stria and the lateral vestibular nucleus. The group Y nucleus' major projection is to the contralateral group Y and superior nuclei.

The projections of the major nuclei are responsible for the reflex connections of the duct and the macular afferents.[23–25] Second-order pathways activated by canal afferents project from the superior and medial vestibular nuclei and course in a parallel fashion to terminate in the trochlear and oculomotor nuclei with rostral terminations in the nucleus of Darkeschewitch and the interstitial nucleus of Cajal (see Figure 1–19). These pathways travel in the medial longitudinal fasciculus (MLF), with the ipsilateral pathway from the superior nucleus being inhibitory and the contralaterally projecting pathway from the medial nucleus being excitatory. They are responsible for the conjugate eye displacement manifesting as nystagmus from canal stimulation or destruction. Neurons from the medial vestibular nucleus project bilaterally to the abducens nuclei. An

additional pathway lateral to the MLF, the ascending tract of Deiters, projects from neurons in the ventral portion of the lateral vestibular nucleus to the subnucleus of the oculomotor nucleus, which supplies the medial rectus muscle. The vestibulo-ocular reflex pathway for horizontal eye movement is completed with an interneuron located in the abducens nucleus, which carries an excitatory charge to neurons serving the contralateral medial rectus muscle (Figure 1–22). The oculomotor pathways for horizontal and vertical rotatory eye movements are separate, with the latter located in more lateral portions of the brainstem (Figure 1–23), whereas the pathways involved in the horizontal eye movement are located beneath the floor of the fourth ventricle (see Figure 1–23). It is this organization of pathways for horizontal and vertical rotatory eye movements that explains the perversion of nystagmus when the lateral canal is stimulated (calorically) in patients with midline cerebellar or brainstem lesions. That is, instead of seeing a horizontal nystagmus, a vertical nystagmus is seen because the afferent pathways to the abducens nuclei are interrupted, whereas those supplying the remaining extraocular muscles are intact.

The projections from the caudal vestibular nuclei, that is, the medial, descending, and entire lateral vestibular nuclei (both ventral and dorsal divisions), travel down the spinal cord to muscles of the trunk and limbs.[25,26] These projections join the vestibulospinal tract (VST) and make up the major output reflex pathway from the maculae, particularly the utricular macula (see Figures 1–20 and 1–21). The major pathway is the lateral vestibulospinal tract (LVST), which arises from the large multipolar neurons in the lateral vestibular nucleus and to a lesser extent from the descending nucleus. This pathway is somatotopically organized so that the vestibulospinal projections to the cervical and upper thoracic regions arise from neurons in the anteroventral portion of the lateral vestibular nucleus, whereas the most caudal and sacral portions of the spinal cord are innervated by the multipolar neurons in the most dorsal

and caudal portions of the lateral vestibular nucleus. Truncal and limb musculature of the intervening segments are organized in orderly fashion between these extremes. This pathway provides excitatory tone to extensor muscles of the limbs. The medial vestibulospinal tracts (MVSTs) travel down the MLF and are largely inhibitory, although some facilitatory connections are made from the descending vestibular nucleus.[21] The projections through the MLF arise from the caudal portions of the medial and descending vestibular nuclei. Since they are largely inhibitory, they act synergistically with the innervation of neck and upper truncal muscles excited by the LVST. The MVSTs extend down to the upper cord levels but do not reach the thoracic, lumbar, and sacral region levels reached by the LVST.

Other pathways exist in the vestibular nuclei that are of importance. One such pathway is the commissural pathway that interconnects the vestibular nuclei (see Figure 1–19). The major intervestibular or commissural projections are between the superior, medial, and descending vestibular nuclei.[21] A minor projection may exist between the lateral vestibular nuclei. As mentioned earlier, the group Y nucleus also forms a significant commissural projection to the contralateral group Y nucleus as well as the superior nucleus. The commissural pathways are largely inhibitory on second-order neurons activated by canal input. It is possible that they serve to potentiate the differential response arising from stimulation of coplanar canals. The commissural projections are important in the recovery of balance following ablation of one set of vestibular sense organs (labyrinthectomy). It has been demonstrated that the commissural pathways are largely responsible for providing the reactivation of input to the denervated side of the brainstem to approximate that in the intact half.[27]

The interaction of vestibular pathways with the cerebellum is emphasized by reference to certain areas of the cerebellum as the *vestibulocerebellum* (VC). These are the nodulus, uvula, flocculus, and ventral paraflocculus (see Figure 1–19). Other areas of the anterior and posterior lobes of the vermis are also included to a lesser extent. This association is based on the projection of the first- and second-order vestibular afferents to the cerebellar cortex by way of mossy fibers.[21] All canal afferents continue through the superior nucleus after termination there, to converge and terminate on neurons in the VC. Second-order neurons in the superior, medial, lateral, and descending nuclei relay input from the utricular and saccular maculae to the same areas. There is also some relay of canal input to the vestibular nuclei on to the cerebellum. The importance of such direct as well as relayed labyrinthine input to the cerebellum is not known but may have some bearing on different information coming in for modification of cerebellar output. For example, the relayed canal input may be modified by commissural inhibition before entering the cerebellum. Furthermore, other afferent input (spinal) may alter the labyrinthine (macular) input before relay to the cerebellum.

Input from the labyrinth and spinal cord, although important, is not the only source of inputting information to this important part of the vestibular system.[21] The visual system also has significant input to the flocculus and nodulus, where overlap with labyrinth input occurs. Therefore, interaction between vestibular and visual signals in the VC has firm anatomic and physiologic support. These various inputs to the VC probably determine the pattern of output from these regions, which will then impact on neurons in the vestibular nuclei.

In a reciprocal fashion, there are extensive projections to the vestibular nuclei from the cerebellar cortex and nuclei.[21] The anterior and posterior parts of the vermis provide extensive projections to the lateral vestibular nucleus, particularly the dorsal half. The output of the VC is distributed throughout the vestibular nuclei, especially to those areas related to the cerebellar input. These cerebellar projections are entirely inhibitory since Purkinje cells are inhibitory neurons.

However, not all cerebellar output is inhibitory. The fastigial nucleus (FN), which receives labyrinthine input, exerts an excitatory effect on the vestibular nuclei. The caudal part of the FN projects to parts of all of the contralateral vestibular nuclei, whereas the rostral region projects to the ipsilateral nuclei. The FN can be a link between the cerebellar cortex and the vestibular nuclei that provides an excitatory input on vestibular neurons.

Efferent Vestibular Pathway

An efferent vestibular pathway has also been demonstrated in lower and higher mammalian forms.[14,28,29] This pathway originates bilaterally from small neurons located lateral to the abducens nucleus near the

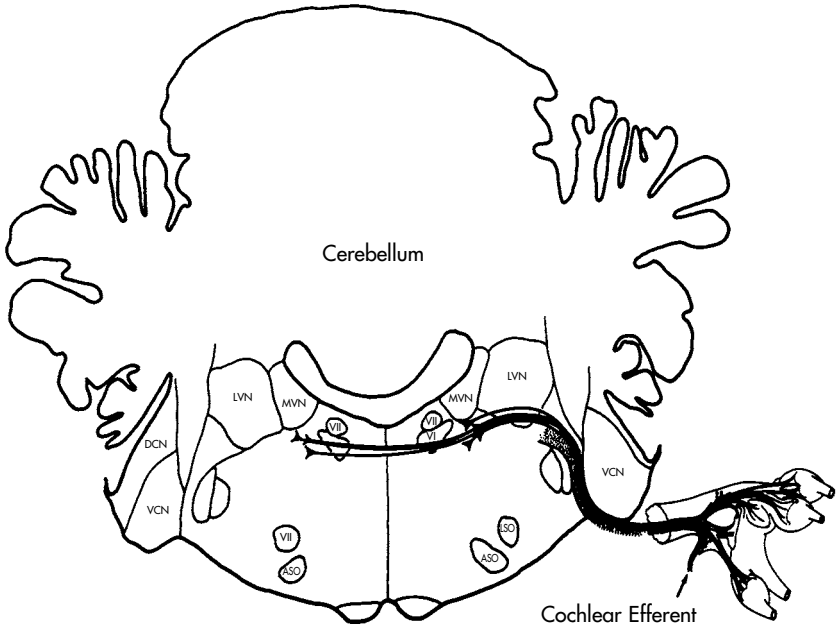

FIGURE 1–24. Diagram of the efferent vestibular pathway (*solid lines*). *Stippled area* = efferent cochlear pathway. LVN = lateral vestibular nucleus; MVN = medial vestibular nucleus; DCN, VCN = dorsal and ventral divisions of the cochlear nucleus; VII = genu of facial nerve; VI = abducens nucleus; ASO = accessory superior olivary nucleus; LSO = lateral superior olivary nucleus. Reproduced with permission from Gacek RR and Lyon M.[30]

medial vestibular nucleus[30] and projects in a symmetric fashion to each vestibular labyrinth (Figure 1–24). The axons, which are fine axons, converge with the olivocochlear bundle as the vestibular root is reached in the brainstem. They travel with the olivocochlear bundle efferents through the vestibular nerve to the point where the vestibular ganglia are reached. At this point, the vestibular efferents diverge from the parent efferent bundle to break up into fascicles and individual axons that then disperse throughout the ampullary and macular nerve branches. They branch and ramify richly along their course within the nerve trunks and after penetration of the basement membrane in the neuroepithelium of the vestibular sense organs. Here they represent fine fibers that form many bouton-like vesiculated endings in termination on type II hair cells and the calyces encapsulating type I hair cells (see Figure 1–16). These fibers are cholinergic, as are the olivocochlear efferents, and can be demonstrated selectively with acetylcholinesterase localization techniques.[15] The number of efferent neurons is relatively small compared with the number of afferent neurons in the vestibular nerve. In the cat, for the 8,000 afferent neurons, there are 200 to 300 efferent neurons that supply through their branching an almost equal number of efferent terminals to the afferent terminals in the sense organs. Although the number of vestibular efferents in the human labyrinth has not been determined, it is presumed that the imbalance in number is similar to that in lower forms. The function of the efferent system to the vestibular sense organs is not known. Most experimental studies indicate an inhibitory effect on afferent vestibular activity.[31] However, an excitatory effect has also been demonstrated in primates.[29] It is possible that the efferent effect is to raise or lower the resting activity level in vestibular afferents, thereby modifying their operating range. Unlike the efferent auditory pathway, the vestibular efferent pathway is represented by small neurons located near the medial vestibular nucleus, where they can be contacted by first-order afferents. Thus, a two-neuron reflex arc exists to type I hair cell afferent terminals and type II hair cell soma.

Fluids of the Inner Ear

As mentioned earlier, there are two fluid compartments of the inner ear, the endolymph and the perilymph. Endolymph is a fluid that has a similar ionic composition to intracellular fluid and fills the membranous auditory and vestibular labyrinth. Endolymph is formed by secretory cells in the stria vascularis and by dark cells near the ampullary ends of the semicircular ducts and the walls of the utricle. The endolymph is thought to be absorbed in the endolymphatic sac. Endolymph composition is characterized by a high potassium level and a low sodium level.[32]

TABLE 1–1. Chemical Composition of Inner Ear Fluids

Mean Value	*Perilymph*	*Endolymph*	*Cap. Serum*	*CSF*
NA^+ (mEq/L)	143	12–16	141	141
K^+ (mEq/L)	5.5–6.25	143.3 (140–160)	5.9	2.9
Protein (mg %)	200 (89–326)	150?	7170	30
Glucose (mg %)	104		104	67
Free cholesterol (mg %)	1.5			0.035
Total cholesterol (mg %)	12		28	
MDH (IU)	95.6–136		63.5	18.3
LDH (IU)	127–155		151	1.9
PO_3^- (mM/L)	0.72		0.95	0.36
CA^{++} (mM/L)	1.16	1.07	2.44	1.12
Lactate (mM/L)	6.78		4.63	3.94

CSF = cerebrospinal fluid; MDH = malate dehydrogenase; LDH = lactate dehydrogenase. Adapted from Smith CA et al.[32]

The membranous labyrinth is suspended within the bony labyrinth by a fine trabecular network in a space that is filled with perilymph. Perilymph, in contradistinction to endolymph, has an ionic composition similar to extracellular fluid, with low potassium and high sodium levels.[32] A comparison of the composition of the two fluids with that of serum and cerebrospinal fluid is found in Table 1–1. This differential chemical makeup in the two fluid compartments is important to the establishment of a standing voltage surrounding the sense organs, which permits the generation of nerve impulse in the hair cell afferent neuron unit. Perilymph is secreted largely as the result of diffusion from the capillary network in the spiral ligament adjacent to the scala tympani with a smaller portion derived from cerebrospinal fluid by way of the cochlear aqueduct.

Blood Vessels of the Ear

Two major vessels have little or nothing to do with the vascular supply of the ear itself but are important in disorders and surgery of the temporal bone. These are the sigmoid sinus and the internal carotid artery. The sigmoid sinus is a continuation of the lateral (transverse) sinus, which is formed by the superior sagittal sinus. It makes an indentation into the posterior fossa plate of the mastoid portion of the temporal bone before taking an abrupt redundant turn on itself (jugular bulb) to exit through the jugular foramen accompanied by cranial nerves IX, X, and XI (see Figure 1–4). This structure is important as it may represent a lethal complication of bacterial mastoiditis (thrombophlebitis) when erosion of its bony covering occurs. The anatomy of the jugular bulb is particularly crucial to the diagnosis and surgical management of neoplasms, which originate in the bulb such as glomus jugulare tumors or schwannomas.

The internal carotid artery enters the temporal bone just anterior to the jugular foramen and travels in a bony canal anterior to the middle ear space, first in a vertical direction and then in a horizontal anteromedial direction medial to the eustachian tube (see Figure 1–4). Its main clinical significance is as an important landmark in surgery of the petrous apex and skull base. Rarely, an anomalous internal carotid artery may appear clinically to be a vascular neoplasm in the middle ear.

The circulatory networks of the external and middle ears and the inner ear are completely separate, with the one being supplied by the carotid system, whereas that of the labyrinth is derived from the vertebrobasilar system.[9] The external ear is supplied by the auriculotemporal branch of the superficial temporal artery and branches of the posterior auricular branches of the external carotid artery. The

middle ear and mastoid are supplied by a different set of arterial branches from the external carotid system. The arterial branches to the middle ear space are the anterior tympanic branch from the internal maxillary artery, which enters through the petrotympanic fissure and travels along the eustachian tube and the semicanal for the tensor tympani. The middle meningeal artery gives off the superior tympanic branch that enters the middle ear through the petrosquamous fissure. The middle meningeal artery also gives off the superificial petrosal artery that travels with the greater superficial petrosal nerve and enters the facial canal at the hiatus. This vessel anastomoses with a branch of the posterior auricular artery, the stylomastoid artery, which enters the facial canal inferiorly through the stylomastoid foramen. A branch of the stylomastoid artery leaves the fallopian canal to travel through the canaliculus with the chorda tympani nerve to enter the middle ear. Finally, the inferior tympanic artery, a branch of the ascending pharyngeal artery, enters the middle ear through the tympanic canaliculus in the hypotympanum with the tympanic branch of the ninth nerve.

The vascular supply to the ossicles is derived from the anterior tympanic artery, the posterior tympanic artery, and branches from the plexus of vessels on the promontory. The most tenuous link in the ossicular chain as regards blood supply is the tip of the long process of the incus, which commonly undergoes necrosis secondary to conditions that compromise its blood supply.[33]

Blood Supply to the Inner Ear The blood supply to the inner ear is derived from the labyrinthine branch of the anterior inferior cerebellar artery off the basilar artery.[9] Occasionally, the internal auditory artery has a direct origin from the basilar artery. This vessel represents an end artery as it receives no known anastomosing arterial vessels. The internal auditory artery as it enters the IAC divides into three branches. The first branch, the anterior vestibular artery, supplies the semicircular ducts, utricle, and saccule. The second branch, the vestibulocochlear artery, supplies the saccule, utricle, posterior duct, and basal turn of the cochlea. Its third and terminal branch is the cochlear artery, which enters the modialus, where it gives off the spiral vessels that form external and internal radiating arterioles. The internal radiating arterioles descend to supply the limbus as well as the basilar membrane and organ of Corti. The external radiating arteriole courses through the interscalar septum to supply the vascular arcades and capillaries of the stria vascularis. This arteriole anastomoses with the venous supply near the spiral prominence, with the venous return being along the floor of the scala tympani, where the veins merge with the collecting venules from the spiral vein to form the posterior spiral vein. This posterior spiral vein, or inferior cochlear vein, then travels along the scala tympani to exit at the cochlear aqueduct through a separate channel and enter the inferior petrosal sinus. The remainder of the labyrinth is drained by a venous system, which parallels to some degree the arterial system. Therefore, an anterior vestibular vein and the posterior vestibular vein drain the posterior duct ampulla as well as the saccule and a portion of the utricle and superior duct ampulla. These merge to join the vein at the cochlear aqueduct. The venous return from the semicircular ducts and the body of the utricle converge to form the vein at the vestibular aqueduct, which travels as the vein of the paravestibular aqueduct. This vein travels along with the endolymphatic duct toward the endolymphatic sac. This venous system drains into the sigmoid sinus.

FACIAL NERVE

The anatomy of the facial nerve and its branches are important in clinical practice, not only because of the cosmetic effects of facial paralysis, whether it be by disease or by surgical injury, but because the various components of facial nerve are important for the diagnosis and localization of lesions in the temporal bone. The facial nerve has sensory function and autonomic afferent and efferent function, together with the motor function for the facial musculature. The neuronal pathway from the motor cortex to the facial nucleus is either two or three neurons in a mono- or disynaptic pathway. The motor control of the facial muscles is located at the inferior end of the presylvian gyrus. The area for facial musculature innervation is located near the area of innervation of laryngeal muscles. Although a modest corticonuclear projection exists, it is not the only higher pathway inputting the facial nucleus. Various extrapyramidal neurons located in the red nucleus as well as the periaqueductal gray nucleus also project to the facial nucleus. The projection to the facial nucleus is largely contralateral, as are most corticobulbar projections, but

there is bilateral innervation to the facial neurons supplying the frontalis muscle.

The facial nerve consists of four major components: the motor component to the facial musculature, a sensory component to receptors in facial muscles as well as to the face, autonomic secretomotor and special sensory pathways. The motor component of the facial nerve is the largest component and arises from the facial nerve nucleus, which is located just caudal to the lateral superior olivary nucleus of the auditory system.[34] Immediately caudal to the facial nerve nucleus is the rostral limit of the nucleus ambiguus, which provides the motor innervation to the laryngeal musculature. It has been demonstrated in the cat with retrograde neuronal tracers that the regional facial muscle groups are supplied by groups of neurons within the facial nerve nucleus in a medial and lateral arrangement.[34] The number of facial motoneurons has been estimated at approximately 10,000 to 20,000. As axons leave the facial nucleus, they travel in a dorsal direction to loop around the abducens nucleus under the floor of the fourth ventricle and then curve in a ventrolateral direction passing between the lateral superior olivary nucleus and the descending trigeminal root to emerge from the brainstem ventral to the eighth nerve. The nerve is joined by the nervus intermedius and travels in the IAC in its anterior and superior compartment. In this portion of the IAC, it has an intimate anatomic relationship with the superior division of the vestibular nerve, and indeed the nervus intermedius may travel within the vestibular nerve for a part of its intracanalicular course. At the distal end of the IAC, the facial nerve diverges in an anterolateral direction to enter the labyrinthine segment of the fallopian canal (see Figure 1–5). At the geniculate ganglion, it makes an acute bend near the floor of the middle cranial fossa to continue within the bony canal in its tympanic segment. The course within the labyrinthine segment of the fallopian canal is associated with an extension of the subarachnoid space. This extension of the subarachnoid space is usually limited by the location of the geniculate ganglion but in a small portion of temporal bones may extend into the tympanic portion of the fallopian canal. The greater superficial petrosal nerve emerges from the geniculate ganglion at the facial hiatus (see Figure 1–9) and courses along the floor of the middle cranial fossa between layers of dura to reach the foramen lacerum, where it joins with the carotid sympathetic nerves to form the vidian nerve in the vidian canal. The tympanic portion of the facial nerve travels superior to the oval window in a posterolateral direction to the level of the horizontal or lateral semicircular canal, where it makes a 90-degree turn in a ventral direction to continue as the mastoid portion of the facial nerve (Figure 1–25). After traveling the length of the vertical canal, the facial nerve emerges from the stylomastoid foramen to enter the parotid gland anterior to the mastoid tip. Before emerging from the stylomastoid foramen, the chorda tympani nerve is given off through a bony canal in a retrograde direction toward the middle ear, where it passes between the neck of the malleus and long process of the incus to enter the epitympanum and leave the middle ear space before joining the lingual nerve. The facial nerve provides innervation to the posterior belly of the digastric muscle just external to the stylomastoid foramen and then emerges into the parotid gland, where it gives rise to four to five branches providing innervation to the facial musculature. Although the motoneurons in the facial nerve are spatially organized within the nucleus, the fibers to the peripheral facial muscle groups are interspersed throughout the course of the facial nerve but gather together again on exiting the temporal bone to provide the four to five distal branches supplying the regional facial musculature.[34]

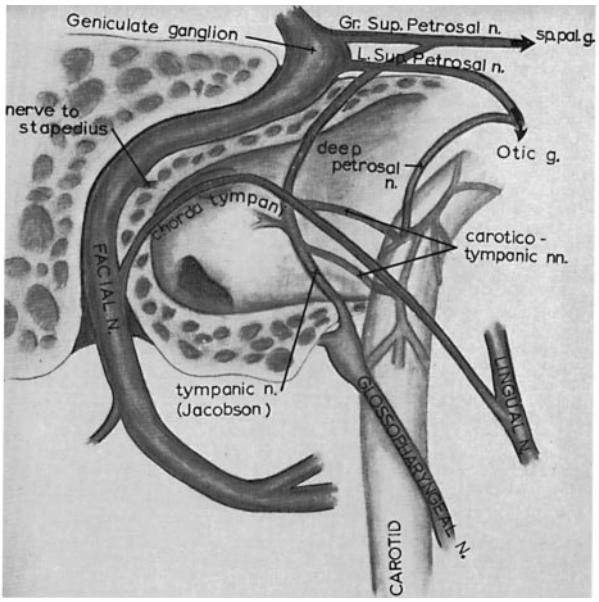

FIGURE 1–25. The facial nerve and its relationships (diagrammatic). Sp.pal.g. = sphenopalatine ganglion.

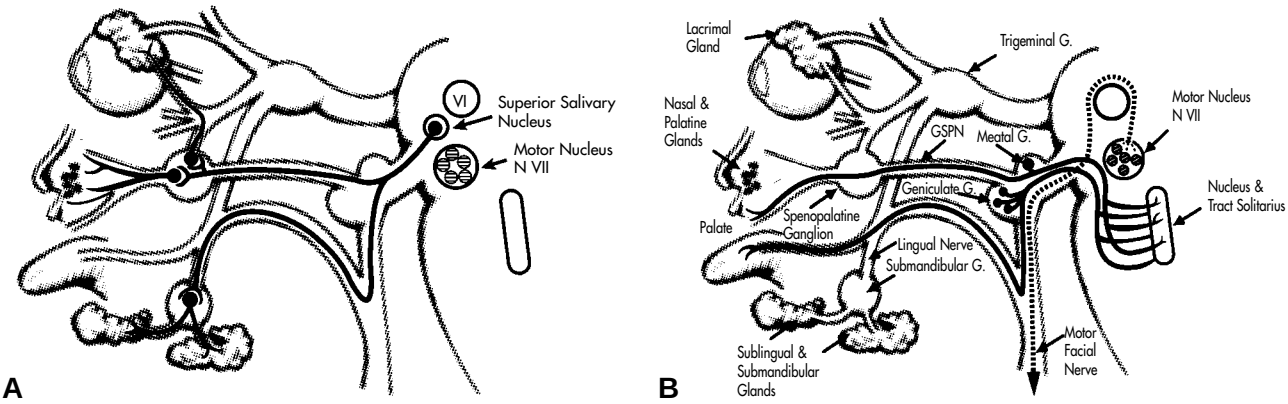

FIGURE 1–26. A, Diagram of the autonomic secretomotor pathways associated with the facial nerve. *B*, Diagram of the special sensory pathways in the facial nerve.

General Sensory Component

An unknown number of sensory afferent neurons are intermixed with the motor axons in the facial nerve trunk. In an animal model (cat), approximately 15 to 20% of the nerve fibers in the medium to large fiber size persist even after total facial nerve transection in the cerebellopontine angle. It is not clear what peripheral receptors these afferents innervate. The possibilities are either spindles within the facial musculature or some sensory receptors in the skin, particularly the dermis.

Autonomic Secretomotor Neurons

Secretomotor or motor preganglionic neurons of the facial nerve are located in the superior salivatory nucleus in the brainstem (Figure 1–26, A). They travel in the nervus intermedius, with some traveling within the vestibular nerve trunk. Those traveling within the vestibular nerve leave in the vestibulofacial anastomosis in the distal part of the IAC to join the nervous intermedius as it travels with the facial nerve trunk in the meatal canal.[9] Some efferent preganglionic neurons pass through the geniculate ganglion to the foramen lacerum and the vidian canal. After leaving the vidian canal, they synapse with postganglionic neurons in the sphenopalatine ganglion that innervate the lacrimal gland and secretory glands of the nose. Other preganglionic neurons travel within the sensory bundle of the facial nerve and leave with the chorda tympani nerve to join the lingual nerve, which carries them to the submandibular ganglion, where they synapse with postganglionic neurons, providing secretomotor function to the submandibular gland. The sensory bundle is located lateral to the motor component throughout the intratemporal course of the facial nerve.[9]

Special Sensory Function

Special sensory function for taste receptors in the anterior two-thirds of the tongue as well as the soft palate and nasopharyngeal mucosa are carried by unipolar ganglion cell masses in the facial nerve (Figure 1–26, B). Taste receptors in the anterior two-thirds of the tongue are innervated by dendrites of the geniculate ganglion and travel by way of the lingual and the facial nerve trunk, where they are contained in the sensory bundle of the facial nerve to ganglion cells in the geniculate ganglion.[35] Axons of these ganglion cells pass into the brainstem in the nervus intermedius to reach the tractus and nucleus solitarius, where they terminate. Taste receptors in the oral cavity, primarily the soft palate and the nasopharynx, are supplied by afferent dendrites, which travel in the vidian nerve and the greater superficial petrosal nerve. They pass through the facial hiatus to join the nervus intermedius, which brings them to their ganglion cells in the meatal ganglion of the facial nerve within the IAC.[35,36] Axons of these neurons also enter the brainstem in the nervus intermedius to terminate in the tractus and nucleus solitarius. The meatal ganglion located within the IAC has special significance in harboring neurotropic viruses (herpes virinae), which gain entry through nerve endings in the oral cavity.[36,37] After long latent periods, the viruses can be reactivated later in life to manifest as viral neuropathies (Bell's palsy, recurrent vertigo).

CHAPTER 2

Development of the Ear

Doris K-W. Wu, PhD, Daniel I. Choo, MD

The development of the human ear begins around the fourth week of embryonic life. Although the three components of the ear (external, middle, and internal) develop concurrently, their origins are diverse.

EXTERNAL EAR

The auricle develops from a series of mesenchymal condensations referred to as the hillocks of His (auricular hillocks), derived from branchial arches 1 and 2. The groove between the two arches deepens to form the external auditory meatus. The six hillocks are apparent in the 6-week embryo but subsequently fuse to form the gross structure of the pinna by the end of the seventh week. The exact structures generated by each hillock have been proposed as in Figure 2–1. However, the precise contributions of individual hillocks to the auricle have not been demonstrated and remain controversial.

The innervation of the external ear reflects these developmental origins. Trigeminal and facial nerve branches (derived from first and second branchial arch contributions, respectively) provide sensory innervation to the external ear. Cutaneous branches of the cervical plexus also provide sensory innervation to the external ear.

Significantly, the pinna rests in a more ventral and transverse position during early embryogenesis and assumes the typical, more rostral, vertically oriented position with maturation. As a result, improper or arrested development of the ear commonly results in low-set, retroverted auricles, as seen in Treacher Collins syndrome and hemifacial microsomia.

Failure of differentiation or fusion of the auricular hillocks is thought to result in developmental malformations of the auricle ranging from anotia to the spectrum of microtias (Figure 2–2).

During embryogenesis, the external meatus begins as a thickening of ectodermal cells at the dorsal end of the first branchial groove (Figure 2–3).

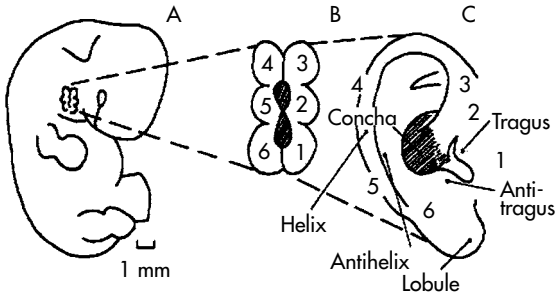

FIGURE 2–1. Development of the external ear. The external ear develops from six mesenchymal condensations known as auricular hillocks, *A* and *B*. Early in gestation, the hillocks rapidly fuse to form the primordial of the auricle. The parts of the auricle generated by the individual auricular hillocks are proposed as labeled in *C*. Courtesy of Drs. Ronan O'Rahilly and Fabiola Müller.

FIGURE 2–2. Grade III microtia showing a discrete earlobe with a cartilaginous and soft tissue rudiment. Grade III anomalies likely result from dysplastic or aplastic development of the auricular hillocks of the first two branchial arches at 5 to 6 weeks of gestation. Microtia is commonly graded from I (mildly dysplastic ears with all components of the auricle present) to III (severely dysplastic ears with most or all components absent).

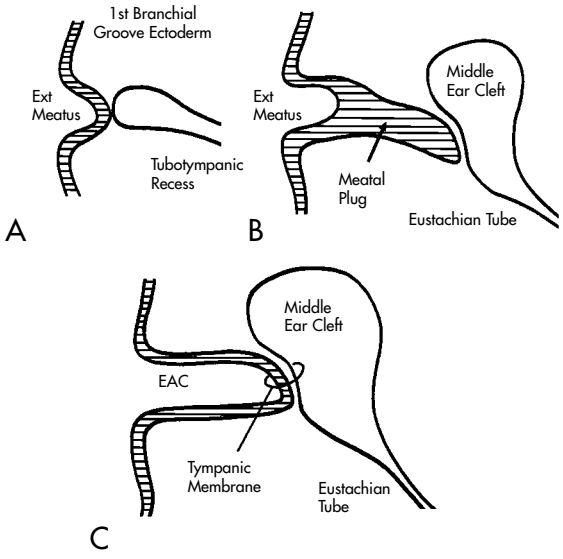

FIGURE 2–3. Drawing showing the development of the external auditory canal and middle ear. Development of the external meatus, ear canal, and middle ear space involves a complex process of ectodermal proliferation, cellular resorption, and coordinated maturation with the tubotympanic recess forming the tympanic membrane and middle ear cleft. The ectodermal cells at the dorsal end of the first branchial groove proliferate and expand medially (*A*, *B*). This solid core of ectodermal cells is referred to as the meatal plug. By the twenty-first week, this meatal plug begins to hollow out, leaving the ear canal lumen. Formation of the ear canal is typically complete by the twenty-eighth week of gestation (*C*). Note that the medial-most ectoderm and endoderm of the tubotympanic recess interface in such a way that these two layers combine to form the tympanic membrane (*C*).

Proliferation of these ectodermal cells generates a meatal "plug" that expands medially. Resorption of cells in the center of this meatal plug leaves a hollow tube-like structure representing the external meatus and ear canal. Failure of this canalization process results in aural atresia. The medial-most ectoderm forms the outer squamous cell epithelial layer of the tympanic membrane. It is noteworthy that external auditory canal development occurs subsequent to external ear morphogenesis. Accordingly, it is possible to see a developmental malformation resulting in isolated aural atresia without any auricular malformations, suggesting abnormal development around the twenty-eighth week. However, it is extremely unusual to see an isolated auricular malformation (indicating abnormal development around weeks 6 to 7) without concomitant middle ear and external auditory canal abnormalities. Therefore, in a child with microtia, imaging studies of the temporal bone are needed to determine the extent of associated middle ear abnormalities.

MIDDLE EAR

The middle ear cavity forms as a lateral extension of the first pharyngeal pouch known as the tubotympanic recess (see Figure 2–3). The proximal end of the extension remains as the eustachian tube. The lateral endoderm of the tubotympanic recess interfaces with the ectoderm of the meatal plug to form the tympanic membrane. The tympanic membrane is a three-layered structure consisting of a medial mucosal epithelium, a fibrous middle layer of mesenchymal origin, and an outermost layer of squamous cell epithelium contiguous with the skin lining the external auditory canal and originating from ectoderm. The malleus and incus appear to develop from a common ossicular mass around the sixth week of development. Both the malleus and the incus are thought to be derived from the neural crest in the first and second arch mesoderm, Meckel's cartilage and Reichert's cartilage, respectively (Figure 2–4). By the sixteenth week, the ossicles attain adult size, and ossification begins at discrete ossification centers (eg, medial surface of the neck of the malleus). Stapes development involves a complex morphogenesis starting as a blastema at 4½ weeks (derived from the neural crest in the second arch mesenchyme). The facial nerve divides the blastema into stapes, interhyale, and laterohyale. By the seventh week, a stapes "ring" forms around the stapedial artery. The interhyale becomes the stapedial muscle and tendon, whereas the laterohyale becomes the posterior wall of the middle ear and also a portion of the fallopian (facial nerve) canal. By the tenth week, the stapes assumes its more typical shape. Notably, the footplate seems to develop in conjunction with the otic capsule, with ossification beginning around the nineteenth week. The mastoid antrum expands late in fetal development and continues to expand significantly after birth.

The two middle ear muscles (the tensor tympani and stapedius muscles) are first and second arch derivatives, respectively. Accordingly, each mus-

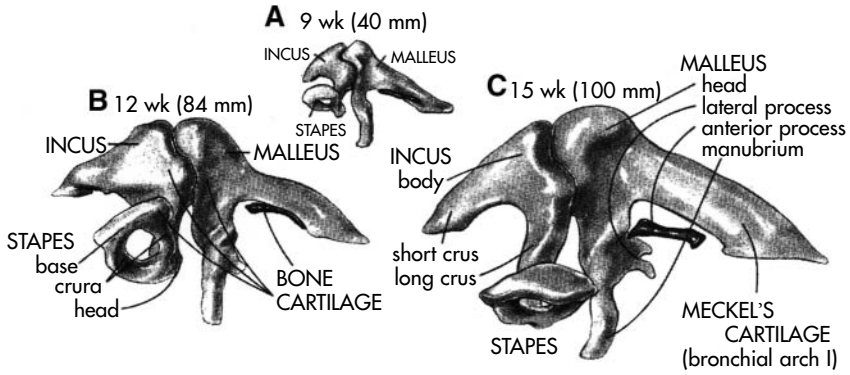

FIGURE 2–4. Ossicular development. *A*, By the ninth week of gestation, the incus and malleus are still fused but begin to differentiate into individual structures. The stapes at this stage has developed beyond the stapes ring stage and more closely resembles the mature stirrup configuration. *B* and *C*, By 12 to 15 weeks, the ossicles are more clearly differentiated and approximate adult size. Shortly following this stage, ossification begins at discrete centers of ossification. Reproduced with permission from Anson BJ, Davies J, Duckert LG. Embryology of the ear. In: Paparella MM, Shumrick DA, editors. Otolaryngology. 3rd ed. Philadelphia (PA): WB Saunders; 1991.

cle obtains its innervation from the respective nerve associated with each branchial arch: trigeminal innervation for the tensor tympani muscle and facial nerve innervation for the stapedius muscle.

INTERNAL EAR

The internal ear consists of two components, a membranous and a bony labyrinth. The membranous labyrinth is derived from the ectoderm, whereas the bony labyrinth/otic capsule is derived from the mesoderm and neural crest surrounding the primordial membranous labyrinth.

Development of the Membranous Labyrinth

The membranous portion of the inner ear orignates from a thickening of the ectoderm adjacent to the hindbrain known as the otic placode (Figure 2–5). In humans, the otic placode is evident at the third week of embryonic development. The otic placode soon invaginates from the surface ectoderm to form an otic cup. By the end of the fourth week, the edges of the otic cup come together and fuse to form the otic vesicle/otocyst. Some cells of the otic epithelium at the otic cup and otocyst stage delaminate from the epithelium and coalesce to form neurons of the statoacoustic (eighth cranial) ganglion just anterior and medial to the otocyst. These neurons subsequently send afferent fibers to innervate sensory organs within the inner ear. Concurrent with the development of the ganglion, the otocyst proper undergoes a complex morphogenesis, and the gross anatomy of the membranous labyrinth is nearly mature by the end of the eighth week of gestation (Figure 2–6).

The first morphologic change in the otocyst is the appearance of a diverticulum that first grows out dorsally and then moves medially and elongates to form the endolymphatic duct and sac. The rest of the otocyst enlarges and lengthens and can be roughly divided into a dorsal vestibular and a ventral saccular and cochlear region. The dorsal region develops into the utricle and three semicircular ducts and their respective ampullae. The ventral region develops into the saccule and the auditory component of the inner ear, the cochlear duct (see Figure 2–6, A).

The three semicircular ducts, superior, posterior, and lateral, develop sequentially during the fifth week, with the superior duct forming first, followed by the posterior and lateral ducts. The superior and posterior ducts form from a vertical outgrowth in the dorsal region of the otocyst. The lateral duct forms from a horizontal outgrowth in the lateral portion of the otocyst. In the central region of each presumptive duct, the opposing epithelia of each outgrowth fuse together and reabsorb, leaving behind a tube-shaped duct (see Figure 2–6, B to D; upper panel). One end of each duct opens into the utricle, and the other end forms a bulge-like struc-

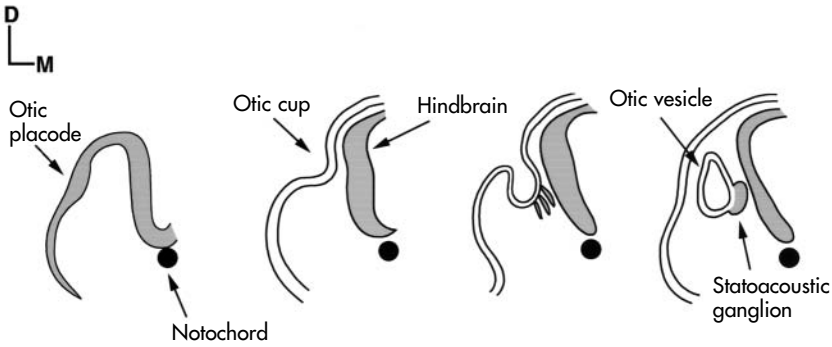

FIGURE 2–5. Diagram of coronal sections illustrating the development of the otocyst. Orientations: D = dorsal; M = medial. Reproduced with permission from Moore KL. The developing human. Philadelphia (PA): WB Saunders; 1977.

ture known as the ampulla that houses one of the vestibular sensory organs, the crista ampullaris. The superior and lateral ampullae form at the anterior end of their respective ducts, whereas the posterior ampulla forms at the posterior end of the posterior duct (see Figures 2–6, E, and 2–7).

The primordium of the cochlear duct evaginates from the ventral portion of the otocyst starting at the fifth week. This evagination extends anteromedially and gradually begins to coil. By the eighth week, the cochlea has formed 1½ turns (see Figure 2–6, E) and at the tenth week, two turns; at the twenty-fifth week, the cochlear duct has acquired the mature 2½ turns. The utricle and saccule start to form during the sixth week. As the cochlear duct extends, the opening between the saccule and cochlea becomes constricted and forms the narrow cochleosaccular duct. In the mature inner ear, two additional ducts are evident medially: the utricular and saccular ducts that connect the endolymphatic duct and sac to the utricle and saccule, respectively (see Figure 2–7).

Development of the Sensory Organs

Six major sensory organs are present in the human inner ear. Only the organ of Corti is responsible for auditory function. The remaining five sensory organs are vestibular in function and include three cristae ampullaris and the maculae of the utricle and saccule. In addition, a small vestibular organ, the macula neglecta, is thought to be present in only 1% of humans. The origin and lineage relationships among these sensory organs during development are not clear. Based on morphologic studies in the chicken, it

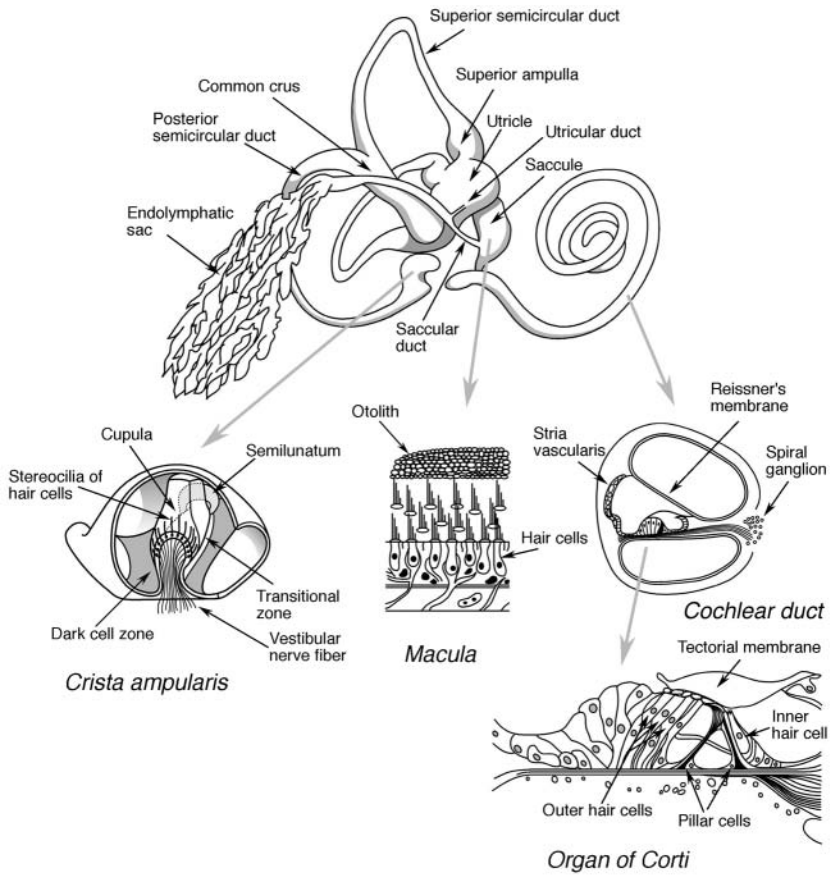

FIGURE 2–7. Diagram illustrating the anatomy of a mature membranous labyrinth and its sensory organs. Reproduced with permission from Schuknecht HF.[3]

has been proposed that all sensory organs in the inner ear originate in the ventromedial wall of the otic cup, and each sensory organ is derived from this common region as morphogenesis continues.[1] Thus far, there are no early fate-mapping studies in chicken or other animal models that lend direct support to this hypothesis. However, early gene expression studies of the inner ear at stages before the onset of histologic differentiation suggest that the sensory organs might be defined differently molecularly. For example, in mice, BMP-4 (bone morphogenetic protein 4) and *Msx1* (muscle segment homeobox gene) are expressed only in the three presumptive cristae and not other sensory organs.[2] Whether these molecular differences represent differences in the origin and/or mechanisms of specification for these sensory organs remains to be verified.

Once the position and type of a sensory organ have been specified, morphologic differentiation follows, and the sensory epithelium can be identified by an increase in the thickness of the otic epithelium into a pseudostratified layer that later differentiates into sensory hair cells and supporting cells. The Notch signaling pathway is used in a variety of tissues for generating cell type diversity and regulating differentiation during development.[4,5] Genes in the Notch signaling pathway have also been implicated in the determination of hair cells and supporting cells in the inner ear. Mutation or deletion of genes in this pathway resulted in the absence or aberrant number of sensory hair cells in zebra fish and mice.[6–8]

Cristae Ampullaris The sensory epithelium for the crista elevates into a ridge-like fold where hair cells and supporting cells develop. Cells surrounding the sensory epithelium are secretory in function and are thought to generate the gelatinous cupula in which the stereocilia of the sensory hair cells are embedded. The mound-like elevation of the crista is evident by the eighth week, and the sensory structure is mature by the twenty-third week (see Figure 2–7).

Maculae The maculae develop in a similar fashion as the cristae except the sensory epithelium is flat, and it is covered by an otolithic membrane that con-

tains superficial calcareous deposits, the otoconia. The maculae appear to be fully differentiated between 14 and 16 weeks (see Figure 2–7).

Organ of Corti The organ of Corti develops from the posterior wall of the cochlear duct. As the cochlear duct increases in length, the cross-sectional shape of the duct changes from round to oval to triangular (see Figures 2–7 and 2–8). The posterior wall develops into the sensory tissue, the organ of Corti; the anterior wall forms part of Reissner's membrane; and the lateral wall forms the stria vascularis. The organ of Corti starts to differentiate at the basal region of the cochlear duct around the seventh week, whereas the epithelium in the apical turn is undifferentiated and pseudostratified at this age. By the twenty-fifth week, the organ of Corti is fully differentiated.

Development of the Statoacoustic Ganglion

Based on studies in animal models, neurons of the statoacoustic ganglion are thought to originate from the otic epithelium, whereas glial cells in the ganglion are derived from the neural crest.[9] Morphologic studies suggest that cells in the anteroventral lateral region of the otic cup/otocyst delaminate from the epithelium, migrate away from the otocyst, and undergo proliferation before aggregating to form the ganglion.[10] In parallel with the growth of the otocyst, the statoacoustic ganglion forms a pars superior and a pars inferior at about the time when the membranous labyrinth is divided into a dorsal vestibular and a ventral cochlear region. The pars superior of the ganglion provides the peripheral neural connections to the superior and lateral cristae and the macula of the utricle. The pars inferior gives rise to a distinct vestibular portion that innervates the macula of the saccule and posterior crista and the spiral ganglion that innervates the organ of Corti.

Helix loop helix transcription factors, such as Neurogenin1, have been implicated in the formation of the statoacoustic ganglion. In mice with a deletion in *Neurogenin1*, the statoacoustic ganglion fails to form.[11] Growth factors such as fibroblast growth factor 3 are also important for the formation of the vestibular ganglion in the mouse.[12] Once the neurons of the ganglion reach their final position and finish proliferation, they express high-affinity neurotrophin receptors and become dependent on neurotrophins secreted by the presumptive sensory organs in the membranous labyrinth. Mice with targeted deletion (knockout) of genes encoding brain-derived nerve growth factor or neurotrophin 3 or their respective receptors had a loss of ganglionic neurons and innervations to the sensory organs.[13] However, this trophic dependency of ganglionic neurons on their target tissues is not reciprocal. In the absence of afferent innervation, the differentiation of sensory hair cells appears unaffected, at least until birth.[14,15]

Development of the Bony Labyrinth

Concurrent with the development of the otocyst, the mesenchymal cells surrounding the otic vesicle differentiate into a cartilaginous otic capsule by the eighth week. As the membranous labyrinth enlarges, vacuoles appear in areas surrounding the otic epithelium as a result of programmed cell death. These vacuoles soon coalesce to form the perilymphatic space that is filled with perilymph. In the cochlea, the perilymphatic space develops in two divisions; the scala tympani forms before the scala vestibuli (see Figure 2–8).

Ossification of the cartilaginous capsule to form the bony labyrinth does not occur until the membra-

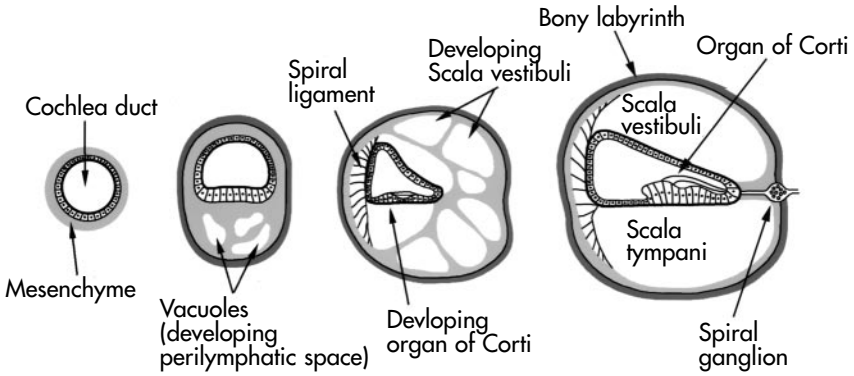

FIGURE 2–8. Diagram showing development of the bony labyrinth. Cross-sections through the cochlea showing the development of the organ of Corti, bony labyrinth, and perilymphatic spaces from the eighth to the twelfth weeks. Reproduced with permission from Moore KL. The developing human. Philadelphia (PA): WB Saunders; 1977.

nous labyrinth has acquired its adult size. Bone formation starts at the fifteenth week and ends by the twenty-first week, with a total of 14 ossification centers. The first ossification center appears at the base of the cochlea, and ossification advances more rapidly in the cochlea than in the canal region, where membranous growth continues to about the twenty-first week. By the twenty-third week, all ossification centers have fused with no "suture lines," thus limiting further growth in the membranous or bony labyrinth.

HUMAN EAR MALFORMATIONS AND MODELS OF MOLECULAR DEVELOPMENT

Many genes causing human deafness have been identified recently. In some cases, the functional deficit is the result of gross malformations of the external, middle, or inner ear or a combination of more than one of these components (Table 2–1). Examples of some of these syndromes are described below. For syndromes that are associated with the lack of proper differentiation and functioning of sensory hair cells, see Chapter 13 on hereditary hearing impairment, as well as a review by Steel and Bussoli.[16]

Branchio-Oto-Renal and Branchio-Oto Syndromes

Branchio-oto-renal (BOR) syndrome is an autosomal dominant disorder characterized by branchial arch anomalies (branchial cleft cysts and sinuses), ear malformations (affecting the external, middle, and inner ear regions), and various renal anomalies ranging from undetected in the branchio-oto (BO) syndrome to bilateral aplasia.[17] Hearing loss is the

TABLE 2–1. Genes Involved in the Development of the Human Ear

Syndrome/Disease	*Gene*	*Type of Product*	*Structures Affected*	*Reference*
Branchio-oto, branchio-oto-renal	*EYA1*	Transcription coactivator	Atresia and stenosis of external auditory canal, malformed auricle Hypoplasia or absence of three ossicles Absent or abnormal semicircular canals and cochlea	16, 20
Crouzon's disease	*FGFR2* *FGFR3*	Growth factor receptor	Atresia of external auditory canal Malformation of ossicles	21, 22 23
Craniosynostosis	*FGFR3*	Growth factor receptor	Sensorineural deafness	24
DFN3/Gusher	*POU3F4/ BRN4*	Pou-domain transcription factor	Conductive hearing loss Abnormally wide connection between internal acoustic canal and the inner ear Stapes fixation	25
Pendred's DFNB4	*PENDRIN*	Anion transporter	Sensorineural deafness Widened vestibular aqueduct Shortened cochlea	26, 27
Proximal symphalangism (SYM1), multiple synostoses (SYNS1)	*NOGGIN*	Secreted factor, antagonist of bone morphogenetic proteins	Fixation of stapes to petrous part of temporal bone	28
Townes-Brocks	*SALL1*	C2H2 zinc-fingered transcription factor	Malformed auricle, sensorineural hearing loss	29, 30
Treacher Collins (mandibulofacial dyostosis)	*TCOF1*	Nucleolar trafficking protein	Atresia of external auditory canal, malformed auricle Middle and inner ear anomalies	31

most common presenting symptom and occurs in 88% of patients with BOR syndrome.[18,19]

The most common external ear anomalies are preauricular pits and skins tags, but microtia and aural atresia are also noted in patients with BOR syndrome. The middle ear cleft is commonly hypoplastic in BOR syndrome, as can be the middle ear ossicles. In the inner ear, aplasia or hypoplasia of the cochlea has been reported as a BOR phenotype (Figure 2–9). The vestibular portions of the inner ear similarly show absent or malformed semicircular canals. Depending on the ear phenotype, hearing loss can be sensorineural, conductive, or mixed, as seen in approximately one half of the patients with BOR syndrome.[17]

The gene responsible for causing BOR and BO syndromes has been identified to be the human homologue of the *Drosophila eyes absent* (*Eya*) gene.[16,19] The spectrum of malformations seen in BOR syndrome suggests a defect in the *EYA1* molecular pathway occurring sometime between the fourth and the tenth week of gestation. The types of DNA mutations identified in patients with BOR syndrome suggest that the developmental malformations result from reduced gene dosage.[19]

Mice with a targeted deletion of *Eya1* also displayed similar severe external, middle, and inner ear *defects, suggesting that the function(s)* of this protein in ear development is evolutionary conserved.[32] In mice, *Eya1* is specifically expressed in the early otocyst along the ventromedial wall and the adjacent statoacoustic ganglion.[33] At later embryonic time points, *Eya1* is expressed along the neuroepithelium that eventually gives rise to key cochlear structures, including the inner and outer hair cells. In addition, *Eya1* is also expressed in the external and middle ear primordia. These results suggest that the encoded protein of *Eya1* plays a direct role in the formation of all three components of the ear in mice as well as in humans.

Studies in *Drosophila* eye imaginal disks show that the *Eya* gene product is a transcriptional coactivator that acts as part of a complex with other transcription factors during eye morphogenesis.[34] Its mode of action in ear development remains to be established.

Pendred's Syndrome

Pendred's syndrome is an autosomal recessive disorder classically characterized by deafness and goiter. The presence of goiter is usually variable in severity; however, most patients have a positive perchlorate discharge test indicative of a defective organification of iodine in the thyroid gland. The onset of deafness is typically congenital, profound, and sensorineural in nature. Cochlear malformation with missing apical turns, known as Mondini's phenotype, and widened vestibular aqueducts are often described in these patients.[35,36]

The gene responsible for causing Pendred's syndrome was identified using a positional cloning approach and was named *PENDRIN*.[25] Functional studies in *Xenopus* oocytes show that the encoded protein functions as a chloride/iodide transporter.[37] The clinical significance of this gene broadened when mutations in *PENDRIN* (*PDS*) were also shown to cause autosomal, recessive deafness locus 4 (DFNB4), a recessive nonsyndromic form of deafness.[27] Expression and gene-targeting studies in mice have provided insights into the etiology of this disorder. In mice, *Pds* is activated during embryonic development. Its expression is restricted to nonsensory regions of the inner ear including the endolymphatic duct and sac, nonsensory regions of the utricle and saccule, and the external sulcus region in the cochlea.[38] *Pendrin* knockout mice are deaf and display variable vestibular defects.[39] However, the cause of inner ear dysfunction in these mice most likely is not attributable to structural malformations as implied by the human disorder. The membranous labyrinth of the *Pds* knockout mice swells during late embryonic development indicative of an ionic imbalance presumably owing to a lack of the transporter function of *Pds*. The sensory hair cells develop and appear normal at birth but degenerate later in life, most likely as a consequence of disrupted fluid homeostasis. It is likely that the etiology of human Pendred's syndrome is similar to that of the *Pds* knockout mouse model, where the deficit lies in ionic imbalance of the endolymph rather than structural malformations during development. The widened vestibular aqueduct associated with Pendred's syndrome supports this hypothesis. Mutant mice containing mutations similar to those found in patients with Pendred's syndrome will help to clarify this issue.

Symphalangism and Multiple Synostoses Syndromes

Symphalangism syndrome (SYM1), an autosomal dominant disorder with aberrant bone fusion at

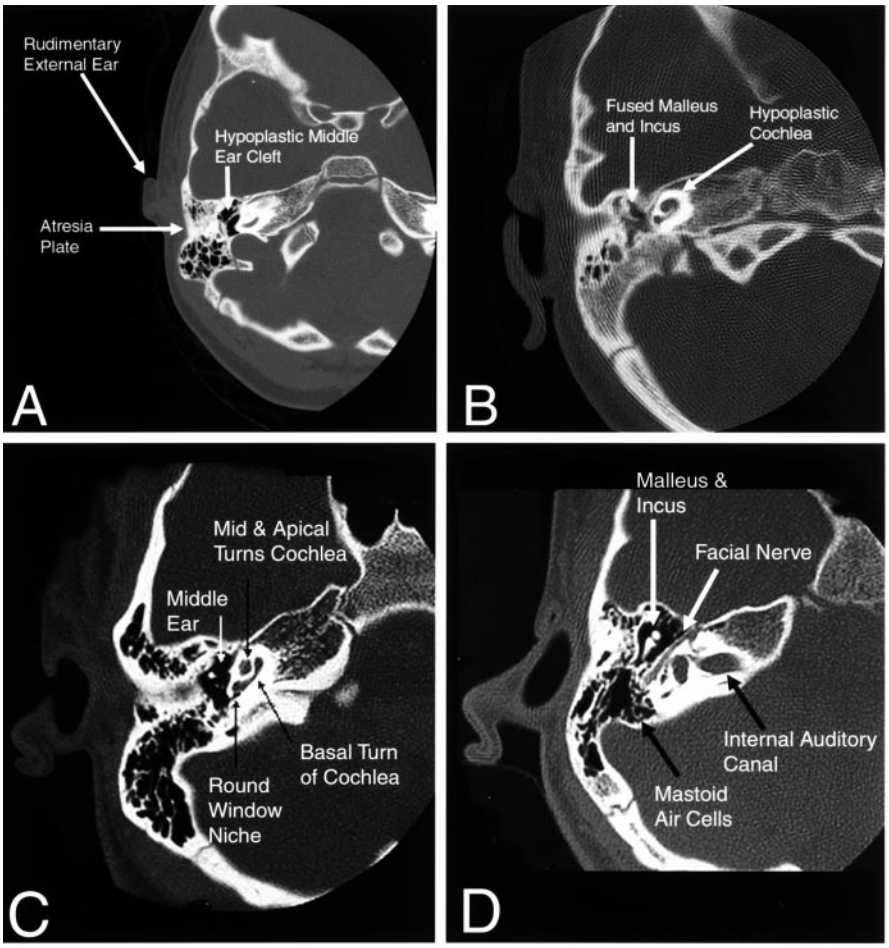

FIGURE 2–9. The external, middle, and inner ears are all potentially affected in branchio-oto-renal (BOR) syndrome. At the external ear level, auricular malformations vary from mild hypoplasia to complete aplasia. *A*, A rudimentary ear lobe is apparent even on this axial computed tomographic (CT) scan of the temporal bones in a child with BOR syndrome. Note also the failure of development of an external auditory canal (aural atresia) and the associated small middle ear cavity. *B*, Another patient with BOR syndrome demonstrates hypoplastic development of the cochlea with a discrete basal turn but poorly differentiated middle and apical turns appearing as a bulbous mass on high-resolution CT imaging. *C* and *D* demonstrate normative CT imaging data with middle and inner ear structures labeled as shown.

interphalangeal joints, is associated with conductive hearing loss. The ear anomaly is attributable to the fixation of the stapes to the petrous part of the temporal bone. Multiple synostoses syndrome (SYNS1) is also associated with joint fusion and conductive hearing loss. Both of these disorders are caused by mutations in *NOGGIN*, which encodes a secreted polypeptide that inactivates members of the transforming growth factor β family, in particular bone morphogenetic proteins (BMP-2 and -4).[28,34,40] *Noggin* knockout mice die at birth with multiple defects, including abnormal joint formation.[41,42] During embryogenesis, *Noggin* is usually expressed in regions closely associated with BMP-producing regions. *NOGGIN* is thought to function by modulating the available levels of BMPs. The abnormal bone fusion at interphalangeal joints and the stapes associated with symphalangism in humans is most likely caused by an alteration of BMP levels in those regions during development.

X-linked, Deafness Locus 3

Another conductive hearing loss disorder with fixation of the stapes is the X-linked DFN3, which is caused by mutations in a member of the POU domain transcription factors, *POU3F4/BRN4*.[25] In mice, *Pou3f4* is important for the development of the ear. Transcription of this gene is activated in mice at the otocyst stage in the mesenchymal cells surrounding the otocyst.[43] *Pou3f4* knockout mice show a variety of deficits, including abnormal fibrocytes surrounding the cochlea, misshapen stapes, and shortened cochlea.[44,45] The deficits caused by mutations of this gene in humans are usually conductive in nature and can be corrected by surgery.

Treacher Collins Syndrome

Treacher Collins syndrome is an autosomal dominant disorder of craniofacial development associated

with bilateral conductive hearing loss, and occasionally malformations of the inner ear have also been reported.[3] This syndrome is caused by mutations in the *TCOF1* gene that encodes for a nucleolar protein.[31,46] *TCOF1* is widely expressed in fetal and adult tissues and is thought to function as a trafficking protein between the nucleolus and cytoplasm.

Crouzon's Disease and Craniosynostosis

Crouzon's disease is characterized by craniofacial abnormalities and hearing loss. The hearing loss is usually conductive owing to anomalies of the middle ear and atresia of the external auditory canal. Mutations in both fibroblast growth factor receptor (*FGFR*) 2 and 3 have been shown to cause Crouzon's disease.[21–23] A unique mutation in *FGFR3* has also been shown to cause craniosynostosis that is associated with deafness and abnormalities on radiographs of hands and feet.[24] In mice, knockout of *Fgfr3* affected the development of the cochlea in which the pillar cells were missing and the tunnel of Corti failed to form.[47]

Townes-Brocks Syndrome

Townes-Brocks syndrome is an autosomal dominant syndrome associated with anal, renal, limb, and ear anomalies. External ear malformations and sensorineural hearing loss are frequently found in this syndrome. Malformations of the malleus and incus have also been reported.[29] This syndrome is caused by mutations in the *SALL1* gene, a putative C2H2 zinc-fingered transcription factor gene.[30]

RETINOIDS AND EAR DEVELOPMENT

Since the early 1950s, it was evident to clinicians that retinoids (vitamin A, retinoic acid [RA], etc) had potent teratogenic effects when administered early in pregnancy.[48] Either excess or inadequate maternal retinoid intake could result in a spectrum of congenital anomalies affecting the central nervous system, eye, and heart or result in craniofacial defects such as midface hypoplasia and cleft lip and palate as well as ear and limb malformations. Retinoic acid is one of the better-studied retinoids whose role in molecular development of the ear has been extensively studied in animal models. Several lines of evidence suggest an essential role for RA in ear development. First, reporter gene assays have demonstrated the endogenous production of RA by the organ of Corti.[49] In addition, several of the key RA receptors, both at the cytoplasmic and nuclear levels, have been demonstrated in the developing ear region.[50] Gain of function studies have revealed in both chicken and mouse that exogenous RA, administered at low levels during early embryogenesis, induces a spectrum of inner ear malformations that are similar to the variety of ear malformations observed with human retinoid embryopathy.[51,52] Intriguingly, delivery of exogenous RA to cultures of the organ of Corti has also been shown to cause development of supernumerary hair cells.[49] Most recently, loss of function studies have probed the role of individual and multiple RA receptors in ear development.[53–55] Generation of null mutant mice carrying targeted deletions of nuclear retinoic acid receptor and retinoid X receptor isoforms and cytoplasmic retinoic acid binding proteins isoforms has demonstrated the complexity of the molecular signaling system existing for RA during development.[56–58] In several examples, loss of individual RA receptor isoforms fails to yield a significant or informative phenotype, possibly owing to redundancy in the molecular pathways.[59] Accordingly, investigators have been forced to recognize the importance of normal RA signaling during development and the compensatory mechanisms in place so that perturbation of normal signaling does not occur, despite interruption of any single signal transduction pathway. Also interesting to note is the interaction of RA receptors with other members of the steroid hormone superfamily of nuclear receptors. For example, data suggest that thyroid hormone nuclear receptors may heterodimerize with activated RA receptors and regulate transcription.[60,61] Such mechanisms would provide a plausible explanation for the widespread developmental effects of retinoids that seemingly affect various organ systems.

Specific to the developing inner ear, RA has been shown to have significant effects on cell growth and differentiation as early as the otocyst stage. Using in vitro[62] and in vivo[51] animal models of inner ear development, exogenous RA has been shown to down-regulate cellular proliferation in the otocyst in association with altered levels of *c-fos* expression. Furthermore, RA has been shown to down-regulate the expression of critical genes such as *Bmp4* that in the chicken and mouse appear to be involved in sensory organ generation. However, a

key consideration in trying to dissect the molecular effects of RA rests in the likelihood that RA impacts multiple signaling pathways; therefore, isolating individual effects and their sequelae will be extremely difficult. However, the extensive work with RA receptor isoform-specific knockouts combined with work on the various (endogenous and synthetic) retinoid metabolites may provide the means with which to start dissecting this complex system and thereby determine the role of RA in ear development.

CHAPTER 3

Molecular Biology of Hearing and Balance

Allen F. Ryan, PhD, David J. Lim, MD

Molecular biology is a branch of modern biology in which biologic processes are studied using physical, biochemical, cellular, and genetic principles at the molecular level. The techniques of molecular biology use deoxyribonucleic acid (DNA) sequences that encode proteins or that regulate protein expression.

This emerging science has contributed to major advances in our understanding of cellular function, in health as well as in disease. It also has resulted in a deeper understanding of the pathogenesis of many diseases and the revolutionary development of new approaches in diagnosis, prevention, and treatment of diseases, including gene therapy. This chapter reviews the rapidly developing molecular methodologies that have made contributions to advance our understanding of the cellular functions and dysfunctions of the auditory and vestibular systems, in molecular terms. It reviews recent advances achieved with these techniques in both the basic and clinical arenas.

MOLECULAR METHODOLOGY

The rapid expansion of molecular research has been the result of the introduction of several powerful methodologies for isolating gene sequences and characterizing their expression. At the center of these methodologies are gene-cloning techniques, which rely on the replication of DNA sequences in bacteriophages and plasmids, generating large amounts of DNA that can be screened, characterized, and sequenced. Another crucial method is reverse transcription of messenger RNA (mRNA), in which viral enzymes capable of copying RNA into DNA are used to generate complementary DNA (cDNA) copies of mRNAs isolated from tissue. Reverse transcription and cloning have allowed the rapid discovery of new genes, usually based on homology with known DNA sequences or on assay of functional characteristics when cDNAs are cloned in expression vectors. This has led to the isolation of many families, some quite extensive, of genes encoding related proteins. Other widely used methods in molecular biology include the polymerase chain reaction (PCR) for amplification of DNA sequences present in low copy numbers[1] and in situ mRNA hybridization for the localization of gene expression to individual cells.[2] (Terms that are frequently used in molecular biology are listed in Table 3–1, and a number of important concepts and methods are illustrated in Figures 3–1 through 3–5).

Gene Expression Systems

The expression of cloned genes in biologic systems ranging from bacteria and *Xenopus* oocytes[3] (Figure 3–6) to eukaryotic cell lines and intact mammals has become a major tool in biologic research. The expression of functional proteins in cells has added to our knowledge of numerous molecules such as neuronal receptors, ion channels, and transcription factors. Targeted mutations in the translated sequences of genes have made fundamental contributions to the molecular determinants of protein function, as in studies that identify the functional domains of potassium channels and provide evidence to support a "ball-and-chain" model of their action[4,5] and amino acid sequences governing interaction between subunits of ion transport adenosine triphosphatases (ATPases).[6] The use of different promoter elements and mutations within promoters has dramatically increased our understanding of the control of gene expression.[7]

Transgenic Animals

The influence of genes in the organism has been studied by placing the gene sequences of interest under control of tissue-specific promoter sequences that target expression to given tissue and inserting

TABLE 3–1. Terms Used in Molecular Methods

Alternative splicing	Different ways of assembling exons to produce different mature mRNAs
Base pair (bp)	A combination of A with T or G with C formed by hydrogen bonding between two antiparallel strands of a DNA double helix
cDNA clone	A vector containing a cDNA molecule from another organism
cDNA	A single strand of DNA complementary to an mRNA and synthesized from it by reverse transcription
DNA library	A set of cloned genomic DNA fragments from an organism or cDNAs from a cell type or tissue
Exon	Any segment of an interrupted gene that is represented in a mature mRNA. Segments of DNA separating exons are called introns.
Gene family	A group of genes related by sequence similarity
Genomic clone	A selected host cell with a vector containing a fragment of genomic DNA from a different organism
Genomic DNA	All DNA sequences of an organism
Host cell	A cell (usually a bacterium) in which a vector can be propagated
Hybridization	Localization of mRNA or DNA in a cell or tissue section by hydrogen bonding of complementary sequences found in a probe that can be detected
Library	A complete set of genomic clones from an organism or of cDNA clones from one cell type
Linkage analysis	A means of identifying the chromosomal location of genes based on the frequency of recombination between the gene of interest and known loci
Oligonucleotide	A short DNA sequence, usually less than 100 base pairs
PCR	The polymerase chain reaction. Exponential amplification of a DNA sequence using paired oligonucleotide primers, DNA polymerase to extend the primers by synthesizing new DNA strands, and thermal cycling to denature the duplex DNA and allow a new round of primer binding.
Phage	Bacteriophage, a bacterial virus, often engineered to carry inserted DNA, as in DNA libraries
Plasmid	A small, circular, extrachromosomal DNA molecule capable of replicating independently in a host cell
Polymorphism	Two or more alleles of the same gene (ie, Rh+ or Rh– individuals) in a breeding population
Promoter	A region of DNA involved in binding RNA polymerase to initiate transcription
Recombination	A reciprocal exchange of DNA between sister chromatid during meiosis
Restriction enzyme	A bacterial enzyme that recognizes and cleaves a particular short DNA sequence. Often used to cut and join two DNA sequences, as in cloning.
Reverse transcription	DNA synthesis from an RNA template, mediated by a retroviral enzyme called reverse transcriptase
RNA splicing	Removal of introns from an RNA sequence to produce a mature mRNA
Transfection	A method for introducing exogenous DNA into eukaryotic cells
Transgene	An artificial gene constructed from a promoter active in the tissue or cell to be studied, a coding sequence of interest, and a termination sequence
Transgenic	Animal (or plant) that has stably incorporated one or more genes from another cell or organism
Transcript	The RNA product produced by template-dependent RNA synthesis from a DNA sequence
Transcription	RNA synthesis on a DNA template, mediated by an enzyme called RNA polymerase
Transcription factor	Term loosely applied to any protein required to initiate or regulate transcription in eukaryotic or prokaryotic cells
Translation	Synthesis of protein on an mRNA template
Transposon	DNA elements that can transpose themselves (move) from one position in a DNA molecule to another

cDNA = complementary deoxyribonucleic acid; mRNA = messenger ribonucleic acid.

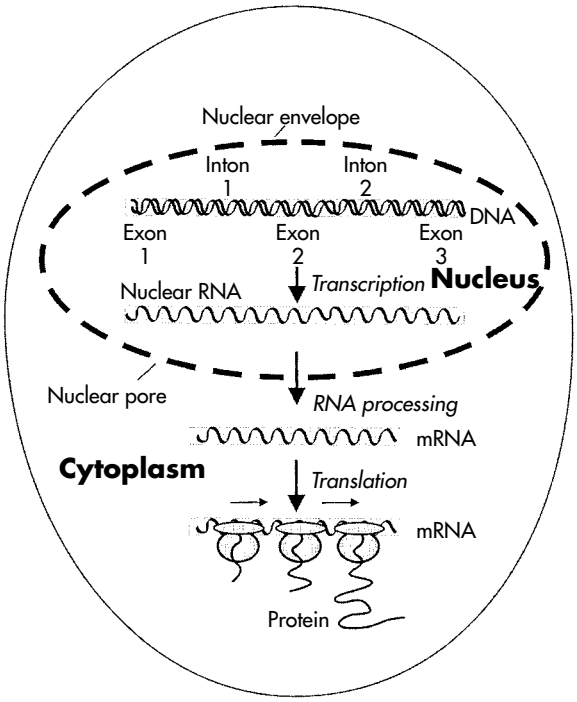

FIGURE 3–1. Summary of steps by which proteins are synthesized by deoxyribonucleic acid (DNA) in a eukaryotic cell. A nuclear envelope with pores segregates the DNA from cytoplasm. Adapted from Gilbert SF, 1.[8] mRNA = messenger ribonucleic acid.

these transgenes into the DNA of mice to create a transgenic animal (Figure 3–7). The resultant transgenic animals then display the effects of transgene expression and can be used to document the effects of genes and/or promoters.[9] A serendipitous by-product of this technique has been insertional mutations. In a small percentage of transgenic animals, insertion of the transgene disrupts an endogenous gene and produces a morphologic or behavioral change completely unrelated to the transgene. In these animals, the mutation site is marked by the inserted DNA sequence,[10,11] simplifying the process of localizing the mutated gene and its normal counterpart. Insertional mutagenesis has led to the identification of several new genes, including genes controlling limb development[12] and motor control.[13] However, transgenic insertions are frequently extremely complex, often involving deletion of hundreds of kilobases at or near the site of transgene insertion. For this reason, the identification of genes mutated by insertion in transgenic animals has sometimes proven to be difficult, if not impossible.

Several insertional mutations in transgenic animals that affect the inner ear have been identified. For example, Crenshaw et al found that 1 of 14 lines of mice with a v-src transgene showed behavior consistent with an inner ear defect.[14] The inner ear of these animals showed collapse and degeneration of the pars superior of the inner ear at about 1 month of age. This was preceded by a period of severe endolymphatic hydrops, suggesting that the gene disrupted in mutation affects inner ear fluid balance. The gene has been localized to a 6 cM (centimorgan) region on chromosome 1, near the interleukin-1 (IL-1) receptor.[15]

Gene Knockouts (Gene Targeting)

A method by which a gene knockout can be created is illustrated in Figure 3–8. Single-gene knockouts can be lethal or have extensive effects on development and adult function. For example, knockouts of key factors in embryonic development are typically lethal prior to birth, and deletion of the genes encoding the neurotrophins or their receptors can produce serious deficits in sensory neurons.[16,17] Alternatively, knockouts can have little influence since the process of development appears to have a high degree of redundancy. An example is the

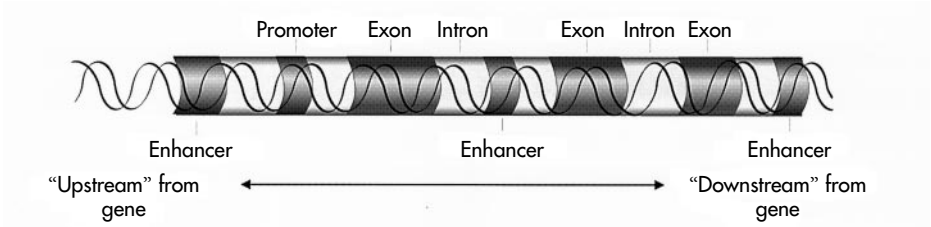

FIGURE 3–2. Basic structure of a developmentally regulated gene is illustrated. The promoters of most genes encoding proteins are found at the 5′ (upstream) end of the gene. Enhancers are often even farther upstream, but they can also occur within an intron of the gene or at the 3′ end. Proteins that bind to promoters and enhancers interact to regulate transcription of the gene. Adapted from Gilbert SF.[8]

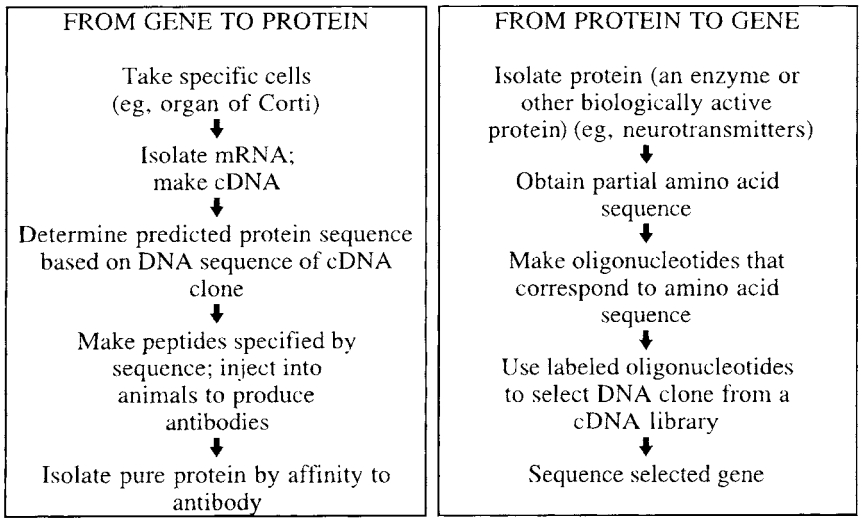

FIGURE 3–3. It is now possible to identify a messenger ribonucleic acid (mRNA) of interest (such as obtained from the inner ear or even the organ of Corti) and to use it to isolate the protein it encodes without knowing the function of that protein. Conversely, it is also possible to sequence part of a protein that has a specific function and then to synthesize an oligonucleotide that can be used to identify and isolate the gene that encodes the complete protein. Adapted from Gilbert SF.[8] cDNA = complementary deoxyribonucleic acid.

regulation of differentiation in muscle, in which several factors act to drive a cell toward the muscle phenotype.[18]

Molecular Diversity (Gene Families)

Gene cloning has revealed the existence of many families of genes that mediate important aspects of cell function, including the genes that encode neuronal receptors such as acetylcholine receptors.[19,20] The first of these receptor genes was identified by injecting RNA molecules transcribed in vitro from cDNA clones isolated from brain cDNA libraries into *Xenopus* oocytes.

When exposed to the appropriate transmitter, the oocytes showed intracellular potential changes consistent with the presence of specific receptors on their surfaces. Subsequent low-stringency screening of cDNA libraries for related sequences yielded families of receptor genes.[21]

Other gene families that have been isolated recently include voltage-gated potassium channels,[22] Ca ATPases,[23] G proteins, and numerous growth factors and their receptors.[24] Several gene families consist of subunits that can be assembled in a variety of combinations, leading to increased diversity of functional expression from a limited set of genes. For example, the nicotinic acetylcholine receptor consists of α and β subunits. The existence of genes encoding several different α and β subunits allows a multitude of different combinations, each with different functional properties.[19] The non–(*N*-methyl-D-aspartate) glutamate receptors have been hypothesized to amalgamate as heteropentamers of subunits, with each subunit isoform capable of complexing with several other isoforms.[25,26] This provides the potential for a very large number of structurally and functionally different glutamate receptors, explaining in part the high level of pharmacologic diversity observed at synapses using the

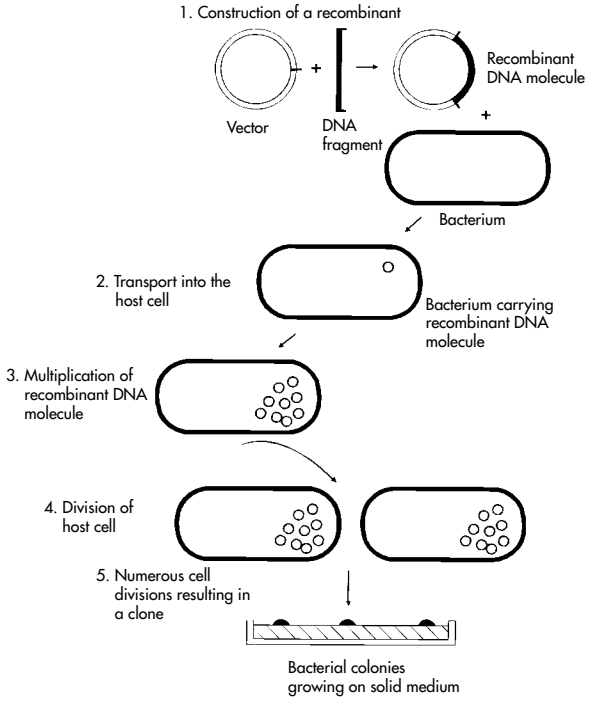

FIGURE 3–4. The basic steps in gene cloning are schematically illustrated. Adapted from Brown TA.[27]

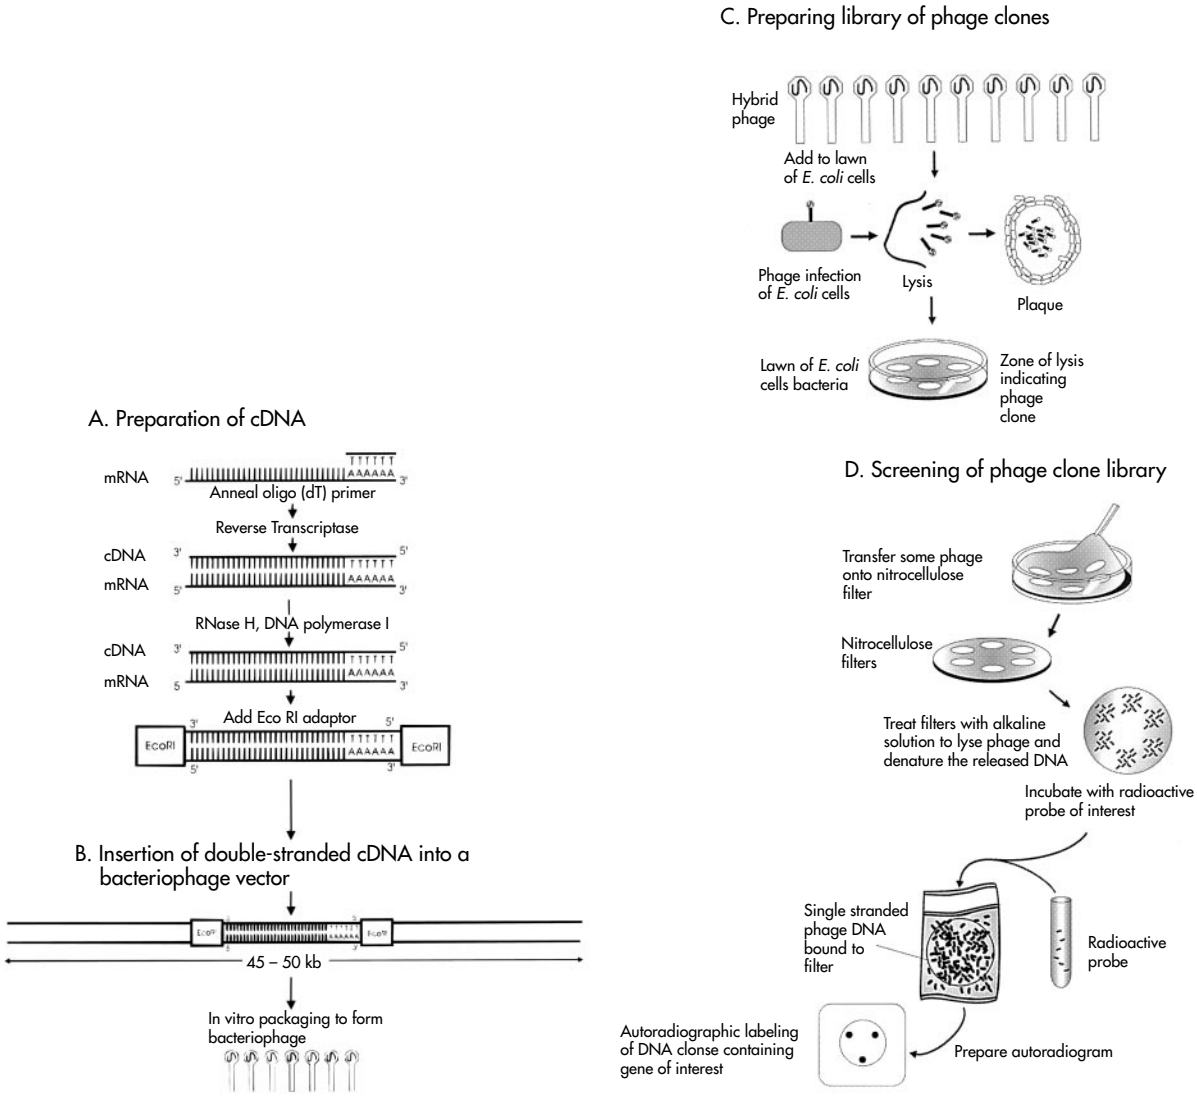

FIGURE 3–5. Schematic illustration of protocol to make complementary deoxyribonucleic acid (cDNA) libraries. Step A: Messenger ribonucleic acid (mRNA) is isolated from a tissue of interest and reverse transcribed into cDNA. This cDNA represents all of the genes being expressed in the tissue. It is made double-stranded in a nick translation reaction, in which ribonuclease H nicks the mRNA strand, creating a primer for second-strand DNA synthesis by DNA polymerase I. Sequences (adapters) that allow ligation into a cloning vector are added to double-stranded cDNA. Step B: The cDNA can then be inserted into specially modified vectors, in this case bacteriophages. Step C: Phages containing the recombinant DNA will infect *Escherichia coli* and reproduce, making many copies and eventually lysing the bacteria forming plaques. Step D: The plaques are transferred to nitrocellulose paper and treated with alkali to lyse the phages and denature the DNA in place. These filters are then incubated in a radioactive probe. This can be a short DNA sequence (oligonucleotide), a cDNA, or other DNA fragment. In the case of differential cDNA library screening, the same phage library is screened with radioactive cDNA probes reverse transcribed from mRNA isolated from two different tissues. This allows the identification of a relatively abundant mRNA that would be found in one type of tissue but not in the other. Adapted from Gilbert SF.[8]

same neurotransmitter. In addition, mRNA transcribed from a single gene can often be assembled into mRNAs encoding functionally different forms of the protein product from different combinations of exons by the process of alternative splicing, leading to even greater variation.[23] Increased understanding of the molecular basis for functional diversity of proteins may be one of the most significant contributions of molecular biology.

Molecular Genetic Methods

Molecular methods have also transformed the field of genetics. Gene localization by kindred analysis classically depended on the linkage of a phenotypic trait associated with a genetic disorder to a relatively small number of phenotypic traits controlled by genes whose locations were already known. Recently, several developments have led to a dramatic increase in our ability to localize genes. The number of genetic markers at known locations in the genome increased exponentially after the introduction of molecular methodology, from a few dozen in the early 1980s to nearly 10,000 in 1991,[28] and the number continues to increase. This increase was the result of several critical technical developments. The isolation of large numbers of restriction enzymes to cut DNA at specific locations has led to the discov-

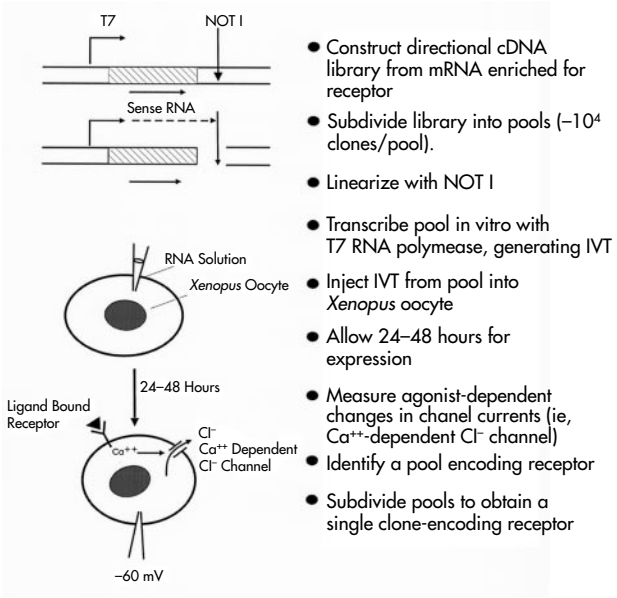

FIGURE 3–6. Expression cloning using *Xenopus* oocytes. The steps required to generate in vitro transcripts from pools of directional complementary deoxyribonucleic acid (cDNA) library clones are shown. Included are in vitro transcription, injection into *Xenopus* oocytes, and voltage clamp assay for a ligand-evoked opening of the calcium-dependent chloride channel. *Shaded boxes* indicate the receptor-coding region. IVT = in vitro transcript. Adapted from Battey JF et al.[3]

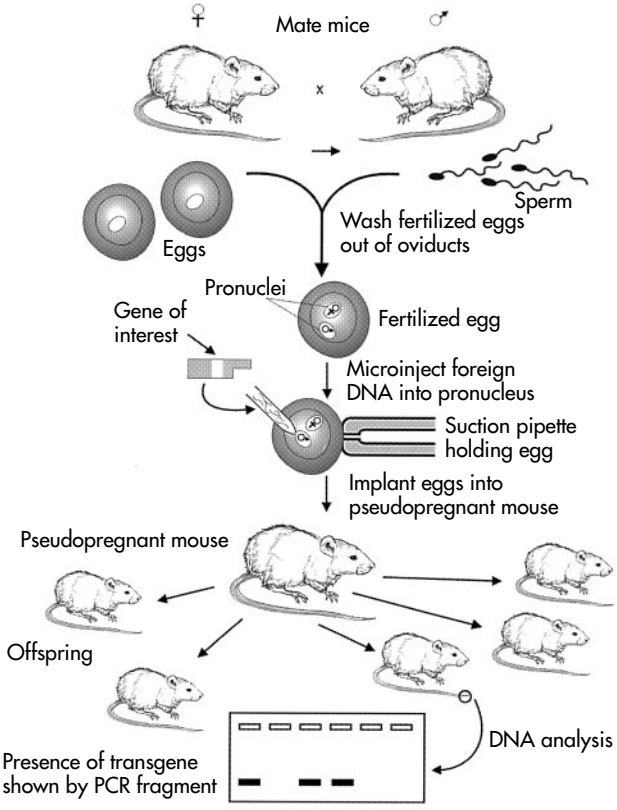

FIGURE 3–7. Schematic illustration of production of transgenic mice using the microinjection technique. A transgene is constructed from a promoter that directs expression in the tissue of interest, the gene to be studied, and a termination sequence. Fertilized eggs are collected from mated females, and the transgene is injected into one of the two pronuclei. The injected eggs are transferred to foster mothers, which are female mice made pseudopregnant by mating with vasectomized males. Three weeks after birth, the offspring are checked for the presence of the transgene by Southern blot analysis of DNA extracted from a small piece of the tail. Screening can be performed rapidly using the polymerase chain reaction (PCR) if suitable primers are available. Three of the offspring carry the transgene in the example given. Adapted from Watson JD et al.[29]

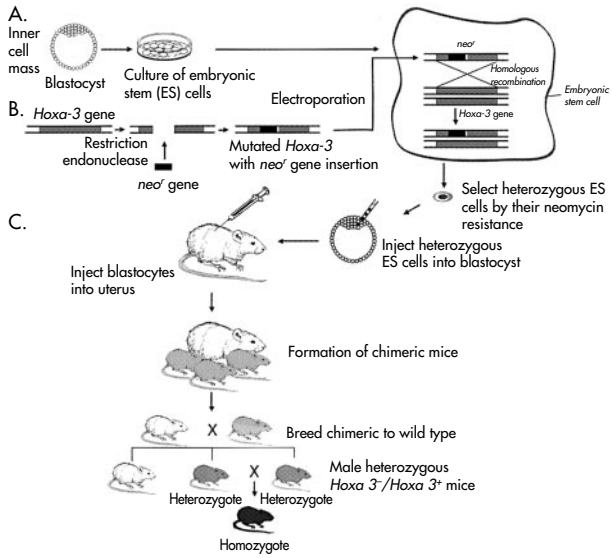

FIGURE 3–8. Schematic illustration of technique for gene targeting using the *Hoxa-3* gene as an example. (A) Embryonic stem (ES) cells are cultured from inner cell mass. (B) The cloned *Hoxa-3* genes are cut with a restriction enzyme, and the neomycin resistance gene is inserted into the region that encodes the DNA-binding site of the protein. The mutant *Hoxa-3* genes are introduced into ES cells, in which homologous recombination exchanges a wild-type gene for the mutant copy. These cells are selected with neomycin. (C) Heterozygous ES cells are inserted into the inner cell mass of a wild-type embryo, and the blastocyte is returned to the uterus. The resulting mouse is a chimera composed of heterozygous *Hoxa-3* tissues and wild-type *Hoxa-3* tissues. Mating of the chimeric mice to wild-type mice produces heterozygous *Hoxa-3* offspring if the ES cells contributed to the germ line of the chimeras. These heterozygous mice can be bred together, and some of their progeny should be homozygous mutants of the *Hoxa-3* gene. Adapted from Gilbert SF.[8]

ery of many restriction fragments at defined chromosomal locations whose length differs between individuals (a phenomenon called polymorphism; the more polymorphic a marker, the more useful it is for gene localization). These differences can readily be identified by Southern blotting (Figure 3–9).

Another family of markers has been developed by exploiting the tendency of DNA to form repeating sequences called minisatellites. Repeats of short DNA sequences, or of C-A or G-T pairs, are ubiquitous in the genome, are often highly polymorphic, and can be identified by PCR. In animals, interspecies crosses between the laboratory mouse *Mus musculus* and closely related mouse species such as *Mus spretus* have been used to generate markers at many loci.

Taken together, these developments have greatly increased both the ease of linkage analysis and the number of defined chromosomal loci against which to test a given phenotype for linkage. This has allowed more precise localization of the genes determining traits of interest, increasing the chance that the genes can be identified at the molecular level by fine mapping, chromosome walking, testing of candidate genes within a region, and/or exon trapping. The proliferation of gene markers has contributed to the location and, in many cases, identification of genes involved in diseases, such as retinoblastoma[30] and Duchenne's muscular dystrophy.[31]

MOLECULAR BIOLOGY OF THE INNER EAR

For the past 20 years, molecular biology has been increasingly applied to research problems in virtually every area of biology and medicine. The expansion of molecular research has been fueled by the introduction of many powerful methodologies for isolating and characterizing gene sequences, determining their expression patterns, inducing expression in cells or organisms, and producing specific mutations. Owing in part to the small size and difficult access of the ear, the research community studying the auditory system was relatively slow to use the techniques of molecular biology, with initial publications using these methods appearing in the early 1990s. Since this time, the use of molecular biology as a tool to study hearing and deafness has increased dramatically. Many auditory laboratories in the United States and worldwide have added molecular methods to their research programs, and several molecular laboratories have begun to study the auditory system. This has led to the identification and characterization of numerous genes involved in hearing and deafness.

Progress beyond the gene identification stage has been more limited. A survey of molecular studies in other fields suggests that our field lags behind other medical disciplines in applying these powerful

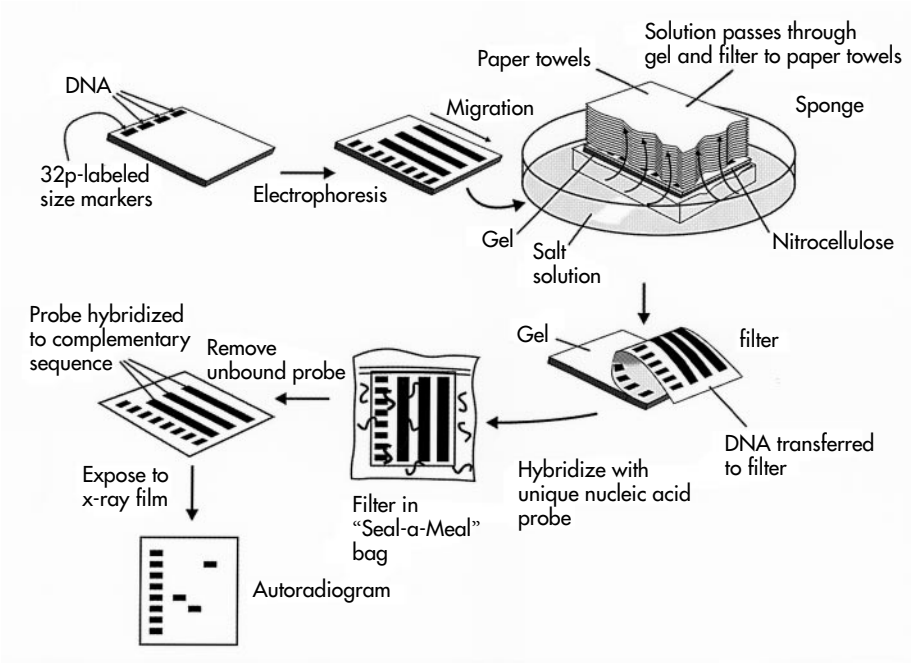

FIGURE 3–9. Schematic illustration of Southern blotting. Deoxyribonucleic acid (DNA) digested with restriction enzymes is loaded onto a gel and electrophoretically separated by molecular size. After the fragments of DNA are separated, the DNA is denatured into single strands. The gel is then placed on a support on top of filter paper saturated with buffer. A nitrocellulose or nylon filter is placed on top of the gel, and absorbent towels are placed on top of the filter. The transfer buffer makes its way through the gel, nitrocellulose paper, and towels by capillary action, taking the DNA with it. The single-stranded DNA sticks to the filter. The filter is then removed, the DNA is immobilized on to the filter, and the filter is hybridized with a radioactively labeled probe. The position of the DNA fragment complementary to the probe appears as a band on x-ray film, which reflects the position of the DNA fragment in the gel. Adapted from Watson JD et al.[29]

methods. The limited amount of tissue that is available from the middle ear, labyrinth, and many central auditory structures, coupled with the diversity of cell types present, has contributed to the disparity. This has slowed the generation of cDNA libraries, especially those for specific cell types. It has also made the application of other methods for cataloguing gene expression, such as gene array technology, difficult. A second impediment to progress is a relative paucity of in vitro models of many aspects of auditory development and function that are appropriate for molecular manipulation. Thus, molecular methods often need to be applied to the intact organism as opposed to culture systems or cell lines.

Molecular biology has been minimally applied in the clinic. Molecular diagnostic techniques are becoming available for genotyping individuals with potential genetic disorders affecting hearing or for identifying disease pathogens as in otitis media (OM). However, molecular therapy has yet to be applied to the ear. However, many otologists recognize the potential of molecular medicine to improve diagnosis and treatment in the future.

As noted above, molecular biologic studies of the ear have increased greatly in the past several years, to the point where it is no longer possible to provide a comprehensive review in the space available. However, some recent highlights are presented below.

Deafness Genes

Molecular Basis of Deafness A notable exception to the generally slower rate of molecular progress in

our field is the molecular genetics of deafness, perhaps because this field is less dependent on extracting molecular information from the auditory tissues themselves. We now know the identity of more than 16 genes of the 60+ loci known to be involved in nonsyndromic deafness in humans, and many new syndromic deafness genes have also been identified.[32] For example, Alport's syndrome has been associated with a mutation in the gene encoding the basement membrane collagen (*COL4A5*).[33,34] Waardenburg's syndrome types I and III have been identified with mutations in the transcription factor gene *PAX3*.[35] Myosin VIIA (MyoIIIA) has been identified as the gene responsible for Usher's syndrome type IB.[36] Linkage of neurofibromatosis 2 (NF2) to chromosome 22q[37,38] led to fine-scale mapping[39] and then to identification of a mutated gene, which encodes a new member of the family of 4.1 cytoskeletal associated proteins known as merlin.[40,41] Neurofibromatosis 2 is an autosomal dominant inherited disease characterized by bilateral vestibular schwannomas and other central nervous system tumors and is often associated with hearing impairment caused by cochlear nerve compression. Similarly, testing of candidate genes near the linkage site for X-linked deafness with stapes fixation (*DFN3* = nonsyndromic deafness X-linked gene third to be discovered) led to the identification of the mutated gene as *Brn-4,* which encodes a transcription factor with a POU domain (*POU3F4*).[42] A mutation in the related gene, *Brn-3.1*, causes nonsyndromic deafness in *DFNA15* (nonsyndromic deafness autosomal dominant gene fifteenth to be discovered). These transcription factors are members of a gene family that is expressed in the cochlea during development.[43] The indentification of mutations in the connexin 26 gene, encoding a gap junction protein,[44] as the basis for DFNA1 is particularly significant. Mutations in this gene are particularly common, and it is estimated that up to 50% of all nonsyndromic hereditary deafness in the United States is caused by mutations in this gene.[45] A defect in mitochondrial DNA that increases susceptibility to aminoglycoside ototoxicity and that, in combination with an autosomal mutation, leads to maternally inherited nonsyndromic deafness has also been characterized.[46–48]

The gene responsible for Usher's syndrome type 1C has been identified and reveals a unique pathologic mutation.[49] Also of note is the finding in DFNA10 of mutations in *EYA4*,[50] a member of a family of genes in which defects in another member, *EYA1*, cause a separate hereditary hearing impairment disorder, branchio-oto-renal syndrome.[51,52]

In addition, around 50 new hearing- and/or balance-defective mouse mutants have been created by two large European ethylnitrosourea (ENU) mutagenesis programs,[53,54] with more becoming available from other, similar programs in the United States. A number of the genes involved in deafness in these new mouse mutants and other older mouse mutations have been identified. An example is the novel unconventional myosin, myosin 15, which is mutated in the Shaker 2 mouse. This example is particularly notable for the use of bacterial artificial chromosome (BAC) transgenic mice to identify the mutated gene.[55] With the completion of draft sequences of the human genome and progress toward completion of mouse genome sequencing, the transition from linkage to gene identification has and will become increasingly more rapid. Many gene knockouts also have effects on the development or function of the ear, which has allowed us to build up rapidly our knowledge of the molecular basis of auditory function and development.[56] Examples include genes encoding PMCA2,[57] Brn-4,[58] and otogelin.[59]

There is an important trend emerging toward using the information obtained from genetic screening to study the functional biology of the inner ear, for example, the work of Karen Steel and others showing changes in susceptibility to ototoxicity in myosin VIIA–deficient animals.[60] Another example is pendrin, which is giving insights into cochlear ion transport processes.[61] Microarray analysis is also beginning to be used to investigate changes in patterns of gene expression resulting from single-gene mutations, giving clues to the pathways affected by the mutations.

Molecular genetics is an arena in which there is extensive interaction between clinicians and basic scientists. In particular, several genes involved in inherited deafness have been first cloned in basic science laboratories or identified with the aid of mouse models.[49,62,63]

Linkage and identification of mutations causing deafness and vestibular disorders have immediate clinical significance since they allow genetic testing and counseling and may eventually provide a basis for gene therapy. They are also proving to be an important means of identifying genes whose expres-

sion is important for normal cochlear development and function.

Inner Ear Development

Many genes involved in auditory ontogeny have been identified by screening for gene expression in developing auditory tissues. Polymerase chain reaction and in situ hybridization have provided a wealth of information regarding which genes are expressed and in which tissues. Whereas expression of a gene in a cell or tissue suggests a functional role, mutation of the gene leading to a phenotype provides much more convincing evidence that the molecule functions within the context of the intact tissue and organism. Many genes involved in syndromic and nonsyndromic deafness appear to be critical developmental regulators, such as the unconventional myosins that are involved in stereociliary morphogenesis.[64] Similarly, despite the risks of redundancy, the targeted deletion of an increasing number of genes has illuminated their role in auditory development and/or function. This includes a variety of developmental genes that influence organogenesis of the labyrinth or the development of inner ear cell types.[56] Many such genes involved in inner ear morphogenesis are known to play roles in the morphogenesis of other developing structures.[65–67]

Several genes have been shown using molecular techniques to affect the basic morphogenesis of the labyrinth, beginning at the stage of the otocyst. For example, retinoids[68,69] affect ear development. The retinoic acid receptor (RAR) family of nuclear receptors for retinoic acid (RA) is one of two groups of DNA binding proteins that are activated by interaction with this ligand. They serve as ligand-inducible regulators of transcription by activating RA responsive promoters. There are three RAR gene isotypes, RARa, RARb, and RARg, each with their own isoforms, and they have widespread expression patterns in the developing inner ear. Retinoic acid receptor a expression is ubiquitous in cochlear sensory and nonsensory structures. Retinoic acid receptor b is expressed mainly in structures of mesenchyme origin and in vestibular sensory epithelia. Retinoic acid receptor g is located in the cochlear and vestibular compartments in the epithelium of the inner ear.[70] Because of functional redundancy, deletion of individual receptor isoforms has relatively little effect on the development of the auditory system. However, deletion of both a and g isotypes results in absence of the stapes, an abnormal incus, a small and incomplete cartilaginous otic capsule, and absence of the organ of Corti and spiral ganglion.[71]

Bone morphogenetic proteins (BMPs) are members of the transforming growth factor-alpha (TGF-α) superfamily. Oh and Wu investigated BMP (BMP-4, -5, -7) expression during development of the chick otocyst.[72] In situ hybridization analysis showed that BMP-4 mRNA was present in the future ampullae of the three semicircular ducts on embryonic day 2.5 to 3. Bone morphogenetic protein 5 mRNA, however, was only found transiently in the future ampulla of the posterior semicircular duct. Bone morphogenetic protein 7 mRNA, on the other hand, was initially expressed in most parts of the otocyst and became restricted to specific regions by embryonic day 3. These investigators suggested that BMPs may play an important role in the differentiation of inner ear sensory organs. Inactivation of BMP-4 results in embryonic lethality[73]; however, mice heterozygous for BMP-4 deletion exhibit abnormal vestibular behavior and malformations of the lateral semicircular canal,[74] suggesting a role in labyrinthine patterning.

In the sensory epithelia of the inner ear, several genes involved in hair cell fate selection and differentiation have recently been identified with this approach. For example, deletion of the *Math1* gene in mice results in failure of cells in the organ of Corti to adopt the hair cell phenotype.[75] In addition, exit of committed hair cells from the cell cycle appears to be dependent on expression of *p27Kip1* since deletion of this gene leads to formation of supernumerary hair cells.[76,77] The related factor *p19Ink4d* may play a similar role (Chen P and Segil N, unpublished observations). Hair cell differentiation requires expression of the POU domain transcription factor Brn-3.1. In mice null for *Brn-3.1*, hair cells never develop cuticular plates or stereocilia, and many eventually die.[78,79] The differentiation of hair cells from supporting cells appears to be regulated in addition by Notch/Delta signaling since deletion of the gene encoding the Delta family protein Jagged 2 results in increased numbers of hair cells, perhaps via down-regulation of *Notch* in supporting cells.[80]

Understanding the lineage relationships between hair and supporting cells and the molecules involved in a cell's decision to become either a hair

or a supporting cell provides insights into mechanisms of hair cell regeneration. Delta appears to be involved in hair cell regeneration in the avian basilar papilla. The underlying supporting cells begin expressing Delta upon hair cell loss.[81] In perhaps the most intriguing recent observation, Zheng and Gao have shown that transfection of the developing organ of Corti with the Math1 coding sequence results in the adoption of the hair cell phenotype by cells far outside the normal location of hair cells.[82] Math1 thus appears to be both necessary and sufficient for promoting hair cell fate selection and differentiation.

Neurotrophic growth factors such as basic fibroblast growth factor (bFGF), TGF-α, and neurotrophins, such as neurotrophin 3 (NT-3) and brain-derived neurotrophic factor (BDNF), are necessary for survival and neurite extension in auditory and vestibular neurons during both early and late stages of ear development.[83] Messenger RNAs encoding both BDNF and NT-3 are expressed in the inner ear during development.[84,85] Cochlear and vestibular neurons both respond to BDNF and NT-3 in vitro.[16] Inhibition of BDNF and NT-3 expression using antisense oligonucleotides prevents neurite extension in vitro.[86] Finally, using mutant mice with knockout of the *BDNF* gene or *NT-3* gene or both genes, Ernfors et al demonstrated that BDNF is critical for survival of the vestibular ganglion and maintenance of both afferent and efferent innervation.[87] These data are consistent with observations in mice lacking a functional *NT-3* gene reported by Farinas et al.[17] In the cochlea, *BDNF* gene–deleted mice showed loss of presumptive type II ganglion cells and afferent innervation to outer hair cells, whereas *NT-3* gene–deleted mice showed loss of presumptive type I ganglion cells and the majority of afferent innervation. The double mutants lose all vestibular and cochlear ganglion cells.[16]

Molecular Substrates of Auditory Function

Hair Cell Transduction The major function of the sensory hair cells in the inner ear is to transduce mechanical energy into neural information. The sensory cells of both the cochlea and the vestibular sensory organs are mechanoreceptors equipped with a geometrically arranged sensory stereociliary bundle on each sensory cell surface. Deflection of the ciliary bundle by mechanical force toward the kinocilium (or basal body in the case of the cochlea) is excitatory and toward the opposite direction is inhibitory for neural discharges. Deflection of the stereociliary bundle toward the excitatory direction is now known to open transduction channels located on the upper part of the stereocilia.[88–90] The opening of the transduction channels is believed to be mediated by filamentous structures connecting the tip of the lower stereocilium to the neighboring taller stereociliary surface known as tip links.[91,92] Most of the molecules responsible for the hair cell transduction process have yet to be identified. However, some progress has been made in the transduction channel[93,94] and the adaptation motor in vestibular sensory hairs.[95] The precise location of the transduction channels is not yet established. It is believed to be associated with tip links because a calcium chelator eliminates both transduction current and tip links.[91] Hackney et al used an antibody to the amiloride-sensitive sodium channel to label the side of the stereocilia just below the tip-link attachment site.[93] A recent advance is the identification of a mechanically sensitive ion channel of the TRP superfamily that is required for mechanotransduction in the bristle organ of *Drosophila*.[96] A mammalian homologue would be an excellent candidate for the transduction channel of hair cells.

To retain sustained sensitivity during transient displacement, the vestibular sensory cell must adapt to sustained stimuli. Adaptation of vestibular sensory cell is thought to be mediated by a "slipping" of tip-link attachment and by an active "tensioning."[97] Readjusting tension of the tip link is necessary for the adaptation of the vestibular sensory cells.[95,98] This tensioning is suggested to be mediated by 120 kDa myosin motors, which are presumably located in the insertional plaque and run on the surface of the stereociliary actin filaments as guides.[94,95,98]

The discoveries of the acoustic emission[99] and the electromotor activity of the dissociated outer hair cells in mammals[100,101] led to the concept of active hearing. According to this concept, amplification of auditory sensitivity and sharp tuning of the basilar membrane frequency response are the result of motor activity by the outer hair cell. There is strong evidence that this motor activity is driven by multiple molecular motors, which are an integral part of the cell membrane.[102,103]

An exciting development is the identification of prestin as a candidate for the outer hair cell motor protein. This molecule, related to the anion transporter pendrid, was one of several identified in a differential screen of cDNAs performed by subtractive PCR between cDNAs derived from outer versus inner hair cells. A full-length cDNA produced membrane motility when transfected into an unrelated cell type, identifying this molecule as a strong candidate for the outer hair cell membrane motor protein.[104] Supporting the evolutionary relationship between prestin and an anion transporter is the observations that the intracellular anions chloride and bicarbonate are required for prestin's voltage sensitivity.[105,106]

Neurotransmitters Afferent and efferent (medial and lateral) systems and the innervation patterns of the auditory organ are relatively well established. Although remarkable progress has been made in recent years, our knowledge concerning inner ear neurochemistry is yet to be completed. Afferent neurotransmission between the cochlear hair cells and spiral ganglion neurons is mediated by an as yet unidentified neurotransmitter. Based on molecular analysis evidence, the strongest candidate for this transmitter is glutamate or a related amino acid.[107] The expression of mRNAs encoding glutamate receptors has been detected in spiral ganglion neurons. These include members of the AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate),[108] NMDA, and kainate[108,109] glutamate receptor families. These observations strongly support the hypothesis that an excitatory amino acid like glutamate is one of the cochlear afferent neurotransmitters. The primary efferent neurotransmitter between the brainstem and cochlea is thought to be acetylcholine, with other transmitters, including γ-aminobutyric acid (GABA), opioid and other peptides, and possibly adenosine triphosphate (ATP), also being involved. Members of several neuronal receptor gene families have been shown to be expressed in the cochlea. Expression of genes encoding nicotinic,[110] muscarinic,[111] and metabotropic[112] acetylcholine receptors; GABA receptors[113]; and ATP receptors[114] has been documented in the cochlea, whereas preproenkephalin mRNA has been found in cochlear and vestibular efferent cell bodies in the brainstem.[115] In particular, the α9 member of the nicotinic acetylcholine receptor has been shown to be strongly expressed in cochlear hair cells and to match exactly the pharmacology of the outer hair cell response to this transmitter.[116] In general, the diversity of receptor and transmitter expression associated with the efferent system matches the complex pharmacology of the inner ear.

Inner Ear Fluid Regulation Differences in the ionic composition between endolymph and perilymph have been shown to play a critical role in inner ear function. It is, therefore, not surprising that the expression of genes encoding a number of ion transport enzymes[117,118] and ion channels[119] has been found in the inner ear. Of particular interest are the Na, K-ATPase genes since this enzyme appears to be the most important determinant of the composition of perilymph and endolymph. In the stria vascularis, the α_1 and β_2 isoforms are the only ones expressed. [117] This combination is not found in isolation in any other tissue in the body. However, the β_2 subunit is associated with transporting sodium against a high electrochemical gradient. In order for the stria vascularis to transport sodium against the highest gradient in the body, perhaps this unique composition of the enzyme is required. Several additional proteins that appear to be involved in circulation of K^+ ions from the organ of Corti to the stria vascularis have been identified via natural or induced mutations.[120] These include connexin 26 expressed in cells of the organ of Corti,[44] a Na-K-Cl cotransporter expressed in basal cells of the stria vascularis,[121] and an ISK potassium channel expressed by marginal cells.[122]

Inner Ear Proteins

Genes important for inner ear function have often been highlighted by mutational analysis. An additional paradigm for identifying functionally important proteins is to look for genes whose pattern of expression is limited to the inner ear and to test if these genes are important for inner ear function, creating animal models with nonfunctional mutant versions of these genes. To date, very few genes showing a pattern of expression limited to the inner ear have been reported. The organ of Corti–specific proteins OCP I and OCP II have been identified,[123] and the OCP II gene has been cloned.[124] Tectorial membrane proteins (tectorins) with little homology to known proteins have also been cloned.[125]

An inner ear–specific novel structural protein in the sunfish saccule has been cloned and characterized.[126] A cDNA, obtained by differential screening of a saccular cDNA library, that encodes an inner ear–specific collagen molecule was identified. The predicted amino acid sequence of this protein showed 40% identity and 56% overall homology with collagen types VIII and X.[127] In situ hybridization with an antisense saccular collagen cRNA showed that transcripts encoding this protein are localized only to the edge of the saccular epithelium, indicating that these specialized epithelial (supporting) cells may secrete this protein, which is believed to be a component of the otolithic membrane.[126]

Much of the molecular data generated to date has involved identification of novel gene sequences for structural proteins and has not been well integrated into the functions of the inner ear. Future studies will be needed to test the importance of these genes and others for normal inner ear function.

Gene Expression in Auditory Tissues

Several laboratories have generated cDNA libraries from specific tissues or cell types of the inner ear, such as outer hair cells,[127] and the National Institute on Deafness and Other Communication Disorders (NIDCD) is currently sponsoring the generation of cDNA libraries from auditory tissues such as the otocyst. Differential screening techniques, such as subtraction, differential display, and suppressive subtractive hybridization (SSH), are currently being employed by a number of laboratories in an attempt to identify genes specifically expressed in different inner ear cell types.[104] Efforts to use gene arrays to provide broad profiles of gene expression in auditory tissues are under way, including efforts sponsored by the NIDCD. A hair cell–specific promoter has been isolated and used to direct expression of green fluorescent protein (GFP) limited to hair cells.[128] Using homologous recombination, Zuo et al introduced GFP into the α9 acetylcholine receptor locus in a BAC, which was used to create a transgenic mouse that showed hair cell–specific expression.[129] Analysis of these and other tissue-specific promoters will help to define the nuclear signals that direct expression to auditory cell types and allow the development of tissue-specific viral vectors for the auditory system. It will also permit the production of other proteins, or antisense RNA for suppression of targeted proteins, as well as cell-specific gene deletions using CRE-LOX recombinant and similar methodologies, in auditory cells.

GENE THERAPY IN ANIMAL MODELS

The use of gene therapy for disorders of the ear remains a prospect for the future. However, research on this topic gives promise to the idea that at least some inner ear conditions might be treated using molecular biologic methodologies.

For example, mutations that delete a critical gene can, in some instances, be corrected by supplying the missing gene. Yoo et al studied the *shiverer* mouse, which has a neurologic disorder caused by a mutation in the gene encoding myelin basic protein and characterized by defects in the myelination of nerve tracts.[130] These mice show deficits in both the amplitude and latency of auditory brainstem responses (ABRs) owing to abnormal conduction in auditory nerve fibers. When a transgene encoding normal myelin basic protein was integrated into the genome of *shiverer* mice, the ABR deficits were partially corrected. A similar approach, combined with in vitro fertilization, might someday be used to prevent certain devastating genetic disorders in humans. Transgenic mice carrying a bacterial antibiotic resistance gene were found to be resistant to ototoxicity.[131] Molecular studies of otologic disease and gene therapy research are both areas in which there is considerable interaction between basic scientists and clinicians.

A more practical form of therapy is one that can be used in the adult organism. Several laboratories are studying methods for gene delivery into the tissues of the inner ear, either for investigative purposes or as the basis for eventual gene therapy. Several viral vectors carrying reporter genes under the control of constitutive promoters have been shown to mediate the transduction of inner ear cells, both in vivo[132,133] and in vitro.[134] These studies have generally found that transduction of hair cells is less effective than that of other cell types, such as Schwann cells or cells lining the perilymphatic spaces. Vectors have also been used to deliver growth factors, resulting in the rescue of damaged inner ear ganglion neurons[135] and hair cells.[136] Ryan et al explored different molecular biologic methods to deliver a factor into the inner ear.[137] They injected

into the adult mouse inner ear fibroblasts that had been genetically engineered to secrete high levels of acidic FGF. To suppress proliferation, the fibroblasts were irradiated, and the researchers found that the irradiated cells were well tolerated in the cochlea, with few side effects, and continued to produce the growth factor for several weeks. Because the ganglion cells are bathed with fluid freely communicating with perilymph, growth factors secreted by the fibroblast in the spiral ligament will be available to the ganglion cells. Staecker et al also found that inner ear injections of fibroblasts engineered to produce BDNF promoted survival of spiral ganglion neurons after hair cell destruction in guinea pigs.[138] However, the use of nonirradiated cells in this study led to destructive overproliferation. Although preliminary, these studies demonstrate theoretical possibilities of molecular genetically based therapy for diseases in the human inner ear.

MOLECULAR PATHOGENESIS OF OTITIS MEDIA

In the middle ear, molecular methods are being applied in diagnosis, research, and experimental treatments for disease. Polymerase chain reaction has proven to be extremely useful in the identification of microbes in OM,[139] and quantitative PCR has been used to measure cytokine production.[140] Genetics has been shown to be an important factor in OM susceptibility.[141] Mechanisms of mucosal proliferation and immunoregulation have been probed using a variety of molecular techniques, including in situ hybridization[142] and the implantation of genetically modified cells.[137] Extraction of RNA from human archival temporal bones may also prove to be useful for the analysis of such samples for the expression of genes involved in the inflammatory process.[143]

Purification and sequencing of gene products are important in understanding the pathogenesis of OM. Cloning bacterial genes has allowed investigators to produce a number of mutant or genetically engineered bacteria, in which a gene is either deleted or altered. These mutants or genetically engineered bacteria can be used to probe the molecular mechanisms of bacteria–host interaction, virulence factors, and immunogenicity. The genetically engineered bacteria can also be used to mass-produce recombinant outer membrane proteins (OMPs) for vaccine candidates. Although not yet fully explored, transgenic and gene knockout animals are being developed for the study of host defense mechanisms against infection.

Bacterial Adherence

To be successful pathogens on a mucous membrane, bacteria must be able to colonize, evade host defense, and express toxins that damage host cells and tissues. To accomplish these goals, the bacteria must be able to adapt to the new environment by altering their phenotypic expression through transcriptional regulation. Although the exact mechanisms by which bacteria attach to the mucosal surface are poorly understood, it is generally believed that receptor ligand–mediated bacterial binding plays a major role, even though nonreceptor ligand binding may also play a role in the adherence. The host receptor for *Streptococcus pneumoniae* is now known to be Glc Nac1-3Gal,[144] whereas the host receptor for nontypable *Haemophilus influenzae* (NTHi) is not yet fully characterized. However, several of the bacterial ligands of NTHi have been described. The suggested ligands include 22 kDa pilin,[145] 27.5 kDa LKP1 (a single serotype) pilin,[146] 36.4 kDa fimbrin,[147,148] and 120 kDa high-molecular-weight OMPs (HMW-1, HMW-2),[149] which may mediate bacterial binding to the host epithelial cell surface. Pilin is a subunit of the rigid, tubular surface appendage pilus and mediates hemagglutination. Fimbrin is a subunit of the surface appendage fimbria, which is a nontubular filament, thinner than pilus and nonhemagglutinating.[146,148]

The gene encoding LKP1 pilus (27.5 kDa) from an NTHi strain obtained from a middle ear effusion has been cloned and expressed in *Escherichia coli,* and the recombinant pili were capable of mediating both the binding of bacteria to the buccal mucosa and hemagglutination.[146] Coleman et al cloned and sequenced the gene encoding the 22 kDa hemagglutinating pilin from another strain of NTHi, found the DNA sequence to be 77% identical to that of the *H. influenzae* type b pilin gene, and showed it to be 68% homologous via the derived amino acid sequence.[145] Because only less than 5% of middle ear isolates and 35% nasopharyngeal isolates expressed pili,[150] the precise role of the pili in the pathogenesis of OM is unclear.

Although it has not yet been established that fimbrial expression is mandatory for the establishment of infection, there is good evidence indicating

that 100% of NTHi isolates from the middle ear of patients with chronic OM with effusion are fimbriated.[151] Sirakova et al sequenced and cloned a 36.4 kDa fimbrial protein from another strain of NTHi recovered from middle ear effusion.[148] The translated amino acid sequence of fimbrin was found to be homologous with various members of the outer membrane protein A (OMP A) family of proteins of other gram-negative bacteria[152] and with type b *H. influenzae* OMP P5, with which it showed 92% identity. Disruption of fimbrin gene resulted in a mutant lacking fimbrial expression and loss of immunoreactivity to the antisera directed against isolated fimbrial proteins.[148] Importantly, this isogenic mutant showed reduced adherence to human oropharyngeal cells in vitro and significantly reduced induction of OM through intranasal inoculation of NTHi in the chinchilla animal model. Thus, fimbrin not only causes adhesin-mediating bacterial adherence but is also a virulence factor for NTHi.[148]

Although the exact mechanism or role of the fimbria in the pathogenesis of OM is not clear, one possibility is that when fimbrin is expressed, it may help to establish an intimate association between the bacteria and host cell.[151] It is possible that through such an interaction, bacterial toxins can be delivered to the host cell, causing cell injury and mediating inflammatory cell responses.

Virulence Factors

Endotoxin plays an important role in the pathogenesis of OM.[153] Evidence indicates that phase variation of the endotoxin lipo-oligosaccharide (LOS) is a virulence factor in type b *H. influenzae*.[154] Phase variation is a reversible switch between two stable genotypes. Phase variation provides bacteria with an advantage in evading host immune response and becoming successful pathogens. The genes responsible for phase variation have been identified, and three *lic* genes (*LIC1, LIC2,* and *LIC3*) are known to be responsible for variable translation of the *lic* loci, which enables a number of different LOS structures to be produced from a limited set of genes.[154,155] Although the loss of phase variation did not affect bacterial colonization, it has affected the ability to invade the bloodstream from the respiratory epithelium when the genes are inactivated.[156] It is possible that similar phase variation of LOS may also exist in NTHi.

Pneumococcal proteins pneumolysin and autolysin contribute significantly to the virulence of pneumococci.[157] *Streptococcus pneumoniae* type 3 mutants deficient in the production of either pneumolysin or autolysin were constructed by transformation of DNA from derivatives of a rough strain, in which the respective genes had been interrupted by insertion-duplication mutagenesis using internal fragments of the cloned genes in the vector.[157] Both the pneumolysin-negative and the autolysin-negative strains had significantly reduced virulence in mice, as judged by survival time after intraperitoneal challenge. When pneumolysin and autolysin productions are restored by back-transformation of the mutants with an intact copy of the respective cloned gene, the mean survival time was indistinguishable from that of mice challenged with the wild-type strain. Thus, pneumolysin and autolysin are important virulence factors in type 3 pneumococci.[157] Mice were challenged with a genetically modified mutant strain of pneumococcus, which was unable to express active pneumolysin. Preimmunization of such mice with autolysin failed to provide any significant protection against the challenge.[158] The authors suggested that the most important contribution made by autolysin to the virulence of *S. pneumoniae* may be its role in mediating the release of pneumolysin from the pneumococcal cytoplasm during infection.

MOLECULAR BIOLOGIC APPROACHES IN THE DEVELOPMENT OF VACCINES AGAINST OTITIS MEDIA

The intention of this section is not meant to be a review on current OM vaccines; rather, it is intended to focus on the molecular biologic aspects of vaccine development. Excellent reviews on the OM vaccine development are available elsewhere.[159,160]

Nontypable *Haemophilus influenzae* Vaccines

Several lines of evidence suggest that a number of OMPs of NTHi are potential candidates for vaccines against this microorganism. The genes encoding several of these OMPs have been cloned, sequenced, and expressed.[161–163] This nucleotide sequence information, together with mapping of bactericidal epi-

tope molecules, enabled investigators to define the structure and function of these OMPs and identify domains that are conserved across the strains.[164,165] Such information is critical in selecting antigens as vaccine candidates. Among those identified as potential vaccine candidates, NTHi OMP P6 (peptidoglycan-associated lipoprotein), which is common to both nontypable and type b *Haemophilus*, is the most promising because P6 is a target of bactericidal antibodies in convalescent sera. A truncated P6 gene without the signal peptide has been constructed by Green and his associates,[166] and the recombinant protein encoded by this construct is capable of eliciting bactericidal antibody in vitro. Using a monoclonal antibody, Murphy and Kirkham identified a region of P6 encoding an epitope recognized by bactericidal antibody.[167] Another OMP, P26, also shows conservation across strains of NTHi and a recombinant preprotein-induced protection in animals.[168]

Another *Haemophilus* OMP known as P6 cross-reactive protein (PCP) is also considered to be an excellent vaccine candidate because polyclonal antisera against PCP are bactericidal. The PCP is antigenically conserved and present in both type b and NTHi. Deich et al recently cloned and sequenced this protein.[169]

Other *Haemophilus* OMPs, believed to mediate bacterial adherence and also considered as potential vaccine candidates, include pilin and fimbrin. Antibody response to such proteins by immunization can block the bacterial adherence mediated by these proteins, thus reducing colonization and infection.[148,150] Another vaccine candidate is a group of high-molecular-weight surface-exposed proteins of NTHi, which are related to the filamentous hemagglutinin protein of *Bordetella pertussis*. The high-molecular-weight proteins are known to be critical adhesion molecules but also are major targets of human serum antibody.[170] To further characterize these proteins, Barenkamp and Leninger cloned and sequenced genes encoding two related high-molecular-weight proteins (120 kDa and 125 kDa).[171]

Streptococcus pneumoniae Vaccines

Many new vaccines including multivalent polysaccharide vaccines and polyvalent pneumococcal conjugate vaccines are under development and being field-tested, and they will not be covered here.

Pneumococcal proteins autolysin and pneumolysin contribute significantly to the virulence of this microorganism. Autolysin and a defined toxoid derivative of pneumolysin were tested for efficacy in a mouse model as antigens protecting against challenge with virulent, wild-type *S. pneumoniae,* and the result showed that each antigen alone provided significant protection.[158] When mice were challenged with a genetically modified mutant strain of pneumococcus unable to express active pneumolysin, preimmunization of mice with autolysin failed to provide any significant protection against the challenge.[158] When mice were immunized with a genetically engineered toxoid version of pneumolysin derived from serotype 2 pneumococcus and challenged with 12 strains of pneumococci covering capsular types 1 to 6, 7F, 8, and 18c, pneumolysin toxoid conferred protection against all nine pneumococcal serotypes.[172] Thus, these investigators suggested that pneumolysin toxoids warrant consideration for inclusion in pneumococcal vaccines. Molecular analysis of pneumococcal surface protein A also reveals several relatively conserved domains,[173] suggesting that this molecule may also be a vaccine candidate.

DNA Vaccines against Respiratory Viruses

Acute OM is frequently preceded by a viral upper respiratory infection. Recent data using PCR demonstrated that a high number of middle ear effusions contained evidence of upper respiratory viruses,[174] and upper respiratory viral infection is causally related to the bacterial OM. It has been shown that attenuated influenza viral vaccine conferred protection against pneumococcal OM in the chinchilla.[175] Thus, preventing upper respiratory viral infection will reduce the incidence of acute OM. In recent years, clinical trials have been initiated with live attenuated vaccines for respiratory syncytial virus, influenza, and parainfluenza viruses and adenovirus.[159] Such trials can provide an excellent opportunity to test the above hypothesis. In a clinical trial in Finland, attenuated influenza virus was administered to children under 4 years old. During a 6-week epidemic, 83% of the children were protected from confirmed influenza A–associated acute OM and 36% from acute OM in general.[176] However, efficacies of viral vaccines against disease in susceptible populations are modest at best owing to rapid

changes of viral surface antigens and heterogeneity of surface antigens among different strains, as well as incomplete knowledge of the characteristics of protective immunity of different upper respiratory viruses.[159]

Most of the current viral and bacterial vaccines are largely using surface antigens. However, such an approach poses a serious problem because a microbe's surface structures frequently change at a rapid rate, rendering vaccines useless. For example, evolution of the genes for surface proteins of influenza virus occurs so fast that a new vaccine must be made every year to be effective. However, proteins in the interior of viruses are more highly conserved (stable) than those of the surface. The discovery that naked DNA from a virus injected into the body could function as a vaccine may provide a new opportunity to develop an effective viral vaccine.[177] Futhermore, investigators described the results of experiments on mice using DNA from influenza virus.[178] The opponents of viral DNA vaccines caution a theoretical possibility of activation of an oncogene, which may induce cancer in the host.

MOLECULAR MECHANISMS OF ANTIBIOTIC RESISTANCE AMONG OTITIS MEDIA PATHOGENS

Antibiotic Resistance in *Haemophilus influenzae*

The genetic basis of ampicillin and chloramphenicol resistance in *H. influenzae* has been well characterized, and the principal mechanism of the resistance is largely enzymatic.[179] The gene that encodes the β-lactamase enzyme is located within a large gene segment, transposon A.[180] Mendelman et al reported a small number of strains that demonstrate ampicillin resistance in the absence of β-lactamase production, which is believed to be mediated by alterations in one or more penicillin-binding proteins (PBPs).[181] The PBPs 3a and 3b showed a decrease in affinity for β-lactams in antibiotic-resistant strains.[182] The gene for the altered PBPs has been cloned.[183] The genetic basis for resistance of *H. influenzae* type b to chloramphenicol has been elucidated, and it is believed to be caused largely by the enzyme acetyltransferase. The genetic sequence that codes for this enzyme is also located within a transposon.[184] Molecular cloning and mechanisms of trimethoprim resistance in *H. influenzae* were elucidated by cloning the gene for trimethoprim resistance into a cosmid vector and transducing recombinant plasmids into *E. coli*.[185] The results indicated that the acquisition of trimethoprim resistance involved a chromosomally mediated rearrangement or change of nucleotide sequences. The mechanism of trimethoprim resistance is overproduction of dihydrofolate reductase.[185]

Antibiotic Resistance in *Streptococcus pneumoniae*

Penicillin resistance to *S. pneumoniae* is believed to be mediated by changes in the production of altered PBPs.[186] The PBPs la, 2b, and 2x have been cloned and sequenced.[186–188] No β-lactamase-mediated penicillin resistance was reported in pneumococci. Dowson and his associates investigated PBP 2b from several sensitive and resistant pneumococci and demonstrated a major change in the carboxyl-terminal sequence.[187] It is postulated that this change is responsible for the development of penicillin resistance.

MOLECULAR EPIDEMIOLOGY AND DIAGNOSIS

Molecular biologic techniques have been used to diagnose bacterial and viral diseases and fingerprint specific microorganisms in epidemiologic surveys.[189] Using a sensitive total genomic DNA restriction fingerprinting method, different isolates of *H. influenzae* have been identified.[190] Restriction endonuclease analysis of bacterial chromosomal DNA was used to compare NTHi obtained from middle ear effusions with that from nasopharynges of patients with OM. The restriction digest profiles of strains isolated simultaneously from the middle ear effusion and nasopharynx of an individual child were identical, whereas the restriction profiles of strains isolated from different children were different from one another.[191] In this study, the isolates from recurring episodes of NTHi in six children were different from those that caused the initial episode.

Like in the NTHi, another gram-negative bacteria, *Branhamella catarrhalis*, was subject to restriction fragment mapping for epidemiologic study for this newly emerging pathogen for OM. Dickinson et

al were able to fingerprint and compare *B. catarrhalis* isolates obtained from middle ear effusions and those from nasopharynges of the same patients using restriction fragment mapping following digestion of genomic DNA with restriction endonuclease such as *Pst*1 and *Cla*1.[192] This microorganism was considered as a normal flora of the nasopharynges of healthy children as well as adults. However, it has become increasingly associated with acute purulent OM and OM with effusion in recent years. Therefore, it is important to learn about strains that are pathogens versus nonpathogens, and the restriction fragment mapping technique allows investigation of the epidemiology of this microorganism reliably.

Polymerase chain reaction assay based on the amplification of pneumolysin gene fragments in sera was developed to diagnose acute pneumococcal pneumonia.[193] Analysis of DNA restriction patterns of genomic DNA provided a sensitive measure of genetic similarity between strains and a convenient method for use in epidemiologic studies.

Response of the Middle Ear Mucosa to Otitis Media

The middle ear mucosa exhibits dramatic responses to OM. It is unique among mucosae in that it has the capacity for extreme hyperplasia when stimulated by inflammatory events. The simple squamous cell epithelium that lines much of the normal middle ear can rapidly proliferate and differentiate into a respiratory mucosa with a well-organized and vascularized stroma and a pseudocolumnar epithelium with ciliated and goblet cells.

Growth Factors and Signal Transduction Extracellular stimuli induce both physiologic and pathologic cellular responses via activation of signal transduction pathways extending from receptors on the cell surface to the transcription factors in the nucleus. Therefore, investigating these signal transduction mechanisms not only provides new insights into molecular mechanisms of physiologic responses, development, and pathogenesis but may also open up novel therapeutic targets for the treatment of ear diseases such as OM.

Progress has been made recently in the studies of signal transduction mechanisms involved in the pathogenesis of OM. Oehl and Ryan used reverse transcriptase PCR to examine the expression of vascular endothelial growth factors (VEGFs) and their receptors (VEGF-Rs), important receptor tyrosine kinases involved in normal and pathologic angiogenesis, and found that VEGF, VEGF-C, VEGF-D, and VEGFR-2 (flk-1) were up-regulated in the mucosa of rat middle ears inoculated with bacteria.[194] DeFoire-Hyrmer and Bakaletz provided evidence to link phosphorylation of tyrosine with NTHi adherence and actin nucleation.[195] Sudhoff et al documented the presence of angiogenic growth factors and receptors in cholesteatoma.[196] Using immunocytochemisry, Huang et al found epidermal growth factor, FGF, and platelet-derived growth factor in cholesteatoma keratinocytes,[197] whereas Ishibashi et al detected keratinocyte growth factor and receptor mRNA.[198] Huang and colleagues found evidence that ras, c-jun, and p53 may be involved in signaling from these receptors.[197,199] Schilling et al observed high levels of tenascin in proliferating cholesteatoma keratinocytes, suggesting a role for integrin signaling.[200] In addition, the role of the signaling molecule phospholipase C (PLC)-γ-1 was explored by Park et al.[201] Their studies suggested a possible involvement of PLC-γ-1 in cholesteatoma pathogenesis.

Expression of interleukins has been documented by several investigators. In general, genes encoding proinflammatory cytokines are expressed very rapidly, within 6 hours of middle ear inoculation with bacteria, and decline by 24 hours.[140,202] Anti-inflammatory and immunoregulatory cytokines are expressed over a much longer time course, with some lasting for weeks.[203,204]

John and Nam reported that the concentration of nitric oxide (NO), an important intracellular second messenger, is higher in middle ear effusion.[205] In experimental chronic OM, endothelial nitric oxide synthase (eNOS) mRNA is increased and inducible nitric oxide synthase (iNOS) gene expression is dramatically up-regulated.[142] In addition to the role of NO in the pathogenesis of OM, Juhn et al provided evidence indicating that NO may be involved in the cochlear transduction process.[206]

The role of mitogen-activated protein (MAP) kinases in the pathogenesis of OM has been explored. Li et al investigated the signal transduction mechanisms involved in *H. influenzae*–induced mucin up-regulation and found that *H. influenzae* up-regulates mucin gene transcription via activation of a Rac-dependent MEKK-SEK-p38 MAP kinase

pathway, suggesting that *H. influenzae* up-regulates mucin transcription via activation of an intracellular signaling pathway different from *Pseudomonas aeruginosa*.[207,208] In addition to the involvement of p38, Xu et al reported that oxygen radical species (ROS) may be involved in activation of p38 MAP kinase, which, in turn, led to the activation of mucin transcription.[209] Chun et al also showed that MAP kinase ERK (extracellular signal regulated) is involved in IL-1-induced down-regulation of surfactant protein B in the middle ear.[210]

Transcription factor nuclear factor kappa B (NF-κB) has been shown to play an important role in inflammatory responses. One possible involvement of NF-κB is to regulate the transcription of proinflammatory cytokines. It has been shown that activation of NF-κB is involved in IL-8 gene expression in human adenoidal fibroblasts.

Mucin Gene Expression in the Middle Ear and Up-regulation of Mucin in Otitis Media Mucins are high-molecular-weight glycoproteins that constitute the major component of mucus in the middle ear, trachea, and digestive and reproductive tracts. They protect epithelia and trap particulates, including bacteria, for mucociliary clearance. In diseases such as OM, chronic bronchitis, and cystic fibrosis, mucin production is up-regulated, which, in turn, contributes to the pathogenesis of diseases. In OM with effusion, overproduced mucin is believed to play an important role in causing conductive hearing loss as well as defective mucociliary clearance and recurrent infection.

Progress has been made in the study of mucin gene expression in the middle ear and eustachian tube. Chun et al examined human mucin gene expression and found that mucin *MUC2, MUC5AC*, and *MUC5B* genes are expressed in human middle ear epithelial cells.[210] A similar result was found in human primary cultures of middle ear epithelial cells by Moon et al.[211] In addition to mucin gene expression in the middle ear, Lin et al also reported the expression of glycoconjugates in human eustachian tubes.[212]

More attention has been given to determining mucin expression in OM middle ear mucosa and effusions. Hutton et al isolated and purified high-molecular-weight mucins from effusions of children with OM with effusion and provided direct evidence for expression of different mucin gene products.[213] In consistence with this study, Jung et al reported that human *MUC5AC, MUC5B, MUC7*, and *MUC8* are all expressed in the middle ear mucosa of patients with chronic OM.[214] In the study reported by Severn et al, human *MUC1* and *MUC2*, in addition to *MUC5AC* and *MUC5B*, were also found to be expressed in middle ear mucosa.[215]

Efforts have also been made toward understanding the molecular mechanisms controlling mucin overproduction. Wang et al investigated the role of *H. influenzae* in mucin up-regulation and found that *H. influenzae* up-regulates mucin *MUC5AC* gene transcription via activation of a p38 MAP kinase pathway, suggesting that *H. influenzae* up-regulates mucin transcription via activation of intracellular signaling pathway different from *P. aeruginosa*.[207,216] Interestingly, in addition to the involvement of p38 in mucin up-regulation, Shuto et al showed that activation of p38 also plays an important role in inflammatory responses.[217] The role of proinflammatory cytokines in mucin regulation has also been studied by Lin et al.[212] Their studies showed that tumor necrosis factor-alpha (TNF-α) up-regulates mucin *MUC2* gene expression in the middle ear of rats. All of these studies suggest the complexity of regulatory mechanisms underlying mucin up-regulation in OM.

Epithelial Antimicrobial Peptides and Proteins in the Pathogenesis of Otitis Media It is now believed that in addition to the components of the adaptive immune system, the homeostasis of the nasopharyngeal tract, eustachian tube, and middle ear is also maintained by epithelial antimicrobial proteins and peptides that function to defend these tissues against microbial invasion. The larger antimicrobial proteins are often lytic enzymes, nutrient-binding proteins, or proteins containing sites that target specific microbial macromolecules. The smaller antimicrobial peptides (defined as peptides containing fewer than 100 amino acids) act, at least in part, by disrupting the structure or function of microbial cell membranes. Included in the molecules of the innate immune system are the defensins, lysozyme, lactoferrin, and members of the collectin family, including the surfactant proteins A and D.[218]

The defensins are cationic (polar) molecules with spatially separated hydrophobic and charged regions. In vitro, the defensins (at micromolar con-

centrations) have a broad spectrum of antimicrobial activity against bacteria, fungi, and even some enveloped viruses.[219] In humans and other vertebrates, the defensins can be divided into the α- and β-defensin subfamilies. The α-defensins are produced by neutrophils and intestinal Paneth's cells.[220] The β-defensins, on the other hand, are mainly produced by epithelial cells of the skin, kidneys, and tracheabronchial lining of nearly all vertebrates.[221] The β-defensins are released on microbial invasion and are located at the host–environment interface, such as mucosal surfaces and skin. Two types of human β-defensins, β-defensins 1 (HBD-1) and 2 (HBD-2), have been identified. Human β-defensin 2 is produced by epithelial cells and exhibits potent antimicrobial activity against gram-negative bacteria and *Candida.* But it is not as effective against gram-positive *Staphylococcus aureus.*[222,223] Human β-defensin represents the first human defensin that is produced following stimulation of epithelial cells by contact with microorganisms or cytokines such as TNF-α and IL-1α. Human β-defensin 2 functions as a NF-κB target gene in the intestinal epithelium, but HBD-1 is not affected by IL-1α and other proinflammatory stimuli.[221] The presence of HBD-1 has been reported in the pars tensa and pars flaccida of the tympanic membrane and in the meatal skin.[224] Recently, Lim et al demonstrated that both HBD-1 and HBD-2 are expressed in human middle ear epithelial cells and that both molecules have bactericidal/bacteriostatic activity against NTHi.[218]

Lysozyme is an important component of innate immunity against pathogens at mucosal surfaces. Human chronic middle effusions contain high levels of this molecule, which is produced by secretory cells of the middle ear mucosal epithelia, as well as by polymorphonuclear leukocytes and macrophages.[218,226] Lim and coworkers have shown that human milk–derived lysozyme, in combination with other innate immune molecules, exhibits antibacterial activity against NTHi.[218]

Lactoferrin is an iron-binding glycoprotein found in the milk and exocrine secretions of mammals that is released from neutrophilic granules during inflammation.[227,228] Lactoferrin has also been detected in middle ear effusion and has been localized to the serous cells of eustachian tube glands, as well as the cuboidal epithelium of the transition zone of the middle ear.[229,230]

The collectins are proteins that are related structurally and functionally to the first component of the classic complement pathway C1q and are known to play significant roles in innate immunity through opsonization and complement activation.[231,232] The collectin family of proteins includes the mannose binding protein, conglutinin, CL-43, and surfactant proteins A and D. Surfactant proteins A and D are expressed in the middle ear and eustachian tube and are likely to be involved in the protection of the tubotympanum against OM pathogens.[218]

Gene Transfer to the Middle Ear Mucosa Ryan et al successfully implanted cells that had been stably transformed to secrete FGF-1 into the subepithelial compartment.[137] Mondain et al demonstrated that an adenovirus vector can be used to transduce cells of the adult guinea pig middle ear mucosa.[233] Similarly, Dazert et al demonstrated adenovirus transduction of mucosal cells in the neonatal rat.[133] These studies demonstrate the feasibility of gene therapy in the middle ear cavity for the treatment of OM.

FUTURE DIRECTIONS

The explosive pace of development of molecular techniques does not allow us to do justice in this chapter to all aspects of molecular biology that are relevant to otology. We have just begun to scratch the surface of many important areas of biology of the ear with these new tools. The availability of such powerful techniques is already beginning to impact our understanding of cellular functions and malfunctions on a molecular level. Identification of genes important for the formation of the ear and the maintenance and normal function of the sensory and nonsensory cells of the inner ear are now possible, and discovery of many new genes of importance will be accelerated. Many more transgenic animals and gene knockout animals of interest will be made available, and these animals will propel our knowledge concerning specific gene functions important for the ear.

Although only limited attempts have been made, many innovations for gene or gene-based therapy will allow scientists to develop new approaches (eg, antisense oligonucleotide therapy) to prevent or cure human diseases, which currently cannot be ameliorated.

For OM, molecular biologic techniques already have made a major impact on our understanding of bacterial pathogenesis at the molecular level. We are beginning to understand the molecular mechanisms involved in bacteria–host interaction. A number of OM-causing bacterial surface antigens important for the protective host immune response have now been identified, and their genes are cloned. Molecular methods will allow us to incorporate this new knowledge in developing strategies to prevent and treat OM. The molecular biology of host responses, including the innate and acquired immune responses, cytokine and β-defensin regulation, inflammatory cell mobilization, B and T cell activation, tissue proliferation, and mucin regulation, constitutes a large body of knowledge that is relevant for understanding the pathogenesis and progression of OM. Rapid progress is being made in these areas, including identification of genes regulating various aspects of host responses, which will impact the way we manage OM in the future.

In summary, molecular biologic techniques are no longer an esoteric scientific curiosity; rather, they are beginning to be used in diagnosis, new vaccine development, and even gene therapy. Many more molecular biology–based innovative approaches will become available in the future, which will ultimately change our understanding and treatment of these diseases.

CHAPTER 4

Physiology of the Auditory and Vestibular Systems

Brenda L. Lonsbury-Martin, PhD, Glen K. Martin, PhD, Anne E. Luebke, PhD

AUDITORY SYSTEM

General Principles

Over the past three decades, major advances have occurred in our knowledge about how the ear achieves its high sensitivity, sharp frequency tuning, vast dynamic range, and precise temporal resolution. This accumulated wisdom has led to a new understanding about the unique functions of the inner hair cells (IHCs) and outer hair cells (OHCs) of the cochlea. Traditionally, the transfer of information about sounds from the environment to the higher centers of analysis in the central auditory nervous system was considered to be entirely a passive process. According to conventional thinking, the salient features of sound, including frequency, magnitude, and timing attributes, were principally encoded by peripheral processes and then simply passed relatively unaltered along the ascending system, from one structure to another, in a forward-moving manner. With the discoveries that the healthy ear can generate sounds in the form of otoacoustic emissions (OAEs) and that OHCs mechanically vibrate in response to depolarizing stimuli, the role of the cochlea in analyzing acoustic signals is now considered to represent an active process. Given the assumption that the vibromechanical aspects of OHC function underlie the production of OAEs and the awareness that the major portion of the cochlear efferent system innervates this particular class of auditory sensory cell, it is clear that central auditory centers may also modify peripherally generated responses in an active manner. Thus, rather than conceptualizing the role of the auditory system as a passive analyzer of environmental sounds, the modern view is to consider it as an active participant in controlling acoustic information so that the most meaningful features are registered.

Auditory Apparatus

A traditional approach toward understanding the primary sensitivity, frequency tuning, and timing functions of the peripheral auditory system is to divide the periphery into three discrete parts. In this manner, the unique contributions that the external, middle, and inner ear (ie, cochlea) make to the overall analysis of sound can best be appreciated.

External Ear

The external ear or pinna of the mammal is regarded as a simple funnel that collects and crudely filters sound. Given the immobility of the human external ear, it is assumed that this frequency tuning function is performed passively. However, evidence from experimental studies suggests that the human pinna serves two functions: (1) it aids in sound localization, especially front-to-back and high-to-low distinctions, where interaural time differences provide no clues, and (2) along with the external ear canal, it increases acoustic pressure at the tympanic membrane in the 1.5 to 5 kHz range, which is the frequency range most important for speech perception. Evidence for the sound-localizing function of the human external ear includes the demonstration of accurate sound localization in patients with monaural hearing and the loss of this localization ability when the pinna of the hearing ear is strapped to the head. In addition, abnormally poor sound localization around an "imperfectly" remodeled pinna has been reported.[1]

In summarizing available data on the role that the external ear plays in boosting sound pressure at the tympanic membrane, Shaw described the contributions of the distinct parts of the head and neck and external ear by successively adding their different components in a model.[2] According to this clas-

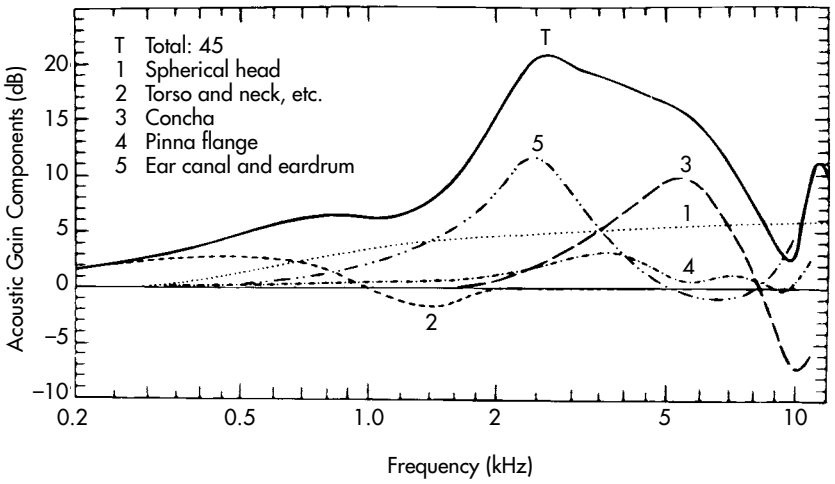

FIGURE 4–1. Pressure gain contributed by the individual components of the outer ear in humans. The total (T) curve plots the overall gain based on the addition of the various components in the order listed with the sound source positioned 45 degrees from straight ahead. Reprinted with permission from Shaw EAG.[2]

sic analysis, shown in Figure 4–1, most of the individual components of the external ear provide complementary gains, resulting in a significant increase in sound pressure from approximately 2 to 7 kHz. When the overall additive effect is appreciated ("T" in Figure 4–1), it can be seen that at certain frequencies this gain is substantial, resulting in sound pressure increases on the order of 20 dB.

Studies of models of the human external ear suggest that the pinna extracts information about sound location by altering the transmission properties of different frequencies according to the location of the sound source relative to the pinna. For example, when the sound source is behind the ear, interference of directly transmitted sound with sound waves scattered off the pinna flange or helix alters the response in the 3 to 6 kHz range. Thus, the external ear modifies the spectrum of the incoming sound, allowing an individual to make judgments about the location of unknown sound sources. This localization ability suggests that the central part of the auditory system can use very subtle spectral cues in the analysis of environmental sounds.[3]

Middle Ear

Figure 4–2 outlines the anatomy of the middle and inner ears. The middle ear ossicles form a transmission pathway that conducts sound energy from the tympanic membrane, at the interface of the external and middle ear, to the oval window of the cochlea. The discussion of middle ear function is separated into two categories: (1) "impedance matching" between the air of the external environment and the fluids (perilymph and endolymph) of the cochlea and (2) the acoustic reflex of the middle ear muscle system.

The widespread use of surgical modification of middle ear structures to improve hearing and the usefulness of immittance audiometry make the concept of acoustic impedance and its relationship to middle ear function important to the clinician. Accordingly, the discussion of the middle ear begins by reviewing some basic principles of acoustic impedance.

Transmission of Acoustic Energy Through the Middle Ear Figure 4–3, A, diagrams the route for the transmission of sound energy through the middle ear into the cochlear portion of the inner ear. The ossicular chain (see Figure 4–2), consisting of the malleus, incus, and stapes, can be thought of as a lever system. The tympanic membrane moves the manubrium or handle of the malleus. In turn, the long process of the incus and manubrium move together because the malleoincudal joint is essentially fixed. In contrast, the joint between the incus and the stapes is flexible. Therefore, because the stapes is fixed at its posteroinferior border, movement of the tympanic membrane causes it to rock in and out of the oval window. The changes in acoustic pressure caused by the stapes moving in and out of the oval window are transmitted instantaneously by the perilymph through the cochlear partition and then to the round window. This pressure transmission through the cochlear partition causes it to move either upward or downward, depending on the direction of the pressure change. The pressure

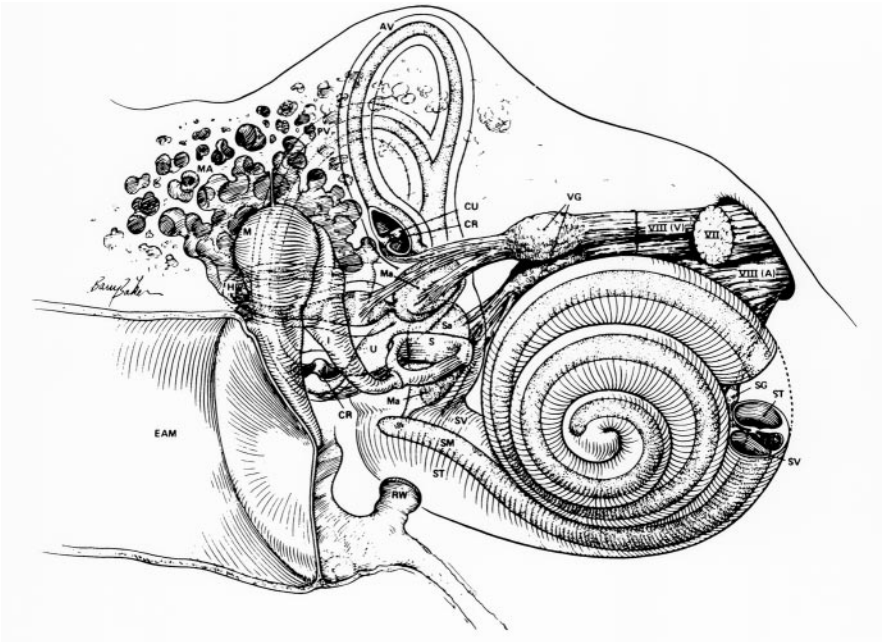

FIGURE 4–2. Schematic drawing of the inner ear (labyrinth), which consists of a series of tunnels within the petrous portion of the temporal bone. The osseous labyrinth (outer tunnel) is clear, and the membranous labyrinth (inner tunnel) is stippled. SV = scala vestibuli; ST = scala tympani; SM = scala media; SG = spiral ganglion, containing the cell bodies of the auditory nerve; VG = vestibular ganglia, containing the cell bodies of the vestibular nerve; VIII (A) = auditory part of the eighth cranial nerve; VIII (V) = vestibular part of the eighth cranial nerve; VII = facial nerve; Ma = macula; CU = cupula; CR = crista; Sa = sacculus; U = utriculus. Semicircular canals are labeled AV (anterior vertical), PV (posterior vertical), and H (horizontal). EAM = external auditory meatus; RW = round window; M = malleus; I = incus; S = stapes; MA = mastoid air cells in temporal bone.

change initiates a mechanical traveling wave, shown in Figure 4–3, B, that reaches a maximum at some point on the basilar membrane depending on the frequency of the stimulating sound. The mechanical traveling wave moves from the base to the apex of the cochlea largely owing to a reduced stiffness of the basilar membrane in the apical direction. As discussed below, this traveling wave disturbance causes the hair cells in the organ of Corti to stimulate the dendritic endings of the cochlear nerve, thus signaling to the central auditory system that a sound stimulus has occurred.

At high sound levels of ~100 to 110 dB SPL (sound pressure level), the mode of vibration of the ossicular chain changes. Thus, instead of rotating about its short axis, as shown in Figure 4–3, A, the stapes footplate turns about its long axis.[4] Because this change results in less efficient sound transmission through the middle ear, it likely serves a protective function. Interestingly, the change in vibration mode occurs at the threshold of feeling, thus suggesting that the somatic sensation caused by excessive sounds may be caused by the detection of the altered ossicular vibration by middle ear bone and tendon receptors.

Impedance Matching by the Middle Ear Hearing by terrestrial animals requires transmission of sound from an air to a fluid environment. A useful way to appreciate the problem in conducting sound effectively between two distinct media is to recall how difficult it is to listen to sounds produced even a few inches above the surface while swimming underwater. Thus, direct transmission of sound across an air/water boundary is extremely inefficient because the specific acoustic impedances of air and water differ greatly. Moreover, whenever energy is transmitted between media with different specific impedances, much of the energy is reflected back from the boundary between the two media. To help solve this problem, the middle ear matches reasonably well the impedances of the air with those of the

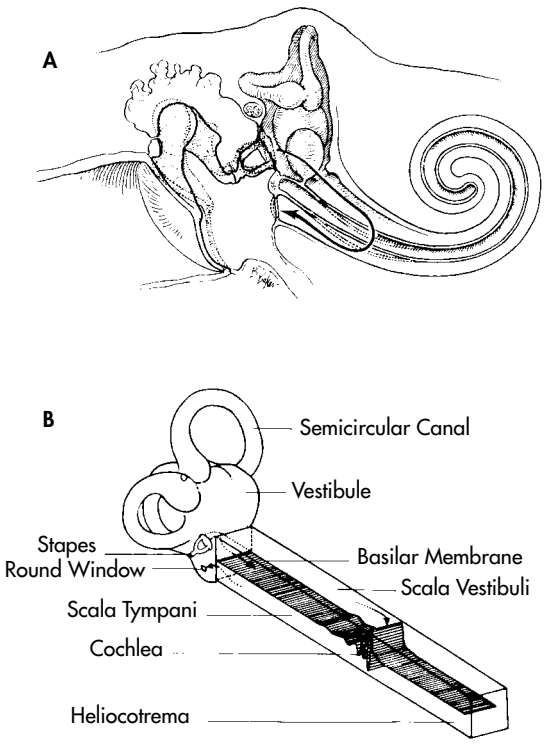

FIGURE 4–3. A, Transmission of tympanic membrane movement to the cochlea via the ossicles. The system at rest is unstippled. The stippled ossicles and dashed cochlear partition illustrate the system when the tympanic membrane is pushed inward by a sound wave. *B*, Inward pressure (*arrows*) initiates a traveling wave that migrates toward the apex of the cochlea (toward the helicotrema). This propagation depends largely on fluid coupling and the fact that the basilar membrane changes in stiffness, with the traveling wave moving from a region of highest stiffness (base) to a point of lower stiffness (apex). Reproduced with permission from Zweig G, Lipes R, Pierce JR. The cochlear compromise. J Acoust Soc Am 1976;59:975–82.

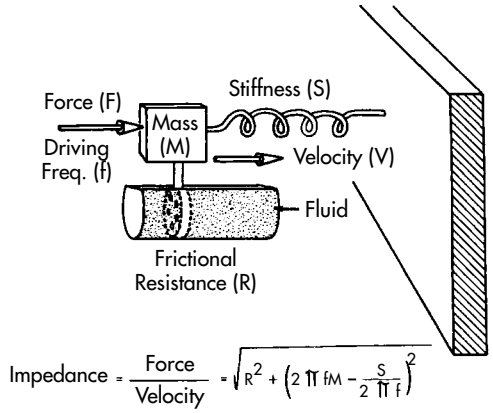

FIGURE 4–4. Principles of mechanical impedance. Frictional resistance is represented by a "dashpot"—a perforated piston operating inside a fluid-filled cylinder. The diagram could be converted to a representation of acoustic impedance by interposing a cylinder, or diaphragm, between the driving force (F) and the driven mass (M) and expressing the displacing input as pressure (ie, force per unit area).

cochlea and thereby greatly increases the efficiency of transmitting acoustic energy from the ambient environment into the cochlea.

The term impedance describes the opposition of a system to movement. Thus, the more force required to move a mechanical system at a given speed, the greater its impedance. Figure 4–4 illustrates the principles of mechanical impedance. The impedance of a mechanical system involves a complex relationship between the three physical parameters illustrated in Figure 4–4. Together, mass, stiffness, and resistance (ie, friction) determine the mechanical impedance of the middle ear system. Friction, the resistive component of impedance, consumes energy and is independent of the driving frequency. Stiffness and mass store energy; thus, they comprise the reactive component of impedance. For example, once the "fluid"-filled cylinder in Figure 4–4 is set in motion, it tends to continue because of inertia, and if the spring representing stiffness is compressed, it tends to push backward.

Acoustic impedance represents a special type of mechanical impedance in which force is replaced by pressure (ie, force per unit area) and the system is driven by sound. Thus, Figure 4–4 could be converted into a diagram of an acoustic system by interposing a piston, or membrane, between the force and the mass.

When air conducts sound, the stiffness component of its acoustic impedance is determined by the elastic coupling between air molecules, the mass component is determined by the mass of the air molecules, and the frictional component is determined by frictional resistance between the molecules. Because water is much denser and less compressible than air, it might seem at first that mass and stiffness create the principal difference between the acoustic impedance of the cochlea and that of air. However, Figure 4–4 demonstrates that transmission of energy into the cochlea does not

involve compression of the cochlear fluid itself. In addition, the elastic restorative forces of the cochlear partition and round window tend to cancel out the effect of the fluid's mass. Thus, the effective acoustic impedance of the cochlea is primarily resistive.[5]

As noted earlier, a primary function of the middle ear is to provide a means of "matching" the low impedance of air with the high cochlear impedance resulting from fluid flow and the distensibility of the cochlear membranes that separate the endolymph from the perilymph. Impedance matching by the middle ear is achieved by three factors: (1) the area of the tympanic membrane relative to the oval window, (2) the lever action of the middle ear ossicles, and (3) the shape of the tympanic membrane. The principles behind these factors are depicted in the three diagrams of Figure 4–5. By focusing the incident sound pressure from the large area of the tympanic membrane onto the small area of the oval window (Figure 4–5, A), the effectiveness of energy transfer between the air of the external ear canal and the fluids of the cochlea is increased greatly. In the human, the area ratio of the tympanic membrane to the oval window is about 20 to 1. However, the tympanic membrane does not vibrate as a whole.[6] Thus, the effective area ratio is only about 14 to 1. The ossicular chain also contributes to the transformer role of the middle ear by a levering action that increases the vibration amplitude (Figure 4–5, B). The ossicular chain lever ratio is around 1.3 to 1. A final factor influencing the efficiency of energy transfer depends on the conical shape of the tympanic membrane that allows a buckling action to occur (Figure 4–5, C). The buckling motion of the tympanic membrane results in an increased force and decreased velocity to produce approximately a fourfold increase in the effectiveness of energy transfer.[7] Together, these actions of the middle ear system result in an estimated overall transformer ratio of 73 to 1.

Middle Ear Muscles Mammals have two small skeletal muscles, the tensor tympani and the stapedius, which are attached to the ossicular chain. In primates, the stapedius muscle, which attaches to

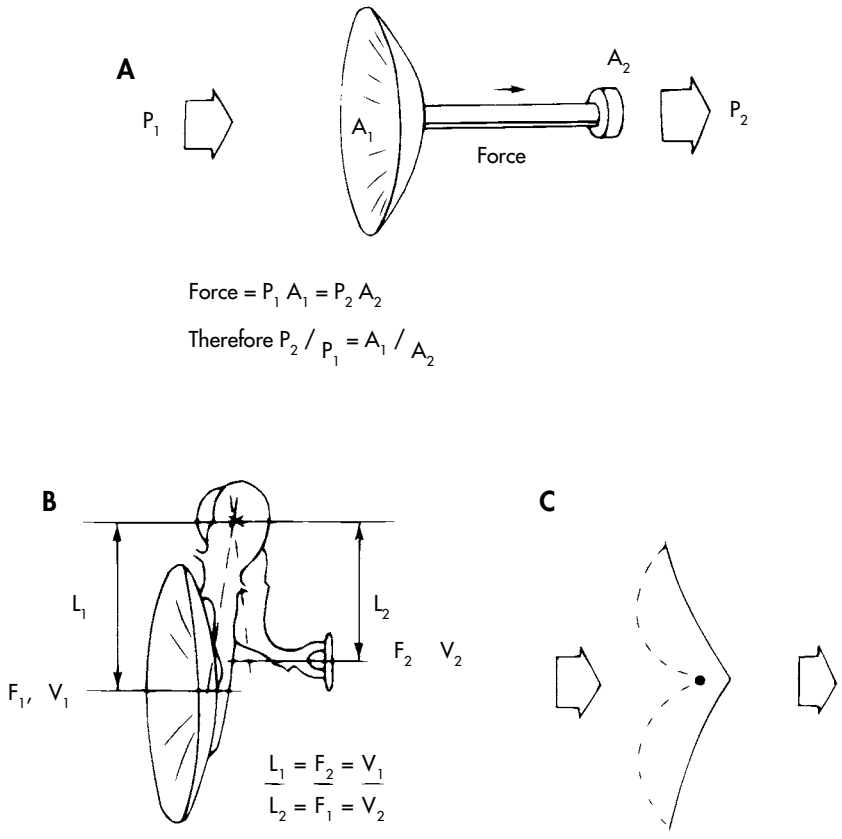

FIGURE 4–5. Illustration of the three principles of impedance matching performed by the middle ear. *A*, The primary factor is the ratio of the area of the tympanic membrane to that of the oval window. *B*, The lever action acts to increase the force and decrease the velocity. *C*, Buckling motion of the tympanic membrane also increases the force while reducing the velocity. Reproduced with permission from Pickles JO.[3]

the stapes and is innervated by the stapedial branch of the facial nerve, contracts reflexively in response to intense sound stimuli. However, the tensor tympani muscle, which attaches to the malleus and is innervated by the trigeminal nerve, probably does not.[8] In laboratory animals such as the cat, rabbit, and guinea pig, both muscles contract in response to loud sound. However, the threshold of the tensor tympani is often higher than that of the stapedius muscle. A four-neuron reflex arc consisting of the afferent fibers of the auditory nerve, neurons of the ventral cochlear nucleus, neurons of the medial superior olive, and facial motoneurons comprises the stapedius reflex pathway illustrated in Figure 4–6 for the rabbit. The reflex arc for the tensor tympani muscle is slightly different in that neurons of the ventral nucleus of the lateral lemniscus are also involved.[9] From the neural pathway depicted in Figure 4–6, it is clear that clinical abnormalities of the acoustic reflex primarily implicate pathology at the level of the lower brainstem.

In Figure 4–7, the sensitivity of the stapedius reflex in humans is plotted as a function of sound frequency. The reflex threshold curve evoked by pure tones parallels the audibility threshold curve but is about 80 dB above it.[10] Not surprisingly, because of their greater overall energy levels, broadband stimuli (eg, white noise) elicit the reflex more effectively than do pure tones.[11] Experimental evidence indicates that the stapedius reflex threshold decreases with increasing stimulus duration, with a time constant of about 200 ms.[12] This value approximates the time constant of temporal summation for the percepts of loudness and sensitivity. These findings, along with the clinical observation that the stapedius reflex exhibits "recruitment" in patients with cochlear hearing loss,[13] suggest that the acoustic reflex threshold correlates more with subjective loudness than with absolute stimulus intensity.

Contraction of the middle ear muscles can also be caused by nonauditory factors, including (1) spontaneous contractions, (2) body movements,[8] (3) vocalizations in which contractions begin prior to vocalization[8] (ie, prevocalization contractions), (4) movements of facial muscles involving only the tensor tympani,[8] (5) stimulation of the external ear canal,[14] and (6) voluntary contractions.[15]

As diagrammed in Figure 4–8, the stapedius muscle moves the stapes footplate backward and into the oval window, whereas the tensor tympani muscle pulls the manubrium inward. The effects of these contractions on the transmission of pure tones through the middle ear are illustrated in Figure 4–9.[15,16] In summary, the transmission of low-frequency sounds is attenuated by contraction of either muscle,[11] but the stapedius is probably a somewhat better attenuator than the tensor tympani.

The function of the human acoustic reflex has been studied by recording (1) gross muscle potentials via the electromyogram,[8] (2) pressure changes in the external auditory canal,[17] and (3) acoustic immittance changes.[11,13] The clinical application of acoustic impedance measurements is known as immittance audiometry, with the terms "impedance" and "immittance" being interchangeable. In Figure 4–10, the time course is shown for the human stapedius reflex as recorded by the immittance change method. The latency or time to the first detectable change generally varies from 10 to 30 ms, whereas the reflex decays over about 500 ms after the onset of the stimulus. The initial reduction in impedance is frequency dependent.

To date, acoustics-based clinical evaluations of middle ear function using immittance audiometry are an important part of the audiologic diagnostic test battery. However, they are not specific enough to represent independent diagnostic tests mainly because of limitations in the frequency range over

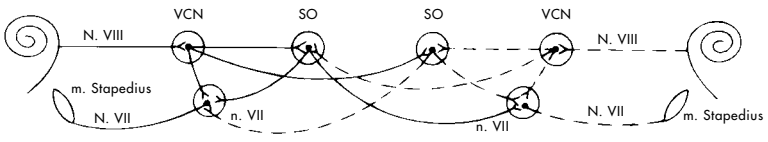

FIGURE 4–6. Neural pathway for the acoustic middle ear reflex in the rabbit. Reflex is mainly a chain of four neurons with a small ipsilateral three-neuron link. N. VIII = auditory nerve; N. VII = facial nerve; VCN = ventral cochlear nucleus; SO = superior olive; n. VII = facial nerve motoneuron. Reproduced with permission from Møller AR. Auditory physiology. FIGURE 4–7. Sensitivity of the human acoustic reflex. *Dashed lines* from four subjects plot stimulus levels required to elicit an acoustic reflex with 10% of the maximum obtainable amplitude (measured with an immittance technique). The *solid line* is the threshold of audibility raised 80 dB. Reprinted with permission from Møller AR.[10]

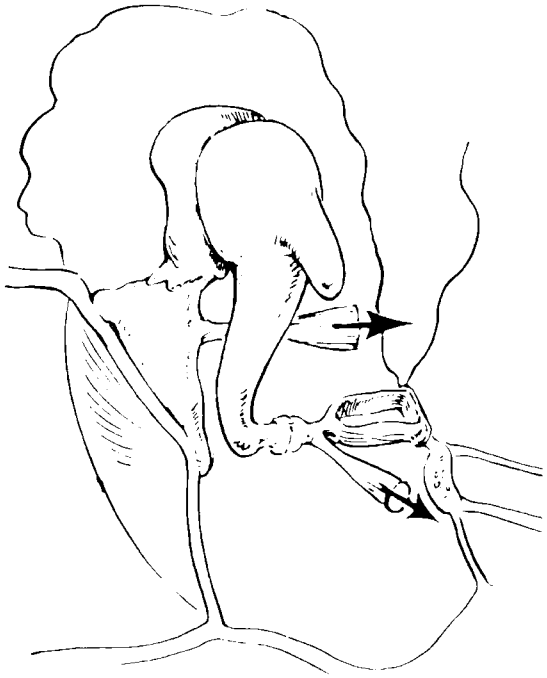

FIGURE 4–8. Action of the middle ear muscles. The view is from behind the head. The muscles are not drawn to scale. The tensor tympani muscle (*top arrow*) attaches to the handle of the malleus and pulls it backward, tensing the tympanic membrane. The stapedius muscle (*bottom arrow*) attaches to the neck of the stapes and pulls the posteroinferior border of the stapes down and into the oval window.

which impedance is easily measured at the tympanic membrane and the wide variations in their normal values. Currently, several new techniques, ear canal reflectance[18] and tympanic membrane velocity measurements,[19] are being investigated to determine if they can act as more specific indicators of middle ear dysfunction.

One major function of the middle ear muscles is to support and stiffen the ossicular chain.[11] In addition, because loud sounds are attenuated by the actions of the acoustic reflex, it is likely that another function of the reflex is to protect the inner ear against the damage that can be caused by overexposure to excessive sounds. This notion is supported by the results of a study investigating the amount of temporary threshold shift in patients suffering from acute Bell's palsy, which represents a disease in which the stapedius muscle is completely paralyzed.[20] These patients showed a greater threshold shift in the affected ear after exposures to low-frequency noise than in the opposite ear with a normal stapedius reflex. However, whether this protective effect is a "true" function of the stapedius reflex has been criticized on the basis that the continuous loud sounds against which the reflex is supposed to protect do not exist in nature.[21]

An alternative middle ear muscle function could be to attenuate low-frequency masking sounds that might otherwise interfere with auditory function. Contractions during chewing and other facial and body movements would attenuate the resultant internal body sounds, which are largely low frequency, while preserving sensitivity to high-frequency external sounds. The low-frequency attenuation produced by contractions prior to vocalization may also be functionally important. Observations that support a middle ear muscle role in vocalization and in speech discrimination are as follows: (1) patients with otosclerosis show significant deficits when administered the delayed feedback test for malingering,[22] (2) stutterers have a deficit in prevocalization middle ear muscle contraction,[23] and (3) absence of the stapedius reflex results in decreased speech discrimination when the level of speech is raised above 90 dB SPL.[23]

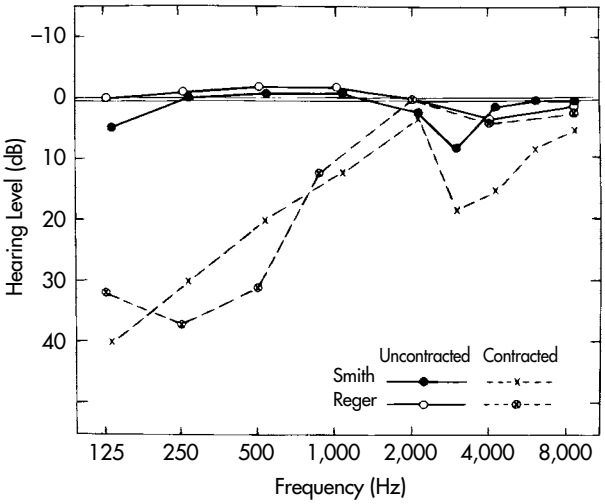

FIGURE 4–9. Effect of middle ear muscle contractions on pure-tone thresholds. The curves were obtained from normal subjects with the ability to voluntarily contract their middle ear muscles.[15,16] Although the effect of voluntary contraction may differ from the effect of normal involuntary contraction, the general observation that middle ear muscle contractions preferentially attenuate low frequencies is probably valid.

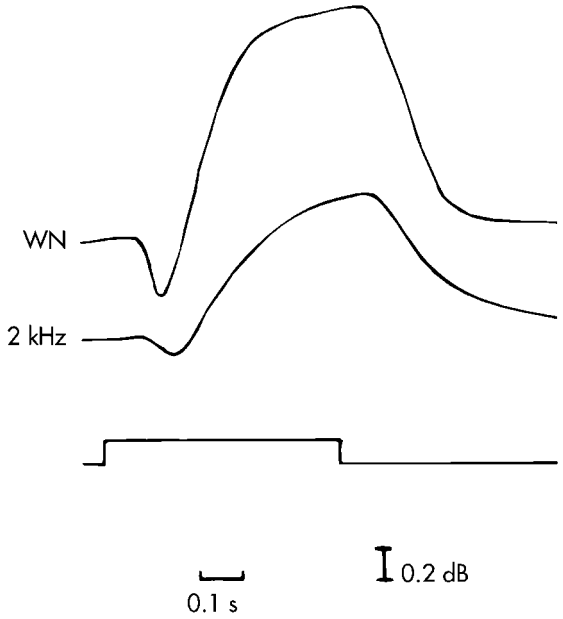

FIGURE 4–10. Time course of human stapedius contractions in response to white noise (WN) and 2 kHz pure-tone stimuli. *Bottom trace* shows stimulus time course. The stimuli were 90 dB above normal threshold and were delivered to the right ear. The muscle contractions were recorded from the left ear by the acoustic immittance change method. COCHLEA

The cochlea performs two basic functions as (1) a transducer that translates sound energy into a form suitable for stimulating the dendritic endings of the auditory nerve and (2) an encoder that programs the features of an acoustic stimulus so that the brain can process the information contained in the stimulating sound. Each of these functions is considered below.

Transducer Function

ANATOMY. As shown in Figure 4–11, A, the cochlea is divided into three tubes or scalae. The middle tube or scala media is the cochlear extension of the membranous labyrinth and is filled with a potassium (K^+)-rich, sodium (Na^+)-poor electrolyte fluid called endolymph. The outer two tubes, the scala vestibuli and the scala tympani, constitute the osseous labyrinth. They are separated by the scala media and filled with perilymph, a Na^+-rich, K^+-poor electrolyte fluid. When the cochlea is activated by sound, the scala media and its contents, bounded superiorly by Reissner's membrane and inferiorly by the basilar membrane, tend to move as a unit. This space is referred to as the "cochlear partition."[4]

The contents of scala media are illustrated in Figure 4–11, B. The auditory nerve fibers synapse at the bases of the hair cells of the organ of Corti. The dendrites of the auditory nerve enter the scala media through the habenulae perforatae, where they lose their myelin sheaths. The reticular lamina and the tectorial membrane are two membranes in the organ of Corti that are particularly critical in stimulus transduction. The reticular lamina, supported by the rods of Corti, resembles a stiff net with its webbing enmeshing the apical surfaces of the hair cells. Together, the rods of Corti and the reticular lamina provide the skeletal support of the organ of Corti.

The boundary separating the high-K^+ and high-Na^+ electrolytes is formed by the reticular lamina. As diagrammed in Figure 4–12, tight junctions, which are generally thought to present a barrier against ionic diffusion, are observed by scanning electron microscopy (SEM) between all cells that face the endolymphatic space. Figure 4–12 also indicates that the junctions between nonsensory epithe-

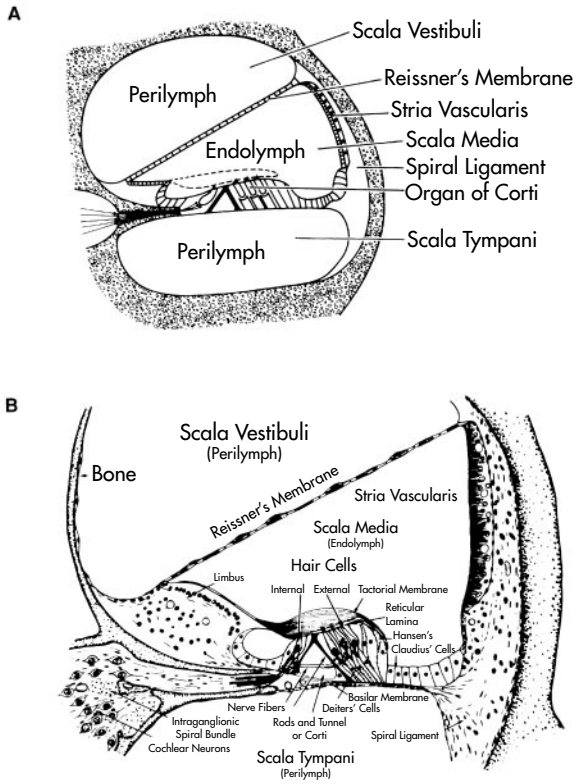

FIGURE 4–11. A, Simplified drawing depicting a cross-section through one turn of the cochlea showing the three compartments (scalae). The middle compartment (scala media) is filled with K^+-rich endolymph. The other two compartments (scala tympani and scala vestibuli) are enclosed in the osseous labyrinth. These compartments are filled with Na^+-rich perilymph. *B*, Semidiagrammatic representation of a cross-section of the guinea pig cochlear duct. *A* reproduced with permission from Salt AN, Konishi T. lium (eg, the cells of Hensen and Claudius, the cells lining the spaces of Nuel, and the cells of Reissner's membrane) are not as "tight" (dotted line) as the junctions between the sensory cells and the basal cells (solid line) of the stria vascularis.[24] The fluid within the organ of Corti (ie, between the basilar membrane and the reticular lamina) has been termed cortilymph.[25] However, the fluid in this space is in free communication with the perilymph of scala tympani via relatively large channels through the basilar membrane.[26] Thus, cortilymph is probably identical to perilymph with respect to its electrolyte content. The tectorial membrane resembles a rather stiff, oval, gelatinous tube. It is attached to the limbus by a flexible membranous band that allows it to move up and down like the cover of a book.[27]

Mammals have three rows of OHCs. A fourth row of OHCs is seen in an occasional cross-section, especially in primates, but there is no well-defined fourth row.[28] There is only one row of IHCs. The fine finger-like projections present on the apical surface of the hair cells are called stereocilia. The detailed arrangements of the stereocilia on the hair cell apices are unique to each class of receptor and are illustrated in the SEM of Figure 4–13. The IHC stereocilia form a longitudinally oriented, relatively shallow curve, whereas the OHC cilia make a radially oriented "V," with a notch at the apex marking the site of the missing kinocilium that degenerates embryonically during development of cochlear hair

cells. The OHC stereocilia vary systematically in length in that they are longest at the apex of the V and shorten progressively from the apex to the distal limbs. Whereas the longest OHC stereocilia attach to the undersurface of the tectorial membrane, it is probable that the shorter cilia do not.[29] However, an interconnecting network of fine fibrils links the entire bundle of stereocilia, both laterally and from tip to tip, so that it moves as a unit.[30]

Until recently, little was known about stereocilia bundles. However, their importance in the transduction process has stimulated considerable research directed toward understanding the morphologic and physiologic properties of hair cell bundles and their separate stereocilia. The detailed structure and arrangement of individual hair cell bundles vary across species and even as a function of position along the organ of Corti. However, a number of general features of stereocilia bundles and individual cilia have been described, including (1) each bundle consists of 30 to 150 stereocilia arranged in several rows of decreasing length, (2) individual cilia range from 0.8 to 0.2 μm in diameter and increase in length from cochlear base to apex, and (3) each stereocilium is covered with a charged cell coat material that has been postulated to keep individual stereocilia from fusing together.[31]

Using various techniques, Flock and coworkers demonstrated that stereocilia contained the proteins actin and fimbrin.[32,33] Whether stereocilia are associated with motile responses owing to their musclelike composition is still not fully resolved. Indeed, one current proposition is that stereocilia and their associated ion channels participate in an amplificatory process that sensitizes and sharpens hearing.[34] However, the unidirectional orientation of the actin filaments[35] suggests that these proteins serve a structural, rather than a contractile, role.

Functional studies of the mechanical properties of stereocilia[36] showed that the cilia are stiff and pivot at their bases. When too much force is applied, the stereocilia break as if they were brittle. Noise exposure studies have also demonstrated the vulnerability of stereocilia to damage.[31] That is, the tallest stereocilia are affected first by becoming floppy owing to alterations in their membrane and cytoskeleton. With continued noise exposure, the stereocilia fuse and then degenerate, resulting in permanent hearing loss. In fact, the earliest measurable hearing changes resulting from noise exposure probably involve alterations in the stereocilia of the cochlea's hair cells.[31]

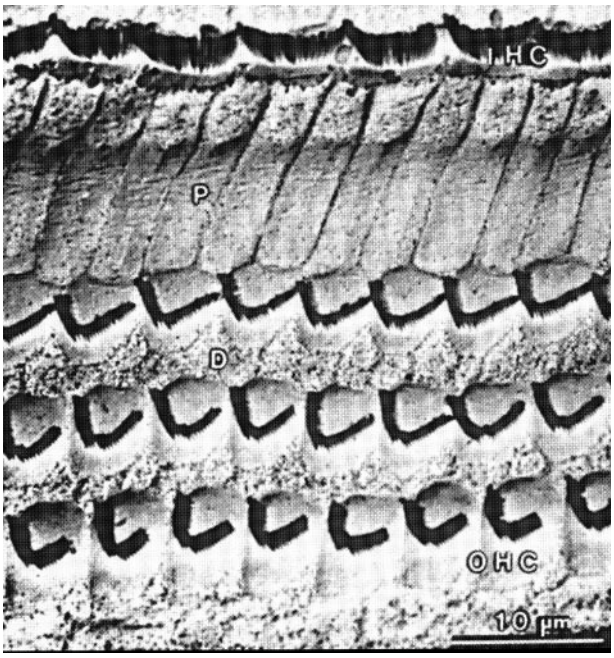

FIGURE 4–13. Scanning electron micrograph of the surface of the organ of Corti after removal of the tectorial membrane. A single row of inner hair cells (IHC) has cilia arranged in a linear (or shallow "U") pattern, whereas the three rows of outer hair cells (OHC) have stereocilia arranged in a "V" pattern. D = Deiters' cells; P = pillar cells. Reproduced with permission from Harrison RV, Hunter-Duvar IM. An anatomical tour of the cochlea. In: Jahn AF, Santos-Sacchi J, editors. Physiology of the ear. New York: Raven Press; 1988.

Mechanical Transduction. The final mechanical event in the cochlear transduction process is the bending of the stereocilia, as illustrated in Figure 4–14. Basilar membrane deformation causes a shearing action between the reticular and tectorial membranes. Because the long OHC cilia are attached to both membranes, they are bent (Figure 4–14, B). In contrast, the IHC cilia, and possibly also the shorter OHC cilia, which are not attached to the tectorial membrane, bend in response to some mechanism other than displacement shear. One proposition is that this process may involve fluid streaming between the sliding parallel plates formed by the reticular and tectorial membranes.[37] Fluid streaming would result from differences between the relative

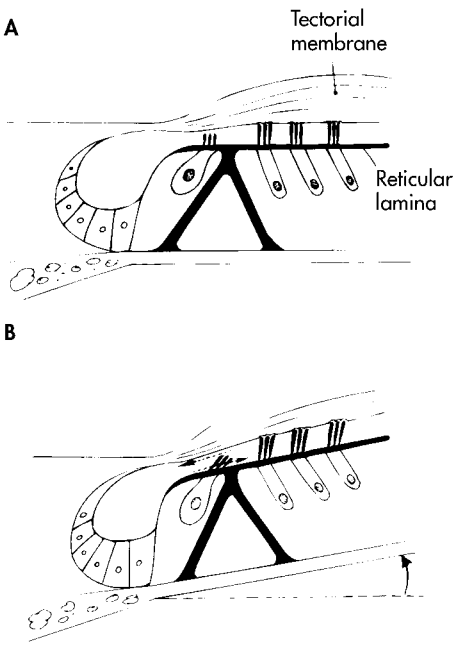

FIGURE 4–14. Translation of basilar membrane displacement (as shown in Figure 4–3) into bending of the hair cell cilia. *B*, Basilar membrane displacement (*arrow*) indicates the shearing action between the tectorial membrane and the reticular lamina bends the OHC cilia, which are attached to both structures. Streaming movement, imparted to the fluid between the reticular lamina and the tectorial membrane, may bend the inner hair cell cilia, which are not attached to the tectorial membrane. Inner hair cell cilia deflection may be longitudinal (ie, perpendicular to the page) rather than radial, as depicted.

velocities of the two membranes rather than by their relative displacements. Thus, the IHCs may be velocity sensors and the OHCs displacement sensors.[38] However, other notions about the unique functions of OHCs versus IHCs have also been proposed.[39] For example, von Békésy noted that the shearing action between the two membranes could reduce the displacement amplitude of the stimulating energy while increasing its force.[4,40] Thus, the shearing action may serve to match the impedances of fluid and solid transmission media, just as the middle ear matches air and fluid impedances.

Electrical Potentials of the Cochlea Using gross microelectrode methods, three cochlear bioelectric events have been studied extensively: (1) the endocochlear potential (EP), (2) the cochlear microphonic (CM), and (3) the summating potential (SP). Whereas the EP is present at rest, the CM and SP appear only when sound stimulates the ear.

Endocochlear Potential. The EP is a constant (DC), +80 mV potential that can be recorded with an electrode in scala media.[41] The majority of evidence indicates that the stria vascularis generates the EP.[42] Because it is extremely sensitive to anoxia and chemical agents interfering with oxidative metabolism,[43] its existence likely depends on the active metabolic ion pumping processes of the stria vascularis. The anatomic distribution of the EP closely approximates the limits of the endolymphatic compartment formed by the tight junction boundaries shown in Figure 4–12. The augmentation of the voltage drop cross the apical ends of the hair cells that the EP provides is thought to be critically important in cochlear transduction.[44]

Cochlear Microphonics and Summating Potentials. When the appropriate stimulus is applied, most sensory end-organs generate bioelectric events called receptor potentials. These potentials differ from action potentials in that (1) they are graded rather than all or none, (2) they have no latency, (3) they are not propagated, and (4) they have no apparent post-response refractoriness.[45] The SP and CM form the receptor potentials of the cochlea and can be recorded indirectly from gross electrodes on the round window or directly from the fluid spaces within the organ of Corti.

The CM reproduces the alternating (AC) waveform of the stimulating sound (hence the name "microphonic"[46]). The SP, illustrated in the lowest inset at the top left of Figure 4–15, represents the DC shift that follows the "envelope" of the stimulating sound.[47] As depicted in Figure 4–15, both the CM and SP are generated across the hair-bearing end of the hair cells.[41,48] Based on experimental findings,[49] it is assumed that the generator site for the receptor potentials is at the apical tips of the stereocilia.

The results of intracellular recordings from IHCs and OHCs suggest that IHCs generate the SP and the OHCs generate the CM.[39] Generation of the SP requires some form of rectification of the acoustic waveform (ie, alteration from a waveform that oscillates above and below the baseline to a waveform that is entirely above or below the baseline). It is reasonably straightforward to model the

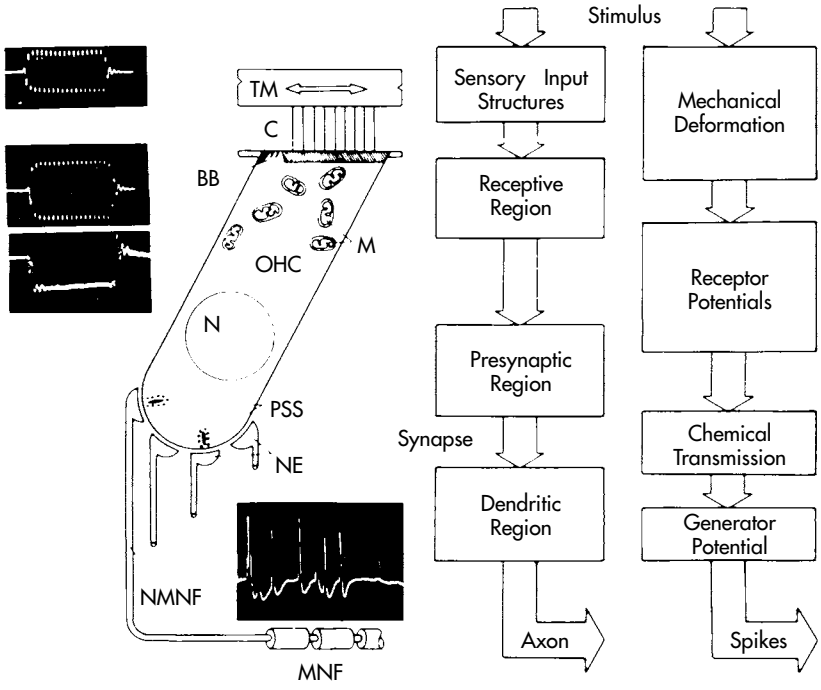

FIGURE 4–15. Generator sites of cochlear potentials (*upper left from top to bottom*: sound stimulus, cochlear microphonic, and summating potential) and functional diagram of the cochlear transducer mechanism (*right*). TM = tectorial membrane; C = cilia; OHC = outer hair cell body; N = cell nucleus; M = mitochondria; PSS = presynaptic structures; NE = afferent nerve endings; NMNF = nonmyelinated segment of nerve fiber; MNF = myelinated segment of nerve fiber; BB = basal body. mechanical coupling of the free-floating IHC cilia in such a way as to produce the mechanical rectification. Thus, the concept that the IHCs generate the SP fits well with what is known about the morphology of this class of hair cell. Other evidence, however, derived from recording in the fluid spaces of the cochlea with OHCs selectively damaged by kanamycin,[50] suggests that both the IHCs and OHCs contribute to the volume-recorded SP and CM. Indeed, this latter notion represents the current consensus of the field.[51]

Generation of the CM can be understood by examination of the resistance battery model of Davis[52] depicted in Figure 4–16. In this conceptualization, the EP serves as the "battery" that provides the driving force to move current through the high resistance of the reticular lamina in which the apical ends of the hair cells are embedded. The traveling wave displaces the basilar membrane, resulting in the deflection of the stereocilia and changes in hair cell resistance. Thus, hair cells acting as variable resistors modulate current flow across the reticular lamina to produce a time-varying potential, the CM, which follows the waveform of the input stimulus.[3]

Role of the Cochlear Potentials in Stimulus Transduction. Wever and Bray's discovery of the CM[53] led to the hypothesis that auditory nerve fiber endings are stimulated electrically.[54] However, studies with the transmission electron microscope (TEM) revealed that the morphology of the interfaces between the afferent nerve endings and the hair cell bases was unmistakably that of a chemical synapse. The chemical synapse-like structures found there include (1) a synaptic cleft (ie, a uniform space between the hair cell and nerve-fiber membranes), (2) synaptic vesicles, and (3) a synaptic bar in the form of an electron-dense disk surrounded by vesicles that resembles the synaptic ribbon of the retina.[55]

The presence of subcellular organelles consistent with a chemical synapse at the hair cell/auditory nerve junction supports the current view that a chemical transmitter released by the hair cell stimulates the auditory nerve endings.[55] Thus, cochlear receptor potentials are probably either directly involved in the cause-and-effect chain leading to chemical stimulation of the auditory nerve or are intimately related to a process that is directly involved but does not stimulate the auditory nerve fibers electrically.[52]

Current thinking about cochlear transduction, which originates primarily from the studies of Hudspeth and colleagues,[56] is illustrated in Figure

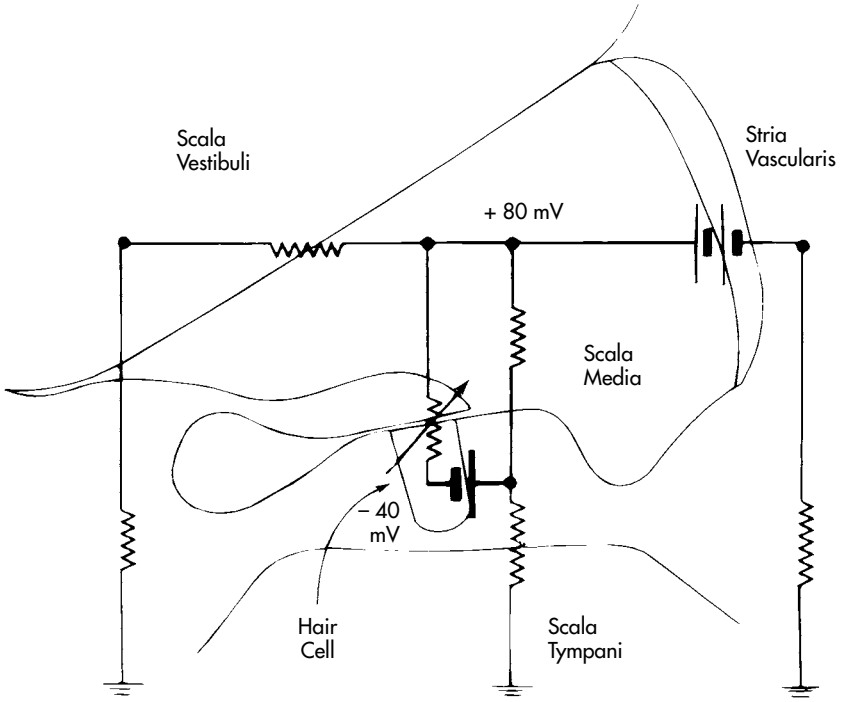

FIGURE 4–16. Diagram of Davis' battery model of transduction in which the positive endocochlear potential and negative intracellular potential provide the force to drive current through the variable resistances at the top of the hair cells. Reprinted with permission from Pickles J.[3]

4–17. In this formulation, displacement of the hair cell bundle opens the transduction channels located at the tips of the stereocilia to allow K^+ to flow into the cell. This influx of K^+ depolarizes the cell, causing calcium (Ca^{2+}) channels at the base of the hair cell to open, thus admitting Ca^{2+} into the cell. The Ca^{2+} ions, in turn, stimulate the transmitter vesicles to fuse with the hair cell membrane and release transmitter into the synaptic cleft. Transmitter substance then diffuses across the synaptic space to initiate action potentials in the adjacent auditory nerve fibers.

Cochlear Transmitters One area of intense research interest in the study of cochlear transduction leading to intercellular communication has been the identification of the afferent transmitter substance that is released onto the primary afferent neurons at the bases of the IHCs and OHCs. In combination with these studies, other efforts have attempted to characterize the efferent neurotransmitter released on the hair cells, and on afferent endings terminating on hair cells, by efferent neurons originating in the brainstem. Recent evidence indicates that the afferent neurotransmitter is probably a single excitatory amino acid, or a structurally related compound, which is responsible for initiating auditory nerve action potentials. Besides this chemical transmitter substance, other chemicals, called neuromodulators,[57] that influence the action of the transmitter are also believed to be released into the synaptic cleft.[58]

In the search for neurotransmitters, several criteria have been established that are requisite for the identification of transmitter substances.[59] These criteria require that (1) the transmitter must produce the same response when applied to the synapse as the natural stimulation of presynaptic elements, (2) extraneous substances that alter natural synaptic transmission such as blocking agents should produce the same effect on the transmitter candidate, (3) stimulation of presynaptic elements should release the transmitter substance, (4) the transmitter substance must be shown to exist presynaptically, (5) enzymes responsible for the synthesis of the transmitter candidate must be present, and (6) a mechanism must be demonstrated that can deactivate the transmitter once it has been released into the synaptic cleft. To date, concrete evidence for the auditory transmitter in the mammalian cochlea is scanty when compared with the findings of other studies of the central nervous system. That is to say, all of the criteria have yet to be met for any candidate afferent transmitter substance. However, based on our present ability to satisfy the above criteria, one of the

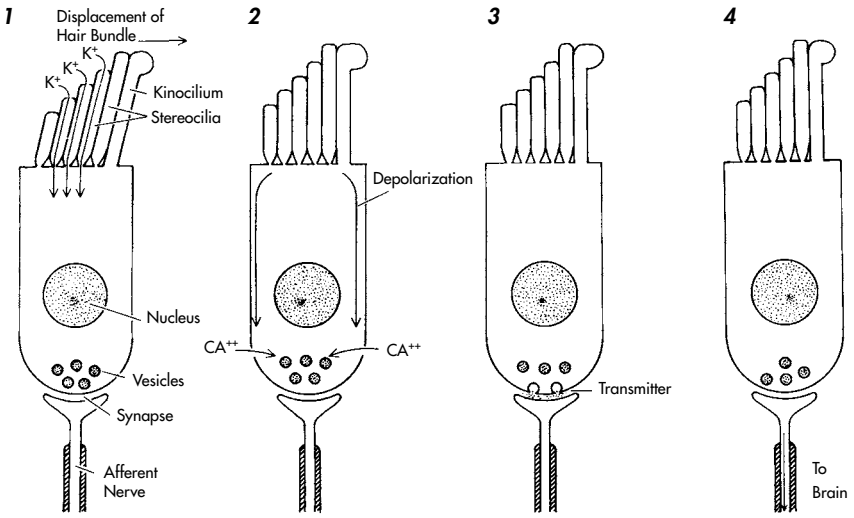

FIGURE 4–17. Schematic representation of the major steps involved in stimulus transduction in hair cells. Deflection of the hair bundle (1) opens the transduction channels to allow K^+ to flow into the hair cell. This results in a reduction of potential difference or depolarization. Depolarization spreads instantly to the lower part of the cell (2), causing Ca^{2+} channels to open. Ca^{2+} ions (3) cause transmitter vesicles to fuse with the basal part of the cell membrane. Fusing vesicles release transmitter substance into the synaptic cleft. (4) Transmitter diffuses across the synaptic cleft to initiate an action potential in the adjacent auditory nerve fiber. Reproduced with permission from Hudspeth AJ.[56]

most likely afferent transmitter substances is believed to be the excitatory amino acid glutamate,[60] and aspartate, too, represents a more recently documented potential candidate.[61]

Documentation regarding the efferent transmitter in the mammalian cochlea is considerably stronger with the most persuasive evidence favoring acetylcholine (ACh). The strongest support for ACh comes from a set of experiments demonstrating that anticholinergic compounds block the effects of efferent stimulation but do not influence afferent cochlear activity.[62] From other histochemical and immunostaining studies of the mammalian cochlea, there is considerable evidence for a GABAergic (ie, γ-aminobutyric acid) efferent innervation of the OHCs, as well as the IHC afferents, including (1) measurements of the uptake of tritiated GABA,[63] (2) immunostaining for glutamic acid decarboxylase,[64] and (3) immunostaining for GABA.[64] Interestingly, evidence that isolated OHCs stain for GABA[65] and that GABA application to isolated OHCs induces membrane hyperpolarization and membrane elongation[66] infers that the functional consequences of this candidate transmitter substance is inhibition of the electromechanical transduction process. For a more in-depth treatment of studies of cochlear transmitters, readers are encouraged to consult an excellent review.[67]

Coding in the Cochlea The cochlea must encode acoustic features into properties of neural activity. The principal acoustic parameters to be encoded are frequency, intensity, and temporal pattern, whereas the basic biologic variables available for neural encoding are place (ie, the location of the activated cell), amount of neural firing, and temporal pattern of firing. Because they are the percepts most studied, the cochlear encoding of frequency and intensity is addressed below. For a recent discussion of temporal processing, see Frisina.[68]

Frequency Coding. In the late nineteenth century, two opposing theories of frequency coding in the auditory periphery were proposed. These classic "place" and "frequency" theories have influenced subsequent thinking about cochlear frequency coding.[3] The place theory of Helmholtz held that the basilar membrane acts as if it were a series of tuned resonators, analogous to a set of piano strings. Each tuned resonator vibrates sympathetically to a different frequency and thus selectively stimulates a particular nerve fiber. Rutherford's frequency theory,

later termed "telephone" theory, proposed that all frequencies activate the entire length of the basilar membrane, which transmits, essentially unchanged, the temporal pattern of the auditory stimulus. According to the telephone theory, it remains for more central neural structures to "decode" these temporal patterns to educe the features of the acoustic stimulus.

Evidence for Place Coding: Mechanical and Neural Tuning Curves. Von Békésy used optical methods to make the first direct observations of the mechanical place analysis of stimulus frequency in the cochlea.[4] Subsequent observations using more sensitive techniques (eg, Mössbauer radioactive source, capacitive probe, laser interferometry) confirmed the general nature of von Békésy's results but, as discussed below, modified his conclusions with respect to several important details.[69]

The principal features of the mechanical responses that von Békésy observed are illustrated in Figure 4–18. Each pure-tone cycle elicits a traveling wave that moves along the cochlear partition from base to apex.[4] As it travels, the wave's amplitude increases slowly, passes through a maximum, and then declines rapidly (Figure 4–18, A). As the frequency of the stimulating tone is increased, the maximum of the traveling wave moves basally toward the oval window.

