The quadrangular membrane attaches anteriorly to the lateral margin of the epiglottis and curves posteriorly to attach to the arytenoid and corniculate cartilages. This structure and the overlying mucosa constitute the aryepiglottic folds. Each fold forms part of the medial wall of each piriform sinus. The inferior edge of the quadrangular membrane constitutes the vestibular ligaments.

The conus elasticus is a thicker elastic structure than the quadrangular membrane. It attaches inferiorly at the superior border of the cricoid cartilage. It then projects upward and medial to its superior attachments, the anterior commissure of the thyroid cartilage and the vocal process of the arytenoid. Between these superior attachments, the conus thickens to form the vocal ligament. Anteriorly, the conus forms the cricothyroid membrane, and in the midline, this membrane condenses to form the cricothyroid ligament (Figures 47–1 to 47–3). The superior extension of the conus (thyroglottic membrane) parallels the superior surface of the true cord. Because it may normally be incomplete, it forms an imperfect barrier to the inferior extension of the transglottic cancers (Figure 47–4).[7]

Muscles

Extrinsic Muscles The extrinsic muscles of the larynx are those muscles of the laryngohyoid complex that serve to raise, lower, or stabilize the larynx.[2–7] Those muscles that elevate the larynx are the thyrohyoid, stylohyoid, digastric, geniohyoid, mylohyoid, and stylopharyngeus. These muscles are important in the elevation and anterior displacement of the larynx during swallowing. They also help to suspend the larynx, via the hyoid bone, from the skull base and mandible. The principal depressors of the larynx are the omohyoid, sternothyroid, and sternohyoid. These muscles displace the larynx downward during inspiration. The middle constrictor, inferior constrictor, and cricopharyngeus muscles are also important extrinsic laryngeal muscles. The proper functioning of these muscles is crucial to the precisely timed swallowing reflex.

Intrinsic Muscles The intrinsic muscles of the larynx are those muscles that are anatomically restricted to the larynx proper. They modify the size of the glottic opening along with the length and tension on the vocal folds. They consist of multiple adductors but only a single abductor. With the exception of the interarytenoid, the intrinsic muscles are paired, and these paired muscles appear to act synchronously (Figure 47–5).

Cricothyroid Muscle. The cricothyroid muscle is located on the external surface of the laryngeal cartilages. It is classically described as consisting of two bellies. The straight portion or pars recta attaches the lateral portion of the anterior arch of the cricoid cartilage to the inferior border of the thyroid cartilage in a fairly vertical direction. The second belly, the pars obliqua, also from the anterolateral border of the cricoid arch, travels obliquely upward to insert on the anterior portion of the inferior cornu. When the right and left cricothyroid muscles contract, they rotate the cricoid at the cricothyroid joint. This action brings the anterior arch of the cricoid superiorly toward the inferior border of the thyroid laminae while displacing the posterior cricoid lamina (and the arytenoid cartilages) inferiorly. This inferior displacement increases the distance between the vocal processes and the anterior commissure; the result of this action is to lower, stretch, and thin the vocal folds while bringing them into a paramedian position. The stretching of the vocal fold also sharpens the edge of the vocal fold and passively stiffens the component layers of the vocal fold (Figure 47–6). Biomechanically, this translates into a higher fundamental frequency produced by the vocal folds.

Posterior Cricoarytenoid Muscle. This muscle is the sole abductor of the vocal folds. It is seated in a depression on the posterior surface of the cricoid lamina, and its fibers run obliquely superior and lateral to attach onto the muscular process of the arytenoid cartilage. It is composed of two compartments: horizontal and vertical bellies. Contraction of these fibers brings the muscular process medial, posterior, and inferior while laterally rotating and elevating the vocal process. This action abducts, elongates, and thins the vocal folds while causing the vocal fold edge to be rounded. The stretching of the vocal fold leads to passive stiffening of its layers. The complex function of this muscle has been studied in the canine in which three distinct neuromuscular compartments are found. It is proposed that the vertical and oblique bellies normally cause vocal fold abduction during respiration, whereas the horizontal belly is primarily used to adjust the position of the vocal process during phonation.[11,12]

Lateral Cricoarytenoid Muscle. This is the main antagonist of the posterior cricoarytenoid. It attaches along the superior border of the cricoid cartilage and then sends its fibers posteriorly to insert on the anterior portion of the muscular process.