The inset at the bottom of Figure 4–18, B, illustrates the tuned behavior of the vibration of a specific locus on the cochlear partition that results from

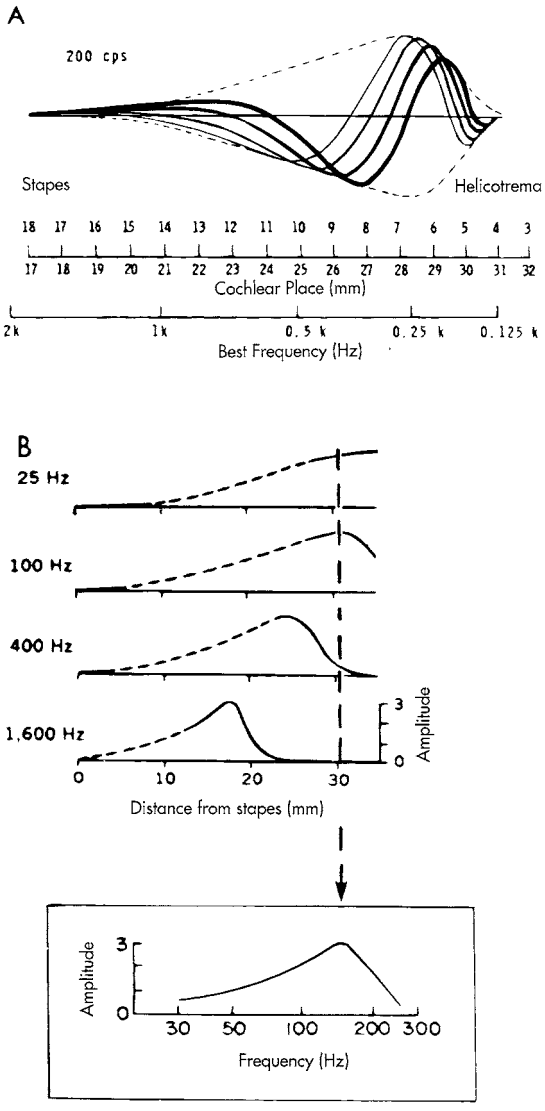

FIGURE 4–18. Mechanical place coding in the cochlea. *A*, The cochlear partition is "uncoiled," showing the traveling wave response to a pure-tone stimulus. Vertical distance represents the amount of cochlear partition displacement. The four *progressively darker lines* show cochlear partition positions at three successive instants during one cycle of a 200 Hz stimulation tone. *Darker lines* represent later points in time. The *fine dashed line* shows the "envelope" of cochlear partition displacement. Scales at the bottom show linear distance along the cochlear partition measured from helicotrema (*upper scale*), from stapes (*middle scale*), and also in terms of one commonly used cochlear partition "frequency map" (*bottom scale*). Reproduced with permision from Greenwood DD. Critical bandwidth and the frequency coordinates of the basilar membrane. J Acoust Soc Am 1961;33:1344. Note the expected peak in displacement pattern envelope at about the 0.2 kHz point on the frequency map. *B*, The top four curves are envelopes of traveling wave responses to pure-tone stimuli of varying frequencies. Each envelope depicts a point on the partition approximately 30 mm from the stapes (indicated by the *vertical dashed line*). Only the upper half of the envelope traced in *A* is shown. At bottom, the response of a single cochlear point is plotted against frequency. This is the mechanical tuning curve of this point. Reproduced with permission from von Békésy G.[4]

the traveling wave patterns generated by stimuli of different frequencies (four plots above). The bottom plot of Figure 4–18, B, called a cochlear mechanical tuning curve, was obtained by plotting the vibration amplitude of a single cochlear partition point against the exciting frequency. The frequency that generates the maximum vibration of a specific place on the cochlear partition is that point's characteristic frequency (CF). Thus, the plot at the bottom of Figure 4–18, B, illustrates the mechanical tuning curve for a place on the cochlear partition with a CF of 150 Hz. Mechanical tuning curves at all cochlear partition locations have the same general shape, that is a rapid falloff for frequencies above the CF (> 150 Hz) and a gradual drop-off for frequencies below the CF (< 150 Hz).

Microelectrode recordings from single hair cells and auditory nerve fibers yield an analog of the cochlear mechanical tuning curve. Figures 4–19 and 4–20, respectively, show examples of neural tuning curves obtained from primary auditory nerve fibers with traditional glass micropipets[70] and mechanical tuning curves for the 9 kHz point on the basilar membrane made by a laser-Doppler vibrometer for a number of vibration criteria.[71] Essentially, neural tuning curves are plots of response threshold against frequency (see Figure 4–19), and similar tuning curves can be recorded from single neurons throughout the auditory neural pathway. Note the relatively similar tuning capabilities of the nerve fiber with the 9 kHz CF (middle panel at the right of Figure 4–19), the most sensitive membrane velocity response (thick solid line of Figure 4–20) with respect to frequency selectivity (ie, the Q_{10dB} "tuning," at 10 dB above threshold, of ~2), and the tip-to-tail distance of about 80 dB.

The tuning curves of primary auditory nerve fibers have the same basic shape (ie, steep high-frequency slope, shallow low-frequency slope) as the mechanical tuning curves. Thus, the mechanical place code of the cochlea is clearly imprinted on the auditory nerve's neural response pattern.

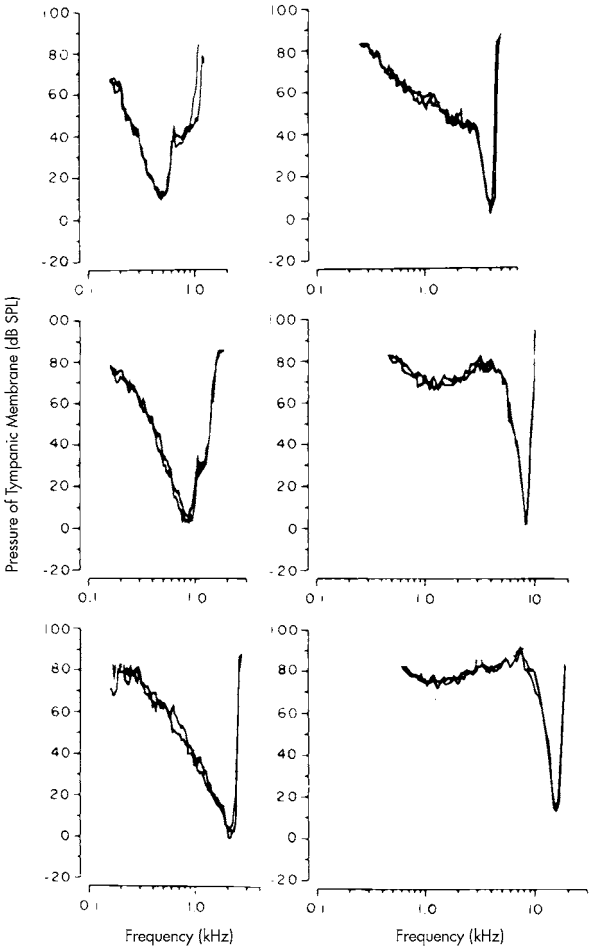

FIGURE 4–19. Representative tuning curves (frequency threshold curves) of cat single auditory nerve fibers are shown for six distinct frequency regions. In each panel, two fibers from the same animal, of similar characteristic frequency and threshold, are shown, indicating the constancy of tuning under such circumstances. Reproduced with permission from Liberman MC and Kiang NYS.[70]

Cochlear Tuning. Two characteristics of cochlear tuning are critical to the determination of its location and mechanism. First, the process by which filtering takes place is too rapid to permit a neural delay; thus, there is no possibility that tuning is sharpened by some sort of neural "lateral inhibition" analogous to that occurring at higher levels in the auditory pathway (see below).[72] The second important characteristic of cochlear filtering is that it is physiologically vulnerable. Almost all damaging agents, including hypoxia,[73] ototoxic drugs,[74] local mechanical damage,[75] and acoustic trauma,[76] detune the neural tuning curves so that they closely approximate the broader mechanical tuning curves. As Figure 4–21 shows, the detuning by damaging agents occurs not only for neural tuning curves but also for mechanical tuning curves, SP tuning curves measured with electrodes placed intracellularly in IHCs, and psychophysical tuning curves from humans with

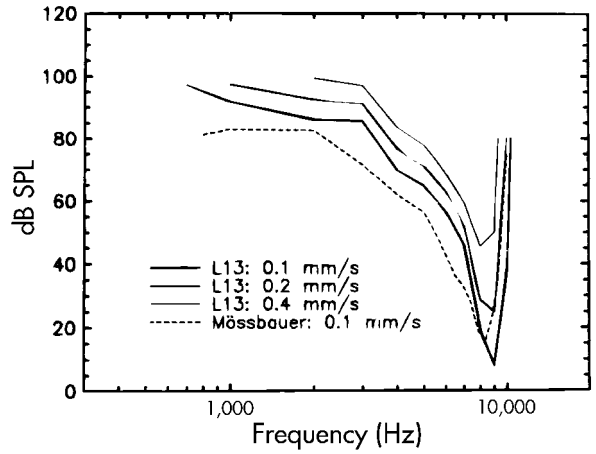

FIGURE 4–20. Isoresponse contours (tuning curves) for basilar membrane velocity responses to tone pips recorded from the chinchilla with the laser-vibrometer (*solid lines*). The ordinate indicates the sound pressure level required at any particular frequency to elicit a given velocity amplitude (0.1, 0.2, or 0.4 mm/s, indicated as the parameter). For the laser-vibrometry responses, sound pressure levels were interpolated logarithmically using a series of isointensity contours for basilar membrane responses to tone pips. For comparison, a 0.1 mm/s tuning curve is shown, which is representative of results obtained using the Mössbauer technique (*dashed line*) at an approximately equivalent basilar membrane site in normal chinchilla. Reproduced with permission from Ruggero MA and Rich NC.[71]

cochlear deficits. Until recently, the vulnerability of mechanical tuning curves was a controversial point. The first published "modern" mechanical tuning curves measured using Mössbauer and capacitive probe techniques were tuned about as poorly as von Békésy's.[77] However, even at this early stage, the sharpness obtained by different laboratories differed.[78]

It has now become clear that the sharpness of cochlear mechanical tuning is extremely vulnerable and that, even when great care is taken, the surgical and other manipulations necessary to obtain mechanical tuning curves in experimental preparations unavoidably cause broadening of the mechanical frequency response.[69] Cochlear mechanical tuning curves obtained under conditions in which extreme precautions were taken to minimize cochlear damage have demonstrated tuning that is as sharp as that of neural tuning curves.[71] In addition, the existence of nonlinear behavior in the normal cochlear mechanical response has been confirmed. Thus, the sharpness of tuning observed at the primary neuron level is already accomplished at the level of the mechanical traveling wave.

The question remains, however, of how the physiologic vulnerable sharpening of mechanical tuning is accomplished. One critical consideration in answering this question is the calculation by Kim and coworkers that mechanically tuning a location on the basilar membrane requires the local addition of mechanical energy.[79] The discovery that OAEs are produced by the healthy cochlea[80] and can be recorded simply from human and animal ear canals provided indirect evidence for the presence of such a mechanical energy generator within the cochlea. The results of further studies on OAEs in vertebrates and more recent investigations of the biophysical properties of isolated OHCs have implicated micromechanical processes at the level of the OHCs as being responsible for the normal frequency selectivity of the cochlea.

The OAEs are traditionally classified into two general categories: those that are elicited with deliberate acoustic stimuli (evoked OAEs) and those that occur in the absence of stimulation (spontaneous OAEs). All OAEs can be simply recorded using conventional averaging techniques by a sensitive subminiature microphone assembly inserted snugly into the external auditory canal. Over the past several decades, four types of emissions, illustrated in Figures 4–22 and 4–23, have been studied extensively. These include the spontaneous OAE (SOAE), which is measured in the absence of acoustic stimulation (see Figure 4–22, A); the stimulus frequency OAE (SFOAE), which is evoked by a low-level, continuous pure tone (see Figure 4–22, B); the transient evoked OAE (TEOAE), which is elicited by clicks or tone pips (see Figure 4–22, C) and distortion-product OAE (DPOAE), which is elicited by two simultaneously applied pure tones (see Figure 4–23) known as the lower- (f_1) and higher-frequency (f_2) primary tones.

The following facts support the notion that OAEs come from the cochlea and are related to the active frequency filtering process: (1) the frequency of the TEOAE varies considerably from subject to subject, and across subjects there is a systematic relationship between the emission's delay (ie, latency) and its frequency.[81] This suggests that the origin of OAEs is the cochlear bandpass filtering mechanism; (2) stim-

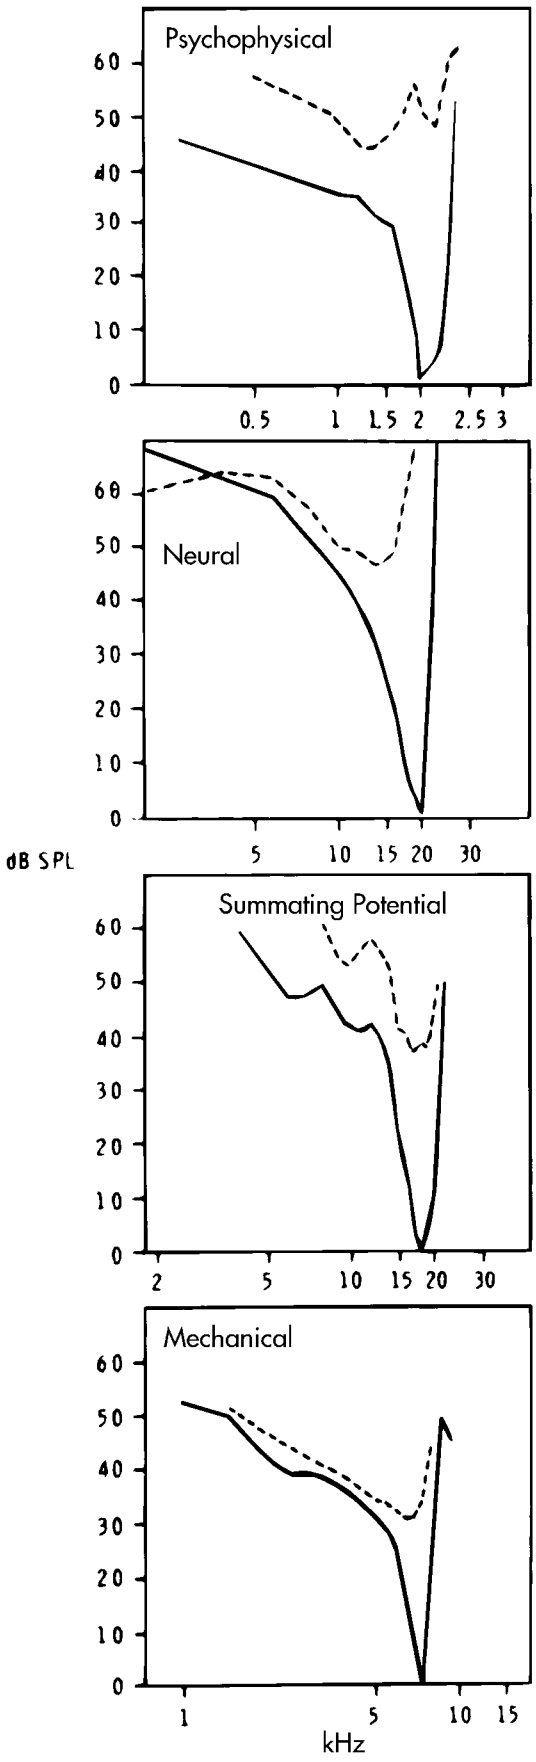

FIGURE 4–21. Collection of tuning curves from several authors illustrating "detuning" with damage. The tuning curves illustrated were obtained from humans (psychophysical) and from animals at the primary auditory neuron (neural), cochlear receptor potential (summating potential), and basilar membrane (mechanical) levels. The psychophysical tuning curves were obtained by a tone-on-tone masking procedure. Reproduced with permission from Gulick WL. Hearing, physiology and psychophysics. New York: Oxford University Press; 1971. The *dashed curve* is from a hearing-impaired listener; the *solid curve* is from a normal listener. The "notch" in the detuned hearing-impaired curve may be a technique-related artifact created by the detection of combination tones or beats made by combining masker and test tones. The neural tuning curves were obtained from guinea pigs before (*solid curve*) and 20 minutes after (*dashed curve*) acoustic trauma.[76] The summating potential curves are 10 μV isoamplitude curves obtained from intracellular hair cell recordings. The *dashed line* is an example of an "insensitive" cell (presumably damaged in the course of exposure); the *solid line* is from a "sensitive" cell.[39] The mechanical tuning curves illustrate the range of results obtained from different animals in the course of Rhode's Mössbauer technique measurements. ulation of the crossed olivocochlear bundle (OCB), which preferentially provides efferent innervation to the OHCs, modulates the magnitude of OAEs[82,83]; and (3) the emission is extremely sensitive to the detrimental effects of cochlear pathology, acoustic trauma, and ototoxic drugs.[83,84] The most parsimonious interpretation of the existence of the various OAE types, their duration, bandwidth, and delayed-onset characteristics and their relationship to the activity of the cochlear efferent system is that they originate in the OHCs, which possess a mechanical energy that generates the frequency-selective output of the cochlea.

Brownell and Zenner and their colleagues were the first to show in in vitro preparations of mammalian hair cells that OHCs display electromotility.[85,86] Using mechanical trituration to dissociate single OHCs from other organ of Corti tissues and video-enhanced imaging to visualize the isolated OHC directly, these investigators used both intracellular and transcellular electrical stimulation[85] or pharmacologic (K^+, cholinergic chemicals) agents[86] to elongate and shorten OHCs from their resting lengths. Because it has been demonstrated that hair cells possess both actin and myosin,[87] it was originally presumed that some aspect of the active motile mechanism is mediated, as in muscle, by interactions between these molecules. However, as more details developed about OHC electromotility, including the

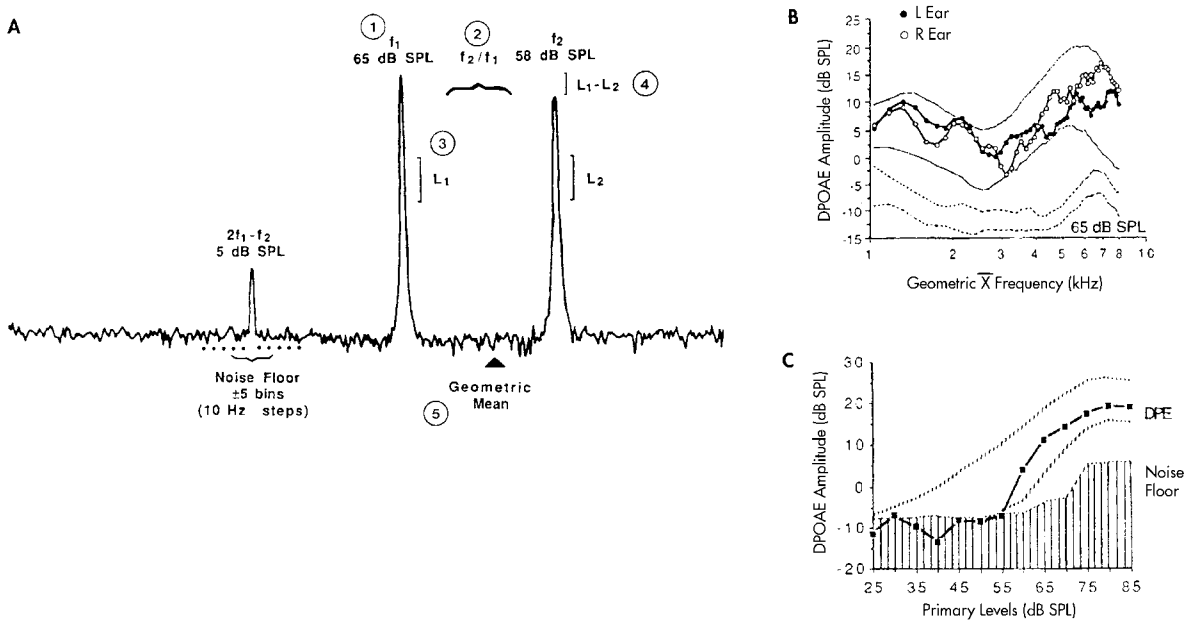

FIGURE 4–23. Distortion-product otoacoustic emissions (DPOAEs). *A*, DPOAE at $2f_1$-f_2 is shown in the spectrum of the ear canal sound. Note the position of the geometric mean frequency (5) with respect to the primary tones (f_1, f_2) and the frequency range over which the noise floor (NF) is measured relative to that of the emission (*dotted region* surrounding the DPOAE frequency). *B*, A typical DPOAE frequency/level function or "DP-gram" elicited by 75 dB SPL primaries is shown for the right (*open circles*) and left (*solid circles*) ears of a normal-hearing individual. The pairs of long (*above*) and short (*below*) *dotted lines* represent the ranges of average activity and their related NF levels, respectively, associated with normal function. *C*, A typical response/growth or input/output curve depicts the growth of the DPOAE (DPE) with progressive increases in the levels of the primary tones. knowledge that they mechanically vibrate at frequencies up to at least 30 kHz, it became clear that a very fast-acting motor molecule,[88] or some instantaneous physical phenomenon induced by an electrokinetic process,[89] formed the basis of the ability of the OHC to vibrate in response to changes in the receptor potential. Most recently, Zheng and colleagues tentatively identified a protein they called prestin as the motor protein of the OHC.[90] The detailed follow-up studies of these investigators further support the proposition that this membrane protein is the motor molecule responsible for the electromotility of OHCs.[91]

Inner versus Outer Hair Cell Function. Figure 4–24 illustrates the salient characteristics of IHC and OHC anatomy, and Figures 4–25 and 4–26 illustrate their afferent and efferent innervation, respectively. There are many differences between IHCs and OHCs in terms of their morphology, biochemistry, physiology, and afferent and efferent innervation patterns. Phylogenetically, OHCs are much younger than IHCs, being present only in the mammalian cochlea. In keeping with their relative phylogenetic youth, OHCs develop later embryologically,[92] are more easily compromised by various damaging agents, and have many unique characteristics that distinguish them from hair cells in other mechanoreceptor systems.

It seems clear that the OHCs and IHCs are functionally different, but our concept of the nature of this difference is changing. The classic view that the relatively insensitive IHC system carries the frequency place code, whereas the OHCs comprise a sensitive low-level detector system that has poor place-coding ability, has been abandoned in favor of more recent notions based on the active biomechanical functioning of the organ of Corti. That the OHCs possess effector abilities supports the pro-

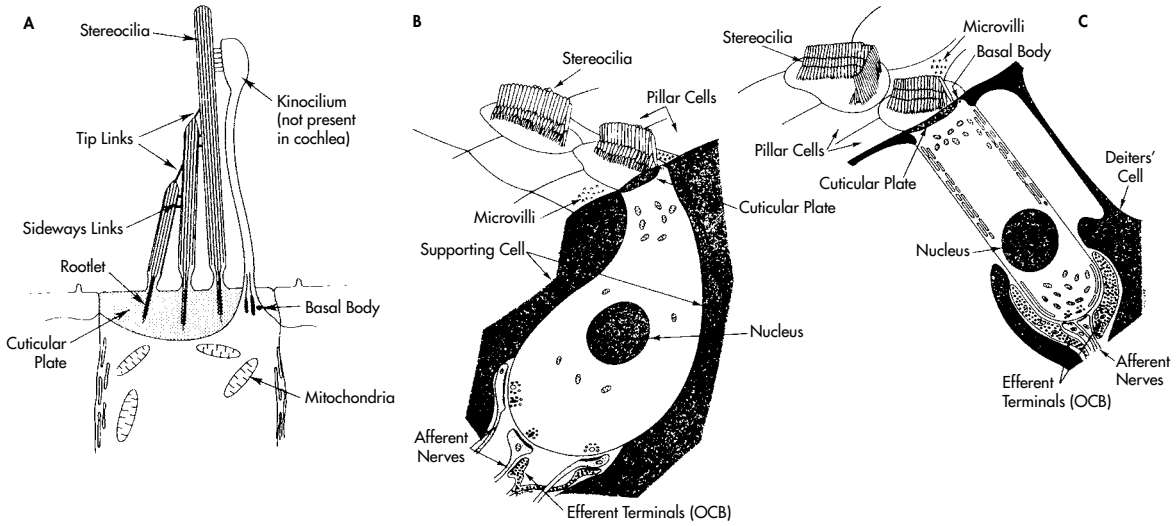

FIGURE 4–24. Schematic drawing of cochlear hair cells. *A*, The common structures on the apical portion of acousticolateral hair cells include rows of stereocilia that are graded in height and joined by cross-links. The tip links may be involved in transduction by opening the transducer channels. The kinocilium is not present in the mature cochlea, although it is present in vestibular hair cells. *B* and *C*, Inner hair cells are shaped like a flask (*B*), and outer hair cells are shaped like a cylinder (*C*). posal of Kim that these receptors are bidirectional transducers that are capable of converting acoustic energy into neural energy (ie, mechanoelectrical transduction) and electrical into mechanical energy (ie, electromechanical transduction).[93] Kim elaborated on this notion by postulating the existence of two distinct but parallel cochlear subsystems that use OHCs as the modulators and IHCs as the carriers of auditory information.[93] Table 4–1 presents a summary of a comparison of the two subsystems.

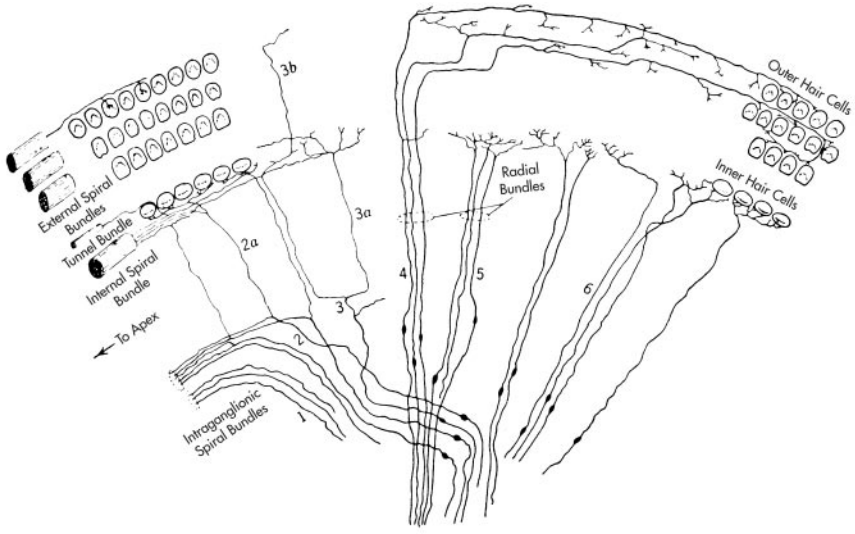

FIGURE 4–25. Diagram of the cochlea's afferent innervation pattern. The view is through Reissner's membrane, looking down on the organ of Corti. Principal fiber bundles are 1 and 2, intraganglionic spiral bundles (fibers labeled "1" are efferent olivocochlear fibers); 2a and 3a = internal spiral fibers; 4 = external spiral fibers, traveling in radial bundle to innervate outer hair cells (OHCs); 5 and 6 = radial fibers, innervating inner hair cells (IHCs). The "V" shape of cilia pattern on the OHCs and the shallower "U" pattern on the IHCs are shown in the upper corners of the diagram. Reproduced with permission from Wever EG.[94]

The descending auditory system. *A*, Origination in the brainstem, distribution, and termination within the cochlea of the olivocochlear bundle efferent fibers of the cat. *B*, Organization of the lateral and medial olivocochlear (OC) systems. Lateral OC neurons project to the region beneath the inner hair cells, where they form axodendritic contacts on the dendrites of type I spiral ganglion cells. Medial OC neurons project to the region beneath the outer hair cells and synapse directly with them. *A* reproduced with permission from Warr WB et al.[95] *B* reproduced with permission from Spangler KM and Warr WB.[96]

There is good evidence that the vulnerable filter sharpening described previously involves some kind of interaction between the IHCs and OHCs including the following: (1) selective damage to OHCs causes detuning of neural tuning curves (Figure 4–27),[97] which presumably are from IHC fibers; (2) crossed OCB stimulation, which presumably affects only OHCs (see below), strongly depresses the auditory nerve's click-evoked, whole-nerve, or compound action potential (CAP), which apparently originates entirely from IHC fibers; (3) crossed OCB stimulation also reduces the amplitude of the receptor potential recorded intracellularly from IHCs[98]; (4) crossed OCB stimulation as well reduces the firing rate and synchronization index[99] and shifts the dynamic range of auditory nerve fibers[100]; and (5) a trapezoid acoustic stimulus elicits from a auditory nerve fiber a spike train with a complex time course, suggesting combined IHC and OHC influences, whereas selective damage to OHCs by kanamycin treatment simplifies the trapezoidal response pattern in a way compatible with isolated IHC influence.[38]

The precise mechanism by which OHCs influence the response of IHCs is unknown at this time. However, because the physiologically vulnerable cochlear filter-sharpening process appears to involve basilar membrane vibrations, the mechanism requires that the OHCs directly influence the mechanical vibration of the basilar membrane. A corollary to this conclusion is that the OAEs recorded from the human ear canal reflect OHC function. Indeed, one intensely studied subfield of

TABLE 4–1. Differences Between Inner and Outer Hair Cells

	Inner Hair Cells	*Outer Hair Cells*
Anatomy (see Figure 4–24)		
Cell shape	Flask (35 μm × 10 μm)	Cylinder [25 μm (base) to 45 μm (apex) × 7 μm]
Relation to supporting cells	Closely approximated to inner phalangeal cell processes	Contact Deiters' supporting cells only at apical and basal ends and are surrounded by large perilymph-filled spaces of Nuel
Cilia	Longitudinally oriented shallow curve	Radially oriented "V"-shaped curve
	Not obviously attached to tectorial membrane	Attached to tectorial membrane
Location of cell nucleus	Central	Basal
Organelles	Resemble hair cells in other systems	Several unique features including submembrane cisternae, numerous mitochondria parallel to cell membrane, Hensen's bodies
Afferent innervation (see Figure 4–25)	Convergent via radial fibers	Divergent via spiral fibers
	95% of fibers in auditory nerve come from IHCs	
	All published nerve-fiber studies are probably from IHCs	No convincing neurophysiologic demonstration of population of nerve fibers from OHCs
	Nerve endings plentiful and show typical chemical synapse morphology	Nerve endings relatively sparse; morphology differs from chemical synapse
Efferent innervation (see Figure 4–26)	Small neurons near LSO	Large neurons near MSO
	Primarily ipsilateral via uncrossed olivocochlear bundle	Primarily contralateral via crossed olivocochlear bundle
	Small endings primarily on afferent nerve terminals	Large endings on OHCs
	Acetylcholinesterase activity poorly visualized	Acetylcholinesterase activity easily visualized
	Enkephalin-like immunoreactivity	Aspartate aminotransferase immunoreactivity
	Distributed evenly along cochlear length	Distributed preferentially in middle and basal cochlea

OAE research is focused on using emitted responses to evaluate the normality of central auditory processing based on the influence of the descending efferent system on OHC-generated activity.[101,102]

Clinical Consequences. The existence of a vulnerable cochlear filtering process and a related cochlear emission that can be recorded noninvasively have some important implications for our understanding of pathophysiologic processes in the cochlea. First, although it is unlikely that the majority of cases exhibiting severe tinnitus are related to spontaneous OAEs, emissions may elucidate the mechanism of at least some kinds of tinnitus.[103] Moreover, by separating the sensory from the neural aspects of ear dysfunction, OAEs may reveal the critical underlying causes of some common but puzzling otologic diseases such as Meniere's disease[104] and sudden idiopathic sensorineural hearing loss.[105] Second, as shown in Figure 4–28, detuning of the neural response in cochlear pathologic conditions may also explain recruitment.[106] As previously described, detuning caused by cochlear pathology eliminates the low-threshold, sharply tuned tip region of the tuning curve but preserves the high-threshold tail region. Elimination of the tip region raises threshold, but preservation of the tail region preserves neural responsiveness at high intensities. Thus, the loudness function (bottom right plot) is made abnormally steep because threshold is elevated. However, at high intensities, loudness is normal because a normal number of neurons are responding.

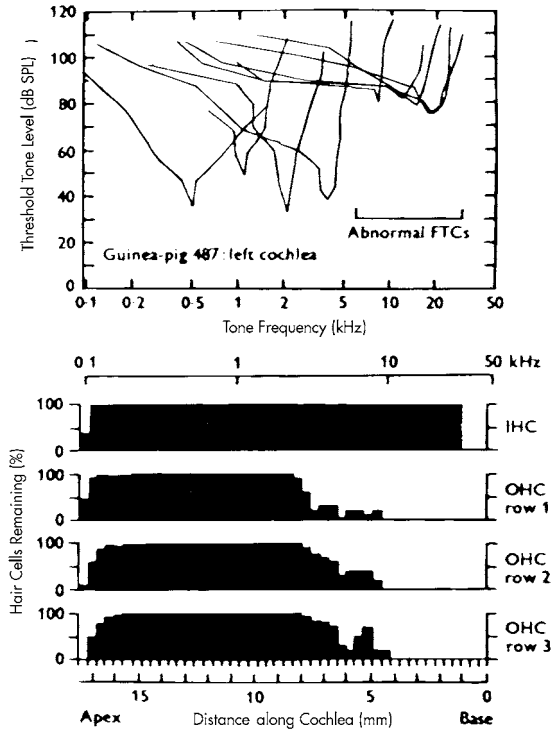

*FIGURE 4–27. C*orrelation between detuning of neural tuning curves and outer hair cell (OHC) damage. The results are shown from a kanamycin-treated guinea pig in which the inner hair cells (IHCs) were intact throughout the cochlea. In the high-frequency region, however, OHCs were damaged, and tuning curves (FTCs), presumably from fibers coming from this region, were detuned. This result suggests that the OHCs participate in the process by which cochlear tuning curves are sharpened. Reproduced with permission from Evans EF and Harrison RV.[97]

Evidence for Telephone Coding. The aforementioned evidence for place coding has not invalidated Rutherford's telephone theory because there is also considerable evidence for a telephone code at low frequencies. For example, cochlear tuning becomes progressively poorer as frequency is lowered, and below about 100 Hz, there are no cochlear partition amplitude maxima and no tuned auditory units.[107] Thus, the physiologically observed frequency place code becomes progressively worse as frequency is lowered.

A neural telephone code has been demonstrated that, in contrast to the place code, becomes

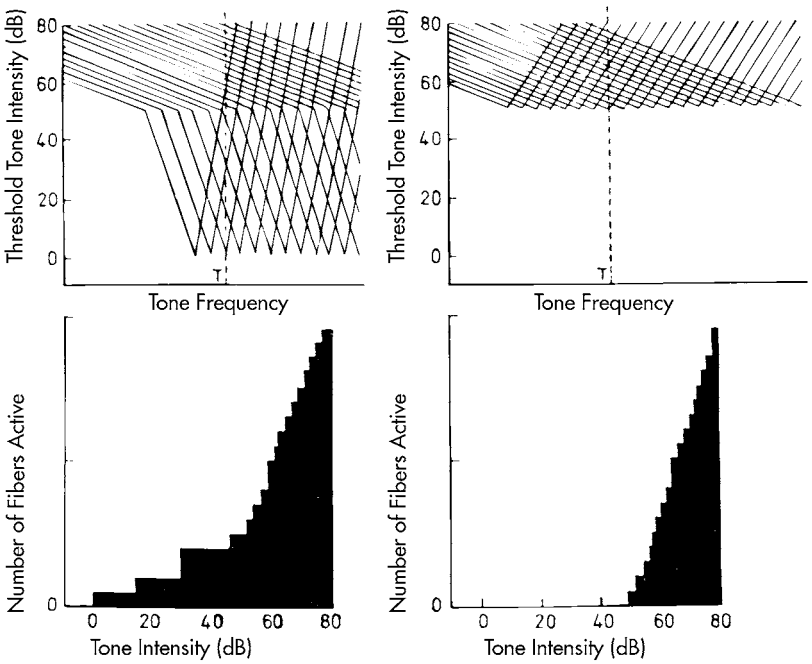

FIGURE 4–28. Possible explanation of recruitment (elevated threshold and abnormal growth of loudness) based on detuning with pathology. *Solid diagrams* at bottom depict increase in number of active auditory nerve fibers as tone level is increased in normal (*left*) and abnormal (*right*) ears. The tone's frequency (T) is indicated by the *dashed line* in the *upper diagram*. Because the effect of disease is to remove the sharply tuned "tips" but leave the broadly tuned "tails" relatively unaffected, the threshold of the pathologic cochlea is increased. However, as tone level is increased into the normal tail regions, the number of active fibers responding becomes normal; hence, loudness grows abnormally rapidly from the elevated threshold. Reproduced with permission from Evans EF.[107]

progressively better as frequency is lowered. Analyzing the spike discharges of single auditory nerve fibers to low-frequency stimulation demonstrated "phase-locking" to the individual cycles of the eliciting tone that preserves the temporal firing pattern.[108] Compiling large numbers of single-unit spikes into spike discharge histograms showed an impressive ability of single auditory unit discharges to reproduce the waveform of the stimulating sound. The upper limit of this phenomenon is generally estimated at about 4 kHz, but critical inspection of quantitative single-unit data suggests that phase-locking becomes poor at around 2.5 kHz.[109]

Another line of evidence supporting the importance of the encoding of phase or timing information comes from the outcome of studies of the responses of auditory nerve fibers to speech sounds. The work of Kiang addressed the limitations of fiber discharge rate place encoding in neurally representing the frequency components in speech signals, especially those of moderate to high intensities.[110] More recently, the single-unit population studies of Sachs and Young on the representation of speech sounds in hundreds of auditory nerve fibers have demonstrated that the temporal pattern of fiber discharges in the form of phase-locking provides considerable information about the frequency content of the stimulus at all levels of stimulation.[111] These population measures of temporal synchrony were based on Fourier transforms of period histograms from fibers with CFs near each frequency component of the sound. Such measures were combined to provide discharge rate profiles for groups of active nerve fibers. Because information concerning rate, timing, and place is represented in these measures, these spectra provide details concerning temporal fine structure from a localized cochlear region and thus represent a type of temporal place code.

"Telephone Place" Theory of Frequency Coding. One shortcoming of the telephone theory became apparent when neural refractoriness was discovered. This process imposed a physical limitation on nerve fiber firing at the very short time intervals associated

with high-frequency stimuli. Thus, to reconcile in part the effects of neural refractoriness on the telephone theory, Wever published an auditory frequency coding theory, which he termed the volley theory, but which has since become known as the "telephone place" or "frequency place" theory.[94] Wever advanced an interesting evolutionary argument in support of the telephone place code theory. Primitive ears (as found in fish, amphibians, and lower reptiles) are telephone coders that cannot analyze high frequencies because of the inherent limitation of the rate at which nerve fibers can respond. Therefore, as evolution progressed, place coding had to be added to allow analysis of high frequencies, which are important in sound localization and directionality.

Our use of sounds in communication is greatly aided by our keen sensitivity to the frequency region between 1 to 4 kHz, and although our sensitivity falls off beyond 4 kHz, we still depend on the higher frequencies for many of our discriminations of consonants and sharp transients. The appearance and elaboration of the place principle for frequency representation, therefore, was a major event in the evolution of the ear.[94]

Intensity Coding Loudness is the approximate subjective correlate of the physical dimension of sound intensity. It is generally assumed that the neural correlate of loudness is the amount of nervous activity, with the amount factor meaning the total number of action potentials delivered by a population of nerve fibers over a given time period. Thus, loudness is encoded as a combination of the number of fibers firing and the rate at which they are firing.

Figure 4–29 compares plots of stimulus level versus single auditory nerve fiber firing rates (left) and stimulus level versus subjective loudness (right). The agreement in the general shapes of the curves supports the view that the amount of auditory nerve firing encodes loudness. On closer scrutiny, however, it is apparent that firing rate changes only over a 20 dB sound intensity range, whereas loudness varies over a 100 dB range. This limited dynamic range is a general property of all primary auditory neurons.[112]

The obvious way to solve this loudness encoding problem is to assume that additional nerve fibers are "recruited" as stimulus level is increased. This process would increase the total number of dis-

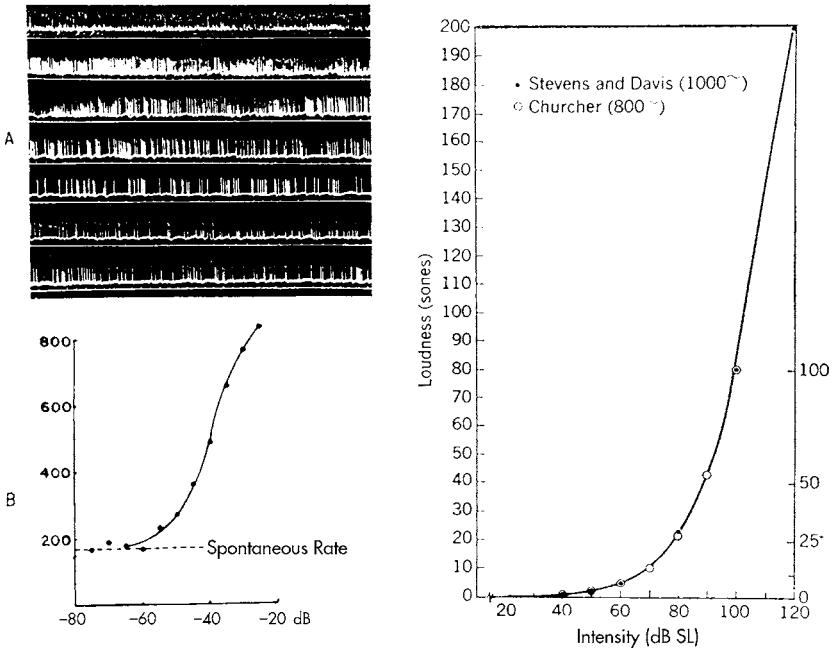

FIGURE 4–29. Effects of sound intensity on subjective loudness (*right*) and auditory nerve fiber firing rate (*left*). The shapes of the curves are similar, but the dynamic range of the single auditory nerve fiber is much narrower than that of the auditory system as a whole. Above the auditory nerve firing rate curve (*B*) are single-fiber responses to sounds of progressively increasing levels (*A*). Subjective loudness curve from Gulick (1971) noted in the legend for Figure 4–21. Auditory nerve curve reprinted with permission from Katsuki Y, Sumi T, Uchiyama H, Watanabe T. Electric responses of auditory neurons in cat to sound stimulation. J Neurophysiol 1958;21:569.

charges per unit time by increasing the number of fibers firing rather than the firing rate for an individual fiber. However, most studies of auditory nerve single units agree that the thresholds of the nerve fiber population fall within a relatively restricted stimulus range, that is, within 20 to 30 dB of behavioral threshold.[113] Thus, there is no possibility of recruiting additional fibers as sound level is increased more than 60 dB above threshold. The fiber recruitment hypothesis also creates problems for frequency place coding because adding new responding fibers as stimulus level is increased would quickly require the spread of activity to fibers of adjacent CFs. This tradeoff between the ability to recruit new fibers and the ability to place code is especially bothersome for explaining the perception of complex sounds for which multiple frequencies must be distinguished simultaneously. Thus, the dynamic range problem becomes apparent.[114] The dynamic range of auditory nerve fibers, that is, the range over which the spike rate changes as stimulus level is altered, is too narrow to account for (at least in simple terms) the extent over which the human ear discriminates sound levels.

Several subsequent observations shed light on the dynamic range problem. Evans and Palmer discovered that approximately two-thirds of the cells in the dorsal cochlear nucleus (DCN) had dynamic ranges that extend to well over 100 dB and thus could easily "code" loudness over the necessary sound intensity range.[115] However, the problem of the input pathway to these DCN cells remains to be resolved. In addition, some auditory nerve units have been found that do, after all, have wide dynamic ranges, but these are only a minority of the total auditory nerve fiber population.[116] Other studies have also demonstrated that relative degrees of phase-locking[117] of different frequency components in complex sounds could code the relative intensity levels of the frequency components. However, because phase-locking does not occur above 3 to 4 kHz, this mechanism could not account for the loudness coding of high frequencies.

Another approach to the dynamic range problem is the concept of an automatic gain control operating at the input of the auditory system.[114] Such a control mechanism would feed back a decreased gain command signal to the input to maintain the cochlear output within an acceptable operating range. Possibilities for such a control system include the middle ear reflex and the olivocochlear efferent system.

Finally, Liberman classified auditory nerve fibers into three functional subclasses according to spontaneous discharge rate as low-, medium-, and high-firing units.[118] Whereas high spontaneous rate (SR) fibers exhibited low thresholds and restricted dynamic ranges of about 20 dB, the medium and low SR units displayed higher thresholds and dynamic ranges as great as 60 dB. Thus, it is possible that although fewer in number than the high SR fibers, the low and medium SR fibers are available to encode the higher-intensity sounds.[119]

Viemeister concluded from his review of the psychophysical and physiologic literature relevant to intensity encoding in auditory nerve fibers that a localized rate code "seems theoretically possible and, at present, appears to be the best candidate for a general intensity code."[120] The conclusion that rate information from a frequency-specific population of active nerve fibers provides the neural basis for a code of stimulus intensity is consistent with the findings discussed above concerning the encoding of high-level speech sounds by a population of auditory nerve fibers that possibly exhibit low to intermediate spontaneous firing rates.

Efferent Auditory System *ANATOMY.* Rasmussen established the existence of a chain of descending auditory neurons that links auditory cortex to hair cells and that parallels the classic afferent projection pathway (discussed below).[121] The OCB, the final link in the descending chain, originates in the superior olivary complex (SOC).

Figure 4–26, A, summarizes schematically the origins, course, and distribution of the OCB to one cochlea, whereas Figure 4–26, B, analyzes the principal relationships between the two afferent and the two efferent innervations of the organ of Corti.[95] The OCB is divided into crossed and uncrossed components. The crossed component is composed primarily of relatively large myelinated fibers that originate in large globular neurons surrounding the medial region of the SOC.[122] Most of the uncrossed component is composed of small fibers,[123] a large percentage of which may be unmyelinated and which originate in the small fusiform neurons in the lateral region of the SOC.[122] The majority of the large crossed fibers innervate OHCs, whereas most of the small uncrossed fibers innervate IHCs.[122]

The crossed olivocochlear fibers decussate just beneath the floor of the fourth ventricle and then enter the vestibular nerve. At this point, they are joined by the uncrossed fibers. The combined crossed and uncrossed fibers travel in the vestibular nerve and cross into the cochlear nerve via the vestibulocochlear anastomosis. Within the cochlea, efferent fibers have been identified among the external spiral fibers (3b in Figure 4–25), the tunnel spiral fibers, and the internal spiral fibers.[124]

Physiology. In cases in which olivocochlear axons have been labeled histochemically and traced following single nerve fiber recordings, the labeled fibers terminate beneath OHCs in cochlear regions with best frequencies corresponding to the CFs of the fiber.[125] Such direct recordings from efferent axons within the periphery have demonstrated that these units possess thresholds and tuning curve properties that are essentially identical to those of primary afferents with similar CFs.[125] Although the proportion of olivocochlear neurons that can be excited by ipsilateral and contralateral stimuli is consistent with the predominant efferent innervation to a given cochlea, many units are binaurally responsive.[126]

The effects of stimulating the crossed OCB are almost certainly mediated by the release of ACh as the major neurotransmitter at the OHCs,[127] as noted above. In turn, ACh acts on ACh receptors (AChRs) located on the OHC postsynaptic membrane to modulate the electrical properties of the OHCs. Elgoyhen and associates established that ACh acts on nicotinic AChRs (nAChRs) containing the α9 subunit, which mediates synaptic transmission between the cholinergic olivocochlear fibers and the OHCs.[128] It has long been known that stimulating the crossed OCB in the floor of the fourth ventricle causes depression of the auditory nerve's response to sound stimulation (ie, the CAP) and a simultaneous increase in the amplitude of the CM.[129] It is likely that the α9 nAChR subunit mediates such efferent inhibition because an α9 knockout mouse model showed no suppression of either CAPs or DPOAEs by electrically stimulating the OCB at the floor of the fourth ventricle.[130] It was further shown that the α9 nAChR protein opens its ion channel via associated Ca^{2+}-activated K^+ channels.[131]

Much less is known about the uncrossed OCB. Stimulation of the uncrossed bundle decreases the click-evoked action potential amplitude, but the effect is much less than for the crossed bundle.[99] In addition, unlike the crossed bundle, the terminations of the uncrossed bundle do not show high concentrations of acetylcholinesterase,[132] and curare does not block the effect of stimulating the uncrossed bundle (although strychnine does).[127] Thus, the uncrossed system may not be cholinergic.

Functional Significance The function of the olivocochlear efferent system is, at present, largely unknown. Several attempts to demonstrate functional deficits after sectioning the crossed OCB have failed.[133] A series of more recent studies has systematically examined the effects of electrically stimulating the crossed OCB on auditory nerve fiber dynamic ranges that have been compressed by broadband noise stimulation.[100] The restoration of dynamic range in the presence of background noise supports the notion that the cochlear efferent system may function to improve the ability to discriminate complex signals (ie, the signal-to-noise ratio). However, the hypothesis that the olivocochlear system primarily provides some sort of input gating mechanism may not be completely correct.

The most recent and unexpected effect of stimulating the crossed OCB is a decrease in the levels of OAEs that are generated mechanically by the cochlea and recorded in the ear canal. Mountain was first to report that electrical stimulation of the olivocochlear efferent system directly affected the active nonlinearities in OHC mechanics inferred from decreases in DPOAEs.[82] A number of other studies evaluating the influence of contralateral acoustic stimulation with wideband noise on OAEs recorded ipsilaterally reported small reductions in TEOAEs[101] and in $2f_1$-f_2 DPOAEs.[134] The influence of contralateral stimulation on OAEs also supports the notion that the cochlear efferent system is involved in the modulation of OHC micromechanics. These effects, along with the reductions in neural discharge rate and tuning, suggest that the function of the crossed OCB is to allow the central auditory system to govern the mechanical properties of the basilar membrane by controlling the vulnerable cochlear tuning mechanism previously discussed. Because detuning a frequency bandpass system increases damping, the detuning effect of the crossed OCB could be useful as a method of improving auditory temporal resolution (eg, to improve speech perception). The consensus view at present is that the active transduction process[135] is regulated in some way through efferent innervation of the

OHCs.[89] Also, as noted above, the olivocochlear efferent system may also contribute toward extending the dynamic range of the auditory system.[136]

In addition, other experimental results suggest that the olivocochlear system may help protect against acoustic trauma.[136] In this work, it was discovered that the amount of threshold shift induced by overstimulation of one ear could be reduced by the presentation of a simultaneous tone to the contralateral ear, thus inferring that activating the efferent system reduced the effects of overexposure. One intriguing line of current research on the traumatic effects of noise exposure is the notion of "training" the cochlea to become less susceptible to damaging sounds.[138,139] One common protocol to induce the training (or conditioning or toughening) effect is to apply daily, moderate-level sound exposures to reduce injury from a subsequent high-level noise exposure.[140] Although the underlying mechanism(s) responsible for the trained protective effect is, at present, unknown, the most likely site is the crossed cochlear efferent system.[141,142] Indeed, LePage demonstrated that loud sound induces a mechanical baseline shift in the position of the cochlear partition.[143] It is highly probable that such a gain control system is effected by cochlear efferents.

Central Auditory Pathway

Each of the five primary senses sends information into the brain via two separate pathways: a direct or specific pathway and a nonspecific pathway. The nonspecific pathway involves structures in the core of the neuraxis, collectively known as the reticular system. In the reticular system, all sensory modalities share the same gross neural structures (hence the name nonspecific). Ascent via the nonspecific structures is multisynaptic and hence is characterized by long delay times.

The direct pathways for each sensory modality are separate and involve long axonal processes, with a minimal number of synapses; consequently, compared with the indirect pathway, transmission along the direct pathways involves minimal delay times. The synapses of the direct pathways tend to congregate in well-defined neural structures called nuclei. Clinically, lesions of the central auditory system are localized according to their level in the direct projection pathway. Therefore, the following discussion emphasizes this pathway.

Anatomy Figure 4–30 diagrams the direct auditory projection pathway. The numbers in each nucleus indicate neuronal order (determined by the number of synapses). The auditory projection pathway is more complex than the pathways of other sensory systems, possibly because it developed relatively late on the phylogenetic scale and had to incorporate pieces of other already developed neuronal systems. Although the basic wiring diagram depicted in Figure 4–30 has remained relatively unchanged for many years, it should be emphasized that within the last 25 years, a number of advances have been made in the development of methods for describing neuronal connectivity.[144] These breakthroughs have relied on the discovery that, when certain amino acids, conjugated enzymes (eg, horseradish peroxidase–conjugated lectin from soy bean), sugars, or immunocytochemicals (eg, polyclonal or monoclonal antibodies) are injected into a neuronal or fluid (eg, cochlear duct) region of interest, they will be taken up by the cells or nerve fiber endings in this region and transported by the normal cellular process of axonal transport in both retrograde and anterograde directions. Other techniques make use of such

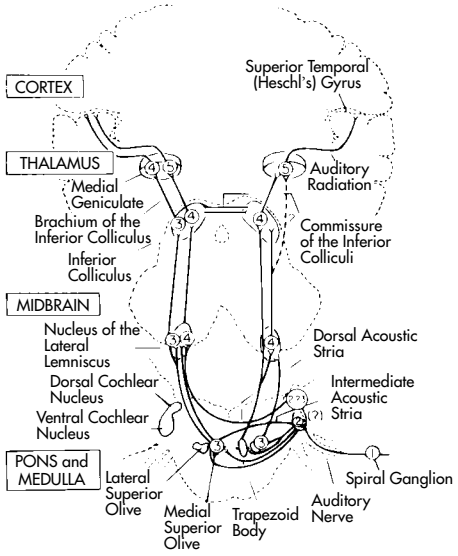

FIGURE 4–30. Diagram of the direct auditory projection pathway. *Numbers* indicate the approximate neuron order as determined by the number of synapses traversed. *Dashed lines* labeled with question marks indicate two areas of uncertainty: (1) whether the dorsal cochlear nucleus primarily contains second- or third-order neurons and (2) whether any nerve fibers bypass the inferior colliculus.

labels as lipophilic dyes (eg, dilinoleyl-tetramethylindocarbocyanine or Dil), which can be retrogradely transported in fixed tissue by diffusion.

Visualization of the location of cellular projections or the cellular/subcellular location of labeled substances at the light and electron microscope levels is achieved either by autoradiography, in the case of radioactive compounds, or by catalyzation of histochemical reactions, which are typically viewed under epifluorescence or darkfield optics. With recent refinement of these tract-tracing and cell component–labeling techniques using immunohistochemical markers, virtually all projection pathways and cell types of the auditory system have been described. Lagging far behind our description of the connections of the neural pathway for hearing is our understanding of how this network of interconnections interacts to produce our complex auditory sensations. Presented below is a brief description of the major projections of the auditory pathway sufficient for the clinician to understand the transfer of information within the auditory system, without consideration of the many lesser connections revealed by modern immunocytochemical staining techniques. The reader is referred to several comprehensive reviews that provide more details of the intricate interconnections of the central auditory system.[96,145]

Cochlear Nucleus. Central processing of the information carried in the auditory nerve begins in the cochlear nucleus (CN), the first obligatory synapse for all nerve fibers. On entering the CN, the auditory portion of the eighth nerve bifurcates into two branches, one that sends fibers to synapse in the anteroventral cochlear nucleus (AVCN) and one that synapses in the posteroventral cochlear nucleus (PVCN) and DCN. The distribution of fibers within the CN is not random but follows an orderly pattern of tonotopic projection throughout the nucleus, with low-frequency fibers projecting ventrally and high-frequency fibers distributed dorsally. Thus, both neurophysiologic and anatomic observations show that cochlear place is represented in an orderly manner throughout the projection pathways of the central auditory system.[146] The security of tonotopic organization is also apparent in the multiple representation of the stimulus frequency domain. For example, typically, along any one penetration of a microelectrode trajectory within a principal nucleus, there are two or more breaks in the orderly progression of best frequencies. Thus, as in the direct projection pathways of all sensory systems, multiple representation of the receptor surface occurs. It is likely that nerve fiber branching in the various nuclei, as described for the CN, is the anatomic basis of this multiple-frequency representation.[147]

All auditory nerve fibers display relatively uniform response characteristics to pure-tone stimuli compared to the activity of CN cells when categorized by the use of a poststimulus time histogram (PSTH).[113] The PSTH plots the number of nerve discharges that occur in small time bins within the period that begins slightly before and extends throughout the duration of the stimulus. Poststimulus time histograms are shown for an auditory nerve fiber and various CN cells in Figure 4–31. The CN consists of at least nine different cell types described for their anatomic characteristics revealed by various staining techniques.[148] It can be seen from the unit activity patterns of Figure 4–31 that the uniform response characteristics of auditory nerve fibers are soon elaborated on by the various cells of the CN to produce a variety of response types named after the patterns seen in the PSTH.[149] When examined in the frequency intensity domain, some CN cells exhibit complex response patterns that describe regions of excitation and inhibition produced by a pure-tone stimulus. An example of such complex response patterns by cells in the CN is shown in Figure 4–32.[149]

Three fiber pathways project information from the CN to higher brainstem centers. These fiber tracts include the ventral (trapezoid body), intermediate, and dorsal acoustic striae. The ventral acoustic stria, originating from AVCN and PVCN regions, projects ventrally and medially to send fibers ipsilaterally to the lateral superior olive (LSO) and the medial superior olive (MSO) and then to the medial nucleus of the trapezoid body (MTB). The fibers then cross the midline to terminate on the contralateral MSO and MTB but do not innervate the LSO on the opposite side. Thus, for any one ear, connections are bilateral only to the MSO and MTB.[150]

The intermediate acoustic stria, the primary output of the PVCN, sends some fibers ipsilaterally to a group of cells around the SOC called the periolivary nucleus (PON), whereas other fibers ascend in the lateral lemniscus (LL). This pathway also crosses the midline to innervate the same structures on the contralateral side. Fibers of the intermediate acoustic stria that enter the LL synapse within the nucleus.

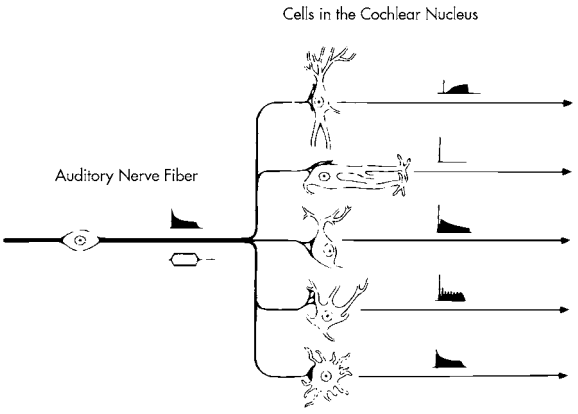

FIGURE 4–31. Diagram showing the diverse single-unit response types obtained from cells in the cochlear nucleus compared to the uniform response pattern found for fibers of the auditory nerve. The poststimulus time histograms were obtained by presenting short 25 to 50 ms tone bursts at the unit's characteristic frequency. Response types from top to bottom are pauser, on_1, primary like with notch, chopper, and primary like. Cell types presumably associated with these response patterns from top to bottom are pyramidal, octopus, globular, multipolar, and spherical. Reproduced with permission from Kiang NYS. Stimulus representation in the discharge patterns of auditory neurons. In: Tower DB, editor. The nervous system. Vol 3. Human communication and its disorders. New York: Raven Press; 1975.

The dorsal acoustic stria, the principal output of the DCN, bypasses the SOC to synapse in the contralateral dorsal nucleus of the LL and the inferior colliculus (IC).[150]

SUPERIOR OLIVARY COMPLEX. The SOC is composed of the LSO, MSO, MTB, and PON. The SOC receives fibers from both CNs and consequently receives information from both ears. This feature allows this group of nuclei to monitor the arrival time and level of sounds to both ears and provides the cues for the localization of sound in space based on the stimulus arrival time and intensity to both ears.[150] In fact, localization of sound in the horizontal plane provides the most straightforward relationships that have been observed between central auditory single-unit behavior and psychophysical function. As sound to one ear is made progressively louder or earlier than sound to the opposite ear, some SOC units change abruptly from inhibitory to facilitatory response patterns. By assuming a facilitatory contralateral input and an inhibitory ipsilateral input (or vice versa), the neurophysiologic behavior of these units can be explained. Thus, slight binaural differences in level and/or arrival time provide the auditory cues for localization of sound in the horizontal plane (sound lateralization). The acoustic image is located on the side of the louder or earlier sound. As a whole, the SOC represents the lowest

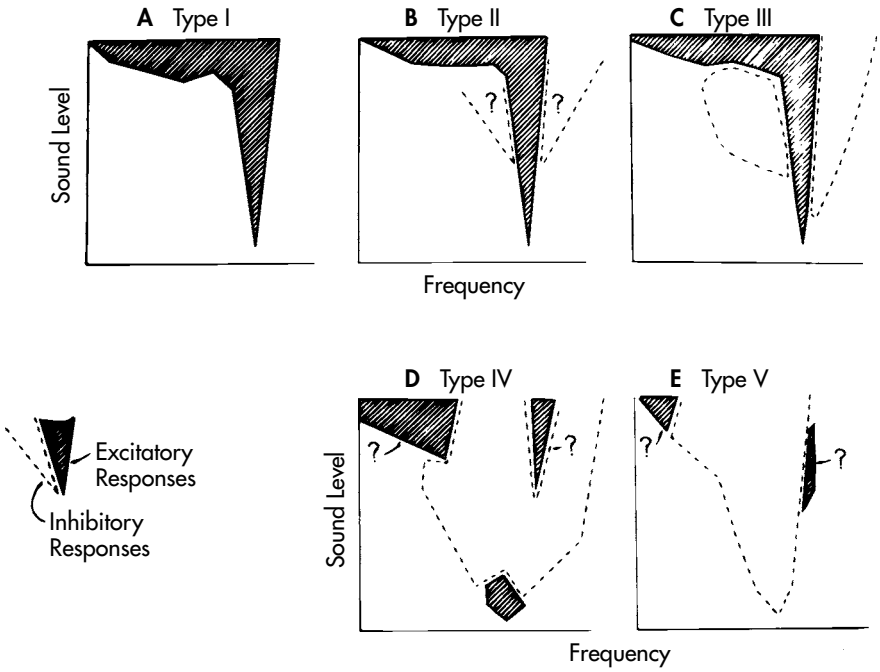

FIGURE 4–32. Tuning curves of excitation and inhibition in the cat cochlear nucleus are shown in order of increasing amounts of inhibition (*A–E*). Purely excitatory responses as in *A* are predominant in the anteroventral cochlear nucleus. Greater amounts of inhibition are found toward the dorsal cochlear nucleus (*D* and *E*). *Question marks* show variable or uncertain features. Reproduced with permission from Young ED.[150]

level in the auditory system at which binaural processing takes place.151 However, at all levels in the auditory projection pathway above the trapezoid body, there are units that are sensitive to binaural time and level differences.152,153

Lateral Lemniscus. The LL is the major ascending projection from the CN and SOC to the IC and contains both contralateral and ipsilateral fibers from lower auditory brainstem structures. Although there are three distinct nuclei within the LL, historical emphasis has been simply on its function as a connection between the SOC and IC. Recently, these nuclei have received more attention in attempts to define their role in auditory processing.[154]

Inferior Colliculus. The IC receives synapses from the majority, if not all, of the fibers projecting from the lower auditory nuclei. The three neuronal areas that make up the IC are the central, external, and pericentral nuclei. The predominant termination zone for the ascending auditory projections is in the ventrolateral region of the central nucleus. This region receives inputs from the SOC and a heavy contralateral input from the DCN. Other major projections come ipsilaterally from the MSO and bilaterally from the LSO. The function of the IC is far from completely understood, with many neurons exhibiting complex excitatory/inhibitory interactions. A simple view is that the IC integrates the frequency analysis features of the DCN with the localization abilities of the SOC.[150]

Medial Geniculate. The medial geniculate (MG) is the thalamic relay nucleus for auditory information. All auditory projections from the IC to the auditory cortex pass through the MG. This nucleus is also composed of three divisions, the ventral, dorsal, and medial nuclei.[155] The ventral nucleus receives heavy ipsilateral projections from the ventrolateral portion of the central nucleus of the IC. This portion of the MG projects to the AI, AII, and Ep regions of the auditory cortex (see below). Again, a wide variety of single-unit response types have been recorded in the MG. In attempting to understand the MG's role in auditory processing, special efforts have been made to examine MG single-unit responses to complex sounds. Thus, David and associates[156] and Keidel[157] demonstrated that MG neurons in the unanesthetized cat were responsive only to specific parameters of complex speech sounds. In general, it has been extremely difficult to attribute specific feature extraction capabilities to neurons in the higher auditory nuclei that cannot be explained by complex responses already present at the level of the CN.

Auditory Cortex. The auditory cortex has been most extensively studied in the cat and can be divided into three areas based on similarity of Nissl-stained cytoarchitectural details.[158] These include a primary area AI, a secondary area AII, and a remote projection region Ep. In human and nonhuman primates, the primary auditory projection area is located in the temporal lobe but hidden by the sylvian fissure. The ventral division of the MG projects almost entirely to AI,[159] which can be considered the primary auditory cortex. Surrounding auditory areas receive projections from all divisions of the MG. Like the auditory relay nuclei, the auditory cortex is also tonotopically organized. As might be expected by the many intricate interconnections of the auditory system prior to input arriving at the cortex, the understanding of cortical processing has been a complex and difficult task. One approach to solving the problem of cortical function has been the use of ablation studies in which the auditory cortex is removed after training an animal to perform a specific auditory task. These studies have demonstrated that cortical ablation does not result in a complete loss of function as do similar lesions in the visual system. In fact, for many simple tasks, no long-term deficits can be detected.[157] Based on these results, it is reasonable to assume that the auditory cortex is involved in numerous details of more complex auditory processing. Consequently, it is unlikely that one simple unifying concept will be uncovered that describes the functional role of the auditory cortex.

Summary Although there have been many studies of single-unit activity in the auditory nuclei over the past 50 years, they have thus far yielded few unifying principles about the data-processing mechanisms of the auditory nervous system. However, a number of recent studies suggest that, in many instances, the brain makes use of patterns of activity distributed over many cells to extract relevant information.[147] Consequently, if future studies focus on describing the responses of individual cells without viewing their participation, as a whole, in some functional

unit, they may be doomed to result in failure as a means of understanding central auditory processing.

Auditory-Evoked Electrophysiologic Responses

Modern averaging techniques have made it possible to record from humans, with surface electrodes, electrical responses reflecting the entire auditory pathway, from cochlea to cortex.[160,161] Clinical applications of this technique have expanded rapidly and are routine in most otolaryngology clinics today. In this section, some basic physiologic principles are discussed on which the clinical applications of auditory evoked potentials are based.

Two major classes of human auditory evoked potentials generated by acoustic transients (clicks) are used clinically. One class is recorded with an electrode located as close to the cochlea as possible, that is, either extratympanic (eg, located on the external ear canal skin) or transtympanic (eg, penetrating the eardrum to rest on the medial wall of the middle ear).[162] Tests based on this class of auditory evoked potentials have been termed electrocochleography (ECochG). The second class of auditory evoked potentials is recorded between one electrode located on the vertex and another near the external ear (eg, either on the mastoid or earlobe). This latter class of evoked potentials has been subdivided conventionally according to their onset latency range into early, middle, and late responses.

Electrocochleographic Responses: Whole-Nerve Compound Action Potential, Cochlear Microphonic, Summating Potential *Description of the Responses.* Figure 4–33 shows a typical example of cochlear and auditory nerve click-evoked potentials recorded from the ear canal. Evoked responses to clicks of opposite polarity are shown in Figure 4–33, A. The whole-nerve CAP has two or more ear canal negative peaks designated N_1, N_2, N_3 (N_2 and N_3 not labeled here), and so forth. Each peak lasts about 1 ms and, in normal ears, N_1 is always the larger peak. In Figure 4–33, B, the CM appears as a series of sinusoidal oscillations, typically about 3 kHz, on the leading edge of the N_1 peak. The SP in

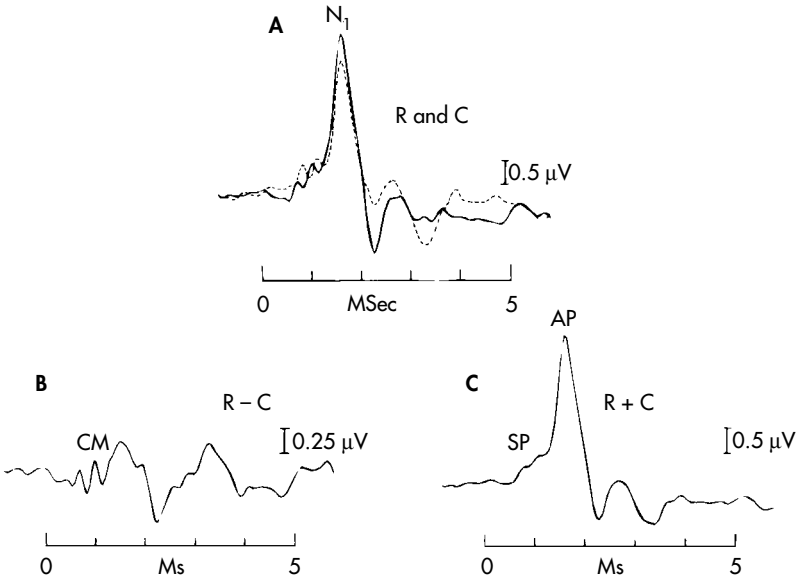

FIGURE 4–33. Examples of cochlear and auditory nerve electrical responses to clicks recorded from the human outer ear canal. The cochlear potentials are the cochlear microphonic (CM) and summating potential (SP). *A*, The whole-nerve compound action potential typically has a large negative peak (N_1). R and C are shown as separate condensation (*dashed line*) and rarefaction (*solid line*) rectangular-pulse click responses recorded from the outer ear canal with a nasion "reference" electrode. *B*, R – C is the waveform produced by subtracting C from R responses. *C*, R + C is the waveform produced by adding C and R responses. Upward deflections represent negativity at the ear canal, and time scale zeroes are set at the leading edge of the rectangular pulse driving the earspeaker. Click rate was 8/s; click level was 115 dB peak equivalent SPL. Each C and R response was the average of 1,000 single sweeps.

Figure 4–33, C, appears as an ear canal negative hump on the leading edge of the N_1 peak, with the CM oscillations superimposed.

The auditory nerve CAP (see Figure 4–33, A) is the sum of the synchronous firing of single-fiber auditory nerve fibers as seen by the distant recording electrode as illustrated in Figure 4–34.[163] The single-unit spikes are triggered by the passage of the cochlear traveling wave. Thus, spikes from basal (high-frequency) fibers appear at the recording electrode earlier than spikes from apical (low-frequency) fibers. Because the degree to which single neural unit responses contribute to the evoked potential is determined largely by their synchrony, high-frequency (basal) fibers contribute more effectively to the whole-nerve CAP and also to the evoked auditory brainstem response (ABR) than do low-frequency fibers.

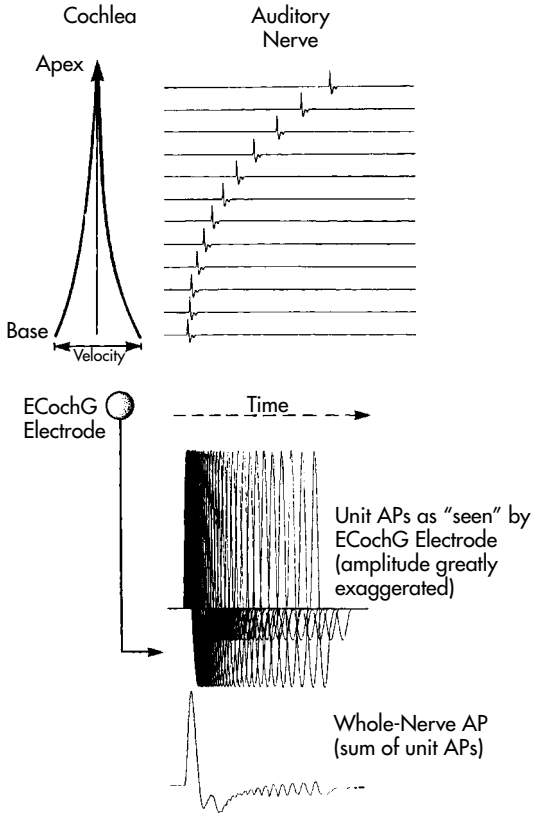

FIGURE 4–34. Summation of the single-unit spikes (amplitude exaggerated) picked up by a distant electrocochleographic (ECochG) electrode to form the whole-nerve compound action potential (CAP). Note that the highly synchronized spikes from the basal end of the cochlea sum more effectively than the poorly synchronized spikes from the apical end of the cochlea. The records of unit action potentials (APs) and the whole-nerve CAP at the bottom are from a simplified computer experiment. Reproduced with permission from Elberling C.[163]

This principle leads to several important conclusions for clinical applications: (1) broadband-click evoked CAPs preferentially reflect high-frequency fiber activity, and, as a corollary, high-frequency clicks are more effective generators of auditory evoked potentials than low-frequency clicks[164]; (2) high-frequency hearing loss caused by selective removal of basal units tends to bias the broadband click-evoked CAP and ABR toward more apical units. Therefore, high-frequency cochlear deficits prolong N_1 peak latencies[164]; and (3) a low-frequency deficit does not cause a corresponding basalward shift because of the already existing heavy bias toward basal units in the normal response. Therefore, low-frequency cochlear deficits have no apparent effect on CAP and ABR latencies. Because the CM response follows the waveform of basilar membrane vibration, it reverses polarity when click polarity is reversed, whereas the envelope-following SP does not. The neural response also maintains the same polarity. Thus, adding together responses to opposite-polarity clicks cancels out the polarity-reversing CM and allows a better view of the SP (see Figure 4–33, C). In contrast, subtracting the condensation and rarefaction responses preserves the CM, while canceling the SP and most of the CAP (see Figure 4–33, B).

The cochlear receptor potentials (CM, SP) can also be separated from the CAP because receptor potentials are nonrefractory and do not adapt, whereas neural responses do. Thus, masking and increasing click rate are often used in clinical testing to depress selectively the neural response while preserving the CM and SP.

Reliable methods for separation of the SP from the other cochlear potentials have made this response useful in the diagnosis of Meniere's disease.[165] A number of studies have demonstrated that the SP is enlarged in a certain percentage of patients with Meniere's disease.[166] Evidence supporting the notion that SP enlargement is specifically related to endolymphatic hydrops is provided by observations that manipulations expected to reduce fluid accumulation within the endolymphatic space (eg, administration of hyperosmotic agents such as glycerol) often shrink abnormally enlarged SPs.[167]

Vertex-Recorded Auditory Evoked Potentials

Description of the Responses Figure 4–35 shows examples of early (A), middle (B), and late (C) vertex-recorded auditory evoked potentials generated by broadband clicks. Commonly used peak designations are also shown. In all traces, upward deflection represents negative voltage at the vertex ("referred" to an electrode on the mastoid). Note the differences in the time and voltage scales. The early response, commonly termed the ABR, is the smallest and also is the most recently discovered.

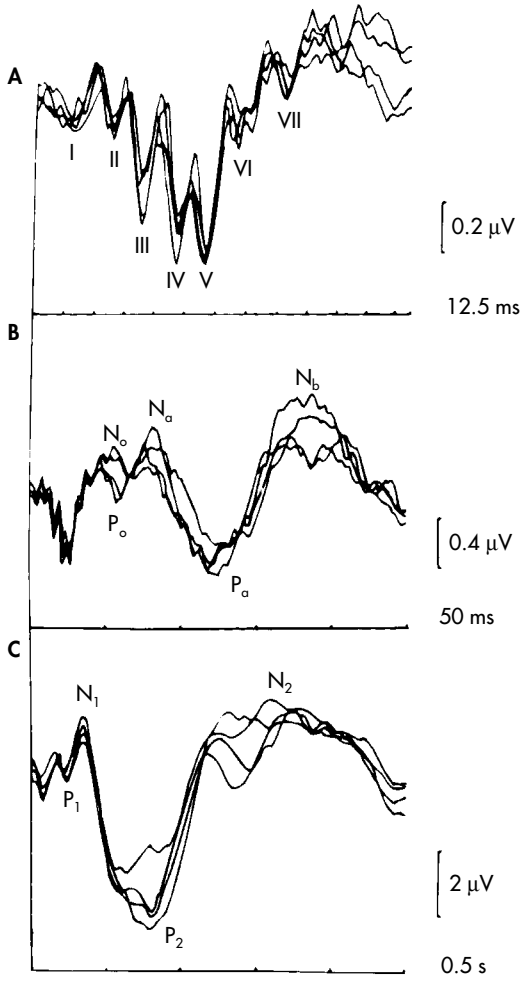

FIGURE 4–35. Averaged human click-evoked potentials, recorded with vertex-mastoid electrodes. Upward deflection represents negativity at the vertex. From top to bottom, the time base is slowed to demonstrate progressively later responses. *A*, Auditory brainstem response (with the polarity opposite to the response recorded with a nasopharyngeal electrode). *B*, Middle latency response. *C*, Late "vertex" auditory evoked response. Each tracing represents the average of 1,024 single responses. Several tracings are superimposed in each record to give an idea of variability. Roman numerals and letters identify individual peaks of the various responses according to accepted convention. Reproduced with permission from Picton TW et al.[161]

Auditory Brainstem Response. An example of an ABR is shown in Figure 4–35, A, in which the peaks of this response are labeled with Roman numerals I to VII. It can be seen that the ABR occurs approximately between 1 and 8 ms after stimulus onset. Wave V is typically the largest and most robust of the potentials, and waves beyond V are seldom used clinically. Studies in humans[168] and animals[169] suggest that wave V is generated at the LL. Thus, the ABR is probably not useful in detecting abnormalities at or above the level of the IC.[170] However, for the lower brainstem, the ABR is one of the best audiologic tests for detecting dysfunction.

The ABR is one of the most frequently used auditory evoked potential procedures because the variables that affect this response have been well described and it provides a good measure of cochlear sensitivity and retrocochlear status. Clinically, the response can be interpreted by quantitative measures of peak latencies, interpeak intervals, and interpeak latency differences. In addition, the presence or absence of the various waves is noted as well as waveform morphology.[171]

Middle Latency Response. The middle latency response (MLR), labeled N_0, P_0, N_a, P_a, and so forth (Figure 4–35, B), occurs between 8 and 40 ms after the auditory stimulus.[172] In animals, wave P_a appears to be generated in the primary auditory cortex by cortical elements on the side contralateral to stimulation.[173] However, in humans, P_a seems to be generated in both hemispheres, even with monaural stimulation. Human cortical mapping localizes this potential to the region of the sylvian fissure,[174] whereas studies based on clinical correlations indicate involvement of thalamocortical projections to the primary auditory area located along Heschl's gyrus in the genesis of this response. Site-of-lesion studies suggest that wave N_a originates in the midbrain, including such structures as the MG and thalamocortical projections.[174]

Although the MLR is not used nearly as frequently as ABR, useful clinical information can be obtained from this response, particularly in conjunction with ABR testing. The MLR is robust at all

frequencies including low frequencies below 1,000 Hz and, consequently, offers a complementary index of high- and low-frequency hearing.[175] The MLR can also be useful in assessment of central auditory system disorders, neurologic evaluation, and, most recently, as a tool for cochlear implant assessment.[176] The most significant disadvantage of MLR is that subject variables such as sleep state or sedation can severely reduce the amplitude of this potential. Thus, behavioral state must be controlled for to obtain meaningful results.

Late Auditory Evoked Response. The relatively high-amplitude late auditory evoked response (LAER), labeled P_1, N_1, and so forth (also called the vertex potential), occurs between 50 and 250 ms after the stimulus (Figure 4–35, C). It is a cortical response, but its long latency suggests that the LAER is not generated within the primary auditory cortex but rather that it originates in the associative cortex.[161] These potentials are often very dependent on the subject's state of alertness and consequently have received little use in clinical situations.

Auditory Brain Mapping One technique that is receiving considerable attention as a new and potentially powerful diagnostic tool is the use of auditory brain mapping. Methods for this procedure are highly similar to those used to obtain the traditional evoked responses already described. The primary difference is that brain mapping simultaneously records the electrical activity from an array of scalp electrodes. Although this mass of data could be viewed as many evoked potentials, the human observer cannot readily interpret such a massive amount of data. Therefore, brain mapping was developed using computer-processing techniques to provide a visual display of the potential fields among all of the electrodes simultaneously. This method reduces the data into a multicolored or shaded plot in which intense activity is usually given the most brilliant color or the darkest shading. An example of the typical electrode placements and the derivation of a simple brain map are shown in Figure 4–36. With this type of visual output, patterns of activity in normal patients can be established and abnormalities easily visualized in pathologic cases. Computer techniques also allow the clinician to view the patterns of activity throughout the duration of the stimulus to produce a motion picture of the evoked electrical activity that occurred over time. This method allows for the visualization of the spatiotemporal patterns of brain activity. Because the data are stored in the computer, a number of advanced mathematical processing methods, which permit further refinement of the data, can be applied

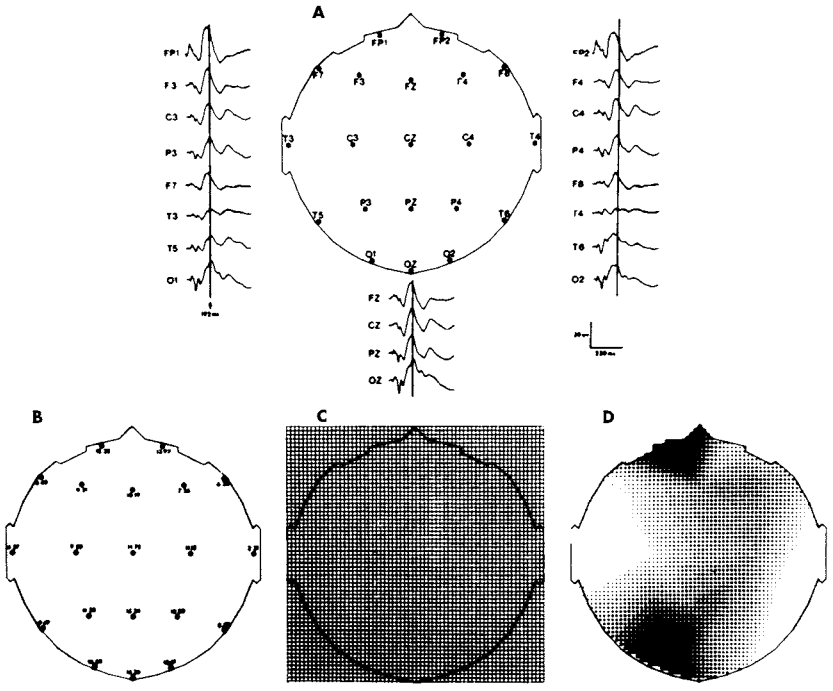

FIGURE 4–36. Example of the construction of topographic images from evoked potential data. *A*, Individual evoked potentials are shown at the electrode locations indicated in the diagram. *B*, Mean voltages are shown for the time interval 192 ms after the stimulus. *C*, Head region is divided into a 64×64 matrix to produce 4,096 spatial domains. Each spatial domain is assigned a voltage derived by linear interpolation from the three nearest recording locations. *D*, A visual image constructed by fitting a discrete-level, equal-interval intensity scale to the points of *C*. Although a visual evoked potential was used to create this topographic map, the same procedure is used for mapping auditory data. Reprinted with permission from Duffy DF.[177]

to aid in the detection of subtle abnormalities. For more information on this topic, the reader is referred to these comprehensive reviews.[177,178]

Magnetoencephalography Magnetoencephalography (MEG) involves the completely noninvasive recording of weak cerebral magnetic fields, which represent about one part in 109 of the earth's geomagnetic field, outside the head.[179] The neuromagnetic technique was made possible by the invention of SQUID (superconducting quantum interference device) magnetometers. Using a whole-head neuromagnetometer, magnetic brain signals are averaged by time-locking them to the onset of acoustic stimulation. It is assumed that the probable sources of cerebral magnetic fields are the electric currents in the synapses of synchronously activated cortical pyramidal neurons, and the sinks or volume currents, to complete the electrical circuit, are generated in the surrounding tissue. The development of multichannel systems increased the speed and convenience of neuromagnetic recording and made it feasible to apply MEG for clinical purposes.

Based on the accurate spatiotemporal resolution of whole-head MEG, Hari and Lounasmaa have been instrumental in applying MEG to investigate the activity of the auditory projection areas, particularly with respect to language-related sites.[179] A schematic illustration of a typical experimental setup for auditory measurements is illustrated in Figure 4–37 and shows the relationship of the SQUID to the patient's head. The inset above indicates the isocontours across the scalp for the component of the magnetic field, which is generated by the active region of the auditory cortex. An example of the averaged magnetic responses from measurement sites anterior (above) and posterior (below) to the sylvian fissure of

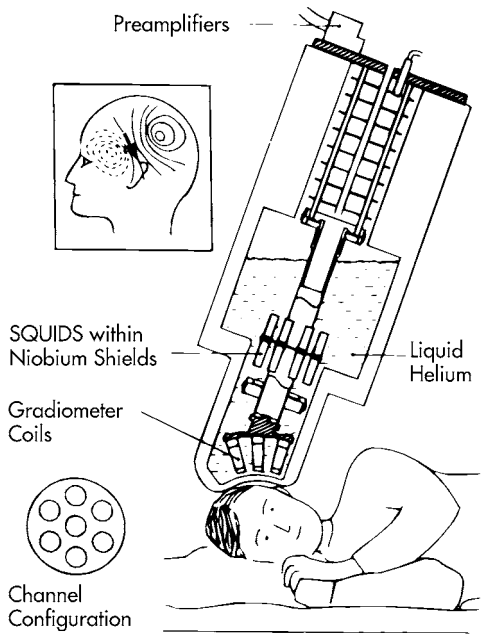

FIGURE 4–37. Schematic illustration of a typical experimental setup for auditory measurements using magnetoencephalography. The most important parts of the seven-channel DC SQUID instrument are shown, with the midpoints of the different channels separated by 36.5 mm. The *inset* above depicts isocontours across the scalp for the radial component of the magnetic field, generated by an active area in the auditory cortex. The *arrow* illustrates the location of the equivalent current dipole. Reproduced with permission from Hari R and Lounasmaa OV.[179]

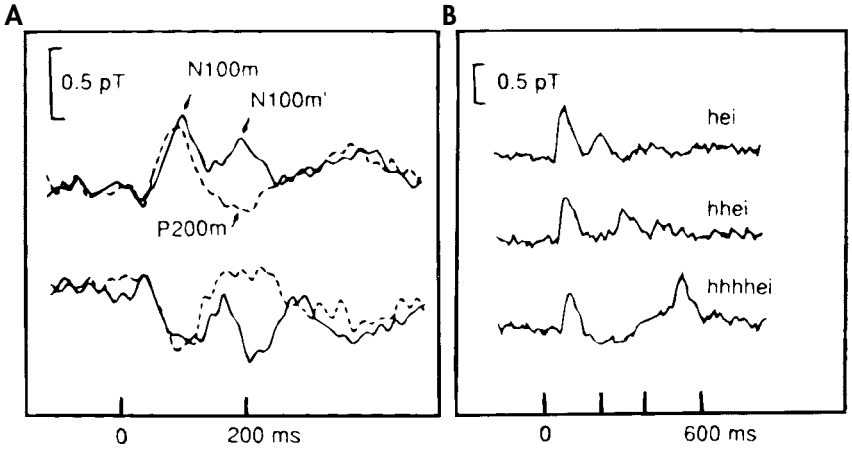

FIGURE 4–38. Averaged magnetic responses from the auditory cortex. *A*, Averaged magnetic response (n = 120) to "hei" words (*solid lines*) and noise bursts (*dashed lines*) from the right hemisphere in one subject; the upper curves are from an anterior and the lower ones from a posterior measurement location near the ends of the sylvian fissure. The passband was 0.05 to 70 Hz. *B*, Effect of increasing the duration of "h" in another subject. Reproduced with permission from Hari R et al.[180]

the right hemisphere (ie, along the superior surface of the temporal lobe) are shown for one subject for a spoken word (solid line) and noise bursts (dashed lines) on the left side of Figure 4–38. The right side of Figure 4–38 illustrates the effects of increasing the duration of the onset of the word in another subject. It is clear that sound evokes a complex magnetic waveform, which lasts several hundred milliseconds after stimulus onset. Interesting and clinically useful data have been obtained about the perception of speech of deaf patients with cochlear prostheses by examining the activity of their auditory cortices with MEG.[180] Information of this real-time sort implies that neuromagnetic recording may be used to assess functional disorders in more detail than what is possible by other clinical evidence; thus, it is likely to become an important diagnostic tool of the future.

Neuroimaging The beginning of in vivo imaging in awake and behaving subjects has revolutionized the ability to relate structure to function, particularly in the human brain. For example, three-dimensional magnetic resonance imaging (MRI) provides detailed static images of the in vivo brain, with spatial resolution on the order of cubic millimeters. Other functionally related techniques in neuroimaging such as positron emission tomography and functional MRI provide excellent spatial and temporal resolutions for recording changes in regional blood flow and cellular metabolism during auditory stimulation. These techniques have been used to study a number of central auditory processes, including speech perception,[181,182] revealing tinnitus-related abnormalities in brain function.[183,184] Although these individual functional imaging approaches still have some limitations, the results are converging to improve our understanding of the neural processes underlying both normal and pathologic auditory function.

Evoked Otoacoustic Emissions One of the principal benefits of OAEs with respect to clinical testing is that they provide an objective and noninvasive measure of cochlear activity, which is completely independent of retrocochlear activity. In particular, OAEs measure the functional responses of OHCs that are uniquely sensitive to agents that damage hearing. Kemp,[80] the pioneer investigator into the basic features of OAEs, has also been instrumental in establishing one class of evoked emissions, the click-based TEOAE (see Figure 4–22, C), as a potentially useful diagnostic indicator of various ear diseases including Meniere's disease[104] and acoustic neurinoma.[185] In addition, Kemp and Ryan have also established the use of the click-evoked OAE as a method of screening for hearing dysfunction in newborns.[186]

Because of the frequency specificity of the eliciting pure tones, DPOAEs (see Figure 4–23) also have a beneficial clinical applicability. This stimulus-related frequency specificity permits DPOAEs to be measured after averaging the responses to only a few stimuli. Thus, under computer control, the fine resolution of DPOAEs in both the stimulus frequency and level domains permits the precise determination of the boundary between normal and abnormal OHC function. Data from our laboratory illustrate this feature of DPOAEs in the plots of Figure 4–39, A,[187] which show the development of ototoxicity during a course of antineoplasm therapy with cisplatin. Comparing the OAE findings with behavioral hearing (top), note the abrupt change in hearing and emission activity between 2 and 3 kHz (open circles), which accurately followed the 40 dB loss in hearing sensitivity produced by the ototoxic agent.

Based on their ability to distinguish between the relative contribution that sensory and neural components of the cochlea make to a hearing loss, OAEs promise to facilitate identification of the anatomic substrate of complex ear diseases. For example, the records shown in Figure 4–39, B, represent a typical pattern of audiometric loss in early Meniere's disease, which is accompanied by thresholds that are > 40 dB HL and, not unexpectedly, no TEOAEs (bottom left) and abnormally low-level DPOAEs (solid circles). Together, these results imply that the OHC system is involved in this patient's disease. However, other patients with Meniere's disease, who show a similar hearing loss, can demonstrate rather robust DPOAEs, even for test frequencies for which behavioral thresholds are > 50 dB HL.[188] Such differential findings for patients with Meniere's disease suggest that OAEs can distinguish between disease states that involve either OHCs (see Figure 4–39, B) or other cochlear processes that are probably neural in origin (eg, degeneration of the unmyelinated dendritic endings of the cochlear nerve). A comparable example of this feature of OAE testing to contribute toward differentiating between cochlear versus noncochlear involvement in hearing disease is illustrated in Figure 4–40 for two patients diagnosed with acoustic neurinomas. The patient in Figure

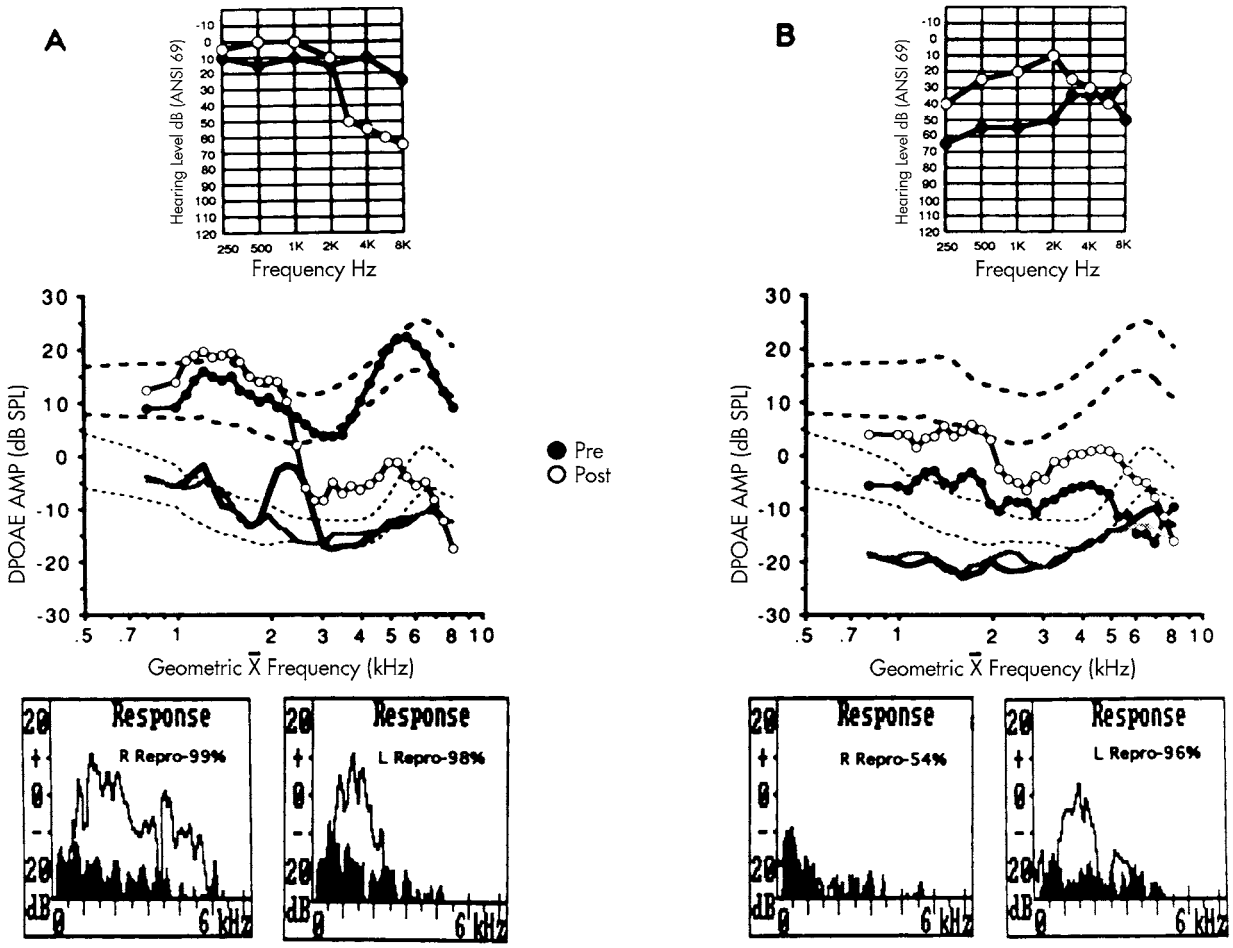

FIGURE 4–39. Conventional audiograms (*top*), distortion-product otoacoustic emission (DPOAE) frequency/level or DP-gram functions (*middle*) relating emission magnitude to stimulus frequency, in 0.1 octave steps from 0.8 to 8 kHz, for primary tone levels of 75 dB SPL, and click-evoked transient evoked otoacoustic emissions (OAEs) (*bottom*) elicited by the "default" mode of the ILO88 Otodynamic Analyser. *A*, Behavioral hearing and evoked OAE findings for the right ear of an 8-year-old girl comparing pre- (*solid circles*) versus post-treatment (*open circles*) responses following a course of antineoplasm therapy with cisplatin. Immittance and speech testing results were normal for the baseline session and were not tested during the post-treatment examination. *B*, Audiometric and OAE results for the left ear of a 49-year-old woman for two test sessions separated by about 2 weeks. The patient complained of a fluctuating hearing loss, tinnitus, aural fullness, and episodic dizziness of several months duration. Immittance findings were normal, whereas the speech discrimination score and speech reception threshold improved from 72 to 96% and 55 to 25 dB HL, respectively, at the last evaluation period (*open circles*). Reproduced with permission from Balkany TJ et al.[187]

4–40, A, displays the expected outcome for OAE testing in the presence of a retrocochlear disease. That is, in the presence of a moderate hearing loss on the tumor side (solid circles), both TEOAEs and DPOAEs are measurable. However, it is clear for the patient in Figure 4–40, B, diagnosed with a right-sided (open circles) acoustic neurinoma, that the tumor has modified cochlear function in a manner that mimics the frequency configuration of the hearing loss. Thus, in certain retrocochlear disorders such as tumors of the cerebellopontine angle, cochlear function can be adversely affected, probably owing to compromise of the vascular supply to the inner ear.

One benefit of OAE testing illustrated in Figure 4–39, B, is its sensitivity to changes in hearing status, which are mediated by the OHC system. In this instance, at the time the patient returned for follow-up testing (open circles), her hearing had improved, particularly over the low-frequency test range. The 20 to 30 dB improvement in low-fre-

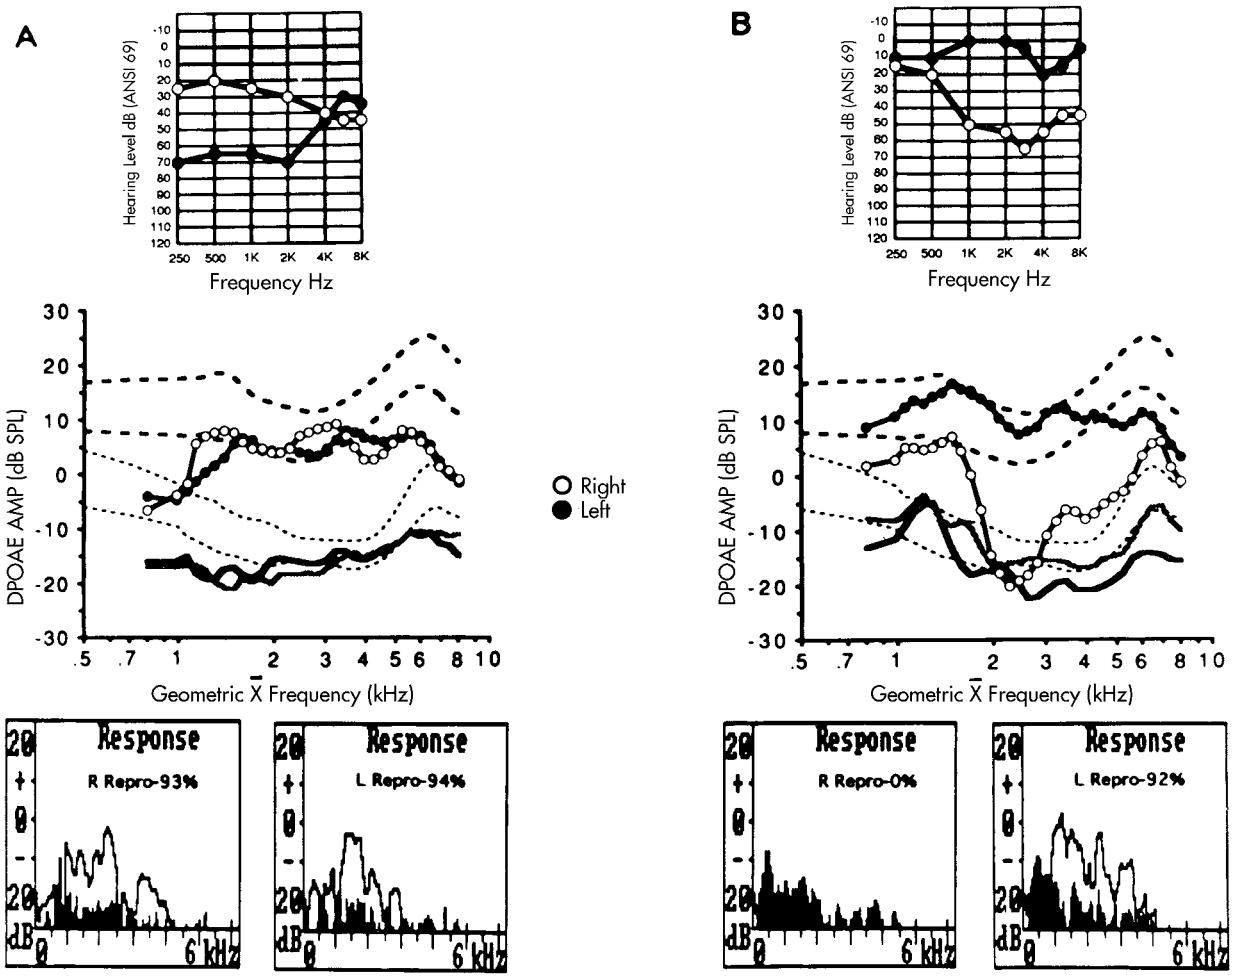

FIGURE 4–40. Audiometric and otoacoustic emission findings for two patients with acoustic neurinomas confirmed by magnetic resonance imaging. *A*, A 39-year-old man with an acoustic neurinoma on the left side who had normal tympanograms but absent reflexes bilaterally. Although speech testing was normal for the right ear (*open circles*), the speech discrimination score and speech reception threshold were 0% and 70 dB HL, respectively, for the involved left ear (*solid circles*). *B*, A 47-year-old woman with a right-sided acoustic neurinoma. Whereas her tympanograms were normal, the only measurable acoustic reflex threshold was for ipsilateral stimuli at 1 kHz. Speech testing was normal for the left ear, whereas the right ear was associated with a speech discrimination score of 60% and a speech reception threshold of 35 dB HL. Reproduced with permission from Balkany TJ et al.[187]

quency hearing was mirrored by a similar increase in DPOAEs and by the ability to now measure TEOAEs.

In addition to the clinical applications noted above for OAEs, a number of studies have also demonstrated the utility of using emitted responses to understand the fundamental basis of a number of cochlear lesions, including the effects of noise-induced hearing loss,[189] hereditary hearing impairment,[190] congenital hearing disorders,[188] ototoxicity,[191] bacterial meningitis,[192] and presbycusis[193] on both TEOAEs and DPOAEs. The interested reader is encouraged to refer to these comprehensive reviews concerning the strengths and limitations of the clinical application of OAEs.[194,195]

VESTIBULAR SYSTEM

General Principles

The nonauditory part of the inner ear (termed the vestibular apparatus) consists of two functional sub-

divisions: (1) the semicircular ducts consisting of two vertical and one horizontal and (2) the otolithic organs consisting of the saccule and the utricle. The semicircular ducts respond to head rotation (ie, angular acceleration), whereas the otolithic organs are stimulated by the effects of gravity and linear acceleration of the head. The primary function of the utricle is to signal head position relative to gravity. Ablation of the saccule produces a less significant deficit than ablation of the utricle; hence, the function of the saccule is less well defined than that of the utricle. In fact, it has been proposed that the saccule is a low-frequency auditory receptor.[196] However, a series of systematic studies using single-unit recordings have revealed that saccular nerve fibers respond only to linear acceleration.[197–199] These findings suggest that the saccular system provides the high-level vertical acceleration signals required to elicit the motor response necessary to land optimally from a fall.[200]

Conventionally, the vestibular system is regarded as one of three sensory systems that function to maintain body balance and equilibrium. The other two are the somatosensory (chiefly proprioceptive) and visual systems. Loss of proprioception (eg, as in tabes dorsalis) or vision causes more significant balance and equilibrium difficulty than does loss of vestibular function. With bilateral vestibular function loss, difficulties occur only when one of the other systems is disrupted (eg, when walking in the dark or on a soft surface) or when balance must be maintained under particularly difficult conditions (eg, walking on a narrow beam).[201] Thus, in humans, under physiologic conditions, the vestibular system is probably the least important of the three balance and equilibrium sensory systems. The most significant functional deficits occur when the vestibular system suffers acute, asymmetric damage and generates "false" head position or head rotation signals.

Vestibular Apparatus

The top portion of Figure 4–2 illustrates the general anatomic plan of the vestibular apparatus. There are many similarities with cochlear anatomy. For example, both end-organs are located in a tunnel that is hollowed out of the petrous portion of the temporal bone (embryologically, both organs come from the same tunnel). The tunnel is divided into an outer perilymph-filled bony labyrinth and an inner endolymph-filled membranous labyrinth. In addition, as in the cochlea, the receptor cells of the vestibular apparatus are ciliated, and these cilia extend into a gelatinous matrix.

The three semicircular canals are oriented orthogonally or at right angles to each other. They can be thought of as lying in a bottom corner of a box. The horizontal (or lateral or external) canal is in the plane of the bottom of the box, and the anterior-vertical (or superior) and posterior-vertical (or posterior) canals are in the planes of the two sides of the box. In humans, the entire canal complex is tilted upward about 30 degrees. In the physiologic position, the head is bent forward about 30 degrees from the earth's horizontal plane; therefore, the 30-degree upward tilt puts the horizontal canal in the horizontal position under everyday conditions.[202] The superior and posterior canals are oriented in vertical planes that form an angle of approximately 45 degrees with the sagittal head plane. Each semicircular canal lies parallel to one of the canals in the opposite vestibular labyrinth. Thus, the right horizontal canal is coplanar with the left horizontal canal, whereas the right superior and posterior canals are coplanar with the left posterior and superior canals, respectively.

The sensory epithelia or cristae of the semicircular ducts are located in enlarged areas, referred to as ampullae, at one end of each duct. The nonampullated ends of the vertically oriented superior and posterior ducts connect to form the common crus. The bony vestibular aqueduct originates in the vestibule (ie, the entrance to the inner ear) and connects to the cerebrospinal fluid space medially. Within the vestibular aqueduct is the fibrous endolymphatic duct that establishes a route between the membranous vestibule and the cranial meninges, where the duct ends in the endolymphatic sac. The utriculosaccular duct, connecting the utricle and saccule, permits communication between the saccule and endolymphatic duct. Although there is no agreement concerning the site of endolymph absorption, it is likely that the K^+-rich fluid is absorbed in the endolymphatic sac.[203] The ductus reuniens connects the saccule with the cochlear duct.

Figure 4–41, A, shows the anatomy of the crista. It is a saddle-shaped mound of tissue, attached to the ampullar wall at right angles to the long axis of the ampulla. The hair cells are on the surface of the crista. The ampullar nerve fibers travel

through the center of the crista to synapse at the hair cell bases. The hair cell cilia protrude from the surface of the crista into the fan-shaped cupula, a gelatinous structure consisting of mucopolysaccharides within a keratin framework.[204] The cupula partitions the semicircular duct by covering the top of the crista and extending to the opposite ampullar wall.

The sacculus and utriculus are two sacs in the membranous labyrinth, located in the vestibule. Their receptor organs, called maculae, can be seen in Figure 4–41, B, as patches of epithelia on the membranous labyrinth walls. The utricular macula lies on the floor of the utricle approximately in the plane of the horizontal semicircular canal. The saccular macula lies on the anteromedial wall of the saccule and is oriented principally in the vertical plane.

Figure 4–42 shows the structure of the macula. It consists of hair cells that are surrounded by supporting cells. The hair cell cilia are attached to a gelatinous otolithic membrane. On the top of the gelatinous membrane is a layer of calcium carbonate crystals called statoconia or otoliths. The otoliths are denser than the surrounding endolymph[205]—hence their ability to respond to gravity and inertial forces.

Figure 4–43 summarizes in a schematic form some TEM observations of vestibular hair cell morphology. First, as shown by Figure 4–43, A, there are two types of hair cells in both the macula and the crista.[206] Type I hair cells are flask-shaped and have "chalice"-type afferent nerve endings that surround all but the hair-bearing end. Efferent nerve terminals synapse with the afferent calyx near its base. Type II hair cells have a cylindrical or test tube shape and have several small bouton-type nerve endings that represent both afferent and efferent innervation only at the cell's base. Type I hair cells are concentrated in the central apex of the crista and the central part of the macula; type II hair cells are more numerous toward the peripheral region of the end-organ.[207] Although significant amounts of filamentous actin occur at the apical surfaces of both the sensory cells and the supporting cells in the hair cell–containing regions of the vestibular organs,[208] motile properties such as the fast rates of lengthening and shortening, which have been observed for cochlear OHCs, have not been shown for vestibular hair cells. However, there is some evidence that slow motility is exhibited by type II hair cells.[209]

The electron microscope has also demonstrated two types of cilia: stereocilia and kinocilia[210,211] (Figure 4–43, B). Each hair cell has only one motile kinocilium and a bundle of 60 to 100 stereocilia.

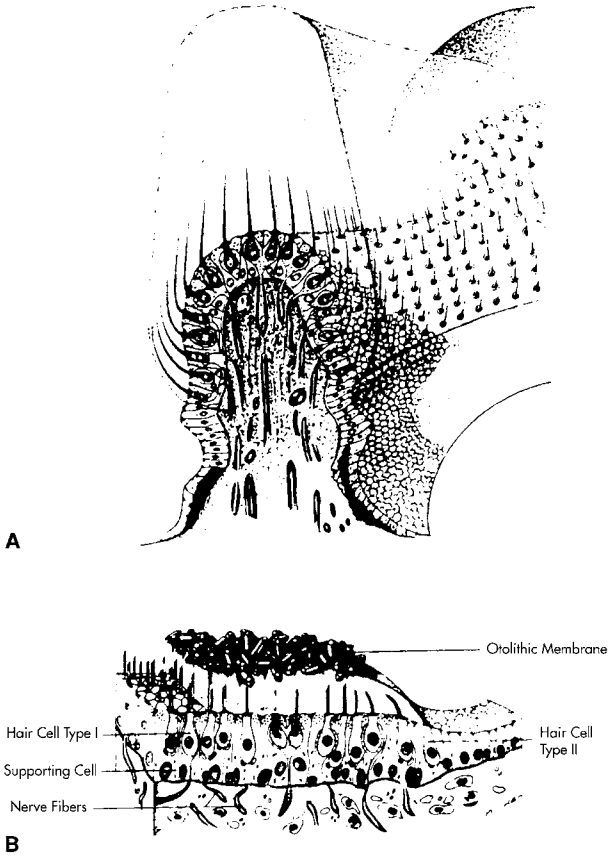

FIGURE 4–41. Sensory receptors of the vestibular system. *A*, Schematic drawing of the crista ampullaris illustrating the sensory cells, their hair bundles (cilia) that protrude into the cupula, and their innervating nerve fibers. *B*, Schematic drawing of a macula, showing how the cilia of the hair cells are embedded in a gelatinous membrane to which are attached calcium carbonate crystals (ie, otoconia). *A* reproduced with permission from Wersall J. Acta Otolaryngol Suppl (Stockh) 1956;126:1. *B* reproduced with permission from Iurato S. Submicroscopic structure of the inner ear. Oxford (England): Pergamon Press; 1967.

Stereocilia are relatively rigid, club-like rods, varying systematically in length in a "pipe organ" fashion, that extend, at the apical end of the hair cell, from a dense cuticular plate that consists of actin and myosin.[33] They are not homogeneous, as was originally thought. Rather, they contain longitudinally oriented microfilaments[212] composed of

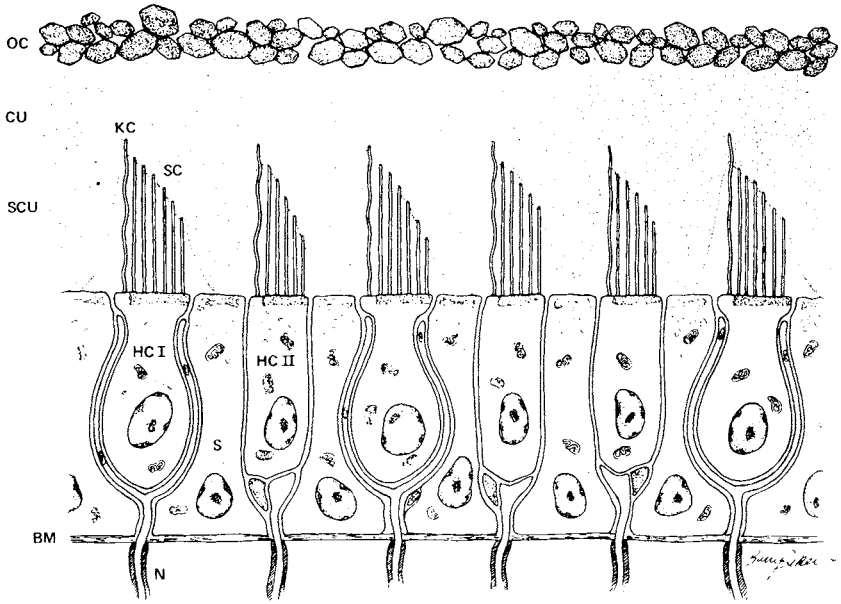

FIGURE 4–42. Schematic drawing of a cross-section of a macula. The gelatinous substance is divided into cupular (CU) and subcupular (SCU) layers. There are two types of cilia: kinocilia, labeled KC (one per hair cell), and stereocilia, labeled SC (many per hair cell). OC = otoconia; HC I = type I hair cell; HC II = type II hair cell; N = nerve fiber; BM = basement membrane; S = supporting cell.

actin.[32] The membrane enveloping the stereocilia is a thickened continuation of the hair cell cuticular membrane.[212] The stereocilia are constricted at their base and, when deflected, move like stiff rods pivoting around the basal constricted area.[36] Interconnections between stereocilia via fibrils or tip links have been demonstrated.[213]

Kinocilia end in basal bodies, located just beneath the hair cell membrane. Within each kinocilium, there are nine peripherally arranged double-tubular filaments, positioned regularly around two centrally located tubular filaments. This 9-plus-2 tubule pattern is found in many motile cilia (eg, respiration epithelia, oviduct epithelium, unicellular flagellates).[214] Stereocilia are coupled to the kinocilium and to each other so that during deflection, all cilia are stimulated as one bundle.[49]

On each hair cell, the single kinocilium is located to one side of the bundle of stereocilia. In both maculae and cristae, hair cells in the same area tend to have kinocilia on the same side of the stereocilia bundle. Thus, the vestibular sensory epithelium has a morphologic directional polarization[210] that is determined by the direction of the cilia alignment. Figure 4–43, C, illustrates the directional polarization of the utricular macula. The kinocilia all tend to point toward a line of demarcation called the striola, or linea alba, running across the approximate center of the macula. In the saccule, the kinocilia point away from the striola. In the horizontal duct crista, kinocilia point toward the utricle, whereas in the pair of vertical cristae, they point away from the utricle. Thus, vertical and horizontal cristae are morphologically polarized in opposite directions.[207]

Transduction and Coding

Mechanical Events As in the cochlea, the final mechanical event in vestibular transduction is the bending of the hair cell cilia. Figure 4–44 illustrates transduction by the macula. When the macular surface is tilted, the heavy otoliths tend to slide downward, carrying the gelatinous membrane and attached cilia with them.

The six semicircular ducts consist of a circular, narrow-bore tube in the temporal bone filled with fluid called endolymph. The tube originates from and returns to a reservoir (the utricle), but each duct may be treated, for practical purposes, like a fluid ring. When the head undergoes an angular acceleration, the fluid is left behind because of its inertia. This causes the endolymph to flow relative to the duct and to push on the cupula, which lies across the duct blocking it. The cupula is attached to the ampulla wall around its entire periphery and billows, like a sail, under endolymph pressure.[215,216] Normal deflections are tiny, in the range of 0.01 to 0.3 mm.[217] The subsequent strain on the hair cells by the bending of their cilia embedded in the cupula creates a generator potential that modulates the discharge rate of primary vestibular afferent fibers.

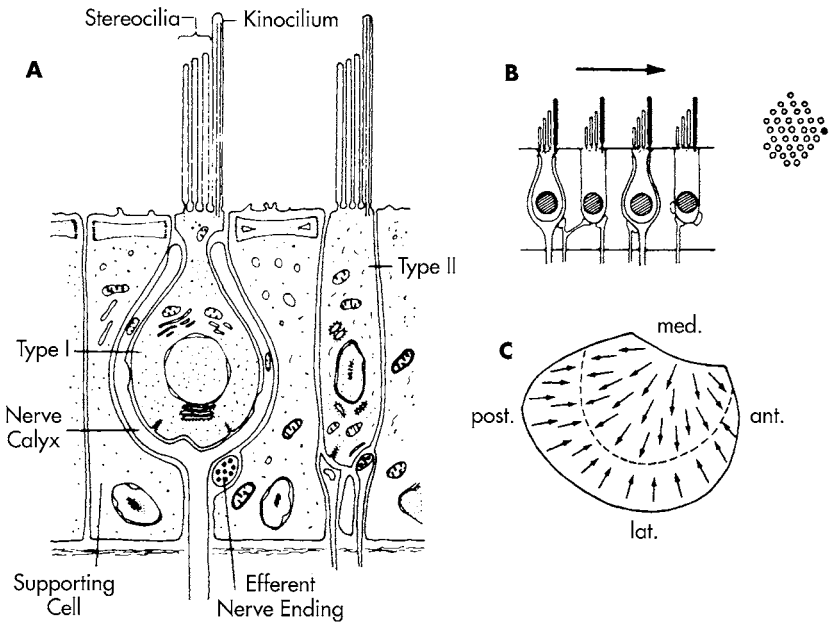

FIGURE 4–43. Microanatomy of the vestibular hair cells. *A*, Schematic drawing of the two vestibular hair cell types. *B*, Diagram showing morphologic polarization of the hair cells. *Arrow* shows the direction of cilia bending that produces excitation. At right is a cross-section through the hair-bearing end of the hair cell showing many stereocilia (*open circles*) and one kinocilium (*filled circle*). *C*, A diagrammatic surface view of the human utricular macula. *Arrows* indicate direction of polarization. *Dashed line* is the linea alba. *A* reproduced with permission from Brodal A.[223] *B* and *C* reproduced with permission from Lindeman HH, Ades HW, Bredberg G, Engstrom H. The sensory hairs and the tectorial membrane in the development of the cat's organ of Corti. Acta Otolaryngol (Stockh)1971;72:229–42 and Wersall J et al, respectively.[206]

The overall behavior of the cupula and duct was first described by Steinhausen.[218] If c is some measure of cupular (and thus endolymph) displacement, the force balance equation for the duct is:

$$m[c(d^2c/dt^2)] + r[c(dc/dt)] + kc = m[H(d^2H/dt^2)]$$

where m represents the net, equivalent moment of inertia of the endolymph, r is the lumped effect of viscous drag on fluid flow (c), and k represents the stiffness of the gelatinous cupula. The term $m[H(d^2H/dt^2)]$ is the driving force on the endolymph owing to head acceleration. During most natural head movements, the inertial reactance, $m[c(d^2c/dt^2)]$, and the cupular restoring force, kc, are very small compared to the viscous term, $r[c(dc/dt)]$, because the narrowness of the tube creates a high resistance to flow. Consequently, the above equation can be reduced to:

$$r[c(dc/dt)] = m[H(d^2H/dt^2)]$$

or, integrating both sides:

$$c = m/r\ [H(dH/dt)].$$

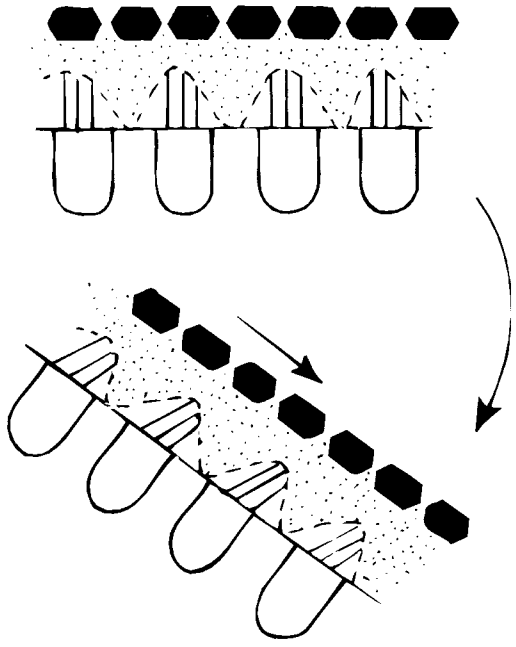

FIGURE 4–44. Diagrammatic representation of the conversion of a head tilt to bending of the hair cell cilia by the otoconia.

Thus, the discharge rate, which is proportional to cupular deflection, carries a signal into the central nervous system proportional to head velocity, not acceleration. In other words, a constant head acceleration applies a constant force on the endolymph, causing it to flow at a constant velocity. Consequently, cupula position, the integral of flow, must be proportional to head velocity (ie, the integral of head acceleration).

In the squirrel monkey, the typical resting discharge rate is 90 spikes/s.[219] The discharge rate increases for deflection of the cupula in one direction and decreases in the other. On the abscissa of Figure 4–45, B, B(dH/dt) may be substituted for c, in which case the slope of the line, Sv, for the average fiber is 0.4 (spikes/s)/(deg/s). Thus, the signal sent from the duct to the brainstem on the average fiber for most normal head movements is 90 + 0.4 [H(dH/dt)].

Response of Primary Vestibular Neurons Microelectrode studies in higher mammals have demonstrated the following characteristics of primary vestibular neuron activity. For example, most of the primary vestibular neurons called regular units exhibit a high (~100/s) and remarkably uniform spontaneous discharge.[220] When listening to such spikes on a loudspeaker, the neurons make a characteristic motorboat sound. There is also a small population of irregular neurons with a lower rate and less regular spontaneous discharge. The high-rate regular units have small-diameter, slowly conducting axons that predominantly innervate the periphery of the end-organ, that is, the type II hair cell region of the crista, whereas the low-rate irregular neurons come from the center of the crista, where most type I hair cells are located.[197] The high, regular spontaneous firing rate of the primary neurons permits the bidirectional sensitivity of the vestibular hair cell receptors.

When the head rotates, causing cupular displacement and a stimulatory deflection of hair cell cilia, the semicircular duct afferents change their discharge rate above, in response to hair cell depolarization, and below, in response to hair cell hyperpolarization, the resting rate depending on the direction of rotation.[221] When the head rotates sinusoidally at velocities encountered during normal function, ampullar nerve discharge rate varies sinusoidally, as shown in Figure 4–46. The phase relation-

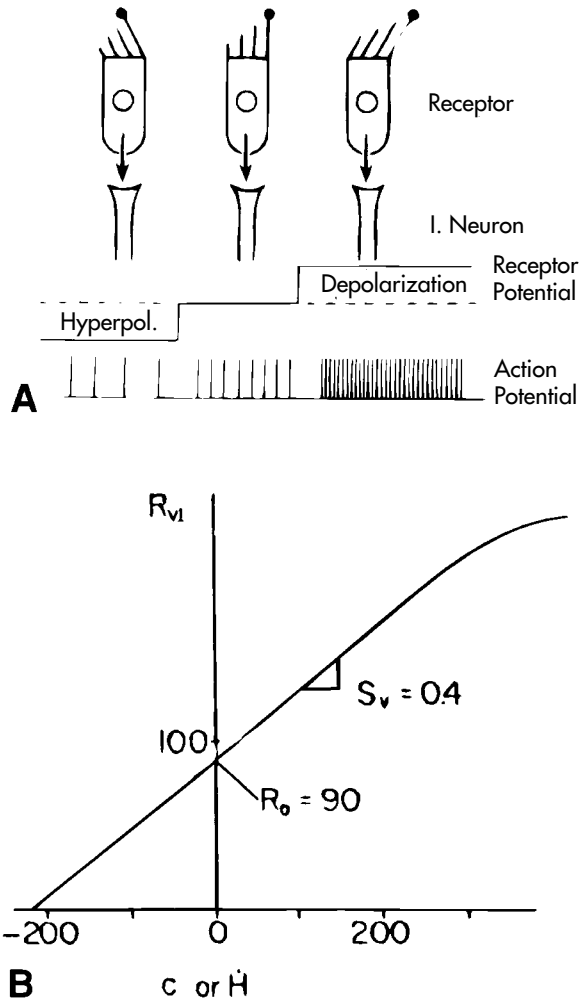

FIGURE 4–45. Motion transduction by vestibular hair cells. *A*, At rest there is a resting rate of action potential discharge in the primary vestibular afferents (*center*). Shearing forces on the hair cells cause either depolarization (*right*) or hyperpolarization (*left*), depending on whether the stereocilia are deflected toward or away from the kinocilium (indicated by longest cilium, with beaded end), respectively. This modulates the discharge rate in the vestibular nerve as shown below (action potential). *B*, Vestibular nerve discharge rate (R_{v1}) is 90 spikes/s at rest (R_o) in the squirrel monkey and changes approximately linearly with cupula deflection (c). When the latter is expressed in equivalent head velocity (H), the slope of the line S_v is about 0.4 (spikes/s)/(deg/s) for the average vestibular afferent fiber. *A* reproduced with permission from Baloh R, Honrubia V. Clinical neurophysiology of the vestibular system. 2nd ed. Philadelphia: FA Davis; 1990. *B* reproduced with permission from Zee DS, Leigh RJ. The neurology of eye movements. 2nd ed. Philadelphia: FA Davis; 1991.

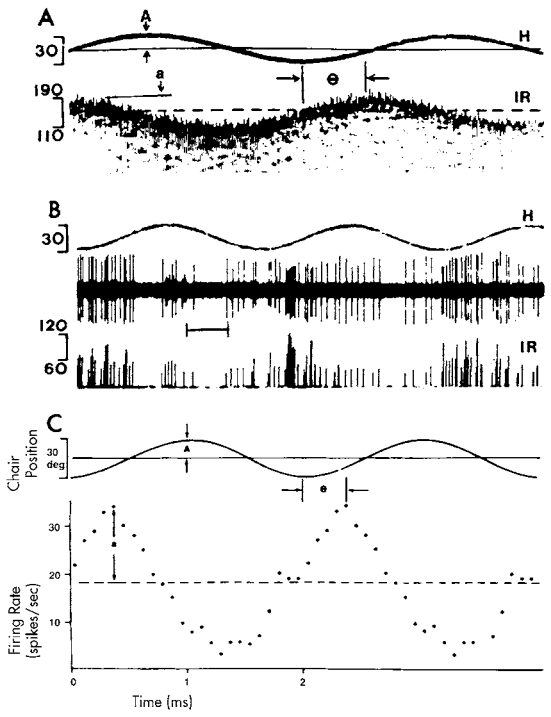

FIGURE 4–46. Peripheral vestibular neuron responses to sinusoidal rotation stimulation in the alert monkey. *A*, A regular (high-rate) neuron. *B*, An irregular (IR) neuron. Sinusoidal curve (H) plots head position. The records immediately below the sinusoidal traces show intervals between neuronal spikes. The height of vertical bars on these records is proportional to the interval between spikes. Because one of these bars occurs for every spike, their frequency reflects the frequency of the recorded spikes. *C*, Response of unit in *B* averaged over 10 cycles; 0 is the phase lag of firing rate (ie, the shortest interval between spikes), which occurs at about the 0 crossing of the head-position signal. Thus, firing rate at the output of the semicircular duct is related most closely to head velocity.

ship between head position and head velocity, which displays a phase lag of about 90 degrees, is such that the maximum discharge rate occurs at the head's zero crossing (ie, at the head's maximum velocity). Thus, the ampullar afferent discharge rate codes head angular velocity. The adequate stimulus is actually angular acceleration, but the hydrodynamics of the semicircular duct system are such that the head's acceleration is integrated to give a velocity output.[222]

Similarly, with the macular afferents, accurate coding by discharge rate of the head's position relative to gravitational vertical can be demonstrated in all species. The more complex orientation of the macular hair cells makes directional correlates more difficult to establish than for semicircular duct afferents. However, Fernandez and Goldberg[197] studied large populations of saccular and utricular neurons and were able to demonstrate neural "sensitivity vectors" among the neuronal populations that corresponded to the relative orientations of the saccular and utricular maculae.

Central Vestibular Pathway

Anatomy *Primary Afferent Connections.* The vestibular system functions primarily as an afferent reflex input to the motor system. In general, vestibular pathway–mediated reflexes involve three muscular systems, including the extrinsic oculomotor, cervical, and antigravity pathways.

As might be expected, the semicircular ducts, or the rotation sensors, connect primarily with the extrinsic oculomotor and cervical muscles (ie, the muscles that compensate for head rotation), whereas the otolithic organs, or position sensors, connect primarily with the antigravity muscles. Figure 4–47 outlines these major central vestibular connections.[223]

Scarpa's, or the vestibular, ganglia, in the internal auditory canal, within the vestibular portion of the eighth nerve, contain the bipolar ganglion cells of the first-order vestibular neurons. The vestibular nerve can be divided into superior and inferior divisions that innervate the sensory epithelia of the duct and otolithic end-organs. The superior portion innervates the cristae of the superior and horizontal semicircular ducts, the utricular macula, and a small region of the saccular macula. The inferior division of the vestibular nerve innervates the crista of the posterior semicircular duct and the remaining part of the saccular macula. Centrally, all first-order vestibular neurons synapse in the vestibular nuclear complex, which occupies a considerable area beneath the floor of the fourth ventricle and lies across the pontomedullary boundary. On entering the brainstem, the vestibular axons bifurcate into the ascending rostral and descending caudal divisions.

The vestibular nuclear complex, as shown in Figure 4–47, consists of four distinct subnuclei: (1) the superior (Bechterew's or angular), (2) lateral (Deiters'), (3) medial (Schwalbe's or principal or triangular), and (4) inferior (spinal or descending) nuclei. There is recent anatomic evidence that the

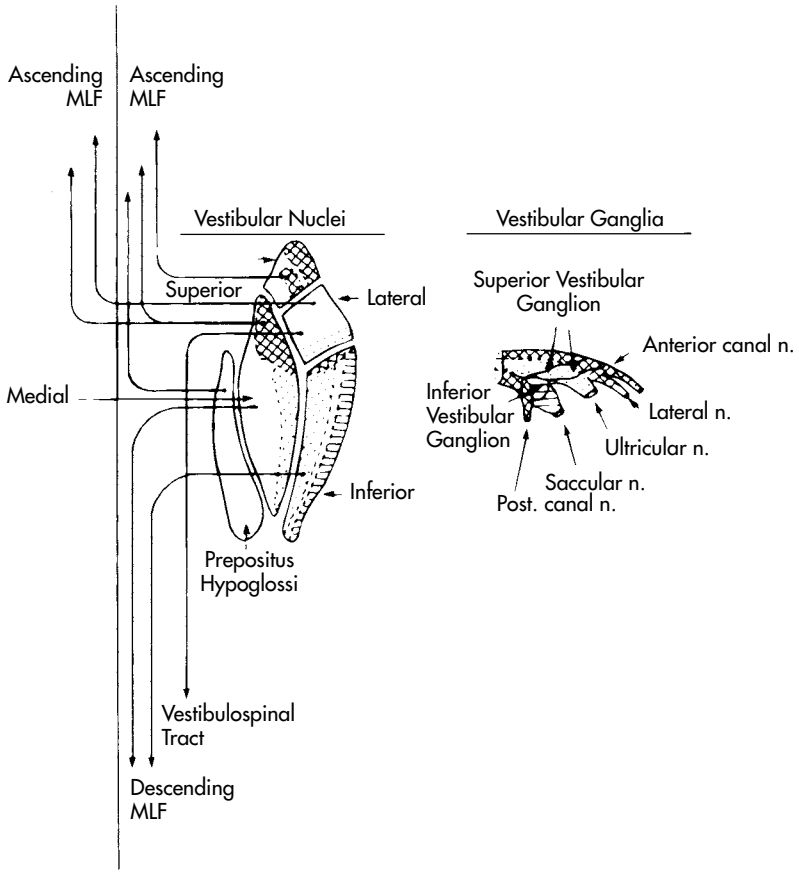

FIGURE 4–47. Diagram of major connections between primary vestibular neurons in the vestibular ganglia and the vestibular nuclei. Also shown are major outflows from the vestibular nuclei. Vestibulocerebellar connections are excluded. The primary afferent connections are modified from Carpenter MG. Human neuroanatomy. 7th ed. Baltimore: Williams and Wilkins; 1976. MLF = medial longitudinal fasciculus.

nucleus prepositus hypoglossi, which is classically thought to relate to taste sensation, has strong efferent and afferent vestibulo-oculomotor, through the medial longitudinal fasciculus (MLF), and cerebellar projections. In addition, microelectrode recordings from awake monkeys have demonstrated that prepositus neurons fire in relation to both vestibularly and visually induced eye movements.[224] Studies on the activity of ocular motoneurons in alert monkeys have shown that the neural commands for all conjugate eye movements (vestibular, optokinetic, saccadic, and pursuit) have both velocity and position commands.[225]

The vestibular input to prepositus is disynaptic and reciprocally organized (ie, ipsilateral input is excitatory, whereas contralateral input is inhibitory). In addition, if cells in the monkey's nucleus prepositus hypoglossi are lesioned with kainic acid, the monkey's eye movements only reflect the velocity command.[226] A great amount of neurophysiologic evidence indicates that the position command is obtained from the velocity command by the mathematical process of integration. That is, a neural network located in the nucleus prepositus hypoglossi integrates, in the mathematical sense, velocity-coded signals; thus, the prepositus is included in the diagram of the vestibular nuclear complex in Figure 4–47.

As indicated in Figure 4–47, each subnucleus has a unique set of connections with the periphery and with specific regions of the central nervous system including the spinal cord, cerebellum, and brainstem oculomotor nuclei (III, IV, VI). Most of the semicircular duct afferents terminate in the superior nucleus and rostral portion of the medial-vestibular nucleus. Both of these nuclei, in turn, project to the oculomotor nuclei of the extraocular muscles via the ascending MLF. The superior nucleus projects only to the ipsilateral MLF, whereas the medial nucleus projects bilaterally. The medial nucleus, via the medial vestibulospinal tracts in the descending MLF, also sends bilateral descending projections to spinal anterior horn cells that control the cervical musculature.[227] Thus, the input and output of the superior and medial vestibular nuclei provide a possible anatomic basis for the nystagmus and head-turning-reflex responses to semicircular duct stimulation (see below).

The otolith organs, particularly the utriculus, project primarily to the inferior nucleus and caudal part of the lateral nucleus. Outputs from these

nuclei, in turn, project downward to the ventral horn region throughout the length of the spinal cord via the lateral vestibulospinal tract. Thus, the afferent and efferent connections of the lateral vestibular nucleus provide a possible anatomic basis for antigravity muscle responses in the limbs (extensors of the legs and flexors of the arms) to postural change. The otolith organs have relatively sparse connections to the extraocular muscles. These may be the connections that produce the ocular counter-rolling response to head tilt.[228]

Efferent Innervation of the Vestibular System The vestibular organs in all vertebrates receive efferent innervation originating in brainstem nuclei. Although there are relatively few parent efferent neurons, their axons branch to innervate more than one end-organ and also ramify extensively in the neuroepithelium of the individual organs. By means of this divergent innervation pattern, efferent fibers provide a major source of synaptic input to type II hair cells, afferent calyces, and other unmyelinated afferent processes. In nonvestibular organs, efferent activation typically reduces afferent activity by hyperpolarizing the hair cell receptor. In contrast, efferent responses in vestibular organs are more heterogeneous. For example, in fish and mammals, there is an excitation of afferents, whereas in frogs and turtles, both excitation and inhibition are observed. In addition, there are variations in the efferent responses of vestibular afferents innervating different parts of the neuroepithelium, which differ in their responses to natural stimulation. Moreover, efferent neurons receive convergent inputs from several vestibular and nonvestibular receptors and also respond in association with active head movements. On the basis of the discharge properties of efferent neurons, one of their proposed functions is that they switch the vestibular organs from a postural to a volitional mode. For a more detailed review of the vestibular efferent system, see a recent summary by Goldberg.[229]

Vestibulocerebellar Connections *Primary Vestibular Fibers.* Primary vestibular neurons project not only to the vestibular nuclei but also to the cerebellum. Most of these fibers are distributed to the ipsilateral flocculus and nodulus and the medially located uvula.[230] Because of this innervation by primary vestibular fibers, these three cerebellar areas have been termed collectively the vestibulocerebellum. As discussed below, the primary vestibular input to the vestibulocerebellum appears to be important in controlling the vestibulo-oculomotor reflex (VOR). Moreover, the primary vestibular input to the vestibulocerebellum and the climbing fiber input from the inferior olive appear to be important in controlling the VOR.

Secondary Vestibular Fibers. The vestibulocerebellum receives secondary fibers primarily from the medial and inferior vestibular nuclei but also from the other divisions. In addition, the fastigial nucleus and the cortex of the vermis receive a strong, somatotopically organized projection from the lateral vestibular nucleus. Since this nucleus is the primary origin of the vestibulospinal tract, connections to it from the cerebellum are probably important in regulating antigravity reflexes that help to maintain an upright body posture.[231]

Projections to Cerebral Cortex Whether the vestibular system has a direct cortical projection has long been a controversial question. The functional corollary to this question is whether we can consciously appreciate a sensation owing to vestibular stimulation. This question also has generated debate because most of the subjective sensations produced by vestibular stimulation (eg, vertigo) are secondary to motor reflex or to autonomic responses, and it is difficult or impossible to separate a primary vestibular sensation from the secondary sensations.[200]

Experiments employing electrical stimulation of the vestibular nerve have demonstrated relatively short-latency localized cortical responses in both the cat and the monkey.[232] The cat's vestibular area is adjacent to both the auditory and somatosensory fields, but in the monkey, and possibly in the human, it is located near the face area of the somatosensory field on the postcentral gyrus. Deecke et al demonstrated that the ventroposteroinferior (VPI) nucleus is the thalamic relay for the vestibulocortical projection.[233] The VPI nucleus lies adjacent to the thalamosomatosensory representation of the face. Prior to this study, the function of the VPI nucleus was unknown.

Vestibular Influence on Postural Control The main unit for the control of tone in the trunk and extremity muscles is the myotactic reflex. These reflexes of the antigravity muscles are under the combined excitatory and inhibitory influence of multiple

supraspinal centers. Two of these supraspinal centers are facilitory, that is, the lateral vestibular nucleus and rostral reticular formation, and four are inhibitory centers including the pericruciate cortex, basal ganglia, cerebellum, and caudal reticular formation. The balance of input from these different centers determines the degree of tone in the antigravity muscles.

Physiology of Vestibular Nuclei *General Characteristics of Neuronal Responses.* Microelectrode studies of responses of vestibular nucleus neurons to electrical stimulation of individual ampullary nerves and to "natural" stimuli, such as those involving rotation and tilt, have established the following general characteristics: (1) neurons can be classified as tilt responders (otolith units) or rotation responders (duct units); (2) the locations of these two types correspond with that expected from the anatomic projections of otolithic and semicircular duct afferents to the vestibular nuclear complex. Thus, the tilt responders are found primarily in the areas innervated by the sacculus and utriculus, that is, the inferior nucleus and caudal part of lateral nucleus, whereas the rotation responders are found mainly in the areas innervated by the semicircular ducts, that is, the superior nucleus and the rostral part of medial nucleus; and (3) among the rotation responders, pathways from individual ducts seem to be preserved. Thus, for example, a neuron that responds to vertical rotation or to electrical stimulation of a vertical ampullary nerve does not respond to horizontal rotation or to stimulation of a horizontal ampullary nerve and vice versa.

Classification of Neuronal Response Types. Both duct and otolithic vestibular nucleus units preserve the basic properties of the primary afferent input, but some respond in the same direction (eg, ipsilateral horizontal rotation increases firing rate); others respond in the opposite direction. A few of the vestibular nucleus neurons respond with either inhibition or facilitation in both directions. Table 4–2 outlines the characteristics of the duct units. The type I units, exhibiting a primary response pattern, are innervated by the ipsilateral labyrinth, whereas the type II units, showing response patterns that are opposite to those of the primary units, are innervated by the contralateral labyrinth.

The analogous classification for otolith responders subdivides all types into (1) "a" units, which increase firing on ipsilateral tilt; (2) "b" units, which decrease firing on ipsilateral tilt; (3) "y" units, which increase firing in response to tilt in both directions; and (4) "o" units, which decrease firing by tilt in both directions. Analogous to the duct units, the relative populations of these units are a > b > y > o.[234]

Commissural Inhibition and Vestibular Compensation Many of the contralateral (type II) semicircular duct responses listed in Table 4–2 are abolished when a midline dorsal brainstem incision is made that interrupts the vestibular crossing fibers. Thus,

TABLE 4–2. Characteristics of Duct Responding Units in Vestibular Nuclei

	Input Side	*Response Directionality*	*Response Time Course*	*Latency*	*Gain*	*Spontaneous Activity*
Type I (67%)	Ipsilabyrinth	Same as 1 degree	—	—	—	—
Kinetic (56%)	Ipsilabyrinth	Same as 1 degree	Fast decay	Long (multisynaptic)	High	None
Tonic (11%)	Ipsilabyrinth	Same as 1 degree	Slow decay	Short (monosynaptic)	Low	High level
Type II (29%)	Contralabyrinth	Opposite 1 degree				
Type III (3%)	?	Facilitated both directions				
Type IV (< 1%)	?	Inhibited both directions				

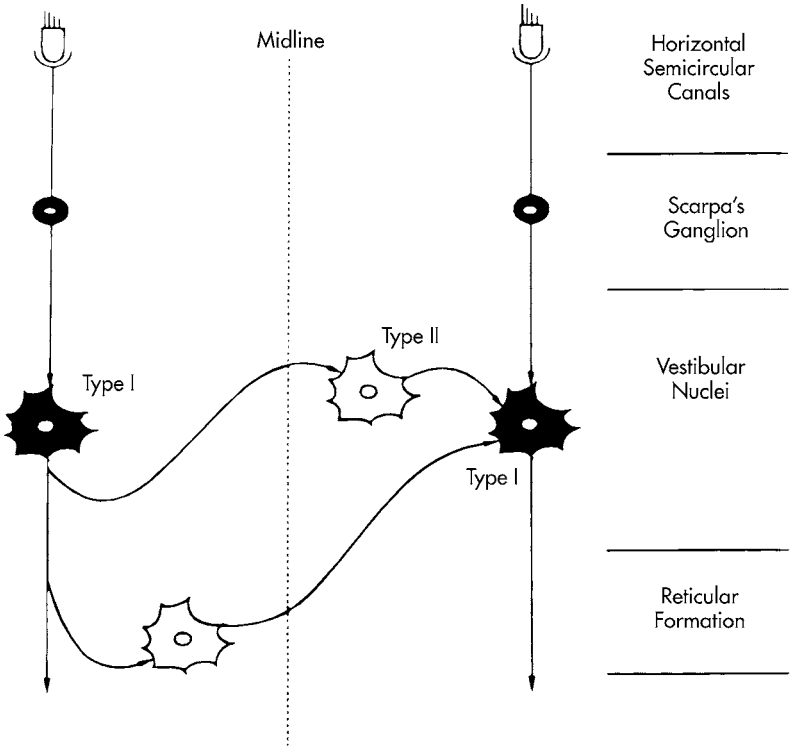

FIGURE 4–48. Interrelation of type I and type II secondary vestibular neurons. Dark neurons are excitatory, and light neurons are inhibitory. Reproduced with permission from Baloh R, Honrubia V. Clinical neurophysiology of the vestibular system. 2nd ed. Philadelphia: FA Davis; 1990.

the "opposite-primary" type II responses are likely elicited by inhibitory input from type I neurons of the opposite labyrinth. Figure 4–48 summarizes the simplest of the probable neuronal interconnections responsible for this contralateral inhibition.

The commissural inhibitory system is also important in the mechanism of compensation following labyrinthectomy. Thus, immediately after labyrinthectomy, the type I units on the labyrinthectomized side show no spontaneous activity and do not respond to rotation. However, within a few days, the deafferented type I units regain their spontaneous activity and, via inhibition from the contralateral pathway, also regain their normal response to rotation. The mechanisms by which this recovery process occurs are unknown, but a contributing factor is the lowered threshold of the deafferented type I neuron for contralateral input.[235] In animal studies, the course of compensation is affected by exercise,[236] visual experience,[237] and drugs.[238] Thus, as a rule, stimulants accelerate and sedatives slow compensation.[237] Fetter and Zee showed further that visual experience was not necessary for the acquisition or for the maintenance of this recovery process.[237]

If a second labyrinthectomy is performed after compensation for the first labyrinthectomy, the animal again develops signs of acute unilateral vestibular loss with nystagmus directed toward the previously operated ear, that is, a condition referred to as Bechterew's compensatory nystagmus.[239] That is, the overall effect is as if the first labyrinthectomy had not occurred. Compensation after the second labyrinthectomy is slightly faster than the first but still requires several days. For a recent review on the molecular mechanisms underlying vestibular compensation, see the summary by Darlington and Smith.[240]

Vestibulo-oculomotor Reflex Although there are neural connections between the maculae and the extraocular muscles, they are less important in humans, both functionally and clinically, than are the semicircular duct connections. This discussion of the VOR will therefore focus on the reflex connection between the semicircular ducts and the extraocular muscles.

An important function of the semicircular ducts is to provide afferent input to the VOR that generates eye movements that compensate for head movements by maintaining a stabilized visual image on the retina during rotation. Such eye adjustments are called compensatory eye movements. Figure 4–49 diagrams the neural connections that stabilize gaze during head movement.

Anatomic Connections. The VOR is subserved by a three-neuron pathway. That is, motions detected by the end-organ are transduced into neural impulses that are sent via the vestibular nerve to the vestibular nuclei and rostrally through the ascending MLF to the oculomotor nuclei of the extraocular muscles. Secondary vestibulo-ocular connections via the reticular formation have been described, but functionally these are less important than the "direct" three-neuron MLF vestibulo-ocular pathway.

Inhibitory crossed connections at the levels of both vestibular and oculomotor nuclei, which were described above, probably also participate in the VOR. The crossed inhibitory oculomotor connections subserve antagonistic extraocular muscles.[241] These inhibitory interconnections are important in the formation of conjugate eye movements.

Functional Connections. A number of investigations have uncovered many details of the facilitatory and inhibitory interactions between neurons of the vestibular nuclear complex and motoneurons of the extraocular eye muscles. For a review, the reader is referred to Wilson and Melvill-Jones.[234] However, in older experiments, the effect of mass stimulation of individual ampullary nerves on eye movements provided the clinician with the most useful integrative concepts of the functional organization of the VOR. The results of all of these ampullary nerve-stimulating experiments agree on the principle, illustrated by Figure 4–49, that stimulation of an ampullary nerve generates conjugate eye movements away from the side stimulated and in the plane of the duct stimulated.

This principle allows a straightforward description of the events leading from endolymph movement in the horizontal duct to the compensatory eye movement depicted in Figure 4–50: (1) head movement to the left generates endolymph movement to the right in the left duct. This is toward the ampulla and therefore increases the ampullary nerve discharge rate; (2) the increased ampullary nerve output, according to the aforementioned rule, causes conjugate eye deviation away from the side stimulated (ie, to the right, which is opposite to the direction of head movement); (3) similarly, head movement to the left generates ampullofugal movement in the right duct, which decreases neural output; and (4) decreased neural output inhibits the extraocular muscles, thus causing the eyes to deviate conjugately to the left, which provides a neural output that is synergistic to the conjugate right-eye deviation, generated by the output of the opposite duct. Figure 4–49, upper right, depicts this sequence of events.

Functionally, the VOR provides more than a simple one-to-one transfer of information from the semicircular duct to the extraocular muscles. It should be recalled that the response of the ampullary nerves reflects head velocity, yet the ocular rotation, at the vestibular reflex output, reflects head position. Therefore, at some point in the transfer from vestibular input to ocular output, some form of neural integration must occur that converts the velocity signal at the input into the displacement signal at the output. The location of this integrator, as noted above, is the nucleus prepositus hypoglossi.[226]

Control of the Gain of the Vestibulo-oculomotor Reflex. In studies of the VOR, the concept of gain is important. Gain of the VOR is simply the amplitude of eye rotation divided by amplitude of the head rotation. Generally, amplitudes of eye and head rotation are expressed as angles.

Because eye rotation is supposed to be equal and opposite to head rotation (ie, to compensate fully and leave gaze steady), it might seem at first that the ideal VOR gain would be –1. However, there are many real-life situations for which the ideal VOR gain is not –1. Functionally, such situations can be divided into long-term (ie, slow) and short-term (ie, fast) adjustments. The short-term or fast VOR gain adjustments occur in the course of visual tracking tasks, in which both the head and the eyes follow the fixation target at varying relative velocities. For example, in a tracking task in which the head and eyes must move in the same direction, the VOR must be completely suppressed. In the clinical test situation, this visual suppression of the VOR is observed as suppression of caloric or rotational nystagmus during visual fixation.

An example of functionally beneficial long-term VOR gain control is the situation in which a prescription for new glasses has been received. The change in magnification of the visual image changes the speed with which the visual image moves across the retina (eg, increasing magnification would increase the speed of movement of retinal images). Therefore, to maintain a stable retinal image after new glasses have been obtained, the VOR gain must be adjusted for the new magnification levels. Such

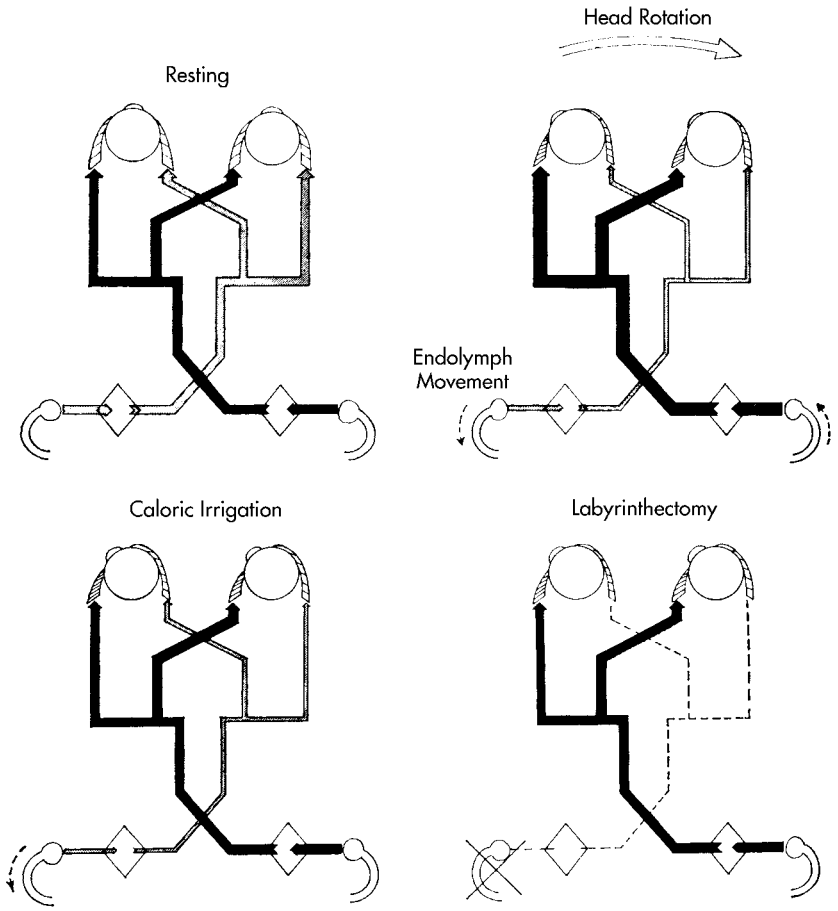

FIGURE 4–49. Generation of the vestibular (slow) phase of different kinds of nystagmus. The thickness of the lines connecting the semicircular duct to the extraocular muscles is proportional to the intensity of neural discharge along the nerve pathways.

adjustments have been demonstrated experimentally in humans by testing the VOR rotational response in the dark after long-term periods of wearing highly corrective lenses.[242]

An extreme example of the plasticity of the VOR gain is provided by adjusting to reversing prisms. Reversing prism glasses cause a normal visual image to be reversed right to left; hence, movement of the visual image, when the head or eyes are rotated horizontally, is exactly opposite of normal. Even in this extreme example, humans and other animals have been shown to function normally after a few days of wearing the prisms,[243,244] even in situations requiring visually controlled movements during head movements (eg, mountain climbing).[245] Testing the VOR in humans after a few days of wearing reversing prisms has demonstrated actual reversal (ie, conversion of a negative to a positive gain) of the VOR.[246]

There is strong evidence that the vestibulocerebellum plays an important role in both short-[247]

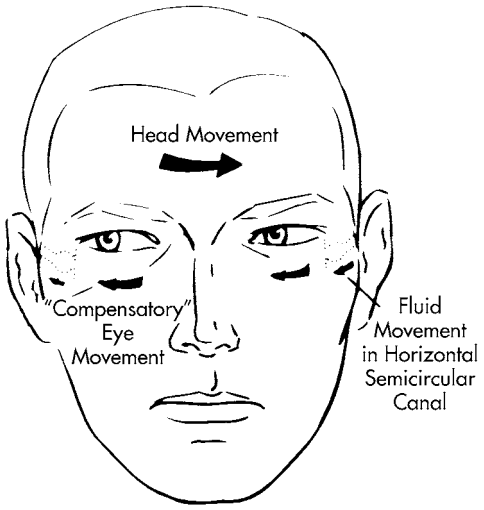

FIGURE 4–50. A compensatory eye movement initiated by the horizontal semicircular ducts. The eyes move in the direction of endolymph movement. If rotation of the head is continued at an ever-increasing speed, the compensatory eye movement becomes the slow phase of a rotational nystagmus.

and long-term[248] control of the VOR gain. The strong primary vestibular afferent projection to the vestibulocerebellum and equally strong projection from the vestibulocerebellum to the oculomotor portion of the vestibular nuclear complex have already been described. There is also a strong input to the vestibulocerebellum from the retina by way of the inferior olivary climbing fibers. Most of these visual units detected in the vestibulocerebellum are "movement detectors."[249] They are thus ideally suited to provide information on "retinal slip" of the visual image, which is needed to modify VOR gain control. The visual and vestibular inputs to the cerebellum converge on the Purkinje cells of the flocculus cortex. Furthermore, experiments on alert monkeys, in which rotation of the animal's visual environment and its head were controlled independently, showed that visual and vestibular inputs modulate Purkinje cell outputs in ways exactly appropriate for the functionally useful control of the VOR gain.

Ablation experiments further support the role of the flocculonodular lobes in control of VOR gain. It has been demonstrated, for example, that removal of the vestibulocerebellum eliminates suppression of caloric nystagmus by visual fixation.[250] An analogous failure of fixation suppression (FFS) of nystagmus is also observed in humans with cerebellar lesions.[251] However, clinical data suggest that FFS can be produced by lesions in the brainstem and, less frequently, cerebral hemispheres, as well as the cerebellum.[252]

Robinson reported the results of a notable ablation experiment that demonstrates the role of the flocculus in causing long-term or plastic changes in VOR gain.[244,248] Specifically, cats wore reversing prisms for several days, and VOR gain was measured each day by rotating the cats in the dark. After several days, as expected, VOR gain dropped from 0.9 to 0.1. When the vestibulocerebellum was removed, the VOR gain promptly increased to about 1.2. Furthermore, it proved impossible to reinstate the VOR gain decrease by continued wearing of prisms after removal of the vestibulocerebellum. In addition, Miles et al uncovered results in the monkey that implicated synaptic changes at other sites, especially in the brainstem.[252] More recently, Lisberger provided further evidence that the modifiable synapses were located between vestibular primary afferents and those second-order and/or possibly third-order vestibular neurons that also received synapses from Purkinje cells.[253] Finally, Luebke and Robinson reversibly silenced the flocculus of alert cats adapted to either high- or low-gain VOR.[254] This reversible floccular shutdown did not alter the adapted VOR gain, yet the animals were subsequently unable to modify their VOR gain, while the flocculus was silenced.

Clinical Considerations of Vestibular Reflexes

General Pattern. It has been stated that the vestibular system functions primarily as an afferent input for motor reflexes and that, at rest, most primary vestibular neurons have high and remarkably regular spontaneous discharge rates. For the purposes of the following clinically oriented discussion, the spontaneous vestibular neuronal activity will be referred to as the resting discharge.

Normally, with the head at rest in the neutral position, the resting discharges in the two vestibular nerves are equal. Vestibulomotor reflexes are elicited when inputs from the two vestibular end-organs or their central projections are made unequal (ie, they are unbalanced). Such unbalancing can occur by an abnormality involving one side to a greater degree than the other. In this case, we term the resultant vestibular reflex spontaneous. Vestibular input from the two sides can also be unbalanced by stimulating one or both of the vestibular end-organs. In this case, the resultant vestibular reflex is termed "induced."

When a vestibular input imbalance is unusually large or prolonged, a constellation of stereotyped responses occurs.[255] These responses are head turning, falling (or swaying), past pointing, vertigo representing a sensation of rotation, and nystagmus involving a rhythmic back-and-forth eye movement, with alternate slow phases in one direction and fast phases in the opposite direction. These slow and fast eye movements are termed the slow and fast phases of vestibular nystagmus. The head turning, falling, past pointing, and nystagmus slow phase are all in the same direction, that is, away from the ear with the greater output. In this discussion, the reference is to the nystagmus slow or vestibular phase. The clinical convention is to designate nystagmus direction by the fast of central phase, presumably because these movements can be easily observed. Thus, the indicated reflex directions may be the opposite of those to which the reader is accustomed. Fast-phase nystagmus is in the direction of the angular acceleration. The rotation sensation, or vertigo, may be

referred either to the subject's body (ie, subjective vertigo) or to the environment (ie, objective vertigo). If the body rotates, it is in the same direction as the nystagmus slow phase; if the environment rotates, it is in the opposite direction.

Methods of Eliciting. Vestibular responses can be generated by rotational, caloric, or galvanic stimulation of the vestibular periphery. The caloric and rotational responses are discussed in the following section. The galvanic vestibular response occurs when an electrical current is applied to the head in the vicinity of the ear.[251] Electrical current applied in this manner elicits the entire constellation of vestibular responses except vertigo. Interestingly, however, some subjects may report a slight sense of disorientation. If the current is positive, the nystagmus slow-phase, past-pointing, and body-sway responses are toward the stimulated ear; in contrast, if the current is negative, these responses are away from the stimulated ear.

Because the galvanic stimulus probably acts at a retrolabyrinthine location (ie, either vestibular nerve, Scarpa's ganglia, or a more central location), it has been suggested as a means of differentiating vestibular end-organ from vestibular nerve lesions. However, this procedure has not found widespread clinical acceptance, possibly because of uncertainty over the exact locus of action. For example, patients with their vestibular nerves sectioned intracranially still have a recognizable body-sway galvanic response,[256] suggesting that at least part of the action of the galvanic stimulus is central to the vestibular nerve (ie, at the level of the brainstem or possibly cerebellum).

Vestibular Nystagmus. Vestibular nystagmus occurs when the semicircular duct system is overstimulated. For example, if the head is continuously rotated in one direction at an ever-increasing speed, the semicircular duct–initiated compensatory eye movement becomes repeatedly interrupted by rapid, snap-back movements and hence becomes a rotational nystagmus. Because the relatively slow compensatory eye movement phase of the nystagmus comes from the semicircular duct system, it is called the vestibular or slow phase of the nystagmus. Conversely, because the fast, snap-back eye movement comes from the brain, it is called the central or fast phase of the nystagmus.

Caloric nystagmus is produced by a temperature change in the region of the vestibular apparatus. In the clinical laboratory, this temperature change is usually produced by running cool or warm water into the external auditory canal. The temperature change is conducted through bone to the semicircular canals. Since the horizontal semicircular canal is closest to the irrigating water, it is the most affected; hence, caloric nystagmus is almost entirely in the horizontal plane.

Figure 4–51 illustrates the generation of caloric nystagmus. The subject is in the supine position, with his head elevated 30 degrees to bring the horizontal canal into the vertical position. The cold caloric irrigation cools the endolymph in part of the horizontal duct. This cooled endolymph becomes slightly denser than the surrounding endolymph and thus falls, causing the eyes to rotate toward the irrigated ear. This vestibular eye movement is repeatedly interrupted by a compensatory rapid central eye movement in the opposite direction. A cold caloric nystagmus is thus created, with its slow phase toward and its fast phase away from the irrigated ear.

Although the slow phase is the vestibular phase of vestibular nystagmus, it is the clinical convention to designate the direction of the vestibular nystagmus by the direction of the fast phase. This convention, as noted above, originated because the fast phase is easier to observe than the slow phase.

Neural Mechanisms of Nystagmus. Figure 4–49 diagrams the neural mechanisms of different kinds

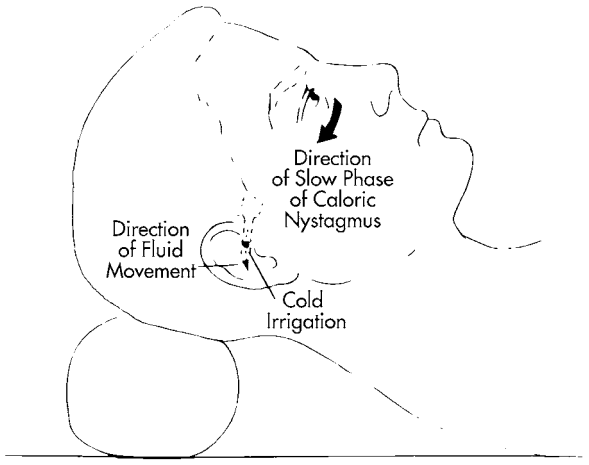

FIGURE 4–51. The mechanism of cold caloric nystagmus. The density of the cooled portion of the endolymph is increased, causing it to fall, thereby producing endolymph movement. The slow phase of the caloric nystagmus is in the direction of endolymph movement.

of vestibular nystagmus.[257] This figure shows the physiologic rather than the anatomic form of the horizontal VOR system. It is drawn to reflect the fact that increased neural activity from a horizontal semicircular duct rotates the eyes horizontally away from the duct.[258]

At rest, both ducts generate equal neural activity, which represents the resting discharge described above. Unbalancing the vestibular inputs from the two ears generates vestibular nystagmus if the imbalance is prolonged. Caloric and rotational stimuli unbalance the vestibular input via the normal transducer action of the semicircular ducts. Lesioning one labyrinth by surgery or disease causes a pathologic imbalance by eliminating or reducing the resting discharge on the involved side.

THE FUTURE

Regeneration of Hair Cells

A great amount of study has focused over the past 15 years on the ability of vertebrate hair cells to regenerate. One popular model has been the bird, in which it has been shown that the sound- or drug-damaged sensory epithelium, that is, the basilar papilla, is capable of undergoing significant structural repair.[258–260] Detailed morphologic examination of damaged cochleae showed that immediately after damage, there is a substantial loss of hair cells, an expansion of the surrounding supporting-cell surface area,[261] and a degeneration of the tectorial membrane overlying the region of the lost hair cells.[262] In the days following acoustic overstimulation, the regenerative processes repair many of the damaged structures so that the hair cells are almost completely replaced by regenerated hair cells,[263] cochlear ganglion cells appear to form new synapses with the regenerated hair cells,[264] and a new tectorial membrane is partially regenerated over the lesioned area.[262] In parallel to the structural repair is a considerable recovery of auditory function as measured with physiologic techniques.[265]

Other investigators have documented the capacity of the avian cochlear and vestibular sensory epithelia to repair following aminoglycoside toxicity[266] and even to restore function.[267,268] Using cell proliferation marker procedures (ie, tritiated-thymidine autoradiography or proliferating cell nuclear-antigen immunochemistry), it has been well documented that the supporting cells are the precursors or progenitors of the regenerated cochlear[269] and vestibular[270] hair cells.

The knowledge that noise- or drug-damaged hair cells of birds, reptiles, and even guinea pigs[271] can regenerate has motivated researchers to learn how to stimulate the regrowth of the sensory cells of the human inner ear. In fact, recently it has been shown that brief treatments with forskolin enhance proliferation and regeneration by increasing the amounts of growth factor receptors at the membrane.[272] It is quite likely that, in the future, it will be possible to correct hearing and balance impairments by stimulating the growth of new hair cells.

Molecular Basis of Hearing and Balance and Clinical Implications A current view is that many of the 60% of cases of hearing impairment that have no obvious environmental origins, that is those other than conditions associated with meningitis, perinatal complications, maternal-fetal infections, acoustic trauma, and ototoxic drugs, have a genetic basis.[273] Moreover, it has been estimated that 30% of prelingual deafness causes are syndromic. Several hundred such syndromes, consisting of hearing loss in association with a variety of anatomic anomalies involving, for example, eye, musculoskeletal, renal, nervous system, and pigmentary disorders, have been described.[274] Syndromic hearing loss can have many modes of transmission including maternal inheritance, owing to a mitochondrial mutation. The forms may be conductive, sensorineural, or mixed defects.

The nonsyndromic forms of hearing loss are collectively referred to as DFN for the X-linked forms (1 to 3% incidence), DFNA for the autosomal dominant forms (15% incidence), and DFNB for the autosomal recessive forms (85% incidence). The autosomal recessive forms of hearing loss are often the most severe and account for the vast majority of cases of congenital profound deafness. To date, 20 DFNB, 14 DFNA, and four DFN loci have been mapped to specific chromosomal positions.[275] In addition, within the past 10 years, 10 genes have been cloned and shown to underlie certain nonsyndromic hearing losses. Two of these genes frequently are the cause of nonsyndromic forms of deafness. First, the connexin 26 gene, which contains a single coding exon, was shown to account for up to 50% of all causes of prelingual, autosomal, and recessive hearing loss.[276] Second, a mutation in the mitochon-

drial 12s ribosomal ribonucleic acid gene was shown to underlie an isolated form of sensorineural deafness and deafness induced by aminoglycoside treatment.[277] In addition, the sequencing of the human genome is expected to be complete in 2003, which will allow more deafness-related genes to be discovered. For certain, new technologies, such as the deoxyribonucleic acid microarrays used to study differential gene expression under various normal and pathologic conditions, promise to rapidly advance our knowledge of the diseases of the ear.[278] For a recent review of this active field of research, see Kalatzis and Petit.[275]

So far, however, this research has yet to result in the development of new treatments for deafness. Currently, the treatments available are the amplification of sound, using analog or digital hearing aids, or the artificial, electrical stimulation of the cochlear nerve via a cochlear implant. Efforts to induce regeneration of inner ear sensory cells and methods to introduce replacement genes via viral vectors[279] will soon become the most exciting treatment options leading to a possible reversal of hearing impairment.

CHAPTER 5

Diagnostic Audiology, Hearing Aids, and Habilitation Options

James W. Hall III, PhD, M. Samantha Lewis, MA

Within the past 25 years, dramatic advances in technology and techniques have contributed to more powerful audiologic test batteries and more effective management options for pediatric and adult populations. With auditory brainstem response (ABR) and otoacoustic emissions (OAEs), newborn infants can be screened for hearing impairment within days after birth and managed audiologically within the next critical 6 months. New techniques and strategies for the assessment of auditory function in adults have also been introduced in recent years. Pure-tone audiometry, immittance measurements (tympanometry and acoustic reflexes), and calculation of word recognition scores continue to be important for hearing assessment, and the traditional audiogram remains very useful in summarizing the results of basic audiologic assessment. Clinical audiology, however, now also includes other behavioral and electrophysiologic test procedures. For example, electrocochleography (ECochG) can contribute to the diagnosis of Meniere's disease. Auditory brainstem response offers a readily accessible and relatively inexpensive means for identification of retrocochlear auditory dysfunction. A variety of speech and nonspeech behavioral measures and several cortical auditory evoked responses are available for clinical assessment of central auditory nervous system dysfunction and associated auditory processing disorders. Finally, OAEs, because of their unique sensitivity and specificity to cochlear dysfunction, have become the latest addition to the clinical audiologic test battery.

The otolaryngologist is in a pivotal position to identify children and adults at risk for hearing loss, to work closely with audiologists in diagnostic hearing assessment, and to contribute to timely and appropriate medical or surgical intervention. In this chapter, we summarize current techniques and strategies for hearing assessment of adults, with an emphasis on the application of a test battery approach that maximizes diagnostic accuracy and efficiency while minimizing test time and costs. The chapter includes a review of current hearing aid technology for nonmedical management of hearing impairment. Following the review is a summary of pediatric audiologic habilitation approaches. At the end of the chapter, we define in a glossary common audiologic terms and abbreviations.

BASIC AUDIOLOGIC TEST BATTERY

Pure-Tone Audiometry

Pure-tone audiometry, the most common hearing test, is a measure of hearing sensitivity using sinusoid stimuli at octave frequencies from 250 Hz up to 8,000 Hz and usually at two interoctave frequencies (3,000 and 6,000 Hz). The normal-hearing young (under 20 years) ear responds to frequencies from 20 to 20,000 Hz. Test results are graphed on an audiogram. Two common audiogram versions are illustrated in Figure 5–1, A and B. All audiograms include, minimally, a graph for plotting hearing threshold levels (HTLs) as a function of the frequency of pure-tone signals, although the exact format and symbols may vary.

The unit of stimulus intensity is the decibel (dB), a logarithmic unit. The intensity of any sound is defined by a ratio of its sound pressure (or sound intensity) compared to a reference sound pressure (or sound intensity). The reference sound pressure is the amount of pressure against the eardrum, caused by air molecules when a sound is present, that vibrates the eardrum and can just be detected by a normal human ear. Briefly, the relationship for sound *intensity* is described as dB = 10 log 10 (sound

intensity/reference intensity) or for sound pressure as dB = 20 log 10 (sound pressure/reference pressure). The reference sound pressure is defined as dB sound pressure level (SPL) and is derived from one of two physical quantities (0.0002 dynes/cm^2, 20 micropascals RMS [root-mean-square], or 2×10^{-5} newtons/m^2 RMS).

Clinically, the intensity of sound is not usually described in dB SPL but, rather, in *dB hearing level* (HL), with a biologic reference level. On audiograms

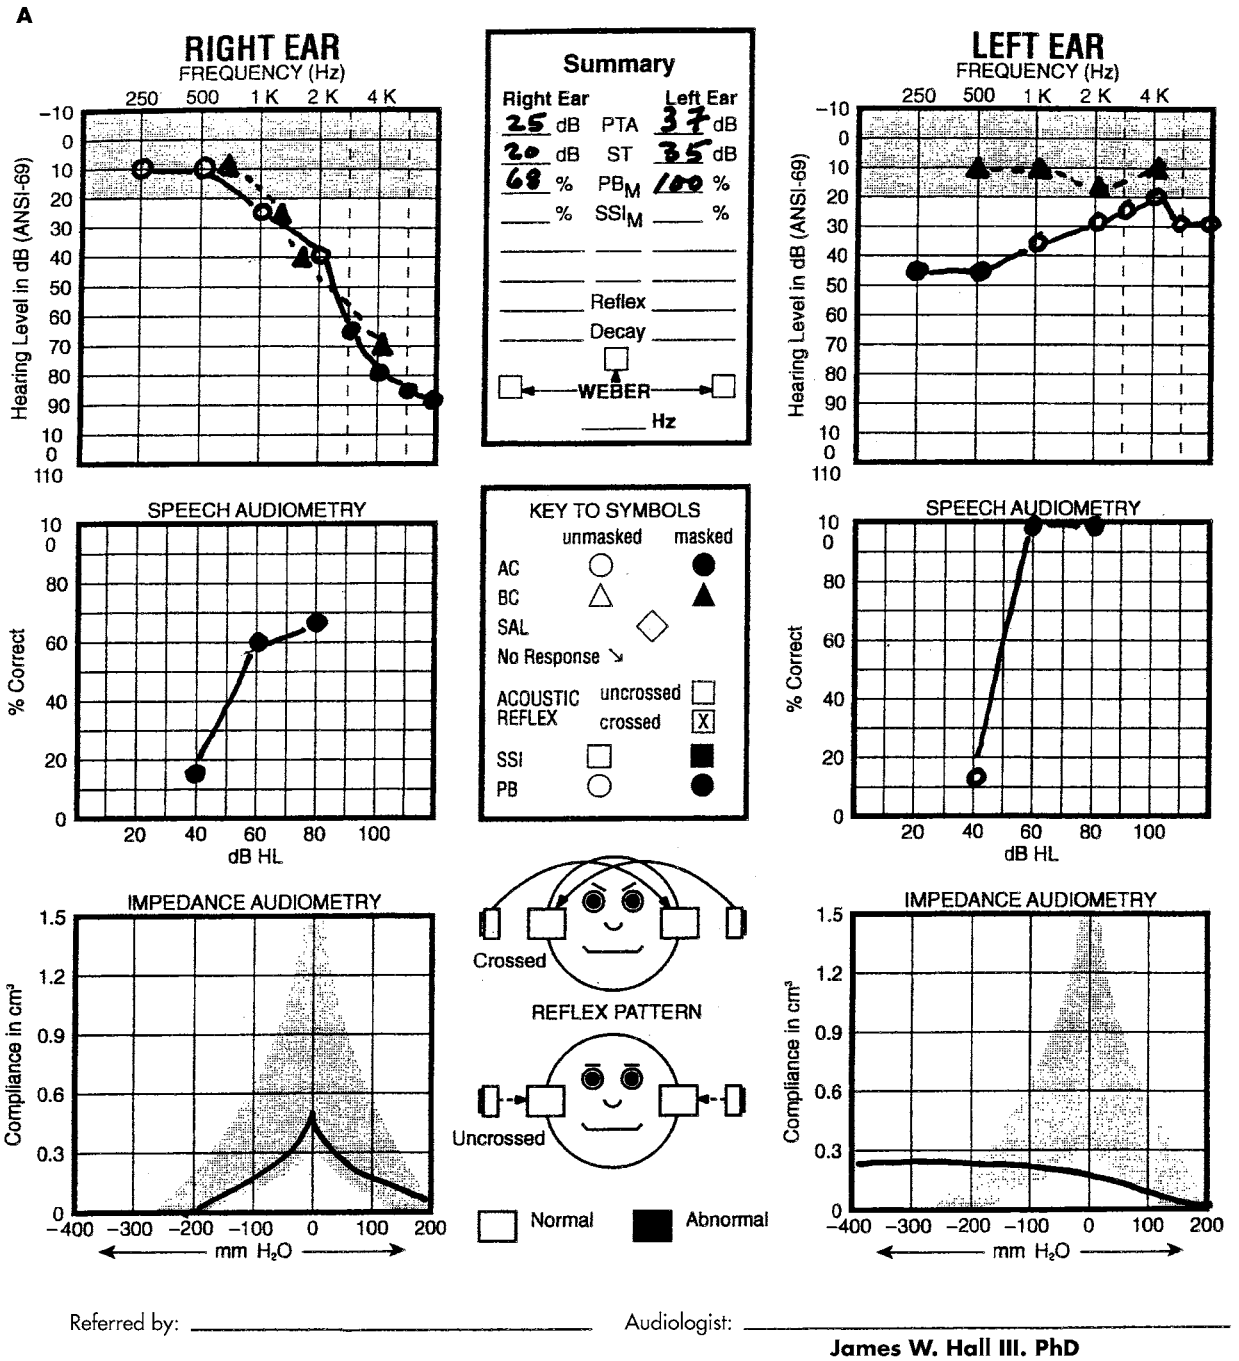

FIGURE 5–1. Two examples of audiogram formats. *A* includes sections for graphically and numerically reporting results for pure-tone audiometry (*top portion*), speech audiometry (*middle portion*), and aural immittance measurement (*bottom portion*). Masking is indicated by *filled symbols*. Findings for the right ear represent a typical sensorineural hearing loss audiometric pattern, whereas left ear findings typify a conductive hearing loss. *continued*

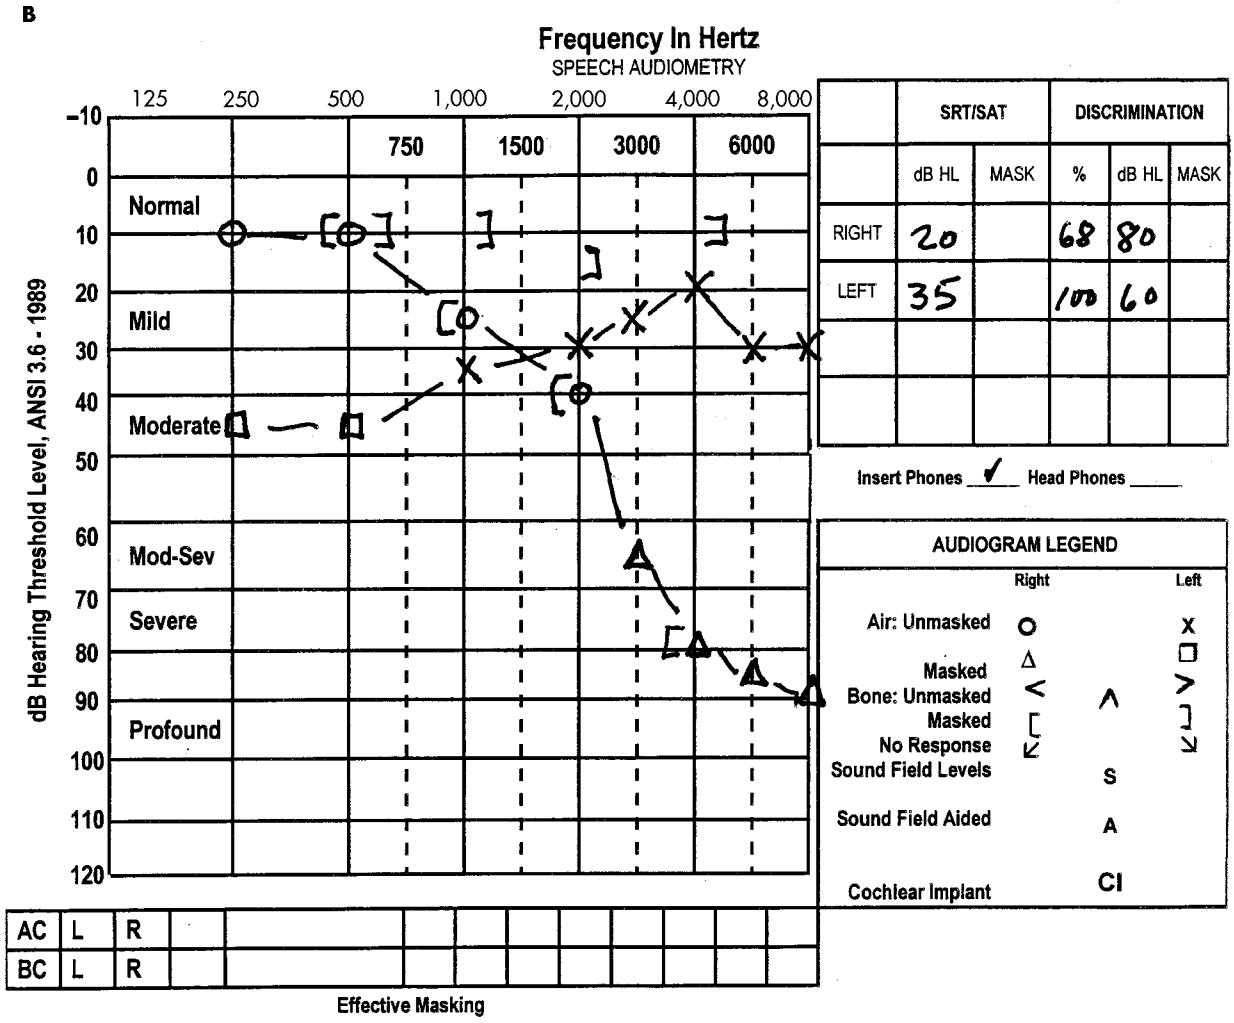

FIGURE 5–1 Continued. With *B*, the results for both ears are plotted on the same graph, requiring a separate symbol system for each ear. The same audiometric findings shown in *A* are also plotted in *B*, producing less clear analysis.

(see Figure 5–1), the dB scale has as its reference 0 dB, which is described as "audiometric 0 (zero)." This is the standard for the intensity level that corresponds to the average normal HTL, the minimal detectable intensity for each test frequency for normal hearers. Another common unit for expressing sound intensity is *dB sensation level* (SL) which is the intensity of the stimulus in dB above an individual's hearing threshold. For example, a word recognition test may be administered at an intensity level of 40 dB SL (40 dB above the patient's pure-tone average).

In adult audiologic assessment, hearing thresholds for tonal or speech signals are measured separately for each ear with earphones (air-conduction stimulation). Insert earphones (ER-3A) are now the transducer of choice for routine audiologic assessment. They offer distinct advantages over the traditional supra-aural earphones, including increased comfort, reduced likelihood of ear canal collapse, greater interaural attenuation, disposability (aural hygiene), and greater acceptance by young children.[1] Pure-tone audiometry can also be performed with stimuli presented by a bone-conduction oscillator or vibrator placed on the mastoid bone. During pure-tone audiometry, all equipment meets ANSI (American National Standards Institute) specifications, and testing is carried out according to clinical adaptations of psychoacoustic methods.[2] Patients are instructed to listen carefully for the tones and to respond (usually by pushing a button that activates a response light on the audiometer or raising their hand) every time they think they hear a tone. To

minimize interference by ambient background acoustic noise, pure-tone audiometry should always be carried out with the patient in a double-walled, sound-treated room meeting ANSI specifications.[1,3]

For adults, the clinically normal region on the audiogram is from 0 to 20 dB HL. The normal region for children is more limited because even very mild hearing loss can interfere with speech and language acquisition. Pediatric hearing threshold levels exceeding 15 dB may be considered abnormal. Thresholds in the 20 to 40 dB HL region constitute a mild hearing loss, 40 to 60 dB HL thresholds define a moderate loss, and threshold levels greater than 60 dB HL are considered a severe hearing loss.[1] As a reference, the intensity level of whispered speech close to the ear is less than 25 dB HL, conversational speech is in the 40 to 50 dB HL region, and a shouted voice within a foot of the ear is at a level of about 80 dB HL. The essential frequencies for understanding speech are in the 500 through 4,000 Hz region, although higher frequencies also contribute to discrimination between certain speech sounds. Hearing sensitivity within the "speech frequency" region is traditionally summarized by calculating the *pure-tone average* (PTA) (hearing thresholds for 500, 1,000, and 2,000 Hz divided by three and reported in dB).

The validity of audiometric results depends on whether the patient's responses result from stimulation of the test ear. If a sound of greater than 40 dB HL is presented to one ear via standard earphones with supra-aural (resting on the outer ear) cushions, it is possible that the acoustic energy will cross over from one side of the head to the other and stimulate the nontest ear. The mechanism for the crossover is presumably bone-conduction stimulation caused by vibration of the earphone cushion against the skull at high stimulus intensity levels. The amount of sound intensity needed before the crossover occurs is a reflection of *interaural attenuation*, that is, the sound insulation between the two ears provided by the head. Interaural attenuation is usually about 50 dB for lower test frequencies and 60 dB for higher test frequencies (such as those contributing to the ABR). Interaural attenuation is considerably higher for insert earphones.[1] With bone-conduction stimulation, interaural attenuation is very limited (at most 10 dB). Clinically, one must assume that interaural attenuation for bone-conducted signals is 0 dB. That is, any sound presented to the mastoid bone of one ear by a bone-conduction vibrator may be transmitted through the skull to either or both inner ears. Actual perception of this bone-conducted signal will, of course, depend on the patient's sensorineural hearing sensitivity in each ear.

Masking is the audiometric technique used to eliminate participation of the nontest ear whenever air- and bone-conduction stimulation exceeds interaural attenuation. An appropriate noise (narrowband noise for pure-tone signals and speech noise for speech signals) is presented to the nontest ear when the stimulus is presented to the test ear. With adequate masking, any signal crossing over to the nontest ear is masked by the noise. Selection of appropriate masking is sometimes difficult, especially when there is bilateral hearing impairment. One should always attempt to verify that appropriate masking was used in interpreting audiologic results when the tester is not known and, particularly, if testing was not performed by an audiologist.

Comparison of the hearing thresholds for air- versus bone-conduction signals is useful in classifying *type of hearing loss*, that is, whether a hearing loss is sensorineural (no air–bone gap), conductive (normal bone conduction and a loss by air conduction), or mixed (loss by bone conduction with a superimposed air- versus bone-conduction gap). *Configuration* refers to hearing loss as a function of the test frequency. With the sloping configuration, hearing is better for low frequencies and then becomes poorer for higher frequencies. High-frequency deficit hearing loss is the most common pattern associated with a sensorineural hearing impairment. A rising configuration is typified by relatively poor hearing for lower-frequency stimuli and better hearing for the high frequencies. The rising configuration can result from varied types of middle ear pathology. One exception to the typical association of conductive hearing loss with rising configuration is Meniere's disease (see Chapter 20). Meniere's disease is a manifestation of a cochlear lesion that produces a rising configuration. A flat audiometric configuration is often recorded from patients with mixed hearing loss, that is, when both sensorineural and conductive components are present.

Speech Audiometry

Speech audiometry measures how well a person hears and understands speech signals. Speech audiometry procedures are used routinely to measure hearing

sensitivity (thresholds in dB) for words or to estimate word recognition (ie, speech discrimination) ability. Spondee reception threshold (SRT), also referred to as the speech reception threshold (SRT) or speech threshold (ST), is the softest intensity level at which a patient can correctly repeat words approximately 50% of the time. Spondee words, two-syllable words with equal stress on each syllable (eg, airplane, baseball, cowboy), are presented to the patient monaurally via earphones. The technique is equivalent to the method for determining pure-tone thresholds described previously.

Because the PTA indicates HTLs in the speech frequency region and ST or SRT is measured with a speech signal, close agreement between the PTA and the ST is expected. If the difference between PTA and ST exceeds ±7 dB, there is reason to suspect that one or both of the measures is invalid. An unusually good ST relative to PTA (eg, ST of 5 dB and PTA of 45 dB) should immediately alert the tester to the possibility of a nonorganic hearing loss, as in malingering. With cooperative adult patients, particularly if pure-tone hearing thresholds are within the normal region from 500 to 4,000 Hz, there is probably little or no clinical benefit in measuring speech thresholds. Test time can be saved, with no loss of diagnostic information, by excluding speech threshold measurement from the test battery for such patients.

The common clinical approach for estimating a person's ability to hear and understand speech is speech recognition for phonetically balanced (PB) words.[1] Usually, a list of 25 or 50 single-syllable words is presented to the patient via earphones at one or more fixed intensity levels, and the percentage of words correctly repeated by the patient is calculated by the tester. One ear is tested at a time. Within the list of words, specific speech sounds (phonemes) occur approximately as often as they would in everyday conversation (they are "phonetically balanced"). Traditionally, these words were spoken into a microphone by the tester, while the level was monitored with a VU (volume unit) meter. Then the words were routed to the patient through the audiometer after selection of the test ear and desired intensity level. This is, however, an outdated and poor clinical practice since it lacks standardization and consistency and increases the variability of test outcome. With adult patients, it is almost always possible and always preferable to use professionally produced (and commercially available) speech materials presented via a compact disc player and an audiometer.[1] Diagnostic speech audiometry using more sophisticated materials (eg, spectrally degraded or temporally distorted speech, or speech in noise materials) is feasible for assessment of the central auditory system.[1,4]

Immittance Measurement

Aural immittance (impedance) measures are an important part of the basic audiometry test battery. Immittance is a term derived from the terms for two related techniques for assessing middle ear function (*im*pedance and ad*mittance*), techniques that have been applied clinically since 1970.[5] Briefly, the external ear canal is sealed with a soft rubber probe tip.[1] Connected to the probe tip is a device producing a tone that is delivered toward the eardrum. Middle ear impedance or admittance is calculated from the intensity and other physical properties (eg, phase) of the tone in the ear canal. A middle ear (tympanic membrane and ossicles) system with low impedance (high admittance) more readily accepts the acoustic energy of the probe tone, whereas a middle ear with abnormally high impedance (low admittance) caused, for example, by fluid within the middle ear space tends to reject energy flow. Thus, impedance (admittance) characteristics of the middle ear system can be inferred objectively with this quick and noninvasive technique and then related to well-known patterns of findings for various types of middle ear lesions.

Tympanometry Tympanometry is the continuous recording of middle ear impedance as air pressure in the ear canal is systematically increased or decreased. The technique is a sensitive measure of tympanic membrane integrity and middle ear function (Figure 5–2). Compliance (the reciprocal of stiffness) of the middle ear, the dominant component of immittance, is the vertical dimension of a tympanogram. Tympanometry is popular clinically because it requires minimal technical skill and less than a minute to perform. Because immittance measurement is an electrophysiologic (versus behavioral) method, it does not depend on cooperation of the patient. Importantly, it is a sensitive measure of middle ear function. Tympanometric patterns, in combination with audiogram patterns, permit differentiation among and classification of middle ear disorders.

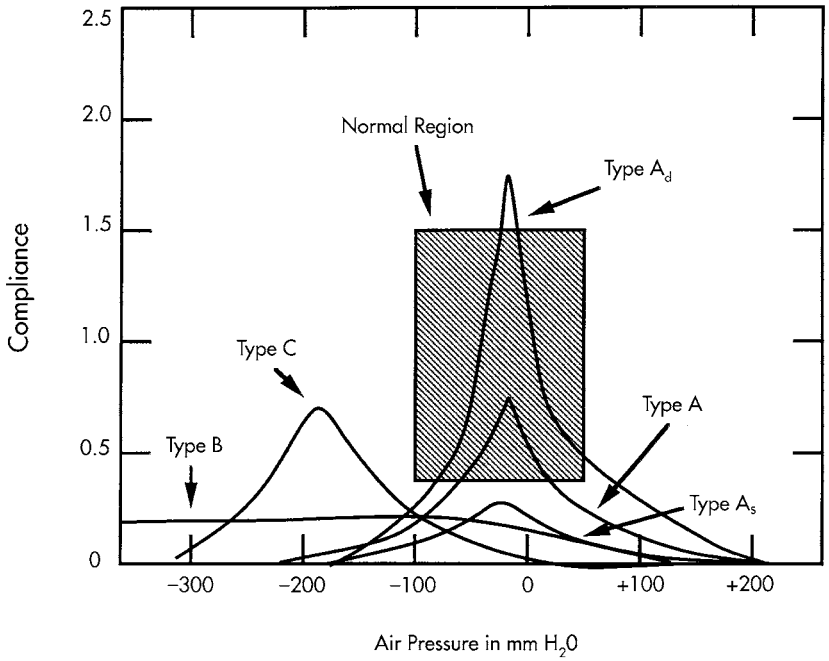

FIGURE 5–2. Classification system for tympanograms. Adapted from Jerger J.[5]

In 1970, James Jerger described what has become the most clinically widespread approach for describing tympanograms. There are three general tympanogram types: *A*, *B*, and *C*. The normal, or type A, tympanogram has a distinct peak in compliance within 0 to –100 mm of water pressure (decapascals) in the ear canal (see Figure 5–2). To be classified as normal, the location of the compliance peak on the pressure dimension and the height of the peak must be within the normal range, indicated in the figure by the stippled area. With a type B tympanogram, there is no peak in compliance but, rather, a flat pattern with little or even no apparent change in compliance as a function of pressure in the ear canal. This pattern is most often associated with fluid within the middle ear space (eg, otitis media), although other middle ear lesions may give rise to a type B tympanogram as well. Type C tympanograms also have a distinct peak in compliance (as with the type A), but the peak is within the negative pressure region beyond –150 mm H_2O (or dkPa). This pattern is usually found in patients with eustachian tube dysfunction and inadequate ventilation of the middle ear space and often precedes the type B tympanogram in the development of otitis media.

The type A_s (see Figure 5–2) is a variation of the type A tympanogram. The "s"stands for shallow. Peak compliance is below the lower normal limits of compliance. That is, middle ear impedance is abnormally high. The type A_s pattern is typically recorded from patients with fixation of the ossicular chain, including those with the diagnosis of otosclerosis. In contrast, with an usually steep and high-compliance tympanogram (type A_d for deep), the peak may actually exceed the upper compliance limits of the equipment. The A_d tympanogram type is recorded from patients with disruption of the ossicular chain, which leaves the middle ear extremely mobile and hypercompliant (ie, very little impedance). In the absence of serious hearing loss, however, this tympanogram pattern is usually associated with minor tympanic membrane abnormality, such as scarring. During the initial portion of the tympanometry procedure, high positive or negative pressure is introduced into the ear canal. This essentially decouples the middle ear system from the measurement. If the immittance device records an abnormally large equivalent volume of air (eg, 2 cm^3 or more in an adult or twice the volume that was recorded for the other ear) between the probe tip and presumably the eardrum at this stage in the procedure, the integrity of the eardrum should be questioned. That is, the immittance device is recording not just ear canal volume but also volume of the middle ear space. This test finding is consistent with either a perforation of the tympanic membrane or an open (patent) middle ear ventilation tube.

Acoustic Stapedial Reflex Measurement Measurement of contractions of the middle ear stapedial mus-

cle to high sound intensity levels (usually 80 dB or greater) is the basis of the acoustic reflex test. The stapedial muscle within the middle ear is the smallest muscle in the body. Acoustic reflex measurement is clinically useful for estimating hearing sensitivity and for differentiating among sites of auditory disorders, including the middle ear, inner ear, eighth cranial nerve, and auditory brainstem. The afferent portion of the acoustic reflex arc is the eighth cranial nerve. There are complex brainstem pathways leading from the cochlear nucleus on the stimulated side to the region of the motor nucleus of the seventh (facial) nerve on both sides (ipsilateral and contralateral to the stimulus) of the brainstem. The efferent portion of the arc is the seventh nerve innervating the stapedius muscle. When the muscle contracts, the result is increased stiffness (decreased compliance) of the middle ear system. This small change in compliance following stapedius muscle contraction (within 10 ms) is detected by the probe and immittance device.

Measurement of the acoustic reflex is useful clinically because it can quickly provide objective information on the status of the auditory system from the middle ear to the brainstem. Distinctive acoustic reflex patterns for ipsilateral and contralateral stimulation and measurement conditions characterize middle ear, cochlear, eighth nerve, brainstem, and even facial nerve dysfunction (see "faces" in lower portion of Figure 5–1, A). Comparison of acoustic reflex threshold levels, the lowest stimulus intensity level that activates the reflex, for tonal versus noise signals permits estimation of the degree of cochlear hearing impairment.[1] This technique is especially valuable in children and difficult-to-test patients.

AUDITORY EVOKED RESPONSES

Auditory evoked responses are electrophysiologic recordings of responses to sounds. With proper test protocols, the responses can be recorded clinically from activation of all levels of the auditory system, from the cochlea to the cortex. More than a dozen subtypes of auditory evoked responses can be recorded beyond the brainstem from auditory regions of the thalamus, hippocampus, internal capsule, and cortex. Prominant among the cortical evoked responses measured for clinical purposes are the auditory middle latency response (AMLR), the auditory late response (ALR), the P300 response, and the mismatch negativity (MMN) response.[1,6] In fact, cortical auditory evoked responses were reported as early as the 1930s, and, with the exception of the MMN, all of the above responses were well described before the ABR was even discovered. Cortical auditory evoked responses are characterized by longer latencies (100 to 300 ms) than ECochG and ABR because they arise from more rostral regions of the auditory central nervous system and are dependent on multisynaptic pathways. Amplitudes of the cortical responses are considerably larger (2 to 20 times larger) than those of the earlier responses because they reflect activity evoked from a greater number of neurons. Measurement parameters are distinctly different for the cortical versus cochlear or brainstem responses. For example, stimulus rate must be slower and physiologic filter settings lower. As a rule, stimulus intensities are moderate rather than high. Cortical evoked responses are best elicited with longer-duration, and therefore frequency-specific, tonal stimuli rather than the click stimuli that are optimal for evoking ECochG and ABR. The analysis time must, of course, extend beyond the expected latency of the response (> 300 ms) for the cortical responses. Recording electrode sites also are different for the cortical responses, with more emphasis on scalp sites over the hemispheres and less concern about electrode sites near the ears.

AUDITORY BRAINSTEM RESPONSE

Among the many auditory evoked responses, the ABR (often referred to by neurologists as the brainstem auditory evoked response or BAER) and ECochG are applied most often clinically. An ABR recording is shown schematically in Figure 5–3. The ABR is generated with transient acoustic stimuli (clicks or tone bursts) and detected with surface electrodes (disks) placed on the forehead and near the ears (earlobe or within the external ear canal). Using a computer-based device, it is possible to present rapidly (eg, at rates of 20 to 30 per second) thousands of sound stimuli and to average reliable ABR waveforms in a matter of minutes. Automated devices are now available for special clinical applications, for example, newborn hearing screening. The anatomic generators of the ABR components have been studied extensively.[6] Waves I through V arise from the eighth cranial nerve and auditory regions

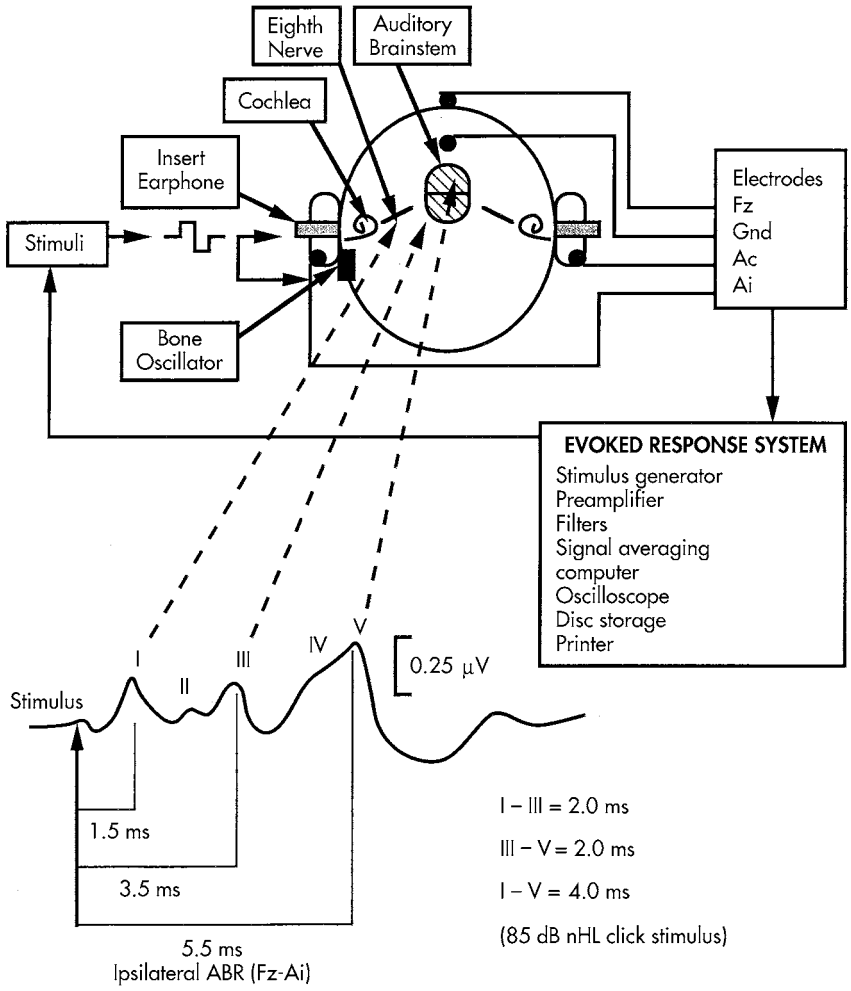

FIGURE 5–3. Schematic of the instrumentation used for recording the auditory brainstem response (ABR) and major relations among auditory anatomy and waveform components. A simple strategy for analysis of ABR waveform in neurodiagnosis is also shown.

in the caudal and rostral brainstem (see Figure 5–3). Wave I clearly represents the synchronously stimulated compound action potentials from the distal (cochlear) end of the eighth cranial nerve. Wave II may also arise from the eighth nerve, but near the brainstem (the proximal end). Waves I and II are generated by structures ipsilateral to the ear stimulated. All later ABR waves have multiple generators within the auditory brainstem. Wave III, which is usually prominent, is generated within the caudal pons, with likely contributions from the cochlear nuclei, the trapezoid body, and the superior olivary complex. The largest and most rostral component of the ABR, wave V, is generated in the region of the lateral lemniscus as it approaches the inferior colliculus, presumably mostly on the side contralateral to the ear stimulated.

The first objective in ABR waveform analysis is to be sure that the response is reliably recorded. Minimally, two replicated waveforms should be averaged. If the response is not highly replicable, modifications in the test protocol should be made, and then potential technical problems must be considered and systematically ruled out. When a replicable response is confirmed, absolute latencies for each replicable wave component and relative (interwave) latencies between components are calculated in milliseconds. These latency data for each ear are assessed for symmetry (wave V should be within 0.4 ms between ears) and also compared with appropriate normative data. Common ABR waveform patterns are illustrated in Figure 5–3. A well-formed and clear wave I at a delayed latency value for the maximum stimulus intensity level is characteristic of a conductive or mixed hearing loss. When wave I is small and poorly formed but interwave latency values are within normal limits (the wave I to V latency value is less than 4.60 ms), a high-frequency sensory (cochlear) hearing loss is suspected. Delayed interwave latency values are the signature of retrocochlear auditory

dysfunction. Abnormal delays between the early wave components (eg, I to III) are consistent with posterior fossa lesions involving the eighth nerve and/or lower brainstem, whereas a prolonged III to V latency suggests intra-axial auditory brainstem dysfunction.

A primary goal in any neurodiagnostic ABR is to record a clear and reliable wave I component. Wave I serves as the benchmark for peripheral auditory function. Subsequent interwave latencies offer indices of retrocochlear (eighth nerve and brainstem) function that are relatively unaffected by conductive or sensory hearing loss. The likelihood that a wave I will be recorded is enhanced by the use of either ear canal (TIPtrode™) or tympanic membrane electrode designs, along with alterations of the test protocol, such as a slower stimulus rate, rarefaction stimulus polarity, and maximum stimulus intensity level. Reports on ABR dating back to the late 1970s confirmed that waveforms evoked by high intensity yielded neurodiagnostic information on cochlear and retrocochlear auditory function and could be applied in the identification of retrocochlear disorders (eg, acoustic neuromas), with a hit rate exceeding 95%. With the development of sophisticated neuroradiologic techniques, such as computed tomography (CT) or magnetic resonance imaging (MRI) with enhancement, reports of normal ABR findings among patients with very small posterior fossa tumors have appeared in the literature. These are clearly false-negative ABR outcomes in patients at risk for retrocochlear auditory dysfunction usually caused by very small intracanalicular vestibular schwannomas. On the other hand, false-positive outcomes for CT and MRI have also been reported for patients with normal ABRs and no surgical evidence of tumor.[1] Auditory brainstem response continues to be a readily available, relatively inexpensive, and reasonably sensitive procedure for initial diagnostic assessment of eighth nerve and auditory brainstem status in patients with retrocochlear signs and symptoms. Auditory brainstem response is also valuable in electrophysiologic monitoring of the eighth nerve and auditory brainstem function during certain neurotologic surgeries (eg, vestibular nerve section, posterior fossa tumor removal).

Electrocochleography

For over 30 years, ECochG has been applied in the assessment of peripheral auditory function. Currently, ECochG is performed most often for intraoperative monitoring of cochlear and eighth nerve status and in the diagnosis of Meniere's disease. Optimal ECochG waveforms are recorded from a small needle electrode placed through the tympanic membrane to the promontory, although tympanic membrane and, to a lesser extent, ear canal electrode locations are also clinically useful. Stimulus and acquisition parameters for recording ECochG have been well defined for decades.[6] The three major components of the ECochG are the cochlear microphonic (CM), the summating potential (SP), and the action potential (AP). The CM and SP reflect cochlear bioelectric activity, whereas the AP is generated by synchronous firing of distal afferent eighth nerve fibers and is equivalent to ABR wave I (Figure 5–4). The typical ECochG analysis technique in neurotology requires determination of the amplitude of the SP and the AP from a common baseline. Then the ratio of the SP to the AP is calculated and reported in percent. Normal SP to AP ratio ranges and cutoffs in percent have been reported for each electrode type. Abnormal SP to AP ratio values are defined as > 50% for the ear canal electrode type (the TIPtrode), > 40% for the tympanic membrane electrode, and > 30% for the transtympanic needle electrode type.[1,6]

The characteristic ECochG finding for patients with Meniere's disease is an abnormal enlargement of the SP amplitude relative to the AP amplitude. With the tympanic membrane electrode technique, sensitivity of ECochG in the diagnosis of endolymphatic hydrops is reported as 57%, whereas specificity is 94% in a series of 100 patients.[7] Only 3 of 30 patients yielded false-positive findings. Thus, an abnormally high SP to AP ratio is highly suggestive of endolymphatic hydrops according to these data. In this study, the likelihood of an abnormal ECochG SP to AP ratio was statistically higher as hearing loss increased and when the hearing loss fluctuated.

OTOACOUSTIC EMISSIONS

Otoacoustic emissions are low-intensity sounds produced by the cochlea in response to an acoustic stimulus.[8] A moderate-intensity click, or an appropriate combination of two tones, can evoke outer hair cell movement or motility. Outer hair cell motility affects basilar membrane biomechanics, resulting in a form of intracochlear energy amplification, as well as cochlear tuning for more precise frequency

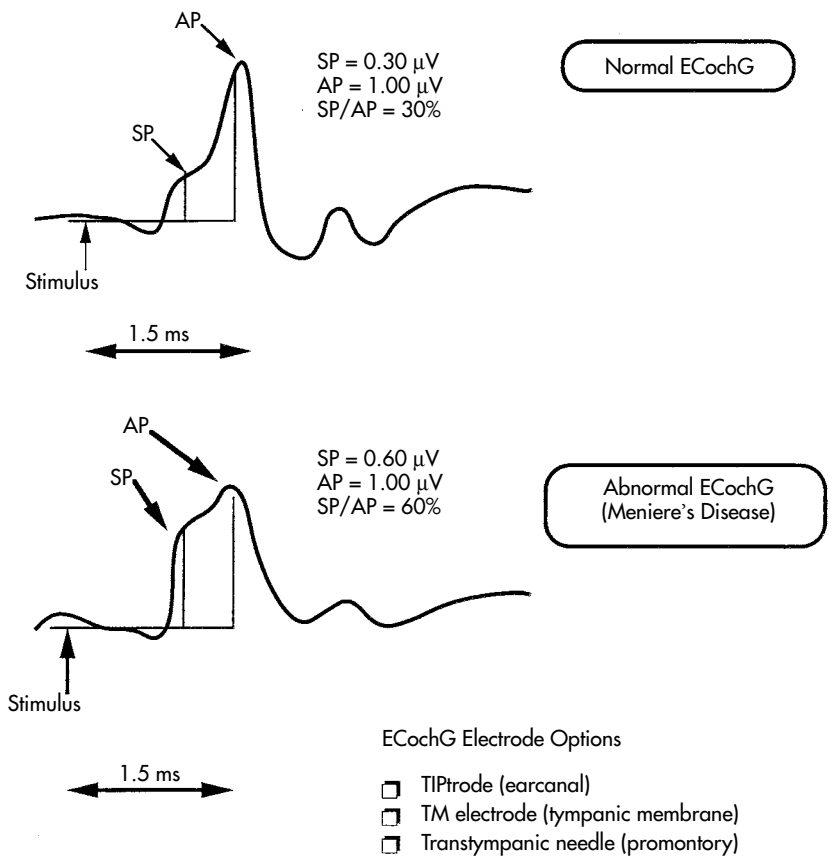

FIGURE 5–4. Electrocochleography (ECochG) waveforms illustrating normal relation of summating potential (SP) and action potential (AP) and abnormally enlarged SP/AP relation in a patient with Meniere's disease. Absolute and relative amplitude values for the SP and AP components and the criteria for definition of a normal response vary significantly for different electrode sites (ear canal versus tympanic membrane versus promontory). For a discussion of ECochG measurement and analysis, see Schwaber MK, Hall JW. A simplified technique for transtympanic electrocochleography. Am J Otol 1990;11:260–5.

resolution. The outer hair cell motility generates mechanical energy within the cochlea that is propagated outward via the middle ear system and the tympanic membrane to the ear canal. Vibration of the tympanic membrane then produces an acoustic signal (the OAE), which can be measured by a sensitive microphone. There are two broad classes of OAEs: spontaneous and evoked. *Spontaneous* otoacoustic emissions (SOAEs), present in only about 70% of persons with normal hearing, are measured in the external ear canal when there is no external sound stimulation. A significant gender effect for SOAE has been confirmed, with females demonstrating SOAEs at twice the rate of males.

Evoked OAEs, elicited by moderate levels (50 to 80 dB SPL) of acoustic stimulation in the external ear canal, are generally classified according to characteristics of the stimuli used to elicit them or characteristics of the cochlear events that generate them. *Stimulus-frequency* otoacoustic emissions (SFOAEs), which are technically difficult to record, are the least studied of the evoked OAEs. *Distortion-product* otoacoustic emissions (DPOAEs) are produced when two pure-tone stimuli at frequencies f_1 and f_2 are presented to the ear simultaneously (Figure 5–5). The most robust DPOAE occurs at the frequency determined by the equation $2f_1$-f_2, whereas the actual cochlear frequency region that is assessed with DPOAE is between these two frequencies and probably close to the f_2 stimulus for recommended test protocols. With all of the five US Food and Drug Administration (FDA)-approved instruments that are commercially available for recording DPOAE, amplitude as detected in the ear canal and described in dB SPL is plotted as a function of the frequencies of the stimuli in a DPOAEgram (see Figure 5–5). *Transient evoked* otoacoustic emissions (TEOAEs) are elicited by brief acoustic stimuli such as clicks or tone bursts. Although there are distinct differences in the methodology for recording DPOAEs versus TEOAEs, and the exact cochlear mechanisms responsible for their generation are also different, each type of evoked OAE is now being incorporated into routine auditory assessment of children and adults.[8] Clinical applications of OAEs, along with their rationale, are summarized in Table 5–1.

When outer hair cells are structurally damaged or at least nonfunctional, OAEs cannot be evoked by

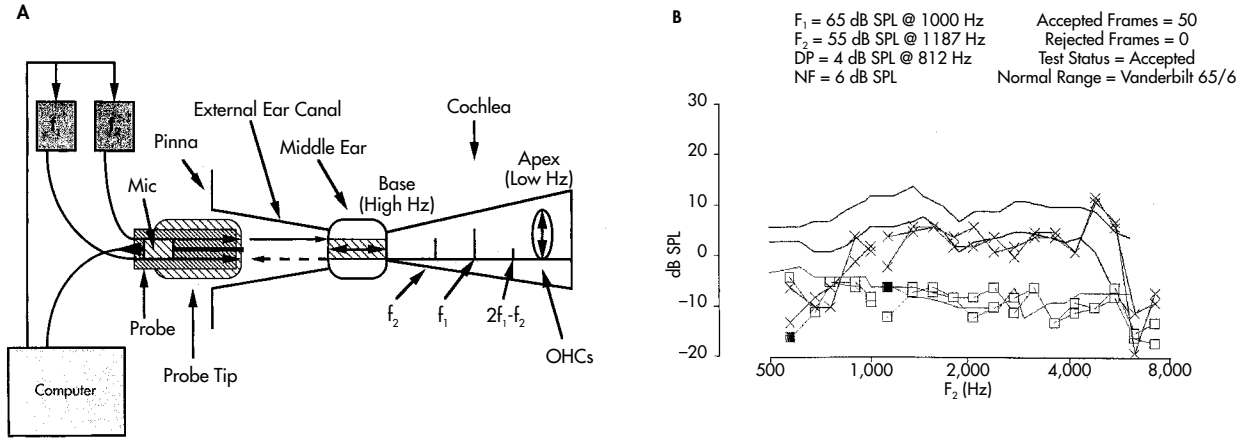

FIGURE 5–5. *A*, Schematic illustration of the generation of distortion-product otoacoustic emissions (DPOAEs) from outer hair cells (OHCs) within the cochlea showing the two stimulus-frequency generators, the probe for delivery of the stimuli and housing of a microphone (Mic) for detection of the OAE in the canal, and the inward propagation of the stimuli to the cochlea and the outward propagation of the DPOAEs from the cochlea. *B*, DPgram recorded from the left ear of a 5-year-old girl with a ventilation tube in the tympanic membrane, yet hearing sensitivity is within normal limits. Replicated plots of DPOAE amplitudes in dB SPL (*the X symbols*) are shown as a function of the f_2 stimuli in a "DPgram" format. Noise levels as a function of frequency are indicated in the lower portion of the DPgram by the *square symbols*. The *faint solid line* represents the upper limits (95th percentile) for normal noise levels. Distortion-product amplitudes are reduced in the low-frequency region (500 to 1,000 Hz), consistent with a slight air–bone gap in pure-tone hearing thresholds. Distortion-product amplitudes for higher frequencies are generally within normal limits (the two *solid lines* representing the 5th to 95th percentile region for normal adult subjects). NF = noise floor.

acoustic stimuli. Among patients with mild cochlear dysfunction, OAEs may be recorded, but amplitudes are below normal limits for some or all stimulus frequencies. Importantly, some patients with abnormal OAEs, consistent with cochlear dysfunction, will have normal pure-tone audiograms. An example is a patient with the symptom of tinnitus yet a normal audiogram. Abnormal OAEs are expected in the frequency region represented by the tinnitus. Up to 30% of a population of outer hair cells may be damaged without substantially affecting the simple audiogram. In such cases, however, abnormal OAE findings are invariably recorded. The noninvasive nature of OAE recording, coupled with their accuracy and objectivity in assessing cochlear, in particular outer hair cell, function suggests diverse potential clinical applications, ranging from auditory screening to sensorineural diagnosis.

INDICATIONS FOR DIAGNOSTIC AUDIOLOGIC ASSESSMENT

CHILDREN

Hearing loss influences speech and language development of infants and young children, and these effects begin within the first 6 months of life.[9,10] Even mild peripheral hearing deficits among preschool- and school-age children interfere with educational development. Therefore, early identification of hearing loss, coupled with timely and appropriate intervention and management, is nec-

TABLE 5–1. Clinical Applications of Otoacoustic Emissions (OAEs) and Their Rationale

Application	*Rationale*
Newborn hearing screening	OAEs can be recorded reliably from newborn infants
	OAE recording can be performed in nursery setting (test performance may be affected by noise)
	Normal OAEs are recorded in persons with normal sensory (cochlear) function
	OAEs are abnormal in persons with even mild degrees of sensory hearing loss; the main objective of screening is to detect sensory hearing impairment
	OAE recording may require a relatively brief test time
	OAE measurement may be performed by nonaudiologic personnel (ie, at reduced cost)
Pediatric audiometry	OAE recording is electrophysiologic and not dependent on patient behavioral response
	OAEs assess cochlear function specifically (behavioral audiometry and ABR are dependent also on the status of the central auditory nervous system)
	OAEs can be recorded from sleeping or sedated children
	OAE recording requires a relatively short test time
	OAEs provide ear-specific audiologic information
	OAEs provide frequency-specific audiologic information
	OAEs are a valuable contribution to the "crosscheck principle"*
Diagnosis of central auditory processing disorders	OAE recording is electrophysiologic and not dependent on patient behavioral response OAEs are a sensitive means of ruling out cochlear (outer hair cell) dysfunction
Assessment in suspected functional hearing loss	OAE recording is electrophysiologic and not dependent on patient behavioral response
	Normal OAEs invariably imply normal sensory function
	OAEs provide frequency-specific audiologic information
Differentiation of cochlear versus retrocochlear auditory dysfunction	OAEs are site specific for cochlear (sensory) auditory dysfunction In combination with ABR, OAEs can clearly distinguish sensory versus neural auditory disorders
Monitoring ototoxicity	OAEs are site specific for cochlear (sensory) auditory dysfunction
	Ototoxic drugs exert their effect on outer hair cell function; OAEs are dependent on outer hair cell integrity
	OAE recording is electrophysiologic and not dependent on patient behavioral response; can be recorded from patients who, owing to their medical condition, are unable to perform behavioral audiometry tasks or from infants and young children
	OAEs can detect cochlear dysfunction before it is evident by pure-tone audiometry
	OAEs provide frequency-specific audiologic information
Tinnitus	OAEs are site specific for cochlear (sensory) auditory dysfunction
	OAEs can provide objective confirmation of cochlear dysfunction in patients with tinnitus and normal audiograms

Continued

TABLE 5–1 *Continued*. Clinical Applications of Otoacoustic Emissions (OAEs) and Their Rationale

Application	*Rationale*
	OAEs provide frequency-specific audiologic information that may be associated with the frequency region of tinnitus
Noise/music exposure	OAEs are site specific for cochlear (sensory) auditory dysfunction
	Excessive noise/music intensity levels affect outer hair cell function; OAEs are dependent on outer hair cell integrity
	OAEs can provide objective confirmation of cochlear dysfunction in patients with normal audiograms
	OAE findings are associated with cochlear frequency specificity, ie, "tuning"; musician complaints of auditory dysfunction can be confirmed by OAE findings, even with a normal audiogram
	OAEs can provide an early and reliable "warning sign" of cochlear dysfunction owing to noise/music exposure before any problem is evident in the audiogram

*The crosscheck principle in pediatric audiology is that the results of any single audiologic test should not be relied on without independent corroboration or crosscheck from another audiologic test.
Adapted from Hall JW.[8] ABR = auditory brainstem response.

essary for children to reach their full communicative and educational potential.[11] A number of factors put children at risk for hearing impairment. Table 5–2 summarizes risk factors for hearing impairment identified by the 2000 Joint Committee on Infant Hearing.[12] Otolaryngologists and audiologists must coordinate efforts in properly and promptly assessing and managing pediatric hearing impairment.

In addition to peripheral hearing impairment secondary to common causes, such as conductive hearing loss with otitis media or sensorineural hearing loss in ototoxicity, one must also consider the possibility of auditory processing disorders (APDs) in children. According to a recent consensus conference report,[4] auditory processing disorders are defined as "deficits in the processing of information that is specific to the auditory modality." Often APDs are related to central auditory nervous system dysfunction. Common risk factors for APDs in school-age children include the following:

- teacher concern about hearing despite a normal audiogram
- academic underachievement
- recurrent middle ear disease
- suggestion of APD on language evaluation
- poor response to language treatment
- attention-deficit disorder (ADD) with or without hyperactivity
- reading delay or disorder
- learning disabilities
- history of central nervous system insult (eg, head injury, neonatal asphyxia)

There are now a variety of behavioral and electrophysiologic measures for diagnosis of APDs. Electrophysiologic procedures were outlined above. Among them, cortical evoked responses are especially appropriate for evaluation of APD. The behavioral procedures include measures of detection (eg, auditory integration tasks), suprathreshold discrimination (eg, temporal ordering tasks), and identification (eg, recognition of speech signals from phonemes to sentences), presented monotically, diotically, and dichotically.[4] Speech and nonspeech materials for assessment of APDs are available in compact disc format from multiple commercial sources.[1,13]

Adults

In adults, risk factors for central auditory nervous system dysfunction include, but are not limited to, advanced age and history or clinical evidence of stroke, head injury, brain neoplasms, Alzheimer's disease, and other disorders affecting the central nerv-

TABLE 5–2. Joint Committee on Infant Hearing Screening 2000 Indicators Associated with Sensorineural Hearing Loss

Birth through age 28 d (neonate)
Family history of congenital or delayed-onset childhood hereditary sensorineural hearing loss
Congenital infection, such as toxoplasmosis, syphilis, rubella, cytomegalovirus, and herpes
Craniofacial anomalies including abnormalities of the pinna and ear canal, absent philtrum, and low hairline.
Birth weight less than 1,500 g (3.3 lb); hyperbilirubinemia at level requiring exchange transfusion
Ototoxic medications including but not limited to the aminoglycosides (eg, gentamicin, tobramycin, kanamycin, streptomycin) used in multiple courses or in combination with loop diuretics
Bacterial meningitis
Apgar scores of 0 to 4 at 1 min or 0 to 6 at 5 min
Mechanical ventilation lasting 5 days or longer
Stigmata or other findings associated with a syndrome known to include sensorineural and/or conductive hearing loss (eg, Waardenburg's or Usher's syndrome).
Age 29 d through 2 y (infant)
Parent caregiver concern regarding hearing, speech, language, and/or developmental delay
Bacterial meningitis and other infections associated with sensorineural hearing loss
Ototoxic medications including but not limited to chemotherapeutic agents or aminoglycosides used in multiple courses or in combination with loop diuretics
Recurrent or persistent otitis media with effusion for at least 3 mo
For use with infants (age 29 d through 3 y) requiring monitoring of hearing
Indicators associated with delayed-onset sensorineural hearing loss
Family history of hereditary childhood hearing loss
In utero infections (eg, cytomegalovirus, rubella, syphilis, herpes, or toxoplasmosis)
Neurofibromatosis 2 and neurodegenerative disorders
Indicators associated with conductive hearing loss
Recurrent or persistent otitis media with effusion
Anatomic deformities and other disorders that affect eustachian tube function
Neurodegenerative disorders

ous system. In general, it is a good clinical policy to always consider the possibility of central auditory dysfunction when a patient's hearing complaints exceed expectations based on the audiogram.

HEARING AIDS

A hearing aid is a medical device that delivers an amplified acoustic signal into the ear canal. The use of some form of amplification to overcome the deleterious effects of a hearing impairment on communication has been used for centuries. The most simplistic "hearing aid" is easily made by cupping one's hand behind the ear. This technique is effective because it helps channel the acoustic signal into the ear canal. Another simple means for improving the reception of an acoustic signal is to move closer to the sound source. When the distance between the listener and the sound source is doubled, the acoustic intensity is reduced by 6 dB at the listener. Similarly, a reduction in the distance by one half increases the intensity by 6 dB. When the acoustic signal is from an electronic device, such as a television or radio, reception can easily be enhanced by adjusting the volume control to make a more intense signal. All of these methods enhance the

reception of a particular acoustic signal and demonstrate that amplification is often an effective means of improving one's ability to hear. Although there are a few exceptions, amplification can be used to improve hearing in virtually all forms of hearing impairment as well.

Electronic hearing aids enhance the signal strength by amplifying the acoustic signals that reach its microphone. Hearing aid design has evolved rapidly with advances in electronics, with instruments becoming smaller, more reliable, and more efficient. Today's hearing aids are small enough to fit completely within the ear canal, and some have advanced technological features that can significantly improve listening in noise. Perhaps the most amazing aspect of hearing aid design is that only a single disposable button-type battery of less than 1.5 V powers most units.[14] Average battery life ranges between 10 and 14 16-hour days.

Electronic hearing aids comprise three basic components: a microphone, an amplifier, and a receiver, which are housed in a plastic case designed to fit behind or in the ear. The *microphone* is located externally and is activated by miniscule fluctuations in air pressure caused by the sound source. These vibrations are converted into an electrical impulse and delivered to the *amplifier*. At this stage, the signal is amplified and filtered. The altered signal is delivered to the *receiver*, which converts the electronic impulse into an acoustic signal. The amplified acoustic signal is then delivered to the ear canal for reception of the signal by the wearer.[15]

Types of Hearing Aids

There are basically two ways in which a hearing aid may be classified. The first is by the style of the hearing aid, which usually refers to the size and placement of the aid. The second is by the technological features of the device.

Hearing Aid Styles The most commonly used hearing aid styles (although other types do exist) are the behind-the-ear (BTE), in-the-ear (ITE), in-the-canal (ITC), and completely-in-the-canal (CIC) hearing instruments (Figure 5–6).

Behind-the-ear hearing aids are aptly named because the body of the hearing aid lies on the posterosuperior aspect of the auricle. The receiver is coupled to the ear canal by a piece of acoustic tubing attached to a custom-made earmold. Behind-the-ear hearing aids are extremely flexible because of their design and large size. Any degree of hearing loss, ranging from mild to profound, and almost any configuration can be managed with a BTE aid. A defective unit can be replaced by removing the tubing/earmold assembly and attaching it to a new unit. Changes in the size of the auricle and the ear canal are inexpensively accommodated by making a new earmold. It is not necessary to modify the body of the hearing aid. For this reason, BTE units have been a popular choice for children. In addition, the earmold can be made of material varying in density from hard (lucite) to very soft (silicone). The choice of earmold material can significantly add to the comfort and flexibility of the instrument. A disadvantage of the BTE instrument, however, is the location of the microphone. The ideal location of a microphone would be deep in the ear canal using the natural resonance of the auricle and ear canal. The microphones of BTE instruments are located above the auricle and are oriented anteriorly. The loss of natural cues must be compensated for by the hearing aid. Currently, BTE hearing aids account for less than 20% of annual hearing aid sales in the United States, and the market share continues to decrease.[14,16]

FIGURE 5–6. Examples of major hearing aid styles. The four types of hearing aids are, in a clockwise direction beginning with the top right corner, behind-the-ear (BTE), in-the-ear (ITE), in-the-canal (ITC), completely-in-the-canal (CIC), and disposable ITC.

In-the-ear hearing aids are housed completely within a custom-made earmold designed to fit in the auricle and ear canal. The body of the hearing aid

completely fills the concha and contains most of the electronic components, the battery, and a volume control. The anterosuperior arm of the ITE hearing aid fits into the helix of the auricle inferior to the triangular fossa and functions primarily to keep the instrument in place. The microphone is sometimes located within this portion of the instrument. The medial portion fits partially in the ear canal and contains the receiver. In-the-ear hearing aids are completely self-contained. There is no tubing or earmold assembly. The hearing aid is essentially built into the earmold. Properly fitted ITE hearing aids are appropriate for mild to severe losses of hearing. The location of the microphone, which is close to the level of the ear canal, is an advantage of the ITE style. However, the size of the instrument within the auricle minimizes the use of its natural resonance. Despite these advantages and its cosmetic appeal, it does have a few disadvantages. First, when the instrument must be repaired or replaced, the patient is usually without a hearing aid for a number of days. A BTE loaner may be provided when coupled with a temporary earmold, but this is usually not an acceptable alternative. Additionally, ITE hearing aids may be difficult for some patients to insert and remove, especially for individuals with manual dexterity problems.

In-the-canal hearing aids fit primarily into the ear canal. Only the faceplate of the hearing aid is visible in the concha area. A properly fitted ITC hearing aid may accommodate up to a moderately severe hearing loss. The location of the microphone is at the opening of the ear canal, taking advantage of the acoustic properties of most of the auricle.[16] Also, these devices are inserted deeper than ITE hearing aids, which creates an increase in gain of about 5 dB. Although the size of the ITC instrument is an acoustic advantage, there are a few disadvantages. First, there is less structure holding the hearing aid in place, making it easier to become dislodged and lost. Second, their small size makes them more difficult to insert and remove, hindering use by those with manual dexterity limitations.

Completely-in-the-canal hearing aids are the smallest of the hearing aid styles and therefore the most cosmetically appealing and most popular. These hearing aids are inserted deeply into the ear canal by the patient and are essentially invisible to the casual observer. These instruments are designed to be placed past the second bend of the ear canal, with the medial end of the hearing aid within 5 mm of the tympanic membrane.[17] They have a nylon cord attached to its lateral surface to aid in retrieval of the instruments from the ear canal. Because of its size and microphone location, these devices have a number of advantages.[17,18] These advantages include a reduction in the occlusion effect, ease of use on the telephone, no problems with wind noise on the microphone, an increase in gain by as much as 15 dB, and an enhancement of the acoustic effects of the auricle and ear canal. Unfortunately, these devices also have a number of disadvantages. These disadvantages include problems getting a good acoustic seal, which may lead to feedback problems, increased repair problems owing to cerumen, difficulty inserting and removing the device from the ear canal, increased expense, reduction in the number of advanced features, and an inability to appropriately fit more severe hearing losses.

Hearing Aid Technology

In the past few years, hearing aid technology has grown by leaps and bounds. Hearing aids today have many advanced components and features. We will now review briefly some of the more important developments in hearing aid technology. Unfortunately, a detailed review of all of the available features is not appropriate here. The reader is referred to a text by Sandlin for a more in-depth review.[19]

Disposable and *instant fit* hearing aids are the newest development to emerge on the hearing aid market. These devices are receiving increased attention because of their ability to be fit immediately. The products are available in a wide range of sizes and technology, from BTE to CIC instruments.[20] An advantage of these devices is their significantly reduced price in comparison with custom-made products. Disposable hearing aids have an added benefit in that there is never a need to replace the battery since the entire hearing aid is replaced after 40 days. However, these devices may only be fit on individuals with milder degrees of hearing impairment, rendering those with severe and profound hearing losses ineligible for this technology.

Conventional hearing aids are the least technologically sophisticated of the custom-made hearing aids. These devices are analog hearing aids. An analog hearing aid receives the acoustic signal from the microphone, converts it into an electrical signal, amplifies and filters it according to the individual's

hearing loss, and reconverts it into an acoustic signal that is delivered to the ear canal.[19] In this type of technology, the audiologist selects a matrix for the hearing aid, which determines its overall gain, slope, and maximum output. Relatively few adjustments can be made directly by the hearing aid dispenser or audiologist. These minor changes may be made by screwdriver controls. Typically, these devices provide linear amplification, although some do provide some forms of compression. Linear amplification refers to the types of hearing aids that provide the same amount of gain regardless of the input signal. As the input signal increases in loudness, so will the resulting output of the hearing aid until the hearing aid's maximum output limit is reached. At this point, signal distortion occurs. Compression, on the other hand, helps eliminate the problem of distortion created by linear hearing aids. In this type of hearing aid, the amount of gain provided by the hearing aid depends on the intensity of the incoming signal. Signals with greater intensity receive less amplification than those with lower intensities. This reduction in gain helps decrease distortion as the signal becomes closer to the maximum output provided by the hearing aid. Typically, these instruments have a volume control that may be adjusted by the user.

Programmable hearing aids provide increased flexibility and options for the wearer. Just as in conventional hearing aids, these instruments have analog amplifiers. However, unlike the conventional hearing instruments, these devices can be modified in the audiologist's office via a computer or handheld programmer. This programming allows for increased flexibility in shaping the frequency response, output limitations, compression characteristics, and enhanced features provided by the hearing aid. Additionally, many of these devices offer multiple memories or programs. The use of these multiple programs allows the patient access to different settings that may be designed for various listening environments. These multiple programs may be accessed via a remote control or a switch on the hearing instrument.

Digital hearing aids are the most popular hearing aid technology available in today's market.[19,21] A digital hearing aid processes the acoustic signal differently than an analog instrument. In this arrangement, the acoustic signal is converted to a digital or binary code, which minimizes the possibility for distortion of the signal. The signal is then amplified and converted back to an acoustic signal that is delivered to the ear canal through the receiver. These devices offer a number of advantages, which include increased flexibility of shaping the frequency response of the instrument, feedback suppression capabilities, improved sound quality, decreased battery drain, and less internal circuit noise. As was noted in programmable hearing instruments, these devices may have multiple memories and may be adjusted via a computer or handheld programmer. The memories may also be accessed via a remote control or a switch on the device. Recently, one hearing aid company produced an instrument that changes the program automatically based on the noise levels in the environment.

The major complaint of individuals with sensorineural hearing loss is the inability to hear in background noise. Currently, *directional microphones* provide the individual with hearing impairment the best opportunity for understanding in noise. Simply put, this microphone arrangement allows the wearer to hear the sound originating from the front, which is where the sound source is usually located, and reduces sounds from the rear, which is usually where noise is located.[19] Recent studies have noted 5 to 8 dB of improvement when listening in noise in comparison with standard, omnidirectional microphones.[19,22] This improvement may result in improvement in speech recognition by as much as 60%. Currently, this microphone technology is available in conventional, programmable, and digital hearing aids. However, the performance of the directional microphone is better in the advanced devices. Additionally, this microphone technology is available in BTE instruments through half-shell ITE instruments.

Indications for Amplification

Hearing aids are indicated whenever it can be demonstrated that the patient's ability to communicate will be significantly improved through the use of amplification. A hearing aid is not recommended under the following conditions:

- effective medical treatment can be implemented to restore normal hearing
- hearing aid use would exacerbate the disease or interfere with treatment
- a hearing aid fails to improve the ability of the patient to communicate

A common myth is that amplification is of no benefit in the case of sensorineural hearing loss. Although there is no evidence correlating the use of a hearing aid with restoration or treatment of the impaired auditory system, hearing aids are routinely used to offset the effects of sensory hearing impairment. Sensory hearing loss accounts for 90% of all types of hearing loss. In excess of 95% of all hearing aids are purchased by patients with sensorineural hearing loss. Amplification is an effective means of improving the communicative abilities of individuals with sensory hearing impairment, as attested by hundreds of research articles published in the last 50 years.

Amplification is an extremely effective means of improving the hearing of patients with conductive hearing loss. A hearing aid is clearly not an acceptable alternative to effective medical treatment of a pathologic condition, but it may be used after the course of treatment to offset residual hearing impairment. Residual conductive hearing loss is commonly present following placement of an ossicular prosthesis, for example. In this case, a hearing aid is often an effective means for further improving hearing sensitivity. In contrast, a hearing aid may be of little benefit for patients with retrocochlear (neural or central) auditory disorders. In some cases, amplification may actually exacerbate the effects of the disorder. The use of amplification must be carefully evaluated in all cases of central impairment. However, there are alternatives for these patients. Perhaps the most common approach is the recommendation of an assistive listening device, like an FM system, for improvement of speech understanding by significantly enhancing the speech signal in relation to background noise.

Benefits of Amplification

It is readily apparent that the use of amplification significantly improves the communicative ability of an individual with hearing impairment. However, recent research has revealed additional benefits in psychosocial and functional health measures.[23] These studies have shown that individuals using amplification reported less depressive feelings, richer social relationships, and less anxiety and paranoia. Additionally, and perhaps as a result of improved communicative psychosocial functioning, these individuals noted improvements in their physical health status. Hence, the use of amplification has the potential to improve significantly the quality of life of an individual with hearing impairment.

Monaural versus Binaural Amplification

A great deal of research has been devoted to the following question: if hearing loss is bilateral, are two hearing aids better than one? The intuitive answer is, of course, that two hearing aids would best offset the effects of a hearing loss in both ears. The question persists, however, because many patients choose monaural fittings. This decision is usually based on cosmetic or financial reasons, although some patients claim to hear just as well with one hearing aid as with two, whereas others appear to hear better with a single instrument.

The benefits of binaural amplification have been well documented in the audiologic literature.[9,16] The most commonly cited benefits are as follows:

- improved word identification, particularly in adverse listening conditions
- improved localization of the sound source
- a sense of "balanced hearing"
- the need for less gain
- elimination of the head shadow effect
- increased perception of high-frequency consonants

In addition to these advantages, a number of recent studies have appeared that document the effects of auditory deprivation in unaided ears. The research indicates that word identification scores in the unaided ear decrease over time relative to the scores in the aided ear in a monaural fitting. In contrast, this decrement is not observed in either ear in a binaural fitting. Further, limited recovery in word identification is observed following the subsequent provision of amplification to the deprived ear.

With regard to this evidence, binaural amplification should be recommended unless specifically contraindicated. Valid contraindications to binaural amplification are as follows:

- unilateral hearing loss
- medical complication in one ear
- one ear cannot be aided owing to insufficient residual hearing
- binaural amplification results in diminished word identification

Hearing Aid Selection

The selection of an appropriate hearing aid requires a combination of factors. First, it is essential that the practitioner thoroughly assess the patient's motivation, concerns, communicative goals, and listening needs before selecting a hearing instrument.[24] Issues such as cosmetics, dexterity, and financial constraints may significantly limit the style and technological options. Additionally, one's communicative goals or typical listening environment may dictate the need for a directional microphone or other advanced features. To aid in this endeavor, the use of self-assessment inventories, which will be discussed in the following section, may be of benefit.

To aid in the selection of a hearing aid, multiple researchers have developed prescriptive formulae that are based on audiometric thresholds or suprathreshold information.[25] The goal of these formulae is to provide the listener with the optimum aided speech intelligibility possible. However, these formulae are not expected to be a panacea but are merely intended to provide the dispenser with a valid approximation, a logical starting point. From here, minimal modifications should be required. Currently, there are a number of prescriptive formulae available, but no standard has been adopted.

Assessment of Hearing Aid Outcomes

Any time treatment is rendered, some measure of efficacy of the service should be performed. In the age of managed care, it is exceedingly important to document the success (or failure) of rehabilitation services. Currently, there are a number of means to assess the efficacy of amplification, which include electroacoustic analysis, functional gain measures, real-ear measures, and self-assessment inventories. Each of these procedures will be discussed briefly in the following sections.

Electroacoustic Analysis On arrival of the hearing instruments from the manufacturer and before dispensing the devices to the patient, it is essential that the devices be evaluated to determine if they are functioning appropriately.[3] According to the American Speech-Language Hearing Association, these devices should be assessed via an electroacoustic analysis according to the ANSI S3.22 standard and a listening check.[26] In this first test, the hearing aid is attached to a 2 cm^3 coupler and evaluated in a test box that analyzes the sound pressure present within this cavity. This analysis provides information regarding the gain characteristics of the hearing aid at each frequency, frequency response, maximum output, battery drain, and distortion of the hearing aid. These results can be compared to the specifications of the hearing instrument provided by the manufacturer. If discrepancies occur, the hearing instruments should be returned to the manufacturer for repair or replacement.

Additionally, a listening check of the instruments should be performed. This check will provide information regarding the sound quality, circuit noise, and any intermittent function of the devices. Once again, if problems are noted, the devices should be returned to the manufacturer.

Functional Gain Measures Functional gain measures are designed to assess the realistic benefit patients derive from their hearing instrument by determining behaviorally the amount the hearing aid improves the patient's thresholds of audibility.[9,25] This procedure is conducted in the sound field, using a speech signal and/or warble tones, to determine the difference in the patient's aided and unaided hearing thresholds. Although this test procedure is designed to assess the patient's "real-world" benefit, it is plagued by a number of limitations. These limitations include poor test–retest reliability, limited frequency response information, lack of maximum output information, and a dependence on the patient's behavioral responses.

Real-Ear Measures Owing to the number of limitations presented by functional gain measures, real-ear measures are currently the most accepted means of verifying hearing aid performance.[3,25,27,28] Real-ear measurement systems use a specially designed probe microphone to measure the sound pressure in the ear canal at the eardrum. This probe microphone is inserted along the side of the patient's ear canal into a position located within 6 to 8 mm of the tympanic membrane. A broadband noise, speech composite noise, an International Collegium of Rehabilitative Audiology (ICRA) noise, or tonal series is presented via a loudspeaker that is located approximately 1 meter away from the patient. Measurements are made and graphically displayed with and without the hearing aid in place. Aided test results are usually compared to and adjusted to match the prescribed

target. At a minimum, this testing should be conducted at an input level of 60 to 70 dB SPL, which is typical of average conversational speech. Additionally, testing of the saturation level of the hearing aid should be conducted to ensure that the maximum output of the hearing aid is set below the patient's threshold of uncomfortable loudness. For nonlinear hearing aids, testing at a high input level (80 to 85 dB SPL) and a low input level (50 dB SPL) should also be included. At each of these input levels, patient feedback regarding the volume of the input signal should be solicited. For a comprehensive discussion regarding real-ear technology and a variety of clinical procedures based on this technique, the reader is referred to a text by Mueller and colleagues[25] and a text by Valente.[27]

Self-Assessment Inventories Perhaps the most compelling evidence of the success of a hearing aid fitting comes directly from the patient. After a brief period of hearing aid use, most patients are quite capable of determining whether the prescribed amplification has improved their ability to hear. This is understandable considering that the vast majority of individuals who purchase hearing aids cope with the hearing impairment before deciding to pursue amplification. After very little experience wearing the new hearing aids, most patients are able to precisely describe the listening situations in which their hearing aids are effective or ineffective. To quantify this valuable patient report, a number of self-assessment inventories have been developed for use by audiologists and hearing aid dispensers.[3] These inventories are widely used to evaluate the initial fitting and the effectiveness of subsequent modifications.

Patient Accommodation to Amplification An individual with hearing impairment requires a period of adjustment to become accustomed to wearing hearing aids. The average patient has developed a hearing loss over a period of years before deciding to pursue amplification. During this time, considerable adaptation has occurred in the central auditory system.[29] The sudden introduction to amplified sound initiates compensatory neurophysiologic changes that may take 5 to 6 weeks to develop. In this time period, adjustments to the hearing instruments are often needed to assist the patient in the process of accommodation. Many hearing aid programs encourage patients to use a wearing schedule that gradually extends the length of time that the hearing aids are worn each day. Some programs also restrict hearing aid use to quiet listening environments during the initial period of accommodation with systematic exposure to more demanding conditions as accommodation progresses.

A common problem arises when a patient is initially unhappy with the performance of the hearing aid. According to federal law, a customer may return a hearing aid to the dispenser within 30 days for a refund. Unfortunately, 30 days is often an insufficient period of time to allow for complete accommodation and/or modification of the instruments. Therefore, prospective hearing aid patients should receive proper counseling before, during, and after the initial fitting to avoid making a premature decision.

Pediatric Issues in Amplification Children present a unique set of issues in the selection and fitting of amplification. These issues primarily exist because of the small size of children's ears in comparison with adult ears, the noncompliance of some children, the increased demands in their communication needs, and a lack of complete audiometric data on which to base these decisions. To address these matters, audiologists have developed a set of standards for selecting and fitting hearing aids for young children. As mentioned previously, BTE instruments are the most popular hearing aid style for children. This style allows for maximum flexibility.[16] First, this design allows for an inexpensive means for accommodating changes in the size of the auricle and ear canal as the child grows. While these changes are being made, the child is still able to use the hearing instrument. Second, these devices are more resistant to feedback problems owing to the increased distance between the microphone and the receiver. Furthermore, using an earmold with superthick tubing may also decrease the likelihood of feedback. Third, this style offers options that aid in the retention of the hearing aid in the ear canal, such as wire retention attachments, kiddie tone hooks, and Huggie-Aids. Finally, a BTE hearing instrument offers many additional features that may not be available on smaller styles.

In addition to the style of hearing aid, a number of other hearing aid options should be considered.[16] Every hearing aid dispensed to a child should have direct audio input, telecoil, and microphone/telecoil options available. These features will provide maximum adaptability with assistive listening devices, such

as FM systems. Additionally, tamper-resistant volume controls and battery doors should be considered. For maximum flexibility, digital hearing aids with feedback suppression, programmable features, and multiple memories that offer both omnidirectional and directional microphone technology are added assets. Finally, owing to the likelihood of the hearing instruments becoming lost or damaged in young hands, a loss and damage warranty for the hearing instruments is highly encouraged.

Noting the difficulties in fitting and the communication needs of young children, a prescriptive formula called the Desired Sensation Level (DSL) was developed.[3,30] This formula calculates a prescriptive target for average conversational speech and maximum output of the hearing instrument from a variety of sources, whether it is pure-tone thresholds obtained under telephonic dynamic headphones (standard earphones for audiometric testing) or ABR thresholds. Additionally, if hearing aid verification and adjustments cannot be made using real-ear measures, these adjustments may be made using a 2 cm^3 coupler in the hearing aid test box by using real-ear to coupler differences (RECDs). Real-ear to coupler difference is the dB difference between the level of sound in the ear canal versus the level that is measured in the 2 cm^3 coupler. This measurement is obtained by taking an unaided measurement in the child's ear canal. If this measurement cannot be obtained, the formula provides average RECDs for children of various ages. Hence, with this prescriptive formula, appropriate amplification can be provided with little dependence on the cooperation of the child.

ADVISING THE PARENTS OF YOUNG CHILDREN WITH HEARING IMPAIRMENT

Although the otolaryngologist is principally concerned with the medical or surgical management of aural disease and disorders, it is important that one has an understanding and an appreciation for the various educational options and communication modalities available to the families of children with hearing impairments.[31,32] Since otolaryngologists are one of the professionals responsible for the identification and diagnosis of hearing impairments, they are often the first, if not only, resource that the parent has for information regarding these difficult choices. The debate over the best communication mode and training has raged since the fourteenth century. Unfortunately, there is no one communication modality that is right for every child.[9,15,31,32] This decision must be made on an individual basis, and consideration should be given to issues such as the characteristics of the child (ie, age of diagnosis and accompanying learning disabilities), available community resources, and the commitment of the family to the child and the chosen communication modality. A basic review of the various communication options will be covered in the following paragraphs. Major methods are summarized in Table 5–3. It is important to keep in mind that variations on these methodologies also exist. (See also Chapter 23, "Cochlear Implants.")

Oral Approaches Two major forms of oral English in practice today are the auditory-verbal approach and the auditory-oral approach.[31,32] These two approaches are based on the idea that all children with hearing impairment can realistically attain receptive and expressive language competence regardless of the degree of hearing loss. The auditory-verbal philosophy places an emphasis on the child's residual hearing through the use of amplification with the goal of developing listening skills through natural communication. In this approach, the child is placed in mainstreamed education beginning in preschool. The auditory-oral approach, on the other hand, emphasizes the development of amplified residual hearing and spoken language, using speechreading cues as a supplement to the auditory signal. In this approach, the child is usually enrolled in an oral program until he or she can be appropriately mainstreamed.

Both of these approaches have their advantages and disadvantages. The biggest benefit of these programs is that they provide the child with the greatest access to the hearing world. Geers and Moog reported that children who attended oral education programs attained better speech production, speech perception, and overall spoken language skills than those students who attended total communication programs.[33] Additionally, evidence suggests that these students attain literacy scores twice the national average for children with hearing impairments. Unfortunately, the success of these programs is dependent on early identification of the hearing loss and amplification use, as well as consistent, quality aural habilitation training. Another major drawback to these

TABLE 5–3. Summary of Strengths and Limitations of Various Approaches for Auditory Habilitation of Children with Hearing Impairment and Deafness

Educational Option	*Benefits*	*Limitations*
Auditory-verbal	Greatest access to hearing world Better speech production, speech perception, and spoken language Higher literacy rates Early mainstream education	Dependent on early identification and intervention Isolation from the Deaf community
Auditory-oral	Greatest access to hearing world Better speech production, speech perception, and spoken language Higher literacy rates	Dependent on early identification and intervention Isolation from the Deaf community
Cued speech	Reading and writing skills on par with hearing peers Access to hearing world	Few educational programs available Few transliterators Isolation from the Deaf community
Total communication	Allows the child access to all means of communication	Few programs put this into practice May overstimulate the child
Bilingual-bicultural	Designed to teach language and culture of the Deaf and hearing communities Promotes increased literacy and academic skills	Little information available regarding its success
Signing Exact English	Uses English syntax and grammatical features	Denial of Deaf culture
American Sign Language	Natural mode of communication for the Deaf child Allows membership in the Deaf community and may improve self-confidence	Syntax not conducive to the development of English language

approaches is isolation from the Deaf community owing to a lack of training in sign language.

Manual Approaches In stark contrast to the aforementioned oral approaches are the manual approaches. American Sign Language (ASL) is the common language of the Deaf community in the United States. It is a vast lexicon of hand shapes and motions, or signs, and has its own syntax and grammar.[9,31,32] Additionally, this mode of communication places a heavy emphasis on the facial expressions and body language of the signer. It is a unique language, having no simple translation to the oral English language. Proponents of ASL believe that it is an easier, more natural mode of communication for the child with hearing loss. Additionally, this system allows for membership into the Deaf community, which has the capability of improving the child's self-esteem and confidence. A major limitation of ASL is that its syntax is not conducive to development of the English language, which may hinder spoken language and literacy skill acquisition.

In an attempt to alleviate the difficulties in learning English language through manual communication, educators developed English-based sign systems.[9,34] The most popular form of the English-based sign systems is Signing Exact English (SEE2). Signing Exact English uses much of the same vocabulary as ASL but adds grammatical features and follows English syntax. This system is primarily geared toward preschool and lower elementary schoolchildren to provide them with access to English during the language-learning years. Opponents of this system

believe that it is a denial of Deaf culture by inflicting the standards of the hearing world on the Deaf child.

Bilingual-Bicultural Approach Recently, momentum has been growing for the development of bilingual-bicultural education for children who are Deaf.[35] This approach is designed to educate the child on the mores, customs, and practices, as well as the languages, of the hearing world and the Deaf culture. In these programs, children are taught ASL as their first language, which provides a foundation for which English is later taught. This early access to language is designed to promote increased literacy and academic skills. However, since these programs are relatively new, little information is available regarding its success.

Combination Approaches A combination of the oral and manual approaches is referred to as a combination approach. The most popular combination approach is total communication. Total communication involves the use of one or more modes of communication at any given time in the child's educational program, whether it be manual, oral, auditory only, or written.[9,31,32,36] The design of this approach is to use whatever communication modality is most appropriate for the child at that stage of development or for that given situation, allowing the child access to all means of communication. Despite its promise, this approach has a number of limitations. First, few programs actually put this philosophy in practice owing to the biases of the instructor and the difficulty of combining all of these methods at the same time. Additionally, the use of all of these modalities may overstimulate the child and be a detriment to the development of communication.

A less popular combination approach is cued speech. Cued speech is a visual communication system that employs eight hand shapes placed at four different locations near the mouth.[9,37] These hand shapes are designed to supplement spoken language and speechreading cues since many sounds may be indistinguishable on the lips. The purpose of this approach is to allow the child to see and hear the English language as it is spoken. Wandel found that children who used this system developed reading and writing skills on par with their hearing peers.[38] The limitations of this approach are that few programs provide this type of education and few transliterators (individuals who cue what an instructor says) are available. Additionally, these individuals are unable to communicate with the Deaf community unless ASL is also learned.

A variety of educational methods are available to the individual with hearing impairment. For the vast majority of families, this important educational decision is often made during a period of emotional turmoil. These parents view the identification of a hearing loss as a loss of their dreams of a normal child and may grieve accordingly. Unfortunately, a lack of understanding of the hearing loss, its implications, and remedial interventions can only exacerbate this emotional reaction. Although most parents would have liked to receive this information, they report that few professionals offer the supportive counseling and information they need.[39]

The concept of critical period of development during which the central nervous system exhibits maximal plasticity is central to any discussion about the education of the individual with hearing impairment. Should one maximize language development or the use of residual hearing within a given time period? With the recent implementation of universal newborn hearing screening, it is logical to ask if early identification and management causes a significant improvement in the acquisition of communication skills. Yoshinago-Itano et al provided evidence that children with hearing loss who are identified prior to 6 months of age and receive immediate intervention have greater language development, better receptive and expressive vocabularies, and higher social-emotional aspects of development than infants who are identified later, regardless of the degree of hearing loss or mode of communication.[10,40] Additionally, no significant differences in language development were noted in terms of time of identification for those children identified after 6 months. This finding suggests that language stimulation within the first 6 months of life is critical for neural development.

In summary, each of the currently available educational methods has its proponents and opponents. Whenever appropriate, and with the support of parents and other caregivers, otolaryngologists should encourage and facilitate maximal use of residual hearing and language development in an attempt to help these children reach their full communicative potential. It is essential that the otolaryngologist provide the parent with supportive, unbiased information regarding the benefits and limitations of the aforementioned modalities. No

matter what the family's educational decision, early intervention services should be highly encouraged.

GLOSSARY

ABLB: Alternate binaural loudness balance. A traditional diagnostic auditory procedure for detecting "loudness recruitment" used in differentiating cochlear versus retrocochlear auditory dysfunction in unilateral hearing loss. The task is to balance the sensation of loudness for the better versus the poorer hearing ear. Loudness recruitment is a cochlear auditory sign.

ABR (BAER): Auditory brainstem response. Electrical activity, evoked (stimulated) by brief-duration sounds, arises from the eighth cranial nerve and auditory portions of the brainstem. The ABR is usually recorded from the surface of the scalp and external ear with disk-type electrodes and processed with a fast signal-averaging computer. Auditory brainstem response wave components are labeled with Roman numerals (eg, I, III, V) and described by the latency after the stimulus (in ms) and the amplitude from one peak to the following trough (in microvolts).

AC: Air conduction. Audiometric signals presented via earphones to the ear canal.

air–bone gap: The difference in pure-tone thresholds for air- versus bone-conducted signals. With calibrated audiometers, the normal ear and the sensorineurally impaired ear show no air–bone gap, whereas conductive hearing losses are characterized by an air–bone gap.

ASL: American Sign Language. A manual mode of communication that is commonly used by the Deaf community.

audiologist: A hearing care professional who is educated and trained clinically to measure auditory system function and to manage nonmedically persons with auditory and communicative impairments. Minimal educational requirements for audiologists are a master's degree and certification and/or state licensure.

BC: Bone conduction. Audiometric signals presented via an oscillator to the skull (eg, mastoid bone or forehead).

BCL: Békésy Comfortable Level. A Békésy audiometry procedure conducted at a comfortable loudness level versus a threshold level.

Békésy audiometry: An audiometric procedure performed with a Békésy audiometer for differentiating cochlear versus retrocochlear auditory dysfunction. Békésy audiometry is based on the comparison of responses to pulsed versus continuous tones varied across a wide frequency range. Four patterns of Békésy responses were classified by Jerger.

BOA: Behavioral observation audiometry. A pediatric behavioral audiometry procedure in which motor responses to sounds (eg, eye opening, head turning) are detected by a trained observer.

BTE: Behind-the-ear hearing aid design.

CIC: Completely-in-the-canal hearing aid design.

configuration: Term used to describe the shape or pattern of an audiogram, that is, how hearing loss varies as a function of the audiometric test frequency. There are three main configurations: rising (low-frequency loss), sloping (high-frequency loss), and flat.

CROS: Contralateral routing of signals. A hearing aid configuration in which a microphone is located on the poorer ear and the sounds are transduced and delivered electrically to the normal or mildly impaired ear.

crossover: Sound stimulus presented to one ear (the test ear) travels around the head (by air conduction) or across the head (by bone conduction) to stimulate the other (nontest) ear. See interaural attenuation.

dB HL: A decibel scale referenced to accepted standards for normal hearing (0 dB is average normal hearing for each audiometric test frequency).

dB nHL: A decibel scale used in auditory brainstem response measurement referenced to average behavioral threshold for the click stimulus of a small group of normal-hearing subjects.

dB SL: Sound level or intensity described in reference to an individual patient's behavioral threshold for an audiometric frequency or some other measure of hearing threshold (eg, the speech reception threshold).

dB SPL: A decibel scale referenced to a physical standard for intensity (eg, 0.0002 dynes/cm^2).

dichotic: Simultaneous presentation of a different sound to each ear.

DPOAE: Distortion-product otoacoustic emission.

DPgram (DPOAEgram): A graph of distortion-product otoacoustic emission amplitude in the ear canal (in dB SPL) as a function of the frequencies of the stimulus tones (in Hz).

ECochG: Electrocochleography. Evoked responses originating from the cochlea (the summating potential or SP and the cochlear microphonic or CM) and the eighth cranial nerve (the action potential or AP).

ENG: Electronystagmography. A test of vestibular function in which nystagmus is recorded with electrodes placed near the eyes during stimulation of the vestibular system.
ENoG: Electroneurography. Myogenic activity recorded from the facial muscles, usually in the nasolabial fold, in response to electrical stimulation of the facial nerve as it exits the stylomastoid foramen.
FM system: A device in which the acoustic information received by a remote microphone is transmitted via FM radio waves to a receiver used by the listener.
ITC: In-the-canal hearing aid design.
ITE: In-the-ear hearing aid design.
interaural attenuation: Insulation to the crossover of sound (acoustic or mechanical energy) from one ear to the other provided by the head. Interaural attenuation varies depending on whether the signal is presented by air conduction (interaural attenuation > 40 dB) or bone conduction (interaural attenuation < 10 dB). Insert earphones offer maximum interaural attenuation.
malingering: Feigning or exaggerating a hearing impairment. Also referred to as functional or nonorganic hearing loss.
masking (masker): A controlled background noise presented usually to the nontest ear in an audiometric procedure to prevent a response from the nontest ear (owing to crossover when interaural attenuation is exceeded).
masking dilemma: A problem encountered in audiometric assessment of patients with severe conductive hearing loss. The level of masking noise necessary to overcome the conductive component and adequately mask the nontest ear exceeds interaural attenuation levels. The masking noise may then cross over to the test ear and mask the signal (eg, pure tone or speech). In the masking dilemma, enough masking is too much masking. The masking dilemma can be reduced by the use of insert earphones. The sensory acuity level (SAL) test is also helpful for measuring ear-specific bone-conduction hearing thresholds in patients presenting the masking dilemma.
MCL: Most comfortable level. The intensity level of a sound that is perceived as comfortable.
MLD: Masking level difference. An audiometric procedure that compares a threshold response with masking noise presented in versus out of phase with a pure tone or speech signal. Release from masking is a normal phenomenon reflecting auditory brainstem integrity.
OAE: Otoacoustic emission. Sound generated by energy produced by the outer hair cells in the cochlea and detected with a microphone placed within the external ear canal.
PB: Phonetically balanced. Word lists developed in the late 1940s that contain all of the phonetic elements of general American English speech that occur with the approximate frequency of occurrence in conversational speech.
PI: Performance intensity. A measure of speech recognition or understanding as a function of the intensity level of the speech signal. See rollover.
PTA: Pure-tone average. The arithmetic average of hearing threshold levels for 500, 1,000, and 2,000 Hz or the speech frequency region of the audiogram. The PTA should agree within ± 7 dB of the speech reception threshold (SRT).
RECD: Real-ear to coupler difference. This is the decibel difference between the level of sound in the ear canal versus the level that is measured in the 2 cm^3 coupler.
rollover: A decrease in speech recognition performance (in percent correct) at high signal intensity levels versus lower levels. Rollover is an audiometric sign of retrocochlear auditory dysfunction.
SAL: Sensory acuity level. An audiometric procedure developed by James Jerger (1970) for assessing bone-conduction hearing in patients with serious conductive hearing loss. Air-conduction thresholds are determined without masking and then with masking presented by bone conduction to the forehead. The size of the masked shift in hearing thresholds corresponds to the degree of conductive hearing loss component.
SAT (SDT): Speech awareness threshold (speech detection threshold). The lowest intensity level at which a person can detect the presence of a speech signal. The SAT approximates the best hearing level in the 250 to 8,000 Hz audiometric frequency region.
SEE2: Signing Exact English. A manual form of communication that uses most of the same vocabulary as American Sign Language but adds grammatical features and follows English syntax.
SISI: Short increment intensity index. A clinical procedure developed by Jerger for assessing the ability to detect a 1 dB increase in intensity. High SISI score is consistent with cochlear auditory dysfunction.
SNR: Signal to noise. The signal-to-noise ratio is the difference between the intensity level of a sound or

electrical event and background acoustic or electrophysiologic energy.

SRT: Speech reception level. The lowest intensity level at which a person can accurately identify a speech signal (eg, two-syllable spondee words). See PTA.

SSI: Synthetic sentence identification. A measure of central auditory function that involves identification of syntactically incomplete sentences (a closed set of 10 sentences) presented simultaneously with a competing message (an ongoing story about Davy Crockett).

SSPL: Saturation sound pressure level. A measure of the maximum power output (MPO) of the hearing aid.

SSW: Staggered spondaic word test. A measure of central auditory function developed by Katz that uses spondee words presented dichotically.

Telecoil: An option on a hearing aid that enables it to receive the electromagnetic signals directly from the telephone. This option may be used to reduce the presence of feedback while the wearer is on the telephone.

TEOAEs: Transient evoked otoacoustic emissions. Otoacoustics emissions elicited by brief (click or tone burst) stimuli.

tone decay test: A clinical measure of auditory adaption in which a tone is presented continuously to a hearing-impaired ear until it becomes inaudible. There are numerous versions of tone decay tests. Excessive tone decay is a sign of retrocochlear auditory dysfunction.

TROCA: Tangible reinforcement operant conditioning audiometry. A pediatric behavioral audiometry technique that reinforces a response to auditory signals with food. TROCA is used mainly with mentally retarded or developmentally delayed children.

UCL/LDL: Uncomfortable level or loudness discomfort level. The intensity level of a sound that is perceived as too loud.

VRA: Visual reinforcement audiometry. A pediatric behavioral audiometry procedure that reinforces localization responses to acoustic signals with a visual event (eg, an animal playing).

CHAPTER 6

Evaluation of the Vestibular (Balance) System

Neil T. Shepard, PhD, David Solomon, MD, PhD, Michael Ruckenstein, MD, Jeffery Staab, MD

In considering the evaluation of the patient with complaints of vertigo, light-headedness, imbalance, or combinations of these descriptors, one must look beyond just the peripheral and central parts of the vestibular system with its oculomotor connections. The various pathways involved in postural control, only part of which have direct or indirect vestibular input, should be kept in mind during an evaluation. Additionally, significant variations in symptoms and test findings can be generated by migraine disorders[1,2] and/or anxiety disorders,[3–5] yet these are diagnosed primarily by history, requiring a specific line of questioning. These issues, as well as the traditional investigation avenues, will be integrated to present an overall view of the evaluation of the "dizzy" patient. Although the focus of this chapter is the laboratory investigations, it is important to be reminded that the principles and techniques behind the laboratory investigations can be applied in detailed direct office examinations of these patients.[6]

The evaluation of the dizzy patient should be guided by what information is needed to make initial and subsequent management decisions. When various tests are reviewed and correlated with high-level activities of daily living, virtually no significant relationships exist for the chronic dizzy patient. Tests considered extent- and site-of-lesion studies, electronystagmography (ENG),[7] rotational chair,[8] and specific protocols in postural control assessment[9] give results that are unable to be used to predict symptom type, magnitude, or the level of disability of an individual patient. Conversely, patient complaints cannot be used to predict the outcomes of these tests. In a limited manner, more functionally oriented evaluation tools, computerized dynamic posturography (CDP)[10] and dynamic visual acuity testing,[11] provide for some correlation among results, patient symptoms, and functional limitations. Add to the testing specific or general health inventories such as the Dizziness Handicap Inventory[12] and predictive assessment of disability is improved but remains significantly limited. It is hypothesized that the reason for this dichotomy in test results versus functional disability and symptom complaints is the inability of the tests to characterize adequately the status of the central vestibular compensation process.[13–15] It is the exception, not the rule, that vestibular and balance laboratory tests return results that would drive management of the dizzy patient. It would be extremely rare that these studies return a diagnosis. Therefore, the routine use of these tools to determine how to proceed with the management of a dizzy patient is a false line of reasoning and not productive in the majority of the patients. What, then, is the role of the laboratory studies of ENG, rotational chair, and CDP? It is the determination of the extent and site of lesion within the peripheral and central parts of the vestibular system and the functional limitations in static and dynamic postural control (this may relate directly to gait abnormalities). The use of this information is in the confirmation of the suspected site of lesion and diagnosis derived from the patient history and direct physical examination, including aspects of the direct office vestibular evaluation. This does not imply a prioritized order to the testing versus the office visit as with chronic dizzy patients it can be very useful to triage them to at least core laboratory evaluations (to be discussed below) prior to the office visit.

To summarize the above discussion, the following are required elements to management decisions for the chronic dizzy patient: detailed neurotologic history, office vestibular and physical examination, and formal audiometric testing given the inescapable anatomic relationship between the peripheral parts of the auditory and vestibular

systems. The following are considered important; however, they are less likely to drive directly the management in the typical case: laboratory vestibular and balance function studies, neuroradiographic evaluations, and serologic tests. It is important to realize that there will be patients for whom unexpected findings on any one of these latter studies will either alter the complete course of the management or add dimensions to the management not originally considered. But for the majority of patients, the vestibular and balance tests will be confirmatory in nature. Consider the following contrasting examples to illustrate this discussion:

- *Case 1* — Testing is confirmatory. A man, 35 years of age, was seen for complaints of sudden onset, 6 months previously, of vertigo, nausea, and vomiting in a crisis event with continuous symptoms lasting 3 days, steadily showing slow improvement and no accompanying auditory symptoms. The continuous vertigo resolved into head movement–provoked spells of light-headedness with imbalance and occasional vertigo lasting seconds to a minute after a movement. All planes of motion would provoke symptoms. Symptoms had continued to improve but still occurred on an infrequent daily basis. He presented with no neurologic focal complaints, and past medical history was noncontributory. Audiometric evaluation was completely normal bilaterally, as was his contrast magnetic resonance imaging (MRI) study of the head. His detailed vestibular examination both with and without visual fixation was remarkable for a positive head thrust test to the left, right-beating post–head shake nystagmus, and spontaneous right-beating nystagmus with visual fixation removed. The full neurologic and oculomotor components of the examination together with the Hallpike maneuver were normal. The history with the examination was strongly suggestive of uncompensated left peripheral vestibular hypofunction secondary to vestibular neuritis. Laboratory vestibular function testing revealed spontaneous right-beating nystagmus with visual fixation removed, a 76% left reduced vestibular response with normal oculomotor testing, and postural control assessment. In this case, the test was, as is typical in most cases, confirmatory of the clinical suspicions from the history and direct examination. Management decisions made at the time of the office visit, to initiate treatment with vestibular and balance rehabilitation therapy (VBRT) and to discontinue vestibular suppressive medication, were not in any manner altered with the obtaining of the laboratory findings. The vestibular function and balance tests were well justified given the length of symptoms and the fact that the testing has better sensitivity for some oculomotor findings than the direct examination, specifically saccade velocity testing and quantification of smooth pursuit. Although it was not needed in this case, sensitivity to mild peripheral vestibular function asymmetry is also better with the laboratory testing. In this case, the magnitude of the peripheral asymmetry made it detectable by both the direct examination and the caloric irrigation studies.
- *Case 2* — Testing drives management. A 31-year-old man presented with the onset of head motion–provoked vertigo with more or less constant imbalance with standing and walking. He denied any vestibular crisis event or auditory complaints. His symptoms were more concentrated in sagittal plane movement and when rolling left or right from a supine position. These symptoms had been ongoing for several years with intervals when the vertigo was resolved and the imbalance was reduced but not absent. He reported an MRI from several years prior to this evaluation that was normal, with a cervical MRI positive for mild disk abnormalities. Audiologic examination was normal. Other than the development of mild paresthesia of the right hand and arm over the last year, he had no other neurologic complaints, and his past medical history was noncontributory. His direct office examination was remarkable for anterior semicircular canal benign paroxysmal positional vertigo (BPPV). The remainder of the examination was normal. He was treated in the office with a canalith repositioning procedure and referred on for a formal VBRT program. Secondary to the length of time of the symptoms and the complaints of persistent imbalance (although this is a common report with BPPV), vestibular and balance function testing was requested. The laboratory studies showed anterior canal BPPV with no other indications of peripheral vestibular system involvement. Pursuit tracking tests were normal, but saccade testing (these will be discussed below) was positive for mild right internuclear ophthal-

moplegia. Postural control abnormalities were collectively consistent with those seen in demyelinating disorders. Secondary to these findings and his report on a return visit of paresthesia starting in the left foot, a new MRI was obtained that showed multiple hyperintense spots throughout the brainstem region. He was referred to neurology and is being followed with a diagnosis of probable multiple sclerosis with BPPV. Unlike case 1, this case was driven strongly by the results of the vestibular and balance function tests. The test results were able to reveal abnormalities too subtle to be detected in a direct examination. This is clearly the exception to the impact that the testing has on a more routine basis in the decisions regarding management of the dizzy patient.

HISTORY

Before consideration of the actual laboratory tests, some discussion of the neurotologic history is needed. Given the various tools for assessment, the history is the single most important factor in determining the course of management and therefore requires discussion.[14,16–22] The differentiation among the various peripheral vestibular disorders is particularly dependent on historical information and the conclusions that the physician draws from the interview. Most vestibular disorders cannot be distinguished from one another simply by vestibular testing or other diagnostic interventions. Failure to discriminate properly among these disorders on historical grounds may be the source of considerable ongoing distress for the patient and may lead to improper management by the physician. Since subsequent treatment decisions will be based on the clinical diagnosis, it is particularly appropriate to spend additional time during the history to clarify important features. In addition, balance function study results are best interpreted in light of a proper clinical history. The main reason that the patient is seeking medical attention for his or her balance disturbance should be identified. Although little specific diagnostic information may be gained, it is often helpful to hear an account of the patient's perception of his or her illness prior to pursuing more specific questions. One can often gain a sense of the degree of functional disability that the vestibular symptoms have produced. The psychosocial impact of the illness may also become clear in the patient's initial comments. Sometimes patients will volunteer that their symptoms are trivial or have resolved completely, but they simply want to make sure that they have not suffered a stroke or developed a brain tumor. If the patient is not permitted to share this information freely, important aspects of the individual's care may be overlooked.

Once the patient has shared the main concerns raised by his or her condition, the first specific questions should be phrased to gain information regarding the initial onset of symptoms. The characteristics and intensity of the balance disturbance at that time provide useful insight for the differential diagnosis. If the patient can recount specifics surrounding the symptom onset such as date and time of day, along with the activity interrupted by intense vertigo, the probability is high that the patient has suffered a significant peripheral labyrinthine insult. Surprisingly, if the professional does not specifically inquire, patients who are preoccupied with recent symptoms and disability may neglect to report a very profound vestibular crisis that occurred initially. If the onset was more insidious and the patient is unable to provide any account of an initial event, an acute peripheral disorder is less likely. Other important issues to discuss at this stage of the interview include the association of physical trauma, barotrauma, or an intercurrent illness prior to the onset of vertigo. Patients should also be asked about previous remote episodes of vertigo.

It is very important to question the patient regarding the association of a hearing loss or other auditory symptoms with the onset of vertigo. A complete audiometric assessment should be performed early in the evaluation. The presence of an associated sensorineural hearing loss, whether stable, progressive, or fluctuating, is the single strongest incriminating factor in identifying a pathologic labyrinth.[23] The presence of other otologic symptoms such as aural fullness and tinnitus may also be helpful in lateralization. Head trauma associated with dysequilibrium and fluctuating sensorineural hearing loss or a history of previous otologic surgery or familial hearing loss is also important.

Most patients with acute vertigo will improve with supportive, expectant management. When this is not the case, they may present for evaluation after several months or years of dizziness. The patient should be asked to describe the progression of symptoms over time, along with the nature and duration of typical spells. Specifically, one wishes to know if

the spells are continuous or occur in discrete episodes. If the symptoms are episodic, it is extremely important to distinguish whether they are spontaneous or motion provoked. If the symptoms are brief and predictably produced by head movements or body position changes, the patient most likely has a stable lesion but has not yet completed central nervous system compensation. Those who describe these symptoms sometimes also note a chronic underlying sense of dysequilibrium or light-headedness. The chronic symptoms may be quite troublesome, but any intense vertigo should be primarily motion provoked. These patients are suitable candidates for vestibular rehabilitation. It is important to point out that historical information is essential in deciding who might benefit from rehabilitation therapy.

If the episodic spells described by the patient are longer periods of intense vertigo that occur spontaneously and without warning, this is probably progressive or unstable peripheral dysfunction. One must also suspect a progressive lesion if the vertigo is accompanied by fluctuating or progressive sensorineural hearing loss. Such patients are managed with medical therapy, and if this fails, they constitute the best candidates for surgical intervention. Such patients are not candidates for vestibular rehabilitation, except as an adjunctive modality.

As discussed above in generalities, two of the critical elements in developing a differential diagnosis involve the determination of spontaneity versus visual or head-movement provocation together with the temporal characteristics of the symptoms. These two features play such a major role in the development of the working diagnosis that a more detailed discussion is appropriate. Table 6–1, which is not intended to be exhaustive, suggests the use of these two aspects of the patient history and the possible sources to consider in the diagnosis. To differentiate among the diagnostic options further, the other historical information and auditory function can be immediately useful.

Additional history regarding current or prior use of medications should be elicited. Many patients are under the mistaken impression that vestibular suppressants will prevent spells of vertigo and take them habitually. Because oversedation from these centrally acting drugs may retard central nervous system compensation for vestibular lesions, one should consider tapering or discontinuing these medications whenever possible. Medications that must be continued should be directed toward particular symptoms that specifically interfere with the patient's recovery process.

Other psychosocial aspects can be important in understanding the patient's situation. Complicating features of anxiety, depression, or excessive dependence on psychotropic medications should be identified. It is desirable to understand the degree of functional disability produced by the patients' vestibular complaints, especially with respect to their professional and favorite social activities. The stability and commitment of their psychological support system should also be evaluated.

LABORATORY TESTS OF VESTIBULAR AND BALANCE FUNCTION

The principal tests that are found in most dedicated balance centers are ENG, rotational chair, and CDP. Other evaluation tools are available for specific tasks. These include head on body studies (autorotation tests),[24] special protocols that use eye movement recordings that can quantify linear horizontal and vertical as well as torsional activity,[25] dynamic visual acuity,[11] and protocols to assess the otolith organs specifically.[26] Although these additional studies can be useful, the primary discussion will be confined to the principal tools of ENG, rotary chair, and CDP.

Assuming that all of the studies are available, it is not necessary for each patient to have all aspects of the major evaluative tools as a selection of the tests may be adequate. One suggested strategy for determining what tests are needed is based on a core set of studies that would be appropriate for all patients, and the use of those studies together with the neurotologic history determines when the other tests are needed. This means that the selection of the tests occurs as the testing is being performed and is not predetermined at the time of referral. When consideration is given to the discussion above regarding the utility for the testing in the management decision process, the better approach is to let the testing determine the studies needed given the strengths of the individual tools that will be discussed below. A suggested core would be the ENG with full oculomotor studies (by computerized system), full history, and screening evaluation of postural control. The basic site-of-lesion investigation and first approximation of the functional assessment of balance can be obtained in this manner.[14] The rationales for proceeding with total-body rotational chair testing are as follows:

TABLE 6–1. Suggested Differential Diagnostic Entries Based on Temporal Course and Symptom Characteristics

Temporal Course of Symptoms	*"Dizziness" Characteristics*	*Auditory Characteristics*	*Differential to Consider*
Episodic (s)	HM-HP provoked	Normal	Benign paroxysmal positional vertigo, uncompensated stable peripheral lesion
Episodic (s–min < 60)	Spontaneous	Normal or mild fluctuations	Migraine, transient ischemic attacks, anxiety disorders
			Meniere's disease (spells over 20 min)
Episodic (min–h < 24)	HM-HP provoked	Normal	Uncompensated stable peripheral lesion, migraine
Episodic (min–h < 24)	Spontaneous	Fluctuant + progressive	Labyrinthine disorders, eg, Meniere's disease; autoimmune disorders
Episodic (min–h < 24)	Spontaneous	Normal or mild fluctuations	Migraine, anxiety disorders, cardiovascular disorders
Days	Spontaneous resolving in 1 to 3 d to HM-HP provoked	Normal	Vestibular neuritis, vascular events
Days	Spontaneous resolving in 1 to 3 d to HM-HP provoked	Sudden loss at time of vertigo onset	Labyrinthitis, posteroinferior cerebellar artery or anteroinferior cerebellar artery distribution strokes
Days typically < 7	Spontaneous or HM-HP provoked relatively constant overall	Normal or mild fluctuation	Migraine
Continuous	May or may not be exacerbated by HM-HP	Normal	Central vestibular disorders, anxiety disorders, nonvestibular disorders such as sensory or motor neuropathy of lower limbs

HM = head movement; HP = head position.

- When the ENG is normal, and oculomotor results are either normal or observed abnormalities would not invalidate rotational chair results. Chair testing is used here to expand the investigation of peripheral system involvement and compensation status.
- When the ENG suggests a well-compensated status (no spontaneous or positional nystagmus), despite the presence of a clinically significant unilateral caloric weakness and ongoing symptom complaints. Chair testing is used here to expand

the investigation of compensation in a patient with a known lesion site and complaints suggesting poor compensation.
- When the caloric irrigations produce nystagmus below 10 degrees/second bilaterally, when caloric irrigations cannot be performed, or when results in the two ears may not be compared reliably owing to anatomic variability. Chair testing is used in these cases to verify and define the extent of a bilateral weakness or to investigate further the relative responsiveness of the peripheral vestibular apparatus bilaterally when caloric studies are unreliable or unavailable.
- When a baseline is needed to follow the natural history of the patient's disorder (such as possible early Meniere's disease) or for assessing the effectiveness of a particular treatment, such as that of chemical ablation of one or both vestibular end-organs.

In a like manner, decisions for use of full postural control studies can be made based on the history and the screening tools for postural control assessment. Therefore, based on the results of the Clinical Test of Sensory Integration and Balance (CTSIB)[27,28] and the patient's full neurotologic history, CDP would be called for under the following conditions:

- If the CTSIB was abnormal with a fall reaction, significantly increased sway, or sudden change of strategy for maintaining stance during a trial. Based on the comparison between CTSIB and CDP, we know that the patient who can perform CTSIB in the normal range is very unlikely to fail the sensory organization portion of CDP. On the other hand, CDP is needed to delineate further postural control difficulties when abnormal performance is noted on the CTSIB.
- If the patient has a major complaint involving unsteadiness when standing or walking, independent of the CTSIB results. Dynamic posturography, especially motor control testing (MCT), is used in this case to investigate further postural control. This patient would also be a candidate for postural evoked response testing, a third special protocol that can be used with CDP in conjunction with lower limb electromyography (EMG) recording, described below.
- If the patient had a history of known pathology involving the postural control pathways that may influence the patient's overall performance, even though unsteadiness is not a major complaint.

Electronystamography

Traditional ENG, using electro-oculography for eye movement recordings, is a process that estimates the position of the eye as a function of time indirectly. The estimates are reliable whether recorded with eyes open or closed and in a darkened or well-lit environment. Changes in eye position are indicated by the polarity of the corneal-retinal potential (dipole) relative to each electrode placed near the eyes (Figure 6–1, A). These electrodes are typically placed at each lateral canthus and above and below at least one eye with a common electrode on the forehead (Figure 6–1, B). Since the primary purpose of the vestibular apparatus is to control eye movements, the movements of the eyes may be used to examine the activity of the vestibular end-organs and their central vestibulo-ocular pathways. More recently, the technique of infrared video-oculography has begun to replace the standard electro-oculography. This technique has the advantages of direct estimate of the eye position as a function of time and reduction in electrical artifacts. A typical horizontal ENG trace of right-beating nystagmus (could be from either electrodes or video techniques) is shown in Figure 6–2. In this figure, a rapid upward deflection of the trace (fast or saccade component of the nystagmus) is seen followed in each case by a slower downward drift of the trace (slow component of the nystagmus). The convention in the recordings is that the upward trace deflections represent rightward (horizontal trace) or upward (vertical trace) eye movements. Conversely, downward deflections of the trace represent leftward and downward eye movements. Calculation of the principal parameter used in the analysis of nystagmus, slow-component eye velocity, is illustrated in Figure 6–3. The ENG evaluation is a series of subtests performed to assess peripheral and central portions of the vestibular system. It is important to understand that assessment of the peripheral part of the vestibular system with ENG is significantly limited, typically reflecting function of the horizontal semicircular canal with restricted information from vertical canals and otolith organs. With the use of computerized ENG systems, which afford significant visual stimulus control and quantitative analysis, evaluation of the central vestibulo-ocular pathways can be quite thorough.

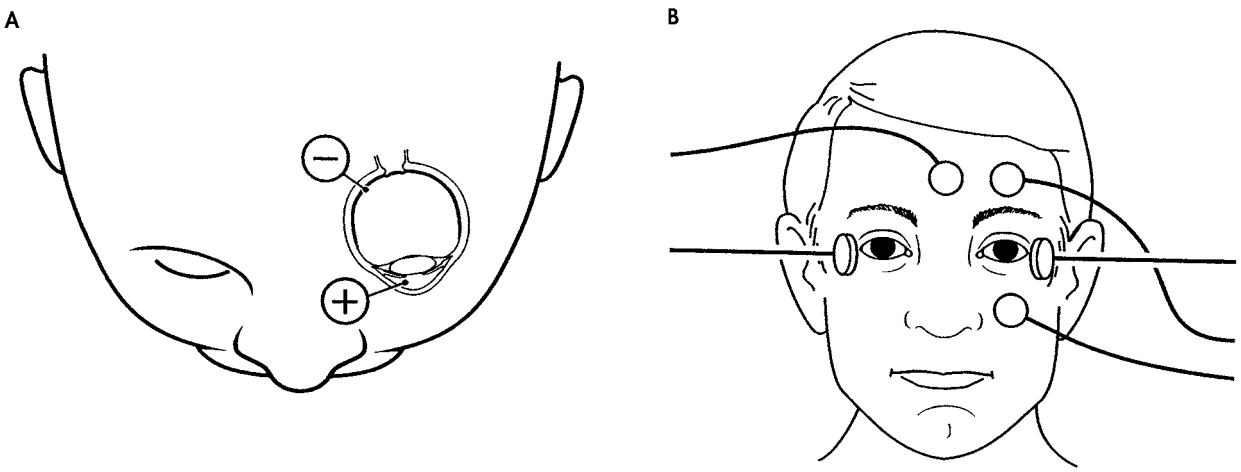

FIGURE 6–1. A, Shown schematically is the corneal-retinal potential that forms the basis for electro-oculography as an indirect recording technique for eye movement position as a function of time. *B*, Typical electrode montage (arrangement) for monitoring eye position as a function of time in both the lateral and vertical dimensions.

The ENG consists of the following groups of subtests: oculomotor evaluation, typically with smooth pursuit tracking, saccade analysis, gaze fixation, and optokinetic stimulation; spontaneous nystagmus; rapid positioning (Hallpike-Dix maneuver); positional nystagmus; and caloric irrigations. The slow-component eye velocity of the nystagmus (see Figure 6–3) is the measurement of interest as it reflects the portion of the nystagmus that is generated by the vestibulo-oculomotor reflex (VOR) (with the fast component generated from the pons area of the brainstem in response to the position of the eye in the orbit). Although traditionally part of the ENG, the Hallpike maneuver should be analyzed by direct examination, not requiring quantification with recording, and should not be analyzed by the typical two-dimensional (horizontal and vertical) recorded eye movements from an ENG. The oculomotor tests are quantified according to the eye movements generated during the task and analyzed by comparison to normative data when a computerized system is used.

Oculomotor Tests Just as the eyes serve as the window for investigating the function of the peripheral part of the vestibular system, they provide a

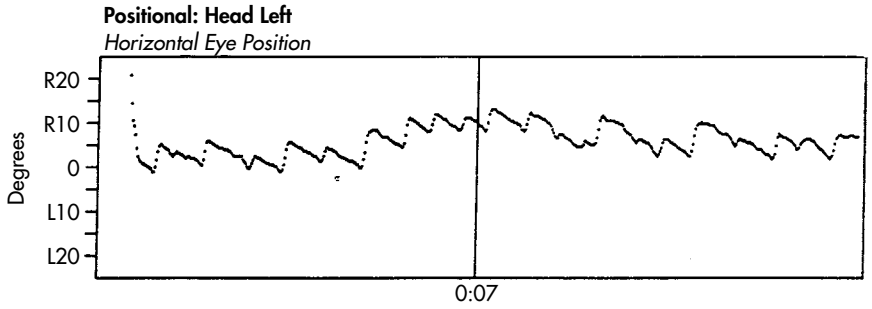

FIGURE 6–2. Right-beating horizontal nystagmus is demonstrated from a patient's eye movement recording with the patient's eyes closed in the head turned left from a supine position. The vertical axis is in degrees of movement, with the horizontal axis in time going from left to right, showing a total of 14 seconds.

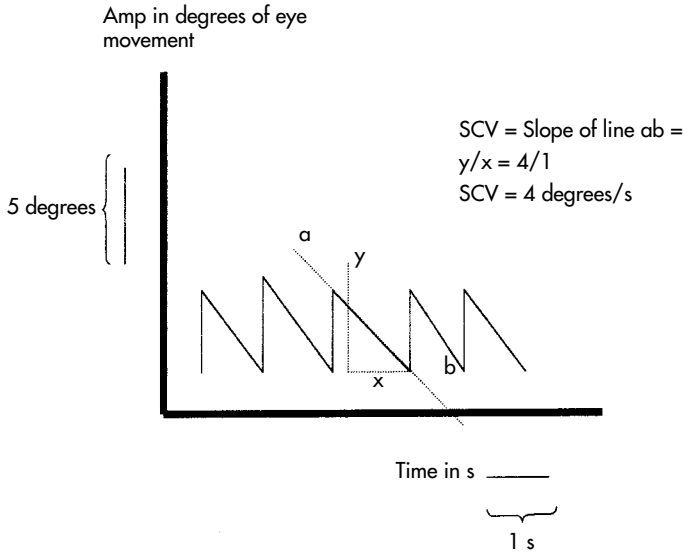

FIGURE 6–3. Right-beating nystagmus is illustrated along with the calculation of slow-component eye velocity, the slope of the line ab. As discussed in the text, upward trace deflections represent rightward eye movement, with downward indicating leftward eye movement. Amp = amplitude; SCV = slow-component eye velocity. Reproduced with permission from Shepard NT. Evaluation and management of balance system disorders. In: Katz J, Medwetsky L, Burkhard B, editors. Handbook of audiology. 5th ed. Baltimore: Williams & Wilkins; 2000.

means to investigate the oculomotor pathways in the brainstem and cerebellum that are required for the function of the VOR.

A variety of testing paradigms can assist in identifying abnormalities in the central oculomotor control systems that may produce the patient's complaints. The smooth pursuit test evaluates the ability to track a moving object with smooth eye movements and head still. Smooth pursuit is the most sensitive of the oculomotor tests but provides poor lesion site localization within the multiple pathways involved in pursuit generation. Abnormalities with pursuit are typically taken as an indication of possible vestibulo-cerebellar region involvement, the final common portion of the multiple pathways for pursuit production.[18] Saccade testing evaluates rapid movement of the eye used to place an object of interest on the most sensitive portion of the retina, the fovea. Saccade testing is not as sensitive as pursuit but when tested with different paradigms can provide for differentiating information concerning brainstem versus posterior cerebellar vermis involvement. Suggestions for possible frontal or parietal lobe involvement can also be obtained from saccade testing. Gaze fixation evaluates the ability to hold the eyes in a fixed direction of gaze without drifting off the target, typically straight ahead and to the right, left, up, and down. Gaze fixation provides general suggestions of brainstem/cerebellar involvement in most instances of abnormal results. There are specific abnormalities of fixation of gaze that can be indicative of specific cerebellar degenerative disorders (saccade intrusions). Optokinetic stimulation measures jerk nystagmus eye movements created by repeated objects moving across the subject's visual field and filling at least 80% of the visual field. Optokinetic stimulation is the least sensitive, probably owing to the combination of both smooth pursuit and saccade systems, allowing the optokinetic nystagmus to be generated by a combination of foveal and peripheral retinal stimulation. At present, it serves best as a cross-check with significant abnormalities seen during pursuit or saccade testing. Illustrated in Figures 6–4 and 6–5 are typical recordings and analysis of smooth pursuit and reactionary saccade testing.

Compared with gaze fixation and saccade testing, smooth pursuit is significantly more sensitive to the presence of pathology. Sensitivity performance of these tests was evaluated in a group of 134 patients diagnosed with multisystem atrophy, olivopontocerebellar atrophy, Friedreich's ataxia, or multiple sclerosis.[14] All had clearly defined brainstem/cerebellar lesions on MRI. Eighty-seven percent had evidence for central vestibulo-ocular pathway dysfunction on oculomotor testing, as indicated by abnormal performance on any single or combined test of gaze fixation, saccades, and smooth pursuit measures. Smooth pursuit measures alone identified central system involvement in 73% of these cases, independent of results on saccade and fixation testing, compared with only 40% identified by saccade

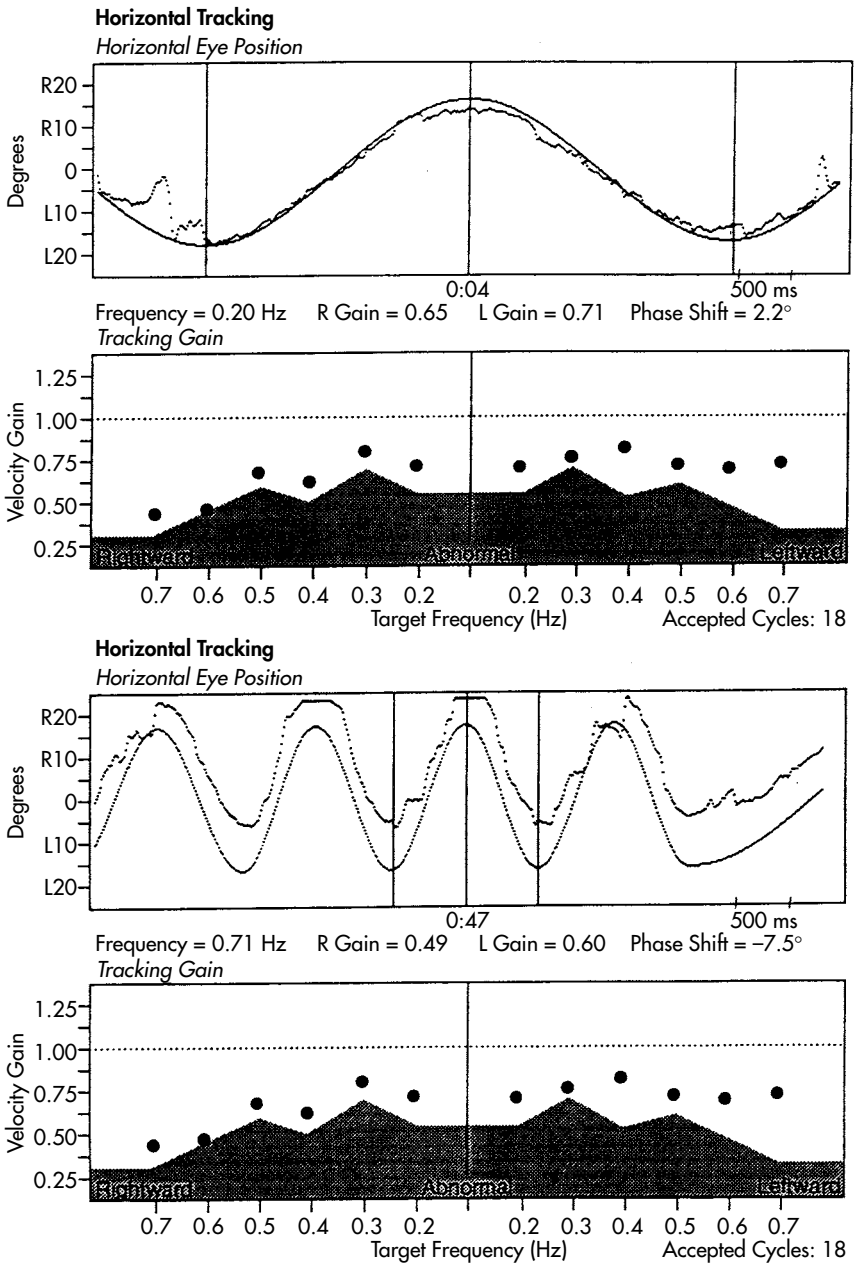

FIGURE 6–4. An example of smooth pursuit eye movement recording with the target at two of the multiple frequencies tested. Shown in both top and bottom panel sets is a plot of horizontal eye position as a function of time (500 ms time mark shown) for sinusoidal tracking (*dotted trace*). In the same plot (*smooth line*), the target position in degrees as a function of time is given. The panel below the eye and target position plots gives the value of velocity gain as a function of frequency of target movement. The *shaded region* represents abnormal performance. The top panel set is for a target frequency of 0.2 Hz, and the bottom panel set is for 0.71 Hz. Reproduced with permission from Shepard NT and Telian SA.[14]

testing alone and 47% for fixation testing. These tools also can suggest central nervous system involvement in patients without obvious structural abnormalities identified by MRI. As it is possible to have abnormal central nervous system function without structural changes on neuroradiographic studies, it is difficult to provide overall true sensitivity figures. Statistically, as normal values are typically based on two standard deviations from the mean performance, a small percentage of those with suspected central involvement will be false positives. An estimate of 86% specificity (14% false positives) for the oculomotor studies is derived from a group of patients suspected of having pure peripheral lesions.[14] Given the advanced nature of the disease states of the groups of patients used for the sensitivity and specificity figures, it is highly likely that both figures are overestimates of performance with actual sensitivity and specificity figures in the 75 to 80% range.

In a review conducted by Shepard and Telian[14] of 2,266 patients seen over a 32-month period, 14% had abnormalities suggesting brainstem and/or cerebellar involvement without any indications of involvement of the peripheral part of the system.

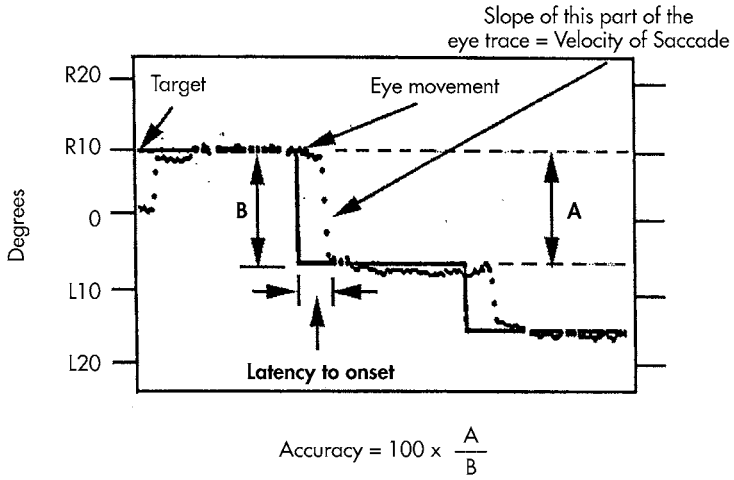

FIGURE 6–5. Schematic of eye and target position in degrees as a function of time demonstrating the calculations of velocity, latency, and accuracy of the saccade eye movement for analysis. The three parameters of velocity, latency, and accuracy are then used to characterize the patient's performance. Reproduced with permission from Shepard NT and Telian SA.[14]

The percentage of those suspected of involvement of the central part of the system increased to 21% when combinations of peripheral and central abnormalities were included. Therefore, since exact sensitivity and specificity performance figures cannot be determined, it seems best to employ test protocols that may reduce the false-positive rate (increase specificity) without decreasing test sensitivity. The three crucial principles to assist in these goals are (1) the use of computerized, quantitative analysis; (2) application of age-appropriate normative data comparisons; and (3) repetition of initially abnormal test measures to obtain optimal performance.

Spontaneous Nystagmus This test is performed with the patient sitting, head straight and eyes closed. The purpose is to record eye movements when visual fixation is removed, without any provocative head movements or positions. Jerk nystagmus is the principal abnormality of interest in most situations. Other forms of abnormal eye movements, such as pendular nystagmus (sinusoidal horizontal repeating eye movements with no distinguishable slow and fast components), may be seen. Clinically significant, direction-fixed nystagmus is interpreted to indicate possible pathology within the peripheral part of the vestibular system if the oculomotor evaluation is normal (Figure 6–6, A).

Head-Shake Nystagmus The head-shake protocol is commonly associated with the direct office examination yet can be usefully incorporated as part of the ENG.[6] As with the office examination, reciprocal horizontal head movements at about 2 to 3 Hz for 10 seconds are presented with fixation removed. When the head is brought to a stop, recording of eye movements is continued long enough to capture nystagmus that had been provoked or no nystagmus if the test is negative. The presence of three or more horizontal nystagmus beats is suggestive of a peripheral asymmetry. In most cases, the direction of the fast component of the nystagmus is away from a paretic lesion; however, this is not always the case, and the nystagmus may beat toward the side with a lesion. Vertical nystagmus resulting from the horizontal head shake is a positive sign for brainstem and/or cerebellar involvement and is referred to as cross-coupling nystagmus. Although the sensitivity for identification of peripheral involvement is reported to be only fair, the ease of the test and its short time for execution make it reasonable to add to the ENG battery.[29]

Hyperventilation Nystagmus This is another of the office examination tools that can be easily and effectively used during an ENG protocol. The use of hyperventilation testing has a dual purpose. The first is identification of nystagmus suggestive of eighth cranial nerve involvement on the side to which the fast component of the nystagmus is directed. The nystagmus results from myelin being absent from a section of the nerve secondary to a demyelination process from disease or a mass lesion.[30] The second use is to identify an individual more likely to be experiencing an anxiety disorder. This is recognized by the production of symptoms of light-headed-

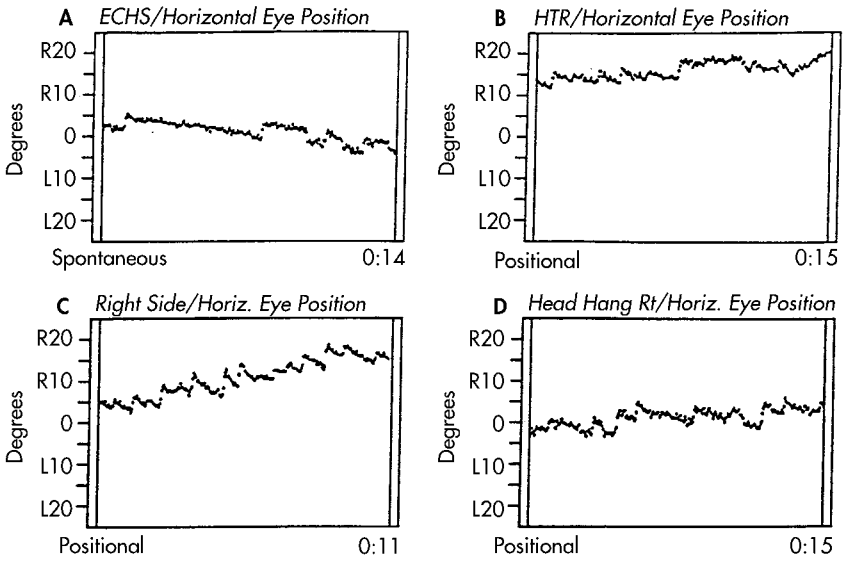

FIGURE 6–6. *A* through *D* plot horizontal eye position in degrees as a function of time, each showing right-beating nystagmus. The time in the lower right corner of each panel is the total elapsed time in seconds for that recording, not the total time shown. Each panel represents 7 seconds of tracing. *A*, ECHS = eyes closed head straight, spontaneous. *B*, HTR = eyes closed head turned right, sitting position. *C*, Eyes closed, lying on the right side (right decubitus position). *D*, Eyes closed, extension of the neck (by approximately 30 degrees) with the head turned to the right. These are 4 of a total of 11 positions tested on this patient. Reproduced with permission from Shepard NT and Telian SA.[14]

ness/imbalance within 30 seconds of starting the hyperventilation, with no nystagmus visualized. Hyperventilation is more likely to provoke dizziness, light-headedness, autonomic symptoms, and acute anxiety attacks in patients with certain anxiety disorders than in the general population.[31] It also may provoke light-headedness and autonomic arousal without significant anxiety in patients with autonomic dysfunction (eg, hyperventilation syndrome).[32] Anxiety disorders or dysautonomia should be suspected in patients who experience a marked reproduction of their symptoms, without nystagmus, during hyperventilation.

Hallpike Maneuver The Hallpike maneuver is a well-known office procedure used primarily to elicit evidence for BPPV. Since this is typically a problem with a single semicircular canal at a time, the description of the nystagmus is critical to identification of the canal involved. Each canal has an individual and unique eye movement signature that can be used to recognize which canal is causing this disorder.[33] In the variants of BPPV, only the horizontal canal variant does not have torsional eye movement; all others involve torsional movements and therefore cannot be recorded with standard electrooculography techniques or typical standard video systems as both are two-dimensional in the printed output.

The Hallpike maneuver is also typically part of the standard ENG protocol (Figure 6–7). Classically, positive Hallpike responses produce a torsional nystagmus (pure rotational movement of the eye about an axis through the center of the globe going from anterior to posterior when that axis is oriented parallel to the axis perpendicular to the plane of the canal involved). The fast component is directed toward the involved ear (left torsional for left ear and right torsional for right ear, from the patient's perspective, relative to the superior pole of the eye). To detect this action adequately, the movements must be viewed by the examiner (directly or with video equipment), not reviewed after the fact by two-dimensional recordings from standard surface electrode or standard video recording techniques.

Positional Nystagmus Positional nystagmus is the most common abnormality noted with ENG evaluation. In this study, the patient is moved slowly into stationary positions. The eye movements are moni-

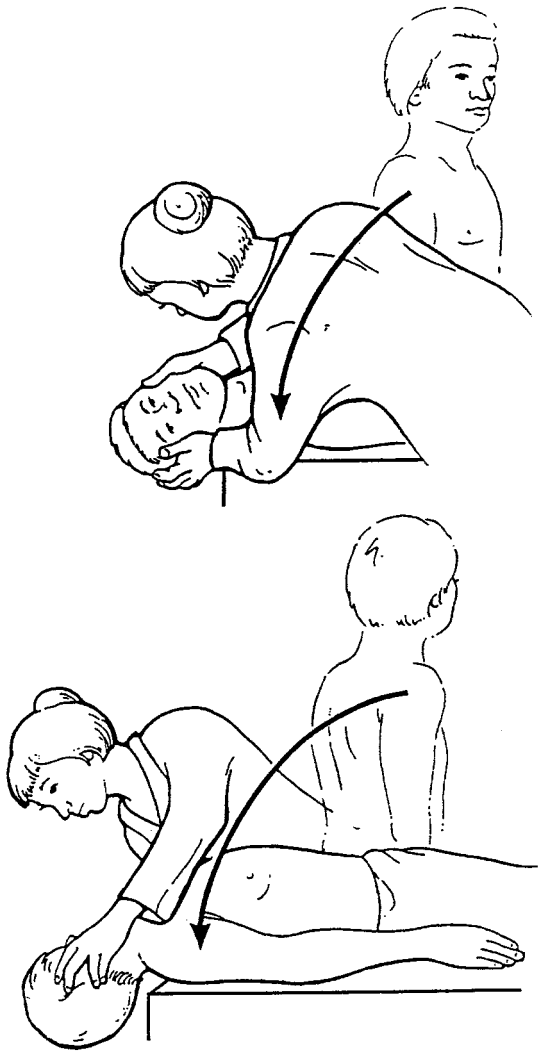

FIGURE 6–7. Illustrations of the technique for the Hallpike maneuver, for right side (*top*) and left side (*bottom*). Note that the patient's eyes are open and fixating on the examiner. Reproduced with permission from Shepard NT and Telian SA.[14]

tored as in the spontaneous nystagmus test and should be done without visual fixation (see Figure 6–6, B to D). The more common positions include sitting head turned right; sitting, head turned left; supine; supine, head turned left; supine, head turned right; right decubitus (right side); left decubitus (left side); and preirrigation position (head and shoulders elevated by 20 to 30 degrees up from the horizontal plane). In cases for which no cervical region injuries or active pathologies are reported, use of head hanging (neck extended by up to 20 degrees) straight, right, and left adds three additional positions for testing prior to preirrigation position. The purpose of this test is to investigate the effect of different head positions within the gravitational field. Positional nystagmus is typically classified by the direction of the fast component of the nystagmus but measured by the velocity of the slow component. It may be either direction fixed (always beating in the same direction) or direction changing (both right- and left-beating nystagmus observed during the examination). Direction-changing nystagmus may be subclassified, when appropriate, into geotropic (toward the pull of gravity, toward the underneath ear) or ageotropic (away from the pull of gravity, away from the underneath ear).

The clinical interpretation of positional nystagmus is taken as indicative of involvement of the peripheral part of the system (with two notable exceptions) as long as the oculomotor studies, done in a thorough manner, requiring a computerized system, are normal. The exceptions to this situation are (1) when the direction-changing nystagmus is observed while the patient remains in one head position, that is, without a change in gravitational orientation, and (2) if persistent vertical nystagmus is noted with no horizontal component. These are typically interpreted as indicative of central pathway involvement (usually low posterior fossa), independent of the oculomotor results, unless an alternative explanation is apparent. If spontaneous, direction-fixed nystagmus is present and no significant change in that nystagmus (average slow-component velocity) is noted, then the nystagmus in the positions is taken as a reflection of the spontaneous findings and not considered as positional. This situation would suggest little or no influence of the otolith organs in the modulation or generation of the nystagmus but would not otherwise alter the general interpretation of involvement of the peripheral part of the system, assuming normal oculomotor studies.

Since positional nystagmus can be produced with central or peripheral lesions, the presence of abnormal oculomotor studies (the most sensitive test indication of central nervous system involvement) precludes the use of positional nystagmus as an indicator of a lesion of the peripheral part of the system. Clinical significance of the positional nystagmus is typically determined by a combination of the number of positions in which it is present and the velocity range of the slow component of the nystagmus. One suggested set of significance criteria based on

studies of the presence of positional nystagmus in a normal population is as follows: slow-component eye velocity > 5 degrees/second, slow-component eye velocity < 6 degrees/second with persistent nystagmus in 4 or more of the 8 to 11 positions, and slow-component eye velocity < 6 degrees/second with sporadic nystagmus in all positions tested and direction changing within a given head position.[34]

Two other conditions that can produce positional nystagmus without oculomotor abnormalities must be considered before involvement of the peripheral part of the system is suggested. Migraine headache conditions can produce these findings, in addition to mild caloric asymmetries.[35,36] No particular patterns of positional nystagmus are indicative of migraine. Since migraines and dizziness related to migraine are diagnoses of exclusion, it is important to keep this in mind if the total presentation of the patient is not convincing for involvement of the peripheral part of the system. Somewhat less well documented in producing positional eye movement abnormalities are anxiety disorders. The most commonly recognized eye movements associated with anxiety, especially related to the testing process, causing symptoms are macrosquare wave jerks (square waves of a 5- to 15-degree subtended arc with normal intersaccade intervals).[18] This type of intrusion saccade is noted only with fixation removed. Classic positional jerk nystagmus of a direction-fixed or direction-changing nature can also be provoked by anxiety disorders.[31]

Caloric Irrigations The caloric test is the study that is most likely to indicate the side of a peripheral lesion with objective, repeatable eye movement data. The stimulus employed is nonphysiologic compared to the normal function of the system during head motion, when one side is stimulated and the other is simultaneously inhibited. Nevertheless, the caloric test is the only portion of the test battery that provides a measure of unilateral labyrinthine function. There are three primary delivery methods for caloric irrigations: closed-loop water (circulates in a thin latex balloon that expands in the external auditory canal), open-loop water (runs into the external auditory canal and drains out), and air irrigation (Figure 6–8). During any of the methods, the fluid or air is set at temperatures above or below that of the body; typically, 44°C for the warm and 30°C for the cool are used for the open-loop water systems. All are reasonably reliable when the tympanic membrane is intact. When a tympanic membrane perforation or short ventilation tube is present, the closed-loop water irrigation method is preferable.

In both terrestrial and weightless environments, there appears to be at least two mechanisms operating to produce the caloric VOR response to the temperature changes. The one that seems to predominate in routine testing involves gravity and the density changes that occur in the endolymph of the horizontal canal when it is heated or cooled (density decreased or increased, respectively). The head is positioned so that the horizontal canal is oriented

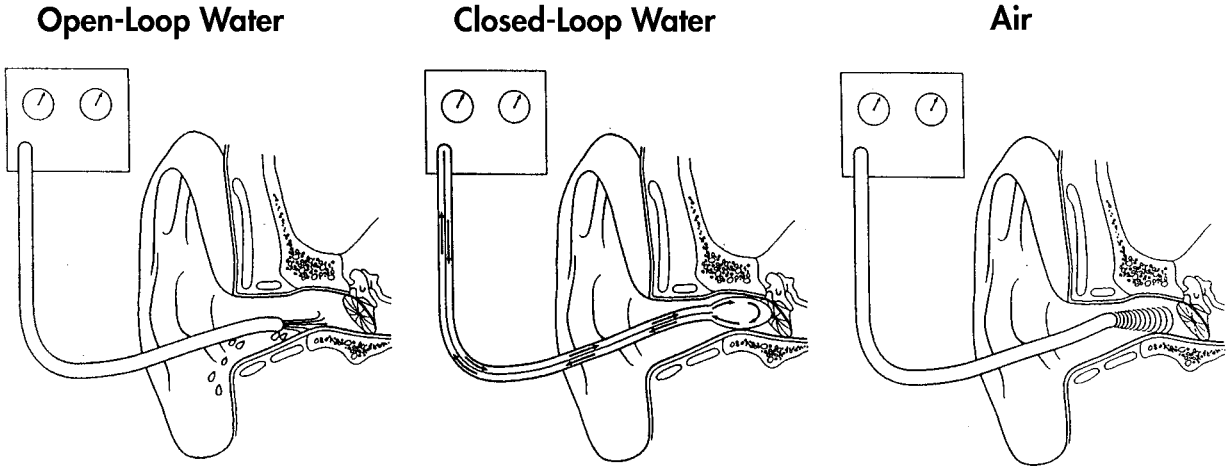

FIGURE 6–8. Three techniques for caloric irrigations are shown. Reproduced with permission from Shepard NT and Telian SA.[14]

parallel to the gravitational vector, with the nose of the patient upward and the head tilted 20 to 30 degrees upward from the horizontal plane. During a warm irrigation, the less dense fluid attempts to rise upward. This produces a deviation of the cupula toward the utricle owing to the pressure differential across the cupula, causing stimulation of the eighth nerve. The reverse action occurs for the more dense area of cooled fluid, causing inhibition. This results in the well-known mnemonic "COWS," which refers to the direction of the fast component of the nystagmus: *C*old *O*pposite, *W*arm *S*ame (relative to the side of irrigation).

The traditional interpretation of caloric stimulation uses a relative comparison of maximum, average slow-component eye velocity on the right versus the left. These values are used to provide a percentage comparison of response magnitude (reduced vestibular response) and direction bias of eye movement (directional preponderance) (Figure 6–9). Traditionally, the four maximum values are combined to produce the two outcomes through the use of Jongkee's formulas.[37]

Although four irrigations are typical, there are situations in which use of "ice water" (4°C) is needed and other situations in which only two irrigations of either warm or cool are sufficient.[14,38] Directional preponderance is interpreted as a bias in the central part of the system, making it easier to produce nystagmus in one direction than another. This bias is most often a result of asymmetric peripheral function, for which the central compensation process is incomplete, and is less likely to be a result of a lesion of the central part of the system.

It is critical in the interpretation of the caloric test to recognize its limitations. The most dominant of these is that the test is one of the horizontal semicircular canal function. Participation by either of the

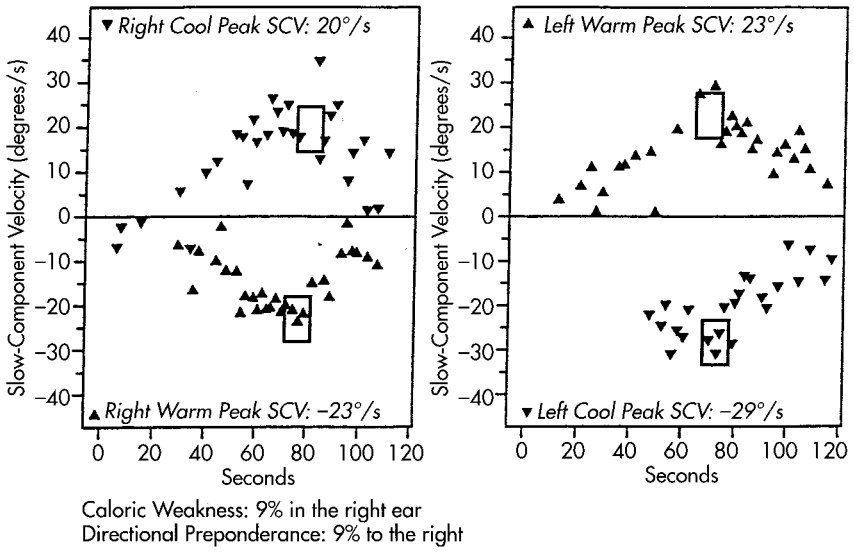

FIGURE 6–9. Plots of slow-component eye velocity (SCV) from nystagmus provoked by open-loop water irrigations as a function of time. Each triangle represents one SCV movement of the eye from the nystagmus trace. Responses for the right ear are shown on the left; those for the left ear are on the right. The orientation of the triangles represents either cool (30°C) or warm (44°C) irrigations. The plots are arranged so that right-beating nystagmus SCVs are on the bottom (right warm, left cool) and left-beating nystagmus SCVs are on the top (right cool, left warm). The velocity values given in the top or bottom of each plot represent the average maximum SCV calculated for the nystagmus beats within the rectangle shown on each plot. These maximum, average SCV values were used to calculate the caloric weakness and directional preponderance values shown at the bottom of the figure. Nine percent in the right ear means a 9% weaker response on the right compared with the left. Nine percent to the right means a 9% greater response for right-beating nystagmus compared with left-beating nystagmus. For purposes of calculations, SCVs from right-beating nystagmus are assigned a negative number and those for left-beating nystagmus are assigned a positive number. Reproduced with permission from Shepard NT and Telian SA.[14]

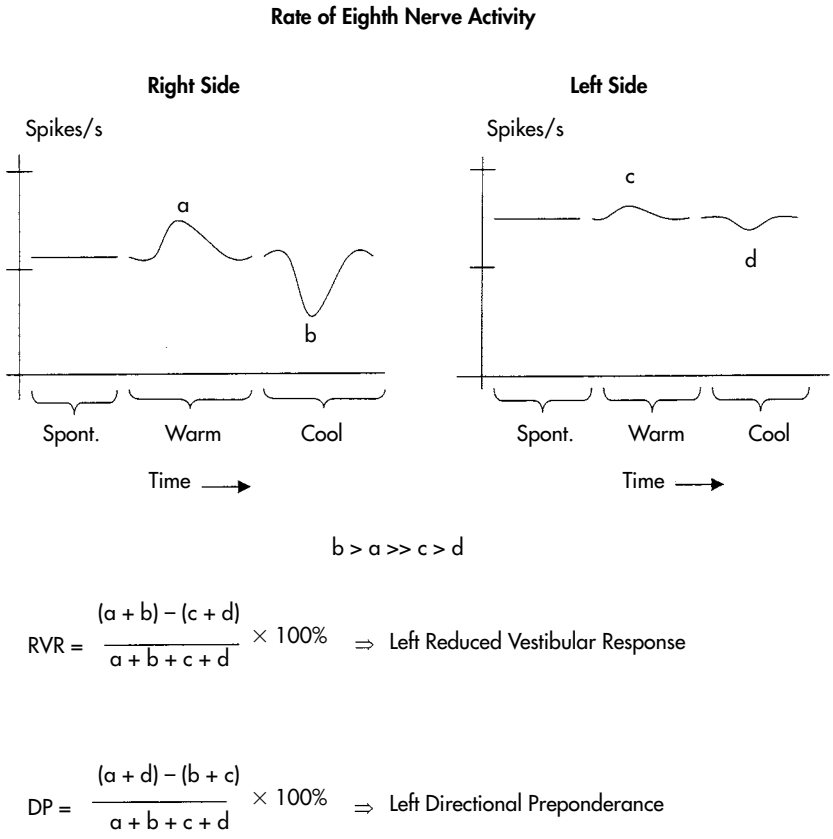

FIGURE 6–10. A schematic representation of a caloric irrigation test giving a left-side reduced vestibular response (RVR) with left directional preponderance (DP). The two plots at the top show in graphic form the estimated firing rate activity in spikes per second on the right and left eighth cranial nerves during the caloric test. The three intervals shown during the test are preirrigation (spontaneous) then the result from warm or cool open-loop water irrigations performed in an alternating bithermal protocol (right warm, followed by left warm, followed by left cool, and finally right cool). The amplitudes of the responses to the irrigations are given with the variables a, b, c, d. The spontaneous preirrigation neural activity on the eighth nerve is greater on the left than the right; however, the responses to irrigations are significantly less on the left than the right. For the caloric response traces, an upward deflection indicates an excitatory response on the nerve with the downward deflection indicating an inhibitory (reduction in firing rate) response. Given the relative values of the responses shown in the figure, the corresponding calculations of RVR and DP would produce the indicated result.

vertical canals is minimal at best. The test is also limited in its frequency response for the peripheral system (discussed in more detail below). Finally, the test is one of relative responsiveness of the peripheral system (horizontal canal) to an attempt at driving the system with an exogenous stimulus. It is not a test that is intented to reveal in a direct manner the ongoing strength of the neural activity of the right versus the left peripheral part of the system. As a result of this, it is possible to have a reduced vestibular response on the same side as that to which spontaneous and positional nystagmus beats and to which the directional preponderance is oriented. Yet nystagmus always beats toward (fast component of the nystagmus toward) the side of greater neural activity. This presents as a dichotomy in that the side with the reduced vestibular response must have the greater neural activity ongoing to have the spontaneous and positional nystagmus, as well as the directional preponderance oriented toward that same side. This is illustrated in the simple model presented in Figure 6–10. Figure 6–11 shows the actual results in a patient with classic Meniere's syndrome. The hearing loss and all auditory complaints for the

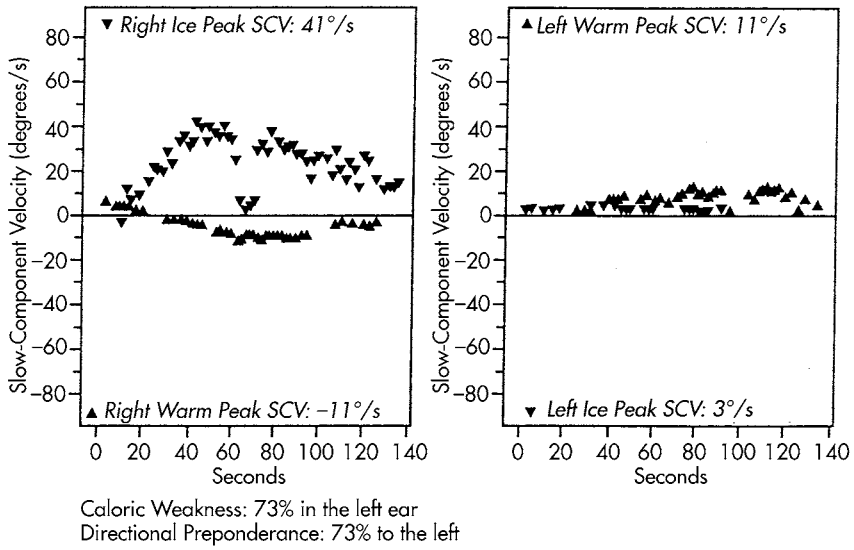

FIGURE 6–11. Plots of slow-component eye velocity (SCV) from nystagmus provoked by open-loop water irrigations as a function of time. Each triangle represents one SCV movement of the eye from the nystagmus trace. Responses for the right ear are shown on the left and those for the left ear on the right. The orientation of the triangles shown on the figure represents either ice water (4°C) or warm water (44°C) irrigations. The plots are arranged so that right-beating nystagmus SCVs are on the bottom (right warm, left ice water) and left-beating nystagmus SCVs are on the top (right water ice, left warm). The velocity values given in the top or bottom of each plot represent the average maximum SCV calculated for the nystagmus beats within the rectangle shown on each plot. These average maximum SCV values were used to calculate the caloric weakness and directional preponderance values shown at the bottom of the figure. For purposes of calculations, SCVs from right-beating nystagmus are assigned a negative number and those from left-beating nystagmus are assigned a positive number (note that left ice water gave a left-beating nystagmus, not a right, as would be expected—hence a positive averaged value). Reproduced with permission from Shepard NT and Telian SA.[14]

patient in this example were on the left. During the ENG, spontaneous left-beating nystagmus was noted and persisted in all positions with fixation removed. This indicates that the neural activity on the left must be greater than that on the right. Yet the caloric results shown in Figure 6–11 demonstrate a significant left reduced vestibular response. Not surprisingly, given the spontaneous nystagmus, a left directional preponderance is shown. This result is referred to as a left paretic lesion with an irritative status. This suggests that although the pathologic process is destructive, it is causing an irritative focus. The two most common disorders to result in an irritative lesion, with or without a paretic component, are early mass lesions of the cerebellopontine angle and Meniere's disease.

An additional feature of the example given in Figure 6–11 is the consequence of using a combination of unequal temperatures, warm and ice water irrigations. As long as the same protocol is performed on both sides, the use of warm and ice water is not a problem. The purpose is to increase the absolute value of the caloric response (as shown for the right irrigations in Figure 6–11) to avoid percentage calculations with numbers at or less than 10 degrees/second. However, as in this example, if both sides are not equivalent in their response to the irrigation, the increased response to ice on one side alone can lead to an artificially increased or falsely produced directional preponderance. In Figure 6–11, the actual directional preponderance, when estimated with the added effect of ice taken into account, is about 36%, not 73%.[14]

The use of the formulas provided in Table 6–2 requires the following assumptions to be met. First, anatomic symmetry between the external auditory canals, middle ears, and lateral aspects of the temporal bones must be present. Once the first assumption is fulfilled, then the second is that, technically, the same temperature of fluid or air must be delivered to

TABLE 6–2. Formulas for the Calculation of Reduced Vestibular Response and Directional Preponderance

Reduced vestibular response (RVR) (values –100% to +100%)	=	$\frac{[(RW + RC) - (LW + LC)] \times 100\%}{RW + RC + LW + LC}$
Directional preponderance (values unlimited)	=	$\frac{[(RW + LC) - (LW + RC)] \times 100\%}{RW + RC + LW + LC}$

RW = right warm; RC = right cool; LW = left warm; LC = left cool.

the plane of the tympanic membrane on each side. These both deal with the establishment of equivalent temperature gradients for stimulating the horizontal semicircular canals. If the first assumption is violated secondary to congenital or acquired processes, the test can still be performed, but the responses, right versus left, cannot be compared. The results can be used to indicate the presence or absence of a response. There are other protocols for calorics that will not be covered in this chapter; however, one in particular, the Torok Monothermal Caloric test, was developed to use data from only one ear irrigation at a time and not via a comparison.[39]

Since the peripheral part of the vestibular system functions across a frequency range, it is reasonable to question what portion of that range a caloric response occupies. The equivalent angular acceleration response falls in the lower-frequency range of response of the system (0.002 to 0.004 Hz). Therefore, absence of a caloric response to warm, cool, or ice water irrigations cannot be taken as an indication of complete lack of function. Testing by rotational chair is the tool needed to help define the true extent of bilateral lesions of the peripheral part of the vestibular system. In addition to the bilateral issue, the frequency response effect for the caloric test allows for a peripheral lesion to be present, yet not affect the caloric, but result in abnormalities on other tests such as the rotational chair (see below) or head on body rotation testing.[24]

Rotational Chair Testing

Rotational chair testing has been used to expand the evaluation of the peripheral part of the vestibular system. As with the ENG findings, the rotational chair evaluation can assist in site-of-lesion determination, counseling the patient, and confirmation of clinical suspicion of diagnosis and lesion site but is not likely to alter or impact significantly the course of patient management, excepting the patient with bilateral peripheral weakness.

The review of 2,266 patients was used to investigate the clinical utility of rotary chair testing in the evaluation of the peripheral part of the vestibular system. Among this group of patients, 16% had completely normal ENG studies. Among those with normal ENG results, rotational chair testing indicated abnormalities suggesting possible pathology in the peripheral part of the system in 80% of the cases. In all cases of bilateral caloric weakness, the chair findings help confirm the bilateral reduction in function of the peripheral part of the system. The test further defines the extent of the bilateral lesions. This additional information plays an important role in designing a vestibular rehabilitation program for these patients. It is the patient with bilateral lesions for whom rotational chair testing can make a direct impact on the management course in a rehabilitation program. There are also patients who for reasons other than vestibular dysfunction have mildly reduced caloric responses. Of these patients, the majority have normal rotational chair responses, suggesting that indication of bilateral paresis was a false-positive finding or that the extent of the bilateral lesions is mild and restricted to only the low-frequency range of function. Rotational chair testing is the only tool currently available for defining the extent of suspected bilateral peripheral lesions.

Patients diagnosed by clinical presentation and hearing test results, independent of balance function test results, with Meniere's disease, labyrinthitis, or vestibular neuritis numbered 311 during the period of this study.[14] Of this group, ENG was abnormal in 90%, suggesting a test sensitivity of this value. Rotary chair testing had a sensitivity suggesting involvement of the peripheral part of the system of only 66%. However, it is important to note that the

66% of patients identified by chair testing did not completely overlap with those identified by ENG as the combination of ENG and chair had a sensitivity of 100% in this group. Since there is no objective gold standard for identification of balance system lesions, there is currently no way to develop specificity figures, that is, the percentage of patients who do not have peripheral or central abnormalities who will have normal test results. Nor is there a good means for developing accurate sensitivity figures. Therefore, as with the discussion of oculomotor performance, the above group of 311 patients were well advanced in their respective disorders, and, clearly, the use of ENG and rotary chair testing together does not have a 100% sensitivity. A better estimate would be in the 80% range based on clinical diagnosis breakdown of the 2,266 patients.

From the above discussion, there appears to be good support for obtaining, in a subgroup of patients, the adjunctive information available from total-body, low-frequency rotary chair testing in the investigation of function of the peripheral part of the vestibular system. It is in this vein that the criteria for use of the rotational chair, discussed above, were developed.

As with the ENG test, the protocols for rotational chair testing are not new, and some have been used for well over a century. When considering the use of the chair protocols, it is important to remember that the sides of the peripheral part of the vestibular system have a "push-pull" arrangement, such that if one side is stimulated with angular acceleration, the opposite side is inhibited in its neural activity. Therefore, the chair is not a tool that can be easily used to isolate one side of the peripheral part of the system from the other for evaluation as each stimulus affects both sides simultaneously.

As with the ENG, electro-oculography or video-oculography can be used to monitor and record the outcome measure of interest, jerk nystagmus, which is generated in response to the angular acceleration stimulus. The VOR is the slow component of the jerk nystagmus and, as with ENG, is the portion of the eye movement for which velocity is calculated for analysis.

It must be remembered that with total-body rotational testing, the stimulus is being delivered to the head via movement of the whole body. Thus, the head must be secured to the chair with a restraint system (Figure 6–12). To make analysis as simple as possible, it is assumed that whenever the chair moves, the head is also making the same movement. Because of the potential for movement of the skin relative to the skull, this assumption becomes increasingly faulty at frequencies of 1 Hz or greater. Because of this, most commercial and clinical research systems have restricted test frequencies to 1 Hz or less. Shown in Figure 6–12 is a generic chair system, consisting of a chair on a computer-controlled electric torque motor. The head is held firmly to the chair, and the system is in an enclosure to allow testing in darkness with the eyes open. Means for providing visual stimuli, such as an optokinetic stimulus, are usual.

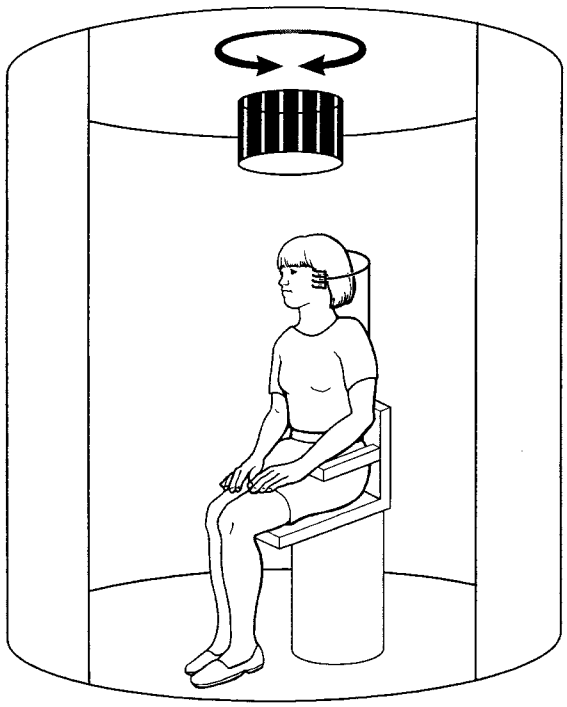

FIGURE 6–12. Generic rotational chair setup. The chair is on a computer-controlled motor within an enclosure and can be rotated in either direction. A device for holding the head to the chair is shown. A means for producing optokinetic stimulation is shown as the drum in the ceiling. Reproduced with permission from Shepard NT and Telian SA.[14]

Sinusoidal Rotation Typically, starting with the lower frequencies, the chair is moved with sinusoidal waveforms at a specific frequency from 0.01 to 1.28 Hz. Signal averaging is used to improve the signal-to-noise ratio and thereby improve the reliabil-

ity and validity of the analysis. Multiple cycles of a given frequency are delivered, producing repetitive to-and-fro movement of the chair in a sinusoidal harmonic acceleration paradigm. The slow-component eye velocity response from each cycle of stimulation is added to subsequent responses and divided by the number of cycles used, providing an average response for the test frequency. The frequency is then changed, and the process is repeated. Ideally, the more cycles that can be averaged, the more reliable the signal. Pragmatically, the number of cycles needs to be considered in light of the period (length of time for a single cycle) of the stimulus. As the period at 0.01 Hz is 100 seconds, to do more than three cycles becomes prohibitive. Unfortunately, the very low frequencies (less than 0.08 Hz) produce the weakest response from the VOR system and therefore have the poorest signal-to-noise ratio. In general, the very low frequencies are also most likely to produce unpleasant neurovegetative symptoms such as nausea and vomiting. The frequencies from 0.16 Hz and above can be completed quickly, allowing responses from as many as 10 cycles to be averaged. For all frequencies tested, the peak chair velocity is typically fixed at 50 to 60 degrees/second. Therefore, as the frequency is increased, the subject experiences increasing acceleration with decreasing excursion of the chair.

Three parameters are measured during rotational chair testing to characterize the function of the VOR and thereby evaluate the function of the peripheral part of the vestibular system. These parameters are phase, gain, and asymmetry. Figure 6–13 shows a schematized version of an averaged slow-component velocity response from multiple cycles of stimulation at a single frequency. The chair velocity is also shown, which correlates to head velocity, assuming that the head is properly stabilized. The parameters that characterize VOR function are developed by comparing the slow-component eye velocity profile to the head velocity profile.

Phase. This parameter of the VOR is the least intuitive of the three but has the greatest clinical significance owing to its ability to document dysfunction of the peripheral part of the system. Phase measurements objectify the timing relationship between head movement and reflex eye movement. Figure 6–13 illustrates findings expected from a normally functioning VOR system at test frequencies below

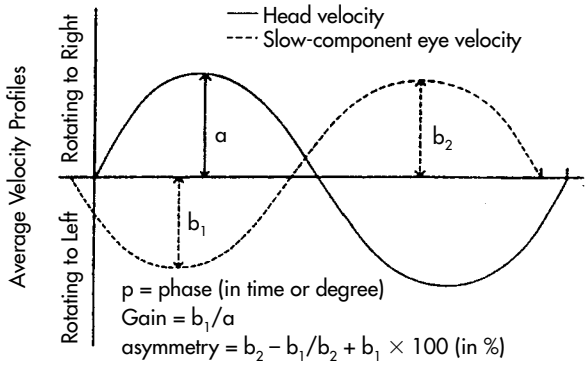

FIGURE 6–13. Averaged head and eye velocity plotted as a function of time or degrees is shown with indications for the development of the three parameters used to characterize performance with chair stimulation by sinusoids. b_1 = the maximum excursion of the slow-component eye velocity trace for rotating to the right; a = the maximum excursion of the head velocity trace for rotating to the right; b_2 = the maximum excursion of the slow-component eye velocity trace for rotating to the left. Reproduced with permission from Shepard NT and Telian SA.[14]

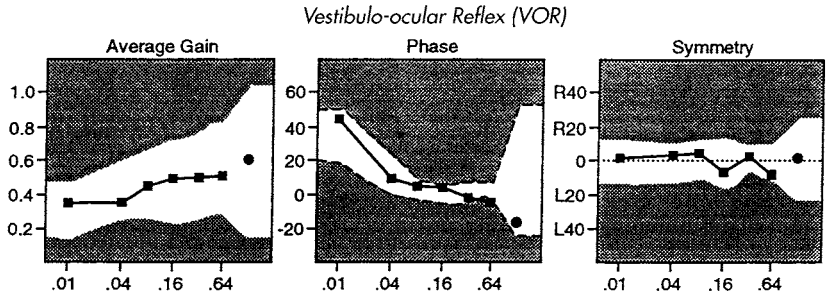
0.08 Hz. Under these circumstances, the compensatory eye movements can lead the head movement, as shown in Figure 6–13. The amount of this phase lead is called the phase angle and is typically measured in degrees. The center panel of Figure 6–14 shows a plot of phase angle versus frequency of rotation in a patient with normal rotary chair findings. The phase results can be used to calculate the system time constant from any frequency tested; however, assumptions can be applied that significantly simplify the calculations if the frequencies are restricted to 0.04 Hz and below.[17] In general, in this restricted frequency range, the relationship between phase angle and time constant is an inverse proportion. As phase angle increases, time constant decreases. In general, phase angle and its complement time constant should be thought of as a measure of the timing relationship of head and eye movement and are parameters that have specific values indicating normal VOR functioning.[17,40]

As seen in the center panel of Figure 6–14, the normal range for phase (based on two standard deviations above and below the mean) is indicated by the clear area. An increase in the phase lead outside this range implies an abnormally low time constant. From experimental studies of the velocity



Freq. Hz	Vel. d/s	Gain	Phase deg.	Symmet.%
■0.010	60	0.35	45	R 2.4

FIGURE 6–14. Normal rotary chair results from a patient. The plot on the left shows gain (eye velocity divided by head velocity) as a function of frequency of chair sinusoidal stimulation. The center plot shows phase angle in degrees as a function of frequency, and the plot to the right gives symmetry data in percent as a function of frequency. The *shaded areas* represent abnormality, and the individual values for gain, phase, and symmetry are given in the table at the bottom of the figure. Normal ranges are two standard deviations above the mean. Reproduced with permission from Shepard NT and Telian SA.[14]

storage integrator (vestibular nucleus region) that regulates the VOR system time constant, we know that damage to the labyrinth or the vestibular portion of the eighth cranial nerve causes a decrease in the time constant. Hence, increased phase lead, implying an abnormally low time constant, strongly suggests pathology in the peripheral part of the system. Caution in this interpretation must be used as other sources for the increased phase lead can result from damage in the vestibular nuclei within the brainstem and possible influence of migraine headache conditions. Therefore, other clinical information is needed to help localize the lesion to the labyrinth or eighth nerve. The significance of an abnormally low phase lead (abnormally high time constant) can suggest a lesion in the nodulus region of the cerebellum, an area that influences the velocity storage integrator in the brainstem.[41]

Gain The second parameter of the VOR measured in rotary chair testing is gain (eye velocity divided by head velocity) (see Figure 6–13). Gain measures give an indication of the overall responsiveness of the system. Unilateral peripheral weaknesses can cause a mild reduction in gain, especially at the lowest frequencies. However, the principal clinical use of gain measures is to define the extent of a bilateral reduction in responsiveness of the peripheral part of the system when using the sinusoidal protocol. The gain value helps verify that severely reduced or absent responses to caloric irrigations accurately reflect a bilateral weakness and did not result from an artifact of alertness or some other test pitfall. Figure 6–14 (left panel) shows normal results for gain as a function of the sinusoidal frequency of the stimulation.

Asymmetry In Figure 6–13, the schematic representation of asymmetry involves a comparison between the slow-component eye velocity to the right (positive values) compared with the left (negative values). It is important to recognize that these values are calculated and named by the direction of the eye movement that is produced by the VOR, that is, the slow component of the nystagmus. The situation is reversed when discussing directional preponderance from caloric irrigations. Directional preponderance values are calculated by slow-component velocity but, by convention, are named by the direction of the fast component of the nystagmus. Therefore, a patient who exhibits a right-beating directional preponderance (left slow-component velocity greater than right slow-component velocity) may show a left

greater than right asymmetry on rotational chair testing, indicating that during chair testing, left slow-component velocity was greater than right slow-component velocity, consistent with the directional preponderance. Directional preponderance and asymmetry from chair testing will not always both be abnormal. Both directional preponderance (caloric testing) and asymmetry (rotary chair testing) give an indication of bias within the system, favoring larger slow-component velocities in one direction versus the other. A bias usually results from a peripheral lesion with incomplete dynamic compensation in the central nervous system. Less commonly, it may indicate the presence of an uncompensated lesion in the central pathways. Whenever a VOR asymmetry is noted on rotary chair testing, the finding may be attributed to abnormalities in either peripheral part of the system: either a peripheral weakness on the side of the stronger slow-component velocity response or an irritative lesion on the opposite side. For example, a patient with an uncompensated right peripheral weakness will generally demonstrate a right greater than left slow-component velocity asymmetry. This is owing to an ability to produce a greater rightward compensatory eye movement when rotated toward the intact left side and a less intense leftward compensatory eye movement response produced after rotation toward the weaker right side. Figure 6–14 (right panel) shows a normal result for the asymmetry measurement.

Step Test This protocol is performed, as in the sinusoidal case, with the test booth in total darkness. A fixed chair velocity between 60 and 40 degrees/second is achieved by applying an acceleration impulse with a magnitude near 100 degrees/second^2. Once the desired velocity is reached, the acceleration is returned to 0 degrees/second^2, and the patient continues at the desired velocity. The VOR response to the initial acceleration stimulus is known as per-rotary nystagmus. The slow-component velocity intensity decays over time if the chair velocity is constant, and the subject falsely perceives that the chair is slowing down. The decay in slow-component eye velocity over time can be used to estimate the system's time constant, as discussed above. Use of a constant-velocity step protocol of 60 to 100 degrees/second works best to calculate the time constant. After 45 to 60 seconds of fixed-velocity rotation, a second impulse is applied to the chair. This is a deceleration step, usually of equal magnitude to the initial acceleration, bringing the chair to a rapid stop. Although the chair is now stationary, the subject will perceive motion in the opposite direction. The VOR response will produce nystagmus beating in the direction opposite to that produced by the initial acceleration, known as postrotary nystagmus. The decay of the slow-component eye velocity over time should be similar to that seen after the acceleration impulse, and, ideally, both should give similar estimates of the system's time constant. The entire procedure is then repeated with the initial rotation in the opposite direction. If a constant velocity of 180 to 240 degrees/second is used, the time constant calculation is not as accurate; however, differences in gain for acceleration to the right versus the left are made apparent in this manner, helping to identify a periphery with a weaker response.

The results are heavily influenced by the noise in both the recording and physiologic systems and the arousal of the patient prior to the acceleration as averaging is not used in this paradigm. As a result, there will be patients for whom the estimates of time constant from this protocol may not agree with estimates from the sinusoidal protocol. Given that both the step test and the sinusoidal acceleration tests are influenced by the noise issue, the two can be employed in parallel to increase the accuracy of estimates of the system time constant and identification of which periphery, if any, is functioning in an abnormal manner.[8,17,40,42,43]

Postural Control Assessment

Just as all patients who are being evaluated in the laboratory need tests for peripheral and central vestibulo-ocular pathway involvement, they also require some assessment of postural control ability. However, just as in the use of ENG and rotational chair testing, not all patients would need high-technology, formal postural control assessment. There are several different general approaches to formal postural control testing, each with specific technical equipment requirements and goals for the testing.[10,14,44] To reduce the scope of this discussion, comments will be restricted to the most common formal assessment tool used in the United States, CDP as formulated in the EquiTest® equipment (NeuroCom International, Inc., Clackamus, OR).[45–48] Briefly, the equipment detects vertical and horizontal forces

from the feet by two independent force plates on which the subject stands. The force plates can be made to translate forward or backward and rotate toes up or down to provoke movement of the subject's center of mass. The rotation movements can also be stimulated by the subject's own movements to create information from the ankle that is inaccurate. The visual surround can also be made to move stimulated by the subject's movements or independent of subject activity. Two principal testing protocols (discussed below) are used in patient evaluation: the Sensory Organization Test (SOT), using patient-stimulated floor and visual surround movements, and MCT using the translation and rotations of the support surface to cause subject movements. As with rotational chair testing, not all patients need to have full formal CDP. Suggested criteria as to when the use of full CDP would be most clinically revealing were presented in the introductory discussion above.

The survey of 2,266 patients with consecutive balance disorder, introduced in the ENG and rotational chair discussions, can again be used to assess the percentage of patients with abnormalities on CDP (EquiTest) and to study the types of patients most likely to have abnormal posturography results. In general, when all patients with indications of involvement of the peripheral part of the system are considered, only 30 to 35% show abnormalities on formal CDP. However, there was a group of 4 to 5% of this total population of 2,266 patients for whom CDP was the only abnormal finding across all of the ENG and rotational chair tests. This group was primarily over 65 years of age, with the chief complaint of unsteadiness with standing and walking. These patients had no complaints when sitting or lying and no perceptions of vertigo or other abnormal movements. These statistics played a principal role in the development of the above discussed criteria for when to proceed for full CDP. The protocols for EquiTest assess various aspects of quiet and dynamic postural control abilities. Although certain aspects of postural control are prerequisites for gait activities and certain abnormalities of postural control may cause problems in ambulation, posturography cannot be used in isolation to evaluate gait deficits. Gait evaluation has its own complete set of parameters that must be tested under a completely different set of conditions.

Sensory Organization Test Briefly, the SOT measures the ability to perform volitional, quiet stance during a series of six specific conditions (Figure 6–15). The first three provide for uninterrupted, accurate foot support surface information on a surface with adequate friction that is larger than the foot size. In condition 1, the eyes are open, whereas in condition 2, the eyes are closed. Under condition 3, the visual surround moves in a pattern that is stimulated by the anterior/posterior sway movements of the patient. Conditions 1 and 2 are a modified Romberg's test (a qualitative clinical test of patient stability when standing with feet together, arms folded, and eyes opened or closed) as the feet are at their normal separation rather than close together. Condition 3 presents a situation of visual conflict, for which visually accurate information is provided but of no significant help in maintaining quiet stance. Condition 3 presents misleading optokinetic and foveal visual cues about the position of the body in space. Conditions 4, 5, and 6 use the same sequence of the three visual conditions but with the foot support surface giving misleading information. As with the movement of the visual surround in condition 3, when testing under conditions 4, 5, and 6, sway movements of the patient in the sagittal (anterior/ posterior) plane drive the movement of the support surface in a rotational manner about an axis parallel to the ankle joint. In this way, somatosensory and proprioceptive information is not removed in conditions 4, 5, and 6 but is of limited use in maintaining upright stance. These conditions provide a disrupted relationship between body position and the ankle angle (that angle made between the upper surface of the foot and the anterior portion of the lower leg). Typically, after the simpler conditions 1 and 2, three trials are given for each of the more challenging conditions. The average performance is taken as representative of the patient's postural control ability under that sensory condition.

The equilibrium score is a percentage representing the magnitude of sway in the sagittal (pitch) plane for each trial of each condition. Details of how this score is obtained will not be repeated here.[48] However, it is important to realize that this score is based on a normal value of 12.5 degrees of anterior/posterior sway about the ankle joint, typically 8 degrees forward and 4.5 degrees backward. It is assumed that this range of sway is available to patients during the test. Some patients may not have this normal range because of physical restrictions at the ankle, or, because of limits of sway, patients have adopted secondary strategies owing to their sense of

SENSORY ORGANIZATION PROTOCOL

Condition	Vision	Support	Patient Instructions
1 	Normal	Fixed	Stand quietly with your eyes OPEN
2 	Absent	Fixed	Stand quietly with your eyes CLOSED
3 	Sway Ref	Fixed	Stand quietly with your eyes OPEN
4 	Normal	Sway Ref	Stand quietly with your eyes OPEN
5 	Absent	Sway Ref	Stand quietly with your eyes CLOSED
6 	Sway Ref	Sway Ref	Stand quietly with your eyes OPEN

FIGURE 6–15. The six sensory organization test conditions, showing which sensory input cues are available or accurate for each condition. Reproduced with permission from NeuroCom International, Inc., Clackamus, OR.

imbalance and fear of a potential fall. It is important to recognize the patient who has a reduction in limits of sway. If the limits of sway are reduced more than 50%, the interpretation of the patient's results may be inaccurate.[14] Figure 6–16 (top panel) is an example of the graphic representation of these results in a patient with normal CDP findings.

As with the overall balance system evaluation, this study is also interpreted using pattern recognition. The combinations of the six conditions that are abnormal are used to define a pattern of abnormality that can then be functionally interpreted. Table 6–3 presents the most common patterns and the related nomenclature.

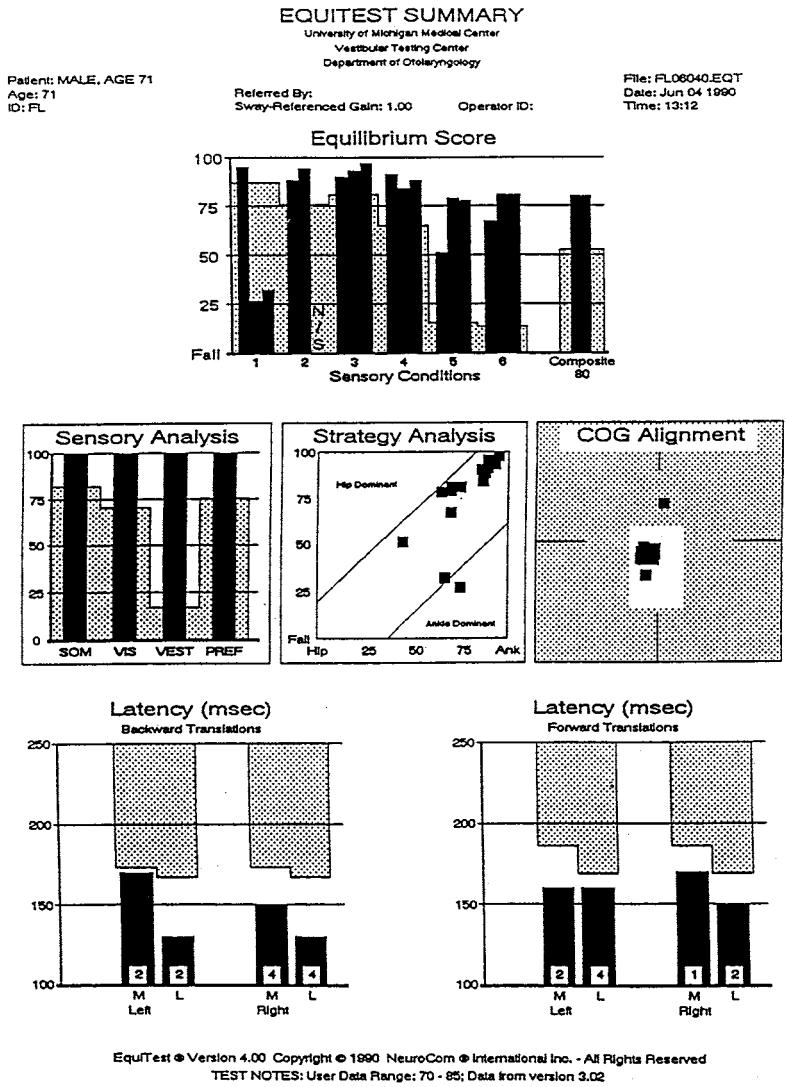

FIGURE 6–16. Results of dynamic posturography testing in a patient with all results interpreted as normal. The bar graph at the top plots a percentage equilibrium score for each of the six sensory organization test conditions (see Figure 6–15). A score of 100 indicates no sway in the sagittal plane, with "Fall" indicating that sway reached a magnitude equal to the theoretical limits of sway for the patient in the sagittal plane. The composite graph is the numeric average of the scores from the six conditions. The left panel of the center three shows a ratio analysis of the six conditions relative to four of the most frequent abnormal patterns. SOM = somatosensory dysfunction; VIS = visual dysfunction (typically combined with vestibular dysfunction); VEST = vestibular dysfunction; PREF = visual preference pattern. See the text for a discussion of these and other patterns. The middle panel in the center row plots a measure of horizontal shear force (an indication of body segment movement strategy) on the abscissa against the equilibrium scores on the ordinate for each of the six test conditions. The right panel of the center row shows a measure of alignment of the center of gravity (COG) in the sagittal and lateral planes for each of the six conditions tested. The bar graphs in the bottom row (from movement coordination portion of the testing) plot latency to onset of active recovery to induced forward sway (left graph) and induced backward sway (right graph). The latencies are given in milliseconds for left and right leg for two sizes of platform translations. See the text for interpretation of these results. Handbook of audiology. 4th ed. Baltimore: Lippincott Williams & Wilkins; 1994.

TABLE 6–3. Common Patterns of Abnormal Performance on the Sensory Organization Test

- Vestibular dysfunction pattern: abnormal on conditions 5 and 6 (alternatively condition 5 alone).
  Vestibular dysfunction pattern indicates the patient's difficulty in using vestibular information alone for maintenance of stance. When provided with accurate visual and/or foot somatosensory information, stance is within a normal range.
- Visual and vestibular dysfunction pattern: abnormal on conditions 4, 5, and 6.
  Visual and vestibular dysfunction pattern indicates the patient's difficulty in using accurate visual information with vestibular information or vestibular information alone for maintenance of stance. When provided with accurate foot support surface cues, stance is within a normal range.
- Visual preference pattern: abnormal on conditions 3 and 6 (alternatively condition 6 alone).
  Visual preference pattern indicates the patient's abnormal reliance on visual information, even when inaccurate. When provided with accurate foot support surface information together with accurate or absent visual cues, or absent vision and vestibular information alone, stance is within a normal range.
- Visual preference and vestibular dysfunction pattern: abnormal on conditions 3, 5, and 6.
  Visual preference and vestibular dysfunction pattern indicates the patient's difficulty in using vestibular information alone and the patient's abnormal reliance on visual information, even when inaccurate. When provided with accurate foot support surface information together with accurate or absent visual cues, stance is within a normal range.
- Somatosensory and vestibular dysfunction pattern: abnormal on conditions 2, 3, 5, and 6.
  Somatosensory and vestibular dysfunction pattern indicates the patient's difficulty in using foot support surface information with vestibular information or vestibular information alone for maintenance of stance. When provided with accurate visual information, stance is within a normal range.
- Severe dysfunction pattern: abnormal on four or more conditions not covered in the above descriptions, for example, 3, 4, 5, and 6; 2, 3, 4, 5, and 6; or 1, 2, 3, 4, 5, and 6.
  Severe dysfunction pattern indicates the patient's difficulty with stance independent of the sensory information (vestibular, visual, and/or somatosensory) provided. Note that these situations often involve a dominant feature such as significantly abnormal conditions 5 and 6, or they may involve equally distributed difficulties on all conditions affected.
- Inconsistent pattern: abnormal on conditions 1, 2, 3, 4, or any combination and normal on conditions 5 and 6.
  Inconsistent pattern indicates that performance of the patient is difficult to explain with normal or typical pathophysiologic conditions and could imply volitional or nonvolitional exaggerated results.

By far the most common pattern is the vestibular dysfunction pattern, comprising approximately 45% of all abnormalities on this test in our facility. The most important aspect of interpretation for the SOT is that it provides information as to which input system cues the patient is unable to use for performing the task of maintaining postural control. In other words, it provides a relative measure of the patient's ability to use the sensory input cues of vision, vestibular, and proprioceptive/somatosensory to maintain quiet upright stance. The test does *not* provide relative information as to which of the sensory systems has lesions, causing postural control abnormalities. Therefore, the SOT of CDP provides no site-of-lesion information; it is strictly a test of functional ability. The test in no way implies that there is a central or peripheral vestibular system lesion, nor does it imply central or peripheral pathway lesions in the visual or somatosensory/proprioceptive systems. The information should be interpreted only to reflect which input information the patient is able (or, conversely, unable) to use for the task at hand.

Dynamic posturography is useful for identification of patients who may be, for whatever reason, exaggerating their condition. Recent work by several

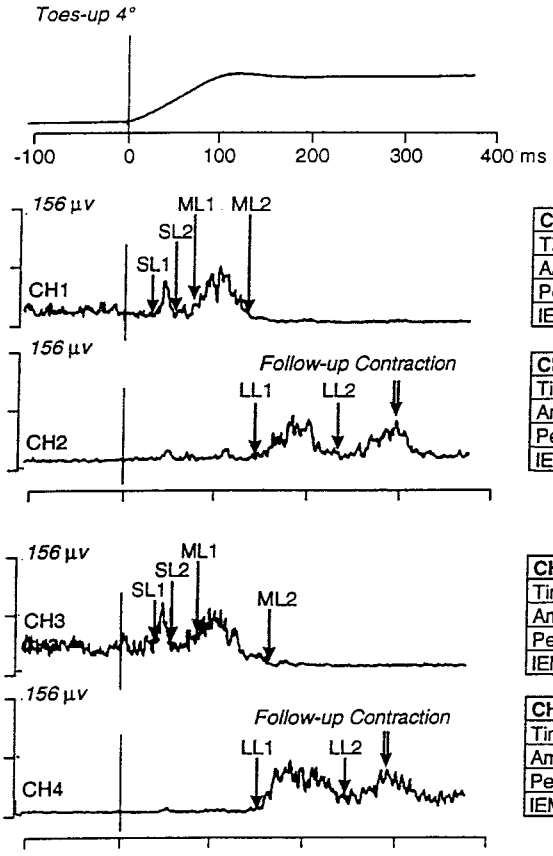
investigators (not all with EquiTest) has attempted to quantify the use of this tool to identify these patients and list qualitative factors that would raise questions in this dimension.[49–51]

Motor Control Test Information about the ability to react to unexpected perturbations in the subject's center of mass position is obtained with the MCT. The center of mass perturbations is created by abrupt anterior or posterior horizontal translations of the support surface. Typically, three increasingly large translations in both directions are administered. The increasing size of the translation creates a stimulus intensity series. The profile of the surface movement is varied for each patient based on height so that all translations are normalized to a 6-foot-tall person.[48] This allows for direct comparison of results across patients. After the three posterior and the three anterior translations, unexpected rotations about the ankle are used. Contrary to the horizontal translations, the typical muscle response that is mapped to the stimulus provoked by rotary stimuli is destabilizing. The patient must then be able to adapt to the new stimulus on repeated trials. Five randomly timed toes-up or toes-down rotations provide relative information about the patient's ability to adapt to this familiar but destabilizing stimulus. For this protocol, as with the SOT, floor reaction force detected by the force plates in the support surface is measured. The principal output parameter is the latency to onset of active recovery from the unexpected translations (see Figure 6–16, bottom panels). Other information obtained from the protocol includes weight distribution onto right or left leg and a relative measure of strength as a function of the size of the perturbation.[48]

This study is used less as a functional evaluation than the SOT and more to evaluate the long-loop neural pathway. This pathway begins with inputs from the ankle, knee, and hip regions (tendon and muscle stretch receptors) and projects to the motor cortex and back to the various muscles of postural control, including upper and lower body. When an abnormal latency to onset of active recovery from induced sway is noted, then problems in the long-loop pathway should be considered. The explanation may be as simple as ongoing joint or back pain, a congenital condition of the back or lower limbs, or an acquired lesion involving the neural pathways of the afferent or efferent tracts. Therefore, abnormalities of the movement coordination test, related to latency, are nonspecific indicators of potential problems in the long tracts or the musculoskeletal system needed to coordinate recovery from unexpectedly induced sway in the sagittal plane. Other abnormalities from this portion of the testing include inappropriate weight bearing or an inability to scale properly the strength of the response to the increasing size of the perturbations. Such findings may provide information that helps explain the patient's complaints of dysequilibrium. These abnormalities are unlikely to directly implicate involvement of the neural pathways if the latency findings are normal. In many cases, the weight shift or scaling problems may be maladaptive behaviors developed in response to the initial symptoms of the vestibular disorder.[9]

Postural Evoked Responses Postural evoked responses are used to define patterns of muscle response that have been associated with specific lesion sites and dieases. Muscle activity from the distal lower extremities is stimulated by sudden toe-up rotations of the support surface (the force plate platform of EquiTest). The muscle activity stimulated by this dorsiflexion movement at the ankle is recorded with surface EMG electrodes.[47,52] The responses from the medial gastrocnemius and the anterior tibialis are recorded. To improve the signal-to-noise ratio of the evoked EMG activity, the rotation is repeated, with random, interstimulus intervals, and the EMG responses are rectified and averaged over 15 to 20 responses. This allows for clearer identification of onset and offset times of muscle contraction following the stimulus. There are three specific responses obtained, as illustrated in Figure 6–17. The short and medium latency responses from the contraction of the gastrocnemius are shown in traces from channels 1 and 3 of Figure 6–17. The third response is the long latency obtained from the contraction of the anterior tibialis, shown in channels 2 and 4 of Figure 6–17.

The EMG patterns for contraction from the gastrocnemius and the anterior tibialis muscles are compared with those that have been associated with specific pathologies, such as multiple sclerosis, Parkinson's disease, or other neurologic lesions. Patterns have been described for lesions in the anterior cerebellum and the basal ganglia, as well as for spinal cord compression. When the contraction pattern is



CH1	SL1	SL2	ML1	ML2
Time (ms)	38	56	79	143

IEMG (mvS)	3.9	

FIGURE 6–17. Postural evoked response results for a normal subject. The plot at the top shows the position profile of the rotation of the surface the subject is standing on as a function of time. Deflection upward indicates toe-up rotation. The four plots on the left give the averaged, rectified surface electromyographic responses in amplitude of contraction (in microvolts) as a function of time. Channels 1 and 3 (CH1 and 3) are results from the left and right gastrocnemius muscles, respectively. Channels 2 and 4 (CH2 and 4) are the results from the left and right anterior tibialis muscles, respectively. The short (SL), medium (ML), and long latency (LL) responses are indicated at onset with a number 1 and offset with a 2. The tables at the right give the numeric values for each response, indicating onset and offset times and amplitudes, peak amplitude contraction, and integrated amplitude (IEMG). Reproduced with permission from Shepard NT and Telian SA.[14]

unrecognized, the interpretation is based on knowledge of the underlying neural pathways considered responsible for the specific muscle activity. In general, these involve mediation of the short latency response via the spinal cord (H-reflex). The medium latency response is primarily controlled via the spinal cord, with amplitude size determined by the brainstem and basal ganglia. The functional stretch reflex, the long latency response, involves brainstem and cortical activity. Defined patterns of muscle response have been associated with specific lesion sites and disease classifications.[53] Normative results for the paradigm have been developed across age and have been shown to have sensitivity and specificity of 68% and 87%, respectively, for identifying the specific disease entities reflected by the defined patterns of abnormal responses.[9,52] As with the MCT, the EMG evaluation does not distinguish afferent from efferent disruptions that may underlie the abnormal muscle responses. With additional clinical investigations of sensitivity in the lower limbs and/or the use of lower limb somatosensory evoked

responses, pathology affecting sensory input may be distinguished from motor output abnormalities.

The CDP tests described above can provide data ranging from purely functional information to that of specific site-of-lesion, postural control pathways by changing the protocol and the output parameters. Therefore, for the patient with a classic peripheral vestibular lesion, the utility of CDP lies in the use of SOT for functional information related to functional dimensions of compensation not available from the extent- and site-of-lesion studies of ENG and the rotary chair. For the patient with a less well-defined lesion site or evidence of central nervous system involvement, the functional information is then supplemented with data that approach a more specific evaluation of the central and peripheral postural control pathways. Additionally, CDP can serve to help in the design and monitoring of vestibular and balance rehabilitation programs, primarily the SOT protocol with the emphasis on functional performance.

OFFICE "BEDSIDE" EVALUATIONS OF THE BALANCE SYSTEM

A variety of test procedures may be used in the office setting to assess the patient with balance disorder. These, like the laboratory studies, assist in the identification of the extent and site of the lesion. These straightforward clinical tests are essentially variations of the related laboratory studies but have less ability to quantify the outcomes. The theoretical basis behind many of these tests is well founded on physiologic considerations (please see Chapter 4). Owing to the subjective nature of these tools, the validity and reliability of these tests are reduced compared to the formal laboratory studies. Unfortunately, little clinical research exists to define the sensitivity/specificity and test reliability for these procedures.[6,14,17,18,26,54,55]

The bedside vestibular and balance evaluation is presented in Chapter 20. In the majority of patients, this evaluation produces the same impressions as the extensive laboratory studies discussed above. These tools are, however, not as sensitive to mild anomalies as the laboratory studies. It is also important that the bedside chair study and the modified CTSIB study of balance[14] be used with the ENG to expand the laboratory investigation when formal equipment such as the rotational chair and posturography are not readily available.

OTHER INVESTIGATIVE MODALITIES

A discussion of the investigation of patients with dizziness and balance disorders would not be complete without a brief description of use of neuroradiographic techniques and serologic studies and when the pursuit of psychological issues may be useful.

Psychological Disorders

Patients with dizziness often have psychological symptoms such as anxiety or depression. From a diagnostic standpoint, psychiatric disorders may be the sole cause of dizziness, but just as often they co-occur with neurotologic illnesses. Therefore, no specific characteristics of dizziness itself are pathognomonic of a psychiatric cause. Rather, the following associated features suggest that a psychiatric illness may be present, with or without vestibular pathology: (1) illusions of movement that are more prominent than true vertigo (typically a rocking or swaying), (2) functional impairment out of proportion to objective medical findings, (3) autonomic symptoms during bouts of dizziness (palpitations, chest pain, dyspnea, tremulousness, paresthesias), (4) changes in sleep or appetite, (5) excessive worry about dizziness, and (6) avoidance of situations associated with dizziness.[3] A recent investigation found that a brief psychological screening questionnaire, the BSI-53, was a useful adjunct to the neurotologic examination for detecting psychiatric disorders in patients with dizziness.[56] Recognition of any of the above features with a clinical impression of anxiety or depression would be sufficient to suggest further investigation by a psychiatrist or psychologist. This should be a professional with whom prior standing arrangements have been established since an understanding of the general area of balance and dizziness disorders is needed to evaluate appropriately the potential impact of a psychological component to the patient's complaints.

Neuroradiographics

The use of MRI, magnetic resonance angiography (MRA), and computed tomography (CT) scans is widespread. The following discussion focuses on when each of the studies would be of utility. Below are the bedside (office examination) signs that would warrant a referral for MRI as each of these is an indicator of possible central nervous system involvement. Some of these same findings are also appreciated on an ENG study. The most prominent

central indicator is that of pure vertical nystagmus (especially when noted with fixation present) or a pure torsional nystagmus with fixation removed.

Additional signs are as follows:

- direction-changing nystagmus in a given head position
- sustained or nonfatiguing positional nystagmus
- dissociated (disconjugate) eye movements most easily noted with saccade testing
- saccadic disruptions to smooth pursuit
- direction-changing gaze-evoked nystagmus
- abnormal posture when seated, inability to stand
- focal motor deficit
- dysarthria, dysphagia, diplopia, dysmetria (limb ataxia)
- Horner's syndrome (sympathetic paresis of the pupil, with unilateral failure to dilate in darkness and ptosis)
- loss of pinprick or temperature sensation on one side of the face and/or on the other side of the body
- intractable hiccups
- hyperventilation-induced nystagmus
- hemifacial or hemibody sensory or motor deficit
- visual inversion (90- to 180-degree reversals of the visual scene, "floor on the ceiling"), drop attacks, visual loss, and/or confusion

There are signs with acute-onset vertigo that should trigger an emergent imaging study. A diffusion-weighted MRI is the preferred technique over CT if it can be obtained within hours of the onset of symptoms. Cerebellar infarcts may mimic peripheral vestibular paresis. These may become hemorrhagic, and swelling during the first few days after the stroke can cause brainstem herniation and death. The signs that necessitate a scan are the following:

- unilateral or asymmetric hearing loss
- brainstem or cerebellar symptoms other than vertigo, most commonly vertical nystagmus, nystagmus not suppressed with fixation, and/or inability to stand unassisted (cerebellar infarctions are usually cardioembolic)
- stroke risk factors (diabetes, hypertension, tobacco use, history of myocardial infarct)
- acute onset associated with neck pain (suggestive of a vertebral artery dissection)
- direction-changing spontaneous nystagmus
- new-onset severe headache

Patients with a history of brainstem or cerebellar symptoms mentioned above lasting from typically 5 to 60 minutes may be having posterior circulation (vertebrobasilar) transient ischemic attacks. This is an indication for the use of MRA to rule out stenosis of the vertebral or basilar arteries. Magnetic resonance angiography can evaluate both intracranial and cervical vessels. Transcranial Doppler studies can be performed on the intracranial circulation and provide evidence of stenosis by showing increased flow velocity. The direction of blood flow can also be determined: with proximal vertebral artery occlusion there can be retrograde blood flow from the basilar into a vertebral artery.

Computed tomography without contrast is the examination of choice for delineating the bony anatomy of the temporal bone. There are several indications for this study in patients with the primary complaint of dizziness. This type of scan may detect a perilabyrinthine fistula secondary to cholesteatoma. In primary lesions of the petrous apex that invade the labyrinth or internal auditory canal, this scan can be used both to aid in the diagnosis and to determine the extent of involvement of the temporal bone. Cholesterol granulomas and cholesteatomas of the petrous apex will appear as homogeneous lesions that gradually expand the margins of the bone.[57–60] Fibrous dysplasia will manifest as an osseous lesion with a heterogeneous, "ground glass" appearance on scan. Sarcomas, such as chondrosarcomas, will manifest as bulky, irregular, and destructive lesions that display a "popcorn" pattern of calcification. Metastases to the temporal bone will appear as irregular, destructive lesions.[60] The degree of bony invasion and destruction of glomus jugulare tumors can also be assessed by this scan. A suggestion of the presence of an acoustic neuroma may be made by the observation of asymmetric widening of the internal auditory canal. In younger patients, congenital osseous dysplasias of the inner ear can be detected by CT scan.[61] A further use of CT, but with very fine (0.1 to 0.5 mm) cuts, is in the detection of superior semicircular canal dehiscence that has been shown to result in a sound- and/or pressure-provoked vertigo. As with other uses of CT and MRI, there are clues in the history and presenting signs that would lead to a request for this specialized study.[62]

Computed tomography of the temporal bone with contrast is rarely indicated for the evaluation of dizziness. The addition of contrast does not improve

the visualization of cholesteatomas, cholesterol granulomas, or other cystic lesions of the temporal bone. In contrast, chondrosarcomas and metastatic lesions will enhance. This examination remains the evaluation of choice to rule out the presence of an acoustic neuroma in patients who cannot undergo MRI.

Of all of the radiologic evaluations available, MRI remains the most useful in evaluating the patient complaining of dizziness. It is the undisputed evaluation of choice to rule out the presence of acoustic neuromas or other neoplasms of the cerebellopontine angle.[63,64] When evaluating the petrous apex, it provides invaluable assistance in determining the specific type of cystic lesion present.[57–60] Cholesterol granulomas are bright on both T_1-weighted and T_2-weighted images and do not enhance. In contrast, epidermoids (cholesteatomas) are bright only on T_2-weighted scans. They are also the imaging study of choice for evaluation of tumors of the jugular foramen region.

The fast spin echo, T_2-weighted MRI scan has been suggested as a useful and economical examination to screen for the presence of acoustic neuromas.[65,66] Although its accuracy has been validated, it has not found universal acceptance. This form of scan is also a useful complement to the CT scan in patients with suspected inner ear dysplasias.

Serologic Studies

Serologic studies can be used for investigation of central disorders and peripheral neuropathy. A listing of the more common of these is given below:

- Vasculitic disorders: erythrocyte sedimentation rate (ESR), complement levels, rheumatoid factor, antineutrophil cytoplasmic antibodies (ANCA) (Wegener's granulomatosis, polyarteritis nodosa), cryoglobulinemia, hepatitis B antigenemia, eosinophilia, systemic lupus erythematosus (antinuclear antibody [ANA] and anti–disease-specific DNA), Sjögren's (autoantibodies SSA and SSB)
- Peripheral neuropathy owing to infectious, metabolic, or neoplastic conditions: rapid plasma reagin (RPR), human immunodeficiency virus, glucose, hemoglobin A_{1c} (diabetes), SPEP, vitamin B_{12} deficiency

When evaluating patients with peripheral neuropathy, one should consider in the history factors known to be toxic to peripheral nerves, such as B_6 overdose, metronidazole, or cisplatinum. Distal sensory loss may also be on the basis of lumbar or cervical spine disease.

In patients with hearing loss associated with true vertigo, serologic testing is usually indicated once a retrocochlear lesion has been ruled out. In these cases, it is mandatory to rule out late secondary or tertiary syphilis using the FTA-ABS (fluorescent treponemal antibody-absorbed) or equivalent test. The VDRL (Venereal Disease Research Laboratory) or RPR test lacks sufficient sensitivity to be used as a screen in this population. Autoimmune testing is reserved for patients with rapidly progressive hearing loss, evolving over a period of weeks to months. Approximately 30% of these patients will manifest vestibular complaints.[67] There is no standardized testing protocol for the workup of these patients. A complete blood count with differential, ESR, electrolytes, blood urea nitrogen, creatinine, and urinalysis should be part of the general screen. The ANA assay has been the most revealing. The role of antiphospholipid antibodies in neurotologic disease has yet to be clarified, but they may prove to be significant mediators of labyrinthine pathology.[68] A Western blot test to detect antibodies directed against the inducible form of heat shock protein 70 is commercially available and may be predictive of the presence of corticosteroid-responsive hearing loss.[69,70] Other tests that may compose part of an autoimmune screen include assays for rheumatoid factor, complement levels, anti-Sjögren's antibodies, and c-ANCA, although the cost effectiveness of these tests has yet to be established. Authorities often advocate the performance of Lyme titers in patients with neurovestibular complaints, although there is little literature to support the association between Lyme disease and peripheral auditory and especially vestibular disorders.[71,72] Similarly, metabolic diseases (diabetes mellitus, hypothyroidism, hypercholesterolemia) have not been established as mediators of neurovestibular disease.

VESTIBULAR AND BALANCE REHABILITATION THERAPY

Although this chapter is dedicated to the evaluative process for the patient with complaints of imbalance, vertigo, or general dysequilibrium, it is during this process that the first suggestions for use of VBRT should be developed. Therefore, closing the chapter with a brief discussion on this topic and the

relationship between the evaluation tools and the use of VBRT is appropriate.

Vestibular and balance rehabilitation therapy is a symptom-driven program for determination of who is an appropriate candidate. Therefore, it is during the history that the first possible indications for the use of this management technique would be developed. For the most part, other than the SOT of posturography, the laboratory tests described above do not provide indications for the use of this treatment option. There are situations in which the symptom complaints are questionable for use of the program, yet findings on postural control studies suggest functional deficits that can be addressed with the VBRT techniques, and its use would be appropriate. In the case of bilateral vestibular paresis, the rotary chair is the only test that can provide information about the extent of the bilateral weakness. With those chair results, VBRT programs can be altered for more realistic goals. Lastly, indications from ENG or rotary chair of a unilateral reduced vestibular response to caloric irrigation or abnormal timing relationship between eye and head movement from rotary chair support the use of adaptation exercises to improve VOR gain. It is unlikely that repeat use of ENG or rotary chair following VBRT would be called for since the utility of these tools in determining compensation status is very limited, and the primary focus in a VBRT program is to enhance the compensation process in many dimensions. However, repeated use of various postural control and dynamic visual acuity assessments[11] would be useful as a monitor and/or final outcome measure of the effectiveness of a VBRT program since these studies are primarily functional in nature. The patients who are the most appropriate for VBRT on first review are suggested from any one of the following:

- Patients with symptoms provoked by head or visual motion
- Symptoms that are continuous with motion exacerbation
- Evaluations revealing balance or gait dysfunction with or without either of the traits listed above

The patients who are most probably not appropriate for use of VBRT as the initial management technique have the following characteristics to their symptoms:

- Symptoms of only spontaneous events that are more frequent than one time every 6 to 8 weeks and last longer than 15 minutes at a time.
- No provocative activity or balance dysfunction can be realized during the therapy evaluation; therefore, nothing is found on which to base exercise activities.
- Progressive central lesions involving gait and balance have not been shown to respond to therapy for balance and gait. These patients may benefit from exercises to reduce eye and head movement sensitivity and improve safety with ambulation-oriented goals.

The general principles of designing vestibular rehabilitation programs involve exposing the patient to the stimuli that provoke vertigo and cause slippage of the visual signal on the retina and challenging areas of deficiency in postural control and ambulation. First, the therapist must identify those activities or environmental situations that provoke symptoms. Second, the patient's functional deficits regarding balance and gait must be identified. These may be caused by the vestibular symptoms, lesions in nonvestibular regions, or maladaptive behavior that has developed in response to the symptoms. Lastly, it is desirable to challenge the sedentary lifestyle that the patient with vestibular disorder often adopts. An active lifestyle including regular exercise that accounts for age and other health constraints will serve as a maintenance program once active therapy is completed. Extensive literature is available to discuss the protocols, techniques, and efficacy of this form of management.[33,73–76]

CHAPTER 7

Imaging of the Temporal Bone

Galdino E. Valvassori, MD

The temporal bone is unique in the human body because it contains, in the small volume of a cubic inch, a concentration of vital osseous and membranous structures surrounded by a more or less extensive system of pneumatic cells. Because of the different densities of its bony components and of the air- and fluid-filled spaces around and within them, the temporal bone lends itself to accurate visualization and assessment by various imaging procedures.

Conventional radiography, computed tomography (CT), magnetic resonance imaging (MRI), and arteriography are the techniques currently used to study the temporal bone and auditory-vestibular pathways. The otolaryngologist should know how to select the proper procedure for the anatomic area and the clinical problem under investigation.

CONVENTIONAL RADIOGRAPHY

Today, the use of conventional radiography is limited to evaluation of the mastoid pneumatization and assessment of the position and integrity of cochlear implant electrodes. The latter cannot be established by tomographic techniques because the wires often are visualized in several contiguous sections; therefore, their continuity cannot be demonstrated. Only three projections are of practical interest: the lateral or Schüller's, the frontal or transorbital, and the oblique or Stenvers'. The other special projections have historical significance but no useful clinical application.

Schüller's or Rungstrom's Projection

The Schüller's projection is a lateral view of the mastoid obtained with a cephalocaudad angulation of the x-ray beam of 25 to 30 degrees. The patient's head is turned so that the sagittal plane of the skull becomes parallel to the tabletop and the side under examination is closer to the film. Proper centering is obtained by placing the external auditory meatus of the side to be examined 1 cm above the center of the film or of the tabletop.

The extent of the pneumatization of the mastoid, distribution of the air cells, degree of aeration, and status of the trabecular pattern are the main features of this projection (Figure 7–1). The anterior plate of the vertical portion of the sigmoid sinus groove (corresponding to the most lateral part of the posterior aspect of the petrous pyramid) casts an almost vertical line, slightly concave posteriorly in its upper portion, superimposed on the air cells. At its upper extremity, this line joins another line that slopes gently forward and downward to form the sinodural angle of Citelli. The latter line is produced by the superior aspect of the lateral portion of the petrous pyramid. The more medial portion of the superior petrous ridge, from the arcuate eminence to the apex, has been displaced downward by the angulation of the x-ray beam and casts a line that extends forward and downward, crossing the epitympanic area and, more anteriorly, the neck of the mandibular condyle. Above this line, the upper portion of the attic with the head of the malleus is usually visible. Finally, the temporomandibular joint is outlined.

Transorbital Projection

This view can be obtained with the patient's face either to or away from the film. The patient's head is flexed on the chin until the orbitomeatal line is perpendicular to the tabletop. For better details, each side should be obtained separately, and the central x-ray beam should be directed at the center of the orbit of the side under examination and perpendicular to the film.

The petrous apex is outlined clearly but foreshortened because of its obliquity to the plane of the films. The internal auditory canal is visualized in its full length as a horizontal band of radiolucency

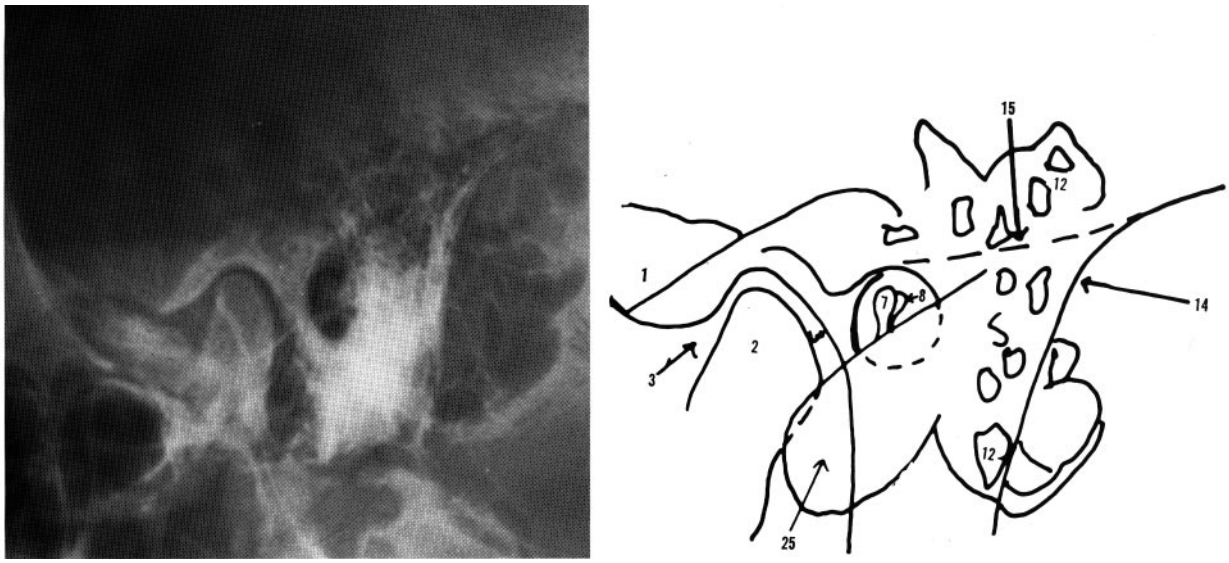

FIGURE 7–1. Schüller's projection: (1) root of the zygoma, (2) condyle of the mandible, (3) temporomandibular joint, (7) malleus, (8) incus, (12) air cells, (14) anterior plate of the sigmoid sinus, (15) dural plate, (25) petrous apex.

extending through the petrous pyramid (Figure 7–2). At the medial end of the canal, the free margin of the posterior wall casts a well-defined and smooth margin, concave medially. Often the radiolucent band of the internal auditory canal seems to extend medially to the lip of the posterior wall into the petrous apex. This band is not caused by the internal auditory canal but is produced by the medial extension of the upper and lower lips of the porus (opening) of the canal and by the interposed groove. Lateral to the internal auditory canal, the radiolucencies of the vestibule and of the superior and horizontal semicircular canals are usually detectable. The apical and middle coils of the cochlea are superimposed on the lateral portion of the internal auditory canal, whereas the basal turn is visible underneath the canal and the vestibule.

Stenvers' Projection

The patient is positioned facing the film, with the head slightly flexed and rotated 45 degrees toward

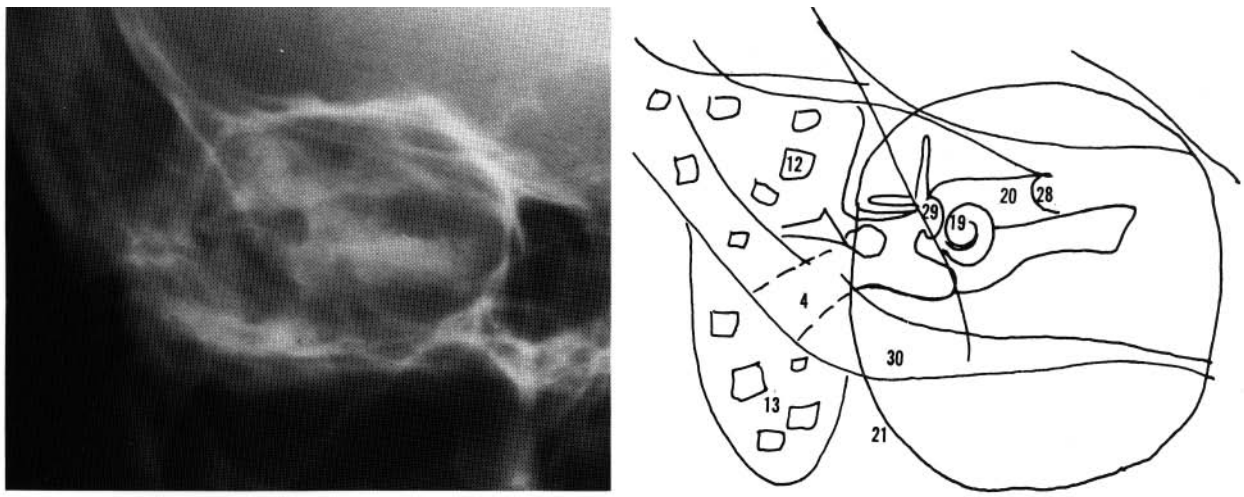

FIGURE 7–2. Transorbital projection: (4) external auditory canal, (12) air cells, (13) mastoid process, (19) cochlea, (20) internal auditory canal, (21) orbital rim, (28) medial lip of the posterior wall of the internal auditory canal, (29) vestibule, (30) base of the skull.

the side opposite the one under examination. The lateral rim of the orbit of the side under investigation should lie in close contact with the tabletop. The x-ray beam is angulated 14 degrees caudad.

The entire petrous apex is visualized in its full length lateral to the orbital rim (Figure 7–3). The porus of the internal auditory canal seen on face appears as an oval-shaped radiolucency open medially and limited laterally by the free margin of the posterior canal wall. Lateral to the porus, the internal auditory canal appears foreshortened. The vestibule and semicircular canals, especially the posterior, which lies in this projection in a plane parallel to the film, are usually recognizable. On the outside, the entire mastoid is outlined, with the mastoid process free from superimpositions.

COMPUTED TOMOGRAPHY

Computed tomography is a radiographic technique that allows measurement of small absorption coefficients and differentials not recognizable by previously available recording or displaying systems.

The scan is initiated at a chosen level, and the x-ray tube, collimated to a thin or pencil beam, rotates around the patient. The transmitted x-rays are picked up by detectors arrayed along the circumference of the tube trajectory, converted into electronic current, amplified, and transmitted to the computer for storing and processing. The computer analyzes these data and develops an image on a 360 by 360 picture element (pixel) matrix, where the brightness of each point is proportional to the attenuation coefficient.

The study is often performed after intravenous injection of iodinated contrast agents that produce an increase in density value or enhancement of several anatomic structures and pathologic tissues.

Recently, conventional CT has been replaced by helical or spiral CT, which allows rapid acquisition of volumetric data of the part of the body under examination. Images are acquired at an angled plane of section and then reconstructed by interpolating the volumetric data set as two-dimensional or high-quality three-dimensional reformations. The continuous acquisition of images is made possible by replacing the former electric cabling of the gantry with slip-ring design that allows continuous rotation of the source detector assembly and by the use of high heat capacity x-ray tubes. The advantage of spiral CT includes the elimination of respiratory misregistration, a decrease of motion artifact, and an obvious improvement in patient comfort owing to the shortening of the examination time. This is particularly important in children, whether they have been administered anesthesia or sedation, and in older patients who have difficulty in extending the head. Reconstruction of axial data in other planes produces satisfactory images provided that a collimation as small as 1 or 0.5 mm is used. A scanning time of less than 1 minute is sufficient to cover the mastoid and petrous portions of the temporal bone.

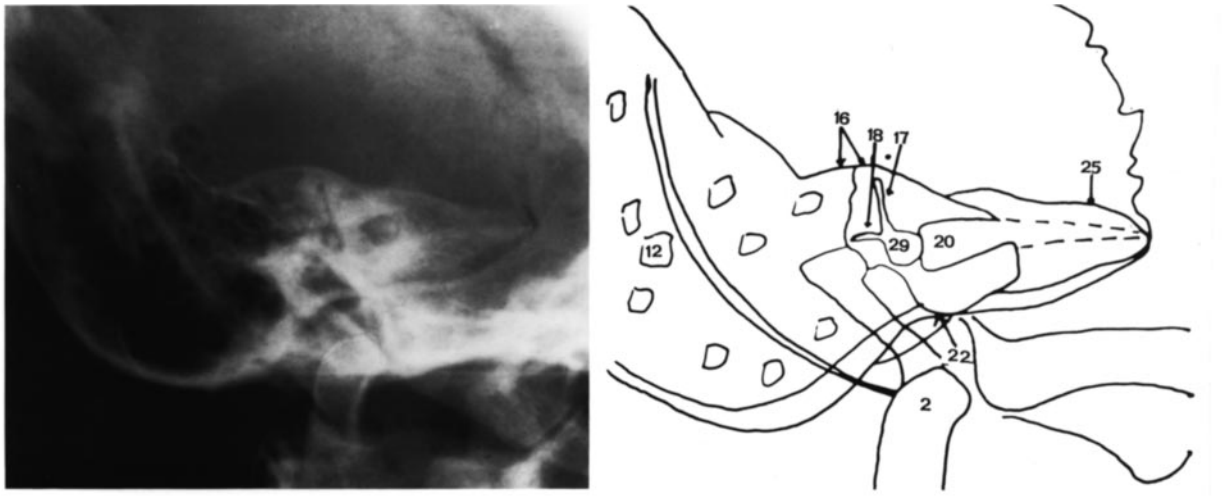

FIGURE 7–3. Stenvers' projection: (2) condyle of the mandible, (12) air cells, (16) arcuate eminence, (17) superior semicircular canal, (18) horizontal semicircular canal, (20) internal auditory canal, (22) basilar turn of the cochlea, (25) petrous apex, (29) vestibule.

New multidetector scanners will further decrease the scanning time. The CT images provide exquisite bony details and excellent demonstration of soft tissue density within the air space of the mastoids, external auditory canal, and middle ear but very limited identification of the type of substance producing the abnormal density. For instance, the density of cholesteatoma is identical to that of a tumor or granulation tissue and even of fluid.

The densitometric readings obtained with a cursor of variable size are often unreliable because of partial volume averaging within the small cavities of the ear. Time-density curves obtained by rapid sequential images of a preselected section after injection of a bolus of contrast are useful for the identification of vascular masses. At present, MRI provides a far more precise identification of the type of tissue within the air spaces and abnormal cavities in the temporal bone. Three-dimensional reconstruction of the temporal bone has not added diagnostic information but is of great value in surgical planning in large lesions of the base of the skull.

Computed Tomographic Projections of the Temporal Bone

Horizontal or Axial Projection This is the basic projection of the CT study.[1] It is comfortable for the patient, who lies supine on the table, and is easy to obtain and reproduce. It allows a good demonstration of the external, middle, and inner ears except for the structures parallel to the plane of section, such as the tegmen (Figure 7–4).

Coronal or Frontal Projection The patient lies on the table, either prone or supine, with the head extended. The gantry of the scanner is often tilted to compensate for an incomplete extension of the head. This projection is indispensable to complement the axial sections but is often difficult to obtain, particularly in young children and older people (Figure 7–5).

Twenty-Degree Coronal Oblique Projection This projection is a modification of the coronal projecton for the study of the medial wall of the tympanic cavity. The medial or labyrinthine wall of the middle ear forms an angle, open posteriorly, of 15 to 25 degrees with the midsagittal plane of the skull. The patient is first positioned as for the coronal projection, and the head is then rotated 20 degrees toward the side under examination so that the medial wall becomes perpendicular to the plane of section. For this projection, we position the patient prone with the head extended. This projection is particularly useful for the study of the oval window, promontory, and tympanic segment of the facial canal. It should be used in all patients with otosclerosis (Figure 7–6).

Sagittal or Lateral Projection It is impossible or extremely difficult to obtain direct sagittal sections. However, computer reconstructed sagittal images can be obtained from the raw data collected for the horizontal sections. This is particularly true if fast or spiral CT is used, and thin sections at 0.5 or 1 mm increments are obtained. These images are satisfactory for the demonstration of the mastoid segment of the facial canal and of the vestibular aqueduct (Figure 7–7).

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging is an imaging modality capable of producing cross-sections of the human body in any plane without exposing the patient to ionizing radiation. Magnetic resonance images are obtained by the interaction of hydrogen nuclei or protons of the human body, high magnetic fields, and radiofrequency pulses. The strength of the MRI signal to be converted into imaging data depends on the concentration of the free hydrogen nuclei or protons and on two magnetic relaxation times, T_1 and T_2, which are tissue specific. One of the characteristics of MRI is the possibility of changing appearance and therefore information of the images by changing the contribution of the T_1 and T_2 relaxation times. This is accomplished by varying the time between successive pulses (TR or by repetition time) and the time that the emitted signal or echo is measured after the pulse (TE or echo time).

Magnetic resonance imaging has undergone multiple changes and refinements to increase definition of the images and to decrease the acquisition time of the image.[2] First, the use of surface coils placed adjacent to the area of interest has increased the signal-to-noise ratio and consequently improved the image. Shorter acquisitions have been obtained by shortening the TR, using pulses with flip angles smaller than 90 degrees (gradient echo imaging), reducing the number of phase-encoded steps, and

increasing the data collected per excitation. The latter technique, known as fast spin echo (FSE), uses multiple echoes (4 to 16 for an excitation), therefore reducing the number of excitations necessary for forming an image.

Examination is performed with the patient supine and the plane extending from the tragus to the inferior orbital rim perpendicular to the tabletop. Different projections are obtained by changing the orientation of the magnetic field gradients without moving the patient's head. Axial, coronal, and sagittal projections are obtained.

T_1 images obtained by a short TR and TE offer the best anatomic delineation. T_2 images obtained with long TR and TE better differentiate normal from pathologic tissues.

Air, cortical bone, and calcifications contain few free protons and therefore appear in the images

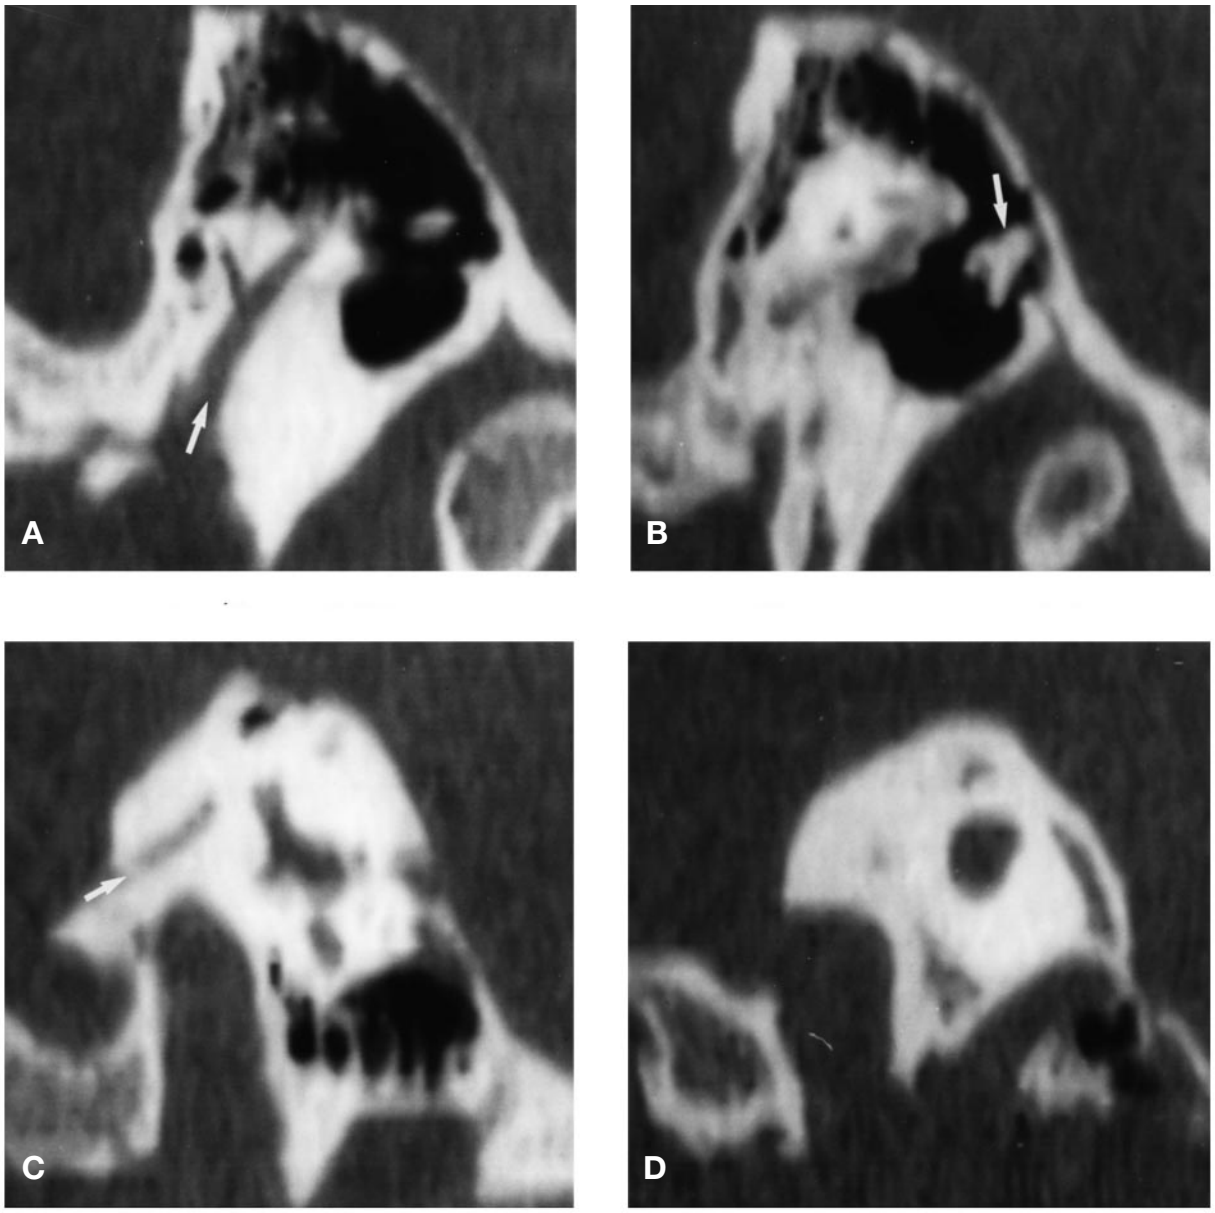

FIGURE 7–7. Reformatted sagittal computed tomographic sections of the right ear showing *A*, the external auditory canal, attic, and vertical segment of the facial canal (*arrow*); *B*, the ossicles (*arrow*) and the horizontal semicircular canal; *C*, the common crus, vestibular aqueduct (*arrow*), and the jugular fossa; *D*, the internal auditory canal.

as dark areas of no signal. Fat and body fluid are rich in free protons and produce signals of high intensity, fat in the T_1- and fluid in the T_2-weighted images. Blood vessels usually appear as areas of signal void because the stimulated protons of the circulating blood have moved out of the section before their emitted signals can be detected. Because cortical or nondiploic bone and air emit no signal, the normal mastoid, external auditory canal, and middle ear appear in the MRI as dark areas without pattern or structures within them. The petrous pyramid is equally dark except for a gray or white cast of the inner ear structures and internal auditory canal produced by the fluid within their lumens (Figure 7–8).

Pathologic processes are demonstrated by MRI whenever the hydrogen density and relaxation times of the pathologic tissues are different from the normal. The intravenous injection of ferromagnetic

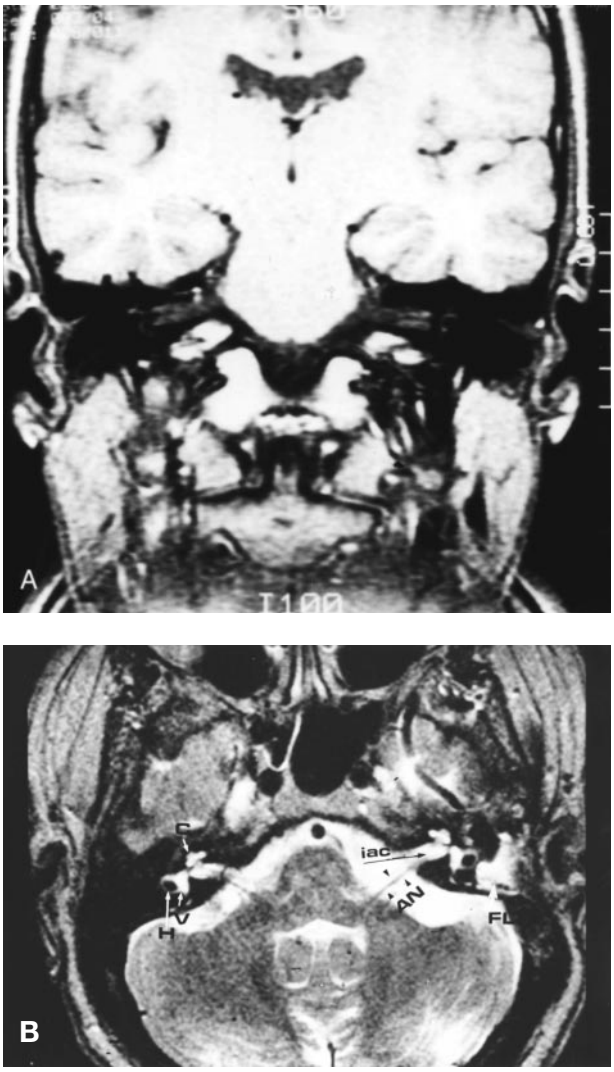

FIGURE 7–8. Magnetic resonance imaging sections of the normal temporal bone. *A*, Coronal T_1. *B*, Axial T_2 fast spin echo. The normal mastoid, external auditory canal, and middle ear cavity appear as dark areas of signal void. The internal auditory canals and inner ear structures are recognizable because of the signal produced by the fluid and the neural structures within their lumens. The cerebrospinal fluid has a low signal in T_1 but a high signal in T_2. AN = acoustic nerve; C = cochlea; FL = fluid in the mastoid and middle ear; H = horizontal semicircular canal; iac = internal auditory canal; V = vestibule.

contrast agents (gadolinium DTPA [diethylenetriamine pentaacetic acid] and gadolinium chelate) has improved the recognition and differentiation of pathologic processes. Because the contrast material does not penetrate the intact blood barrier, normal brain does not enhance except for structures such as the pituitary gland and several cranial nerves that lack a complete blood-brain barrier. Enhancement of brain lesions occurs whenever the blood-brain barrier is disrupted provided that there is sufficient blood flow to the lesions. Extra-axial lesions such a meningiomas and neuromas lack a blood-brain barrier and therefore undergo a strong enhancement.

Fluid, blood, and soft tissue masses within the temporal bone are identified readily by MRI as areas of abnormally high signal intensity. The exact location, extent, and involvement of bony structures such as the ossicles, scutum, and labyrinthine capsule cannot be detected, however. For this reason, CT remains the study of choice for the assessment of intratemporal pathology with the exception of the petrous apex.

The images shown in this chapter were obtained with a super-conducting magnet and a magnetic field of 15,000 gauss or 1.5 tesla.

ANGIOGRAPHY

Gradient echo techniques and flow-encoding gradients have enabled the development of magnetic resonance angiography (MRA). Time of flight angiography is a gradient echo technique in which the stationary tissues within the imaging plane are saturated with the magnetic field so that they will not produce a signal. Blood flowing within the same plane is unsaturated and will be the only tissue to produce a signal.

Phase-contrast angiography is acquired differently. Instead of saturating the stationary tissues with radiofrequency pulses, a bipolar gradient of magnetization is applied to the entire slice, first with a positive value and then with a negative value. In the stationary tissues, the two opposite gradients cancel each other out. In the flowing blood, however, the two opposite gradients cannot cancel each other out because the blood will have moved to a different plane in the region before the inverse gradient is applied.

The obtained slices are reconstructed into projection images, which can be rotated in different planes to separate vessels and eliminate superimposition. Magnetic resonance angiography of the intracranial vasculature has been particularly useful in the demonstration of aneurysms (Figure 7–9) in the region of the circle of Willis, arteriovenous malformation (AVM) (particularly a small dural AVM

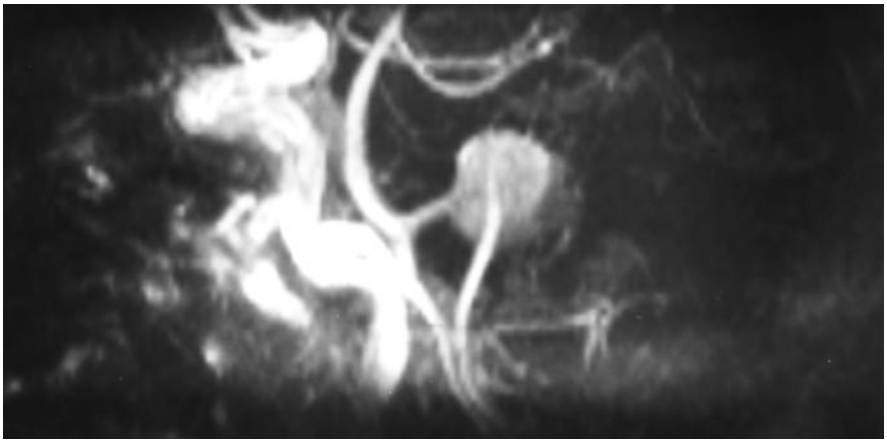

FIGURE 7–9. Magnetic resonance angiography demonstrating an aneurysm of the left vertebral artery. The aneurysm compresses the acoustic nerve and mimics an acoustic neurinoma.

that may not be visible on routine spin-echo images), and vaso-occlusive pathology, including dural sinus thrombosis. Magnetic resonance angiography of the extracranial circulation provides excellent information about the patency of the carotid and vertebral arteries. These vessels may be compressed or displaced by neck masses and their lumens stenosed or obstructed by thrombosis or atheromatous plaques.

The introduction of ultra-fast CT has opened the possibility of obtaining excellent angiographic images. In CT angiography, the continuous acquisition of the images allows the following of the transit of a rapidly intravenously injected bolus of contrast through the arteries and veins of the area under investigation. The reconstructed images can be rotated in the plane that best demonstrates the vessels.

Conventional angiography is seldom required for the diagnosis of vascular tumors or anomalies within or adjacent to the temporal bone. Arteriography is, however, mandatory for identifying the feeding vessels of lesions, usually glomus tumors, whenever embolization or surgical ligation is contemplated. Subtraction is necessary to delineate the vascular mass and feeding vessels, which are otherwise obscured by the density of the surrounding temporal bone. The injection should be performed in the common carotid artery to visualize both internal and external carotid circulation. A vertebral arteriogram may also be performed.

Retrograde jugular venography is rarely used for the diagnosis of a high jugular bulb or glomus tumor. The study is done by percutaneous puncture of the vein with a Seldinger needle.

PATHOLOGIC CONDITIONS

The pathologic conditions of the ear and temporal bone will be reviewed by anatomic location. Seven sites of involvement are considered: mastoid, external auditory canal, middle ear, inner ear, petrous pyramid, facial nerve, and cerebellopontine angle.

Mastoid

The development of the mastoids varies from person to person and, to a lesser degree, from side to side of the same individual. In some mastoids, the pneumatization is limited to a single antral cell; in others, it may extend into the mastoid tip and squama of the temporal bone and may even invade the adjacent zygoma and occipital bone. The nonpneumatized mastoid process may be made up of solid bone or contain spongy diploic spaces filled with fatty marrow. In MRI, the fatty marrow produces a high signal in the T_1 sequence that decreases in the T_2 and should not be confused with fluid or other pathologic processes that have a high signal in the T_2 sequence. One should also remember that it may be impossible by MRI to distinguish a small mastoid containing a larger aerated cell from a sclerotic mastoid since both produce an identical signal void.

Lateral Sinus The lateral or sigmoid sinus forms a shallow indentation on the posterior aspect of the mastoid. Occasionally, the sinus courses more anteriorly and produces a deep groove in the mastoid, best seen in the axial sections. In some cases, only a thin bony plate separates the sinus from the external auditory canal (Figure 7–10). Without this informa-

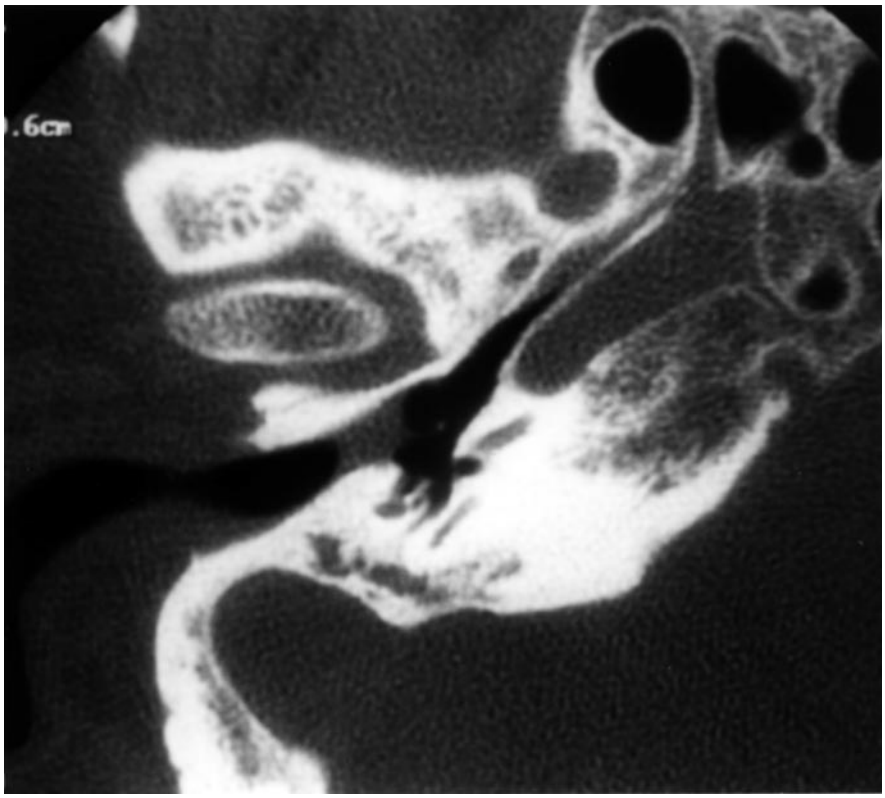

FIGURE 7–10. Anteriorly situated lateral sinus. Axial computed tomographic section. The sinus produces a deep groove in the posterior aspect of the mastoid and reaches the posterior wall of the external auditory canal.

tion, the otologist could enter the sinus with consequent severe bleeding and possible complications from sinus thrombosis.

Tegmen The tegmen of the mastoid and attic usually passes in a horizontal plane slightly lower than the arcuate eminence produced by the top of the superior semicircular canal. A depression of the tegmental plate is not unusual, particularly in patients with congenital atresia. As seen in the coronal sections, the floor of the middle cranial fossa deepens to form a groove lateral to the attic and to the labyrinth (Figure 7–11). The low-lying dura may cover the roof of the external auditory canal and, when the canal is

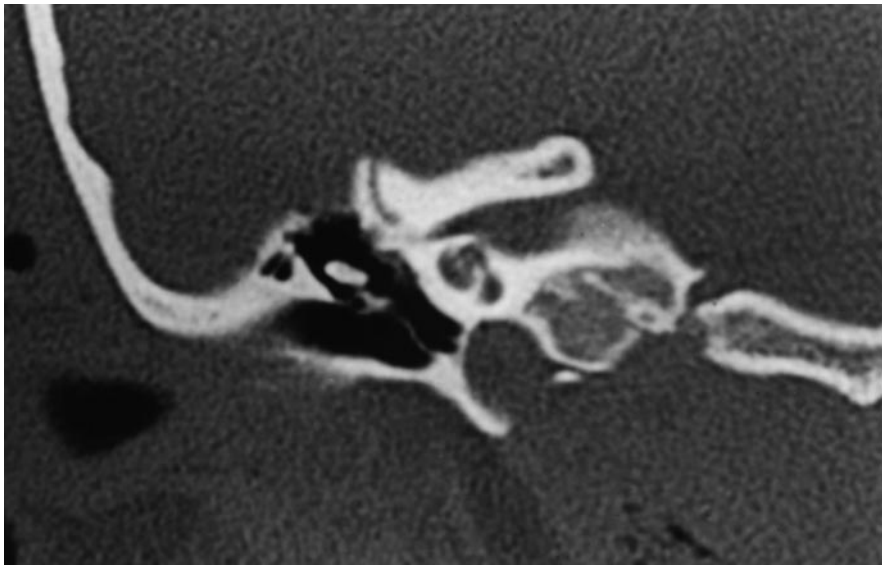

FIGURE 7–11. Low tegmen. Coronal computed tomographic section. The low-lying dura covers the roof of the external auditory canal and the middle cranial fossa deepens to form a groove lateral to the attic.

not developed, extend lateral to the mesotympanum. Unless aware of this feature, the otologist may penetrate the cranial cavity during surgery.

Acute Mastoiditis The early findings of acute mastoiditis are diffuse and homogeneous clouding of the middle ear cavity and mastoid air cells and often air-fluid levels within the air cells (Figure 7–12, A). With the progression of the process, the mastoid trabeculae first become demineralized and then destroyed, with formation of coalescent areas of suppuration.[3] Erosion of the cortex of the mastoid results in subperiosteal abscesses (Figure 7–12, B). Involvement of the posterior sinus plate often leads to thrombophlebitis of the lateral sinus and to posterior fossa abscesses (Figure 7–13), whereas erosion of the tegmen may lead to extension of the infection into the middle canal fossa with formation of extradural (epidural) or temporal lobe abscesses.