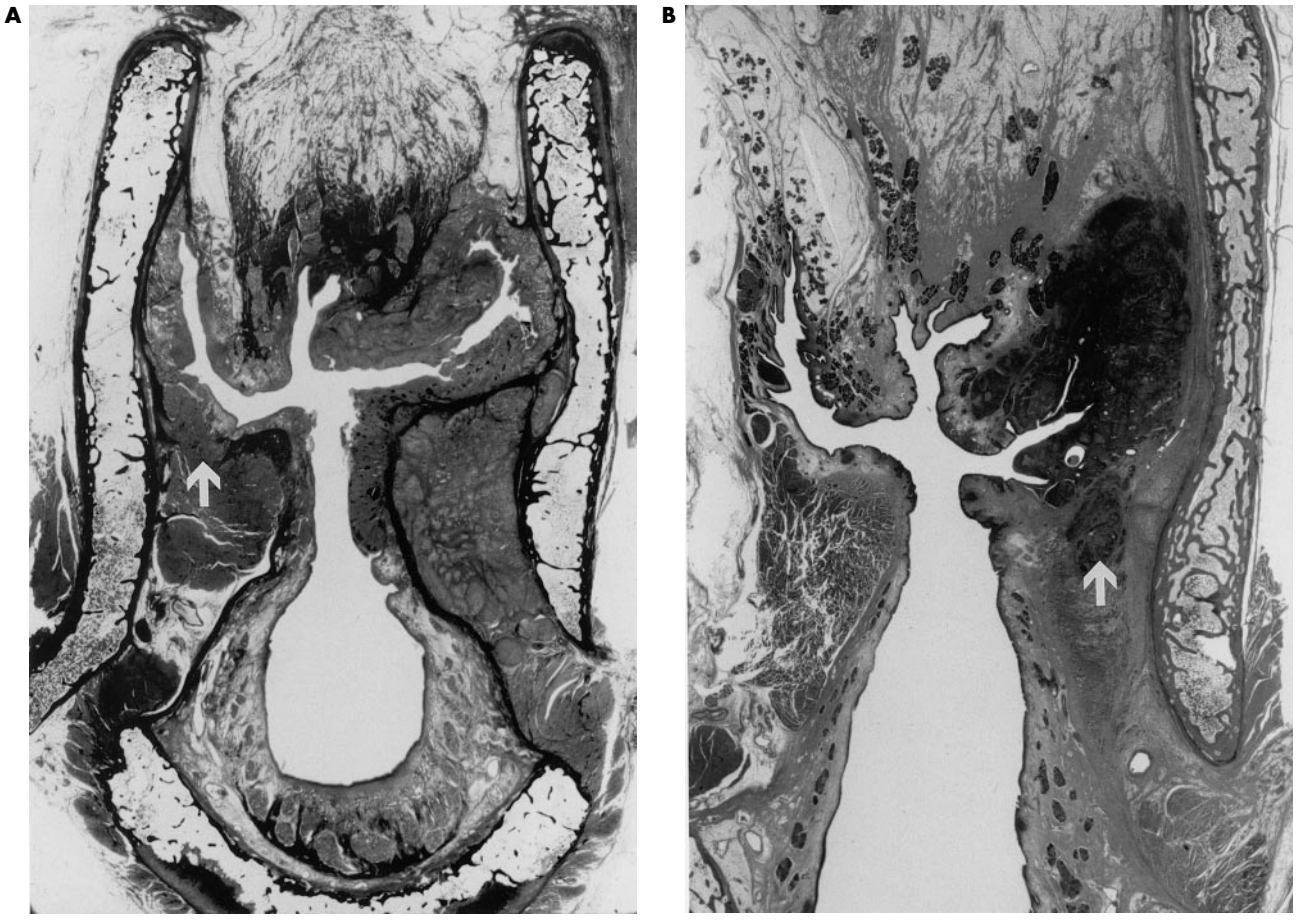

FIGURE 47–4. A, The thyroglottic membrane may be naturally dehiscent (*arrow*). *B*, Dehiscence in the thyroglottic membrane can allow transglottic cancer to extend inferiorly along the paraglottic space (*arrow*). Courtesy of Dr. John A. Kirchner.

Contraction of this muscle brings the muscular process anterolaterally while adducting and lowering the vocal process. This results in adduction, elongation, and thinning of the vocal folds. The edge of the vocal fold becomes sharper, and its component layers are passively stiffened.

Interarytenoid/Aryepiglottic Muscle. The interarytenoid is the only unpaired intrinsic muscle, consisting of two types of muscle fibers. The bulk of the muscle consists of transverse fibers passing from the posterior surface of one arytenoid cartilage to the posterior surface of the other. This muscle contracts to bring together the arytenoid cartilages, thus assisting in closing the posterior portion of the glottis. This does not significantly affect the mechanical properties of the vocal folds. Along with these transverse fibers are oblique fibers. These oblique fibers pass from the posterior portion of the arytenoid on one side to the apex of the arytenoid on the other side, thus crossing in the midline. Some fibers insert at the apex, whereas others travel along the quadrangular membrane. These fibers contract to narrow the laryngeal aditus. Those fibers traveling along the quadrangular membrane (thus the aryepiglottic fold) constitute the aryepiglottic muscle.

Thyroarytenoid Muscle. This muscle is classically divided into the thyroarytenoid internus and externus. These have the same attachments, but the internus lies deep or internal to the externus. In addition, the internus is more well developed than the externus.

Copyright Urban & Fischer Verlag.

The thyroarytenoid externus arises from the anterior commissure and inserts onto the lateral surface of the arytenoid cartilage. It contracts to bring the vocal process and anterior commissure closer to each other, thus adducting the vocal folds. It also contracts to adduct the false cords. The externus sends a few slips of muscle fibers onto the quadrangular membrane to establish the thyroepiglottic muscle. This muscle, like the aryepiglottic muscle, acts to narrow the laryngeal inlet.

The thyroarytenoid internus or vocalis muscle attaches at the anterior commissure and inserts onto the vocal process, sending a few slips of fibers below the vocal ligament onto the conus elasticus. It contracts to adduct, shorten, thicken, and lower the vocal fold while rounding its edge. The body (muscle) of the vocal fold is actively stiffened, whereas the cover is passively slackened.

Recently, immunohistochemical staining for myofibrillar adenosine triphosphatase reveals that

the majority of fibers in internus are slow-twitch and those in externus fast-twitch, suggesting its unique human specialization for speech function.[13,14]

Internal Anatomy

The internal anatomy of the larynx consists of three compartments separated by two folds (see Figure 47–3).[2–7] The three compartments are the vestibule, ventricle, and infraglottic cavity. The false and true vocal folds separate the above compartments. These mucosa-lined compartments demarcate two spaces of importance: the preepiglottic space and the paraglottic space.

Vestibule A laryngoscopic view of the larynx reveals the vestibule as that portion of the larynx from the tip of the epiglottis to the false or vestibular folds. Thus, the vestibule is bound by the epiglottis anteriorly, the aryepiglottic folds laterally, and the arytenoid and corniculate cartilages with the interarytenoid muscle posteriorly. In the laryngoscopic view, the anterior commissure is frequently hidden by the protuberance of the epiglottis known as the tubercle.

As previously discussed, the vestibular folds are formed by mucosa overlying the vestibular ligament

(inferior border of the quadrangular membrane). The submucosa of the ventricle contains numerous seromucinous glands. The secretions produced by these exocrine glands provide both mechanical and immune (lysozyme) protection for the vocal folds.[15]

Ventricle The ventricle or sinus of Morgagni is the small space between the false and true vocal folds. The ventricle is often hidden during laryngoscopic examination of the larynx unless exposed by lateralization of the false vocal fold. At the anterior end of the ventricle is a diverticulum known as the laryngeal saccule. The saccule (of Hilton) is lined with mucous glands, which are thought to lubricate the vocal folds. Fibers of the thyroarytenoid muscle line the walls of the saccule and are thought to express mucus from the saccule when they contract. The size of the saccule is quite variable; however, it seldom extends above the superior border of the thyroid cartilage. Abnormal dilatation of the saccule results in an air-filled laryngocele that should be distinguished from a mucocele of the saccule (saccular cyst), which lacks free communication with the ventricle and thus is not air filled.[16] The vocal folds that form the inferior boundary of the ventricle are described in more detail in a separate section.

Infraglottic Cavity The infraglottic cavity extends from the glottis down to the inferior border of the cricoid cartilage. Its lateral boundary is formed by the conus elasticus and walls of the cricoid cartilage.