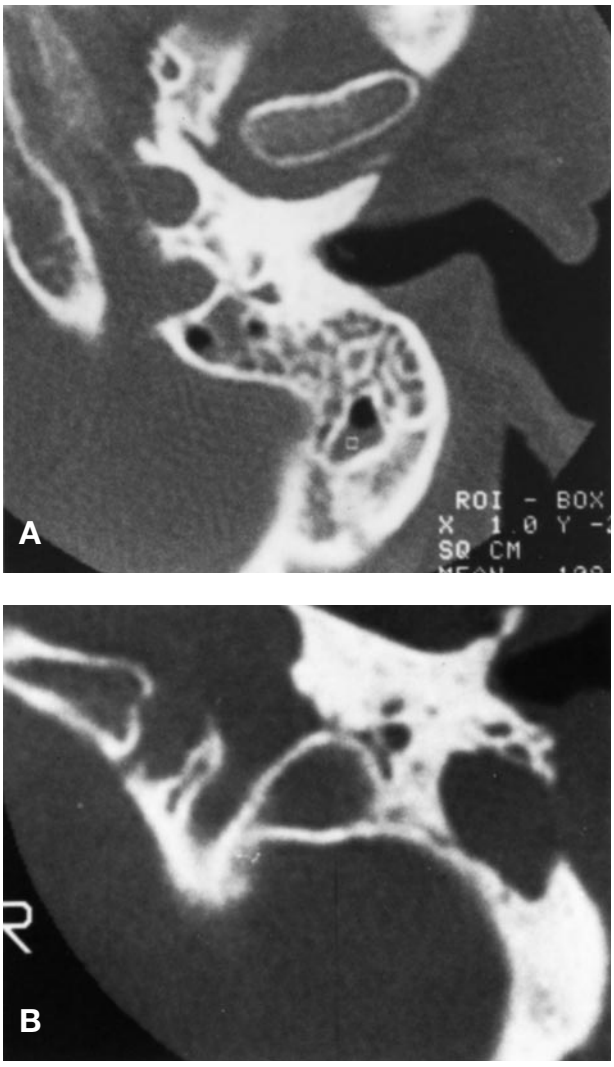

FIGURE 7–12. A, Acute mastoiditis. This axial computed tomographic (CT) section of the left mastoid shows clouding and air-fluid levels within the air cells. The trabecular pattern is intact. *B*, Coalescent mastoiditis, axial CT section of the left mastoid. A large coalescent cavity is noticed in the mastoid with erosion of the outer cortex and formation of a subperiosteal abscess.

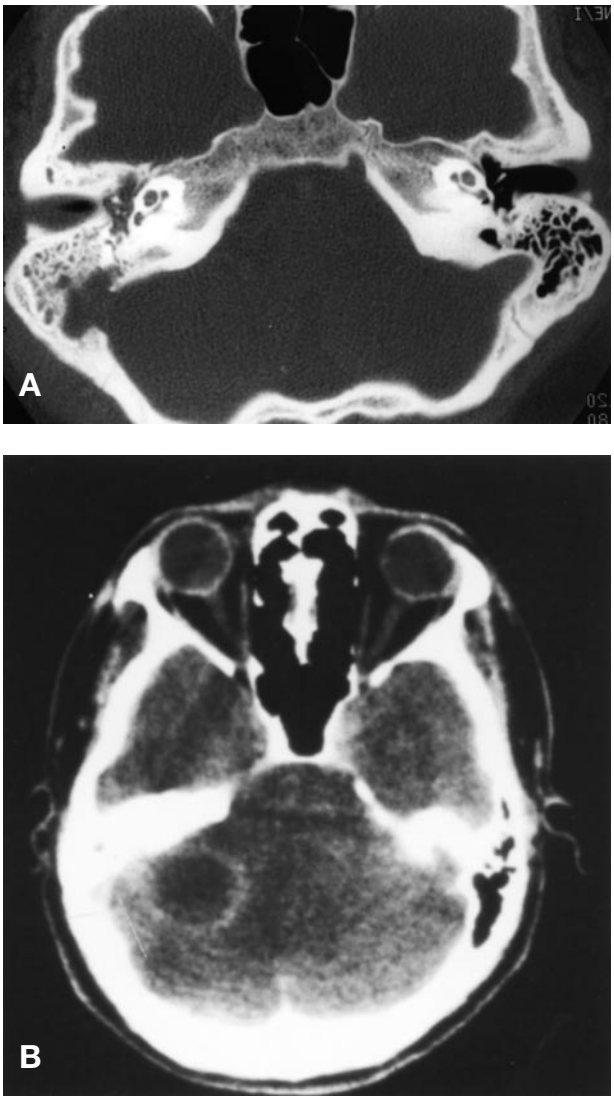

FIGURE 7–13. Acute mastoiditis with perisinus and epidural abscess. *A*, Axial computed tomographic (CT) section. There is a coalescent cavity in the posterior aspect of the mastoid with erosion of the sinus plate. *B*, Axial CT section after injection of contrast. A ring of enhancement surrounds an area of low density produced by the cerebellar abscess.

Chronic Mastoiditis The mastoid is often poorly pneumatized, and the mastoid antrum and mastoid air cells appear nonhomogeneously cloudy. Reactive new bony formation produces thickening of the trabeculae (Figure 7–14), which may lead to complete obliteration of the air cells (sclerotic mastoiditis).

Eosinophilic Granuloma Lytic lesions of variable size are observed in the mastoid and temporal squama. In the involved areas, the trabecular pattern is completely erased and the mastoid cortex may be thinned out, destroyed, or expanded (Figure 7–15).

External Auditory Canal

Computed tomography is the study of choice, but MRI may add useful information whenever the lesion extends outside the confines of the canal into the adjacent structures.

Congenital Malformations Microtia of varying degrees is often associated with dysplasia of the external auditory canal, although no direct correlation exists between the two anomalies. The degree of malformation of the external auditory canal varies from complete agenesis of the tympanic bone and canal (Figure 7–16) to stenosis of its lumen (Figure 7–17) and atresia of an otherwise well-developed canal by a bony plate, usually lateral. The small tissue tag and pit often observed in patients with atresia of the canal often have no topographic relationship to the underlying mastoid and middle ear.

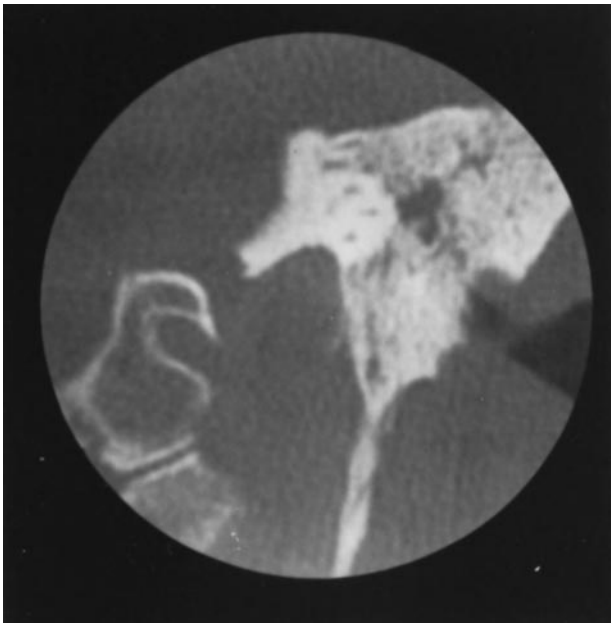

FIGURE 7–14. Chronic mastoiditis, coronal computed tomographic section. The trabeculae are thickened and the air cells cloudy and partially obliterated.

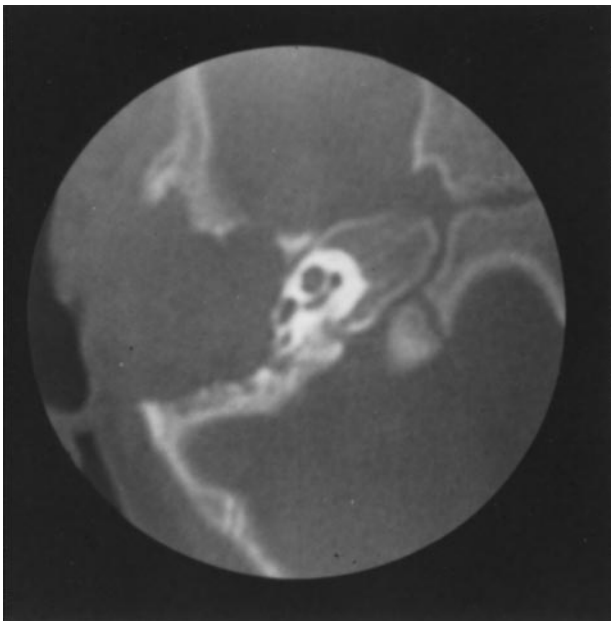

FIGURE 7–15. Eosinophilic granuloma, axial computed tomographic section of the right ear. A large lytic lesion involves the right mastoid, external auditory canal, and middle ear. A soft tissue mass fills the cavity.

Necrotizing External Otitis This condition, also known as malignant external otitis, is an acute osteomyelitis of the temporal bone that occurs in debilitated, diabetic, and immunosuppressed patients and is usually caused by the *Pseudomonas* bacterium. The infection starts in the external canal and spreads rapidly to the other portions of the temporal bone and adjacent areas. Computed tomography reveals erosion of the external canal, particularly of its floor, and stenosis of the lumen of the canal caused by soft tissue swelling (Figure 7–18). The infection may then spread inferiorly along the undersurface of the temporal bone to the facial nerve at the stylomastoid foramen, anteriorly to the temporomandibular fossa, posteriorly to the mastoid, and medially into the middle ear and petrous pyramid.

External Auditory Canal Cholesteatomas These lesions are caused either by blockage of the canal,

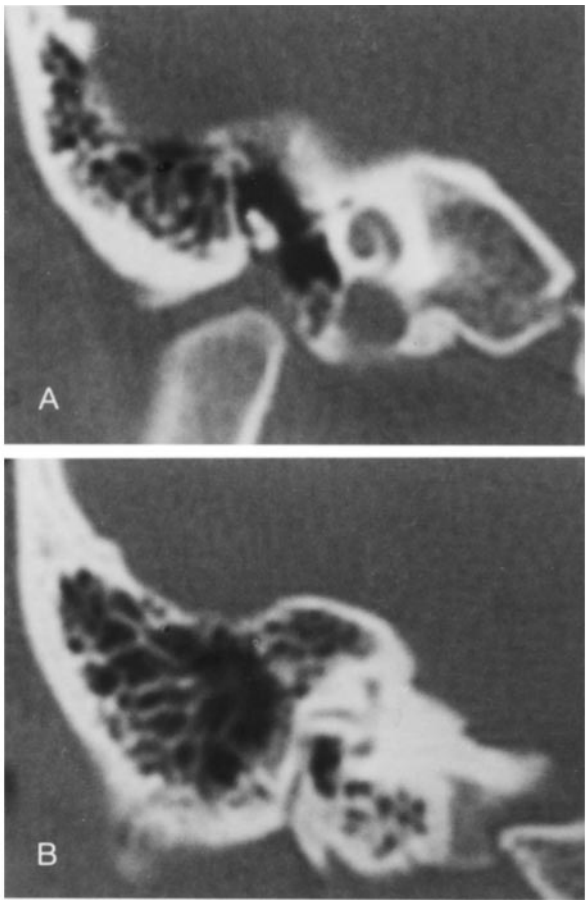

FIGURE 7–16. Agenesis of the right external auditory canal, coronal computed tomographic sections. *A*, The external auditory canal is absent and the mandibular condyle is displaced posteriorly and lies lateral to the atretic plate. The middle ear cavity is aerated and normal in size, but the head of the malleus and body of the incus appear malformed and fused. *B*, The mastoid is well pneumatized and clear. The vertical segment of the facial canal is rotated slightly outward.

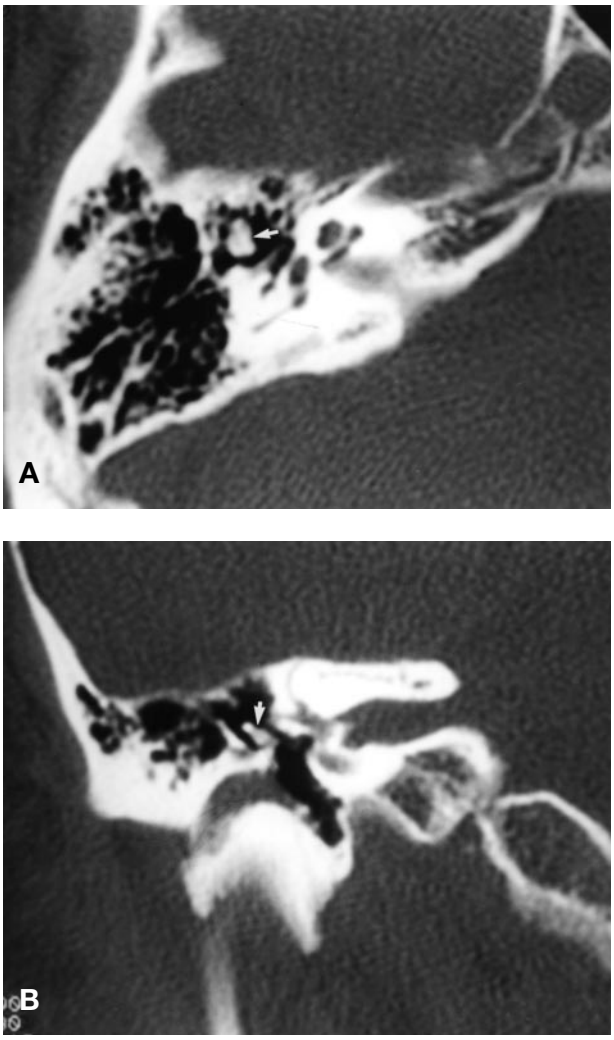

FIGURE 7–17. Stenosis of the right external auditory canal with malformation of the ossicular chain. *A*, Axial; *B*, coronal computed tomographic sections. The external auditory canal is markedly stenotic and closed laterally by a thin atretic plate. The head of the malleus and the body of the incus appear malformed and fused (*arrows*).

with consequent accumulation of epithelial debris (keratosis obliterans), or by dyskeratosis with localized accumulation of debris on the floor of the canal (invasive keratitis). In the first type, a soft tissue mass fills and expands the canal medial to the site of stenosis or obstruction (Figure 7–19). In the second type, the lumen of the canal is patent, but areas of bony erosion are demonstrated in the involved portion of the canal. When the cholesteatoma is large and erodes the annulus, it may extend into the middle ear cavity.

Carcinoma Carcinoma of the temporal bone usually arises in the external auditory canal. The CT findings vary with the extent of the lesion. In an early lesion, portions of the bony wall of the external auditory canal are eroded (Figure 7–20). When further destruction occurs, the tumor may spread anteriorly into the temporomandibular fossa; posteriorly into the mastoid, where it often reaches the facial canal; and medially into the middle ear, jugular fossa, petrous pyramid, and labyrinth. Extension into the mastoid and petrous pyramid causes a typ-

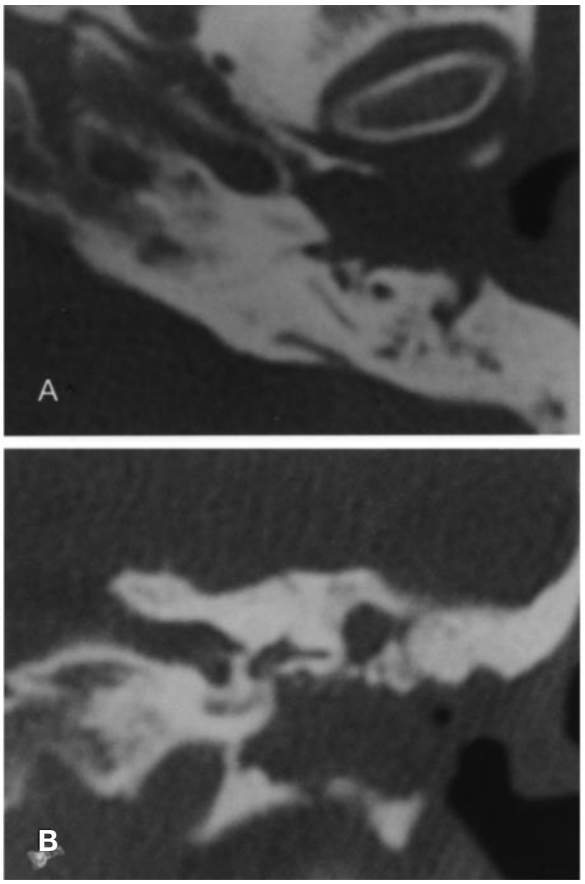

FIGURE 7–18. Necrotizing external otitis. Axial (*A*) and coronal (*B*) computed tomographic sections of the left ear. There is erosion of all walls of the external auditory canal with stenosis of the lumen of the canal caused by soft tissue swelling. The infection has eroded the lateral wall of the attic and spread into the middle ear.

ical moth-eaten appearance because of infiltration of the bone.

Middle Ear and Ossicular Chain

Computed tomography is the study for pathologic processes that arise in the middle ear and involve the ossicular chain.

Because granulation tissue enhances after the injection of paramagnetic agents, MRI with contrast is useful in some cases to differentiate granulation tissue from fluid and cholesteatoma, which have a similar density in the CT sections.

Congenital Malformations Malformations of the middle ear space vary from minor hypoplasia to

FIGURE 7–19. External auditory canal cholesteatoma, coronal section of the right ear. The cholesteatoma fills and obstructs the bony external auditory canal. The cholesteatoma erodes the inferior margin of the lateral wall of the attic and extends into the attic lateral to the ossicles.

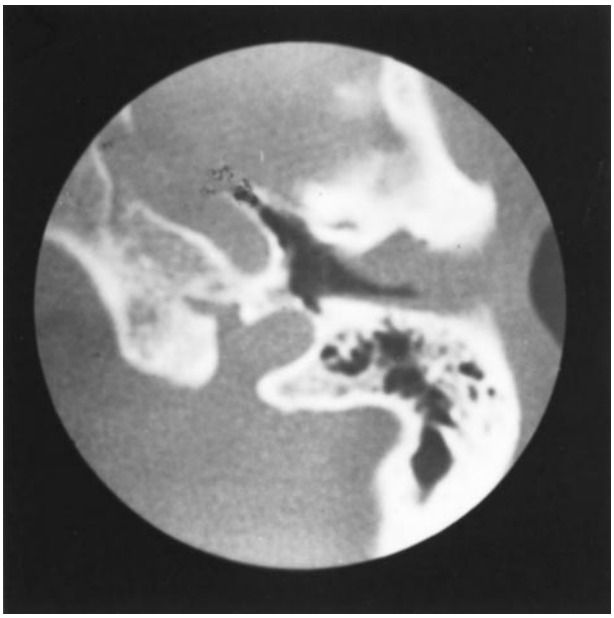

FIGURE 7–20. Carcinoma of the left external auditory canal, axial computed tomographic section. The anterior wall of the external auditory canal is eroded by an adjacent soft tissue mass. The lesion does not extend into the middle ear cavity.

complete agenesis. In the majority of cases with an atretic external auditory canal, the middle ear cavity is normal in size and aerated. The head of the malleus and body of the incus are often fused and fixed to the atretic plate at the level of the malleus neck (see Figure 7–16). If the middle ear cavity is grossly hypoplastic, the malleus and incus form a rudimentary amalgam that is often in an ectopic position (Figure 7–21). A congenital anomaly may be confined to the ossicular chain, which may be malformed or fixed.

Malformation of the stapes superstructure and fixation of the stapes footplate are not uncommon, isolated defects. Computed tomographic sections in 20-degree coronal oblique projection are useful for the study of the stapes and oval window.

The jugular bulb sometimes projects into the hypo- or mesotympanum. The bulb may be covered by a thin bony shell or may be exposed in the middle ear, often in contact with the medial surface of the tympanic membrane, thus mimicking a glomus tumor. The MRI appearance of a high jugular bulb may be misread as showing a glomus tumor because of the mixed signal within the bulb produced by turbulent flow. However, whereas a glomus tumor contains multiple punctate areas of signal void within a mass of medium or high signal, in a high jugular bulb, linear streaks of high and low signal are seen within the lumen of the bulb, usually paralleling its wall, owing to variations in flow velocity. In questionable cases, an MR venogram should be performed using a two-dimensional (2–D) time of flight technique sensitive to slow flow or a two-dimensional phase contrast using short velocity encoding.

The intratemporal segment of the carotid artery may take an ectopic course through the middle ear. In these cases, the CT examination shows a soft tissue mass extending throughout the entire length of the middle ear cavity to regain its normal position in the petrous apex (Figure 7–22). The proximal portion of the carotid artery, rather than being located underneath the cochlea, enters the temporal bone through a canal or defect in the floor of the posterior part of the hypotympanum. A carotid arteriogram, or MRA, may be used to confirm the anomalous course of the artery.

Trauma The middle ear cavity is usually involved in longitudinal fractures of the temporal bone. Computed tomography permits precise evaluation of the course of the fracture and status of the ossicular chain. A fracture line may disappear at a certain level only to reappear a few millimeters distant. This apparent gap is not caused by interruption of the fracture line but rather by a change in its course so that the fracture becomes invisible in some of the

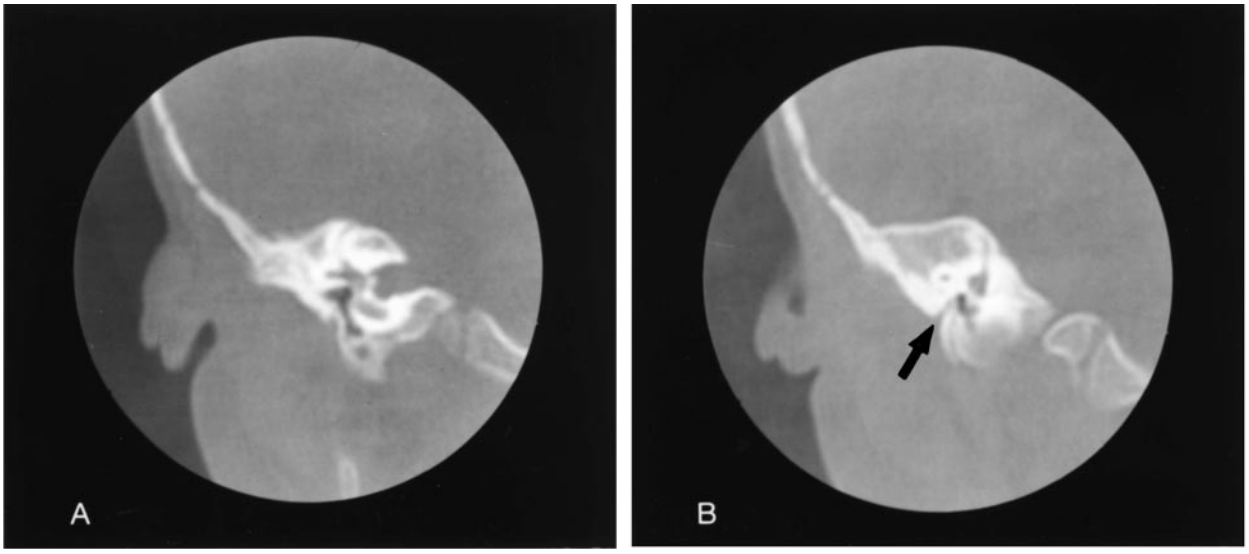

FIGURE 7–21. Congenital malformation of the right external and middle ears, coronal computed tomographic sections. *A*, Agenesis of the external auditory canal with hypoplasia of the attic and rudimentary ossicular mass. *B*, Notice the lack of development of the mastoid pneumatization and the outward rotation of the vertical segment of the facial canal (*arrow*).

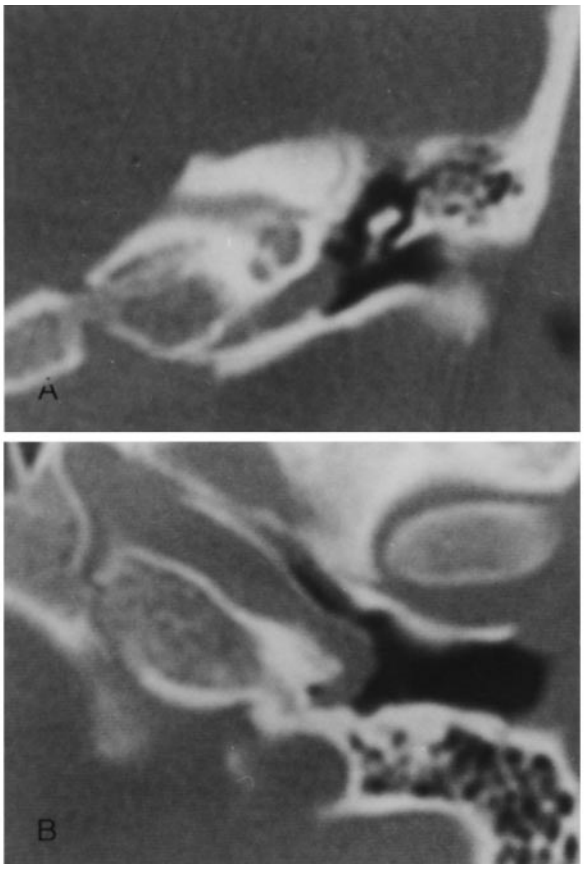

FIGURE 7–22. Ectopic left internal carotid canal. Coronal (*A*) and axial (*B*) computed tomographic sections. The ectopic carotid artery courses throughout the entire length of the middle ear cavity. Notice the absence of the proximal portion of the carotid canal normally seen underneath the cochlea and of the bony wall dividing the anterior part of the mesotympanum from the horizontal segment of the carotid canal.

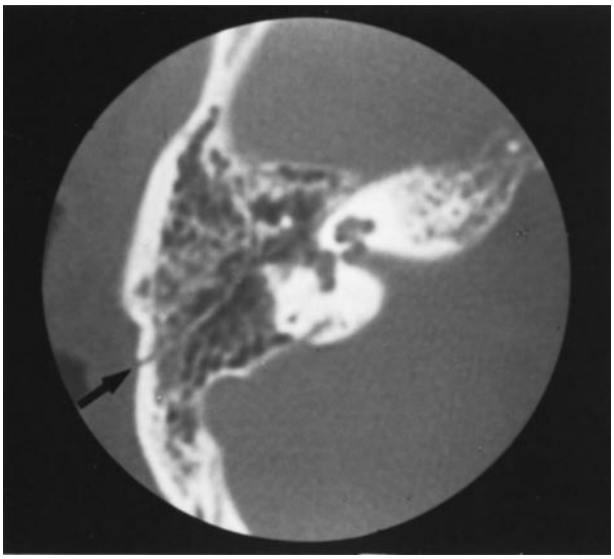

FIGURE 7–23. Longitudinal fracture of the right temporal bone, axial computed tomographic section. The longitudinal fracture extends from the cortex of the posterior portion of the mastoid to the posterosuperior canal wall (*arrow*). The fracture reaches the attic and disrupts the ossicular chain. The body of the incus is displaced laterally and posteriorly.

sections. The tegmen is usually involved, and cerebrospinal fluid otorrhea or rhinorrhea occurs whenever the dura is torn. Anterior extension of the fracture may reach the eustachian tube, which becomes obstructed. Conductive hearing loss is usually secondary to disruption of the ossicular chain. The body of the incus is usually rotated and displaced superiorly, posteriorly, and laterally (Figure 7–23). Interruption at the incudostapedial connection results from a fracture of the lenticular process of the incus or of the stapes superstructure and from a dislocation of the incudostapedial joint (Figure 7–24).

Meningoceles and Meningoencephaloceles A soft tissue mass contiguous to a defect in the tegmen of the mastoid suggests the possibility of a meningocele or meningoencephalocele. If the brain and meninges herniate into the small space of the antrum or epitympanum, the constant pulsation of the cerebrospinal fluid is transmitted through the walls of the meningocele to cause a gradual resorption of the surrounding bony walls. Computed tomography demonstrates the bony defect in the tegmen and a soft tissue mass protruding through the defect into the mastoid or middle ear cavity (Figure 7–25, A). This soft tissue lesion cannot be reliably differentiated from a recurrent cholesteatoma since the absorption coefficients of both lesions are similar. A more definite diagnosis of meningoencephalocele is reached with CT by injecting, by means of lumbar puncture, a small amount of metrizamide that will diffuse in the subarachnoid space and produce an enhancement of the herniated mass.[4] The differentiation between a meningocele and a cholesteatoma can best be made by MRI. On MRI, cholesteatoma appears as a lesion of medium signal in the T_1 and high signal intensity in T_2 images. A meningocele will have the same characteristics as cerebrospinal fluid: low signal intensity in T_1 and high intensity in the T_2 images. On MRI,

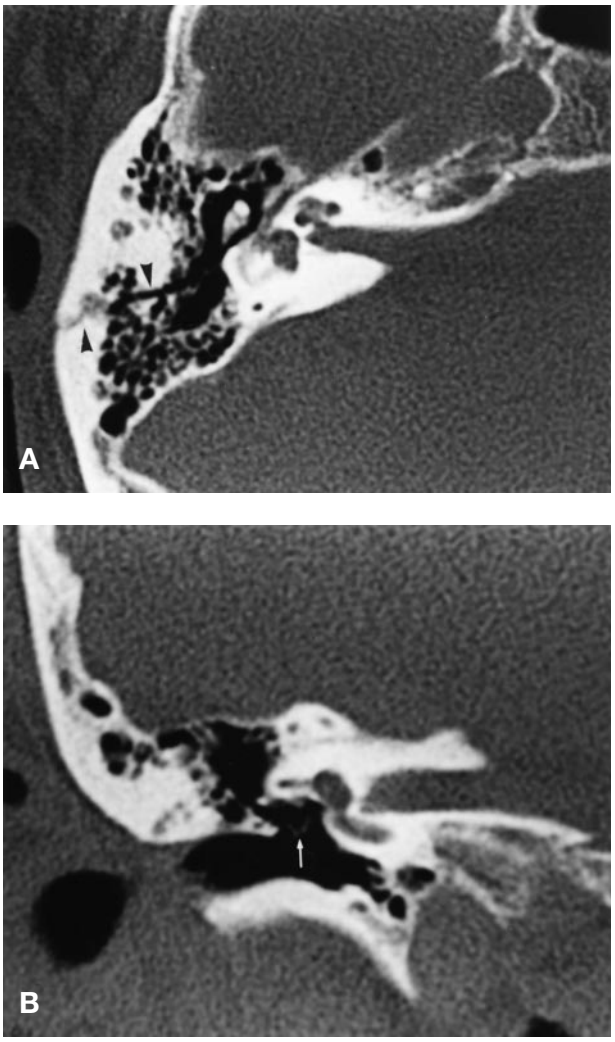

FIGURE 7–24. Longitudinal fracture of the right temporal bone. *A*, Axial; *B*, coronal computed tomographic sections. A fracture extends from the mastoid cortex to the region of the aditus (*black arrows*). The head of the malleus and the body of the incus are in normal relationship, but the incudostapedial joint is disrupted (*white arrows*).

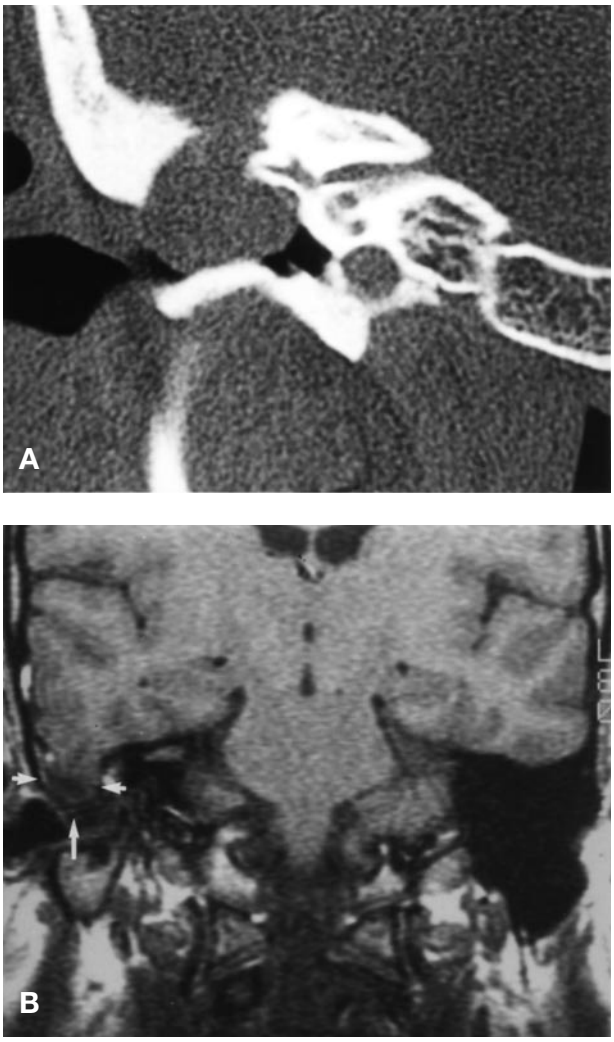

FIGURE 7–25. Meningoencephalocele, after modified radical mastoidectomy. *A*, Coronal computed tomographic section showing a large defect in the tegmen of the cavity with a soft tissue mass underneath it. *B*, T_1 coronal magnetic resonance image clearly identifying the soft tissue mass (*arrow*) as a brain herniation.

encephaloceles have the same characteristics of the adjacent brain, which are quite different from a cholesteatoma (Figure 7–25, B).

Acute Otitis Media The CT sections demonstrate a nonspecific and diffuse clouding of the middle ear cavity. The tympanic membrane is often swollen and bulges externally.

Chronic Otitis Media There are two types of chronic otitis media. In chronic suppurative otitis media, a partial, nonhomogeneous clouding of the middle ear cavity is caused by granulation tissue, polyps, and fluid or pus. Because the tympanic membrane is perforated, some aeration of the middle ear space is present. Erosion of the long process of the incus is a common finding, whereas erosion of the body of the incus and the head of the malleus is rare unless a cholesteatoma is present. In chronic adhesive otitis media, the middle ear space is contracted because of retraction of the tympanic membrane onto the promontory (Figure 7–26). The handle of

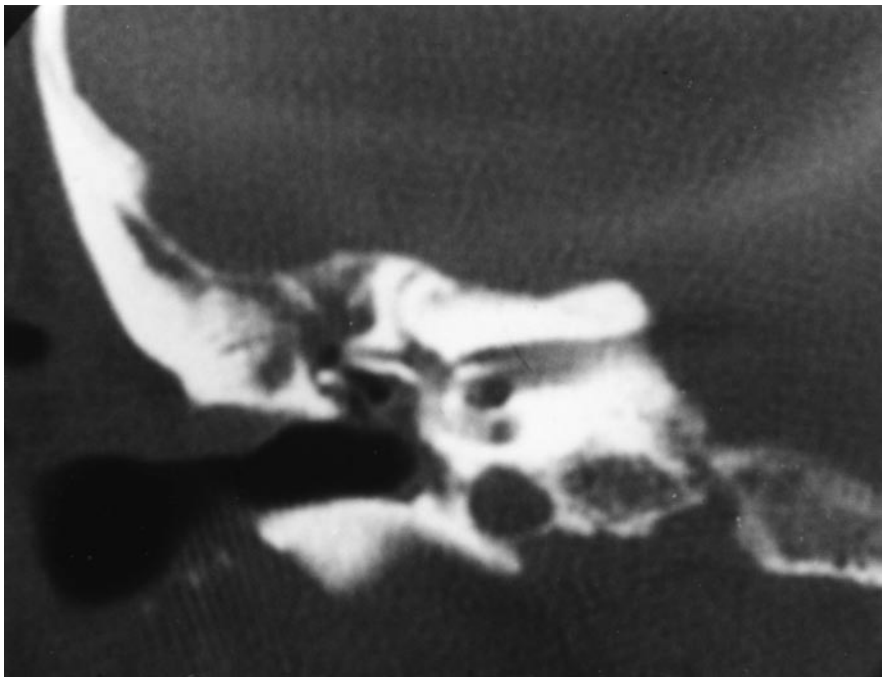

FIGURE 7–26. Right chronic otitis media, coronal computed tomographic section. The tympanic membrane is thickened and retracted. The mesotympanum is markedly contracted, and the mastoid air cells appear cloudy. The lateral wall of the attic and incudostapedial junction are intact.

the malleus is foreshortened, and the long process of the incus is often thinned out or eroded. In these cases, the retracted tympanic membrane may be attached to the head of the stapes with formation of a natural myringostapediopexy. Tympanosclerotic deposits are recognizable by CT whenever they are sufficiently large and calcified. The deposits appear as punctate or linear densities within the tympanic membrane or the mucosa covering the promontory. Large deposits of tympanosclerosis in the attic may surround and fix the ossicles.

Active and vascular granulation tissue undergoes a nonhomogeneous enhancement in the T_1 MRIs obtained after injection of contrast. This approach may occasionally be useful to differentiate granulation tissue from cholesteatoma, cholesterol granuloma, or other masses occurring in the middle ear.

Cholesteatomas Congenital cholesteatomas appear as well-defined soft tissue masses often producing an outward bulge of the intact tympanic membrane (Figure 7–27). If there is accompanying serous otitis media, the fluid may obscure the mass as the entire tympanic cavity becomes cloudy. If the lesion extends into the attic, the medial aspect of the lateral wall of the attic is eroded from within.

Acquired cholesteatoma produces a soft tissue mass in the middle ear and typical erosion of the lateral attic wall, posterosuperior canal wall, and ossicles. If the middle ear cavity is aerated, the soft tissue mass is well outlined. When fluid or inflammatory tissue surrounds the cholesteatoma, the margin of the mass is obscured because the x-ray densities of cholesteatoma, inflammatory tissue, and fluid are similar. Magnetic resonance imaging with contrast may be useful in these cases to differentiate the enhancing granulation tissue from fluid and cholesteatoma. Different patterns of x-ray findings are observed. Cholesteatomas that arise from the pars flaccida of the tympanic membrane produce erosion of the anterior portion of the lateral wall of the attic and tympanic spine (Figure 7–28). The lesion extends into the attic lateral to the ossicles, which may become medially displaced. Cholesteatomas arising from the pars tensa, usually from the posterosuperior margin of the tympanic membrane, appear as a soft tissue mass in the middle ear, eroding the long process of the incus and extending into the attic medial to the ossicles that may be displaced laterally (Figure 7–29). The lateral wall of the attic is usually intact, but the posterosuperior canal wall is often eroded. Sometimes a cholesteatoma may involve both the pars flaccida and tensa, producing a mixed x-ray pattern. In advanced cholesteatoma of all types, extensive bony destruction occurs, and no distinct pattern remains. The ossicles in the attic,

FIGURE 7–27. Left congenital cholesteatoma, coronal computed tomographic section. A well-defined soft tissue mass lies in the mesotympanum and extends from the intact tympanic membrane to the promontory. The remainder of the middle ear cavity and the mastoid are well aerated.

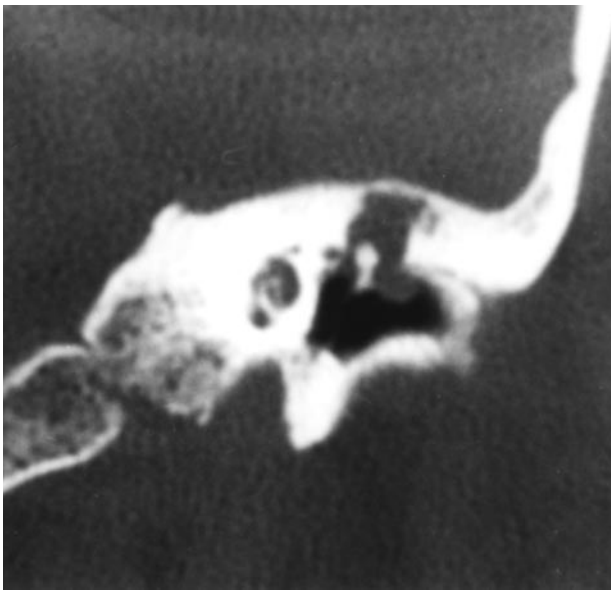

FIGURE 7–28. Left attic cholesteatoma, coronal computed tomographic section. The lateral wall of the attic is eroded by a soft tissue mass extending into the attic lateral to the ossicles. A polyp protrudes into the external auditory canal through a perforation of the pars flaccida of the tympanic membrane.

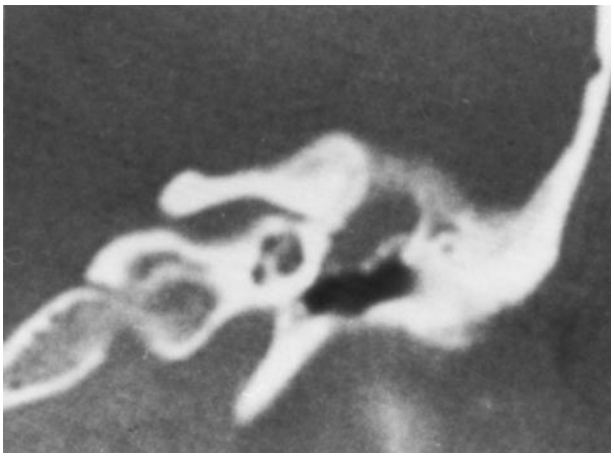

FIGURE 7–29. Left cholesteatoma, pars tensa perforation type, coronal computed tomographic section. The cholesteatoma extends into the attic medial to the ossicles and displaces the ossicles laterally.

particularly the body of the incus, are eroded, the aditus is widened, and the mastoid antrum becomes enlarged, cloudy, and smooth in outline because of erosion of the air cells lining the walls of the antrum. Further extension into the mastoid causes destruction of the trabeculae with formation of large cavities. Erosion of the tegmen may lead to meningeal and intracranial complications. Labyrinthine fistulae occur most commonly in the lateral portion of the horizontal semicircular canal (Figure 7–30). The CT sections show flattening of the normal convex

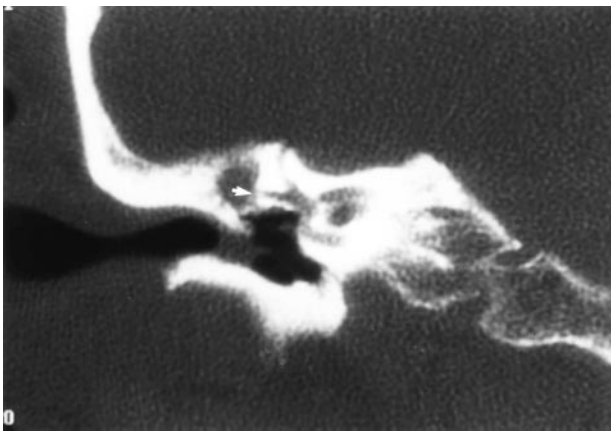

FIGURE 7–30. Right cholesteatoma with labyrinthine fistula. Coronal computed tomographic section: a soft tissue mass fills the attic, eroding the ossicles and the lateral aspect of the horizontal semicircular canal (*arrow*).

contour of the horizontal semicircular canal and erosion of the bony capsule covering the lumen of the canal. Further complications of cholesteatoma are extension into the petrous pyramid, which usually occurs in well-pneumatized bones, and erosion of the facial nerve canal, which may lead to facial paralysis.

Tumors Osteomas are frequent in the external auditory canal but also occur in the middle ear, where they may cause conductive hearing loss by impinging on the ossicular chain. Glomus tumors, also called chemodectomas or nonchromaffin paragangliomas, arise in the middle ear or jugular fossa from minute glomus bodies. Glomus tympanicum tumors arise from glomus bodies along Jacobson's nerve on the promontory. The CT sections reveal a soft tissue mass of variable size, usually in the lower portion of the middle ear cavity (Figure 7–31, A). As the lesion enlarges, it may cause a lateral bulge of the tympanic membrane, smooth erosion of the promontory, and involvement of the mastoid and hypotympanic air cells. If the lesion erodes into the jugular fossa, it becomes indistinguishable from a glomus jugulare tumor. Rapid sequential CT images of a preselected section showing the tumor mass, obtained after injection of a bolus of contrast material, generate a curve with a high quasiarterial peak rather than the high but delayed venous peak of a high jugular bulb[5] (Figure 7–31, B). Selective arteriography with subtraction is indicated to identify feeding vessels before embolization. Carcinomas extend into the middle ear from the external auditory canal. Adenocarcinoma is rare and produces a nonspecific soft tissue mass, often eroding the walls of the middle ear.

Otosclerosis Otosclerosis that involves the oval window causes fixation of the stapes and consequent conductive hearing loss. A 20-degree coronal oblique is far superior to the other projections for the study of the oval window. In active otosclerosis or otospongiosis, the margin of the oval window becomes decalcified so that the window seems larger than normal. In mature otosclerosis, the oval window becomes narrowed or closed (Figure 7–32), and in severe cases, the entire oval window niche is obliterated by calcified otosclerotic foci. The x-ray assessment is useful before surgery to confirm the clinical diagnosis and in some bilateral cases for selection of

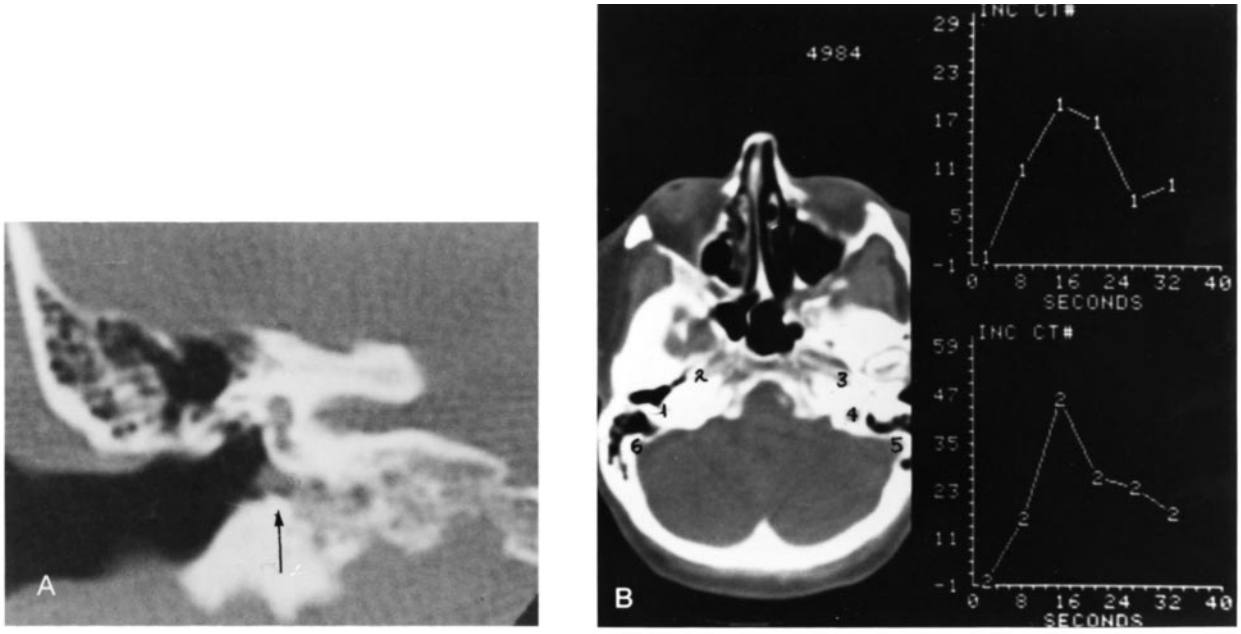

FIGURE 7–31. Right glomus tympanicum. *A*, Coronal computed tomographic (CT) section showing a small soft tissue mass in the lower portion of the middle ear cavity (*arrow*). *B*, Dynamic CT study of the preselected section showing the mass. Graphic display of the circulation in the tumor (1) and internal carotid artery (2). Notice the high peak of the tumor at quasiarterial time.

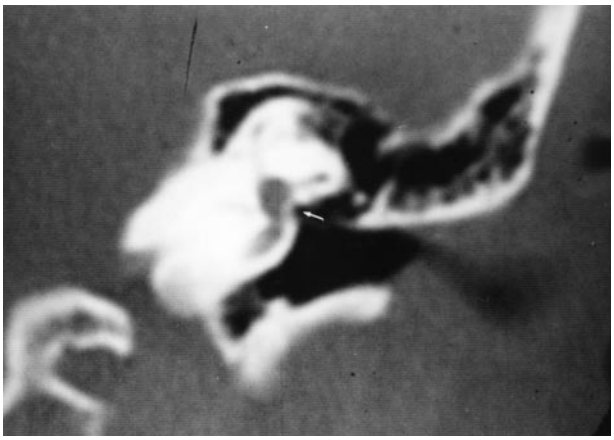

FIGURE 7–32. Stapedial otosclerosis, 20-degree coronal oblique section of the left ear. The footplate of this stapes appears thickened (*arrow*).

the ear to be operated on. More important is the study of the poststapedectomy ear in determining the cause for recurrent or persistent hearing loss and of immediate or delayed vertigo. Computed tomography can demonstrate protrusion of the prosthesis into the vestibule, reobliteration of the oval window with fixation of the strut, dislocation of the medial end of the prosthesis from the oval window, and separation of the lateral end of the strut from the incus or necrosis of the long process of the incus.

Inner Ear

Both CT and MRI are used for the study of the inner ear structures. Computed tomography is best for the study of the labyrinthine capsule; MRI is best for the assessment of the membranous labyrinth.

Congenital Anomalies Most cases of congenital sensorineural hearing loss have abnormalities limited to the membranous labyrinth and are therefore not demonstrable by CT.[6] Defects in the otic capsule are visible by CT. Anomalies may involve a single structure or the entire capsule. The most severe anomaly is the Michel type, which is characterized by hypoplasia of the petrous pyramid and almost complete lack of development of the inner ear structures (Figure 7–33). A less severe but more common malformation is the Mondini defect, which is characterized by hypoplasia or absence of the bony partitions between the cochlear coils, a short but wide vestibular aqueduct, and dilatation of the vestibule and ampullated ends of the semicircular canals (Figure 7–34). Enlargement of the vestibular aqueduct, hypoplasia of the cochlea and internal auditory canal, and deformity of the vestibule and semicircular canals may occur as isolated anomalies.[7] Dilatation of the cochlear aqueduct may be responsible for cerebrospinal fluid gush, which sometimes occurs

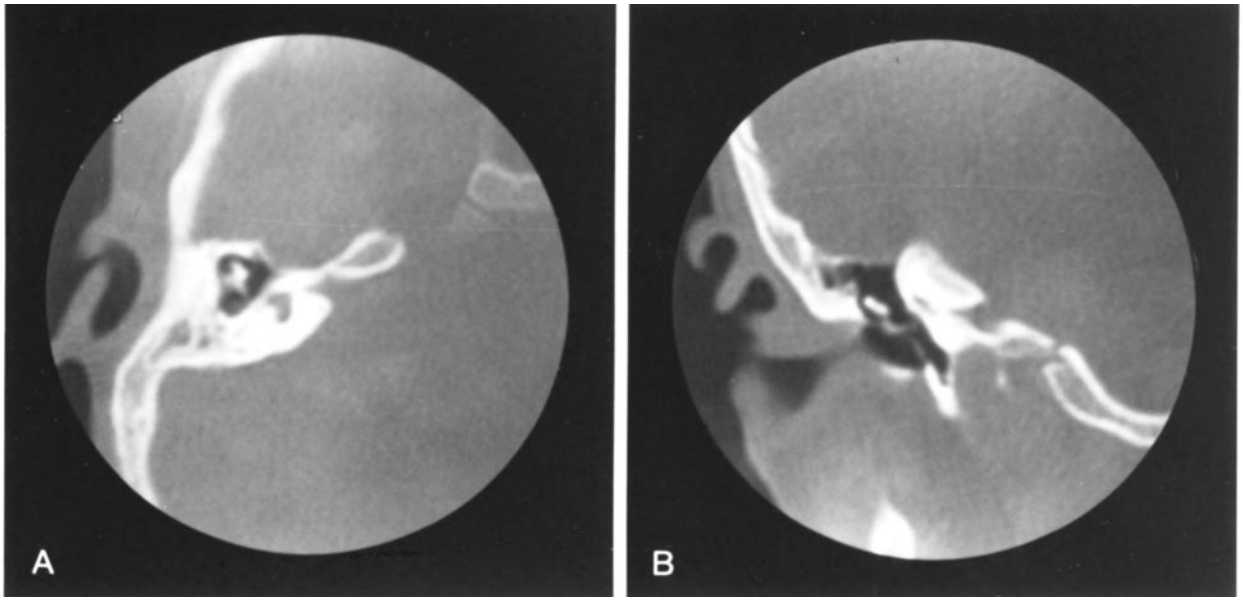

FIGURE 7–33. Michel malformation of the right inner ear structures. Axial (*A*) and coronal (*B*) computed tomographic sections. The middle ear cavity is normal, but the petrous pyramid is hypoplastic. The cochlea is absent or markedly hypoplastic. Notice the cavity in the region of the vestibule with rudimentary semicircular canals.

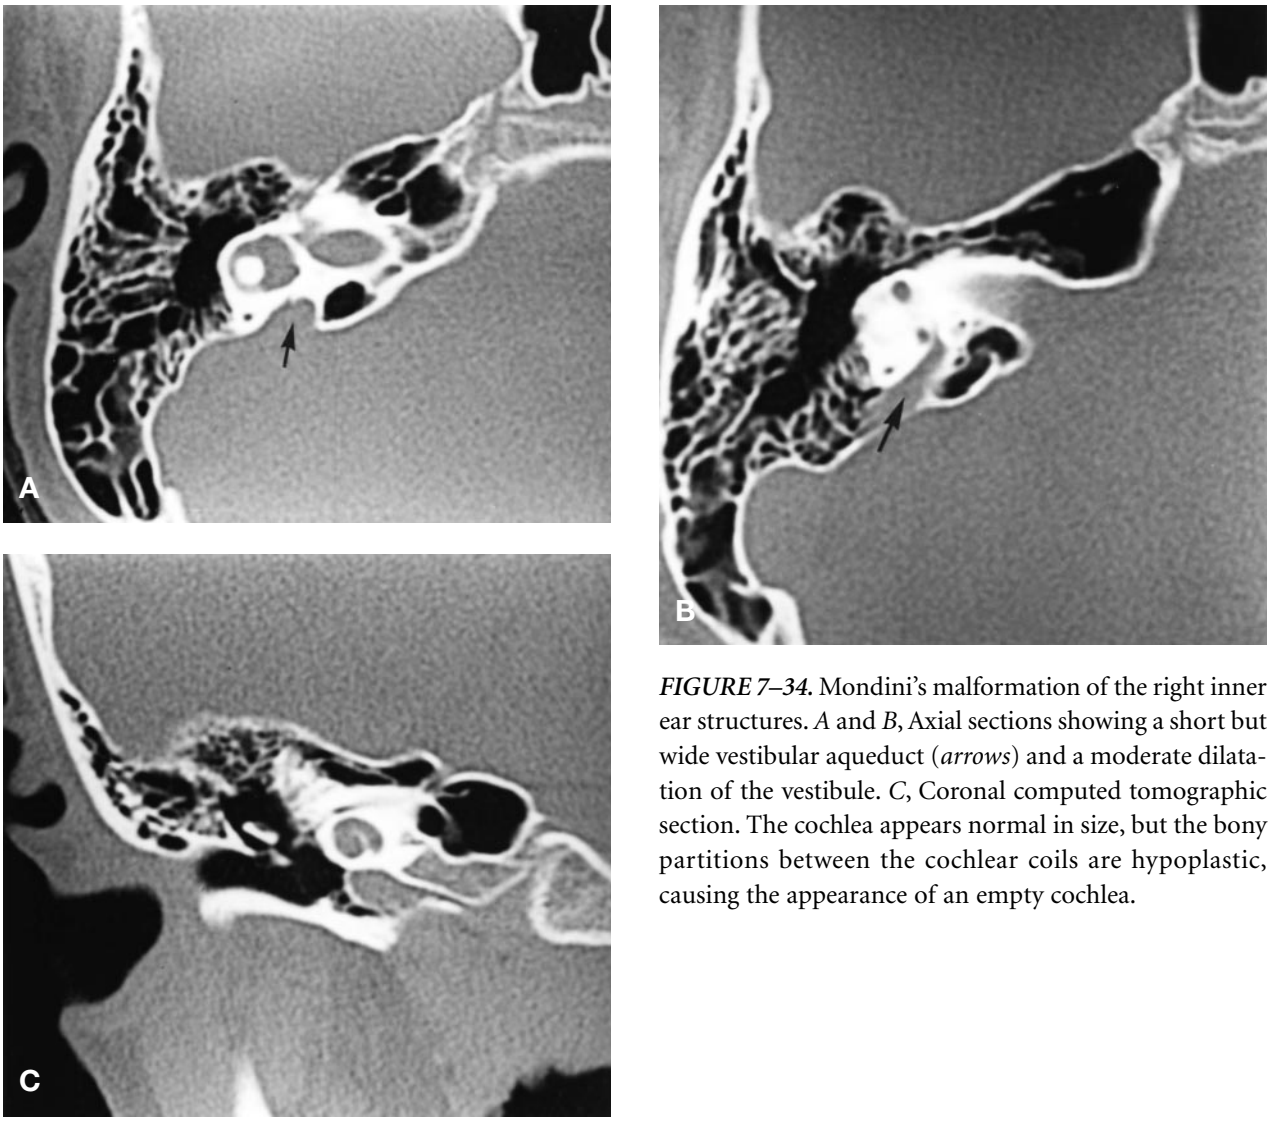

FIGURE 7–34. Mondini's malformation of the right inner ear structures. *A* and *B*, Axial sections showing a short but wide vestibular aqueduct (*arrows*) and a moderate dilatation of the vestibule. *C*, Coronal computed tomographic section. The cochlea appears normal in size, but the bony partitions between the cochlear coils are hypoplastic, causing the appearance of an empty cochlea.

during a stapedectomy for congenital footplate fixation or otosclerosis.

Trauma Bleeding within the lumen of the inner ear structures may occur after trauma. If bleeding occurs by concussion without actual fracture, MRI may be indicated to confirm the diagnosis. The study should be performed at 36 hours after the injury to allow the transformation of deoxyhemoglobin into methemoglobin, which has a bright signal in both T_1 and T_2 images (Figure 7–35).

The inner ear structures are seldom crossed by longitudinal fractures of the temporal bone but are usually involved in transverse fractures. These fractures typically cross the petrous pyramid at a right angle to the longitudinal axis of the pyramid and extend from the dome of the jugular fossa to the superior petrous ridge. Laterally placed fractures involve the promontory, vestibule, horizontal and posterior semicircular canals, and occasionally the tympanic segment of the facial nerve (Figure 7–36). Medially situated fractures involve the vestibule, cochlea, fundus of the internal auditory canal, and common crus.

Labyrinthitis Enhancement within the lumen of the bony labyrinth is often observed in MRI obtained after injection of contrast material in patients with acute bacterial or viral labyrinthitis and sudden deafness[8–10] (Figure 7–37).

Chronic labyrinthitis varies from a localized reaction caused by a fistula of the bony labyrinth to

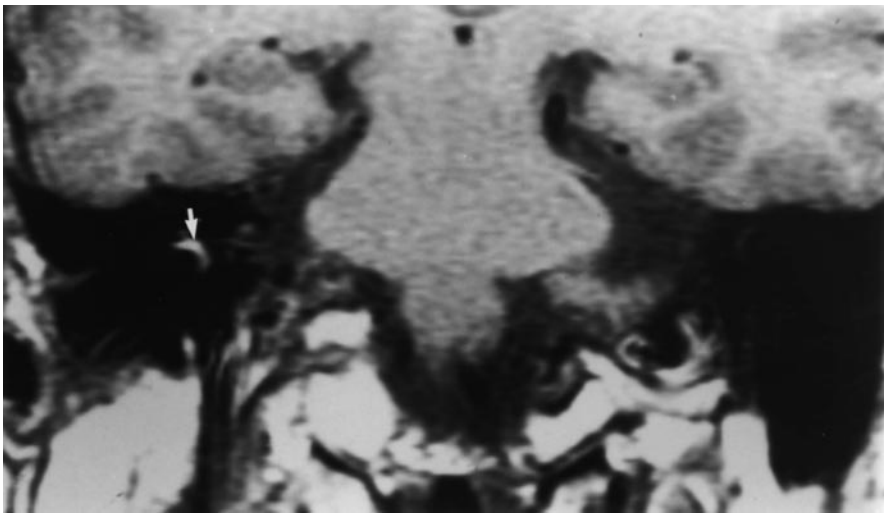

FIGURE 7–35. Labyrinthine concussion with bleeding. This T_1 coronal MR section shows an area of high signal intensity within the right vestibule (*arrow*) and adjacent portion of the semicircular canals.

a diffuse process. The lumen of the inner ear is partially or totally filled with granulation and fibrous tissues. Osteitis of the bony labyrinth occurs, which may lead to a partial or complete bony obliteration of its lumen (Figure 7–38). Whereas bony obliteration of the inner ear is readily identified by CT, fibrous obliteration is recognizable only by MRI. In the T_2 images, the high signal seen within the normal inner ear structures is absent, therefore making involved structures no longer recognizable.

Labyrinthine Schwannomas In the past, small schwannomas have been found within the vestibule and cochlea during postmortem dissection of the temporal bone. These lesions are usually not recognizable by CT but are well demonstrated as small, enhanced masses in MRI examinations performed after injection of contrast material (Figure 7–39).

Endolymphatic Sac Tumors Endolymphatic sac tumors are locally aggressive papillary adenomatous

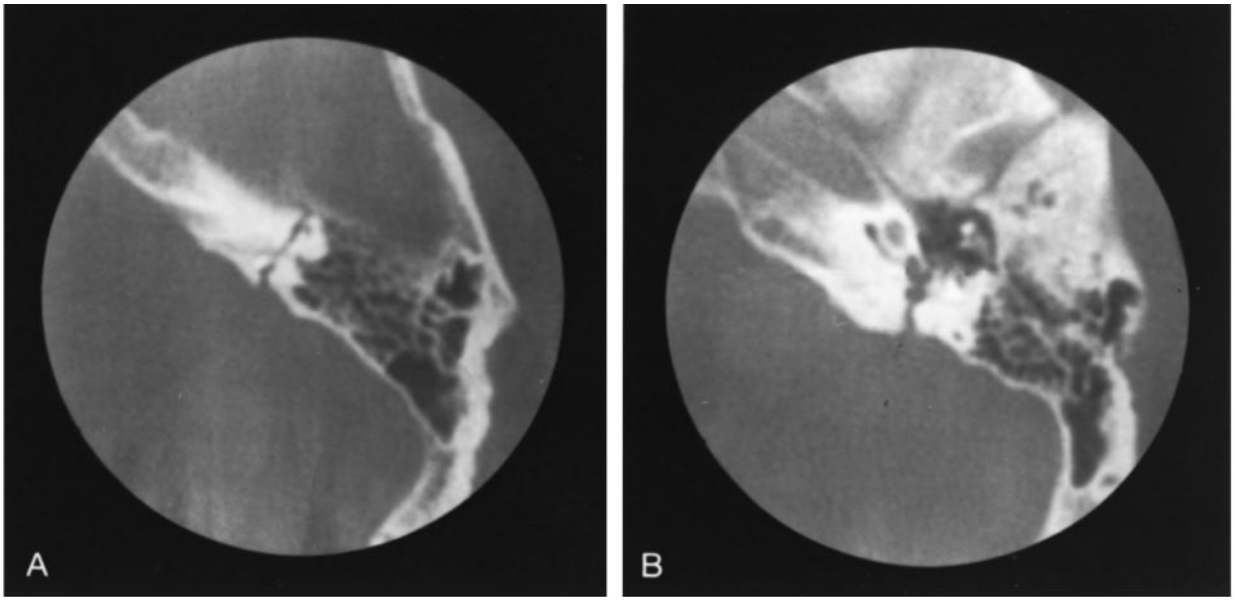

FIGURE 7–36. Transverse fracture of the left petrous pyramid. *A* and *B*, Axial computed tomographic sections. The fracture extends from the superior part of the petrous ridge to the undersurface of the temporal bone crossing the superior semicircular canal, vestibule, and promontory of the cochlea.

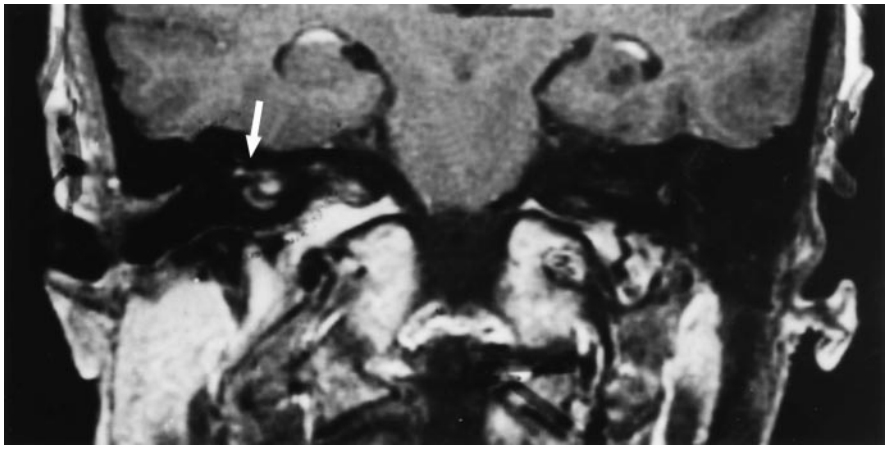

FIGURE 7–37. Acute labyrinthitis, presumably viral. This T_1 coronal MR image obtained after injection of gadolinium diethylenetriamine pentaacetic acid reveals enhancement within the lumen of the right cochlea (*arrow*).

tumors.[11] They are often associated with von Hippel-Lindau disease, a genetic multisystem neoplastic disorder. An early finding in endolymphatic sac tumors is a sensorineural hearing loss. At first, endolymphatic sac tumors involve the adjacent dura and endolymphatic duct. From there the lesion extends to the vestibule, semicircular canals, mastoid, and middle ear cavity, where it appears through an intact tympanic membrane as a bluish mass, often confused with a glomus tumor. Continuous growth leads to complete replacement of the mastoid and petrous pyramid by tumor. Axial CT images initially show a localized area of erosion of the posterior aspect of the petrous pyramid in the region of the endolymphatic sac (Figure 7–40, A). As the lesion enlarges, destruction of the petrous pyramid is observed with involvement of the inner ear structures. In the T_1 MRI, the tumor has a heterogeneous appearance with areas of high signal owing to cysts filled with blood or high proteinaceous fluid and multiple small areas of signal void owing to calcifications and blood vessels. Following administration of contrast, the solid portion of the mass undergoes a nonhomogeneous enhancement (Figure 7–40, B).

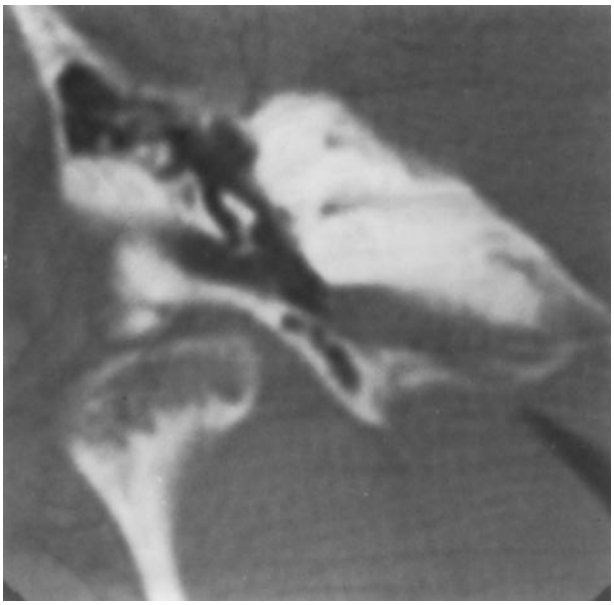

FIGURE 7–38. Obliterative labyrinthitis, coronal computed tomographic section of the right ear. Notice the complete bony obliteration of the cochlear lumen.

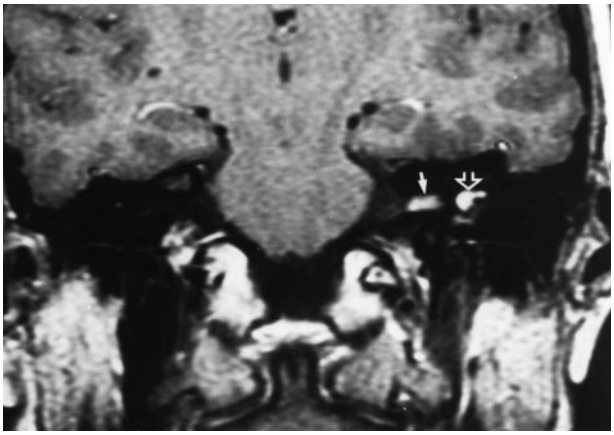

FIGURE 7–39. Left labyrinthine schwannoma. T_2 coronal magnetic resonance image after injection of contrast material. An enhancing soft tissue mass fills the vestibule and extends into the horizontal semicircular canal (*open arrow*). A second, seemingly not connected, mass is seen within the left internal auditory canal (*solid arrow*).

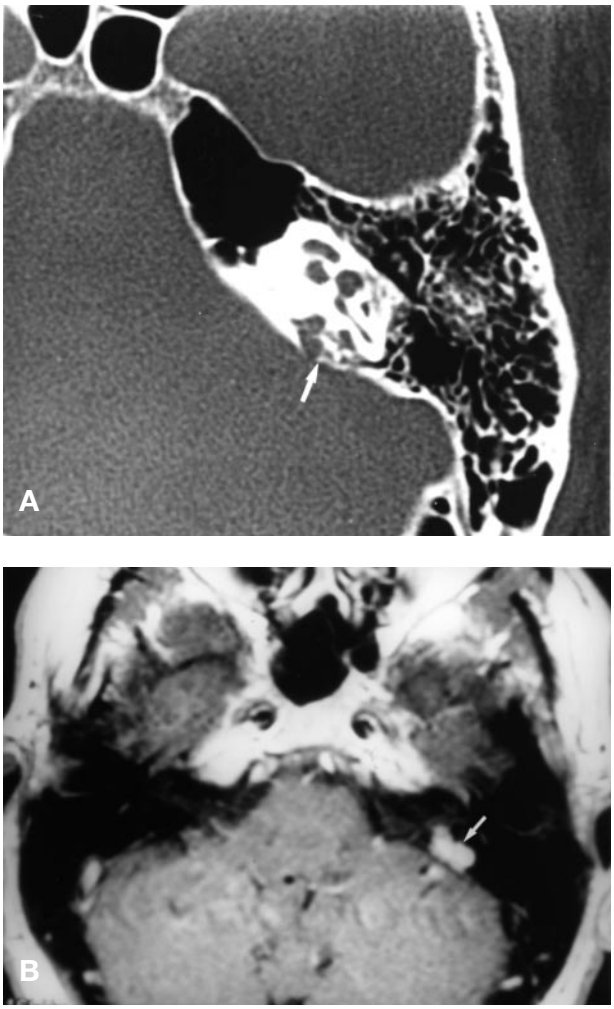

FIGURE 7–40. Endolymphatic sac tumor. *A*, Axial computed tomographic section of the left petrous pyramid. There is erosion of the posterior aspect of the petrous pyramid in the region of the endolymphatic sac with formation of an irregular cavity (*arrow*). *B*, T_1 axial magnetic resonance image. The tumor mass enhances after injection of contrast (*arrow*).

Otosclerosis Otosclerosis involving the cochlear capsule is often responsible for sensorineural hearing loss by an unknown mechanism. Cochlear otosclerosis is caused by progressive enlargement of the perifenestral foci or by single or multiple foci in other locations in the cochlear capsule. The CT findings vary with the stage of maturation of the process. In the active or spongiotic phase, small areas of demineralization are first observed in the normally sharp contour of the capsule. These foci may enlarge and become confluent, producing large areas of demineralization and finally complete dissolution of the capsule. A typical sign of active cochlear otosclerosis is the "double ring" caused by confluent spongiotic foci within the thickness of the capsule (Figure 7–41). In the mature or sclerotic stage, localized or diffuse areas of thickening of the capsule are present. A precise and quantitative assessment of the involvement of the cochlear capsule is accomplished by CT densitometric readings. The contour of the cochlear capsule is scanned with the smallest cursor (0.25 × 0.25 mm), and 31 or more densitometric readings are obtained. A profile of the density of the capsule is obtained by plotting densitometric values versus the points where the readings were made. The obtained curve is then compared with the densitometric profile of the normal capsule, which was previously determined[12] (Figure 7–42, A). Variations in density exceeding the standard deviation of 10 to

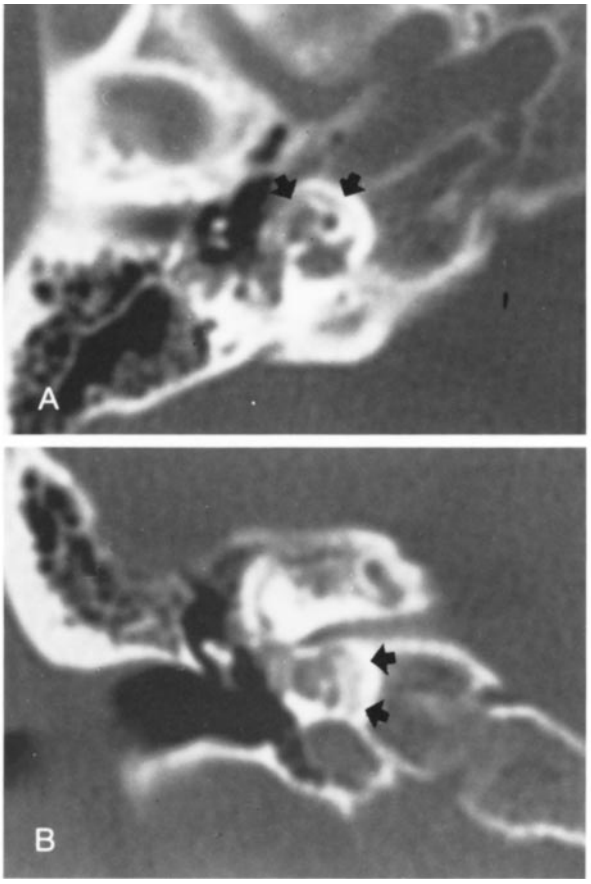

FIGURE 7–41. Cochlear otosclerosis. Axial (*A*) and coronal (*B*) computed tomographic sections. Multiple spongiotic foci are noted in the cochlear capsule with formation of a double ring (*arrows*).

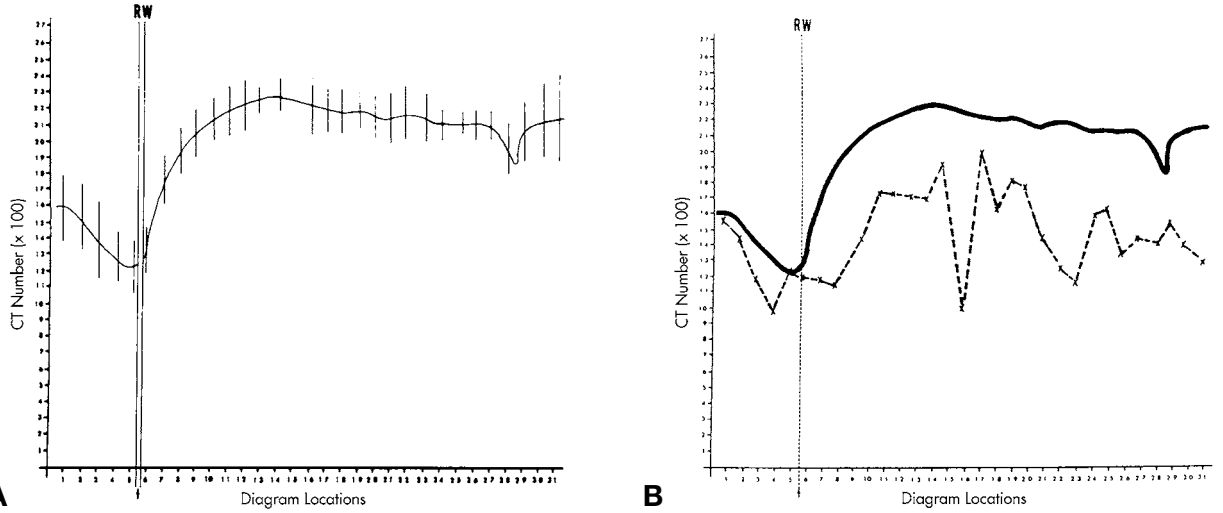

FIGURE 7–42. A, Densitometric profile of the normal cochlear capsule with standard deviations. *B*, Densitometric profile of the patient shown in Figure 7–41 (*interrupted line*). Comparison with the densitometric profile of the normal capsule (*solid line*) shows a diffuse demineralization of the cochlear capsule that is more severe in the region of the middle and apical coils. RW = round window.

15% are considered significant (Figure 7–42, B). With comparison of the original densitometric profile with follow-ups, it is possible to assess the evolution of the otosclerotic process and, when surgical or medical treatment was performed, to determine if any change has occurred in the maturation and extent of the disease.

Petrous Pyramid

Petrous Apex The petrous apex may be extensively pneumatized or made up of compact or diploic bone. In an MRI study, the signal intensity of the apex varies with the bony texture: high or bright in the T_1 images when diploic, low or dark when highly pneumatized or compact. Often the bony texture of the two petrous apices of the same person is different, resulting in one apex being brighter than the other (Figure 7–43).

Petrositis Extension of an acute suppurative mastoiditis and otitis media into a pneumatized petrous apex leads to petrositis. The air cells of the petrous pyramid become cloudy, and the cells' walls are first ill defined and later destroyed with formation of coalescent cavities. The infection may spread intracranially with consequent serious complications.

Glomus Jugulare Tumors These tumors arise from minute glomus bodies found in the jugular

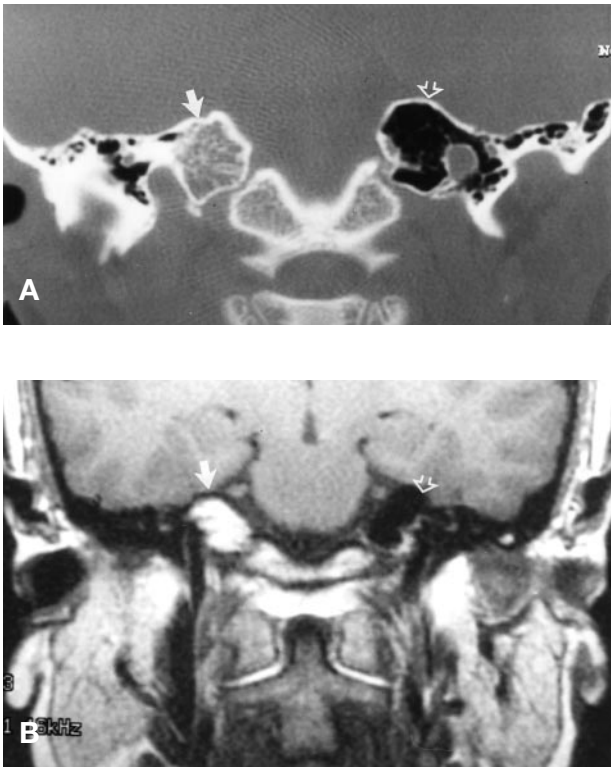

FIGURE 7–43. Petrous apex. *A*, Coronal computed tomographic section; *B*, coronal T_1-weighted magnetic resonance image (MRI). The right petrous apex (*solid arrow*) is diploic, whereas the left (*open arrow*) is pneumatized. The right diploic apex is bright in the MRI, whereas the left pneumatized apex appears as an area of signal void.

fossa. The typical CT findings include enlargement of the jugular fossa with erosion of the cortical outline, the septum dividing the jugular fossa from the outer opening of the carotid canal, and the hypotympanic floor with extension of the tumor into the middle ear cavity. As the lesion enlarges, the posteroinferior aspect of the entire petrous pyramid becomes eroded (Figure 7–44), as well as the adjacent aspect of the occipital bone, including the hypoglossal canal. Large tumors protrude extradurally in the posterior cranial fossa and inferiorly below the base of the skull along the jugular vein. These extensions are better demonstrated by MRI, in which the tumor appears in both T_1- and T_2-weighted images as a mass of medium signal intensity containing several small areas of signal void produced by blood vessels. After the injection of contrast material, the tumor undergoes a moderate enhancement (Figure 7–45). The signal intensity of the glomus tumor is differentiated easily from the surrounding intra- and extracranial structures. In addition, MRI allows determination of displacement, encroachment, narrowing, or obstruction of the jugular vein and internal carotid artery because these large vessels are well visualized, with no need for invasive vascular procedures. Jugular venography and carotid arteriography are seldom needed, and carotid arteriography is limited to preembolization.

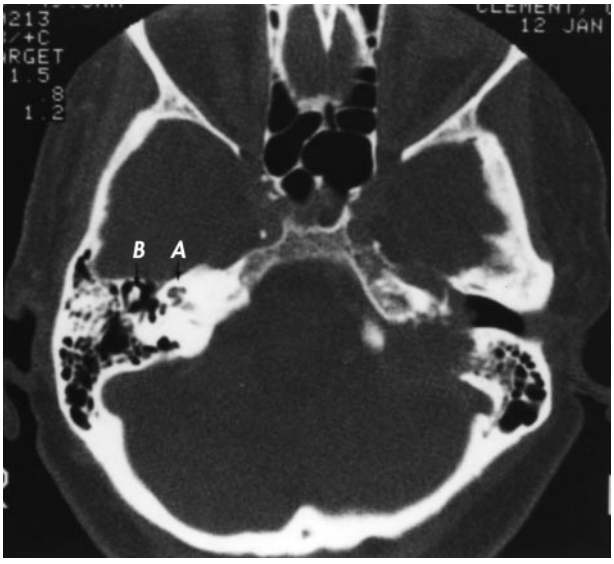

FIGURE 7–44. Left glomus jugulare tumor, axial computed tomographic section. The posterior aspect of the left temporal bone in the region of the jugular fossa is eroded. A soft tissue mass extends into the middle ear cavity through a large defect in its posterior wall. A = cochlea; B = ossicles, on the right side.

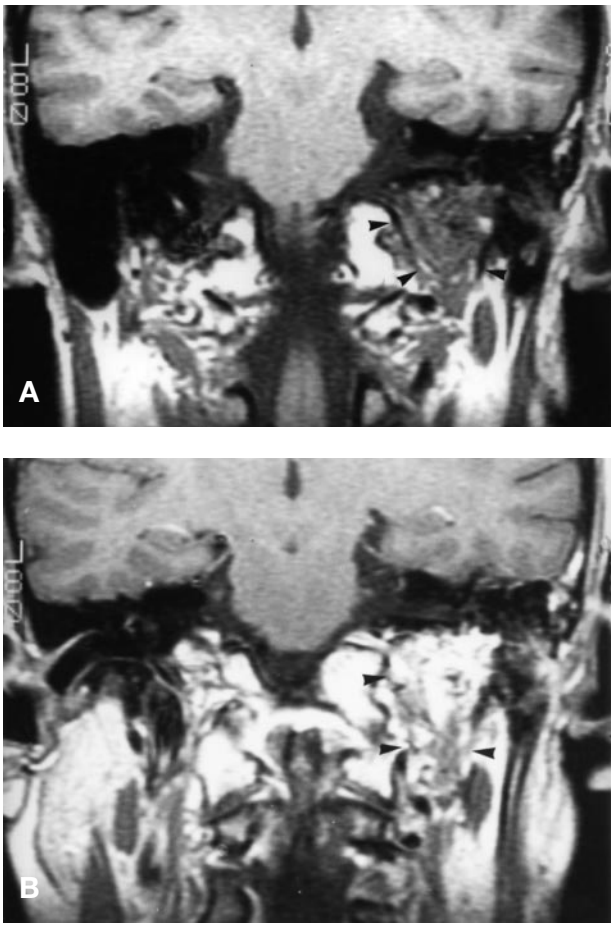

FIGURE 7–45. Glomus jugulare tumor. Coronal T_1-weighted magnetic resonance image (*A*) prior to and (*B*) after injection of contrast. A large and enhancing soft tissue mass (*arrowheads*) is present in the region of the left jugular fossa. The tumor extends into the lower portion of the middle ear cavity and erodes the undersurface of the petrous pyramid. Multiple areas of signal void, produced by blood vessels, are seen within the tumor mass, producing the classic "salt and pepper" appearance.

Congenital Cholesteatomas and Cholesterol Granulomas Congenital cholesteatomas may arise in the petrous pyramid. In the CT images, the involved area of the pyramid appears expanded by a cyst-like low-density lesion that often reaches and erodes the internal auditory canal and labyrinth. A CT study with infusion shows no enhancement of

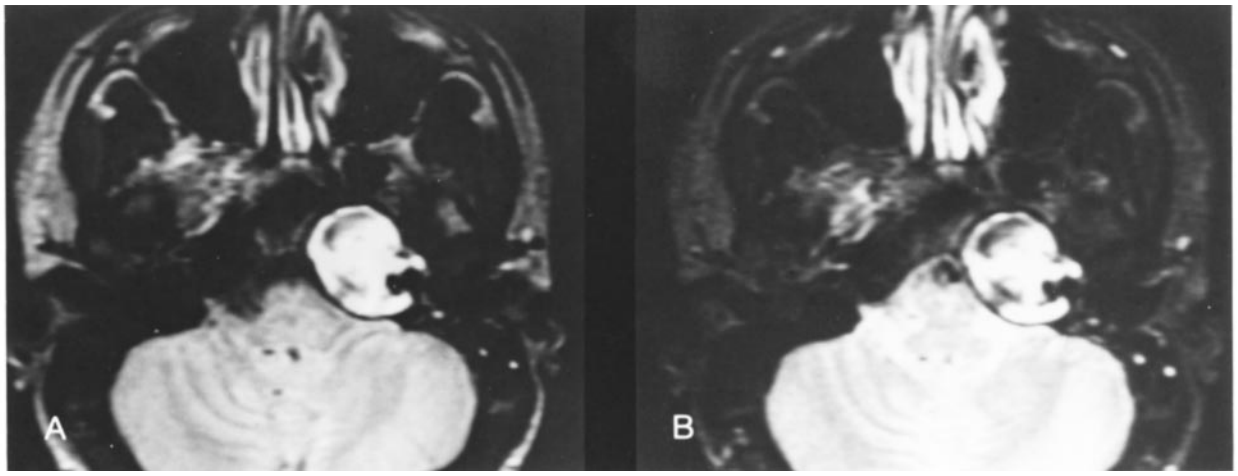

FIGURE 7–46. Cholesterol granuloma. Axial spin density (*A*) and axial T_2-weighted (*B*) magnetic resonance images. A mass of high signal intensity in both sequences is demonstrated in the left petrous apex. The areas of signal void within the mass are produced by deposits of hemosiderin.

the mass except for its capsule. With CT, a congenital cholesteatoma of the petrous apex is difficult to differentiate from a cholesterol granuloma cyst that occurs in extensively pneumatized petrous pyramids. The two lesions can be differentiated by MRI because congenital cholesteatomas produce a signal of medium intensity in the T_1 images and high intensity in T_2, whereas cholesterol granulomas have a similar high signal in both T_1 and T_2 sequences. Areas of signal void are often observed in cholesterol granulomas produced by deposits of hemosiderin (Figure 7–46).

Meningiomas These tumors arise from the meningeal covering of the temporal bone and from the meningeal extension into the internal auditory canal. The latter mimics, both clinically and in imaging, the appearance of an acoustic schwannoma. Meningiomas that arise from the petrous ridge are usually recognizable in the CT images as highly enhancing masses producing hyperostotic or lytic changes in the adjacent petrous pyramid. In meningiomas en plaque, only the bony changes are recognizable. Magnetic resonance images obtained after injection of paramagnetic contrast demonstrate a strong and usually homogeneous enhancement of the tumor. En plaque lesions are recognizable as areas of enhancing meningeal thickening (Figure 7–47).

Hemangiomas These uncommon tumors of the petrous pyramid usually arise in the region of the geniculate ganglion and extend into the internal auditory canal. Facial paralysis is often the first symptom. Computed tomography shows a poorly defined lytic lesion containing an almost pathognomonic bony spiculation[13] (Figure 7–48, A). With MRI, the tumor is of medium signal intensity in T_1 images, undergoes a strong enhancement after injection of contrast, and contains linear areas of signal void owing to bony spiculae (Figure 7–48, B).

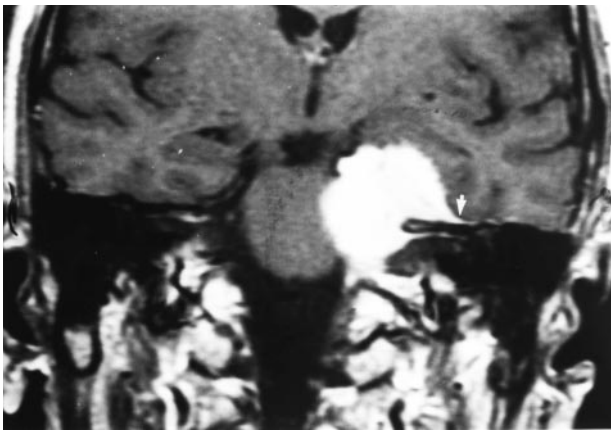

FIGURE 7–47. Meningioma coronal T_1-weighted magnetic resonance image section after injection of contrast material. A large enhancing mass extends above and below the left side of the tentorial notch. The tumor spares the internal auditory canal. Notice the lateral en plaque extension of the lesion (*arrow*).

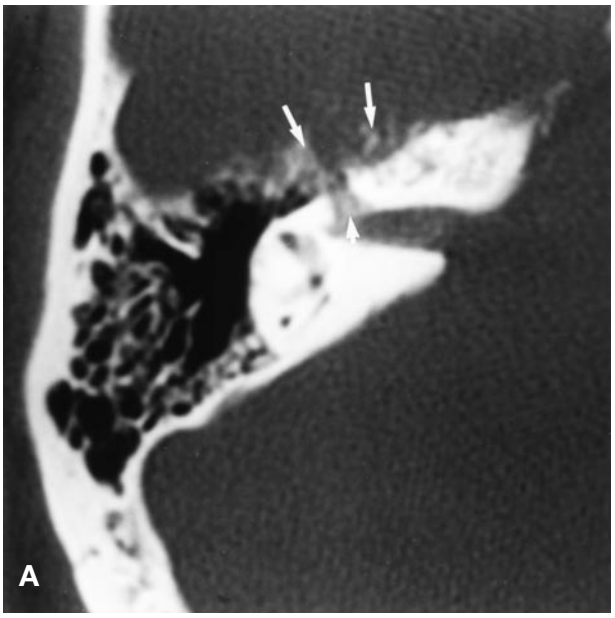

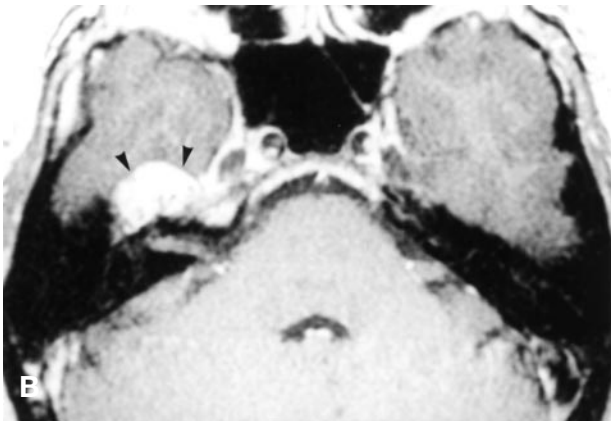

FIGURE 7–48. Hemangioma, right petrous pyramid. *A*, Axial computed tomographic section; *B*, axial T_1-weighted magnetic resonance image after contrast. The anterior aspect of the right petrous pyramid is eroded by an enhancing soft tissue mass (*arrowheads*) extending into the attic, labyrinthine segment of the facial nerve canal, and fundus of the internal auditory canal. Note the characteristic bony spiculation within the tumor mass (*arrows*).

Paget's Disease Paget's disease often affects the calvarium and the base of the skull, including the petrous pyramids. The disease usually spreads from the petrous apex laterally and produces a typical washed-out appearance of the involved pyramid caused by extensive demineralization (Figure 7–49). The internal auditory canal is usually involved first, followed by the otic capsule, which first becomes thinned out and is then completely erased. In the late stage of the disease, deposition of irregularly mineralized bone occurs and results in thickening of the petrosa, narrowing of the internal auditory canal, and fixation of the footplate of the stapes.

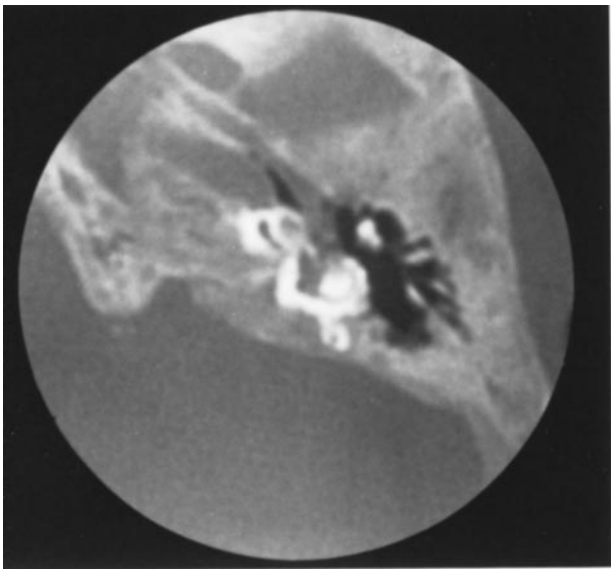

FIGURE 7–49. Paget's disease, axial section of the left temporal bone. Notice the severe demineralization of the petrous pyramid and mastoid with thinning of the otic capsule, particularly of the cochlea.

Facial Nerve

Computed tomography is the study of choice of the facial nerve canal. The examination should be performed in two or three planes to visualize the various segments of the canal. Magnetic resonance imaging visualizes the facial nerve itself, particularly when the nerve is thickened.

Congenital Anomalies Congenital anomalies involve the size and course of the facial canal. The canal may be partially or completely absent, hypoplastic, or unusually narrow. Minor variations of the course of the facial nerve are common and of no clinical significance. More severe anomalies should be identified to avoid serious damage to the nerve during surgery. The horizontal segment may be displaced inferiorly to cover the oval window or lie exposed on the promontory. In congenital atresia of the external auditory canal, the mastoid segment of the facial canal is rotated laterally. The rotation varies from minimal obliquity to a true horizontal course.

Trauma Traumatic lesions of the intratemporal portion of the facial nerve occur in approximately 20% of longitudinal fractures of the temporal bone and 50% of transverse fractures. The most common site of involvement in longitudinal fractures is the anterior genu (Figures 7–50 and 7–51) and in transverse fractures the labyrinthine or intracanalicular segments. The facial nerve may be transected by the fracture, compressed, sheared by a depressed fragment of the canal wall, or simply contused by the violent shock.

Facial Neuritis Moderate bilateral enhancement of the normal facial nerve, particularly in the region of its anterior genu, is often observed in MRI obtained after injection of contrast material.

Asymmetric enhancement of the facial nerve more prominent on the paralyzed side is common in patients with Bell's palsy and Ramsay Hunt syndrome. In Bell's palsy, the involvement is segmental and usually confined to the anterior genu and adjacent labyrinthine and tympanic segments (Figure 7–52). In Ramsay Hunt syndrome, the involvement by the herpes zoster virus is more continuous and often extends to the nerve within the internal auditory canal.

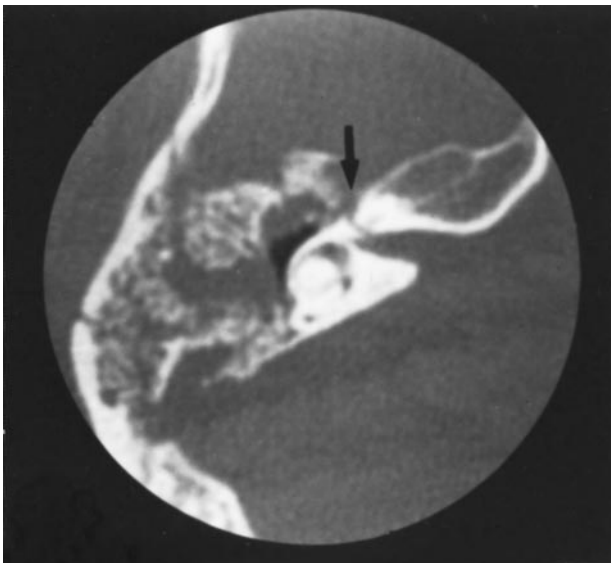

FIGURE 7–50. Longitudinal fracture of the right temporal bone, axial computed tomographic section. The fracture passes from the mastoid through the attic into the petrous pyramid anterior to the labyrinth. The fracture reaches and involves the facial canal at its anterior genu (*arrow*).

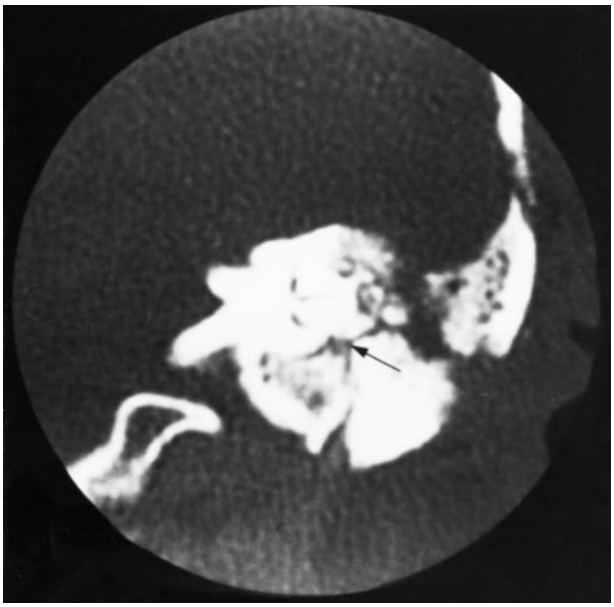

FIGURE 7–51. Comminuted fracture of the left mastoid, coronal computed tomographic section. Multiple fractures are noticed in the mastoid. One of the fractures passes underneath the posterior semicircular canal and transects the vertical segment of the facial canal (*arrow*).

In viral neuritis, the nerve is usually not thickened. In sarcoidosis, the involvement is similar to Bell's palsy, but the nerve is moderately thickened.

Tumors Primary tumors of the facial nerve are rare. Facial neurinomas cause thickening of the nerve and expansion of the canal (Figure 7–53, A). Further enlargement of the lesion results in erosion of the bony canal, extension into the middle ear space, and involvement of the mastoid and petrous pyramid. Magnetic resonance imaging is useful to differentiate large facial nerve neurinomas from other lesions. The mass has a nonspecific low signal in T_1-weighted images and a high signal in T_2-weighted images but changes to bright in T_1 images obtained after injection of gadolinium DTPA (Figure 7–53, B).

The facial canal, particularly its vertical segment, is often involved by carcinoma arising in the external auditory canal and malignancies arising in the parotid gland and extending into the temporal bone.

Internal Auditory Canal

Acoustic Schwannomas Acoustic schwannomas account for 90% of the tumors of the cerebellopon-

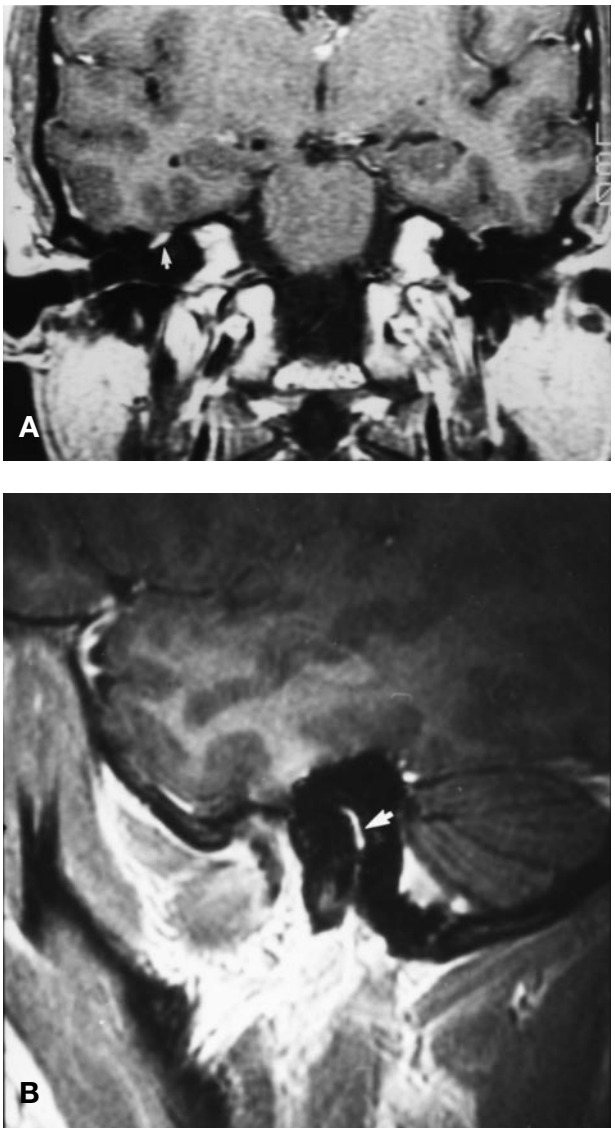

FIGURE 7–52. Facial neuritis. Coronal (*A*) and sagittal (*B*) T_1-weighted magnetic resonance images after injection of contrast material. There is enhancement of the right facial nerve in the regions of the anterior genu and proximal portion of the mastoid segment (*arrows*).

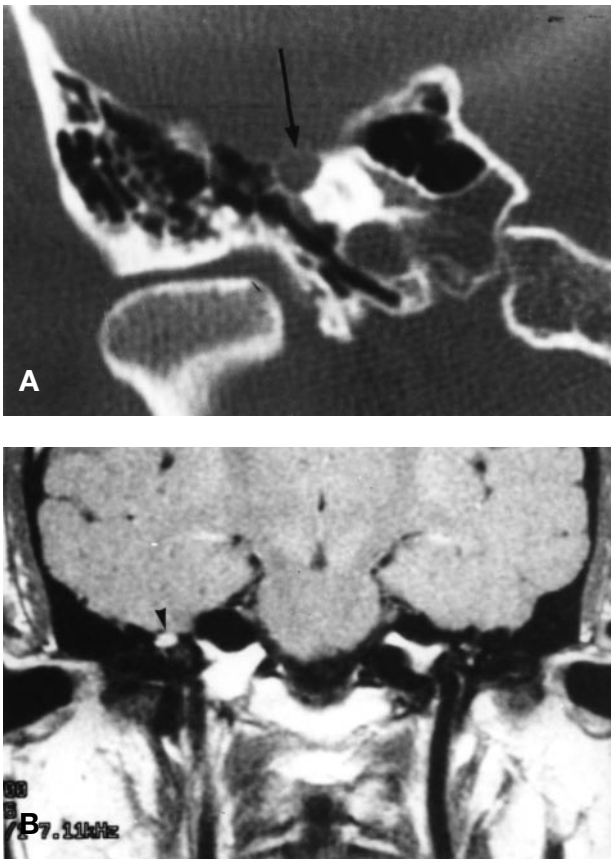

FIGURE 7–53. Facial neurinoma. *A*, Coronal computed tomographic section revealing expansion of the right facial canal at the anterior genu (*arrow*). *B*, The coronal T_1-weighted magnetic resonance image section obtained after injection of gadolinium diethylenetriamine pentaacetic acid shows the actual enhancing tumor mass (*arrowhead*).

tine angle. These tumors usually arise within the internal auditory canal, which becomes enlarged. Expansion of the internal auditory canal, shortening of its posterior wall, and erosion of the crista falciformis are well visualized in high-definition CT images targeted for bone. Both sides should always be examined to compare significant differences. Acoustic schwannomas are not visualized in plain CT scans because the tumor is isodense to the surrounding brain and is not surrounded by edema. After infusion of iodinated contrast material, the mass enhances and becomes visible (Figure 7–54). Intracanalicular lesions and cisternal masses smaller than 0.8 cm usually are not visualized by the infusion technique and, if MRI is not available, a CT pneumocisternogram is indicated. This examination requires a spinal puncture for the injection in the subarachnoid space of air, carbon dioxide, or oxygen. With proper positioning, the gas is moved into the cerebellopontine angle under investigation, and several thin sections are obtained. In normal cases, the gas fills the cerebellopontine cistern and the internal auditory canal outlining the seventh and eighth cranial nerves. If a small tumor is present, the gas outlines the localized swelling of the nerve; if the

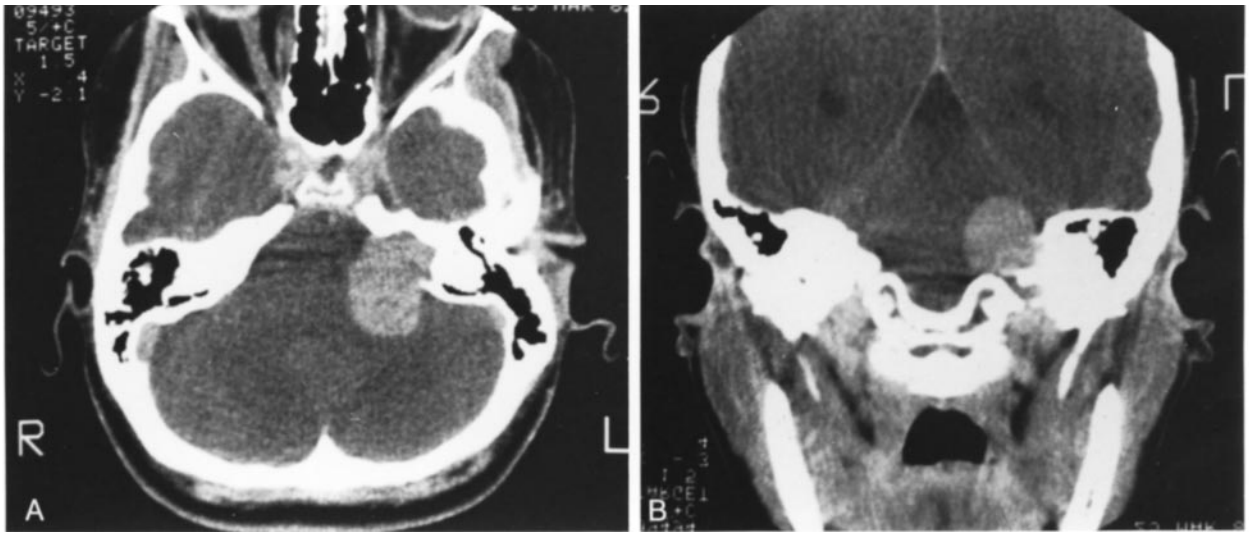

FIGURE 7–54. Left acoustic schwannoma, postinfusion study. *A*, Horizontal computed tomographic (CT) section. *B*, Coronal CT section. The left internal auditory canal appears grossly expanded and eroded. A large tumor mass fills the canal and the cerebellopontine cistern. Notice the displacement to the right of the brainstem and fourth ventricle.

tumor is large, it outlines the convex medial aspect of the mass, obstructing the canal (Figure 7–55).

Magnetic resonance imaging is the study of choice for diagnosis of acoustic schwannomas without exposing the patient to ionizing radiation and without the necessity for spinal puncture.[14,15]

Thin MRIs are obtained in the axial or coronal plane prior to and after injection of paramagnetic agents. In the precontrast image, the tumor is brighter than cerebrospinal fluid and isointense to gray matter. In the postcontrast study, the mass undergoes a marked enhancement as the contrast

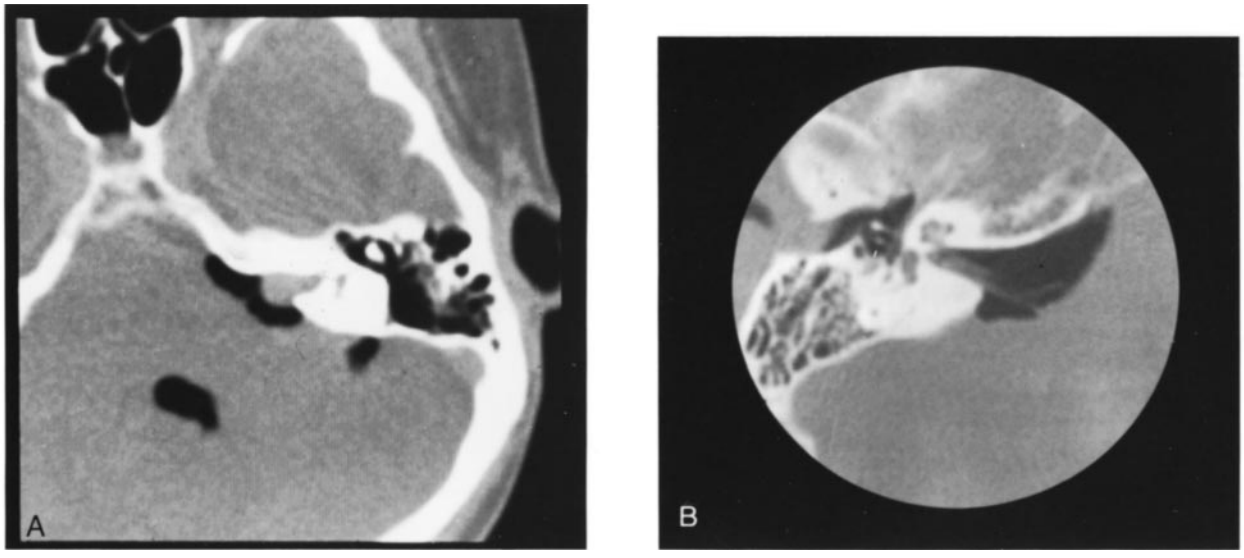

FIGURE 7–55. Left acoustic schwannoma. *A*, The computed tomographic pneumocisternogram demonstrates a tumor mass filling the left internal auditory canal and slightly protruding into the cerebellopontine cistern. Notice the uninvolved portion of the eighth cranial nerve extending from the medial aspect of the tumor to the brainstem. *B*, The right cerebellopontine cistern and internal auditory canal are well filled by air. The eighth cranial nerve courses from the brainstem through the cistern to the internal auditory canal.

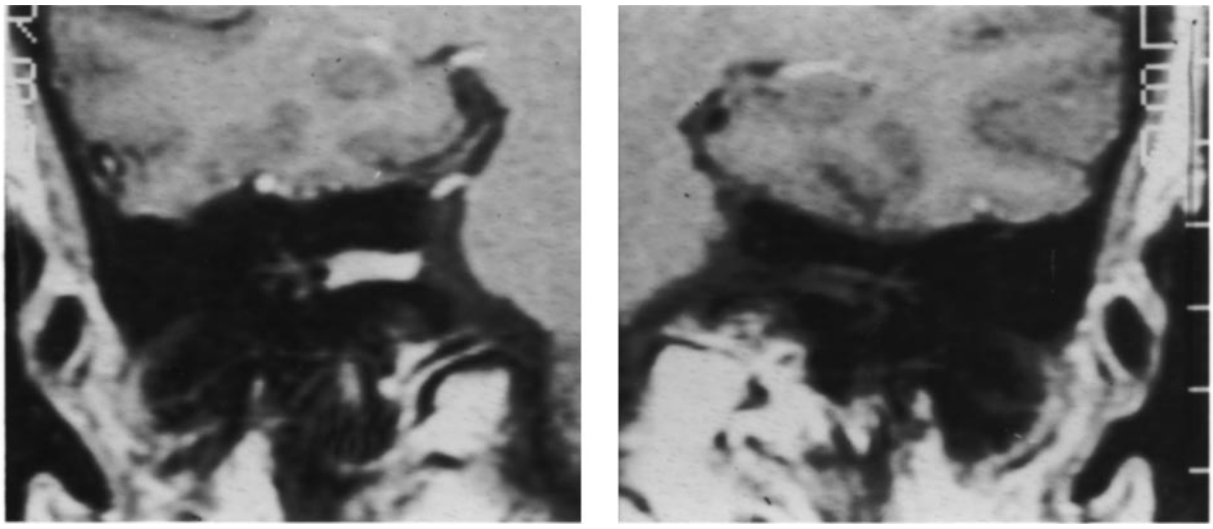

FIGURE 7–56. Right vestibular schwannoma. Right and left coronal T_1-weighted magnetic resonance images after contrast. An enhancing soft tissue mass fills the right internal auditory canal.

concentrates within the tumor with consequent shortening of the T_1 relaxation time (Figures 7–56 and 7–57). These images clearly show the size of the tumor within the internal auditory canal and cerebellopontine cistern, as well as possible extension into the modiolus, which carries a poor prognostic value unless the cochlea is sacrificed at surgery.[16] Extension of the tumor within the facial canal is usually indicative of a schwannoma arising from the facial nerve.

Meningiomas Meningiomas account for approximately 3 to 4% of the cerebellopontine angle tumors. The lesion has a signal intensity less than the brain in the T_1 sequences. In the T_2 images, the lesion has variable characteristics, either a pathognomonic further decrease in signal intensity or a nonspecific increase in brightness. After intravenous injection of gadolinium DTPA, in the T_1 images meningiomas show a marked increase in signal intensity similar to that seen in acoustic schwannomas. Unlike the latter tumor, meningiomas usually arise in the cerebellopontine cistern and spare the fundus or the entire internal auditory canal (see Figure 7–47).

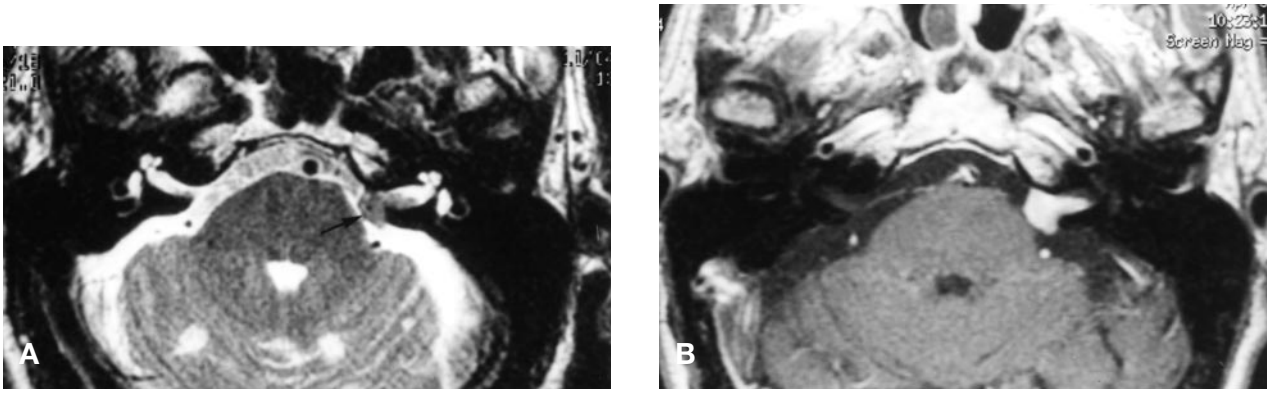

FIGURE 7–57. Left acoustic schwannoma. Axial magnetic resonance images. *A*, T_2 fast spin echo. *B*, T_1 postcontrast. An enhancing soft tissue mass partially fills the left internal auditory canal and protrudes into the cerebellopontine cistern. Note that the tumor is well seen in the fast spin echo image (*A*) as a filling defect within the bright signal of the cerebrospinal fluid (*arrow*).

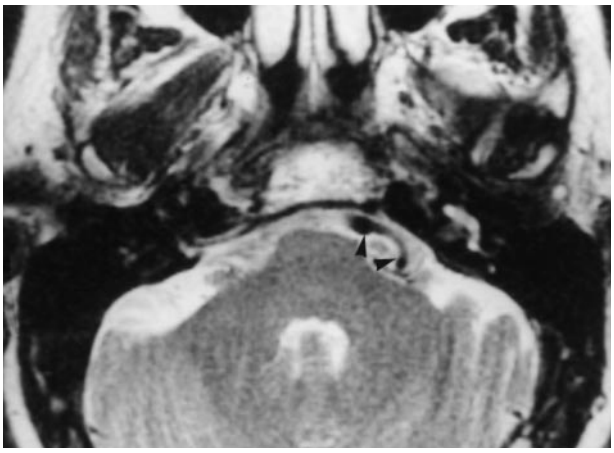

FIGURE 7–58. Vascular loop. Axial T_2 fast spin echo image. A prominent left vertebral artery loops within the left cerebellopontine cistern (*arrowheads*) crossing and presumably compressing the acoustic nerve.

Vascular Abnormalities The anterior inferior cerebellar artery often loops within the cerebellopontine cisterns, and in over 20% of cases, it actually enters the internal auditory canal. In addition, tortuous vertebral or basilar arteries often form prominent loops within the cerbellopontine cistern (Figure 7–58). Cross-compression of the acoustic nerve usually occurs at its takeoff from the brainstem owing to absence of slack in the nerve at this point or in a narrow internal auditory canal. In the past, vascular loops were identified by CT pneumocisternography. At present, we use T_2 FSE images in both axial and coronal planes.

Aneurysms Aneurysms in the internal auditory canal are extremely rare. An aneurysm appears on T_1- and T_2-weighted MRIs as a small mass of high signal presumably owing to a thrombosis or slow flow. Following the injection of contrast, the lesion becomes slightly larger. An aneurysm within the cerebellopontine cistern may compress the acoustic or facial nerve and mimic the symptomatology of a schwannoma. The MRIs obtained prior to and after contrast reveal a nonhomogeneous high signal produced by the blood clotting within the aneurysm (see Figure 7–9). If the lumen of the aneurysm is partially patent, the flowing blood will appear as an area of signal void.

Hemangiomas Small hemangiomas or AVMs limited to the lumen of the internal auditory canal are rare. They appear in preconstrast images as areas of high signal intensity owing to slow flow, which become larger following injection of contrast. The mass has nonhomogeneous intensity and may contain signal void areas owing to calcifications.

Malignant Neoplasms Leukemic and lymphomatous infiltrations have been described as occurring within the internal auditory canal and cerebellopontine cistern. The enhancing lesions are usually poorly defined and extend into the leptomeningeal space and meninges.

Metastatic deposits may occur within the internal auditory canal. In the author's experience, the most frequently encountered primaries are breast or lung carcinoma and melanoma. Whenever there is no bone involvement, the diagnosis of metastasis is difficult, although it should be considered whenever the patient has a history of neoplasia (Figure 7–59). Magnetic resonance imaging is the study of choice. The lesion has a signal of medium intensity in the T_1-weighted images, which becomes brighter in the T_2 images. Following the injection of contrast, the mass undergoes a homogeneous or nonhomogeneous enhancement.

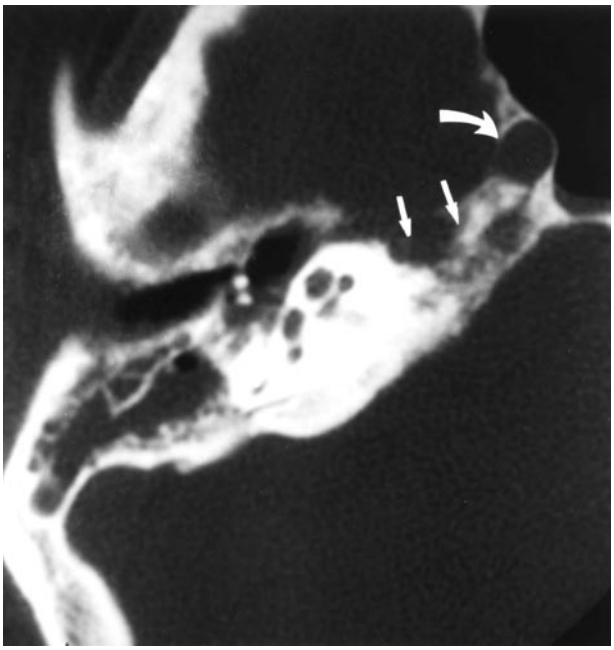

FIGURE 7–59. Metastatic lesion from carcinoma of the breast. Axial computed tomographic section showing a mottled area of bone erosion in the right petrous apex (*arrows*). The carotid canal (*curved arrow*) is intact.

CHAPTER 8

Diseases of the External Ear

Timothy T. K. Jung, MD, PhD, Tae Hoon Jinn, MD

The external ear is composed of the auricle, the external auditory canal (EAC), and the epithelial surface of the tympanic membrane. Diseases of the external ear include trauma, infections, and neoplasms.

ANATOMY

The auricle is composed of fibroelastic cartilage to which the skin and a small amount of subcutaneous tissue are closely attached. The skin on the external (anterior) surface of the auricle is attached firmly to the underlying cartilage, with the connective tissue of the dermis condensing to form perichondrium. The skin on the undersurface or posterior surface of the auricle, by contrast, has a true subcutaneous layer. This feature of the auricular integument, combined with the exposed position of the auricle, is responsible for the majority of clinical problems that involve the auricle: trauma, exposure, and infection. Fluid accumulation consequent to these processes results in separation of perichondrium from the cartilage. Unless this separation is promptly relieved, necrosis of cartilage will result because of interference with its perfusion from the vessels of the perichondrium. The topography of the auricle is determined by the contour of its underlying cartilaginous frame (Figure 8–1). The auricle is attached to the skull by a series of ligaments, muscles, and skin.

The EAC is approximately 2.5 cm in length and is divided into bony and cartilaginous parts. The medial two-thirds is osseous, and the lateral one-third is cartilaginous (Figure 8–2). Because of the oblique position of the tympanic membrane, the posterosuperior part of the canal is about 6 mm shorter than the anteroinferior portion. The osseous-cartilaginous junction forms an isthmus that is the narrowest segment of the EAC. Foreign bodies that make their way medial to this point are more difficult to remove.

The EAC serves as a channel for sound transmission to the middle ear and also protects the middle and inner ear from foreign bodies and fluctuation

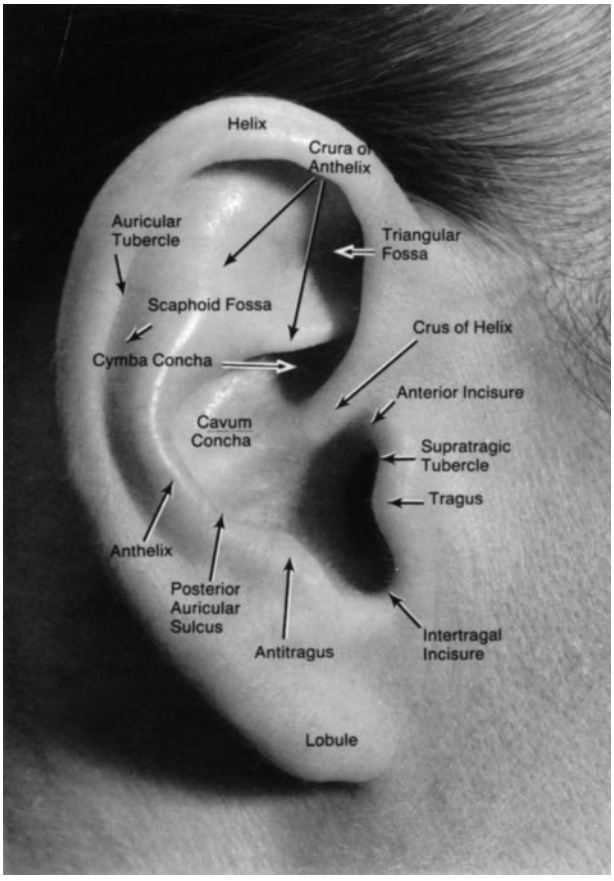

FIGURE 8–1. The right auricle showing the principal anatomic features of its lateral surface. Reproduced with permission from Schuknecht HF, Gulya AJ. Anatomy of the temporal bone with surgical implications. Philadelphia: Lea & Febiger; 1986.

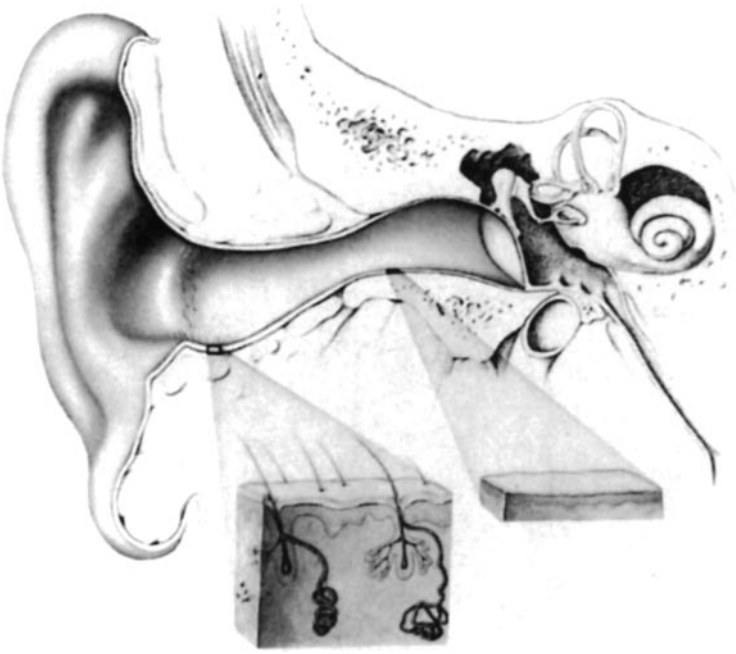

FIGURE 8–2. Coronal section of ear canal with magnification of the skin of the cartilaginous and osseous canals. Reproduced with permission from Senturia BH, Marcus MD, Lucente EF. Diseases of the external ear: an otologic-dermatologic manual. 2nd ed. New York: Grune & Stratton; 1980.

of temperature. The dehiscences in the anterior wall of the cartilaginous portion of the canal are known as the fissures of Santorini, which may allow spread of tumor or infection from the EAC into the parotid gland or temporomandibular joint. The epithelial lining of the EAC is continuous with the epithelial covering of the auricle and the outer layer of the tympanic membrane. The exfoliated squamous cell epithelium and earwax migrate in a lateral direction, serving a self-cleansing function.

The skin of the bony canal is much thinner than that of the cartilaginous portion, about 0.2 mm in thickness, and is continuous with the epithelial layer of the tympanic membrane (see Figure 8–2). There are no glands or hair follicles in the subcutaneous layer. Because of the thinness of the skin in the bony EAC, it can be easily traumatized, for example, during the removal of cerumen.

The skin of the cartilaginous part of the EAC is thicker, averaging from 0.5 to 1 mm, with four layers of epidermis and a true subcutaneous layer. It contains hair follicles and sebaceous and apocrine glands (Figure 8–3).

The external ear is innervated by contributions from the trigeminal (cranial nerve V), facial (cranial nerve VII), glossopharyngeal (cranial nerve IX), and vagal (cranial nerve X) nerves, as well as from the cervical plexus through the greater auricular nerve (C2–3). The extrinsic muscles of the ear are supplied by the facial nerve (cranial nerve VII).

The lymphatic drainage of the EAC is an important channel for the spread of infections or neoplasms. The anterior and superior parts of the EAC drain to the preauricular lymphatics in the parotid gland and the superior deep cervical lymph nodes. The inferior portion of the EAC drains into the infra-auricular lymph nodes near the angle of the mandible. The posterior part of the EAC drains into the postauricular lymph nodes and the superior deep cervical lymph nodes.

TRAUMA TO THE EXTERNAL EAR

Trauma to the external ear is common in all age groups. The unprotected auricle is at risk for all kinds of trauma including cold or hot thermal injury and blunt or sharp injury resulting in ecchymosis, hematoma, laceration, or fracture.

Auricular Hematoma

Hematoma of the auricle usually develops after blunt trauma and is common among wrestlers and boxers. The mechanism usually involves traumatic disruption of a perichondrial blood vessel. Blood accumulation in the subperichondrial space results in separation of

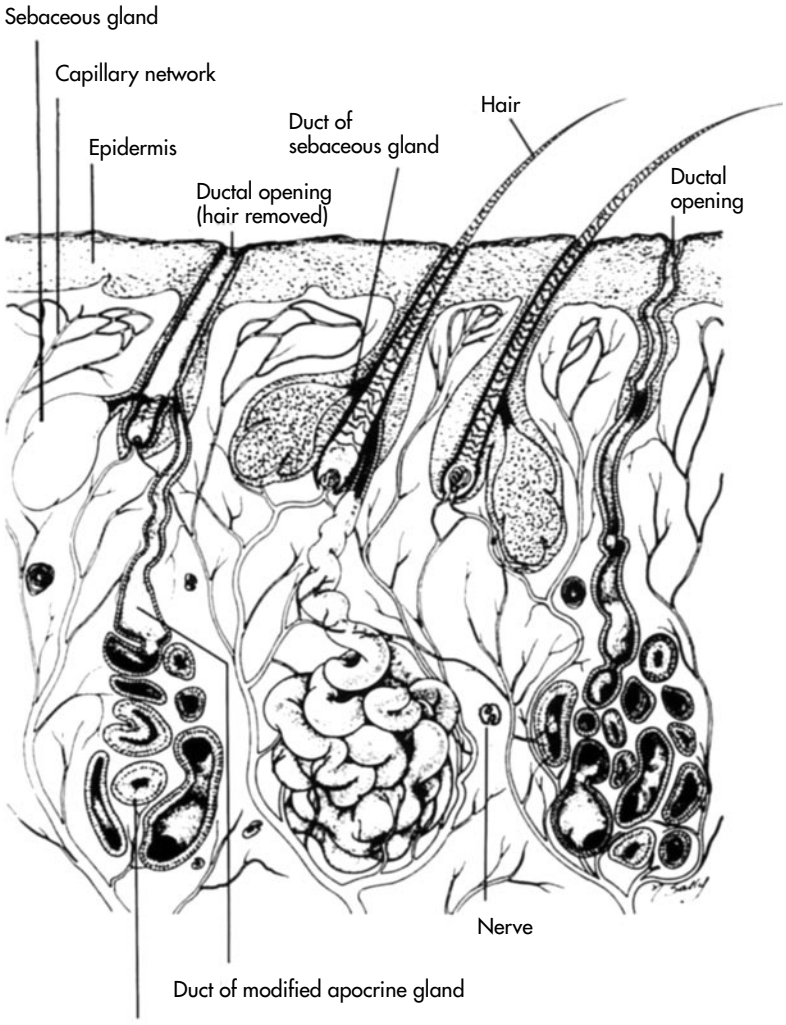

FIGURE 8–3. Schematic drawing illustrating the adnexae and secretory system of the skin of the external auditory canal. Reproduced with permission from Main T, Lim D. The human external auditory canal, secretory system—an ultrastructural study. Laryngoscope 1976;86:1164–76.

perichondrium from the cartilage. If the cartilage is fractured, blood seeps through the fracture line and extends to the subperichondrial plane on both sides.[1] This creates a bluish swelling, usually involving the entire auricle, although it may be confined to the upper half. If the lesion is not treated early, the blood organizes into a fibrous mass, causing necrosis of the cartilage because of interference with its circulation. This mass forms into a twisted scar, especially after repeated trauma, creating the deformity known as "cauliflower ear" (Figure 8–4).

Treatment is based on evacuation of the hematoma and application of pressure to prevent reaccumulation of blood. Simple needle aspiration is inadequate treatment and frequently results in fibrosis and organized hematoma. The most effective treatment for auricular hematoma is adequate incision and drainage with through-and-through suture-secured bolsters (Figure 8–5). The incision should be placed in the scapha, paralleling the helix. Sufficient exposure should be obtained to remove the entire hematoma and to inspect the cavity. If delay has resulted in some organization, sharp ring curettes may be used to remove the clot. Dental rolls are cut to proper size, applied to both sides of the auricle, and tied using through-and-through nylon or silk sutures. An antibiotic ointment is applied over the incision. The dental rolls are left in place for 7 to 14 days.

Lacerations

Auricular lacerations with or without loss of parts of the auricle are common from sharp trauma. Excellent results are possible if sound surgical principles are applied. An attempt should be made to repair, preserving all remaining viable tissue. When

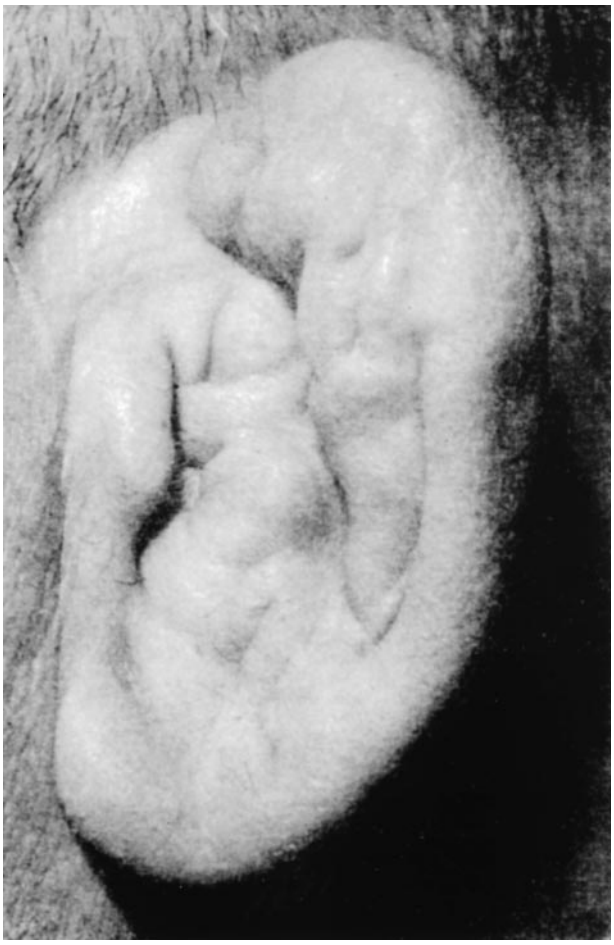

FIGURE 8–4. Cauliflower ear resulting from auricular hematoma.

the auricle is not totally severed, it can be reattached most of the time.

Frostbite

The auricle is particularly susceptible to frostbite because of its exposed location and lack of subcutaneous or adipose tissue to insulate the blood vessels. The anesthesia that develops in the area exposed to severe cold deprives the patient of any warning of impending danger. Initially, there is vasoconstriction, leaving the ear, especially the edges of the helix, blanched and cold to the touch. Hyperemia and edema follow and are caused by a marked increase in capillary permeability. Ice crystallization of the intracellular fluid may be primarily responsible for this, as well as cellular necrosis in the surrounding tissues. The ear becomes swollen, red, and tender, and bullae may form under the skin, resembling a first-degree burn.

The frostbitten ear should be rapidly warmed. Wet sterile cotton pledgets at 38 to 42°C are applied until the ear is thawed. The ear should be treated gently owing to the risk of further damage to the already traumatized and devitalized tissue. Analgesics and prophylactic antibiotics may be necessary. Necrotic tissue is débrided, the topical thromboxane inhibitor aloe vera is applied, and antiprostaglandin drugs such as ibuprofen may be beneficial.[2]

Burns

Burns are traditionally classified in three degrees of severity: erythema (first degree), blistering (second degree), and full-thickness destruction (third degree). Burns caused by scalding liquids or fire are often full thickness. Untreated, they may lead to perichondritis. It is important to avoid pressure on the ear, and gentle cleansing and topical antibiotic applications are used. Prophylactic use of antipseudomonal antibiotics is advocated. The antibiotic may be injected subperichondrially at several different injection sites over the anterior and posterior surfaces of the auricle.[3] Application of mafenide acetate (Sulfamylon) cream after cleaning the wound is recommended. In the late stage, débridement and skin grafting may be necessary. Perichondritis and chondritis should be treated with antibiotic iontophoresis, early débridement, and grafting.

Cerumen

Cerumen is a combination of the secretions produced by sebaceous (lipid-producing) and apocrine (ceruminous) glands admixed with desquamated epithelial debris. This combination forms an acidic coat that aids in the prevention of EAC infection. The pH of the cerumen is high in diabetic patients compared with 6.5 to 6.8 in the normal EAC.[4] There are genetically and racially determined differences in the physical characteristics of cerumen that vary its appearance and consistency and may be associated with immunoglobulin and lysozyme content.[5] Some individuals have a scanty amount, and others tend to form obstructive masses. The geriatric and mentally retarded populations have a tendency to accumulate excess cerumen. Accumulation of cerumen represents the most common and routine otologic problem. It may interfere with the clinician's view of the tympanic membrane, cause hearing loss and discomfort, or

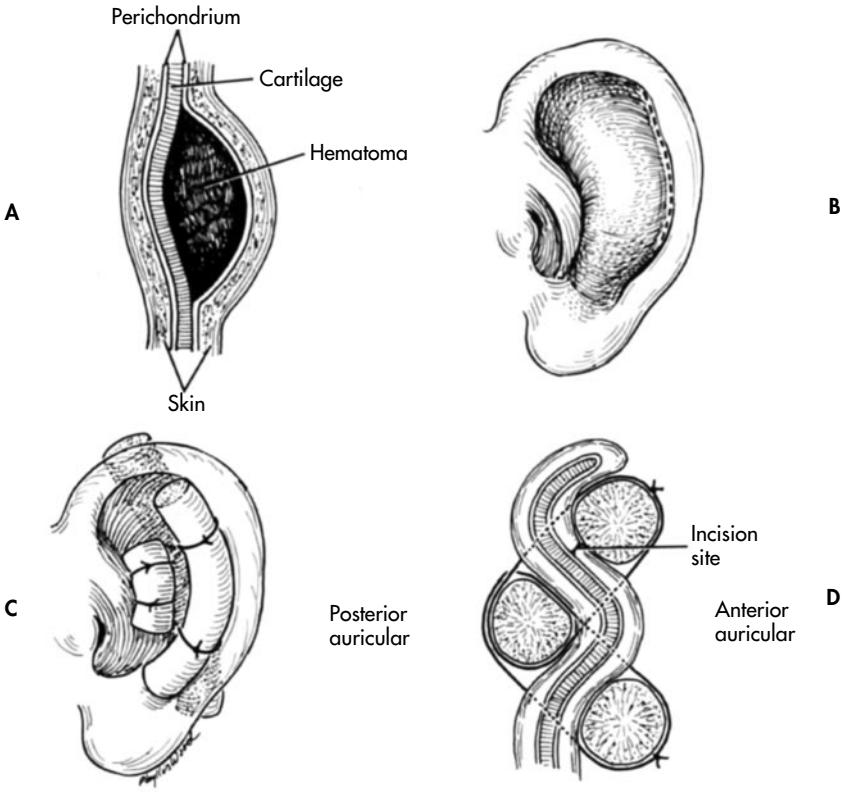

FIGURE 8–5. Otohematoma. *A*, Hematoma of the auricle. *B*, Hematoma incised and evacuated. *C*, Anterior dental rolls tied to posterior dental roll on the surface of the ear. *D*, Side view, showing how bolsters are secured. St. Louis: Mosby Co.; 1986. p. 2912.

become a source of infection. Some patients make routine attempts to remove cerumen with cotton swabs, making it worse by pushing cerumen medially.

Several techniques are available for the removal of cerumen and may be used in a variety of ways. Before starting to remove cerumen, one should make sure that the patient does not have a history of tympanic membrane perforation. If perforation is suspected, the irrigation method should not be used. The irrigation method works best for soft and greasy cerumen. The canal may be irrigated with warm water, either with a syringe or with a pressure-driven irrigating bottle (Figure 8–6). The canal is straightened by pulling the auricle up and back. The water stream is directed along the superior canal wall, and outflow is caught in a basin held below the ear. Remaining irrigating solution or residual cerumen can be suctioned out using a Frazier No. 5 or 7 suction catheter. An alternative method is the use of a cerumen curette to dislodge and remove the cerumen. First the cerumen and desquamated layer of epithelium are gently separated from the canal wall with a ring curette, and the loosened cerumen is grasped with an alligator forceps and teased out. The use of an operating microscope with the patient in a supine position helps to prevent head movement and to perform this procedure painlessly.

If impaction of hard cerumen persists or is too painful to remove, the patient may be sent home with instructions for using an agent to soften the cerumen. Such agents include a variety of common corticosteroid and antibiotic otic drops, ceruminolytic solutions (Cerumenex), or hydrogen peroxide. Following its use for a few days, the patient is re-examined and the softened remaining cerumen can be removed with irrigation or suction. This approach is particularly useful in pediatric patients.

Foreign Bodies

Foreign bodies in the EAC are found most frequently in the pediatric age group or in mentally retarded institutionalized patients. Any objects small enough to enter the EAC can become prospective foreign bodies. These include animate, inanimate, or mineral objects. They may cause symptoms of irritation, pain, and hearing loss.

The removal of a foreign body can be safely done under direct visualization, preferably under an operating microscope with the patient in a supine position. Instruments helpful for this task include

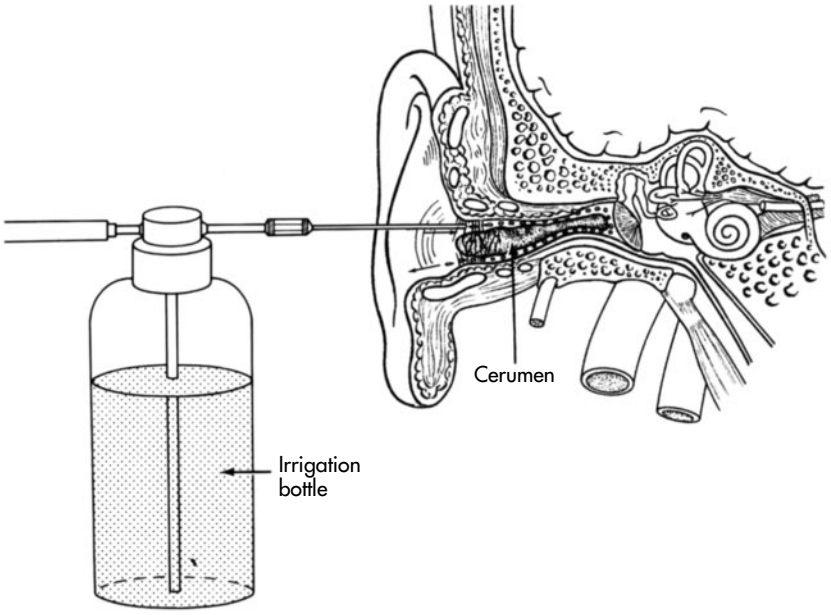

FIGURE 8–6. Cerumen irrigation with compressed air irrigation bottle system. Reproduced with permission from Goodhill V. Ear diseases, deafness, and dizziness. Hagerstown (MD): Harper & Row; 1979.

the alligator forceps, ring curettes, and hooks. Inanimate objects located lateral to the isthmus of the canal are removed with an alligator forceps or by placing a hook or ring curette behind it and pulling it out. Suctioning with Frazier suction catheters is useful in removing an object with a smooth surface that is hard to grasp. Irrigation can be used in certain instances. Objects located medial to the isthmus of the canal are more difficult to remove and may require local or general anesthesia.

Some foreign bodies may incite more inflammatory reaction and be damaging. Vegetable and plant debris can adhere to the skin of the EAC or tympanic membrane. Miniature round batteries used for cameras and hearing aids, once placed in the canal, can cause reaction and damage canal skin or even the tympanic membrane. A live insect in the EAC should be immobilized before removal by instilling mineral oil or alcohol into the canal.

The best chance for removal of a foreign body in the EAC is the first attempt. When it fails, the ear may become extremely painful, and proper anesthesia may be necessary. Four-quadrant canal skin injection with a local anesthetic agent is sufficient in adults. For young children, it is best to use general anesthesia.

Fractures of the External Auditory Canal

A strong blow to the mandible can drive the mandibular condyle into the ear canal, resulting in fracture of the anterior canal wall. The patient is treated for this fracture by repositioning lacerated or avulsed tissue and bone in the canal and packing the canal with antibiotic-saturated gauze. Fractures of the canal can be a part of temporal bone fractures. Longitudinal temporal bone fractures may extend into the bony ear canal, usually passing through the bony tympanic ring at the junction of the scutum and the tympanomastoid suture. Blood with cerebrospinal fluid may drain for a while. There may be an area of ecchymosis over the mastoid (Battle's sign). These fractures usually heal spontaneously with an occasional stenosis remaining in the bony annulus. If the patient develops a conductive hearing loss owing to ossicular damage or cholesteatoma caused by entrapped skin in the fracture line, tympanoplasty and ossiculoplasty or tympanomastoidectomy may be required later.

INFECTION AND INFLAMMATION OF THE EXTERNAL EAR

Infection and inflammation may involve skin or cartilage of the auricle, EAC, or epithelial layer of the tympanic membrane. It may be acute or chronic. The infectious agent may be bacterial, fungal, viral, or mixed.

Auricle

Cellulitis of the Auricle Cellulitis is a bacterial infection that usually follows abrasion, laceration, or

ear piercing. The auricle is red, swollen, painful, and tender to manipulation. It is usually caused by gram-positive cocci such as *Staphylococcus* or *Streptococcus* and rarely other microorganisms such as *Pseudomonas*. In the absence of a history of trauma, a topical allergic reaction or relapsing polychondritis should be considered. Treatment includes oral or intravenous antibiotic and wound care. Erysipelas is a cellulitis caused by group A β-hemolytic *Streptococcus* and may involve the auricle. It is marked by systemic toxicity with fever and chills, erythema, pain, and swelling. It is contagious. Treatment of choice is oral or intravenous penicillin G and wound care.

Allergic Dermatitis of the Auricle Allergic dermatitis of the auricle is characterized by localized erythema, swelling, and itching in the area of allergen exposure. A patient with neomycin allergy, who has been using eardrops containing neomycin, will present with swelling and redness in the area exposed to the drops, such as the meatus, EAC, and inferior part of the auricle. A patient with metal allergy will present with a red swollen ear lobule owing to contact with the earring. Treatment includes removal of the allergen, topical corticosteroid cream, and oral antihistamines.

Perichondritis and Chondritis Perichondritis or chondritis is a bacterial infection of perichondrium or cartilage of the auricle. This condition may follow inadequately treated auricular cellulitis, acute otitis externa, accidental or surgical trauma, or multiple ear piercing in the scapha. The affected ear is painful, red, and swollen and drains serous or purulent exudates. The surrounding soft tissues of the face and neck may be affected. The most common pathogen is *Pseudomonas*.

In the early stage, oral fluoroquinolone antibiotics (ciprofloxacin [Cipro], levofloxacin [Levaquin]), local antibiotic drops, and débridement are sufficient. In the advanced stage with involvement of regional lymph nodes and surrounding soft tissue, the patient may need to be hospitalized with aggressive intravenous antibiotics using ceftazidime or fluoroquinolones and local treatment. Topical antibiotic irrigation with indwelling catheters may be tried.

Relapsing Polychondritis Relapsing polychondritis is an autoimmune disease manifested by intermittent episodes of inflammation of cartilage throughout the body. Type II collagen antibodies have been found in these patients.[6] Auricular cartilage is most commonly involved, whereas nasal and laryngeal cartilages are less frequently involved.[7] The typical patient presents with a red, swollen tender auricle. Recurrent episodes may result in a floppy and distorted auricle. The disease may involve both auricles simultaneously, or there may be alternate involvement. The patient may develop a saddle deformity with destruction of nasal septum and hoarseness and subglottic stenosis owing to involvement of the larynx or trachea.

Treatment of relapsing polychondritis includes corticosteroid, salicylate, or indomethacin for acute episodes. Dapsone (Avlosulfon), 100 mg once or twice daily after an initial trial of 50 mg/day, has been successfully used for chronic disease with systemic manifestations.[8]

External Auditory Canal

Although the EAC is a well-protected and self-cleansing structure, various forms of infection may develop in the EAC. Otitis externa is one of the most common diseases in clinical practice.

Acute Localized Otitis Externa (Furuncle) Acute localized otitis externa is an infection of a hair follicle, beginning as a folliculitis but usually extending to form a small abscess or furuncle. The infecting microorganism is usually *Staphylococcus aureus*. It involves the lateral cartilaginous portion of the EAC, usually at the meatus. Pain is severe in this condition, and examination is difficult owing to pain and swelling. If the abscess occludes the canal, hearing loss may develop. Discharge is not usually present until the abscess ruptures.

Acute localized otitis externa should be treated the same as an abscess in any part of the body. If it is seen before suppuration has taken place, resolution may occur with the use of topical and systemic antibiotics. If a localized abscess has formed, it should be treated by incision and drainage and topical antibiotic ointment with or without oral antibiotics.

Acute Diffuse Otitis Externa (Swimmer's Ear) *Etiology/Predisposing Factors.* Acute diffuse otitis externa is a bacterial infection of the EAC and the most common form of otitis externa. It is caused by the removal of the protective lipid film from the canal, allowing bacteria to enter. It usually begins with itching in the canal and skin maceration and

local trauma from scratching the canal with a cotton swab, bobby pin, fingernail, or other object. Predisposing factors include frequent swimming; a warm and humid climate; a narrow and hairy ear canal; presence of exostosis in the canal; trauma or foreign body in the canal; impacted or absent cerumen; use of hearing aids or earplugs; diabetes or an immunocompromised state; skin conditions such as eczema, seborrhea, and psoriasis; and excessive sweating. Absence of cerumen may be a predisposing factor because the act of cerumen removal may be traumatic and lead to breaks in the fragile EAC skin, and cerumen serves an antimicrobial role through physically protecting the EAC skin; establishing a low-pH, inhospitable environment for pathogens; and containing compounds such as lysozyme.

The usual pathogens for acute diffuse otitis externa are *Pseudomonas aeruginosa, Proteus mirabilis,* or *S. aureus*. Culture of the canal is usually not done except for recurrent or recalcitrant infections.

Diagnosis/Stage of Disease. The typical patient presents with one or all of the symptoms including pain, itching, fullness, and hearing loss. On physical examination, there are various degrees of tenderness and narrowing of the ear canal with red swollen skin. Clear to purulent exudates may be present. One of the classic signs is pain elicited by pulling the auricle upward and backward.

Senturia and colleagues proposed three clinical stages of otitis externa: preinflammatory, acute inflammatory, and chronic inflammatory.[9,10] The acute inflammatory stage may be mild, moderate, or severe. The preinflammatory stage begins when the stratum corneum becomes edematous owing to the removal of the protective lipid layer and acid mantle from the canal, resulting in itching, edema, and the sensation of fullness. The mild acute inflammatory stage is characterized by increased itching and pain. Mild erythema and edema are present on examination. As inflammation increases to the moderate phase, the patient complains of intermediate pain and itching. The lumen of the EAC is decreased by edema and debris from the thickened, irritated skin (Figure 8–7). Secretions are exudative and more profuse. In the severe inflammatory stage, the canal lumen becomes completely obstructed because of the increasing hyperemia, edema, and purulent otorrhea. The patient complains of intense pain, especially on chewing or tragal manipulation. In the severe stage, the clinician often sees evidence of extension of infection beyond the EAC to involve adjacent soft tissues and cervical lymph nodes.

Treatment Certain principles of management must be observed in every case of otitis externa. These are frequent inspection and cleansing of the canal, control of pain, use of specific medication appropriate to the type and severity of the disease, acidification of the canal, and control of predisposing causes. Frequent inspection with cleaning using suction-débridement under an operating microscope and drying of the ear canal is the single most important step in obtaining resolution of all forms of otitis externa.

The preinflammatory and mild stage of inflammation can be managed with thorough cleaning and débridement of the canal, preferably under a microscope. Acidifying/antiseptic agents such as gentian violet may be applied. Antibiotic-hydrocortisone drops can be used for a few days. Patients are advised to avoid water and resist using cotton swabs or digital manipulation of the ear canal.

In the moderate stage of inflammation, treatment may include gentle cleaning-débridement of the canal and application of acidifying/antiseptic/ antibiotic agents. If the canal is severely swollen, a cotton or Pope wick may be inserted and otic drops instilled on it. A variety of eardrops are available for treatment. Most of the eardrops contain a combination of antipseudomonal antibiotics with or without corticosteroids (neomycin sulfate, colistin sulfate [Cortisporin], ofloxacin [Floxin], ciprofloxacin hydrochloride [Cipro HC]). Most of these agents are acidic to inhibit the proliferation of bacteria and fungi. The major adverse reaction to the use of an acidic agent is burning on application. Ophthalmic preparations tobramycin and dexamethasone (gentamicin, [Tebradex], ciprofloxacin [Ciloxan]) are pH neutral and may be tolerated better than otic drops. An additional advantage of ophthalmic drops is a low viscosity, allowing improved penetration. Fluoroquinolone antibiotics, such as ciprofloxacin and ofloxacin, may be a better choice because of an appropriate antimicrobial spectrum and low ototoxicity, especially for patients with neomycin sensitivity.[11–13] Instillation of otic powder containing a combination of ciprofloxacin/chloramphenicol, amphotericin B (Fungizone), and hydrocortisone is helpful to deliver high doses of medications locally. An oral analgesic is often

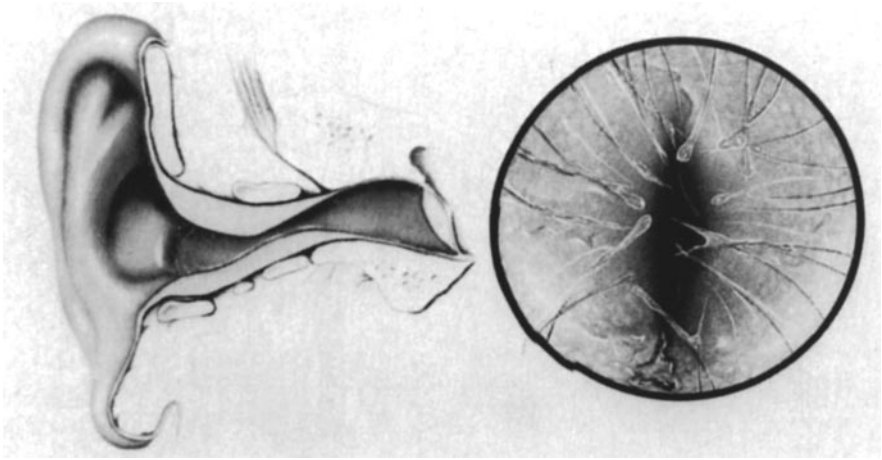

FIGURE 8–7. Moderate inflammatory phase of acute diffuse external otitis. Canal skin has become more erythematous and edematous. Greenish secretion coats skin. Reproduced with permission from Senturia BH et al.[10]

needed. System antibiotics are usually not necessary. Patients are advised to avoid any predisposing factors.

In the severe stage, the lumen of the EAC may be swollen shut by edema and debris to such a degree that antibiotic drops cannot be instilled into the canal. As discussed above, a cotton or Pope wick must be gently inserted into the canal to carry the topical medication to the affected canal skin. After 2 or 3 days, the canal usually opens, permitting cleaning and instillation of the medication. If infection extends beyond the limit of the EAC, oral antipseudomonal quinolone antibiotics (eg, ciprofloxacin, levofloxacin) should be used in adults. For pediatric patients, intravenous ceftazidime should be considered.

Chronic Otitis Externa Chronic otitis externa is a low-grade, diffuse infection and inflammation of the EAC that persist for months or years. It is characterized by pruritus and dry hypertrophic skin of the EAC. It results in a thickening of the EAC skin and progressive narrowing of the lumen of the EAC (postinflammatory stenosis). Although bacterial or fungal infection is the main cause of chronic otitis externa, skin conditions, such as seborrheic dermatitis, psoriasis, neurodermatitis, and sensitization to an otic drop, can result in chronic otitis externa.

The goal of treatment is to prevent the stenosis and restore the EAC skin to its normal healthy state. Antibiotics and corticosteroid otic drops can decrease the inflammation and edema of the EAC. The routine use of antibiotic otic drops such as neomycin is not recommended because of the high risk of sensitization. The most important treatment is frequent inspection and thorough débridement of the EAC. The canal can be painted with gentian violet, and otic powder may be applied. Painting the canal with triamcinolone/nystatin (Mycolog) cream helps to relieve pruritus and clear chronic otitis externa. Patients are instructed not to touch the EAC or use a cotton swab.

Surgical Treatment. In case of medical treatment failure, especially with canal stenosis, surgical procedures are indicated to restore canal patency and hearing. Canalplasty with skin graft can be used to enlarge the canal (Figures 8–8 and 8–9).[14,15] The abnormal canal skin is removed entirely. The denuded canal is enlarged, using diamond burs, to an optimum size, increasing gradually in diameter. A split-thickness skin graft is harvested from the upper medial surface of the arm with a dermatome. The graft is placed in the canal to cover all exposed surfaces. A "rosebud" type of packing with Owen's silk strips and cotton balls is placed over the skin graft for 2 weeks (see Figure 8–9). Crusting may occur for several weeks and requires meticulous removal and cleansing until complete healing takes place.

Prevention. Preventive measures are recommended in patients who demonstrate a propensity for recurrent episodes of otitis externa. Patients are instructed not to touch or place any objects such as cotton swabs, paper clips, or any other objects into the canal. Swimmers are instructed to use earplugs and are advised to use alcohol-vinegar (1:1) drops after swimming.

Necrotizing (Malignant) External Otitis Malignant external otitis is a progressive, potentially lethal

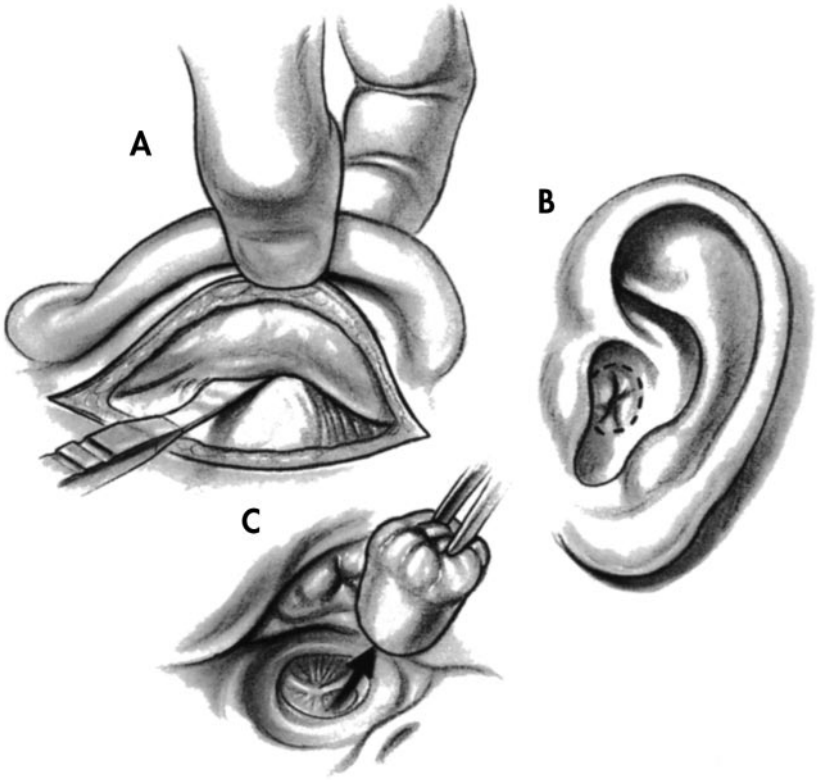

FIGURE 8–8. Canalplasty for refractory otitis externa. *A*, A postauricular incision is made and the cartilaginous canal is sectioned. *B*, A circumferential through-and-through incision is made at the meatus. *C*, A diseased stenotic plug of canal skin is removed along with the infected meatus and outer squamous cell layer of the tympanic membrane. The bony canal is widened by drilling. Reproduced with permission from Jung TT.[15]

infection of the EAC, surrounding tissue, and skull base typically seen in elderly diabetic or other immunocompromised patients. The term malignant external otitis was first coined and presented in a case series by Chandler in 1968.[16] Diabetic patients were almost exclusively the population at risk. However, a number of cases of malignant external otitis without diabetes have been documented.[17,18] Most of these patients had an underlying disease that resulted in neutropenia or immunosuppression, such as leukemia, treatment with bone marrow–suppressive drugs, and acquired immune deficiency syndrome. *Pseudomonas aeruginosa* is the most common pathogen in malignant otitis externa.

Pathophysiology. The infection begins in the EAC. The local infection in the EAC progresses to cellulitis, chondritis, osteitis, and, finally, osteomyelitis. The disease may gain access to the osseous auditory canal and skull base through Santorini's fissures. From there, the infection usually progresses along the base of the skull. Once access to the bony skull base has occurred, there is progressive replacement of compact bone with granulation tissue. Facial nerve paralysis occurs when there is involvement of the stylomastoid foramen, and cranial nerve IX, X, or XI palsies occur when the jugular foramen becomes involved. The jugular vein may become thrombosed, progressing to a lateral sinus thrombosis, which usually ends in death.

Diagnosis. A high index of suspicion for malignant external otitis is needed in diabetic or immunocompromised patients with otitis externa. Granulation tissue in the floor of the EAC near the bony-cartilaginous junction is a typical otoscopic finding. Patients usually complain of severe otalgia. Facial nerve paralysis and jugular foramen syndrome are poor prognostic signs.

A culture of purulent discharge usually reveals *P. aeruginosa*. Sensitivity testing to all antipseudomonas antibiotics should be sought. The erythrocyte sedimentation rate is a nonspecific test but is useful in following the response to antibiotics. A biopsy of the granulation tissue in the EAC is necessary to exclude carcinoma of the ear canal or *Aspergillus* skull base osteomyelitis since they have clinical and radiologic findings similar to those in necrotizing external otitis.

Radiologic examinations are required to determine the extent of disease. High-resolution com-

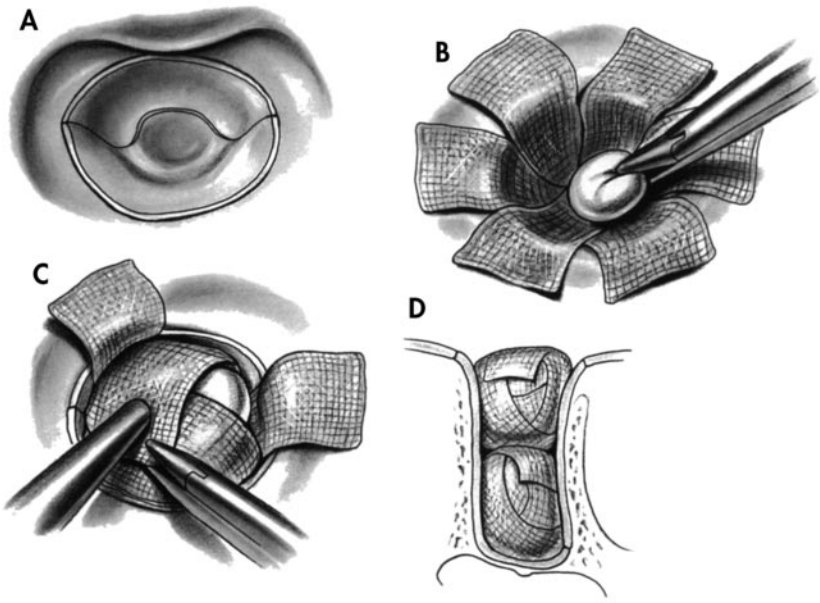

FIGURE 8–9. Canalplasty for refractory otitis externa, skin graft. *A*, The longer convex piece of skin is laid out on the drumhead and posterior half of the canal. The shorter concave piece covers the anterior half of the canal. *B* and *C*, A "rosebud" packing is placed with strips of Owen's silk and pieces of cotton balls saturated in an antibiotic-corticosteroid suspension. *D*, A second pack may be placed lateral to the first pack. Reproduced with permission from Jung TT.[15]

puted tomography (CT) is recommended to assess the extent of disease at initial evaluation.[19] It is of little use in monitoring the resolution of infection because remineralization is required for the bony changes to return to normal. Magnetic resonance imaging (MRI) is of no use in detecting bony changes, but it is better for evaluation and follow-up of soft tissue involvement, especially meningeal enhancement and changes within the osseous medullary cavity.[19]

Bony involvement in patients with early malignant external otitis can be detected with technetium scan (bone scan).[20] Although it is nonspecific, bony involvement can be detected when there is absence of destruction on CT scans.[21] But a technetium scan may remain positive even after the resolution of osteomyelitis. Thus, it is not useful for therapeutic monitoring.

A gallium scan is a sensitive indicator of infection. In the presence of infection, there is increased uptake of gallium, which may occur in soft tissue or bone. The gallium scan becomes negative as the infection clears. Therefore, the gallium scan is best for monitoring resolution of disease and is useful in determining duration of antimicrobial therapy.[20,22,23]

Treatment. The standard treatment is hospitalization of the patient and treatment of diabetes, if present, together with the use of high doses of antibiotics specific for *Pseudomonas* for an extended period of time. Daily débridement of the EAC is performed, and culture of débrided material and sensitivity testing should be repeated during the initial phase of management.

Antipseudomonal otic drops are instilled with placement of a wick when necessary. Standard antibiotic therapy has been aminoglycosides combined with either an antipseudomonal penicillin or cephalosporin for dual-drug therapy as primary intervention. Special precaution must be taken during aminoglycoside treatment because of nephrotoxicity and ototoxicity. Blood levels must be obtained regularly to ensure adequate dosage. Creatinine levels should be obtained three times a week to measure renal function. Electrolyte disturbances such as hypokalemia may occur; therefore, regular determination of electrolytes should be performed. Periodic hearing tests should be obtained if possible, particularly of the uninvolved ear. Because of potential nephrotoxicity/ototoxicity of aminoglycosides, oral quinolones (eg, ciprofloxacin) have been used successfully as an alternative to treat malignant external otitis.[24–26] Quinolone antibiotics have the advantage of being equally effective whether administered parenterally or orally. The duration of antimicrobial therapy

depends on serial gallium scans performed at 4-week intervals.[21] A strict control of diabetes is essential for the treatment of malignant external otitis. Without the control of diabetes, malignant external otitis cannot be controlled.

Pain can be severe and worsens as the infection fails to respond. A mastoidectomy with possible facial nerve decompression or subtotal petrosectomy or even partial temporal bone resection may be necessary. Hyperbaric oxygen therapy has been used as an adjunctive measure. Lessening of pain is the first indication of a favorable therapeutic response.

Fungal Otitis Externa (Otomycosis) Fungal infection of the EAC is usually caused by *Aspergillus* and/or *Candida*.[27] Otomycosis develops most commonly in a patient with chronic otitis externa that has been treated with a variety of topical or oral antibiotics. The most common presenting symptom is pruritus. Other common symptoms include hearing loss, drainage, discomfort, and feeling something in the ear. Otomicroscopy reveals erythematous canal skin with black, gray, or white fungal growth on the canal skin or on the debris in the canal. It may progress to a complete occlusion of the canal lumen with a fungal ball. Treatment consists of frequent and meticulous cleansing and topical medication. A topical agent, such as gentian violet or thimerosal, can achieve acidification and drying of the ear canal. Topical antifungal agents may be effective in powder form and/or in a cream (Mycolog). Oral antifungal agents can be used in the rare case refractory to topical therapy.

Herpes Zoster Herpes zoster is the most frequent virus to affect the external ear. The virus stays dormant in the sensory ganglia and reactivates under conditions of decreased immune competence. The virus causes blisters on the auricle, the EAC, and even on the lateral surface of the tympanic membrane. Typically, the blisters are short-lived, rupture, dry, crust, and heal. Some patients with herpes zoster infection develop involvement of the facial and cochleovestibular nerves. This clinical syndrome with facial palsy, with or without hearing loss and dizziness, owing to herpes zoster is called *herpes zoster oticus* or *Ramsay Hunt syndrome*. This infection is mostly self-limiting, and treatment is primarily supportive. Patients with full-blown herpes zoster oticus are treated with acyclovir (Zovirax) and corticosteroid.

Tympanic Membrane

Bullous Myringitis Bullous myringitis is an infection of the tympanic membrane characterized by rapid onset, severe pain, and varying sizes of blister formation on the tympanic membrane and adjacent bony ear canal. Although virus, *Mycoplasma*, and other bacteria have been suspected, definite causative microorganisms have not been established. The bullae may be filled with serous or hemorrhagic fluid. Treatment includes analgesia, topical antibiotics, and corticosteroid drops. Rupturing the blisters and packing or irrigation of the canal should be avoided.

Granular Myringitis Granular myringitis is an inflammation of the tympanic membrane characterized by persistent granulation tissue on the lateral surface of the pars tensa with an intact tympanic membrane. The eardrum is thickened, inflamed, and moist with foul-smelling drainage. The patient complains of mild otalgia and drainage. The etiology is not clear, but granular myringitis is believed to be caused by local trauma or infection that denudes the epithelial layer of the tympanic membrane. Treatment includes cauterization with silver nitrate sticks and topical antibiotic and corticosteroid drops. Most cases respond to local treatment, but some progress to inflammatory thickening of the tympanic membrane and even to obliteration of the medial part of the EAC.

TUMORS OF THE EXTERNAL EAR

Skin and its appendages, bone, cartilage, and other connective tissues that make up the external ear may give rise to a variety of benign and malignant tumors.

Benign Tumors of the External Ear

Vascular Tumors *Angiomas* are congenital tumors and are one of the most common tumors of childhood. They may involve the auricle together with other areas of the face and neck. These tumors occur in various forms. *Capillary hemangioma* consists of masses of capillary-sized vessels and may form a large flat mass. A central large vessel feeds the "port-wine stain" or spider nevus, which is a branching network of capillaries. The *spider nevus* is not a major problem, being small and fixed in size. Treatment, when necessary, usually consists of needle coagulation of the central vessel. The port-wine stain

is much more of a problem, increasing in size gradually until adolescence, and generally is disfiguring.

Cavernous hemangioma is the most alarming of these lesions, consisting of raised masses of blood-filled endothelial spaces. Often termed a "strawberry tumor," it increases rapidly in size during the first year of life but usually regresses thereafter. Much less common is the *lymphangioma*. It has the appearance of multiple pale circumscribed lesions, like a cluster of fish or frog roe.

The major problem in these tumors is cosmetic. In general, the lesion should be allowed to regress maximally and the residual tumor treated. Various modalities have been recommended, including cryosurgery, surgical excision and skin grafting, radiation, electrolysis, and tattooing for port-wine staining. Therapy should only be undertaken with caution and after the best available consultation has been sought.

Cysts Sebaceous cysts are common around the ear. They usually occur on the posterior surface of the lobule, in the skin over the mastoid process, and in the skin of the inferior or posterior parts of the cartilaginous portion of the canal (Figure 8–10). These soft, nontender swellings may become infected and may be confused with furuncles. Treatment for a sebaceous cyst is excision. Infection, if present, is treated first. The cyst is removed by sharp dissection, with care being taken to keep the walls of the cyst intact to ensure complete removal. The ductal tissue leading to the cyst as well as its external opening are removed, including a small segment of the overlying skin.

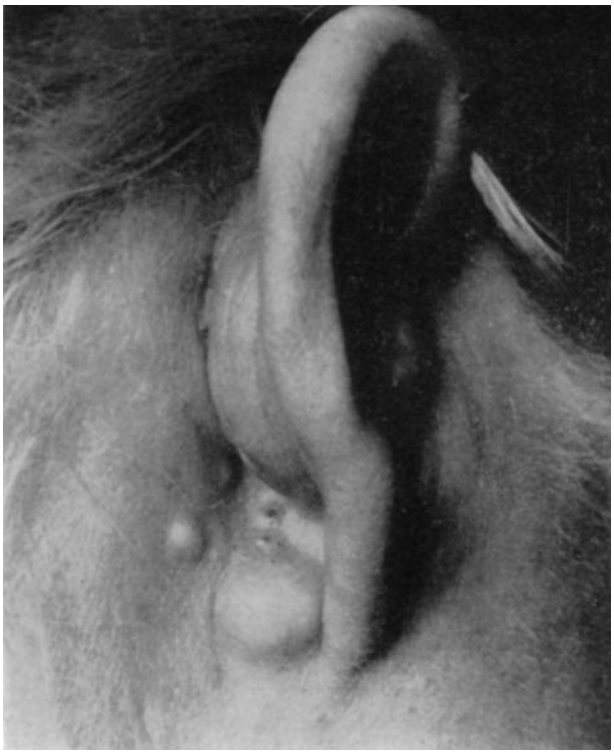

FIGURE 8–10. Sebaceous cysts in the postauricular area.

Preauricular Pits and Sinuses Preauricular pits and sinuses are of congenital origin, arising from faulty developmental closure of the hillocks of first and second branchial arches that form the auricle. They present as small openings in the skin just anterior to the crus of the helix (Figure 8–11). From this opening, a long branched tract may run under the skin between the helix and tragus and anterior to the tragus. The tract, which is lined with squamous cell epithelium, is often cystic, and the patient is frequently seen initially because of infection of the cyst.

Treatment is not necessary unless recurrent infection occurs. Treatment includes complete removal of the cyst along with the fistula tract. Incomplete removal is associated with the formation of draining sinuses, requiring even more difficult and radical surgery for their elimination. The difficulty of the surgery is caused by the branching of the fistula, which makes it hard to define the complete extent of the tract. One suggestion to aid in their removal is to inject the tract before the operation with methylene blue so that the stained tissue may be used as a rough guide to the extent of the fistula.

Keloids Keloids represent an unchecked healing response in individuals with a genetic predisposition to their development. The formation of a keloid is stimulated by trauma to the skin. A keloid is composed of massive collections of collagen interspersed with active fibroblasts and normal thin collagenous strands. Keloid formation is seen most frequently in dark-skinned races, particularly in blacks. Keloids around the ear are most frequently seen as pedunculated tumors on the lobule following ear piercing. They may also occur in mastoidectomy and endaural scars, resulting in disfigurement or stenosis of the canal. Treatment is excision followed by periodic injection of a small amount of corticosteroids (eg, triamcinolone) into the surgical site to prevent keloid reformation.

FIGURE 8–11. Preauricular cyst and fistula. *Arrow* indicates the fistula opening. Anterior to this is an inflamed swelling owing to an infected preauricular cyst.

Winkler's Nodule (Chondrodermatitis Nodularis Chronica Helicis) Chondrodermatitis nodularis chronica helicis is a benign nodular growth usually occurring on the rim of the helix in older men (Figure 8–12). It appears as a firm elevated nodular lesion with a grayish crust on the surface. It is characterized by exquisite tenderness with digital compression, out of proportion to its size. It must be differentiated from other lesions such as basal cell carcinomas. The cause of chondrodermatitis nodularis chronica helicis is unknown. It can be treated with injection of a corticosteroid for pain relief. Definitive treatment requires full-thickness excision, including a wedge of cartilage.

Keratoacanthoma Keratoacanthoma is a benign tumor resembling carcinoma and is believed to be related to actinic exposure. The common location of the tumor is anterior to the tragus. It is characterized by a central crater that contains a keratin plug. The lesion tends to grow rapidly after its initial appearance and then slowly regresses. Although the disease is self-limiting, excisional biopsy is required to rule out a malignant tumor.

Keratosis Obturans Keratosis obturans is characterized by the accumulation of large plugs of desquamated keratin in the bony portion of the EAC. This condition is usually asymptomatic and bilateral and is discovered incidental to examination for conductive hearing loss. Removal of the keratin plug reveals diffuse hyperemia of the canal skin. There is marked inflammation in the subepithelial tissue but no bone erosion. The cause is unknown. It has been associated with chronic pulmonary disease and sinusitis. Bronchiectasis has been present in a high percentage of these patients, especially those with an onset before the age of 20 years. The disease may be controlled in most cases by regular cleaning.

Cholesteatoma of the EAC and *keratosis obturans* are different clinical and pathologic processes.[28] External auditory canal cholesteatoma consists of a localized erosion of the bone by squamous cell tissue. It is usually unilateral and is not associated with systemic disease. Treatment consists of periodic cleaning and surgery.[29]

Exostosis and Osteoma Exostoses are the most common tumors of the EAC. A benign growth of

FIGURE 8–12. Typical raised, tender, firm nodule of chondrodermatitis nodularis chronica helicis.

bone from periosteum gives rise to the onionskin histologic appearance (lamellar bone) (Figure 8–13). Exostoses are not traditionally considered neoplastic. Large exostoses can cause retention of cerumen, recurrent inflammation of the canal skin, and even conductive hearing loss. Exostoses are common in patients who have histories of swimming or bathing frequently in cold water. They are usually bilateral and appear as two or three smooth sessile protrusions on opposing surfaces of the bony canal medial to the isthmus.

An osteoma occurs as a single larger cancellous (trabecular) bone formation near the lateral end of the bony canal. It is a benign tumor of bone and is usually pedunculated. It invariably occurs unilaterally and may resemble a foreign body or cyst.

These bony growths are benign and may be ignored unless of sufficient size to obstruct the canal or cause repeated infection from retention of debris. Canalplasty is frequently used for the removal of a large exostosis or osteoma.[15] Skin over the lesion is elevated and preserved. After the lesion is exposed, it is drilled out with a cutting or diamond bur using continuous suction and irrigation. After all of the lesions are removed and the rest of the canal wall is smoothed, the skin flap is laid back. The EAC is packed with Gelfoam saturated with an antibiotic solution or Owen's silk strips and pieces of cotton packing (rosebud packing). In some instances, an exostosis interferes with middle ear surgery, in which case the canalplasty becomes a part of the tympanoplasty, with the skin flap becoming a tympanomeatal flap.

Fibrous Dysplasia The temporal bone may be the site of monostotic or, less commonly, polyostotic fibrous dysplasia. The mastoid and petrous portions of temporal bone are most often affected. In comparison with other craniofacial sites, the temporal bone is less commonly involved and is often asymptomatic. The most common presentation of temporal bone fibrous dysplasia is a progressive conductive hearing loss secondary to occlusion of the EAC or impingement on the ossicular chain. Progressive narrowing of the ear canal may lead to the development of a cholesteatoma. Diagnosis of fibrous dysplasia is based on radiographic and histologic findings. On plain radiographs, a fibrous dysplastic lesion consists of varying degrees of radiolucency and sclerosis, giving a "ground-glass" appearance. Surgery is indicated for diagnostic biopsy, presence of cholesteatoma, hearing loss, and correction of significant cosmetic deformity.[30]

Adenoma Adenomas of various sorts occur in the EAC. These are derived from sweat glands, sebaceous glands, or aberrant salivary gland tissue. Differentiation of these tumors depends on microscopic examination because each appears as a smooth, skin-covered, polypoid mass arising from the canal wall. Symptoms are minimal unless the growth completely occludes the canal. Pain suggests malignancy.

Ceruminous glands are modified apocrine sweat glands emptying into hair follicles. They are present only in the dermis of the cartilaginous portion of the EAC.[31] A *ceruminoma* is an adenoma of sweat gland origin. Because it is difficult to distinguish clinically a benign ceruminous gland tumor from malignant counterparts, biopsy is essential. There remains controversy regarding the behavior of ceruminous gland tumors.[31]

The treatment is surgical excision. Some of these lesions occasionally become malignant, and

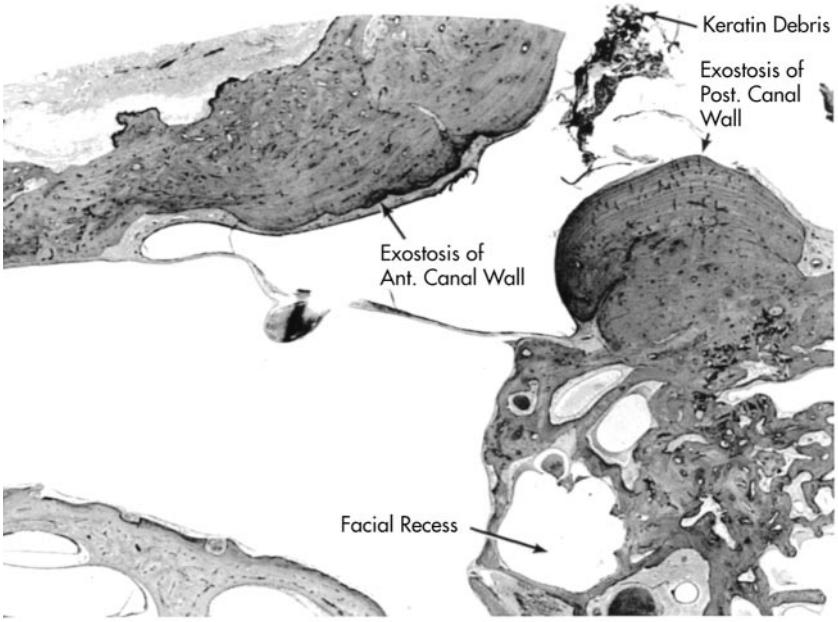

FIGURE 8–13. Photomicrograph showing occult (asymptomatic) exostoses of the anterior and posterior walls of the external auditory canal (male, age 75 years). Reproduced with permission from Schuknecht HF, Gulya AJ. Anatomy of the temporal bone with surgical implications. Philadelphia: Lea & Febiger; 1986.

pathologic examination is required in each case. Most of these adenomas may be removed through a transmeatal approach, although with large growths, an endaural incision may be needed. Any mass occurring within the EAC should be removed for histologic examination.[32] Lesions thought to be polyps, granulomas, or other benign tumors have proved to be malignant on occasion, usually squamous cell carcinoma. Because these tumors are often associated with chronic discharge from the ear, the patient with such discharge, especially associated with pain and bleeding, should be considered to have a malignant tumor.

Malignant Tumors of the External Ear

The most common malignant tumors of the external ear are squamous cell and basal cell carcinomas. Other malignant tumors include melanomas, adenoid cystic carcinomas, adenocarcinomas, and sarcomas.

Squamous Cell Carcinoma of the Auricle Cancer of the auricle accounts for about 6% of all skin cancers. Prolonged exposure to the sun is a risk factor for the development of skin malignancy. The degree of pigmentation plays a major role. Malignancy of the auricle is common in fair-skinned whites and rare in blacks. Squamous cell carcinoma represents about 55% of all malignant tumors of the auricle.[33]

Squamous cell carcinomas present as ulcerated lesions with an area of surrounding erythema and induration (Figure 8–14). They occur more often on the helix. The treatment of choice for squamous cell

FIGURE 8–14. Squamous cell carcinoma of the helix.

carcinoma of the auricle is wide excision and reconstruction (Figure 8–15). Frozen sections to check the margins of excision should be done at the time of resection. A full-thickness skin graft from the neck to the defect is an excellent method of reconstruction, especially for the central area farther away from the helix.

Basal Cell Carcinoma of the Auricle Basal cell carcinoma presents as painless, well-circumscribed ulcers with raised margins. The tumors are often found in the preauricular or postauricular areas as well as on the helix and anterior surface of the auricle. Treatment is excision, as described above. The surgical margin need not be as large as that for squamous cell carcinoma.

Squamous Cell Carcinoma of the External Auditory Canal Malignant tumors can arise from the EAC, middle ear, and temporal bone. The tumor type, clinical presentation, prognosis, and treatment are determined by the anatomic location of the tumor. When patients present with advanced neoplasms, it may not be possible to define the sites of origin. The majority of cancers of the middle ear and mastoid originate in the EAC. Squamous cell carcinoma is the most common malignant tumor found in the EAC and middle ear space.

Carcinoma arising from the EAC often mimics chronic suppurative ear disease. Common symptoms include pain, otorrhea, bleeding, fullness, and decreased hearing. The most common finding is a growth in the EAC, which is clinically difficult to differentiate from an aural polyp, granulation tissue, and otitis externa. When a tumor is found in the canal, the location, size, and extent of the tumor should be thoroughly evaluated under an operating microscope. Malignancy should be suspected whenever otalgia or bleeding is associated with the tumor and a biopsy should be taken with local anesthesia using a cupped biopsy forceps. A difficult diagnostic challenge is the differentiation of carcinoma from malignant external otitis. The presentation of malignant external otitis may be indistinguishable from that of carcinoma of the EAC.

Either CT or MRI is helpful in defining the extent of a carcinoma. Computed tomography is unsurpassed for assessing the integrity of osseous structures of the temporal bone and middle ear. Magnetic resonance imaging is superior to CT in the evaluation of soft tissues and may be used to assess dural, intracranial, and extracranial soft tissue involvement.

Treatment consists of wide surgical excision and postoperative radiation therapy. Anterior canal tumors may spread through Santorini's fissures into a preauricular lymph node.[34] If the tumor has extended anteriorly and medially, the excision should include the cartilaginous and bony anterior canal wall, the superficial lobe of the parotid gland, and possibly the condyle of the mandible. When a malignant tumor is small, involving the posterior part of the EAC, and has not extended to the drumhead, a complete modified radical mastoidectomy is

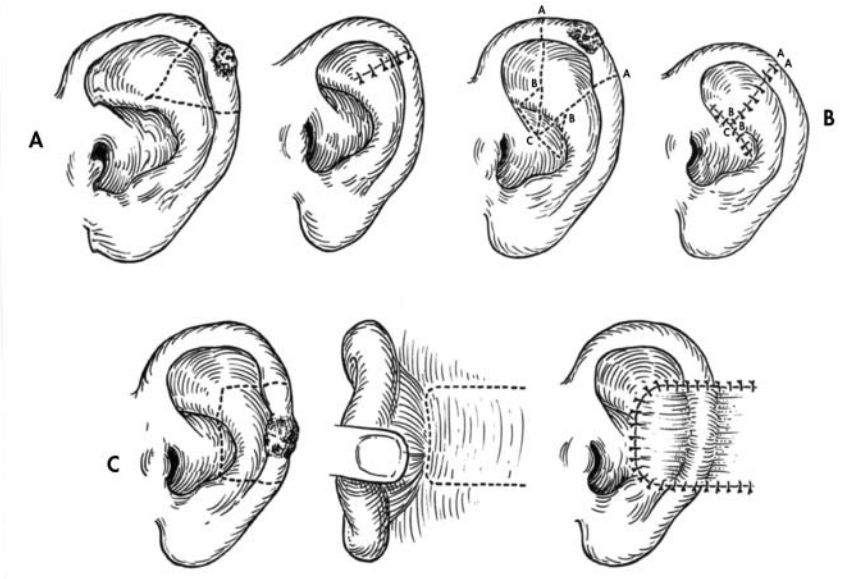

FIGURE 8–15. Surgical techniques for removal of small carcinomas of the auricle. *A*, Wedge excision; *B*, stellate excision; *C*, advancement flap. done. If the tumor is close to the drumhead, a radical mastoidectomy is performed. If a malignant tumor is extensive and involves the middle ear and mastoid, subtotal or total temporal bone resection may be needed.

Malignant Melanoma Melanomas of the external ear are rare. Melanoma may occur either on the auricle or in the EAC, more commonly in the former location. Diagnosis should be suspected when a pigmented lesion begins to increase in size or change in color. Lymphatic spread, treatment, and prognosis are greatly influenced by location. Tumors on the helical rim carry a better prognosis than those in the central areas, tragus or retroauricular regions. Treatment is wide excision.

CHAPTER 9

Otitis Media and Middle Ear Effusions

Gerald B. Healy, MD, Kristina W. Rosbe, MD

Infections of the middle ear space and their sequelae have plagued mankind from the beginning of time. First described by Hippocrates in 450 BC, this universally observed process continues to present one of the most perplexing medical problems of infancy and childhood, while being the leading cause of hearing loss in this age group. It is estimated that 70% of children will have had one or more episodes of otitis media (OM) by their third birthday.[1] This disease process knows no age boundaries but occurs mainly in children from the newborn period through approximately age 7 years, when the incidence begins to decrease. It occurs equally in males and females. A racial prevalence exists, with a higher incidence occurring in specific groups such as Native Americans, Alaskan and Canadian Natives, and Australian aboriginal children. African American children appear to have less disease than do American white children, but this observation has yet to be adequately explained.

Important epidemiologic factors include a higher incidence of OM in children attending daycare centers, a seasonal variation with more disease being present in the fall and winter versus the spring and summer, and a genetic predisposition to middle ear infection. Other epidemiologic factors include a lower incidence and duration of OM in breast-fed children and a higher incidence in children with altered host defenses.[2] Anatomic changes such as cleft palate and other craniofacial anomalies as well as congenital and acquired immune deficiencies are also important factors. One of the earliest signs of acquired immune deficiency syndrome (AIDS) in infants is recurring episodes of OM. This has been observed in more than 50% of neonates with AIDS.[3]

DEFINITIONS

Unfortunately, numerous terms have been used to describe the various inflammatory conditions of the middle ear space (Table 9–1). This has resulted in both confusion and a lack of uniformity in reporting. An attempt to standardize nomenclature was undertaken in the early 1980s and will be used throughout this chapter when discussing this disease process.[4]

Otitis media represents an inflammatory condition of the middle ear space, without reference to cause or pathogenesis.

Middle ear effusion is the liquid resulting from OM. An effusion may be either serous (thin, watery), mucoid (viscid, thick), or purulent (pus). The process may be acute (0 to 3 weeks in duration), subacute (3 to 12 weeks in duration), or chronic (greater than 12 weeks in duration).

Otitis media may occur with or without effusion. In those cases without effusion, inflammation of the middle ear mucous membrane and tympanic membrane may be the only physical finding. Occa-

sionally, infection may involve only the tympanic membrane (myringitis), without involving the mucosa of the middle ear space.

This chapter deals primarily with two disease processes: acute otitis media (AOM) and chronic otitis media with effusion (COME). Acute otitis media represents the rapid onset of an inflammatory process of the middle ear space associated with one or more symptoms or local or systemic signs. These usually include otalgia, fever, irritability, anorexia, vomiting, diarrhea, or otorrhea. Physical examination usually reveals a thickened, erythematous or bulging tympanic membrane with limited or no mobility to pneumatic otoscopy. Erythema of the tympanic membrane may be an inconsistent finding and may be absent in certain systemic illnesses such as immune deficiency, when the patient cannot mount a sufficient inflammatory response to present this more classic finding. The acute onset of fever, otalgia, and, on occasion, a purulent discharge is usually evidence of AOM. Following such an episode, the patient may move into a subacute or even chronic phase in which fluid is present in the middle ear space, although active infection may be absent.

Chronic otitis media with effusion indicates the presence of asymptomatic middle ear fluid, usually resulting in conductive hearing loss. The tympanic membrane may present numerous physical findings including thickening, opacification, and impaired mobility. An air-fluid level and/or bubbles may be observed through a translucent tympanic membrane. This entity is distinguished from AOM in that the signs and symptoms of acute infection are lacking (eg, otalgia, fever, otorrhea).

ETIOLOGY

Eustachian tube (ET) dysfunction is considered the major etiologic factor in the development of middle ear disease. Politzer first proposed the ex vacuo theory of OM in 1867.[5] The theory postulates that chronic negative pressure, secondary to ET malfunction, results in the development of a transudate into the middle ear space. Numerous experiments have been carried out by many authors to substantiate this theory. It is traditionally maintained that the effusion is sterile; therefore, therapy should be aimed chiefly at relieving ET dysfunction. Most proponents of the theory have proposed that there are essentially two types of ET obstruction resulting in middle ear effusion: mechanical and functional. Mechanical obstruction may be either intrinsic or extrinsic. Intrinsic mechanical obstruction is usually caused by inflammation of the mucous membrane of the ET or an allergic diathesis causing edema of the tubal mucosa. Extrinsic mechanical obstruction is caused by obstructing masses such as adenoid tissue or nasopharyngeal neoplasms.

Some observers believe that infants and younger children may suffer from *functional ET obstruction* as a result of either decreased tubal stiffness or an inefficient active opening mechanism. Proponents believe that either form of obstruction results in inadequate ventilation of the middle ear with resulting negative middle ear pressure. This theory supports the development of a rational medical or surgical approach to alleviate the obstruction and thus overcome negative pressure.

The ET has three functions (1): ventilation of the middle ear associated with equalization of air pressure in the middle ear with atmospheric pressure, (2) protection of the middle ear from sound and secretions, and (3) drainage of middle ear secretions into the nasopharynx with the assistance of the mucociliary system of the ET and middle ear mucous membrane.

The second etiologic theory was first suggested by Brieger in 1914 and proposes an inflammatory origin to OM.[6] Since that time, several other authors have supported this theory. In 1958, Senturia reported a 41% incidence of positive bacterial cultures in 130 specimens taken from patients with a diagnosis of "serous otitis media."[6] Other series have supported this finding.[7] Sade's observation that the basic histopathologic mechanism in otitis media with effusion (OME) is an inflammatory hypertrophy of the middle ear mucous membrane and hyperplasia of its mucous glands also tends to support an inflammatory basis.[8]

Protein analysis of middle ear effusions indicates a higher concentration of total protein, lactate dehydrogenase, malate dehydrogenase, and acid phosphatase than in serum. This finding has led to the speculation that this material represents an exudate rather than a transudate, giving further evidence that this is an inflammatory process. Some proponents of the inflammatory theory feel, how-

ever, that inflammation occurs secondary to ET dysfunction; thus, the inflammatory response is not the primary etiologic factor.

Numerous other factors may well contribute to the development of middle ear disease. These include allergy, ciliary dysfunction, nasal and/or sinus disease, and immaturity of the immune system.

In the last 10 years, the role of allergy in OME has been extensively investigated.[9,10] Otitis media in the pediatric population is felt to be associated with allergy in 5 to 80% of cases. Inhalant allergies are felt to play a greater role than food allergies. Most studies have been unable to demonstrate, however, an increase in serum immunoglobulin E (IgE) in children with OME.[11]

Allergic rhinitis, itself, is not felt to be the cause of OME. A viral or bacterial infection may prime the environment, which, in response, produces inflammatory mediators. These mediators begin the physiologic cycle, creating ET dysfunction, pressure gradients, and transudation of fluid.[12]

Middle ear mucosa is rarely the target organ. The nasopharynx is felt to be the major site of action with subsequent spread via the ET to the middle ear. Allergy is felt to affect ET function in several ways. Nasal obstruction can occur secondary to mast cell degranulation with increased vascular permeability, increased mucosal blood flow, and increased mucus production. Retrograde extension of inflammatory mediators from the anterior nose to the nasopharynx as well as allergen contact with the nasopharynx can cause ET edema and obstruction with a secondary increase in the pressure gradient through nitrogen gas exchange and subsequent transudation of fluid.[12]

Animal models have demonstrated immune-mediated inflammation as a contributing factor in the pathogenesis of OME. The role of immune complexes in experimental models has also been established. Normal middle ear mucosa is not felt to be immunocompetent tissue. During inflammation, however, it is transformed into a secretory epithelium containing multiple goblet cells with infiltration of macrophages and lymphocytes. This immune response may result from circulating antibodies that enter the middle ear through increased vascular permeability.

Otitis media–prone children have been shown to have higher levels of IgG antibody and IgG-antigen immune complexes in their serum and middle ears versus a non–OM-prone cohort. Immunoglobulin may be the predominant immune mechanism in the middle ear. It is felt that bacteria may actually cause immunosuppression of cell-mediated immunity. Immunoglobulin A is thought to be a late defense mechanism and may actually prevent bacteriolysis by IgG and complement, acting as a blocking antibody. Others have proposed an IgE-mediated hypersensitivity reaction to viral antigens.

"Immune tolerance" is the concept that immunization through the oral or pulmonary route may modulate the middle ear immune response. Studies have shown that oral immunization after systemic sensitization actually increased immune-mediated OME. Vaccines are now becoming available, including the recently US Food and Drug Administration (FDA)-approved pneumococcal conjugate vaccine.[13]

MICROBIOLOGY

Numerous studies have documented the microbiology of OM.[14,15] Approximately 30% of middle ear effusions demonstrate known pathogens for OM.[16] Although the treatment of AOM is directed toward the elimination of the bacteria from the middle ear space, viruses may also play an important etiologic role in this disease process.[17] The most common bacterial pathogens responsible for acute infection include *Streptococcus pneumoniae* and nontypable *Haemophilis influenzae*. These two microorganisms account for approximately 60% of the cases associated with bacterial infection. Group A *Streptococcus, Branhamella catarrhalis, Staphylococcus aureus*, and gram-negative enteric bacteria are less frequent causes of OM (Figure 9–1).

Because of the difficulty in obtaining viral cultures, fewer specific data are available regarding their occurrence in patients with OM. However, *respiratory syncytial virus* accounts for a majority of the viral infections of the middle ear space.[17] Otitis media may accompany exanthematous viral infections such as infectious mononucleosis and measles.

Over the years, chronic effusions have been thought to be sterile. However, more recent studies have confirmed the presence of bacteria in middle ear fluid, and studies show that the bacterial spectrum closely resembles that found in AOM.[18] This

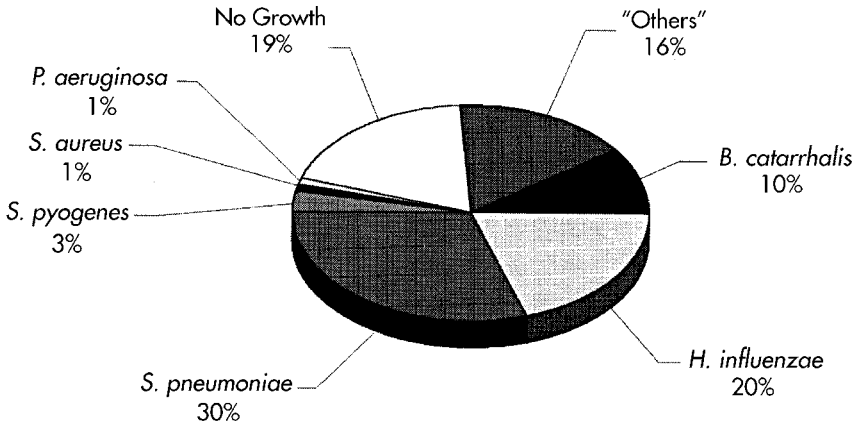

FIGURE 9–1. Bacterial incidence in acute otitis media with effusion.

information becomes increasingly important when consideration is given to the treatment of patients with both of these disease processes (Figure 9–2).

DIAGNOSIS

In most cases, a careful history and physical examination will lead to the accurate diagnosis of OM.

A careful history should elicit classic symptoms of OM. In the patient with the acute form of the disease, otalgia, fever, irritability, vomiting, and diarrhea may be present. Less frequently, otorrhea, vertigo, and facial paralysis may be associated with an acute infection of the middle ear space. In those patients in whom infection has spread into the mastoid air cell system and beyond, swelling of the postauricular area may be present.

In COME, hearing loss may be the only symptom. The most definitive part of the diagnosis is an appropriate physical examination to confirm the presence or absence of middle ear pathology. A complete examination of the head and neck should be undertaken first to identify the possibility of any predisposing condition such as craniofacial anomaly, nasal obstruction, palatal defect, or adenoid hypertrophy. In patients with unilateral OM, the nasopharynx should be visualized to rule out the possibility of neoplasm.

Otoscopy represents the most critical part of the examination to establish the diagnosis of OM (Figure 9–3). Use of the pneumatic otoscope is essential. The existence of chronic middle ear effusion is most easily confirmed when there is a definite air-fluid level or when bubbles are clearly visible within the middle ear space (Figure 9–4). However, findings commonly associated with OME include a severely retracted tympanic membrane with apparent foreshortening of the handle of the malleus and a reduction in tympanic membrane mobility (Figure 9–5). Occasionally, the tympanic membrane may be dull or thickened and have an amber hue (Figure 9–6). In severe cases, middle ear fluid may become purplish or blue, indicating hemorrhage within the tympanic cavity.

The color of the tympanic membrane is important but is not conclusive in making a diagnosis. An erythematous tympanic membrane alone

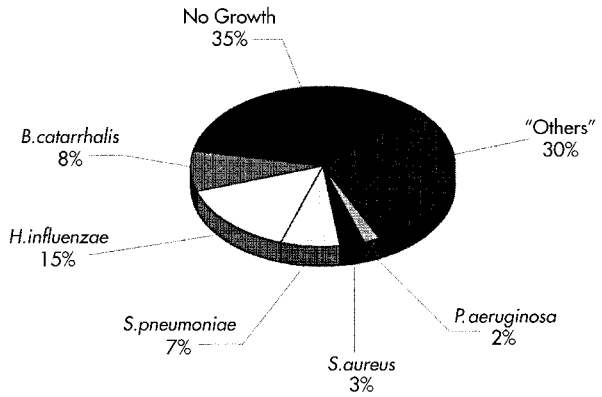

FIGURE 9–2. Bacterial incidence in chronic otitis media with effusion.

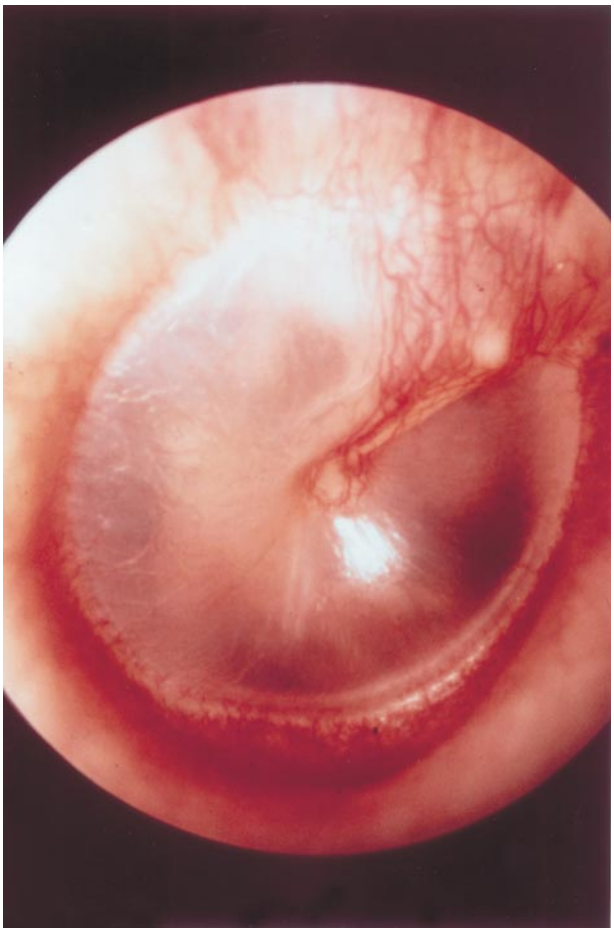

FIGURE 9–3. Normal right tympanic membrane at otoscopy.

may not be indicative of a pathologic condition because the vasculature of the tympanic membrane may be engorged as a result of the patient's crying or the presence of fever.

Acute otitis media usually presents with a hyperemic tympanic membrane that is frequently bulging and has poor mobility (Figure 9–7). Occasionally, perforation may be present, and purulent otorrhea is clearly visible.

The use of tympanometry has been popularized to confirm the findings of pneumatic otoscopy. This modality provides an objective assessment of the mobility of the tympanic membrane as well as the ossicular chain. By measuring tympanic membrane impedance, one can accurately predict conditions of the middle ear space (see Chapter 5).

The ultimate diagnostic test to confirm the presence of OM involves aspiration of middle ear contents. In acute situations, myringotomy or tympanocentesis may be undertaken to confirm the diagnosis, obtain material for culture, and relieve pus under pressure in an effort to avoid further complications. This may be necessary in patients who are unusually ill or toxic secondary to OM or in patients with severe suppurative complications. It may also be necessary in those patients who are having an unsatisfactory response to antibiotic therapy, in toxic newborns, or in patients who are significantly immune deficient.

With the rise in bacteria resistant to initial antibiotic therapy, tympanocentesis has been examined for its role in more specific antibiotic therapy.[19] Bluestone recommends tympanocentesis for several indications: (1) OM in patients with severe otalgia or toxic patients; (2) unsatisfactory response to antimicrobial therapy; (3) onset of OM in a patient already receiving antibiotics; (4) OM associated with a confirmed or potential suppurative complication; and (5) OM in a newborn, sick neonate, or immunosuppressed patient. This procedure does have significant risks including conductive and sensorineural hearing losses if not done properly. Otolaryngologists and pediatricians must be well trained in the technique to prevent these serious complications.

The hearing loss associated with OM should be documented whenever possible, especially in patients in whom chronic effusion is present. Although the presence of a conductive hearing loss does not confirm the diagnosis of COME, its presence does contribute to the confirmation of middle ear fluid. It is also important in documenting response to therapy.

MANAGEMENT

Acute Otitis Media

Acute otitis media represents one point in a continuum of the disease process known as "otitis media." The current standard of care strongly indicates that patients diagnosed as having an acute middle ear process should receive antimicrobial therapy for at least 10 to 14 days. In light of the fact that culture material is usually not readily available, therapy is begun on an empiric basis with treatment being aimed at the more common microorganisms found

FIGURE 9–4. Otitis media with effusion. Note bubbles confirming the presence of fluid.

in the acute process. Some have recommended withholding antimicrobial agents in certain cases.[20] However, in light of the fact that suppurative complications have markedly declined during the antibiotic era, antibiotic therapy is still strongly recommended in the acute process.[20]

The standard initial treatment for AOM is amoxicillin, 40 mg/kg every 24 hours in three divided doses, or ampicillin, 50 to 100 mg/kg every 24 hours in four divided doses for 10 days. In children allergic to penicillin, a combination of erythromycin, 40 mg/kg every 24 hours, and sulfisoxazole, 120 mg/kg every 24 hours in four divided doses, may be substituted. If β-lactamase-producing *H. influenzae* or *B. catarrhalis* is suspected, either amoxicillin-clavulanate, 40 mg/kg every 24 hours in three divided doses, or trimethoprim-sulfamethoxazole, 8 mg/kg of trimethoprim and 40 mg/kg of sul-

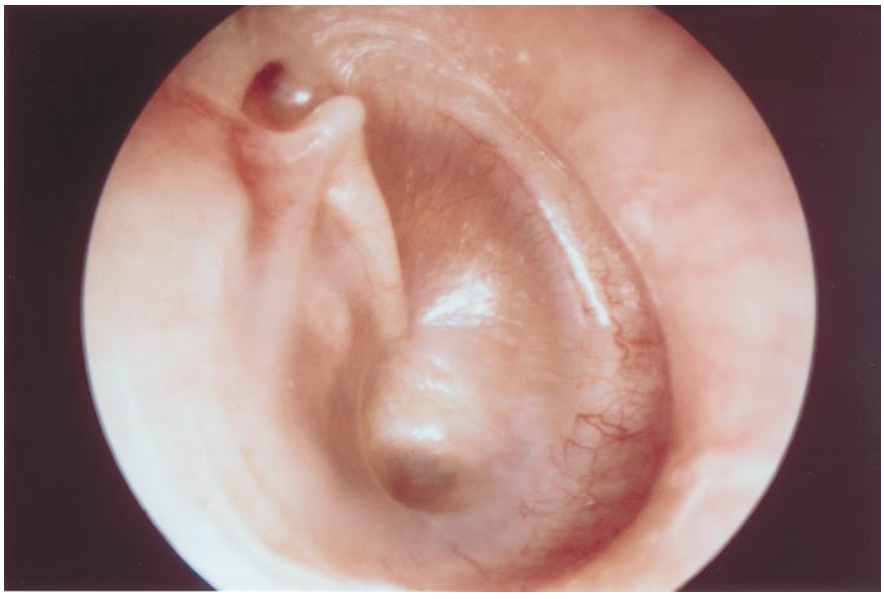

FIGURE 9–5. Advanced otitis media with effusion with markedly retracted right tympanic membrane, with an apparent foreshortened handle of the malleus and thick, mucoid effusion.

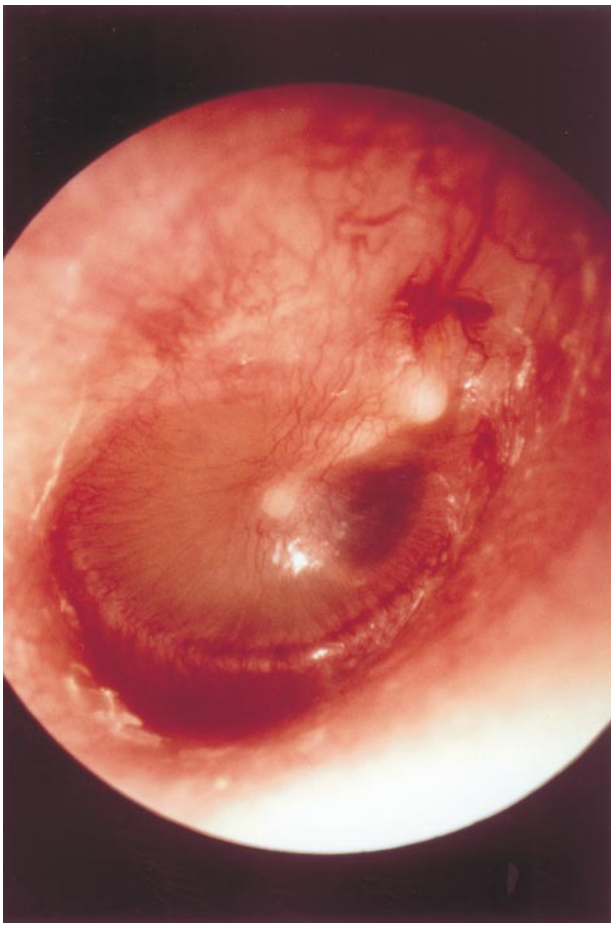

FIGURE 9–6. Chronic otitis media with effusion.

famethoxazole every 24 hours, may be used in two divided doses. Cefixime (Suprax, Lederle Laboratories, Wayne, NJ), 8 mg/kg in one dose, or cefprozil (Cefzil, Bristol-Myer-Squibb, Princeton, NJ), 15 mg/kg every 24 hours in two divided doses, may also be used effectively. A single intramuscular injection of ceftriaxone (Rocephin, Hoffman-Roche, Nutley, NJ), 50 to 100 mg/kg mixed with 1% lidocaine, not to exceed 1.5 mL, may be used in patients with vomiting (Table 9–2). Newer treatment for β-lactamase-producing microorganisms include high-dose amoxicillin at 80 mg/kg every 24 hours.[21] Dosages of appropriate antimicrobial agents for use in AOM are noted in Table 9–2.

Most patients who are receiving antibiotic therapy for AOM have significant improvement within 48 hours. If the child has not improved or the condition has worsened, tympanocentesis for culture and possibly myringotomy for drainage may be indicated. The patient may be re-examined some time during the course of therapy to ensure that the treatment has been effective.

Most children will have an effusion present at the completion of a 10- to 14-day course of antibiotic therapy. Such effusions may last up to 12 weeks before spontaneous clearance can be expected.[22]

Additional therapy such as analgesics, antipyretics, and oral decongestants (antihistamines and sympathomimetic amines) may be useful. Oral decongestants may relieve nasal congestion, providing some aeration of the ET. Their efficacy has not been proven, however.

The patient may remain in a subacute phase of the disease process for several weeks.

Repeated episodes of AOM plague many children, especially during the first 3 to 4 years of life. Several issues should be considered and evaluated in the management of such patients. A search should be made for a concomitant source of infection in the upper respiratory tract such as chronic adenoiditis or chronic sinusitis. Mild immune immaturity, especially in the IgG subclass group, may be responsible for this relentless process. Testing of immunoglobulins should be considered in relentless cases.

Such patients may be divided into two groups, the first being children who clear their effusion between episodes, whereas the second is made up of patients who have a persistent effusion between

TABLE 9–2. Daily Dosage for Common Antibiotic Agents in Acute Otitis Media

Agent	*Dosage/24 hr*
Amoxicillin	40 mg/kg in 3 doses
Ampicillin	50–100 mg/kg in 4 doses
Erythromycin-Sulfisoxazole	40 mg/kg (E) and 120 mg/kg (S) in 4 doses
Amoxicillin-clavulanate	40 mg/kg in 3 doses
Trimethoprim-sulfamethoxazole	8 mg (TMP) and 40 mg (SMZ)/kg in 2 doses
Cefixime	8 mg/kg in 1 dose

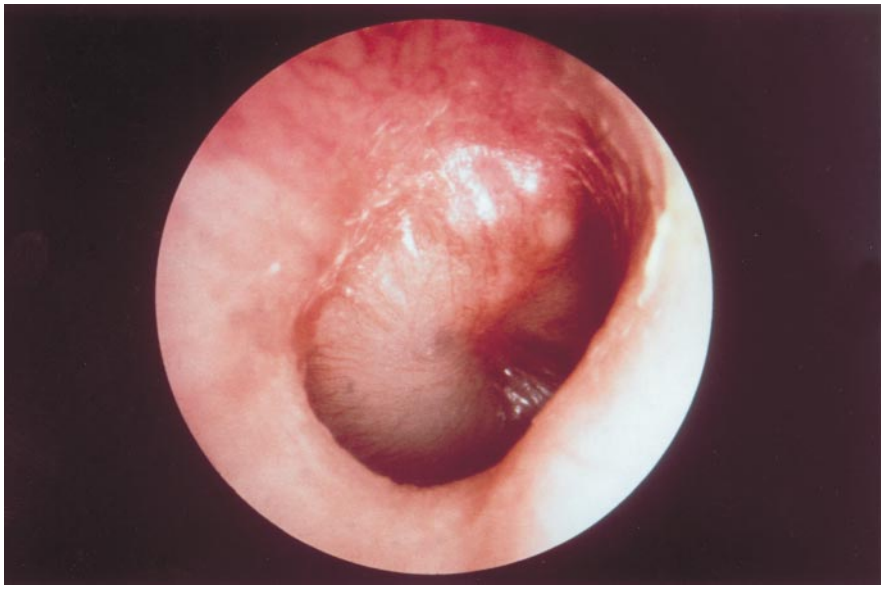

FIGURE 9–7. Acute otitis media showing an erythematous, bulging tympanic membrane.

episodes. In the latter group, chronic hearing loss becomes an additional major issue, especially as it impacts speech and language development.[1]

Several options are available for those patients who clear their effusion between episodes. The first option includes antibiotic therapy for each separate episode; a second option would be the use of antibiotic prophylaxis on a prolonged basis, whereas the third would include myringotomy and ventilation tube insertion. The administration of pneumococcal vaccine also may be useful.

Amoxicillin, or a suitable substitute in penicillin-allergic patients, may be given once daily at bedtime as prophylaxis. This form of therapy is usually administered during the months in which OM has its highest prevalence.

In children in whom the middle ear does not clear between acute episodes, ventilation tubes may be necessary to address the concomitant hearing loss associated with the process. Their use may also be necessary in those patients with antibiotic allergy or intolerance.

Chronic Otitis Media with Effusion

Medical Therapy Chronic otitis media with effusion may occur as a sequela to AOM or in patients who have had no documented recent episodes of acute suppurative disease. Numerous associated factors must be considered; thus, a careful history should be taken for the possibility of underlying allergy, sinus disease, or nasopharyngeal obstruction, which may be secondary to hypertrophic adenoids or even neoplasm.

Numerous methods of management have been advocated over the years for the persistent form of the disease. Antihistamine-sympathomimetic amine preparations were used frequently to clear the effusion. However, controlled clinical trials have demonstrated a lack of efficacy.[23] The use of corticosteroids, either applied topically in the nose or given systematically, has been reported to be advantageous in clearing middle ear fluid.[24] Unfortunately, there is a paucity of data to demonstrate efficacy; therefore, their use cannot be strongly recommended at this time.

The most effective medical therapy used to this point has been antibiotic administration. Numerous trials have concluded that some patients may respond to a 21- to 30-day course of full-dose antibiotic therapy.[25] The demonstration of viable bacteria in the middle ear effusions of chronically diseased ears has led to this recommendation. In light of the similarity of the bacterial spectrum, the same antibiotics recommended for AOM may be used in this disease. This form of therapy is strongly rec-

ommended in any child who has not received antibiotic treatment before consideration is given to myringotomy and ventilation tube insertion and/or adenoidectomy.

Historically, there was debate as to whether OME should be treated with antibiotics since there exists a certain spontaneous resolution rate. Physicians in other countries have traditionally not treated OM with antibiotics as frequently as is done in the United States. Rosenfeld and Post's meta-analysis of studies of antibiotic therapy for OME found a statistically significant efficacy for short-term resolution of OME.[16] Gates stated that approximately 40% of children with OME treated with antibiotics still have an effusion after 30 days, whereas 10% have a documented effusion 3 months after initial therapy.[26] Another factor that has not been studied well to date is what the impact of COME is on language development and learning in the child with conductive hearing loss secondary to COME and at what time point this deficit becomes an unacceptable risk. The success of prophylactic antibiotic therapy for OME had also not been studied in a systematic fashion.

In children with concomitant disease of the upper respiratory tract such as chronic sinusitis or adenoiditis, consideration must be given to the simultaneous control of these diseases. In addition, systemic problems such as allergy or immunodeficiency must also be addressed if long-term reversal of the middle ear abnormality is to be achieved.

With the emerging role of allergy in OME, the role of corticosteroid therapy has been re-examined. Investigators have demonstrated that a brief course of oral corticosteroids is efficacious for the short-term cure of OME. The proposed therapeutic mechanisms include stabilization of phospholipids to prevent arachidonic acid formation and subsequent inflammatory mediator formation, possible decrease in peritubal lymphoid tissue size, enhanced secretion of ET surfactant, and reduced middle ear fluid viscosity by action on mucoproteins.[27] The risks of oral corticosteroid therapy in children remain a concern, however. Studies have demonstrated an increase in the development of AOM if corticosteroids are not prescribed with antibiotics, transient depression in adrenal function, and the potential for disseminated varicella infection and its complications. Because of these risks, Rosenfeld recommends a trial of antibiotics and corticosteroids only if the next step would be tympanostomy tube placement. There have been no good randomized controlled trials to examine the risk-to-benefit ratio.[27] Relapses have been demonstrated within several weeks after treatment. The effects of nasal corticosteroids or immunotherapy on OME have not been studied.

Surgery The use of ventilation tubes with or without adenoidectomy has become the ultimate treatment of COME. This surgical intervention immediately corrects the conductive hearing loss associated with the middle ear process and diminishes the patient's tendency toward recurrent infection. It should be strongly considered in the following situations:

1. Recurrent AOM
   a. Unresponsive to antibiotic therapy
   b. Significant antibiotic allergy or intolerance
2. Negative middle ear pressure with impending cholesteatoma
3. Chronic effusion of the middle ear space with a duration of greater than 3 months
   a. Conductive hearing loss of greater than 15 dB
   b. Nasopharyngeal neoplasm for which treatment such as radiation therapy may be necessary

Although some controversy exists over the use of ventilation tubes, they do provide a safe method for normalizing middle ear pressure and, in most cases, restoring hearing to normal. They are usually associated with minimal morbidity, although tympanosclerosis or persistent perforation may be seen in a few instances. In most circumstances, it is difficult to determine whether these findings are a result of the underlying middle ear pathology with middle ear atelectasis or secondary to the ventilation tube itself. Numerous types of tubes are available for ventilation of the middle ear space, but, basically, they are all designed to provide equalization of pressure across the tympanic membrane (Figure 9–8). Some designs favor intubation of greater duration but also carry a slight risk of an increased incidence of persistent perforation upon extrusion.

Depending on the age of the patient, tube insertion may be carried out under local or general anesthesia.

It is usually advisable to allow spontaneous extrusion of the tubes to occur. Most tympanostomy tubes remain in the tympanic membrane for

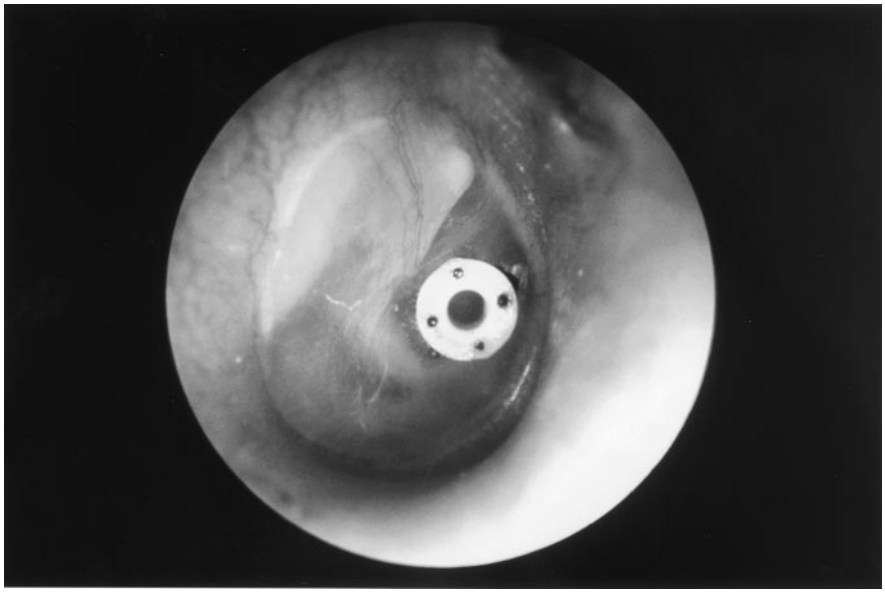

FIGURE 9–8. Ventilation tube in place in the right tympanic membrane.

approximately 6 to 12 months, with some extruding earlier and some later.

The most common complication of tube insertion is otorrhea. This may be secondary to either reflux of nasopharyngeal secretions, especially during an upper respiratory infection, or as a result of pathogens entering the middle ear through the lumen of the ventilation tube. It is commonly believed that contaminated water that is allowed to enter the middle ear through the tympanostomy tube may result in AOM media with otorrhea. In these instances, the external ear canal should be carefully cleaned and a culture obtained from the middle ear by aspirating through the tympanostomy tube. After this has been accomplished, oral antibiotics should be initiated as well as topical antibiotic therapy. The usual treatment includes the use of antibiotic agents commonly prescribed for other forms of AOM.

To avoid this possible complication, water protection of the ears is usually advised when contamination may be a possibility. This may be accomplished through the use of earplugs or cotton covered with petrolatum jelly, both of which can be inserted into the ear canal to provide adequate protection. In summary, tympanostomy tubes can provide a useful means of ventilating the middle ear space, controlling hearing loss secondary to middle ear effusion, and controlling recurrent infection.

Adenoidectomy may be useful as an adjunct to myringotomy in the treatment of middle ear effusion.[28] Removal of adenoid tissue improves the ventilatory function of the ET, thus allowing for appropriate equalization of pressure. The adenoid has been felt to play a role in OM in two ways: when hypertrophic, by causing mechanical obstruction of the ET, and when small, as a bacterial reservoir.[29] The adenoid is thought to be an important site for primary contact of inhaled microorganisms. Two studies are frequently cited regarding the use of adenoidectomy in OME. Gates demonstrated greater long-term efficacy in the treatment of OM in children 4 to 6 years of age when adenoidectomy was added to tympanostomy tube placement or myringotomies even if this was the first surgical intervention in a child.[26] Paradise et al, on the other hand, recommend adenoidectomy only if a child fails initial tympanostomy tube placement.[30] Studies have also shown that the recurrence rate of AOM may be reduced by adenoidectomy.[30] In addition, other confounding factors may warrant adenoidectomy such as evidence of chronic adenoiditis, nasal obstruction, or recurrent or chronic sinusitis secondary to nasal obstruction.

CONCLUSION

The future solution to OM, acute or chronic, does not lie in current therapy regimens. Manipulation of the immune system to provide enhanced protection will probably result in a significant decrease in the incidence of this disease process. Vaccination may play a significant role in this endeavor. Both nontypable *H. influenzae* and *S. pneumoniae* are leading etiologic factors in the development of bacterial OM and have polysaccharide capsules. Polysaccharide vaccines lack immunogenicity in infants and children under 2 years. Based on the same premise as the successful *H. influenzae* type b vaccine, in which the capsular polysaccharide is conjugated with a protein, a heptavalent pneumococcal conjugate vaccine, PCV7 (Prevanar, Wyeth-Lederle Vaccines), has become available. PCV7 and other pneumococcal vaccines may prove to be an important step in the prevention of AOM. This vaccine is recommended for universal use in children 23 months and younger. The American Academy of Pediatrics recommends that if immunization is initiated in infants younger than 7 months, four doses of PCV7 be given concurrently with other recommended childhood immunizations at 2, 4, 7, and 12 to 15 months. If immunization is initiated in infants who are between 7 and 23 months of age, who have not received their prior doses of PCV7, fewer doses are recommended. Children with congenital immunodeficiency, chronic cardiac disease, and infection with human immunodeficiency virus, chronic pulmonary disease, and other serious chronic conditions are especially vulnerable to pneumoccocal infection.[31] Attempts are under way to develop conjugated vaccines against nontypable *H. influenzae* and *B. catarralis*, which also has a polysaccharide capsule. It is too early to determine the impact of vaccination on the incidence of AOM. Other factors such as the role of gastroesophageal reflux or the role of such substances as surfactant have yet to be determined.

Currently, OM represents a costly medical problem worldwide. In some cultures, its morbidity with associated hearing loss, learning difficulties, and secondary central nervous system complications are almost unmeasurable. This significant medical problem deserves more research attention than it receives so that significant costs and morbidity associated with it can be reduced. Berman et al have developed a cost-effectiveness model for OME therapy.[32] Their recommendations include a trial of corticosteroids and antibiotic therapy at the 6-week follow-up visit if no resolution, another course of antibiotics at the 9-week visit, and tympanostomy tube placement if no resolution at 12 weeks. With OM continuing to be one of the most common reasons for physician visits in children today, finding the safest, most efficacious, and cost-effective treatment remains an important goal.

CHAPTER 10

Chronic Otitis Media

Steven A. Telian, MD, Cecelia E. Schmalbach, MD

CLASSIFICATION

At first glance, chronic otitis media (COM) might appear to be an overwhelming and enigmatic topic. A great deal of the confusion stems from the lack of a universally accepted system of nomenclature for chronic middle ear disease and the related surgical procedures.

A unifying definition of the term "chronic otitis media" is any structural change in the middle ear system associated with a permanent defect in the tympanic membrane (TM). Usually, but not always, there is associated inflammatory mucosal disease in the middle ear, which may also involve the mastoid cells. If there is persistent or intermittent otorrhea through a nonintact TM, the amplified designation "chronic suppurative otitis media" is preferred. The condition is considered "chronic" if the TM defect is present for a period greater than 3 months. Thus, a draining middle ear that is associated with a perforation from acute otitis media would not qualify for this diagnosis if it responds to treatment within 3 months. Possible causes for the TM defect include infection, trauma, retraction pockets developing from chronic negative middle ear pressure, and therapeutic interventions such as ventilation tubes. Histologically, COM is defined as irreversible mucosal changes within the middle ear cleft.

Perforations of the Tympanic Membrane

Perforations of the TM are described according to their anatomic location and are separated into two categories.

Central perforations involve the pars tensa and are circumferentially surrounded by residual TM. The umbo of the malleus is used as a reference point to divide the pars tensa into four quadrants, allowing one to describe the location of the perforation. Subtotal perforations describe large defects in which there is only a narrow rim of residual pars tensa near the annulus. Central perforations are rarely associated with cholesteatoma and for this reason have generally been considered "safe" ears. However, serious complications in the setting of a central perforation, such as intracranial abscess, have been reported.[1] The term "tubotympanic disease" is sometimes used to describe COM with a central perforation. This term stems from the fact that the TM defect exposes both the middle ear mucosa and eustachian tube but generally does not produce inflammatory changes in the mastoid.

Marginal perforations have no remnant of TM adjacent to the bone of the posterior canal wall. As a result, the bony external canal wall, attic, antrum, and mastoid cells can be involved with inflammation. Hence, this condition has been referred to as atticoantral disease. Retraction pockets produce marginal perforations and also occur in the pars flaccida, where they are known as attic perforations. In addition, total perforations with complete loss of the pars tensa result from necrotizing otitis media.

Cholesteatomas

Cholesteatomas are retraction pockets or cysts lined with squamous cell epithelium and filled with keratin debris occurring within the pneumatized spaces of the temporal bone. They are frequently associated with marginal perforations. The name is a misnomer as cholesteatoma is not a true neoplasm and does not contain cholesterol, but this familiar term retains wide popularity in clinical parlance. Cholesteatomas have a propensity for growth, bone destruction, and chronic infection. Therefore, COM with cholesteatoma is considered an "unsafe" ear and generally requires surgical treatment.

Cholesteatomas are categorized as congenital or acquired. Congenital cholesteatomas appear as white pearly masses deep to normal, intact TMs. Prior history of otorrhea, perforation, or otologic procedures excludes this category. However, patients may have a prior history of uncomplicated acute otitis media.[2]

Acquired cholesteatomas are much more common and develop in the setting of a retracted or perforated TM. Primary acquired cholesteatomas arise from retracted but intact drumheads, most often within an attic. Secondary acquired cholesteatomas result from ingrowth of squamous cell epithelium into the middle ear, usually through marginal perforations.

Cholesteatomas may also be described according to their anatomic location. Pars tensa cholesteatomas usually involve the posterosuperior quadrant of the TM and commonly cause erosion of the long process of the incus with discontinuity of the incudostapedial joint and conductive hearing loss. The disease frequently extends into the posterior tympanic spaces, facial recess, and sinus tympani. Attic cholesteatomas arise from pars flaccida defects and tend to be associated with scutum defects owing to erosion of the outer wall of the epitympanum. The ossicles are frequently engulfed or eroded by the cholesteatoma, which may then extend into the mastoid antrum.

Atelectatic and Adhesive Otitis Media

Although not associated with an actual perforation of the TM, atelectatic otitis media is also considered a form of COM. This condition involves collapse and retraction of an atrophic TM into the middle ear cleft. As a result, the middle ear space becomes partially or completely obliterated, but the membrane is not adherent to the underlying mucosa. Adhesive otitis media refers to the condition in which the middle ear space is completely obliterated, and the TM is irreversibly adherent to the medial bony wall. In adhesive otitis media, the normal mucosal lining of the middle ear space is replaced with a scarred membrane comprising the mucosa and the remnant of the TM.

EPIDEMIOLOGY

Because of the variable expression and insidious nature of COM, epidemiologic studies are limited and rely heavily on retrospective research. It is recognized that specific racial groups such as Native Americans, Canadian and Alaskan Inuits, Australian Aborigines, and New Zealand Maoris are more prone to COM. The Canadian Inuits offer a unique population for the study of COM. Prior to the 1950s, ear disease was almost nonexistent in this population. However, after World War II, the Inuits began living in overcrowded, overheated, prefabricated homes with significant smoke exposure, substandard sanitation, and poor dietary habits. These conditions probably represent risk factors for COM.[3] This theory is further supported by the decrease in COM among Maori children between 1978 and 1987 when improvements were made in their socioeconomic status, living conditions, and access to medical care.[4] Studies of COM involving these distinct ethnic groups must be interpreted with caution since findings in these communities may not generalize to other populations. Chronic otitis media in these distinct ethnic groups is rarely associated with cholesteatoma, and the disease tends to present earlier, usually by the age of 2 years.

The natural history of COM has been investigated with a retrospective review of 200 Israeli patients with perforations of the TM.[5] Seventy-six percent of the patients were found to have perforations, whereas the remaining 24% had COM with cholesteatoma. Regardless of the presence of cholesteatoma, approximately one-third of the patients had middle ear disease of the contralateral ear. Surprisingly, an average duration of 10 to 14 years elapsed between the onset of symptoms and presentation to an otologist. During this period, patients were seen by a general practitioner an average of four times a year for the first 7 years of life and were subsequently treated for an additional 5 to 8 years by a general otolaryngologist. However, cultures, audiograms, and radiographic studies were rarely used. This delay in referral was thought to be related to the slow, sometimes relatively asymptomatic evolution of COM as well as some lack of awareness of therapeutic interventions that are available.

Studies specific to COM with cholesteatoma reveal an annual incidence ranging between 6 and 12 per 100,000.[6–8] The current literature suggests that 10% of cholesteatomas are bilateral.[7] In a 10-year retrospective study of 500 patients with cholesteatoma, approximately three-fourths of the patients suffered from suppurative otitis media on one or more occasions. In addition, 10% of the

patients underwent placement of one or more sets of pressure equalization tubes.

PATHOGENESIS

Chronic otitis media is an insidious process, and patients tend to present with long-standing disease. As a result, the etiology and natural course of this process remain obscure, although several credible theories have been advanced.

Continuum Theory

Traditionally, COM has been thought to follow a bout of acute otitis media (AOM) that resulted in TM perforation. However, this direct correlation has fallen out of favor for several reasons. First, AOM is one of the most common childhood diseases. Comparatively speaking, COM is quite rare. In addition, the majority of TM perforations secondary to AOM result in complete healing of the drumhead.[9] Second, whereas streptococcal otitis media, which causes necrotizing infections resulting in large perforations, is seldom seen today, the incidence of COM has remained constant.[10] Third, in a study of 200 patients with TM perforations, only 50% clearly recalled an acute, painful ear infection associated with the onset of otorrhea. Instead, 40% described the insidious onset of drainage or gradual hearing loss.[5]

Although COM may not result directly from a single episode of AOM, it has been suggested that all cases of otitis media represent different stages in a continuum of events.[11–13] For example, histologic studies have demonstrated that persistent effusion in chronic secretory otitis media leads to degradation of the fibrous layer of the TM. Loss of the fibrous layer results in a weakened, atrophic, two-layered drumhead that is vulnerable to atelectasis or perforation and hence chronic middle ear disease.[9,14]

Atelectatic and Adhesive Otitis Media

It is acknowledged that eustachian tube dysfunction plays an important role in the development of COM.[15] The eustachian tube serves to ventilate the middle ear so that pressure equalization occurs between this space and the surrounding environment. In persisting eustachian tube dysfunction, especially as seen in Down syndrome and cleft palate, the middle ear space is continually exposed to negative pressure. As a result, the TM is retracted medially. In atelectatic or adhesive OM, the middle ear space is partially or completely obliterated. In long-standing atelectasis, patients are at risk for secondary acquired cholesteatomas.

Poor mastoid pneumatization is also associated with chronic middle ear disease.[15] Although pneumatization is not completed until adulthood, the majority of the process takes place during the first 5 years of life. Infancy and early childhood infections occurring during this period are thought to prevent normal cellular development of the mastoid and thus lead to chronic middle ear disease. Temporal bone histopathologic studies also demonstrate that infection of a pneumatized cleft incites sclerosis, obliteration of air cells, and chronic middle ear disease in the setting of poor mastoid pneumatization.[9]

Ventilating tubes can be placed within an atelectatic TM in an attempt to equalize the pressure and allow the TM to return to its normal anatomic position. Fifty percent of patients with pressure equalization tubes experience at least one episode of otorrhea, and 3% will have symptoms persisting beyond 6 weeks.[16] After extrusion of the tube, the majority of iatrogenic TM perforations will heal. Residual perforation rates are 2 to 3% for button or grommet tubes but as high as 47% for T tubes.[17,18] Continued eustachian tube dysfunction, persistent otorrhea, and ingrowth of squamous cell epithelium through the defect can prevent spontaneous healing. In accordance with the continuum theory, patients are then at risk for secondary infections and COM.

Chronic Otitis Media without Cholesteatoma

Recurrent infections of the middle ear generally result in irreversible mucosal changes. Histologic studies have shown that as the inflammatory process enters the chronic phase, there is a shift in cellular population from infiltrating leukocytes toward mononuclear cells such as macrophages, lymphocytes, and plasma cells.[19] These mononuclear cells secrete inflammatory mediators and growth factors that increase capillary permeability and lead to edema and hyperemia of the middle ear mucosa. In chronic inflammation, the mucosa undergoes metaplasia from a single layer of ciliated cuboidal or columnar epithelium to mucosa resembling that of the respiratory tract with increased numbers of gob-

let and glandular cells. Consequently, there is an increase in the volume and viscosity of the mucus. These changes further overwhelm the already compromised mucociliary clearance capability of patients suffering from chronic middle ear disease.[19,20]

Granulation tissue consisting of vascular connective tissue with inflammatory infiltrates has been found to be the prominent pathologic feature of COM. Granulation tissue was identified in over 95% of the temporal bones studied from individuals with a history of COM.[21] Tympanosclerosis was present in 43%, cholesteatoma in 36%, and cholesterol granuloma in 21% of patients in one large histologic study of temporal bone pathology. A pathologic review of 800 temporal bones revealed that granulation tissue had both a higher prevalence and more generalized distribution when compared to cholesteatoma.[22] Both studies demonstrated identical pathologic changes within the middle ear cleft regardless of the presence of a TM perforation.

As granulation tissue matures, it becomes dense and fibrotic with decreased vascularity. This process leads to scarring and adhesions associated with the ossicular chain and TM.[23] Irreversible changes such as subepithelial edema and mucoperiosteal fibrosis occur deep to the epithelial lining.[24] As the inflammation persists, sclerosis, along with new bone formation, can cause a reduction in mastoid and antral pneumatization. Other late changes such as bone erosion, tympanosclerosis, and cholesterol granuloma are discussed in detail below.

Chronic Otitis Media with Cholesteatoma

Congenital cholesteatomas are thought to result from an error in embryogenesis that causes squamous epithelial cell arrest behind an intact TM. This theory has gained popularity since the identification of an "epidermoid formation," consisting of squamous cells in the anterior epitympanum of developing fetal temporal bones.[25] This location coincides with the most common location of congenital cholesteatomas. The epidermoid formation plays a role in organizing the formation of the tympanic ring, medial layer of the TM, and epithelial lining of the eustachian tube. It is not generally found beyond 33 weeks gestation, but failure to atrophy is thought to result in congenital cholesteatomas. Another theory is that squamous cell epithelium intended for the external canal is pinched off during the formation of the TM. Consequently, squamous cell epithelium trapped in the middle ear with an intact drumhead leads to congenital cholesteatoma formation.

The pathogenesis of acquired cholesteatoma has been debated for well over a century. Although no single theory has been universally accepted, the most popular explanation for attic cholesteatomas is the invagination theory.[26] Eustachian tube dysfunction is thought to cause retraction of the TM. The pars flaccida, lacking a fibrous layer, is more vulnerable to this effect. As the retraction pocket deepens, desquamated keratin accumulates and cannot be cleared from the pocket, and a cholesteatoma develops. On otoscopic examination, it may appear that the patient has a perforated TM, but closer examination reveals an intact drumhead with an attic retraction pocket. The term primary acquired cholesteatoma is applied to describe this mechanism of cholesteatoma formation.

It has also been theorized that cholesteatomas may develop as a result of the ingrowth of squamous cell epithelium from the lateral surface of the TM through a perforation. Convincing evidence comes from a study of cytokeratin 10, which is found in both the meatal epidermis and cholesteatoma matrix but not in the middle ear mucosa.[27]

The implantation theory proposes that squamous cell epithelium is displaced into the middle ear owing to surgery, trauma, or a foreign body. The prevalence of cholesteatomas following tympanostomy tubes is only 0.5%.[28] However, it is thought that ventilation tubes probably prevent far more cholesteatomas than they cause.

Another, less popular concept is the metaplasia theory in which healthy cuboidal cells transform into squamous cell epithelium in chronic inflammation. Although in situ metaplasia has been demonstrated, actual formation of cholesteatoma has not been proven.[29] In addition, this theory does not explain the common location of cholesteatomas in the posterosuperior aspect of the middle ear despite diffuse mucosal inflammation throughout the entire middle ear space. Lastly, it is proposed that cholesteatomas may develop from papillary ingrowth of basal cells through the basement membrane.[30]

Bone Erosion

Bone erosion is an important aspect of COM because it can lead to various complications ranging from hearing loss and labyrinthine fistula to facial

nerve paralysis and life-threatening intracranial complications. Originally, it was believed that pressure from the cholesteatoma itself led to necrosis of bone. However, experimental evidence is lacking. Cholesteatomas have been found to exert pressures between 1.31 and 11.88 mm Hg. These pressures fall well below the capillary perfusion pressure of 25 mm Hg. For this reason, it is unlikely that cholesteatoma, which is often associated with a perforation and open cavity, can produce enough pressure to occlude directly capillary flow and cause tissue anoxia. However, it is thought that the pressure exerted on adjacent bone by cholesteatoma causes bone erosion through the activation of osteoclasts.[31]

Histologic examination of the lytic zone between the submucosa and the necrotic bone reveals marked capillary proliferation along with infiltration of histiocytes that contain lysosomal enzymes such as protease, hyaluronidase, cathepsin, and acid phosphatase.[32] For this reason, it is argued that hyperemia in the setting of osteolytic enzymes, as opposed to anoxia, is responsible for bony erosion. Animal and human studies further support this theory.[33] In bone erosion, osteoclasts, which are known to be responsible for bone reabsorption, and collagenase have been identified. Prostaglandin E_2 and interleukin-1α are among various other mediators found to regulate bone reabsorption.[34]

Studies clearly demonstrate that bone erosion occurs in COM with or without the presence of cholesteatoma.[33,35] Although the true mechanism is not fully understood, it is generally accepted that inflammation is a major factor since granulation tissue is often associated with ossicular erosion.[36] The inflammatory process is thought to lead to infiltration and activation of osteoclasts and mononuclear cells containing various proteolytic enzymes. Microscopically, a subepithelial layer of granulation tissue has been identified adjacent to eroded bone. The cellular components of this layer are identical in cases with and without cholesteatoma.[37] The higher frequency of bone destruction in the setting of cholesteatoma may be related to the excellent environment cholesteatomas provide for persistent bacterial infection and chronic inflammation.

Tympanosclerosis

Tympanosclerosis is common in patients with a history of recurrent AOM, COM, or multiple ventilation tubes. Macroscopically, white crescent-shaped deposits are seen within the TM. In this setting, the term myringosclerosis is sometimes applied to indicate that the process is restricted to the TM. Microscopically, hyalinization of collagen and deposition of calcium are found within the lamina propria. Tympanosclerosis need not be limited to the TM. It may extend into the middle ear cleft to involve the ossicular heads and basement membrane of the middle ear mucosa. If the oval window is involved, stapes fixation may result and contribute to a significant conductive hearing loss.

Cholesterol Granuloma

Cholesterol crystals are frequently found within the submucosal lining of ears with COM. The process probably results from hemorrhage into the mucosa of the middle ear or within obstructed mastoid air cells, with the crystals representing breakdown products of the erythrocyte cell membrane. A foreign body response to these crystals leads to formation of a cholesterol granuloma. On macroscopic examination, a yellow-brown murky viscous material is found within the middle ear space or within the obstructed mastoid cells. Microscopically, the cholesterol crystals, foreign body giant cells, and associated inflammatory cells are identified.

DIAGNOSIS

History

Approximately one-third of individuals with COM have their diagnosis made as an incidental finding during routine physical examination. However, when symptomatic, the two hallmark presenting symptoms are otorrhea and hearing loss. Pain is unusual with COM and indicates either a reactive external otitis or the possibility of a developing intratemporal or intracranial complication.

The nature of the otorrhea is helpful in describing the specific type of COM. Profuse, intermittent, mucoid drainage is commonly noted in chronic suppurative otitis media without cholesteatoma. Malodorous otorrhea is rare in this setting. Conversely, patients with COM associated with cholesteatoma often describe scant but persistent, purulent, and foul-smelling otorrhea. Blood-stained drainage is often noted with granulation tissue or polyps. It is important to realize that cholesteatoma is frequently hidden beneath this abnormal inflammatory tissue.

Some patients with chronic middle ear disease will have normal hearing or only mild hearing loss because the granulation tissue or cholesteatoma successfully transmits sound energy to the inner ear. When present, hearing loss is usually conductive or mixed in nature.

The degree of hearing loss will depend on the size and location of the TM perforation and the status of the middle ear. Large perforations will generally cause greater hearing loss compared with smaller defects. In addition, perforations overlying the posterior part of the mesotympanum, and thus the round window niche, usually cause more severe degrees of conductive hearing loss because the TM is no longer protecting the round window membrane from direct sound energy transfer. As a result, there is reduction of the "baffle" effect, leading to a change in the cochlear mechanics.[38] Ossicular chain involvement will also cause conductive hearing loss. Chronic otitis media is often associated with bone erosion, leading to discontinuity of the ossicular chain. The long process of the incus is particularly vulnerable to postinflammatory necrosis, resulting in discontinuity or fibrous union at the incudostapedial joint. Tympanosclerosis may also arise in the setting of chronic inflammation. Usually, this is limited to fairly innocent changes in the TM but may involve the middle ear as well. As a result, the stapes footplate or other ossicles may become fixed. Finally, fibrosis or inflammatory granulation tissue within the middle ear can lead to limitation of TM and ossicular mobility.

Patients who have previously undergone a tympanoplasty with or without mastoidectomy for treatment of middle ear disease will often be left with a grafted TM that may be thickened, poorly mobile, and lacking the normal conical shape. Such changes, along with a shallow middle ear space and disruption of the ossicular chain, will also lead to conductive hearing loss.

Although an association between COM and conductive hearing loss is clearly acknowledged, the relationship to sensorineural hearing loss (SNHL) remains controversial. Several retrospective studies have compared the preoperative bone-conduction thresholds of diseased ears to the normal contralateral ears in patients with unilateral COM. These results have demonstrated an association between SNHL and COM.[39,40] However, the magnitude of hearing loss was small, ranging between 5 and 12 dB depending on the frequency tested. From a clinical standpoint, this hearing loss is less significant compared with the conductive losses caused by COM.

One proposed mechanism for SNHL is that inflammatory toxins cross the round window membrane, entering the scala tympani and causing irreversible cochlear damage. In this setting, one would expect high-frequency hearing thresholds to be most affected owing to the tonotopic arrangement of the cochlea, with high frequencies stimulating those cells closer to the round window in the basal turn. One retrospective review, limited to those patients diagnosed with unilateral COM with cholesteatoma, showed statistically significant interaural differences in both speech discrimination scores and pure-tone thresholds at 4,000 Hz independent of patient age.[41] Given that speech discrimination is believed to be significantly influenced by high-frequency cochlear function, these findings lend support to the theory of inflammatory toxins entering the inner ear. However, temporal bone studies of individuals with a history of COM failed to demonstrate histologic changes associated with inflammation near the round window membrane, even though an interaural difference in bone-conduction thresholds was appreciated.[42] Thus, although there is convincing evidence demonstrating a relationship between COM and SNHL, the clinical implications and actual mechanism of injury remain to be determined.

Physical Examination

Examination should include inspection of the pinna and postauricular region. Any scars from prior otologic surgery should be noted. Otoscopic examination with the use of a binocular microscope is imperative. Care should be taken to clear all cerumen and debris from the external auditory canal (EAC) so that the entire drumhead is visible. The EAC should be evaluated for signs of secondary otitis externa as well as scarring, which, again, would suggest prior surgery. The presence and specific location of aural polyps and granulation tissue should be noted. Attention is then turned to the TM. The size and location of any perforation should be detailed in the medical record, usually in the form of a diagram or photograph. Chronic otitis media in the absence of cholesteatoma is usually associated with a central perforation, whereas cholesteatomas are commonly observed in the setting of defects in

the pars flaccida or marginal perforations of the TM. Depending on the size of the perforation, as well as the presence of granulation tissue and polyps, the middle ear mucosa can often be examined. In the case of a dry perforation, the mucosa may appear completely normal. However, otorrhea is usually associated with edematous, inflamed mucosa. An attempt should be made to suction the middle ear space free of all secretions. If microbiologic specimens are indicated, fluid should be obtained from the middle ear, rather than the EAC, and it should be sent for both aerobic and anaerobic cultures. Perforations of the TM can also provide an opportunity to inspect the middle ear bony structures. Particular attention is focused on bone erosion and ossicular disruption. Depending on the patient's age and pain threshold, the microscopic examination and cleaning might have to be performed in the operating room with the use of sedation.

The physical examination should also include a fistula test if the patient reports vestibular symptoms, inspection of the nasopharynx, including the eustachian tube orifices, and gross assessment of hearing with a 512 Hz tuning fork.

Audiometric Testing

Every initial evaluation for COM should include audiometric testing with air and bone pure-tone thresholds. Appropriate clinical masking is imperative as patients often have bilateral involvement and mixed hearing loss. The degree of hearing loss is often helpful in determining the extent of the middle ear disease. Perforations of the TM can account for 15 to 20 dB of conductive hearing loss. When perforations are accompanied by ossicular chain damage, the hearing loss can increase to between 30 and 50 dB. Finally, ossicular chain disruption with an intact drumhead can account for 55 to 65 dB of conductive hearing loss.

Speech discrimination testing is also useful. Specifically, speech reception thresholds can help determine whether a patient is a candidate for middle ear reconstructive surgery. Usually, the speech discrimination and hearing loss correlate, but a small percentage of patients have an unexpectedly low speech reception threshold and thus may benefit less from surgical intervention. Furthermore, ears with very poor speech discrimination scores are not suitable for middle ear reconstruction unless there is reason to believe that the poor scores are owing to an inability to present a stimulus intense enough to obtain the maximal discrimination score.

Radiographic Studies

With the advent of high-resolution computed tomography (CT) in the 1980s, temporal bone plain films and polytomography have essentially become obsolete. The advantages of CT scanning over these traditional studies include superior definition of both bone and soft tissue detail and lower levels of exposure to radiation compared with polytomography (Figure 10–1).

Standard temporal bone CT technique involves 1.5 mm sequential cuts in both the axial and coronal projections. The axial images should extend from the arcuate eminence superiorly to the jugular fossa inferiorly. These views will be most helpful in evaluating the sinus tympani, facial recess, lateral semicircular canal, ossicles, and horizontal portion of the facial nerve. The coronal images span from the bony portion of the eustachian tube anteriorly to the posterior semicircular canal posteriorly and will be of value in assessing Prussak's space, the tegmen tympani, the ossicles, and the perigeniculate and vertical seg-

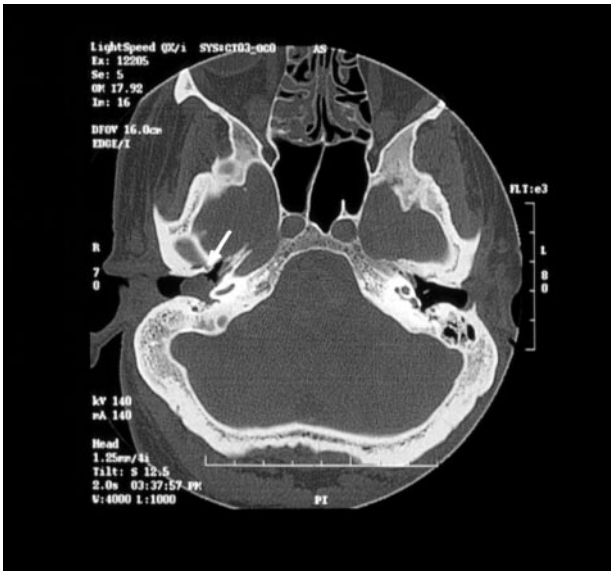

FIGURE 10–1. Axial computed tomographic scan showing inflammatory soft tissue (*arrow*) filling the right middle ear with a large fibrotic polyp extending into the external auditory canal and obscuring visualization of the tympanic membrane.

ments of the facial nerve (Figures 10–2 to 10–4). Cholesteatoma does not enhance with intravenous contrast, and it is not routinely administered unless there is a high suspicion for a vascular abnormality, tumor, or intracranial complication.[43]

Although superior for soft tissue resolution, magnetic resonance imaging (MRI) findings are usually nonspecific in COM. Bony details are not defined because both bone and air appear dark. Although an inflamed matrix may enhance with gadolinium administration, cholesteatoma is extremely difficult to differentiate from edematous mucosa, inspissated secretions, and granulation tissue. Studies have confirmed that CT scan is superior to MRI in the evaluation of cholesteatoma and uncomplicated COM.[44,45] However, MRI with gadolinium enhancement will serve to delineate intracranial complications better and is warranted when intracranial involvement is suspected (Figure 10–5).

Information provided by preoperative CT scans includes extent of disease and temporal bone pneumatization, both of which may influence the surgical approach and the management of the posterior canal wall. Anatomic variations such as a low-lying tegmen mastoideum, a large or anterior sigmoid sinus, or an anomalous facial nerve may also be appreciated and thus influence operative decisions. Computed tomography also allows identification of potential risks such as bony dehiscence

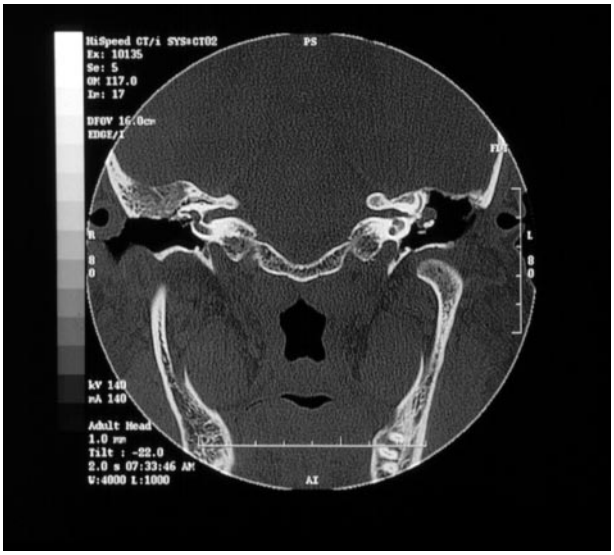

FIGURE 10–2. Coronal computed tomographic scan scan demonstrating attic cholesteatoma engulfing the ossicular chain in the left ear.

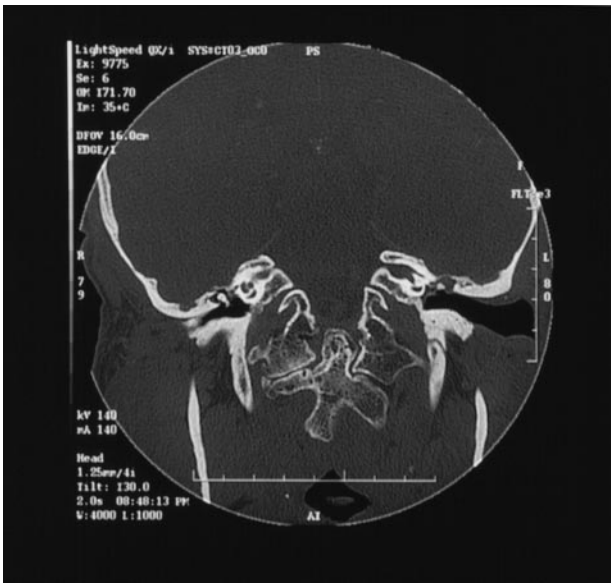

FIGURE 10–3. Coronal computed tomographic scan scan demonstrating cholesteatoma in Prussak's space with erosion of the scutum in the left ear.

of the tegmen tympani, facial nerve, lateral semicircular canal, jugular bulb, or sigmoid sinus. When using CT to evaluate disease in the temporal bone, one must remember that volume averaging of thin bony plates may lead to a false impression of bony dehiscence. Such misinterpretations can be minimized by examining the coronal sections of the temporal bone and comparing the diseased ear with the contralateral ear.

In an attempt to define the clinical utility of CT scans in COM, a study was conducted of 42 patients who underwent preoperative imaging prior to surgical intervention.[46] The most reliable finding was complete absence of soft tissue within the middle ear space. In all seven cases failing to demonstrate soft tissue on CT scan, no cholesteatoma was identified at the time of surgery. Soft tissue accompanied by bone erosion was found to correlate reliably with cholesteatoma. Only one-third of patients with soft tissue masses in the absence of bone erosion were ultimately diagnosed with cholesteatoma. Thus, CT scanning lacks specificity in differentiating cholesteatoma from granulation tissue, mucosal edema, and effusion unless bone erosion has occurred. Although CT is accepted as the "gold standard" radiographic study for COM, universal guidelines dictating its use have not been established.[47] Radiographic imaging does not alter surgical man-

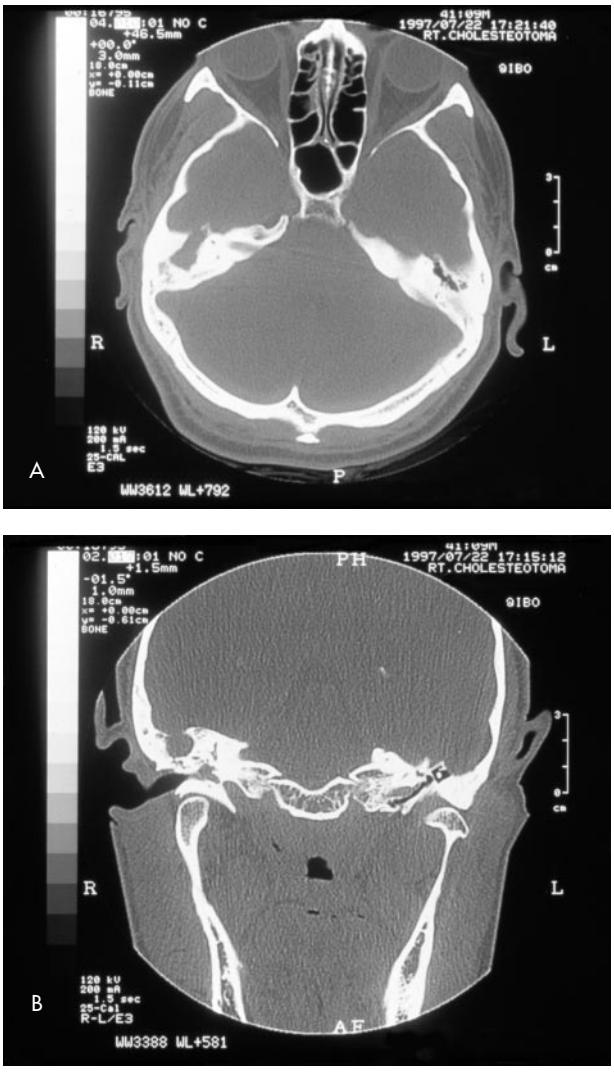

FIGURE 10–4. *A*, Axial scan showing poor pneumatization bilaterally, with aeration of the underdeveloped left mastoid antrum but cholesteatoma expanding the mastoid antrum on the right. *B*, Coronal scan of the same patient showing circular expansion of the antrum and dehiscence of the tegmen mastoideum by bone erosion.

agement of most COM cases because the extent of the middle ear and mastoid disease is ultimately exposed during surgical intervention. Given this limited clinical utility, along with cost considerations, radiation exposure, and need for sedation in children, most otologists recommend CT scanning only on a selective basis. Computed tomography is especially helpful in revision cases, when previous anatomic modifications are unknown to the surgeon, or when there is concern for recurrent cholesteatoma that may be hidden from otoscopic view. Other indications include congenital ear malformation, vertigo, a positive fistula test, and facial nerve paralysis. Finally, imaging is warranted in the setting of suspected central nervous system complications such as a brain abscess, cerebritis, or lateral sinus thrombosis.

Special Considerations

Histiocytosis X, an uncommon idiopathic disease associated with proliferation of histiocytes, can present in a fashion that mimics COM.[48] The most common otologic symptom is middle ear suppuration or otorrhea. Other manifestations include otitis externa, SNHL, vertigo, and mastoid destruction. Poor response to antibiotics, the presence of granulation tissue in the absence of suppuration, or associated signs of histiocytosis X such as hepatosplenomegaly, diabetes insipidus, bone lesions, and exophthalmos should alert one to this possibility. A mastoidectomy is often required to obtain tissue for diagnosis. A high index of suspicion is necessary because treatment of histiocytosis X entails low-dose radiation and occasionally chemotherapy. Eosinophilic granuloma, a related idiopathic condition that usually has a monostotic presentation, may present in a similar fashion. Again, the diagnosis is made based on histologic examination of tis-

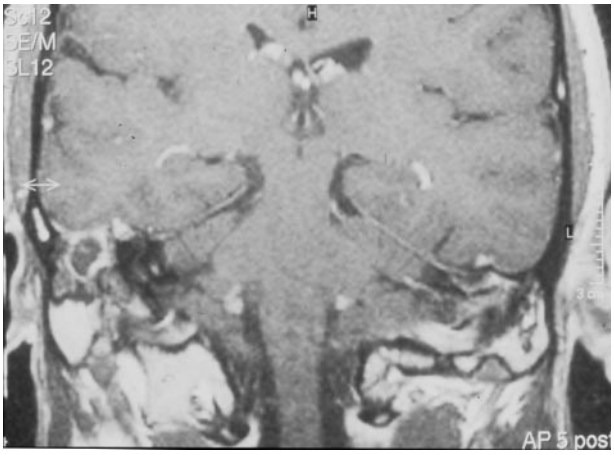

FIGURE 10–5. Magnetic resonance image of the patient in Figure 10–4 demonstrates hypointense signal in the center of the mass, consistent with cholesteatoma. Note also the enhancement of the surrounding matrix and the intact adjacent dura of the middle fossa. This finding rules out the possibility of an encephalocele, which may have been suspected from the computed tomographic findings.

sue obtained at surgery. These conditions should always be suspected when there is bone destruction in the absence of cholesteatoma.

Another rare cause of COM is tuberculosis. Patients present with thin, odorless otorrhea that is often insidious and painless. Multiple TM perforations are typically found on otoscopic examination. Labyrinthine involvement can lead to SNHL. Diagnosis is important because patients require treatment with multiple antituberculous agents. After successful medical eradication of active infection, tympanoplasty may be performed.

A final consideration in the evaluation of COM is the potential complication of Meniere's disease, which has been found to occur subsequent to, and in some cases simultaneously with, COM.[49] In such patients, endolymphatic hydrops develops that is secondary to the chronic inflammation, leading to vertigo and/or fluctuating SNHL. The differential diagnosis includes labyrinthine fistula and toxic (serous) labyrinthitis.

BACTERIOLOGY

Although a severe episode of AOM can precede COM, the microorganisms responsible for each diagnosis differ significantly. Whereas *Streptococcus pneumoniae, Haemophilus influenzae*, and *Moraxella catarrhalis* are the common microorganisms responsible for AOM, *Staphylococcus aureus* and *Pseudomonas aeruginosa* are the common aerobic isolates in COM. Both are indigenous microorganisms. *Staphylococcus aureus* is a gram-positive coccus that colonizes the nares. *Pseudomonas aeruginosa* is a gram-negative rod that is extremely common in moist environments and is generally found colonizing the EAC. Thus, it is not surprising that it is often an important pathogen in chronic middle ear disease.

Anaerobic microorganisms may also play an important role in COM. Individual isolates and percentages differ somewhat from study to study, most likely because of differences in culture technique.[50] However, when fastidious microbiologic techniques are employed, the most common anaerobic microorganisms cultured include *Fusobacterium* sp, pigmented *Prevotella, Bacteroides fragilis*, and *Porphyromonas* (previously known as *Bacteroides melaninogenicus*).[51]

Overall, COM should be viewed as a polymicrobial disease since multiple isolates are usually recovered from a single culture. In addition, nearly one half of all COM is caused by a combination of aerobic and anaerobic microorganisms.[50]

MEDICAL MANAGEMENT

The treatment of COM generally begins with local care of the ear and outpatient medical management. For medical management to be successful, aural toilet is imperative. This intervention requires repeat microscopic examination of the ear and diligent suctioning. The main goal is to remove debris from the EAC overlying the TM and middle ear cleft so that topical antimicrobial agents can successfully penetrate to the middle ear mucosa. For patients with otorrhea secondary to cholesteatoma, the hope is to minimize granulation tissue and perhaps achieve a dry ear prior to surgical intervention. However, this is not always feasible, and some refractory cases will require surgery to eliminate the otorrhea.

It may be possible to reduce the amount of granulation tissue contributing to the ongoing otorrhea, particularly in the infected mastoid cavity. Before proceeding, one must be reasonably convinced that the critical landmarks are properly identified and that there is not a dural defect with an encephalocele present. Judicious suctioning of immature granulation tissue or polyps may be undertaken provided that the otologist is certain of the landmarks in the cavity. Once the base of the granulation tissue is reached, topical cautery with silver nitrate or 30% trichloroacetic acid is helpful. Silver nitrate is more hemostatic. Sometimes topical 2% gentian violet is helpful as an astringent if the bed of granulation remains active despite initial or repeated treatment. If the granulation tissue is of significant thickness or if a polyp is present, cup forceps may be needed to reach the base of the granulation. A wick may be indicated if significant canal edema has resulted from secondary otitis externa.

Most often, it is appropriate to proceed to surgery if the ear does not respond to microscopic débridement and ototopical management. However, if more aggressive medical management is contemplated to avoid surgery or to obtain a dry ear prior to surgery, any soft tissue that is removed from the external canal or mastoid cavity should be sent for microbiologic culture and sensitivity testing. When otorrhea is cultured, specimens should ideally be obtained from direct middle ear aspiration rather than from the ear canal whenever possible. Care

must be taken to avoid contaminating the aspirate with debris from the EAC since microorganisms colonizing this region, *Pseudomonas* in particular, are recovered from the middle ear space in only 50% of cases.[52] Cultures with sensitivity are necessary to guide antibiotic therapy because most patients with COM have been treated with multiple prior antibiotic regimens. For this reason, it is not surprising that two-thirds of all COM patients are infected with β-lactamase-producing microorganisms.[53]

Topical medications may include antibiotics, antifungals, antiseptics, and corticosteroid preparations alone or in combination with other medications. If otorrhea is profuse, it may be helpful to have the patient irrigate the ear daily with a body temperature half-strength solution of acetic acid (50% white vinegar diluted with warm water) prior to application of otic drops.

Popular topical antimicrobial agents have included aminoglycosides such as gentamicin, tobramycin, and neomycin in combination with polymyxin B sulfate because of their antipseudomonal properties. Controversy has surrounded these agents since animal studies have demonstrated ototoxic effects.[54,55] However, human studies have failed to show evidence that otic drops cause SNHL in patients with COM.[56] This discrepancy may be primarily attributed to the fact that the animals used in these experimental models have a round window membrane that is much thinner than in humans, particularly when there is no reactive inflammation. Furthermore, the round window niche is extremely shallow and completely exposed in these experimental animals, but it tends to be deep and often protected by a mucosal pseudomembrane in humans.[55] More importantly, most otolaryngologists believe that the risk of SNHL from uncontrolled infection owing to COM itself is greater than the risk associated with potentially ototoxic drops.

The use of neomycin in ototopical preparations continues to be extremely widespread owing to long-standing prescribing habits and low cost, despite the fact that almost no strains of *Pseudomonas* remain sensitive to this medication. In addition, there is a fairly high incidence of localized and diffuse allergic reactions to the topical use of neomycin. For these reasons, preparations containing neomycin should eventually fade from the ototopical armamentarium.

More recently, fluoroquinolone antibiotics such as ciprofloxacin and ofloxacin have gained popularity because of their antipseudomonal properties, minimal bacterial resistance, lack of ototoxicity, and potential oral route of administration. Studies have found topical ciprofloxacin to be as efficacious as topical tobramycin and to be superior to topical gentamicin.[57,58] According to US Food and Drug Administration (FDA) regulations, fluoroquinolones are contraindicated in children, pregnant women, and nursing mothers.

Studies have revealed that the addition of topical corticosteroids in combination with antimicrobial agents improves response rates compared with placebo or corticosteroids alone.[59,60] The anti-inflammatory properties of corticosteroids are thought to allow increased antibiotic levels in the middle ear mucosa by decreasing tissue edema. Currently, the ototopical combination that provides the best profile of efficacy and safety consists of a fluoroquinolone and corticosteroid preparation in suspension form. This preparation is significantly more costly than traditionally prescribed eardrops.

The use of systemic antibiotics in COM is limited by several factors. Once again, antibiotic penetration into the middle ear may be hampered by mucosal edema. Systemic aminoglycosides carry a risk of ototoxicity and require parenteral administration with monitoring of serum levels. Oral ciprofloxacin has proven to be a safe and effective treatment for adults with COM; however, safety in patients under 18 years of age has not been established.[61] Thus, the pediatric population is limited to parenteral antibiotics such as broad-spectrum penicillins, cephalosporins, and aminoglycosides.

Patients with a TM perforation should be instructed about the importance of keeping their ear canal and middle ear dry. An ear plug or a cotton ball impregnated with petrolatum jelly should be used when showering, and ear plugs should be worn when swimming. Hearing aid molds can cause an increase in middle ear humidity, which may initiate or perpetuate mucosal infection. For this reason, patients with recalcitrant otorrhea who are resistant to medical treatment and are not candidates for tympanoplasty should be fitted with bone-conduction hearing aids or osseointegrated bone-anchored hearing aids.

Medical management of COM may be difficult for both the patient and the physician. Multiple

office visits are often required for adequate aural toilet. In addition, patients are asked to comply with a regimen that may include not only daily irrigation but also multiple administrations of otic drops throughout the day. Medical treatment usually requires 14 to 21 days. It is disappointing that up to 50% of patients will have actively draining ears even when diligently compliant with a combination of corticosteroid and antibiotic drops.[59]

SURGICAL MANAGEMENT

The primary goal of surgery for COM is to eradicate disease and obtain a dry, safe ear. Restoration of hearing is by necessity a secondary consideration because any attempt at middle ear reconstruction will fail in the setting of persistent inflammation and otorrhea.

Absolute indications for surgical intervention include impending or established intratemporal or intracranial complications as described in Chapter 11. Various pathologic conditions within the middle ear, such as cholesteatoma and chronic fibrotic granulation tissue, are irreversible and require elective surgical attention. In addition, patients with otorrhea failing to respond to medical treatment are surgical candidates, as well as those who respond but are left with a correctable conductive hearing loss or a TM defect.

There are numerous surgical techniques used to address COM. Ultimately, the procedure chosen will depend on the nature and extent of the disease, as well as the surgeon's training and experience. If possible, it is ideal to restore eustachian tube function prior to surgical intervention. However, attempts at performing eustachian tuboplasty have been found to be extremely cumbersome and ineffective. Studies have proven that transtympanic ventilation can lead to successful surgical results, even in the setting of eustachian tube dysfunction.[62]

Nomenclature in Surgery for Chronic Otitis Media

- *Myringoplasty*—an operation limited to superficial repair of TM defects, without exploration of the middle ear cleft. These are generally performed in an office or ambulatory operating room setting.
- *Tympanoplasty*—an operation involving exploration of the middle ear cleft through a transcanal approach or through a postauricular incision. This is performed to eradicate disease from the middle ear, repair TM defects, and reconstruct the ossicular chain. This procedure is frequently performed in conjunction with a mastoidectomy.
- *Canalplasty*—an operation to widen the bony portion of the EAC, generally performed to improve access and visualization for tympanoplasty and postoperative care. This is often required for prominent bony overhangs associated with the tympanomastoid and tympanosquamous sutures.
- *Ossiculoplasty*—a procedure to reconstruct the ossicular chain.

Open (Canal Wall Down) Mastoidectomy Techniques These procedures have as their unifying theme a surgical strategy involving removal of varying portions of the bony EAC to obtain improved access to the epitympanic and mesotympanic spaces for management of chronic ear disease. These approaches also leave some or all of the diseased spaces of the temporal bone permanently exteriorized to help avoid recurrent disease:

- *Radical mastoidectomy*—an operation to eradicate or exteriorize extensive middle ear disease by removing the posterior bony ear canal to open the middle ear, mastoid, and epitympanum into one common cavity. In doing so, remnants of the tympanic membrane, malleus, and incus are removed, leaving only the remaining portions of the stapes. The TM is not reconstructed, and the eustachian tube may be left open or permanently obstructed with tissue grafts.
- *Modified radical mastoidectomy*—differs from a radical mastoidectomy in that an attempt is made to preserve or reconstruct the middle ear. Sometimes healthy TM and ossicular remnants are preserved. In the classic Bondy modified radical procedure, atticoantral cholesteatoma is exteriorized without disturbing the intact pars tensa of the TM or the intact ossicular chain. This procedure is appropriate in the rare instance when the disease extends from the pars flaccida region lateral to the ossicles with extension into the antrum. More commonly, the ossicles are engulfed or eroded by disease, and primary or staged reconstruction is required. When associated middle ear reconstruction is performed,

many surgeons still apply the term modified radical mastoidectomy, but the procedure is more appropriately called an open or canal wall down mastoidectomy with tympanoplasty.

- *Atticotomy*—removal of ear canal bone including the lateral wall (scutum) of the epitympanum to expose and exteriorize limited attic disease, usually lateral to healthy ossicles.
- *Atticoantrostomy*—a strategy that ultimately creates a defect similar to the modified radical mastoidectomy by pursuing a posterior extension of the atticotomy approach. The surgeon's intent is to exteriorize rather than resect the matrix of the cholesteatoma. The operation is performed by entering the attic from the ear canal and then proceeding posteriorly, gradually removing posterior ear canal bone and exposing disease in the aditus and antrum until it is fully exteriorized. This approach is appealing in that it exposes only that portion of the mastoid affected by disease; however, it provides limited opportunity to identify the surgical landmarks needed to prevent injury to the facial nerve.
- *Meatoplasty*—an operation performed to widen the cartilaginous and bony external auditory meatus of patients undergoing a canal wall down procedure. The operation allows postoperative inspection of the mastoid cavity and routine cleaning of debris from the mastoid bowl.

Closed (Intact Canal Wall) Mastoidectomy Techniques

- *Cortical mastoidectomy*—removal of disease that is limited to the mastoid antrum and air cell system, preserving the posterior bony EAC wall. Generally, when this operation is performed without a tympanoplasty, it is for chronic mucosal disease rather than cholesteatoma. The middle ear contents are not disturbed, although a tympanostomy tube may be placed for improved ventilation.
- *Tympanoplasty with intact canal wall mastoidectomy*—an operation in which disease is removed from the mastoid and middle ear while preserving the posterior bony wall of the EAC. Often the mesotympanum is exposed by developing a posterior tympanotomy through the facial recess. Middle ear reconstruction may be performed primarily, but it is often staged in cholesteatoma cases.
- *Obliteration technique*—a procedure in which muscle or a musculoperiosteal flap is used to obliterate a portion of the cavity following a canal wall down mastoidectomy. If successful, the size of the defect is minimized, which may avoid the need for long-term cavity care.
- *Canal wall reconstructive technique*—reconstruction of the posterior canal wall may be undertaken following a canal wall down mastoidectomy, either primarily or at a later operation. In doing so, an attempt is made to convert the open cavity into a closed cavity.

Anesthesia and Patient Preparation

Otologic surgery can be performed using local or general anesthesia. The length of the procedure, patient's age and ability to cooperate, and the anticipated level of stimulation must all be factored into the decision. Children will obviously require general anesthesia. However, local anesthesia may be preferred in cases primarily involving ossicular reconstruction since it is possible to assess hearing improvement intraoperatively. When surgery involves the TM, some surgeons will request that the anesthesiologist avoid use of nitrous oxide, which may increase middle ear pressure and interfere with positioning of the graft or TM.

Facial nerve monitoring is recommended in congenital temporal bone anomalies because of the associated risk of injury to a malpositioned facial nerve. Monitoring is also recommended for revision cases if the surgeon is uncertain of prior anatomic modifications or if the canal of the facial nerve is known to be dehiscent. Some surgeons advocate the routine use of a facial nerve monitor in every chronic ear operation. Although this is a controversial issue, those on both sides of the argument strongly agree that monitoring is no substitute for detailed knowledge of temporal bone anatomy and adequate technical preparation on the part of the surgeon.[63]

The use of perioperative, prophylactic antibiotics has been debated for decades. Many surgeons advocate the preoperative use of a broad-coverage antibiotic such as a cephalosporin, although controlled studies have suggested that the use of antibiotics does not reduce the risk of postoperative infection.[64]

Local injection of 1 or 2% lidocaine with epinephrine (1:100,000) provides excellent vasoconstriction for transcanal procedures. More concentrated epinephrine solutions prepared by the surgeon or an assistant might provide improved vasoconstriction, but errors in preparation have led to fatal consequences owing to the induction of cardiac arrhythmias. A 27- or 30-gauge needle mounted on a 1 mL syringe is recommended for ear canal injections. The most important injection is along the thick vascular strip region of the canal skin, lying between the tympanomastoid and tympanosquamous sutures. A subperiosteal injection will dissect freely under the skin and provide excellent vasoconstriction and anesthesia. Another subperiosteal injection inferior to the tympanomastoid suture will control bleeding from the inferior canal wall skin. Slow infiltration will avoid the formation of a bleb beneath the canal skin that may obscure the surgical field. When performing surgery under local anesthesia, additional injections should be made at the bony-cartilaginous junction in all four quadrants. In addition, the local anesthetic is injected into the scalp overlying the mastoid for postauricular procedures. Such injections are made prior to preparation of the ear to allow adequate time for vasoconstriction.

Most cases will not require extensive shaving of hair. Instead, adhesive drapes can be used to keep hair out of the surgical field. The ear and postauricular region are prepared in the standard fashion, recognizing that it is not possible to sterilize the ear canal completely. If the patient has an open middle ear cleft owing to a TM perforation, a cotton ball should be placed in the canal to prevent ingress of the antiseptic solution.

Tympanoplasty

Hearing restoration is of secondary importance in the surgical management of COM since any attempt at tympanoplasty and ossicular chain reconstruction will fail in the setting of persistent otorrhea, inflammation, and eustachian tube dysfunction. Eradication of mucosal disease remains the priority, and if it is not reasonable to reconstruct the ossicular chain at the first operation, middle ear reconstruction can be performed at a later date.

Graft Material and Tympanoplasty Techniques The goal of tympanoplasty is to repair the TM with a connective tissue graft in the hope that squamous cell epithelium will migrate over the graft and seal the perforation. Various grafting materials are available. Autogenous temporalis fascia is used most often because it is readily available through a postauricular incision and is extremely effective. Other alternatives include tragal perichondrium, periosteum, and vein. Preserved homograft materials such as cadaveric TM, dura, and heart valve have limited application because of concern for viral infection and the transmission of Creutzfeldt-Jakob disease.

The two classic types of tympanoplasty are the lateral technique and the medial technique. The terms lateral and medial refer to the final relationship of the graft to the fibrous layer of the TM remnant and the annulus tympanicus. In both approaches, the graft is secured medial to the malleus handle, if present. The lateral technique is more technically demanding, but many surgeons believe that it provides more reliable results when repairing large anterior or pantympanic defects. It is also useful when the ear canal anatomy is unfavorable, requiring an extensive canalplasty. The medial technique tympanoplasty is commonly employed for smaller perforations in the posterior and central portions of the TM. However, with careful attention to surgical principles, this technique can be applied regardless of the size or location of the defect.

Incisions Although various incisions have been described in the past, the two most common approaches used today are the transcanal tympanomeatal flap and the postauricular approach with creation of a vascular strip. Each incision has advantages and disadvantages. Ultimately, the ear canal anatomy, the position of the perforation, and the surgeon's judgment will determine the approach selected.

The tympanomeatal flap is created by making longitudinal canal incisions superiorly, along the tympanosquamous suture line (12 o'clock) and inferiorly (6 o'clock). The incisions extend laterally from the TM approximately 6 to 8 mm and are connected by a transverse incision parallel to the annulus. Elevation of the skin and periosteum anteriorly creates a medially based U-shaped flap. The tympanomeatal flap allows for excellent exposure of the posterior part of the mesotympanum and is ideal for perforations located in this area. The flap is usually elevated using a transcanal approach and does not require a

postauricular incision. Closure is simple, postoperative pain is modest, and the ear heals quickly. However, it is important to realize that in inexperienced hands, the transcanal approach can be cumbersome owing to limited exposure imposed by the use of a speculum and the ear canal configuration.

The major disadvantage of the transcanal approach using a tympanomeatal flap is poor exposure of the anterior mesotympanum. As the flap is reflected forward, it remains within the surgical field and obscures visualization of this area. As a result, anterior perforations are difficult to address, especially in the setting of a prominent anterior canal wall bulge. It is also difficult to visualize and address irreversible mucosal disease in the protympanum and eustachian tube orifice, both of which may contribute to surgical failures by preventing satisfactory postoperative eustachian tube function. The swinging door technique may be used to improve anterior exposure. The tympanomeatal flap is bisected by an incision that extends medially through the annulus and TM remnant into the posterior margin of the perforation. The divided tympanomeatal flap can be reflected superiorly and inferiorly for increased exposure. Separating the drumhead remnant from the malleus handle may also be helpful in improving exposure to the anterior mesotympanum.

The postauricular, vascular strip approach is an alternative means to achieve excellent exposure of the entire mesotympanum. A superior ear canal incision is made longitudinally along the tympanosquamous suture line. An inferior incision is made along the tympanomastoid suture line. These incisions outline the so-called vascular strip, the thickest and most vascular portion of the ear canal skin. A medial incision is made parallel to the annulus, connecting the two longitudinal incisions. These incisions may be made through the ear canal at the beginning of the procedure. However, they are positioned more reliably when they are fashioned from behind after the posterior canal skin has been elevated through the postauricular incision. Some surgeons elect not to divide the vascular strip from the squamous cell epithelium of the TM, preferring instead to use this connection to simplify elevation of squamous cell epithelium from the fibrous remnant.

The postauricular incision is carried down to the level of the temporalis fascia superiorly and the mastoid cortex inferiorly. If a TM graft is planned, temporalis fascia or loose connective tissue lateral to the fascia can be harvested and set aside to dry (Figure 10–6). To ensure adequate exposure, the soft tissue elevation continues to the zygomatic root, exposing the superior portion of the bony canal. The ear canal skin is elevated and the vascular strip is incised, exposing the lumen of the bony EAC and the TM defect (Figure 10–7). Although the vascular strip approach provides excellent exposure of the middle ear, it does have certain drawbacks. The approach requires a postauricular incision and thus increases postoperative discomfort. Proper elevation and replacement of the vascular strip can be technically challenging, and there may be some residual areas of exposed bone after it is replaced. As a result, healing may be delayed and problematic.

Regardless of the approach selected, 1 to 2 mm of tissue at the margin of the TM perforation should be excised (Figure 10–8). This disrupts the mucocutaneous junction at the border of the perforation and starts the wound healing process essential to successful tympanoplasty. It is also essential to remove any squamous cell epithelium that might have extended under the edge of the perforation onto the medial surface of the TM. Retained squamous elements can later develop into a cholesteatoma, requiring repeat surgical intervention. In addition, any portions of the TM that are

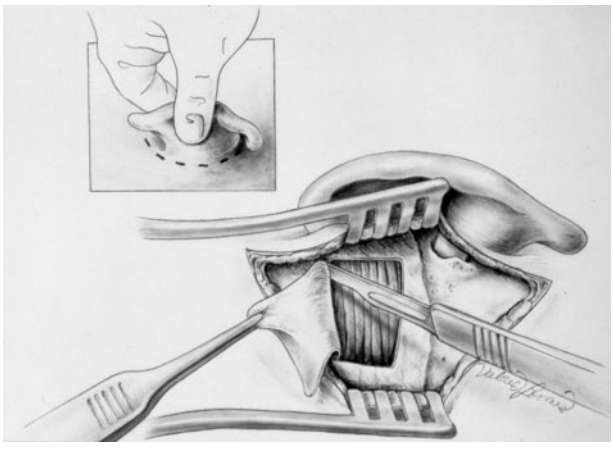

FIGURE 10–6. A right ear is pictured. The postauricular incision has been made, exposing the temporal bone and external meatus. A temporalis fascia graft is being harvested. FIGURE 10–7. After the pinna and vascular strip are turned forward, the posterior wall of the bony external auditory canal and the perforation are visualized. A prominent bulge of the bony canal corresponding to the temporomandibular joint usually obscures the anterior portion of the tympanic membrane and middle ear. Reproduced with permission from Telian SA, Kemink JL. Lateral technique tympanoplasty. Oper Tech Otolaryngol Head Neck Surg 1992;3:214–9.

severely atrophic or calcified with tympanosclerosis should be excised.

Removal of overhanging areas of the tympanosquamous or tympanomastoid suture may be necessary to improve exposure for tympanoplasty. To visualize the anterior sulcus better and ensure proper placement of TM grafts in this area, removal of the anterior canal wall bulge may also be required. This step is essential when performing lateral technique tympanoplasty but is rarely required in medial technique tympanoplasty.

Lateral Technique Tympanoplasty The lateral technique tympanoplasty requires removal of the anterior canal skin after the vascular strip is retracted forward. An anterior canal incision is made just medial to the bony-cartilaginous junction, connecting the two longitudinal flap incisions. The remaining ear canal skin and periosteum are elevated medially to the level of the annulus tympanicus (Figure 10–9). Complete de-epithelialization of the TM is imperative since this technique entails placement of the graft lateral to the fibrous layer. This will prevent formation of cholesteatoma arising from any residual squamous cell epithelium left between the graft and the fibrous remnant. Elevation of the squamous cell layer begins medially at one of the canal incisions near the annulus. The entire bony ear canal and fibrous layer of the tympanic remnant are freed of squamous cell epithelium. The anterior canal skin is trimmed of useless tags and is stored in a moist sponge. The lateral edge

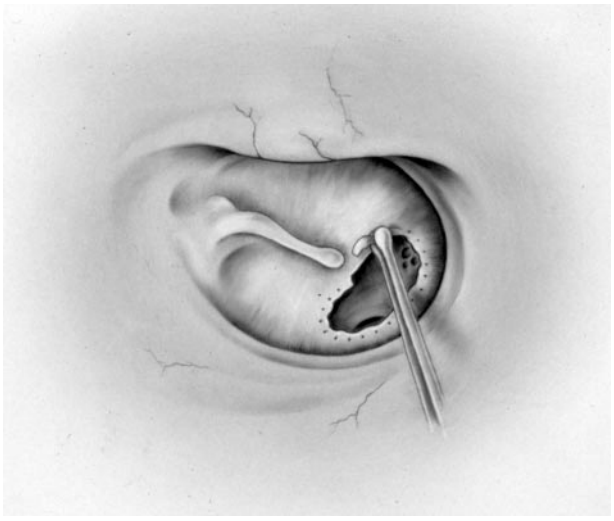

FIGURE 10–8. A fresh perforation is created by resecting the mucocutaneous junction at the margins of the perforation. This results in a slightly larger perforation and initiates wound healing along the graft.

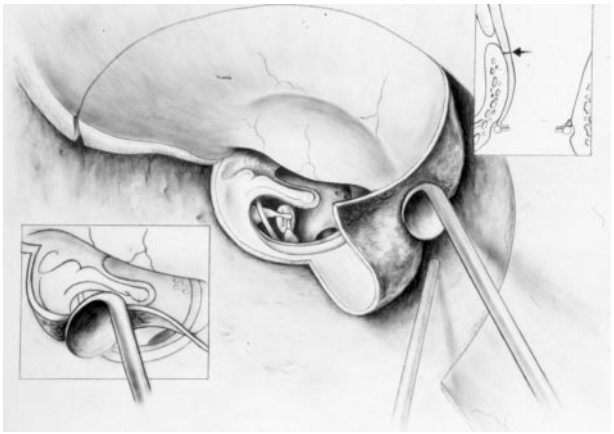

FIGURE 10–9. For a lateral technique tympanoplasty, the anterior canal skin is incised near the bony-cartilaginous junction (*upper inset*). The skin is elevated from the anterior and inferior canal wall and then from the tympanic membrane remnant (*lower inset*). Reproduced with permission from Telian SA, Kemink JL. Lateral technique tympanoplasty. Oper Tech Otolaryngol Head Neck Surg 1992;3:214–9.

of the squamous cell epithelium is marked to facilitate proper orientation when it is replaced.

The canalplasty is performed to remove the anterior canal wall bulge and allow visualization of the anterior sulcus. The goal is to change the acute angle formed by the TM and anterior bony canal to approximately a 90-degree angle, with the entire annulus easily visible through the canal. Prior to drilling down this bony ledge, the skin overlying the anterior canal wall is either removed entirely or reflected medially. Drilling begins in the superior and inferior corners of the anterior bony canal (Figure 10–10). When drilling in the medial portion of the superior corner, care should be taken to avoid contact with the short process of the malleus. Otherwise, a SNHL can result from inner ear trauma.

The bony bulge is gradually taken down between the two corners in a lateral to medial direction (Figure 10–11). It is also important to remember that this bony prominence represents the posterior wall of the temporomandibular joint (TMJ). Copious irrigation will allow underlying soft tissue to become evident before the joint is violated. If the soft tissue of the joint is violated, the posterior portion of the TMJ can be eroded, allowing prolapse of the mandibular condyle into the ear canal. This feared complication of lateral technique tympanoplasty is extremely difficult to correct and should be assiduously avoided. After achieving adequate exposure, the middle ear should be copiously irrigated to remove bone dust.

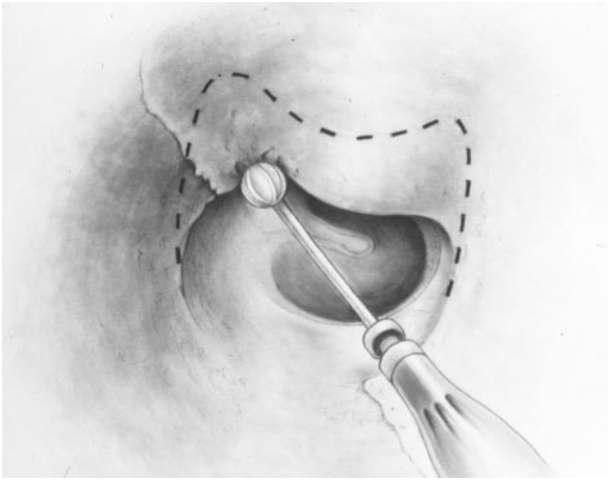

FIGURE 10–10. After all of the squamous cell epithelium is removed from the bony canal, the anterior canal wall is drilled to remove the bone as outlined. Reproduced with permission from Telian SA, Kemink JL. Lateral technique tympanoplasty. Oper Tech Otolaryngol Head Neck Surg 1992;3:214–9.

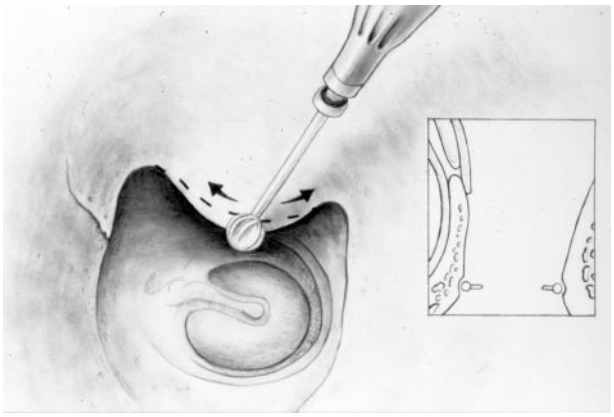

FIGURE 10–11. The superior and inferior corners are drilled initially, followed by careful polishing of the anterior bulge. A 90-degree angle at the anterior sulcus is desirable after the drilling is completed (*inset*). Reproduced with permission from Telian SA, Kemink JL. Lateral technique tympanoplasty. Oper Tech Otolaryngol Head Neck Surg 1992;3:214–9.

The annulus may be elevated from the sulcus tympanicus anteriorly in continuity with the mucosa of the lateral wall of the eustachian tube. This provides a nice pocket between the annulus and the bony wall of the eustachian tube to support the anterior portion of the graft. If there was a significant degree of mucosal resection performed in the middle ear, the surgeon may wish to place a sheet of gelatin film or thin Silastic sheeting over the promontory to prevent adhesions. Gelfoam can be placed in the middle ear to prevent retraction, but this is not mandatory with the lateral technique, particularly if there is a substantial remnant of the fibrous layer to support the graft peripherally. When a substantial remnant does remain, incisions should be made sharply alongside the malleus handle to permit insinuation of the connective tissue graft.

The dried tissue graft is trimmed so that it is long enough to drape onto the posterior canal wall and wide enough to cover the entire TM region and a portion of the superior canal wall (Figure 10–12). A superior slit is fashioned to allow the surgeon to wrap the graft around the neck of the malleus. The reconstruction is accomplished by placing the graft into the TM defect, medial to the malleus handle and

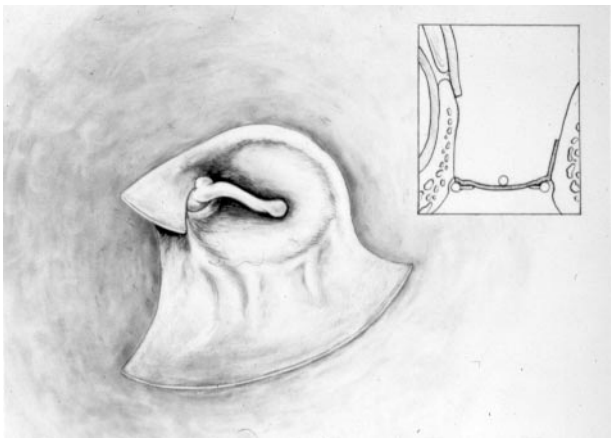

FIGURE 10–12. The fascia graft is placed medial to the malleus handle and lateral to the tympanic membrane remnant. A portion of the anterior fascia is draped over the region of the pars flaccida. *Inset:* cross-sectional view of graft position. Reproduced with permission from Telian SA, Kemink JL. Lateral technique tympanoplasty. Oper Tech Otolaryngol Head Neck Surg 1992;3:214–9.

lateral to the fibrous layer (see Figure 10–12, inset). It is best to position the graft medial to the malleus before it becomes floppy from rehydration. The tissue anterior to the slit is delivered onto the superior canal wall, and the base of the slit is pulled snugly onto the malleus neck. The region of the notch of Rivinus is covered by draping the tissue anterior to the slit onto the tissue that is posterior to the slit. The graft is then rotated around the axis of the malleus to bring the inferior and anterior edges into proper position. The anterior edge is positioned lateral to the fibrous annulus or tucked into the pocket created lateral to the eustachian tube orifice. Care must be taken to ensure that the graft does not extend onto the anterior bony canal wall because this may lead to anterior blunting or lateralization of the graft.

The anterior canal skin is retrieved from the moist sponge and returned to the ear canal, where it is shifted a couple of millimeters medially from its original anatomic position. It should just overlap the anterior portion of the previously placed connective tissue graft. The skin graft should be carefully positioned into the right angle formed by the bony canal and the TM graft. It is then supported by a rolled piece of pressed dry Gelfoam that is tucked firmly into the anterior sulcus and allowed to expand (Figure 10–13). Additional Gelfoam is placed over the tissue grafts, except for that portion of the fascia that extends onto the posterior ear canal wall. The pinna and vascular strip are then returned to the anatomic position. The vascular strip should overlie the portion of the fascia graft resting on the posterior canal wall. The remainder of the canal is packed with Gelfoam and a cotton ball is placed into the lateral third of the ear canal. The postauricular wound is closed in layers, taking care not to lift the vascular strip from the ear canal during suturing. A mastoid dressing is applied.

The lateral technique tympanoplasty offers the experienced practitioner the advantage of reliable (better than 95% in most published series) repair of large and anteriorly located TM perforations. However, the results of the technique in inexperienced hands are considerably poorer.[65] The primary disadvantages include increased technical demands of the surgery, longer operative time, and sometimes delayed healing of the ear canal. In addition to the risk of epithelial cyst formation or cholesteatoma from retained squamous cell epithelium mentioned earlier, there is also the possibility that the patient could develop a conductive hearing loss owing to postoperative blunting or lateralization of the TM graft, especially if certain key technical principles are neglected or misunderstood.[66]

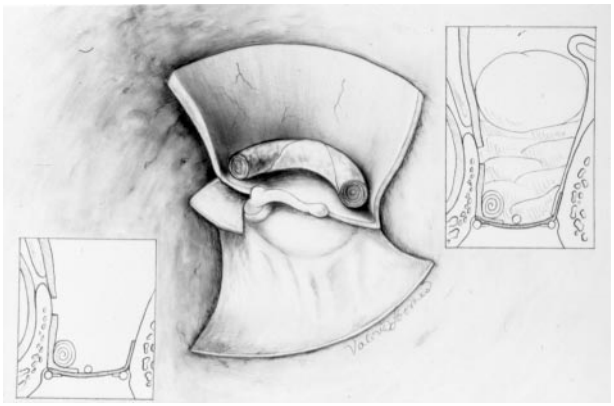

FIGURE 10–13. The canal skin graft is placed onto the fascia graft anteriorly and draped onto the canal wall. The anterior sulcus must be tightly packed, maintaining the 90-degree angle to prevent blunting (*lower inset*). After returning the vascular strip to the anatomic position, it should overlie the fascia posteriorly. The remainder of the canal is packed with Gelfoam and a cotton ball is placed in the lateral third of the canal (*upper inset*). Reproduced with permission from Telian SA, Kemink JL. Lateral technique tympanoplasty. Oper Tech Otolaryngol Head Neck Surg 1992;3:214–9.

Medial Technique Tympanoplasty As a result of the potential disadvantages discussed above, many otologic surgeons prefer the medial technique tympanoplasty. When the connective tissue graft is placed medial to the TM remnant, the risk of retained squamous cell epithelium beneath the graft and the subsequent development of cholesteatoma is essentially eliminated.

A medial technique tympanoplasty begins by elevating a tympanomeatal flap through a transcanal or postauricular approach, exposing the middle ear (see Figures 10–7 and 10–8). The drum may be completely elevated off the malleus handle, depending on the exposure required. The surgeon must take care to remove all squamous cell epithelial ingrowth on the medial surface of the TM remnant and malleus handle. Any irreversible mucosal disease is then removed from the middle ear. Unlike the lateral technique tympanoplasty, the fibrous layer of the TM has been elevated and will not provide support for the connective tissue graft. Therefore, the middle ear and eustachian tube orifice are filled with Gelfoam to prevent medial displacement of the graft. The connective tissue graft is seated medial to the handle of the malleus and TM remnant (Figure 10–14). The tympanomeatal flap is returned to its anatomic position, and the ear canal is filled with Gelfoam and a cotton ball.

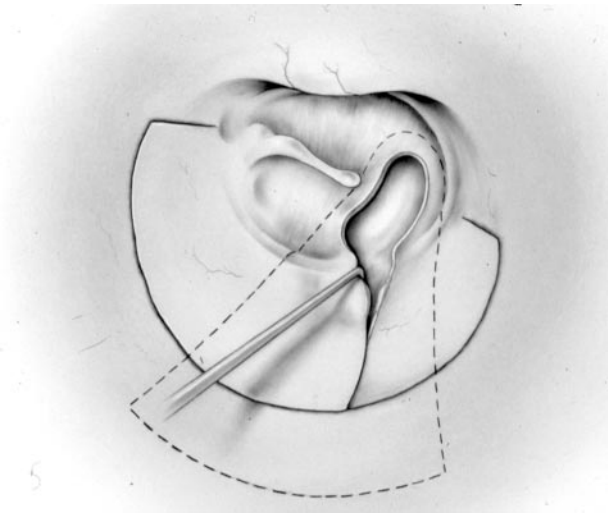

FIGURE 10–14. For a medial technique tympanoplasty, the fascia graft is placed medial to the tympanic membrane remnant and is supported by packing. After proper positioning of the graft, the divided limbs of the tympanomeatal flap are replaced into their original anatomic position to secure the graft.

Atelectatic Tympanic Membrane Nonperforated TMs as seen in atelectatic and adhesive otitis media may also require tympanoplasty if there is significant conductive hearing loss, retraction pockets with early cholesteatoma formation, or persistent infection. The atrophic, scarred TM is excised with preservation of the tympanic annulus. A tragal cartilage graft may be used to support the connective tissue graft in an attempt to prevent recurrence. Gelfilm (Upjohn, Kalamazoo, Michigan), or Silastic sheeting may be placed in an attempt to maintain ventilation of the middle ear cleft.

Postoperative Care Patients should refrain from strenuous exercise, air travel, and vigorous nose blowing during the immediate postoperative period to help prevent graft dislocation. The patient is examined approximately 1 to 2 weeks following the surgery, at which point the cotton ball is removed from the lateral canal and superficial Gelfoam is suctioned. Corticosteroid-antibiotic eardrops are prescribed for use two times a day. The patient should be examined every 2 weeks until healing is complete. All Gelfoam should be removed by the second or third postoperative visit. It is not unusual to require 8 to 12 weeks for complete healing, and crusting is common for the first few months. The ear should be observed periodically for the development of delayed healing problems, lateralization of the graft, or severe anterior blunting, which may require repeat surgery. If a pearl of cholesteatoma develops between the TM remnant and the graft, it will become evident on otoscopic examination. These cholesteatoma pearls are generally only a minor nuisance if detected early and can often be treated by simple marsupialization and extraction in the office without anesthesia.

Summary Techniques for tympanoplasty offer various options with respect to incision, graft material, and graft placement. Ultimately, the decision will depend on the location of the perforation, the bony anatomy of the EAC, and the surgeon's experience. Regardless of the method employed, experienced surgeons may expect that approximately 90% of tympanic perforations will be successfully repaired and 80% of the patients will have a con-

ductive hearing loss measuring 10 dB or less if the ossicular chain was intact at the time of surgery.[67]

Ossicular Chain Reconstruction

The numerous techniques and middle ear prostheses available to the otologic surgeon lend credence to the idea that ossicular chain reconstruction techniques remain to be perfected. However, in experienced hands, reconstruction should achieve closure of the air–bone gap to within 20 dB in two-thirds of the patients with an intact stapes arch and in one half of the patients missing the stapes superstructure.[68,69]

Some surgeons have been hesitant to perform ossiculoplasty in children for fear of failure associated with persistent eustachian tube dysfunction, higher infection rates, and increased risk of cholesteatoma. However, studies have demonstrated that hearing results in children can mirror those reported in adults.[70,71]

Autografts Autograft ossicles are removed from the patient and sculpted to serve as interposition grafts. The incus is used most often. Immediate availability, obvious biocompatibility, and a low extrusion rate have made autograft ossiculoplasty very popular. However, extensive bone erosion owing to middle ear disease may limit availability. Concerns have also been expressed regarding the use of ossicles from ears with cholesteatoma because of the risk of residual disease. Although cholesteatoma may involve the ossicular surface, histologic evidence of intraossicular cholesteatoma is lacking, even in the setting of gross bone erosion.[72] Once cholesteatoma remnants are removed from the ossicle with the use of a diamond bur, the bone is suitable for grafting. Caution must be taken when using autografts because bony fixation to adjacent bone of the cochlear promontory or the canal wall can lead to failure.

Homografts Homograft ossicles and en bloc TMs with attached ossicles can be harvested from human cadavers and are available for purchase through regional tissue banks. Graft rejection is extremely rare. Although donors are screened for known transmissible diseases and tissue preservation is performed using ethyl alcohol, formaldehyde, and glutaraldehyde, which should inactivate most viruses, the fear of potential transmission of HIV, hepatitis, and Creutzfeldt-Jakob disease limits the use of homografts.

Allografts More recently, bioengineers and surgeons have joined forces in an attempt to design biocompatible prostheses suitable for ossicular reconstruction. Allografts offer the advantage of sterility, availability, and, in some cases, tissue bonding to the ossicular chain or TM. However, these advantages come with a significant price tag compared with autograft ossicles.

Bioinert implants are so named because a mechanical bond, often consisting of fibrous tissue, forms between the implant and surrounding bone. Metals such as stainless steel and titanium fall within this category, as do solid polymers such as polytetrafluoroethylene (Teflon) and polydimethylsiloxane (Silastic). Owing to high extrusion rates, the use of metal and solid polymers has been largely abandoned.

In an effort to increase stability, porous polymers have been developed to allow ingrowth of human tissue into the prosthesis. Proplast 1 (Teflon-vitreous carbon composite) and Proplast 2 (Teflon-aluminum oxide composite) are two such examples (Vitek, Inc., Houston, Texas). Plastipore (Richards Medical Company, Inc., Memphis, Tennessee), a high-molecular-weight polyethylene sponge designed in a columellar fashion, has gained considerable popularity. Plastipore partial ossicular replacement prostheses (PORPs) are available to bridge the gap between the TM and stapes capitulum (Figure 10–15). In the absence of the stapes arch, a total ossicular replacement prosthesis (TORP) is seated between the drumhead and footplate (Figure 10–16). Intraoperative modifications can be made to the Plastipore prosthesis with the use of a knife. An alternative to Plastipore is Polycel (Treace Medical Inc., Memphis, Tennessee), consisting of thermally fused, high-density polyethylene sponge. It is available for both total and partial ossicular replacement.

Several large series have demonstrated that hearing levels achieved with Plastipore ossicular implants are equal or superior to those achieved with incus autografts.[73,74] The most common reason for failure is extrusion, especially in the setting of advanced mucosal disease.[75] Placement of cartilage, usually harvested from the tragus, between the TM and prosthesis head has decreased the extrusion rate to as low as 7%.[68]

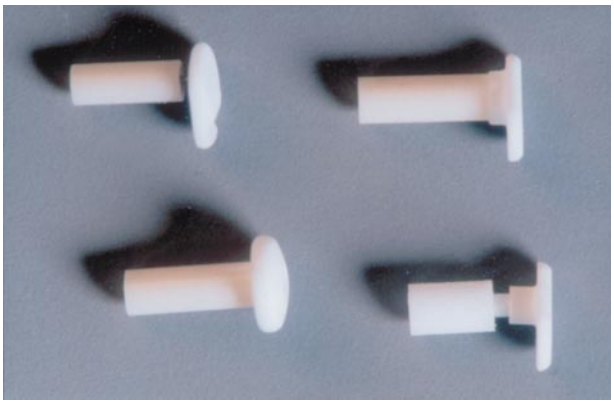

FIGURE 10–15. Photograph of several synthetic partial ossicular replacement prostheses (PORPs). Note the option of flat or rounded hydroxyapatite caps that may be placed directly under the tympanic membrane graft and alternative versions with a groove to allow secure positioning under the malleus handle.

Bioactive materials, which form chemical bonds allowing ion exchange with surrounding bone, have also been implemented in ossicular chain reconstruction. Included within this category are glass ceramics such as Cervital and Bioglass. The most popular bioactive material is hydroxyapatite (HA), a calcium phosphate ceramic resembling the mineral matrix of human bone. Although this substance is highly biocompatible, it is also quite brittle and therefore difficult to modify intraoperatively without risking a fracture of the implant. Thus, HA is generally used in the cap of the prosthesis, and the shafts are often made of a different substance that is easier to cut and perhaps even malleable. HAPEX, a homogeneous composite of HA and reinforced high-density polyethylene mixture, is also available (Richards Medical Company Inc.) and is much easier to cut than pure HA. Most prostheses are columellar in shape, with the exception of the Wehrs incus replacement and incus-stapes prosthesis.

FIGURE 10–16. Photograph of two synthetic total ossicular replacement prostheses (TORPs). The shafts may be made of rigid or malleable materials. The option exists to obtain smooth caps to place against the tympanic membrane graft or caps with a groove to engage the malleus handle.

A long-term study of HA prostheses demonstrated an extrusion rate of only 1.2%.[69] For this reason, it is argued that bioactive materials are better tolerated in the middle ear compared with their bioinert counterparts. Because of this low extrusion rate, many of the newer PORPs and TORPs in use today have a HA head, which is seated against the TM and therefore does not require the interposition of tragal cartilage. Nevertheless, some surgeons prefer to use cartilage in every case to minimize the long-term risk of extrusion.

Reconstructive Technique The technique chosen for ossicular reconstruction will ultimately depend on the remaining ossicles, with the two most important structures being the stapes superstructure and the malleus handle. The most commonly encountered ossicular defect is erosion of the long process of the incus (36%), followed by the stapes superstructure (18%) and the entire incus (17%).[10] Erosion of the incus long process should be expected with TM retraction onto the bone. In these cases, the incus should be inspected closely for erosion, and the integrity of the ossicle can be tested by gently palpating the long process with a pick. If there is a fibrous union at the incudostapedial joint instead of a healthy connection, palpation of the incus will not produce the usual motion of the stapes.

In COM, it is important to realize that conductive hearing loss may result from factors other than ossicular erosion by the disease process. For example, with cholesteatoma, removal of the incus and malleus head may be necessary to remove disease from the attic. Sometimes tympanosclerosis of the oval window or osteogenesis surrounding the stapes footplate may occur secondary to chronic inflammation. Such cases will require either a total stapedectomy with oval window grafting or removal of the stapes superstructure with stapedotomy to accomplish ossicular reconstruction. In addition,

tympanosclerosis of the malleus head and incus may cause fixation of the ossicles in the epitympanum, requiring mobilization or extraction of the ossicles.

If only the tip of the long process of the incus is absent, ossicular continuity can be restored using bone cement or a biocompatible incudostapedial joint prosthesis that fits onto the remaining long process. If complete erosion of the long process is discovered, the incus body can be extracted, sculpted, and used as an autograft to bridge the gap between the malleus handle and the stapes capitulum. A diamond bur is used to drill an acetabulum that fits over the stapes head and a groove to secure the autograft to the handle of the malleus. Figure 10–17 demonstrates two common ways in which the incus may be sculpted and placed into position. The method chosen depends on the relationship between the stapes and the malleus handle. Biocompatible prostheses are also available in similar configurations (Figure 10–18).

Loss of the incus long process along with the stapes superstructure is quite common in COM. Depending on the status of the residual incus, an interposition autograft from drumhead or malleus to stapes footplate can be used. The long process or short process of the incus is seated medially on the stapes footplate, depending on the height required to reach the TM. It is difficult to stabilize such a graft on the footplate, and the results are less reliable than those obtained when connecting to the stapes head. Alternatively, a TORP or various other HA incus stapes replacement prostheses are available.

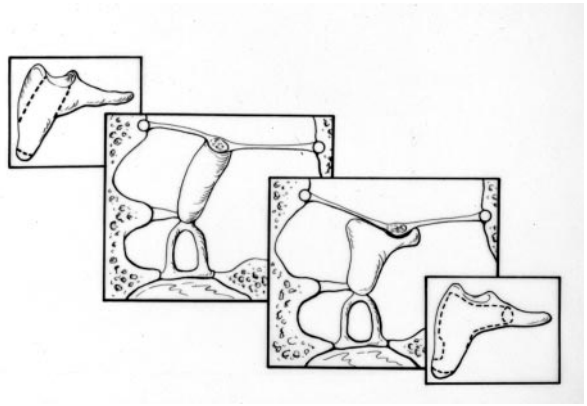

FIGURE 10–17. If the anatomic relationships are favorable, the incus may be sculpted to connect the malleus handle directly to the stapes capitulum. More commonly, the stapes is eccentrically placed posterior to the malleus handle, requiring an interposition graft that hooks onto the malleus and bridges the gap between the tympanic membrane and the stapes head.

FIGURE 10–18. Synthetic hydroxyapatite incus replacement strut.

If both the malleus handle and incus are absent when undertaking reconstruction of the ossicular chain, the use of a biocompatible PORP or TORP will be required, depending on the status of the stapes. With the probable exception of bioactive materials such as HA, any prosthesis seated directly against the TM will require a cartilage graft between the prosthesis cap and the drumhead to avoid extrusion.

Cortical Mastoidectomy

Tympanoplasty failures often occur with eustachian tube dysfunction and persistent inflammatory disease. For this reason, a cortical mastoidectomy is often recommended as an adjuvant to tympanoplasty.[76,77] The goal is to eliminate all irreversible mucosal disease, improve mastoid ventilation, and increase the buffering action of the mastoid cavity by enlarging its volume. In accordance with Boyle's law, significant changes in middle ear pressure may be better tolerated with minimal effect on the position of the TM.

A cortical mastoidectomy is usually performed through a postauricular incision. On children under

2 years of age, the mastoid tip has not fully developed, and care must be taken to avoid injury to the superficially positioned facial nerve. The incision is carried down to the mastoid cortex, and soft tissue is elevated to expose the surface landmarks of Macewen's triangle. The superior boundary is the temporal line extending posteriorly from the zygoma. This line corresponds to the probable level of the tegmen mastoideum, the bony plate separating the middle cranial fossa from the mastoid air system. The posterior boundary is a vertical line tangential to the posterior bony canal wall. Macewen's triangle is also bound by the bony projection of the posterosuperior external auditory meatus known as the spine of Henle. Contained within these boundaries is a collection of bony perforations know as the cribriform area. The mastoid antrum is directly deep to this area.

After identifying the surface landmarks, the cortex of the mastoid is opened using a large cutting bur. Dissection should always proceed from a lateral to medial direction, beveling all bony overhangs to allow adequate exposure of the cavity. The tegmen tympani and sigmoid sinus must be identified and clearly defined to avoid injury. In doing so, the sinodural angle is opened. The petrosquamous septum, also known as Körner's septum, is removed and all mastoid air cells anteromedial to the sigmoid sinus are opened (Figure 10–19). At this point, the mastoid antrum, the short process of the incus, and the horizontal semicircular canal are identified. Dissection of the mastoid tip air cells may be performed not only to increase the cavity volume but also to remove all mucosal disease that could potentially lead to future infection. On opening the mastoid tip, the digastric ridge is defined medially. On occasion, dissection of the zygomatic root is necessary to achieve adequate exposure of the epitympanum.

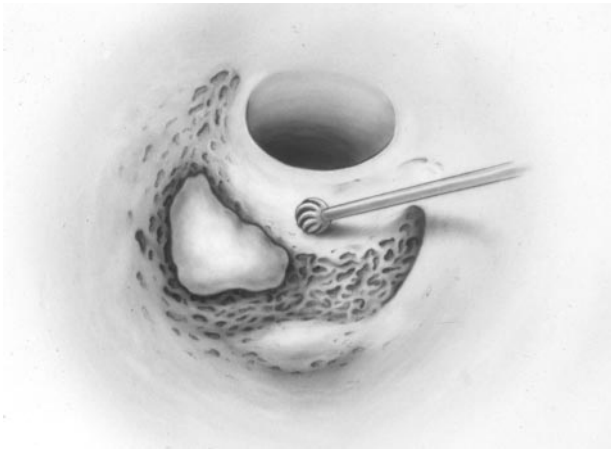

FIGURE 10–19. The cortical mastoidectomy is completed. Disease in the mastoid antrum has been exposed, with wide beveling of the cortical margins and skeletonization of the tegmen and sigmoid sinus plates.

It is important to realize that in the setting of chronic inflammation, the temporal bone tends to be sclerotic, limiting easy access to some of the important landmarks that often serve to guide the surgeon. It is vital to identify the tegmen and follow it forward to the antrum if injury is to be avoided. Liberal use of irrigation is essential, and final polishing of the tegmen plate with a diamond bur reduces bleeding.

Intact Canal Wall Tympanoplasty with Mastoidectomy

In an attempt to expose and eradicate middle ear disease better while preserving normal anatomic relationships for improved sound conduction, the posterior tympanotomy approach was introduced.[78] This technique allows access from a cortical mastoidectomy defect into the posterior mesotympanum by removal of the bony wall between the fossa incudis, the second genu of the facial nerve, and the chorda tympani. Since the access point into the middle ear is the facial recess of the posterior part of the tympanum, this operation is often referred to as a "facial recess approach." Alternative names for this approach include closed cavity tympanoplasty with mastoidectomy, intact canal wall tympanoplasty with mastoidectomy, and combined-approach tympanoplasty.

The major advantage of the intact canal wall tympanoplasty with mastoidectomy is the avoidance of a mastoid bowl that requires lifelong cleaning. In addition, healing is more rapid, and water exposure precautions are unnecessary. By avoiding a mastoid cavity and the associated meatoplasty, patients can usually wear hearing aids within the canal. However, these advantages come with a higher risk of residual and recurrent disease. The overall rate of recidivism is reported to range between 5 and 71% depending on the surgeon's experience, although most series report rates in the vicinity of 25%.[79,80] Preservation of the posterior canal wall limits visualization and access to the middle ear, especially to disease within the important

regions of the epitympanum, facial nerve, and oval window. As a result, residual middle ear disease may be left behind in any of these locations.

With respect to recurrent disease, an intact canal wall preserves a large cavity that must be ventilated by a marginally functional eustachian tube. If negative pressure persists, retraction pockets may recur and lead to the formation of recurrent cholesteatomas. Interventions such as the placement of Silastic sheeting within the middle ear may decrease the rate of postoperative adhesions and retraction pockets.[81,82] The middle ear mucosa is allowed to regenerate, and the plastic sheeting may be removed at a later date if ossicular reconstruction is undertaken at a second-stage procedure. In some cases, the presence of Silastic may be counterproductive by leading to intense middle ear fibrosis, further compromising ventilation. Reconstruction of canal wall defects that result from bone erosion by disease or the surgical approach itself has decreased the incidence of retraction pockets and associated recurrent disease.[83]

Because an intact canal wall tympanoplasty with mastoidectomy does not address the problem of negative pressure in the middle ear, ideal candidates are individuals with large pneumatized mastoids and well-aerated middle ear clefts. Patients with small sclerotic mastoids and poor eustachian tube function are often better served by removing the posterior canal wall as described in the next section.

As a result of the high rate of recidivism associated with an intact canal wall tympanoplasty with mastoidectomy procedures, most surgeons advocate a second-stage procedure when treating cholesteatoma. This is especially true for children since cholesteatomas in this population seem to behave more aggressively.[78,82,84] This second procedure usually takes place between 6 and 18 months postoperatively. During the operation, the middle ear and mastoid are explored for residual disease. If the middle ear is healthy, ossicular chain reconstruction is completed at that time. In the future, the use of endoscopes may replace the need for open second-look procedures in select cases.[85]

Intact canal wall tympanoplasty with mastoidectomy can be a technically challenging procedure. A postauricular approach is used, and the order of middle ear exploration and mastoidectomy remains the surgeon's decision. On completion of the cortical mastoidectomy, attention is turned to the facial recess, a variably pneumatized triangle bounded laterally by the TM, medially by the second genu and descending portion of the facial nerve, superiorly by the bone of the fossa incudis, and inferiorly by the chorda tympani. The bony EAC must be thinned to allow access for the facial recess dissection and eventual visualization of the most posterior mesotympanic structures, such as the round window and the stapedius tendon. Dissection should parallel the path of the facial nerve and chorda tympani nerve. Copious irrigation will reduce the risk of thermal injury to these nerves and will allow identification through intact thin bone of both the white neural sheath and associated capillary vessels. This process is known as "skeletonizing" the nerve and should be accomplished without exposing the nerve sheath. The facial nerve may be skeletonized and followed medially along the floor of the facial recess into the middle ear space.

Successful completion of the facial recess approach will allow visualization of the long process of the incus, the incudostapedial joint, the stapes superstructure, the distal tympanic segment of the facial nerve, the round window niche, and possibly the eustachian tube orifice and the cochleariform process. However, the oval window and stapes footplate are difficult to assess owing to the angle of visualization and the position of the facial nerve. The anterior epitympanum and sinus tympani are impossible to assess through the facial recess, and residual disease can be left in these areas unless visualized and removed through the ear canal. Often in the presence of cholesteatoma, the incus is eroded or requires removal. In this setting, the epitympanic dissection can be extended through the fossa incudus into the facial recess, improving visualization of the mesotympanic structures (Figure 10–20).

After removing all disease from the mastoid and middle ear, Gelfilm or Silastic sheeting may be placed in the middle ear space if extensive mucosal dissection was required. This is placed in an attempt to prevent adhesions between the TM graft and any exposed bone of the cochlear promontory, facial recess, and epitympanum. The TM graft is then placed. If there is a scutum defect owing to erosion of the superior ear canal bone, this may be reconstructed using a HA attic reconstruction plate or an autogenous cartilage graft. Tragal cartilage may be harvested with attached perichondrium and trimmed to the size of the scutum defect (Figure

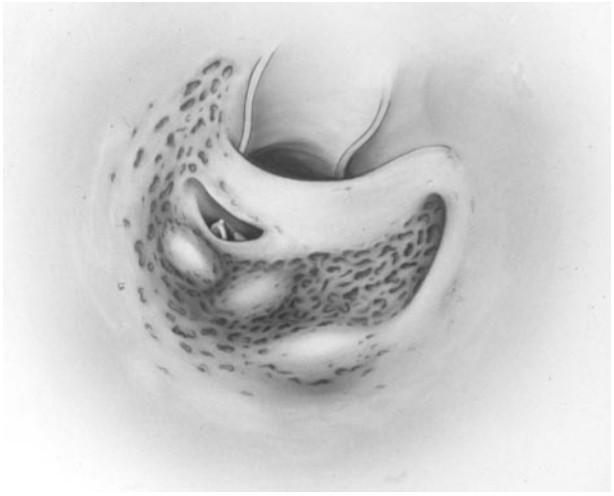

FIGURE 10–20. The facial recess has been dissected and now communicates with the epitympanum after removal of the incus. This allows visualization of the facial nerve, stapes, and other middle ear structures, facilitating dissection of disease using an intact canal wall approach.

10–21). The attached perichondrium may be used to repair a superior TM defect and/or may be draped over the remaining EAC bone to help secure the position of the cartilage in the defect. Ossicular remnants removed during exploration may be banked for possible use in ossicular chain reconstruction during a second-stage procedure. Closure and postoperative care are identical to that of a tympanoplasty, although special care should be taken to close the mastoid periosteal layer specifically to avoid a deep depression of the postauricular scar into the mastoid defect.

It is important to realize that although an intact canal wall tympanoplasty with mastoidectomy avoids the demands for routine cleaning of a mastoid cavity, close follow-up is nevertheless imperative. Recurrent cholesteatoma formation has been identified as late as 15 years after intact canal wall procedures.[86] For this reason, microscopic examination of the ear should be performed on a regular basis. With preservation of the posterior canal wall, the mastoid cavity and epitympanum will not be accessible for inspection. Thus, a potential disadvantage of the intact canal wall tympanoplasty with mastoidectomy is that early recurrent disease may go undiscovered. Radiographic imaging of the temporal bone region with a CT scan is helpful but not always diagnostic if there is concern for recurrent cholesteatoma (Figure 10–22).

Modified Radical Mastoidectomy

Gustave Bondy introduced the modified radical mastoidectomy, now often called the Bondy mastoidectomy, as a treatment for epitympanic cholesteatoma.[87] This procedure requires an open cavity mastoidectomy with removal of the posterior canal wall to create a common cavity between the mastoid and EAC. The middle ear space is not entered, and a tympanoplasty is not performed. The indications for a Bondy mastoidectomy are described above.

Today, the classic modified radical mastoidectomy is used infrequently since it addresses only the rare instance when one is treating isolated atticoantral cholesteatoma with disease lateral and posterior to the ossicles. Modifications have been made to the original approach to explore the middle ear and correct the conductive hearing loss, which often results in the setting of cholesteatoma. This combination of the open mastoidectomy and tympanoplasty with or without ossicular chain reconstruction is what most surgeons mean today when they use the term "modified radical

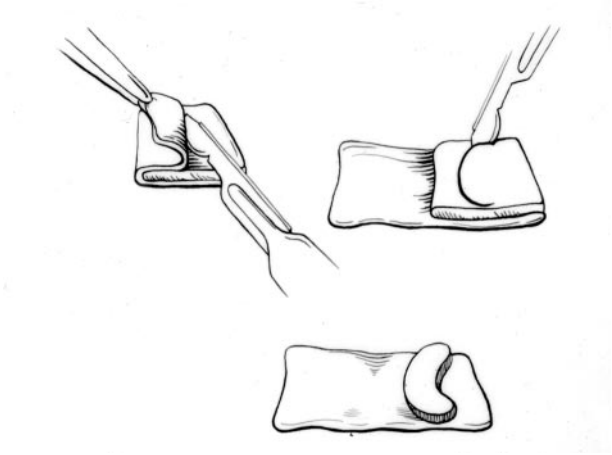

FIGURE 10–21. The tragal cartilage is harvested through a small incision behind the dome of the tragus, with its perichondrium attached on both sides. The perichondrium is elevated from one side of the cartilage, leaving the other side attached. The cartilage is trimmed to the size of the scutum defect, as pictured. After the cartilage is placed into the defect with the perichondrial side facing outward, the short extension of perichondrium is placed medial to the tympanic membrane remnant. The longer tail is draped onto the remaining ear canal bone and covered by the vascular strip.

FIGURE 10–22. Coronal computed tomographic scan years after intact canal wall mastoidectomy shows the preserved bony canal wall and a well-aerated middle ear and mastoid cavity, free of any soft tissue density that might suggest recurrent disease. Such findings may eliminate the need for a second-stage procedure.

mastoidectomy." An alternate, less ambiguous term for this operation is "tympanoplasty with canal wall down mastoidectomy." Since the posterior canal wall is removed, it may also be called a canal wall down tympanoplasty with mastoidectomy or open-cavity technique.

The major advantage of a modified radical mastoidectomy is excellent exposure during dissection of cholesteatoma, which reduces the rate of residual or recurrent disease, usually precludes the need for a second-stage operation, and is therefore cost effective. Postoperative examination is ideal because only that disease hidden in the mesotympanum might go unnoticed. With removal of the canal wall, all other areas are exteriorized and can be inspected during follow-up.

The major disadvantage of this approach is the need for periodic mastoid bowl cleaning. To achieve adequate aural hygiene, a meatoplasty is performed at the time of the original surgery. This alteration in anatomy may lead to difficulty in the use of hearing aids within the meatus and precludes in-the-canal fittings. Water exposure restrictions are required in most patients to prevent infection as well as vertigo. Cold wind may also pass easily through the enlarged external auditory meatus and can produce dizziness. At one time, it was argued that hearing results following the open cavity technique were inferior to those of the closed cavity technique. However, with the advances in middle ear reconstruction, removal of the posterior canal wall appears to make little difference in the hearing outcome.[88,89]

One of the most passionate and long-standing debates within the field of otology surrounds the management of the posterior canal wall when performing a tympanoplasty with mastoidectomy. Ultimately, the decision will depend on the nature of the disease, the patient's anatomy, and the surgeon's training and experience. Often the final decision is made intraoperatively. A small, sclerotic mastoid, a low-lying middle cranial fossa dura, and an anteriorly positioned sigmoid sinus will limit surgical exposure and often necessitate removal of the canal wall. Sometimes this is best performed by simply enlarging the attic defect and extending it posteriorly until the entire cholesteatoma is exteriorized (Figure 10–23).

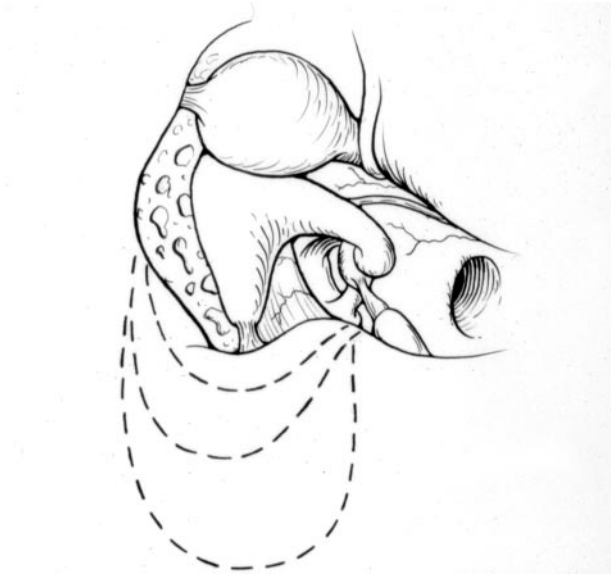

FIGURE 10–23. An atticotomy has been performed by removing the bone of the lateral epitympanum and exposing the ossicle heads, in preference to performing a formal mastoidectomy for attic cholesteatoma. The same defect may be progressively extended posteriorly (*dashed lines*) to expose disease in the antrum. In such cases, the operation is called an atticoantrotomy, or more colloquially an "inside-out mastoidectomy." This approach is most commonly used in very sclerotic mastoids but may also be used to avoid a large cavity when exteriorizing limited cholesteatoma in a well-pneumatized temporal bone.

This approach avoids the need for a more extended mastoidectomy but provides limited ability to identify surgical landmarks. Other indications to take down the canal wall include extensive cholesteatoma in the only hearing ear, presence of a large labyrinthine fistula, recurrent retraction cholesteatoma in the epitympanum, and significant destruction of the scutum or posterior canal wall. Patients who are unlikely to follow faithfully postoperative protocols, who are unwilling to undergo a second-stage procedure, or who are high risk for general anesthesia will also benefit from a canal wall down mastoidectomy.

The procedure is usually carried out through a postauricular incision. A tympanomeatal flap is elevated for middle ear exploration and eradication of disease as described in the tympanoplasty section. A cortical mastoidectomy is performed, with identification of the sigmoid sinus, antrum, short process of the incus, and horizontal semicircular canal. The digastric ridge may be followed forward to the stylomastoid foramen, identifying the height of the facial nerve as it descends from the second genu. After identification of the fallopian canal, the bony posterior canal wall is removed to the level of the facial nerve, leaving a thin layer of bone over the nerve called the facial ridge. To gain adequate exposure to the medial part of the epitympanum and the superior aspect of the mesotympanum, it is often necessary to remove the incus and the head of the malleus. The superior and posterior walls of the epitympanum are thinned, allowing for smooth communication between the tegmen mastoid and tegmen tympani. The anterior buttress of the ear canal is removed to produce a smooth transition between the anterior part of the epitympanum and the ear canal remnant (Figure 10–24).

The success of a canal wall down tympanoplasty with mastoidectomy depends on several key technical factors.[90] All air cells, especially within the sinodural angle, along the tegmen, and in the perilabyrinthine region, must be opened. The posterior canal wall must be lowered through the level of the facial recess to the descending portion of the facial nerve. In addition, the mastoid tip cells are exenterated and the bony tip is amputated, leaving the bony plate over the sigmoid sinus as the highest structure in the posterior part of the mastoid cavity. This allows for obliteration of the tip area and any cells posterior to the sigmoid sinus by postauricular scalp soft tissue. Otherwise, the patient is left with a dependent aspect of the mastoid cavity that will accumulate debris in the less accessible tip region. Ideally, the mastoid cavity should be widely saucerized with smooth bony walls achieved by wide beveling of the cavity during drilling.

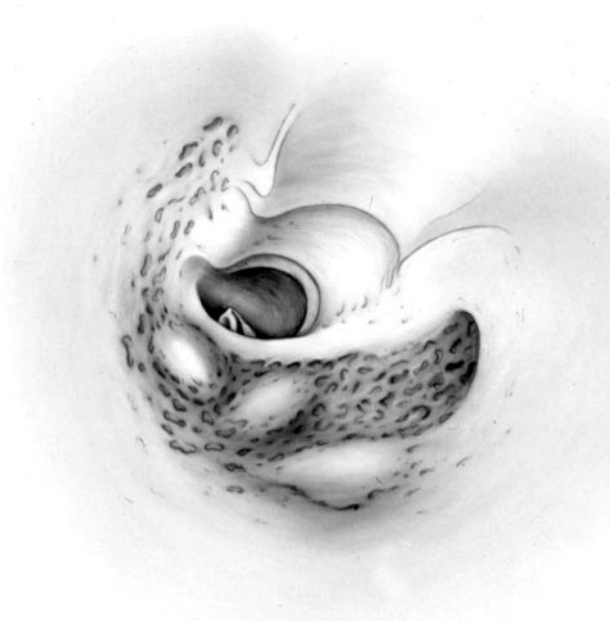

FIGURE 10–24. After removal of the posterior bony ear canal wall and smoothing of the facial ridge, an open cavity mastoidectomy has been completed. This allows maximum access to the middle ear structures for either removal or complete exteriorization of the cholesteatoma matrix.

Lastly, a successful canal wall down tympanoplasty with mastoidectomy requires an adequately sized meatoplasty. Enlargement of the meatus allows not only adequate visualization and cleaning of the mastoid bowl but also sufficient ventilation to maintain a dry cavity. The size of the opening should correlate with the size of the mastoid cavity. Ideally, the meatus should accommodate the surgeon's finger during construction. To create an adequate meatoplasty, it is essential to resect a significant portion of the conchal cartilage and underlying fibroadipose tissue while retaining the overlying skin to resurface a portion of the defect. A superior ear canal incision is made and carried to the facial skin by extending the incision through the incisura between the cartilage of the tragus and the helical root. An inferior canal incision is carried into the conchal bowl. The conchal skin and ear canal

skin are elevated, and a crescent-shaped portion of the conchal cartilage is excised. The underlying soft tissues are excised, and hemostasis is obtained (Figure 10–25).

After removal of the posterior canal wall, the grafted TM cannot be returned to its original anatomic location at the end of the procedure. Instead, it must be draped from the anterior annulus over the facial ridge and the horizontal semicircular canal. In doing so, a shallow middle ear space is created. If the stapes remains intact and the footplate is mobile, the TM graft can be seated directly on the stapes capitulum to allow adequate sound conduction. If the facial ridge is fairly high, it may be necessary to place a sculpted ossicle head or a piece of cartilage from the meatoplasty over the stapes to improve contact with the graft. In the absence of a stapes, a sculpted incus can be interposed, or a commercially available TORP may be selected. Some of these are specifically designed with short necks to accommodate the shallow middle ear space associated with an open cavity. If the entire cholesteatoma matrix has been removed, the fascia graft should be large enough to resurface the antrum and obliterate any perilabyrinthine air cells. This will result in a smaller cavity with a smoother lining and will help prevent mucosalization of the antrum during the healing phase.

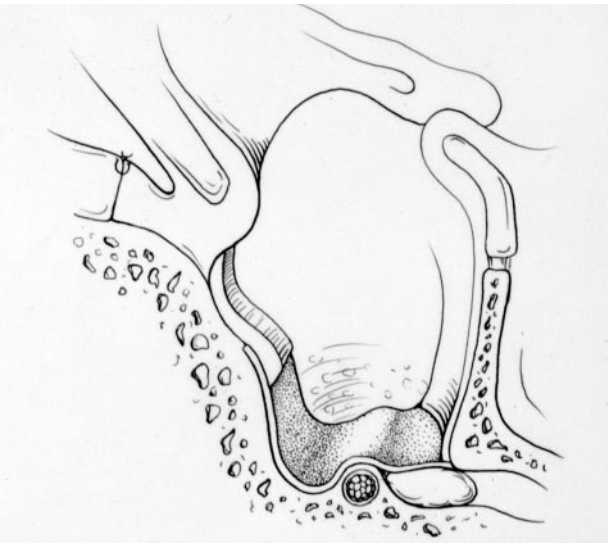

FIGURE 10–25. The successful canal wall down mastoidectomy requires a generous meatoplasty with removal of conchal cartilage and underlying soft tissues, with beveling of the cavity edges. This drawing demonstrates grafting of the middle ear cleft and draping of the graft into the posterior cavity, where it is overlaid with the vascular strip.

At the conclusion of the surgery, the meatus is tacked open by suturing the base of the skin flaps posteriorly to the mastoid periosteum. These sutures must be placed strategically to avoid distortion of the pinna's natural appearance. The periosteal layer is closed, and the conchal bowl and EAC skin flap are rotated medially into the defect. Ideally, the medial edge of the skin flap will reach onto the posterior aspect of the fascia graft used to graft the middle ear and line the antrum. The grafts are covered with a layer of Gelfoam, and the mastoid cavity is filled with antibiotic ointment. Merocel packs are placed laterally in the meatus and expanded with otic drops to prevent early collapse of the meatoplasty, which could lead to stenosis. A mastoid dressing is then applied and kept in place for 24 to 48 hours. Since the meatoplasty wound tends to have persistent oozing of blood, a light dressing may be needed subsequently for several more days. The packing and superficial Gelfoam are removed at the first postoperative visit, about 10 days after the operation. Open cavities take a considerable amount of time to heal, on the order of 6 to 10 weeks. During this period, patients are seen every 2 to 3 weeks for débridement of the cavity and management of granulation tissue. Early granulations are suctioned away, and the base is cauterized with silver nitrate or 30% trichloroacetic acid. Early neomembrane formation should be recognized and disrupted before fibroblast ingrowth causes mature scars that result in unfavorable cavity anatomy. Ototopical drops with an antibiotic and a corticosteroid should be continued until there is no granulation tissue and the cavity is lined with skin. As the healing progresses, immature squamous cell epithelium that tends to weep and form crusts may be painted with gentian violet. Patients can also participate in cavity hygiene during this later healing phase by performing daily irrigations with dilute acetic acid. Postoperative visits may become less frequent after this stage, although newly healed cavities tend to form crusts that may lead to inflammation and cavity infections. These crusts should be removed at each visit, and any underlying granulation tissue may be cauterized.

Long-term care entails visits every 6 months to 1 year, depending on the condition of the mastoid cavity. Microscopic examination and removal

of all crusts should be performed. Patients prone to accumulation of dry crust benefit from application of baby oil or mineral oil to the cavity once or twice a week. Some cavities require the ongoing use of occasional dilute vinegar irrigations, particularly if they are prone to infection from swimming, from hearing aid use, or during the humid months of summer.

Radical Mastoidectomy

Radical mastoidectomy entails exteriorization of the entire middle ear and mastoid by combining a canal wall down mastoidectomy with removal of the TM and the ossicles (with the exception of the stapes if present). In doing so, the mastoid, middle ear, and EAC become one common cavity. There is no attempt at middle ear reconstruction, and patients are left with a substantial conductive hearing loss. Given this significant functional deficit, radical mastoidectomy is considered a last resort, usually after previous surgical attempts have failed or when it is not possible to remove mesotympanic cholesteatoma. Radical mastoidectomy is also indicated if middle ear ventilation is impossible owing to complete inadequacy of eustachian tube function.

The incision, mastoidectomy, and removal of the posterior canal wall follow that described above. In addition, all remnants of the TM as well as the malleus and incus are excised. The inferior aspect of the tympanic ring is drilled down to remove disease in the hypotympanic air cells and allow communication between the cavity and the hypotympanum. The eustachian tube mucosa is inverted, and the orifice is sealed with an ossicular remnant, bone chips, muscle, or fascia in an attempt to prevent access of nasopharyngeal inflammation and secretions into the cavity. A meatoplasty is required for postsurgical care and surveillance. Postoperative care follows that of a canal wall down tympanoplasty with mastoidectomy.

Despite the extensive nature of this surgery, aural drainage may persist owing to mucosalization of the middle ear space from the eustachian tube or the hypotympanic cells. This is a particular problem if both ears are involved. In such cases, use of conventional hearing aids may be impossible, and a bone-conduction hearing aid or bone-anchored hearing aid is indicated. Other disadvantages of the radical mastoidectomy include lifelong need for mastoid cavity cleaning as well as water exposure precautions.

Mastoid Cavity Obliteration

The mastoid cavity created by a radical or modified radical mastoidectomy is at risk for chronic infection and persistent drainage. In the setting of a potentially large cavity, some surgeons elect to perform a mastoid obliteration procedure. The goal of the procedure is to provide a dry ear that is compatible with the use of a hearing aid and also to eliminate the need for annual cavity cleaning.

Various materials such as bone pate, cartilage, acrylic, and HA cement have been used to obliterate the mastoid cavity. Free abdominal fat grafts have been used; however, postoperative atrophy must be taken into consideration. Many surgeons prefer the use of regional soft tissue flaps because of the associated blood supply. Such alternatives include pedicled temporalis muscle or postauricular musculoperiosteal flaps as described by Rambo and Palva, respectively.[91,92]

The major disadvantage associated with obliteration of the mastoid is that disease can be buried within the cavity. A CT scan may be required to evaluate patients adequately for recurrent disease. Thus, contraindications to mastoid obliteration include widespread cholesteatoma and infected bone at the time of surgery. Generally, if the surgeon observes the surgical principles and postoperative care guidelines outlined above, the need for a mastoid obliteration procedure would be unusual.

Rarely, the surgeon may elect to perform a complete closure of the external canal to isolate the cavity internally rather than a meatoplasty to exteriorize it. This is most suitable when treating chronic inflammation without cholesteatoma in the setting of a profound hearing loss in the involved ear. In such a case, the need for extended healing and long-term cavity care are obviated. The modified Rambo closure is recommended to provide a cosmetically acceptable and problem-free external closure (Figure 10–26).[93] Care must be taken to remove all squamous elements from the ear deep to the point of closure. The primary and potentially serious risk of such a procedure is the development of an expanding undetectable cholesteatoma in the temporal bone. This may grow silently for many years, causing no symptoms until a serious problem such as facial

FIGURE 10–26. Photograph of an overclosed external auditory meatus after a modified Rambo technique. The smooth contours created using this method of closure eliminate any need for periodic cleaning of the meatus. In natural lighting conditions, the shadow that is cast by the tragus provides a natural appearance, creating the illusion of an external meatus.

nerve paralysis or an intracranial complication develops. Since the cavity cannot be examined otoscopically, the patient must undergo a postoperative CT scan about 2 years postoperatively. If the scan shows that the internal temporal bone defect is ventilated via the eustachian tube and is free of disease, no further imaging is required (Figure 10–27). If the defect contains soft tissue, additional interval CT scans will be required to rule out an expanding cholesteatoma.

COMPLICATIONS OF CHRONIC OTITIS MEDIA

Complications of COM range from mild hearing loss to life-threatening intracranial infections.

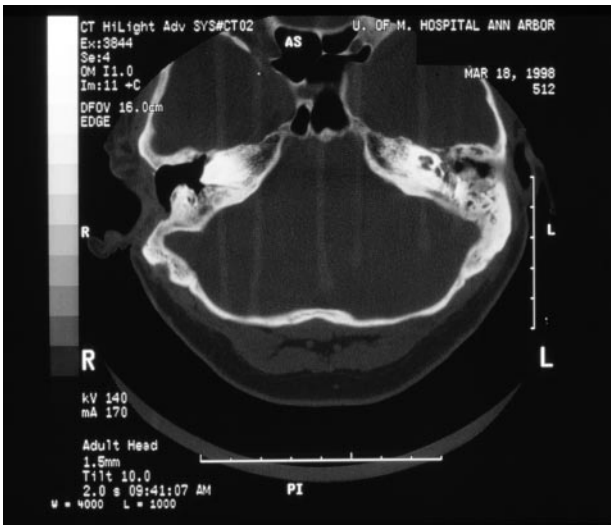

FIGURE 10–27. Axial computed tomographic scan of the patient pictured in Figure 10–26. Note the osteoneogenesis of the cochlea that led to deafness as a complication of chronic otitis media. Since hearing rehabilitation was impossible in this ear, a meatal closure was performed to eliminate the need for a mastoid cavity. The scan shows excellent aeration of the resulting cavity through the eustachian tube and no evidence of cholesteatoma or inflammatory disease.

Intratemporal complications include facial nerve paralysis, labyrinthitis, labyrinthine fistula, coalescent mastoiditis, subperiosteal abscess, postauricular fistula, and petrositis. If infection spreads beyond the confines of the temporal bone, intracranial complications such as epidural abscess, subdural abscess, lateral sinus thrombophlebitis, meningitis, and brain abscess may result. For a detailed description of the complications associated with COM and their management, see Chapter 11.

CHAPTER 11

Cranial and Intracranial Complications of Acute and Chronic Otitis Media

Lee A. Harker, MD

Complications of acute and chronic otitis media can cause grave morbidity and even mortality. Even though the incidence and prevalence of these complications have dramatically declined, their potential gravity requires physicians to have a thorough understanding of the diagnosis and management of each one. Because of the decreased prevalence of these complications and changes in the health care delivery system, many otolaryngologists-in-training today have no opportunity to see patients with these problems. This chapter first provides an overview of the complications of acute and chronic otitis media, including their etiology, pathology, pathophysiology, diagnosis, and treatment. The latter part of the chapter presents a review of each complication.

Cranial and intracranial complications of otitis media can occur in individuals of any age, but they occur much more commonly in children in the first two decades of life. Table 11–1 illustrates the age distribution of extracranial (cranial), intracranial, and combined complications in a large series of patients from the rural Natal province in South Africa. Nearly 80% of cranial complications and 70% of intracranial complications occurred in children in their first two decades of life. Cranial complications, led by postauricular abscess, most commonly occurred in children under age 6 years.[1] In a series of 93 intracranial and cranial complications of otitis media that occurred in Turkey during the 1990s, 58% were present in patients under age 20 years.[2] For unexplained reasons, males are affected nearly twice as often as females.

People who are poor, live in overcrowded surroundings, and have poor personal hygiene, poor health, decreased resistance to infection, inadequate health education, and limited access to medical care have the highest incidence of these complications.

TABLE 11–1. Age Distribution of 268 Patients with Complications of Otitis Media between January 1985 and December 1990.

Age (yr)	*Cranial (n = 87) %*	*Intracranial (n = 150) %*	*Cranial and Intracranial (n = 31) %*
0–5	33.3	8.0	6.5
6–10	23.0	21.3	19.4
11–20	21.8	39.3	38.7
21–30	9.2	8.6	12.9
31–40	3.4	12.6	9.7
41–50	5.7	6.0	6.5
51–60	3.4	0.6	3.2
> 60	0.0	3.3	3.2

Adapted from Singh B and Maharaj TJ.[1]

For example, most of the current reports of otogenic brain abscesses come from South Africa and developing countries. Only an occasional reported series is from North America. Although the number of patients with acquired or iatrogenic immunodeficiency has increased, large series of patients with complications of otitis media have not been reported in patients with human immunodeficiency virus (HIV) infection or acquired immune deficiency syndrome (AIDS) or in those receiving immunosuppressive therapy following organ transplantation, even though such individuals do have suppurative ear disease.

Table 11–2 shows the classification of cranial and intracranial complications, and Table 11–3 illustrates the relative frequencies of those complications reported in two recent series.[1,2] The dominant cranial complication is postauricular abscess, and the dominant intracranial complication is meningitis. Unlike many areas of medicine, the complications tend to occur multiply, especially the intracranial complications, as shown in Tables 11–4 and 11–5. Whereas all of the complications originate from infection in the pneumatized spaces of the middle ear and mastoid, the mechanisms by which complications occur in acute otitis media differ from those leading to complications in chronic otitis media. Therefore, these two entities are briefly discussed separately.

Acute Otitis Media

An estimated 85% of all children experience at least one episode of acute otitis media, making it the most common bacterial infection of childhood.[3] Predisposing factors include being of a young age or the male sex, receiving bottle feedings, and being exposed to a daycare environment, crowded living conditions, or smoking within the home. Medical conditions such as cleft palate, Down syndrome, and mucous membrane abnormalities such as cystic fibrosis, ciliary dyskinesia, and immunodeficiency states also predispose individuals to otitis media.

Acute otitis media is a bacterial infection of the middle ear space characterized by vascular dilatation and proliferation (manifested externally by erythema), mucosal edema, exudation, bacterial proliferation, white blood cell infiltration, and pus formation. Acute otitis media refers only to an acute infection that arises de novo, from a previously normal middle ear, rather than an acute clinical infection arising in a chronically abnormal middle ear, such as one with long-standing otitis media with effusion. This distinction is important because the pathophysiology of the otitis and the development of complications are different in acute versus chronic otitis media. Acute otitis media may resolve completely and spontaneously with or without treatment, or it may cause a complication while remain-

TABLE 11–2. Classification of Complications of Acute and Chronic Otitis Media

Cranial Complications	*Intracranial Complications*
Coalescent mastoiditis	Meningitis
Chronic mastoiditis	Brain abscess
Masked mastoiditis	Subdural empyema
Postauricular abscess	Epidural abscess
Bezold's abscess	Lateral sinus thrombosis
Temporal abscess	Otitic hydrocephalus
Petrous apicitis	
Labyrinthine fistula	
Facial nerve paralysis	
Acute suppurative labyrinthitis	
Encephalocele and cerebrospinal fluid leakage

ing in its acute stage. Conversely, it may persist into a subacute or chronic state. Factors that favor the acute infection progressing to a subacute or chronic otitis media include microorganism virulence, decreased host resistance, and inadequate or inappropriate antibiotic therapy.

After the first few weeks of life, acute suppurative otitis media is caused primarily by three microorganisms: *Streptococcus pneumoniae, Haemophilus influenzae,* and *Branhamella catarrhalis,* compromising roughly 30, 20, and 10% of isolates, respectively.[3] Optimal treatment for acute suppurative otitis media with complications includes appropriate antibiotic treatment of the underlying infection for 10 days, in addition to tympanocentesis, or myringotomy and placement of a ventilating tube. Tympanocentesis is used primarily to obtain material for culture to identify the offending microorganism and its antibiotic sensitivities, but it can also somewhat reduce the bacterial population. Doing a myringotomy and tube placement also provides the physician with material to identify the involved microorganism while simultaneously allowing the physician to remove most of the bacteria from the middle ear space and to introduce topical antibiotic therapy. After treatment, the physician should document that the acute otitis media has completely resolved by otoscopy and a normal tympanogram. If the complication was intracranial, a computed tomographic (CT) scan or a magnetic resonance image (MRI) should be obtained.

Chronic Otitis Media

Whereas acute otitis media is primarily a middle ear infection that extends into the contiguous mastoid, chronic otitis media often displays a dominant mastoid infection with concurrent otitis media. In the mastoid, infection persists in the numerous small air cells easily or more easily than it does in the relatively large single cell of the middle ear. Chronic otitis media is present when an infectious process persists for a period longer than the 1 to 3 weeks usually necessary for acute otitis media to resolve in a previously normal ear. Chronic otitis media can occur with or without a cholesteatoma when there is a tympanic membrane perforation. A third type of chronic otitis media is emerging, especially in young children who develop persistent otorrhea with a patent middle ear ventilating tube.

TABLE 11–4. Intracranial Complications in 181 Patients with Otitis After Singh and Maharaj[1]

Complication	*n*	*No. with Associated Complications*	*AC%*
Meningitis	22	4	18.2
Brain abscess	93	15	16.1
Subdural empyema	36	12	33.3
Epidural abscess	19	19	100.0
Lateral sinus thrombosis	36	10	27.8

AC% = percentage of patients with each complication who also had additional cranial or intracranial complication(s). Adapted from Singh B and Maharaj TJ.[1]

When the infection in the middle ear and mastoid will not resolve, mucosal edema and exudation increase, and the mucous glands and secretory elements proliferate. Mucosal edema in the small spaces between the mesotympanum and the epitympanum and in the aditus between the epitympanum and mastoid antrum block the normal pathways for aeration and decrease both oxygenation and vascularity. At the same time, the blockage prevents topical antibiotic and anti-inflammatory agents from reaching the attic and mastoid. Radiographically, the mastoid air cell system is partly or completely opaque, reflecting the loss of aeration.

These changes are accompanied by a dramatic change in the bacterial flora from acute to chronic otitis media and mastoiditis. Harker and Koontz cultured 30 cholesteatomas at surgery and isolated at least one anaerobic microorganism in 67% of the cases, at least one aerobic microorganism in 70%, and both aerobes and anaerobes in 50%.[4] In 57% of the cholesteatomas, multiple microorganisms were cultured, and in 30%, five or more bacteria were identified. Even when there was no clinical infection, anaerobic microorganisms, such as *Propionibacterium acnes,* were frequently isolated. Significantly, the study showed that an ear with a cholesteatoma is highly likely to harbor multiple bacteria of both anaerobic and aerobic types. Multiple microorganisms and anaerobic bacteria also have been identified frequently in chronic otitis media without cholesteatoma.

Chronic otitis media that develops in patients with indwelling middle ear ventilating tubes has a different bacterial flora. In most instances, these cases begin during an upper respiratory infection or when the external auditory canal is contaminated with water. A series of events, including treatment with antibiotic drops, treatment with oral antibiotics, repeated contamination, repeated cultures and sensitivities, increasing patient and physician frustration, decreasing patient compliance, and fungal overgrowth, frequently results in resistant microorganisms developing. The resistant bacteria most often found are *Pseudomonas aeruginosa, Achromobacter xylosoxidans,* and even methicillin-resistant *Staphylococcus aureus*. It is also common to have a clinically significant fungal infection of both the external auditory canal and the middle ear and mastoid. Although the author has not seen cranial and intracranial complications from this type of infection, granulation tissue he has noted at surgery suggests that possibility.

Patients with intracranial or multiple complications often appear more systemically ill than they should be from otitis alone. They can present with toxicity or with obtundation, manifesting depressed

TABLE 11–5. Interrelationship of Intracranial Complications

Complication	*n*	*Men*	*BA*	*EA*	*SE*	*LST*

Men = meningitis; BA = brain abscess; EA = epidural abscess; SE = subdural empyema; LST = lateral sinus thrombosis.

levels of consciousness that can vary from lethargy to total unresponsiveness. Focal neurologic signs may be absent, subtle, or florid. The physical examination of the ear itself usually does little to pinpoint a specific complication unless there is an obvious postauricular, cervical, or temporal abscess.

Pathophysiology

Sometimes a complication occurs during the first few days of an episode of acute otitis media. This can result from bacteremia accompanying acute otitis media initiating a hematogenous complication such as meningitis, or the bacteria proliferating in the middle ear can gain access to adjacent or distant structures and continue the infection at the new location. A patient may develop partial or complete facial paralysis if he or she has a congenital dehiscence of the bony fallopian canal above the stapes. If there are preformed pathways leading to the meninges or the labyrinth, patients with acute otitis media are at risk of developing meningitis, subdural effusion, or suppurative labyrinthitis. Developmental labyrinthine abnormalities, such as enlarged vestibular aqueducts or Mondini's deformity, often have such pathways. In older children and adults, bacteria can propagate along preformed pathways left from previous surgery or temporal bone fractures. But with acute otitis media, rarely is there granulation tissue formation or bone destruction; complications develop by hematogenous dissemination or by direct extension of infection along preformed pathways. Accordingly, the usual medical treatment of the acute otitis media will resolve the otitis portion, and mastoidectomy is not necessary. Therefore, it is critical to know that the middle ear was normal before the current bout of otitis media began.

In chronic otitis media and mastoiditis, complications are always associated with some combination of bone destruction, granulation tissue formation, or the presence of cholesteatoma. Bacteria gain access to the involved structures most commonly by direct extension from mastoid infection and by infecting and propagating along veins leading from the mastoid to adjacent structures. Direct extension can come about as a result of bone resorption from cholesteatoma or osteitis, or it can occur without bone erosion if the patient has preformed pathways from previous mastoid surgery, temporal bone fracture, congenital dehiscences, or other conditions that removed the intervening bone. The mechanisms by which bone is actively resorbed, although incompletely understood, probably include enzymatic degradation, suppuration, and decreased blood supply.

Diagnosis

History Because a thorough understanding of the chronology of the events is critical to determining the pathophysiology, the clinician must obtain a complete history of the present illness. The clinician must establish when the patient's ear was last free of disease and perfectly normal to differentiate acute otitis media from chronic otitis media because the bacteriology, medical treatment, and most probable complications are different for each. Answers to questions such as (1) when did a physician last examine the involved ear? (2) what is the past history and treatment of the patient's otitis media? (3) did the patient use an antibiotic for otitis media in the involved ear in the past month? and (4) what were the order of appearance and the magnitude of the different symptoms that comprise the present problem? are essential to an accurate diagnosis. Finally, the physician must obtain any objective evidence that the ear was normal recently (tympanogram, radiographic study that included the ears). The physician must gather from the patient or a knowledgeable accompanying person or through telephonic contact with physicians' offices and hospitals information about the involved ear including previous diagnoses, all operations, and recent medical and surgical treatment.

Symptoms of acute otitis media include pain, fever, and fussiness, but otorrhea is relatively uncommon. The cardinal symptom of chronic otitis media is painless, purulent drainage. Changes in the drainage may suggest the possibility of a complication. The cessation of drainage with the onset of pain suggests the presence of aditus or epitympanic block with increased pressure within the mastoid. The onset of imbalance or vertigo at the same time suggests the possibility of imminent labyrinthitis.

Intracranial complications, most notably meningitis, intraparenchymal brain abscess, and subdural empyema, can alter the patient's level of consciousness. Fifteen percent of Singh and

Maharaj's patients were drowsy on admission, 18% were stuporous, and 2% presented in coma.[1] Establishing the chronology of this alteration of sensorium will help the physician differentiate among diagnoses of brain abscess, meningitis, and subdural empyema. A brain abscess takes weeks to develop, whereas it takes only a few hours to several days for meningitis and subdural empyema to be fulminant and progress to coma.

In eliciting the patient's past history, social history, family history, and review of systems, the clinician should gather not only information relevant to the present illness but also all of the information the anesthesiologist needs to evaluate a patient for a several-hour surgical procedure.

Physical Examination The vital signs, especially the temperature, provide a pretreatment baseline and one parameter for following the course of the disease and the treatment; however, if the patient has previously received oral or parenteral antibiotics, he or she may present without a fever. Some patients remain afebrile during the entire course of illness, despite having significant cranial or even intracranial complications, but the temperature curve can sometimes provide useful information (see "Lateral Sinus Thrombosis").

A complete neurologic examination is essential. Make a thorough mental assessment of the patient, and note any alteration in mental state. Evaluate the station and gait and perform Romberg's and sharpened Romberg's tests. Evaluate the motor and sensory function of the extremities and perform a complete cranial nerve evaluation, including an assessment of vision, extraocular muscle function, facial nerve function, and facial sensation. Note whether there is nystagmus, either in the straight-ahead cardinal position or with the eyes deviated 30 degrees to the left and to the right. Evaluate cerebellar function by checking the alternate motion rate of the extremities, determining if past pointing is present or absent, and performing the finger-to-nose test. Assess ocular saccades and smooth pursuit. It is critical to determine if nuchal rigidity is present and, if so, to perform Kernig's and Brudzinski's tests. Observe the optic disks with an ophthalmoscope to determine if papilledema is present. Write down all of your positive and negative findings so that there is a written record of the patient's status at a specific time to compare to any subsequent changes. Changes in the patient's symptoms and the physical signs provide valuable information for understanding the evolving pathophysiology and determining the appropriate treatment.

Begin the otologic examination with an assessment of the color, size, shape, and position of the pinna compared with the opposite side. Make note of any erythema, tenderness, or drainage and any evidence of trauma, excoriation, or protrusion outward or downward. Next observe the regions adjacent to the auricle and note any swelling, erythema, tenderness, purulent drainage, or fluctuance.

Examine the external auditory canal and tympanic membrane using a microscope and fine suction. If purulent secretions are present, culture them. Document the presence of any edema and whether it primarily affects the posterior superior bony canal wall or if it affects the entire canal circumference. Make a drawing of the tympanic membrane illustrating any perforation, granulation tissue, or epithelial debris and any erosion of the scutum. Perform pneumatic otoscopy looking for conjugate deviation of the eyes that strongly suggests the presence of a labyrinthine fistula. Make a clinical impression whether the patient has acute otitis media, chronic otitis media with perforation, or a cholesteatoma before obtaining any imaging studies.

The tympanic membrane may appear normal or near normal even when an otitic complication is present because it reflects only the status of the middle ear medial to it. Whereas mastoid infection always begins with a middle ear infection, suppuration in these two locations may proceed differently in that the middle ear may revert to normal or near normal under treatment, whereas the mastoid may not. Especially in the presence of an aditus block, the middle ear may appear nearly or completely normal after several courses of antibiotics, whereas symptoms from the mastoid persist (see "masked mastoiditis"). When evaluating a patient with any infectious condition that could be caused by acute or chronic otitis media, the clinician should obtain a CT scan to rule out chronic otitis as the cause even if the tympanic membrane appears normal and there is no history of ear disease.

Laboratory Examination The complete blood cell count will document the patient's relative degree of leukocytosis and ensure that his or her hemoglobin and hematocrit are adequate for safe general anes-

thesia. The individual health needs of the patient and the necessity for a general anesthetic will determine the need for any other hematologic studies.

Imaging Techniques Computed tomographic scanning is essential for all patients suspected of having complications of otitis media. It is a fast and reliable method for assessing the status of the middle ear and mastoid air cell system and diagnosing intracranial complications of otitis media.[5,6] It is unparalleled for showing the bony details of the middle ear, epitympanic, and mastoid structures and documenting the degree to which the normally aerated pneumatized spaces may be opacified by the inflammatory process. It clearly shows demineralization and loss of the bony septae of air cells in coalescent mastoiditis and reveals erosion of the bony plates covering the sigmoid sinus and cerebellum or tegmen of the middle ear and mastoid, even erosions of the bony labyrinth itself. Computed tomographic scans must include views taken in an algorithm to assess soft tissue changes and wide ("bone") algorithm views to evaluate bone erosion.

Computed tomographic scans can help to establish the specific primary otologic diagnosis (acute otitis media, chronic otitis media, cholesteatoma) as well as the diagnosis of several of the specific cranial and intracranial complications of otitis media. In addition to their diagnostic value, CT scans are useful to assess the results of therapy and to provide a baseline post-treatment study of the mastoid for comparison in case of further complications.

When the patient is somnolent or unstable and when intracranial complications are suspected, CT scanning may be the initial study of choice because it is fast and gives the health care team better access to the patient during the study than MRI does. Even without enhancement, CT scanning may be an adequate diagnostic tool for a febrile, stuporous patient with meningeal irritation when ruling out the presence of an intraparenchymal brain abscess or communicating hydrocephalus prior to performing lumbar puncture to establish the diagnosis of meningitis. However, when using CT to diagnose cerebritis, cerebral abscess, subdural empyema, and ventriculitis, intravenous injection of an iodinated contrast agent is essential.

Magnetic resonance imaging is a far more sensitive imaging technique than CT scanning for diagnosing intracranial complications because paramagnetic contrast agents such as gadolinium-DTPA (diethylenetriamine pentaacetic acid) cross the blood-brain barrier in areas of cerebritis or abscess. Meningeal enhancement is much more easily seen with MRI than with CT scanning in which the adjacent bony skull often obscures the meninges. The T_2-weighted images of an MRI can demonstrate intraparenchymal edema from subtle brain infection much earlier than can a CT scan. When otitic complications are suspected, the clinician usually obtains both CT and MRI scans if the patient's condition allows because much of the information from the two studies is complementary.

Lumbar Puncture To determine the presence of meningitis, the physician must perform a lumbar puncture, measure the patient's cerebrospinal fluid (CSF) pressure at the beginning and end of the procedure, examine the CSF sample for the presence of bacteria on direct smear, and determine the concentrations of glucose, chloride, and protein for comparison with their concentrations in serum. Lumbar puncture should be undertaken only after ophthalmoscopic examination and CT scan have ruled out significant increased intracranial pressure that could result in herniation of the cerebellar tonsils during or after the procedure. Lumbar puncture is contraindicated in the presence of brain abscess and subdural empyema.

Treatment

Although each complication has its own separate treatment, there are certain general management principles for treating the underlying otitis. For each patient, the treatment of the underlying acute or chronic otitis media and the treatment of any complications can be medical or surgical and can be administered sequentially or concurrently. In nearly all instances of complications resulting from acute otitis media, appropriate antibiotic therapy will be sufficient to resolve the otitis without any need for surgery. This will usually include aspiration by tympanocentesis or myringotomy, as previously discussed.

When the complications have resulted from chronic otitis media and mastoiditis, initial antibiotic therapy should employ broad-spectrum antibiotics effective against anaerobic as well as aerobic

microorganisms. In all of these cases, some form of mastoidectomy will be required. When surgery is necessary for intracranial complications, the neurosurgeon operates first, immediately followed by the otologist performing a mastoidectomy at the same sitting if the patient's condition permits. In most instances (except for brain abscess and subdural empyema), both the chronic otitis media and its complications are treated entirely through the mastoid. When both neurosurgery and otologic surgery are necessary, the surgeons must carefully and methodically plan and coordinate the order of the procedures, patient preparation, draping, and incisions to decrease the duration of general anesthesia and to optimize the chances of a safe and effective surgical result.

Performing a mastoidectomy under these circumstances is difficult because vascularity increases and landmarks are more obscured. The following general principles are helpful guidelines. After removal of the mastoid cortex, complete all bony dissection using diamond instead of cutting burs and use copious suction-irrigation. This will minimize the chance of inadvertent trauma to important underlying structures. If preoperative scanning identified the sites of the complications, complete the surgery in the portions of the mastoid away from the complication sites first. This will improve hemostasis and visibility. When no cholesteatoma is associated with the mastoiditis, leave the external auditory canal wall intact unless visibility is inadequate.[1] Remove the canal wall and perform an open cavity procedure in the presence of cholesteatoma.

The rate of mortality in these cases correlates most with the patient's level of consciousness on admission. In the South African series, mortality was 1% when patients were fully conscious, 7% when drowsy, 30% when stuporous, and 67% when comatose.[1] The complications most likely to be lethal are brain abscess, meningitis, and subdural empyema.

Postoperative follow-up is an essential part of the general treatment of patients who experienced life-threatening complications of acute or chronic otitis. Even when the patient responded perfectly, the surgeon should seriously consider follow-up CT scan to confirm objectively the status of the mastoid at the termination of treatment because there is a risk of recurrence or emergence of new intracranial complications. In patients who have experienced lateral sinus thrombosis, epidural abscess, subdural empyema, or brain abscess, follow-up evaluation with enhanced MRI 2 to 4 weeks after treatment is recommended.

CRANIAL (INTRATEMPORAL) COMPLICATIONS

Coalescent Mastoiditis

Etiology Sometimes when a patient has acute otitis media and mastoiditis that persists unabated for 2 to 4 weeks, coalescent mastoiditis sets in. This is an acute progressive clinical infection with corresponding changes in the bone and mucoperiosteum of the mastoid air cell system. Coalescent mastoiditis is a disease of the young, especially males. Most patients are 4 years old or younger. Bacterial virulence and decreased host resistance are important in its etiology, but mastoid development also plays a role. The condition rarely develops in children who have had chronic ear disease or in those with poorly pneumatized mastoids containing few air cells. Rather, it tends to occur in patients with well-developed air cell systems that contain numerous small pneumatic spaces and in those who have had little or no previous otologic disease.

Pathology Initially, hyperemia and edema of the mucoperiosteal lining of the mastoid air cells block the narrow aditus and disrupt aeration. The mucous membrane thickens, and impaired ciliary function prevents normal middle ear drainage through the eustachian tube. The serous exudate becomes purulent as inflammatory cells accumulate. Continued inflammation, hyperemia, and accumulation of purulent debris cause venous stasis, localized acidosis, and decalcification of the bony septae. The osteoclastic activity in the inflamed periosteum softens and decalcifies the bony partitions, causing the small air cells to coalesce into a larger cavity.[7]

Pathophysiology As the infection grows, pressure within the mastoid cavity increases and conditions become progressively more favorable for it to extend beyond the confines of the mastoid. In the presence of such an intense inflammation and infection, phlebitis and periphlebitis are common and spread the infection to the adjacent meninges, sigmoid sinus, cerebellum, and temporal lobe.[8] The infection sometimes extends directly to the meninges, sigmoid sinus, labyrinth, or facial nerve because of bone ero-

sion. The most common pathway for infection to extend beyond the mastoid is through the lateral cortex behind the ear. Less commonly, it can extend to the soft tissues in the upper portion of the neck (see "Bezold's Abscess") and rarely to the soft tissue anterior and superior to the auricle either by direct extension through eroded bone or by phlebitis and periphlebitis. Go et al reviewed the records of 118 children with acute mastoiditis at Texas Children's Hospital between 1986 and 1998 and found only 8 patients in whom the mastoiditis had caused an intracranial complication.[9]

Diagnosis The symptoms and signs of coalescent mastoiditis—purulent otorrhea, fever, toxicity, and ear pain—are the same as those seen in patients with uncomplicated acute otitis media. The strongest historical suggestion of coalescent mastoiditis is the chronology of the infection in which purulent drainage or significant otalgia persists for 2 or more weeks, recurs after 10 to 14 days, or significantly worsens after that time interval. As a group, children with coalescent mastoiditis look sicker and have more toxicity with higher and more persistent fevers than those with acute otitis media. Older children may be able to localize the pain to the postauricular area rather than the ear canal. Physical findings that are most helpful include mastoid tenderness to percussion, mastoid erythema, and sagging of the posterior superior external auditory canal wall.

The clinician should order a complete blood count and hematologic studies followed by CT scanning, which can establish the diagnosis by documenting the breakdown of the bony air cell walls and opacification of the pneumatized spaces. If any suggestion of an intracranial complication exists, the clinician should obtain an enhanced MRI scan.

Treatment The treatment for coalescent mastoiditis can be either medical or surgical. Without question, complete mastoidectomy with ventilating tube placement in conjunction with appropriate antibiotic therapy provides prompt, precise eradication of all infected tissue in an expeditious, cost-effective manner. However, because the increased vascularity and granulation tissue greatly increase the difficulty of the operation, it should not be undertaken lightly. Another consideration is that pneumatization has not progressed to incorporate the mastoid tip in children under the age of 2 years, so there is risk of surgical injury to the facial nerve. However, the author's experience with cochlear implant surgery in children 12 to 24 months of age suggests that the facial nerve does not exit through the lateral surface of the mastoid in this age group as is commonly taught, and the risk of facial nerve injury in this age group is not substantial.

It is equally true that appropriate intravenous antibiotics for a minimum of 3 to 6 weeks also will eradicate the disease process in the majority of infected infants who have no additional complications. The therapeutic choice for a specific patient will depend on the clinical factors present and regional preferences. At the end of medical therapy, it is essential to document that the disease process has been completely eradicated. The patient should continue receiving antibiotic therapy until a CT scan produces evidence that the mastoid air cell system is no longer opacified and the middle ear is normally aerated.

Chronic Mastoiditis

Etiology Chronic mastoiditis can occur in association with a long-standing tympanic membrane perforation, with cholesteatoma, or as a complication from an infection following placement of a middle ear ventilating tube. As noted above, ventilating tube mastoiditis tends to occur in young children who have experienced water contamination and have undergone cultures and treatment with multiple antibiotic drops and oral antibiotics. Mastoiditis with tympanic membrane perforation occurs when an episode of acute otitis media with perforation pursues a course of chronic infection rather than resolving or developing into coalescent mastoiditis. Chronic mastoiditis of this type may also begin when an uninfected ear with a long established central perforation becomes infected, the infection extends to the mastoid, and the ear continues to drain chronically. Even though cholesteatoma frequently remains uninfected for long periods of time, it tends to suppurate, form granulation tissue, and erode bone. Once any type of mastoiditis causes continuous purulent drainage for 8 or more weeks, the likelihood of a complete resolution with antibiotics significantly decreases. Chronic mastoiditis requires surgical intervention to heal, and an infected cholesteatoma requires surgical ablation,

regardless of duration. Complications in patients with chronic mastoiditis with tympanic membrane perforation may develop at any time, but they often occur only after weeks or months of otorrhea. In contrast, cholesteatoma typically requires months or years to produce complications.

Masked Mastoiditis

Chronic otitis media with granulation tissue formation and bone erosion can occur without otorrhea. It can persist in spite of a normal or near-normal tympanic membrane. This has been referred to as "masked mastoiditis," and it usually occurs in patients who have received numerous courses of antibiotics. In this complication, the epitympanum and aditus become blocked so that the middle ear responds to the antibiotics, but the mastoid does not. Recently, the author has seen three patients with this problem. Each patient had aural and postauricular pain, slight but definite tenderness to percussion of the mastoid cortex, and CT scan evidence of very localized areas of opacification in an otherwise normal mastoid. Surgical excision relieved the patients of all of their symptoms. There are two keys to the successful management of masked mastoiditis: (1) mastoid disease is not always reflected by the appearance of the tympanic membrane, and (2) chronic mastoiditis is a surgical condition, regardless of the appearance of the tympanic membrane. In this regard, the diagnosis and management of masked mastoiditis are no different from those of mastoiditis with otorrhea emanating from other causes.

Samuel and Fernandez described 21 cases of mastoiditis with retroauricular swelling and an intact tympanic membrane in a South African population (19 patients were under age 13 years) in whom the duration of symptoms was shorter than that usually seen with coalescent mastoiditis.[10] The predominant finding at mastoidectomy was granulation tissue filling the mastoid cavity and the antrum. The tympanic membrane was described as hyperemic, dull, bluish, bulging, or retracted. In addition to their mastoiditis, 10 patients had postauricular abscesses, 3 had Bezold's abscesses, and 2 had facial nerve palsies. Four patients had cellulitis or abscess in the posterior fossa. Although these cases do not represent masked mastoiditis, they demonstrate the important fact that medically significant mastoiditis can exist without purulent otorrhea.

Postauricular Abscess

Postauricular abscess is the most common complication of mastoiditis. It is most often seen accompanying coalescent mastoiditis in young children. The infection extends from the mastoid to the subperiosteal space. Usually, this occurs by direct extension subsequent to bone destruction or by phlebitis and periphlebitis of mastoid veins. The tiny pits in adult temporal bones that make up the cribriform area of the mastoid near the spine of Henle exist in newborns as a series of open vascular channels between the interior of the mastoid and the cortex. In very young children, infection can pass directly from the mastoid to the subperiosteal space until these channels have closed. Regardless of how it starts, soft tissue infection leads to tissue necrosis and abscess formation. The surrounding soft tissue will exhibit thickening, inflammation, erythema, tenderness, and fluctuance.

The diagnosis is usually obvious. The tissue edema and the abscess drive the auricle downward and laterally because only the upper part of the mastoid is pneumatized (Figure 11–1). In earlier stages, if fluctuance is not obvious, the clinician should use imaging studies or ultrasonography to document the presence of air within the soft tissue or an abscess

FIGURE 11–1. Postauricular abscess associated with coalescent mastoiditis. The auricle is displaced laterally and inferiorly.

cavity with its capsule. When mastoiditis has produced an abscess, the case for excision and drainage in conjunction with mastoidectomy is much stronger. Only in the most unusual of circumstances would treatment by prolonged antibiotics and drainage of the abscess without mastoidectomy be appropriate.

Bezold's Abscess

In his 1913 textbook *Diseases of the Ear*, Kerrison gave the following description of Bezold's abscess:

> This condition is caused by a perforation in the bony plate forming the inner surface of the tip of the mastoid. It occurs presumably in cases in which the tip cells are especially large and in which the bony plate forming the inner or medial wall of the tip is very thin, and the outer cortex thick. Pus escaping through such a perforation burrows downward in the neck beneath the sternomastoid, or may be confined between layers of the deep cervical fascia.[11]

The cervical infection develops into an abscess in the upper neck deep to the sternocleidomastoid muscle. Bezold's abscess can also develop without any erosion or penetration of the inner and outer cortex of the mastoid if phlebitis and periphlebitis propagate the infection to the same area. Because infants have limited mastoid pneumatization, Bezold's abscess occurs more commonly in older children in whom pneumatization has extended into the mastoid tip and in adults who have either chronic mastoiditis or cholesteatoma.

The diagnosis of Bezold's abscess is often not considered immediately in young patients with deep, tender, upper cervical masses because inflamed lymph nodes from many causes are so common. If the history and physical examination do not reveal a specific cause, the clinician should obtain a CT scan to identify or rule out a mastoid source.

The recommended treatment is complete surgical excision of the mastoid pathology, drainage of the abscess, and removal of any associated granulation tissue. The surgeon should use bipolar electrocautery, copious suction irrigation, and coarse diamond burs to allow him or her to visualize the pathology adequately and exenterate thoroughly all of the diseased cells. The surgeon should drain both the mastoid and the abscess cavity.

Temporal Root Abscess

The soft tissues above and even those anterior to the auricle can become infected and form an abscess from suppuration that involves the cells of the zygomatic process of the temporal bone. As is the case with postauricular and Bezold's abscesses, temporal root abscesses can form by direct extension through eroded zygomatic process cells or by phlebitis and periphlebitis. The clinical picture can be very confusing because abscesses in this location are rare, but there are so few other etiologic possibilities. Computed tomographic scanning is always recommended to rule out mastoiditis as the source, and surgery is the appropriate treatment.

Petrous Apicitis

A petrous apex can be undeveloped (sclerotic), can contain marrow, or can exhibit some degree of pneumatization. Pneumatization of the petrous apex develops in only 30% of temporal bones.[8] Much has been written about the different cell tracts that extend into and pneumatize the petrous apex. These cells can extend into the apex from above (supralabyrinthine; Figure 11–2, A and B), behind (retrolabyrinthine; Figure 11–3, A and B), beneath (infralabyrinthine; Figure 11–4, A and B), and/or in front of the labyrinth (anterior labyrinthine). Petrous apicitis is essentially mastoiditis that occurs in the petrous apex. It is rare because infection in sclerotic or marrow-containing petrous apices is uncommon and the prevalence of pneumatization is low. Petrositis develops by direct extension of a mastoid infection, but the mastoid may respond to medical or surgical treatment without resolution of the apical infection. Just as there can be disjunction between the state of infection in the middle ear and the mastoid, the same disjunction can exist between the mastoid and the petrous apex.

The pathology of the infection can mirror that seen in coalescent mastoiditis with dissolution of thin cellular septi and coalescence, or it can form granulation tissue and erode bone like chronic mastoiditis. Only rarely does cholesteatoma extend to the apex. Imaging studies will usually include both CT and MRI. A CT scan will show the bony details of the septae of the air cells and the size and contour of the apex as a whole. Magnetic resonance imaging will differentiate marrow from mucus or CSF. Both CT and MRI

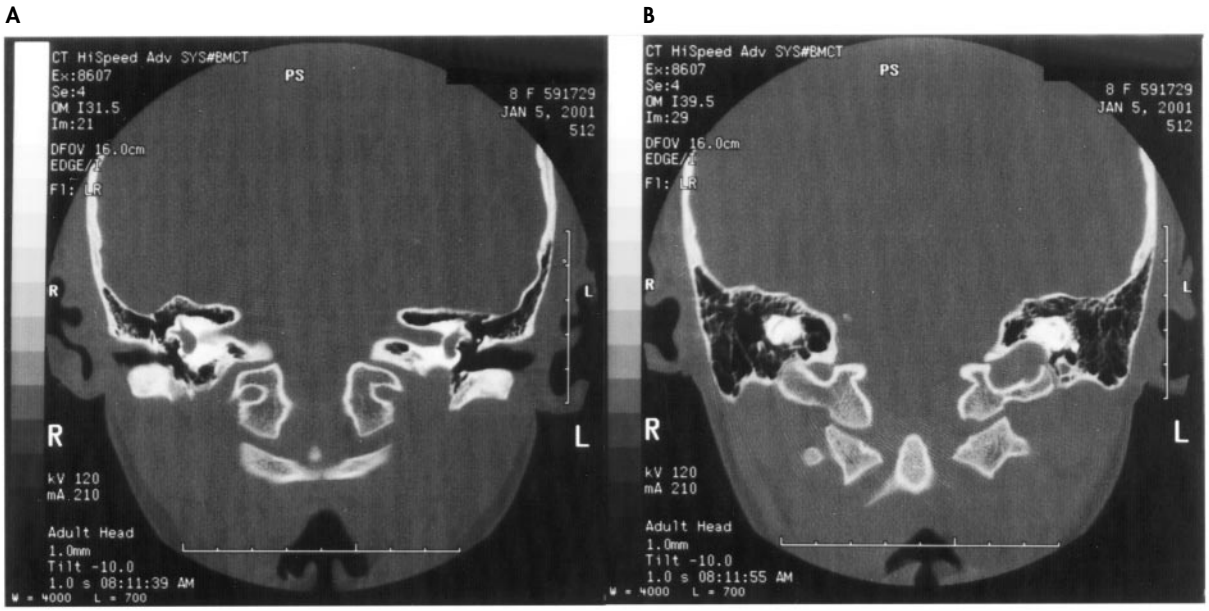

FIGURE 11–2. Petrous apex pneumatization via the supralabyrinthine cell tract at the level of the vestibule (*A*) and posterior semicircular canal (*B*).

studies are essential to establish opacification of the air cells in the suspected petrous apex. When one petrous apex is well pneumatized, a small sclerotic or marrow-containing apex on the opposite side can be misinterpreted as a pneumatized apex opacified by fluid or infection unless both studies are obtained.

The symptomatology of infection in the petrous apex reflects the innervation of the air cells and the structures adjacent to the apex itself. Whereas increased pressure within the mastoid air cell system causes pain in the region of the mastoid and the ear, increased pressure in the petrous apex is usually

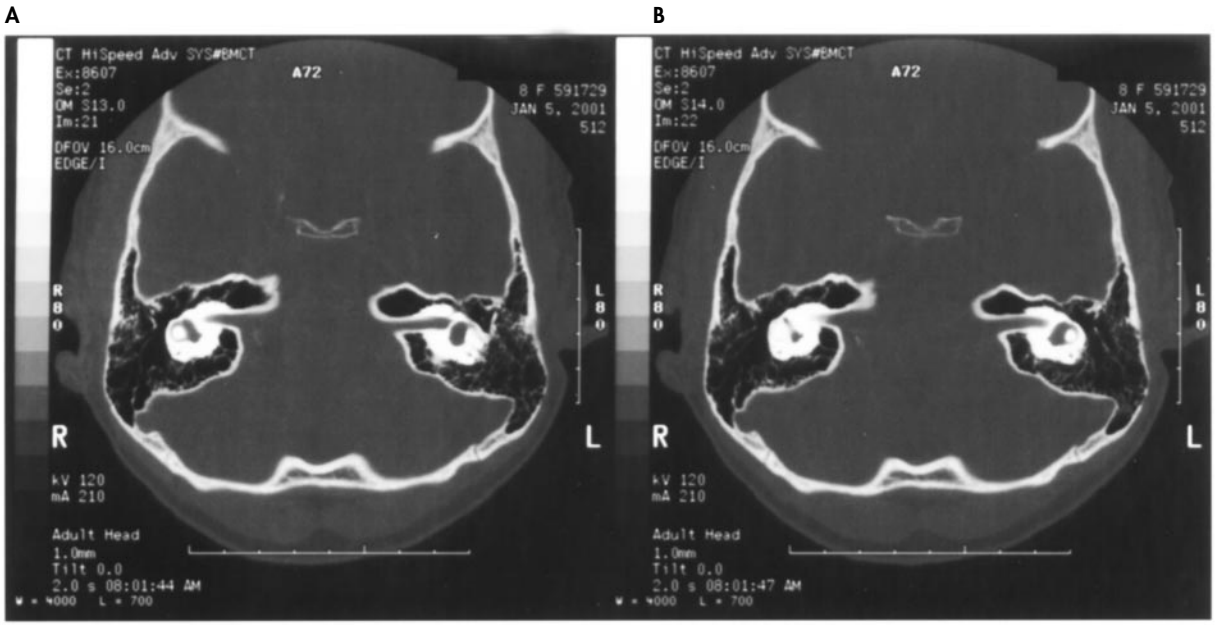

FIGURE 11–3. Petrous apex pneumatization via the retrolabyrinthine cell tract at two levels (*A* and *B*) of the internal auditory canal and vestibule.

referred to the retro-orbital area or deep within the skull. Patients with petrous apicitis have symptoms of infection in the middle ear and mastoid, as well as symptoms from the apex. The most common symptoms from infection in the petrous apex are retro-orbital pain from irritation of the contiguous trigeminal ganglion in Meckel's cave, paralysis of the sixth cranial nerve as it passes through Dorello's canal abutting the apex, or dysfunction of the facial, acoustic, or vestibular nerves as they course through the temporal bone. In 1904, Gradenigo described the triad of retro-orbital pain, sixth nerve paralysis, and otorrhea, which has since been known as Gradenigo's syndrome.[8] Only a minority of patients with petrous apicitis exhibit the full triad today.

How petrous apicitis is best treated depends on its duration, its severity, and whether additional complications are present. Because the labyrinth, carotid artery, and internal auditory canal are housed in the petrous pyramid, it is difficult or impossible to excise all of the air cells, which is done so routinely in the mastoid. Therefore, prolonged antibiotics are necessary, even when surgery is performed. When necrotic bone is obvious, surgical drainage is a necessary adjunct to intravenous antibiotic therapy. Even partial apicectomy can reduce the bacterial load sufficiently to allow antibiotics and host defenses to control the disease. The best surgical approach to the apex depends on the portion of the apex that is involved and which air cell tracts connect the apex to the mastoid. In some temporal bones, the apex can be reached by a route posterior to the posterior semicircular canal (see Figure 11–3, A and B); in others, the best route is infralabyrinthine (see Figure 11–4, A and B). In a small percentage of temporal bones, limited drainage can be achieved by removing cells extending over the top of the superior semicircular canal and through its center (the "hole in the doughnut"; see Figure 11–2, A and B). The original anterior petrous apex drainage procedure described by Julius Lempert incorporated a radical mastoidectomy operation and is rarely done today.[12] The middle cranial fossa approach can provide excellent access to obtain material for culture and to remove infected tissue when the air cell tracts from the mastoid to the apex are inadequate. Postoperative CT scans are useful to verify that the disease has been excised and as a reference for future studies.

Labyrinthine Fistula

A labyrinthine fistula results from the erosion of the endochondral bone of the bony labyrinth. The loss of this bone allows the underlying endosteum, perilymph, and structures of the endolymphatic compartment to move when the pressure in the external

auditory canal is changed. Motion of the fluids in the endolymphatic compartment brings on the symptoms of labyrinthine fistulae. Almost all labyrinthine fistulae affect the lateral semicircular canal; the superior and posterior semicircular canals, vestibule, and cochlea are rarely involved. Cholesteatoma is the cause in nearly all cases, and fistulae were seen to occur in 7% of the cholesteatomas in Gersdorff and Nouwen's large series.[13] Higher percentages have been reported, but the actual incidence is unknown. Most reports of labyrinthine fistulae are from tertiary care referral centers that include many patients with large or previously operated cholesteatomas, which artificially elevates the incidence. On the other hand, studies reviewing suppurative complications of otitis media often do not include labyrinthine fistulae if the fistula is not infected or does not cause significant symptoms or if the surgeon first detects it at operation.

The mechanisms by which a cholesteatoma causes bone erosion are not fully understood, but the dense endochondral bone first becomes demineralized and then is absorbed so that a progressively smaller amount of bone exists between the endosteal membrane overlying the perilymph and the cholesteatoma matrix above it. When the bone is completely resorbed, the surgeon can see what appears to be a "blue line" parallel to the underlying semicircular canal lumen because the illuminating light at the blue line is no longer reflected off the dense bone but is absorbed into the underlying fluid.

Manolidis recently reviewed the records of 111 inner-city Texas patients with labyrinthine fistulae and looked for any coexisting complications.[14] Two associations were prominent. The facial nerve was involved with cholesteatoma or was damaged by the cholesteatoma in 60% of the patients, and dehiscences of the tegmen occurred in 39%. The majority of these patients had two or more operations, with an average of 2.6 operations per patient. Surgeons should suspect a triad of complications: lateral semicircular canal fistula, facial nerve exposure, and tegmen erosion in all patients undergoing revision surgery for cholesteatoma or in patients with primary acquired cholesteatomas that developed in well-pneumatized mastoids.

Labyrinthine fistulae cause mostly vestibular symptoms. Patients describe short periods of imbalance, dysequilibrium, or vertigo but have normal equilibrium most of the time. Some recall that they feel suddenly off balance when they hear a sudden loud sound, which is called Tullio's phenomenon, or when they push on their external ear canal, for example, when cleaning their ear with a washcloth.

After obtaining a history that suggests the presence of a fistula, the physician should perform the fistula test, a specific maneuver that can establish the diagnosis. The examiner occludes the external auditory canal with the pneumatic otoscope and alternately increases and decreases the pressure slightly so that pressure changes are transmitted from the canal to the middle ear and mastoid air cell system through either an intact or a perforated tympanic membrane. During the test, the patient is told to look directly ahead at a specific object, and the physician observes the patient's eyes for any horizontal deviation. In a normal ear, changes in external canal pressure cause no motion of the eyes and no symptoms. When a lateral canal fistula is present, positive pressure transmitted from the external auditory canal compresses the lateral semicircular canal endosteum and causes utriculopetal endolymph flow. This produces a positive fistula sign, conjugate deviation of the eyes away from the side of the compression. Negative external auditory canal pressure produces a conjugate deviation toward the ear being tested. The patient may become slightly nauseated or perceive a to-and-fro motion of the environment during the test. Only 55 to 70% of patients with lateral canal erosions have a positive fistula test, but in those patients, it is a highly reliable indication that a fistula is present and allows the surgeon to plan the operation so that he or she can avoid entering the fistula during surgery. Inadvertently opening a labyrinthine fistula usually causes total loss of hearing in that ear.[15] Computed tomographic scanning also can suggest the diagnosis. Images in the bone algorithm will show erosion of the lateral semicircular canal and any other signs of cholesteatoma.

Surgery is the recommended treatment for labyrinthine fistulae. Usually, the surgeon will remove the posterior external auditory canal wall and perform an open-cavity mastoidectomy. If the patient has no other complications, the temporal bone is well pneumatized, and the exposure of the lateral semicircular canal is good, the surgeon can consider performing a canal wall up technique. Whether the canal wall is left up or removed, the surgeon completes the operation and removes all of the cholesteatoma except for a small area around

the fistula site. After carefully removing the overlying cholesteatoma debris without disturbing the matrix, the surgeon looks for the "blue line" that identifies the site of the fistula and the thin layers of lateral semicircular canal bone on either side. The surgeon develops a dissection plane between the cholesteatoma matrix and the endosteum using high microscopic magnification and a flat dissector that is 2 to 3 mm wide. The matrix is elevated with a fine microsuction to improve visualization of the dissection plane. A small piece of tissue or a thin cap of bone is placed over the site and secured with fibrin glue or packing after the cholesteatoma is successfully removed. If the endosteum is torn, it is best to replace the matrix and terminate the procedure.

Spontaneous vestibular symptoms usually improve after the fistula is repaired, but symptoms from ear canal pressure changes may persist for some time, and a positive fistula sign will persist until there is a regrowth of bone over the site of the fistula. The principal risk in removing the cholesteatoma matrix from the fistula is total or partial loss of hearing, which occurs in less than 20% of carefully managed fistula cases.[16]

Facial Nerve Paralysis

Facial nerve paralysis can result from acute otitis media, chronic otitis media without cholesteatoma, or cholesteatoma. Bacteria reach the nerve because of a congenital dehiscence of the bony fallopian canal or because the canal is eroded by granulation tissue or cholesteatoma. Facial nerve function is lost because of edema secondary to pressure and inflammation or because suppurative neuritis destroys the neural elements. If the edema persists, avascular necrosis of the axons can lead to axonal degeneration.

Facial paralysis in young children that is caused by acute otitis media is frequently incomplete and probably occurs only in infants with congenital dehiscence of the fallopian canal in the middle ear adjacent to the stapes. Facial weakness in these cases rarely lasts longer than 3 weeks even when complete paralysis is present.

Facial nerve paralysis secondary to chronic otitis media without cholesteatoma also usually affects the horizontal portion of the facial nerve near the stapes.[17] In these cases, the clinical course of the paralysis is more likely to be prolonged, with a gradual progression from slight weakness to full paralysis. Sometimes the progression to complete paralysis is rapid. Facial nerve paralysis secondary to cholesteatoma is also most likely to involve the nerve in the middle ear because it is there where most cholesteatomas arise. Extensive erosion of the horizontal segment of the fallopian canal is especially common in large, uninfected primary acquired cholesteatomas. When there is no infection, the nerve usually retains normal function. An erosive cholesteatoma can expose the facial nerve anywhere in the temporal bone and cause paralysis. In these cases, the onset of the paralysis is usually gradual, and sometimes the progression is so slow that patients do not seek medical attention for months. When the onset of facial paralysis is this slow, the paralysis is more likely to persist after surgical treatment.

The clinical presentation of facial paralysis is discussed more fully in Chapter 24. Facial nerve dysfunction secondary to temporal bone infection is not usually accompanied by significant pain or a facial tic but is simply expressed as muscle weakness or paralysis.

When facial paralysis is caused by acute otitis media, appropriate antibiotic therapy for the acute otitis may be adequate, although myringotomy with evacuation of the purulent material and reduction of the numbers of bacteria is recommended. When facial nerve paralysis follows chronic suppurative otitis media (with or without cholesteatoma), the surgeon should remove the infection surrounding the nerve as part of the mastoidectomy. The surgeon should address the diseased area of the facial nerve after the rest of the operation is completed in the same way that he or she would manage a labyrinthine fistula. The surgeon gradually approaches the granulation tissue or cholesteatoma overlying the nerve from the proximal and distal portions of the nerve that are uninvolved by the chronic infection using diamond burs to carefully remove the bone of the fallopian canal on both sides of the diseased portion. The surgeon uses a flat blunt instrument to dissect the chronic inflammatory tissue from the nerve while elevating the diseased tissue with a small suction tip. It may be necessary to use sharp dissection to separate the inflammatory tissue from the epineurium. The outcome for surgical decompression of the facial nerve secondary to chronic suppurative otitis media primarily depends on whether the nerve has undergone complete degeneration before surgery.

Acute Suppurative Labyrinthitis

Bacterial invasion of the labyrinth is always promptly followed by total loss of both auditory and vestibular function. Usually, acute otitis media extends into the labyrinth through a weakened or dehiscent oval window membrane, as seen in congenital labyrinthine deformities, such as Mondini's deformity and enlarged vestibular aqueduct syndrome, and in individuals who have undergone stapes surgery. Although it is not proven, suppurative labyrinthitis may be a common mechanism for unilateral anacusis in children with Mondini's deformity. These children are at additional risk. The foramina of the internal auditory canal opening into the medial aspects of the labyrinth may also be weak or dehiscent, and those foramina and the cochlear aqueduct can permit bacterial infection to progress from the labyrinth to the meninges or vice versa. It is not known how frequently suppurative labyrinthitis causes meningitis or how often meningitis subsequently causes bacterial labyrinthitis, but both probably occur, especially in the special population of children with congenital labyrinthine abnormalities.

Direct bacterial invasion of the labyrinth through a cholesteatomatous lateral semicircular canal fistula is another cause of acute suppurative labyrinthitis. In this situation, infected granulation tissue beneath the cholesteatoma matrix lies directly on the endosteal membrane and the underlying perilymph. The bacteria causing the labyrinthitis are those either of the underlying acute otitis media or of the cholesteatoma. The diagnosis is clinical. Within 30 to 60 minutes from the beginning of the infection, tinnitus and dizziness are followed by whirling vertigo, pallor, diaphoresis, nausea, and vomiting. The vestibular symptoms continue at their maximum for at least 8 to 12 hours even if the patient is totally immobile and receiving intravenous antiemetics. Brisk labyrinthine nystagmus directed toward the opposite ear accompanies the vertigo. After continuing for several hours, the spontaneous vertigo and nystagmus gradually abate. Symptomatic improvement continues during the next few days, but any motion of the head will evoke vertigo and nausea. Over the next 2 or 3 weeks, central nervous system compensation occurs, and normal or near-normal balance is restored. The tinnitus also abates, but all hearing is lost.

When the physician recognizes the typical clinical picture in a patient with a predisposing condition and acute or chronic otitis media, no specific diagnostic studies are necessary. Although there is no possibility of reversing the clinical course, appropriate antibiotic treatment for 10 days is recommended to eradicate the labyrinthine infection and prevent propagation to the meninges. Other therapeutic measures are dictated by the underlying otitis, but labyrinthectomy is not necessary in labyrinthitis secondary to acute otitis media.

Encephalocele and Cerebrospinal Fluid Leakage

Encephalocele (brain hernia, brain fungus, meningoencephalocele) and CSF leakage may be associated with other cranial or intracranial complications in acute or chronic otitis media. Three different clinical patterns can occur.

Spontaneous CSF leakage from defects in the tegmen tympani (less commonly the tegmen mastoideum) have been reported in more than 50 patients who have not undergone previous otologic surgery.[18,19] Seventy to 80% of the patients are over 45 years of age. The defects range in diameter from 2 mm to 2 cm and are sometimes multiple. Usually, an encephalocele protrudes through the defect. Although there is no agreement as to why the dura breaks down and allows cerebral herniation and CSF leakage in these older patients, Jackson and associates have suggested that aging, increased intracranial pressure, low-grade inflammation, arachnoid granulation, and irradiation can play a part.[20] Patients frequently present because of hearing loss owing to reduced ossicular motion from the middle ear fluid or the encephalocele. Myringotomy and placement of a ventilating tube release a profuse watery otorrhea that tests positive for CSF. Other patients present with signs and symptoms of meningitis, and many of these patients have already experienced one or more episodes of meningitis.

Encephalocele and CSF leakage secondary to chronic otitis media occur when a cholesteatoma and granulation tissue erode through the bony plates that separate the mastoid from the temporal lobe and the cerebellum and then erode through the dura. The mastoid and epitympanic tegmen are involved more frequently than the cerebellar plate. It usually takes many months to years for a cholesteatoma to cause this degree of bone erosion, cerebral prolapse, and dural erosion.

Traumatic encephalocele and CSF leakage are the most common pattern. Although a few of these cases occur secondary to temporal bone fracture, the great majority are the consequence of an operation in which portions of the tegmen or cerebellar plates were removed and the dura was exposed or traumatized. In these cases, both the disease process and the surgery contribute to the bony and dural trauma that facilitates the development of an encephalocele, CSF leakage, and intracranial complications.

Management of temporal bone encephalocele requires prompt surgical repair. Jackson and associates have written an excellent review of this subject.[20] The size of the bony defect and the volume of herniated brain are two of the important factors in choosing a surgical approach. Small defects usually can be adequately managed through the mastoid, but multiple and large defects are best repaired by a combination of transmastoid and middle cranial fossa approaches. Jackson et al recommended a combined transmastoid intradural middle cranial fossa approach for large encephaloceles. To reduce the risk of infection, the defects are usually repaired with autogenous graft materials.

INTRACRANIAL COMPLICATIONS

Meningitis

Meningitis is by far the most common intracranial complication of acute and chronic otitis media. In Gower and McGuirt's series of 100 consecutive patients with intracranial complications of acute and chronic otitis, 76 had meningitis, and 53 of those were under 2 years of age.[21] In infants and toddlers, the great majority of cases occur by hematogenous dissemination of infection during acute otitis media. Sometimes these patients are not included in reports that document the complications of otitis, and the frequency of otogenic meningitis appears to be low.[1]

Conditions that allow CSF to gain access to the middle ear cavity predispose the patient to developing or suffering a recurrence of bacterial meningitis. Cerebrospinal fluid otorrhea is common after lacerations of the dura by longitudinal temporal bone fractures and occasionally is seen in patients who spontaneously develop defects of the tegmen of the middle ear or mastoid with associated encephaloceles. Unrecognized injury to the dura of the posterior or middle cranial fossa during mastoid surgery is an overlooked source of CSF leakage that can lead to meningitis. Patients with syndromic or nonsyndromic congenital stapes fixation, Mondini's dysplasia, and enlarged vestibular aqueducts are also at risk for a bacterial middle ear infection spreading to the CSF. The pathway can be obvious, as, for example, when a "perilymph gusher" is discovered during stapes surgery, or it can be more subtle, as when there are microscopic disruptions of the continuity of the oval or round windows, internal auditory canal, and cochlear aqueduct. Meningitis can occur even in individuals with normal middle ear and labyrinthine anatomy if acute otitis media complicates conditions such as traumatic stapes dislocation or perilymphatic fistula and then progresses to acute suppurative labyrinthitis.

The predominant symptom of meningitis is a generalized, severe headache. The patient will tend to lie quietly, vomit frequently, and exhibit photophobia and general hyperesthesia. The patient's level of consciousness may be normal, somnolent, stuporous, or unresponsive. Fever, often high and sustained, is nearly universal. Nuchal rigidity and pain when the clinician attempts to flex the patient's neck are ominous signs that should compel the clinician to perform other neurologic tests. In Brudzinski's sign, passive flexion of the head on the chest is followed by involuntary flexion of both thighs and both legs. In Kernig's sign, when the patient is in the supine position and one thigh is flexed to a right angle, attempts at passive extension at the knee are accompanied by pain and resistance owing to spasm of the hamstring muscles. Fundoscopic examination may reveal the presence of papilledema.

Whenever meningitis is suspected, a CT scan is critical to rule out the presence of brain abscess, cerebritis, or subdural empyema and to determine that it is safe to perform lumbar puncture (ie, intracranial pressure is not inordinately increased). Cerebrospinal fluid from the lumbar puncture is examined for intrathecal pressure, cells, bacteria, glucose, protein, chloride, and other factors. Cerebrospinal fluid pressure increases early in the course of the disease and protein and glucose concentrations increase in comparison to serum values as the disease progresses, but bacteria are not present until late in the disease.

When meningitis is secondary to acute otitis media or acute otitis media with suppurative labyrinthitis, antibiotic treatment of the meningitis is also adequate treatment for the otitis, and no sur-

gery is indicated. Tympanometry and otoscopy should be performed after treatment is complete to document that the middle ear has returned to normal. However, when meningitis develops from chronic otitis media and mastoiditis, the mastoid must be exenterated, and all disease must be excised. Even though the patient has already had a CT scan before the lumbar puncture, an enhanced MRI should be obtained to rule out the presence of any additional intracranial complications. The neurologic condition of the patient determines the timing of the surgery, and the mastoidectomy should be performed as soon as the patient is stable. Meningitis is one of the gravest complications of acute or chronic otitis. Further, meningitis appears to be more lethal when secondary to chronic otitis media and mastoiditis than when it is a hematogenous complication of acute otitis media in the first 2 years of life.

Brain Abscess

The incidence and mortality of intraparenchymal brain abscesses have decreased considerably. Nearly all reports in the past two decades come from centers outside North America and Western Europe. However, recent reports from Africa and Asia, where new imaging techniques are used, have documented substantial improvements in diagnosis and therapy and clarified some aspects of surgical treatment. Yen and associates' recent series of 122 consecutive patients seen in a Taiwan hospital between 1981 and 1994 revealed that otitis was the third most common cause of intraparenchymal brain abscess, exceeded only by those associated with cyanotic congenital heart disease and those secondary to head injury or neurosurgery.[22] Seventy-five percent of abscesses occurred in males, principally from the lower socioeconomic classes. In the 1990s, four reports from India, Turkey, and South Africa discussed 149 patients with otogenic brain abscesses.[1,2,23,24] Abscesses from acute and chronic otitis media occurred nearly always on the same side as the otitis and nearly equally in the temporal lobe or cerebellum. Almost three-fourths were secondary to cholesteatoma, half occurred in patients in the second decade of life, and two-thirds affected males.

A brain abscess begins when bacteria propagate in and around venous channels leading from the mastoid into the adjacent brain parenchyma. As soon as the bacteria arrive in the cortex or white matter, polymorphs migrate into local capillaries, producing endothelial swelling and focal cerebritis. The tissue becomes edematous, hemorrhagic, and necrotic. The abscess may vary greatly in size. Often it has an irregular shape and is multilocular. At first, the capsule is poorly defined, but over time it firms and can be easily stripped from the underlying edematous brain.[25]

In addition to manifesting symptoms and signs of general intracranial sepsis, patients with cerebellar abscesses often exhibit coarse horizontal nystagmus, dysmetria, dysdiadochokinesia, or action tremor. Temporal lobe abscess may cause homonymous visual field defects, contralateral hemiparesis, and other focal signs listed below for subdural empyema. The physician should carefully examine the patient and the imaging studies because up to two-thirds of patients with intraparenchymal abscesses will have more than one intracranial complication.[23]

The physician should immediately begin broad-spectrum intravenous antibiotics directed at both aerobic and anaerobic microorganisms. If imaging studies suggest no other complications and the patient's condition is stable, neurosurgical drainage or abscess excision is performed within the first 24 hours of admission, followed immediately by mastoidectomy performed through a separate surgical field. Mortality has decreased to approximately 10%.

Subdural Empyema

Subdural empyema is a fulminating purulent infection that develops between the dura and the pia-arachnoid membranes. It is one of the most immediate of neurosurgical emergencies. It comprises only about 20% of all cases of localized intracranial bacterial infection, and an otitic origin is uncommon compared to bacterial contamination (from trauma or a neurosurgical operation), suppurative paranasal sinus disease, or meningitis. At least two-thirds of the cases occur in men, and most occur during the second decade of life. The abscess usually begins by direct spread from adjacent infected bone or by retrograde venous propagation. Once infection enters the subdural space, pus forms rapidly and spreads widely. Thrombophlebitis of cortical veins is virtually guaranteed. Swelling, necrosis, and infarction of the cortex account for many of the clinical features and explain how a

barely detectable, thin layer of subdural pus can cause such devastating consequences as raised intracranial pressure, focal signs, and seizures.[26]

Clinically, patients exhibit a cascade of symptoms that begins with a severe headache, the most persistent symptom. The temperature rises dramatically as the disease progresses. General malaise, chills, and nuchal rigidity indicate that the patient is becoming seriously ill. After an unpredictable period of time, the patient's level of consciousness may abruptly decline and focal signs and symptoms may develop. Most patients with collections of pus on the left side of the brain develop aphasia and a progressive contralateral hemiparesis. Paralysis of conjugate gaze to the contralateral side and deviation of the eyes toward the side of the lesion are also common. Jacksonian seizures are common at this stage, and papilledema may be evident. In patients with subdural empyema in the posterior fossa, localizing signs are often absent, but marked neck stiffness and papilledema are always present. The entire clinical picture of subdural empyema may develop in as little as a few hours or as long as 10 days.

In a well-developed subdural empyema, a contrast-enhanced CT scan will show a crescent-shaped, low-density collection of pus displacing the brain from the inner table of the skull, with enhancement of the adjacent edge of cortex. Unfortunately, the scan may appear normal early in the course of the disease. When this happens, the clinician should obtain an enhanced MRI or repeat the CT scan after a suitable time interval. Lumbar puncture is dangerous and is contraindicated because it may precipitate transtentorial coning; however, it may be unavoidable when the CT scan fails to detect the lesion and focal signs are absent because meningitis and brain abscess must also be ruled out.

Emergency neurosurgical drainage and appropriate antibiotic therapy are necessary. The patient's likelihood of survival will be related to his or her level of consciousness at the time of surgery. The presence of localizing signs in any patient with chronic otitis media whose level of consciousness is declining requires immediate and decisive action.

Subdural empyema can also develop in neonates as a complication of meningitis. Up to 30% of infants and children with *H. influenzae* meningitis develop a collection of fluid in the subdural space (usually bilaterally) that varies from 5 to 100 mL.[27] This problem is less common after meningitis from other microorganisms. Its frequency has also decreased since universal immunization against *H. influenzae* has dramatically reduced the incidence of meningitis. Uninfected subdural collections after meningitis are called "subdural effusions." If bacteria are evident on direct examination of the fluid, the collections are called "infected subdural effusions," and if the fluid is grossly purulent, they are classified as "subdural empyemas." In this age group, subdural collections from meningitis secondary to chronic otitis media that require otologic attention are rare.

Epidural Abscess

Epidural abscess results from bone erosion caused by cholesteatoma, granulation tissue, or coalescence. In addition to the bone erosion, an intense inflammatory response to the infection results in granulation tissue formation and forms an abscess between the temporal bone and the dura mater. The involved dura thickens in response to its contact with granulation tissue on its surface (pachymeningitis). Although it can occur as the only complication of chronic mastoiditis, epidural abscess is frequently associated with lateral sinus thrombophlebitis, meningitis, and cerebritis or brain abscess. Rarely, epidural abscess can result from acute otitis and mastoiditis in the same way as will be described for lateral sinus thrombosis.

Most patients experience deep mastoid pain, but there are no signs or symptoms specifically attributable to epidural abscess, and many small epidural abscesses without associated complications are discovered only at surgery. If the abscess is large enough, it can be detected on enhanced CT or MRI scans as a fluid-filled cavity between the temporal bone and the enhanced dura. Surgery is the only recommended treatment. The surgeon performs the type of mastoidectomy that is appropriate for the underlying otitis and mastoiditis. After removing the cortex, he or she should progressively exenterate the air cells, proceeding from lateral to medial and from regions of less disease to those with more disease. When the locus of pathology is the cerebellar plate, the surgeon should first smooth the tegmen mastoideum and tegmen tympani and then thin the posterior aspect of the bony

external auditory canal and remove the tip cells to maximize exposure and hemostasis. Then the surgeon approaches the diseased area along the cerebellar plate from the superior, inferior, lateral, and, finally, medial directions, removing the overlying bone until only a thin plate remains. Because the dura has been thickened by the infection, blunt flat instruments, such as a Freer elevator or large curettes, can safely scrape the granulation tissue from the abscess cavity and help the surgeon identify the most centripetal extent of the abscess. The surgeon should remove all of the bone overlying the abscess using diamond burs, rongeurs, or curettes until healthy dura without granulation tissue is evident on all margins of the abscess. When the abscess involves the tegmen, the surgeon should change the order of the surgical steps to complete the surgery in the other areas first and address the tegmental abscess last.

Lateral Sinus Thrombosis

Thrombosis of the lateral sinus usually forms as an extension of a perisinus abscess that develops after mastoid bone erosion from cholesteatoma, granulation tissue, or coalescence.[27] The perisinus abscess exerts pressure on the dural outer wall of the sinus, and necrosis results. The necrosis extends to the intima and attracts fibrin, blood cells, and platelets, and a mural thrombus forms. The mural thrombus becomes infected, enlarges, and occludes blood flow through the sinus. Fresh thrombus can propagate in a retrograde direction to the transverse sinus, the torcular Herophili, and even to the superior sagittal sinus. In the opposite direction, clot can extend via the jugular bulb into the internal jugular vein in the neck or via the inferior and/or superior petrosal sinuses to the cavernous sinus. The infected clot frequently showers the bloodstream with bacteria, which give rise to the signs and symptoms of septicemia and the possibility of metastatic abscesses (most commonly to the lungs).

Because of the relative frequencies of the various types of mastoiditis and the ages of those affected, lateral sinus thrombosis today is most common in adults or older children with cholesteatoma and develops less commonly from the other types of chronic mastoiditis. In addition to those cases arising by direct extension from bone erosion, however, lateral sinus thrombosis can also be caused by osteothrombophlebitis during acute otitis media and mastoiditis. In this situation (and in occasional cases of chronic mastoiditis), the bony sinus plate is intact at the time of surgical exploration.