Piriform Sinus Although the piriform sinus is anatomically part of the hypopharynx, understanding its anatomy and its relationship to the larynx is essential. The piriform sinus is a gutter formed by the aryepiglottic fold, arytenoid, and superior cricoid medially and the thyrohyoid membrane and internal surface of the thyroid lamina laterally. Superiorly, it begins at the lateral glossoepiglottic fold. Inferiorly, the apex of the sinus blends with the esophageal inlet at about the superior border of the cricoid (Figure 47–7). Thus, cancer invasion of the apex implies the necessity of removing a portion of the cricoid if conservation laryngectomy is planned.[7]

There are two important markings within the piriform sinus. Anteriorly in the floor of the sinus, a small fold can be seen, which marks the course of the superior laryngeal nerve. This submucosal course of the nerve makes it possible to anesthetize the nerve topically in the piriform sinus. The second, more variable landmark is the protrusion made into the sinus from the superior cornu of the thyroid cartilage. This smooth protrusion, which usually presents in the elderly, should not be confused with neoplasm.

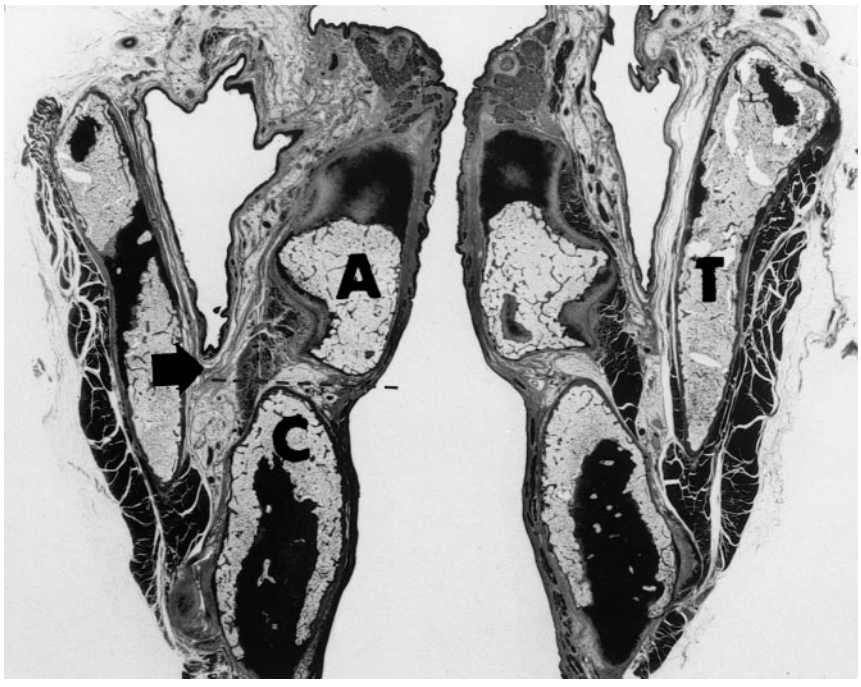

FIGURE 47–7. Coronal section through the human larynx demonstrating the relationship of the cricoid cartilage (C) with the apex of the piriform sinus (*arrow*). A = arytenoid cartilage; T = thyroid cartilage. Courtesy of Dr. John A. Kirchner.

Mucosa The mucosa of the larynx is of two types: pseudostratified ciliated columnar cell (respiratory) epithelium and squamous cell epithelium. Much of the larynx is surfaced by respiratory epithelium; however, the superior portion of the epiglottis, upper portions of the aryepiglottic folds, and free edges of the vocal folds are surfaced by squamous cell epithelium. Beneath this covering epithelium is a variable basement membrane, and separating these two is a layer of loose fibrous stroma. It should be noted that this loose fibrous layer is absent on the true vocal folds as well as the laryngeal (posterior) surface of the epiglottis. The absence of this layer on the posterior surface of the epiglottis accounts for the more intense swelling of the lingual (anterior) surface of the epiglottis in inflammatory conditions of the larynx.

Preepiglottic Space The preepiglottic space, as its name implies, lies anterior to the epiglottis, which serves as its posterior boundary. It is bound superiorly by the hyoepiglottic ligament and mucosa of the valleculae and inferiorly by the thyroepiglottic ligament. The anterior boundaries are the thyrohyoid membrane and the inner surfaces of the thyroid laminae. Laterally, the preepiglottic space opens in the paraglottic spaces. Cancer on the infrahyoid portion of the epiglottis can penetrate this structure and gain access to the preepiglottic space.

Paraglottic Space A paraglottic space, as its name implies, lies on each side of the glottis. This space lies above and below the true and false vocal folds and is important in the transglottic and extralaryngeal spread of neoplasms. Medially, the space is bound by the quadrangular membrane, ventricle, and conus elasticus. Laterally, it is bound by the perichondrium of the thyroid lamina and the cricothyroid membrane. Anterosuperiorly, the space opens in the posterior portion of the preepiglottic space. The mucosa of the piriform sinus forms the posterior boundary. The relationships of this paraglottic space make it important in considering the spread of laryngeal cancer. Supraglottic cancer invading into this space may quickly extend extralaryngeally.

Vocal Folds

The anatomy of the vocal folds is complex and is thus considered separately. The vocal fold is considered the structure between the vocal process of the arytenoid and the anterior commissure. The vocal folds and the slit between them (rima glottidis) constitute the glottis. The glottis can be divided by a horizontal line between the tips of the vocal processes. This imaginary line divides the glottis into an intermembranous portion and an intercartilaginous portion. The anterior to posterior (length) ratio of the intermembranous portion to the intercartilaginous is 3 to 2; however, the ratio of cross-sectional areas defined by them is 2 to 3. Thus, owing to its more rectangular shape, the intercartilaginous portion is larger. Some have called this the respiratory portion of the rima.[4,17] The membranous or vibratory portion of the vocal folds consists of three well-defined structural layers. From superficial to deep, they are the epithelium, lamina propria (three layers), and vocalis muscle. Hirano divided these layers according to a body-cover concept (see Figure 47–6, A).[17] The cover consists of the overlying epithelium and the gelatinous superficial layer of the lamina propria. The body consists of the vocalis muscle, which he likened to thick rubber bands. Between these exists a transition zone composed of the intermediate (elastic) and deep (collagenous) layers of the lamina propria. According to this concept, the vocal folds consist of a multilayered vibrator with increasing stiffness from the cover to the body. Thus, the cover is responsible for most of the vibratory action of the vocal folds. At the anterior and posterior ends of the vocal folds exists an anterior and a posterior macula flava, respectively. These are essentially a thickening of the intermediate (elastic) layer of the lamina propria and are thought to function as "cushions" protecting the ends of the vocal folds from vibratory damage. It should be noted that the same body-cover concept does not apply to the larynx of children because of the more homogeneous nature of the lamina propria. It is not until nearly the end of adolescence that the lamina matures into its adult form. In the senile larynx, the elastic layer and the vocalis muscle tend to atrophy, whereas the collagenous layer thickens. The cover becomes thickened and edematous secondary to changes in the superficial layer of the lamina, whereas the epithelium itself changes little.

The shape of the true and false vocal folds carries biomechanical significance. When seen in coronal section, both appear as valve-like structures, with the leaflets of the false folds pointing inferiorly and those of the true folds pointing superiorly (see Figure 47–3). Thus, the false folds passively impede egress of air, whereas the true folds impede its ingress. Work-

ing with cadaver larynges, Brunton and Cash demonstrated that the false folds offered a resistance equaling 30 mm Hg to the egress of air from below, whereas the true folds offered a resistance equaling 140 mm Hg to the ingress of air from above.[18] Both structures offered little resistance to the opposite flow of air (ie, they act as one-way valves).

Vessels

Arteries and Veins The arterial supply to the larynx consists of the superior and inferior laryngeal arteries.[2–7] After the superior thyroid artery branches off the external carotid, it courses lateral to the laryngohyoid complex and gives off the superior laryngeal artery at approximately the level of the hyoid bone. This artery then runs anteromedially with the internal branch of the superior laryngeal nerve to enter the thyrohyoid membrane inferior to the nerve. It then enters the submucosa of the piriform sinus and is distributed to intralaryngeal structures. The superior thyroid also gives off a cricothyroid branch that courses horizontally below the thyroid cartilage. The inferior laryngeal artery is a branch of the inferior thyroid artery that comes off the thyrocervical trunk branching from the subclavian artery. After coursing posterior to the cricothyroid joint with the recurrent laryngeal nerve, the artery enters the larynx by passing through a gap in the inferior constrictor muscle known as the Killian-Jamieson area. The artery is then distributed to the remainder of the internal larynx, making multiple anastomoses with the superior laryngeal artery. The venous supply parallels the arterial supply.

Lymphatics An appreciation of the lymphatics of the larynx is prerequisite to understanding the spread of cancer of the larynx, as well as the operative procedures designed to eradicate the disease.[2–7,19] The lymphatics of the larynx are divided into superficial (intramucosal) and deep (submucosal) groups. The deep network is further divided into right and left halves, with little communication between them. These two halves can be further divided into supraglottic, glottic, and subglottic, with special consideration given to the ventricle in the supraglottic region. Although the superficial network is richly anastomotic throughout the larynx, it is the deep network that is important in the spread of cancer and will be given further consideration.

The drainage of the supraglottic structures (aryepiglottic folds and false cords) follows the superior laryngeal and superior thyroid vessels. Thus, the lymphatics flow from the piriform sinus through the thyrohyoid membrane to end primarily in the deep jugular chain around the carotid bifurcation. It should be noted that the epiglottis is a midline structure; thus, its lymphatic drainage is bilateral.

The lymphatic drainage of the ventricle is different from the other supraglottic structures. Dye injected into the ventricle enters the paraglottic space and is quickly spread by the lymphatic system through the cricothyroid membrane and also into the ipsilateral lobe of the thyroid (justifying its resection in laryngectomy).

The true vocal folds are devoid of lymphatics, accounting for the high curability of cancer localized to this structure.

The subglottic larynx has two lymphatic drainage systems. One system follows the inferior thyroid vessels to end in the lower portion of the deep jugular chain as well as the subclavian, paratracheal, and tracheoesophageal chains. The other system pierces the cricothyroid membrane. This system appears to receive lymphatics from both sides of the larynx and disseminate bilaterally to the middle deep cervical nodes as well as the prelaryngeal (Delphian) nodes.

PHYSIOLOGY

As previously stated, the three functions of the larynx in order of priority are (1) protection of the lower airway, (2) respiration, and (3) phonation.[1] A flawless performance of these functions requires an intact neuromuscular system to respond to both volitional and reflex signals presented to the larynx.

Innervation

The pattern of innervation to and from the larynx and the type and distribution of its receptors determine the functional capabilities of the larynx. The larynx is innervated by the superior and inferior laryngeal nerves. The superior laryngeal nerve leaves the nodose ganglion to pass between the carotid artery and the laryngohyoid complex. It divides into a larger internal and smaller external branch. The internal branch pierces the thyrohyoid membrane with the superior laryngeal artery and becomes the

sensory supply to the ipsilateral supraglottic larynx, whereas the external branch innervates the cricothyroid and inferior constrictor muscles. The inferior laryngeal nerve originates from the recurrent laryngeal nerve and runs in the tracheoesophageal groove. It enters the larynx posterior to the cricothyroid joint and classically divides into an anterior adductor and a posterior abductor branch. This branching, however, is quite variable, as is the muscular innervation from the branches.[4]

The receptors of the larynx can be divided into mucosal, articular, and myotatic. These receptors mediate much of the reflex activity of the larynx. The mucosal receptors respond to stimuli such as touch, mucosal deformation (mechanoreceptors), and liquids. The articular receptors are located in the joint capsule and respond to deformation of the capsule. The myotatic receptors respond to muscular stretch and appear to be most abundant in the vocalis muscle.[20]

Afferent System The sensory innervation to the mucosa of the supraglottic larynx is carried by the internal branch of the ipsilateral superior laryngeal nerve, which is divided into three divisions. The superior division mainly supplies the mucosa of the laryngeal surface of the epiglottis, the middle division supplies the mucosa of the true and false vocal folds and the aryepiglottic fold, and the inferior division supplies the mucosa of the arytenoid, part of the subglottis, the anterior wall of the hypopharynx, and the upper esophageal sphincter.[21] The cricoarytenoid joint and thyroepiglottic ligament are both innervated by the internal branch of the superior laryngeal nerve. The inferior laryngeal nerve supplies the major portions of mucosa below the glottis as well as muscle spindles of intrinsic muscles. The external branch of the superior laryngeal nerve contains afferent fibers from the cricothyroid joint and from deep muscle receptors.