Because the sinus is a continuation of the cerebellar dura mater, extension of an infection by only a few millimeters can result in the equally grave complications of meningitis, epidural abscess, subdural empyema, cerebritis, or cerebellar abscess. In two recent series, 14 of 19 patients with lateral sinus thrombosis had one or more of these additional complications.[28,29]

Although its frequent association with other complications obscures its clinical picture, a diagnosis of lateral sinus thrombosis can be strongly suspected when there are signs and symptoms of septicemia such as chills and spiking fever or blockage of blood flow through the sinus. A picket-fence fever pattern with diurnal temperature spikes that exceed 103°F has been described with this condition for decades. Some recent articles have suggested that this pattern is not seen as frequently, in part because many patients present with previous or current antibiotic therapy; however, Singh reported that the majority of his 36 patients were on intravenous antibiotics and still exhibited that fever pattern.[30] Unless the patient has been transferred from another hospital, only the patient's temperature on admission is available; nonetheless, the clinician who observes such a high fever spike should suspect the possibility of sigmoid sinus thrombophlebitis. Singh also noted that the neck pain in lateral sinus thrombosis may be mistakenly attributed to the neck stiffness of meningitis, when it is actually pain and tenderness occurring along the anterior border of the sternocleidomastoid muscle. Singh further identified percussion tenderness of the mastoid tip as another important sign.

More ominous are the signs of sudden intracranial hypertension secondary to decreased venous drainage from the skull (see "Otitic Hydrocephalus" below). The most prominent sign is the occurrence or sudden worsening of a severe headache. This is most likely to occur when the patient's dominant venous drainage system is obstructed (the right side in 60% of individuals). More grave is progressive obtundation. This may herald the development of cerebral edema from increased intracranial pressure secondary to involve-

ment of the superior sagittal sinus or the cavernous sinus. It carries a very high mortality rate.

Imaging studies and lumbar puncture are essential to sort out the possible types of complications in obtunded patients. If the patient's condition permits, both enhanced CT scan and enhanced MRI should be performed. The diagnosis can be made preoperatively when the clinician identifies enhancement of the wall of the sigmoid sinus on CT scan, the Delta sign. Sinus wall enhancement is more sensitively evaluated by MRI, which also can document abscess formation within the sinus and can exclude nearby subdural empyema, cerebritis, or cerebellar abscess.

All patients with sigmoid sinus thrombosis will require mastoidectomy to treat the underlying mastoid disease adequately. Treatment controversies exist in the timing of the mastoid surgery and the management of the infected clot and sinus wall. When a brain abscess is also present, surgical drainage of that abscess takes precedence over any mastoid procedure (see "Brain Abscess"). If the patient's condition permits, neurosurgical drainage of the brain abscess should be followed in the same anesthetic by expeditious mastoidectomy. When meningitis is present in conjunction with lateral sinus thrombosis, mastoid surgery should be completed as soon as the patient is neurologically stable.

Management of the clot can include anticoagulation, ligation of the jugular vein in the neck, and opening the sinus and evacuating the infected clot. Use of anticoagulants is rarely indicated, but it should be strongly considered when extension of the clot to the transverse sinus or cavernous sinus is documented or suspected. Other considerations in these deteriorating patients include neurosurgical decompression and corticosteroids. Similarly, ligation of the jugular vein in the neck should not be routine, but it should be considered whenever there is evidence of extension of the clot into the neck and should be strongly considered when septic emboli are present.

The sinus is usually addressed only after the mastoidectomy portion of the operation has been completed. The surgeon then widely exposes the sinus and the adjacent dura by removing the overlying bone with rough diamond burs. The surgeon passes an 18- or 20-gauge needle through the sinus wall and, if there is no free blood on aspiration, makes a linear incision through the sinus wall and evacuates the abscess and any infected clot. Some surgeons recommend extending the exposure, incision, and clot evacuation proximally and distally until free bleeding occurs. The author recommends a more conservative approach, extending the surgery proximally and distally only as far as a grossly infected clot is found to remove as much infection as possible. The mastoid and cerebellar walls of the sinus are usually thickened and relatively tough as a result of the chronic infection. The surgeon can safely scrape them gently with a broad flat instrument such as a Freer elevator to remove the infected tissue. Syms and associates reported treating six patients with lateral sinus thrombosis and concomitant additional intracranial complications with mastoidectomy without opening and evacuating the lateral sinus clot.[29] All patients survived, but the average hospital stay was more than 49 days—38 days when the patient with the longest stay was omitted. In contrast, Kaplan and Kraus's 13 patients underwent surgery that included incision of the sinus and evacuation of the clot or abscess.[28] Their mean hospital stay was only 17 days.

Otitic Hydrocephalus

Seventy years ago, Symonds described otitic hydrocephalus as a disease in which signs and symptoms of acute hydrocephalus followed some form of otitis.[31] Controversy and disagreement about the entity still exist today. Some authors view otitic hydrocephalus as a distinct clinical entity consisting of intracranial hypertension and resolved or resolving (usually acute) otitis media without any relationship to lateral sinus thrombophlebitis.[21] Others view it as a pathophysiologic consequence of lateral sinus thrombosis from any cause. The latter viewpoint holds that whether symptoms will develop following lateral sinus occlusion depends on (1) the size of the involved lateral sinus relative to that of the opposite side, (2) the adequacy of the collateral venous network including the cavernous sinus and the opposite inferior petrosal sinus, and (3) whether propagation of the process has occluded additional venous outflow. The physician should recognize the possible relationship among the symptoms, ear disease, lateral sinus, and emergent nature of the condition.

In the early stages, a diffuse, severe headache dominates the clinical picture. In uncomplicated cases with (or occasionally without) medical management, the continuous headache gradually ame-

liorates and dissipates over 3 to 7 days as collateral venous outflow increases to accommodate arterial inflow. If collateral venous drainage is inadequate and intracranial pressure remains elevated, signs of the sensorium dulling or decreased visual acuity from retinal vein occlusion will appear. The physician must recognize that these developments are an extreme emergency, obtain immediate neurosurgical consultation, and begin high doses of intravenous corticosteroids and diuretics. Rapid progression to coma and death is possible.

In assessing any patient suspected of having otitic hydrocephalus, the physician must make three determinations: (1) whether the patient has increased intracranial pressure, (2) whether the patient has active acute or chronic mastoid infection, and (3) whether there is free flow of blood through the involved lateral sinus. The physical examination and the imaging studies are paramount in making these determinations. The results of these inquiries will allow the physician to formulate the appropriate treatment of the mastoid, lateral sinus, and increased intracranial pressure.

CHAPTER 12

Otosclerosis

Herman A. Jenkins, MD, Omid Abbassi, MD, PhD

The term otosclerosis is derived from the Greek words for "hardening of the ear." Although first recognized as a pathologic entity by Valsalva early in the eighteenth century,[1] it was not until the mid-nineteenth century, with the observations of authors such as Magnus,[2] von Tröltsch,[3] Politzer,[4] and Toynbee,[5] that the clinical presentation of the disease was clearly defined. Today, otosclerosis is recognized as an alteration in bony metabolism of the endochondral bone of the otic capsule. The ongoing process of resorption and redeposition of bone results in fixation of the ossicular chain and conductive hearing loss.

PREVALENCE

Otosclerosis occurs most commonly among Caucasians,[6] with an incidence of 1%, followed by Asians at 0.5%. It is far less common in African Americans. In postmortem examinations of temporal bones, Guild found evidence of a higher prevalence rate histologically, with 8.3% of Caucasians and 1% of African Americans manifesting the disease.[7] Although encountered in all age groups, usually the clinical presentation occurs between the second and fifth decades of life. The disease process has a female predominance of 2 to 1, and its progression tends to accelerate with hormonal changes, particularly during pregnancy or the use of birth control pills. Bilateral disease is present in 80% of patients.

HISTOPATHOLOGY

The otosclerotic process is divided into two phases histologically. Bone resorption and increased vascularity characterize the early phase. When present near the periosteum of the middle ear, this hyperemia is responsible for Schwartze's sign. As the mature collagen content diminishes, the bone acquires a spongy appearance (otospongiosis).[8] On hematoxylin-eosin staining, it assumes a bluish coloration, referred to as the blue mantles of Manasse.[9] In the late stage, the reabsorbed bone is replaced with dense sclerotic bone—thus the name otosclerosis.

When involving the stapes, otosclerosis often starts from the fissula ante fenestram, although focal lesions involving the posterior annular ligament are also seen. In general, it progresses from an anterior focal lesion to complete footplate involvement and, in more advanced cases, may fill the oval window niche entirely with new bone (obliterative otosclerosis). In contrast, the round window is less frequently involved, and complete obliteration is a rare finding. Involvement of the cochlea can result in sensorineural hearing loss.

ETIOLOGY

Evidence for inflammatory and infectious causes has been reported. A genetic component has long been recognized, and transmission has generally been accepted to be autosomal dominant with incomplete penetrance. The gene for otosclerosis has not been clearly identified, but authors in one study narrowed its location to chromosome 15q25-26.[10] Others have related otosclerosis to the *COL1A1* gene that encodes for type 1 collagen. Investigators have noted its similarities to osteogenesis imperfecta[11] and Paget's disease,[12] both sharing lesions in the otic capsule nearly identical to that of otosclerosis. A role for autoimmunity as been suggested, but the data remain inconclusive.[13]

Recent investigations on the role of infectious agents have implicated the measles virus as having, at least, an inciting role in patients with a genetic predisposition for otosclerosis.[14] Elevated titers of

immunoglobulin G specific for measles virus antigens have been found in the perilymph of patients with otosclerosis. Immunohistochemical evidence of measles antigen has also been demonstrated in active otosclerotic foci, using reverse transcription polymerase chain reaction amplification of measles virus ribonucleic acid.[15] However, the actual role of the virus in producing the disease is not established.

CLINICAL PRESENTATION

The clinical presentation of otosclerosis is a progressive conductive hearing loss in an adult. It is thought to occur in less than 20% of genetically affected individuals. Some patients report improved speech understanding in a noisy environment (known as paracusis of Willis). Tinnitus is the second most common complaint reported. Vestibular symptoms are uncommon. In women, an increase in the rate of progression of the hearing loss is reported with hormonal changes such as those associated with pregnancy. Sensorineural hearing loss may be associated with the conductive changes in the disease. However, an isolated sensorineural hearing loss owing to otosclerosis is rare.

Physical examination shows a normal appearance of the external auditory canal and tympanic membrane. Schwartze's sign, a reddish hue over the promontory caused by increased vascularity of the bone immediately under the periosteum, may be seen in the early stages of the disease but is not present in all patients.

LABORATORY TESTING

Depending on the stage of the disease, audiometric studies typically show a mild-to-moderate conductive hearing loss. The air–bone gap is wider at the lower frequencies. Carhart's notch is characteristic of otosclerosis and appears as a sensorineural hearing loss at 2 kHz that is spurious since the bone conduction in the mid-frequency range is not reliable. Stapes fixation interferes with the bone conduction of the acoustic signal, and up to 15 dB of the apparent sensorineural hearing loss disappear after surgery for otosclerosis. With progression of the conductive loss, the Rinne test demonstrates greater bone conduction than air conduction, and Weber's test lateralizes to the affected side. The tympanogram is either depressed (A_s) or normal. The stapedial reflex may be normal in the early stages but cannot be elicited as stapes fixation proceeds. Speech discrimination is often normal, except in patients with cochlear involvement. Clinically, other diagnostic studies such as high-resolution computed tomography (CT) and magnetic resonance imaging (MRI) are of little use in evaluation of otosclerosis. With high-resolution CT, however, one may be able to identify the sclerotic lesion.

MEDICAL MANAGEMENT

Medical management of otosclerosis remains controversial and is primarily directed at maturing the involved bone and decreasing osteoclastic activity. Shambaugh and Scott introduced use of sodium fluoride as treatment, based on its success in osteoporosis.[16] However, this required high doses, and the efficacy has not been clearly established. Bisphosphonates that inhibit osteoclastic activity and cytokine antagonists that inhibit bone resorption may offer hope for the future. At present, no medical treatment is recommended on a consistent basis. Hearing aids, however, do offer an effective means of nonsurgical management of hearing loss in otosclerosis.

SURGICAL MANAGEMENT

History

The history of surgery for otosclerosis dates back to Kessel in 1877 with early attempts at mobilization and extraction of the stapes.[17] Other otologists subsequently attempted similar procedures, notably Miot in 1890, who described extensive experience with surgery and suggested various surgical techniques.[18] His successes were many. However, the report by Seibenmann at the turn of the twentieth century was less encouraging and condemned the surgery.[19] This effectively ended these early ventures into stapes surgery for conductive hearing loss.

Interest in this field of ear surgery lay dormant until 1938, when Lempert described the fenestration procedure that became popular with otologists of the era, rekindling interest in surgery for otosclerosis.[20] The focus returned to the stapes with Rosen's report of stapes mobilization and the restoration of hearing.[21] Shea introduced the stapedectomy, a technique of stapes extraction with tissue coverage of the oval window and polyethylene strut reconstruction of the stapes, in the 1950s, ushering in the modern

approach to stapes surgery.[22] In the intervening years, techniques have changed, and new materials for reconstruction have been introduced; however, the principles still remain basically the same.

The surgical goal in otosclerosis is restoration of the transmission mechanism for sound from the tympanic membrane, going through the ossicular chain to the oval window, bypassing the resistance of the fixed stapes footplate. Today, a variety of techniques are used to correct for stapes footplate fixation. Generally, the stapes arch is removed, and either a perforation or a partial to complete removal of the footplate is performed. A prosthetic implant is employed to connect the incus to the oval window.

Patient Selection

Selection of patients for operation is based on audiologic findings and physical examination. Preferred are patients with normal middle ear aeration, free of any infection or tympanic membrane perforation and with a Rinne test that demonstrates bone conduction to be greater than air conduction. When bilateral disease presents, the worse hearing ear is treated first followed by the other ear several months later. Experienced otologists should perform surgery on the only hearing ear, exclusively and with great trepidation.

Informed Consent

Preoperative consent is obtained, informing the patient of the risks of loss of hearing, vertigo, injury to the facial nerve, loss or alteration of taste, tympanic membrane perforation, prosthesis extrusion, prosthesis mobilization, and residual conductive hearing loss. Singers and musicians are informed of a possible change in quality of sound perception that may affect their professional performance. Individuals who are exposed to or plan to be involved in activities associated with rapid and/or considerable change in pressure, such as scuba diving and piloting nonpressurized airplanes, are advised to refrain from stapedectomy.

Perioperative Treatment

The operation may be performed under either general or local anesthesia. With improvements in anesthesia, more otologists are now performing the operation under general anesthesia. Use of any anticoagulants during the 2 weeks prior to the operation should be avoided, including anti-inflammatory agents. Muscle relaxants in conjunction with anesthetic agents are not recommended because of their effect on facial nerve activity. Perioperative antibiotics are at the surgeon's discretion, but antiemetic agents are recommended.

Whether a general or local technique is employed, injections of local anesthetics should be administered in such a manner as to avoid unintentional involvement of the facial nerve medial to the mastoid tip. Sterility of the operative field is of paramount importance since a direct connection to the labyrinth is established during parts of the operation. Routine operative site scrub technique, including installation of antibacterial preparation solution into the external auditory canal, is recommended. Facial nerve activity is monitored by direct vision of the face through a transparent occlusive drape.

Surgical Technique

Stapes surgery may be performed via an endaural or anterior incisural incision. The endaural incision requires use of a speculum held stationary with the left hand or a speculum holder assembly. In contrast, the anterior incisura incision is held open using one or two self-retaining retractors, eliminating the need to operate through a speculum. The cosmetic result of the incision is rarely noticeable. The latter also provides direct access to the tragal cartilage if a perichondrial graft is desired.

Regardless of the approach, a tympanomeatal flap is raised, the annulus is identified, and hemostasis is established prior to entering the middle ear space. A 1% lidocaine with 1:100,000 epinephrine or an 1:1,000 epinephrine-soaked piece of Gelfoam is used in this step. The tympanomeatal flap is elevated anteriorly, and the chorda tympani nerve is dissected free toward the malleus. A portion of the scutum should be curetted to expose the incus and the incudostapedial joint. Fixation of the stapes is determined by palpation of the malleus while viewing the suprastructure and footplate of the stapes.

The distance between the mid-shaft of the long process of the incus and the footplate is measured (Figure 12–1, A). The incudostapedial joint is separated, and the stapedial tendon is severed. The stapes suprastructure is fractured inferiorly and removed from the middle ear (Figure 12–1, B).

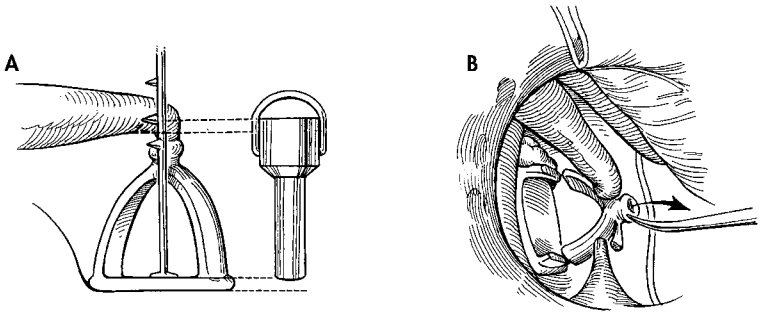

FIGURE 12–1. *A*, Proper measuring technique for a stapes prosthesis. *B*, Fracturing the superstructure of the stapes. Reproduced with permission from Coker NJ, Jenkins HA. Atlas of otologic surgery. Philadelphia: WB Saunders; 2001.

Establishing contact with the perilymphatic space may be done in several ways. The trend within the last decade has moved to smaller fenestra to protect the inner ear as much as possible. Typically, a small fenestra is created, or the footplate is partially removed. When the surgeon removes the footplate, a stapedectomy is performed. Depending on the training and preference of the otologist, the posterior half of the footplate is removed (Figure 12–2). In the technique demonstrated, the footplate is fractured in half, with the posterior portion being removed. A perichondrial graft from the tragus or a vein graft is placed over the defect, and the prosthesis is positioned over it and secured to the incus.

In the stapedotomy technique, a perforation in the footplate is made, just large enough to allow passage of the prosthesis. Figure 12–3 illustrates the technique popularized by Fisch in which a perforation is gradually enlarged with a handheld drill to 0.6 mm in diameter. The stapes replacement prosthesis of choice is placed in the perforation and attached to the incus. The length of the prosthesis used is longer (by 0.25 mm) than the distance between the medial aspect of the long process of the incus and footplate, measured earlier, since the tip of the prosthesis has to go through the footplate. The addition of fresh clotted blood to the area also helps reduce the risk of a perilymphatic fistula.

Many otologists have advocated use of a laser in performing a stapedotomy. The advantage of the laser is decreased manipulation of the suprastructure and footplate. The thermal effect is negligible.[23] The disadvantage is the extra time, expense, and instrumentation needed. Perkins and Curto popularized a combination laser stapedotomy with tissue coverage of the perforation.[24] Figure 12–4 demonstrates this

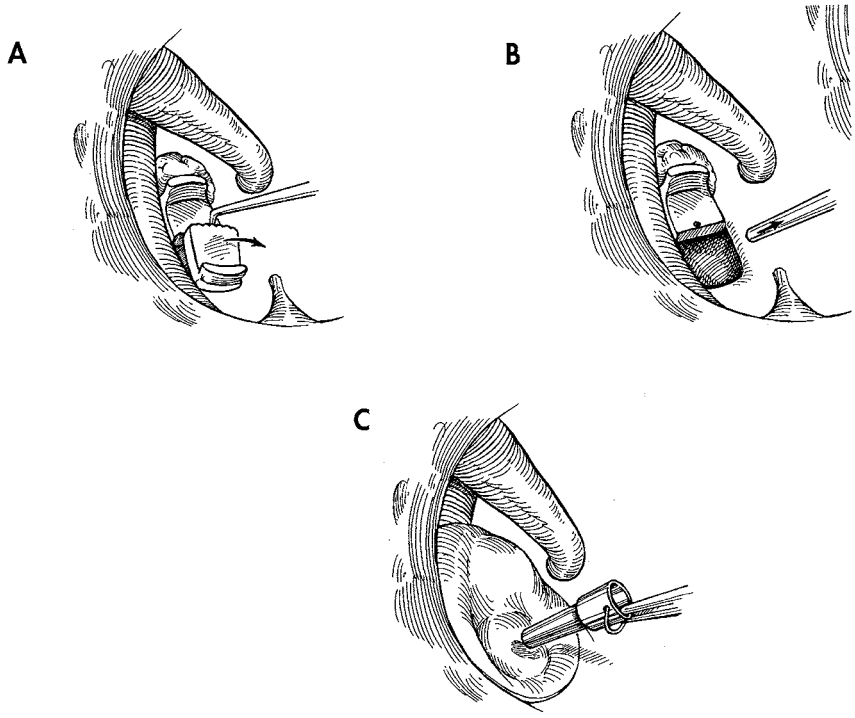

FIGURE 12–2. *A*, Partial stapedectomy with extraction of the footplate. *B*, Aspiration technique: place suction to the side of the oval window and avoid suctioning directly over the footplate. *C*, Perichondrial graft in place. technique. A vein graft is placed over a drilled hole in a Teflon block. A prosthesis is placed in the hole, and the vein graft is allowed to dry and become adherent to the prosthesis. Rosettes of charred bone are created by the laser and gently removed with a pick. The prosthesis and graft are positioned over the fenestra with the tip projecting into the vestibule, and the prosthesis is positioned under the incus.

Postoperative Management

Postoperatively, the patient is sent home to bed and to remain on light activity for several days. Pain management requires mild oral medication, and antibiotics are not necessary. Postoperative vertigo is treated with ondansetron (Zofran) or promethazine (Phenergan). Stool softeners help reduce straining and decrease the chance of a perilymphatic fistula formation. Patients are cautioned against blowing their noses and sneezing with their mouths closed.

Postoperative follow-up is scheduled in 1 week to remove the suture and packing and assess the integrity of the tympanic membrane. Hearing testing is done 4 to 6 weeks following the operation.

Pitfalls

The pitfalls of the surgery include inadequate exposure and anatomic variations. The endaural incision and speculum produce a narrower opening when compared to the anterior incisura approach. The scutum can cover the long process of the incus and the posterior half of the stapes. Adequate removal of the scutum ensures proper visualization of the foot-

plate in the crucial stage of footplate perforation and prosthesis placement. An aberrant facial nerve may prohibit a stapedectomy, and relocation of the nerve, which carries a risk of facial weakness and paralysis, is not recommended. A dehiscent nerve has a higher chance of facial nerve injury.

Advanced otosclerosis with obliteration of the oval window requires drilling of the footplate and significant experience with temporal bone anatomy. Sclerotic obstruction of the round window is of less importance since only a small opening over the round window is necessary to allow proper cochlear function. Drilling out the round window often results in a severe hearing loss and is avoided.

If the footplate should drop into the vestibule, attempts should be made to remove it. However, this should be done only if one can easily grasp the edge and gently remove it. Never go fishing for bony fragments that descend into the vestibule, away from the annular rim.

During the stapedectomy, the protective function of the stapedius muscle is destroyed. A new technique in which the stapedius muscle is left in place and the posterior crus of the fractured suprastructure is shaped and used as an autologous stapes replacement graft has been proposed and used. The efficacy of this technique in preserving the acoustic reflex is controversial.

Results

Otosclerosis surgery has withstood the test of time since its reinstitution in the 1950s. Shea, in his review of 40 years of stapes surgery, reported closure to within 10 dB of the preoperative bone-conduction level in over 95% of patients.[25] Glasscock et al reported over 91% closure to within 5 dB.[26] Both groups reported significantly less success in revision surgery. Persson et al contrasted stapedectomy and stapedotomy in the review of their series.[27] They demonstrated that partial and total stapedectomy had better results at all frequencies with the exception of 4 kHz. However, the hearing results in this group tended to deteriorate more quickly than the stapedotomy patients. Others have reported similar preservation of high frequencies with stapedotomy.[28] Outcome in the training situation demonstrates significantly poorer results.[29] A definite learning curve in stapes surgery is present after training.[30] The accepted overall rate of anacusis following stapes surgery is in the range of 1 to 2%.[28]

Complications

The complications of the stapes surgery are immediate and delayed in nature. Immediate complications are those occurring during the operation, such as facial nerve paralysis secondary to infusion of the local anesthetic or injury, vertigo, and/or hearing loss caused by suctioning of the perilymphatic fluid from the oval window during the operation or persistent postoperative perilymphatic leakage from the oval window. Bed rest and light activities are recommended for vertiginous patients, and most recover shortly after the operation. Metallic taste and loss of taste caused by manipulation of or injury to the chorda tympani nerve are not uncommon. Labyrinthitis, although possible, occurs rarely under sterile conditions.

Delayed postoperative complications, including perilymphatic fistula,[31] granuloma,[32] and prosthesis dislocation, have been reported. Immediate treatment with antibiotics and rest is recommended. Re-exploration should be entertained to correct for the fistula should persistent vertigo occur. Granuloma formation can occur for totally unknown reasons and in the best of settings. Keeping all foreign material, such as the talc powder of the glove and bone dust, away from the footplate area may decrease the chances of granulomas. A dislocated prosthesis requires re-exploration and revision.

CHAPTER 13

Hereditary Hearing Impairment

Richard J. H. Smith, MD, Stephen W. Hone, MD

Hearing impairment may be classified etiologically as either inherited or acquired and temporally as either prelingual (congenital) or postlingual (late in onset). Although useful, these types of classification belie the complex interaction of genetics and environment that make the study of hearing impairment, particularly late-in-onset deafness, difficult. For example, although presbycusis and noise-induced hearing loss might be dismissed as the end result of accumulated age and environmental trauma, animal studies have shown that genetic background is an important determinate of final outcome. By focusing on congenital hereditary hearing loss, the confounding effects of environment are minimized, and our understanding of the genetics of aural development and auditory function is simplified.

Approximately 50% of congenital deafness is inherited,[1,2] and among school-aged children, 1 child in 650 to 2,000 has some form of hereditary deafness.[3,4] As the incidence of deafness owing to infectious and iatrogenic causes diminishes, and as our ability to diagnose abnormalities improves, the relative importance of hereditary factors as causes of deafness increases.

Patterns of Inheritance

Genetic information is passed from one generation to the next encoded in the human genome. The human genome is comprised of 46 chromosomes, 22 pairs of autosomes, and the sex chromosomes, XY in males and XX in females. The autosomes vary in size and can be arranged by karyotype from largest to smallest (Figures 13–1, A and B). Variances in shape are caused by the centromere, which divides a chromosome into two arms. A chromosome is described as metacentric if the centromere is in the center, submetacentric if it is off center, or acrocentric if it is near an end. The shorter of the two arms is designated "p" (for petite), and the longer arm is designated "q." Chromosomes are further labeled by the banding pattern that is produced by staining (see Figures 13–1, A and B). Band patterns are distinct for each chromosome and are individually numbered (7q31 refers to chromosome 7, long arm, band three, one).

Individuals inherit half of their autosomal chromosomes from their father and half from their mother. Therefore, every gene exists as a pair, with one copy of paternal origin and the other copy of maternal origin. Each copy is referred to as an allele. The alleles of a gene pair may be identical, or subtle differences may be present. If the alleles are identical, an individual is said to be homozygous for that gene pair; alternatively, if the alleles are different, an individual is said to be heterozygous. For example, if a gene has two possible alleles, A and A′, and an AA′ by AA′ mating occurs, the progeny will have genotypes AA, AA′, or A′A′. If normal function of this gene is essential for normal hearing, and A′ encodes an allele of the gene that is associated with hearing impairment, deafness could result. If progeny with genotypes AA′ or A′A′ are hearing impaired, one can assume that A′ is dominant over A. Alternatively, if all progeny have normal hearing except those with genotypes A′A′, one can assume that A′ is recessive with respect to A. In the first case, both parents will be hearing impaired, whereas in the second case, only A′A′ progeny will be hearing impaired. These patterns of allele segregation are referred to as autosomal dominant and autosomal recessive inheritance, respectively (Figures 13–2, A and B).

Deafness caused by genes on the X chromosome is usually inherited as an X-linked recessive trait (Figure 13–2, C). The deafness is rarely penetrant in a carrier female, but half of all sons are affected, and half of all daughters are carriers. If the affected gene is inherited through the father, there are no affected offspring, although all daughters are carriers. Mitochon-

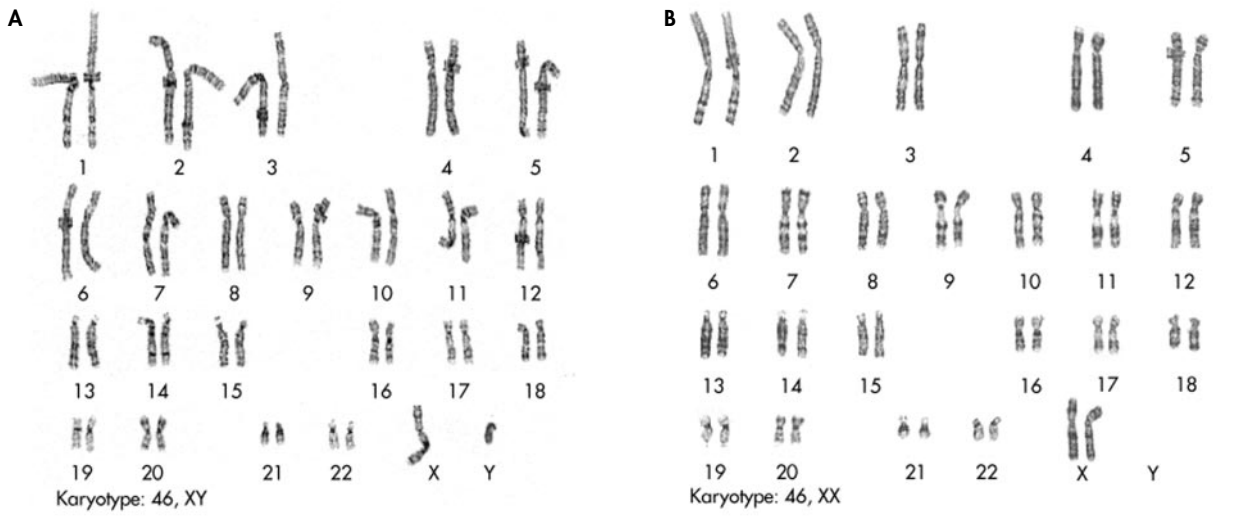

FIGURE 13–1. *A*, Male karyotype, 23,XY. *B*, Female karotype, 23,XX.

drial deafness is inherited only through the mother,[5,6] and sons and daughters may be affected equally.

When hereditary deafness is classified by mode of inheritance, 60 to 70% of cases are autosomal recessive, 20 to 30% are autosomal dominant, and 2% are X-linked.[2,7] In nearly 33% of cases, other phenotypic characteristics cosegregate with the hearing loss. These types of hearing impairment are known as "syndromic" and make the unequivocal diagnosis of hereditary deafness much easier. Typically, a wide range of phenotypes occurs, even in individuals carrying the same deafness-causing genetic mutation, a phenomenon known as variable expressivity. An affected individual may exhibit a few, some, or all of the phenotypic manifestations typically associated with a particular genetic abnormality. On rare occasions, an individual may have no abnormal physical findings, and the genetic mutation is said to be nonpenetrant. In the absence of cosegregating physical findings, inherited deafness is said to be "nonsyndromic." Nonsyndromic deafness is subclassified by mode of inheritance as DFNA, DFNB, or DFN for dominant, recessive, or X-linked, respectively (DFN for *deafness*). Loci are numbered in order of discovery. Mitochondrial deafness is designated by mutation type.

SYNDROMIC HEARING IMPAIRMENT

Hearing loss has been described in over 400 syndromes.[8] Although there are many classifications for these syndromes, one of the more useful is based on the involved organ system (Table 13–1). Some of the more common forms of syndromic hearing impairment are discussed in more detail with particular reference to recent advances in the understanding of their genetic basis (Table 13–2).

Autosomal Dominant Syndromic Hearing Impairment

Branchio-Oto-Renal Syndrome Although the association of branchial arch anomalies with hearing impairment has long been recognized, it was not until 1975 that Melnick and colleagues described branchio-oto-renal (BOR) syndrome.[9] Affected persons have branchial clefts or fistulae, otologic abnormalities, and renal anomalies (Figure 13–3). The pattern of inheritance is consistent with autosomal dominant transmission, and although gene penetrance approaches 100%, there is considerable variation in expression. Disease prevalence approximates 1 in 40,000 in the general population, but in the Deaf community, BOR syndrome may be responsible for over 2% of profound deafness.[10]

Hearing impairment is the single most common trait of BOR and is found in over 90% of affected individuals. The loss can be conductive, sensorineural, or mixed, with differences occurring even within families. Age of onset varies from early childhood to young adulthood, and both stable and progressive hearing loss have been reported.[11–14]

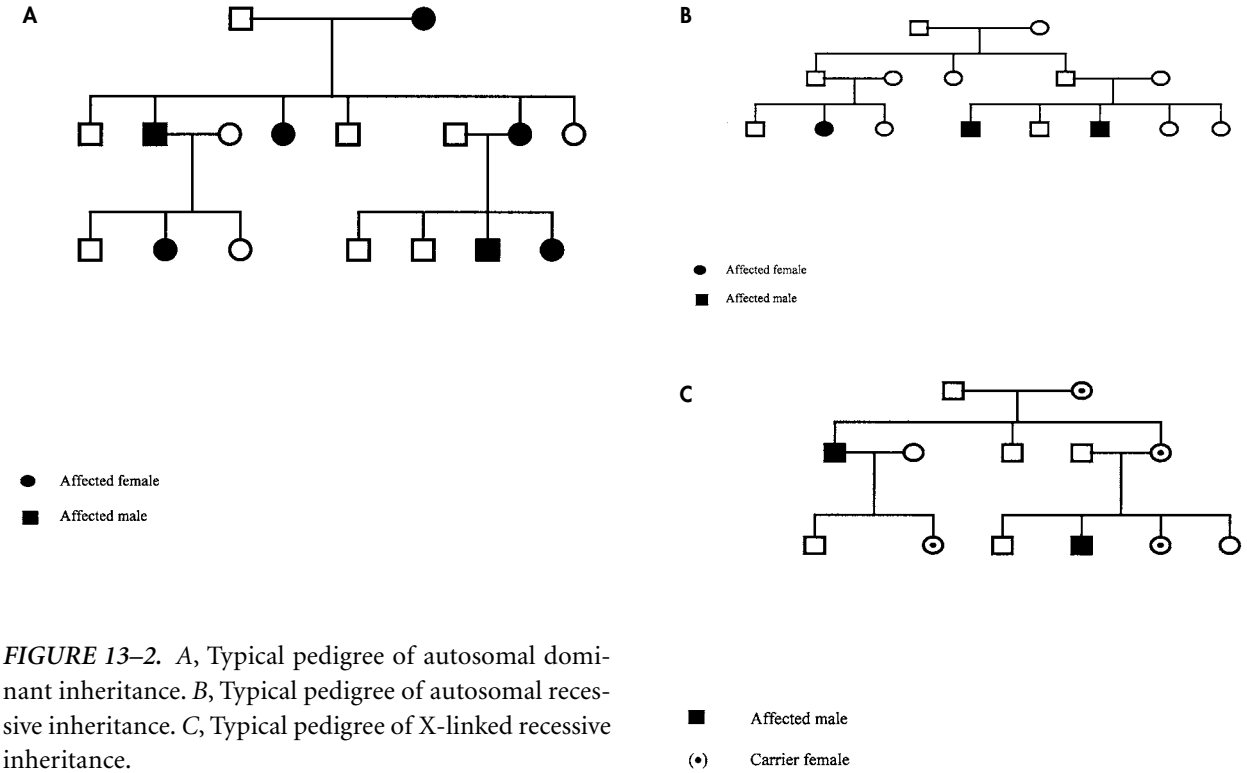

FIGURE 13–2. *A*, Typical pedigree of autosomal dominant inheritance. *B*, Typical pedigree of autosomal recessive inheritance. *C*, Typical pedigree of X-linked recessive inheritance.

Progressive loss is likely to be attributable to associated temporal bone abnormalities such as a dilated vestibular aqueduct (DVA).[13] Other associated temporal bone abnormalities include cochlear hypoplasia, bulbous internal auditory canals, deep posterior fossae, acutely angled promontories, and anomalous facial nerve course. Table 13–3 outlines the most common features of BOR syndrome. Early studies probably underestimated the true incidence of renal anomalies, which occur in up to 75% of cases and include renal agenesis, renal hypoplasia, renal dysplasia, pelvic ureteral junction obstruction, and polycystic kidneys. Glomerular lesions and vesicoureteral reflux progressing to renal failure have been described as well.

In the early 1990s, the BOR gene was mapped to chromosome 8q, and in 1997, the causative gene was cloned.[15–17] This gene is a human homologue of the *Drosophila* eyes absent gene (*eya*) and has been called *EYA1*. Its expression pattern suggests a role in the development of all components of the inner ear. In the kidney, murine *Eya1* plays a role in the development of the metanephric cells surrounding the "just-divided" ureteric branches.

A variety of missense and nonsense mutations, as well as insertions and deletions, have been identified in families with BOR syndrome; however, in about 70% of persons with a BOR syndrome phenotype, *EYA1* mutations cannot be found. This finding, together with marked phenotypic variability, has suggested to some investigators that BOR syndrome is a heterogeneous disease, a hypothesis recently confirmed with the identification of a second BOR syndrome locus on chromosome 1p31.[18]

Crouzon's Disease Crouzon's disease (CD) is another autosomal dominant type of syndromic hearing impairment, although one-third of cases are attributable to new mutations. It is diagnosed in about 5% of newborns with craniosynostosis and occurs with an estimated incidence of 1.65 in 100,000 births.[19] In addition to craniosynostosis, it is characterized by hypertelorism, midface hypoplasia, and exophthalmos.[20] One-third of affected persons have conductive hearing loss secondary to external or middle ear abnormalities. Frequently, there is an associated sensorineural component.[21]

Mutations in fibroblast growth factor receptor (*FGFR*) genes are implicated in a number of craniosynostosis syndromes including CD.[22] These genes

TABLE 13–1. Classification of Syndromic Hearing Impairment

System Involved	*Examples*	*Phenotypic Features*
Cardiac	Jervell and Lange-Nielsen syndrome	Prolonged QT interval, sudden death
Craniofacial/cervical	Apert's syndrome	Craniosynostosis, syndactyly
	Goldenhar's syndrome	Oculoauriculovertebral dysplasia
	Crouzon's disease	Craniosynostosis
	Treacher Collins syndrmoe	Mandibulofacial dysostosis
	Pierre Robin syndrome	Micro-/retrognathia, cleft palate
Chromosomal abnormalities	Down syndrome (trisomy 21)	Flat facial profile, oblique palpebral fissures, mental retardation
	Turner's syndrome	Short stature, amenorrhea, webbed neck
Endocrine	Pendred's syndrome	Goiter
	Diabetes mellitus and deafness	Diabetes mellitus
Integumentary	Waardenburg's syndrome	Dystopia canthorum, pigmentary anomalies of hair and skin
	Neurofibromatosis 1	Café-au-lait spots, neurofibromas
	Neurofibromatosis 2	Bilateral acoustic schwannomas
Metabolic	Hurler's syndrome	Dwarfism, hepatosplenomegaly, corneal clouding
	Hunter's syndrome	Dwarfism, hepatosplenomegaly
Nervous	Charcot-Marie-Tooth disease	Progressive neuropathic (peroneal) muscular atrophy
Ocular	Usher's syndrome	Retinitis pigmentosa
	Alström syndrome	Retinal degeneration, diabetes mellitus, infantile obesity
Renal	Alport's syndrome	Hereditary nephritis
	Branchio-oto-renal syndrome	Branchial and renal anomalies
Skeletal abnormalities	Osteogenesis imperfecta	Blue sclera, fractures

are tyrosine kinases that span the cell membrane and are important in mitogenesis and cell migration, development, and differentiation. *FRGR2* mutations cause CD.[23]

Neurofibromatosis 2 Neurofibromatosis 2 (NF2) is a central form of neurofibromatosis characterized by bilateral vestibular schwannomas. Other features include meningiomas, spinal cord dorsal root schwannomas, and posterior subcapsular cataracts. Criteria for diagnosis include one of the following[24]: (1) bilateral internal auditory canal/cerebellopontine angle tumors; (2) a first-degree relative with NF2 and a unilateral eighth nerve tumor; (3) a first-degree relative with NF2 and two of the following: neurofibroma, meningioma, glioma, schwannoma, or juvenile posterior subcapsular lenticular opacity.

The causative gene encodes a protein called merlin that shows similarity to a group of cell membrane-cytoskeleton protein linkers that regulate cell adhesion and morphogenesis. Inactivation of merlin in the mouse by targeted mutagenesis produces a variety of malignant tumors with a high rate of metastasis, suggesting that merlin also functions as a

tumor suppressor.[26,27] A variety of mutations have been described, and it appears that there is some genotype-phenotype correlation as truncating or inactivating mutations lead to severe phenotypes with an earlier age of onset, whereas missense mutations are associated with milder disease and a later age of onset.[28,29]

Stickler's Syndrome Stickler (STL) syndrome, also known as hereditary arthro-ophthalmopathy, is characterized by marfanoid features, spondyloepiphyseal dysplasia, joint hypermobility, midface hypoplasia, severe myopia, and varying degrees of Robin sequence (cleft palate, micrognathia, and glossoptosis). Because of the possibility of retinal detachment, ophthalmologic assessment is mandatory. Approximately 15% of affected individuals have a mixed hearing loss.[30–32] Gene linkage studies have demonstrated considerable genetic heterogeneity, with mutations in *COL2A1*, *COL11A2*, and *COL11A1* implicated in STL1, STL2, and STL3, respectively.[33–35] Because *COL11A2* is not expressed in the eye, persons affected with STL2 do not have myopia.

Treacher Collins Syndrome Treacher Collins syndrome (TCS) is a disorder of craniofacial development affecting structures derived from the first branchial arch. It is characterized by midface hypoplasia, micrognathia, macrostomia, colobomas of the lower eyelids, downward slanting palpebral fissures, cleft palate, and conductive hearing loss owing to external and middle ear abnormalities.[36] Inner ear abnormalities are rare, although enlargement of the utricle and aplasia of the horizontal canal have been reported.[37] The reported incidence of TCS is about 1 in 50,000 live births.[38]

The causative gene, *TCOF1*, encodes a protein called treacle that is structurally related to nucleolar phosphoproteins and may play a role in nucleolar-cytoplasmic transport.[39] Up to 60% of affected per-

sons have *TCOF1* mutations, the majority of which result in premature stop codons.[40] Its role in the inner ear is unknown.

Waardenburg's Syndrome Waardenburg's syndrome (WS), an auditory-pigmentary syndrome caused by the scattered absence of melanocytes from the skin, hair, eyes, and stria vascularis, was first described by Petrus Waardenburg in 1951.[41] He estimated the prevalence of this syndrome in the general population to be 1 in 42,000 and 1.43% among the congenitally deaf. Four clinical types are recognized: WS1, WS2, Klein-Waardenburg syndrome (WS3), and Shah-Waardenburg syndrome (WS4) (see Table 13–2). Klein-Waardenburg syndrome is a severe variant of WS1 with associated limb and skeletal abnormalities. The features of WS2, together with Hirschsprung's disease, characterize Shah-Waardenburg syndrome.[42]

The presence of dystopia canthorum in WS1 distinguishes it from WS2. Formal clinical criteria have been adopted to diagnose WS1, and criteria have been suggested for WS2, although its clinical definition covers any auditory-pigmentary syndrome that cannot be clearly classified (Table 13–4).[43,44] As such, WS2 includes a mixed collection of melanocyte defects and is likely to exhibit considerable genetic heterogeneity. Apart from dystopia canthorum, all features of WS1 and WS2 show marked interfamilial and intrafamilial variability.

Dystopia canthorum is the most common feature of WS1 and results from fusion of the eyelids medially leading to a reduction in the visible sclera medial to the iris (Figure 13–4). Hearing loss occurs in over 60% of cases of WS1 and in over 80% of cases of WS2.[45] The loss is typically sensorineural, prelingual, and nonprogressive and varies from mild to profound; profound bilateral loss is most common.

Both WS1 and WS3 are caused by mutations in *PAX3*, some cases of WS2 are associated with mutations in the microphthalmia gene (*MITF*), and the WS4 phenotype results from mutations in *EDNRB*,

its ligand *EDN3*, or *SOX10* (see Table 13-2). Recent studies have confirmed a complex interaction between these genes, with SOX10 and PAX3 proteins synergistically activating *MITF* expression.[46–51] Numerous different allele variants in these genes have been reported as causing deafness.

Autosomal Recessive Syndromic Hearing Impairment

Jervell and Lange-Nielsen Syndrome Jervell and Lange-Nielsen syndrome (JLNS) is characterized by profound prelingual sensorineural hearing loss, syncope, and sudden death owing to a prolonged QT interval. The syndrome was first described in Norway, where its estimated prevalence is 1 in 200,000. Diagnostic criteria include a QTc > 440 ms in males and > 460 ms in females.[52] Syncopal attacks are usually associated with exertion or emotion, and with prompt diagnosis and antiarrhythmic treatment, the high mortality rate can be significantly reduced.

Mutations in *KCNQ1* and *KCNE1,* which encode subunits of a voltage-gated potassium channel protein, have been shown to cause JLNS. However, there is likely to be considerable genetic heterogeneity as mutations have not been identified in a number of families. Some heterozygous individuals may have a prolonged QT interval in the absence of hearing loss and are prone to life-threatening arrhythmias. Genetic counseling should be offered to affected persons and their families to minimize potential morbidity and mortality.[52]

Pendred's Syndrome Pendred's syndrome (PS) is characterized by congenital sensorineural hearing loss and goiter. Prevalence estimates range from 1 to 7.5 per 100,000 newborns, suggesting that it may account for up to 7.5% of all childhood deafness.[53,54] The degree of hearing loss is variable but is most frequently profound and is associated with temporal bone abnormalities ranging from a DVA to Mondini's dysplasia (Figure 13–5). Goiter may be apparent at birth but typically presents in mid-childhood. The thyroid defect involves organification of iodine and can be diagnosed by administering perchlorate, which releases unbound iodide from thyroid follicular cells. Despite this abnormality, affected individuals usually remain euthyroid.

The disease is caused by mutations in *PDS*, a member of the solute carrier 26 gene family. The encoded protein pendrin transports chloride and iodide and mediates the exchange of chloride and formate, properties that suggest tissue-specific function.[55] In the thyroid gland, pendrin has been immunolocalized to the apical membrane of the thyrocyte, where it may allow intracellular iodide to pass into the colloid space to be bound to thyroglobulin. In the kidney, pendrin probably functions as a chloride/formate exchanger, which is important for chloride transport in the proximal tubule. The role of pendrin in the inner ear is unknown.

TABLE 13-4. Diagnostic Criteria for Waardenburg's Syndrome Type 1

*Major Criteria**	*Minor Criteria*
Sensorineural hearing loss	Congenital leukoderma (areas of hypopigmented skin)
Pigmentary disturbance of the iris	Synophrys or medial eyebrow flare
Complete heterochromia	
Partial or segmental heterochromia	
Hypoplastic blue eyes	
Hair hypopigmentation (white forelock)	Broad, high nasal root
Dystopia canthorum (W>1.95)	Alae nasi hypoplasia
Affected first-degree relative	Premature graying of hair (before 30 y)

*An affected individual must have at least two major criteria or one major criterion and two minor criteria. Criteria for Waardenburg's syndrome type 2 have been suggested that include premature graying as a major criterion instead of dystopia canthorum.
W = Waardenburg index.

FIGURE 13–4. Mother and child with Waardenburg's syndrome (WS). Note the characteristic dystopia canthorum of WS1. The child exhibits heterochromia iridis (see color figure on the CD-ROM).

Over 45 different deafness-causing *PDS* mutations have been reported, and although many families have "private mutations," in about half of affected persons, one of three different mutations is found (L236P, T416P, 1001+1G→A).[56,57] *PDS* allele variants can be identified in approximately 80% of multiplex families segregating for either DVA or Mondini's dysplasia, suggesting that mutations in this gene are the major genetic cause of these two temporal bone anomalies.

Usher's Syndrome Usher syndrome (USH) is the most common autosomal recessive syndromic form of hearing impairment. Characterized by blindness caused by retinitis pigmentosa and sensorineural hearing loss, it is responsible for half of all deaf-blindness in the United States and an estimated 3 to 10% of all congenital deafness.[58] It can be classified into three different types based on clinical presentation (Table 13–5). USH1 and USH2 are most common, whereas USH3 is quite rare, accounting for only 5 to 15% of all USH.[59,60]

Vestibular dysfunction differentiates USH1 from USH2. Persons with USH1 have vestibular areflexia and, as infants, fail to achieve normal motor developmental milestones.[61] They are late in sitting and walking and have absent ice-water responses to caloric testing. Hearing loss is typically profound, and hearing aids are frequently ineffectual as a habilitation option. Accordingly, most persons with USH1 integrate into the Deaf community. Persons with USH2, in contrast, have normal vestibular function and usually have a moderate-to-severe hearing loss. They use hearing aids effectively and communicate orally. Persons with USH3 have progressive vestibular and auditory dysfunction.

Initial visual problems with USH begin as nyctalopia or night blindness. This problem can occur in the preschool years, although visual acuity usually remains good until the third decade. By the fifth decade, 40% of persons with USH are blind; by the seventh decade, this figure increases to 75%.[62,63] Constriction of the visual fields accompanies the loss in visual acuity. Studies of multiplex families have documented considerable intrafamilial variation in the rate and degree of visual deterioration. Electroretinography (ERG) may uncover early retinitis pigmentosa and should be considered in all cases of congenital deafness to identify early USH.[64]

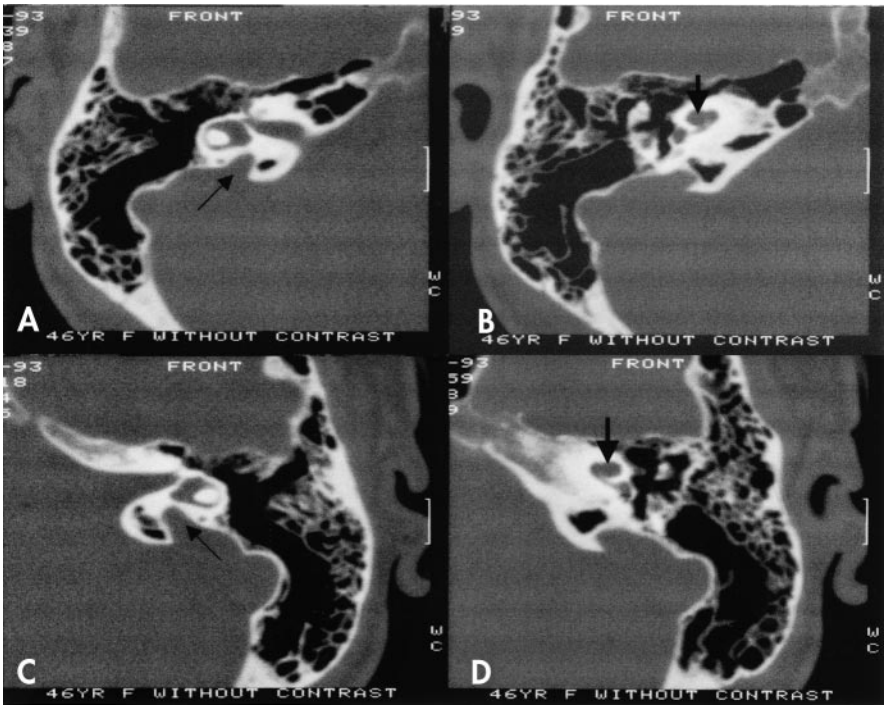

FIGURE 13–5. Axial computed tomograms of temporal bones in a patient with Pendred's syndrome (*A* and *B*, left temporal bone; *C* and *D*, right temporal bone), illustrating dilated vestibular aqueducts (*small arrows*) and Mondini's dysplasia (*large arrows*). The normal two and a half turns of the cochlea are replaced by one and a half turns in Mondini's dysplasia.

Usher's syndrome demonstrates considerable genetic heterogeneity. To date, seven USH1 loci (USH1A-1G), three USH2 loci (USH2A-C), and one USH3 locus have been identified.[65–70] Five of the relevant genes have been cloned, *MYO7A*, *USH1C*, *USH2A*, and *CDH23*, and PCDH1S mutations in which cause USH1B, USH1C, USH2A, and USH1D, and USH1F respectively.[71–73] *MYO7A* is an unconventional myosin expressed mainly in inner and outer hair cells. In the eye, it is localized to microvilli projections in retinal pigmentary epithelial cells and photoreceptor cells. Because there are no mutational hotspots, mutation detection in at-risk families requires considerable work. Mutations in this gene also cause DFNB2 and DFNA11.

The *USH1C* gene encodes a PDZ domain–containing protein called harmonin, which may function as a rafting protein in gating complexes in the stereocilia.[72] Several different mutations have been found in USH1C patients. The *USH2A* gene encodes a protein designated usherin, which has both laminin epidermal growth factor and fibronectin type III domains.[74] The 2299delG-allele variant is the most frequent mutation and is found in about 15% of persons with USH2A. The USH1D gene *CDH23* is a member of the cadherin gene family, and its encoded protein is important for the formation of tight junctions. Mutations in this gene also cause DFNB12.

X-Linked Syndromic Hearing Impairment

Alport's Syndrome Progressive glomerulonephritis, sensorineural hearing loss, and specific eye findings characterize Alport's syndrome (AS), which can be inherited as an X-linked or autosomal disorder. To facilitate diagnosis, four clinical criteria were established in 1988.[75] In the presence of unexplained hematuria, a person can be considered affected if three of the following criteria are met: (1) a positive family history of hematuria or chronic renal failure; (2) electron microscopic renal biopsy evidence of AS; (3) characteristic eye signs of anterior lenticonus, white macular flecks, or both; (4) high-frequency sensorineural hearing loss.

Since light microscopy of renal biopsy specimens is usually normal in children and because findings are nonspecific in adults, electron microscopy is essential. This degree of resolution reveals splitting of segmental areas of glomerular basement membrane, accompanied by thickening and electron-lucent areas containing dense granulations. Serial biopsies demonstrate progressive deterioration.[76] The eye findings characteristic of AS are rarely noted in child-

TABLE 13–5. Clinical Characteristics of Usher's Syndrome

Type	*Hearing Loss*	*Vestibular Response*	*Onset of Retinitis Pigmentosa*
I	Profound HI from birth	Absent	First decade
II	Moderate HI from birth	Normal	First or second decade
III	Progressive HI	Variable	Variable

HI = hearing impairment.

hood and may become apparent only with renal failure. These include anterior lenticonus (conical projection of the anterior surface of the lens), macular flecks, and peripheral coalescing flecks. The progressive myopia caused by anterior lenticonus is considered by some authors to be sufficient to diagnose AS.[77] Hearing loss is postlingual, progressive, and sensorineural.

The typical male with X-linked AS presents with hematuria at age 3 to 4 years, often following an upper respiratory tract infection. Toward the end of the first decade, hearing loss is detectable, and in the mid-teens, hypertension develops. By 25 years of age, over 90% of affected males have abnormal renal function.[76] The clinical course in female carriers is much more variable. Most are clinically asymptomatic through life. Although nearly all have evidence of microscopic hematuria, about one-third will have macroscopic hematuria. One-third will develop hypertension, whereas the risk of chronic renal failure may be as high as 15%.

X-linked AS is caused by mutations in *COL4A5*, a member of the type IV collagen gene family.[78] In a comprehensive review of the type IV collagen mutations, Lemmink and colleagues reported more than 160 different AS-causing mutations in *COL4A5*.[79] The mutation spectrum is broad; about 15% of affected males have large *COL4A5* deletions, and in 30%, a variety of missense and nonsense mutations are found. In many patients, however, no mutations are identified.

Mitochondrial Syndromic Hearing Impairment

Hearing loss may be associated with a number of syndromic mitochondrial diseases. Most frequent are the acquired mitochondrial neuromuscular syndromes and maternally inherited diabetes mellitus associated with deafness.

Kearns-Sayre Syndrome Kearns-Sayre syndrome is a multisystem disorder characterized by progressive ophthalmoplegia, pigmentary retinopathy, cardiac conduction abnormalities, and cerebellar ataxia. It usually presents in the second decade. Mixed hearing loss may be an additional feature.[25]

Maternally Inherited Diabetes and Deafness Studies of diabetic patients from different populations have confirmed an association between diabetes mellitus, sensorineural hearing loss, and mitochondrial mutations.[80,81] The hearing loss and the diabetes are felt to result from an impairment of oxidative phosphorylation. The most frequently found mutation, a 3243 A-to-G transition, is present in 2 to 6% of diabetic patients in Japan.[81] Over 60% of these patients have hearing loss, which usually develops after the onset of their diabetes. The same mutation is also found in MELAS.

MELAS Syndrome (Mitochondrial Encephalopathy, Lactic Acidosis, and Stroke-Like Episodes) MELAS syndrome is a childhood disease characterized by intermittent vomiting, proximal limb weakness, and recurrent cerebral insults that resemble strokes and cause hemiparesis and cortical blindness. MELAS syndrome is frequently associated with short stature. Hearing loss occurs in approximately 30% of affected individuals.[25]

MERRF Syndrome (Myoclonic Epilepsy and Ragged Red Fibers) Myoclonus, epilepsy, and ataxia characterize MERRF. Dementia, optic atrophy, and hearing loss frequently occur. The degree of hearing loss is variable.[25]

NONSYNDROMIC HEARING IMPAIRMENT

Over 70 different nonsyndromic hearing impairment loci have been mapped, and a number of the relevant genes have been cloned. The protein prod-

ucts of these genes include ion channels, membrane proteins, transcription factors, and structural proteins.

Autosomal Dominant Nonsyndromic Hearing Impairment

Autosomal dominant modes of inheritance account for 15% of cases of nonsyndromic deafness (ADNSHI).[82] The typical phenotype is one of postlingual hearing loss that starts in the second to third decades of life and progresses until it is moderate to severe in degree. However, the frequencies that are initially affected vary. For example, DFNA1, DFNA6, DFN14, and DFNA15 are characterized by a low-frequency hearing loss that progresses to involve the remaining frequencies. With other loci, hearing loss starts in the mid- or high frequencies before progressing. The DFNA3, DFNA12, and DFNA23 phenotypes are exceptional as they are congenital hearing losses on which age-related changes become superimposed. Many of the genes for ADNSHI have now been cloned (Table 13–6).[25]

Autosomal Recessive Nonsyndromic Hearing Impairment

Up to 85% of cases of nonsyndromic hearing loss are inherited in a recessive mendelian fashion (ARNSHI).[83] The typical phenotype is more severe than in ADNSHI and accounts for the majority of cases of congenital profound deafness. However, DFNB8 is an exception as it presents as a postlingual progressive hearing loss. To date, 30 ARNSHI loci have been identified and 8 genes cloned (see Table 13–6).[25] The first locus was published in 1994, 6 years after the first X-linked locus and 2 years after the first dominant locus were reported.[84] Three years later, the gene responsible for DFNB1, *GJB2* (gap junction beta 2), was discovered.[85] This gene encodes connexin 26 (Cx26), one of a class of proteins involved in gap junction formation. A group of six connexins oligomerize to form a torus-like structure called a connexon. Two connexons dock to form a transmembrane channel that links neighboring cells and facilitates the exchange of molecules up to 1 kD in size.[86] Immunohistochemical studies have demonstrated Cx26 expression in two groups of cochlear cells, supporting cells in the sensory epithelium and fibroblasts. It is postulated that Cx26 gap junctions allow potassium ions that enter hair cell stereocilia during mechanoelectrical transduction to be recirculated into the stria vascularis.[85,87]

The most significant discovery in the field of genetic deafness to date has been the finding that mutations in Cx26 are responsible for over half of moderate-to-profound congenital deafness in many world populations.[88,89] In certain regions of the Mediterranean, the prevalence may be as high as 79%, although studies in India and Pakistan reveal a much lower incidence.[90,91] Numerous different deafness-causing allele variants have been identified. In the United States and much of northern Europe, the most prevalent mutation is the deletion of a single guanine nucleotide from a sequence of six guanines at positions 30 to 35. Referred to as the 35delG mutation, this shift in codon reading frame results in premature termination of translation.[88] In the midwestern United States, the carrier rate for this mutation is 2.5%, whereas the carrier rate for all deafness-causing Cx26 mutations is 3%.[92] In the Mediterranean population, the carrier rate is even higher and approaches 5%. Other "common" mutations are found in different populations, such as the 167delT mutation in Ashkenazi Jews.[93]

These discoveries have had immediate application to clinical practice. In many populations, a definitive diagnosis can now be made in 50% of cases of suspected hereditary hearing loss. This ability to establish causality affects recurrence risk estimates and makes genetic counseling an important part of the evaluation of hereditary deafness. However, the degree of hearing loss in a child with Cx26-related deafness cannot be used to predict the degree of deafness in another offspring. There can be enough intrafamilial variability to make one affected child a candidate for cochlear implantation, whereas a sibling effectively uses hearing aids[94] (Figure 13–6).

X-linked Nonsyndromic Hearing Impairment

X-linked nonsyndromic hearing impairment is rare and makes up only 1 to 3% of nonsyndromic hearing loss. It exhibits considerable phenotypic heterogeneity, but most affected males have a congenital hearing loss, which can vary from severe to profound. Hearing loss is mild to moderate in carrier females. The losses associated with DFN1 and DFN6 may be progressive.[83]

TABLE 13–6. Nonsyndromic Hearing Impairment Genes Cloned to Date

Locus	*Location*	*Gene*	*Function of Encoded Protein*
DFNA1	5q31	*HDIA1*	Regulates polymerization of actin, a major component of the cytoskeleton of inner ear hair cells
DFNA2	1p34	*GJB3*	Connexin 31, a gap junction protein important for intercellular communication
		KCNQ4	Forms a functional potassium channel; found only in outer hair cells
DFNA3	13q12	*GJB2* *GJB6*	Gap junction proteins important for intercellular communication
DFNA5	7p15	*DFNA5*	Function unknown
DFNA9	14q12-q13	*COCH*	Probable extracellular matrix protein; function unknown
DFNA11	11q12.3-q21	*MYO7A*	Moves actin filaments using actin-activated adenosine triphosphatase, maintains stereocilia integrity; present in inner and outer hair cells
DFNA12	11q22-q24	*TECTA*	Interacts with β-tectorin to form noncollagenous matrix of tectorial membrane
DFNA13	6p21	*COL11A2*	An α-chain polypeptide subunit of type XI collagen, a minor fibrillar collagen; cochlear function unknown
DFNA15	5q31	*POU4F3*	Transcription factors; developmental regulators for determination of cellular phenotypes; expressed only in hair cells
DFNB1	13q12	*GJB2*	As above
DFNB2	11q13.5	*MYO7A*	As above
DFNB3	17p11.2	*MYO15*	Constitute a new class of myosins designated myosin XV; necessary for actin organization in hair cells
DFNB4	7q31	*PDS*	Chloride-iodide transport protein
DFNB9	2p22-p23	*OTOF*	Involved in calcium ion–triggered synaptic vesicle-plasma membrane fusion
DFNB10	21q22.3	*TMPRSS3*	Transmembrane serine protease; cochlear function unknown
DFNB21	11q	*TECTA*	See above
DFN1	Xq22	*DDP*	Probably evolutionarily conserved novel polypeptide necessary for normal human neurologic development
DFN3	Xq21.1	*POU3F4*	Transcription factors; expressed in the mesenchyma of the inner and middle ear

Adapted from Van Camp G and Smith RJH.[25]

Mitochondrial Nonsyndromic Hearing Impairment

Mitochondrial mutations may play a role in age-related hearing loss and have been implicated in a type of nonsyndromic deafness associated with increased susceptibility to aminoglycoside ototoxicity.[95]

Age-Related Hearing Loss Mitochondrial mutations may be a contributing factor to age-related

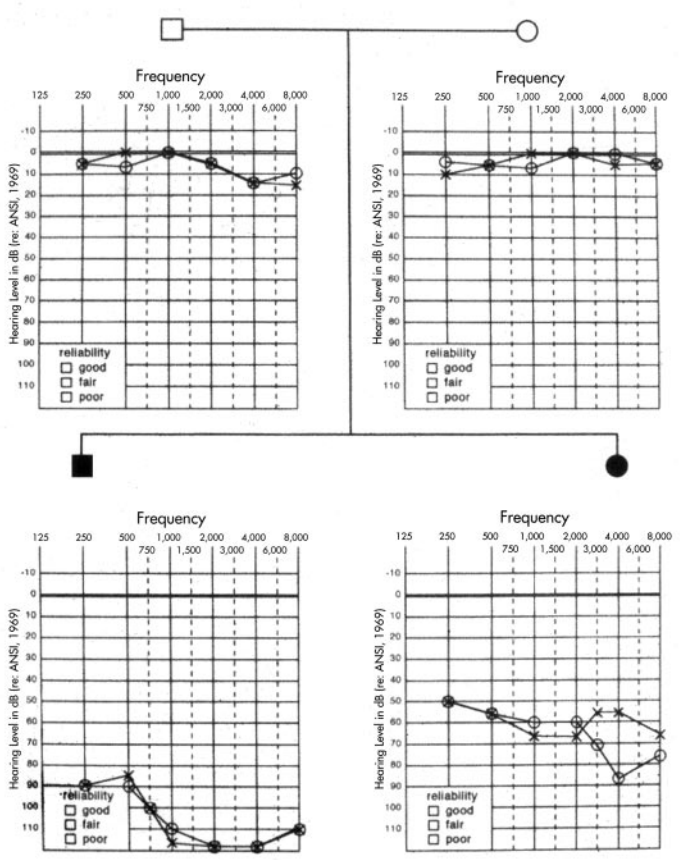

FIGURE 13–6. A pedigree of two siblings homozygous for the 35delG mutation in *GJB2*. Both parents have normal hearing. One sibling exhibits a profound sensorineural hearing loss and the other only a moderate loss.

hearing loss (presbycusis). The number of mutation-carrying mitochondria per cell increases with age, resulting in progressive reduction in oxidative phosphorylation capacity, the impact of which is tissue dependent. Ueda and colleagues detected high rates of mitochondrial DNA deletions in lymphocytes of persons with idiopathic sensorineural hearing loss and noted that the number of deletions increased with increasing hearing loss.[96] They posited that at least some cases of sensorineural hearing loss should be categorized as a mitochondrial phosphorylation disease. Temporal bone studies have also shown an increased load of mitochondrial mutations in persons with age-related hearing loss when compared with controls.[97]

Familial Aminoglycoside Ototoxicity A point mutation at base pair 1555 (adenine-to-guanine) in the 12s ribosomal ribonucleic acid (rRNA) causes both maternally inherited nonsyndromic deafness and maternally inherited susceptibility to aminoglycoside ototoxicity. This mutation makes the 12s rRNA more similar to bacterial rRNA and thus a target for aminoglycoside binding.[98] In countries such as China, where aminoglycosides are used frequently, aminoglycoside-induced ototoxicity is a major cause of hearing loss. One study in Shanghai found that 22% of the profoundly deaf had aminoglycoside-induced ototoxicity.[99] In the United States, over 15% of persons with aminoglycoside-induced hearing loss carry this mutation, a point of major clinical relevance for the prevention of aminoglycoside hearing loss.[100] Based on these data, it is prudent to inquire about any family history of aminoglycoside ototoxicity prior to drug administration. Individuals who develop ototoxicity should be tested for the 1555 mutation and offered family counseling if the mutation is detected.

CLINICAL DIAGNOSIS OF HEARING IMPAIRMENT

History

A complete history is an important element in the diagnosis of hereditary hearing impairment. Directed

questions should focus on prenatal, perinatal, and postnatal history, specifically reviewing maternal illnesses, drug use, alcohol intake, and smoking. Recognized risk factors for hearing loss in the perinatal period include low birth weight, prematurity, time spent in a neonatal intensive care unit, hyperbilirubinemia, sepsis, use of ototoxic medications, and birth hypoxia.[101–104] Risk factors in the postnatal period include viral illnesses such as mumps and measles as well as bacterial meningitis.[105] A record of speech and language milestones can establish whether the hearing loss is pre- or postlingual. However, even deaf infants coo and babble naturally up to the age of 6 months. A history of poor motor development may indicate vestibular dysfunction.

It is important to inquire about hearing loss in first- and second-degree relatives, especially if the loss started before the age of 30 years. Consanguinity or common origins from ethically isolated areas should increase suspicion of hereditary deafness.[106,107] If there are a number of family members with hearing loss, constructing a pedigree may delineate the mode of inheritance.

Physical Examination

Most cases of hereditary hearing impairment are nonsyndromic, so physical findings are absent. However, even in cases of syndromic hearing impairment, physical findings may be subtle. The physical examination should include a general inspection and systematic evaluation of all systems. Note hair color, the presence of a white forelock, facial symmetry, and skull shape. Fundoscopy, eye color, and relative position should be noted, taking specific biometric measurements in suspected cases of WS1. Examine the ears for auricular pits or sinuses and skin tags, noting the shape and size of the pinnae and checking for abnormalities of the external ear canal and tympanic membrane. Check the neck for branchial anomalies and thyroid enlargement and the oral cavity for clefts. Note the number, size, and shape of the digits and complete a thorough inspection of the skin for areas of pigmentation/hypopigmentation and café-au-lait spots. Do a complete neurologic examination, including tests of gait and balance to assess vestibular function.

Audiology

The test of choice for infants and young children with suspected hearing impairment is the auditory brainstem response, which gives accurate hearing thresholds from 1 to 4 kHz.[108] In older children or adults, a standard audiogram can be obtained. The presence or absence of hearing loss in other family members should be documented by formal audiometric testing.

Laboratory Testing

Specific laboratory tests should be ordered on the basis of the history, physical examination, and age of the patient (Table 13–7). For example, if PS is suspected, a perchlorate challenge test can be obtained to detect a defect in thyroid organification of iodide. If AS is being considered, urinalysis should be performed. An electrocardiogram should be ordered and the QT interval calculated if there is a history of syncopal episodes or a family history of sudden infant death syndrome (SIDS), as might be seen with JLNS. Serology can be used to rule out acquired causes of early deafness, such as cytomegalovirus infection, toxoplasmosis, and congenital rubella.

Chromosomal karyotyping is indicated in a child born to parents with a history of miscarriages, when the constellation of anomalies in a child is not recognizable as a previously reported syndrome, or if there are associated central nervous system or cardiac defects. Genetic testing for most of the types of deafness discussed in this chapter is not yet clinically available; however, it is likely that in the next 5 years, many new tests will be offered, making some older tests obsolete.

Radiology

Computed tomography of the temporal bones is the single best radiologic test for the evaluation of hearing impairment, with the reported incidence of anatomic abnormalities ranging from 6.8 to 28.4%.[109,110] Cochlear abnormalities such as Mondini's dysplasia and DVAs suggest the diagnosis of PS, although temporal bone anomalies are also seen with many other syndromes, including TCS and BOR syndrome. If the latter is being considered, renal ultrasonography should be performed.

Other Consultations

An ophthalmologic opinion should be obtained in all children with severe-to-profound hearing impairment as half will have ocular abnormalities.[111]

TABLE 13–7. Evaluation by Age of Onset

Type of Evaluation	*Neonate/Infant*	*Child/Adolescent*	*Adult*
To rule out acquired causes of HI	High-risk register Viral titers Viral cultures (urine, throat) Syphilis serology	Viral titers Syphilis serology	Viral titers Syphilis serology
Audiology and vestibular testing	Impedance testing ABR testing Otoacoustic emissions	Impedance testing Behavioral audiometry Conventional audiometry ABR Balancing testing	Impedance testing Conventional audiometry Cortical evoked response audiometry Electronystagmographic testing
Chromosomal karyotyping	Dysmorphic features History of miscarriage	Dysmorphic features Mental retardation	
Radiology	Temporal bone CT Renal ultrasonography	Temporal bone CT Renal ultrasonography	Temporal bone CT MRI of CP angle if hearing asymmetry
Ophthalmologic testing	Fundoscopy (CMV retinopathy)	Fundoscopy ERG	Fundoscopy ERG
Neurologic tests		Syndromes associated with mental retardation	Ataxia and neuropathies
Cardiac testing	ECG (Jervell and Lange-Nielsen syndrome)	ECG	
Dental evaluation		Osteogenesis imperfecta	
Renal evaluation	Ultrasonography (BOR)	Urine protein (Alport's syndrome) Urine dermatan sulfate, heparin suppurate (mucopolysaccharidoses)	Urine protein Ultrasonography

HI = hearing impairment; ABR = auditory brainstem response; CT = computed tomography; MRI = magnetic resonance imaging; CP = cerebellopontine; CMV = cytomegalovirus; ERG = electroretinography; ECG = electrocardiography; BOR = branchio-oto-renal syndrome.

Although most of these abnormalities are refractive errors, the correction of which is essential, ERG may uncover signs of early retinitis pigmentosa. Referral to a clinical geneticist should be requested to ensure that parents and patients adequately understand the issues such as recurrence risk.

MANAGEMENT OF HEARING IMPAIRMENT

Early identification of hearing impairment in infants and young children and early rehabilitation are essential for the development of age-appropriate speech and language skills. Children whose hearing losses are identified and in whom intervention is instituted before 6 months of age show significant advantage in communicative skill development compared with infants identified later.[112] To achieve this goal, newborn hearing screening programs have been implemented in most states and linked to rehabilitative programs. The level of habilitative intervention that is required depends on the degree of hearing impairment. Counseling of the family, proper hearing aid selection, hearing aid fitting, and continued

audiologic assessment are important. Schools that teach sign language, oral-aural communication, and a combination of both may be necessary. Cochlear implantation may be an option in persons with severe and profound hearing impairment.[113]

A variety of support systems exist, particularly on the World Wide Web. In the United States, the National Institute on Deafness and Other Communication Disorders established the Hereditary Hearing Impairment Resource Registry (HHIRR) (<www.boystown.org/hhirr>) to disseminate information on hearing impairment to professionals and families. The registry also collects information from individuals interested in supporting and participating in research projects and lists relevant resources and links to other organizations.

FUTURE DEVELOPMENTS

The rapid advances in the genetics and molecular biology of hearing and deafness that occurred during the last decade of the twentieth century are continuing at pace. Inexpensive genetic tests are becoming available for early detection of hearing impairment, and the use of these tests will ultimately impact management decisions by better defining therapeutic and habilitative options. It is also becoming increasingly possible to identify individuals at risk for environmental damage (noise, drugs, age) to their hearing. In the next decades, it is likely that physicians will be able to offer patients new, practical, and effective treatments for sensorineural hearing impairment.

CHAPTER 14

Trauma to the Middle Ear, Inner Ear, and Temporal Bone

Mitchell K. Schwaber, MD

EXTERNAL AUDITORY CANAL

Two types of injury are likely to involve the external auditory canal: blunt and penetrating trauma and thermal and caustic burns.

Isolated blunt trauma to the ear canal is most often caused by the insertion of a foreign object into the ear to scratch the skin or to remove wax. The skin of the ear canal, particularly the anterior and inferior part of the canal, is quite thin, with a minimal subepithelial layer. The tender skin of this portion of the canal is easily abraded and will bleed readily, particularly if the patient is on anticoagulant or antiplatelet therapy. In most instances, the pain and the sight of blood from the ear canal cause the patient to seek medical attention. In some cases, however, a secondary infection develops, and pain, hearing loss, or infected drainage causes the patient to seek help. The canal should be gently cleaned using microscopic technique, and blood clots, debris, and wax should be removed. When the bleeding site has been identified, placing a small pledget of Gelfoam coated with antibiotic ointment over it can readily control the bleeding. Alternatively, Gelfoam soaked with topical thrombin can be applied to the bleeding site. In rare cases, the site must be cauterized and then packed with a Merocel wick. In contrast, the skin of the posterosuperior part of the canal is much thicker and is more resistant to abrasions and injuries. Posterior lacerations usually stop bleeding because the subepithelial layer is more developed; therefore, vessels in this area readily contract and clot off.

After microscopic cleaning of the canal, the tympanic membrane should be inspected to determine the extent of injury. If an injury to the middle ear or temporal bone is discovered in this process, a complete neurotologic examination should be performed to evaluate the patient. Audiometric assessment is also obtained at this point to assess the function of the ossicular chain and the cochlea. Radiographs are not usually indicated unless an extremely severe injury is found. Ciprofloxacin and hydrocortisone otic drops are prescribed to prevent infection and to dissolve the Gelfoam pack.

Blunt injuries to the temporal bone typically result from the head being forced against a stationary object in a deceleration injury or from an object being thrown directly at the head. Most injuries involving this region occur as a result of a glancing blow to the temporal region. Although soft tissue injuries to the auricle and canal occur, they are often accompanied by fractures of the external auditory canal, middle ear structures, otic capsule, or surrounding structures. Mandibular injuries, particularly those that drive the mandible posteriorly into the jaw joint, will occasionally fracture the anterior wall of the ear canal, resulting in laceration of the skin and exposure of bone. Following blunt trauma to the ear and temporal bone, the external auditory canal should be carefully cleaned and bleeding controlled as described earlier. If exposed bone is found, it should not be débrided at this point but rather assessed later when the canal has healed. Radiographs, including facial bone computed tomographic (CT) scans and pantomographic mandibular views, should be obtained in these patients to define the injuries. Occasionally, a direct blow to the auricle results in an isolated fracture of the external auditory canal and mastoid process, that is, a fracture not involving the deeper parts of the temporal bone that are in contact with the dura mater. Regardless of where the fracture has occurred, the clinician should be aware that squamous cell epithelium can be entrapped by the fracture fragments, leading to the development of a canal

cholesteatoma. Canal fractures can also lead to chronic infection, bone sequestration, and stenosis of the canal. The development of any of these sequelae may necessitate surgical débridement, grafting, reconstruction, or meatoplasty to ensure a healthy open ear canal.

Penetrating injuries of the external auditory canal are usually caused by gunshot or stab wounds. Penetrating injuries in which the missile enters anteriorly through the parotid gland often involve the external auditory canal; the mechanism is thought to involve dissipation of the missile's energy on and reflection of the missile off the anterior aspect of the mastoid process. Other factors that influence the injury include the force and trajectory of the missile and, if a bullet, its type, hardness, and caliber. As a consequence, facial nerve injury, tympanic membrane perforation, and ossicular dislocation can result from gunshot wounds of the external auditory canal even when the apparent course of the missile would not traverse these structures (Figure 14–1). The facial nerve is most likely to be injured at the stylomastoid foramen apparently because it is relatively fixed at that point. In the absence of any of these additional injuries, gunshot wounds of the ear canal require cleaning, a light dressing, and prophylactic antibiotics. Occasionally, the canal must be stented following a gunshot injury, and in this case, a soft Merocel wick coated with ciprofloxacin and hydrocortisone otic drops is usually satisfactory.

Lacerations of the external auditory canal can occur either anteriorly or posteriorly and are often accompanied by partial avulsion of the auricle. These patients should be carefully evaluated for injury to the facial nerve and the great vessels; radiographic studies including arteriography may be indicated in these patients. Most external auditory canal lacerations require cleaning, gentle débridement, and suturing to realign the various parts of the ear canal and auricle. Surprisingly, stenosis does not usually occur in these patients.

Burns and caustic injuries to the ear canal often represent a potentially complicated situation in that severe burns can lead to circumferential scarring and stenosis of the canal. Most of these injuries are attributable to one of three mechanisms: a thermal burn, a caustic burn, or a welding injury. Thermal and caustic burns of the ear canal are usually associated with additional injury to the auricle, which may in itself lead to loss of cartilage, cicatrix formation, and stenosis of the canal. Most thermal burns of the ear canal are caused by flash injuries, fires, lightning strikes, or hot liquids such as oil. Like burns elsewhere on the body, the depth and extent of the burn should be determined and documented. Superficial thermal burns of the ear canal are usually treated with the application of antibiotic ointment. If more than half of the ear canal is involved or has third-degree burns, in addition to the application of antibiotic ointment, the canal is stented with soft Silastic tubing. Canal stenting is performed in an effort to prevent stenosis of the canal, which leads to the trapping of squamous debris and ultimately a destructive ear canal cholesteatoma. Stenosis of the canal is treated aggressively with corticosteroid injections, frequent dilations, and, in some cases, skin grafting or even meatoplasty.

Caustic burns are usually caused by a chemical spill or a foreign object such as an alkaline battery. Thermal and acid burns cause coagulation necrosis, whereas alkaline burns cause liquefaction necrosis, which leads to much more extensive injury over time. Kavanagh and Litovitz reported a series of battery-related injuries to the ear canal that were much more frequent and severe than expected, including tympanic membrane perforation, exposed bone of the ear canal, sensorineural hearing loss, ossicular destruction, and facial paralysis.[1] They also noted that otic drops must be withheld in these patients as they provide an external electrolyte bath for the battery, enhancing leakage and generation of an external current with subsequent tissue electrolysis and hydroxide formation. The foreign body should be removed as soon as possible, under general anesthesia if needed.[2] Once the injury has been assessed, caustic burns are treated much like thermal burns described earlier, with microscopic cleaning, antibiotic eardrops, and stenting if indicated. Because of the high incidence of exposed bone, skin grafting of the ear canal is often indicated in these patients. Skin grafting, tympanoplasty, and ossicular reconstruction should be delayed for 4 to 6 months, if possible, to allow the full extent of the injury to be determined.

Welding injuries occur when hot slag or molten metal enters the meatus, usually resulting in either a small and localized burn of the ear canal or a tympanic membrane perforation. In most patients, microscopic cleaning, ciprofloxacin and hydrocortisone otic drops, and observation are the only meas-

ures indicated for welding injuries of the external auditory canal.

TYMPANIC MEMBRANE AND THE MIDDLE EAR

Trauma to the tympanic membrane and the middle ear can be caused by (1) overpressure, (2) thermal or caustic burns, (3) blunt or penetrating injuries, and (4) barotrauma. *Overpressure* is by far the most common mechanism of trauma to the tympanic membrane. The major causes of overpressure include slap injuries and blast injuries. Slap injuries are extremely common and can be a result of either a hand or water slap. Slap injuries usually result in a triangular or linear tear of the tympanic membrane (Figure 14–2). Most of these perforations cause mild hearing loss, aural fullness, and mild tinnitus. Blast injuries, although much less common, are potentially much more serious. Blast injuries may be caused by bomb explosions, gasoline explosions, and air-bag deployment in automobile accidents. Blast injuries from bomb explosions not only disrupt the tympanic membrane but also can cause temporal bone fracture, ossicular discontinuity, or high-frequency sensorineural hearing loss owing to cochlear injury. In addition, blast injuries can cause a perilymphatic fistula (PLF), with progressive and fluctuant hearing loss, vertigo, and dysequilibrium.

In a report by Hallmo, air- and bone-conduction audiometry in the frequency ranges of 0.125 to 18 kHz and 0.25 to 16 kHz, respectively, was performed on 38 patients with unilateral traumatic tympanic membrane perforation, mostly caused by overpressure injuries.[3] Bone-conduction threshold elevations were found in 16 ears. Both bone-conduction threshold elevations and tinnitus diminished with time, but in 9 patients it was permanent. Closure of the tympanic membrane perforation resulted in a 7 to 20 dB improvement of air-conduction thresholds, somewhat less in the upper than in the lower frequencies. A 3 dB mean final conductive hearing loss was found approximately 5 months after injury, probably owing to scars at the sites of the former perforations.

Following an overpressure injury, blood, purulent secretions, and debris should be carefully suctioned from the ear canal, and the perforation size and location should be recorded. Irrigation and pneumatic otoscopy should be specifically avoided in these patients. The ability to hear a whisper as well as tuning fork tests should be documented, and an audiogram should be obtained as soon as the patient's condition allows. A complete neurotologic examination should also be performed in these patients to document the status of the cranial nerves

including the facial nerve and the vestibular nerve as well as the central nervous system. If the tympanic membrane perforation is dry, it should be observed (ie, drops are not indicated). If there is drainage through the tympanic membrane perforation, the clinician should determine and note if the drainage is consistent with cerebrospinal fluid (CSF). If a CSF leak is suspected, immediate CT scan of the temporal bone should be obtained to rule out a fracture. If the drainage is not consistent with CSF, oral antibiotics and ciprofloxacin and hydrocortisone otic drops should be prescribed. A history of vertigo or nausea and vomiting and an audiogram showing a conductive hearing loss of more than 30 dB suggest disruption of the ossicular chain. Profound sensorineural loss also may signify oval window or cochlear damage.

Thermal injuries to the tympanic membrane include welding and lightning injuries. Welding injuries occur when hot slag enters the ear canal and passes through the tympanic membrane. Most of these injuries result in an inflammation in the middle ear with drainage. Panosian and Dutcher reported two patients with facial paralysis caused by hot slag in the middle ear.[4] One of their patients also sustained a sensorineural hearing loss. Welding injuries often result in nonhealing perforations, either as a result of infection or possibly because the slag acts to cauterize or devascularize the tympanic membrane as it passes through it. If infection occurs, the patient is treated with ciprofloxacin and hydrocortisone otic drops and an oral antibiotic. If the perforation is dry, it should be observed for a period of 12 weeks for spontaneous healing. If the drumhead does not heal, tympanoplasty should be performed.

Lightning and electrocution injuries are not rare, and the most frequent ear injury is perforation of the tympanic membrane. The most common vestibular disturbance is transient vertigo. Other clinical findings include sensorineural hearing impairment, conductive hearing loss, tinnitus, temporal bone fracture, avulsion of the mastoid process, burns of the ear canal, and facial nerve paralysis.[5] Jones et al reported one patient with bilateral oval window PLF following a lightning strike.[6] The initial management of the patient struck by lightning consists of life support measures. Thereafter, the patient should have a thorough audiovestibular assessment. Tympanic membrane perforations caused by lightning injury often do not heal, perhaps as a result of cauterization or devascularization of the tympanic membrane, much like welding injuries. These injuries are treated much like that described earlier for welding injuries. Tympanoplasty should be delayed in these patients for 12 weeks because spontaneous healing may take that long.

Caustic injuries to the tympanic membrane can cause a perforation. With alkaline caustics, the tympanic membrane is damaged by liquefaction necrosis, that is, the alkaline caustic penetrates the tympanic membrane, causing occlusion of the vasculature that may extend farther than the visible perforation. As a result, the size of the perforation may not be fully appreciated until all of the inflammation resolves. Furthermore, after caustic injuries, the middle ear can develop an extensive granulation reaction with scarification, ossicular fixation, and a chronic infection. Caustic injuries also can lead to canal blunting as the raw surfaces that surround the canal form a cicatrix, leading to narrowing of the ear canal and loss of the vibratory surface of the tympanic membrane. Similarly, following a caustic injury, chronic myringitis can develop on the surface of the tympanic membrane, creating a raw weeping surface with granulation on the surface of the drumhead. Caustic injuries are initially treated with ciprofloxacin and hydrocortisone otic drops, oral antibiotics, and analgesics. Audiologic assessment and a complete neurotologic evaluation are indicated in caustic injuries to determine the extent of injury. When the ear has stabilized, and preferably when drainage has diminished, the middle ear and tympanic membrane can be reconstructed.

Tympanic membrane perforations historically have a healing rate that approaches 80%. Kristensen reviewed more than 500 texts regarding the matter and found that the spontaneous healing rate appeared to be 78.7% in 760 evaluable cases of traumatic tympanic membrane perforations of all sorts seen within 14 days after injury.[7] A relative, causally related variation of spontaneous healing could be demonstrated in this review, with air pressure/hand slap injuries the most likely to heal. Ruptures induced by heat or corrosives, foreign objects, and water pressure were less likely to heal, perhaps because they were larger or more likely to be infected. Rybak and Johnson also reported that water slap injuries were less likely to heal as a result of infection.[8]

Griffin reported 227 traumatic perforations treated in his practice from 1969 to 1977.[9] He concluded that larger perforations, lightning and welding injuries, and infected ears were less likely to heal. Good hearing results were found regardless of the method of tympanoplasty, although spontaneous healing resulted in the best hearing outcome.

Regardless of the method used, successful tympanoplasty requires adequate exposure, débridement of middle ear granulation and scar tissue, de-epithelialization of the perforation, and careful graft placement including support of the graft until healing occurs. The author prefers to perform transcanal underlay tympanoplasty only on small perforations confined to the posterior portion of the tympanic membrane. In this circumstance, perichondrium harvested from the tragus is most often used as a graft material because of ease of handling and access. In larger perforations or perforations that extend anterior to the malleus, the author prefers to perform postauricular underlay tympanoplasty, using temporalis fascia as the graft material. In this technique, large "swinging door" flaps, based on the canal skin and normal tympanic membrane, are created. These flaps can be advanced to cover the entire mesotympanum if needed, a technique that is particularly useful in welding injuries as the adequacy of the vasculature of the residual drumhead may be uncertain. More information regarding tympanoplasty can be found in Chapter 10.

Penetrating trauma to the middle ear can, of course, result in perforation of the tympanic membrane, but unlike overpressure and thermal injury, the incidence of ossicular disruption, facial nerve, and other middle ear injuries is much greater. The most common causes are low-velocity gunshots followed by injury with a foreign object such as a stick or instrument. This type of injury should be suspected in patients with a tympanic membrane perforation, blood in the middle ear or ear canal, and the presence of vertigo or dizziness, a conductive loss greater than 25 dB, a sensorineural hearing loss, or a facial paralysis. In these patients, the ear canal should be gently suctioned and cleaned under microscopic vision, and the tympanic membrane and middle ear should be carefully inspected. A complete neurotologic examination, including facial nerve evaluation and examination for nystagmus, gait stability, fistula test, Romberg's test, and Dix-Hallpike test, should be performed. Imaging studies including CT scans of the temporal bone, magnetic resonance imaging (MRI), and even arteriography may be indicated depending on the type of injury suspected.

TEMPORAL BONE FRACTURES

Fractures of the temporal bone are caused by blunt injuries, and depending on the force and direction of the blow delivered, different types of fractures occur. Blunt trauma can be delivered by an object striking the head or by the head being thrown against a solid object. Traditionally, temporal bone fractures are classified as either longitudinal (extracapsular) or transverse (capsular) with respect to the long axis of the petrous portion of the temporal bone (Figure 14–3). Both are basal skull fractures and are associated with ecchymosis of the postauricular skin (Battle's sign).

Longitudinal fractures are, by far, the most common, accounting for 70 to 90% of temporal bone fractures, and typically result from a direct lateral blow to the temporal or parietal aspect of the head. The longitudinal fracture begins in the external auditory canal and extends through the middle ear and along the long axis of the petrous pyramid. Characteristically, there is bleeding from the ear canal owing to laceration of its skin and from blood coming through the perforated tympanic mem-

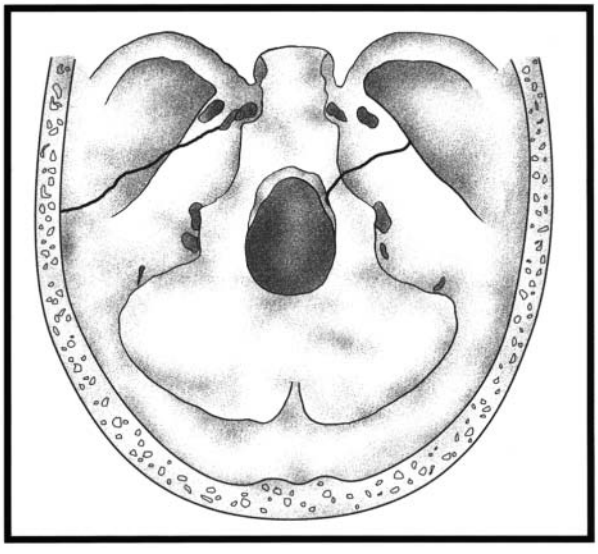

FIGURE 14–3. Drawing depicts the anatomy of the skull base. On the left is a longitudinal or extracapsular fracture. On the right is a transverse or capsular fracture.

brane. Facial paralysis occurs in 15%, and sensorineural hearing loss occurs in 35%.

Transverse fractures typically result from deceleration impacts in the occipital area. The fracture line transverses the long axis of the petrous portion of the temporal bone and usually extends through the cochlea and fallopian canal, resulting in sensorineural hearing loss and facial paralysis in most cases. There is bleeding into the middle ear, but the tympanic membrane remains intact and becomes blue-black owing to the hemotympanum.

Post-traumatic Ossicular Chain Disruption

Post-traumatic ossicular chain abnormalities include incudostapedial joint separation, dislocation of the incus, fracture and dislocation of the stapes, massive dislocation of the entire chain, and ossicular fixation owing to scarring or ossification. Incudostapedial joint separation is the most common ossicular abnormality and is more often seen with penetrating trauma as well as longitudinal or extracapsular temporal bone fractures (Figure 14–4). The forces that cause this type of fracture occur parallel to the long axis of the temporal bone and tend to displace the malleus and incus medially and inferior. As a consequence, incudostapedial joint separation is most common with longitudinal fractures, followed by dislocation of the incus. In patients in whom significant conductive hearing loss (ie, greater than 25 dB) is found, incudostapedial joint separation or incus dislocation should be suspected. In patients in whom mixed hearing loss is found or significant vertigo occurs, a fracture or dislocation of the stapes should be suspected. In this situation, the force may have sheared the crura off the footplate, or the entire stapes may be dislocated (Figure 14–5). This distinction is important in management in that incus subluxation or incudostapedial joint separation can be observed once the hemotympanum and swelling have resolved. In most cases, because of the tendency of the drumhead to adhere to the stapes, the residual conductive hearing loss is minimal after healing and requires no surgery. On the other hand, stapes dislocation with vertigo and/or progression of the sensorineural hearing loss is an indication for timely surgical exploration and repair to prevent anacusis.

If a significant conductive hearing loss is found after resolution of the hemotympanum and ventilation of the middle ear, the patient should be offered hearing rehabilitation either through surgery or the use of a hearing aid. Middle ear surgery in this case is usually performed through a transcanal approach, although a postauricular approach may be indicated if a large fracture or canal defect is present. After elevating a tympanomeatal flap, the middle ear and the ossicles are carefully visualized. Fibrous adhesions should be carefully dissected, and the fragility of the stapes should be respected. One of four procedures is used to correct the ossicular abnormality.

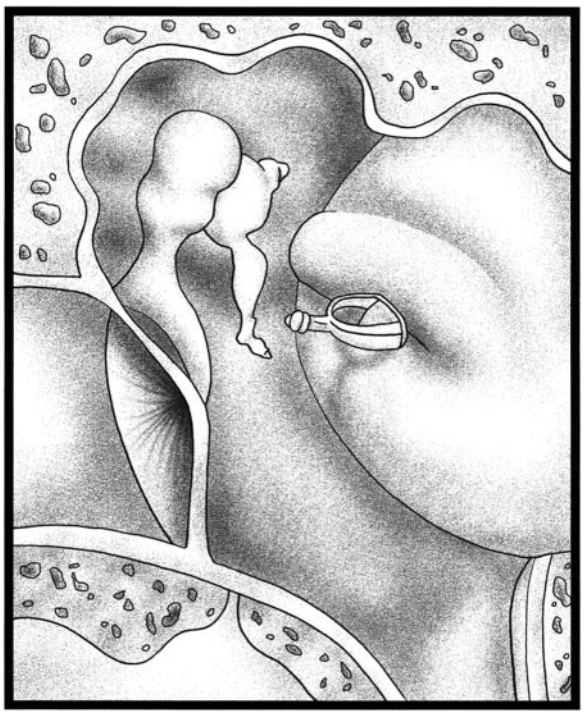

FIGURE 14–4. Drawing depicts incudostapedial joint disarticulation. Note that the incus is displaced inferiorly.

In the vast majority of patients, the incus is so displaced that it cannot be used efficiently. In these patients, the surgeon may choose to place a partial ossicular replacement prosthesis (PORP), linking the stapes directly to the drumhead. In these patients, the incus and the malleus handle must be removed, and the PORP is attached to the stapes capitulum and then covered with a thin wafer of cartilage (Figure 14–6, A). Alternatively, the surgeon may choose to link the stapes to the malleus, using either a commercially available prosthesis or a sculpted incus. These two techniques give comparable results, usually resulting in a 15 to 20 dB air–bone gap. In

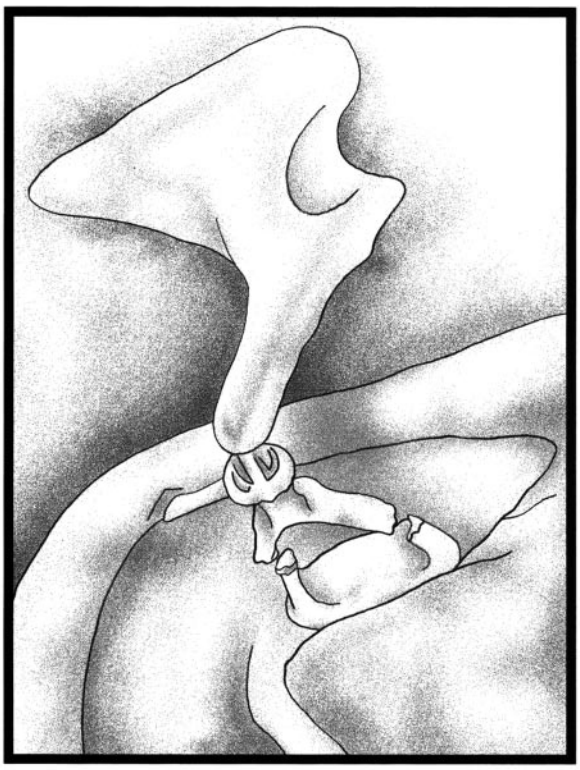

FIGURE 14–5. Drawing illustrates fracture through the stapes superstructure. In this case, the footplate is not displaced.

some cases, the surgeon may choose to place a total ossicular replacement prosthesis (TORP), with an intact stapes. This type of placement offers greater stability for the prosthesis, which can be placed between the tympanic portion of the facial nerve canal and the superstructure of the stapes (Figure 14–6, B). A small perichondrial graft placed on the footplate between the crura further stabilizes this assembly, as does linking the prosthesis to the malleus. Like the PORP technique, a thin wafer of cartilage should be placed over the TORP to link it to the drumhead.

Of course, a TORP can be used in patients in whom the stapes superstructure is disrupted or fractured. In these patients, the incus and malleus may not be usable because the displacement is so great or they are damaged. The stapes footplate should be covered with a perichondrial graft to stabilize the TORP and to ensure that any footplate fractures are covered. The TORP is placed on the perichondrial graft and linked to the tympanic membrane. In some patients, the stapes superstructure is damaged or the footplate is disrupted, in the presence of an otherwise normal malleus and incus. In these patients, a stapes prosthesis can be used. The first step in this circumstance is to ensure that a depressed stapes is carefully elevated out of the vestibule. Aggressive manipulation should be avoided, as should excessive suctioning. If the stapes can be restored to a more normal position, it can be reinforced with small bits of perichondrium and fibrin glue. Once the stapes footplate is in a satisfactory position, it is covered with perichondrium, and a stapes prosthesis can be linked from the incus to the footplate or from the malleus to the footplate. This technique should closely resemble the standard one used for otosclerosis except that the footplate is not removed. The prosthesis should be slightly shorter than in the standard situation because of the intact footplate. Although the author prefers to use a thin stemmed bucket-handle prosthesis in these patients, a crimped piston is also certainly appropriate.

Post-traumatic Perilymphatic Fistula

Severe head trauma, whether blunt or penetrating, is associated with a high incidence of sensorineural hearing loss. Nearly one-third of these patients develop a high-frequency hearing loss, which is thought to arise from a cochlear concussion, shearing of the basilar membrane, hair cell degeneration, and avulsion of auditory nerve fibers. Excessive stapes footplate excursion can also cause this same pathophysiologic consequence, so differentiating a concussion from a PLF can be difficult. Traumatic PLF can result from penetrating trauma with resultant fracture or subluxation of the stapes, from an overpressure injury such as a blast or a severe barotrauma event, or from a fracture of the temporal bone. The mechanics of these injuries are consistent with the implosive mechanism described by Goodhill.[10]

A PLF is a persistent, abnormal communication between the inner ear and the middle ear air space. In most cases, this communication occurs through the oval or round windows, although, occasionally, a fistula through a semicircular canal is discovered. As opposed to a cochlear concussion, the hearing threshold in PLF cases continues to fluctuate or to deteriorate. Tinnitus and fullness are also common complaints of these patients. However, the features that differentiate a PLF from a labyrinthine concussion are episodic vertigo, movement-trig-

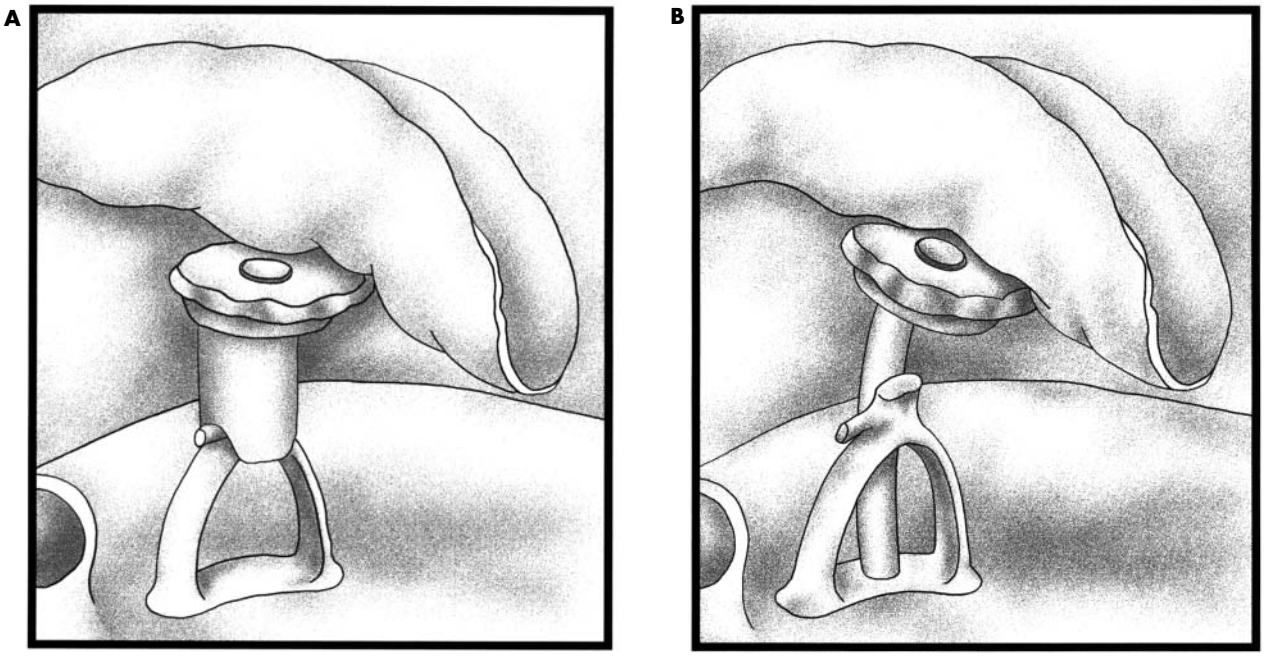

FIGURE 14–6. A, Drawing depicts the placement of a partial ossicular reconstruction prosthesis. *B,* Drawing depicts the placement of a total ossicular reconstruction prosthesis with an intact stapes superstructure. This technique provides better stabilization of the prosthesis, particularly if a graft is placed on the footplate.

gered vertigo, persistent unsteadiness, and often nausea. The vertigo in these patients lasts several minutes up to several hours. In the setting of trauma, with progressive hearing loss and episodic vertigo, a PLF should be suspected. The clinician should remember that there are no specific patterns to diagnose conclusively a PLF.

The evaluation of patients suspected of having PLF begins with a history and examination. The type of trauma suffered and the degree of injury are important features of the history. Also, the precipitating factors that lead to vertigo should be noted including ear manipulation, straining, and head positioning. Antecedent events such as increased tinnitus, ear fullness, or hearing fluctuation prior to vertigo are also significant. On examination, hemorrhage, laceration, and tympanic membrane perforation are all signs that point to the possibility of a PLF. In performing the neurotologic examination, special attention should be given to the evaluation for spontaneous nystagmus, an abnormal Romberg's test, a positive fistula sign, a positive Dix-Hallpike sign, an unsteady gait, or an abnormal step test. Audiometric assessment may show a mixed hearing loss or a pure sensorineural hearing loss. Additional audiovestibular testing is not usually obtained unless the drumhead and canal have healed, in which case an electronystagmographic (ENG) or a computerized dynamic posturographic test can add support for the abnormal physical examination findings. In addition, imaging studies should be reviewed with the radiologist to determine if a temporal bone fracture or some unsuspected central nervous system injury has occurred. In most cases, however, unless ossicular disruption is particularly severe, a PLF is not usually detected through imaging studies.

If a PLF is suspected, bed rest, corticosteroids, and even diuretics can be tried for a period of 2 to 3 days to determine if spontaneous healing might occur. If symptoms persist, the middle ear should be explored as soon as the patient's condition allows. Altered mental status and other injuries might delay middle ear exploration for a significant period of time, unfortunately. The middle ear in these patients can be explored either through a postauricular or transcanal approach, obtaining either temporalis fascia or tragal perichondrium for the repair. After elevating the tympanomeatal flap, the middle ear structures are carefully visualized and the necessary dissection is performed to visualize the stapes foot-

plate and the round window niche. A subluxed stapes should be carefuly elevated, as previously described, and secured in position using perichondrium and fibrin glue. If the oval window is indeed intact, the surgeon should carefully inspect the round window niche and membrane. At this point, several maneuvers are performed to visualize a PLF, including Trendelenberg positioning, neck compression, and Valsalva-like maneuver administered by the anesthesiologist. A PLF is likely present if fluid emanates from the oval window or pools in the round window niche with these maneuvers. Whether or not a PLF is found, most authors apply a soft tissue patch to the round and oval windows at this point. This should be done carefully to line the windows with tissue, not invaginate the tissue into the vestibule or the scala tympani. The soft tissue grafts are reinforced with Gelfoam, and the tympanomeatal flap is returned to its normal position. The canal is filled with antibiotic ointment or Gelfoam. Rest and avoiding heavy lifting are recommended for 5 to 7 days to allow the tissue seal to solidify. Following PLF repair, the episodic vertigo significantly improves in the vast majority of patients. However, the hearing results are much less predictable as only 15 to 20% of patients demonstrate substantial hearing improvement. The hearing threshold is usually stabilized, however.

Post-traumatic Vestibular Dysfunction

The most common type of post-traumatic vestibular dysfunction, by far, is benign paroxysmal positional vertigo (BPPV). This occurs in 50% of patients with temporal bone fractures and in 25% of patients with a head injury without fracture. In this circumstance, the dizziness usually begins within a few days of the injury, although it can be delayed for several months. Post-traumatic BPPV is thought to occur because deceleration forces disrupt the macula of the utricle, with release of the otoconia that ordinarily rest in a gel layer that covers the surface of the macula. The otoconia float into a dependent canal, most often the posterior semicircular canal, but the problem has been described in other canals. This mechanism is commonly called canalithiasis. The shifting of the mass of otoconia actually displaces the fluid in the canal on head tilting. As a consequence, a short burst of vertigo occurs, with a typical 5- to 7-second delay, lasting 20 to 30 seconds. Typically, post-traumatic BPPV is unilateral and is triggered by placing the affected ear in the down position. This condition can be diagnosed by performing a Nylen-Bárány or Dix-Hallpike maneuver and observing the nystagmus that is triggered. Although this should ideally be performed with Fresnel's glasses, the nystagmus can be observed without them in the vast majority of patients. Typically, in this maneuver, the nystagmus has a rotary motion, either clockwise or counterclockwise, toward the down and affected ear. Untreated, this condition usually lasts 3 to 4 months and gradually resolves. Treatment consists of vestibular suppressants such as alprazolam 0.50 mg or clonazepam 0.50 mg given twice daily in addition to antinauseants such as meclizine or promethazine as needed. Treatment also consists of vestibular rehabilitation or physical therapy, specifically using particle-repositioning maneuvers such as the modified Epley[11] or Semont[12] maneuver. In approximately 80% of patients, the symptoms are immediately alleviated by this method of treatment.

Post-traumatic vestibular dysfunction can also be caused by shearing of labyrinthine membranes as a result of concussive forces. In this circumstance, the patient may complain of chronic unsteadiness rather than true vertigo. In these patients, the nature of the injury should be carefully investigated with ENG as well as with computerized dynamic posturography. A vestibular deficit on either study adds support for this diagnosis as opposed to a postconcussion syndrome. In cases of chronic unsteadiness, a program of vestibular rehabilitation therapy, as well as low doses of clonazepam, can be extremely helpful. Unfortunately, since many of these cases follow automobile accidents, litigation issues often cloud the exact severity of symptoms.

Post-traumatic vestibular dysfunction also occurs after transverse temporal bone fractures. With a transverse fracture, a severe episode of vertigo occurs, which gradually improves, much like a patient who has undergone a labyrinthectomy. Following a transverse temporal bone fracture or a severe disruption of the stapes with total loss of hearing, the labyrinth repairs itself by a process called labyrithitis ossificans. This process is slow and takes several months before the semicircular canals ultimately ossify. Complete ossification, in effect, fixes the ampullae and maculae in solid bone so that they no longer respond to movement. If the vestibule or the posterior canal does not completely

ossify, symptoms such as movement-triggered vertigo or positional vertigo can be noted in addition to constant unsteadiness. Electronystagmographic examination usually reveals spontaneous nystagmus and absent caloric responses in patients with transverse fractures of the temporal bone. In symptomatic patients, caloric excitability and positional nystagmus indicate residual function in the traumatized labyrinth. In these rare patients, a case can be made for a transmastoid labyrinthectomy to eliminate all vestibular function.

Post-traumatic vestibular dysfunction can also occur if the central portion of the vestibular system is injured, such as that seen with cerebellar injury, brainstem nuclei injury, or even vestibular nerve avulsion. It should be noted here that these types of injuries nearly always involve multiple cranial nerve injuries, widely varied neurologic dysfunction, and prolonged unconsciousness following the injury. Careful evaluation with audiovestibular testing can determine if a predominantly central vestibular injury has occurred, as might be suggested by eye tracking abnormalities on ENG in the presence of normal symmetric caloric tests or abnormal auditory brainstem testing with normal otoacoustic emissions. Treatment considerations in these patients might include vestibular rehabilitation therapy, special glasses, and antinauseants.

Post-traumatic Cochlear Dysfunction

In addition to PLF, sensorineural hearing loss following trauma can be attributable to a variety of mechanisms including fracture of the otic capsule, concussion of the inner ear without fracture, noise- or blast-induced injury, and central auditory pathway injury. Transverse fractures of the temporal bone usually cross the vestibule or the basal turn of the cochlea, resulting in total, sudden sensorineural hearing loss. The exact nature of the loss remains a matter of conjecture, that is, it is possibly caused by loss of fluid mechanics, hair cell dysfunction, or vascular injury to the cochlea. It does not appear that most transverse temporal bone fractures result in significant cochlear neuronal injury. This is based on the information that three of four cochlear implants performed in the United States on patients with transverse fractures are functioning extremely well.

It is common to find high-frequency sensorineural hearing loss following head injury with or without fracture, blast injuries, and extreme noise exposure (ie, transient noise louder than 120 dB). These three mechanisms affect the cochlea in a similar fashion. Most often the hearing loss centers around 4 kHz, although more severe injuries can certainly affect all of the frequencies. According to Schuknecht, concussive forces on the cochlea result in a pressure wave that damages the outer hair cells in the basal turn of the cochlea, features identical to those seen with noise-induced hearing loss.[13] Alternatively, deceleration, blast injuries, and extreme noise transmit forces to the stapes footplate that result in disruption of the basilar membrane and the organ of Corti, with resultant degeneration of the spiral ganglion of the cochlea. Some common causes of this type of injury include air-bag detonation in automobile accidents, gunshot blasts, and loud music speakers in vehicles and in night clubs.

If high-frequency sensorineural hearing loss is found after a head injury, blast injury, or extreme noise injury, the author recommends bed rest, liberal fluid intake, a short course of oral corticosteroids, and avoidance of loud noise. In some patients, improvement in thresholds is observed 2 weeks after the onset. If not, these patients should receive auditory rehabilitation, including use of a hearing aid.

Post-traumatic hearing loss can also be found in injuries of the auditory nerve, brainstem, and temporal cortex. Because of the severity of the injury, most patients with this type of injury do not survive. However, the author has managed two documented and two likely cases of cochleovestibular nerve injury in the last 20 years. In one patient, the cochleovestibular nerve was avulsed from the brainstem, a situation discovered during the course of performing a translabyrinthine facial nerve exposure in which the facial nerve was followed from the stylomastoid foramen to the brainstem. This patient had bilateral temporal bone fractures and subsequently required a hypoglossal nerve to facial nerve crossover procedure to reanimate the face. This patient was operated after a prolonged period of altered mental status and was discovered to have a complete facial paralysis a year after the injury. The other three patients were seen after neurosurgical colleagues performed microvascular decompression of the facial and trigeminal nerves for hemifacial spasm or trigeminal neuralgia. In two of these patients, a complete hearing loss, vertigo, and facial palsy occurred, findings that may have been owing to either stretch-

ing of the cochleovestibular nerve or to occlusion of the vessels that feed the nerves. Neither of these patients recovered auditory or vestibular function, although both regained modest House-Brackmann grade III (see Chapter 24) facial function. One of these patients underwent a transmastoid labyrinthectomy a year after the injury, and the labyrinth in this case was not ossified, which suggests that the injury could not be attributable to vascular occlusion. In a third patient who postoperatively had a 90 dB sensorineural hearing loss, an abnormal auditory brainstem response, and normal otoacoustic emissions (findings that clearly suggest an auditory neuron injury), the hearing recovered to the 30 dB level at 6 months. In patients with temporal lobe injury following head trauma, typically there are complaints of difficulty understanding speech in noisy environments. In the few documented cases, speech understanding is indeed diminished as measured with hearing-in-noise tests or synthetic sentence intelligibility testing. Rehabilitation in these circumstances includes special listening devices and auditory training using neuroplasticity techniques (ie, fast forward therapy to improve temporal processing).

Vascular Injuries

Penetrating injuries of the temporal bone and skull base can cause injuries to the major vessels either in the temporal bone or immediately outside the temporal bone as these structures enter or exit from it. Vascular injury may include transection, laceration, thrombosis, and aneurysm formation. Vascular injuries can be quite alarming because of the volume of blood loss. Immediate management includes stabilization of the cardiovascular system with fluid and blood replacement, compression with dressings, and expedient evaluation with arteriography, MRI, magnetic resonance angiography, or high-resolution CT scans. Furthermore, since cranial nerves are in close proximity to the internal carotid artery and jugular vein, an evaluation for their function should be carried out as soon as possible. This specifically includes cranial nerves VI through XII, with particular attention to the vagus, spinal accessory, and hypoglossal nerves. Life-threatening hemorrhage can be quickly managed by an interventional neuroradiologist using balloon occlusion, although this procedure is usually avoided because of the possibility of acute or delayed stroke. Hemorrhage from the sigmoid sinus or the jugular bulb can be managed surgically by gaining transmastoid exposure of the sinus and placing extraluminal packing at the site of the injury.

The most common vascular injury in the temporal bone is to the lateral sinus with subsequent occlusion of the jugular bulb and lateral sinus. Venous occlusion rarely requires intervention, although delayed hydrocephalus is a concern in these patients. Occlusion of the petrous portion of the internal carotid artery is also common following injury. Arterial vascular occlusion is ordinarily managed through careful observation with radiologic evaluation. In some patients, occlusion of the distal part of the internal carotid artery is performed to prevent extension of a clot or an embolus into the downstream cerebral circulation. Occasionally, an aneurysm of the petrous or cavernous part of the internal carotid artery develops after a penetrating or blunt injury. Neurologic and radiologic consultation is recommended in this circumstance also. In these patients, the artery may be stented or may be bypassed using an external carotid or facial artery to middle cerebral artery bypass approach. In some cases, an aneurysm can be occluded using intra-arterial coils on the nondominant side.

In patients in whom the carotid artery is injured as it enters the skull, consultation with a vascular surgeon or neurosurgeon is recommended. In expanding lesions, exploration and repair may be indicated, and the otolaryngologist can provide additional exposure of the region through mobilization and retraction of the mandible, parotid gland, and facial nerve branches.

Eustachian Tube Injury

Penetrating injuries of the temporal bone occasionally cause blockage of the eustachian tube, usually through cicatrix formation. This problem may not be appreciated for a period of time after the injury, when persistent effusion in the middle ear space is noted. In some patients, a tympanostomy tube can provide sufficient ventilation to keep the middle ear open. In some patients, however, there is persistent infection and drainage through the tympanostomy tube. In these patients, exploration of the eustachian tube through a transmastoid facial recess approach is indicated. If the function of the eustachian tube cannot be restored, the patient usually prefers leaving the drumhead intact and the use of a hearing aid.

Injuries to Children in a Bomb Blast

As a direct result of the Oklahoma City truck bomb blast at the Alfred P. Murrah Federal Building, 816 adults and children were injured or killed. Among the 19 pediatric patients killed in this tragedy, 17 suffered skull fractures and 15 suffered cerebral evisceration. A variety of other injuries were found in this group, including abdominal and thoracic injuries, amputations, extremity fractures, burns, and contusions and lacerations.[14] Nonfatal injuries occurred in 47 pediatric patients, 7 of whom required hospitalization. Among the group hospitalized, 2 suffered depressed skull fractures, 2 closed head injuries, and 5 tympanic membrane perforations. A bomb blast is associated with a high incidence of cranial and temporal bone injury.

CHAPTER 15

Occupational Hearing Loss

Peter W. Alberti, MB, PhD

Worldwide, exposure to excessive sound is the most common cause of acquired adult sensorineural hearing loss. It is incurable but should be entirely preventable. This chapter discusses the effect of noise on the ear, noise-induced hearing loss (NIHL), and its prevention.

Noise is any unwanted sound that at low intensity may be irritating and at high intensity may damage hearing. Noise has physical, physiologic, and psychological connotations, all of which differ. Physically, sound can be measured and is defined in terms of duration, frequency (measured in Hz), and intensity measured in sound pressure levels (SPLs) expressed as decibels (dB). Sound may be continuous, intermittent, impulsive, or explosive.

HISTORY

Although hearing loss produced by noise has been known for centuries, it became a major problem with the discovery of gunpowder and a more widespread problem with the Industrial Revolution. It was recognized in the United States, Germany, and the United Kingdom in the 1870s and 1880s. In 1886, Thomas Barr of Glasgow wrote, "It is familiarly known that boilermakers and others who work in very noisy surroundings are extremely liable to dullness of hearing. In Glasgow, we would have little difficulty finding hundreds whose sense of hearing has thus been damaged, by the noisy character of their work."[1] Indeed, the riveting associated with shipbuilding gave the generic title "boilermakers' deafness" to NIHL. Barr's work stands the test of time as an excellent, well-conceived, and well-executed epidemiologic survey.

The histology of noise-induced hearing loss in the organ of Corti was already described by Habermann in 1890.[2] Audiometrically, Fowler was the first to comment on the 4 kHz dip produced by noise,[3] and Bunch gave an excellent account of the audiometric features of NIHL in 1939.[4]

As a result of the technical advances of the Second World War, machinery became larger, more efficient, and noisier, and as developing countries have rapidly industrialized, NIHL has become a global problem. Currently, with the advent of amplified music and inexpensive motorized transportation, social, recreational, and community sound also plays a major disturbing role. So, although NIHL has been well recognized for a century, its evaluation, accurate quantification, and prevention have only recently become important. We each live in a personal soundscape.

EFFECT OF SOUND ON THE EAR

Sound, depending on its intensity, may produce (1) adaptation, (2) temporary threshold shift (TTS), and (3) permanent threshold shift (PTS) in hearing.

Adaptation, which occurs whenever the ear is stimulated by sound, is a physiologic phenomenon, and for sounds of 70 dB SPL or less, recovery occurs within half a second.

Temporary threshold shift is a short-term effect usually measured in minutes and hours rather than seconds or days, in which the hearing threshold elevates temporarily after exposure to noise. It occurs following intense sound stimulation. With a low-frequency stimulus, the maximum threshold shift may occur an octave above the center frequency of the stimulating tone; as the stimulating frequency increases, the point of maximum shift moves closer to the stimulating tone. Tones of higher frequency cause more TTS than tones of lower frequency of similar intensity. The amount of TTS increases for the duration and intensity of the sound exposure. It lasts from minutes to a few hours and is also a physiologic phenomenon. For further details on adaptation and TTS, the reader is referred to works by

Mills[5] and Kryter.[6] Permanent threshold shift is a permanent elevation of hearing threshold; the term is usually confined to post–noise exposure elevation of hearing threshold.

The relationship between TTS and PTS has been the subject of much investigation but remains unclear. Mills studied the effect of continuing sound stimulation and TTS on certain psychophysical responses of the ear such as temporal integration and simultaneous masking.[5] He found that, as long as the sound continued, TTS grew, but the rate of growth varied according to the frequency of the sound. Periodic rest periods are protective. At 4 kHz, no TTS occurs until the SPL reaches 74 dB. Thereafter, a 4 kHz sound produced an asymptotic threshold shift of 1.7 dB for each decibel increase in sound level. The lower the frequency, the higher the base level and the slower the growth of the TTS. Thus, at 1 kHz, there was no TTS below 82 dB. Figure 15–1 summarizes the findings of Mills and shows how difficult it is to define any one "safe" sound level in terms of a composite single intensity level. A safe sound varies according to its frequency components.

Most TTS recovers in a few hours. If the noise exposure is sufficiently intense, however, TTS may last for several days or weeks.[7] The cutoff point seems to be a TTS of approximately 40 dB. Below this, recovery is swift; above this, it is delayed. This is pathologic TTS, almost always accompanied by some residual PTS. One mechanism for TTS has been elegantly demonstrated by Puel and colleagues in a series of experiments that suggest that glutamate oversecretion at the synapses between hair cells and the auditory nerve fibers leads to synaptic overload, swelling of synaptic terminals, and damage both to the primary auditory nerve fibers and hair cells.[8] Both recovered. This led to much experimentation to produce biochemical blockage of the damage.

One of the practical problems of TTS is its effect on accurate quantification of hearing loss in both audiometric screening and pension evaluation.

PERMANENT THRESHOLD SHIFT

The main purpose of this chapter is to discuss PTS produced by exposure to intense sound. This is associated with pathologic changes in the cochlea, although the direct correlation between hearing loss and anatomic injury is not as clear-cut as was once thought.

HISTOPATHOLOGIC CHANGES RESULTING FROM EXCESSIVE SOUND EXPOSURE

The effect of sound stimulation on the ear has been studied by means of light microscopy and surface preparations, as well as scanning and transmission electron microscopy. An excellent review by Saunders et al pointed out that acoustic injury to the ear has a dynamic and a static phase.[9] The dynamic phase begins during acoustic stimulation, which results in cellular elements in the ear undergoing structural and functional changes that may be permanent or that may recover. Outer hair cells are more susceptible to damage. When the sound trauma ceases, the structure of the ear may recover completely or partially, scar, or disappear. This leads to a static phase in which hearing and the anatomic changes are stable. Cochlear changes following damaging noise exposure may thus be described as temporary/permanent/degenerative and reparative.

The difficulties of studying the cochlea should not be minimized. Human material is difficult to obtain and relatively unfresh; history regarding presbycusis and other ototoxic exposure such as infection and drug ingestion is usually unknown. Animal experimentation is essential. There is no absolute correlation between the results of animal experiments and NIHL or among electrophysiologic tests, behavioral audiograms, and histopathology in animals with noise-damaged hearing. Cytocochleograms performed for areas of hair cell loss frequently do not correlate with changes in behavioral hearing threshold. However, this "all or none" approach to cochlear damage—hair cells present or absent—is very crude. Current electron microscopy and molecular biology techniques allow detailed examination of individual hair cells and their components, which are able to show intermediate amounts of damage. Merely to look at hair cell destruction is too crude. When more subtle damage such as damage of the rootlet of the stereocilia or linkages between the cilia is looked for, there is much better correlation.[10,11] A critical level of noise exposure appears to exist. Below this level, there is biochemical and perhaps reversible change in the cochlea and, above it, major mechanical and irreparable damage.

In turn, physiologic thinking about the structure of the cochlea has moved from a macro- to a

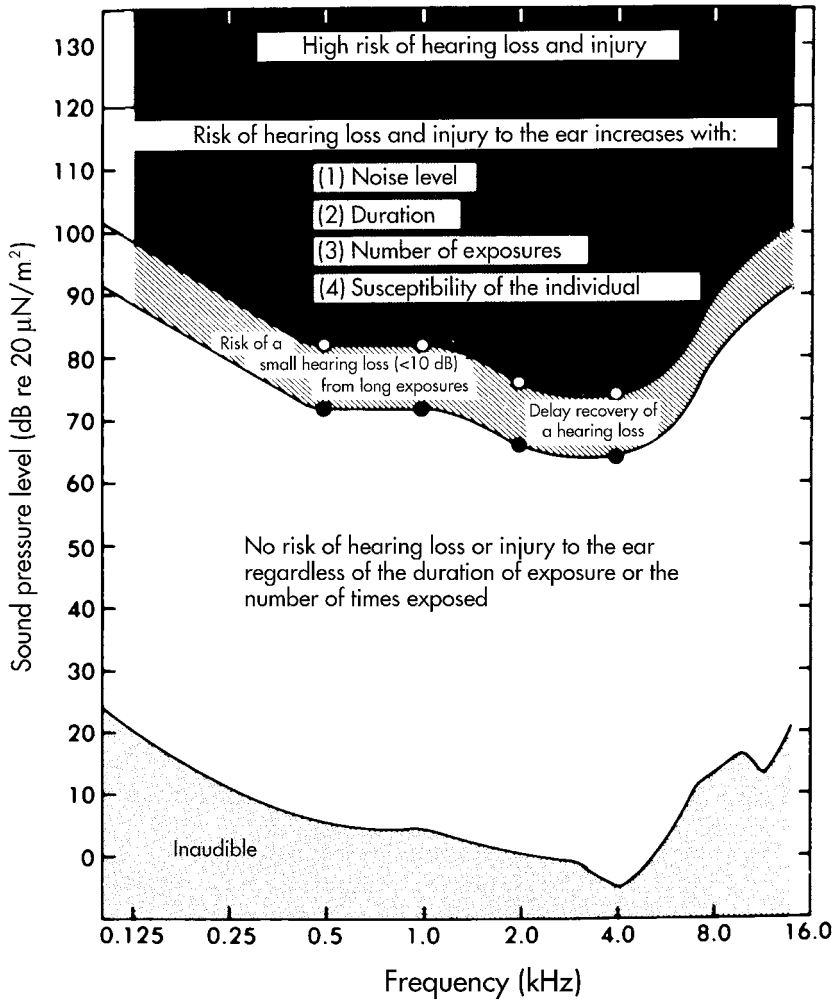

FIGURE 15–1. Most of the range of human audibility is categorized with respect to the risk of injury and hearing loss. Reproduced with permission from Mills JH.[5]

microdynamic model. No longer is the main focus of attention the traveling wave. Current studies emphasize the functional integrity of individual hair cells and their innervation, interaction between outer and inner hair cells, and knowledge obtained from single auditory nerve fibers and their characteristic frequencies, both normal and noise damaged. It is now apparent that outer hair cells contract in response to a sound stimulus; this enhances and sharpens the mechanical displacement transmitted to inner hair cells, which alone appear to transduce mechanical stimulation to initiate an eighth nerve afferent signal. The use of tracers such as horseradish peroxidase has allowed study of the concomitant central nervous system connection and damage. The reader is referred to work by Kiang et al[12] and to work by Schacht and Canlon for biochemical changes.[13]

HAIR CELL INJURY

Cochlear hair cells are damaged by exposure to excessive sound. The degree and type of damage are related to the amount of noise exposure. Newer electron microscopy techniques have allowed the demonstration of subtle changes that, when studied in conjunction with current views of cilia as containing actively contractile actin molecules, are beginning to lead to a better understanding of the damage that occurs. The first sign is shortening of the cilial rootlet.[11] This acute finding, produced by least damaging noise, is associated with floppy cilia and is partly reversible. The resistance of cilia to deformation after noise stress is reduced. The first signs of an irreversible change are damage to the intercilial connections and actual fracture of the

rootlet at the level of the cuticular plate. The cilia fall over and ultimately are absorbed. With these greater degrees of damage, intracellular changes also occur, including damage to lysosome granules, mitochondria, and the nucleus. As with other tissues in the body, there is a process of damage and repair. The repair with mild degrees of injury is within the cell itself; with greater degrees of injury, healing and scar formation occur by migration of other cells.[14] An elegant series of experiments by Gao et al demonstrated, by means of electron photomicrographs, responses of hair cells to intense and very intense stimuli; in the former, the cilia flop slightly but do not collapse, and they appear to recover completely; in the latter, they flop significantly and never recover; indeed, they are scavenged and disappear.[15] High levels of stimulation release excess of neurotransmitter in inner hair cells, which, in turn, leads to damage to associated nerve rootlets, which may be temporary or permanent.[8]

Over the past decade, the biochemical and molecular basis of NIHL has become clearer; this is leading to the possibility of fuller preventive and even curative strategies.[16,17] It appears that oxidative stress is a major cause of hair cell damage both in NIHL and antibiotic ototoxicity. Excessive stimulation by noise produces toxic levels of reactive oxygen species (ROS), which damage phospholipids in cell and nuclear membranes and deoxyribonucleic acid (DNA); it increases intracellular Ca^{++} and up-regulates cell death genes.[18] There may be ways of preventing or diminishing the formation of ROS, as, for example, by increasing endogenous antioxidant systems by administering substances such as *N*-acetylcysteine. The administration of glutathione, a powerful antioxidant, to guinea pigs prior to noise exposure leads to less cochlear damage and hearing loss than in matched noise-exposed animals that are not protected.[19] Antioxidants also protect the inner ear of chinchillas from the damaging effects of impulse noise.[20] Glial cell line–derived neurotrophic factor also provides protection from noise. It and heat shock protein (which protects hair cells against excessive stimulation) are produced when the ear is exposed to mild noise exposure and may account for "toughening" of the ear to noise by prior sound exposure. Although promising, none of these mechanisms currently have any practical application in humans.

It is also clear from the work of Puel and Pujol,[8] Duan et al,[21] and Canlon et al[22] that damage from noise and aminoglycosides affects nerves as well as hair cells. So protective strategies, although so far mainly based on hair cell protection from ROS, also include protection of axons by neurotrophins.

The development of NIHL is also related to feedback from the central nervous system (CNS). That nerve supply of the outer hair cells is by efferent fibers has been known for years, but their function was poorly understood. It now appears that there is an active feedback system, which may be responsible for depressing the contractile activity of outer hair cells, thereby diminishing the stimulus to the associated inner hair cells. This may function to sharpen frequency discrimination and perhaps to eliminate the effect of low masking sound.

This mechanism may also explain why exposure to enjoyable sound of equal intensity and duration produces less hearing loss than exposure to noise (eg, industrial of similar intensity and duration).

As early as 1988, Canlon et al showed that prior exposure to low-level sound "toughened" ears against subsequent exposure to harmful levels of sound.[22] Prior toughening appears to work by up-regulating the production of antioxidants such as glutathione.[21]

There has been much discussion in the literature about the role of other factors in noise damage, including potentiation by exposure to other industrial toxins such as carbon monoxide and various organic solvents. These will be described below.

AUDITORY NERVE AND CENTRAL NERVOUS SYSTEM DAMAGE AFTER ACOUSTIC INJURY

There is also evidence of eighth nerve and CNS injury after chronic traumatic acoustic exposure. There certainly is good evidence of damage to the dendrites and nerve endings surrounding the hair cells following acoustic overstimulation and, in chronic preparations, spiral ganglion cell degeneration spreading into the cochlear nucleus.[23]

PHYSIOLOGIC AND PSYCHOPHYSICAL CHANGES TO NOISE EXPOSURE

It has long been known, but only recently appreciated, that 90% of afferent nerve fibers from the

cochlea, which presumably carry information about sound stimulation to the CNS, arise from inner hair cells, and yet damage to outer hair cells is associated with hearing loss from noise exposure. Outer hair cells are overwhelmingly innervated by efferent fibers, and it is becoming clear that stimulation of efferent fibers can alter the sensitivity of the cochlea by 20 or 30 dB. In other words, outer hair cells have a tuning effect on inner hair cells. Outer hair cells themselves contract in response to sound stimulation, providing mechanical enhancement of the traveling wave motion transmitted to inner hair cells.

The contractions produce audible sounds detected as otoacoustic emissions (OAEs). These have been intensively studied to see if alteration of OAEs after sound exposure can be used to predict susceptibility to noise exposure. To date, there are no definite outcomes.[24]

Much psychophysical work has been directed toward single nerve fiber tuning curves, which have demonstrated a broadening of tuning curves of individual nerve fibers following cochlear damage. At their most sensitive, they are less frequency selective than normal, and this is associated with outer hair cell damage. In humans, the tuning curve of the cochlear nerve becomes broader with increasing hearing loss, and, certainly, damage from noise is associated with reduced suprathreshold hearing function.

NOISE-INDUCED HEARING LOSS

Intense acoustic overstimulation, whether acute or chronic, can produce TTS and PTS. The noise source may be continuous, intermittent, or mixed. Acoustic damage can also occur from a single intense sound such as an explosion or even a single gunshot. Typically, the first audiometric change in both TTS and PTS is a drop in hearing at 3, 4, or 6 kHz, with normal hearing below and above these levels. This is known as an acoustic notch. In the early phases, the subject usually recovers. It has long been known that the previously unexposed ear is more easily damaged by noise (green ears) than one accustomed to listening to loud sound,[25] and there is recent evidence of the "toughening of ears" by noise exposure.[22] This is a topic of great current interest and has been well reviewed by Hamernik and Ahroon[26] and Yoshida and Liberman.[27]

The recovery period following TTS is of interest. It has been studied in detail by Mills[28] in humans and in many animal studies. Most recovery takes place within the first 12 hours after noise exposure and is overwhelmingly complete within 48 hours, although in detailed animal studies, slight recovery continues for many weeks.[28] This recovery is so slight that it is within the confidence limits of normal clinical audiometric tests. However, after a single massive insult such as an explosion, recovery may continue for many weeks until the hearing loss is stable. This is usually accompanied by some PTS.

NOISE-INDUCED PERMANENT THRESHOLD SHIFT

Noise-induced permanent threshold shift (NIPTS) has many synonyms, one of the earliest being boilermakers' deafness and the currently popular one being NIHL. This is probably now the most common cause of acquired hearing loss in North American adults—indeed throughout the world—and is overwhelmingly caused by chronic exposure to excessive sound levels in the workplace, whether civilian or military. It may be potentiated by additional social and recreational noise exposure. The speed of onset and the degree of loss are related to the total quantity of noise exposure (ie, its intensity and duration) and to the individual's susceptibility to damage by the noise. In general terms, industrial noise exposure is less intense but more prolonged than military noise exposure.

It is difficult to quantify accurately the relationship between prolonged noise exposure and hearing loss because, over the years, workplace noise exposure changes, machinery is altered, jobs change, and hearing protection is provided. There are remarkably few long-term longitudinal studies equating hearing loss with noise exposure, and the likelihood of further studies in the future is becoming increasingly remote because, as the hazards of noise have been recognized, companies that are interested enough to take regular noise measurements also provide hearing protection. The well-studied group of jute workers in Dundee in the 1960s is the benchmark against which most of this work is measured.[29]

NATURAL HISTORY OF NOISE-INDUCED PERMANENT THRESHOLD SHIFT

There is interest in the progress of NIPTS over time. What is the rate of growth of hearing loss? Does it

spread into other frequencies? Does the rate of increase level off, accelerate, or remain the same? These are difficult questions to answer because of the lack of good longitudinal studies. It is unlikely that PTS will occur without TTS, and it is also unlikely that PTS will be greater than TTS. Other than that, there is little relationship between the two, and attempts to predict PTS from TTS have not been successful. Permanent threshold shift usually starts in the higher frequencies characteristically at 4 or perhaps at 3 or 6 kHz and gradually spreads into neighboring frequencies. To begin with, the hearing loss is asymptomatic, and only when it spreads into the lower frequencies such as 2 kHz does it give rise to complaints. As time goes on, the notch disappears for the hearing in the higher frequencies also worsens (perhaps as a result of aging rather than noise) so that the audiogram becomes indistinguishable from many other sensorineural hearing losses. It is stated, probably correctly, that after 10 years of exposure to an average workplace noise, say between 90 and 94 dB, the loss in the higher frequencies stops worsening, but gradually the loss spreads into the lower frequencies. The major part of the loss may occur quite early in the first 2 or 3 years,[30] and late losses are usually contaminated with presbycusis, which becomes the dominant cause of worsening hearing. The rate of spread and the degree of loss are related to both the intensity of sound and the individual's susceptibility to noise. This is as important with sound exposure as with other physical insults such as response to sunlight; individuals vary greatly, and, unfortunately, there is no good way of predicting the unduly susceptible individual. In mice, it has been shown that there is a genetic susceptibility to hearing loss from noise, and it is postulated that the same is true in humans, adding to predictive difficulties.[31] If the International Standards Organization (ISO) tables of risk are correct, it is probable that in later years too much hearing loss has been blamed on noise and too little on presbycusis. Furthermore, it appears that in mice, a recessive gene (*Ahl*) that is responsible for premature age-related hearing loss is also implicated in excessive susceptibility to NIHL.[32] If this is also true in humans, it may help explain some of the variability noted in response to sound exposure.

DAMAGE RISK CRITERIA

Many attempts have been made to define the relationship between noise exposure and hearing loss. It is currently accepted that, within a significant range with a lower boundary of safe sound and an upper boundary of sound so intense that it produces acute permanent damage, equal amounts of sound exposure produce equal amounts of damage. This is true whether sound exposure is spread over a short or long period. In other words, a given sound experienced for 8 hours does as much harm as twice that sound experienced for 4 hours or half that sound experienced for 16 hours. The reader must remember that decibels are a logarithmic scale. Doubling sound intensity is equivalent to a 3 dB increase in SPL. Thus, a 93 dB sound is twice as intense as a 90 dB sound, and a 103 dB sound is twice as intense as 100 dB sound. This equal energy concept, promulgated by Burns and Robinson,[33] has been widely adopted in Europe for many years and is gaining acceptance in North America. However, it is now suggested that if noise exposure is intermittent, as is usually the case in industry, the ear has time to recover and the 3 dB rule may be too strict. The best fit is probably a 4 dB halving and doubling, although no single rule fits all circumstances. This issue is well reviewed by Ward.[34]

The appropriate technique of evaluating the harmful effects of impact sound is still debated. Rifle fire is a good example of military impact sound; a drop forge, a pile driver, and a hammer blow are all examples of industrial impact noise. The characteristics of impact sound vary widely; they are measured by rise and decay time and peak intensity and are difficult to measure because of the transient nature of the sound. Hamernik and Hsueh give a good review of the nature and measurement of impulse sound.[35] It is probable that impulse noise is more damaging than steady-state noise of the same intensity.

Attempts have been made to codify risks into national and international standards for noise exposure, which are used both to define the upper limit of safe exposure and to quantify the risk of hearing damage at various levels of intense sound. International standards have been based on the equal energy (3 dB halving and doubling) concept and were initially embodied in ISO 1999 (New York, ISO, 1971) and revised as ISO 1999 (New York, ISO, 1984), and again as ISO 1999 (1990[E]),[36] which takes into account such factors as other ear disease and aging. In North America, tables based on 5 dB halving and doubling were introduced in the mid-1960s after a Committee On Hearing, Bioacoustics and Biomechanics

(CHABA) of the US National Research Council report in 1966 and codified in the Walsh-Healey Public Contracts Act of 1969 (Federal Register 34, no. 96, 1969). Here it is assumed that the trading relationship is 5 dB for halving and doubling of exposure, known as L_{OSHA} (US Occupational Safety and Health Administration), as opposed to the European 3 dB loudness equivalent known as Leq. There is a significant, but in practical terms frequently unnecessary, debate about these trading relationships. It is important to know that with a 90 dBA (dB on the A-weighted scale) sound exposure for 8 hours a day, 5 days a week, 15% of the population is at risk for significant hearing loss after 10 years of exposure, and that for 85 dBA exposure 8 hours a day, 5 days a week, after 10 years, only 7% of the population is at risk. It is prudent, therefore, to initiate hearing conservation measures from 85 dB upward,[37] and from a hearing conservation standpoint, little is to be gained from further dissection of these tables. Where they are significant is in attempting to equate total noise exposure in terms of medicolegal investigations. Few jobs have a steady noise exposure throughout the working day or working week, and attempts to equate actual noise measurements at work over a period of years in which several jobs have been held into a single risk figure for legal purposes are dramatically affected by which table of risk is used (Table 15–1). The tables of risk are based on human hearing threshold changes and are difficult to correlate with histologic damage and hair cell destruction in noise-exposed animals. Better correlation will be found as more subtle changes in hair cells are sought. The human studies are based on large samples of workers, including a large General Motors study and studies of Austrian industrial workers. They have been extensively evaluated in the literature in a series of publications by Passchier-Vermeer.[38]

TABLE 15–1. Comparison of Hours of Equivalent Sound Exposure*

Hours of Permitted Exposure	L_{OSHA}	L_{eq}

TINNITUS

Tinnitus is a distressing and frequent concomitant of NIHL. Transient tinnitus is experienced commonly after exposure to intense sound and almost invariably after a blast injury, but it usually clears. After years of exposure, however, it may become permanent and is present permanently in 50 to 60% of those with NIHL,[39] higher in those exposed to impact noise. The incidence and severity of tinnitus usually increase with increased hearing loss. This was not found by McShane et al in NIHL compensation claimants,[40] highlighting the difficulty of distinguishing the organic from the nonorganic components of this distressing but immeasurable complaint. There has been abundant literature about tinnitus in recent years: the reader is referred to a recent handbook edited by Tyler[41] and to Chapter 22.

WORSENING OF HEARING AFTER NOISE EXPOSURE ENDS?

It is frequently asked if hearing loss from noise exposure can progress after removal from noise. Although hearing loss improves rather than worsens after removal of chronic noise exposure, there is considerable controversy in the literature about the interaction among noise, presbycusis, and progression of hearing loss. In mice strains that show premature age-related hearing loss, which are also usually susceptible to the effects of excessive noise exposure, there is a suggestion that after cessation of noise exposure, hearing worsens more rapidly than in similar but non–noise-exposed mice.[31] The overwhelming body of opinion, however, strongly suggests that hearing loss that progresses after removal of noise exposure is from some other cause. Tschopp and Probst undertook a longitudinal study of hearing after exposure to a single sound; they found no worsening.[42] The matter remains controversial and is frequently raised in medicolegal claims.

COMBINED EFFECTS OF OTOTRAUMATIC AGENTS

Many things are known to injure the inner ear, for example, drugs, infections, trauma, age, and noise.

The ear is also affected by premature degenerative disorders such as familial hearing losses. Most of these agents have a final common pathway: they damage the hair cells and other structures of the cochlea. There is great interest in and concern about how they interact: whether they are synergistic, additive, or protective. Is the noise-exposed ear more or less affected by aging or is the effect additive? Is an old ear more likely to be damaged by noise than a young ear or is age irrelevant? Matters are compounded by species differences among animals and between animals and man, and it is not always reasonable to extrapolate from one to the other.

Unfortunately, the ears that are most readily studied and about which there is a large body of knowledge, those of the guinea pig and chinchilla, do not necessarily behave in the same way as human ears. With this caveat, in guinea pigs it has been shown that kanamycin given after noise exposure is more damaging than kanamycin alone, although the reverse is not true. Aminoglycoside antibiotics and excessive sound exposure both exert their effect on hearing by releasing free oxygen radicals, which explains their synergy; it also suggests ways of protection by exposing the hair cells to antioxidants. The ototoxic/cytotoxic drug cisplatin acts synergistically with other ototoxic drugs and noise in the same way.

Certain industrial solvents and chemicals are ototoxic. Jet fuel and styrene are predominantly vestibulotoxic but also appear to impair central auditory function. Rybak published an exhaustive review in which he suggested that there may be a synergistic effect between inhaling styrene and noise exposure. He draws similar conclusions about inhaled carbon disulfide.[43] Toluene is the most commonly used, most studied, and probably the most ototoxic industrial chemical. It produces hearing loss and potentiates the effect of noise exposure.[44] Morata et al have provided convincing epidemiologic studies demonstrating the synergistic effects of noise exposure and toluene[44,45] and between noise and petrochemicals inhaled in the oil refining industry. Noise and vibration act synergistically in those who suffer from white hand and work in the cold such as foresters using chain saws or shipbuilders.[46]

The interaction between noise exposure and aging is hotly debated. At most, it appears that presbycusis is additive to noise change, and even this is not demonstrated unequivocally. Studies by Macrea[47] and others before him (summarized by Robinson[48]) give some evidence for additivity, although they all say that there is no interaction. This matter is of considerable concern in terms of pension assessments, which are frequently made only at a time when presbycusis might already be present. ISO 1999[36] implies an additive mechanism, which has been modeled by Macrea (1991)[47] and Dobie (1992).[30] Robinson reviewed the subject at length.[48] It now seems that in later years, aging is a much more dominant cause of worsening hearing than further noise exposure; indeed, at the higher frequencies by the age of 80, hearing is the same, whether the ear is noise exposed or not! The best model known to the author is that of Corso, who gave a thoughtful discussion of the topic and concluded that, at best, there is limited additivity.[49] There is a good recent discussion by Dobie that concluded that except for high noise exposure levels, the effects are additive.[50]

Is an already noise-damaged ear more or less susceptible to damage from further noise exposure than an undamaged ear? This question is frequently raised when hearing-impaired workers attempt to move from one noisy industry to another only to fail to find employment in the belief that, because of previous damage to their ears, their hearing is more likely to degenerate more rapidly than in a normal ear. The little existing evidence suggests that this is wrong and that the ear will continue to degenerate at a steady rate with a natural history appropriate for it.

ACOUSTIC TRAUMA

Explosion and other single loud sounds can cause hearing loss. Early examples were "telephone ear," produced by static in early telephones. Other examples include workers inside metal tanks, the outside of which is struck by sledge hammers, quarrymen too close to a blasting accident, and armed forces personnel near a single explosion. The most recent examples are hearing loss produced by the inadvertent ringing of a cordless telephone into the ear of the listener[51] and the detonation of air bags in automobile accidents.[52] Perhaps, globally, the most pervasive examples at present are firecrackers and high-power weapons. An older but excellent review of the topic is given by Phillips and Zajtchuk.[53]

SOCIOACUSIS

The ear does not distinguish between occupational and social noise exposure. All noise is additive. Leisure pursuits may add significantly to total daily noise exposure and turn a marginally safe job, from a noise standpoint, into an acoustically hazardous one. The noise levels of everyday life are steadily increasing, and to this should be added the voluntary sound levels of recreation. Transportation is the main cause; automobiles, particularly on thruways, motorcycles, trains, planes, and the substitution of diesel for gasoline engines have all helped to produce sound levels that in some cities (eg, Bangkok) exceed 100 dB in the city center. There is voluminous literature about this, and the reader is referred particularly to *The Effects of Noise on Man* by Kryter[6] and the recent World Health Organization (WHO) document on community noise.[54] The worker exposed to sound levels of 88 dBA for an 8-hour workday who then experiences 94 dBA for 2 hours traveling to and from work is at risk for hearing loss from noise because of the additive effects of the sounds. At home, too, the blender, vacuum cleaner, and lawnmower all add to noise. In North America, ambient sound level ranges from 20 dBA on the north rim of the Grand Canyon to over 80 dBA in city centers near motorways. Noise levels within public transportation are high; some subway systems have sound levels above 90 dBA. Public pressure for noise reduction can be effective, and the quieting of airplanes is a major result of such activity. Environmental noise is a particular hazard in the megacities of Asia, with transportation noise being the dominant sound source, although by no means the only one. Two-stroke engine noise from motorcycles and motorized rickshaws (frequently unsilenced); old, poorly maintained diesel-powered trucks and buses; air horns; bazaar noise; and sounds from small roadside metal-forming shops all add to produce a cacophony that not only makes living unpleasant but also puts hearing at risk.[55]

Recreational noise also is hazardous. Firecrackers can produce sudden deafness in children, and their use in public festivities, such as national day celebrations, or religious ceremonies, may produce permanent hearing loss.[56,57]

Recreational vehicles such as snowmobiles and motorcycles are frequently considered by their users to be more fun if loud. Chain saws and radial-arm saws produce damaging sound levels for the hobbyist. There is much concern about the use of personal radios and cassette and compact disc players and the potential harmful effect of pop, rock, and disco music, although it would appear that they are not harmful. Clark reviewed current North American sources of potentially harmful social noise and highlighted the sound output of power tools and horticultural equipment.[58] Children from rural areas appear particularly at risk from firearms, tractors, and other farm equipment.[59] Indeed, farm workers are a major at-risk group for occupational hearing loss, working long hours, driving diesel tractors and other equipment, and being exposed to grain dryers, chain saws, and pigs (which may squeal in excess of 100 dB).

MEDICAL NOISE

Compression chambers may be an aural hazard from both pressure equalization and noise near the air valves. There is at least one reported case of deafness inside such a chamber.[60] Drills used for ear surgery have raised concern; although it appears that airborne sound levels from drills are high, Kylen et al concluded that for the patient, the mixture of air- and bone-conducted sound may be damaging, particularly if large burs are used.[61] The smaller the bur is, and the greater the number of teeth, the less the sound level. Man and Winerman, however, studied bone-conduction thresholds in operated and normal unoperated ears and found that the normal unoperated ear was unaffected by drilling.[62] Because bone-conducted sound is transmitted across the skull without loss, this is strong evidence that sensorineural loss in chronic otitis media is caused by factors other than bur noise. Concern has also been raised about the noise of suction units that, at the ear, is extremely intense.

Hospitals contain many noise hazards. Apart from normal commercial industrial workshops, dishwashers, and air-conditioning units, sound levels in intensive care units and incubators are high. The noise in intensive care units can certainly be disturbing. The background signals from many life support devices working at once make hearing and localizing warning signals difficult. Magnetic resonance machines are very loud at the patient's head

position, and use of rubber or foam earplugs is advocated.

NONAUDITORY EFFECTS OF NOISE

There is great controversy about noise as a cause of hypertension. This is a difficult subject to untangle. Certainly, sound may precipitate acute cardiovascular changes, but these are almost certainly normal physiologic responses to warning signals. Whether this leads in turn to chronic change remains debatable. Large population studies suggested that living in areas of high noise is more likely to produce hypertension, although a well-controlled study in the US Air Force by Von Gierke and Harris failed to demonstrate such an effect.[63] If it exists, it is extremely small. Sleep deprivation produced by loud sounds is also a matter of concern. These and other factors are summarized by Kryter[6] and in the WHO guidelines for community noise.[54]

There have been persistent reports of an association between excessive community noise exposure and mental disease. These have been extensively reviewed by Kryter.[6] There probably is no direct association. This has been confirmed by a careful study by Stansfeld et al.[64] Children's education may be hindered by chronic noise exposure because of interference with speech perception and because of the development of strategies to block out sound. The behavior of teachers may also be affected.[65]

SOCIAL ANTHROPOLOGY OF HEARING LOSS

The interaction between the individual with hearing impairment and the general population is currently much studied and is known as the social anthropology of hearing loss. One aspect is the impact on the lives of those with occupational hearing loss and their families. The middle-aged male with NIHL is isolated from his family; his children may become alienated as they feel that their father is disinterested in their activities, and he, in turn, feels that he is being excluded from family conversation. There may be considerable stress between husband and wife; communication becomes more difficult, producing anger, fatigue, and feelings of guilt on both sides.[66,67]

CLINICAL FEATURES OF NOISE-INDUCED HEARING LOSS

There are no clear-cut clinical features that distinguish NIHL from several other causes of sensorineural hearing impairment. The diagnosis is based on history, physical examination, and appropriate laboratory investigation including full hearing tests. Although there are audiometric configurations suggestive of the diagnosis, they may have many variations, and no one configuration fits all cases or excludes a case. To compound matters, NIHL, like any other chronic disorder, may coexist with other lesions. The diagnosis, which is circumstantial, is largely based on a careful history and is frequently made by exclusion, that is, if other causes of hearing loss have been excluded, noise exposure has been adequate, and there is an appropriate hearing loss, it is customary to attribute the loss to that cause. The diagnosis must be made individually, and one should avoid the epidemiologic error of believing that noise exposure and hearing loss are necessarily causally related. To believe this is to believe that working in noise protects one from all other forms of ear disease. In a large consecutive series of claims for NIHL taken at random from a working population in Ontario, at least 5% had other ear disease as the major cause of their hearing loss.[68]

Noise-induced hearing loss may be superimposed on other diseases such as chronic middle ear disease, Meniere's disease, familial hearing loss, otosclerosis, and the like. Unfortunately, people's memory about their own health is short, and little current information is available in the literature about the prevalence of ear disease in industrial populations.

The history includes questions about familial hearing loss, length of symptoms, childhood problems, school screening (whether school hearing screening has ever been failed), ear discharge, other diseases related to hearing loss such as renal problems, potential use of ototoxic drugs, and head injuries. The audiogram quantifies the hearing loss. Its pattern may give a clue toward the diagnosis because it may help to distinguish among various sites of lesion, conductive, cochlear, or retrocochlear. Where indicated, further investigation should be initiated, including hematologic, serologic, and imaging with computed tomography and magnetic resonance. When noise exposure is believed to be the cause of the hearing loss, various venues of loss must

be sought (eg, recreational, military, and occupational). Even within the realm of occupational hearing loss, it is often difficult to attribute the cause to a specific employer and ultimately may become a matter of clinical skill and exquisite judgment to establish both the cause of the hearing loss and the proportion of it that should be attributed to any given employer.

The responsibility of the assessing physician is to the patient: to quantify the hearing loss accurately, establish a diagnosis, and make a recommendation about treatment or rehabilitation. If physical signs or symptoms suggest other ear disease, this should be followed through, and, in particular, causes of asymmetric hearing loss should be investigated. It is possible to have an asymmetric hearing loss from noise exposure, such as, for example, individuals who fire guns off one shoulder, concert violinists, workers who use certain industrial equipment such as rock drills, and people who drive farm tractors with one ear to the engine and the head constantly turned over the shoulder, protecting the other ear. A dosimeter study showed a 9 dB difference in sound level between the ears when using a heavy handheld drill to make holes in a concrete form. Unequal hearing thresholds were present in about 10% of a large series of claimants for occupational hearing loss,[69] much of which was attributable to other ear disease, as well as asymmetric industria1 exposure from machinery and unequal damage to ears from explosions at work. The significance of asymmetric hearing loss in military personnel has recently been evaluated by Caldera and Pearson[70] There are recent thoughtful discussions about the diagnosis of NIHL from a North American standpoint by Dobie[50] and from a British view by Coles et al.[71]

HEARING TESTS

Hearing tests used in occupational hearing loss are of two types, screening and diagnostic. Screening tests will be dealt with under "Hearing Conservation Programs." This section deals with diagnostic tests. The degree of accuracy required here is greater than in routine clinical diagnostic audiology; it cannot be overemphasized that the tester must be experienced in this type of work. The basis for most pension and compensation awards is the pure-tone audiogram, which must be accurate to be fair to both employer and employee. At the time of testing, there should be no TTS. Authorities have legislated different time periods out of noise for this, ranging from 6 months to 48 hours. It is the author's view that if the claimant has been subjected to chronic noise exposure, a period of 48 hours free of noise is adequate for compensation assessment, and, in fact, anything much longer is impractical, particularly if the employee is continuing to work. The situation is different after a major blast accident or head injury, in which recovery may continue for a period of many weeks, and a compensation assessment should not be undertaken for a minimum of 3 months after the episode.

The types of tests to be undertaken vary by local use rather than any intrinsic factors related to the tests. They must be undertaken with properly calibrated equipment and in appropriately calibrated soundproof enclosures. Although screening tests make much use of the automatic Békésy audiometry, a test to quantify hearing loss accurately requires standard behavioral audiometry: air-conduction, bone-conduction, and speech reception thresholds. Further tests are undertaken as indicated. If there is an asymmetric loss, site-of-lesion tests are performed; if there is doubt about the accuracy of the behavioral test, the appropriate special tests are performed.

Many audiometric tests are used to identify exaggerated hearing loss, but there are few that quantify it. Quantification for compensation purposes must be frequency-specific and parallel tonal audiometry. In unilateral hearing loss, the Stenger test is effective. In bilateral hearing loss, electric response testing is necessary, and in this group of patients, slow vertex response (SVR) audiometry is the most effective. Auditory brainstem responses, currently much in vogue, usually provide only a click threshold, which gives a general idea of the level of hearing but not a simulacrum of an audiogram. To obtain this by means of brainstem audiometry requires expensive filtering techniques and a much lengthier test. The relative merits of various evoked response tests have been well described by Hyde et al[72] and the SVR audiometry in this type of patient by Alberti et al.[73] They use certain guidelines to identify the patient who should have SVR audiometry and place considerable emphasis on the discrepancy between speech reception threshold and pure-tone average and on the 500 Hz air-conduction threshold. Klockhoff et al[74] and Alberti et al[75] both demon-

strated that the probability of a hearing loss of 40 dB or greater at 500 Hz being caused by something other than noise is high. These patients produce a high yield of other ear disease and of nonorganic hearing loss.

THERAPY AND REHABILITATION

Experimental work suggests that symptoms of an acute traumatic hearing loss can be helped by the use of hyperbaric oxygen[76] or carbogen,[77] but this treatment does not have widespread acceptance. The use of antioxidants is also still experimental in that there is no easy delivery system to the cochlea.

The clinical onset of occupational hearing loss is usually insidious, but ultimately the complaints are those of any sensorineural hearing loss: difficulty in distinguishing one voice from many, difficulty in hearing in crowds, family complaints about the loudness of the television set, and inattentiveness. The psychological impact on the worker and his or her family has recently received considerable attention. Denial of problems, withdrawal, and lack of family interaction may have a severe effect on interpersonal family relationships.[66,67]

Much can be done to ameliorate the impairment with both specific and general devices. We have found a telephone handset amplifier (obtainable from most telephone companies), a louder bell, and a specific television amplifier to be the most useful. Many patients use a hearing aid to amplify television, but this also amplifies all other sounds in the environment, such as paper rustling, children crying, dishes clattering, and other people talking. A specific amplifier or television such as a headphone or extension loudspeaker serves both to make the sound louder and to improve the signal-to-noise ratio. Hearing aids are useful for and well accepted by those with NIHL.[78] They should not be withheld.

HEARING CONSERVATION PROGRAMS

Noise-induced hearing loss is incurable but largely preventable. The technique of prevention is known as hearing conservation. A hearing conservation program has four main features: sound measurement, engineering and administrative controls, personal hearing protection, and audiometric monitoring of the population at risk, with the following elements: (1) noise hazard identification, (2) engineering controls, (3) personal hearing protection, (4) monitoring, (5) record keeping, (6) health education, (7) enforcement, and (8) program evaluation.

A good hearing conservation program is multidisciplinary, involving the industrial hygienist, engineer, nurse, audiometric technician, and frequently supervisory audiologist and otologist. Good reviews of such programs are found in specific texts on hearing conservation.[79] Sound measurement is a skilled task devised to answer two questions: (1) What are the absolute sound levels in the work place? and (2) What is the sound exposure of the individual? Carefully performed sound surveys measuring sound levels throughout the plant and throughout the working day indicate the absolute environmental levels and help identify those who may be exposed to potentially hazardous noise. The exposure of individual workers, if the job is static, may be extrapolated from these measurements, but it is far better to undertake individual noise dosimetry studies. Dosimeters are small but expensive devices that sample and store the total sound received. The measurement of impact and impulsive noise is particularly difficult and may require special laboratory equipment.

A great effort must be made to have total collaboration of the workforce; to be successful, it requires bottom up planning and implementation and top down guidance.

SOUND ABATEMENT AND ADMINISTRATIVE CONTROL

The most effective way of reducing the risk of NIHL is to engineer out noise at the source by either silencing machinery or enclosing it. It is sometimes possible to retrofit machinery and provide sound-silencing barriers. Vicarious noise exposure should be eliminated; for example, there is no need to have a workbench beside a drop forge and to expose the mechanic, as well as the forge operator, to the noise of the forge. This happens all too often. In many industrial plants, it is possible to put the equipment operator inside a sound-enclosed booth and separate him from noisy machinery, for example, in ships' engine rooms, hydroturbine halls, and paper-making plants.

PERSONAL HEARING PROTECTION

Hearing protectors are widely used where noise levels remain hazardous even after appropriate engineering and administrative controls have been put in place. It is, however, not enough to provide a protector; there must be a program to encourage their use and instruct in their proper fitting and maintenance. The plant physician has a major role to play in this area and should be familiar with the various types of protectors, their advantages and disadvantages, and their application. Earplugs are by far the most commonly used; they constitute about 85% of personal protector devices in use in the United States.[80] Earplugs should fit firmly and may require a few days of use before they are comfortable. The preformed plugs of the V51R or fir cone Comfit type must be sized appropriately for the individual user. Workers usually choose one size too small because it is more comfortable. Universal plugs, which are compressed before being placed in the ear canal and expand to close it, are widely used and range from waxed wool to the commonly used foam polyurethane EAR or Deci-Damp. They work well for most people but are difficult to fit into those with small ear canals, particularly some women. Soft, individually molded plugs, which were widely used, have not proven effective on a large scale. Theoretically, the most effective type of hearing protector is the earmuff, consisting of a solid cup containing a sound-absorbing material such as foam, sealed to the side of the head with a soft malleable gasket and applied with sufficient pressure to produce an airtight seal. Muffs are, however, less comfortable to wear than plugs, and hard hats and safety glasses interfere with their performance. They tend to be reserved for heavy industry and industries in which intermittent use of a protector is appropriate. Figure 15–2 shows the average attenuation of a wide range of hearing protectors under average-use conditions —a far cry from manufacturers' claims. Because the majority of industrial noise lies in the mid–90 dB range, however, 10 dB of attenuation are, in fact, effective. One must guard against inappropriate protection as well as underprotection.

One of the problems with hearing protectors is that they distort external sounds by attenuating high-frequency more than low-frequency sound; another is that they exclude ambient signals as well as unwanted noise. Increasing use is therefore being made of active hearing protectors consisting of good-quality muffs with built-in microphone and amplifier, which, however, cut out above certain predetermined ambient noise levels. They act much like a good-quality compression hearing aid with less and less amplification as the ambient noise rises, and, above a predetermined figure, usually 85 dB, the amplifier automatically cuts out when the device becomes a passive hearing protector. They are particularly useful in intermittent and impact noise and have been widely adopted by hunters who wish to hear the sounds of the countryside but to protect their ears from the sound of gunshots. These muffs have widening application.[80] Modifications have also been made to passive muffs by the incorporation of filters that flatten the attenuation curve and provide a more natural environment for their user.[81]

HEARING SCREENING

A crucial feature of any hearing conservation program is the regular monitoring of workers' hearing. New employees must be screened and the effectiveness of the program monitored by routine, usually annual, hearing tests. The annual hearing test has many functions; important among them is the opportunity it provides to reinforce the hearing conservation program and to monitor proper use of hearing protectors. It detects those with hearing loss and identifies individuals with changes and whether a total program is effective. It indicates whether a program is working, whether an individual worker needs counseling, or if the whole plant needs further instruction. There are practical problems related to hearing screening. When should one do the test? Is TTS a problem? It used to be taught that screening should not be performed unless the worker was out of noise for 16 and preferably 48 hours before the test. This is impractical, and now testing is done throughout the workday, for in an effective program, there should be no TTS. Those who fail can be retested after a period in quiet.

What is a failure? Many suggestions have been made in the literature. The current belief is that a change of 15 dB or more in two or more frequencies should be an indication for a further referral. Ten dB changes are usually assumed to be within the realm of test–retest variability of screening audiometry. Proposed new federal regulations have been delayed.

Reproduced with permission from Alberti PW, Riko K, Abel SM, Kristensen R. The effectiveness of hearing protectors in practice. J Otolaryngol 1979; 8:354–9.

A further question is how, and for how long, to store records. This issue has been significantly reduced by the introduction of computer programs designed to deal with the mass of figures generated, which are becoming widely used. The ideal system of hearing screening includes direct computer storage of the audiometric results from the audiometer and a printout of the current hearing test results, the most immediate prior one, and the first one on record.

MEDICAL, LEGAL, AND SOCIAL IMPLICATIONS

There is no clear-cut method of determining the impairment produced by hearing loss, and definitions vary. In turn, there is little congruity about levels at which compensation should be paid, for what, and for how long. One may compensate for loss of earnings or loss of enjoyment of life. Compensation may be paid only while retraining occurs or for life.

Differences in philosophy have given rise to widely differing practices. The American Academy of Otolaryngology-Head and Neck Surgery suggests that hearing loss should be compensated if the average loss of the frequencies 500, 1,000, 2,000, and 3,000 exceeds 25 dB. States vary widely in their interpretation of these recommendations.

CHAPTER 16

Ototoxicity

Leonard P. Rybak, MD, PhD, John Touliatos, MD

Ototoxicity can be defined as the capacity of a drug or chemical to damage inner ear structure and/or function. The damage may occur in the auditory or vestibular portion or in both parts of the inner ear. A large number of agents with the propensity for ototoxicity exist. This chapter deals with several of the more common drugs and chemicals likely to cause hearing loss and/or cochlear injury. These agents include aminoglycoside antibiotics, the antineoplastic drugs cisplatin and carboplatin, loop diuretics, and salicylates. The risk factors, pharmacokinetics, and monitoring of blood levels are discussed.

AMINOGLYCOSIDE ANTIBIOTICS

Although they were not the first drugs with adverse effects on the inner ear, it was the widespread use of aminoglycoside antibiotics in the late 1940s and 1950s as chemotherapy against tuberculosis that drew the attention of the medical community to the problem of ototoxicity.

The aminoglycosides provide bactericidal activity against gram-negative aerobic bacteria and include streptomycin, dihydrostreptomycin, tobramycin, gentamicin, neomycin, netilmicin, sisomicin, amikacin, and kanamycin. Netilmicin appears to be the least ototoxic drug in the group.

Amikacin and kanamycin have more of an effect on the cochlea than on the vestibular system, whereas streptomycin and gentamicin appear to exert greater effects on the vestibular system than on the cochlea, although auditory damage does occur with their use. However, with any of these drugs, both auditory and vestibular toxicity can occur simultaneously.

Because only about 3% of an orally administered dose is absorbed from the gastrointestinal tract, these drugs usually are given parenterally. Tissue concentrations of aminoglycosides are usually about one-third of corresponding serum concentrations. Penetration of aminoglycosides across the blood-brain barrier is minimal, except in neonates.

Aminoglycosides are excreted in the urine by glomerular infiltration; therefore, concentrations in the urine may exceed those in the serum. Impaired renal function reduces the rate of excretion and may lead to accumulation in the body. Doses are frequently adjusted downward in patients with decreased renal function.

In ototoxic doses, the cochleotoxic agents (neomycin, kanamycin, amikacin, sisomycin, lividomycin) appear to elicit patterns of injury to the cochlea in experimental animals that are similar to the patterns seen in human temporal bones. These compounds tend to cause selective destruction of the outer hair cells in the basal turn of the cochlea, with progression toward the apex as the dose and duration of treatment are increased.

Several prospective studies of aminoglycoside ototoxicity have been carried out. Fee[1] and Smith et al[2] compared gentamicin ototoxicity with tobramycin ototoxicity and found cochlear damage in 10 to 16% of patients and vestibular toxicity in 5 to 15%.

The ototoxic potential of aminoglycoside administration is determined by total serum concentration over time. In practice, however, monitoring peak and trough levels is more practical and provides reasonable protection against toxicity, as well as ensures that the therapy is adequate. Lerner and associates found an association of ototoxicity with elevated mean trough levels.[3]

Moore et al reported that bacteremia, elevated temperatures, liver dysfunction, and elevated serum urea nitrogen-to-creatinine ratios were risk factors associated with ototoxicity in prospective double-blind clinical trials of gentamicin, tobramycin, and amikacin.[4] In another study, univariate and multi-

variate analysis of risk factors of ototoxicity showed only age as a predisposing factor for toxicity.

One of the newly identified risk factors may be genetic susceptibility. Hypersensitivity to aminoglycoside ototoxicity can be transmitted by mothers as a genetic trait. A mitochondrial deoxyribonucleic acid (DNA) polymorphism, 1555[G], is associated with aminoglycoside-induced deafness.[5] The basis for this hypersensitivity to ototoxicity may be based on the three-dimensional structure of the ribosome, favoring the binding of aminoglycoside, leading to disruption of protein synthesis and cell death in the cochlea.[6]

Acute damage to the cochlea is often preceded by tinnitus, although ototoxic effects can occur in the absence of tinnitus. The loss of hearing that results from the use of these drugs initially affects the high frequencies. Since patients do not complain about or have noticeable hearing losses until they have 30 dB losses that include frequencies as low as 3,000 to 4,000 Hz, the detection of ototoxicity is difficult unless audiometric monitoring is performed. Monitoring is particularly important in high-risk patients, such as those with renal insufficiency, those on higher-than-usual drug doses, those with persistently elevated serum levels despite dosage adjustments, or those with some degree of a baseline hearing or balance disorder. When audiometric measurements are obtained, the usual definition of ototoxicity is a hearing loss of 10 dB bilaterally at any frequency; some authors have used 20 dB as the cutoff. Again, since the usual threshold for perception of hearing loss by patients is a 30 dB drop, there will be at least that much of a loss by the time evaluation of the patient's complaints is begun.

The formation of free radicals (reactive oxygen species, reactive oxygen metabolites) by aminoglycosides has come to the forefront as the etiologic mechanism responsible for ototoxicity. The observation that gentamicin may act as an iron chelator was key to establishing that the formation of free radicals by aminoglycosides is an important mechanism in the development of ototoxicity.[7]

Several protective models are currently being investigated to prevent free radical–induced apoptotic cell death in cochlear hair cells. Those models that have been experimentally successful include administration of appropriate neurotrophins or growth factors, administration of caspase-specific inhibitors that remove the essential catalyst caspase from the apoptotic cascade, and gene therapy to enhance expression of genes that will synthesize neurotrophins or other protective substances.

ANTINEOPLASTIC DRUGS: CISPLATIN AND CARBOPLATIN

Cisplatin

After a 1-hour intravenous infusion of 70 mg/m^2 of cisplatin, the plasma platinum concentrations were found to have a biphasic clearance with half-life values of 23 minutes and 67 hours. Seventeen percent of the administered dose was excreted in the first 24 hours. Renal excretion is primarily by glomerular filtration. Ninety percent of cisplatin is bound to serum proteins,[8] and this cisplatin-protein complex is inactive against tumor cells. The serum levels of non–protein-bound platinum display different kinetics than those found for total platinum levels in serum. It is not known whether toxic metabolites of cisplatin are formed either in the inner ear or in the other parts of the body. However, the liver has been shown to convert cisplatin into nontoxic metabolites within 1 hour.

Early after its introduction, standard cisplatin doses were 50 mg/m^2. Subsequent cisplatin treatment regimens have been developed using higher doses of cisplatin (100 to 120 mg/m^2 = high dose and 150 to 225 mg/m^2 = very high-dose regimens). These increased-dosage regimens have resulted in a higher incidence of hearing loss than that observed with the lower dosage of 50 mg/m^2, as well as some different perspectives on cisplatin-induced hearing loss. In a study of 54 patients receiving high-dose cisplatin, Laurell and Jungnelius found that 81% of the patients had significant threshold elevations (15 dB or more at one frequency and 10 dB or more in three frequencies).[9] After therapy, which ranged from one to seven courses, 41% of the patients had significant deterioration of hearing in the speech frequency range of 500 to 2,000 Hz. Twenty-five percent of patients lost 25% of their remaining high-frequency hearing after each course. Preexisting hearing loss did not seem to predispose to ototoxicity, but advanced age was slightly associated with risk of hearing loss. The audiogram after the first course did not predict future deterioration of hearing during treatment with high-dose protocols. In this study, the ototoxic risk was determined more by the amount of the sin-

gle dose than by the cumulative dose levels. No ototoxic effects were seen at a peak plasma concentration of less than 1 μg/L. Based on their findings, the authors recommended that patients undergoing high-dose cisplatin treatment undergo audiometric testing before the initiation of therapy and before each of the subsequent courses. Less frequent testing was deemed necessary for patients receiving low- and moderate-dose treatment.[9]

Kopelman et al reported that all of their patients complained of decreased hearing after very high-dose cisplatin administration (150 to 225 mg/m^2). Ototoxic reactions appear to be more likely in patients with low serum albumin and in those with anemia.[10]

The exact incidence and severity of cisplatin-induced auditory effects is difficult to assess because of inconsistencies including variable dosing in previous studies and the lack of complete data from patients too ill to cooperate for pretreatment and post-treatment audiograms. Symptoms that strongly suggest cisplatin ototoxicity include otalgia, tinnitus, and subjective hearing loss. Tinnitus has been reported in 2 to 36% of patients receiving cisplatin. Often the tinnitus is transient, lasting from a few hours up to a week after cisplatin therapy. The incidence of hearing loss among patients treated with cisplatin has been as low as 9% and as high as 91%.[11] In patients with head and neck cancer treated with cisplatin, about half develop hearing loss.[12] The hearing loss is usually bilateral and appears first at high frequencies (6,000 and 8,000 Hz). Progression to lower frequencies (2,000 and 4,000 Hz) may occur with continued therapy. The hearing loss may be asymmetric and may not appear until several days after treatment. Patients may experience some degree of reversibility, but when the hearing loss is profound, it appears to be permanent. Because the hearing loss tends to occur at the higher frequencies, it may escape detection without audiometry. Cochlear toxicity may be detected earlier with high-frequency audiometry (up to 20 kHz) than with conventional audiologic testing.[13] Speech discrimination scores may be markedly reduced when cisplatin ototoxicity occurs. The hearing loss may be gradual, progressive, and cumulative or may present suddenly. Several patterns of hearing loss have been described.[14]

The critical cumulative dose of cisplatin has been reported as 3 to 4 mg/kg body weight. Since ototoxicity may be more severe after bolus injection, the ototoxic effects can be reduced by using slow infusion and dividing the doses over several months.[11] Bokemeyer et al evaluated a group of adult patients treated with cisplatin for testicular cancer.[15] Symptoms of ototoxicity persisted in 20% of patients (tinnitus and/or hearing loss). Ten percent had experienced completely reversible ototoxic symptoms that lasted from 1 to 18 months after treatment. Statistically significant risk factors for ototoxicity were (1) a high cumulative dose of cisplatin, (2) a history of noise exposure, and (3) a high dose of vincristine, which seemed to cause reversible ototoxic symptoms. Persistent ototoxicity may occur in about 20% of patients with testicular cancer who are treated at a standard dose but may affect more than 50% of patients receiving cumulative doses of cisplatin exceeding 400 mg/m^2. Previous noise exposure may also result in a threefold increased risk for cisplatin ototoxicity. Future studies should examine these risk factors as important stratification criteria for trials to prevent or, at least, minimize cisplatin ototoxicity.

A new method of treatment for superficially accessible tumors of the head and neck, esophagus, and trunk has been reported. Cisplatin is injected as a gel, which also contains epinephrine. The antitumor agent was injected weekly for 4 weeks in 45 patients. The initial dose of cisplatin was 1 mg/cm^3 tumor volume and escalated up to 6 mg/cm^3 as needed, depending on observed toxicities. The overall objective tumor response was 50%, with 40% complete response with a median-response duration of 160 days. No dose-limiting cisplatin-related toxicities, such as nephrotoxicity, neurotoxicity, or ototoxicity, were observed with this method.[16]

Children receiving high cumulative doses of cisplatin (above 540 mg/m^2) have a high incidence of hearing loss, which is cumulative and dose dependent.[17] However, a plateau effect has been reported with no further deterioration of hearing at doses greater than 600 mg/m^2. Still, a number of patients will develop more severe hearing losses in the 2,000 to 8,000 Hz range even after one or two courses of therapy, showing exceptions to the plateau effect.[18] Adults with a preexisting history of otologic problems are said to experience a higher incidence of ototoxicity of cisplatin affecting both lower (1,000 to 8,000 Hz) and higher (10,000 to 18,000 Hz) frequencies.[19] Ototoxicity of cisplatin appears to be enhanced by cranial irradiation.[20]

A study of otoacoustic emissions was carried out in pediatric patients treated with cisplatin chemotherapy. Transient evoked otoacoustic emissions could be measured in 11 of 12 patients studied. When the middle ear status was normal, a significant correlation was found between the transient evoked otoacoustic emissions and the pure-tone threshold, and 90.5% of patients had a significant sensorineural hearing loss at 8,000 Hz. Increased hearing loss was associated with young age at first dose of cisplatin, high number of chemotherapy cycles, and high cumulative dose of cisplatin.[21]

Temporal bones removed from patients with cisplatin-induced hearing loss have demonstrated the following: large, fused stereocilia; damage to the cuticular plate of the outer hair cells; and extensive loss of sensory cells in the vestibular labyrinth in specimens studied with scanning electron microscopy.[22] In addition to noting outer hair cell degeneration in the basal turn of the cochlea, Strauss et al reported degeneration of spiral ganglion cells and cochlear neurons in patients with documented cisplatin ototoxicity.[23] However, the vestibular neurons appeared normal. In a study of human temporal bones removed from patients treated with cisplatin, radiation, or a combination of both treatments, the spiral ganglion cells and inner and outer hair cells were decreased in number, and the stria vascularis was found to be atrophic. The otopathology identified in these temporal bones also included vascular changes, serum effusion, or fibrosis that accompanied sensorineural hearing losses.[24]

Carboplatin

Clinical Studies Carboplatin is a newer analog of cisplatin that was introduced into clinical trials in 1981. This drug was found to have less nephrotoxicity than does cisplatin. Initial reports suggested that carboplatin was also less ototoxic than is cisplatin. The primary dose-limiting toxicity of carboplatin has been bone marrow suppression.[25] This toxic effect has been overcome by the use of autologous stem cell rescue and/or the use of hematopoietic growth factors. This has allowed the use of higher doses of carboplatin and increased antitumor effectiveness.

A study of children with neuroblastoma who were treated with higher-dose carboplatin (2 g/m^2 total dose) showed that 9 of the 11 children (82%) had hearing loss in the speech frequencies that was severe enough that hearing aids were recommended. These children had all previously been treated with cisplatin, and several patients had previously received aminoglycoside antibiotics. The investigators concluded that high-dose carboplatin is ototoxic, especially in children who have been exposed to previous platinum therapy or other ototoxic agents. They felt that in children in whom hearing losses are inevitable, owing to cumulative ototoxic exposure, parents need to be properly informed of the balance of risks and benefits.[26]

Studies by Van Der Hulst et al[19] and Kennedy et al[25] have shown a significant incidence of hearing loss in carboplatin-treated patients. Seventy-five percent of patients treated with carboplatin had measurable hearing loss in the former study, whereas 20% of patients treated with carboplatin in the latter study had hearing loss. The authors in the latter study stated that no clinically significant hearing loss occurred.[26] On the other hand, cumulative sensorineural hearing loss has been shown in 11 of 22 children who received carboplatin chemotherapy.[27]

Carboplatin has been successfully used to treat malignant brain tumors when administered in conjunction with osmotic blood-brain barrier disruption with mannitol. Unfortunately, a larger percentage of patients developed high-frequency hearing loss when they were treated with this regimen. Twenty-nine patients received various doses of the protective agent sodium thiosulfate, given intravenously 2 hours after carboplatin. Doses of sodium thiosulfate were escalated from 4 g/m^2 to 8, 12, 16, and 20 g/m^2 in consecutive months. Audiograms were performed before treatment and monthly after treatment with carboplatin. These audiograms were compared with those of 19 historical control patients who were treated similarly but who did not receive sodium thiosulfate. The incidence of hearing loss in the control group was 79% (15/19). The group of patients protected with sodium thiosulfate lost only 3.7 ± 2 dB at 8,000 Hz after one carboplatin treatment, compared with the historical group, which had an average loss of 20.8 ± 5.9 dB. Patients in the sodium thiosulfate–treated group with excellent baseline hearing had little change in hearing thresholds at 8 kHz after the second treatment (8.0 ± 8.3 dB) compared with the historical control patients with excellent baseline hearing (40.5 ± 8.6 dB). These findings support the concept that sodium

thiosulfate in doses of 16 or 20 g/m^2 decreases carboplatin-induced hearing loss. Because the thiosulfate does not seem to cross the blood-brain barrier, there would appear to be no interference with the antitumor action of carboplatin in these patients.[28]

An intriguing study predicted carboplatin ototoxicity in patients with ovarian cancer, who were treated with a combination of cisplatin and carboplatin. A total of 105 patients with ovarian cancer who received up to six courses of carboplatin (300 mg/m^2) were evaluated, and values for first-course carboplatin area under the curve (AUC = area under the plasma drug concentration versus time curve, a measure of drug exposure) were determined retrospectively. Thrombocytopenia of grade 3 to 4 was found in 10% of patients with low AUC (< 4 mg/mL × min). No patients in the low AUC group had ototoxicity, but 12% of patients in the high AUC group were found to have ototoxicity and 44.6% had thrombocytopenia. These data could prove valuable for prevention of thrombocytopenia and ototoxicity for the first cycle of combined treatment with carboplatin and cisplatin.[29]

LOOP DIURETICS

Loop diuretics are a group of potent synthetic drugs that act on the loop of Henle to inhibit the reabsorption of sodium, potassium, and chloride ions by the Na^+-K^+-$2Cl^-$ cotransporter system. The ototoxicity of these agents has been reviewed.[30]

Most administered furosemide is excreted in the urine. Furosemide essentially follows a three-compartment pharmacokinetic model with an average half-life for renal elimination of 29½ minutes. Furosemide elimination decreases greatly in patients with advanced renal failure, in whom the half-life can be prolonged to 10 to 20 hours. Long half-lives also have been observed in patients with congestive heart failure, especially those undergoing long-term furosemide treatment. The plasma half-life of furosemide is approximately 45 to 92 minutes in healthy subjects but is prolonged to approximately 3 hours in patients with renal failure. The gastrointestinal uptake of furosemide is high; most authors have concluded that approximately 65% of an oral dose of furosemide is absorbed. Plasma levels exceeding 50 mg/L are frequently associated with hearing disturbances.[30]

Although the use of ethacrynic acid is very low currently, occasionally, it is used in patients who are allergic to furosemide or refractory to its diuretic effect.

A study by Arnold et al revealed some morphologic effects in the temporal bones from a patient who received a total of 5,000 mg of furosemide plus 250 mg of ethacrynic acid over 5 days before dying of renal failure.[31] The inner and outer hair cells were normal at both the light and electron microscopic levels, but the stria vascularis had marked cystic changes, as has been reported in animal studies. The dark cell areas of the vestibular system were found to have marked cystic changes, with dilation of the intracellular fluid spaces, suggesting effects on fluid transport within the inner ear.

Tuzel summarized the reported incidence of hearing loss, as documented by pure-tone audiometry in 179 patients treated with bumetanide and 62 patients receiving furosemide.[32] Among patients receiving bumetanide, only 2 (1.1%) had audiometric changes of 15 dB or greater. Patients treated with furosemide had a 6.4% incidence of hearing loss. Tuzel did not report whether these hearing losses were temporary or permanent. Although most cases of loop diuretic ototoxicity are temporary and fully reversible, some appear to be permanent. New loop diuretics are being developed and tested in animals, and some may prove to be even less ototoxic than bumetanide when clinical trials are performed.

Permanent, profound mid- and high-frequency sensorineural hearing loss in a transplant patient receiving ethacrynic acid illustrates that deafness from loop diuretics continues to be a problem that is clinically significant.[33] Permanent hearing loss has been reported in high-risk premature neonates treated with furosemide.[34]

SALICYLATES

Orally administered salicylates are absorbed very rapidly in the gastrointestinal tract, with an apparent half-life of 6 to 15 minutes. Absorption of salicylates is influenced significantly by gastric emptying time and by the presence of food in the stomach; food may more than double the absorption half-life of aspirin. Aspirin is broken down in the body to salicylic acid, with a biologic half-life of 15 to 20 minutes.[35] Salicylates are distributed mainly to the extracellular water compartments.[36] Concentrations of the salicylates are higher in the liver and kidney than in the serum, whereas brain concentrations are

usually about 10% of those in the serum. Salicylates are excreted mainly in the urine.

Salicylate concentrations of 20 to 50 mg/dL in serum have been associated with hearing losses of up to 30 dB.[37] Human volunteers receiving aspirin at various doses experienced hearing loss and tinnitus at relatively low concentrations of total plasma salicylate. A linear relationship between hearing loss and unbound salicylate concentrations has been reported.[38] Hearing loss can be observed at salicylate concentrations below 20 mg/dL, and there seems to be no threshold for salicylate-induced hearing loss. The severity of tinnitus increases as plasma salicylate concentrations exceed 40 mg/L. Work by Lue and Brownell links the reversible salicylate ototoxicity to reduction of lateral membrane stiffness in outer hair cells.[39]

CHAPTER 17

Idiopathic Sudden Sensorineural Hearing Loss

Robert A. Dobie, MD

DEFINITION, CLINICAL PRESENTATION, AND PROGNOSIS

Idiopathic sudden sensorineural hearing loss (ISSNHL) is a term that requires little elaboration. Most patients describe waking up with hearing loss that was not present the night before, or they can identify the time of day when hearing loss began. Nevertheless, the literature reflects a consensus to consider onset over a period of less than 3 days as "sudden."

Hearing loss, whether sudden or more gradual in onset, can obviously range from barely detectable to profound, but, once again, a convention has evolved: ISSNHL is generally defined as demonstrating a threshold change for the worse of at least 30 dB in at least three contiguous audiometric frequencies. Occasionally, this change can be assessed by comparing current to prior audiograms. More often, the affected ear is compared with the unaffected ear, assuming that the two ears were equal before. Fortunately, ISSNHL is almost always unilateral.

According to Byl, ISSNHL affects about 1 person per 10,000 per year[1]; this would correspond to over 25,000 cases per year in the United States. In contrast, Hughes and colleagues estimate only 4,000 cases per year in the United States.[2] All ages and both sexes are affected; the peak ages are 30 to 60 years.[3]

Tinnitus is usually present. Vertigo is frequent, either spontaneous (as in acute vestibular neuronitis) or as isolated positional vertigo.[4] Sixty-five percent of patients recover completely with or without treatment, most within 2 weeks.[5] Low-frequency losses have a better prognosis than high-frequency losses; of course, this is true of all types of rapidly progressive or fluctuating sensorineural hearing loss (SNHL), not just ISSNHL.[6]

ETIOLOGY

Since ISSNHL is, by definition, idiopathic, the cause of any individual case is not known. Nevertheless, there has been considerable speculation about viral and vascular causes, with rather more evidence for the former than the latter.

Viral

Many otologists believe that viral infection (or reactivation of latent viruses) is the most important cause of ISSNHL. The circumstantial evidence for that belief can be summarized as follows:

1. Many viral diseases (eg, mumps) can cause congenital or sudden SNHL.
2. Cochlear histopathology after these diseases resembles that seen after ISSNHL.
3. Patients with ISSNHL often demonstrate immunologic evidence for viral infection.
4. Viruses such as herpes simplex may lie dormant in neural tissue for years and have been identified in human spiral ganglia.

Intrauterine viral infection may damage many organ systems. The rubella (German measles) virus caused thousands of cases of congenital deafness during a 1964–1965 epidemic[7]; most were associated with a syndrome that included eye, heart, and brain abnormalities. Since the introduction of the mumps-measles-rubella (MMR) vaccine, the congenital rubella syndrome has virtually disappeared in the United States.

At present, the most important viral cause of congenital deafness is cytomegalovirus (CMV), a member of the herpes virus family. Cytomegalovirus has been cultured from the inner ear[8] and causes cochlear lesions in experimentally infected animals.[9]

Congenital CMV syndrome includes deafness and lesions of the eye, brain, liver, and spleen.[10] It is important to note, however, that most CMV-infected neonates do not demonstrate the full-blown CMV syndrome. Indeed, "asymptomatic" CMV infection causes more hearing loss than "symptomatic" (syndromic) CMV infection. Neonatal CMV screening has shown an infection rate (virus cultured from urine) of 1.3%[11]; 10% of these cases had either congenital or progressive hearing loss. Most of the babies who had (or developed) hearing loss were otherwise healthy and would have been missed by conventional high-risk criteria for congenital hearing loss. No vaccine is yet available to reduce or eliminate hearing loss from CMV.

Neonatal herpes simplex virus (HSV) infection is associated with hearing loss in about 10% of cases.[12]

Mumps (viral parotitis) is the prototypical example of sudden unilateral hearing loss in childhood. Rare since the widespread use of the MMR vaccine, mumps deafness occurred in about 5 of every 10,000 mumps cases[13] and was usually unilateral. Like CMV, the mumps virus has been cultured from the inner ear[14] and causes cochlear lesions in experimental animals.[15] Measles (rubeola virus) accounted for 3 to 10% of bilateral deafness in children prior to the MMR vaccine.[16]

The varicella-zoster (or herpes zoster) virus causes chickenpox in children and shingles in adults. When the geniculate ganglion is involved, with facial paralysis plus auricular bullae, it is called herpes zoster oticus (HZO) or Ramsay Hunt syndrome. About 6% of HZO cases exhibit SNHL,[17] making HZO probably the most common type of hearing loss in adults in which a viral cause is reasonably certain. Herpes zoster viral deoxyribonucleic acid (DNA) has been identified in temporal bone tissue taken from a patient with HZO and sudden hearing loss.[18]

Human immunodeficiency virus (HIV) may cause hearing loss directly but more commonly makes the host more susceptible to other viruses, many of which (CMV, HSV, adenovirus) have been cultured from the HIV-infected inner ear,[19] as well as to other infectious agents.

Schuknecht and Donovan first showed that ears from patients who had suffered ISSNHL demonstrated atrophy of the organ of Corti and tectorial membrane and spiral ganglion cell losses; these findings were similar to those seen in cases (mumps, measles) known to be caused by viral infections and different from the cochlear pathology (fibrous and osseous proliferation) seen after ischemic deafness.[20]

Given the otopathologic similarity between ISSNHL and hearing loss of known viral origin, investigators looked for immunologic evidence of viral infection in ISSNHL. Veltri and colleagues showed that patients with ISSNHL frequently had seroconversion (increasing antibody levels) for several viruses, including mumps, influenza (coincidental?), measles, HSV, rubella, and CMV.[21] Wilson focused specifically on HSV, noting that 16% of ISSNHL patients showed seroconversion compared with only 4% of controls.[22] The identification of DNA from HSV in human spiral ganglion[23] and the development of an animal model for HSV neurolabyrinthitis[24] have added to suspicion that this virus may be an important cause of ISSNHL. Pitkaranta and colleagues noted that there are many negative serologic studies, failing to implicate HSV or other viruses, but also noted that long-dormant neurotropic viruses can reactivate and cause localized disease without triggering changes in systemic immunoglobulin levels.[25] This is true for herpetic cold sores, for example, and may also be true for diseases such as ISSNHL, Bell's palsy, and vestibular neuronitis. Unfortunately, the difficulty of inner ear culture or biopsy makes proving this hypothesis in individual cases impossible.

Vascular

Diseases of blood vessels affect many organ systems and constitute some of the most important causes of death and disability in developed countries. Risk factors for vascular disease include diabetes, hypertension, obesity, and hyperlipidemia; controlling these risk factors can reduce the incidence of heart attacks, strokes, blindness, kidney failure, and premature death. Equally important (but uncontrollable) risk factors include age, sex, and family history. Since no organ can survive without adequate blood supply and since vascular disease affects so many different organ systems, it is natural that investigators have looked for evidence that SNHL is linked to vascular disease (or to its risk factors). Given the intensity of their efforts, the evidence is extremely weak.

In other organ systems, vascular disease may cause either gradual or sudden/stepwise deteriora-

tion of function. Congestive heart failure may develop insidiously in some patients, whereas others have sudden-onset myocardial infarctions. Even when the disease process (eg, atherosclerotic narrowing of arterial lumen) is gradual, the symptoms and signs of dysfunction are often sudden, when a critical point is reached or a new event such as thrombosis or embolism totally shuts off blood flow. If vascular disease is important for a particular organ (eg, the cochlea), one should expect it to cause both sudden and gradual changes in function.

Unfortunately, otologists cannot yet measure cochlear blood flow in clinical practice, so whether a person (or an ear) has cochlear ischemia cannot be determined. Reliance must be placed on correlations between hearing loss and vascular disease risk factors (or established vascular disease elsewhere in the body) and to a lesser extent on histopathologic evidence.

Consideration can begin with age-related hearing loss (ARHL). Age is not really a cause of SNHL but rather an association; still, after excluding common causes of SNHL (noise, head injury, etc), the vast majority of people with adult-onset SNHL cannot be labeled any more precisely than to call them age related. If vascular disease was an important component of ARHL, it might be expected that patients (and longitudinal studies of ARHL) would describe stepwise progression, with substantial asymmetry as one ear suffers ischemic events whereas the other escapes, at least for a while. The rarity of such reports in ARHL should already cast doubt on the vascular hypothesis, but those doubts can momentarily be put aside and one might ask whether vascular disease and its risk factors are correlated with ARHL. For example, do diabetics have more hearing loss than nondiabetics of the same age and sex? The extensive literature addressing this issue has been reviewed and can best be described as inconclusive.[26] If vascular disease is responsible for some proportion of ARHL, its contribution is small.

Focusing on patients presenting with ISSNHL, are some of these cases attributable to "vascular accidents" (thrombosis, embolism, or hemorrhage) affecting the cochlea? If vascular disease caused a substantial fraction of ISSNHL, the incidence of ISSNHL would be expected to be much higher in men than in women and to rise sharply with age; neither is true. Frequent recurrences and (over time) bilaterality would also be expected, yet most people who suffer ISSNHL have only one event, affecting only one ear. Studies of vascular disease and risk factors have shown only that diabetics with ISSNHL have a poorer prognosis,[27] not that any of these factors predict the likelihood of suffering ISSNHL.

None of this proves that vascular disease is totally irrelevant to ISSNHL. Inner ear hemorrhages with sudden deafness do occur rarely in patients with leukemia, sickle cell disease, and thalassemia,[28–30] although the temporal bone histopathologic findings after hemorrhage or ischemia are very different from those seen in patients who have suffered ISSNHL, as previously discussed. Sudden SNHL may[31] or may not[32] be an occasional complication of cardiopulmonary bypass surgery (presumably owing to emboli). Until otologists are able to assess cochlear blood flow reliably and noninvasively in their patients, we will probably never know much about the role of vascular disease in ISSNHL (or SNHL in general); at this point in time, it appears to be somewhere between small and negligible.

Other

Simmons postulated that double inner ear membrane breaks could be responsible for some cases of ISSNHL,[33] and it is hard to prove that he was wrong, but there is little evidence that he was right either. Because Simmons hypothesized that one of these membrane breaks would involve the oval or round window, producing a perilymph fistula (PLF), the 1980s saw a wave of enthusiasm for middle ear exploration, looking for PLF, in patients with ISSNHL. Today, most otologists believe that PLFs do occur, causing SNHL and dizziness, but almost exclusively in the context of identifiable barotrauma: after scuba diving, violent nose blowing, or extreme exertion during breath holding (eg, weight lifting with improper technique). In the absence of such a history, few otologists would diagnose membrane breaks and/or PLF or recommend therapy appropriate to such a diagnosis (bed rest, middle ear exploration).

DIFFERENTIAL DIAGNOSIS

Table 17–1 shows that dozens of otologic and systemic disorders have been associated with sudden SNHL. Many of these disorders (eg, Meniere's disease, autoimmune inner ear disease) typically cause

rapidly progressive or fluctuating hearing loss rather than truly sudden loss. The more important identifiable causes of sudden SNHL (by definition, these are not "idiopathic") are clinically easy to diagnose, for example, meningitis, acoustic trauma, head injury. Others, such as multiple sclerosis, are usually missed when sudden SNHL is the first manifestation. In areas where Lyme disease is endemic, it is probably wise to ask patients with sudden SNHL about recent rash or arthralgia.

TABLE 17–1. Some Causes of Sudden Sensorineural Hearing Loss

Infectious
Meningitis (bacterial, fungal)
Labyrinthitis (bacterial, fungal, viral, parasitic, spirochetal)
Traumatic
Head injury (with/without fracture)
Barotrauma (with/without perilymph fistula)
Acoustic trauma
Iatrogenic injury
Neoplastic
Acoustic tumor
Metastases (to meninges or temporal bone)
Hematologic malignancies (leukemia, myeloma)
Immunologic
Autoimmune inner ear disease
Systemic immune diseases (Cogan's, Wegener's granulomatosis, polyarteritis, temporal arteritis)
Ototoxic
Vascular (see text)
Neurologic
Multiple sclerosis
Focal pontine ischemia
Metabolic
Disturbance of iron metabolism
Renal failure/dialysis
Miscellaneous
Meniere's disease
Functional hearing loss

Adapted from Hughes GB et al.[2]

INVESTIGATIONS

Patients presenting with sudden unilateral hearing loss without obvious antecedent cause should receive a careful otologic history and examination, as well as an audiogram (including the Stenger test to detect functional hearing loss). Otoacoustic emissions (OAEs) are sometimes present (implying sparing of outer hair cells) in ISSNHL,[34] but it is unclear whether OAE testing is clinically useful, that is, whether the results can assist in selecting therapy.

Routine blood testing in ISSNHL is of dubious value. Children with ISSNHL (rare!) should receive a complete blood count as a screening test for leukemia. If there are clinical clues pointing toward Lyme disease, confirmatory testing is indicated. Patients with symptoms of systemic disease should probably be referred to an internist rather than receive blood tests selected by an otolaryngologist. If corticosteroid therapy is being considered in a patient who has not been tested for diabetes in recent years, a blood glucose test is probably in order.

About 1% of patients presenting with sudden SNHL have acoustic tumors,[35] and even complete recovery does not completely rule out this diagnosis. When hearing in the affected ear is quite poor (> 60 dB at 2 kHz), magnetic resonance imaging (MRI) with gadolinium contrast injection is the most appropriate study to detect or rule out a tumor. For patients with better hearing, either MRI or auditory brainstem response (ABR) testing (with MRI reserved for patients showing abnormal ABR) may be appropriate.

The increasingly frequent use of MRI in cases of sudden SNHL has shed additional light on the etiology. Precontrast films can document inner ear hemorrhage in the rare cases associated with hematologic disorders.[29] Soon after the onset of hearing loss, gadolinium enhancement of the cochlea is seen in typical cases of ISSNHL, probably owing to a transiently leaky blood-brain barrier.[36] Six months or more after onset, no fibrotic or osseous prolifera-

tion (such as would be expected after ischemic damage) could be identified.[37]

INTERVENTIONS

Wilson et al showed, in a randomized clinical trial, that patients receiving oral corticosteroids achieved substantial recovery (defined as more than 50% recovery vis-à-vis the uninvolved ear) more frequently than patients receiving placebo.[38] This benefit was apparent only for "moderate" degrees of loss (Figure 17–1); 78% of patients in this category who received corticosteroids recovered at least half of their loss, compared with 38% of those who received placebo. Patients with mid-frequency losses did well with or without steroids; those with profound losses did poorly regardless of treatment.

Unfortunately, Wilson et al's is the only randomized trial of corticosteroid therapy to date. A nonrandomized study by Moskowitz and colleagues showed benefits similar to those seen in the Wilson et al study (89% recovery with corticosteroids, 44% recovery without treatment).[39] Many, if not most, otologists offer oral corticosteroids to patients with ISSNHL who have no contraindications (eg, diabetes, active duodenal ulcer, tuberculosis). A typical regimen is prednisone, 1 mg/kg/day, for 7 to 10 days, with or without a taper. Useful oral antiviral drugs have been available in recent years but have yet to be found helpful for patients with ISSNHL.[40]

The vascular hypothesis is extremely popular in Europe, where treatments such as oral pentoxifylline and intravenous dextran (intended to reduce blood viscosity), apheresis (intended to remove low-density lipoprotein cholesterol from the blood), carbogen (a mixture of 10% carbon dioxide and 90% oxygen), and papaverine (intended to dilate blood vessels) are often used. None of these has been shown to be superior to placebo.[41–46]

When a cause for sudden SNHL is found (see Table 17–1), the case is not idiopathic, and the treatment should depend on the diagnosis. The management of persistent tinnitus and hearing loss, when recovery is incomplete, is nonspecific. Some patients choose to try hearing aids, but, for most, sympathetic counseling is the best approach.

CHAPTER 18

Perilymphatic Fistulae

Robert I. Kohut, MD

A perilymphatic fistula (PLF) is an abnormal passage through the bony labyrinthine capsule that is permeable to perilymph, causing abnormal, sometimes reversible, cochlear or vestibular function.

The author's attention to this disorder occurred with a patient encounter. This patient's severe vestibular symptoms had previously been incorrectly attributed to a central neurovascular event and later to psychological problems. The presence of a positive unilateral Hennebert's sign/symptom in this patient who had no other signs of syphilis (and was proven to be free of syphilis) prompted the conclusion that the findings were owing to a pathologic process in which the positive and negative air pressure applied to the external ear canal was transmitted to the inner ear. On exploration of the middle ear, fluid reaccumulation just anterior to the stapes was observed, and this site was grafted. Dramatic rapid improvement occurred in this patient.[1]

The purpose of this chapter is to make available to the reader a set of diagnostic criteria to be used during clinical or research activities concerning PLF that cause balance disorders, sensory hearing disorders, or both. To achieve this purpose, a summary of historical facets and research activities extending over 20 years related to this disorder will be reviewed. Following this review, discussion will concern a predictive masked experimental paradigm, which was used to test the diagnostic criteria. In these experiments, the temporal bone histologic diagnostic criteria were developed whereby clinical events were predicted based on the presence of specific histologic findings. Then, using these histologic diagnostic criteria, another experiment was designed in which the presence of the histologic diagnostic criteria for each donor temporal bone pair was predicted on the basis of clinical chart data recorded during life.

The treatment methods that will be described are the products of the experience of many otologists, and these are still in a dynamic phase of development.

The reader is encouraged to consider the thoughts shared in this chapter, to criticize them, and help develop, through his/her own clinical experience and investigative efforts, further knowledge concerning this disorder. Many in the recent past have considered PLF as a nonentity. However, the preponderance of clinical and investigative data has given most of these clinicians reason to pause and recognize the pathogenic process called PLF or perilymphic leaks. A very thorough review article was published by Friedland and Wackym.[2] Their conclusion that PLF is an uncommon disorder appears to be based on clinical reports, particularly the findings on endoscopic examination. The potential weakness of this type of examination is discussed elsewhere in this chapter and relates to the heat produced by the endoscope with possible evaporation of the minute quantity of perilymph present, thereby precluding fluid detection.

HISTORY OF PERILYMPHATIC FISTULAE

In 1883, Gellé observed, during manipulation (without dislodgment) of a patient's exposed stapes, that the patient suffered vertigo with each movement of the ossicle. He attributed this to hypermobility of the stapes.[3]

Hennebert, some 22 years later, observed that compression and rarefaction of the air in the external auditory canal in some patients, having intact tympanic membranes, caused small-amplitude, brief, nystagmic movement of the eyes (Hennebert's sign).[4] Some patients having this provoked nystagmus also experienced a sense of displacement in space: vertigo (Hennebert's symptom).[5] Many, but

not all, of Hennebert's patients had syphilis. Since syphilis was a popular medical topic at that time, a generalization was developed wherein a patient with an intact tympanic membrane and with the findings of a nystagmic response to a fistula test (compression and rarefaction of the air of the external canal) was considered to have syphilis.

A positive fistula test, before Hennebert, had been observed in patients with bone-eroding ear disease such as cholesteatoma, and these were documented surgically. Yet there was no evidence in Hennebert's patients of an opening in the bony labyrinthine capsule as seen in these bone-eroding processes.

Discovering no bone-eroding process and reflecting on Gellé's observation, it seemed reasonable to conclude that the symptoms were attributable to a hypermobile stapes. However, there were some who thought that the symptoms and/or signs caused by a positive fistula test in patients having an intact tympanic membrane were most like those of patients having erosive otic disorders in which there was an opening through the bony labyrinthine capsule joining the middle ear and the inner ear (labyrinthine fistula). Some of these individuals were prominent otologists such as Alexander, Leidler, and McKenzie.[1]

When no fistula was found at surgery in patients having an intact tympanic membrane and a positive fistula test, the surgeons were criticized as having performed needless surgery. Note that the surgery was performed without the availability of the operating microscope.