Histologic examination has revealed the presence of free nerve endings, Merkel cells, Meissner's corpuscles, and taste buds scattered in the larynx. Mechanoreceptors are located either in the superficial mucosa or in the muscles and laryngeal joints. Some of them are spontaneously active, whereas others are silent until stimulated. The supraglottic larynx also has chemical and thermal sensors. A large number of taste buds populate the laryngeal surface of the epiglottis and extend caudally along the aryepiglottic folds, reaching peak density at the caudal extreme of the folds.[22,23] This sensory distribution facilitates the supraglottic larynx in its role of preventing foreign material from penetrating into the larynx.[24] These respond to a number of chemical stimuli and to water. The taste buds of the larynx tend to be most sensitive to the pH and tonicity of the stimulus. In this regard, the water receptors of the epiglottis appear to play a role in the production of prolonged apnea. When stimulated, they lead to a slowing of respiration with an increase in tidal volume. Chemoreceptors of the larynx are adapted to detect chemicals that are not saline-like in composition and can play an important role in modifying reflexes involved in the maintenance of upper airway patency.[23] It is important to note that this same response does not occur with saline. It is felt that the receptors may be responding to the washout of chloride ions.[20] Theoretically, this may be the mechanism by which cold-steam mist assists the child with croup (slowing and deepening breathing, thus decreasing turbulent flow).[25] Interestingly, this response is more potent early in life. This apneic response has also been implicated in sudden infant death syndrome.[20] The vocal folds also have touch receptors that are more abundant posteriorly than anteriorly. The afferent impulses generated are delivered to the tractus solitarius through the ganglion nodosum.

Efferent System The motor innervation is primarily through the inferior laryngeal nerve. This nerve innervates all of the intrinsic muscles of the larynx except the cricothyroid, which is innervated by the external branch of the superior laryngeal nerve. Each nerve is responsible for the muscles on the ipsilateral side of the larynx, with the exception of the interarytenoid muscle. Thus, the only unpaired muscle of the larynx receives its innervation from both inferior laryngeal nerves. Injury to the recurrent laryngeal nerve leaves the injured cord in the paramedian position, resulting from the adductor effect of the intact cricothyroid. Unilateral injury to the superior laryngeal nerve causes the posterior glottic opening to rotate to the paralyzed side, bowing the paralyzed cord.[4,24] These changes in the larynx can be seen on laryngeal endoscopy.

Neurophysiology of Protective Function

The glottic closure reflex is a polysynaptic reflex that allows the larynx to protect the lower airway from

penetration and aspiration. However, when exaggerated, this reflex accounts for the production of laryngospasm. Protective closure of the larynx occurs in three tiers.

In the first tier, the laryngeal inlet is contracted by collapsing the aryepiglottic folds medially. The anterior and posterior gaps are filled by the epiglottic tubercle and the arytenoid cartilages, respectively. In the second tier, the false vocal folds are brought together. The final and most important tier occurs at the level of the true vocal folds. Because the valvular action of the true vocal folds resists ingress of material, they offer the most important level of protection. It should be noted that it is the thyroarytenoid or slips from this muscle that contract at each level of closure. This muscle is one of the fastest contracting of all striated muscles in the body. Classically, the afferent limb of this reflex occurs through stimulation of touch, chemical, or thermal receptors in the supraglottic larynx.[26]

Laryngospasm occurs when stimulation of the superior laryngeal nerve leads to a prolonged adductor response. This response is maintained well after the initiating stimulus is removed, and section of the superior laryngeal nerves abolishes the response. Clinically, this is typically seen in the setting of endotracheal intubation/extubation or after manipulation of the airway, especially if blood has contaminated the laryngeal inlet. The response is dampened in the face of barbiturates, hypercapnia, positive intrathoracic pressure, and severe hypoxia.[27]

Although not classically considered part of the protective reflex, reflex swallowing from stimulation of the superior laryngeal nerve may have protective functions. It has been shown that reflex swallowing occurs with application of hypotonic fluids to the supraglottic larynx, particularly the laryngeal surface of the epiglottis, glottis, and internal larynx. Although this is not the normal mechanism to initiate swallowing, it may serve to protect the larynx against fluid that enters the laryngeal inlet.[20]

Neurophysiology of Respiratory Function

It is intuitive that if the larynx is the sphincter to the lower airway, for respiration to occur, the sphincter needs to be actively opened during inspiration. Also, the opening of the folds must be synchronous with, but slightly precede, the descent of the diaphragm. Through the work of many individuals, this observation is well supported.[24,28,29] The respiratory center of the medulla, with the help of higher central nervous system and peripheral input, maintains eupneic respiration. It drives the synchronous opening of the glottis and descent of the diaphragm during inspiration. The opening of the glottis is primarily through the action of the posterior cricoarytenoid. However, in hyperpneic conditions, the cricothyroid contracts rhythmically with the posterior cricoarytenoid.[28,29] The contraction of both of these muscles increases the glottic aperture in both anteroposterior and horizontal dimensions. During phonation, the cricothyroid lengthens and passively adducts the vocal folds. However, during respiration, when contracted in concert with the posterior cricoarytenoid, the effect is to lengthen the open glottis, thus increasing the cross-sectional area for airflow.

Understanding the role that the cricothyroid plays as an accessory muscle of inspiration underlies the rationale for superior laryngeal nerve section in the face of bilateral recurrent laryngeal nerve paralysis. Bilateral paralysis produces dyspnea, which will lead to cricothyroid contraction, further adducting the paralyzed folds. Unilateral superior laryngeal nerve section reduces glottic resistance by preventing its full adduction.

The rhythmicity of the phrenic nerve and the posterior cricoarytenoid can be increased by hypercapnia and ventilatory obstruction. It is lessened by hypocapnia. The effect of ventilatory resistance on posterior cricoarytenoid activity has been extensively studied in the canine model. In this model, when ventilatory resistance is eliminated, so is the reflex abductor activity of the posterior cricoarytenoid. It is felt that the afferent limb of this reflex resides within the ascending vagus nerve and that the end-organ receptors are located within the thorax, although their precise location is unknown. The longer abductor activity is lost, the more difficult it is to re-establish.[30] This is the rationale for downsizing tracheotomy tubes (thus gradually increasing ventilatory load) prior to decannulation.

The role of the larynx in controlling expiration must also be considered. It is well known that the control of respiratory rate occurs primarily through variation of the expiratory phase. The time of expiration is dependent on the ventilatory resistance pro-

duced by the glottis. As discussed above, the cricothyroid contracting with the posterior cricoarytenoid will give the maximal glottic opening and hence the lowest ventilatory resistance. In this regard, cricothyroid contraction during expiration occurs when the critical subglottic pressure change of 30 cm H_2O/s is exceeded and continues as long as positive subglottic pressure is maintained. As expected, this threshold for activation is reduced in hypercapnia (allowing for quicker expiration and a faster respiratory rate) and increased in hypocapnia.[31]

Neurophysiology of Phonation

The complex mechanisms of phonatory control coordinate central and peripheral components. Electromyographic investigation of the control of peripheral neuromuscular systems involved in phonation has demonstrated specific intrinsic and extrinsic muscle function in humans. Central mechanisms are less well understood and often rely on animal models, which may only infer function in the unique phonatory systems of the human.

As a general model, the larynx, as a system, must respond to central commands from linguistic and motor centers. Signals are then relayed to the motor cortex in the precentral gyrus and on to motor nuclei in the brainstem and spinal cord. These signals are transmitted to the respiratory, laryngeal, and articulatory muscles responsible for speech and voice production. These messages are influenced by the extrapyramidal system, including the cerebral cortex, cerebellum, and basal ganglia, exerting fine control of respiration, phonation, and articulation.[32]

Specific connectivity and the central control of brainstem motor neurons responsible for voluntary control of phonation remain illusive. Laryngeal reflexes, which are key to the coordination of respiration, phonation, and deglutition, are understood primarily from the research focused on respiration and deglutition.[20] Further, central projections to laryngeal mechanisms are not consistent across species and may differ from nonhuman primates to humans as well. The nucleus tractus solitarius (NTS), periaqueductal gray, parabrachial nucleus, locus caeruleus, and ventromedial nucleus of the thalamus are all areas anatomically associated with the laryngeal system.[20] Figure 47–8 illustrates branching of the superior laryngeal nerve with central connectivity and projections of the NTS. However, specific mechanisms of control are not well defined. In some cases, the central terminations of specific sensory receptors and the origin of the motoneuron fibers are known, as in somatotopic organization for the face and limbs. To date, studies of the role of the cerebral cortex in phonation in primates reveal no such individual muscle representation or somatotopic mapping of the laryngeal system.[20]

The role of peripheral mechanisms in phonatory control has been studied more successfully using electromyography, airflow, and pressure studies in the vocal tract as well as imaging techniques, which allow observation of the vocal tract during phonatory postures. It is important to consider that phonation takes place in concert with upper articulators, the lip, tongue, jaw, and velum.

Mechanical tissue deformation and, in particular, the pull of the upper articulators on the larynx via the laryngeal-hyoid complex necessarily influence the phonatory environment. For example, Figure 47–9 illustrates vocal tract shaping for four distinct vowels. Note the apparent pull of the tongue high and forward for production of /i/ (labeled "iy"), in contrast to posterior and low posture for /a/ (labeled "aa"). The consequent constriction or, conversely, the opening of the posterior pharynx plays a key role in the acoustics of sound produced for each of these postures and influences laryngeal posturing for phonation.[33]

Electromyographic studies of specific muscle function indicate firing rates uniquely suited for fine control of laryngeal function. Contraction times for the intrinsic muscles in several species are presented in Table 47–1. Further, the high innervation ratio for human laryngeal muscles, estimated at 100 to 200 cells per motor unit,[34] makes laryngeal muscles capable of a great degree of precise control as required for adjustment of speaking frequency and intensity.

Intrinsic and extrinsic musculature, described previously in this chapter, influence specific action of laryngeal muscles during phonatory shaping of the glottis in sound production as described by Hirano (see Figure 47–5).[32] Table 47–2 summarizes the influence of each of these muscles on the shape and tension of the glottis during phonation.

It has been shown that the laryngeal muscles start to contract about 100 to 200 ms prior to the onset of phonation.[35] Further, the most important muscle in varying the phonation style (from

hypotense to hypertense) is the thyroarytenoid muscle.[36] The frequency of vibration depends on the following: (1) vibratory mass of both vocal folds, (2) the anterior to posterior tension, (3) functional damping at high pitch, and (4) subglottic pressure. In this regard, Gay and associates showed that in the chest register, the cricothyroid and vocalis, with the possible contribution of the posterior cricoarytenoid, most consistently control changes in fundamental frequency.[37]

Lovquist and others later described electromyographic recordings obtained from four

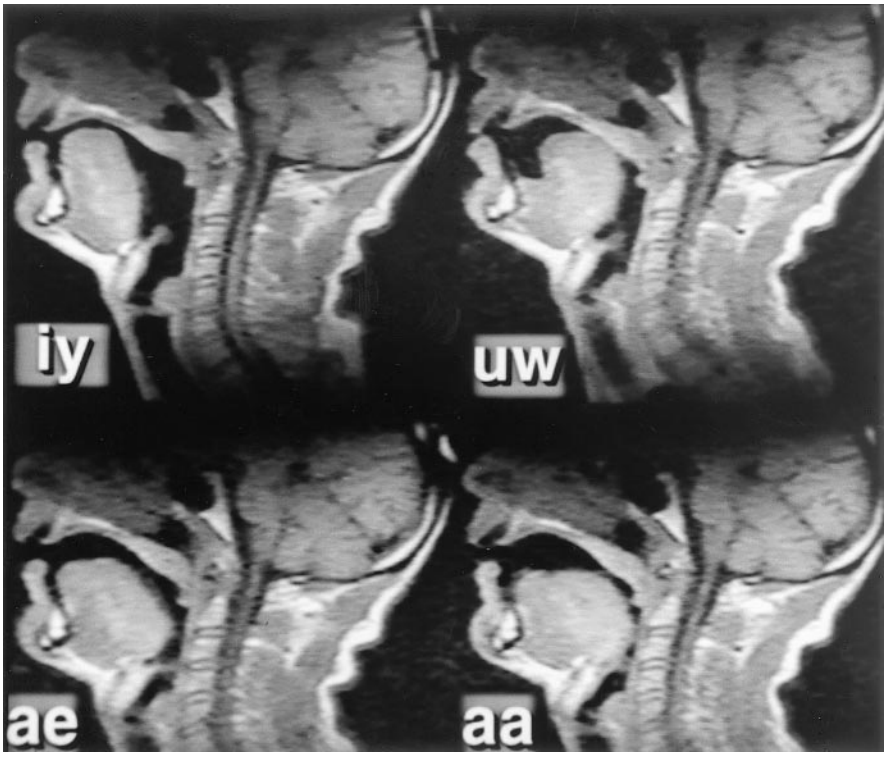

FIGURE 47–9. Magnetic resonance images of the vocal tract during sustained production of four vowels illustrate contrast in shape as viewed in sagittal section. Courtesy of C. Gracco.