The Nobel Laureate Robert Bárány, in 1910, concluded that because of the negative surgical findings and the previous proposals of stapes hypermobility, the hypermobile stapes hypothesis seemed reasonable.[6] This seemed to be confirmed later in 1921, when Ruttin reported the histologic findings of the temporal bones from a patient having a Hennebert's sign: no abnormal labyrinthine fistulae were histologically identified.[7]

This thought, that a positive Hennebert's sign was diagnostic of syphilis, was not re-examined until the advent of stapes surgery. In 1967, PLF were reported as a postoperative complication of stapedectomy for otosclerosis. The main concern here was hearing loss.[8,9] One year later, Fee reported a patient having a PLF caused by nonsurgical trauma.[10] Over the next decade, this was followed by similar reports, which indicated that sudden or rapidly progressive hearing loss[11–15] in patients with or without vertigo, or even with vertigo alone, some having a positive fistula test (Hennebert's sign or symptom), could be caused by a PLF.[12–17]

Okano and associates demonstrated a crack-like formation about the oval window or connecting the round window niche and the posterior semicircular canal ampulla.[18,19] Although not clinically correlated, these openings were suggested as a form of opening between the middle ear and the inner ear, perhaps related to inner ear disease. This type of histologic opening had not been considered by Ruttin.[7]

In 1986, Kohut et al reported a relationship between patencies of the fissula ante fenestram (FAF) and/or patencies of the fissure connecting the round window niche/posterior semicircular canal ampulla (round window fissure [RWF]) and specific fistula symptoms and signs.[16] These findings were supported by subsequent studies wherein these patencies could be predicted as being present or absent histologically based on archival medical record data.[17]

It appeared that histologic changes (noninterrupted formations of the FAF and/or RWF) could be predicted on strict clinical data related to PLF. Clinical prediction of pathologic findings, of course, is the "acid test" for disorders such as appendicitis, Laënnec's cirrhosis, malignancies, and other disorders related to histologically defined criteria. Cracks of the labyrinthine capsule in other areas existed in some of the temporal bone specimens examined; however, these never seemed to be related to clinical signs or symptoms.[17]

Since specific clinical criteria for PLF were related to vertigo and/or hearing loss, challenging temporal bone histologic investigations included one by El Shazly and Linthicum in which patencies of the labyrinthine capsule were not found to be related to sudden sensory hearing loss.[20] In this study, the authors found that the presence of labyrinthine capsule patencies did not predict the presence of sudden sensory hearing loss.[20] This was not in disagreement, although, at first glance, it appears so, with the previous studies by Kohut et al and Hinojosa et al.[21,22] The presence of sudden sensory hearing loss in Kohut et al's study predicted patencies of the labyrinthine capsule, not vice versa.[21]

Again, El Shazly and Linthicum's study tested the hypothesis that patencies of the labyrinthine

capsule predicted sudden sensory hearing loss,[20] not sudden hearing losses predicting the presence of patencies. As such, the studies are not in conflict.

However, one small series of temporal bones from patients having had sudden sensory hearing loss during life lacked the use of the necessary diagnostic exclusionary criteria for PLF described below. In this series, no patencies of the FAF or RWF were found. Yet in two specimen pairs (the only pairs that met the diagnostic exclusionary criteria), there was histologic evidence of patencies of the central portions of the stapes footplates. This condition has been seen by the author during surgery for PLF and has been repaired with improvement of symptoms.[23] Current studies suggest that this histologic change is not a normal variant.[24,25]

In another temporal bone histopathologic study by the author and other colleagues, the prevalence of patencies of the FAF or RWF using 200 temporal bone pairs from consecutive autopsies, therefore representing a cross-section of society, was 24%, which is surprisingly high. Logic compels one to conclude that the prevalence of patients having PLF symptoms and signs are magnitudes smaller. Therefore, the mere histologic presence of these specific patencies seems not to predict the presence of symptoms of PLF during life. On the other hand, when hearing or balance symptoms had been present during life, the presence of these labyrinthine capsule patencies predicts the specific set of symptoms and signs related to PLF. One explanation to this seeming dilemma seems plausible, that is, there is another variable, perhaps distinguishable only with special histologic techniques. The author and his colleagues are engaged in an investigation testing the hypothesis that "some patencies are permeable to fluid, some are not, and only those permeable to fluid are related to clinical manifestations." So far, in preliminary studies, differences in proteoglycans (extracellular mucopolysaccharides bound to protein chains in covalent complexes) appear to be so related.[26] Definitive studies await completion.

COMMENTS REGARDING OVERALL CLINICAL PERSPECTIVES

The diagnostic criteria for PLF are simple but do require specific exclusionary criteria: a PLF cannot be accurately diagnosed if any of these exclusionary disorder types are present: inflammation, granuloma, neoplasia, or anatomically related neurologic disorders with symptoms and signs similar to PLF. These disorders can mimic symptoms and signs otherwise attributable to PFL. Symptoms and signs of PLF are related to the vestibular system and cochlear function separately, even though they can be present in combination.

As has been reviewed, the temporal bone histopathologic/clinical studies tested specific clinical criteria. The studies indicate that the probability and accuracy of these criteria are $p < .001$, sensitivity 59%, and specificity 91%. It appears reasonable to present the criteria used in these studies to the reader. A sensitivity of 59% suggests underdiagnosis; therefore, a heightened alertness to the possibility of a PLF appears reasonable. Additional diagnostic refinements are required to identify clinically the remaining 41% (100 – 59 = 41) of patients having PLF who are now presumably misdiagnosed as having another disorder. These refining new diagnostic criteria remain the responsibility of the readers or others to identify.

DIAGNOSTIC EXCLUSIONARY CRITERIA

For all clinical considerations regarding PLF, initially, there must be the exclusion of inflammation, granuloma, neoplasia, or anatomically related neurologic disorders. These are easily accomplished with a sedimentation rate, a microhemoagglutination assay for antibodies to *Treponema pallidum* for syphilis, magnetic resonance imaging for tumor, and a neurologic evaluation pertinent to this disorder as regularly accomplished by otologists. All of the above occur after arrival at the clinical suspicion of PLF, which is developed following a detailed clinical history and otoneurologic evaluation. The clinical elements that allow a heightened suspicion of PLF are very specifically related to either hearing or balance or both, as described below.

Hearing

For hearing, each patient with sudden sensory hearing loss (hours to days) or rapidly progressive sensory hearing loss (weeks to months) is suspected of having a PLF.

After the hearing loss occurs, rapid evaluation of these patients is required (no more than 3 days and preferably within several hours).

Balance

For disorders of balance or concomitant physical findings in patients with hearing loss but perhaps unrecognized vestibular symptoms, the aspects of the clinical examination are very deliberate. Without recognition of the subtleties, the diagnosis may be missed. The three diagnostic criteria include (1) constant dysequilibrium, however mild; (2) a positive Hennebert's sign or symptom; and (3) positional nystagmus or postural vertigo. The common tests for these elements are inadequate and will lead the clinician to false conclusions. Therefore, sensitive tests are warranted and easily accomplished. Be aware that all three types of findings can sometimes not be present during a single examination. This requires that in some patients, repeat testing is necessary to determine the presence or absence of any of the sought finding(s).

For dysequilibrium, observe the patient walking with eyes closed. Often the patient will be surprised that there is dysequilibrium, which was never before recognized; eyes are usually open during ambulation, adding vision to aid stability. On rare occasion, the patient must "walk on tiptoes" (the balls of the feet) with eyes closed to allow the physician to observe and the patient to recognize the presence of dysequilibrium.

For Hennebert's sign or symptom, the patient should be standing so that the vestibulospinal reflex appears most sensitive. The patient should be standing with eyes closed and feet together (as close to this as possible if unstable). The fistula (Hennebert's) test is then performed using a Bruening otoscope, usually with a flexible tympanogram earpiece fitted over the speculum earpiece to allow a convenient ear canal seal. Other clinical otoscopes do not provide an adequate air seal. There should be enough pressure to cause the ear canal skin to move or blanch with pressure and rarefaction. Be prepared to catch or support the patient quickly should he/she lose balance. A positive vestibulospinal response is the observation of body sway (sign) or the patient's sensation of sway or loss of balance (symptom). Interestingly, some of these patients also exhibit a Tullio phenomenon (vertigo or nystagmus in response to high-intensity sound).

For eye movement observation with fistula tests, naked eye observation will most often be nonrevealing. Frenzel lenses may allow for the observation of one, two, or three nystagmic beats but often will give a false-negative result. Electrode eye movement recordings result in false positives. The most sensitive test for a Hennebert's sign (a few small-amplitude nystagmic beats) requires the use of infrared nystagmography with video recording and with time-locked signals for positive and negative ear canal air pressure. In this way, with infrared observation in darkness, visual fixation is avoided, which can quell the diagnostic nystagmic beats. Be aware that both the vestibulospinal and vestibulo-ocular responses fatigue quickly, so serial repeat testing is usually not confirmatory and can give one a false impression of a negative result.

For positional nystagmus or vertigo, the usual Hallpike maneuvers are employed. However, the usual methods of no lenses or Frenzel lenses are often inadequate. Therefore, infrared eye movement recordings are often necessary to give objective evidence to the patient's report of postural vertigo. While seeking the above information, the results of a posturography test are often revealing. Any evidence of dysequilibrium in patients complaining of postural vertigo heightens one's suspicion of the presence of a PLF.

Again, be aware that repeat testing at the initial or a subsequent clinical visit is often required to find the positive results that allow accurate diagnosis.

The Possibility of a Perilymphatic Fistula: Elements That Heighten One's Awareness; Absence Not an Excluding Factor For either hearing loss (sudden sensory or rapidly progressive) or vestibular symptoms, there is often a precipitating factor related to barometric pressure change, sometimes severe, as with scuba diving, or as mild as a travel venture with ascent or descent of a mountain or even an airplane flight. The patient says, "When I got off the plane, I noticed I had lost some of my sense of balance" or "The hearing loss occurred after diving." The absence of historical events of trauma does not exclude the presence of PLF in that the event can be as mild as a vigorous sneeze. It appears that only the absence of the array of clinical findings on repeat testing is exclusionary.

CLINICAL MANAGEMENT

Diagnostic Aids

The use of fluorescin or other perilymphatic indicators, thus far, appears to be not regularly reliable.

When a positive result is present, it is supportive of the diagnosis, but a negative result means nothing. Therefore, specific surgical observations remain our best form of confirmation of a PLF diagnosis. Diagnostic variables based on outcome analysis of treatment should be judged and evaluated with caution, considering the need for further refining of diagnostic criteria related to this disorder, which are not yet defined but are anticipated. There are also possible unrecognized treatment variables that may occur coincidentally with the intended treatment changes for other disorders when the correct diagnosis of PLF has been missed.

There is a question regarding the value of endoscopic middle ear examination for evidence of perilymph.[27] It appears that the endoscope becomes hot. Not only is this important to patient comfort, but perhaps even more significant in terms of diagnostic accuracy. The volume of perilymph present at the specific sites of accumulation (FAF or RWF) is often just a few microliters, easily evaporated by modest amounts of heat. In fact, even at surgery, a touch of the minute amount of fluid with a sharp-pointed instrument may be necessary to confirm its presence by the resulting light-reflection change.

Medical Management

The initial treatment for PLF usually should be medical management except for sudden sensory hearing loss. Sudden hearing loss requires more intense and immediate restrictions. The general elements of patient instructions are quite simple but specific and and relate to hydrodynamics:

1. Keep the head above the level of the heart.
2. Avoid lifting anything over 10 pounds.
3. Have someone elevate the head of the bed 4 inches by putting blocks under the headboard bedposts.

Equivalents of these should be recognized and avoided (eg, straining at stool, vigorous sneezing [should open mouth], and hard nose blowing).

These elements of management allow vestibular symptom improvement in about 40% of patients; for hearing loss, it appears to be significantly less. These modifications should be followed for 6 weeks. If there is no significant improvement, surgery should be considered. Sudden hearing loss is a special consideration. For sudden sensory hearing loss, 5 days of inpatient bed rest with the head of the bed elevated and bathroom privileges with help are required for patients who have been seen shortly after the onset (weeks). Audiograms (bedside) are performed daily. If adequate improvement occurs, the patient is given the above restriction directions and is discharged from the hospital. If there is no improvement, surgery is performed on the sixth day. If there is worsening of hearing, surgery is performed at the time of worsening.

Surgery

Whenever possible, surgery is performed under local anesthesia with minimal or no sedation to avoid postanesthetic straining and masking of surgically related symptoms. Exposure of the middle ear is accomplished using a standard tympanomeatal flap designed to give generous exposure of the oval window and round window niche. Care should be taken to provide visualization of the area of the FAF just anterior to the stapes. Also, although rarely involved, the area of the fossula post fenestram (FPF) posterior to the stapes should be considered. The RWF is located on the floor of the round window niche extending anteriorly, often initially obscured by mucosal bands (not to be confused with the round window membrane).

The surgical manipulations should be done in such a way as to avoid blood entering the middle ear. If such should occur, careful suctioning should be used to remove it. Use as small a suction tip as possible to avoid the "hair dryer" evaporation qualities of air movement, which have the potential of evaporating the small quantities of perilymph present.

After exposure, carefully examine the area just anterior to the stapes footplate for crystal clear fluid collecting in minute quantities. Often there is a roughened appearance or a minute cleft-like formation of the bony surface. With a 26-gauge suction tip, aspirate any fluid present in this area. Repeated reaccumulation of fluid often but not always takes several minutes and is diagnostic of the presence of perilymph.[28] Not infrequently, the presence of fluid is not immediately apparent because its total volume is only a few microliters (total inner ear perilymph volume is 76 μL). In these instances, touching the area(s) in question with a sharp needlepoint instrument will cause the fluid to flash a sparkle as its reflective surface is altered.

Not infrequently, the perilymph is present only under the mucosa. With careful surgical (nonbloody) mucosal reflection and subsequent suction drying of the area in question, diagnostic reaccumulation of fluid is observed unrelated to the distant reflected mucosal edges. If laser is used for mucosal obliteration, removal of any char with a fine pick is necessary prior to observation for fluid as this can inhibit fluid flow.

After diagnostic reaccumulation perilymph has been observed, sampling of the fluid can be done. The author prefers to use glass micropipettes with a tip size of about 10 μm. Often preuse tip breakage is necessary in that the usual micropipette has a tip size of 3 to 5 μm, too small to allow the fluid to rise in the pipette by capillary action. Often the fluid volume is so small that only the frustum of the pipette will fill, sometimes just a portion of the frustum. Other times, a whole pipette full can be obtained, about 10 μL. Surprisingly, there does not seem to be a relationship between fluid volume and symptom or sign intensity.

After the surgical diagnosis (reaccumulation of fluid) has been made, graft site preparation is necessary and is meticulously performed. The mucosa is reflected or desiccated by laser away from the site of fluid origin (FAF or RWF). Care must be taken at the round window niche in that the singular nerve may be herniated and exposed at the middle ear surface.[19] Any tissue debris, even the slightest amount, must be removed and the mucosal edges reflected far enough from the site to allow graft pieces to be placed without a risk of overlaying any mucosal element. The mucosal edges must be identified as being free from the graft elements after graft replacement.

Graft Materials The most effective graft material appears to be the loose areolar fibrous tissue overlying the temporalis muscle fascia.

The graft material is easily obtained through a 1 cm postauricular incision. Rarely will any preoperative postauricular shaving be necessary. A piece of graft 1 cm in diameter is more than enough. Once obtained, the graft is minced in very fine pieces, almost pinpoint in size. These pieces are cut on a hard surface, usually metal.

The graft application to the recipient site is performed using slightly blunted needle-tip ear picks. These picks are loaded with individual pieces of graft by the person assisting the otologic surgeon. The first is placed in the area of leak source, with subsequent pieces placed over and around the initial piece to help hold it in position. The opening producing the fluid passage is only 50 μm in maximal diameter; therefore, the initial graft piece must be very small and specifically placed. (It appears histologically that there is fibrous tissue ingrowth of this graft material and/or fibrous elements stimulated by this graft material into the FAF. Interestingly, the RWF appears to seal differently, with a dense collagen formation.[23])

Alternative Surgical Method There are some patients whose general condition may not allow the surgery described above. Although the author has no experience with the method, it appears simple and has been reported as effective for poststapedectomy PLFs (JB Causse, personal communication, March 2001). Simply, autologous blood is injected into the middle ear through the tympanic membrane. Presumably, a fibrous seal results owing to the sterile inflammatory response to the blood.

Additional Surgical Considerations, Including Recurrence For vestibular disorders caused by PLF, an operation can be considered successful if after 6 weeks the patient is significantly improved or symptom free. Symptom fluctuation before 6 weeks is not unusual. Any evidence of the return or worsening of symptoms after a 6-week period of symptom improvement should be considered a recurrence. Recurrences will occur in about 25% of patients. In this instance, medical management should be followed as described above before considering reoperation, assuming hearing stability. If surgery is warranted, the procedures are as described above with care to re-examine all areas of risk (FAF, FPF, and RWF), even those seemingly not involved at the time of the previous operation.

For hearing, although rapid improvement has been seen, it is not the rule. Stability is sought. Any sudden worsening prompts measures considered for sudden hearing loss (above).

Special Consideration Concerning Endolymphatic Hydrops In histologic studies, endolymphatic hydrops has been seen at times to be present in specimens from patients meeting the clinical diagnostic criteria and diagnosed as having PLF dur-

ing life and having the predicted FAF or RWF patencies histologically.[17]

Similarly, clinical studies without histologic confirmation of patients with PLFs have indicated that some patients exhibit clinical findings consistent with the presence of endolymphatic hydrops. In these patients, an endolymphatic shunt appeared to be helpful to those who used an outcome analysis experimental study design.[29] The only difference between the histologic studies and the clinical study is the number or percentage of patients so afflicted. There appeared to be a greater frequency in the clinical study. This raises the additional question of possible long-term tissue changes in cases of endolymphatic hydrops—a possible time-related resolution of the otherwise histologically identifiable tissue distention of endolymphatic hydrops. The answer to this question will await appropriate clinical/histologic studies.

Postoperative Care After surgery for a PLF, the author has had patients remain in the hospital for 5 days, with the head of the bed elevated 30 degrees, and has only allowed bathroom privileges with help. The personal help is required because of the risk of falls. Immediate postoperative exacerbation of vestibular symptoms is not unusual. The 5 days of bed rest are ordered to avoid, as much as possible, graft dislodgment. The author has the experience of reoperating on the patients of other surgeons who have experienced recurrence. The only apparent change in care was the 5-day hospitalization followed by 6 weeks of house confinement, and there were the usual successes. All patients are reinstructed regarding the physical restrictions required for medical management (above).

Unusual Locations of Perilymphatic Leak On a few occasions, the author has observed the source of perilymph leakage in the central portion of the stapes footplate. In these instances, the surgical repair was performed as described above. Ballottement of the mucosa of the stapes footplate may be necessary to give evidence of the trapped mucosal-covered fluid leaking from the stapes footplate defect. Again, the defect may be minute, and recurrent fluid emission may be the only evidence of a PLF.

Anticipated Postoperative Course Not infrequently, patients become dramatically improved or even free of their preoperative vestibular symptoms. Unfortunately, this is not the rule for sensory hearing loss. Usually, in this case, improvement is slow. However, there are rare cases in which hearing is improved dramatically in but a few days or even as short as 12 hours. Just as infrequently, the author has observed cases in which socially inadequate hearing has improved to socially functional hearing over the course of several years. The physiologic mechanisms and dynamics of the inner ear causing hearing loss or vestibular symptoms remain unexplained. However, the dramatic sudden improvement in some suggests a bioelectric or biochemical process and not a biomechanical process.

Complications Few complications are experienced by patients undergoing medical or surgical PLF repair. Infection has been experienced by two of the author's patients, both of whom had allowed their ears to get wet before healing occurred. They did not lose hearing or vestibular function. The infection remained restricted to the external canal/middle ear.

The hoped for improvement in hearing sometimes does not occur, and progression of the hearing loss continues. When the preoperative symptoms were vestibular only, a mild sensory hearing loss has occurred in some patients postoperatively.

In all instances, the author has advised the patients preoperatively that any complication is possible (including death), particularly the risk to any structure in the surgical field, specifying these structures and their function.

THOUGHTS REGARDING FUTURE NEEDED STUDIES

Knowledge regarding the pathogenic mechanisms of PLFs remains conjecture based on an extension of pilot studies concerning intracellular proteoglycans related to fluid. Definitive studies are needed, or the disorder will remain a medical mystery.

In that the disease mechanism related to PLF appears to be bioelectric, there should be a search for measurement methods that are applicable in vivo by which these phenomena can be identified, perhaps substituting for the sought perilymph indicators. The implications of this type of measurement for other ear disease may indeed be more significant than its singular use for PLF.

The current methods of treatment of PLF, developed clinically using the best techniques avail-

able, remain crude: patching a minute hole and/or altering endolymph dynamics by manipulation of the endolymphatic sac. Even in these two instances, the physiologic consequences remain an enigma. It appears, however, that they help patients improve in their health status. Is this "dumb luck?"

Regarding PLF, as with all other disease, "what" remains the junior question, and "how" and "why" the cascade of events are triggered are of paramount importance. With about 25% of the population having these temporal bone pathways, patencies, but apparently only a fraction of these having fluid permeable patencies, the questions "how" and "why" loom as all important.[26] Proteoglycan dynamics may provide insight.

CHAPTER 19

Autoimmune Inner Ear Disease

Jeffrey P. Harris, MD, PhD, Elizabeth M. Keithley, PhD

BASIC SCIENCE

The idea that immunity might participate in the etiology of inner ear disease has only recently become accepted. Using the brain as a model, the inner ear was initially viewed as an immunologically "privileged" site, separated from cellular and humoral immunity by a blood-labyrinthine barrier. Apart from inner ear inflammation associated with viral or bacterial labyrinthitis, it seemed inconceivable that the immune system could operate within the bony labyrinth. However, experiments beginning in the 1980s demonstrated that antigen introduced into the inner ear of naive or systemically primed animals resulted in a brisk systemic immune response as well as a local one.[1–4] Moreover, antigen introduced into the inner ear of a systemically immunized animal resulted in hearing loss and even profound deafness owing to a vigorous secondary immune response[2,5,6] (Figure 19–1). The endolymphatic sac also becomes inflamed (Figure 19–2). The magnitude of these responses was dependent on an intact endolymphatic sac since ablation of the sac or even blockage of the endolymphatic duct reduced inner ear immune responses.[7,8] Experiments then demonstrated that the inner ear, although protected by systemic immunity, was damaged by bystander injury when cell-mediated immunity became involved. For example, systemic immunity can protect the inner ear from viral infection through circulating antiviral antibodies.[9,10] If, however, there is a cellular response to viral inoculation of a naive animal, there is hearing loss and cochlear damage. This damage can be reduced by systemic immunosuppression.[11] The route of entry of the inflammatory cells into the inner ear following antigen or viral challenge of the inner ear appears predominantly to be via the spiral modiolar vein (Figure 19–3). During the inflammatory response, this vein takes on characteristics of an activated venule and expresses intercellular adhesion molecule-1 (ICAM-1) on the endothelial cell surface that facilitates the passage of circulating immunocompetent cells into the scala tympani.[12–15] Once within the inner ear, these cells divide,[15] release inflammatory mediators, and set in motion events that lead to cellular proliferation and eventually osteoneogenesis[6] (Figure 19–4). Shortly after entering the cochlea, hearing loss occurs.[16] Endolymphatic hydrops often accompanies these end-stage reactions (see Figure 19–4). Of note, after the single inoculation of antigen, cells may continue to be stimulated, undergoing cell division for up to 6 weeks.[17]

CLINICAL STUDIES

In 1979, McCabe first brought attention to a possible discrete clinical entity when he presented a series of patients with bilateral, progressive hearing loss showing improvement following treatment with corticosteroids.[18] Although others had over the years described patients with ear-related illnesses associated with systemic immune disorders,[19–21] none had collected such a large series or speculated that these patients might have an organ-specific illness. Since that time, autoimmunity has been proposed as a cause for other inner ear disorders, including Meniere's disease,[22] sudden sensorineural hearing loss (SNHL),[23] and acute vertigo.[24] A relationship between inner ear disorders and systemic autoimmune disease has also been documented. A number of systemic autoimmune disorders such as polyarteritis nodosa, systemic lupus erythematosus (SLE), relapsing polychondritis, ulcerative colitis, and Wegener's granulomatosis include auditory and vestibular symptoms.[25] Moreover, some patients with suspected autoimmune inner ear disease (AIED) have either presented with or later developed systemic autoimmune diseases.[26,27]

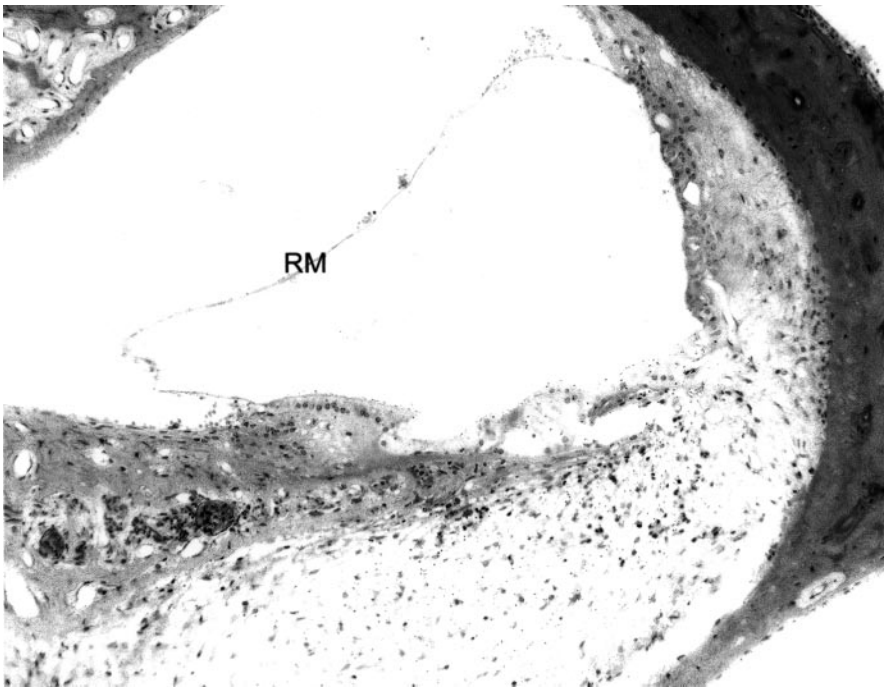

FIGURE 19–1. Photomicrograph of the middle turn of an inflamed guinea pig cochlea (× 20 original magnification). The scala tympani contains inflammatory cells and fibrotic tissue, and the position of Reissner's membrane (RM) suggests endolymphatic hydrops. Toluidine blue staining of plastic embedded tissue.

Unlike other organs and tissues, the inner ear is not amenable for biopsy for the express intent of investigating the underlying immunopathogenesis of purported autoimmune disorders affecting it. What little histopathology has been published from patients with suspected AIED shows fibrosis and/or bone deposition in the labyrinth, consistent with the late sequelae of inflammation.[28–31] Specific immune reactivity against inner ear antigens is often detected in patients with suspected AIED, but the results vary. Lymphocyte migration assays using inner ear tissue as a target have been disappointing, providing at best low stimulation indexes.[32] More promising results have been obtained with Western blotting. Significantly more patients with suspected AIED show reactivity against a 68 kD antigen (Figure 19–5) than do matched normal-hearing or rheumatic controls.[27,33] Autoimmune inner ear disease has also been associated with reactivity against antigens of different molecular weights, especially 45 to 50 kD, 30 kD, and 20 kD.[34] Although reactivity of patient sera against tissue sections of the inner ear has produced reproducible inner ear labeling,[35] it does not appear to be as practical or as useful as immunoblotting.

A number of animal studies have supported an autoimmune cause for some types of SNHL. Immunization of animals with crude extracts of inner ear tissues results in hearing loss in approximately one-third of subjects.[36] Circulating monoclonal antibodies against inner ear tissues also produce hearing loss.[37] Animal models of systemic autoimmune disease, such as the MRL-Fas^{lpr} mouse model of SLE, display hearing loss.[38]

ETIOLOGY

Because of the relative rarity of this condition and its recent recognition, as noted above, very few temporal bones with a diagnosis of AIED have been evaluated. More studies have assessed the inner ears of patients with systemic autoimmune disorders. Recently, Sone et al assessed 14 temporal bones from 7 individuals with SLE.[39] The duration of disease and ages varied widely. The most consistent findings were hair cell and spiral ganglion cell loss. However, unusual accretions were observed in the stria vascularis of 6 of 14 temporal bones.

Animal models have been valuable adjuncts in the study of AIED since the antigen and immunization history can be rigorously controlled, and histopathology is routinely available. Initial studies using immunization of guinea pigs with bovine inner ear extracts resulted in the development of

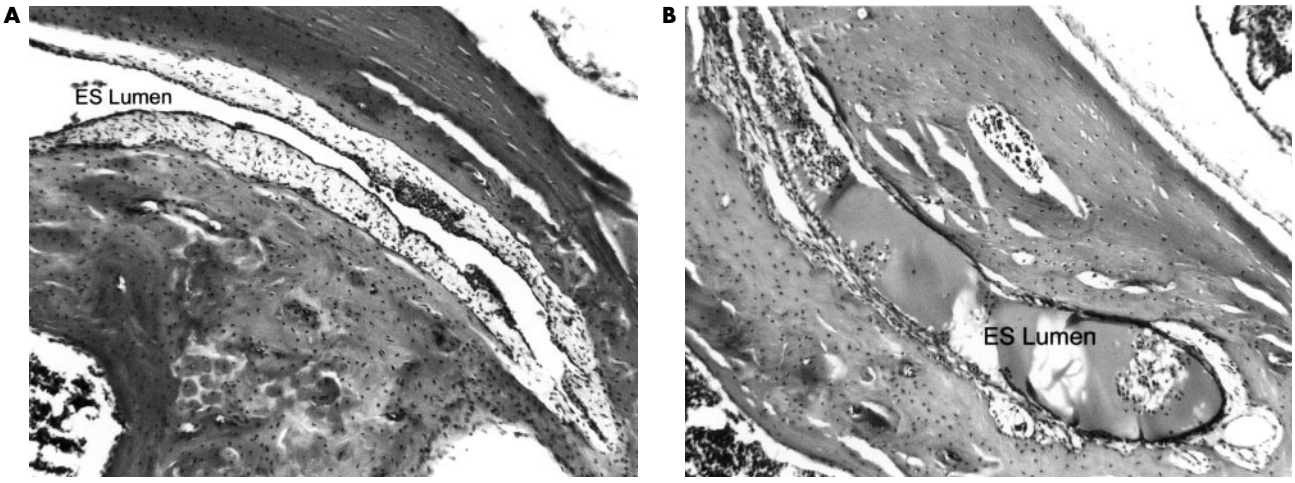

FIGURE 19–2. A, Photomicrograph of a normal endolymphatic sac (ES) in the guinea pig inner ear. Hematoxylin and eosin–stained paraffin section (× 20 original magnification). *B,* Photomicrograph of an ES from a guinea pig with cochlear inflammation following cochlear challenge with a foreign protein to which the animal was sensitized (× 20 original magnification).

hearing loss and mild inflammatory changes in the inner ears of a subset of animals.[36] More recent work has confirmed these findings and indicated that the hearing losses induced by this procedure tend to be modest. Bouman et al found that immunization of animals with swine inner ear extracts produced modest declines in compound action potentials recorded from the guinea pigs 2 and 6 weeks after immunization but no changes in the cochlear microphonic.[34] This suggests that the events responsible for hearing loss occurred at the level of the inner hair cell and/or spiral ganglion neuron rather than at the level of the outer hair cell. Hearing losses were associated with increased Western blot reactivity to 68 kD and other antigens.[34]

Immunization with specific proteins has also resulted in hearing loss. Based on the observation that myelin protein P0 was associated with immunoreactivity against a 30 kD inner ear protein in patients with AIED,[40] Matsuoka et al immunized mice with purified bovine P0.[41] They observed an approximately 10 dB hearing loss and a monocellular infiltrate in the eighth nerve within the cochlear modiolus. Experimental autoimmune encephalomyelitis can be induced by immunization with the neuronal S-100β calcium-binding protein and by passive transfer of T cells sensitized to this antigen. Based on this earlier finding, Gloddek et al found that passive transfer of S-100β-reactive T cells produced a 10 dB hearing loss in rats as well as a cellular infiltrate into the perilymph.[42,43] A monoclonal antibody raised against cochlear tissues of approximately 68 kD that specifically reacts with supporting cells in the organ of Corti has been shown to produce high-frequency hearing loss in mice carrying the hybridoma.[37] More recently, Nair et al infused this antibody into the cochlear perilymph using an osmotic minipump.[44] After 13 days, an approximately 20 dB hearing loss developed, associated with minor losses of hair cells.

To explore the origin of lymphocytes in the region of the endolymphatic sac and the reaction of T cells to self-antigens in the inner ear, Iwai et al used a model of graft-versus-host disease.[45] T cells from C57BL/6 mice injected into the systemic circulation of BALB/c mice infiltrated and proliferated in the perisaccular region surrounding the endolymphatic sac but not into other regions of the inner ear. These findings confirm the role of the endolymphatic sac region in mediating immunity in the inner ear, as well as the communication of the normal sac with circulating lymphocytes. This provides an additional foundation for autoimmunity as an etiology in disorders involving the sac, such as Meniere's disease.

Animal models have also been used to study the relationship between systemic autoimmune disease and the inner ear. The MRL-Fas^{lpr} mouse is used as a model of SLE owing to the accumulation of

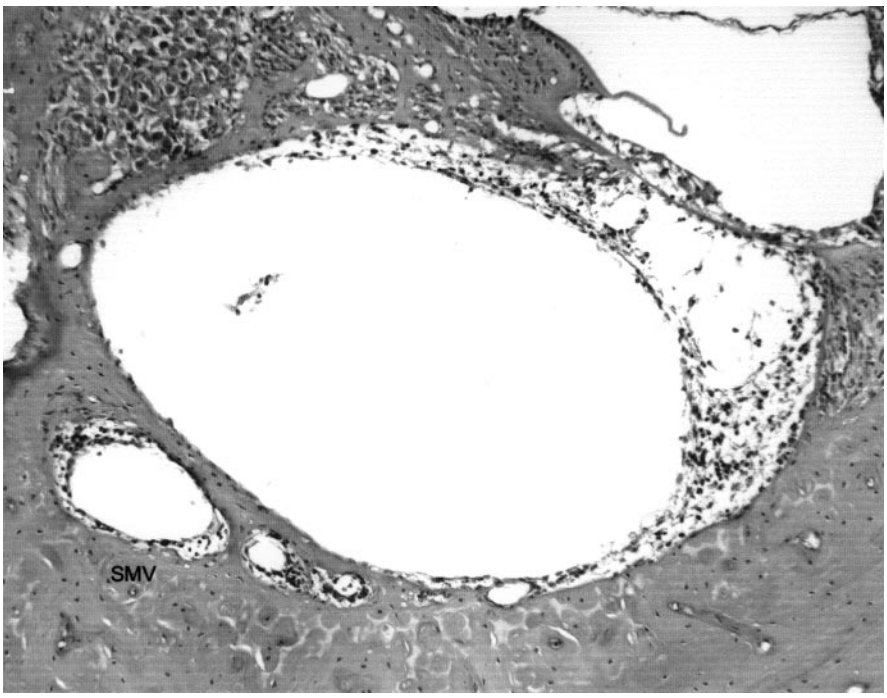

FIGURE 19–3. Photomicrograph of the middle turn of an inflamed guinea pig cochlea. Extravasated immunocompetent cells can be seen within the bony channel surrounding the spiral modiolar vein (SMV) and its tributary on their way to the scala tympani.

autoreactive T cells normally eliminated by Fas-mediated apoptosis. This model also displays progressive hearing loss. Ruckenstein et al found that the most striking inner ear pathology in this model was observed in the stria vascularis,[38] with progressive, hydropic degeneration of intermediate cells, consistent with the strial pathology observed in human SLE temporal bones as described above.[39] In addition, Ruckenstein and Hu observed the deposition of both complement-fixing and non–complement-fixing antibodies in the stria vascularis and, to a lesser extent, in other structures.[46] All antibodies were bound to the capillary walls and were not associated with signs of inflammation. The same group found that systemic treatment with dexamethasone suppressed antibody deposition within the stria and other structures of the inner ear.[38] However, the treatment failed to suppress strial degeneration and hearing loss, suggesting that perhaps the hearing loss seen in these animals had a genetic basis. In contrast to this result, Wobig et al found that systemic prednisolone treatment protected hearing in MRL-Fas^{lpr} mice.[47] The Palmerston-North mouse is also employed as a model of SLE with hearing loss. These animals develop abnormal mineralization of connective tissue in the region of the eighth nerve root within the modiolus. However, there is no deposition of antibody in or cellular infiltration of the cochlea in this strain.[48]

As better imaging becomes available, the localization of inflammatory processes to specific regions of the inner ear should become possible. Having this information will certainly improve our diagnostic capability as well as our knowledge of the basic pathogenesis of this disorder.

DIAGNOSIS

Diagnosis of AIED is still problematic. There is no universally accepted set of diagnostic criteria or diagnostic test for a condition that appears to have several independent etiologies. In general, in all cases of idiopathic, rapidly progressive, bilateral hearing loss, AIED should be suspected. However, there is no doubt that involvement of the second ear may occur months or even years after presentation of symptoms in the first ear. Hearing loss may be manifested as either diminished hearing acuity, decreased discrimination, or both and may involve significant fluctuations over time. In bilateral Meniere's disease, with its triad of vestibular dysfunction, low-tone, fluctuant hearing loss, and tinnitus, AIED should also be suspected, especially when the second ear becomes involved within a short period of time of

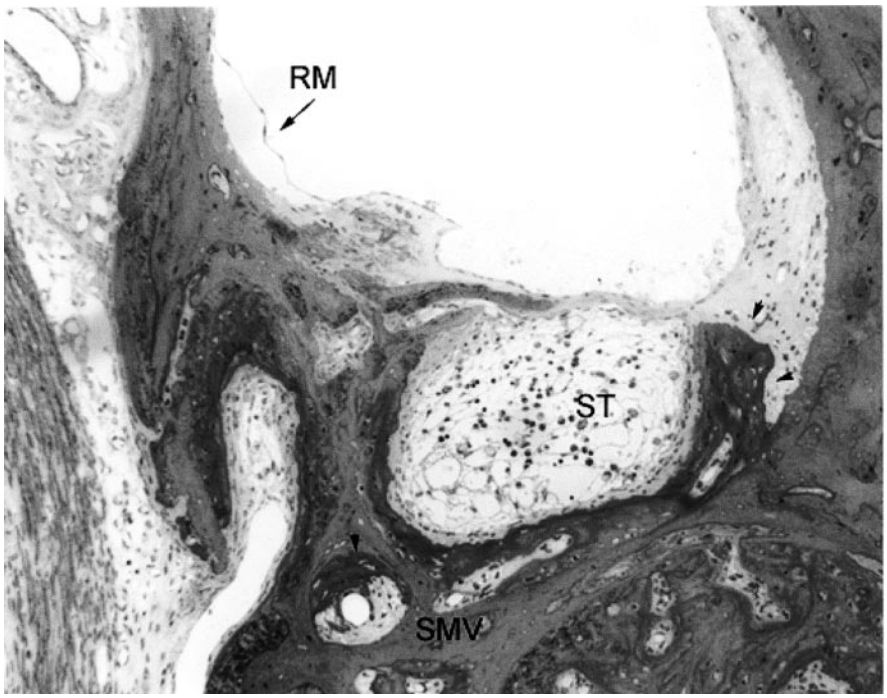

FIGURE 19–4. Photomicrograph of the middle turn of an inflamed guinea pig cochlea 4 weeks following challenge with a foreign protein to which the animal was sensitized. The scala tympani still contains infiltrated inflammatory cells, but the fibrotic matrix has begun to ossify both within the scala tympani (ST) and around the spiral modiolar vein (SMV) (*arrowheads*). The location of Reissner's membrane (RM) indicates severe hydrops.

the first. Aside from an empiric trial with high-dose corticosteroids showing improved inner ear function, Western blot assays are currently the most widely used category of diagnostic test for AIED. The initial assays used for this purpose were based on proteins extracted from bovine inner ear tissue, and inner ear extracts are still used. Reactivity to an approximately 68 kD antigen was detected in a significant proportion of patients with AIED and Meniere's disease.[27,33,49–51] This or an antigen with shared epitopes was later shown to be present in kidney and to be a member of the heat shock protein (HSP) family.[52,53] Reactivity against inner ear antigens of other molecular weights, especially in the 45, 30, and 20 kD ranges, has frequently been reported.[34,40] Few of these other antigens have been characterized or found to be present in statistically significant proportions of hearing loss versus control populations. For example, studies examining the antigenic profile of inner ear tissues consistently demonstrate a multitude of antigens against which human sera reacts; however, these bands seen on Western blot, failed to reach significance when carefully matched against controls.[33,49,54] Immunoreactivity to a 30 kD antigen has been associated with myelin protein P0.[41] The 68 kD antigen has been associated with HSP 70, and immunoreactivity against the bovine HSP 70 (bHSP 70) has been found to be correlated with AIED.[52] However, preabsorption with bHSP 70 does not remove all reactivity to the 68 kD inner ear antigen,[52] and immunization of animals with HSP 70 does not appear to produce hearing loss.[55] Antibodies against other antigens have also been implicated. Several investigators have reported that immunoreactivity to inner ear proteins with molecular weights in the 42 to 45 kD range is also positively correlated with AIED, although with a lower level of specificity than the 68 kD protein or HSP 70. For example, Atlas et al found that positive Western blots against 68 and/or 42 to 45 kD inner ear proteins were present in significantly more patients with Meniere's disease than in normal controls, whereas reactivity against 35 to 36 and 20 kD proteins was not different in the two groups.[51] Moreover, reactivity appeared to be related to disease state in that patients with active disease (at least one episode of vertigo within 1 month) were significantly more likely to be positive than those with inactive disease. Other specific antigenic targets have also been studied. Modugno et al observed antithyroid antibodies in 27% of patients with benign paroxysmal positional vertigo, significantly more than were observed in a group of normal controls.[56] Using immunoblotting and

enzyme-linked immunosorbent assay, Yamawaki et al observed antibodies against the sulfoglucuronosyl glycolipid SGLPG, but not SGPG, in 37 of 74 patients with AIED, as compared with only 3 of 56 pathologic and 2 of 28 healthy controls.[57] In a negative result, Lopez-Gonzalez et al found that anti–type II collagen antibodies and stimulation indexes were unrelated to idiopathic or sudden sensorineural hearing loss or Meniere's disease.[58]

In one of the few prospective studies attempting to correlate the significance of Western blotting for the 68 kD antigen with response to treatment, Moscicki et al found that a positive result for 68 kD was associated with a 75% rate of hearing improvement with corticosteroids, compared with 18% of patients who were Western blot negative.[50] In this study, disease activity was an important predictor of a positive antibody response and response to treatment. Eighty-nine percent of patients with active bilateral progressive hearing loss had a positive 68 kD antibody, whereas patients with inactive disease were uniformly negative.

A number of other recent studies have focused on the diagnostic utility of antibodies against HSP 70. In a retrospective case series, Hirose et al evaluated a variety of assays for systemic autoimmune disease, as well as a Western blot assay against bHSP 70, for their utility in predicting the responsiveness of rapidly progressive SNHL to corticosteroids.[59] Again in this study, positivity in the HSP 70 blot assay was the best predictor of corticosteroid responsiveness in AIED. Although the sensitivity was low (42%), the specificity was 90% and the positive predictive value was 91%. Bloch et al tested the serum of 52 patients with bilateral, progressive, idiopathic hearing loss or Meniere's disease in Western blot assays to recombinant bHSP 70 and recombinant human HSP 70.[60] Reactivity against recombinant bHSP 70 was observed in 40 of 52 patients. Only 12 also reacted to recombinant human HSP 70. They also tested the positive sera against a panel of recombinant peptide fragments of bHSP 70. Reactivity was observed to widely separate epitopes. However, most positive patients reacted preferentially or only to an amino acid segment from the carboxy terminus of rbHSP (recombinant bovine), aa 427-461. Within this dominant epitope, the bovine peptide differs from the corresponding human peptide by only one amino acid.

Western blotting has also been used to explore the possibility that a subset of patients has Meniere's disease with an immunologic basis. Gottschlich et al demonstrated that 32% of patients with Meniere's disease were anti–68 kD positive.[33] Rauch et al reported that anti–HSP 70 antibodies were found in 47% of patients with Meniere's disease and that level increased to 58% when the disease was bilateral.[61] Recently, however, Rauch et al had a similar level of sensitivity in 134 patients with Meniere's disease but a much lower level of specificity owing to a relatively

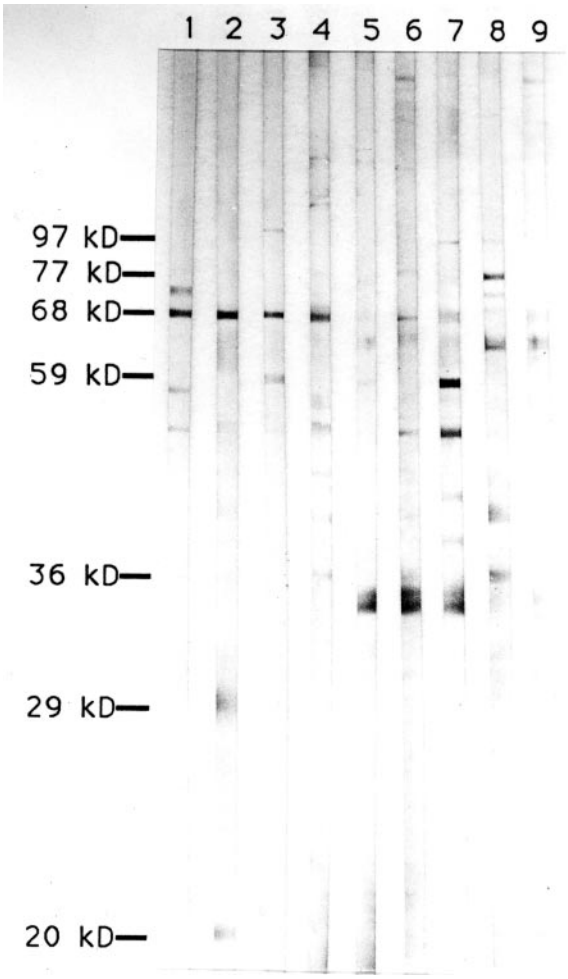

FIGURE 19–5. Western blot indicating reactivity of patient sera against antigens extracted from bovine inner ear tissue. Lanes 1 to 3 and 5 to 8 are sera from patients with sensorineural hearing loss. Sera have reactivity against a 68 kD protein or 33 to 35 kD proteins. There is also reactivity with 77, 52, and 58 kD antigens. Lane 4 is serum from a patient with giant cell arteritis and lane 9 is from a normal-hearing individual. Reproduced with permission from Gottschlich S et al.[33]

high level of reactivity in blood donor control sera.[62] This high rate of positivity in the control serum was unexplained and contradicts the previously low level of positives in control sera as well as those high rates of positivity reported by others.[27,53,61] Serial serum samples revealed no correlation between antibody level and the clinical course of the disease. These observations led them to question the clinical utility of the HSP 70 assay in Meniere's disease. The answer to whether a subset of patients with classic Meniere's disease is immune mediated is currently unclear.

A number of investigators have reacted patient sera against tissue sections to detect immunoreactivity against inner ear antigens. This technique has been used on a research basis since the 1980s, when Arnold et al reported a high degree of labeling within the cochlea with patient serum.[63] Bachor et al detected immunoreactivity to rat cochlear sections in 14 of 15 patients showing progressive or sudden hearing loss in the cochlea opposite an ear deafened by trauma or inflammation.[64] Using rat cryosections of the inner ear, Arbusow et al detected antibodies against vestibular sensory epithelia in 8 of 12 patients with idiopathic bilateral vestibular pathology as compared with 1 of 22 healthy controls and 0 of 6 patients with systemic autoimmune disease.[65] Ottaviani et al detected immunoreactivity against endothelial cells using sections of rat kidney tissue in 8 of 15 patients with sudden hearing loss, as compared with 2 of 14 normal controls.[66] Helmchen et al observed positive but low levels of immunoreactivity against inner ear sections using serum from patients with Cogan's syndrome.[67] However, unlike anticorneal antibodies, the anticochlear immunoreactivity levels were not correlated with disease stage.

CLASSIFICATION OF AUTOIMMUNE INNER EAR DISEASE

Over the past two decades since McCabe's published article on AIED,[18] many patients have been diagnosed and treated for rapidly progressive SNHL and many have had their hearing maintained or even improved with treatment. As a result of the growing experience with patients with corticosteroid sensitive hearing loss, a pattern has begun to emerge that warrants a classification scheme to sort out patients better as they present with such a broad category of inner ear dysfunction. Although the following classification scheme is intended specifically for that purpose, it is likely that over the next few years it will be further refined:

Type 1: Organ (Ear) Specific

- Rapidly progressive bilateral SNHL
- All age ranges, although middle age is most common
- No other clinical evidence of systemic autoimmune disease
- Positive Otoblot (Western blot 68 kD or HSP 70)
- Negative serologic studies (antinuclear antibody [ANA], erythrocyte sedimentation rate, rheumatoid factor (RF), C1q binding assay, etc)
- Greater than 50% response rate to high-dose corticosteroids

Type 2: Rapidly Progressive Bilateral Sensorineural Hearing Loss with Systemic Autoimmune Disease

- Rapidly progressive bilateral SNHL
- Hearing loss often worst with flare of autoimmune condition
- Other autoimmune condition is present (SLE, ulcerative colitis, polyarteritis nodosa, vasculitis, rheumatoid arthritis, Sjögren's syndrome)
- Otoblot may be positive or negative
- Serologic studies will be positive in accordance with the illness (ie, ANA-high titers, RF positive, circulating immune complexes)
- Corticosteroid responsive and may be managed with targeted therapies for underlying illness

Type 3: Immune-Mediated Meniere's Disease

- Bilateral, fluctuating SNHL with vestibular symptoms that may predominate
- Subset of patients with delayed contralateral endolymphatic hydrops or recent instability of better-hearing ear in a patient with burned out Meniere's disease
- Otoblot positive 37 to 58%; may show presence of circulating immune complexes
- Corticosteroid responsive; may require long-term immunosuppression owing to relapses

Type 4: Rapidly Progressive Bilateral Sensorineural Hearing Loss with Associated Inflammatory Disease (Chronic Otitis Media, Lyme Disease, Otosyphilis, Serum Sickness)

- Evidence of profound drop in hearing with long-standing chronic otitis media

- May show inflammation of the tympanic membrane and perforations
- Hearing loss progresses despite treatment of the infectious agent (treponemal or rickettsial)
- Otoblot negative; serologic tests for the underlying disease may be positive; patient should be evaluated for granulomatous disease and vasculitis by biopsy if tissue is available
- Corticosteroid responsive and may require long-term immunosuppression
- Serum sickness has been reported after vaccinations, although anecdotal

Type 5: Cogan's Syndrome

- Sudden onset of interstitial keratitis and severe vestibuloauditory dysfunction
- Otoblot negative for 68 kD but positive for 55 kD antigen
- Responds to high-dose corticosteroids, although becomes resistant over long term

Type 6: Autoimmune Inner Ear Disease-Like

- Young patients with idiopathic rapidly progressive bilateral SNHL leading to deafness
- Severe ear pain, pressure, and tinnitus
- Otoblot and all serology negative
- May have an unrelated, nonspecific inflammatory event that initiates ear disease
- Not responsive to immunosuppressive drugs, although they are tried

TREATMENT

Once a diagnosis of AIED is established or considered highly presumptive, high-dose prednisone is the mainstay of treatment for this condition. Early institution of 60 mg of prednisone daily for a month is now widely used as short-term or lower-dose long-term therapy and has either been ineffective or fraught with the risk of relapse. Prednisone is then tapered slowly if a positive response to therapy is obtained. If during the taper hearing suddenly falls, reinstitution of high-dose prednisone is indicated. One sensitive predictor of imminent relapse can be the appearance of loud tinnitus in one or both ears. If patients show corticosteroid responsiveness but attempts at taper result in relapse, the addition of a cytotoxic drug should be considered. The most widely used of these agents are methotrexate (MTX) and cyclophosphamide (Cytoxan). The former has the advantage of being less toxic and has fewer long-term hematopoietic risks, such as the development of neoplasia.[68] If MTX is used, it should be given as an oral dose 7.5 to 20 mg weekly with folic acid. The patient should be monitored closely for toxicity with complete blood count, platelets, blood urea nitrogen, creatinine, liver function tests, and urinalysis. It should be noted that the prednisone-sparing effects of MTX may take 1 to 2 months to achieve; therefore, prednisone should be maintained until such effects are obtained. Also, if high-dose prednisone has not been effective in restoring hearing, it is unlikely that MTX will offer additional efficacy. Therefore, for patients with severe hearing losses, positive 68 kD Western blots, and nonresponsiveness to prednisone or MTX therapy, consideration should be given to a trial of cyclophosphamide.[26] At oral doses of 1 to 2 mg per day taken each morning with liberal amounts of fluid, the risk of hemorrhagic cystitis or drug effects on the bladder can be minimized. Again, appropriate monitoring of peripheral blood counts is required. Cyclophosphamide should not be administered to children, and the risk of permanent sterility should be outlined. If, on the other hand, no response to high-dose prednisone is achieved, and the patient is 68 kD Western blot negative, it may be futile to continue potentially toxic drugs, with little evidence for AIED as the cause. As this field continues to evolve, there are, however, no hard and fast rules, and a practitioner may be justified in trying cytotoxic drugs on an empiric basis because unrelenting progressive deafness is a serious handicap for a previously normal-hearing person. Luetje recommended plasmapheresis for difficult to manage patients,[69] and this can be a useful adjunct to the above-mentioned immunosuppressive drugs. At the time of writing, a multi-institutional clinical trial is under way to compare the efficacy of MTX and prednisone versus prednisone alone for the management of AIED. The results of this trial should help to delineate appropriate therapy for suspected AIED.

Parnes et al noted that local corticosteroids appear to be more effective in the treatment of other autoimmune disorders, such as corneal inflammation owing to Cogan's syndrome.[70] They therefore investigated the pharmacokinetics of hydrocortisone, methylprednisone, and dexamethasone in perilymph and endolymph after oral, intravenous, or

intratympanic administration. Dexamethasone was found to be largely excluded from the cochlea by the blood-labyrinthine barrier. Both methylprednisone and hydrocortisone reached inner ear fluid after systemic administration, attenuated presumably by the blood-labyrinthine barrier. Much higher levels of all three drugs were observed in cochlear fluid after intratympanic administration, with rapid declines over a 6- to 24-hour period. Similar results were noted by Chandrasekhar et al.[71] Parnes et al also reported that repeated intratympanic administration of corticosteroids in a small series of patients with hearing loss of diverse origins was followed by improvement in some patients, but no control group was included.[70] In contrast, Yang et al found that local immunosuppression had no effect on experimental immune-mediated SNHL in an animal model.[72] It should be noted that local effects are not, of course, the only basis for the therapeutic efficacy of immunosuppressants. By decreasing peripheral blood leukocytes, these agents reduce the population of cells that can be recruited to the inner ear to participate in immune and inflammatory damage. An experiment designed to prevent entry of cells into the cochlea using antibodies to ICAM-1 did show a reduced number of infiltrated inflammatory cells in the cochlea following antigen challenge.[73] Although the inflammation was not entirely prevented, such a strategy may be worth pursuing. An analogous situation exists for ocular immune disorders such as uveitis. Despite the greater accessibility of the eye to topical drugs than the inner ear, ophthalmologists would never consider local therapy in lieu of high-dose corticosteroids for these disorders. Perhaps a lesson taken from their experience might lessen the enthusiasm that currently exists for treatment solely by local middle ear corticosteroid instillation.

DISCUSSION

Debate continues as to whether AIED exists as a separate entity. Some authors prefer to refer to this condition as immune-mediated inner ear disease. Clearly, the evidence for specific autoimmunity is indirect. Hearing and vestibular problems that are diagnosed as autoimmune in origin are often responsive to corticosteroids. Although this suggests that the condition involves inflammation, one cannot infer the involvement of specific immunity. The fact that inner ear disease is often present in systemic autoimmune disorders provides strong evidence that autoimmune processes can damage the labyrinth but does not speak to the issue of organ-specific disease. Animal models of hearing loss and/or vestibular dysfunction secondary to immunization with inner ear antigens provide stronger evidence of specific autoimmunity.

Autoimmune inner ear disease is difficult to diagnose. Although it is generally agreed that the condition should be bilateral and rapidly progressive, the involvement of the second ear may take months or even years to manifest. Although rapidly progressing conditions are more readily held to be autoimmune, AIED is increasingly considered as a potential cause of Meniere's disease and as a less likely cause of sudden hearing loss.

Improved diagnostic tests are clearly required. No one test appears to be positive in more than 30 to 40% of patients who otherwise fit the criteria for autoimmune disease. One possible explanation for this is that rapidly progressive SNHL has a number of different causes, including autoimmune, viral, genetic, developmental, vascular, and perhaps metabolic. Many of these cannot be separated by their presentation; therefore, it would not be unusual or unexpected for many of these patients to have negative antibody testing, and some who were not autoimmune might even improve with corticosteroids (eg, viral). Another possibility is that autoimmunity exists to a variety of inner ear antigens. Given the variety of autoimmune disorders that can affect the inner ear, the variety of antigens with which sera from patients with AIED will react, and the fact that immunization with a variety of proteins can lead to hearing loss in animal models, this would appear to be a strong possibility.

The usefulness of Western blotting for antibodies directed against the 68 kD or HSP 70 antigen as diagnostic assay seems clear, although there is little evidence to support an etiologic role for HSP 70. It is possible that HSP 70 shares one or more epitopes with an inner ear antigen, although reactivity to widely variable epitopes of HSP 70[60] argues against this. Alternatively, HSP 70 immunoreactivity may all be a well-correlated epiphenomenon, perhaps produced by immunization of self-proteins during inflammatory responses arising from other causes. Lastly, initial studies with serum tested by Western blotting were with the use of 68 kD inner ear tissue as the target antigen. After the recognition

that HSP 70 showed results similar to 68 kD by several investigators, a number of groups have adopted HSP 70 as the target for immunologic testing. In fact, this may be the wrong approach if HSP 70 merely shares epitopes with but is not the actual antigen in 68 kD inner ear immunoreactivity. Future studies will certainly improve our knowledge of the actual antigenic target(s) involved in AIED.

Despite uncertainty over etiology and difficulties in diagnosis, this condition is frequently responsive to treatment with immunosuppressive drugs. Since there are few forms of SNHL that can be treated other than symptomatically, AIED represents a unique opportunity to reverse SNHL and vestibular disorders. For this reason alone, the diagnosis should be considered when symptoms are appropriate, and both clinical and basic research on this condition is warranted.

CHAPTER 20

Meniere's Disease, Vestibular Neuronitis, Paroxysmal Positional Vertigo, and Cerebellopontine Angle Tumors

Jacob Johnson, MD, Anil K. Lalwani, MD

The value and function of the vestibular system may often be underestimated when considering the various special senses that we possess. However, of all of the special senses, unilateral loss of the vestibular system may cause the most significant detriment for our daily function and survival.[1] This chapter discusses the common disorders that affect the vestibular system and provides a framework for evaluation, diagnosis, and treatment of patients with vestibular disorders. The common disorders affecting the peripheral vestibular system include benign paroxysmal positional vertigo (BPPV), Meniere's disease, and vestibular neuronitis. The most common disorder of the vestibular nerve is a vestibular schwannoma (VS), accounting for 80% of all cerebellopontine angle (CPA) lesions.[2] This chapter also discusses some of the other common (meningiomas and epidermoids) and uncommon tumors of the CPA that present by injuring the cochleovestibular system.

SIMPLIFIED VESTIBULAR ANATOMY AND FUNCTION

A brief review of vestibular anatomy and function, nystagmus, and central compensation to vestibular injury will facilitate the discussion of peripheral vestibular disorders and explain the lack of significant vestibular symptoms in patients with CPA tumors. The vestibular system provides positional information at rest and positioning information during movement. This information allows us to have visual tracking, perception of space, sense of direction, and postural balance during movement and rest. The components of the vestibular system include the peripheral organs, the vestibular division of the eighth cranial nerve (CN), the vestibular nuclei, and the projections to and from the vestibular nuclei. The peripheral organs are endolymph-filled membranous sacs suspended in the perilymph of the bony labyrinth and consist of two otolith organs, the saccule and the utricle, and three orthogonally oriented semicircular ducts. The saccule is joined to the cochlear duct (scala media) via the ductus reuniens. The sensory receptors (vestibular hair cells) are located in the cristae of the semicircular ducts and the maculae of the saccule and utricle. The cristae respond to angular acceleration associated with head rotation, and the maculae are stimulated by linear acceleration caused by translational or tilting head movements. The cristae are normally not sensitive to gravity, and this information is transduced by the maculae. The vestibular organs are innervated by the superior (utricle, lateral and superior semicircular ducts) and inferior (saccule and posterior semicircular duct) vestibular nerves. The posterior semicircular duct is innervated by the posterior branch of the inferior vestibular nerve that passes through the foramen singulare. The superior and inferior vestibular nerves travel in the internal auditory canal (IAC) with the cochlear and facial nerves. The vestibular nerves join with the cochlear nerve to form CN VIII, which crosses the CPA to reach the vestibular nuclei. The vestibular nuclei are located in the pons and have primary projections to the oculomotor, spinal, cerebellar, autonomic, and cerebral areas.[3]

The vestibular nerves have a baseline tonic firing rate. The fundamental strategy of the vestibular system is to compare the relative change in the fir-

ing rate based on the response of paired peripheral organs located in each temporal bone for any given head movement. For example, a brief head rotation to the right in the horizontal plane causes deflection of the cupulae of the right and left horizontal semicircular ducts. The right cupula is deflected toward the ampullated end of its semicircular duct, which leads to an increase in the firing rate of the right vestibular nerve, and the opposite effect occurs at the left horizontal duct and left vestibular nerve (Ewald's laws). This information regarding right angular acceleration is processed in the vestibular nuclei and shared with the visual system to allow visual fixation during the head movement and the cerebellum and spinal areas to maintain balance and posture. The response of the visual and balance systems to head movements provides a way to study the vestibular system and assess its function during injury. The most studied response is the vestibular oculomotor-reflex (VOR). The VOR holds an image on the retina during brief head movement. Understanding the VOR allows us to predict how the eyes should move in response to head movement. In the above example of a brief head movement to the right, the right part of the vestibular system is stimulated relative to the left part of the vestibular system. The VOR is manifest by contraction of the right medial rectus and left lateral rectus muscles. This allows the eyes to stay fixed on a point by relatively moving the eyes to the left as the head moves to the right. A "fast" reset of the eyes by the opposing pair of eye muscles allows visual acquisition of a new object along the new line of sight. This rapid type of eye movement to acquire a new target is called a saccade. If the right semicircular duct is persistently stimulated as in a warm caloric test, these eye movements (slow phase to the left and fast phase to the right) become repetitive and are called jerk nystagmus. The fast phase of the eye movement is to the right; therefore, the nystagmus is called right-beating nystagmus. A few rules will allow predicting the expected nystagmus for stimulation of the various semicircular ducts. The eye movements occur in the same plane as the stimulated semicircular duct, and the fast phase is toward the side of the stimulated duct or away from an injured vestibular organ (Ewald's laws).[1]

Injury to the peripheral or central vestibular system causes asymmetry in the baseline input into the vestibular centers, and this causes vertigo, nystagmus, vomiting, and a sense of falling toward the side of the injury.[4] Vertigo is defined as the illusion of movement. However, the chief complaint of patients with injury to the vestibular system is usually not vertigo but dizziness. If the complaint is clarified to be vertigo, the duration, periodicity, and circumstance of the vertigo and the presence of other neurologic signs or symptoms allow for categorization of the vertigo. The proximity of the vestibular system to the auditory system often causes vertigo to be coupled with hearing loss. Knowing the duration of the vertigo or dysequilibrium and the presence or absence of hearing loss allows narrowing the differential diagnosis[5–7] (Table 20–1). The vertigo may be caused by injury of the peripheral or central parts of the vestibular system. Often the presence of other neurologic abnormalities leads to an investigation for a central cause of the vertigo. However, central vestibular injury caused by a mass lesion or stroke may mimic a peripheral vestibular disorder. In the section on vestibular neuronitis, the nystagmus characteristic of peripheral versus central vestibular disorders is presented.

The central compensation for vestibular injury occurs via the cerebellum. The cerebellum provides a "clamping" response to the injured vestibular system to reduce the effects of the abnormal vestibular signal. In an acute injury, such as vestibular neuronitis, the vertiginous response lasts 3 to 5 days, and then the central compensation is able to modulate the signal from the injured vestibular system.[8] In episodic insults, such as that occur in Meniere's disease, the central compensation is not able to be as effective, so with each new episode there are acute vertiginous symptoms. In a slowly evolving process such as a VS, the central compensation occurs in step with the vestibular dysfunction, and the patient may have minimal to no vestibular symptoms. The central compensation is enhanced by vestibular activity and delayed by prolonged use of medical vestibular suppression. This observation has led to the development of vestibular rehabilitation programs. Vestibular rehabilitation programs use three strategies: (1) habituation exercises, which facilitate central compensation by extinguishing pathologic responses to head motion; (2) postural control exercises; and (3) general conditioning exercises. Vestibular rehabilitation is critically important in the elderly since their ability to have optimal central compensation is diminished.[9]

TABLE 20–1. Differential Diagnosis of Vertigo Based on Time Frame of Vertigo and Presence or Absence of Hearing Loss

Duration of Vertigo	*Hearing Loss Absent*	*Hearing Loss Present*
Seconds	Benign paroxysmal positional vertigo	Perilymphatic fistula Cholesteatoma
Minutes	Vertebral/basilar artery insufficiency Migraines	
Hours	Vestibulopathy	Meniere's disease
Days	Vestibular neuronitis	Labyrinthitis
Weeks	Central nervous system lesions Lyme disease Multiple sclerosis	Vestibular schwannoma Autoimmune processes Psychogenic

COMMON PERIPHERAL VESTIBULAR DISORDERS

Millions of people present annually to their physicians with the complaint of dizziness. In addition to the vestibular system, dizziness may be caused by poor vision, decreased proprioception (diabetes mellitus), cardiovascular insufficiency, cerebellar or brainstem strokes, neurologic conditions (migraines, multiple sclerosis), metabolic disorders, and side effects of medications. The role of the otolaryngologist includes clarifying the subset of patients who have vertigo owing to injury to the vestibular system and differentiating central from peripheral vestibular disorders. The evaluation includes a complete head and neck and vestibular examination (Table 20–2). Diagnostic evaluation includes audiology, vestibular testing, and imaging. The majority of patients with peripheral vestibular disorders will have BPPV, Meniere's disease, or vestibular neuronitis. These patients generally improve with supportive or conservative care (medical or physical therapy). The small percentage of medically recalcitrant patients can then be helped with surgical intervention. The surgical interventions, in general, ablate the vestibular system and rely on central compensation and vestibular rehabilitation to improve the patient.

Benign Paroxysmal Positional Vertigo

Benign paroxysmal positional vertigo was first recognized by Bárány in 1921 and was further characterized by Dix and Hallpike in 1952.[10] Benign paroxysmal positional vertigo is one of the most common peripheral causes of vertigo. Patients complain of vertigo lasting seconds when in certain positions, with no associated hearing loss. The most common cause of this disorder is the presence of debris in the posterior semicircular duct. The diagnosis is made by noting a characteristic nystagmus when the patient is in the Dix-Hallpike position. The use of specific maneuvers to reposition the debris into the utricle provides relief for the majority of patients.

Epidemiology The average age of presentation is in the fifth decade, and there is no gender bias. The incidence may range from 10 to 100 cases per 100,000 persons per year.[11] Nearly 20% of patients seen at vertigo clinics will be given the diagnosis of BPPV. Ten to 15% of patients will have an antecedent history of vestibular neuronitis, and another 20% will have a history of head trauma.[12,13]

Pathogenesis Benign paroxysmal positional vertigo occurs because a semicircular duct has debris attached to the cupula or free floating in the endolymph. The crista of the semicircular duct is stimulated by the movement of these particles in response to gravity. As described earlier, the semicircular ducts normally sense angular acceleration, not gravity. The study of temporal bones from patients with BPPV shows basophilic deposits adherent to the cupula, and this finding was termed cupulolithiasis.[14] During posterior semicircular canal (PCSS)

TABLE 20–2. Vestibular Evaluation

1. Head and neck examination including evaluation of cranial nerves
2. Spontaneous and gaze-evoked nystagmus with Fresnel glasses
   - Direction: fixed-peripheral, changing-central
   - Form: jerk-peripheral, pendular-central
   - Fixation: suppression-peripheral, enhanced-central
3. Smooth pursuit: "Follow my fingers"
4. Saccades: "Look to my left or right finger when I say to"
   - Dysmetric: cerebellar
   - Slow: brainstem
   - Late: frontal lobe
   - Dysconjugate: multiple sclerosis
5. Head thurst
   - Normal: no refixation saccade
   - Abnormal: refixation saccade (peripheral)
6. Head shake: "10 degrees, 2 cycles/second, 20 seconds"
   - Normal: no nystagmus
   - Abnormal: horizontal nystagmus-peripheral, vertical nystagmus-central (brainstem)
7. Dynamic visual activity: "Look at Snellen chart with head shake"
   - Normal: < 3 line drop
   - Abnormal: 3 or more line drop—bilateral vestibular loss
8. Fixation suppression: "Look at your thumb during rotation"
   - Normal: no nystagmus
   - Abnormal: nystagmus-central (flocculus)
9. Positional testing: Dix-Hallpike maneuver
   - Normal: no nystagmus
   - Abnormal: downbeat, fatigable, rotatory nystagmus
10. Cerbellum: finger to nose, rapid alternating movements, heel to shin
11. Posture: Romberg's test

occlusion in patients with resistant BPPV, free-floating debris has been observed in the endolymph and has been termed canalolithiasis.[15] Electron microscopy of these particles shows that they are likely otoconia originating from the macula of the gravity-sensitive utricle.[16]

The cupula of the semicircular duct has the same specific gravity as the endolymph and so is not sensitive to gravity. However, the debris in the semicircular duct moves in response to gravity, and when the patient places the semicircular duct in a dependent position, the particles move and entrain endolymph with them and cause deflection of the cupula. The unexpected gravity-sensitive response from the semicircular duct causes vertigo. The majority of BPPV is caused by debris in the posterior semicircular duct, but debris may also enter the horizontal and superior semicircular ducts.[17]

Natural History The natural history of BPPV includes an acute onset and remission over a few months. However, up to 30% of patients may have symptoms for longer than 1 year. The majority of patients will improve with a repositioning maneuver. Patients may have unpredictable recurrences and remissions, and the rate of recurrence may be 10 to 15% per year.[12] These patients may be retreated with a repositioning maneuver. A subset of patients who have adapted by not using certain positions to avoid the vertigo or who have other balance disorders will benefit from balance rehabilitation therapy.

Symptoms and Signs The patient usually complains of a sudden onset of vertigo that lasts 10 to 20 seconds with certain head movements. The triggering movements include rolling over in bed into a lateral position, getting out of bed, looking up and back, and bending over. The vertigo may be associated with nausea. The patients have normal hearing, no spontaneous nystagmus, and normal neurologic evaluations.[10]

Diagnostic Evaluation *Dix-Hallpike Test.* Benign paroxysmal positional vertigo is diagnosed by observing a characteristic nystagmus when performing the Dix-Hallpike test[10] (Figure 20–1). For testing the right PSCC, the patient sits on the examination table and turns the head 45 degrees to the right. This places the PSCC in the sagittal plane. The examiner stands facing the patient on the patient's

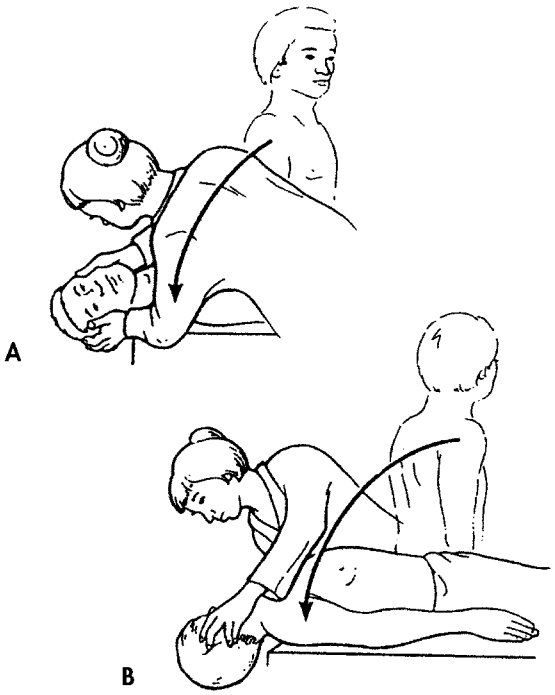

FIGURE 20–1. Benign paroxysmal positional vertigo is diagnosed by observing a characteristic nystagmus when performing the Dix-Hallpike test. For testing the right posterior semicircular canal, the patient sits on the examination table and turns his/her head to the right 45 degrees. The patient is moved by the examiner from the seated to supine position with the head slightly hanging over the edge of the table. The eyes are observed for the characteristic down-beating, rotatory nystagmus. The nystagmus has a 1- to 2-second latency and is fatigable. Reproduced with permission from Shepard NT, Telian SA. Practical management of the balance disorder patient. San Diego: Singular; 1996.

right side or stands behind the patient. The patient is then moved by the examiner from the seated to the supine position with the head slightly hanging over the edge of the table. The right ear is down, and the chin is pointing slightly up. The eyes are observed for the characteristic nystagmus. There is a latency of 1 to 2 seconds prior to the onset of the nystagmus and vertigo. The nystagmus is mixed with a torsional and vertical component and is geotropic (downbeat, rotatory nystagmus). The nystagmus follows Ewald's law for excitation of the dependent PSCC. The nystagmus is in the plane of the canal and the fast phase is toward the stimulated canal. The vertigo and nystagmus increase and then decrease within 20 seconds. The vertigo and nystagmus are reduced with repeated Dix-Hallpike tests, so the nystagmus is fatigable. All of these criteria need to be present to diagnose a patient with BPPV caused by debris in the PSCC.

Imaging. Imaging is reserved for patients who do not have the characteristic nystagmus, have associated neurologic findings, or do not respond to treatment. The imaging choice is a magnetic resonance imaging (MRI) scan with gadolinium contrast to evaluate the brainstem, CPA, and IAC. The MRI is the most sensitive and specific test to identify posterior fossa tumors.

Management *Repositioning Maneuver.* The primary management for BPPV includes maneuvers to reposition the debris into the utricle. The most widely used set of maneuvers was described by Epley[18] (Figure 20–2). The patient is taken through four moves starting in the sitting position with head turned at a 45-degree angle toward the affected side. First, the patient is placed into the Dix-Hallpike position (supine with the affected ear down) until the vertigo and nystagmus subside. Second, the patient's head is turned to the opposite side, causing the affected ear to be up and the unaffected ear to be down. Third, the whole body and head are then turned away from the affected side to a lateral decubitus position with the head in a face down position. The fourth step is to bring the patient back to a sitting position with the head turned toward the unaffected side. The maneuver may be repeated if the patient is still symptomatic. A bone vibrator may also be placed on the mastoid bone during the maneuvers to loosen the debris. Eighty percent of patients will be cured by a single repositioning maneuver. The maneuver may be repeated in resistant patients or patients with recurrences. Other maneuvers and exercises are available for resistant patients.[19]

Surgical Management. For a very small number of patients with intractable BPPV, surgical treatment is available. These patients have failed repositioning maneuvers and have no intracranial pathology on imaging studies. The primary surgical option is PSCC occlusion.[20] A standard mastoidectomy is performed, and the PSCC is fenestrated. The membranous duct is occluded with muscle, fascia, or bone

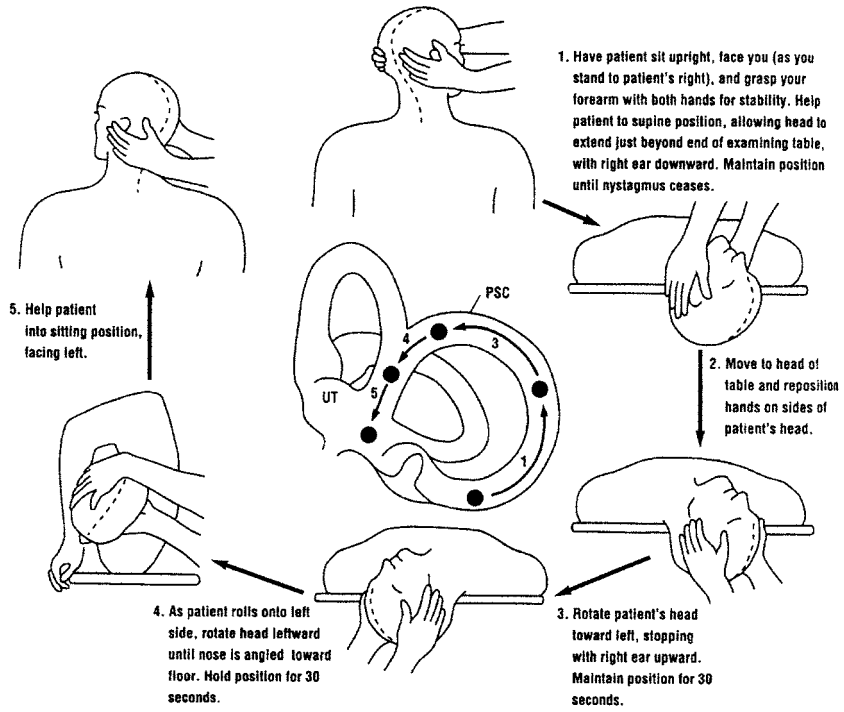

FIGURE 20–2. The primary management for benign paroxysmal positional vertigo includes maneuvers to reposition the debris in the posterior semicircular canal (PSC) into the utricle (UT). The Epley maneuver is shown in this diagram. Eighty percent of patients will be cured by a single repositioning maneuver. The maneuver may be repeated if the patient is still symptomatic. A bone vibrator may also be placed on the mastoid bone during the maneuvers to loosen the debris. Reproduced with permission from Foster CA, Baloh RW. Episodic vertigo. In: Rakel RE, editor. Conn's current therapy. 47th ed. Philadelphia: WB Saunders; 1995. p. 837–41.

pate or collapsed with a laser. The occlusion prevents debris and subsequent endolymph movement to deflect the cupula. There may be a temporary mixed hearing loss that usually recovers. The success rate for PSCC occlusion is high. A more technically challenging surgical option with increased risk to hearing involves ablating the nerve supply of the PSCC via a singular neurectomy.[21]

Meniere's Disease

History and Pathogenesis Meniere's disease or endolymphatic hydrops is an idiopathic inner ear disorder characterized by attacks of vertigo, fluctuating hearing loss, tinnitus, and aural fullness.[22] The history of Meniere's disease parallels our understanding of vestibular anatomy and physiology and provides a rationale for treatment of Meniere's disease and other vestibular disorders. The recognition that hearing loss originated in the inner ear has been long-standing. However, the recognition that vertigo was linked to the inner ear rather than only to central sources was first clearly described by Prosper Meniere in 1861.[23] In the decade following Meniere's description, the function and microscopic anatomy of the vestibular system were further refined. In 1869, Boettcher described the normal microscopic appearance of the utricle, saccule, and endolymphatic sac.[23] In 1870, Friedrich Goltz clarified the function of the vestibular system by concluding that the semicircular canals were responsible for mediating equilibrium only and were not involved with hearing. The next step in understanding the pathogenesis of Meniere's disease was provided by Knapp in 1871. He believed that Meniere's disease was caused by elevated intracochlear (endolymphatic) pressure. The clinician's ability to evaluate vertigo and nystagmus with caloric, rotational, and galvanic testing and to differentiate and categorize peripheral and central vestibular disorders was developed and introduced by Robert Bárány in the late nineteenth and early twentieth century.

The treatment strategies for Meniere's disease were developed based on the mentioned advances in vestibular anatomy and physiology. In 1902, Parry performed a CN VIII division for vertigo in a patient with suspected Meniere's disease.[23] In 1904, Milligan and Lake performed a labyrinthectomy for vertigo, providing a safer alternative than CN VIII section.[23] The effectiveness of CN VIII section for Meniere's disease was shown by Dandy in 1928.[23] These procedures caused hearing loss, so hearing preservation treatments were developed.[23] In 1931, McKenzie performed a selective vestibular neurectomy.[24] The the-

ory of increased endolymphatic pressure prompted Portman to open the endolymphatic sac (ES) via a transmastoid approach in 1926.[23] The patients had improvement in vertigo and hearing preservation. The medical management proposed by Frustenberg in 1934 to treat the increased endolymphatic pressure included a low-sodium diet and ammonia salts (acting as diuretics).[23]

In 1938, Hallpike and Cairns made the most significant advance in understanding the pathogenesis of Meniere's disease by describing the histopathology of Meniere's disease.[25] They noted gross dilation of the saccule and scala media with obliteration of the perilymph spaces of the vestibule and scala vestibuli and confirmed the concept of endolymphatic hydrops. Their descriptions caused the treatment strategies to focus on the labyrinth. In the 1940s and 1950s, Cawthorne popularized the transmastoid labyrinthectomy as the standard of care for Meniere's disease.[23] In 1948, Fowler used streptomycin, an aminoglycoside, to perform a chemical labyrinthectomy.[23] The development of the operative microscope by Nylén allowed House to perform the first microsurgical vestibular nerve sections in 1960.[26] The microsurgical approach improved preservation of hearing and maintenance of facial nerve function. The 1990s have seen a resurgence in the use of intratympanic gentamicin (a vestibular selective aminoglycoside) for the treatment of Meniere's disease.[23,27]

The cause of the endolymphatic hydrops seen by Hallpike and Crains in 1938 continues to elude us. The cause of Meniere's disease has been attributed to anatomic, infectious, immunologic, and allergic factors. The focus of most studies has been on the endolymphatic duct and sac, the basic premise being that there is increased endolymphatic fluid owing to impaired reabsorption of the endolymphatic fluid in the endolymphatic duct and sac. A histopathologic study has shown blockage in the longitudinal flow of endolymph in the endolymphatic duct, ES, utricular duct, saccular duct, and ductus reuniens.[28] Hebbar and colleagues have reported that the ES in patients with Meniere's disease is smaller, has less absorptive tubular epithelium, and has increased perisaccular fibrosis.[29] A blinded, controlled study, however, did not show any difference in the connective tissue or fibrosis surrounding the ES in Meniere's disease.[30] The vestibular duct has also been found to be smaller in Meniere's disease. In recent studies, a decrease in type II vestibular hair cells has been demonstrated in Meniere's disease. The role and significance of the decrease of these type II hair cells are currently not known.[31] The ES has been shown to be important in inner ear metabolic homeostasis. The ES secretes glycoprotein conjugates in response to osmotic challenges, and preliminary studies have shown alteration in glycoprotein metabolism in Meniere's disease. There has been no conclusive proof of an infectious agent related to Meniere's disease.[30,32]

The role of allergy and immune mechanisms in Meniere's disease is under investigation. The "seat" of immunity in the inner ear may be the ES. The ES is able to process antigens and mount a local antibody response. The ES may be vulnerable to immune injury because of the hyperosmolarity of its contents and the fenestrations in its vasculature. These two properties increase the risk of immune complex deposition and injury. Immunoglobulin (Ig) G deposition is seen in the ESs of patients undergoing ES shunt procedures. Meniere's patients also have elevated IgM complexes and C1q component of complement and low levels of IgA complexes in their serum. Patients with Meniere's disease have also shown vulnerability to autoimmune (cytotoxic) reactions. Thirty percent of patients with Meniere's disease had autoantibodies to an inner ear antigen by Western blot analysis. The response of some patients with Meniere's disease to corticosteroid therapy and the increased rate of expression of certain human leukocyte antigens (A3, Cw7, B7, and DR2) in Meniere's disease support the presence of an underlying immune mechanism.[33] A similar argument may be made regarding Meniere's disease and allergy. A significant percentage (50%) of patients with Meniere's disease have concomitant inhalant and/or food allergy, and treating these allergies with immunotherapy and diet modification has improved the manifestations of their allergy and their Meniere's disease. The fenestrated blood vessels of the ES may be vulnerable to vasoactive mediators, such as histamine, that are released during an IgE-mediated allergic reaction. Some have suggested a synergistic role of allergy or viral infection in potentiating the immune abnormalities in Meniere's disease.[34]

Epidemiology The incidence of Meniere's disease ranges from 10 to 150 cases in 100,000 persons per

year. There is no gender bias, and patients typically present in the fifth decade of life. A new diagnosis of Meniere's disease in someone less than 20 or over 70 years is unusual. There is no right or left ear predilection for the disease.[35]

Natural History Meniere's disease is characterized by remissions and exacerbations, making it difficult to predict its future behavior in any individual patient based on the patient's own history, diagnostic evaluations, or epidemiologic profiles. The initial manifestation may be vertigo or hearing loss, but within 1 year of onset, the typical syndrome (attacks of vertigo, tinnitus, fluctuating hearing loss, and aural fullness) is present. Longitudinal studies have shown that after 10 to 20 years, the vertigo attacks subside in most patients and the hearing loss stabilizes to a moderate-to-severe level (50 dB HL). Meniere's disease usually affects one ear initially, but the risk of developing Meniere's disease in the other ear appears to be linear with time. Twenty-five to 45% of patients may develop disease in the second ear.[35,36]

Symptoms and Signs Meniere's disease occurs as episodic attacks lasting for hours. The four symptoms and signs include unilateral, fluctuating sensorineural hearing loss; vertigo lasting minutes to hours; constant or intermittent tinnitus typically increasing in intensity before or during the vertiginous attack; and aural fullness. The acute attack is also associated with nausea and vomiting, and following the acute attack, patients feel exhausted for a few days. Table 20–3 shows the diagnostic scale for Meniere's disease created by the Committee on Hearing and Equilibrium of the American Academy of Otolaryngology-Head and Neck Surgery.[22] As emphasized in the diagnostic scale, the diagnosis of Meniere's disease is based on the longitudinal course of the disease rather than on a single attack.

Diagnostic Evaluation Meniere's disease is a clinical diagnosis. The diagnostic evaluation of Meniere's disease primarily includes audiometry and a fluorescent treponemal antibody absorption to rule out syphilis. Electrophysiologic studies, other serologic studies, and imaging are obtained as needed. The role of allergy testing continues to be defined. There is no diagnostic test for Meniere's disease.[37]

TABLE 20–3. Diagnostic Scale for Meniere's Disease of the American Academy of Otolaryngology-Head and Neck Surgery*

Certain Meniere's disease
Definitive Meniere's disease, plus histopathologic confirmation
Definitive Meniere's disease
Two or more episodes of vertigo of at least 20 min
Audiometrically documented hearing loss on at least one occasion
Tinnitus and aural fullness
Probable Meniere's disease
One definite episode of vertigo
Audiometrically documented hearing loss on at least one occasion
Tinnitus and aural fullness
Possible Meniere's disease
Episodic vertigo without documented hearing loss
Sensorineural hearing loss, fluctuating or fixed, with dysequilibrium but without definitive episodes

*In all scales, other causes must be excluded using any technical methods (eg, imaging, laboratory, etc). Adapted from Committee on Hearing and Equilibrium.[22]

Audiology. Audiologic assessment initially shows a low-frequency or low- and high-frequency (inverted V) sensorineural hearing loss. As the disease progresses, there is a flat sensorineural hearing loss.[36] A glycerol dehydration test involves measuring serial pure-tone thresholds and discrimination scores during diuresis.[38] The diagnosis of Meniere's disease is supported if there is improvement in the patient's hearing. The test is positive in only 50% of patients suspected of having Meniere's disease.

Electrocochleography. Electrocochleography measures the sound-evoked electrical potentials from the inner ear. The three phenomena measured from the external auditory canal, tympanic membrane, or promontory in response to clicks include the cochlear microphonic, summating potential, and action potential. The endolymphatic hydrops of Meniere's disease causes a larger summating potential, so the ratio of the summating potential to the

action potential (SP/AP) is elevated.[39] The SP/AP lacks the specificity or sensitivity to use it to diagnose Meniere's disease consistently or to predict its clinical course.[37]

Vestibular Testing. Vestibular testing (electronystagmography [ENG] with caloric testing) shows peripheral vestibular dysfunction. The caloric response decreases during the first decade of the disease and usually stabilizes at 50% of normal function.[40]

Serology. Fluorescent treponemal antibody absorption is mandatory in any patient given the diagnosis of an idiopathic disease since syphilis may perfectly imitate Meniere's disease. Autoimmune inner ear disease may present initially with a Meniere's picture. The distinguishing characteristics of an autoimmune inner ear disease include a more aggressive course and early bilateral involvement. Autoimmune serologic tests may also be helpful. A promising test is a Western blot looking for anticochlear antibodies that can bind to a 68 to 70 kD antigen.[41]

Imaging. Magnetic resonance imaging with gadolinium contrast allows the exclusion of retrocochlear pathology, such as a VS. An imaging scan is not mandatory with a classic course of Meniere's disease leading to a clinical diagnosis. Imaging should be obtained if the initial presentation or course is unusual or if surgical management is planned.

Management In considering the management of Meniere's disease, an observation by Dandy rings true: "The syndrome is one that lends itself well for a time to statistical conclusions because of the marked variations in the frequency of attacks. Some patients will go for months or even years between attacks and what is done last gets the credit for the free interval…"[24] Since the introduction of aminoglycoside therapy in 1948, no significant conceptual advances have been made in the treatment of Meniere's disease. The current treatments focus on relieving vertigo without further injuring the hearing. Hearing may be temporarily improved or stabilized by the current treatments, but the hearing does not have long-term stability.

Medical Treatment. The primary management of Meniere's disease involves a low-sodium diet (1,500 mg/d) and diuretics (hydrochlorothiazide).[42] Van Deelen and Huizing, in a hydrochlorothiazide, double-masked, placebo-controlled, crossover study, showed that diuretics seem to improve the vestibular complaints but have no effect on hearing or tinnitus.[43] Some patients benefit from dietary restrictions on caffeine, nicotine, alcohol, and theophylline-containing foods (chocolate). Acute attacks are managed with vestibular suppressants (meclizine, diazepam) and antiemetic medications (prochlorperazine suppository). The majority of patients are controlled with conservative management. Medically refractory patients with serviceable hearing may undergo intratympanic gentamicin therapy, ES surgery, or vestibular nerve section. Patients without serviceable hearing may undergo intratympanic gentamicin therapy or transmastoid labyrinthectomy.

Aminoglycoside. Intratympanic gentamicin was introduced by Schuknecht in 1957 and has seen a resurgence in the 1990s by the work of Nedzelski and others.[27] Intratympanic gentamicin is absorbed into the inner ear primarily via the round window and selectively damages the vestibular hair cells relative to the cochlear hair cells. Gentamicin may also decrease endolymph production by affecting dark cells in the stria vascularis.[44] Intratympanic gentamicin has nearly a 90% vertigo control rate with a follow-up of at least 2 years, and the extent of hearing loss depends on the protocol for gentamicin delivery. A variety of treatment protocols (daily, biweekly, weekly, monthly injections) using fixed-dose or titration end-point regimens exist, but few trends are present. Treatments are stopped if there is persistent hearing loss. Vertigo control is nearly always obtained if vestibular function is ablated. However, the risk of hearing loss increases as the total dose and frequency of gentamicin injections are increased. Current protocols are reducing the dose and frequency of injections to decrease hearing loss and still obtain vertigo control. Vertigo control may be obtained with some residual vestibular function present, and this residual function may be useful if patients develop bilateral Meniere's disease. Recent studies with weekly or monthly injections have shown nearly 90% vertigo control with 7 to 17% < 30 dB hearing loss and less than 1% ≥ 30 dB hearing loss.[27,44,45]

Surgery. Patients who have failed medical and gentamicin treatment may require surgical intervention.

Endolymphatic sac surgery and vestibular nerve sections preserve hearing, whereas labyrinthectomy ablates hearing.

Endolymphatic Sac. Endolymphatic sac surgery involves a mastoidectomy and locating the ES on the posterior fossa dura (Figure 20–3, A). The sac is medial to the sigmoid sinus and inferior to the PSCC. The ES is also located along an imaginary line (Donaldson's line) in the plane of the horizontal semicircular canal. The ES may be decompressed or have a shunt placed that communicates into the subarachnoid space or mastoid cavity. The "sham" study, a double-masked, placebo-controlled comparison of the endolymphatic mastoid shunt versus a cortical mastoidectomy, by Thomsen et al showed that ES surgery provides no greater benefit than performing a cortical mastoidectomy.[46] A 9-year follow-up showed 70% control of vertigo in both surgical groups.[47] Reanalysis of the sham study suggested a greater benefit in the ES surgery group, and a recent study with a 5-year follow-up showed an 88% functional level 1 or 2 response after an endolymphatic mastoid shunt operation.[48] The success rates have great variation in the literature, so the benefit of ES surgery is not universally accepted. Endolymphatic shunt surgery provides a nondestructive option for patients who fail medical or aminoglycoside therapy and have good hearing. The role of endolymphatic surgery is currently in decline with the renewed interest in intratympanic aminoglycoside therapy.

Vestibular Nerve Section. Vestibular nerve section provides a definitive treatment of unilateral Meniere's disease in patients with serviceable hearing. Ninety-five percent of patients achieve vertigo control, and hearing is preserved in over 95% of patients.[37] The vestibular neurectomy may be approached via a retrosigmoid or middle fossa approach (Figure 20–3, B). These procedures are described in detail in the CPA section. The risk to the facial nerve is less than 1% in the retrosigmoid approach and less than 5% in the middle fossa approach. The advantage of the middle fossa approach is sectioning the vestibular nerves in the IAC lateral to where they join the cochlear nerve in the CPA.[49] The patients are acutely vertiginous and have nystagmus (fast phase away from the operated ear) for a few days until central compensation takes effect. The hearing appears to degenerate in the postoperative patient in accordance with the natural history of Meniere's disease.

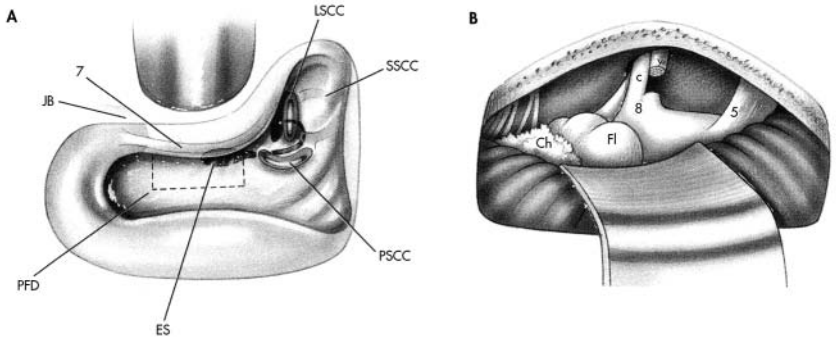

FIGURE 20–3. Two hearing-preserving operations for Meniere's disease include endolymphatic sac (ES) surgery and vestibular nerve section. *A*, Endolymphatic sac surgery (left ear) involves a mastoidectomy and locating the ES on the posterior fossa dura (PFD). The sac is located posterior to the mastoid segment of the facial nerve (7), inferior to the posterior semicircular canal (PSCC), and superior to the jugular bulb (JB). The ES may be decompressed or have a shunt placed that communicates into the mastoid cavity. Endolymphatic shunt surgery provides a nondestructive option for patients who fail medical or aminoglycoside therapy and have good hearing. LSCC and SSCC = lateral and superior semicircular canals. *B*, Vestibular nerve section provides a definitive treatment of vertigo in patients with serviceable hearing. The vestibular neurectomy may be approached via a retrosigmoid or middle fossa approach. The artwork shows a completed left retrosigmoid vestibular neurectomy with sectioning of the vestibular nerve (v) and preservation of the cochlear nerve (c). 8 = vestibulocochlear nerve near the pons; 5 = trigeminal nerve; Fl = flocculus; Ch = choroid plexus. Reproduced with permission from Jackler RK.[50]

Labyrinthectomy. A transmastoid labyrinthectomy with fenestration of the bony semicircular canals and vestibule and removal of the membranous neuroepithelium provides control of vertigo in nearly all patients with unilateral Meniere's disease and poor hearing. The rate of control may decline by 10 years owing to development of vertebral basilar artery insufficiency (aging), poorer vision, and development of Meniere's disease in the contralateral ear. The complete loss of unilateral vestibular function owing to the labyrinthectomy leads to unsteadiness in up to 30% of patients.[51]

Vestibular Neuronitis

A case of vestibular neuronitis was described in 1909 by Ruttin, and the term vestibular neuronitis was coined by Hallpike in 1949.[52] Vestibular neuronitis is the third most common cause of peripheral vestibular vertigo following BPPV and Meniere's disease.[53] The presentation includes acute vertigo. Like Meniere's disease, the pathogenesis is not known, but the majority of patients recover, with no sequelae. The primary role of the physician is to rule out a central cause of the acute vertigo. The treatment is primarily supportive care.

Epidemiology Vestibular neuronitis has no gender bias and typically affects middle-aged people. Less than half of the patients will have an antecedent or concurrent viral illness.[52]

Pathogenesis The proposed causes of vestibular neuronitis include viral infection, vascular occlusion, and immune mechanisms. The evidence to support a viral cause is limited by lack of pathologic tissue to study, and the evidence based on seroconversion remains unconvincing. Therefore, support for the viral cause remains rare and circumstantial. The study of the available temporal bones of patients with vestibular neuronitis shows a spectrum of injury. There may be no abnormality seen to significant degenerative changes in the vestibular nerve, Scarpa's ganglia, and vestibular neuroepithelium. The injury is often seen in the superior vestibular nerve. In terms of a vascular cause, there was no evidence of vascular occlusion affecting the vestibular system in any of the temporal bones studied.[52,54]

Natural History The natural history of vestibular neuronitis includes an acute attack of vertigo that lasts a few days with complete or at least partial recovery within a few weeks to months. Some patients (15% in one study) may have significant vestibular symptoms even after 1 year.[55] Recurrent attacks in the same or contralateral ear have been reported but are unusual. Some patients may later develop BPPV. The majority of patients have complete recovery. The few patients who have persistent vestibular symptoms should have vestibular rehabilitation therapy.

Symptoms and Signs The presentation of vestibular neuronitis includes the sudden onset of vertigo with nausea and vomiting. The patient has normal hearing and a normal neurologic examination. The patient may have postural instability toward the injured ear but is still able to walk without falling. The patient usually does not have a headache. The patient has spontaneous nystagmus characteristic of an acute peripheral vestibular injury. The nystagmus is usually horizontal with a torsional component and is suppressed by visual fixation. The reduction in vestibular signal in the injured ear leads to relative vestibular excitation in the opposite ear. The result is that the slow phase of nystagmus is toward the injured ear and the fast phase is away from the injured ear. The nystagmus is intensified by looking toward the fast phase and is decreased by looking toward the slow phase or toward the injured ear. This principle is Alexander's law. The direction of the nystagmus does not change with changes in the direction of gaze.[56]

Diagnostic Evaluation The diagnosis of vestibular neuronitis is based on the constellation of findings described above. The need for further evaluation is necessary only if there is a concern for a central cause of the acute vertigo or the acute vertigo does not substantially improve in 48 hours.[56] The primary central cause for acute vertigo lasting days is a brainstem or cerebellar stroke. In the majority of cases, there will be other neurologic findings: diplopia, dysmetria, dysarthria, motor and sensory deficits, abnormal reflexes, inability to walk without falling, and central nystagmus. Central nystagmus is not affected by visual fixation and may change directions with changes in gaze. Purely vertical or purely torsional nystagmus is highly suggestive of a central disorder.[57] In the event of an isolated inferior cerebellar stroke, the presentation may be indistinguishable from

vestibular neuronitis. Twenty-five percent of patients with risk factors for stroke who present with vertigo, nystagmus, and postural instability have had an inferior cerebellar stroke.[58] Therefore, patients with significant risk factors for stroke should have an imaging study if they present with acute vertigo, nystagmus, and postural instability.

Vestibular Testing. Vestibular testing in vestibular neuronitis shows an absent or reduced caloric response in the injured ear in the majority of patients. The caloric responses eventually become normal in 42% of patients.[59]

Imaging. Magnetic resonance imaging with emphasis on identification of both infarction and hemorrhage in the brainstem and cerebellum is obtained in patients with risk factors for stroke, patients with additional neurologic abnormalities, and patients who do not show improvement within 48 hours. The other option is a computed tomographic (CT) scan with thin cuts evaluating the brainstem, cerebellum, and fourth ventricle.

Management *Supportive Care.* The primary management includes symptomatic and supportive care during the acute phase of the illness. Patients are given vestibular suppressants and antiemetics to control the vertigo, nausea, and vomiting. These medications are withdrawn as soon as possible to not interfere with the central vestibular compensation.[8]

Cerebellopontine Angle Tumors

The CPA consists of a potential cerebrospinal fluid (CSF)-filled space in the posterior cranial fossa bounded by the temporal bone, cerebellum, and brainstem. The CPA is traversed by CNs V to XI, and the facial (VII) and vestibulocochlear (VIII) nerves are most prominent. Cerebellopontine angle tumors account for 10% of all intracranial tumors (Table 20–4). Nearly 90% of all CPA tumors are VSs (acoustic neuromas) and meningiomas.[60] Other CPA lesions include congenital rest lesions (epidermoids, arachnoid cysts, lipomas), schwannomas of other CNs, intra-axial tumors, metastases, vascular lesions (paragangliomas, hemangiomas), and lesions extending from the skull base (cholesterol granulomas, chordomas).[61] Cerebellopontine angle lesions become clinically symptomatic by causing compression of the neurovascular structures in and around the CPA. The classic description of these symptoms by Cushing includes initially unilateral hearing loss, vertigo, nystagmus, altered facial sensation, facial pain that later progresses to facial palsy, vocal cord palsy, dysphagia, diplopia, respiratory compromise, and death (Table 20–5). This description highlights the untreated natural history of CPA tumors.[62]

TABLE 20–4. Cerebellopontine Angle (CPA) Lesions

Common CPA lesions
Schwanommas (cranial nerves VIII, VII, V)
Meningiomas
Epidermoids
Congenital rest lesions
Epidermoids

tumors include placing an emphasis on earlier diagnosis by Cushing in 1917 and a dogma change in 1925 by Dandy from rapid tumor enucleation to meticulous, hemostatic total tumor removal.[63] Fundamental technical advances allowing diagnosis and surgical removal include the advent of modern imaging and the introduction of the surgical microscope by House and Doyle in 1961. House helped create the field of neurotology and brought the surgical management of CPA tumors into the modern era.[23,24]

The focus of this section includes understanding the anatomy of the CPA; describing the pathogenesis of VSs, meningiomas, and epidermoids; and providing a clinical context to diagnose, counsel, and treat patients with various CPA tumors.

Anatomy The CPA is roughly triangular shaped in the axial plane and is filled with CSF (Figure 20–4). The superior boundary is the tentorium, and the inferior boundary is the cerebellar tonsil and medullary olives. The anterior border is the posterior dural surface of the petrous bone and clivus, and the posterior border is the ventral surface of the pons and cerebellum. The medial border is the cisterns of the pons and medulla, and the apex is the region of the lateral recess of the fourth ventricle. The lateral opening of the fourth ventricle, the foramen of Luschka, opens into the CPA. Cranial nerves V to XI traverse the cephalic and caudal extent of the CPA. The central structures crossing the CPA to and from the IAC are the facial (CN VII) and vestibulocochlear (CN VIII) nerves, respectively.[64]

Cranial nerves VII and VIII are covered with central myelin provided by neuroglial cells as they cross the CPA and carry a sleeve of posterior fossa dura into the IAC. The transition to peripheral myelin made by Schwann cells occurs at the medial opening of the IAC. The vestibulocochlear nerve divides into three nerves: the cochlear nerve and the superior and inferior vestibular nerves in the lateral extent of the CPA or medial part of the IAC. The IAC is divided into four quadrants by a vertical crest, called Bill's bar, and a transverse crest. The CN VII comes to lie in the anterosuperior quadrant and is anterior to the superior vestibular nerve and superior to the cochlear nerve, whereas the inferior vestibular nerve lies in the posteroinferior quadrant and is inferior to the superior vestibular nerve and posterior to the cochlear nerve (see Figure 20–4). The anterior inferior cerebellar artery (AICA) is the main artery in the CPA and is the source of the labyrinthine artery. The labyrinthine artery courses via the IAC and is an end artery for the hearing and balance organs. The AICA has a variable relationship to CN VII and VIII and to the IAC.[64]

Common Cerebellopontine Angle Lesions The three most common tumors of the CPA are schwannomas, meningiomas, and epidermoids. Each of these tumors has a similar clinical presentation, and they are primarily differentiated by their imaging characteristics. The treatment for these three lesions is surgical resection without injuring the neurovascular structures of the CPA.

Vestibular Schwannomas. Vestibular schwannomas are nerve sheath tumors of the superior and inferior vestibular nerves.[65] They arise in the medial part of the IAC or lateral part of the CPA and cause clinical symptoms by displacing, distorting, or compressing adjacent structures in the CPA.

Epidemiology. Vestibular schwannomas, incorrectly called acoustic neuromas, are by far the most common tumor involving the CPA.[2] Vestibular schwannomas make up 80% of CPA tumors and 8% of all intracranial tumors. Various epidemiologic studies

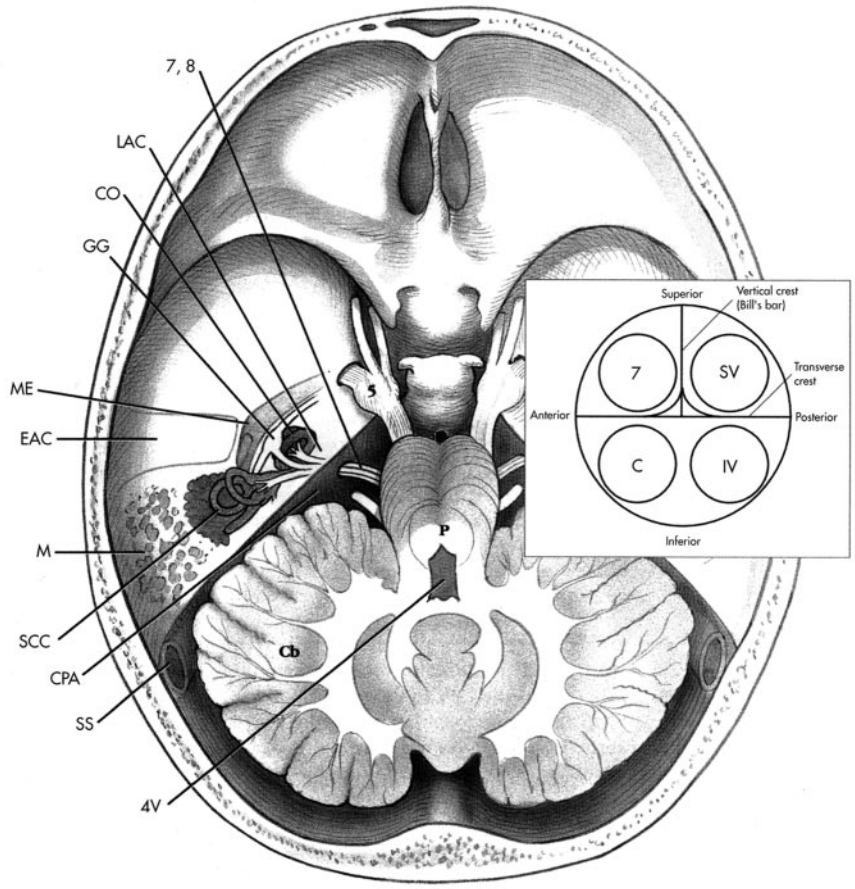

FIGURE 20–4. In the axial plane, the cerebellopontine angle (CPA) has a triangular shape. The CPA is bounded by the cerebellum (Cb), petrous bone, and brainstem. Cranial nerves V (5) to XI traverse the cephalic and caudal extent of the CPA. The central structures crossing the CPA to and from the internal auditory canal (IAC) are the facial (7) and vestibulocochlear nerves (8), respectively. The vestibulocochlear nerve divides into three nerves: the cochlear nerve (C) and the superior (SV) and inferior vestibular (IV) nerves in the lateral extent of the CPA or medial part of the IAC. The *inset diagram* shows a cross-section of the IAC. The IAC is divided into four quadrants by a vertical crest, called Bill's bar, and a transverse crest. The facial nerve comes to lie in the anterosuperior quadrant and is anterior to the superior vestibular nerve and superior to the cochlear nerve, whereas the inferior vestibular nerve lies in the posteroinferior quadrant and is inferior to the superior vestibular nerve and posterior to the cochlear nerve. CO = cochlea; GG = geniculate ganglion; ME = middle ear; EAC = external auditory canal; M = mastoid; SCC = semicircular canals; SS = sigmoid sinus; 4V = fourth ventricle; P = pons. Reproduced with permission from Jackler RK.[50]

have shown an incidence of 10 in 1 million individuals per year.[66] This figure correlates with the 2,000 to 3,000 people diagnosed with VSs each year in the United States. There is no gender bias. The age of presentation is 40 to 60 years of age. Ninety-five percent of VSs occur in a sporadic fashion. The remaining 5% of patients have neurofibromatosis 2 (NF2) or familial VSs. The age of presentation is earlier in nonsporadic VSs, and patients usually present in the second or third decade of life.

PATHOGENESIS. Vestibular schwannomas originate from the Schwann cells of the superior or inferior vestibular nerves at the transition zone of the peripheral and central myelin. This transition zone occurs in the lateral part of the CPA or medial part of the IAC. Therefore, VSs most often arise in the IAC and occasionally arise in the CPA. Schwannomas rarely arise from the cochlear nerve and are rarely malignant. The propensity to develop from the vestibular nerves may be owing to the vestibular

ganglia in the IAC having the highest concentration of Schwann cells.[67]

Recent studies have improved our molecular understanding of VSs. Vestibular schwannomas occur owing to mutations in the gene for the tumor suppressor protein merlin, located on chromosome 22q12.[68,69] Merlin is a cytoskeletal protein and may have a role in cell-cell contact inhibition.[70] The formation of VSs requires mutations of both copies of the merlin gene. One functioning merlin gene will prevent the formation of VSs. Somatic mutations in both copies of the merlin gene will result in sporadic VSs. The probabilities of two spontaneous, independent mutations at one locus predict a unilateral VS presenting in the fourth to sixth decade of life.[71]

In contrast, familial VSs occurring in NF2 require only one somatic mutation event. In NF2, patients inherit one mutated merlin gene and one normal merlin gene. A mutation in the normal allele leads to bilateral VSs by the age of 20. Therefore, NF2 is autosomal recessive at the gene level since disease expression requires mutations in both alleles of the gene, but the inheritance is autosomal dominant (pseudodominant) since inheritance of one mutated allele often leads to the disease state. Neurofibromatosis 2 is a central form of neurofibromatosis, with patients having central nervous system tumors including schwannomas, meningiomas, and gliomas. The great majority of these patients will develop bilateral VSs. In comparison, patients with NF1 (von Recklinghausen's disease) have intra- and extracranial tumors, and less than 5% of these patients will form unilateral VSs.[72,73] Interestingly, the cranial evaluation of two children recovered from a 4,000-year-old burial site showed widened IACs. These siblings likely had VSs owing to NF2.[74]

Genetic screens for the NF2 mutation have been developed and are the basis for genetic counseling for family members of NF2 patients. The severity of mutation involving the merlin gene in NF2 can predict the severity of disease manifestation.[71] The study of VSs in NF2 has provided insight into not only this disease but also the cause of sporadic VSs and has demonstrated a very interesting genetic inheritance mechanism.

PATHOLOGY. ***Gross.*** Vestibular schwannomas have a smooth surface with a yellow to gray color. The tumor is usually solid, with occasional cystic components, and therefore has a firm to soft texture depending on the solid to cystic components.

Microscopic. Microscopic evaluation shows the surface connective tissue capsule to be only 3 to 5 μm in thickness.[75] The classic histologic findings include areas of densely packed cells with spindle-shaped nuclei and fibrillar cytoplasm intermixed with hypocellular areas containing vacuolated, pleomorphic cells. These dense regions are called Antoni A areas, and the hypocellular regions are called Antoni B areas. Within the Antoni A areas, the palisades of the nuclei are termed Verocay bodies.[76] Histologic sections also show prominent, thick-walled vessels. As stated earlier, the cell of origin is the Schwann cell, so VS sections stain with S-100 immunoperoxidase.

NATURAL HISTORY. The natural history of VSs includes a slow rate of growth in the IAC and then into the cistern of the CPA. Studies show that periods of growth are intermixed with periods of quiescence. The average growth rate is 1.8 mm/year.[77] This slow growth causes progressive and often insidious symptoms and signs as there is displacement, distortion, and compression of the structures first in the IAC and then in the CPA. This slow growth via cellular proliferation provides a predictable progression of symptoms and signs. Occasionally, the tumor may undergo rapid expansion owing to cystic degeneration or hemorrhage into the tumor. A rapid expansion causes rapid movement along the subsequently described phases of VS symptoms and may cause rapid neurologic deterioration.

The initial intracanalicular growth affects the vestibulocochlear nerve in the rigid IAC and causes unilateral hearing loss, tinnitus, and vertigo or dysequilibrium. These three symptoms are the typical presenting complaints of not only patients with VS but also of those with other lesions of the CPA. Interestingly, the motor component of the facial nerve is resistant to injury during this phase of growth, and patients have normal facial function. The tumor then grows into the CPA cistern and grows freely without causing significant new symptoms because structures in the CPA are initially displaced without injury (Figure 20–5, A). As the tumor approaches 3 cm, the tumor abuts on the boundaries of the CPA and results in a new set of symptoms and signs. Compression of the CN V causes corneal and midface numbness or pain. Further distortion of CN

VIII and now CN VII causes further hearing loss and dysequilibrium, as well as facial weakness or spasms. Brainstem distortion leads to narrowing of the fourth ventricle (Figure 20–5, B). Further growth leads to the final clinical spectrum described by Cushing in the CPA syndrome.[62] The patient develops cerebellar signs owing to compression of the flocculus and cerebellar peduncle. The patient also develops obstructive hydrocephalus owing to closure of the fourth ventricle. The increasing intracranial pressure manifests in ocular changes, headache, mental status changes, nausea, and vomiting. If the VS continues to grow without intervention, death occurs owing to respiratory compromise.[78]

Symptoms and Signs. Hearing loss is present in 95% of patients with VSs.[78,79] Conversely, 5% of patients will have normal hearing, so unilateral vestibular or facial complaints without hearing loss do not rule out retrocochlear disease. Of the patients with hearing loss, most will have slowly progressive hearing loss with noise distortion. Twenty percent will have an episode of sudden hearing loss.[80] The improvement of hearing loss with or without treatment does not rule out retrocochlear disease. The level of hearing loss is not a clear predictor of tumor size.

Tinnitus is present in 65% of patients. The tinnitus is most often constant, with a high-buzzing pitch. This symptom is often not reported by patients because of the focus on the accompanying hearing loss. Similarly, because of the central compensation for the slowly evolving vestibular injury, patients tolerate and adapt well to the dysequilibrium. The majority of patients will have self-limiting episodes of vertigo. The dysequilibrium is initially mild and constant and often does not prompt a medical visit. Dysequilibrium is present in 60% of patients.

Facial and trigeminal nerve dysfunction occurs after the auditory and vestibular impairments. Patients usually have midface (V2) numbness and often have an absent corneal reflex. The motor supply of the trigeminal nerve to the muscles of masti-

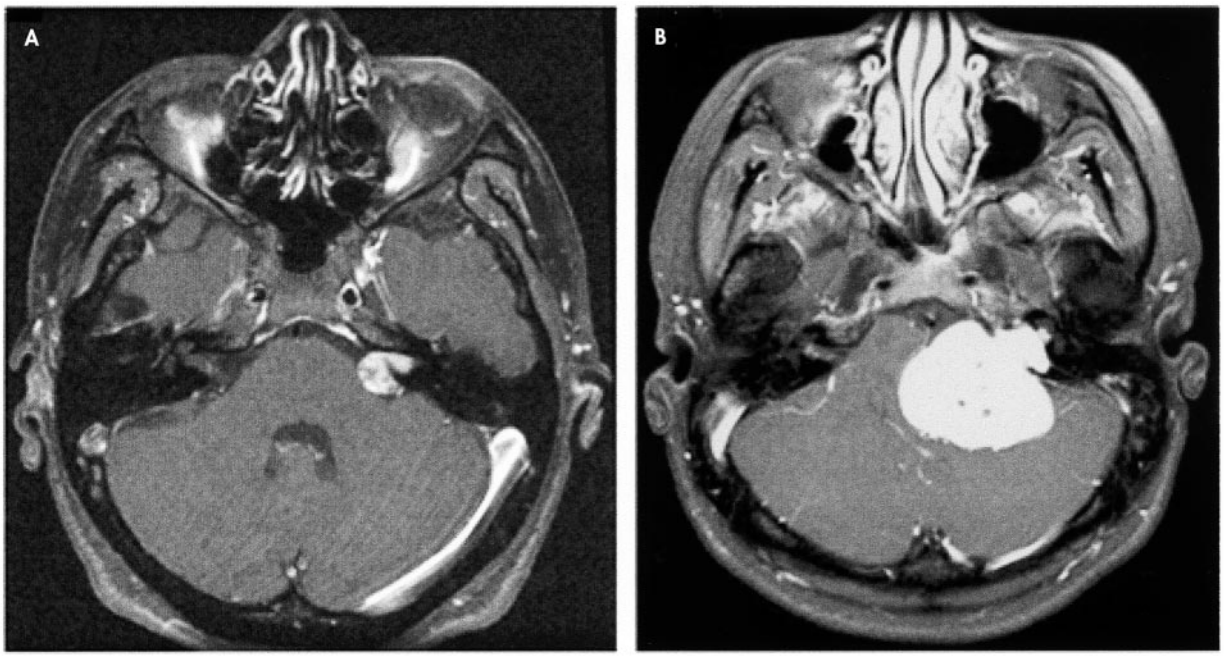

FIGURE 20–5. Axial T_1-weighted magnetic resonance images with gadolinium show the progressive growth pattern of a vestibular schwannoma. Vestibular schwannomas are centered in the internal auditory canal (IAC), expand the IAC, are globular in shape, and enhance with gadolinium. *A*, Vestibular schwannoma involves the IAC and cistern of the cerebellopontine angle. The tumor has solid and cystic components. *B*, Vestibular schwannoma has expanded the IAC and is causing significant compression of the brainstem and cerebellum. The brainstem distortion leads to narrowing of the fourth ventricle. (Courtesy of Nancy J. Fischbein.)

cation is rarely affected. The sensory component of the facial nerve is first affected, which causes numbness of the posterior part of the external auditory canal and is referred to as Hitzelberger's sign. Facial weakness or spasm occurs in 17% of patients and usually leads to a diagnosis of VS within 6 months.[78,79]

With large VSs or tumors that have undergone rapid expansion, patients will have visual complaints of decreased visual acuity and diplopia owing to compromise of CN II, IV, or VI. Hydrocephalus leads to complaints of headache, altered mental status, nausea, and vomiting; on examination, patients have increased intracranial pressure and papilledema. Compression of the lower CNs IX and X causes dysphagia, aspiration, and hoarseness, and examination reveals a poor gag reflex and vocal cord paralysis.

Diagnostic Evaluation. The average patient will require 4 years from the onset of symptoms to diagnosis. The diagnostic dilemma lies in choosing the appropriate patient to pursue audiologic and imaging studies. Although 5% of patients with VSs may present in an atypical fashion, the majority of patients will present with complaints of unilateral hearing loss or hearing distortion, unilateral tinnitus, vertigo or dysequilibrium, or facial numbness, weakness, or spasm. These patients with unilateral auditory, vestibular, and facial complaints are not a diagnostic dilemma and need to undergo careful evaluation to rule out retrocochlear disease. The initial step in the evaluation includes an audiologic assessment. If the audiologic assessment suggests a retrocochlear lesion, then imaging of the CPA is performed to rule out a retrocochlear lesion. Vestibular testing lacks specificity in diagnosing VSs.

Audiology. The standard auditory evaluation should include pure-tone audiometry, speech discrimination scores (SDSs), acoustic reflex thresholds, and acoustic reflex decay. Pure-tone audiometry of patients with VSs shows asymmetric, down-sloping, high-frequency, sensorineural hearing loss in almost 70% of patients. The hearing may also be normal, or the hearing loss may involve only the low frequencies or have a flat, trough, or peak configuration.[81] Retrocochlear hearing loss causes SDSs to be lower than predicted by the pure-tone thresholds. This out-of-proportion depression of SDSs is further accentuated when retested at a higher speech intensity. This phenomenon is called rollover. Poor SDSs are present in about one half of the patients with VSs. An abnormal SDS should trigger an imaging evaluation, but a normal SDS does not rule out a VS. Loss of the acoustic reflex or acoustic reflex decay is noted in most patients with VSs, but normal acoustic reflexes do not preclude a VS. In summary, asymmetric hearing loss, out-of-proportion deterioration in the SDS, and abnormal acoustic reflexes mandate an imaging evaluation to rule out a retrocochlear lesion. The majority of patients with VSs will have one of these abnormalities on audiologic analysis. The minority of the patients with subtle complaints and normal auditory evaluations fall into an area of diagnostic dilemma.[82] The likelihood of having a retrocochlear lesion may be very small, but the patient or physician may feel compelled by the patient's complaints to obtain audiometric testing. There is no clear management algorithm, and the physician must make a decision whether imaging evaluation is needed. Regardless of the decision, the most important part of the diagnostic plan should include patient counseling regarding the future symptoms and signs of CPA tumors and the need for planned follow-up.

Vestibular Testing. Vestibular testing does not provide a sensitive or specific means of diagnosing VSs. The most common test obtained to evaluate vestibular complaints is ENG with caloric testing. An ENG in a patient with a VS will show reduced caloric response in the affected ear. The extent of vestibular function present predicts the amount of postoperative vertigo. The location of the VS on the inferior or superior vestibular nerve may also be predicted by the ENG since the ENG primarily evaluates the lateral semicircular canal. The lateral semicircular canal is innervated by the superior vestibular nerve.[83]

Auditory Brainstem Response. Auditory brainstem response (ABR) is the measured electrical response of the cochlea and its brainstem pathway to short-duration broad-band clicks. The evoked response is a characteristic waveform with five identifiable peaks (I to V). The absolute latency or timing of each wave is recorded. In patients with VSs, the ABR is partially or completely absent, or there is a delay in the latency of wave V on the affected side. The delay may be an absolute delay based on normative data or a delay compared to the latency of wave V on the other side. An interaural delay of wave

V greater than 0.2 ms is considered abnormal. Overall, ABR has a sensitivity of > 90% and a specificity of 90% in detecting VS. However, when only considering intracanalicular tumors, 18 to 33% of tumors will be missed.[84] As the detection limits and costs of imaging studies have improved, the role of ABR in diagnosis of VS has dramatically declined. In the future, there will likely be no clear role for ABR in VS diagnosis.

Imaging. Magnetic resonance imaging with gadolinium contrast provides the gold standard for VS diagnosis or exclusion.[85] The MRI scan also allows for surgical planning. Typically, a series of T_1-weighted images in which CSF is dark and fat is bright, a T_1-weighted image with gadolinium contrast, and a T_2-weighted image in which CSF is bright are obtained. The images are in 2 to 4 mm contiguous or overlapping slices. The various lesions within the CPA may be differentiated based on their varying imaging and enhancing characteristics. The MRI characteristics of a VS include a hypointense globular mass centered over the IAC on a T_1-weighted image with enhancement when gadolinium is added. Vestibular schwannomas are iso- to hypointense on T_2-weighted images[86] (see Figure 20–5). The two detractors to the many advantages of MRI, including lack of radiation exposure, are the time and cost of each scan. These two issues are being addressed by developing imaging sequences that focus on the CPA and do not use contrast administration. One example is a high-resolution fast spin echo T_2-weighted sequence.[87] This scanning strategy uses CSF as the contrast agent. Fast spin echo T_2-weighted scans can be done in 15 to 20 minutes and cost less compared with a standard MRI with intravenous contrast administration. The drawback is a slight loss in sensitivity owing to false-negative readings of very small tumors. The steady improvements in the quality and cost of MRIs have made MRI the preferred diagnostic modality for CPA tumors.

In situations for which MRI cannot be used or is not accessible, a CT scan with iodine contrast or an ABR offers a reasonable alternate screening modality. A CT scan with contrast provides consistent identification of CPA tumors over 1.5 cm or CPA tumors that at least have a 5 mm CPA component. Vestibular schwannomas appear as ovoid masses centered over the IAC with nonhomogenous enhancement. A CT scan with contrast can miss intracanalicular tumors unless there is bony expansion of the IAC.

MANAGEMENT. ***Surgery.*** The primary management for VSs is surgical removal. The roles of observation and radiotherapy are currently for patients who cannot tolerate a surgical procedure or have a life span of less than 5 years. The role of radiotherapy is expanding. The majority of patients will undergo surgical excision because the natural history of VSs is to grow and eventually cause significant compression of the structures surrounding the CPA, as described above. In addition, the ability to accomplish total tumor removal with the least morbidity is generally related to the size of the tumor, so significant surgical delay is not recommended.

Surgical approaches to the CPA include translabyrinthine, retrosigmoid, and middle fossa craniotomies (Figure 20–6, A). The appropriate approach for a particular patient is based on the hearing status, size of the tumor, extent of IAC involvement, and experience of the surgeon (Table 20–6). The approaches are either hearing preserving or ablating. The retrosigmoid and middle fossa approaches are hearing preserving. However, they have limitations of exposure to all aspects of the CPA and IAC. The middle fossa approach is well suited to patients with good hearing and a tumor less than 2 cm. The retrosigmoid approach is well suited to patients with good hearing and a tumor less than 4 cm and not involving the lateral part of the IAC. The lateral part of the IAC is usually only directly accessible via a retrosigmoid approach by removing the PSCC. The violation of the PSCC will lead to hearing loss. The translabyrinthine approach causes total hearing loss and so is appropriate for patients with poor hearing (pure-tone average > 30 dB) or patients with good hearing and tumors not accessible by the hearing-preserving approaches. The surgical technique for these procedures will be briefly described. Three critical issues inherent to all three techniques are the extent of exposure of the IAC and CPA, identification and preservation of the facial nerve, and extent of brain retraction. These operations use electrophysiologic monitoring of CN VII and an ABR in hearing-preserving approaches. The use of high-speed drills, craniotomies, and operating microscopes has brought VS removal into the modern age.[50,88]

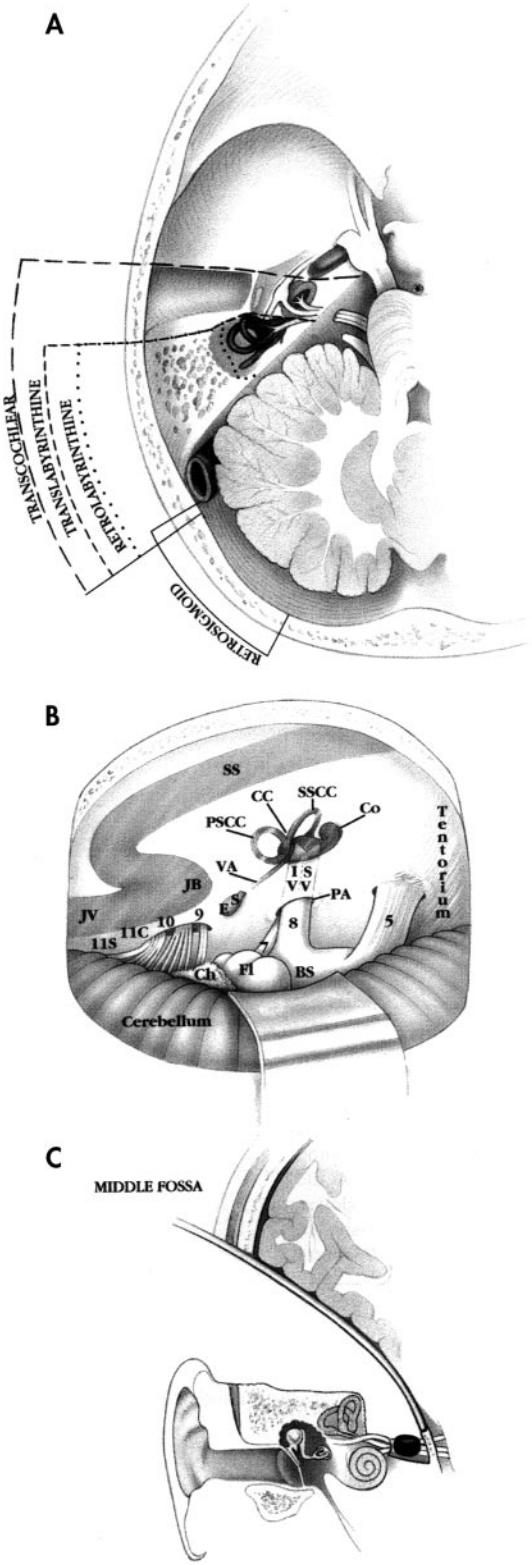

FIGURE 20–6. The surgical approaches to the cerebellopontine angle (CPA) include transcochlear, translabyrinthine, retrolabyrinthine, retrosigmoid, and middle fossa craniotomies. *A*, The axial view of the skull at the level of the internal auditory canal (IAC) and CPA shows the extent of resection needed for these four posterior fossa craniotomies. The main posterior fossa approaches to CPA lesions are the translabyrinthine and retrosigmoid craniotomies. The translabyrinthine approach requires a mastoidectomy, decompression of the sigmoid sinus, and vestibular labyrinthectomy and provides excellent access to the IAC and CPA. However, labyrinthectomy leads to complete hearing loss. *B*, The retrosigmoid craniotomy is positioned posterior to the sigmoid sinus and requires cerebellar retraction. The retrosigmoid approach is a versatile approach with a panoramic view of the CPA from the foramen magnum inferiorly to the tentorium superiorly. The medial two-thirds of the IAC are also accessible without violating the inner ear, therefore preserving hearing. SS = sigmoid sinus; JB = jugular bulb; JV = jugular vein; Co = cochlea; SSCC = superior semicircular canal; PSCC = posterior semicircular canal; CC = common crus; VA = vestibular aqueduct; ES = endolymphatic sac; SV = superior vestibular nerve; IV = inferior vestibular nerve; 5, 7 to 11 = cranial nerves V, VII to XI; S = spinal; C = cranial; BS = brainstem; Fl = flocculus; Ch = choroid plexus. *C*, The middle fossa approach provides access to the IAC by extradural elevation of the temporal lobe. This exposure allows removal of intracanalicular tumors while preserving hearing. An intracanalicular vestibular schwannoma is depicted in the diagram. Reproduced with permission from Jackler RK.[50]

TABLE 20–6. Surgical Approaches to the Cerebellopontine Angle and Their Indications

Hearing preserving
Retrosigmoid: good hearing and tumor not involving the lateral internal auditory canal
Middle fossa: good hearing and tumor less than 2 cm, internal auditory canal tumors
Hearing ablating
Translabyrinthine: poor hearing or larger tumors not accessible by other approaches

Translabyrinthine Approach. The primary approach for removal of VS is the translabyrinthine approach. The boundaries of the approach include the facial nerve and cochlear aqueduct anteriorly, middle fossa dura superiorly, posterior fossa dura posteriorly, and jugular foramen inferiorly (see Figure 20–6, A). These boundaries are approached via the familiar postauricular incision. A complete canal up mastoidectomy is accomplished, with identification of the incus, tegmen, sigmoid sinus, and facial nerve. A compete labyrinthectomy is then performed with medial skeletonization of the middle and posterior fossa dura and decompression of the sigmoid sinus to the jugular foramen. After bony skeletonization of the IAC, the dura of the IAC is opened and the facial nerve is identified medial to the vertical crest (Bill's bar). Once the facial nerve is identified in the fundus or lateral aspect of the IAC, tumor removal occurs from lateral to medial along the IAC. In large tumors, the tumor is debulked internally, and then the tumor capsule is removed from the surrounding structures including the facial nerve. After tumor removal, abdominal fat is placed into the defect.

The three advantages of the translabyrinthine approach are the ability to remove tumors of all sizes, minimal retraction of the brain, and the ability to visualize directly and preserve the facial nerve. The rate of facial nerve preservation is 97%. The rate of CSF leak presenting under the incision or draining through the nose via the eustachian tube is 5%. The majority of these CSF leaks resolve with conservative management, which includes mastoid dressing and fluid restriction.[89] There is a minimal risk of meningitis associated with a CSF leak.

Retrosigmoid Approach. The retrosigmoid approach is a modification of the traditional suboccipital approach used by neurosurgeons to address most posterior fossa lesions. The retrosigmoid approach is a versatile approach with a panoramic view of the CPA from the foramen magnum inferiorly to the tentorium superiorly (Figure 20–6, B). The medial two-thirds of the IAC are also accessible without violating the inner ear; therefore, hearing is preserved.

The surgical technique starts with a curvilinear skin incision 6 cm behind the ear over the retromastoid region. The soft tissue and posterior nuchal musculature are elevated to expose the mastoid and retromastoid bone. A 5 × 5 cm craniotomy is performed with the sigmoid sinus as the anterior boundary and the transverse sinus the superior boundary. Elevation of a bone plate is technically difficult, so the bone may be removed by drilling. The bone fragments are collected and will be replaced during closure. The bone fragments will reform a bone plate and prevent adherence of the musculature to the dura. If decompression of the sigmoid sinus is needed for exposure, a mastoidectomy may also be performed. The dura is then opened along the sigmoid sinus, and the cerebellum is seen. The CSF from the cisterna magnum should be released prior to retracting the cerebellum. Medial retraction of the cerebellum allows visualization of the CPA. To address the IAC component of the tumor, the posterior bone of the IAC should be removed. The bone dust created is carefully confined and removed to prevent meningeal irritation. The extent of IAC skeletonization is limited by the proximity to the inner ear. The endolymphatic duct and sac serve as landmarks to the proximity of the PSCC and allow preservation of the inner ear and hearing. The facial nerve is normally anterior to the tumor, or its position is ascertained with facial nerve monitor-

ing. The tumor removal is as previously described. After tumor removal and hemostasis, air cells along the IAC and mastoid are closed with bone wax or bone cement to eliminate paths for CSF leak. A fat or muscle graft may also be placed into the petrosal defect to prevent CSF leak. The dura mater is closed, and the bone plate or bone pate is replaced. The musculature and soft tissue are meticulously closed.[90]

The primary advantage of the retrosigmoid approach relative to the translabyrinthine approach is the ability to preserve hearing in properly selected tumors. If hearing preservation is not an issue, the retrosigmoid approach allows a versatile approach to the CPA and IAC. The relative disadvantages compared with the translabyrinthine approach include persistent postoperative headache, increased difficulty in resolving CSF leaks, need for cerebellar retraction, and inability to have direct access to the facial nerve. The combination of intradural drilling leading to meningeal irritation by bone dust and dissection of suboccipital musculature causes nearly 10% of patients to have a persistent, severe postoperative headache.[91] In the case of extensive pneumatization of the IAC and mastoid, the air cells may be difficult to seal completely, and the inability to address the aditus ad antrum or the eustachian tube causes CSF leaks to be persistent despite conservative treatment. The extent of cerebellar retraction is minimal in small tumors, but the amount of retraction increases with larger tumors. The surgical control of the facial nerve is adequate in the retrosigmoid approach, but the exposure of the facial nerve is superior in the translabyrinthine approach.

Middle Fossa Approach. The middle fossa approach provides a hearing-preserving approach to intracanalicular tumors with a less than 1 cm cisternal component. The surgical technique involves an inverted U-shaped incision centered over the ear. The temporal muscle is reflected inferiorly to expose the squamous portion of the temporal bone. A 5×5 cm temporal craniotomy is performed and is centered over the zygomatic root. Extradural elevation of the temporal lobe is accomplished to reveal the temporal bone. The greater superficial petrosal nerve leading to the geniculate ganglion reveals the anterior, lateral boundary of the IAC, and the arcuate eminence reveals the posterior boundary of the IAC (Figure 20–6, C). These landmarks may be difficult to identify, and the IAC dura may have to be identified medially by drilling toward the porus acousticus. Once the IAC is identified and well skeletonized medially, the bone removal continues laterally. However, the extent of IAC skeletonization laterally is limited by the basal turn of the cochlea anteriorly and superior semicircular canal posteriorly. The IAC dura is opened posteriorly to avoid injury to the facial nerve. The tumor is dissected free of the facial nerve and removed in a medial to lateral direction. Any air cells are sealed, and the dural defect is covered with a fat or muscle plug. The craniotomy bone flap is replaced, and the incision is closed.

The middle fossa approach is unique compared with the posterior fossa craniotomies (translabyrinthine, retrosigmoid) because the entire IAC is accessible without violating the inner ear. This exposure allows removal of intracanalicular tumors while preserving hearing. The limitations of the middle fossa approach include tumors with a greater than 1 cm cisternal component. In situations of hearing preservation, an extended middle fossa approach with further removal of bone around the IAC and elevation or division of the superior petrosal sinus and tentorium allows improved exposure into the CPA. The relative merits of the procedure with increased temporal lobe retraction and limited access to the posterior fossa in the event of bleeding relative to a retrosigmoid approach continue to be defined. The disadvantages of the middle fossa approach include temporal lobe retraction and possible poor surgical position of the facial nerve relative to the tumor. Temporal lobe retraction may cause transient speech and memory disturbances and auditory hallucinations. The facial nerve, especially if the tumor originates from the inferior vestibular nerve, will be between the surgeon and the tumor. The increased manipulation of the facial nerve during tumor removal increases the risk of transient facial paresis.

Operative Complications. The intraoperative complications for all three approaches include vascular injury, air embolism, parenchymal brain injury, and cranial nerve injury.[92] The AICA originates from the basilar artery and supplies the labyrinthine artery and the lower portion of the cerebellum and the vein of Labbé, which can be the only venous drainage of the temporal lobe, are vulnerable during VS surgery. In the event of an air

embolism via an open vein, the patient should be placed into a left lateral and Trendelenburg position to trap the air in the right ventricle and then the air can be aspirated via a central venous catheter. The cerebellum during a retrosigmoid craniotomy and the temporal lobe during a middle fossa craniotomy are at risk from retraction injury.

Postoperative Complications. Postoperative complications include hemorrhage, stroke, venous thromboembolism, syndrome of inappropriate antidiuretic hormone, CSF leak, and meningitis.[92] Postoperative hemorrhage will manifest as neurologic and cardiovascular deterioration and will require evacuation. Studies have shown that postoperative low-molecular-weight heparin in addition to compression stockings and intermittent pneumatic compression devices may reduce the risk of thromboembolism in high-risk patients (elderly, obese) without increasing the risk of an intracranial bleed.[93] The most common complication is a CSF leak, which occurs in 10 to 15% of patients either via the wound or via a pneumatic pathway to the eustachian tube. The majority of these leaks resolve with conservative care, which includes placing wound sutures at the leak site, replacing the mastoid dressing, decreasing intracranial pressure with acetazolamide, restricting fluid intake, and resting in bed. Some patients will also require a lumbar subarachnoid drain, and a very few patients will need surgical reexploration.[94] A related complication is meningitis. Meningitis occurs in 2 to 10% of patients and may be aseptic, bacterial, or lipoid owing to irritation from the fat graft. The distinction between aseptic and bacterial meningitis is necessary because the treatment for aseptic meningitis is a corticosteroid with taper and for bacterial meningitis is antibiotics.[95] Delayed meningitis should be considered bacterial and is likely to be caused by a CSF leak.

Prognosis and Rehabilitation. Patients are most concerned about deafness, imbalance, and facial nerve weakness. The most important factors for hearing preservation are tumor size and preoperative hearing level. Hearing preservation ranges from 20 to 70%. Patients with good contralateral hearing tolerate the unilateral loss or may be helped with a CROS (contralateral routing of signals) hearing aid, and patients with poor contralateral hearing may be rehabilitated with a cochlear implant if the cochlear nerve fibers are preserved. Almost half of patients will have vertigo or imbalance beyond the postoperative period, but these symptoms have a minimal impact on daily activities. The rapidity of vestibular compensation after unilateral vestibular loss is determined by the patient's efforts to exercise and challenge the vestibular system. Patients who continue to have dysequilibrium in the extended postoperative period should have vestibular rehabilitation therapy. Facial nerve function is also best predicted by tumor size. In smaller tumors, over 90% of patients will have House-Brackmann grade 1 or 2 function (grade 1 is normal and grade 6 is complete paralysis). If all sizes are considered, approximately 80% of patients will ultimately have grade 1 or 2 function.[96]

The rehabilitation of facial nerve injury is based on general principles of nerve injury, recovery, and rehabilitation. If the nerve is transected intraoperatively, the nerve should be repaired primarily if possible or with a greater auricular interposition graft. Postoperative function may be predicted in an anatomically intact nerve by the intraoperative stimulability of the nerve. If the nerve can be stimulated at less than 0.2 V, there is an over 85% chance of grade 1 or 2 function at 1 year.[97] The lack of facial function (grade 6) at 1 year and no reinnervation potentials on electromyography (EMG) should lead to a hypoglossal-facial transposition, interposition nerve graft, or a cross-facial graft. If facial rehabilitation has been delayed and there is electrical silence of the facial muscle on EMG, muscle transpositions with the temporalis or masseter muscle to the lip give improved tone and symmetry to the lower face. The upper face can be rehabilitated with a brow lift and gold weight for the eyelid. The eye must be protected with lubrication, ointment, and eye bubble if there is incomplete eye closure or lack of sensation to the cornea owing to trigeminal nerve involvement. Lack of eye care will lead to corneal injury and blindness.

In summary, all three approaches have mortality rates of less than 1% with an over 90% rate of tumor removal and facial nerve preservation.[92] The translabyrinthine approach has facial nerve preservation rates as high as 98%. The retrosigmoid approach allows 50% hearing preservation, and the middle fossa approach allows up to 70% hearing preservation.[98,99] The recurrence rate is less than 1.5%, and the majority of patients feel that they can return to full preoperative activities by 3 months.[100]

These three approaches allow the management of most CPA tumors. A small subset of patients will not be surgical candidates and will require observation or radiation therapy.

Observation. The predictable correlation between VS size and significant neurologic symptoms and the relative slow growth of VSs allow observation to be a management option for VSs. Patients may be observed if their life expectancy is shorter than the growth time required for the VS to cause significant neurologic symptoms. The growth pattern of the VS should be assessed in these patients with a second radiologic evaluation in 6 months and then yearly radiologic evaluations. Studies have shown that 15 to 24% of patients undergoing conservative management will require surgery or stereotactic radiation.[101,102] If the growth rate in the first year exceeds 2 to 3 mm per year, the patient will likely need treatment for the VS. The patient should understand the opportunity costs of conservative management, including having to treat a tumor that is larger and less amenable to hearing preservation procedures and/or stereotactic radiation.

Stereotactic Radiation. The goal of stereotactic radiation is to prevent further growth of the VS while preserving hearing and facial nerve function. This goal directly differs from the goal of complete tumor removal in microsurgical therapy. The mechanism of stereotactic radiation relies on delivering radiation to a specific intracranial target by using several precisely collimated beams of ionizing radiation. The beams take various pathways to the target tissue, creating a sharp dose gradient between the target tissue and the surrounding tissue. The ionizing radiation causes necrosis and vascular fibrosis, and the time course of effect is over 1 to 2 years. There is an expected transient swelling of the tumor for 1 to 2 years. The ionizing radiation is most commonly delivered using a 201-source cobalt 60 gamma-knife system. The standard linear accelerator can also be adapted to deliver stereotactic radiation. The practical aspects include that the patient wears a stereotactic head frame, computer-assisted radiation planning using a MRI, and a single treatment for delivery of the radiation.[103]

The success of stereotactic radiation to arrest tumor growth depends on the dose of radiation delivered. However, the rate of cranial neuropathies, including hearing loss, is decreased by lowering the radiation dose. The current trend has been to lower the marginal radiation dose, and long-term tumor control with these current dosing plans is under investigation.[104] Since VSs have a slow growth rate, these studies will require 5- to 10-year follow-ups to be confident about tumor control. Studies have shown control rates from 85 to over 95%. The hearing preservation rate decreases each year after radiation and stabilizes after 3 years at 50%. The rate of facial nerve dysfunction varies from 3 to 50% based on the radiation dose at the margin of the tumor and the length of the facial nerve in the radiation field. Approximately 20% of patients will have trigeminal neuropathy. The persistence and extent of these neuropathies with the lower dosing protocols continue to be studied. Hydrocephalus is also a complication of radiation.[105,106]

As the long-term effectiveness and sequelae of stereotactic radiation are further defined, the indications for radiation therapy will become further defined. Radiation therapy is useful in patients in whom arrest of tumor growth is acceptable. These patients have either short life expectancies or high surgical risk. Stereotactic radiation may improve hearing preservation in patients with 2 to 3 cm VSs compared to microsurgery. Radiation therapy in large tumors (> 3 cm) or tumors causing brain compression will exacerbate symptoms owing to initial tumor swelling.[107]

Nonvestibular Schwannomas. Vestibular schwannomas represent over 95% of all CPA schwannomas. In addition to CN VIII, schwannomas of CNs V, VII, IX, X, XI, and XII can involve the CPA.[108] Cerebellopontine angle schwannomas share clinical, pathologic, and imaging characteristics. The primary treatment, similar to that for VSs, is surgical resection. The surgical approach is based on the location of the schwannoma and the patient's hearing status. Resection of cranial nerve schwannomas may lead to significant CN dysfunction, so preoperative CN function and postoperative rehabilitation are important issues to consider.

Facial Nerve Schwannomas. Facial nerve schwannomas most commonly occur at the geniculate ganglion but can involve any portion of the facial nerve. Similar to VSs, facial nerve schwannomas present with hearing loss, tinnitus, and imbalance (CPA symptoms). Facial nerve symptoms, such as facial spasm or weakness, usually present with larger

tumors. Audiovestibular testing shows abnormality in acoustic reflex testing because of impairment of CN VII motor supply to the stapedius muscle. Facial nerve schwannomas are associated with reduction of electroneuronographic potentials on the ipsilateral side even when there is no clinically evident palsy. Imaging often does not allow differentiation between a VS and a facial nerve schwannoma. Distinguishing features on imaging of facial nerve schwannomas include expansion of the fallopian canal, extension from the geniculate ganglion into the middle fossa, and location of the schwannoma in the anterosuperior portion of the IAC (a position eccentric to the axis of the IAC).[108] These schwannomas may be observed until facial nerve function has deteriorated or a neurologic complication becomes imminent as resection usually requires division and grafting of the facial nerve. Mimetic function following interposition grafting is poor.[109] The best facial function attainable is a House-Brackmann grade 3.

Trigeminal Nerve Schwannomas. Trigeminal nerve schwannomas initially present with ipsilateral facial hypesthesia, paresthesias, neuralgia, and difficulties with chewing.[110] Trigeminal nerve schwannomas arise from the gasserian ganglion in the middle fossa and grow posteriorly to involve the CPA or arise from the root of the nerve and directly involve the anterior part of the CPA and Meckel's cave. These tumors frequently involve both the middle and posterior fossae, and a combined approach may be necessary for resection.

Lower Cranial Nerve Schwannomas. Schwannomas of CNs IX, X, and XI cause smooth enlargement of the jugular foramen and may grow superiorly into the CPA or inferiorly into the parapharyngeal space. Cranial nerve IX, X, and XI schwannomas produce symptoms based on their CN functions and so cause hypesthesia and weakness of the palate, vocal cord, and shoulder, respectively. Patients will present with dysphagia, hoarseness, and shoulder weakness. Cerebellopontine angle involvement will also lead to CPA symptoms. Schwannomas of CN XII cause hemiatrophy of the tongue and expansion of the hypoglossal canal. The treatment is surgical removal and rehabilitation of the patient's functional deficit.[111]

Meningiomas. Meningiomas are the second most common CPA tumors and account for 3 to 10% of tumors at this location.[112] Compared with schwannomas, meningiomas are a more heterogeneous group of tumors in regard to pathology, anatomic location, and treatment outcome. The majority of these tumors are benign and slow growing, and 1% will become symptomatic. Meningiomas differ in pathogenesis, anatomic location, and imaging characteristics from VSs but are nearly indistinguishable in terms of clinical presentation and audiovestibular testing. Meningiomas are primarily managed by surgical excision.

Pathogenesis. Meningiomas arise from arachnoid villi cap cells and are located along dura, venous sinuses, and neurovascular foramina. Meningiomas are most commonly sporadic but may occur in familial syndromes such as NF2, Werner's syndrome, and Gorlin's syndrome. More than one-third of patients with NF2 have meningiomas. Molecular studies have shown deletions in chromosome 22 in nearly 75% of meningiomas. Specifically, mutations in the NF2 gene, merlin, have been shown in 30 to 35% of meningiomas. Although the majority of meningiomas are benign, 5% are malignant. Chromosomal abnormalities in 1p, 6q, 9p, 10q, and 14q are seen in more aggressive or malignant meningiomas.[113]

Pathology. ***Gross.*** Meningiomas may be globular or flat (en plaque) and have a firm, gritty consistency with a thin capsule. They are densely adherent to the dura and may either cause reactive hyperostosis of the underlying bone or infiltrate the bone via haversian canals. Hyperostosis is seen in 25% of meningiomas.[114]

Microscopic. Meningiomas have an epithelial and mesenchymal differentiation. These tumor cells generally have a uniform distribution. Some meningiomas may demonstrate a papillary pattern interspersed in the uniform distribution. Calcification of the tips of these papillary whorls leads to the formation of calcospherite or psammoma bodies. The ratio of epithelial to mesenchymal differentiation and the presence of psammoma bodies are the basis for histologic classification of meningiomas. The four groups include meningotheliomatous (syncytial), transitional, fibrous, and angiomatous.[115] The syncytial type is the most common category. The syncytial type is usually benign and lacks papillary whorls or psammoma bodies. The transitional type has an increased amount of connective tissue and

psammoma bodies relative to the syncytial type. The transitional type lies histologically between the syncytial and fibrous types. The fibrous type has increased connective tissue, mesenchymal differentiation, and some psammoma bodies. The angiomatous types may actually be sarcomas rather than meningiomas and have a more aggressive growth pattern with bone invasion. The microscopic identification of a malignant meningioma includes increased mitotic figures, atypical mitosis, necrosis, lack of cellular uniformity, and brain invasion.[116]

SYMPTOMS AND SIGNS. From the onset of symptoms, meningiomas take an average of 5 years to be diagnosed. The typical patient is a woman in her fourth or fifth decade of life. Unlike VSs, there is a 2 to 1 female bias.[117] Meningiomas presenting in younger patients or multiple meningiomas in the same patient should prompt an evaluation for NF2. The most common complaints are the same as those attributable to VSs and include unilateral hearing loss (80%), vertigo or imbalance (75%), and tinnitus (60%). Symptoms and signs more common with meningiomas relative to VSs include trigeminal neuralgia (7 to 22%), facial paresis (11 to 36%), lower CN deficits (5 to 10%), and visual disturbances (8%).[112,117,118]

DIAGNOSTIC EVALUATION. ***Auditory-Vestibular Evaluation.*** The hearing loss has no characteristic audiometric pattern. The SDSs suggest a retrocochlear lesion in 50% of patients. The ABR may be normal in 25% of patients.[119]

Imaging. Imaging provides the diagnosis of meningioma and allows the differentiation between meningioma and VS[120] (Table 20–7). A CT scan without contrast shows an iso- or hyperdense mass with areas of calcification in 10 to 26% and provides information regarding hyperostosis or bony invasion. Meningiomas enhance homogeneously with CT contrast, and 90% of meningiomas can be detected by contrast-enhanced CT.[114] Magnetic resonance imaging is the study of choice for the diagnosis of meningiomas. Meningiomas are hypo- to isointense on T_1-weighted images and have a variable intensity on T_2-weighted images. Areas of calcification appear dark on both T_1-weighted and T_2-weighted images (Figure 20–7). Unlike VSs, meningiomas are broad based (sessile) and are usually not centered over the porus acusticus internus. The broad-based attachment to the petrous wall leads to an obtuse bone-tumor angle. There is no widening of the IAC. Also, unlike VSs, meningiomas more commonly herniate into the middle fossa. T_1-weighted enhanced images can show an enhancing dural tail (meningeal sign) adjacent to the bulk of the tumor in 50 to 70% of meningiomas.[121]

MANAGEMENT. The two primary management options are observation and surgery. Observation is indicated in patients with limited life expectancy or in whom the expected morbidity of surgical excision is not justified. Surgical treatment ideally consists of total meningioma removal, excision of a cuff of surrounding dura, and drilling of the underlying bone. The surgical approach is based on the tumor location and the patient's hearing status. In contrast to VSs, the anatomic location of posterior fossa meningiomas is varied (Figure 20–8). The site of the meningioma is a major determinant of the types of morbidity from the tumor and the success of treatment. A simple classification differentiates whether the tumor is present medial or lateral to the IAC. Meningiomas medial to the IAC are more common. These meningiomas commonly arise along the inferior petrosal sinus and may involve the petrous apex, lateral part of the clivus, and Meckel's cave. Meningiomas lateral to the IAC involve the sigmoid sinus, jugular bulb, and superior petrosal sinus. In an uncommon pattern, meningiomas may be centered on the IAC and closely mimic a VS. Internal auditory canal meningiomas may invade the inner or middle ear. Meningiomas may also be superior to the IAC and be considered midpetrosal meningiomas.[112]

Meningiomas lateral to the IAC are reached via a retrosigmoid approach. The facial nerve in lateral meningiomas is most often displaced anteriorly and so does not lie between the surgeon and the tumor. Therefore, the facial nerve is less traumatized during tumor removal. The retrosigmoid approach also allows hearing preservation. Limited intracanalicular meningiomas may be managed by the middle fossa approach, especially if hearing preservation is possible. Meningiomas involving the IAC and having poor hearing are reached via the translabyrinthine approach. If the tumor invades the cochlea and has anteromedial extension to the clivus or Meckel's cave, a transcochlear approach should be considered[122] (see Figure 20–6, A). The transcochlear approach sacrifices hearing and requires rerouting

TABLE 20–7. Radiologic Differentation of Meningioma versus Vestibular Schwannoma

	Meningioma	*Vestibular Schwannoma*
Shape	Sessile	Globular
Internal auditory canal	Eccentric, extrinsic, and not eroded	Centered, penetrates, and eroded
Calcification	Present	Absent
Hyperostosis	Present	Absent
Tumor-bone angle	Obtuse	Acute
Meningeal sign	Present	Absent

of the facial nerve. Sixty percent of CPA meningiomas involve the middle fossa and may require a combined middle and posterior fossa craniotomy. The type of posterior fossa craniotomy in the combined approach will depend on the need for hearing preservation and the extent of surgical exposure required.

Total tumor removal is accomplished in 70 to 85% of patients with meningiomas. Incomplete tumor removal is often associated with adherence of the meningioma to the brainstem or cavernous sinus involvement.[123] The long-term recurrence after total tumor removal is between 10 and 30%, whereas that of subtotal removal is over 50%.[124] Hearing preservation is more likely than in VSs and approaches 70%. The facial nerve function has a 17% rate of deterioration from preoperative levels.[125] The other complications include gait disturbance and CSF leak (8%). The operative mortality is between 1 and 9%.[126]

Adjunctive therapies include external beam and stereotactic radiation therapy. Radiation therapy should be considered in cases of inoperable tumors, subtotal resection, recurrent tumors, and malignant tumors. Retrospective reviews of patients in whom subtotal tumor removals were carried out have shown that external beam radiation reduces recurrence rates.[127] The role of stereotactic radiation therapy in meningiomas continues to be defined.

EPIDERMOIDS. Epidermoids are much less common than VSs or meningiomas. They account for approximately 5% of CPA lesions. Epidermoids are slow growing and often grow to a large size before causing CPA symptoms because they initially grow around structures via paths of least resistance rather than cause compression. Epidermoids are treated by surgical excision, but total removal is more difficult than with VSs because epidermoids become adherent to normal structures.[128]

PATHOGENESIS. Epidermoids likely develop from ectodermal inclusions that become trapped during embryogenesis. These ectodermal inclusions lead to a keratinizing squamous cell epithelium in the CPA. The squamous cell epithelium produces a cyst filled with sloughed keratinaceous debris.[129]

PATHOLOGY. The gross appearance is that of a nodular cyst. The cyst is lined with squamous cell epithelium, and the cyst is filled with lamella of desquamated keratinaceous debris. The majority of epidermoids are benign, but there are a few reports of squamous cell carcinoma arising in epidermoids.[130]

SYMPTOMS AND SIGNS. The presentation is similar to other CPA lesions, with hearing loss being the most common symptom. Epidermoids have a higher rate of preoperative facial (40%) and trigeminal (50%) nerve involvement relative to VSs. Patients may present with hemifacial spasm, facial hypesthesia, neuralgia, or wasting of the muscles of mastication.[131]

DIAGNOSTIC EVALUATION. ***Auditory-Vestibular Evaluation.*** Auditory-vestibular testing does not provide any distinguishing patterns for epidermoids.

Imaging. On CT, epidermoids are hypodense compared to brain. A distinguishing characteristic relative to VSs and meningiomas is that epidermoids show no enhancement with intravenous contrast.

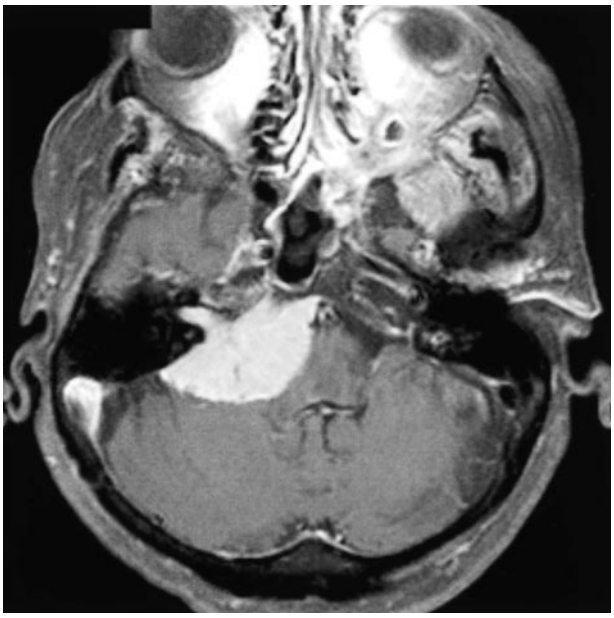

FIGURE 20–7. Axial T_1-weighted magnetic resonance image with gadolinium enhancement demonstrating a cerebellopontine angle meningioma. Unlike vestibular schwannomas, meningiomas are broad based (sessile), have a dural tail, and are eccentric to the internal auditory canal. The broad-based attachment to the petrous wall leads to an obtuse bone-tumor angle. (Courtesy of Nancy J. Fischbein.)

Epidermoids have irregular borders, are not centered on the IAC, and do not usually widen the IAC (Figure 20–9). Epidermoids have characteristics similar to CSF on MRI (hypointense on T_1-weighted images and hyperintense on T_2-weighted images) and again do not enhance with gadolinium contrast.[132]

MANAGEMENT. The primary treatment of epidermoids is surgical. The approaches include retrosigmoid in hearing preservation and translabyrinthine in patients with significant hearing loss. Any extension into the middle fossa can usually be removed via the posterior fossa craniotomy. The ability to remove the tumor completely is limited by the propensity of epidermoids to adhere to neurovascular structures. Attempts at complete tumor removal may increase the rate of postoperative transient or permanent CN palsies. Total tumor removal is accomplished in less than 50% of patients, and the recurrence rate may be as high as 50%. Nevertheless, the majority of patients have excellent or good postoperative function.[133]

Congenital Rest Lesions Congenital rest lesions involving the CPA include epidermoids, arachnoid cysts, and lipomas. These lesions occur owing to errors in embryogenesis. These errors allow vestigial structures to remain and grow during adult life. These lesions are not aggressive but rather are slow growing and have a tendency to envelop the neurovascular structures in the CPA. The presenting symptoms are very similar if not indistinguishable from those of VSs, and only imaging allows their differentiation. The imaging characteristics on CT scan are very similar and include a well-encapsulated, hypodense mass that does not enhance with contrast. Magnetic resonance imaging allows differentiation based on the signal characteristics of desquamated epithelium, CSF, or fat. The treatment is surgical, but total removal is more difficult than in VSs and is not always necessary.[61]

ARACHNOID CYSTS. Arachnoid cysts are CSF-filled cysts surrounded by an epithelial lining. This epithelial lining originates from a duplication of the arachnoid membrane and has secretory capabilities. The rate of growth is unpredictable, and patients may present with arachnoid cysts in the CPA or IAC at any age. The key imaging point is that these cysts match the signal intensity of CSF on every MRI sequence and do not enhance with gadolinium. The treatment involves diuretics, shunting procedures, and marsupialization of the cyst into the subarachnoid space.[134]

LIPOMAS. Lipomas are rare lesions of the CPA and IAC. They are caused by congenital malformations that lead to proliferation of adipocytes in subarachnoid cisterns or ventricles. Magnetic resonance imaging parallels the intensities of fat, so lipomas are hyperintense on T_1-weighted images, show no enhancement with gadolinium, are hypointense on T_2-weighted images, and become hypointense on T_1-weighted images with fat suppression. The neurovascular structures of the CPA travel through the lipoma. Therefore, the surgical treatment of these lesions, if they become symptomatic, is conservative debulking.[135]

Vascular Lesions A variety of vascular lesions may involve the CPA directly or via extension. These include paragangliomas (glomus jugulare tumors), hemangiomas, and aneurysms.

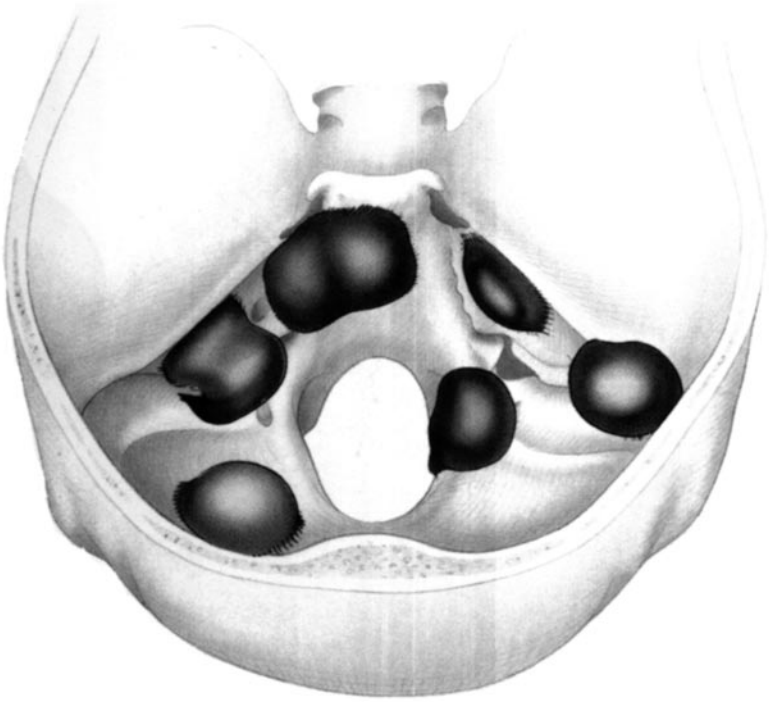

FIGURE 20–8. Meningiomas arise from arachnoid villi cap cells and are located along dural edges, venous sinuses, and neurovascular foramina. The site of the meningioma is a major determinant of types of morbidity from the tumor and the success of treatment. A simple classification differentiates whether the tumor is present medial or lateral to the internal auditory canal (IAC). Meningiomas medial to the IAC commonly arise along the inferior petrosal sinus and may involve the petrous apex, lateral part of the clivus, and Meckel's cave. Meningiomas lateral to the IAC involve the sigmoid sinus, jugular bulb, and superior petrosal sinus. In an uncommon pattern, meningiomas may be centered on the IAC or superior to the IAC and considered a midpetrosal meningioma. Reproduced with permission from Jackler RK.[50]

Paragangliomas (Glomus Jugulare Tumors) Glomus jugulare tumors arise from paraganglionic tissues (chief cells) and have intracranial extension in 15% of patients. These tumors are slow growing and present initially with pulsatile tinnitus and conductive hearing loss. Further growth at the jugular foramen causes lower cranial neuropathies, and then intracranial extension into the posterior fossa may lead to sensorineural hearing loss and dizziness.[136] Paragangliomas have a variable appearance on CT scans, but bone algorithms show the extent of temporal bone involvement. Paragangliomas cause irregular expansion of the jugular foramen, whereas lower CN schwannomas cause smooth enlargement of the jugular foramen. Paragangliomas have a salt and pepper appearance on T_2-weighted MRI and have pronounced enhancement with gadolinium. Magnetic resonance imaging also shows the extent of intracranial involvement and the presence of flow voids.[137] Magnetic resonance angiography (MRA) and traditional angiography provide information on involvement of the great vessels and allow preoperative embolization of larger tumors. The treatment requires surgical excision. Jugular bulb involvement may be addressed by a transmastoid neck approach. Extension to the carotid artery or intracranial extension will require an infratemporal fossa approach.[138]

Hemangiomas. Hemangiomas of the temporal bone often involve the geniculate ganglion and the internal auditory meatus. Hemangiomas are benign, slow-growing vascular hamartomas. Hemangiomas involving the geniculate ganglion cause progressive facial paresis. Patients also complain of facial twitches, tinnitus, and facial pain. Hearing loss, if present, is conductive owing to middle ear involvement. Facial paresis occurs sooner with hemangiomas than with facial nerve schwannomas.

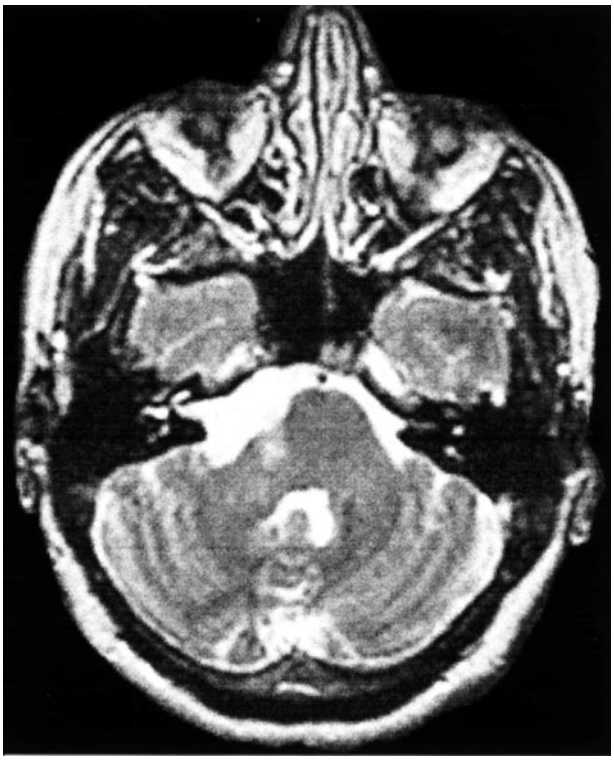

FIGURE 20–9. Axial T_2-weighted magnetic resonance image (MRI) of an epidermoid involving the clivus, petrous bone, internal auditory canal (IAC), and cerebellopontine angle. Epidermoids have irregular borders, are not centered on the IAC, and do not usually widen the IAC. Epidermoids have imaging characteristics similar to cerebrospinal fluid on MRI (hypointense on T_1-weighted images and hyperintense on T_2-weighted images) and, in contrast to vestibular schwannomas and meningiomas, do not enhance with gadolinium contrast. (Courtesy of Nancy J. Fischbein.)

Computed tomographic imaging shows a small, soft tissue mass at the geniculate ganglion with surrounding smooth or irregular enlargement of the fallopian canal. The small size of the soft tissue mass, irregular bony erosion, and presence of calcium in the tumor are all suggestive of geniculate ganglion hemangioma versus facial nerve schwannoma. Magnetic resonance imaging shows isointense T_1-weighted images, intense enhancement, and hyperintense T_2-weighted images.[139] Hemangiomas in the IAC present similarly to VSs, and a preoperative differentiation may be very difficult. The treatment involves surgical removal when there is significant facial nerve dysfunction. Because hearing is often intact, the middle fossa approach provides good surgical exposure and allows hearing preservation. The chance of an intact facial nerve after removal of a hemangioma is higher than a facial nerve schwannoma. Nevertheless, facial nerve anastomosis or grafting is often required.[140]

Aneurysms. Aneurysms and vascular anomalies of posterior circulation (AICA, posterior inferior cerebellar artery, carotid artery, vertebral artery, basilar artery) are rare but produce CPA symptoms by causing compression of neurovascular structures. Aneurysms are seen as enhancing lesions on CT scan. In addition to MRI, MRA and angiography allow characterization of these vascular lesions.[141]

Intra-axial Tumors Intra-axial tumors of the brainstem (glioma), cerebellum (medulloblastoma, astrocytoma, hemangioblastoma), and fourth ventricle (ependymoma, choroid plexus papilloma) may extend into the CPA and present with CPA symptoms.[142] The CPA extension occurs owing to exophytic growth and growth into the CPA via the foramina of Luschka and rarely owing to extra-axial origin directly in the CPA from an embryonic rest. These intra-axial tumors involving the CPA must be differentiated from extra-axial CPA masses to counsel and treat the patient appropriately. The differentiation is based primarily on imaging characteristics. Imaging characteristics suggestive of an extra-axial tumor include bony changes, widening of the subarachnoid cistern, displacement of brain and blood vessels away from the skull or dura, and sharp definition of the tumor margin. Characteristics suggestive of intra-axial tumors include an irregular and poorly defined brain-tumor margin, widening of a foramen of Luschka, brain edema out of proportion to the CPA component of the tumor, and hydrocephalus.[143] The management of intra-axial lesions includes angiography, conservative surgical resection, and adjunctive therapy.

Lesions Extending from the Skull Base Lesions involving the skull base, specifically the petrous apex (cholesterol granulomas), clivus (chordomas), and petro-occipital fissure (chondrosarcomas), may grow posteriorly and laterally to involve the CPA. Each of these lesions has characteristic presentations and imaging criteria but at times may present solely

with CPA symptoms. The treatment is primarily surgical.

Cholesterol Granulomas. The petrous apex of the temporal bone lies anterior and medial to the inner ear and posterior and lateral to the clivus and contains pneumatized air cells in one-third of temporal bones. Obstruction of these air cells leads to inflammation and hemorrhage into the air cells. The phagocytosis of red cells leads to deposition of cholesterol crystals and a foreign body reaction in the petrous apex. This process leads to a cholesterol granuloma that may extend beyond the petrous apex to involve the CPA. Patients may have CPA symptoms in addition to symptoms of headache and sixth nerve dysfunction. The key differential diagnosis in the petrous apex and CPA of a cholesterol granuloma is an epidermoid. The distinguishing factor is that cholesterol granulomas are hyperintense on T_1-weighted and T_2-weighted images, whereas epidermoids are hypointense on T_1-weighted images. The treatment is surgical drainage rather than complete excision when symptomatic. The petrous apex may be accessed via a transmastoid or transcanal approach.[144,145]

Chordomas. Chordomas arise from remnants of the notochord, and skull base chordomas occur at the clivus (spheno-occipital synchondrosis). Patients usually present with headache and diplopia, but posterolateral extension to the CPA may lead to CPA symptoms. Computed tomographic scans show an isodense mass with bone destruction, intratumor calcifications, and marked enhancement with contrast. Magnetic resonance imaging shows hypointense T_1-weighted images, marked gadolinium enhancement, and hyperintense T_2-weighted images. The midline location and bony destruction without sclerosis are characteristic of chordomas. The treatment is complete surgical excision and radiation for subtotal removal or recurrence.[146]

Chondrosarcomas. The main differential diagnosis of chordomas is chondrosarcomas.[146] These tumors arise along the spheno-occipital synchondrosis and are laterally located relative to chordomas. Chondrosarcomas may arise from embryonal cartilage rests located at the skull base synchondrosis. Tumor growth laterally will cause involvement of the IAC and CPA. Hearing loss may very well be the presenting complaint. The differential from chordoma may require immunohistochemistry stains since chondrosarcomas, unlike chordomas, do not stain positively with epithelial tissue markers.[147]

Metastases Metastatic disease from lung, breast, skin (melanoma), prostate, nasopharynx, lymphoma, and kidney are the most common extra-axial malignant neoplasms of the CPA.[148] In contrast to benign lesions of the CPA, malignant lesions of the CPA cause rapid progression of CPA symptoms. On imaging, the lesions are small and isointense to brain on T_1-weighted and T_2-weighted MRI and enhance with gadolinium. There is a high likelihood of parenchymal brain metastases and bilateral CPA lesions. The extent of treatment is based on the extent of the metastatic and primary disease and includes multimodality treatment with surgical biopsy or resection, radiation, and chemotherapy. The other aspect of treatment includes relieving symptoms of hydrocephalus or brainstem compression. The primary extra-axial malignancies of the CPA are exceedingly rare and include lymphomas, squamous cell carcinomas, malignant VSs, and malignant meningiomas.[61]

CHAPTER 21

Presbyacusis

John H. Mills, PhD, Paul R. Lambert, MD

Presbyacusis is defined generally as the hearing loss associated with increasing chronologic age. It is a common problem today and will become even more significant in the future. Currently, according to the National Center for Health Statistics, some 20 million Americans have impaired hearing, and approximately 75% of these people are over age 55. In the 25-year period between 1976 and 2000, the number of persons below age 75 increased by 23%, the number between age 75 and 84 increased by 57%, and the number over age 84 increased by 91%. Indeed, by the year 2030, the elderly will comprise 32% of the population, an increase of 250%. As many as 60 to 75% of these older persons will have clinically significant hearing loss. Because of the increasing number of older Americans, high-prevalence problems such as age-related hearing loss and other chronic disabling conditions (balance, vision, arthritis) will place extensive and novel demands on the health care system.

BACKGROUND

The medical-scientific history of presbyacusis is relatively recent and rich. Although Toynbee in 1849 was perhaps the first to write about age-related hearing loss and to prescribe a treatment (application of solutions of silver nitrate or mercurous chloride to the external auditory canal),[1] Zwaardemaker in 1891 is credited with the first accurate description of presbyacusis.[2] With the clever use of Dalton whistles, Zwaardemaker demonstrated that older persons had far more difficulty detecting high-pitched sounds than younger persons. By the use of bone-conduction testing, he correctly considered age-related hearing loss to be of cochlear origin. Since the 1930s, anatomic and histopathologic changes have been observed at nearly every location in the aging auditory system from the external ear with collapsing ear canals to neural degeneration extending from the auditory nerve to the auditory brainstem and temporal lobe. Before reviewing the pertinent literature on presbyacusis, it is necessary to review terminology.

TERMINOLOGY

There are several definitions of the term presbyacusis. Indeed, even the spelling is an issue, that is, presbyacusis versus presbycusis. Here we use "presbycusis." It is used loosely to describe a seemingly endless list of genetic, environmental, and disease states that can cause hearing loss in an older person. Often presbyacusis is used to refer to hearing loss purely caused by the natural process of aging. More often, hearing loss is called presbyacusis if the person is beyond the fifth decade, without consideration of disease, genetics, or other factors. In many studies, older persons are considered homogeneous and are grouped regardless of hearing levels or are grouped if their hearing loss exceeds an arbitrary criterion.

Some of the confusion associated with the use of the term can be eliminated or reduced by the appropriate use of the terms presbyacusis, socioacusis, and nosoacusis.[3] A generic definition of presbyacusic is age-related hearing loss (or threshold shift) that is the effect of aging in combination with lifelong exposures to nonoccupational noise, ototoxic agents, diet, drugs, and other miscellaneous factors. A more restrictive, precise definition of presbyacusis is hearing loss that increases as a function of chronologic age and is attributable to "aging" per se. This "purely aging" hearing loss probably has a genetic basis. It may be correlated with age-related deterioration or declines in other senses, especially balance, vision, and touch.

Socioacusis is defined as the hearing loss produced primarily by exposure to nonoccupational noise in combination with lifestyle factors such as

diet and exercise. Nosoacusis is the hearing loss attributable to diseases with ototoxic effects. Thus, the hearing loss assessed in a person into the fifth decade and beyond is the combined result of aging, nosoacusis, socioacusis, and possibly, for many persons, exposure to occupational noise. It is important for medical and legal reasons to differentiate presbyacusis from socioacusis, nosoacusis, and occupational hearing loss.

ADDITIVITY OF PRESBYACUSIS, SOCIOACUSIS, AND NOSOACUSIS

Most laboratory (with animals) and field studies indicate that hearing losses caused by exposure to noise are additive (in decibels) with the hearing loss attributed to presbyacusis (in the strict sense of the word).[4] A small sensorineural hearing loss (SNHL) of 25 dB at age 25, for example, seemingly has little social or medical relevance; however, by age 70, a hearing loss of 25 dB caused almost totally by the aging process is added to the existing SNHL. The result is a moderate-to-severe SNHL of 50 dB. In other words, a seemingly minor hearing loss at a young age becomes a severe loss when the effects of presbyacusis become evident.

Rules for combining hearing losses attributable to presbyacusis, nosoacusis, and socioacusis are not always straightforward. In the medicolegal assessment of hearing loss, it is assumed that presbyacusic effects (aging plus socioacusis plus nosoacusis) add in decibels to the hearing loss produced by noise. As stated above, this approach is supported by some laboratory and field data for groups of subjects under a limited set of exposure conditions; however, for individual subjects and for complicated noise exposures, the procedures for allocation of hearing loss into different components are controversial.[4]

EPIDEMIOLOGY

Over the past 25 years or so, there has been a significant epidemiologic effort to describe hearing levels as a function of chronologic age. Two sets of data have survived extensive scrutiny and are now part of an international standard, International Standards Organization (ISO) 1999, "Acoustics: Determination of Occupational Noise Exposure and Estimation of Noise-Induced Hearing Impairment." Figure 21–1, A, shows age-related permanent threshold shifts at audiometric frequencies for males and females. These data are referred to as Data Base A in the ISO 1999 standard and are considered to represent highly screened subjects. That is, the data in Figure 21–1, A, represent "pure aging" effects as well as socioacusis. Most of the hearing loss attributable to occupational hearing loss has been eliminated, although a small nosoacusic effect may be present. Figure 21–1, B, gives epidemiologic data, referred to as Data Base B in the ISO 1999 standard, which are considered to reflect "pure aging" effects, socioacusis, some nosoacusis, and some effects attributable to occupational hearing loss. As shown in Figure 21–1, hearing loss in the higher frequencies is measurable by age 30; it increases systematically to age 60 (and beyond), is largest at 4 and 6 kHz, and is much larger in males than in females. There are also significant differences between Figure 21–1, A (Data Base A), and Figure 21–1, B (Data Base B), presumably owing to differences in subject selection. Small effects caused by occupational noise and nosoacusis were eliminated in Data Base A. Significant debate exists currently about the appropriateness and validity of Data Base A and B, particularly in a medicolegal context involving the assessment of occupational noise-induced hearing loss.

Data from Figure 21–1, A and B, have been replotted in Figure 21–2 to show the average hearing loss at 0.5, 1, 2, and 3 kHz as a function of chronologic age. The mean hearing loss at these particular audiometric test frequencies is especially meaningful because this combination of test frequencies comprises those used in the computation of hearing handicap as recommended by the American Academy of Otolaryngology-Head and Neck Surgery (AAO). As Figure 21–2 shows, hearing loss increases systematically from age 20 through age 75. There are at least two remarkable features to Figure 21–2. One is that the largest difference between the worst case (males, Data Base B) and best case (females, Data Base A) is about 5 dB. One could suggest, perhaps strongly, that much of the debate about Data Base A and B is "much ado about nothing," that is, 5 dB. This line of thinking is supported by the fact that, even at age 75, the hearing loss is only about 20 dB. According to the AAO 1979 definitions of hearing handicap, the average hearing loss at 0.5, 1, 2, and 3 kHz must exceed 25 dB to be considered a hearing handicap. In other words, according to the data of

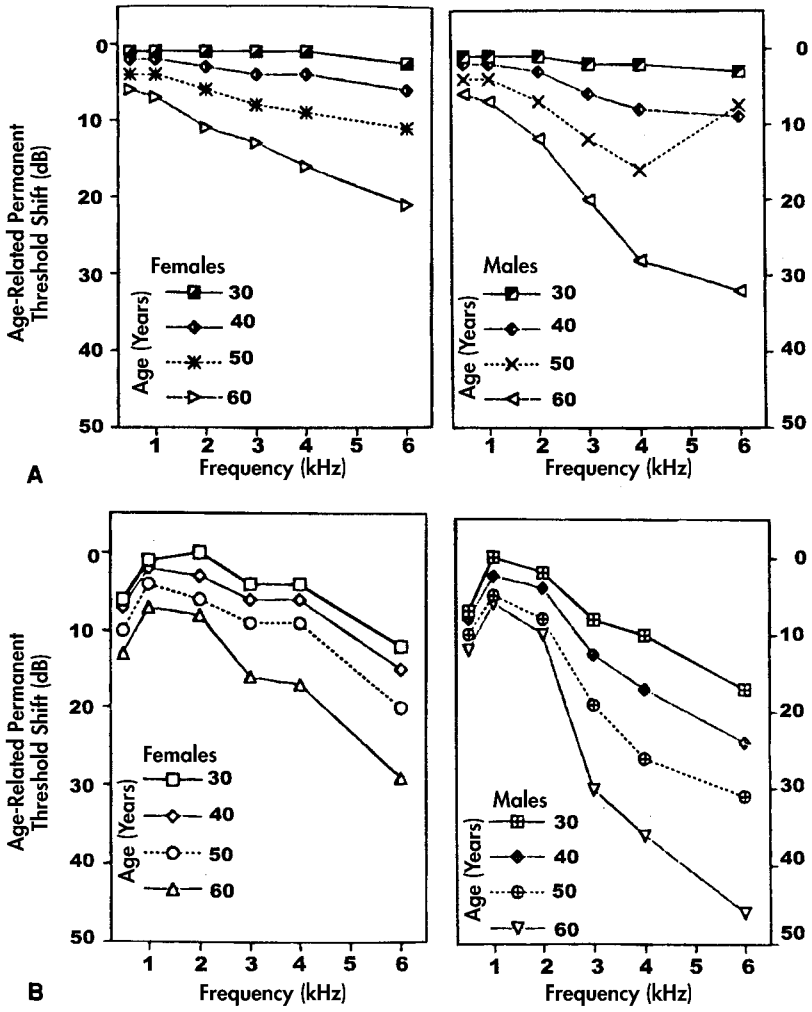

FIGURE 21–1. Epidemiologic data showing hearing levels and chronologic age from an international standard, ISO 1999. The top panel, *A*, is referred to as Data Base A and represents a sample that was highly screened to eliminate the potential influence of the effects of noise. The bottom panel, *B*, is also from ISO 1999 and is referred to as Data Base B. This sample is less well screened than *A* and may contain data from persons with a history of exposure to noise.

Figure 21–2 and the AAO 1979 definition of hearing handicap, substantially less than 50% of the population, male or female, have a hearing handicap even at age 75.

Other less selective epidemiologic data suggest that the prevalence of hearing handicap among older persons is substantially higher than that indicated by the epidemiologic data used in the ISO 1999 standard. Using 1,662 subjects from the famous Framingham study of cardiovascular disease, Gates et al reported that 55% met or exceeded the AAO 1979 medicolegal definition of hearing handicap.[5] The difference between the results of Gates et al and those of ISO 1999 reflect sampling differences and the inclusion of subjects older than age 75 in the Gates et al sample.

In addition to an audiologic assessment, hearing handicap can be assessed more subjectively using questionnaires such as the Hearing Handicap Inventory for the Elderly.[6] The correspondence between objective, audiologic measures of hearing handicap and subjective measures from self-reports and questionnaires suggests that the AAO measure of handicap tends to overestimate handicap for older persons with mild-to-moderate hearing losses and to underestimate handicap for older persons with severe hearing losses. Of course, there are many reasons for discrepancies between subjective and audiologic estimates of hearing handicap. One general rule emerges from questionnaires and epidemiologic studies of hearing handicap in older persons, namely, that the pure-tone average (PTA) of 0.5, 1, 2, and 3 kHz must exceed about 30 dB before most older persons consider themselves to have a hearing problem. Thus, there are indeed millions of older hearing-handicapped persons in the United States.

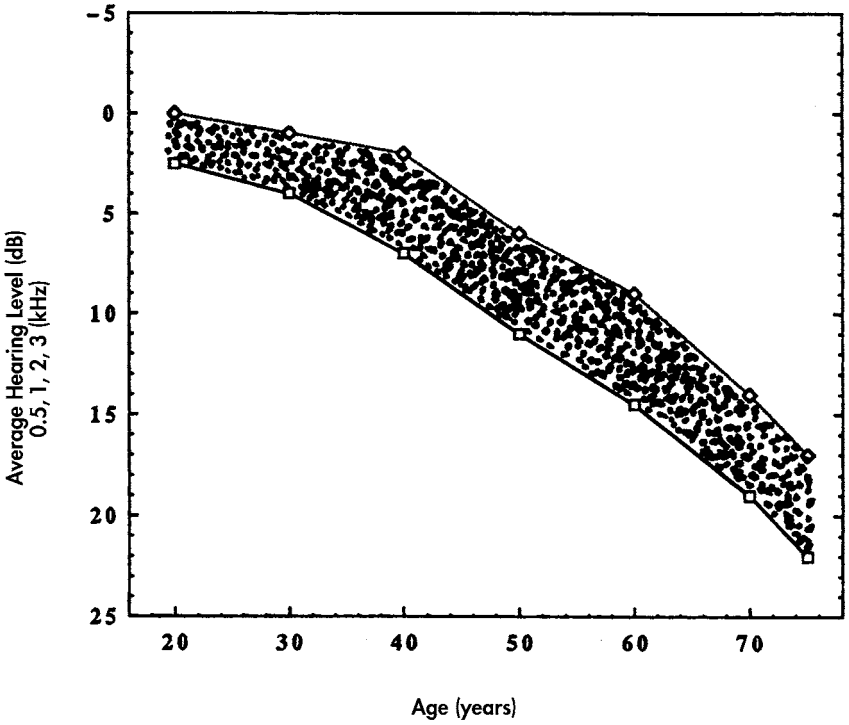

FIGURE 21–2. Data from Figure 21–1 have been replotted to show the average hearing level at 0.5, 1, 2, and 3 kHz as a function of age. The *shaded area* represents the difference between the best case, that is, the women of Data Base A, and the worst case, that is, the men of Data Base B.

Although much of the discussion has centered on the audiometric frequencies from 0.5 to 3 kHz, one of the more dramatic features of age-related hearing loss is the decline of auditory sensitivity at higher frequencies.[7,8] Figure 21–3, A, shows increasing hearing loss from age 20 to 29 to age 50 to 59 for test frequencies at and above 8 kHz. By age 50 to 59, the hearing loss at 16 kHz is greater than 60 dB. Figure 21–3, B, shows longitudinal threshold changes (the same group of observers) over the age range of 70 to 81 years, including thresholds for test frequencies up to 8 kHz. Hearing levels at 4 and 8 kHz exceed 50 dB by age 70 and at 8 kHz exceed 70 dB by age 79. Hearing loss at frequencies above 8 kHz is even more pronounced and is not predictable by hearing levels in the 1 to 4 kHz range.[9] Clearly, there is a dramatic age-related decline in auditory sensitivity at high frequencies. It appears that hearing loss starts in the second decade (or earlier) in the frequency range between 16 and 20 kHz, proceeds systematically in magnitude in the 16 kHz region, and spreads systematically downward in the frequency domain. By the eighth decade, the hearing loss is moderate to severe, even at 1 and 2 kHz.

The interpretation of epidemiologic data that show a loss of high-frequency sensitivity at 16 to 20 kHz, when 10 and 19 year olds are compared with 20 to 29 year olds, is not straightforward. One point of view is that these age-related changes in hearing thresholds, as well as systematic declines in the number of outer hair cells starting at birth and continuing throughout the lifetime of the individual,[10] are genetically determined, age-dependent events. That is, these age-related events are totally endogenous in origin. They are independent of exogenous factors such as diet, exposure to environmental noise (socioacusis), and disease (nosoacusis). As part of the Framingham heart study, Gates and colleagues have estimated the role of genetics in age-related hearing loss.[11] Their heritability estimates suggest that as much as 55% of the variance associated with age-related hearing loss is attributable to the effect of genes. These heritability estimates of age-related hearing loss are similar in magnitude to those reported for hypertension and hyperlipidemia, are much stronger in women than in men, and can be used to support the point of view that age-related changes in the ear and hearing reflect the combined effect of genetics, socioacusis, and nosoacusis. In some views of presbyacusis, socioacusis is given a major role, almost surely because of the famous Mabaan study.[12]

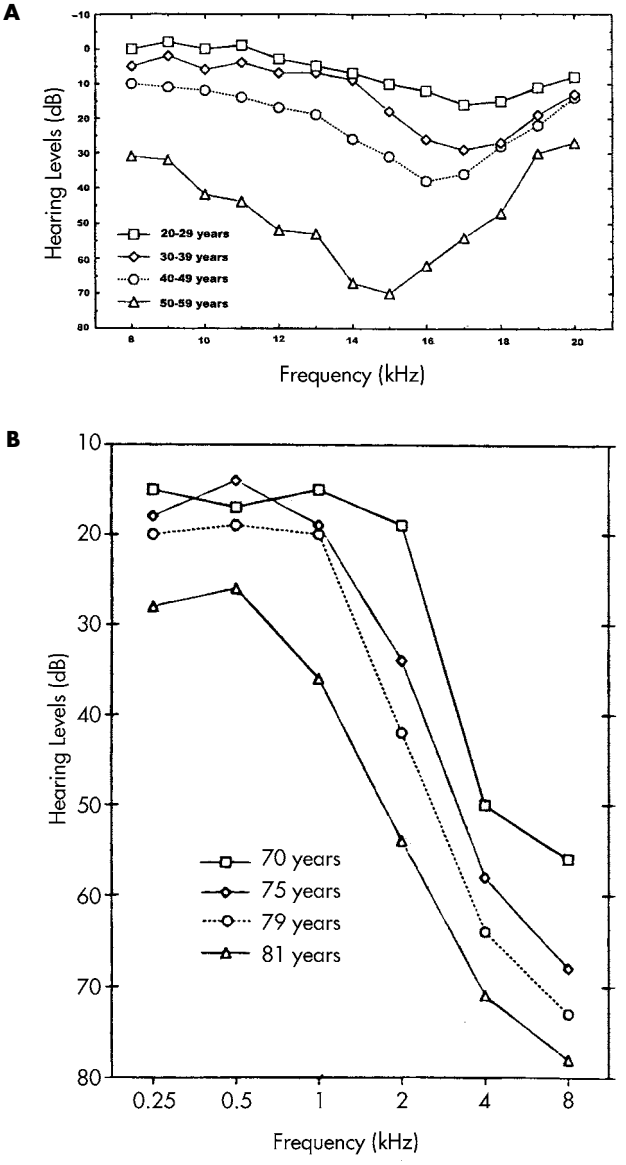

FIGURE 21–3. Hearing loss at high frequencies. *A*, Hearing levels above 8 kHz over the age range 20 to 59 years. *B*, Hearing levels from 0.25 to 8 kHz covering the age range 70 to 81 years, measured longitudinally. Adapted from Stelmachowicz PG et al[7] and Moller MB.[8]

A hearing survey of Mabaans, a tribe located in a remote and undeveloped part of Africa, showed exceptionally good auditory sensitivity for males and females in their sixth to ninth decades. In addition to the lack of exposure to occupational noise, no exposure to firearms, and exposure only to low levels of environmental noise, the Mabaans were reported to lead a low-stress lifestyle, have a low-fat diet, and have a low prevalence of cardiovascular disease. This study was quoted widely in lay and professional publications and became the scientific basis for the thesis that persons in Western industrialized societies were at risk of deafness because of socioacusis. Later analysis of the Mabaan data indicated few differences between hearing levels of Mabaans and hearing levels of well-screened individuals from industrialized societies. One possible exception was that the hearing levels of Mabaan males over the age of 60 were slightly better in the high frequencies than their Western male counterparts. Additional criticism of the original Mabaan data involved the accuracy of the age of the Mabaan subjects. Apparently, the exact ages of the Mabaan subjects could not be confirmed. Lastly, important epidemiologic details of the Mabaan sample could not be determined; thus, the validity of the sampling was questionable (ie, a highly biased sample). It is possible, for example, that only the healthiest subjects were available and that these subjects also had the best hearing. Thus, the Mabaan data are equivocal in their support of the thesis of profound effects of socioacusis and nosoacusis on age-related hearing levels.

Whereas the Mabaan data are equivocal in their support of the role of nosoacusis and socioacusis in age-related hearing loss, experiments with laboratory animals clearly support the idea of an age-related hearing loss that is independent of socioacusis, nosoacusis, and exposure to occupational noise. In light of the complexities of the genetic, environmental, and disease-state factors that may affect the hearing of older persons, there are several ongoing efforts to develop animal models of presbyacusis. An appropriate animal model may allow identification and control of the most pertinent variables as well as permit systematic studies of the biologic basis of presbyacusis. It is also important to examine laboratory studies with humans and make comparisons with laboratory animal data when possible.

LABORATORY STUDIES: HUMANS AND ANIMALS

Of the many investigations of presbyacusis, perhaps the most quoted and most extensive source of histopathologic data is the temporal bone studies of Schuknecht and colleagues.[13] From a number of studies of human temporal bones, they have identi-

fied four types or categories of presbyacusis: (1) sensory, characterized by atrophy and degeneration of the sensory and supporting cells; (2) neural, typified by loss of neurons in the cochlea and central nervous system (CNS); (3) metabolic, characterized by atrophy of the lateral wall of the cochlea, especially the stria vascularis; and (4) mechanical, where the inner ear changes its properties with a resulting inner ear conductive hearing loss. Each of these categories was hypothesized to have a characteristic audiometric configuration (ie, sloping, flat) and therefore to be audiometrically identifiable. In subsequent studies, considerable difficulty was encountered in correlating the audiometric configuration with histopathologic observations and in differentiating one type of presbyacusis from another on the basis of the audiometric configuration.[14] The problem is that the audiometric configurations of older persons do not form clearly defined categories, and histopathologic changes at the level of light and electron microscopy are almost always observed at multiple sites in a given aging ear.

In 1993, Schuknecht and Gacek revised the traditional categories of presbyacusis described above.[15] The revision is based on hundreds of observations of human temporal bones and is summarized by the following:

> 1) Sensory cell losses are the least important type of loss in the aged; 2) neuronal losses are constant and predictable expressions of aging; 3) atrophy of the stria vascularis is the predominant lesion of the aging ear; 4) no anatomical correlation for a gradual descending hearing loss …reflect a cochlear conductive loss; and 5) 25% cannot be classified using light microscopy.

This conclusion by Schuknecht and Gacek is important for at least two reasons. One is that the significance of sensory cell losses is de-emphasized in presbyacusis. The second is that the dominance of strial degeneration is emphasized. These two points bring a consensus to human temporal bone results and those obtained from experiments with animals.

In many species of animals, auditory thresholds estimated from electrophysiologic potentials arising from the auditory nerve and brainstem increase as a function of chronologic age.[16,17] The age-related decline in auditory function occurs in animals who are born and reared in acoustically controlled environments where sound levels rarely exceed 40 dBA. In addition to control of the acoustic environment, none of the animals received antibiotics or other drugs. Conductive hearing loss was eliminated as a potential source of the measured hearing loss. Clearly, environmental noise, drugs, disease, and trauma did not have a causative role in the hearing losses observed in the aging animals. Thus, the notion that presbyacusis is not an aging effect per se but the combined effect of socioacusis and nosoacusis is not supported by laboratory experiments with several species of animals.

Perhaps the most dramatic feature of age-related hearing loss in laboratory animals is the variability between animals. For example, in a longitudinal study of aging gerbils, some animals, at the one extreme, had normal or nearly normal auditory sensitivity from 1 to 16 kHz, whereas at the other extreme, some animals did not respond to signals presented at levels of 80 dB SPL. The variability of this magnitude is remarkable given that chronologic age, environment (temperature, humidity, air quality), acoustic history, and diet of the animals were virtually identical. These data and others involving different inbred strains of mice suggest a strong genetic role for age-related hearing loss, at least in laboratory animals.

In addition to a qualitative/quantitative correspondence between age-related hearing loss measured in aging rodents and audiograms of 60- to 70-year-old humans,[16] many of the histopathologic observations made on human temporal bones have been confirmed and extended on experimental animals.[17–19] In aging rodents, there is usually a small loss of sensory (outer) hair cells in the most basal and the most apical regions of the cochlea. Nerve loss, as indicated by loss of spiral ganglion cells, is pronounced throughout the cochlea. The lateral wall of the cochlea, including the stria vascularis, usually shows degeneration originating in both the base and apex and extending to midcochlear regions as the animal ages; however, in some animals, there is a patchy loss of stria vascularis. Thus, in several species of animals, anatomic studies of cochlear material demonstrate at least three of the histopathologic conditions described in humans by Schuknecht and colleagues, namely, sensory, neural, and metabolic presbyacusis.[13] In animals, all three types are usually present in each animal.

As with humans, the most prominent (dominant) type of presbyacusis in laboratory animals

(with the exception of mice, C57) is the metabolic category.[18–23] In addition to age-related, systematic degeneration of the stria vascularis starting in both the apex and base of the cochlea and proceeding to the midcochlear region, preceding and accompanying this degeneration is a loss of the protein Na, K-adenosine triphosphatase. Sometimes the loss of this important protein, which is detectable using immunohistochemical techniques, occurs when the stria vascularis appears normal under light and electron microscopic examination. Thus, a normal-appearing stria vascularis in an older ear is no assurance that the stria vascularis is normal. Accordingly, the prevalence of "metabolic presbyacusis" may prove to be substantially higher in humans when the appropriate immunohistochemical techniques are applied to the study of human temporal bones of the aged.

The stria vascularis and underlying spiral ligament have a prominent role in generating electrochemical gradients and regulating fluid and ion homeostasis in the cochlea. As mentioned above, these tissues undergo age-related changes in a number of species, including humans. In accordance with its name, the stria is heavily vascularized and has an extremely high metabolic rate. Conceivably, alterations in strial microvasculature could compromise cochlear blood flow and ultimately lead to strial degeneration. Changes in blood flow in aging and in noise-exposed ears are inconsistent. Histopathologic studies on aging gerbil, on the other hand, have provided strong evidence for vascular involvement in age-related hearing loss. Morphometric analyses of lateral wall preparations stained to contrast blood vessels (Figure 21–4) have revealed losses of strial capillary area in aged animals.[19,20] The vascular pathology first presented as small focal lesions mainly in the apical and lower basal turns and progressed with age to encompass large regions at both ends of the cochlea. Remaining strial areas were highly correlated with normal microvasculature and with the endocochlear potential (described below).[20] Not surprisingly, areas of complete capillary loss invariably correlated with regions of strial atrophy. Subsequent ultrastructural analysis has revealed a significant thickening of the basement membrane,[21] which is accompanied by an increase in the deposition of laminin and an abnormal accumulation of immunoglobulin, as shown histochemically.[22,23] Thus, considerable support exists for the major involvement of strial microvasculature in age-related degeneration of the stria vascularis; however, the question of what constitutes the initial injury remains unanswered. Although it is tempting to speculate that atrophy of the stria vascularis occurs secondarily to vascular insufficiency resulting from capillary necrosis, the reverse could very well be true.

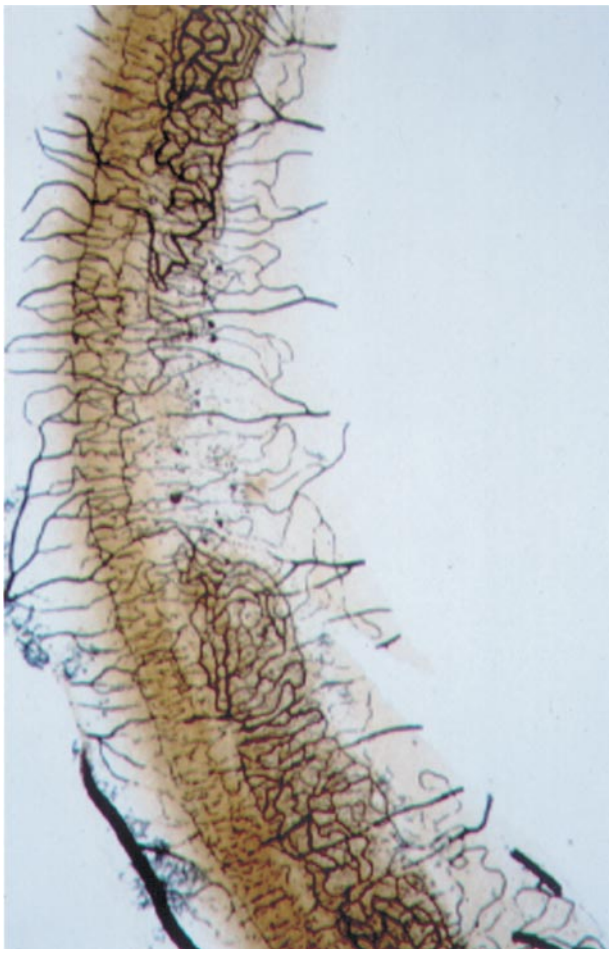

FIGURE 21–4. Surface preparation of stria vascularis/lateral wall dissection from an old gerbil stained with diaminobenzidine for endogeneus peroxidase to contrast with blood vessels (× 100 original magnification). The strial capillary bed overlies vessels of the spiral ligament. The slide shows substantial atrophy of the capillary bed. Adapted from Grattan MA et al.[19]

The most prominent changes in the physiologic properties of the aging ear are losses of auditory nerve function as indicated by increased thresholds of the compound action potential (CAP) of the auditory nerve.[24] Slopes of input-output functions of the CAP in aging animals are decreased even when the loss of auditory thresholds is only 5 to

10 dB. In other words, as the signal intensity is increased, the amplitude of the CAP increases by a fraction of that observed in young animals with normal hearing or young animals with noise-induced or drug-induced hearing losses. These shallow input-output functions of the CAP are also reflected in shallow input-output functions of auditory brainstem responses (ABRs). Thus, what appears to be abnormal function of the auditory brainstem in older animals reflects only the abnormal output of the auditory nerve. The reduced amplitudes of action potentials observed in aging ears are probably reflective of asynchronous or poorly synchronized neural activity in the auditory nerve. The pathologic basis of asynchronized activity in the auditory nerve is unknown but probably involves the nature of the synapse between individual auditory nerve fibers and the attachment to the inner hair cell, primary degeneration of spiral ganglion cells, and reductions in the endolymphatic potential, which are described below.

A second major difference between the presbyacusic ear and the ear with noise-induced hearing loss is the endolymphatic potential, that is, the 80 to 90 mV DC resting potential in the scala media of the cochlea.[18] In aging animals, this DC potential is often reduced significantly and proportionally to losses/degeneration of the stria vascularis. Moreover, in experimental animals, hearing losses can be reduced by introducing a DC voltage into scala media and raising a low endolymphatic potential, that is, 15 mV, to a value approaching 60 to 70 mV. Degeneration of the stria vascularis with the resultant decline in the endocochlear potential has given rise to the "dead battery theory" of presbyacusis.