intrinsic laryngeal muscles with simultaneous transillumination and acoustic signals.[38] The vocalis and lateral cricoarytenoid muscles were observed to participate in the control of both articulation and phonation. The interarytenoid muscle appeared to be involved only in articulatory adjustments. Activity in the cricothyroid was primarily related to changes in fundamental frequency. This muscle also showed an increase in activity for voiceless sounds. In addition, the vocalis muscle appeared to participate in glottal adduction without complete closure in voiceless clustered sounds, with the lateral cricoarytenoid and the interarytenoid playing no particular roles. Studies such as these underscore the complex interactive nature of laryngeal musculature in phonatory/articulatory interaction.

In considering the phonatory process, a variety of factors necessarily contribute to the acoustic product as defined in Table 47–3. The psychoacoustic parameters of pitch, loudness, quality, and fluctuation are correlated with acoustic qualities of fundamental frequency, amplitude, waveform, and

acoustic spectrum. High-speed photography and observation of vocal fold vibration via videostroboscopic endoscopy reveal much about the behavior of the glottis during phonation.[32,39]

The vibrations of the vocal folds are a passive phenomenon and represent the basis of the aerodynamic theory of sound production. Vibration of the vocal folds changes DC airflow into AC airflow, converting aerodynamic energy to acoustic energy. The mucosal wave produced by these vibrations has been captured on ultrahigh-speed photography by Hirano.[32] The vibratory cycle is described as having

three phases: opening, closing, and closed. By convention, the cycle is described as beginning with the vocal folds closed. Frames 1 to 5 (see Figure 47–6, B) represent the opening phase. During this phase, subglottic pressure increases, forcing the vocal folds apart from an inferior to superior direction until the glottis opens, letting air escape and thus releasing subglottic pressure. As the elastic recoil of the vocal folds forces them back together, the portion of the vocal fold that was the last to open (superior portion) is the last to close. Thus, the vocal folds close from inferior to superior (frames 6 to 8). The folds then remain closed until the subglottic pressure builds up enough to force them open again. Anatomically, the movement of the mucosal wave depends on the soft and compliant lamina propria and a healthy layered structure. In extracting complex details of glottal area waveforms from videostrobolaryngoscopic recordings using modern computers and software (Figure 47–10), Woo demonstrated male and female differences as well as influences of pitch and loudness.[39] Women commonly demonstrate small posterior glottal gaps that seem to have no pathologic acoustic significance, whereas their glottal cycles have shorter closed phases than those of men. Mean peak glottal area is smaller in women, not only because of their smaller anatomic size but also owing to the fact that their higher frequency of vibration limits the lateral excursion of the vocal folds, thereby reducing the amplitude of vibration. As intensity increases, the closing phase becomes shorter and the closed period becomes longer, suggesting that the closing patterns of vocal folds are an especially important feature in normal and pathologic phonation.

The coordination of higher cortical centers interacts with specific musculature in the vocal tract

to produce acoustic products recognized as speech. The laryngeal contribution to this product continues to be revealed in basic studies of phonation as an interactive process.

CHAPTER 48

Development of the Larynx

Ronan O'Rahilly, MD, DSc, Fabiola Müller, Dr. habil rer nat

Human prenatal life is divided into embryonic and fetal periods. The embryonic period, which comprises the first 8 weeks, is subdivided into 23 developmental stages, the details of which have been described elsewhere.[1] Prenatal age is postfertilizational. Postmenstrual weeks (which are not age) are useful clinically, but the term gestational age is meaningless.[2] A summary of the developing respiratory system in relation to staging was published by O'Rahilly and Boyden,[3] and many further details were provided by O'Rahilly and Müller.[4] Since the classic study of the larynx by Soulié and Bardier,[5] the development of this organ has been investigated by, among others, O'Rahilly and Tucker[6] and Müller et al,[7,8] and there has been an excellent study in the mouse.[9] Many references to the earlier literature can be found in these publications.

It is known that the hyoid bone is derived from the cartilaginous elements of pharyngeal arches 2 and 3, and the thyroid and other cartilages of the larynx are believed to be associated with the more caudally situated arches. The details of the developing larynx have been identified stage by stage. A summary of the development of the larynx is provided in Table 48–1.

EMBRYONIC PERIOD

In a certain sense, the larynx may be considered as a diverticulum of the future laryngopharynx, with which (except for a temporary embryonic closure) it communicates throughout life.

Three to Four Weeks

At 3 to 4 weeks, when the embryo is only about 3 mm long (stage 10), a median pharyngeal groove (internally) and ridge (externally) are discernible, and the groove includes the laryngotracheal sulcus. Within a few days (stage 12), the "lung bud" appears as a respiratory diverticulum that projects from the digestive tube into the mesenchyme ventral to the foregut.

Right and left lung buds are soon detectable (stage 13), and the trachea becomes visible in the more advanced specimens. The bifurcation point of the trachea then begins to descend.

The Tracheo-Esophageal Septum

The term tracheo-esophageal septum was used historically for a supposed fusion between medially growing internal folds in the wall of the foregut, which were believed to advance caudorostrally. Such a septum, however, does not exist.[10] In point of fact, as the respiratory primordium grows caudad, it becomes separated from the digestive primordium by tracheo-esophageal mesenchyme. The summit of this mesenchymal partition is the separation point between the trachea and the esophagus, and it remains at a constant vertebral level during the first 6 postfertilization weeks (Figure 48–1).

Four to Six Weeks At about 5 weeks (stages 14 and 15), the future larynx begins its differentiation. The lateral epithelial walls become apposed in the median plane, thereby forming what is known as the epithelial lamina. This bilaminar plate is situated between the arytenoid swellings, behind which the pharyngeal lumen still communicates with the trachea (pharyngoinfraglottic duct or canal). The hypopharyngeal (formerly called hypobranchial) eminence does not represent the epiglottis, which is identifiable a little later.