A third difference between the physiology of the aging ear and the ear with noise-induced or drug-induced injury of the cochlea involves the nonlinear phenomenon of two-tone rate suppression, that is, activity of the auditory nerve elicited by one tone is suppressed or eliminated by the addition of a second tone of different frequency.[24] In ears of quiet-reared aging animals, the mechanism of two-tone rate suppression appears to remain intact. In contrast, in noise-induced or drug-induced injury of the cochlea, a reduction or complete loss of two-tone rate suppression may be the first indicator of injury of the cochlea, usually outer hair cells. These data are an excellent indicator that the pathologic basis of age-related hearing loss is fundamentally different from the pathologic basis of most forms of noise-induced or drug-induced hearing loss.

Otoacoustic emissions, both transient evoked and distortion product, are nonlinear phenomena that are assumed to reflect the integrity of sensory cells, especially outer hair cells. Given this assumption, one would expect to find very high correlations between loss of outer hair cells and changes in otoacoustic emissions; however, inconsistent relations among distortion products, threshold measures, and sensory cell pathology have been reported from widely different types of experiments. Indeed, there are reports of normal emissions in the presence of missing outer hair cells as well as reduced emissions in the presence of a complete complement of outer hair cells.[25] In the aging ear of experimental animals with a minimal, if any, loss of outer hair cells, distortion-product emissions are reduced somewhat in amplitude but are clearly present and robust.[26] In aging human ears, transient emissions are present in about 80% of persons with a PTA hearing level better than 10 dB, present in about 50% with PTA of 11 to 26 dB, and absent in about 80% with a PTA greater than 26 dB. Thus, the presence of a transient otoacoustic emission suggests excellent hearing levels for most persons, whereas its absence reveals very little. Indeed, the major application of otoacoustic emissions may be in hearing screening of infants.

A recent development is the association of mitochondrial deoxyribonucleic acid (mtDNA) deletions with SNHL and age-related hearing loss. Ueda et al, using DNA specimens extracted from peripheral blood leukocytes, found a higher rate of mtDNA deletions in patients with SNHL than in controls.[27] Seidman, in a rat study, tied mtDNA deletions to presbyacusis and mtDNA deletions to reactive oxygen metabolites (ROMs).[28] These are highly toxic molecules that can damage mitochondrial DNA, resulting in the production of specific mtDNA deletions. Thus, compounds that block or scavenge ROMs should attenuate age-related hearing loss. Rats were assigned to treatment groups including controls, caloric restriction, and treatment with several antioxidants, including vitamins E and C, and were allowed to age in a controlled environment. The calorie-restricted groups maintained the best hearing, the lowest quantity of mtDNA deletions in brain and ear tissues, and the least amount of outer hair cell loss. The antioxidant-treated subjects had better hearing than the controls and a slight trend

for fewer mtDNA deletions. The controls had the poorest hearing, the most mtDNA deletions, and the most outer hair cell loss. These data suggest that nutritional and pharmacologic strategies may prove to be an effective treatment that would limit age-related increases in ROM production, reduce mtDNA deletions, and thus reduce age-related hearing loss. Reactive oxygen metabolites (or reactive oxygen species) and oxidative stress have also been implicated in noise-induced hearing loss, ototoxic hearing loss, and cumulative injury that presents as age-related hearing loss. It is speculated that there is a genetic impairment of antioxidant protections that leads to the production of both age-related and noise-induced hearing loss by placing the cochlea in a state of vulnerability.[29,30] Although an age-related hearing loss gene has been identified, the murine Ahl mutation,[31,32] the discovery of the molecular/genetic basis of presbyacusis, noise-induced hearing loss, and SNHL in general are truly just beginning.

In summary, animal experiments conducted under strict conditions show age-related declines in auditory function that indicate a pure aging hearing loss. Most of the pathologic anatomy associated with this "pure aging" hearing loss is in the cochlea, where the dominant pathology is degeneration of the stria vascularis. In experimental animals, most of the hearing loss can be accounted for by anatomic, physiologic, and biochemical changes in the auditory periphery. Indeed, there is no need to include the auditory CNS in an explanation of age-related hearing loss, even when the criterion measure of age-related hearing loss is derived from potentials arising from the auditory brainstem. Nearly all changes observed in auditory brainstem potentials can be explained by alterations in the auditory periphery.

Explanations of age-related changes in auditory brainstem potentials in terms of alterations in the auditory periphery run counter to the current dogma that there is a significant, perhaps dominant, component of presbyacusis that involves degeneration of the auditory CNS. Indeed, there are significant, age-related changes in the auditory CNS involving subtle to gross changes in anatomy and neurochemistry. One prominent change is a reduction in γ-aminobutyric acid (GABA) affecting neural inhibition. Another is increases in the release of aspartate in the cochlear nucleus following cochlear injury and leads to increased excitatory neurotransmission. The role of the CNS in age-related hearing loss is almost surely substantial but remains largely unknown.

PERCEPTION OF AUDITORY SIGNALS AND SPEECH

In addition to age-related declines in auditory sensitivity, there are age-related declines in differential sensitivity for intensity, frequency, and time. Until recently, these age-related declines in the basic properties of the ear and hearing were almost always measured in older persons with significant hearing losses. Thus, it was nearly impossible to separate the effects of a hearing loss from the effects of aging. Recently, however, both discrimination in intensity and discrimination in frequency have been shown to decline with age only at low frequencies and independently of any hearing loss.[33] These results are important because they are negative effects measured in the presence of normal hearing and may very well represent age-related declines in information processing capability. It remains unclear whether these age-related declines represent age-related effects of the auditory periphery or CNS.

The term "phonemic regression" was coined to describe a disproportionate difficulty in speech perception relative to the magnitude of hearing loss of older persons. Later, many studies of speech discrimination and other complex listening tasks showed results with older subjects that were difficult to explain solely on the basis of the audiogram alone. With the ready availability of many published articles showing degenerative changes in the auditory brainstem and cortex of older persons, there evolved a viewpoint that a significant component of age-related hearing loss is attributable to the decline of the auditory CNS. Of course, the auditory CNS is involved in age-related hearing loss; however, the extent of the involvement of the CNS in presbyacusis is currently receiving much debate. Here we examine the CNS issue beginning with data on speech discrimination by older persons.

Perhaps the largest qualitative/quantitative description of speech discrimination as a function of age and hearing loss is provided by Jerger from the clinical records of 2,162 patients.[34] Figure 21–5 shows percent correct on phonetically balanced (PB) words as a function of chronologic age. The parameter on the figure is the PTA of 0.5, 1, and

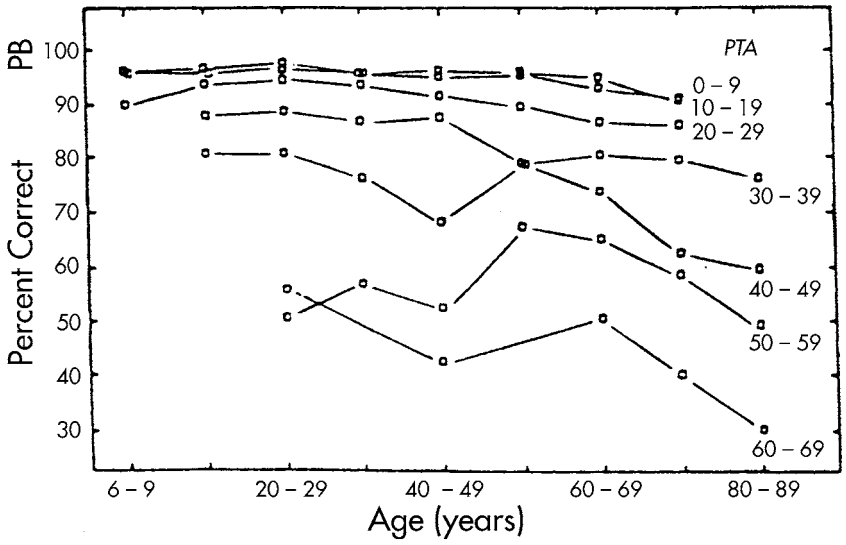

FIGURE 21–5. Speech discrimination as a function of age with average hearing loss at 0.5, 1, and 2 kHz as parameter. PB = phonetically balanced; PTA = puretone average. Adapted from Jerger J.[34]

2 kHz. Figure 21–5 shows that speech discrimination declines systematically as a function of chronologic age; however, the decline with age is dramatically dependent on hearing loss. That is, for subjects with very little hearing loss (less than 30 dB), the decline with age is measurable but small through age 70. On the other hand, for subjects with moderate-to-severe hearing losses, the decline with age is noteworthy, particularly for persons between the ages of 45 and 85 with hearing losses of 40 to 49 dB, 50 to 59 dB, and 60 to 69 dB. In other words, when hearing loss as indicated by the PTA is held constant, speech discrimination scores decreased between the ages of 40 and 80 for moderate (greater than 40 dB) to severe (60 dB) hearing losses. In contrast, age had very little effect as long as the PTA is less than about 30 to 39 dB. A remarkable and perhaps the most noteworthy feature of Figure 21–5 is that persons over the age range of 50 to 80 perform as well as 25 year olds as long as their average hearing loss at 0.5, 1, and 2 kHz is less than 35 dB or so. This fact runs counter to the stereotype of 70- to 80-year-old persons.

Performance on tests of speech discrimination by older persons is shown (Figure 21–6) for PB words, three versions of the Speech Perception in Noise (SPIN) test, and synthetic sentence identification (SSI).[35] Subjects in whom hearing levels were nearly identical (± 3 dB) were placed into three age groups over the range from 55 to 84 years. Statistical analysis of the speech discrimination data showed that performance on all tests were not affected by age. That is, when hearing levels were equated, there were no age-related declines in performance on tests of speech discrimination in persons over the age range of 55 to 84 years. In additional analyses using partial correlations, Dubno et al showed significant gender effects, that is, significant declines with age for males in word recognition, SSI, and SPIN in high-context sentences.[36] Age-related declines were not observed for females.

There are many additional studies of speech discrimination using background noises, degraded speech signals, reverberation, and other variations that resulted in more difficult listening tasks than the usual speech discrimination test, which is done in quiet listening conditions.[36,37] Many of these studies show age-related effects; however, the interpretation of many of these data showing age-related declines in auditory behavior is not straightforward because the subjects usually have significant hearing loss, as indicated by the audiogram. Accordingly, some persons believe that there is a large CNS component to presbyacusis, whereas others believe and have shown that speech discrimination by older persons is predictable given the audiometric hearing loss and the audibility of the speech material. Indeed, as much as 95% of the variance in speech discrimination results can be accounted for on the basis of the audiogram.[38] In other cases for which predictions of performance by older persons under noisy listening conditions are in error by 20 to 25%, it is still not

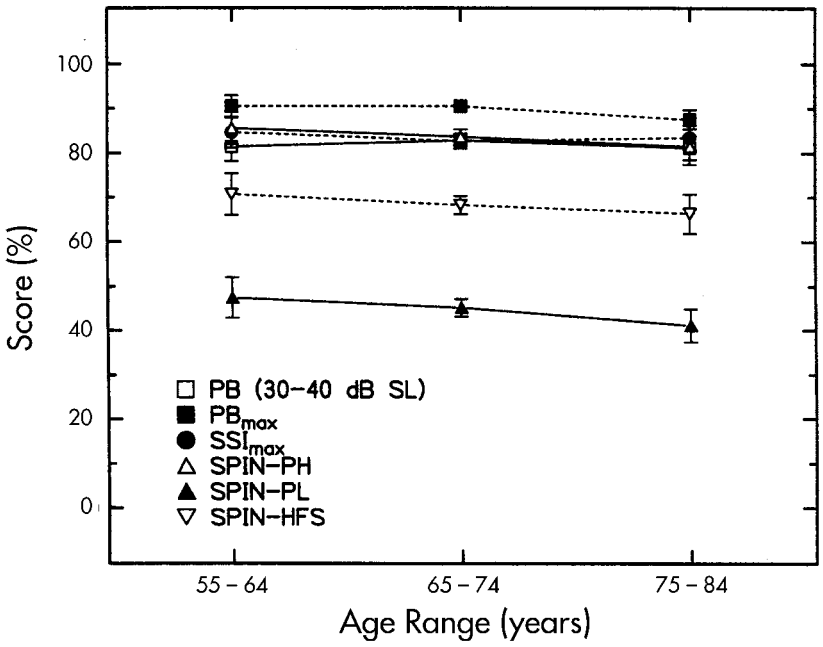

FIGURE 21–6. Speech discrimination as a function of age for different speech material. Hearing level is the same for each age group. PB = phonetically balanced; SSI = synthetic sentence identification; SPIN = Speech Perception in Noise; PH = high probability; PL = low probability. Adapted from Dubno JR et al.[35]

necessary to invoke the involvement of the CNS, although this is usually the interpretation.

Although there are large individual differences in auditory behavior among individuals that are predictable by individual differences in auditory thresholds, there are many age-related declines in auditory behavior that are not strongly associated with auditory thresholds. This is most evident using binaural listening tasks conducted under acoustically stressful conditions. In many binaural experiments using older subjects, age-related declines are observed that appear to be independent of peripheral hearing loss; however, it is often difficult to separate truly central processing disorders from disorders initiated by a pathologic input from the aging cochlea.

AUDITORY EVOKED POTENTIALS

With the development of straightforward techniques to measure evoked potentials arising from the auditory nerve, brainstem, and auditory cortex, there has been significant progress in evaluating the aging auditory nervous system of human subjects. In regard to the ABRs, most studies show age-related declines in the amplitude of wave V, which should be interpreted to reflect peripheral hearing loss rather than changes in the brainstem. Even in older persons with excellent hearing levels, ABR waveforms are of "poor quality" and reduced amplitude, probably reflecting pathology of the cochlea and auditory nerve as well as a reduction in synchronized neural activity. For young subjects with normal and abnormal hearing, auditory thresholds measured behaviorally are about 10 dB better than auditory thresholds estimated from the ABR. For aging subjects, this behavioral/ABR disparity is 20 dB, reflecting the poor quality/low amplitude of the ABR. Other evoked potentials show inconsistent results. The P300 arising from the auditory cortex shows age-related declines, whereas the amplitude-modulated following response may remain unaffected by aging. In contrast, the frequency-modulated following response may be enhanced in older subjects, perhaps reflecting the well-documented age-related decline in GABA. Although much of this research is in progress, it appears that evoked potentials produced by short-duration signals (onset responses such as ABR and CAP) are decreased in amplitude in older subjects, whereas those evoked potentials produced at higher levels in the CNS by long-duration signals may be unaffected or even increased in amplitude. Age-related increases could reflect a number of factors, including efforts by the CNS to compensate for peripheral deficits or age-related changes in the excitatory/inhibitory balance of the auditory CNS.

ALLEVIATION/TREATMENT

Assuming that any problems with the external and middle ear are diagnosed and treated, that other medical issues are under control, and a diagnosis of presbyacusis in the general sense, the best treatment currently available is a hearing aid. The successful use of hearing aids by older persons and the hearing impaired in general is mixed. There is a literature of substantial magnitude that reports on the successful or unsuccessful use of hearing aids by the elderly. Many older persons who would clearly benefit from an aid do not use one. The reasons for not using an aid or being a dissatisfied user include cost, stigma of a hearing handicap and of being old, difficulty in manipulating controls, and too little benefit, particularly in the presence of background noise.

In a large group of older persons (N = 516) who are participants in a longitudinal study of age-related hearing loss, 53% (n = 272) are candidates for a hearing aid. Candidacy by very conservative audiologic criteria is a speech reception threshold greater than 30 dB in the better ear or hearing level greater than 40 dB at 3 and 4 kHz in the better ear. Using these criteria, nearly half (n = 131 of 272) of those who are considered to be excellent candidates have never tried a hearing aid, and only 38% (n = 104 of 272) of candidates were successful hearing aid users. Thirty-seven persons, for one or several reasons, were dissatisfied hearing aid users. Of those who did not meet the conservative criteria for a hearing aid (n = 244), our clinical judgment suggested that at least 40 to 50% of these persons would benefit from an aid. Clearly, the older persons in our longitudinal study were uninformed about hearing aids, poorly served, or underserved. Indeed, it is our opinion that as a result of excellent advances in hearing aid technology in combination with improved fitting techniques, nearly every older hearing-impaired person should be considered a potential candidate for a hearing aid.

ACKNOWLEDGMENT

Preparation of this chapter was supported by NIH (P01 DC00422). Lois J. Matthews provided data on hearing aid use and transient otoacoustic emissions. Nancy Smythe assisted in preparation of the figures and final document.

CHAPTER 22

Tinnitus and Hyperacusis

Pawel J. Jastreboff, PhD, ScD, Margaret M. Jastreboff, PhD

TINNITUS

Tinnitus is commonly described as a perception of sound that is not related to an external acoustic source or electrical stimulation.[1] It is an extremely common condition, but only a fraction of those who experience tinnitus are significantly disturbed.[2–4] Moreover, it has been shown that perception of tinnitus can be evoked in 94% of young, healthy subjects by putting them in a sufficiently low level of sound.[5] Although many unanswered questions regarding tinnitus remain and there is a lack of objective measures and no clear agreement as to the most efficient way to help those suffering with tinnitus, significant progress has been made over the last 20 years in the tinnitus field. Still, most patients are left with proverbial advice: "Learn to live with it."

Tinnitus is not a disease. It is a symptom that, similar to pain, headache, or fever, can vary in severity and can affect patients' lives to varying degrees. Sounds described by patients have different spectra and loudness, can change in loudness and type of sound, and can persist or be transient.[1,2] Tinnitus can be annoying to those who experience it and lead to a vicious circle whereby the tinnitus becomes the center of attention in patients' lives. Additionally, tinnitus can exist independently or as part of a complex medical condition.[6] There is no truly tracked etiology, specific site, or molecular/cellular mechanism that has been proven. Tinnitus affects people of all ages.

Frequently, tinnitus is accompanied by decreased sound tolerance and hearing loss.[4,6–8] Decreased sound tolerance can represent hyperacusis and/or misophonia. There is no consensus regarding the testing of loudness discomfort levels (LDLs) to evaluate the problem, and there are no established normative data. The prevalence and epidemiology of hyperacusis are not well documented, and its etiology and mechanisms are poorly understood. Hyperacusis can occur alone or as an adjunct to complex medical conditions. Gradual desensitization can lead to the successful treatment of the problem.

Definitions

Writings about tinnitus can be found in ancient documentation of Babylonian, Egyptian, Greek, Indian, and Assyrian medicine. Throughout the world, a variety of terms have been used to describe a ringing, tinkling (Latin, *tinnire*), buzzing, whistling, or unpleasant sound (French, *acouphnes*) in the ears or in the head, leaving us with the two most commonly used terms, tinnitus (in English) and *acufenos* (in Spanish). The historical review of tinnitus may be found in a number of publications, particularly those by Stephens[9] and Feldmann.[10,11]

There is no precise, short, and distinctive definition of tinnitus. Today, commonly used definitions of tinnitus focus on different characteristics. Patient experience–oriented definition describes tinnitus as ringing, buzzing, the sound of escaping steam, hissing, humming, cricket-like, or noise in the ears.[1,4] Tinnitus as "a phantom auditory perception" represents a physiologic definition of tinnitus pointing out a lack of a physical acoustic stimulus related to tinnitus.[12,13] There is also the definition proposed by the Committee on Hearing, Bioacoustics and Biomechanics of the US National Research Council: "a conscious experience of sound that originates in the head" of its owner.[1]

Etiology and Prevalence

The results of studies conducted in numerous places around the world have shown a significant variability in the estimation of tinnitus prevalence in the general population.[2–4,14–18] Six to 17% of people experience tinnitus lasting for a period of at least 5 minutes. About 3 to 7% of the general population seek help for their tinnitus, and 0.5 to 2.5% report

severe effects of tinnitus in their lives.[1–4,18] The prevalence of tinnitus in adults with hearing problems is very high (59 to 86%), and it is estimated that tinnitus is present in 50% of patients with sudden hearing loss, 70% with presbycusis, and 50 to 90% with noise-induced hearing loss.[19]

The prevalence of tinnitus increases significantly with aging, but people of all ages experience tinnitus.[2,4,8] Although frequently not reported, children are also affected by tinnitus, and the estimated prevalence is similar to that reported in adults. Nodar, in a sample of 2,000 children, reported the average prevalence of 15%, with 13.3% for children with normal hearing and 58.6% with hearing loss.[20] Similar data were reported by others with a general prevalence in the range of 15 to 29% in healthy children and approximately 50% in children with otologic problems or hearing loss.[21,22] A significant proportion of children reported having problems with tinnitus including sleep disturbance (42%), problems with concentration (47%), and sensitivity to sound (33%).[23] In younger healthy children (age 5 to 16 years), 29% have tinnitus, and 9.6% reported their tinnitus as troublesome.[21]

Extensive studies have been performed in an attempt to link various factors with tinnitus prevalence.[1,2,8,14] Hearing loss, specifically the extent of high-frequency impairment in the worse ear, is one of the main predicting factors for tinnitus.[2] Conductive hearing loss seems to be a separate factor,[24] and noise exposure has been correlated with tinnitus as well.[14] Tinnitus is also experienced by those with normal hearing; 18% of tinnitus patients were reported to have normal hearing.[24]

Other epidemiologic factors do not appear to be correlated with tinnitus. There is no clear effect of gender on tinnitus prevalence, although pregnancy has been shown to increase significantly the probability of tinnitus.[25] Neither smoking, coffee, nor alcohol has been shown to increase tinnitus prevalence directly.[26–28]

Mechanisms and Models

Our knowledge of the mechanisms of tinnitus is still limited and based more on theoretical speculations than on strong research data or stringent clinical studies. Past models were focused on peripheral mechanisms,[29–35] whereas recent models tend to involve or even focus on processing information within the central auditory pathways and central nervous system.[12,36–38] The neurophysiological model of tinnitus combines all of the levels and differentiates between the perception of tinnitus versus tinnitus-induced activation of nonauditory structures in the brain.[7,12,37–39] Table 22–1 summarizes the approaches to the mechanisms of tinnitus.[19,29,37,40–44]

Tinnitus as a Symptom of Medically Treatable Diseases

Tinnitus may also be a part of more complex medical conditions. The most common ones are listed in Table 22–2.[37,45]

DECREASED SOUND TOLERANCE

Tinnitus is frequently accompanied by decreased sound tolerance (oversensitivity to sound),[3,6,12,17,46–51] which, in many cases, is a sum of hyperacusis and misophonia.[46,52]

Definitions

There is no generally accepted definition for decreased sound tolerance to suprathreshold sounds, although a variety of terms have been proposed, with hyperacusis used most frequently. According to *Stedman's Medical Dictionary*,[53] hyperacusis is defined as "Abnormal acuteness of hearing due to increased irritability of the sensory neural mechanism. Syn: auditory hyperesthesia," with hyperesthesia defined as "Abnormal acuteness of sensitivity to touch, pain, or other sensory stimuli" or, according to *American Heritage Dictionary*, as "An abnormal or pathological increase in sensitivity to sensory stimuli, as of the skin to touch or the ear to sound."[54] It has been recognized that decreased sound tolerance might reflect physical discomfort or be related to a fear of sound.[6]

We proposed the approach to decreased sound tolerance based on neurophysiology, recognizing the systems that can be involved, the auditory system (both peripheral and central parts) and the limbic and autonomic systems, and consequently propose the following definitions. Hyperacusis can be defined as abnormally strong reactions to sound occurring within the auditory pathways. At the behavioral level, it is manifested by a subject experiencing physical discomfort as a result of exposure to

moderate/weak sound that would not evoke such reaction in the average population. The strength of a reaction is linked to the physical characterization of a sound, for example, its spectrum and intensity. Misophonia and phonophobia can be defined as abnormally strong reactions of the autonomic and limbic systems without abnormally high activation of the auditory system, resulting from enhanced connections between the auditory and limbic systems. At the behavioral level, patients have a generally negative attitude to sound (misophonia, from Greek: *miso* meaning strong dislike, hate) or could

TABLE 22–1. Main Concepts Related to Proposed Mechanisms of Tinnitus

Structures involved
Auditory system
Periphery (cochlea, auditory nerve)
Central auditory pathways
Auditory and central nervous system
Manifestation of tinnitus-related neuronal activity
Increase in spontaneous activity
Modification in temporal patterns of discharges, including bursting activity
Synchronization of the activity between neurons
Proposed mechanisms responsible for the emergence of tinnitus-related neuronal activity
Abnormal coupling between neurons
Local decrease of spontaneous activity enhanced by lateral inhibition
Discordant damage/dysfunction of outer and inner hair cells
Unbalanced activation of Type I and II auditory nerve fibers
Abnormal neurotransmitter release from inner hair cells
Decreased activity of the efferent system
Mechanical displacement within the organ of Corti
Abnormalities in transduction processes
Various aspects of calcium function
Physical/biochemical stress on the auditory nerve
Enhanced sensitivity of the auditory pathways after decreased auditory input
Level of interest
Molecular—ion channels, synapses, cellular membranes
Single neuron—processing information within one cell
Neuronal assemblies—interaction within group of cells
System—interaction between various systems in the brain
Somatosounds
Included as "objective tinnitus"
Separated, with name tinnitus reserved to auditory phantom perception

specifically be afraid of sound (phonophobia; phobia, fear). The strength of a reaction will be only partially determined by the physical characterization of a sound and will depend on the patient's previous evaluation of a sound (eg, potential threat, beliefs that it can be harmful), the patient's psychological profile, and the context in which the sound is presented.

Note that neither hyperacusis nor phonophobia has any relation to the threshold of hearing, which can be normal or can reflect hearing loss.

Most frequently, decreased sound tolerance results from a combination of hyperacusis and phonophobia. It is important to assess the presence and the extent of both phenomena in a patient as each needs to be treated using different methods. Terms used in the literature do not differentiate these problems, and since the reported decreased sound tolerance is typically dominated by hyperacusis, we will use the term hyperacusis in describing reports in the literature. As misophonia is a new term, and phonophobia is commonly used, in this chapter, when the word "phonophobia" is used, it actually denotes "misophonia/phonophobia."

Additionally, note that the term recruitment is not related to a decreased sound tolerance or hyperacusis. Recruitment refers to unusually rapid growth of loudness as the level of a tone is increased, occurs in association with hearing loss, and is purely a cochlear phenomenon. It might coexist with hyperacusis, but there is no functional link between these two phenomena.

Prevalence and Epidemiology of Decreased Sound Tolerance

There are limited data available on the prevalence of hyperacusis. Questionnaires provide an assessment of hyperacusis prevalence in the general population. Recent data gathered from 10,349 randomly selected subjects showed that 15.3% reported hyperacusis.[17]

Patients being evaluated for other otologic problems frequently undergo audiologic evaluation, which involves assessment of speech discomfort level and pure-tone LDLs. There are no good normative data. Several studies indicated that in the normal population, LDLs are in the range of 90 to 110 dB SPL, with varied results depending on the specific method used (eg, stimuli: pure tone, warble tone, noise; presentation: free field, insert earphones, headphones; and instructions given to patients).[55–57]

TABLE 22–2. Medical Conditions That May Be Associated with Tinnitus

The results tend to cluster within 95 to 110 dB SPL for frequencies from 500 to 8,000 Hz, which correspond to approximately 90 to 100 dB HL.[55,58]

Hyperacusis and tinnitus frequently coexist, and it has been postulated that in some patients, hyperacusis might actually be a pretinnitus state.[12] Approximately 40% of tinnitus patients exhibit decreased sound tolerance, with 27% requiring specific treatment for hyperacusis.[46,59,60] Conversely, study of 100 patients with hypersensitivity to sound showed that 86% of them suffered from tinnitus.[61] Considering the clinical observation that approximately 27% of tinnitus patients required treatment for hyperacusis and 86% of hyperacusis patients reported tinnitus and accepting that about 4 to 5% of the general population have clinically significant tinnitus, it is possible to estimate that significant hyperacusis exists in approximately 1 to 1.5% of the general population. An even larger proportion has some hyperacusis that, although detectable in questionnaires, is not sufficiently strong to initiate intervention.

Evaluation of Tinnitus

We do not have any objective method to detect and measure tinnitus. Therefore, interview and psychoacoustic characterization are typical approaches in clinical practice, sometimes expanding into the direction of physiologic testing. New advances in research offer the possibility to detect tinnitus in an objective manner using imaging techniques[62–65] or magnetoencephalography.[13] These techniques are very promising but cannot yet be implemented into clinical practice owing to their complexity and cost. Table 22–3 lists the methods used for evaluation of tinnitus.

Problems Evoked by Tinnitus

As tinnitus can present as part of a complex medical condition, full physical examination is needed to exclude all medically treatable problems that can be linked to tinnitus. Even though tinnitus is classified as a symptom and not a disease, it does require treatment as it can cause significant emotional and somatic distress and can significantly influence patients' quality of life, particularly if allowed to become a chronic problem. The list of reported associated complaints is long and includes emotional problems such as irritation, annoyance, anxiety, and depression; hearing problems such as difficulty with speech comprehension; and somatic problems such as headache, neck pain, and jaw pain.[1,6,73] Tinnitus can be very intrusive and may cause difficulty with sleep and concentration and a decreased ability to participate in everyday activities and social events; it may also create problems in relationships. A detailed interview, aimed at characterizing the specifics and degree of tinnitus impact on patients, coupled with otolaryngologic evaluation, provides the most thorough assessment and allows the practitioner to address all of the issues that need to be considered, including potential intervention of a psychologist/psychiatrist to accompany the commencement of a specific tinnitus-oriented treatment.

Hyperacusis and Misophonia as a Problem

Decreased sound tolerance can have an extremely strong effect on patients' lives and can be even more debilitating than tinnitus. Whereas tinnitus may affect

attention, sleep, work, and life enjoyment and make social contact less rewarding, hyperacusis can *prevent* people from exposing themselves to louder environments and therefore prevent them from working and interacting socially; it can also control a patient's life. In extreme cases, patients do not leave their homes, and their lives and the lives of their families are controlled by the issue of avoidance of sound. Misophonia can have similar effects, and since it is inevitable in all cases with significant hyperacusis, misophonia further enhances the effects of hyperacusis.

Decreased Sound Tolerance as a Symptom of Medical Conditions

Hyperacusis has been linked to a number of medical conditions (Table 22–4).[46,74–86]

TABLE 22–4. Medical Conditions Linked to Hyperacusis

Tinnitus

Etiology and Potential Mechanisms of Decreased Sound Tolerance

In the majority of cases, the cause of hyperacusis is unknown. Hyperacusis has been linked to sound exposure (particularly short, impulse noise), head injury, stress, and medications. The lack of strong epidemiologic data and of animal models of hyperacusis prevents proving the validity of any potential mechanism responsible for hyperacusis.

At the peripheral level, it is possible to speculate that the abnormal enhancement of vibratory signals within the cochlea by the outer hair cells might result in overstimulation of the inner hair cells and subsequently results in hyperacusis.[12] Indeed, in some cases, it is possible to observe high-amplitude distortion-product otoacoustic emissions and distortion products evoked by low-level primaries.[87] The presence of asymmetric hyperacusis[46] might indicate a peripheral mechanism since central mechanisms would more likely act similarly on both sides.

Laboratory research has shown that damage to the cochlea or a decrease in the auditory input results in a decrease of the threshold of response in a significant proportion of neurons in the ventral cochlear nucleus and inferior colliculus.[88] Studies with evoked potentials indicated abnormal increase of the gain in the auditory pathways after such manipulations.[89] Some of the medical conditions listed in Table 22–4 can be linked to the central processing of signals and modification of the level of neuromodulators as possible factors inducing or enhancing hyperacusis. Moreover, serotonin has been implicated in hyperacusis,[90] and a case report indicated that serotonin reuptake inhibitors might be helpful for hyperacusis.[83]

Mechanisms of misophonia could involve enhancement of the functional links between the auditory and limbic systems, both at the cognitive and subconscious levels.[12] Alternatively, a tonic high level of activation of the limbic and autonomic nervous systems may result in strong behavioral reactions to moderate sounds.[39,91]

Methods of Evaluation of Decreased Sound Tolerance

Whereas there is no one clearly accepted method for the evaluation of decreased sound tolerance, hyperacusis, and misophonia, there is a general agreement that LDLs provide a good estimation of the problem. There are several variants of the protocols of LDL evaluation with various features, for example, continuous, pulsed, or beeps of sound; pure tone;

narrow-band noise; etc.[56,92,93] The approach we are pursuing incorporates modifications of the standard procedure[55] aimed at obtaining results dominated by hyperacusis by decreasing the effects of the misophonic component to a minimum. To achieve this, a situation is created during testing in which patients have the feeling of full control over the maximal sound level to which they will be exposed.[46] A detailed interview is needed with each patient to determine the relative contribution of hyperacusis and misophonia to decreased sound tolerance, reflected in decreased values of LDLs. As normative data are not uniform and there is substantial individual variability (even while using one method) in measuring LDL,[57] it is advisable to pay attention to the potential presence of hyperacusis when average LDL values are lower than 95 to 100 dB HL.

Review of Treatments

The list of approaches and techniques attempted to help tinnitus patients is very long. Table 22–5 lists the most commonly used of these treatments.[45]

Antireassurance Over the years, the most common advice to tinnitus patients has been the statement, "Nothing can be done—go home and learn to live with it."[7,48] This is actually a very powerful form of negative counseling, sufficient on many occasions to convert a person who just experiences tinnitus to a patient who suffers from it.[12,47,52]

Pharmacology Many pharmacologic agents have been considered for tinnitus treatment (Table 22–6),[6,94] but no single, effective, specific, secure, and reliable drug has yet to be identified. In this respect, strong consideration must be given to the side effects of pharmacologic treatments such as tolerance, dependence, and withdrawal effects. A recent review of randomized clinical trials of drugs for tinnitus has shown that all studied drugs have failed to prove their efficacy, as compared with a placebo.[94] Future double-blind randomized studies, with proper outcome measurements and adequate sample size, might identify some promising pharmacologic agents.

Surgery Surgery can offer help to some patients with somatosound, conductive hearing loss, and Meniere's disease.[6] However, there is no specific surgical procedure shown to be consistently effective for tinnitus that does not have a clear surgically treatable cause. Neither transection nor microvascular decompression of the auditory nerve, promoted in the past,[95,96] has proven to be effective.[45,97]

Electrical Suppression Electrical suppression of tinnitus was first reported in 1855.[98] Over the years, many different approaches have been attempted (Table 22–7),[98,99] and methodologies based on electrical stimulation are still raising significant interest. Recently, two new variants of electrical stimulation for tinnitus have been introduced. The first involves deep brain stimulation, sometimes performed for movement disorder and chronic pain.[100] Anecdotal reports of patients receiving deep brain stimulation initiated an investigation that demonstrated that, indeed, some patients experienced a decrease in their tinnitus with deep brain stimulation.[101] A second approach involves high-frequency electrical stimulation of the cochlea performed by placing an electrode on the promontory or via a cochlear implant (Rubinstein, personal communication, 2001). Both approaches are at a very early stage of investigation.

Only intracochlear (or with the electrode on the promontory) stimulation has shown consistent and positive results in approximately 50% of patients.[99,102,103] Other approaches were less effec-

tive.[98] Although positive direct/pulsed current can provide tinnitus suppression,[104] it has no clinical application as it would damage the cochlea if used for a prolonged period of time.

Masking The use of an external sound to cover tinnitus and thus bring immediate relief to patients, known as masking, was first used in 1825 by Itard.[9] At the end of the 1970s, Vernon and Schleuning revisited this idea and introduced the first commercial masker.[105,106] Initial reports proclaimed high success of maskers,[106,107] but the approach did not withstand the test of time.[94] The problem was the criterion used in evaluating the effectiveness of masking; for example, if the masker was still in use after 6 months, it was counted as a success.[107,108] Obviously, patients may continue using maskers even while not getting relief from their tinnitus. Presently, this method of alleviation of tinnitus is rarely used.

Psychology Psychological management of chronic tinnitus can be helpful for some patients.[109] As tinnitus affects patients' well-being, the application of cognitive behavioral therapies may have a positive impact on the quality of life by improving their ability to cope with tinnitus. Cognitive therapies, behavioral modifications, coping strategies, and minimizing distress are examples of the psychological approach.

Neurophysiological Model of Tinnitus and Tinnitus Retraining Therapy

More than a decade has passed since the introduction of the neurophysiological model of tinnitus and, based on it, treatment, which is known as tinnitus retraining therapy (TRT).[7,110,111] Several observations led to the neurophysiological model of tinnitus and hyperacusis. It is known that tinnitus induces distress in only about 25% of those who perceive it.[2,4,8] There is no correlation among the psychoacoustic characterization of tinnitus, tinnitus-induced distress, and the treatment outcome.[112] The experiment by Heller and Bergman showed that the perception of tinnitus cannot be pathologic since essentially everyone (tinnitus emerged in 94% of people without prior tinnitus when isolated for several minutes in an anechoic chamber) experiences it when put in a sufficiently quiet environment.[5] These observations strongly argue that the auditory system plays a secondary role, and other systems in the brain are dominant in clinically relevant tinnitus (ie, tinnitus that creates discomfort and annoyance and requires intervention).

Analysis of the problems reported by tinnitus patients, who exhibit a strong emotional reaction to its presence, a high level of anxiety, and psychosomatic problems, indicated that the limbic and autonomic nervous systems are crucial in individuals with clinically relevant tinnitus. It was postulated that the sustained activation of the limbic and autonomic nervous systems is essential in creating distress and, therefore, clinically relevant tinnitus.[12]

Tinnitus-related neuronal activity is processed by the parts of the central nervous system involved in memory and attention. It is possible to distinguish several feedback loops, with two major categories: loops involving the conscious perception of tinnitus and those that act at a subconscious level (Figure 22–1), with the subconscious loop dominant in most patients.[7,39] It is further suggested that the activation of the limbic and autonomic nervous systems by tinnitus-related neuronal activity follows the principles of conditioned reflexes.[39,52]

The processing of tinnitus-related neuronal activity occurs in a dynamic balance scenario, with continuous modification of the weights of synaptic connections. Both learning and memory have a physiologic basis in the modification of the strength of synaptic connections.[113] A continuous presence of tinnitus, combined with attention given to it, results in plastic modifications of synaptic connections, yielding the modification of receptive fields corresponding to the tinnitus signal and its subsequent enhancement.[37,39] Recently, this postulate has been proven using magnetoencephalography.[13]

Whereas the initial signal provided by the auditory system is needed to start the cascade of events, its strength is irrelevant, as the extent of activation of the limbic and autonomic nervous systems depends on the strength of negative associations linked to tinnitus and the susceptibility of the feedback loops to modification.[114] It appears that tinnitus-related neuronal activity may result from compensatory processes that occur within the cochlea and the auditory pathways to minor dysfunction at the periphery.[12,37]

Notably, once plastic modifications of neuronal connections occur, the peripheral signal itself may become of little importance, as is similarly observed in chronic pain.[38] Indeed, there are clear similarities between tinnitus and chronic pain, including the phenomenon of prolonged exacerbation of tinnitus as a result of exposure to sound, which is observed in some patients.[52,59]

The neurophysiological model includes several systems of the brain involved in analysis of clinically relevant tinnitus. All levels of the auditory pathways, starting from the cochlea through the subcortical centers and ending at the auditory cortex, are essential in creating the perception of tinnitus.[12] When subjects are not bothered or annoyed by tinnitus, auditory pathways are the only pathways involved, and tinnitus-related neuronal activity is constrained within the auditory system. Therefore, although subjects are perceiving tinnitus, they are not disturbed by it.[2,39,114]

In approximately 20% of those with tinnitus, strong negative emotions are induced, which, in turn, evoke a variety of physiological defense mechanisms of the brain. The limbic and autonomic nervous systems play a crucial role, and improper

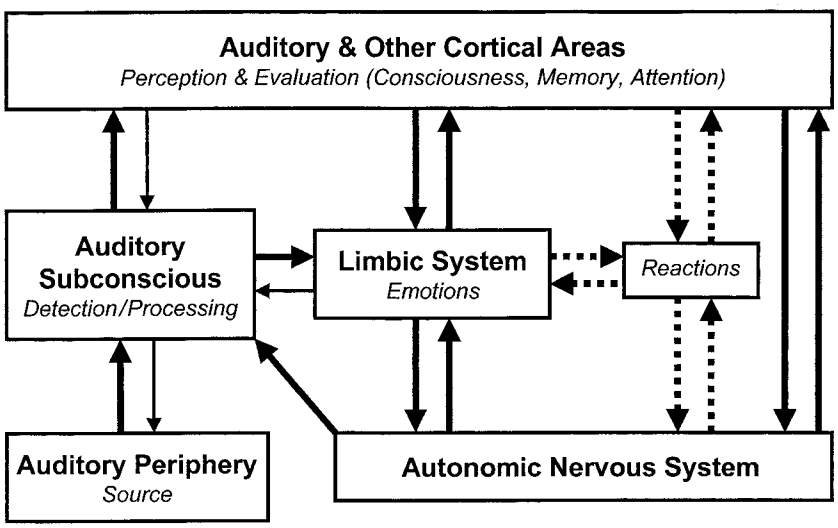

FIGURE 22–1. Neurophysiological model of tinnitus.

activation of these systems by tinnitus-related neuronal activity results at the behavioral level in the problems described by patients. The connections between the auditory, limbic, and autonomic systems with various cortical areas, as proposed in the neurophysiological model of tinnitus, are outlined in Figure 22–1.[6,7,12,37,39,60]

The model points out that the sustained activation of the limbic and autonomic nervous systems is responsible for the distress induced by clinically relevant tinnitus. Activation of both systems can be achieved through two routes. The first includes stimulation of the autonomic and limbic systems from higher-level cortical areas, which are involved in our awareness, verbalization, and beliefs. The second arises from the subconscious and provides stimulation from the lower-level auditory centers. The activation going through these two routes changes the strength of synaptic connections, enhancing the stimulation of the limbic and autonomic nervous systems by the tinnitus-related neuronal activity during the process of development of tinnitus as a clinical problem.

The question of how the neutral signal of tinnitus can evoke persistent strong distress can be answered by the principles of conditioned reflexes.[115] Basically, to create a conditional reflex, the temporal coincidence of sensory stimuli with negative (or positive) reinforcement is sufficient (Figure 22–2).[110,114–116] This initial association can be coincidental, without any real dependence. These types of associations of sensory stimuli are constantly created in normal life.

As long as the sensory stimulus is limited in time and there is no functional link between stimulus and reinforcement, this conditioned reflex will gradually disappear (habituate) owing to passive extinction of the reflex (the sensory stimulus is present but is not accompanied by a reinforcement) (see Figure 22–2). Since the 1930s, habituation has been defined as "The extinction of a conditioned reflex by repetition of the conditioned stimulus, … the method by which the nervous system reduces or inhibits responsiveness during repeated stimulation."[115] Habituation of perception of this stimulus will follow in the same manner as for all unimportant stimuli.

Notably, there are two different types of habituation. The first, *habituation of reaction*, is defined as "disappearance of a reaction to a neutral stimulus due to its repetitive appearance without reinforcement."[117] The second, *habituation of perception*, occurs when awareness of this particular stimulus disappears (Figure 22–3).[7] Habituations of reaction and perception are natural processes. Habituation is a crucial characteristic of brain function necessitated by the brain's inability to perform two tasks requiring complete attention simultaneously. When forced to carry out

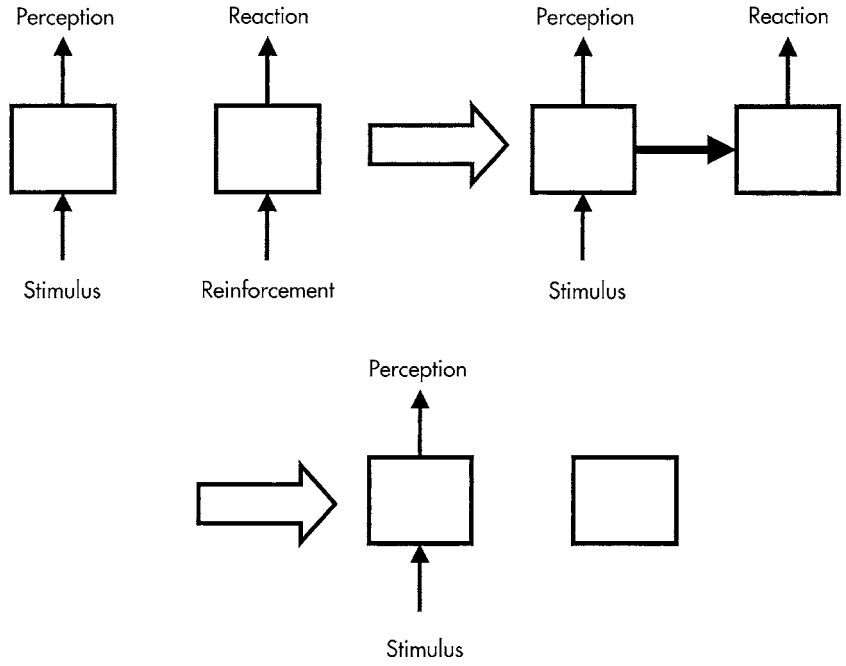

FIGURE 22–2. Principles of establishing conditioned reflexes and their passive extinction.

two tasks concurrently that require full consciousness, the brain uses its function of task switching by actually devoting consciousness to only one task at a time. Recently, brain areas involved in task switching have been indicated by a functional magnetic resonance imaging study.[118] If forced to monitor all of the incoming sensory stimuli, our brain would not be able to perform any tasks, except that of switching perception from one sensory stimulus to the other, ultimately paralyzing us in our actions.

To solve this problem, the central nervous system screens and categorizes all stimuli at the subconscious level. If the stimulus is new and unknown, it is passed to a higher cortical level, where it is perceived and evaluated. However, in the case of a stimulus to which we have previously been exposed, the stimulus is compared with patterns stored in memory. If the stimulus was classified as nonimportant and does not require action, it is blocked at the subconscious level of the auditory pathways and does not produce any reactions or reach the level of awareness. The reaction to this stimulus and its perception is habituated. In everyday life, habituation occurs to the majority of sensory stimuli surrounding us.

However, if a specific stimulus was once classified as important and, on the basis of comparison with the patterns stored in memory, was linked to something unpleasant or dangerous, this stimulus is perceived and attracts attention. Furthermore, the sympathetic part of the autonomic nervous system is activated, inducing reaction to this stimulus (frequently of the "fight or flight" category), which further reinforces memory patterns associated with this stimulus. Consequently, if the previous assessment of the importance of a stimulus has been confirmed, this specific stimulus becomes even more important, and its next appearance will result in faster identification, even in the presence of other competing stimuli, preventing the habituation of this stimulus. In the case of auditory stimuli, our auditory system becomes tuned into recognizing specific patterns of sound that have negative links. Under such conditions, the natural habituation of the tinnitus signal becomes impossible. In everyday life, this results in people having problems with their work, concentration, and sleep.

A simplistic description of the above process can be outlined to a patient as increased concern for tinnitus results in an increase of its significance, which ultimately increases the amount of time a person pays attention to it. This is a classic feedback loop or the "vicious circle" scenario, which increases patients' level of distress up to the limit of mental and physical endurance. At this stage, the patient will move from acute tinnitus, which can be easily relieved by proper counseling, into a chronic stage, which is much more difficult to deal with.

In the case of tinnitus, it is impossible to remove the reactions induced by the excitation of the sympathetic autonomic nervous system or even change them in a substantial manner. The solution to achieve the passive extinction of conditioned reflex, in which both stimulus (tinnitus) and nega-

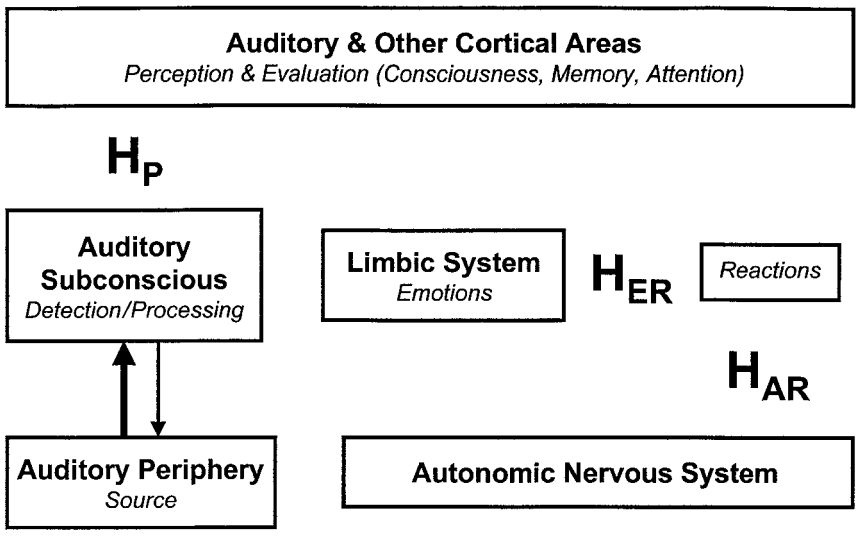

FIGURE 22–3. Habituation of autonomic (H_{AR}) and emotional reactions (H_{ER}) and habituation of perception (H_P).

tive reinforcement are continuously present, is to decrease the magnitude of this negative reinforcement over a period of time. This will result in partial weakening of the reflex but has to be applied consistently to yield positive effects. Moreover, it is fundamental that patients understand these principles so that the enhancement of this reflex by inducing too much verbal thinking and beliefs can be minimalized.

Once activation of the autonomic nervous system is lowered, this decreases negative reinforcement to a signal that is continuously present and gradually decreases the strength of the conditioned reflex. This causes further decreases in the reaction. Once tinnitus has achieved a neutral status, its habituation is inevitable as the brain is continuously habituating to all types of stimuli, assuming that they are not significant.

Consequently, retraining counseling (the first component of TRT) is oriented toward removal of the patient's negative associations with tinnitus and reclassification of tinnitus into a category of neutral stimuli. This is accomplished by educating the patients that their tinnitus results from a normal compensatory mechanism, which occurs in the auditory system, to typically minor changes in the cochlea. As part of counseling, it is also important to demystify the mechanisms through which tinnitus may affect a patient's life. Counseling in TRT is a teaching session aimed at providing patients with a new frame of reference by explaining potential mechanisms of tinnitus generation, neurophysiological mechanisms through which tinnitus is influencing various aspects of their lives, and that by activating a naturally occurring mechanism of brain function (habituation and the plasticity underlying it), it is possible to achieve primarily habituation of the tinnitus-induced reaction of the brain and the body and secondarily habituation of the tinnitus perception. The clear goal of achieving an active and selective block of tinnitus-induced reactions is set for the patients.

In addition to decreasing the strength of the activation of the limbic and autonomic nervous systems, initiated during the counseling session, the second component of TRT is sound therapy.[91,110] All of our senses are working on the principle of differences of the stimuli from the background, and the perceived strength of a signal is not linked directly to the physical strength of a stimulus. At this moment, we cannot easily suppress tinnitus-related neuronal activity, but by increasing background neuronal activity, we are effectively decreasing the strength of this signal, which activates the limbic and autonomic nervous systems and which is being processed in all of the centers involved. There is no simple proportional relationship between the differences in tinnitus and background neuronal activity and the reactions induced by it. Nonetheless, we can achieve a decrease of reactions induced by the tinnitus and, through this, facilitate extinction of the conditioned reflex.

It is important to analyze the theoretical relationships existing between the physical intensity of sound and its effectiveness on tinnitus habituation (Figure 22–4). Five principles influence this relationship[91,110,111,119]: (1) stochastic resonance (enhancement of the signal by adding low-level noise); (2) dependence of the signal's strength on its contrast with the background; (3) total suppression of the signal, preventing any retraining and consequently habituation; (4) partial suppression ("partial masking"), which does not prevent retraining but does make it more difficult as the training is performed on a different stimulus than the original; and (5) activation of limbic and autonomic nervous systems by too loud or unpleasant sounds, yielding an increase in tinnitus and contracting habituation.

It is intuitive that if the sound level is significantly below the threshold level of detection, there is no basis to believe that it asserts any effect on the auditory system and tinnitus. On the other hand, when external sound becomes strong enough to suppress detection of tinnitus-related neuronal activity, by definition, any kind of retraining (including habituation) is prevented because the brain cannot change reactions to a stimulus it cannot detect.

When the sound level is still below but close to the threshold of detection, the phenomenon of stochastic resonance (eg, addition of a low level of noise can decrease the threshold of detection of the stimulus and enhance it when the stimulus is weak and close to the threshold of detection) comes into play.[117] Recently, the presence of stochastic resonance has been shown at the level of hair cells and the auditory nerve, and preliminary data indicate its effect on the loudness of tinnitus.[119–121] The effective sound level inducing stochastic resonance covers a range of about 15 to 20 dB, beginning from about –5 dB below the threshold of detection of the origi-

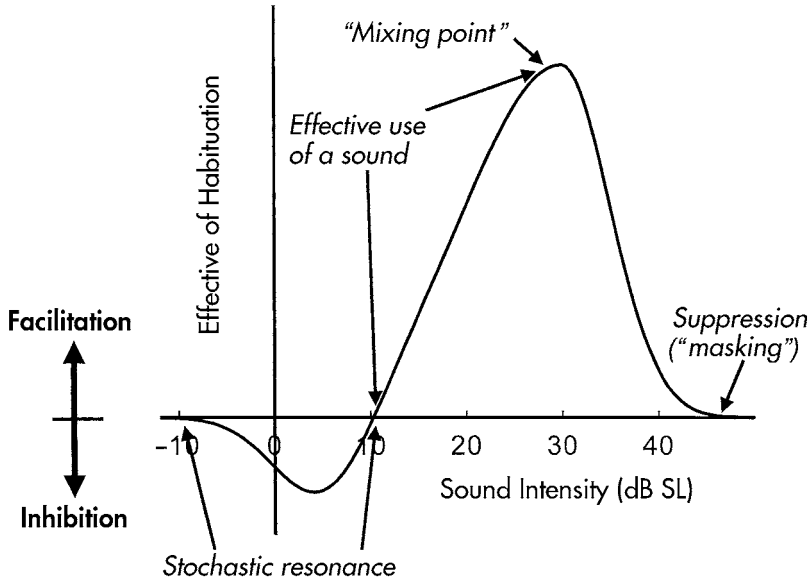

FIGURE 22–4. Functional dependence of habituation effectiveness on physical intensity of a sound. Notice the need to avoid sound levels close to threshold of hearing and those inducing partial or total suppression.

nal signal. Thus, owing to stochastic resonance, by adding low-level external noise (eg, by using sound generators set at the threshold of hearing), paradoxical enhancement of the tinnitus signal occurs. This will, in turn, make habituation more difficult. The results of a study in which a comparison was performed among groups with counseling only (including advice on using environmental sounds), counseling combined with sound generators set at the threshold of hearing, and counseling combined with sound generators set close to the "mixing" point fully support the prediction of the importance of stochastic resonance. The group that performed the worst was the one with the sound level set close to the threshold of hearing, whereas the group that performed the best was the one with the sound level set at the "mixing point," with the counseling-only group in the middle.[122]

When sound level is increased further, the mechanism involving the decreased difference between the tinnitus signals and background neuronal activity becomes the dominant factor. As with all perception, the difference between signal and background plays a dominant role. By decreasing the difference between the tinnitus-related neuronal activity and the background ongoing neuronal activity, the effective strength of the tinnitus signal decreases, and this weaker signal is passed to the higher-level cortical areas and, most importantly, to the limbic and autonomic nervous systems. This helps in initiating and sustaining the process of passive extinction of conditioned reflexes that link tinnitus to negative reactions.[39,110] As the background activity is the sum of spontaneous and evoked activities, a decrease in the difference between the tinnitus signal and the background neuronal activity can be achieved by exposing patients to additional external sound.

This principle, if working alone, would imply that we should use a sound that is as intense as possible. Two other factors (3 and 4), however, become dominant. First, once the tinnitus signal is suppressed, habituation will not occur by definition owing to the lack of a signal to habituate (principle 3). Second, when the sound level surpasses the threshold of partial tinnitus suppression ("partial masking"), it will modify not only the intensity but also the quality of the tinnitus signal. Then retraining of neuronal networks will occur to the modified tinnitus signal and not to the original one. Owing to the generalization principle (eg, reaction can be induced to stimuli similar to the original, with the strength depending on the difference between the original and the modified signals), some habituation may still occur. The higher the external sound is above the threshold of partial masking, the smaller its contribution to habituation. Finally, once a level of total suppression is reached, the effectiveness of habituation is decreased to zero as the brain is unable to retrain to an undetectable signal.

The optimal setting of the sound level is different when hyperacusis is the dominant or only problem. In this situation, the effect of stochastic resonance is of secondary importance to the primary need not to overstimulate the auditory system. Patients start with a sound level closer to their threshold but as high as their sound sensitivity allows, with the aim to be above the range of stochastic resonance. Once a partial reversal of hyperacusis is achieved, the sound level can be increased rapidly to address tinnitus directly. At this point, the rules previously outlined for patients with tinnitus should be followed.

The need to preserve stimulation in the low-frequency range yields a strong recommendation for people who have relatively normal low-frequency hearing to be provided with devices or hearing aids with fittings as open as possible. It is not sufficiently appreciated that in the normal acoustic environment there is a high proportion of low-frequency sounds, below 200 Hz, which provide constant stimulation of the auditory pathways. Since the majority of patients have relatively normal hearing in this frequency range, they benefit from this stimulation. Consequently, blocking the ear canal with closed ear molds decreases the auditory input, and many patients experience enhancement of tinnitus when their ears are blocked.

Note that even the best hearing aids act as earplugs in low frequencies when they are the in-the-canal type or are fitted with a closed mold as they are unable to reproduce frequencies below 200 to 250 Hz owing to restriction based on the physics of sound generation by a loudspeaker. Note that hearing aids for patients with tinnitus are used primarily as a part of sound therapy to provide extra amplification of background sounds and only secondarily for communicative purposes. Other tools may also be used to enrich the auditory background such as nature sounds, neutral music, or tabletop sound generators.

Both counseling and sound use are dependent on patient categorization, and issues related to sound are summarized in Table 22–8. This categorization provides general guidance for treatment with TRT.[59,111] During the process of treatment, patients may move from one category to another (eg, hyperacusis can be totally eliminated and consequently the patient may move from category 3 to 1), and recommendations regarding sound use should be modified. This is one of the reasons why follow-up contacts are important; first, to continue counseling, second, to check patient status; and third, to modify protocol if necessary.

Typically, the first effects of TRT are seen in about 3 months, with clear improvement in about 6 months, and many patients achieve a high level of control of their tinnitus by about 12 months.[47,52,59,125] Patients are advised to follow the TRT protocol for approximately 18 months to prevent a relapse. Improvement in hyperacusis is typically faster, and the success rate is higher than that of tinnitus without hyperacusis. The results from other centers and ours using TRT show satisfactory results in over 80% of patients.[122,124–127]

Treatments for Hyperacusis

Treatments for hyperacusis go into two contrary directions. First, the most common approach is to advise patients to avoid sound and use ear protection. This is based on reasoning that because patients became sensitive to sound, this may indicate that they are more susceptible to sound exposure and consequently need extra protection. Patients easily embrace this philosophy and start to protect their ears, even to the extent of using earplugs in quiet environments. Unfortunately, this approach actually makes the auditory system even more sensitive and further exacerbates hyperacusis.

The second approach involves the desensitization of patients by exposure to a variety of sounds. The desensitization approach has been promoted for some time with a variety of protocols and types of sounds used, such as the recommendation of using sound with certain frequencies removed, short exposures to moderately loud sound, or prolonged exposures to low-level sounds.[50,52,128] According to principles of the neurophysiological model of tinnitus, the latter approach is recommended and is used as part of TRT. Note, that the misophonic component cannot be removed by desensitization, and a separate approach needs to be implemented.

Tinnitus Retraining Therapy for Decreased Sound Tolerance Tinnitus retraining therapy can help patients with both tinnitus and hyperacusis, and the presence of hyperacusis is one of the crucial factors in categorization of the patients (see Table 22–8) and determining the optimal protocol for

TABLE 22–8. Categories of Patients with Tinnitus and Hyperacusis

Category	*Impact on Life*	*Tinnitus*	*Subjective Hearing Loss*	*Hyperacusis*	*Prolonged Sound-Induced Exacerbation*	*Treatment (always involves counseling and use of enriched background sound)*
0	Low	Present	—	—	—	Abbreviated counseling
1	High	Present	—	—	—	Sound generators set at mixing point
2	High	Present	Present	—	—	Hearing aid with stress on enrichment of the auditory background
3	High	Not relevant	Not relevant	Present	—	Sound generators set above threshold of hearing
4	High	Not relevant	Not relevant	Present	Present	Sound generators set at the threshold; very slow increase of sound level

Hyperacusis is significant sensitivity to environmental sounds typically associated with loudness discomfort levels below 100 dB HL; Prolonged Sound-Induced Exacerbation of tinnitus/hyperacusis is when the effects persist to the following day; Subjective Hearing Loss is perceived subjectively by patients as having a significant impact on their life; Impact on Life is the extent of impact of tinnitus and/or hyperacusis on the patient's life. Common treatment for each category involves counseling and the use of an enriched auditory background.

their treatment. It is recommended that if hyperacusis is present, it has to be treated first. Although TRT offers only a treatment for tinnitus (not a cure), it can, in some patients, totally remove hyperacusis and misophonia, thus providing a cure for these conditions.[59,60,111]

In some patients, tinnitus and hyperacusis are two manifestations of the same internal mechanisms of increased gain within the auditory pathways, and the improvement in hyperacusis results in the improvement in tinnitus as well. Moreover, the removal of hyperacusis yields a decrease in general anxiety and stress, which, in combination with proper counseling, significantly facilitates tinnitus habituation.

A few parameters of the TRT protocol are of specific importance in treating patients with hyperacusis: avoidance of silence and continued exposure to sound are even more important than for patients with only tinnitus. The level of sound should be better controlled during the treatment, which necessitates the use of wearable sound generators. The sound used should never induce discomfort or annoyance.

The setting of sound generators for hyperacusis is more complex than for tinnitus treatment. There might be a need for a low setting of initial sound level, which might bring patients to the range of effects of stochastic resonance. The use of real-ear measurements, as a guide in setting and checking sound level for all patients with instrumentation during initial and follow-up visits, is crucial in the case of hyperacusis patients.

The method of desensitization works on the auditory system and consequently will not affect misophonia, which needs to be addressed using active extinction of conditioned reflexes between the auditory and limbic systems. This is achieved in practice by instructing patients to engage systematically in activities involving sound as a fundamental component and that are pleasant (such as actively listening to music).

CONCLUSION

Tinnitus and hyperacusis are still challenging topics to study and symptoms to treat. Many questions remain unanswered. Mechanisms of tinnitus and hyperacusis are speculative and not yet proven. We do not yet have objective methods for detection and evaluation of tinnitus. We believe that the neurophysiological model of tinnitus and TRT provide a

promising approach that may ultimately result in a better understanding of tinnitus and in providing greater help to patients with tinnitus and hyperacusis.

CHAPTER 23

Cochlear Implants

Richard T. Miyamoto, MD, Karen Iler Kirk, PhD

Hearing loss poses a monumental obstacle to the acquisition and maintenance of effective communication skills. The perception and the production of speech are highly dependent on the ability to process auditory information. Early identification of hearing loss is an important first step in managing the effects of hearing impairment. Once identified, the level of residual hearing, if any, must be determined and an appropriate sensory aid recommended. Conventional amplification is usually the initial procedure of choice. If little or no benefit is realized with hearing aids, cochlear implants become therapeutic options. Communication skills and needs must be assessed and a communication mode selected. A sophisticated multidisciplinary team approach that addresses the varied needs of the deaf recipient is required. Essential components of the aural/oral (re)habilitation program include listening skill development, speech therapy, speech-reading training, and language instruction.

Djourno and Eyries first described direct electrical excitation of the auditory nerve in 1957.[1] Since then, increasingly more sophisticated cochlear implants have been developed. Cochlear implants seek to replace a nonfunctional inner ear hair cell transducer system by converting mechanical sound energy into electrical signals that can be delivered to the cochlear nerve in profoundly deaf patients. The essential components of a cochlear implant system are a microphone, which picks up acoustic information and converts it to electrical signals; an externally worn speech processor that processes the signal according to a predefined strategy; and a surgically implanted electrode array that is in the cochlea near the auditory nerve.

The processed signal is amplified and compressed to match the narrow electrical dynamic range of the ear. The typical response range of a deaf ear to electrical stimulation is on the order of only 10 to 20 dB, even less in the high frequencies. Transmission of the electrical signal across the skin from the external unit to the implanted electrode array is most commonly accomplished by the use of electromagnetic induction or radiofrequency transmission. The critical residual neural elements stimulated appear to be the spiral ganglion cells or axons. Damaged or missing hair cells of the cochlea are bypassed.

COCHLEAR IMPLANT SYSTEMS

Multichannel, multielectrode cochlear implant systems are designed to take advantage of the tonotopic organization of the cochlea. The incoming speech signal is filtered into a number of frequency bands, each corresponding to a given electrode in the array. Thus, multichannel cochlear implant systems use place coding to transfer spectral information in the speech signal as well as encode the durational and intensity cues of speech.

Nucleus Cochlear Implant Systems

The Nucleus 22-channel cochlear implant manufactured by Cochlear Ltd. of Australia was the first multichannel cochlear implant to receive US Food and Drug Administration (FDA) approval for use in adults and children, and it has been used in more patients than any other cochlear implant system worldwide.[2] The Nucleus CI24M cochlear implant received FDA approval for adults and children in 1998.

Early speech processing strategies (F0F2 and F0F1F2) for the Nucleus 22-channel cochlear implant used feature extraction strategies that conveyed information about key speech features such as the amplitude and frequency of vowel formants and the fundamental frequency of voiced sounds. The third-generation speech processing strategy, MPEAK, encoded additional high-frequency information by stimulating two of three more basal fixed

electrodes; the goal was to provide additional information that would yield improved consonant recognition scores.

Three processing strategies are currently available for use with the Nucleus cochlear implants. Two of the strategies use the *n-of-m* approach, in which the speech signal is filtered into *m* bandpass channels and the *n* highest envelope signals are selected for each cycle of stimulation.[3] The spectral peak (SPEAK) strategy is the most widely used with the Nucleus 22-channel cochlear implant and is available to users of either the Nucleus 22-channel or the Nucleus CI24M system. This strategy filters the incoming speech signal into 20 frequency bands; on each stimulation cycle, six electrodes (on average) are stimulated at a rate that varies adaptively from 180 to 300 pulses per second. An *n-of-m* strategy using much higher rates of stimulation, known as the Advanced Combined Encoder (ACE) strategy, can be implemented in the new Nucleus CI24M device. The third processing strategy available with the Nucleus CI24M system is the Continuous Interleaved Sampling (CIS) strategy.[4] The CIS strategy filters the speech signal into a fixed number of bands, obtains the speech envelope, and then compresses the signal for each channel. On each cycle of stimulation, a series of interleaved digital pulses rapidly stimulates consecutive electrodes in the array. The CIS strategy is designed to preserve fine temporal details in the speech signal by using high-rate, pulsatile stimuli.

Two different speech processors are available for new Nucleus cochlear implant recipients. The body-worn SPRINT processor (Cochlear Ltd., Australia) can implement any of the three current speech processing strategies. The ear-level ESPRIT speech processor (Cochlear Ltd., Australia) can currently implement only the SPEAK processing strategy.

Clarion Cochlear Implant System

The Clarion multichannel cochlear implant system is manufactured by Advanced Bionics Corporation (Sylmar, Calif.).[5–7] This device has been approved by the FDA for use in adults (1996) and children (1997). The Clarion multichannel cochlear implant has an eight-channel electrode array. Two processing strategies can be implemented through a body-worn processor. The first is CIS, described above, which is used to stimulate monopolar electrodes. The second strategy, Simultaneous Analog Stimulation (SAS), filters and then compresses the incoming speech signal for simultaneous presentation to the corresponding enhanced bipolar electrodes. The relative amplitudes of information in each channel and the temporal details of the waveforms in each channel convey speech information.

Medical Electronic (Med-El) Cochlear Implant System

The Combi 40+ cochlear implant system manufactured by the Med-El Corporation in Innsbruck, Austria, is currently undergoing clinical trials in the United States. The Med-El cochlear implant has 12 electrode pairs and has the capability of deep electrode insertion into the apical regions of the cochlea.[8] This device uses the CIS processing strategy and has the capacity to provide the most rapid stimulation rate of any of the cochlear implant systems currently available. Both body-worn and ear-level speech processors (the CIS Pro+ and Tempo+, respectively) are available for the Med-El cochlear implant.

New Developments in Cochlear Implant Electrode Design

New designs of the internal electrode array have recently been introduced for the Nucleus and Clarion cochlear implants. The Nucleus Contour electrode array is a curved electrode that is straightened by a stylet for insertion purposes. After surgical placement into the scala tympani, the stylet is withdrawn. The electrode then assumes its preformed shape, more closely approximating the modiolar wall of the cochlea (Figure 23–1). The Clarion HiFocus electrode is positioned closer to the modiolar wall by inserting a separate positioner into the scala tympani. Because the spiral ganglion cells are thought to be the sites stimulated by cochlear implants, directing the electrodes toward the modiolus and further positioning the array may improve spatial specificity of stimulation and reduce the current need to drive the electrodes.[9]

PATIENT SELECTION

The selection of cochlear implant candidates is a complex process that requires careful consideration of many factors. Current selection considerations are as follows.

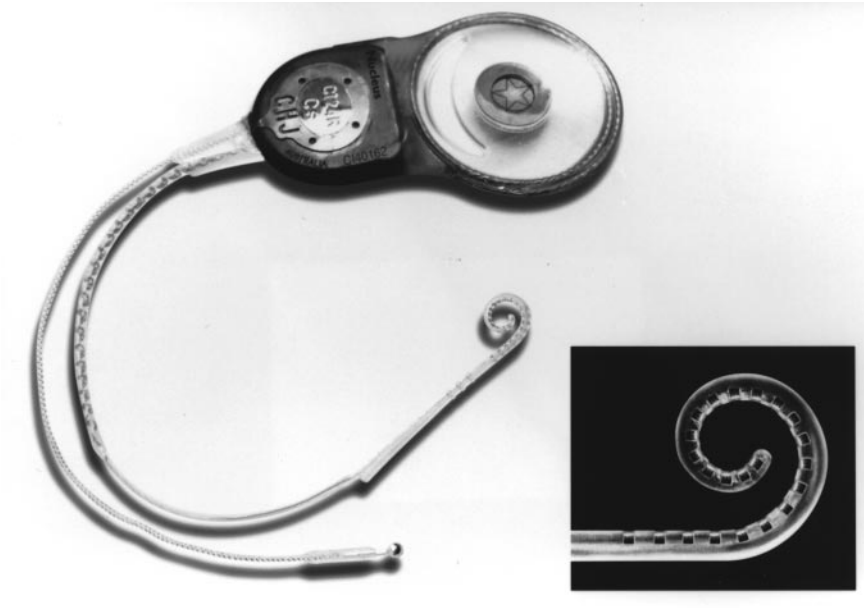

FIGURE 23–1. New electrode design that hugs the modiolus after the insertion stylus is withdrawn. Courtesy of Cochlear Ltd.

Adults

Cochlear implantation was initially limited to postlingually deafened adults who received no benefit from hearing aids and had no possibility of worsening residual hearing. This population, particularly those with a recent onset of deafness, has been the most readily identifiable beneficiary of cochlear implants. A period of auditory experience adequate to develop normal speech perception, speech production, and language skills before the onset of deafness is an invaluable prerequisite. Experience gained with this initial cochlear implant population served to establish expected performance limits.[10]

Table 23–1 presents the current cochlear implant candidacy criteria for adults. Adult candidacy criteria are based primarily on aided speech recognition abilities. No upper age limit is used in the selection process as long as the patient's health will permit an elective surgical procedure under general anesthesia. In a survey of Nucleus 22-channel cochlear implant recipients over the age of 65 years, Horn et al showed that elderly cochlear implant patients obtained benefits that were similar to those obtained by younger adult patients with the same device.[11]

Adult candidacy criteria recently have been broadened to include adults with severe-to-profound hearing loss who derive some limited benefit from conventional hearing aids. Implantation of an ear with any residual, aidable hearing carries the risk that the implanted ear could be made worse than that ear with a hearing aid. Current investigations are testing the hypothesis that an ear with some residual hearing may have a better neuronal population, increasing the likelihood of superior performance with a cochlear implant, especially with more complex multichannel stimulation.

Adults with prelingual hearing loss are generally not considered good candidates for cochlear implantation.[12] However, prelinguistically deafened adults who have followed an aural/oral educational approach may receive significant benefit.

TABLE 23–1. Adult Candidacy Criteria for Cochlear Implantation

Criteria
≥ 18 years of age
Bilateral severe-to-profound hearing loss
Minimal benefit from conventional hearing aids (typically defined as sentence recognition scores < 50 to 60% correct in the best aided condition)
No medical contraindications

Children

Cochlear implant technology complicates the already challenging management of the deaf child. The general selection guidelines applied to adults are applicable to children; however, the selection of pediatric cochlear implant candidates is a far more complex and ever-evolving process that requires careful consideration of many factors. Pediatric candidacy criteria are presented in Table 23–2. In contrast to adults, both pre- and postlingually deafened children are candidates for cochlear implantation.

A trend toward earlier cochlear implantation in children has emerged in an attempt to ameliorate the devastating effects of early auditory deprivation. Electrical stimulation appears to be capable of preventing at least some of the degenerative changes in the central auditory pathways.[13]

Implanting very young children remains controversial because the audiologic assessment, surgical intervention, and postimplant management in this population are challenging. Profound deafness must be substantiated and the inability to benefit from conventional hearing aids demonstrated. This can be difficult to determine in young children with limited language abilities. For very young children, parental questionnaires are commonly used to assess amplification benefit.

Until recently, the youngest age at which children could be implanted under FDA clinical trials was 2 years. In 1998, the age limit was dropped to 18 months, and the most recently initiated clinical trials of new cochlear implant systems permit implantation of children as young as 12 months of age. Because the development of speech perception, speech production, and language competence normally begins at a very early age, implantation in very young congenitally or neonatally deafened children may have substantial advantages. Early implantation may be particularly important when the etiology of deafness is meningitis as progressive intracochlear ossification can occur and preclude standard electrode insertion. A relatively short window of time exists during which this advancing process can be circumvented.

Special consideration must be given to the small dimensions of the temporal bone and to potential problems from postoperative temporal bone growth. In addition, the high incidence of otitis media in children under the age of 2 years might compromise the biosafety of cochlear implants. None the less, extension of implant candidacy to the 6- to 12-month age group is feasible on an anatomic basis. The cochlea is adult size at birth, and by age 1 year, the facial recess and mastoid antrum, which provide access to the middle ear for electrode placement, are adequately developed.[14]

CLASSIFICATION OF COCHLEAR IMPLANT RECIPIENTS

Cochlear implant recipients can be divided into three main categories. Significantly different performance outcomes can be anticipated:

1. *Postlingually deafened adults and children.* Patients who become deaf at or after age 5 years are generally classified as postlingually deafened. These patients have developed many or all aspects of spoken language before the onset of their deafness. However, once they lose access to auditory input and feedback, they frequently

TABLE 23–2. Pediatric Candidacy Criteria for Cochlear Implantation

Children Aged 12 to 23 Mo	*Children Aged 24 Mo to 17 Yr, 11 Mo*
Bilateral profound hearing loss	Bilateral severe-to-profound hearing loss
Lack of auditory skills development and minimal hearing aid benefit (documented by parent questionnaire)	Lack of auditory skills development and minimal hearing aid benefit (eg, word recognition scores < 30% correct)
No medical contraindications	No medical contraindications
Enrolment in a therapy of education program emphasizing auditory development	Enrolment in a therapy of education program emphasizing auditory development

demonstrate rapid deterioration in the intelligibility of their speech. Implantation soon after the onset of deafness can potentially ameliorate this rapid deterioration in speech production and perception abilities. A postlingual onset of deafness is an infrequent occurrence in the pediatric population. If this were to be the only category for which cochlear implants positively impacted deaf children, there would be limited applicability for this technology in children.

2. *Congenitally or early deafened children.* Congenital or early acquired deafness is the most frequently encountered type of profound sensorineural hearing loss in children. The acquisition of oral communication skills can be a difficult process for these children. However, with early implantation and appropriate habilitation, many children in this category are developing spoken language. Although considerable outcome variability exists, the most successful pediatric cochlear implant recipients demonstrate age-appropriate speech and language skills.
3. *Congenitally or early deafened adolescents and adults.* When cochlear implantation is considered in adolescence or young adulthood for a patient who has had little or no experience with sound because of congenital or early-onset deafness, caution must be exercised because this group has not demonstrated high levels of success with electrical stimulation of the auditory system.

AUDIOLOGIC ASSESSMENT

The audiologic evaluation is the primary means of determining suitability for cochlear implantation. Audiologic evaluations should be conducted in both an unaided condition and with appropriately fit conventional amplification. Thus, all potential candidates must have completed a period of experience with a properly fit hearing aid, preferably coupled with training in an appropriate aural re(habilitation) program. The audiologic evaluation includes measurement of pure-tone thresholds along with word and sentence recognition testing. Aided speech recognition scores are the primary audiologic determinant of cochlear implant candidacy. For very young children or those with limited language abilities, parent questionnaires are used to determine hearing aid benefit.

MEDICAL ASSESSMENT

The medical assessment includes the otologic history and physical examination. Radiologic evaluation of the cochlea is performed to determine whether the cochlea is present and patent and to identify congenital deformities of the cochlea. High-resolution, thin-section computed tomographic (CT) scanning of the cochlea remains the imaging technique of choice.[15] Intracochlear bone formation resulting from labyrinthitis ossificans can usually be demonstrated by CT scanning; however, when soft tissue obliteration occurs following sclerosing labyrinthitis, CT may not image the obstruction. In these cases, T_2-weighted magnetic resonance imaging is an effective adjunctive procedure providing additional information regarding cochlear patency. The endolymph/perilymph signal may be lost in sclerosing labyrinthitis. Intracochlear ossification is not a contraindication to cochlear implantation but can limit the type and insertion depth of the electrode array that can be introduced into the cochlea. Congenital malformations of the cochlea are likewise not contraindications to cochlear implantation. Cochlear dysplasia has been reported to occur in approximately 20% of children with congenital sensorineural hearing loss.[16] Several reports of successful implantations in children with inner ear malformations have been published.[17–21] A thin cribriform area between the modiolus and a widened internal auditory canal is often observed[22] and is believed to be the route of egress of cerebrospinal fluid (CSF) when it occurs during surgery or postoperatively. A CSF gusher was reported in several patients. Temporal bone dysplasia also may be associated with an anomalous facial nerve, which may increase the surgical risk.

The precise etiology for the deafness cannot always be determined but is identified whenever possible; however, stimulable auditory neural elements are nearly always present regardless of cause of deafness.[23] Two exceptions are the *Michel deformity*, in which there is congenital agenesis of the cochlea, and the *small internal auditory canal syndrome*, in which the cochlear nerve may be congenitally absent.

Otoscopic evaluation of the tympanic membrane is performed. An otologically stable condition should be present prior to considering implantation. The ear proposed for cochlear implantation must be

free of infection, and the tympanic membrane should be intact. If these conditions are not met, medical or surgical treatment before implantation is required. The management of middle ear effusions in children who are under consideration for cochlear implantation or who already have a cochlear implant deserves special consideration. Conventional antibiotic treatment usually accomplishes this goal, but when it does not, treatment by myringotomy and insertion of tympanostomy tubes may be required. Removal of the tube several weeks before cochlear implantation usually results in a healed, intact tympanic membrane. When an effusion occurs in an ear with a cochlear implant, no treatment is required as long as the effusion remains uninfected. Chronic otitis media, with or without cholesteatoma, must be resolved before implantation; this is accomplished with conventional otologic treatments. Prior ear surgery that has resulted in a mastoid cavity does not contraindicate cochlear implantation, but this situation may require mastoid obliteration with closure of the external auditory canal or reconstruction of the posterior bony ear canal.

PSYCHOLOGICAL ASSESSMENT

Psychological testing is performed for exclusionary reasons to identify subjects who have organic brain dysfunction, mental retardation, undetected psychosis, or unrealistic expectations. Valuable information related to the family dynamics and other factors in the patient's milieu that may affect implant acceptance and performance are assessed.

SURGICAL IMPLANTATION

Cochlear implantation in both children and adults requires meticulous attention to the delicate tissues and small dimensions. Skin incisions are designed to provide access to the mastoid process and coverage of the external portion of the implant package while preserving the blood supply of the postauricular skin. The incision used at the Indiana University Medical Center has eliminated the need to develop a large postauricular flap. The inferior extent of the incision is made well posterior to the mastoid tip to preserve the branches of the postauricular artery. From here the incision is directed posterior-superiorly and then superiorly, without a superior-anterior limb. In children, the incision incorporates the temporalis muscle to give added thickness. A subperiosteal pocket is created for positioning the implant induction coil (Figure 23–2). A bone pocket well tailored to the device being implanted is created, and the induction coil is fixed to the cortex with a fixation suture or periosteal flaps.

Following development of the skin incision, a mastoidectomy is performed. The horizontal semicircular canal is identified in the depths of the mastoid antrum, and the short process of the incus is identified in the fossa incudis. The facial recess is opened using the fossa incudis as an initial landmark. The facial recess is a triangular area bound by (a) the fossa incudis superiorly, (b) the chorda tympani nerve laterally and anteriorly, and (c) the facial nerve medially and posteriorly (Figure 23–3). The facial nerve can usually be visualized through the bone without exposing it. The round window niche is visualized through the facial recess about 2 mm inferior to the stapes. Occasionally, the round window niche is posteriorly positioned and is not well visualized through the facial recess or is obscured by ossification. Particularly in these situations, it is important not to be misdirected by hypotympanic air cells. Entry into the scala tympani is accomplished best through a cochleostomy created anterior and inferior to the annulus of the round window membrane. A small fenestra slightly larger than the electrode to be implanted (usually 0.5 mm) is developed. A small diamond bur is used to "blue line" the endosteum of the scala tympani, and the endosteal membrane is removed by using small picks. This approach bypasses the hook area of the scala tympani, allowing direct insertion of the active electrode array (Figure 23–4). After insertion of the active electrode array, the cochleostomy area is sealed with small pieces of fascia.

Special Surgical Considerations

Cochlear Dysplasia In cases of cochlear dysplasia, a CSF gusher may be encountered on fenestrating the cochlea while performing the cochleostomy. The flow of CSF has been successfully controlled by entering the cochlea through a small fenestra, allowing the CSF reservoir to drain off, inserting the electrode into the cochleostomy, and tightly packing the electrode at the cochleostomy with fascia. It is postulated that the source of the leak is through the lateral end of the internal auditory canal. Supplementally, a lumbar drain can be placed to reduce the

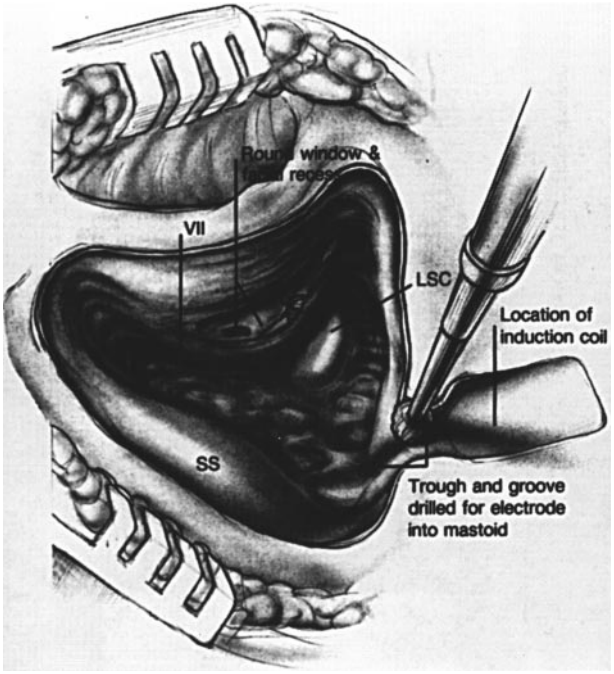

FIGURE 23–2. Mastoidectomy performed to gain access to facial recess. Location of induction coil and trough and groove drilled for electrode implantation into the mastoid. VII = facial nerve VII; LSC = lateral semicircular canal; SS = sigmoid sinus.

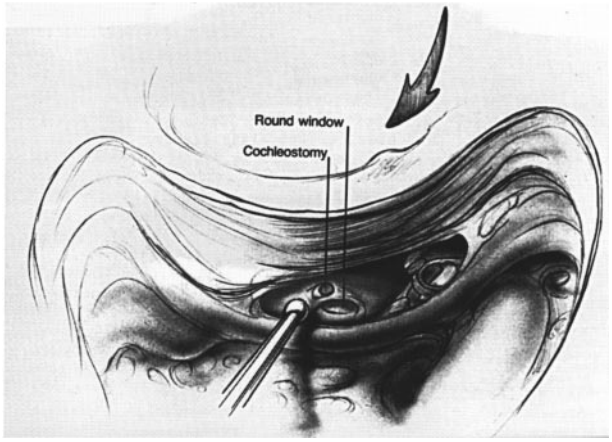

FIGURE 23–3. The facial recess is bounded by the fossa incudis superiorly, the chorda tympani nerve laterally and anteriorly, and the facial nerve medially and posteriorly. A cochleostomy is created anterior and inferior to the round window.

spinal fluid reservoir until a satisfactory tissue seal has occurred. In severe dysplasia cases with a common cavity deformity, the electrode array may be inserted directly by a transmastoid labyrinthotomy approach. The otic capsule is opened posterosuperior to the second genu of the facial nerve, and the common cavity is entered. Several patients have been treated in this way with no vestibular side effects.[24]

Aberrant Facial Nerve In patients who have malformations of the labyrinth, and occasionally in patients with otherwise normal anatomy, the facial nerve may follow an aberrant course. Although not all aberrant facial nerves impact cochlear implant surgery, those that do must be recognized and dealt with effectively. Two anomalous courses of the facial nerve that place it at risk are the laterally and anteriorly displaced vertical portion of the facial nerve and a facial nerve that courses over the promontory over or anterior to the round window.[25]

Intracochlear Ossification Ossification at the round window is common in patients after meningitis and has been encountered in approximately one half of the children whose cause of deafness was meningitis who have received a cochlear implant at our center. In these patients, a cochleostomy is developed anterior to the round window and the new bone is drilled until an open scala is entered. A full electrode insertion can then be accomplished. Less frequently, labyrinthitis ossificans with extensive intracochlear bone formation may occur with complete obliteration of the scala tympani. In these cases, our preference has been to drill open the basal turn of the cochlea and create a tunnel approximately 6 mm deep and partially insert a Nucleus electrode. This allows implantation of 10 to 12 active electrodes, which has yielded very satisfactory results. More recently, a specially designed split electrode developed by the Med-El Corporation has been used wherein one branch of the electrode array is placed in the tunnel described above and the second active electrode is inserted into an additional cochleostomy developed just anterior to the oval window. Gantz and his colleagues described an extensive drill-out procedure to gain access to the upper basal turn.[26] Steenerson et al described insertion of the active electrode into the scala vestibuli in cases of cochlear ossification.[27] Although this procedure has merit, the scala vestibuli is frequently ossified when the scala tympani is completely obliterated.

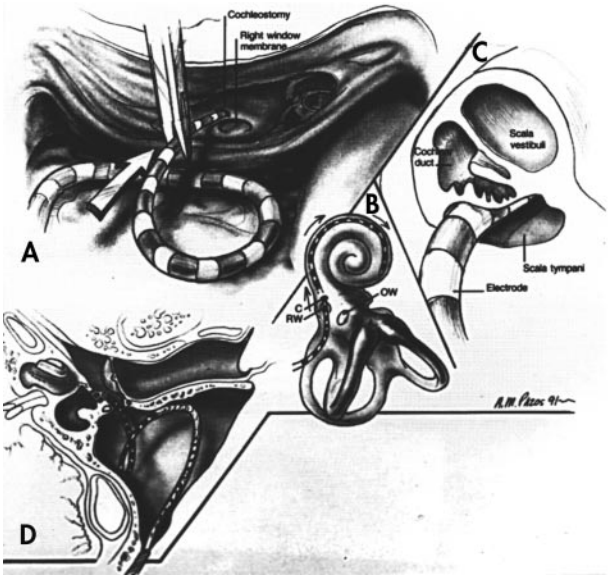

FIGURE 23–4. A, Electrode introduced into the basal turn of the cochlea. *B*, Electrode in the scala tympani (*C*, cross-section of the basal turn on the cochlea). *D*, Receiver-stimulator with a redundant loop of electrode in the mastoid.

Complications Complications have been infrequent with cochlear implant surgery and can largely be avoided by careful preoperative planning and meticulous surgical technique. Among the most commonly encountered problems are those associated with the incision and postauricular flap and facial nerve injury.[28] Using the incision we describe, we have experienced only one flap breakdown in our pediatric cochlear implant population. (This occurred several years postoperatively after head trauma.) We experienced one transient delayed facial paresis and one CSF gusher in a child with a Mondini deformity.[29] Several additional patients with the large vestibular aqueduct syndrome have also had gushers.

Because children are more susceptible to otitis media than adults, justifiable concern has been expressed that a middle ear infection could cause an implanted device to become an infected foreign body, requiring its removal. Two children in our series experienced a delayed mastoiditis (several years after the implant surgery), resulting in a postauricular abscess. These patients were treated by incision and drainage and intravenous antibiotics without the need to remove the implant. Of even greater concern is that infection might extend along the electrode into the inner ear, resulting in a serious otogenic complication, such as meningitis or further degeneration of the central auditory system. To date, although the incidence of otitis media in children who have received cochlear implants parallels that seen in the general pediatric population, no serious complications related to otitis media have occurred in our patients.

CLINICAL RESULTS

Cochlear implants are an established therapeutic option for selected deaf adults and children. However, there remains a wide range of performance with current implant systems. Some cochlear implant recipients can communicate without the benefit of speech reading and are able to communicate on the telephone without a telephone code, whereas others use their implants primarily to reestablish environmental contact and enhance their speech-reading abilities. This variation in performance levels is thought to relate to biologic and cognitive factors. It would be expected that poor auditory nerve survival or atrophic central auditory systems would correlate with poor performance, whereas a more intact auditory nervous system should permit better results, given a well-designed and fitted cochlear prosthesis.[30]

Performance Results in Adults

Early Nucleus cochlear implant systems using feature extraction speech processing strategies yielded moderate vowel and consonant recognition[31] but only limited auditory-only word recognition.[32] However, with each successive generation of Nucleus speech processing strategy, substantial gains were achieved in open-set word and sentence recognition and were reported with mean word and sentence recognition scores of 36 and 74%, respectively, for adults with the SPEAK strategy.[33–38] Similar performance levels have been reported for adults who use either the Clarion or the Med-El cochlear implant system.[39,40] Compared with the results obtained with previous generations of cochlear implants, adults who use the current devices achieve higher word recognition skills and acquire those skills at a faster rate. Many adults now demonstrate substantial speech understanding as early as 3 months following cochlear implantation.[41] On average, multichannel cochlear implant systems provide

moderate to good levels of auditory-only speech understanding to the majority of adult users. However, a great deal of variability in performance remains. Some adults are unable to understand any speech through listening alone, whereas others can communicate successfully on the telephone. As Wilson and his colleagues pointed out, a number of within-subject factors also contribute to successful cochlear implant use.[42] Two such factors are age at implantation and duration of deafness.[41,43–47] Specifically, patients who are implanted at a young age and have a shorter period of auditory deprivation are more likely to achieve good outcomes. The findings regarding other predictive factors have been less conclusive. For example, Gantz et al found that measures of cognitive ability were not associated with patient performance,[32] whereas Cohen et al reported that measures of IQ were significantly associated with good speech perception skills.[44] Other factors that have been found to significantly correlate with adult outcomes include speech-reading ability[44,45] and degree of residual hearing.[45,48]

Performance Results in Children

Postlingually deafened adults and children use the information transmitted by a cochlear implant to make comparisons to previously stored representations of spoken language. However, the majority of children who receive cochlear implants have congenital or prelingually acquired hearing loss. These children must use the sound provided by a cochlear implant to acquire speech perception, speech production, and spoken language skills. Furthermore, because young children have limited linguistic skills and attention spans, the assessment of performance in this population can be quite challenging. To evaluate the communication benefits of cochlear implant use in children effectively, a battery of tests that are developmentally and linguistically appropriate should be employed.[49,50]

Speech Perception Outcomes In early investigations, children who used the Nucleus cochlear implant with a feature extraction strategy demonstrated significant improvement in closed-set word identification (ie, the ability to identify words from a limited set of alternatives) but very limited open-set word recognition.[51,52] The introduction of newer processing strategies yielded greater speech perception benefits in children, just as in adults. Many children with current cochlear implant devices achieve at least moderate levels of open-set word recognition. For example, Cohen et al reported word recognition scores for a group of 19 children that ranged from 4 to 76% words correct with a mean of 44%.[53] Similarly, Osberger et al reported average scores of approximately 30% correct on a more difficult measure of isolated word recognition in children with the Clarion cochlear implant.[54] The development rate of postimplant auditory skills seems to be increasing as cochlear implant technology improves and as children are implanted at a younger age.[53–55] Furthermore, comparison studies have shown that the speech perception abilities of pediatric cochlear implant recipients meet or exceed those of their peers with unaided pure-tone average thresholds ≥ 90 dB HL who use hearing aids.[56,57]

A number of demographic factors have been shown to influence performance results in children with cochlear implants. Early results suggested better speech perception performance in children deafened at an older age, with a corresponding shorter period of deafness.[52,58,59] However, when only children with prelingual deafness (ie, < 3 years) were considered, age at onset of hearing loss was no longer a significant factor.[60] It is evident that earlier implantation yields superior cochlear implant performance in children.[61–66] Although the critical period for implantation of congenitally or prelingually deafened children has not been determined,[67] preliminary evidence suggests that implantation prior to age 3 years may yield improved results.[68–70] Finally, the variables of communication mode and/or unaided residual hearing also influence speech perception performance.[71–74] Oral children, and those who have more residual hearing prior to implantation, typically demonstrate superior speech understanding. This has led to some controversy regarding whether to implant the better- or the poorer-hearing ear.[48,72]

Speech Intelligibility and Language Improvements in speech perception are the most direct benefit of cochlear implantation. However, if children with cochlear implants are to succeed in the hearing world, they must also acquire intelligible speech and their surrounding linguistic system. The speech intelligibility and language abilities of children with cochlear implants improve significantly over time[67,75–78] and, on average, exceed those of their

age- and hearing-matched peers with hearing aids.[77,78] Speech intelligibility and spoken language acquisition are significantly correlated with the development of auditory skills.[76,79] Although a great deal of variability exists, the best pediatric cochlear implant users demonstrate highly intelligible speech and age-appropriate language skills. These superior performers are usually implanted at a young age and are educated in an oral/aural modality.[76]

CONCLUSION

Cochlear implants are an appropriate sensory aid for selected deaf children and adults who receive minimal benefit from conventional amplification. Improvements in technology and refinements in candidacy criteria have secured a permanent role for cochlear implantation. With improved postoperative performance, a clear justification for implanting not only patients with bilateral profound sensorineural hearing loss but also patients with severe sensorineural hearing loss has been established. Patients as young as 12 months of age may be implanted under current FDA guidelines for clinical trials, and experience with even younger children is accumulating.

Wide intersubject performance variability continues to exist. However, most postlingually deafened adults with current cochlear implants achieve auditory-only word recognition and communicate very effectively when auditory cues are combined with speech reading. The best adult recipients can converse fluently without speech-reading cues. Children using cochlear implants have acquired speaking and listening skills and have developed a spoken language system that is beyond what previously could be achieved with hearing aids. Children who are implanted at a young age and use oral communication have the best prognosis for developing intelligible speech and age-appropriate language abilities.

Challenges remain in effectively assessing peripheral auditory neuronal survival and matching electrically transmitted signals to the future potential of the central auditory system in deaf subjects.

CHAPTER 24

Facial Paralysis

Phillip A. Wackym, MD, John S. Rhee, MD

Facial nerve abnormalities represent a broad spectrum of lesions, including numerous congenital and acquired causes.[1] The patient who suffers with facial paralysis experiences not only functional consequences but also the psychological impact of a change in self-image and impaired communicative ability. In fact, a 1991 poll revealed that the level of discomfort that Americans felt on meeting those with facial abnormalities was second only to that associated with interacting with the mentally ill, and this discomfort far exceeded anxiety about encountering the senile, mentally retarded, deaf, blind, and those confined to a wheelchair.[2]

FACIAL NERVE ABNORMALITIES

Congenital

Möbius' Syndrome (Congenital Facial Diplegia) Möbius' syndrome is a rare congenital disorder, which usually includes bilateral seventh nerve paralysis and unilateral or bilateral sixth nerve paralysis. Since the disorder was described, many authors have studied families with the syndrome.[3] It is considered to have an autosomal dominant inheritance pattern with variable expressivity. The inheritance pattern is thought to be no higher than 1 in 50 in families in whom myopathies or other extremity anomalies such as clubfoot, arthrogryposis, or digital anomalies are not present.

The etiology of Möbius' syndrome is unclear. Neuropathologic studies have noted that the nuclei of cranial nerves (CNs) VI, VII, and XII are abnormal, with lesser abnormalities being found in the nuclei of CNs III and XI.[4] Other authors have reported that the facial nerves are smaller or absent at autopsy.[5] Pitner et al advanced yet another hypothesis based on their observation that normal facial nuclei were present on postmortem analysis; they suggested that there was a primary failure of facial muscle development.[6]

The clinical observation of congenital extraocular muscle paralysis and facial paralysis is the typical presentation of this disorder (Figure 24–1). No mass lesions will be found on magnetic resonance imaging (MRI). Ophthalmologic consultation and management are mandatory. Reinnervation procedures such as crossfacial grafts or hypoglossal-facial nerve anastomosis yield poor results, either owing to the paucity of motor end plates or the atrophic seventh nerves. Significant improvements of resting tone and voluntary animation can result from temporalis muscle transposition, which brings in a new neuromuscular system.

Hemifacial Microsomia The term hemifacial microsomia refers to patients with unilateral microtia, macrostomia, and mandibular hypoplasia. Goldenhar's syndrome (oculoauriculovertebral dysplasia) is considered to be a variant of this complex and is characterized by vertebral anomalies and epibulbar dermoids. Although approximately 25% of patients with hemifacial microsomia have facial nerve weakness, one patient with Goldenhar's syndrome has been reported to have aplasia of the facial nerve.[7]

Osteopetrosis Osteopetrosis is a generalized dysplasia of bone that may have an autosomal dominant or recessive inheritance pattern. The recessive form is more rapidly progressive and causes hepatosplenomegaly and severe neural atrophy secondary to bony overgrowth at neural foramina. Optic atrophy, facial paralysis, sensorineural hearing loss, and mental retardation are common in the recessive form, and death usually occurs by the second decade. However, in these severe cases of osteopetrosis, which were previously fatal, bone marrow transplantation has been reported to be of value.[8]

The dominant form causes progressive enlargements of the cranium and mandible and clubbing of

FIGURE 24–1. Möbius' syndrome. *A*, Left facial paralysis and right facial paresis photographed at rest. *B*, With smiling and rightward gaze, the right facial paresis and right sixth nerve paralysis are apparent. Reproduced with permission; copyright © 1992 P. A. Wackym.

the long bones. Increased bone density is seen radiographically. Progressive optic atrophy, trigeminal hypesthesia, recurrent facial paralysis, and sensorineural hearing loss are common. Complete decompression of the intratemporal facial nerve should be performed in patients with recurrent facial paralysis and radiographic evidence of osteopetrosis.

Acquired

Trauma Approximately 90% of all congenital peripheral facial nerve paralysis spontaneously improves, and most can be attributed to difficult deliveries, cephalopelvic disproportion, high forceps delivery, or intrauterine trauma. These types of congenital facial paralysis are often unilateral and partial, especially involving the lower division of the facial nerve. Since these causes involve extratemporal compression, surgical exploration or bony decompression is not indicated.[9]

Blunt trauma resulting in temporal bone fracture is best evaluated with high-resolution temporal bone computed tomographic (CT) scans (Figures 24–2 and 24–3). Temporal and parietal blows to the head may occur anywhere along a coronal arc, from the vertex to the cranial base. When the vector of force is directed toward the base, it classically passes toward the external auditory canal, deflects off the otic capsule, and extends anteromedially along the anterior edge of the petrous bone to the foramen lacerum and foramen ovale. The resulting fracture is described as a longitudinal temporal bone fracture. This is the most common type of temporal bone fracture (approximately 90%) and is also the most common type of fracture associated with facial nerve injury. The geniculate ganglion region of the facial nerve is most frequently injured. The indications for facial nerve decompression and exploration are the same as those discussed in detail under the Bell's palsy section of this chapter.

Frontal and particularly occipital blows to the head tend to result in transverse fractures of the temporal bone. More severe head injury is usually required to cause these fractures.[10] Since they often extend through the internal auditory canal or across the otic capsule, hearing loss and vertigo commonly result. Although only 10 to 20% of temporal bone fractures are transverse in orientation, they cause facial nerve injury in approximately 50% of patients. The anatomic region of the facial nerve most commonly injured is the labyrinthine segment.

Penetrating injuries to the extratemporal facial nerve should be explored urgently to facilitate identification of the transected distal branches using a facial nerve stimulator. If primary repair is not possible, the principles of facial nerve repair using cable grafts, described later in this chapter, should be followed. In infected wounds, urgent exploration and tagging of identified distal branches should precede

FIGURE 24–2. Axial computed tomographic scan with bone windows demonstrates a left longitudinal temporal bone fracture. Reproduced with permission; copyright © 1998 P. A. Wackym.

control of the infection and granulation. Subsequent repair usually requires the use of cable grafts.

Facial nerve injury may occur with otologic surgery. The risk of injury of the facial nerve is particularly high in children with congenital ear malformations.[11,12] Additional groups at higher risk for injury to the facial nerve include infants who are undergoing mastoid surgery since the mastoid tip has not become pneumatized and the facial nerve exits the stylomastoid foramen laterally. In these young children, a semihorizontal, curvilinear skin incision should be used, and, as is the case with all otologic surgery, a facial nerve monitoring system should be used.

Infection *Bacterial.* Facial paralysis as a complication of otitis media has become rare in children owing to the ready access to medical care and antibiotics. Takahashi et al published their series of over 1,600 patients with facial paralysis and found that only 11 of these patients were younger than 20 years old and had facial paralysis owing to otitis media (0.67%).[13] They described the facial paralysis in this group of patients to have a slower progression and less complete paralysis than that seen in Bell's palsy. Temporal bone CT should be performed in all patients to eliminate the diagnosis of coalescent mastoiditis. Intravenous antibiotics in combination with myringotomy and tympanostomy tube placement remain our initial management algorithms for bacterial otitis media complicated by facial paralysis. Bacterial cultures should always be obtained at the time of myringotomy, and antibiotic selection should be tailored to the culture results.

Facial paralysis complicating mastoiditis or cholesteatoma is also rare. In Sheehy's series of over 180 children undergoing surgery for cholesteatoma, only 1 patient (0.5%) had facial nerve weakness.[14] The surgical management of these patients includes mastoidectomy, excision of the cholesteatoma, and appropriate antibiotic therapy.

Infection with the spirochete *Borrelia burgdorferi* (Lyme disease) can result in facial paralysis. This tick-borne infection is endemic to the northeastern United States and is named for the town of Lyme, Connecticut. Widespread infections have been reported from the west coast, Midwest, and east coast, as well as throughout Europe and Australia. As is the case with other spirochete infections, the clinical manifestations of Lyme disease are protean. Facial diplegia has been reported in Lyme disease[15] and should be considered in children presenting with facial paralysis. Serologic diagnosis should be followed by antibiotic therapy. Tetracycline is considered to be the agent of choice; however, erythromycin and penicillin have been successfully used.

Viral. Ramsay Hunt Syndrome (Herpes Zoster Oticus). James Ramsay Hunt (1872–1937), an American neurologist, published his seminal article associating the clinical syndrome that now bears his name with herpetic inflammation of the geniculate ganglion.[16] Critical to the development of this hypothesis was the publication of the pathologic studies of Head and Campbell in 1900, which advanced a new hypothesis regarding the etiology of herpes zoster.[17] This work inspired Hunt to first postulate that the etiology of herpes zoster oticus was recrudescence of herpes varicella-zoster virus (VZV) in the geniculate ganglion.[16] Clinically, Ramsay Hunt's syndrome may have a variety of manifestations. However, the original four classifications of the disease by Hunt included (1) disease affecting the sensory portion of the CN VII, (2) disease affecting the sensory and motor divisions of the CN VII, (3) disease affecting the sensory and motor divisions of the CN VII with auditory symptoms, and (4) disease affecting the sensory and motor divisions of the CN VII with both auditory and vestibular symptoms.

Herpes zoster oticus is the cause of 2 to 10% of all cases of facial paralysis, including 3 to 12% of adults and approximately 5% of children.[1,18–23] Patients may experience paresis or complete paralysis, with the poorest prognosis for recovery in the latter group. Approximately half of patients with Ramsay Hunt syndrome retain some facial motor disturbance; only a few maintain a complete paralysis.[18–21]

Based on the sensory distributions reflected by the VZV recrudescence observed by Hunt over his career,[16,24,25] the most common site of vesicular eruption is in the concha of the auricle (Figure 24–4). In addition, he described three other areas where vesicles can be found during herpes zoster oticus: a small strip of skin on the posteromesial surface of the auricle, the mucosa on the palate, and the anterior two-thirds of the tongue.[24] In his final publication, he detailed the sensory distributions of the facial nerve associated with the geniculate ganglion

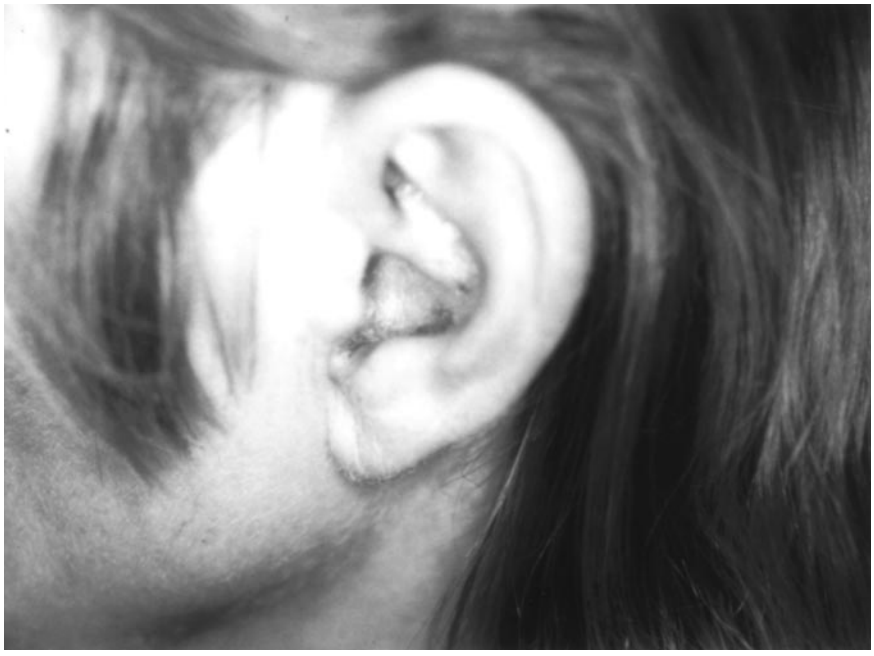

FIGURE 24–4. Vesicles in the concha of a patient with Ramsay Hunt syndrome (herpes zoster oticus) of the left facial nerve. Reproduced with permission; copyright © 2000 P. A. Wackym.

that subserve the axonal transport of the recrudescent VZV to form the vesicles visible during Ramsay Hunt syndrome.

With the advent of gadolinium diethylenetriamine pentaacetic acid (Gd-DTPA)-enhanced magnetic resonance imaging (MRI), acute imaging of the facial nerve is possible throughout the clinical course of Ramsay Hunt syndrome.[26] Despite histopathologic reports of diffuse inflammation along the entire intratemporal facial nerve in the disorder,[18,27–30] Korzec et al found that in three of the six patients with Ramsay Hunt syndrome who were studied with Gd-DTPA MRI, enhancement of the involved nerve was localized to the geniculate ganglion, labyrinthine segment, and the premeatal regions of the affected facial nerve, whereas there was no enhancement at all in the remaining three patients.[26] Likewise, in none of their six patients did they find enhancement of the vertical or tympanic segments of the facial nerve. These findings suggest that in the early stages of the clinical syndrome, the majority of the inflammation is found near the geniculate ganglion, whereas in the later stages, as examined postmortem, the inflammation has extended throughout the intratemporal facial nerve. However, the senior author has seen diffuse enhancement of the facial nerve on MRI examination of patients with Ramsay Hunt syndrome (Figure 24–5).

Blackley et al reviewed the histopathology associated with Ramsay Hunt syndrome in their one case and five others.[27] Aleksic et al added another histologic case.[31] Payten and Dawes reviewed the pathologic studies of herpes zoster oticus with facial paralysis for a 60-year interval.[32] Wackym et al used a molecular approach to demonstrate the presence of VZV deoxyribonucleic acid (DNA) combined with traditional histopathologic techniques to the study of the temporal bones from two patients with Ramsay Hunt syndrome.[30,33] The most consistent observation was diffuse inflammatory infiltration throughout the involved facial nerve; in addition, several investigators have shown lymphocytic infiltration of the geniculate ganglion, alteration of the geniculate ganglion somata, or both conditions.[18,27,29–31] Based on the models of VZV and herpes simplex virus (HSV) latency and reactivation,[34] these findings are expected. Unlike HSV, which remains dormant directly within sensory neuronal somata, VZV remains latent within the non-neuronal satellite cells surrounding each sensory neuronal somata. With recrudescence, the replication VZV virions are released from satellite cells into the extracellular matrix, where some are taken up by the sensory cell body and transported via the axons back to the skin or mucosa. This release of VZV into the extracellular matrix within the geniculate ganglion would cause an immune response that could result in inflammatory infiltrates throughout the intratemporal facial nerve. Therefore, the diffuse lymphocytic infiltration of the entire facial nerve remains consistent with Hunt's hypothesis.[29,30,32] Furuta et al reported the distribution of VZV DNA in 11 (79%) of 14 trigeminal ganglia and in 9 (69%) of 13 geniculate ganglia collected at autopsy of adults.[35] These data suggest that latent VZV in the geniculate ganglion is a common biologic phenomenon; however, the small sample size and the lack of clinical history

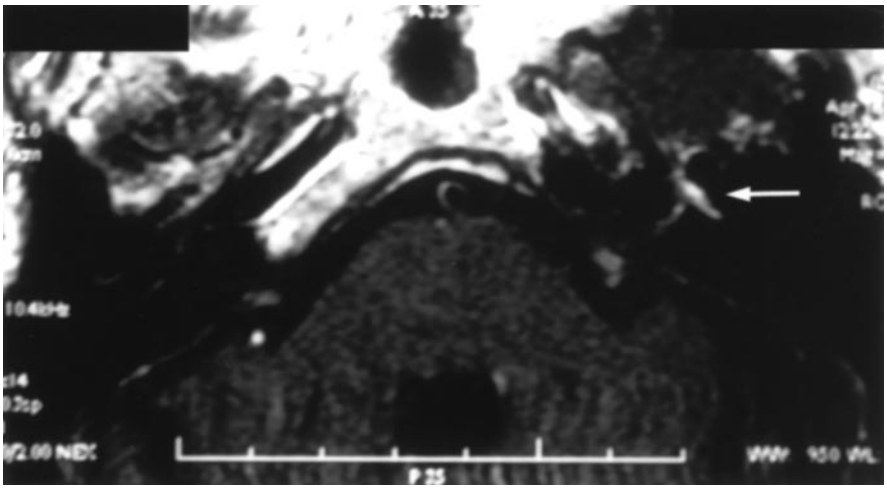

FIGURE 24–5. Magnetic resonance image (MRI) of a facial nerve in Ramsay Hunt syndrome (herpes zoster oticus). regarding whether the patients experienced herpes zoster oticus during their lifetime necessitate confirmation of these observations with a much larger sample size of well-characterized patients.

Other authors have suggested that Ramsay Hunt syndrome represents a cranial polyneuropathy.[28,36,37] Care must be taken in interpreting the histopathologic findings in each case as some may represent cephalic zoster with neuritis of multiple cranial nerves.[28,37] Severe central neurologic deficits or multiple cranial motor neuropathies are well recognized in cephalic zoster.[38,39]

Surgical management with decompression of the facial nerve in Ramsay Hunt syndrome has been advocated by some authors (reviewed by Crabtree).[19] Although the advent of facial electroneuronography (ENoG) has resulted in a better idea about which patients with facial paralysis have severe facial nerve injuries requiring surgical decompression,[40] the diffuse inflammatory edema common in Ramsay Hunt syndrome has led most clinicians to avoid completion of facial nerve decompression.

Experience with the use of intravenous acyclovir (Zovirax) during the acute presentation of Ramsay Hunt syndrome suggests that antiviral medications may facilitate recovery and minimize the morbidity associated with facial paralysis.[23,41–43] This intravenous route has more inherent expenses than an oral route of administration. However, tissue levels of acyclovir delived by an oral route are not high enough to treat varicella-zoster infections. Alternate antiviral agents such as valacyclovir (Valtrex) (1 g orally three times a day for 10 to 14 days) or famciclovir (Famvir) (500 mg orally three times a day for 10 days), which achieve adequate levels by an oral route, are now available as an alternative to intravenous acyclovir for the treatment of patients with Ramsay Hunt syndrome.[44] Because the oral route is much more cost effective, this route is preferred. Likewise, oral corticosteroids have been advocated in patients with Ramsay Hunt syndrome.[45]

BELL'S PALSY. Bell's palsy is responsible for 60 to 75% of all cases of facial paralysis. In the past, Bell's palsy was defined as an "idiopathic facial paralysis" or as a mononeuropathy of undetermined origin. Recent observations have linked the cause to HSV 1.[46,47] Burgess et al, using polymerase chain reaction amplification, identified HSV 1 DNA in paraffin-embedded sections of the geniculate ganglion from a patient who died 6 days after the onset of Bell's palsy.[46] Furuta et al found HSV DNA in 71% of geniculate ganglia and in 81% of trigeminal ganglia in eight random autopsy specimens taken from adult cadavers.[48] These data suggest that latent HSV in the geniculate ganglion may be a common biologic phenomenon; however, the small sample size and the lack of clinical history regarding whether the patients experienced Bell's palsy during their lifetime necessitate confirmation of these observations with a much larger sample size of well-characterized patients. However, genetic, immunologic, vascular, entrapment, and other infectious causes have all been advanced in the etiology of Bell's palsy.[49]

Bell's palsy is an acute, unilateral paresis or paralysis of the facial nerve in a pattern consistent with peripheral nerve dysfunction (Figure 24–6). The onset and evolution are typically rapid, less than 48 hours, and the onset of paralysis may be preceded by a viral prodrome. The symptoms during the early phase of facial paralysis include facial numbness, epiphora, pain, dysgeusia, hyperacusis (dysacusis), and decreased tearing. The pain is usually retroauricular and sometimes radiates to the face, pharynx, or shoulder. Physical findings of this subtle polyneuritis include hypesthesia or dysesthesia of the CNs V and IX and of the second cervical nerve.[50] Motor paralysis of branches of the CN X is seen as a unilateral shift of the palate or vocal cord paresis/paralysis.

Recurrence of Bell's palsy occurs in 7.1[51] to 12%[1] of patients. In the series of 140 patients with recurrent Bell's palsy reported by Pitts et al, ipsilateral recurrences were as common as development of contralateral Bell's palsy.[51] Also of note in this series was the observation that the incidence of diabetes mellitus was 2.5-fold greater than nonrecurrent cases.

Gadolinium-enhanced MRI has been advocated as a diagnostic tool in assessing Bell's palsy. Gadolinium enhancement of the normal facial nerve does not occur. Therefore, enhancement of this structure would be owing to increased extracellular fluid from edema, inflammation, or neoplasm. Our observations with gadolinium-enhanced MRI in Bell's palsy, as well as those of others,[26] are supportive of Fisch's hypothesis of axoplasmic damming at the meatal segment with subsequent edema and nerve conduction impairment (Figure 24–7).[52] However, one study demonstrated that there was no

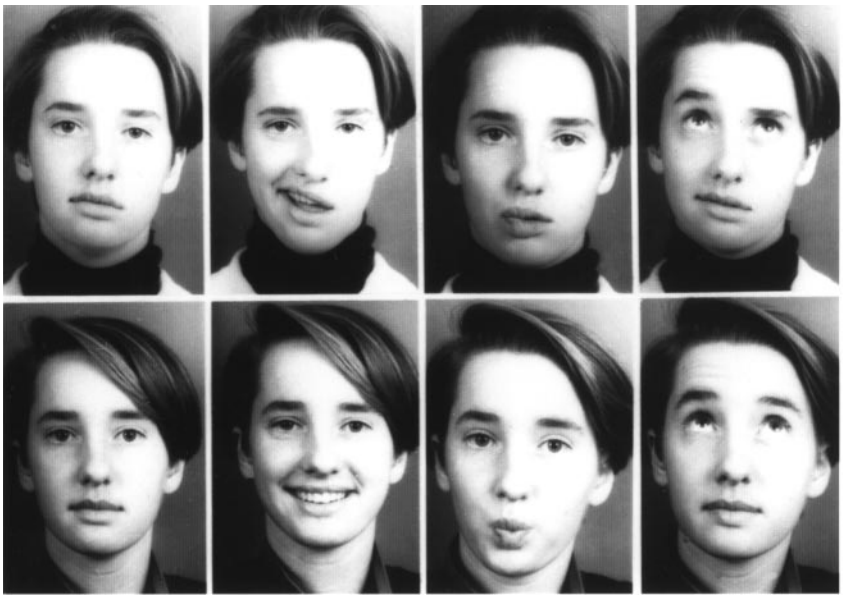

FIGURE 24–6. Preoperative facial photographs of a child with complete facial paralysis owing to Bell's palsy, *top row*. prognostic significance of gadolinium enhancement of the facial nerve on MRI in patients with Bell's palsy.[26] Therefore, gadolinium-enhanced MRI is not indicated in every patient with facial paralysis. In patients suspected of having a tumor from clinical or electrodiagnostic data, gadolinium-enhanced MRI, along with high-resolution CT of the internal auditory canal (IAC), fallopian canal, skull base, and parotid, should be performed.

Adour and colleagues examined the outcome of treating patients with Bell's palsy with both acyclovir and corticosteroids in a prospective, randomized, double-blind trial.[53] Half of the patients received a 10-day course of oral acyclovir (400 mg five times per day) and prednisone. The control group received prednisone and a placebo. All study patients began treatment within 3 days of the onset of facial paralysis. The placebo-prednisone group had lower facial function recovery scores (House-Brackmann grade III or IV in 23%) and was almost three times as likely to have an unsatisfactory result as the acyclovir-prednisone group (only 7% of the acyclovir-prednisone group had a House-Brackmann grade III or IV).

Electroneuronography provides a quantitative assessment of facial nerve function and allows a relative comparison between the normal and affected sides and will be discussed in more detail later in this chapter. Our criteria for surgical decompression include ENoG degeneration greater than 90% relative to the unaffected side, no voluntary facial nerve electromyographic (EMG) activity on the affected side, and the operation within 14 days of onset.[40,54,55] Decompression is limited to the meatal and labyrinthine segments through a middle cranial fossa approach.[55–57] Fisch and Esslen, in 1972, were the first to propose that the most likely site for neural compression and conduction block in Bell's palsy was at the entrance to the meatal foramen, the narrowest bony point through which the facial nerve passes.[58] Interestingly, intraoperative evoked EMG documented the conduction block at this area in 94% of decompressed cases, and marked swelling proximal to this point was the typical observation.[58,59] Gantz et al published a prospective study in which a well-defined surgical decompression of the facial nerve was performed in a population of patients with Bell's palsy who exhibited the electrophysiologic features associated with poor outcomes (ENoG degeneration greater than 90% relative to the unaffected side, no voluntary facial nerve EMG activity on the affected side).[55] Subjects who did not reach 90% degeneration on ENoG within 14 days of paralysis all returned to House-Brackmann grade I (n = 48) or II (n = 6) at 7 months after onset of the paralysis. Control subjects self-selecting not to undergo surgical decompression when > 90% degeneration on ENoG and no motor unit potentials on EMG were identified had a 58% chance of having a poor outcome at 7 months after onset of paralysis (House-Brackmann grade III or IV [n = 19]). A group with similar ENoG and EMG findings undergoing middle fossa facial nerve decompression exhibited House-Brackmann grade I (n = 14) or II (n = 17) in 91% of the cases. It is recommended that these criteria and this surgical algorithm be followed.

Other Viral Infections. Other viral infections such as primary chickenpox, mononucleosis, mumps, and poliomyelitis can result in facial paralysis that may or may not resolve spontaneously. For these specific viral infections, immunization, when available, is the most effective preventive measure, and supportive care is required during the active infection. Facial reanimation procedures are sometimes required after adequate follow-up suggests that spontaneous recovery will not occur.

Benign or Malignant Neoplasms Tumor involvement of the facial nerve should be considered in facial paralysis if one or more of the following clinical features are present: facial paralysis that progresses slowly over 3 weeks, recurrent ipsilateral facial paralysis, facial weakness associated with muscle twitching, long-standing facial paralysis (greater than 6 months), facial paralysis associated with other CN deficits, or evidence of malignancy elsewhere in the body.

Several benign and malignant tumors can involve the facial nerve along its intracranial, intratemporal, or extracranial course (Table 24–1). Schwannoma is the most common primary tumor of the facial nerve. It is benign and usually involves the labyrinthine, tympanic, and mastoid segments of the facial nerve. Nerve resection and interpositional nerve grafting may initially be necessary for restoration of continuity[60,61]; however, decompression will often give patients many years of facial nerve function before resection and grafting must be completed.

The use of radiographic imaging is indicated if the characteristics of the facial paralysis are suggestive of a neoplasm. Radiographic studies should include visualization of the entire course of the facial nerve, from the brainstem to the facial musculature. Gadolinium-enhanced MRI (Figure 24–8) is extremely useful in imaging solid tumors involving the facial nerve, and high-resolution CT scans are useful in identifying bony erosion of the fallopian canal.

Tumors may arise in the vicinity of the facial nerve and cause facial weakness either by compression or direct invasion. When the tumor is benign, the continuity of the facial nerve should be preserved at all costs by sharp dissection and mobilization techniques. This is appropriate management, whether the nerve is compromised in the IAC by an acoustic neuroma or in the parotid gland by a pleomorphic adenoma. A malignant process with direct invasion of the nerve usually mandates resection of the involved portion of the nerve with immediate interpositional nerve grafting. If the management of the disorder involves chemotherapy or radiation therapy rather than surgical intervention, facial

TABLE 24–1. Causes of Facial Paralysis

Birth and Congenital
- Aplasia of the facial nerve
- Molding
- Forceps delivery
- Myotonic dystrophy
- Möbius' syndrome

Trauma
- Barotrauma
- Brainstem injuries
- Cortical injuries
- Facial (soft tissue injuries)
- Penetrating injury to middle ear
- Temporal bone fractures

Neurogenic
- Millard-Gubler syndrome (abducens palsy with contralateral hemiplegia owing to lesion in base of pons involving corticospinal tract)
- Opercular syndrome (cortical lesion in facial motor area)

Infection
- Bell's palsy
- Acute or chronic otitis media
- Cholesteatoma, acquired and congenital
- Herpes zoster oticus (Ramsay Hunt syndrome)
- Mastoiditis
- Malignant otitis externa
- Meningitis
- Parotitis
- Chickenpox
- Encephalitis
- Poliomyelitis
- Mumps
- Mononucleosis
- Leprosy
- HIV (human immunodeficiency virus)
- Influenza
- Coxsackie virus
- Malaria
- Syphilis
- Tuberculosis
- Botulism
- Mucormycosis
- Lyme disease

Vascular
- Endovascular embolization (external carotid artery branches)
- Intratemporal aneurysm of internal carotid artery
- Anomalous sigmoid sinus

Neoplastic
- Facial neuroma
- Acoustic neuroma (rapid expansion or post resection)
- Paraganglioma (glomus jugulare)
- Leukemia
- Meningioma
- Hemangiopericytoma
- Hemangioma
- Hemangioblastoma
- Pontine glioma
- Sarcoma
- Hydradenoma (external auditory canal)
- Teratoma
- Fibrous dysplasia
- von Recklinghausen's disease
- Carcinomatous encephalitis
- Cholesterol granuloma
- Carcinoma (invasive or metastatic)

Genetic and Metabolic
- Diabetes mellitus
- Hyperthyroidism
- Pregnancy
- Hypertension
- Alcoholic neuropathy
- Sickle cell disease
- Bulbopontine paralysis
- Oculopharyngeal muscular dystrophy
- Camurati-Engelmann disease (hereditary diaphyseal dysplasia)

Toxic
- Thalidomide (cranial nerves VI and VII with atretic external ears [Miehlke syndrome])
- Tetanus
- Diphtheria
- Carbon monoxide
- Lead intoxication

Iatrogenic
- Anesthesia, local (mandibular block, face, mastoid)
- Tetanus vaccination
- Vaccine treatment for rabies exposure
- Otologic and neurotologic skull base surgery, parotid surgery
- Interventional neuroradiology (embolization)

Multiple sclerosis	Kawasaki's disease
Myasthenia gravis	

reanimation procedures may be indicated if there is persistent facial nerve dysfunction.

Hemifacial Spasm Hemifacial spasm is typically a disorder of the fourth and fifth decades of life and occurs twice as often in women as it does in men. Electrophysiologic and surgical observations indicate that the facial nerve hyperactivity in hemifacial spasm is caused by vascular compression of the facial nerve.[62] Trigeminal neuralgia, hemifacial spasm, glossopharyngeal neuralgia, tinnitus, and disabling positional vertigo have all been associated with vascular compression.[63] Microvascular decompression operations involve separating the compressive vessel from its point of contact with the CN root entry or exit zone and interposition of a prosthesis (usually Teflon felt) to prevent further nerve compression.[62] Drawing from the experience with the more common microvascular compression syndrome of the trigeminal nerve, large series have reported that 62 to 64% of trigeminal neuralgia patients have a compressive artery, 12 to 24% have a compressive vein, 13 to 14% have both an artery and a vein, and 8% have either a tumor or vascular malformation pressing on the trigeminal nerve.[64] The initial failure rate for microvascular decompression for trigeminal neuralgia is 2 to 7%, with a 3.5% per year incidence of a major recurrence.[65–67] In the series of 1,185 patients who underwent microvascular decompression for trigeminal neuralgia reported by Barker et al in 1996, there was a mean follow-up of 6.2 years, and 30% of patients experienced a major recurrence, with 11% requiring a second microvascular decompression.[68] The absence of a clear site of arterial compression has been associated with high recurrence rates.[68,69] Patients found to have only venous compression and no arterial compression are more likely to suffer a recurrence.[68] Kureshi and Wilkins reported their surgical experience with 31 posterior fossa re-explorations for recurrent or persistent trigeminal neuralgia and hemifacial spasm.[70] They discovered 3 (10%) cases in which there was new or previously unrealized arterial compression of neural structures. Similarly, a series of

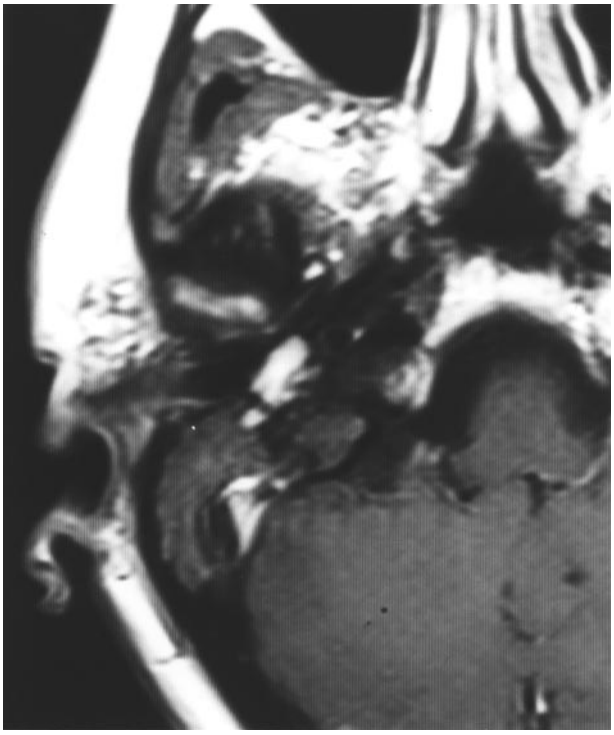

FIGURE 24–8. Gadolinium-enhanced axial magnetic resonance image shows an extensive facial neuroma with extension into the cochlea and internal auditory canal. Reproduced with permission; copyright © 2000 P. A. Wackym.

116 patients with microvascular compression syndrome reoperated on after failure reported the identification of previously unseen arterial compression in 65.5%.[71] Liao et al discovered persistent vascular compression in three of five patients undergoing repeat microvascular decompression.[72]

Although some have doubted that microvascular compression of a CN can represent the cause of hemifacial spasm, the literature indicates that the identification of an arterial vessel compressing the facial nerve in hemifacial spasm and subsequent decompression results in higher cure rates and decreased recurrences than when a specific artery is not identified. We believe that some microvascular decompression procedures fail because the offending vessel has not been identified at the primary operation.[62] Some of these failures occur because the microscope provides incomplete information about the anatomic relationship between the nerves and vessels. The zero-degree endoscope provides a panoramic view of the cerebellopontine angle, and with angled endoscopes, provision for "looking around corners" is made. Magnan et al used an endoscope in 60 patients with hemifacial spasm and demonstrated that the operating microscope was able to visualize the offending vessel in 28% of patients, whereas the endoscope was effective in 93% of the same patients.[73] We have advocated the adjunctive use of the endoscope in microvascular decompression surgery and believe that this will improve surgical outcomes.[62]

Miscellaneous Disorders The onset of simultaneous bilateral facial paralysis suggests Guillain-Barré syndrome, sarcoidosis, sickle cell disease, or some other systemic disorder. Guillain-Barré syndrome is a relatively common neurologic disorder and is an acute inflammatory polyradiculoneuropathy that progresses to varying degrees of paralysis. The etiology remains unknown; however, autoimmune or viral mechanisms have been considered. Classic histopathologic features of the syndrome include a lymphocytic cellular infiltration of peripheral nerves and destruction of myelin. The facial paralysis is typically bilateral and often resolves spontaneously after a prolonged course of paralysis. Although there is no role for surgical decompression of the facial nerve in this disorder, reanimation is only considered late in the course of the disease.

Melkersson-Rosenthal Syndrome Melkersson-Rosenthal syndrome is a neuromucocutaneous disease with a classic triad of recurrent facial (labial) edema and recurrent facial paralysis associated with a fissured tongue. Patients with Melkersson-Rosenthal syndrome may not present with the complete triad, and although facial paralysis is the most commonly recognized neurologic symptom, it is not mandatory for the diagnosis. Headache, granular cheilitis, trigeminal neuralgiform attacks, dysphagia, laryngospasm, and a variety of CN and cervical autonomic dysfunctions may also occur. The patient with Melkersson-Rosenthal syndrome may present at any age and with any variety of classic and associated features, which may wax and wane. Approximately one-third of the patients have recurrent facial paralysis as part of their syndrome. The underlying etiologic factor has been thought to be a neurotropic edema causing compression and paralysis of the facial nerve as it passes through the fallopian canal. Since the anatomically most constricted area of the fallopian canal is the meatal foramen and because most prior reports observed recurrence after transmastoid decompression, Graham and Kemink elected to decompress the proximal segment in addition to the mastoid segment of the facial nerve in all such cases by performing a combined transmastoid and middle cranial fossa facial nerve decompression and neurolysis of the nerve sheath.[74] The preliminary data presented by Graham and Kemink suggest that edematous involvement of the facial nerve in recurrent facial paralysis does occur intratemporally and that the recurrent paralysis can be prevented by transmastoid and middle cranial fossa total facial nerve decompression with neurolysis of the facial nerve sheath.[74] Recurrent paralysis over a prolonged period of time usually results in increasing residual dysfunction. If evidence of residual paresis exists, facial nerve decompression of the labyrinthine segment and geniculate ganglion through a middle cranial fossa exposure is recommended at the time of the next episode of paralysis.

SURGICAL ANATOMY OF THE FACIAL NERVE

Detailed knowledge and familiarity with the complex course of the facial nerve and its anatomic relationship to other vital structures are essential to the surgeon who plans to operate in this area. The facial

nerve (CN VII) exits the brainstem at the pontomedullary junction approximately 1.5 mm anterior to the vestibulocochlear nerve (CN VIII). The facial nerve is smaller in diameter (approximately 1.8 mm) than the oval CN VIII (approximately 3 mm in the largest diameter). A third smaller nerve, the nervus intermedius, emerges between CN VII and CN VIII and eventually becomes incorporated within the sheath of CN VII. After leaving the brainstem, CN VII follows a rostrolateral course through the cerebellopontine cistern for 15 to 17 mm, entering the porus of the IAC of the temporal bone (Figure 24–9). Other important structures in the cerebellopontine cistern include the anterior inferior cerebellar artery (AICA) and the veins of the middle cerebellar peduncle. The AICA passes near or between CN VII and CN VIII; the veins are more variable in position and number. On entering the IAC, the facial nerve occupies the anterosuperior quadrant of this channel for 8 to 10 mm. Then it enters the fallopian canal at the fundus of the IAC. The IAC is anterior to the plane of the superior semicircular canal (SSC). Superiorly, the bone overlying the IAC is within a 60-degree angle, whose vertex is the SSC ampulla. At the entrance of the fallopian canal (meatal foramen), CN VII narrows to its smallest diameter, 0.61 to 0.68 mm.[75,76] Only the pia and arachnoid membranes form a sheath around the nerve at this point since the dural investment terminates at the fundus of the IAC. Many authors believe that the small diameter of the meatal foramen is an important factor contributing to the etiology of facial paralysis in certain diseases such as Bell's palsy and Ramsay Hunt syndrome.[52,59,75,77]

The intratemporal course of the facial nerve has three distinct anatomic regions: the labyrinthine, tympanic, and mastoid segments. The labyrinthine segment is shortest (approximately 4 mm), extending from the meatal foramen to the geniculate ganglion. This segment travels anterior, superior, and lateral, forming an anteromedial angle of 120 degrees with the IAC portion. The basal turn of the cochlea is closely related to the fallopian canal and lays anteroinferior to the labyrinthine segment of the facial nerve. At the lateral end of the labyrinthine segment, the geniculate ganglion is found, and the nerve makes an abrupt posterior change in direction, forming an acute angle of approximately 75 degrees. Anterior to the geniculate ganglion, the greater superficial petrosal nerve exits the temporal bone through the hiatus of the facial canal. The hiatus of the facial canal is quite variable in its distance from the geniculate ganglion. The hiatus of the facial canal also contains the vascular supply to the geniculate ganglion region. The tympanic, or horizontal, segment of the nerve is approximately 11 mm long, running between the lateral semicircular canal superiorly and the stapes inferiorly, forming the superior margin of the fossa ovale. Between the tympanic and mastoid segments, the nerve gently curves inferiorly for about 2 to 3 mm. The mastoid, or vertical, segment is the longest intratemporal portion of the nerve, measuring approximately 13 mm. As the nerve exits the stylomastoid foramen at the anterior margin of the

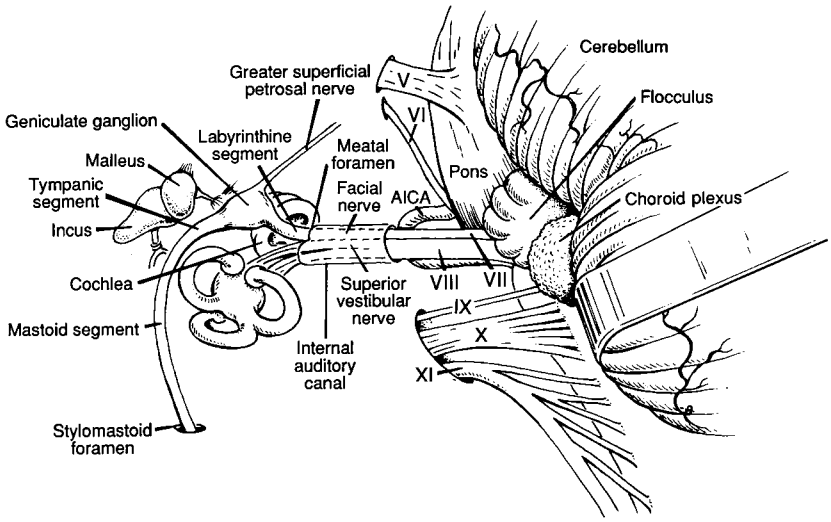

FIGURE 24–9. Course and relationships of the left facial nerve from the pontomedullary junction to the stylomastoid foramen. AICA = anterior inferior cerebellar artery. Reproduced with permission ©2001 P. A. Wackym.

digastric groove, an adherent fibrous sheath of dense vascularized connective tissue surrounds it. The stylomastoid artery and veins are within this dense sheath.

NERVE INJURY AND NEURODIAGNOSTIC TESTS

Facial Nerve Histology

A connective tissue layer, the endoneurium, surrounds each myelinated axon (Figure 24–10). This layer is closely adherent to the Schwann cell layer of each axon. The importance of the endoneurial sheath, in the context of nerve injury and repair, is that it provides a continuous tube through which a regenerating axon can grow. The second layer of the nerve sheath is the perineurium. The perineurium provides tensile strength to the nerve. The perineurium is also the primary barrier to the spread of infection. The outermost layer is the epineurium. This layer contains the vasa nervorum, providing the blood supply as well as the lymphatic vessels.

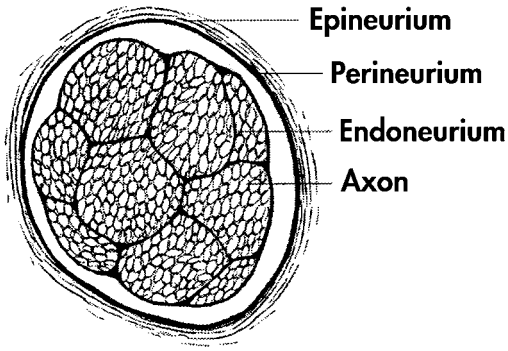

FIGURE 24–10. Schematic illustration of a cross-section of the facial nerve demonstrating the relationships among endoneurium, perineurium, and epineurium. Reproduced with permission; copyright © 2001 P. A. Wackym.

Facial Nerve Injury

It is necessary to review the types of nerve damage to understand better electrodiagnostic testing of the facial nerve, prognosis for recovery, and the development of synkinesis, as well as the rationale for facial nerve decompression. Table 24–2 summarizes the Sunderland and Seddon classifications of nerve injuries.[78,79] A facial nerve grading system has been established by the American Academy of Otolaryngology-Head and Neck Surgery (Table 24–3).[80] The House-Brackmann scoring system was developed as a means of reporting facial recovery after facial nerve paralysis caused by idiopathic facial nerve paralysis or recovery after removal of an acoustic neuroma when an injury to the facial nerve had been sustained.[80] Although this scale is useful when measuring facial nerve function in patients who have suffered an incomplete nerve injury (Sunderland degree I to IV [see Table 24–2]), it is inappropriate for assessing patients who have suffered Sunderland degree V injury and have undergone facial nerve repair or grafting. Gidley et al identified three reasons why it is difficult to apply the House-Brackmann grading system to a repaired facial nerve: (1) all repairs result in mass movement, (2) most patients regain complete eye closure and competent oral sphincter function, and (3) almost none have the ability to raise their forehead.[81] Consequently, they have proposed a grading system that more accurately grades the outcome from facial nerve grafting or repair procedure (Table 24–4). A letter

TABLE 24–2. Sunderland and Seddon Classifications of Nerve Injuries

Pathology	*Sunderland*[78]	*Seddon*[79]
Conduction block, damming of axoplasm	First degree	Neurapraxia
Transection of the axon with intact endoneurium	Second degree	Axonotmesis
Transection of nerve fiber (axon and endoneurium) inside intact perineurium	Third degree	Neurotmesis
Above plus disruption of perineurium (epineurium remains intact)	Fourth degree	Neurotmesis
	Fifth degree	Neurotmesis

TABLE 24–3. House-Brackmann Facial Nerve Grading System

Grade	*Description*	*Characteristics*
I	Normal	Normal facial function in all areas
II	Mild dysfunction	*Gross:* slight weakness noticeable on close inspection; may have very slight synkinesis
		At rest: normal symmetry and tone
		Motion: forehead—moderate to good function; eye—complete closure with minimal effort; mouth—slight asymmetry
III	Moderate dysfunction	*Gross:* obvious but not disfiguring difference between the two sides; noticeable but not severe synkinesis; contracture and/or hemifacial spasm
		At rest: normal symmetry and tone
		Motion: forehead—slight to moderate movement; eye—complete closure with effort; mouth—slightly weak with maximal effort
IV	Moderately severe dysfunction	*Gross:* obvious weakness and/or disfiguring asymmetry
		At rest: normal symmetry and tone
		Motion: forehead—none; eye—incomplete closure; mouth—asymmetric with maximum effort
V	Severe dysfunction	*Gross:* only barely perceptible motion
		At rest: asymmetry
		Motion: forehead—none; eye—incomplete closure; mouth—slight movement
VI	Total paralysis	No movement

Adapted from House JW and Brackmann DE.[80]

grading system was chosen to avoid confusion with the House-Brackmann classification.

Electroneuronography and Electromyography
The two most useful objective electrodiagnostic tests of facial nerve function are ENoG and EMG.

Facial Electroneuronography. Electroneuronography uses supramaximal electrical stimulation of the facial nerve at the level of the stylomastoid foramen to produce a compound muscle action potential. This evoked electromyogenic response is recorded with surface electrodes placed over the perioral (nasolabial) muscles since a large representative population of facial nerve fibers would be sampled by recording the evoked response from this group of muscles. Needle electrodes are not used because intramuscular needle electrodes would not sample a sufficient number of motor units to yield the representative maximal amplitude. A supramaximal bipolar stimulation (galvanic) is provided to saturate the nerve and produce a complete and synchronous depolarization. The galvanic stimulation is typically delivered as rectangular pulses, with a duration of 200 μs and an interpulse interval of 1 s. The amplitude of the evoked response is plotted as a function of time after stimulation. Both the normal and affected sides are tested, and the amplitude of the responses is compared. The percentage of degenerated fibers is calculated arithmetically, as follows:

$$\text{Percentage of degenerated fibers} = 100 - \left(\frac{\text{Amplitude of evoked response [in } \mu\text{V] Affected side}}{\text{Amplitude of evoked response [in } \mu\text{V] Normal side}} \times 100 \right)$$

TABLE 24–4. Repaired Facial Nerve Recovery Scale

Score	*Function*
A	Normal facial function
B	Independent movement of eyelids and mouth, slight mass motion, slight movement of forehead
C	Strong closure of eyelids and oral sphincter, some mass motion, no forehead movement
D	Incomplete closure of eyelids, significant mass motion, good tone
E	Minimal movement in any branch, poor tone
F	No movement

Adapted from Gidley PW et al.[81]

This electrodiagnostic test depends on the physiologic premise of neural injury proposed by both Seddon and Sunderland (see Table 24–2). Injuries that are limited to producing a conduction block within the nerve (neurapraxia) do not disrupt axoplasmic continuity and will continue to conduct a neural discharge if the electrical stimulus is presented distal to the conduction block. With more severe injuries, axoplasmic disruption (axonotmesis) or neural tubule disruption (neurotmesis) will result in wallerian degeneration distal to the site of injury. Nerve fibers that undergo wallerian degeneration cannot propagate electrically evoked potentials distal to the injury. Axonotmesis, in contrast to neurotmesis, has a better prognostic outcome. With resolution of the neural injury, in a nerve that has undergone axonotmesis, the axon will regenerate through the intact neural tubule, potentially allowing complete return of motor function to the muscle fiber innervated by that nerve fiber. The more severely disrupted neural tubule injury of neurotmesis has the potential to regenerate in an unsuccessful manner and can thereby result in misdirection of fibers, clinically causing synkinesis and incomplete return of motor function. Electroneuronography can be used to differentiate nerve fibers that have minor conduction blocks (neurapraxia) from those that have undergone wallerian degeneration; however, ENoG cannot differentiate the type of wallerian degeneration (axonotmesis versus neurotmesis). The severity of the injury can be inferred from the rate of degeneration after injury. More rapid wallerian degeneration is associated with neurotmesis, whereas nerves that degenerate more slowly are more likely to exhibit axonotmesis.[40,54,55]

The timing for performing ENoG should take into consideration the time course of wallerian degeneration. With a known complete transection of the facial nerve (eg, traumatic injury), 100% wallerian degeneration occurs over 3 to 5 days as the distal axon slowly degenerates. Therefore, early testing, within 3 days of paralysis, may not be representative of the degree of injury, and as outlined above, the time course of degeneration may reflect the degree of injury. An important technical detail to be attentive to is the need to stimulate the nerve at the stylomastoid foramen 10 to 20 times before making an amplitude measurement. The initial stimulation will improve the synchronization within the nerve and therefore improve the reliability of the test.

As discussed earlier in this chapter, our criteria for surgical decompression include ENoG degeneration greater than 90% relative to the unaffected side, no voluntary facial nerve EMG activity on the affected side, and the operation within 14 days of onset.[40,54,55] Decompression is limited to the meatal and labyrinthine segments through a middle cranial fossa approach.[55–57] Gantz et al published a prospective study in which a well-defined surgical decompression of the facial nerve was performed in a population of patients with Bell's palsy who exhibited the electrophysiologic features associated with poor outcomes (ENoG degeneration greater than 90% relative to the unaffected side, no voluntary facial nerve EMG activity on the affected side).[55] Subjects who did not reach 90% degeneration on ENoG within 14 days of paralysis all returned to House-Brackmann grade I (n = 48) or II (n = 6) at 7 months after onset of the paralysis. Control subjects self-selecting not to undergo surgical decom-

pression when > 90% degeneration on ENoG and no motor unit potentials on EMG were identified had a 58% chance of having a poor outcome at 7 months after onset of paralysis (House-Brackmann grade III or IV [n = 19]). A group with similar ENoG and EMG findings undergoing middle fossa facial nerve decompression exhibited House-Brackmann grade I (n = 14) or II (n = 17) in 91% of the cases. It is recommended that these criteria and this surgical algorithm be followed.

Electromyography. Facial nerve EMG is important to use as an adjunctive tool when making decisions regarding surgery. Early in the time course of recovery, regenerating nerve fibers conduct at differing rates, producing dyssynchrony, and, therefore, overestimate the degree of wallerian degeneration based on ENoG testing. In fact, it is possible to record "100% degeneration" with ENoG in patients with early recovery from Bell's palsy while voluntary movement is observed. It is for this reason that a voluntary EMG is performed when the ENoG shows greater than 90% degeneration within 14 days of injury and surgical decompression is being considered. Needle electrodes are placed into the orbicularis oculi and orbicularis oris muscles, and the patient is asked to make voluntary contractions. If voluntary contractions occur during the first 2 weeks after the onset of paralysis, early deblocking of the neural conduction block has taken place, and a good recovery of facial function will most likely follow. It is also important to keep in mind that ENoG is useful only during the acute phase of the injury, between days 3 and 21, and after complete loss of voluntary function. Electromyography is the more useful single diagnostic study after 3 weeks of facial paralysis. As will be discussed later in the chapter, EMG testing is also important when deciding whether to perform nerve substitution procedures and other reamination procedures.

GENERAL PRINCIPLES IN FACIAL NERVE SURGERY

Whenever the facial nerve is to be surgically exposed, several technical points must be observed. First, a system for monitoring facial nerve function during the operation should be employed.[82] Historically, visual observation during critical stages of the operation was performed. However, the standard practice for most otologists is to use intraoperative facial nerve EMG with placement of needle electrodes into the orbicularis oculi and orbicularis oris muscles.

Instrumentation is crucial to successful exposure of the facial nerve. The largest diamond bur that the operative site can safely accommodate should be used when the surgeon is near the fallopian canal. Cutting burs have the potential to catch and jump unexpectedly and can consequently cause severe injury to the nerve. Continuous suction-irrigation keeps the burs clean and also dissipates heat, which can induce neural damage.

Blunt elevators, such as the Fisch raspatory (Leibinger, Dallas, Texas), should be used to remove the final layer of bone over the nerve. These instruments are thin but strong enough to remove a thin layer of bone. Stapes curettes are usually too large and can cause compression injury to the nerve. If a neurolysis is to be performed, disposable microblades are available (Beaver No. 59-10). Sharp dissection is less traumatic than blunt elevation when the nerve must be lifted out of the fallopian canal. The medial surface of the nerve usually adheres to the bone and contains a rich vascular supply. Cauterization near the nerve should be performed only with an irrigating bipolar electrocautery, low current, and insulated microforceps.

Middle Cranial Fossa (Transtemporal) Approach: Internal Auditory Canal Porus to Tympanic Segment

The middle cranial fossa exposure is used to expose the IAC and labyrinthine segment of the facial nerve when preserving existing auditory function is desirable.[57,83] The geniculate ganglion and tympanic portion of the nerve can also be decompressed from this approach.

Technique The patient is placed supine on the operating table with the head turned so that the involved temporal bone is upward (Figure 24–11, A). The hair is shaved 6 to 8 cm above and anterior to the ear and 2 cm posterior to it. The surgeon is seated at the head of the table with the instrument nurse at the anterior side of the patient's head. A 6 × 8 cm posteriorly based trapdoor incision, or a preauricular incision, is marked in the hairline above the ear (Figure 24–11, B). If exposure of the mastoid is necessary, the inferior limb of the incision can be carried postauricularly (Figure 24–11, B, dashed

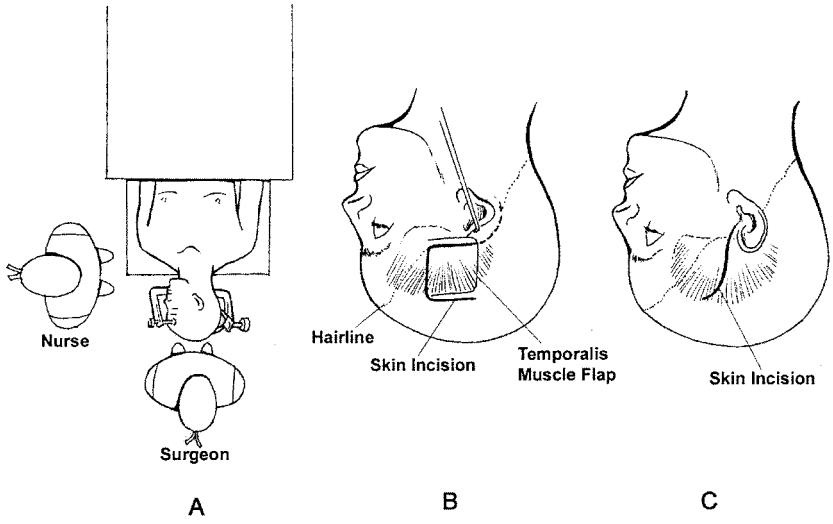

FIGURE 24–11. Patient positioning and incision design for the middle cranial fossa approach. *A*, Patient is in the supine position with the operated ear upward. Surgeon is seated at the vertex of the head. *B*, Posteriorly based trapdoor scalp incision (*bold line*). Surgical position illustrating the skin incision (*solid line*) for the middle cranial fossa approach. The *dashed line* shows the extension of the scalp incision that is required to reach the mastoid area for total facial nerve exposure. Design of anteriorly based temporalis muscle, fascia, and periosteal flap (*thin line*). *C*, Alternative preauricular incision for the middle cranial fossa approach if mastoid exposure is not necessary. line). The skin flap is elevated to expose the temporalis muscle and fascia. A 4 × 4 cm temporalis fascia graft is harvested for use during closure of the IAC dural defect. Alternatively, Alloderm (LifeCell Corp., Woodlands, Texas) can be used. An anteriorly based trapdoor incision is used to elevate the temporalis muscle and periosteum (see Figure 24–11, B, thin line). Staggering the levels of the muscle and skin incisions provides for a double-layer, watertight closure at the completion of the procedure. If exposure of the mastoid is not necessary, a preauricular incision is often used (Figure 24–11, C).

The temporal root of the zygoma is exposed during elevation of the temporalis muscle. This landmark represents the level of the floor of the middle fossa. Dural fishhooks are placed in the skin and temporalis muscle flaps for retraction. A 3 × 5 cm bone flap for facial nerve decompression, or a 4 × 5 cm bone flap for tumor excisions, centered above the temporal root of the zygoma is fashioned with a medium-cutting bur (3 mm). It is important to keep the anterior and posterior margins of the craniotomy parallel to facilitate placement of the self-retaining retractor.

Branches of the middle meningeal artery are occasionally embedded within the inner table of the skull; therefore, elevation of the bone flap must be performed in a controlled manner. Bipolar coagulation and bone wax may be necessary to control bleeding. Elevation of the dura from the floor of the middle fossa can be one of the most difficult steps. Blunt dissection and magnification greatly facilitate dural elevation. The dura is elevated from the posterior to anterior direction to prevent accidental injury to an exposed geniculate ganglion and greater superficial petrosal nerve. Bipolar coagulation is used to cauterize dural reflections within the petrosquamous suture before transection with scissors.

The elevation proceeds until the petrous ridge is identified medially and the arcuate eminence, meatal plane, and greater superficial petrosal nerve are exposed anteriorly. No attempt is made to identify the middle meningeal artery and accompanying troublesome bleeding veins. The tip of a self-retaining retractor (Fisch, Leibinger) is placed at the petrous ridge anterior to the arcuate eminence and medial to the meatal plane (Figure 24–12). A medium diamond bur (2 to 3 mm) and a suction-

irrigation apparatus are used to identify the blue line of the SSC. A preoperative Stenvers projection radiograph helps to determine the level of the SSC in relation to the floor of the middle fossa and the degree of pneumatization above the SSC (Figure 24–13).

Drilling begins posterior to the arcuate eminence over the mastoid air cells until the dense yellow bone of the otic capsule is identified. Otic capsule bone is slowly removed until the blue outline of the SSC is seen. The IAC is located by removing bone with a 60-degree angle anterior to the blue line of the SSC and with the vertex based at the SSC ampulla. This dissection is continued until approximately 180 degrees of the IAC are exposed for facial nerve decompressions (see Figure 24–12) or 270 degrees of the IAC are exposed for schwannomas. Because of the close proximity of the SSC and the basal turn of the cochlea, only approximately 120 degrees of the circumference of the IAC can be safely removed in its lateral 5 mm or so. The facial nerve occupies the anterosuperior portion of the IAC. Laterally, the vertical crest (Bill's bar) marks the division between the superior vestibular nerve and the meatal foramen containing the facial nerve.

The entrance to the fallopian canal is the narrowest, most delicate portion of the facial nerve and consequently the most challenging portion of the dissection. At the meatal foramen, the facial nerve turns anterior and slightly superior. The basal turn of the cochlea can be within 1 mm inferiorly, and the ampulla of the SSC can be directly posterior to the nerve. The labyrinthine segment is followed to the geniculate ganglion. If the facial nerve needs to be exposed distal to the geniculate ganglion (eg, as with facial neuromas or with some traumatic injuries to the facial nerve), the tegmen tympani is removed with care to avoid injury to the head of the malleus and incus. The tympanic segment is easily seen to turn abruptly posterior; it is followed to where it courses inferior to the lateral semicircular canal. It is advisable to leave a thin shell of bone covering the nerve until its entire course is identified. Small blunt elevators are used to remove the final layer of bone. The nerve is tightly confined within the labyrinthine segment of the fallopian canal; larger curettes should be avoided to prevent compression injury. If the nerve is to be decompressed, a neurolysis is the final step. A disposable microscalpel (Beaver No. 59-10) is used to slit the periosteum and epineural sheath.

Alternative methods to locate the facial nerve may be necessary, especially in traumatic cases. The greater superficial petrosal nerve can be traced pos-

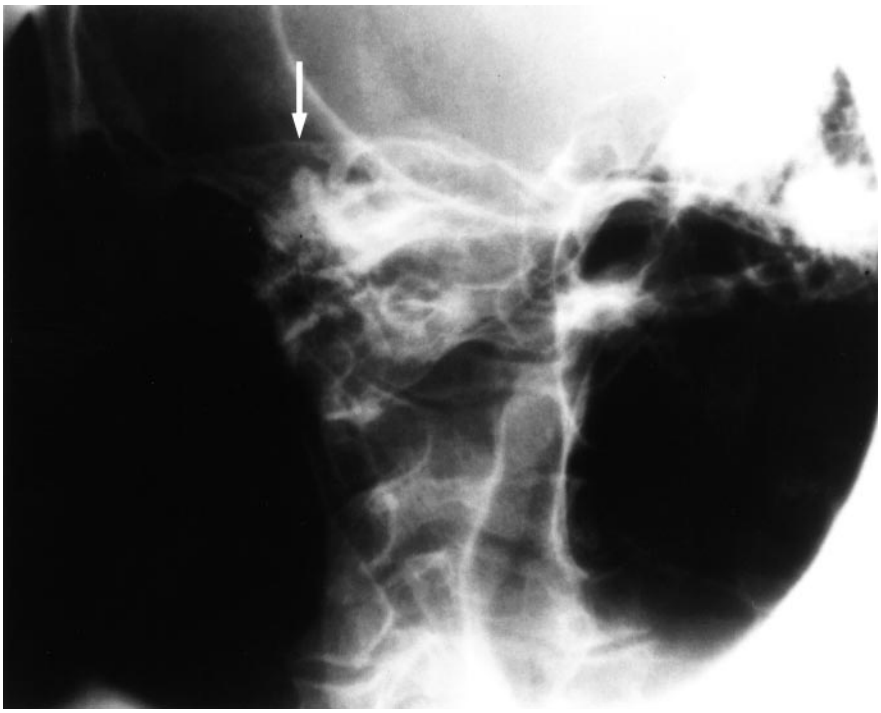

FIGURE 24–13. Stenvers projection radiograph demonstrating the anatomic variation of pneumatized air cells beneath the floor of the middle cranial fossa and the superior semicircular canal (*arrow*). Reproduced with permission; copyright © 1995 P. A. Wackym.

teriorly to the geniculate ganglion, or the tegmen tympani may be fractured and the tympanic segment visible through the fracture. The tympanic segment is then used to locate the geniculate ganglion and labyrinthine segments.

At the end of the procedure, a free temporalis muscle graft is placed within the IAC and a corner piece of the bone flap is fashioned to cover the defects in the tegmen tympani and IAC (Figure 24–14). Alternatively, titanium mesh (Synthes Maxillofacial, Paoli, Pennsylvania) between layers of Alloderm can be used. This prevents herniation of the temporal lobe into the middle ear or IAC. The temporalis fascia previously harvested is placed over the free bone graft to help seal the dural defect at the IAC. The craniotomy defect is then repaired using titanium mesh (Synthes Maxillofacial) and hydroxyapatite cement (BoneSource, Leibinger), and the temporalis muscle is closed with interrupted absorbable sutures. The skin is closed in layers with particular care in closing the galea. No drain is placed. A mastoid-type pressure dressing is applied.

Advantages and Uses The middle cranial fossa route is the only method that can be used to expose the entire IAC and labyrinthine segment with preservation of hearing. This, in combination with the retrolabyrinthine and transmastoid approaches, enables visualization of the entire course of the facial nerve and still preserves function of the inner ear. The middle cranial fossa technique is the most commonly used for decompression of the facial nerve in Bell's palsy[52,57] and longitudinal temporal bone fractures. However, as described earlier in this chapter, this approach may be useful in the management of patients with schwannomas of CN VII or CN VIII, as well as with patients with Melkersson-Rosenthal syndrome.

Postoperative Care/Complications and Their Management The anatomy of the floor of the middle cranial fossa is quite variable and presents some difficulty in identification of landmarks. The Stenvers projection radiograph provides important anatomic information regarding the degree of pneumatization above the SSC and should be performed in all cases to minimize the risk of surgical injury to the SSC. In addition, the surgeon must have a precise knowledge of three-dimensional anatomy of the temporal bone. Many hours in a temporal bone dissection laboratory are required to attain the delicate microsurgical skills that are necessary for this type of surgery.

Middle cranial fossa facial nerve decompression can result in conductive and/or sensorineural hearing loss. Conductive hearing loss can be sec-

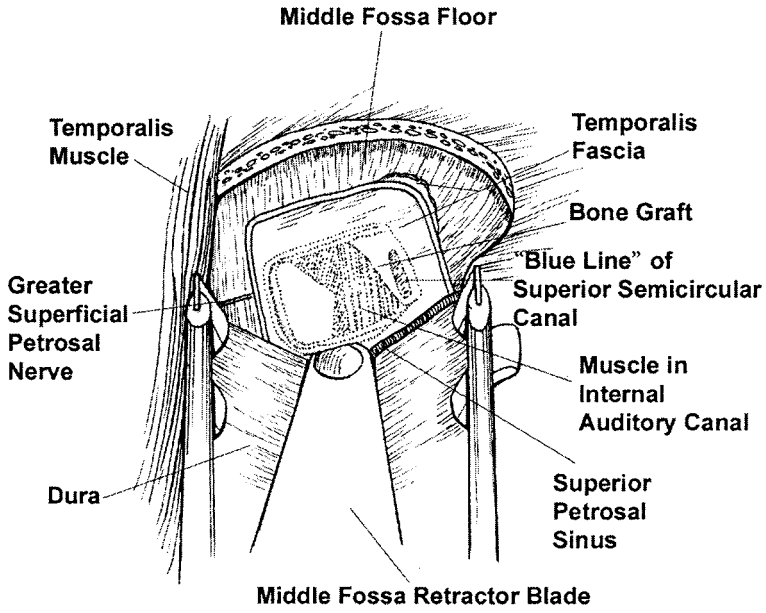

FIGURE 24–14. Reconstruction following right middle cranial fossa facial nerve decompression. Temporalis muscle is placed within the internal auditory canal (IAC) surgical defect to fill the dural and bony defect at the conclusion of the facial nerve surgical decompression. Temporalis fascia or Alloderm (LifeCell Corp., Woodlands, Texas) is placed over the floor of the middle cranial fossa and muscle graft. A free bone graft or titanium mesh (Synthes Maxillofacial, Paoli, Pennsylvania) is placed perpendicular to the axis of the IAC to prevent herniation of the temporal lobe onto the facial, cochlear, and vestibular nerves. Temporalis fascia or Alloderm is then used to seal the temporal lobe dura and cover the bone graft or titanium mesh. Reproduced with permission; copyright © 2001 P. A. Wackym.

ondary to temporal lobe herniation or ossicular disruption during dissection in the attic. A free bone graft, as already described, prevents temporal lobe herniation. Sensorineural hearing loss can result from direct injury to the inner ear by the drill exposing the cochlea or semicircular canals or from translational injury by the drill striking an ossicle. Should the SSC be entered during the surgical dissection, the fenestration should be immediately occluded with bone wax. Injury to the internal auditory vessels within the IAC can also result in loss of inner ear function. Loss of vestibular function can occur by the same mechanisms.

Postoperative intracranial complications including meningitis, temporal lobe edema, and epidural hematoma formation are possible. Perioperative antibiotics administered over 48 hours are recommended. Fluid restriction and dexamethasone (Decadron) are used for the first 3 days postoperatively to minimize temporal lobe edema following intraoperative retraction. In addition, our longer craniotomy flap decreases the amount of temporal lobe retraction required for complete exposure of the IAC and fallopian canal. With adequate intraoperative hemostasis using the bipolar cautery, oxidized cellulose (Oxycel), and dural tacking sutures, we have never had a clinically significant postoperative epidural hematoma develop.

Leakage of cerebrospinal fluid (CSF) must be avoided to prevent meningitis. All exposed mastoid air cells must be obstructed with bone wax. A temporalis muscle–free graft is placed into the superior aspect of the IAC to separate the posterior fossa from the extradural floor of the middle cranial fossa. Temporalis fascia or Alloderm is then used to provide a second layer of closure between the posterior fossa and the extradural middle fossa. Meticulous care must be taken to ensure that there are no dural dehiscences overlying the temporal lobe through which CSF may drain. If these are identified, a temporalis fascia, muscle, or Alloderm patch must be used to repair the dural tears to prevent CSF leaks. After a three-layer watertight closure of the temporalis muscle, galea, and scalp, a mastoid-type dress-

ing is applied daily for 5 days postoperatively. Should CSF leakage persist, a temporary lumbar fluid drain is placed, and the patient is kept at bed rest. If the CSF leakage does not resolve within 5 to 7 days after placement of the lumbar drain, re-exploration of the surgical field is indicated to identify and seal the area of CSF egress.

Uncontrolled bleeding or injury to the AICA poses the most serious complication during the operation; however, this is rare. The middle cranial fossa approach does not provide adequate access to the entire cerebellopontine angle. The AICA and accompanying veins can loop into the IAC. Control of bleeding of these vessels may require a suboccipital exposure. Injury to the AICA results in brainstem and cerebellar infarction of a variable degree, depending on its size and the area of its terminal arterial supply.

NERVE REPAIR

Whenever the continuity of the facial nerve has been disrupted by trauma, iatrogenic injury, or tumor invasion, every effort should be made to restore its continuity. In some instances, an end-to-end reapproximation can be accomplished, but if any tension occurs at the anastomotic site, an interposition nerve graft has a better chance of providing facial movement. All nerve repair techniques produce synkinesis, but sphincteric function of the mouth and eye is usually restored. Newer microsuture techniques and instrumentation should be employed to enhance return of function.

In general, the injured ends of the nerve should be freshened at a 45-degree angle. Experimental evidence has shown that cutting the nerve at this angle exposes more neural tubules and improves regrowth of the nerve.[81,84] In addition, a fresh razor blade induces less crush injury to the nerve than a scalpel blade or scissors does. We have found that the perineurium of CN VII does not hold 9-0 sutures, and attempting to suture it increases trauma to the neural tubules. Removing a portion of the epineurium before suturing prevents connective tissue growth at the anastomotic site. If the epineurium is cleaned from the end of the nerve for approximately only 0.5 mm, sutures can still be placed in the epineurium for reapproximating the nerve segments. Three or four 9-0 nylon sutures are placed with jeweler's forceps or longer instruments (19 cm microforceps) for anastomosis in the cerebellopontine angle. At the brainstem, two or three sutures are placed (Figure 24–15).

When an interposition graft is required, the greater auricular and sural nerves are the preferred graft donor sources. The greater auricular nerve is readily available near the operative field if it is not involved in resection of a neoplasm and has approximately the same diameter as that of the facial nerve. It is easily located midway, perpendicular to a line drawn between the mastoid tip and the angle of the mandible. If a graft of greater than 8 to 10 cm is required, the sural nerve should be used. The sural nerve has another advantage in that the peripheral portion of the nerve has many branches that can be used to reconstruct the branching pattern of the facial nerve. There is little discomfort from removing the sural nerve since it provides only a small area of sensation to the lateral lower leg and foot. The sural nerve is found immediately posterior to the lateral malleolus, along the saphenous vein. The nerve graft should be 10 to 20% larger in diameter than the facial nerve and long enough to ensure a tension-free anastomosis.

FACIAL REANIMATION PROCEDURES

Contemporary strategies for management of patients with facial paralysis have been a product of a gradual evolution of past clinical successes and

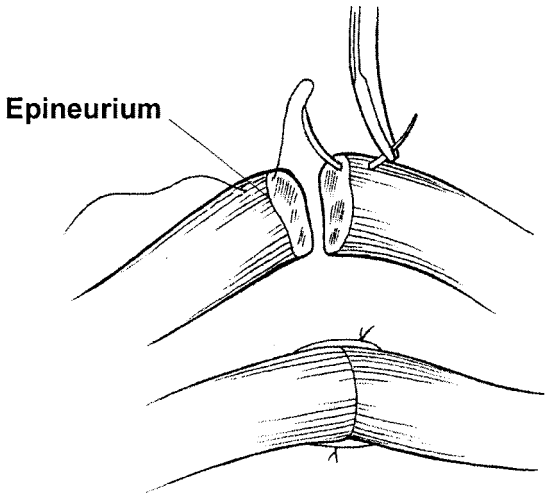

FIGURE 24–15. Epineurial end-to-end nerve repair using 9-0 nylon sutures. Reproduced with permission; copyright © 2001 P. A. Wackym.

failures over the past 100 years. The surgeon must consider the functional and cosmetic goals of reconstructive surgery, as well as the patient's desires, expectations, and motivations. Functional deficits include incomplete eye closure, speech difficulties, oral incompetence, and nasal airway obstruction. The cosmetic deficiencies of facial asymmetry and dysmorphism can be emotionally devastating for some patients. It is the achievement of facial balance and muscle coordination that continues to be the more challenging and elusive goal.

Management of Upper Third of the Face

Eye Care Protection of the eye is paramount (Figure 24–16). It is necessary to protect the cornea from foreign bodies and drying. Dark glasses should be worn during the day, artificial tears instilled at the slightest evidence of drying, and a bland eye ointment used during sleep. Patients who demonstrate a poor Bell's phenomenon or have trigeminal nerve deficits are particularly at risk for corneal damage. Taping of the eye closed is not usually recommended, but early-exposure keratitis may require patching or, rarely, a tarsorrhaphy. A formal ophthalmologic examination is recommended prior to any surgical intervention.

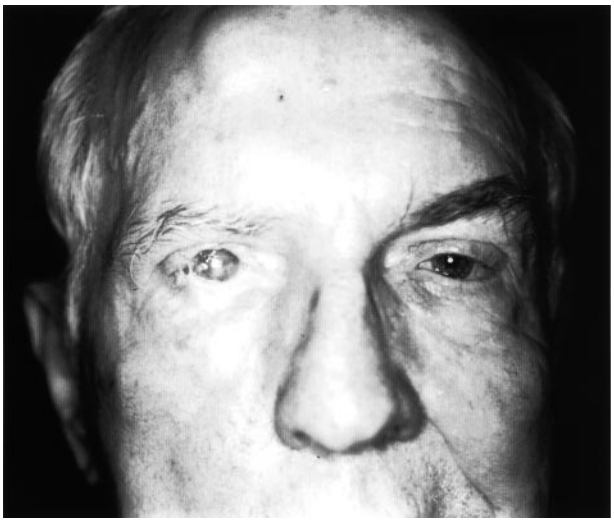

FIGURE 24–16. Inadequate eye care following a complete facial paralysis owing to acoustic neuroma resection at another institution resulted in corneal opacification. Reproduced with permission; copyright © 2000 P. A. Wackym.

Eyebrow Ptosis of the eyebrow can have functional and cosmetic consequences. In the elderly patient, the functional loss of the frontalis and orbicularis oculi muscles is compounded by the loss of tissue elasticity and decrease in the bulk of the subcutaneous tissue. This can lead to significant brow ptosis and hooding of the upper eyelid, which may cause lateral visual field compromise.

The two most commonly used procedures to correct brow ptosis are the midforehead lift and the direct brow lift. Both procedures require direct skin and subcutaneous tissue excision, followed by suspension of the orbicularis oculi muscle to the frontal bone periosteum. Slight overcorrection is needed as the brow position will settle during the next few weeks. The endoscopic approach for cosmetic browlifting is not commonly used owing to the severity of the brow ptosis associated with the complete loss of frontalis muscle function. However, there have been some recent anecdotal reports of successful outcomes using the endoscopic browlift technique.[1,85]

Upper Eye Lid Historically, tarsorrhaphy had been the standard of care in patients with facial paralysis. Today, this procedure should be reserved for only those patients with a severe risk for exposure keratitis or those who have failed upper eyelid reanimation procedures. The most commonly used procedure is the insertion of a prosthetic, specifically a gold weight implant or a palpebral wire spring.

In experienced hands, the palpebral wire spring can produce excellent results, affording the capability of mimicking, to some extent, the spontaneous blink. However, the insertion of the palpebral wire spring is technically more difficult, with a higher reported extrusion and infection rate. In addition, these springs often need postoperative adjustment for optimal function.[1]

Gold weight implantation is a relatively simple procedure that is highly successful, well tolerated by patients, and easily reversible if facial muscle function returns (Figure 24–17). The ideal candidates for gold weight placement are those with the following factors: some existing ability to lower the upper lid, good Bell's phenomenon, normal corneal sensation and tearing, prominent supratarsal lid crease, and nonprotruding eyes.

Prefabricated gold weight implants come in weights ranging from 0.8 to 1.6 g. Custom weighting

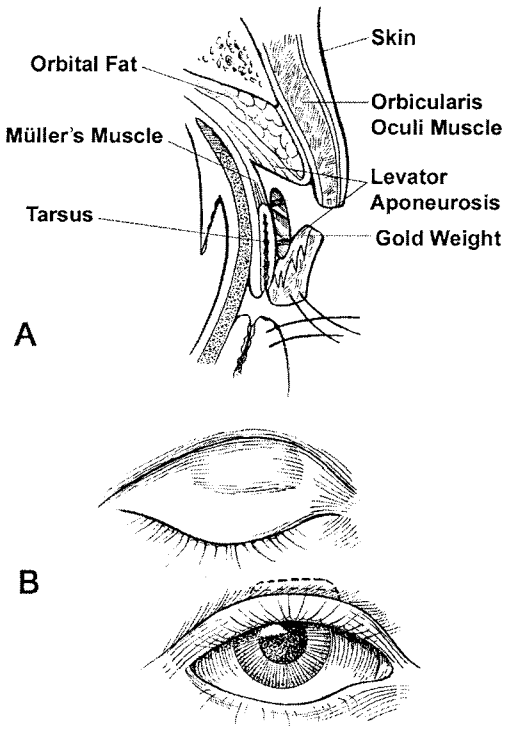

FIGURE 24–17. A, Gold weight implant in position, superficial to the tarsal plate, deep to the levator aponeurosis. *B*, Correct gold weight position in relation to the lid margin and pupil. Reproduced with permission; copyright © 2001 P. A. Wackym.

can be requested, if needed. All patients should be correctly sized by taping different size weights to the eyelid in an upright position. The largest weight allowing eyelid closure without causing more than slight lid ptosis should be chosen; the most common weights are 1.0 and 1.2 g. The patient should be informed that the weights are often not helpful when lying supine. In fact, eyelid closure may be worse in some cases owing to the weight of the implant pulling the eyelid open when supine. Eye care, as described above, should be continued following the reanimation procedure.

After selecting the proper size implant, the procedure is performed under local anesthesia. An incision is made along the supratarsal fold down to the orbicularis oculi muscle. Sharp scissor dissection is carried down through the muscle to the tarsal plate. Dissection is continued inferiorly over the surface of the tarsal plate to within 3 mm of the lash line. An exact pocket is made for the implant to be placed just slightly medial to the center of the pupil. The gold weight is then inserted and suture fixated to the tarsus using 6-0 clear prolene sutures. The incision is closed in layers, 6-0 chromic suture for the levator aponeurosis/orbicularis muscle layer and 6-0 fast gut suture for the skin.

The most common problems associated with gold weight implantation are lid underclosure, excessive lid ptosis, and implant extrusion. The reported extrusion rate in the literature is greatly varied, from as low as 1% to as high as 43%.[1,86,87] The risk of implant extrusion can be minimized by meticulous surgical technique and proper patient selection. Removal of the implant is performed once facial nerve function has returned; however, the gold weight can also be used as a permanent means to achieve eye closure.

Lower Eye Lid The goals for lower lid management are to improve lower lid margin approximation to the globe, correct ectropion, and maximize the efficiency of the tear drainage system. Lid-tightening procedures must not disturb the delicate interface between the lacrimal punctum and the globe. A lateral traction test, simulating a lid-tightening procedure, will demonstrate the effect of the procedure on lid position and the displacement of the punctum. As a general rule, up to one-eighth of the lid can be resected without disturbing the relationship of the inferior punctum to the globe. If the lateral traction test indicates excessive punctum displacement (greater than 2 mm) or does not provide proper lid support, then alternative or adjunctive surgical procedures are indicated. Excessive punctum lateralization indicates medial canthal tendon laxity, thus indicating the necessity for a medial canthoplasty. If further elevation of the lower lid is needed, then "spacer" grafts (palate mucosa, conchal cartilage) are used to provide vertical height to the eyelid.

Lower lid–tightening procedures include the Bick procedure, tarsal strip, and midlid wedge resection. The Bick procedure is our procedure of choice for lower lid tightening. The procedure involves resecting a lateral wedge of the lower lid, developing a tongue of tarsus, and resuturing the lateral edge of the lid to the lateral orbital rim (Figure 24–18). The procedure allows for fine adjustment of the tension on the lower lid by resecting a precise amount of tissue. Care must be taken not to overshorten the lower

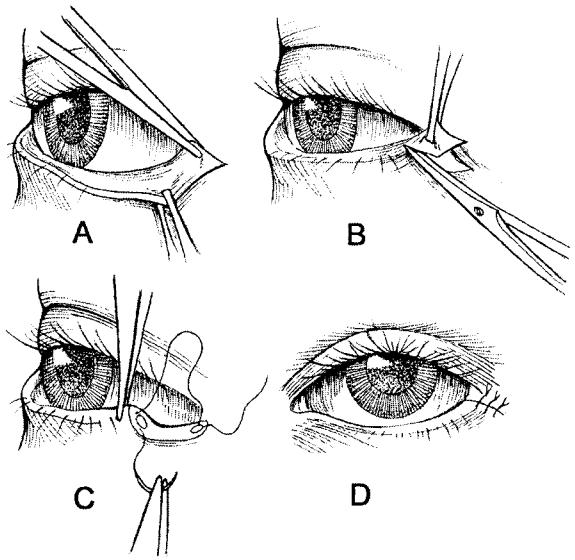

FIGURE 24–18. Bick procedure for lower lid ectropion repair. *A*, Lower lid is grasped and canthotomy and cantholysis are performed. *B*, Appropriate amount of lax lower lid (skin, muscle, conjunctiva, tarsus) is sectioned. *C*, Lateral margin of tarsus is sutured to canthal tendon and orbital periosteum. *D*, Canthotomy is closed with absorbable sutures. lid, creating a hammock effect, with the lower lid actually bowing down under the globe.

Management of Lower Two-Thirds of the Face

The ultimate goal in treatment of the lower two-thirds of the face is to create symmetric, mimetic movement of the facial musculature. The best chance for this outcome is with primary repair of the facial nerve, with or without nerve interposition grafting. However, primary nerve repair is not always possible, and alternative procedures must be entertained. The choice of procedure is dictated by a number of factors including duration of paralysis, prognosis of the underlying illness, concomitant CN deficits, comorbid medical conditions, and the patient's wishes and motivations.

Role of Electromyography in Planning Facial Reanimation Procedures The degree of motor end-plate degeneration and prognosis for spontaneous recovery of the facial nerve can be assessed with EMG. The presence of normal or polyphasic action potentials at 1 year following facial nerve injury portends a favorable outcome, and no reanimation procedures are indicated. If fibrillation potentials are found, this indicates intact motor end plates but no evidence of reinnervation. This finding supports the use of a nerve substitution procedure to take advantage of the potential neurotized tone and movement of the intrinsic facial musculature. Electrical silence obtained from EMG indicates complete denervation and atrophy of the motor end plates. Neurotized reanimation procedures are contraindicated, and other reanimation procedures should be entertained.

Nerve Substitution Procedures Nerve substitution procedures are indicated when primary facial nerve repair is not possible. In addition, the following conditions are required for these procedures: intact proximal donor nerve, intact distal facial nerve, and viable motor end-plate function. Although these procedures provide facial tone and resting symmetry, they do not restore involuntary, independent mimetic facial expression. However, the majority of patients do achieve some voluntary facial movement with rehabilitation. The most commonly described nerve substitution procedures are the XI–VII crossover, VII–VII crossfacial, XII–VII crossover, and XII–VII jump graft.

The XI–VII procedure (accessory to distal facial nerve) has largely been abandoned owing to the morbidity of loss of trapezius muscle function. The VII–VII crossfacial grafting involves linking a functional branch of the facial nerve on the nonparalyzed side to a division of the facial nerve on the paralyzed side by using a long interposition nerve graft (sural, medial antebrachial cutaneous) (Figure 24–19). The disadvantages of this procedure include the sacrifice of a portion of the normal facial function on the contralateral side, a long interval for innervation (9 to 12 months), and a lack of substantial neural "firepower" owing to the relatively few number of axons grafted. Theoretically, the advantage of this technique is the possibility of symmetric, mimetic movement. Disappointing results from several investigators[1,88] have made this procedure less appealing.

Hypoglossal-facial (XII–VII) crossover is most appropriately performed for complete and permanent facial paralysis up to 2 years after injury (Figure

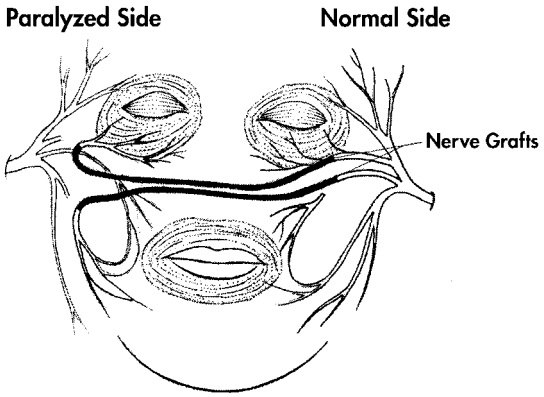

FIGURE 24–19. Facial-crossfacial nerve substitution technique. Reproduced with permission; copyright © 2001 P. A. Wackym.

24–20). This situation may arise following radical parotidectomy, temporal bone resection, skull base surgery, severe temporal bone trauma, or cerebellopontine angle tumor resection. An EMG finding consistent with viable motor end plates of the facial muscles is a prerequisite for surgery. Poor candidates for the XII–VII crossover include patients with multiple lower CN deficits. Sacrifice of the hypoglossal nerve may not be well tolerated and compensated for in the presence of other cranial neuropathies.

Improved facial tone and symmetry occur in 90% of patients following XII–VII anastomosis.[1] The results are more impressive in the midface and less in the frontalis and lower portions of the face. The return of muscle tone is seen within 4 to 6 months following neurorrhaphy, with better results seen in earlier repairs.[89] Voluntary facial movements follow with progressive improvements over the next 1 to 2 years. True spontaneous facial expressions are rare, although through motor sensory re-education, patients may develop spontaneous animation with speech.

Pensak et al, in their series of 61 cases of XII–VII crossover, rated their results as excellent in 3%, good in 39%, fair in 49%, and poor in 10% of patients.[90] Conley and Baker, in their series of 122 cases, reported good or excellent results in 65%, fair in 18%, and poor in 17%.[89] They also noted better results in those patients who underwent "immediate" repair (< 2 years) than in those who were "delayed" (> 2 years).

Synkinesis, hypertonia, and hemilingual atrophy are all noted deficiencies of the classic XII–VII crossover. Most studies report minimal disabling sequelae owing to loss of unilateral hypoglossal function unless concomitant ipsilateral CN deficits exist.

The XII–VII jump graft technique was devised by May et al to offset some of the above noted disadvantages of the classic XII–VII crossover.[91] The procedure entails placing an interpositional nerve graft between a partially transected hypoglossal nerve trunk, distal to the hypoglossal descendens,

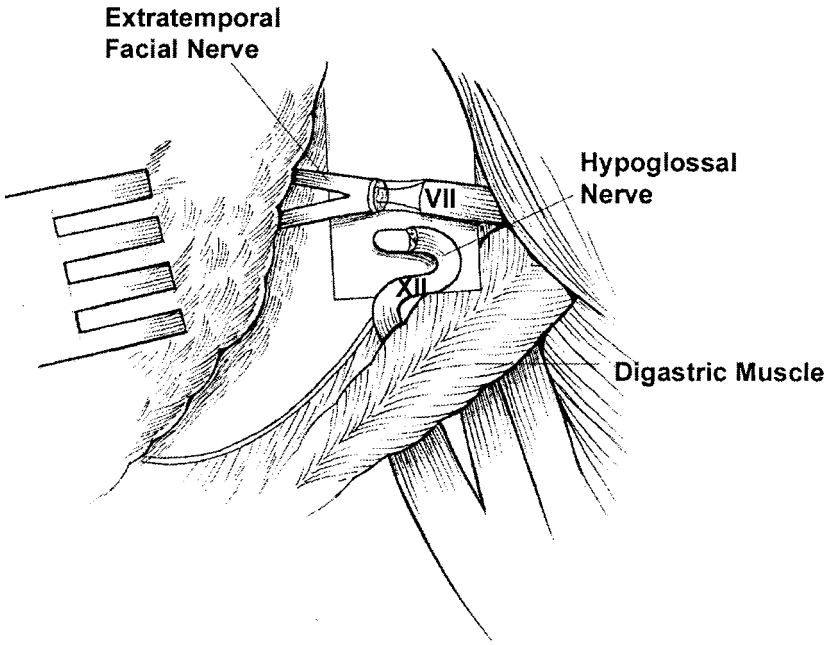

FIGURE 24–20. Hypoglossal-facial nerve crossover technique. Hypoglossal nerve is brought medial to digastric muscle to gain additional length and decrease tension at the suture line. Reproduced with permission; copyright © 2001 P. A. Wackym.

and the distal facial nerve trunk (Figure 24–21). Several authors have reported functional results comparable to the XII–VII crossover; however, the problems of hypertonia and mass facial movements have not been encountered.[91,92] Kartush and Lundy further modified this approach with anastomosis to only the lower division of the facial nerve, thereby reducing potential synkinesis.[93]

Muscle Transposition Procedures (Dynamic) Regional muscle transposition can provide dynamic reanimation of the mouth in patients with long-standing facial paralysis (over 2 years). It is indicated for patients with congenital facial paralysis (Möbius' syndrome) or when facial nerve grafting or nerve substitution techniques are contraindicated. It can also be performed in conjunction with facial nerve grafting or nerve substitution procedure in select cases to augment results. The temporalis muscle is most commonly used because of its length, contractility, and favorable vector of pull. Masseter muscle transposition can be useful following radical parotid surgery or when the temporalis muscle is not available.

Temporalis Muscle Transposition The temporalis is a fan-shaped muscle arising from the temporal fossa. The motor branch of the trigeminal nerve innervates it, and branches off the internal maxillary artery provide its blood supply. Preoperative evaluation includes the assessment of the function and strength of the temporalis muscle.

To perform a temporalis muscle transposition procedure, the temporalis muscle and fascia are both exposed by extending a modified facelift incision into the parietal region of the scalp (Figure 24–22). The pretragal incision is carried down to the subdermal region, above the superficial musculoaponeurotic system of the face. A tunnel is created from the zygomatic arch in a subdermal plane

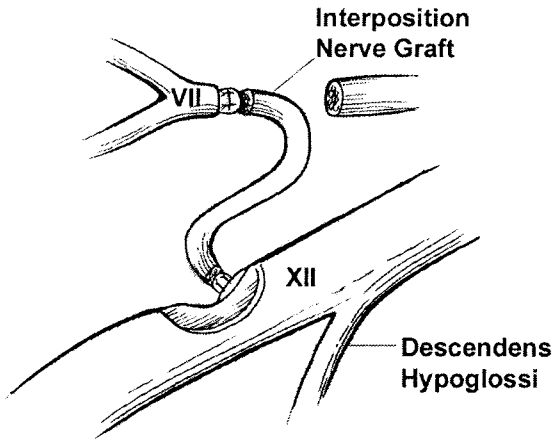

FIGURE 24–21. Hypoglossal-facial interpositional nerve graft technique. Approximately one-third of the hypoglossal nerve (XII) is sectioned, distal to the hypoglossal descendens. The nerve graft is sewn end to side with the hypoglossal nerve and end to end with the facial nerve (VII). Reproduced with permission; copyright © 2001 P. A. Wackym.

FIGURE 24–22. between the temporal fossa and the cheek-lip crease incision (adult) or the oral commissure incision (children). The lateral portions of the zygomatic arch can be burred down to reduce the bulging appearance of the muscle at this fulcrum point. Only the midportion of the temporalis muscle is used. A portion of the pericranium is dissected with the muscle and its fascia to create additional length. The muscle is then transposed over the zygomatic arch, through the subcutaneous tunnel, and into the lip-cheek incision. The muscle-fascia-pericranium complex is sutured to the orbicularis oris muscle near the submucous layer of the corner of the mouth. Additional sutures are placed from the muscle to the subdermal layer of the upper aspect of the lip-cheek incision to accentuate the lip-cheek crease. Overcorrection is necessary for an optimal final result. The depression in the temporal area is corrected by rotating the remainder of the temporalis muscle into the deficient area. The redundant facial skin is resected as in a facelift, and wounds are closed in layers. Two closed suction drains and a compressive dressing are used for 48 hours postoperatively.

Ideally, the overcorrection of the lateral oral commissure and lip-cheek crease will resolve by 3 to 6 weeks. The results of the transposition should be evident by 4 to 6 weeks, with the patient able to produce a broad smile by tensing the temporalis muscle. Complications include infection, hematoma, and seroma. The most common reasons for failure of the procedure are inadequate overcorrection and suture dehiscence at the orbicularis oris–temporalis muscle interface.[94]

Suspension Procedures (Static) Static suspension procedures are indicated for those patients who are not candidates for nerve substitution or dynamic reanimation procedures. These procedures can provide permanent support, or, in cases in which reinnervation of the facial muscles is expected, static procedures can provide temporary or additional support until reinnervation of the facial muscles is complete. A variety of materials are available for static suspension procedures, ranging from autografts (palmaris longus tendon, fascia lata tendon) to alloplasts, such as Gore-Tex (GORE S.A.M., WL Gore & Associates Inc., Flagstaff, Arizona) and acellular human dermis (Alloderm).[95,96] The choice of material is dependent on patient factors and desires, as well as the surgeon's preference and experience.

The static suspension procedure is most often used to lateralize the corner of the mouth and lip-cheek crease. The procedure is similar in approach to the temporalis muscle transposition. The autograft or allograft is placed in a subcutaneous tunnel from the lip-cheek crease to the zygomatic arch. In cases in which reinnervation of the facial muscles is expected, it is important not to injure the deeper facial nerve branches when creating the tunnel. Sutures are used to secure the graft to the orbicularis oris muscle and lip-cheek incision, whereas wires or screws are used for anchoring at the zygomatic arch (Figure 24–23).

A separate local suspension can also be performed to lateralize the nose in cases of alar valve compromise. The nasal base is exposed with incisions along the alar-facial and nasolabial creases. An allograft or autograft is then sutured to the deep aspect of the nasal base. The nasal base is then pulled laterally to its desired position. After the periosteum of zygomaticomaxillary buttress is exposed, the other end of the graft is fixated to the bone with a screw.

Innervated Free Muscle Transfer

The ideal indication for innervated free muscle transfer is in the patient with Möbius' syndrome, for whom both facial nerve and musculature are not available. It is also indicated as an alternative to regional muscle transfers or static procedures in patients with long-standing facial paralysis (> 2 years). It is usually performed as a two-stage procedure in which an initial crossfacial nerve graft is combined with a subsequent free muscle transfer (most commonly, gracilis or serratus anterior).[97] Alternatively, the innervated free flap may be grafted to the hypoglossal nerve, performed as a single-stage procedure.[98]

In select patients, this procedure provides the possibility for dynamic, mimetic movement that cannot be achieved by static procedures. The disadvantages, however, are manifold, including donor site morbidity, risk of vascular thrombosis, lengthy operative time, long interval for reinnervation, and muscle bulkiness.

NEUROMUSCULAR FACIAL RETRAINING TECHNIQUES

For patients who have experienced some recovery of facial nerve function, and also for those patients who

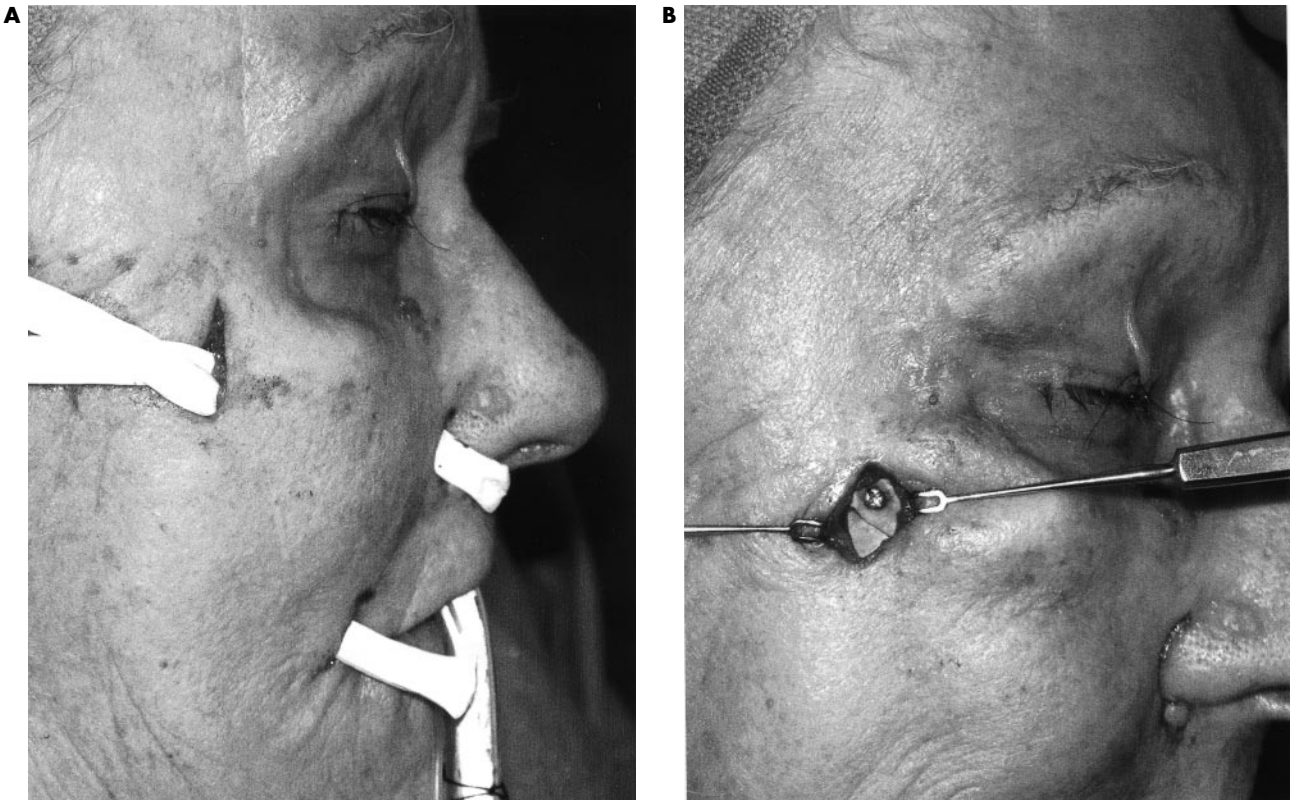

FIGURE 24–23. Static suspension procedure using allograft (Gore 2 mm nonreinforced sheet, W.L. Gore & Associates, Inc., Flagstaff, Arizona). *A*, Strips of allograft placed in the subcutaneous cheek tunnel. *B*, Allograft anchored to the malar eminence with a single titanium screw.

experience synkinesis, neuromuscular facial retraining therapy is an important treatment modality. These techniques can be applied before and after reanimation procedures to optimize outcome. In general, these techniques can be used to address loss of strength, loss of isolated motor control, muscle tension hypertonicity, and/or synkinesis. This method combines techniques such as patient education in basic facial anatomy, physiology, and kinesiology; relaxation training; sensory stimulation; EMG biofeedback; voluntary facial exercises with mirror feedback; and spontaneously elicited facial movements.[99–101] Botulinum toxin injections may be used to augment the results of neuromuscular facial retraining when dealing with synkinesis and hypertonicity.[102]

SUMMARY

The etiology and pathogenesis of several disorders that produce facial paralysis have been reviewed. Likewise, the diagnostic methods and algorithms that are used to make decisions regarding medical versus surgical management in acute facial paralysis have been summarized. Anatomy and surgical principles were highlighted and treatment alternatives for reanimation or neuromuscular facial retraining outlined.

CHAPTER 25

Surgery of the Skull Base

Richard J. Wiet, MD, Richard Hoistad, MD

The skull base is a complex anatomic region that can be the site of a diverse group of pathologic processes. Surgical access to this area is necessary for a variety of neoplasms as well as nontumorous conditions such as vertigo, facial paralysis, and hemifacial spasm.

Treatment of skull base disorders can be quite complex, but recent advances allow more accurate assessment and more reliable outcomes. Improved imaging techniques (especially magnetic resonance imaging [MRI]) allow more accurate planning of surgery and counseling of the patient. Diagnostic techniques such as auditory brainstem responses (ABRs) and electronystagmography (ENG) allow early identification of abnormalities. Intraoperative neural monitoring allows quicker, more reliable localization of important structures during surgery. As more experience is reported in this area, ideas and treatments are being refined and improved.

An important aspect of skull base surgery, and a large factor for optimal outcome, is cooperation among physicians. Consultation with a neuroradiologist maximizes the benefit of imaging techniques and allows interventional procedures such as embolization. Neurosurgical assistance is desirable when intracranial exposure is necessary. In selected cases, participation of other physicians such as vascular surgeons may also be beneficial.

Recent advances in technology, including image guidance systems and endoscopes, are being applied to skull base surgical procedures.

Image guidance systems consist of either an electromagnetic tracking system or an optical infrared tracking system.[1,2] In the field of otolaryngology, the more common application has been in sinus surgery, but recent interest has arisen for application to skull base procedures. Image guidance systems are particularly appealing for middle fossa approaches to skull base lesions.[3] Both systems have been found to be reliable and accurate within 2 mm for anatomic localization.

Adjunctive use of endoscopy for posterior fossa surgery and acoustic neuroma surgery has also been found to be useful.[4] Endoscopy provides better visualization than the microscope in certain areas of the skull base, particularly in identifying neurovascular structures, inspecting acoustic neuroma tumor removal along the internal auditory canal (IAC), and identifying open petrous air cells, thus lowering the postoperative cerebrospinal fluid (CSF) leak rate.[5,6]

ANATOMY

Superiorly, the floor of the cranial cavity, or skull base, serves as a support for the brain and intracranial structures. Inferiorly, it attaches to the facial bones anteriorly and serves as the attachment for the head and neck muscles laterally and posteriorly. The floor of the cranial cavity is composed of the frontal, ethmoid, sphenoid, temporal, and occipital bones (Figure 25–1) and is broadly classified into the anterior, middle, and posterior fossae. Numerous foramina allow passage of vascular and neural structures between the intracranial and extracranial space. The area below the midlateral portion of the skull base (essentially the temporal bone) is designated the infratemporal fossa.

Anterior Cranial Fossa

The anterior fossa is composed of the frontal bone anteriorly and laterally, the cribriform plate of the ethmoid bone centrally, and the body and lesser wing of the sphenoid bone posteriorly and centrally. Immediately anterior to the cribriform plate is the foramen cecum, through which an emissary vein

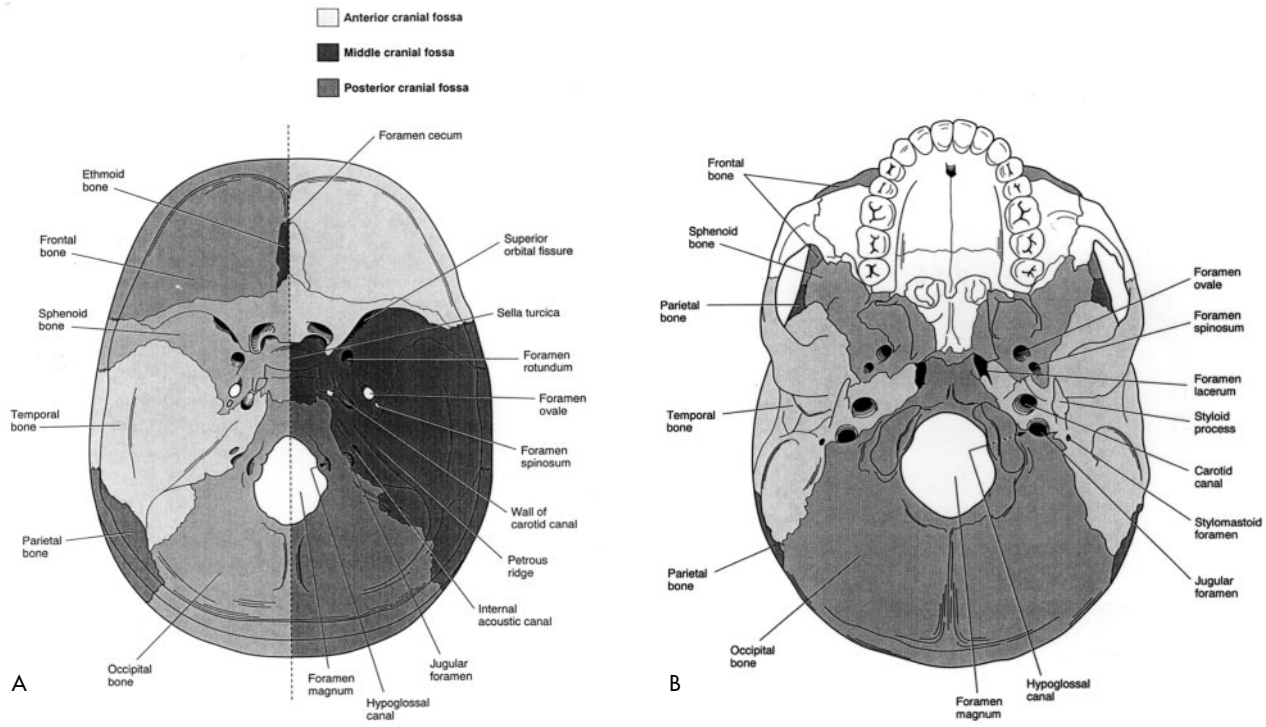

FIGURE 25–1. *A*, View of the skull base from above shows the foramina discussed in the text (*right*), the three divisions of the skull base (*right*), and the bones comprising this area (*left*). *B*, View of the skull base from below with the foramina labeled on the right side of the figure and individual bones comprising the skull base on the left.

passes to the nasal cavity. The perforated cribriform plate allows passage of the olfactory nerve fibers traveling from the olfactory epithelium of the superior part of the nasal cavity to the olfactory bulb. The sella turcica contains the pituitary gland in the posterior central area of the anterior fossa at the junction with the middle and posterior fossae. The optic chiasm rests anterior and superior to the pituitary in the chiasmic groove. The cavernous sinus lies lateral to the pituitary gland and sella turcica.

Middle Cranial Fossa

The middle fossa is formed by the greater wing of the sphenoid bone anterocentrally and the temporal bone centrally, laterally, and posteriorly. It extends from the superior orbital fissure (greater wing of the sphenoid) anteriorly to the superior petrosal sinus along the petrous ridge posteriorly and from the cavernous sinus medially to the squamous portion of the temporal bone laterally. Anteromedially, the foramen spinosum allows passage of the middle meningeal artery into the cranial space, where it courses laterally along the outer surface of the dura. The trigeminal nerve originates in the posterior cranial fossa and enters the middle cranial fossa through a fold of dura over the medial part of the petrous ridge, Meckel's cave. The fifth cranial nerve (gasserian) ganglion lies immediately anterior to this and rests over the horizontal portion of the carotid artery. From the gasserian ganglion, the three branches arise. The mandibular division of the trigeminal nerve exits the cranial cavity anteromedial to the foramen spinosum through the foramen ovale. Further anteromedially, the foramen rotundum allows for the exit of the maxillary branch of the trigeminal nerve in an anterior and horizontal direction to the pterygopalatine space. The ophthalmic branch of the trigeminal nerve, along with cranial nerves III, IV, and VI and the ophthalmic vein, pass through the cavernous sinus and then enter the orbit through the superior orbital fissure. After entering the central portion of the temporal bone from the neck, the carotid artery curves medially 90 degrees and runs a near-horizontal course in a medial direction in the foramen lacerum before entering the intracranial space and passing through the cavernous sinus.

The middle cranial fossa is the one portion of the skull base with significant structures contained within the underlying bone, namely, the seventh cranial nerve and the labyrinth. Their anatomy is presented in Chapter 1. Access to and around these structures is a frequent issue in skull base surgery.

Posterior Cranial Fossa