The hyoid condensation begins to appear, and by 6 weeks, the cricoid can be identified in mesenchyme (Figure 48–2). This is followed by the appearance of a single cartilaginous cricoid center.[11]

The larynx is clearly definable by 6 weeks (stage 17) (see Figure 48–2, B). At this time, or a few days earlier, the front portion of the epithelial lam-

Pharyngoinfraglottic duct connects digestive and respiratory tubes																
Epithelial lamina is complete; coronal cleft (not vestibule) of larynx identifiable																
Hyoid and cricoid condensations																
Skeleton of pharyngeal arches and larynx is dense mesenchyme; infraglottic cavity; ansa cervicalis and recurrent laryngeal nerve																
Hyoid chondrification begins; cricothyroid, posterior cricoarytenoid, arytenoid, and "thyrocricoarytenoid" muscles																
Epithelial lamina closes respiratory canal from pharynx																
Mesenchymal epiglottis																
Thyroarytenoid and lateral cricoarytenoid muscles																
Solid primordium of ventricle of larynx begins to appear; epithelial lamina begins to disintegrate																
Perioral reflex responses															?	
Aryepiglottic and thyroepiglottic muscles; ventricles that are angulated to the coronal cleft; intraepithelial receptors in laryngopharynx and nasal epithelium																
Epiglottis and palate are not yet in contact; vestibule becomes connected to infraglottic cavity; right and left leaves of epithelial lamina begin to separate; infrahyoid and most laryngeal muscles are present, eg, cricothyroid (oblique and straight parts); adult pattern of motor innervation, sensory incomplete																

ina can be regarded as its vestibular part. Lateral expansions of this portion soon form the embryonic vestibule (coronal or transverse cleft) (see Figure 48–2, B). The laryngeal cavity is now T-shaped in transverse section, but the transverse cleft that constitutes the embryonic vestibule corresponds to only a portion of the adult vestibule, which also includes the median cleft.

The appearance of the epithelial lamina at 6 weeks (stage 18) resembles type 1 congenital atresia, which may be essentially a persistence of the embryonic condition.[4] The rostral end of the tracheal

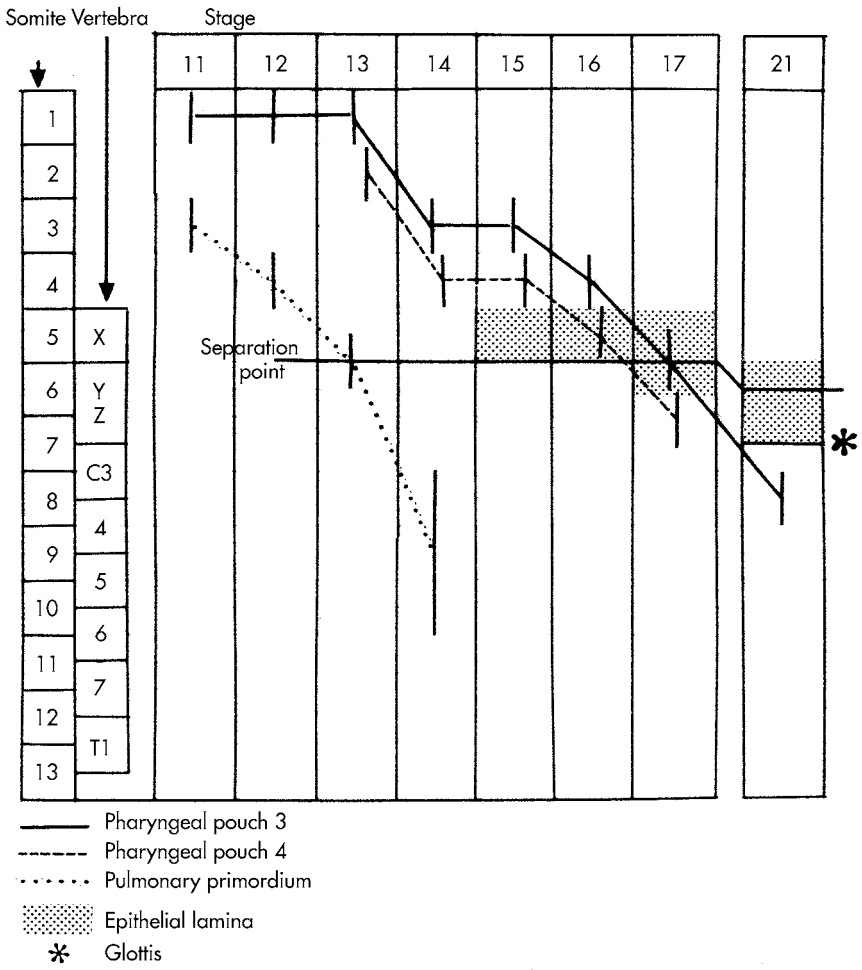

FIGURE 48–1. Graph showing the descent of pharyngeal pouches 3 and 4, and of the respiratory primordium from 4 to 7 postfertilizational weeks with reference to the only reliable landmarks, the somites and the vertebrae. The epithelial lamina and the separation point between trachea and esophagus remain at a constant level during the first 6 weeks. X, Y, Z are portions of the future axis. Based on the authors' reconstructions.

lumen is believed to represent the future infraglottic cavity. A tendency for the vestibule and the trachea to communicate with each other (vestibuloinfraglottic duct or canal) is characteristic. Laryngeal muscles are beginning to develop, but acceptable evidence for the existence of one or two common sphincters initially is lacking.[5,7] The hyoid condensation is undergoing chondrification, and condensation for the thyroid laminae begins to appear.

Importance of Vertebral Levels

In the assessment of levels, the only reliable landmarks are first the somites and then, also postnatally, the vertebrae. Soft tissues, such as pharyngeal pouches and spinal ganglia, are unreliable because they shift in position during development. Pharyngeal pouch 4, for example, used by several authors as a landmark,[10–12] is initially at the level of somite 2 (future basioccipital) but changes to somites 6 and 7 (base of the axis) by 6 weeks (see Figure 48–1). The pouch is then caudal to the epithelial lamina and does not represent the border between the pharynx and the larynx, as claimed.[11] Indeed, it is as low as the level of the future cricoid cartilage, and there is no room for a fifth pharyngeal pouch, supposed to correspond with the laryngeal ventricle.[10] In contrast, what we have termed the separation point between the trachea and esophagus, that is, the summit of the tracheoesophageal mesenchyme,[4] is remarkably stable (see Figure 48–1), which is said to be caused by its catenoid structure.[13]

Seven to Eight Weeks The pharyngoinfraglottic duct is largely, if not entirely, open in most embryos, and the track of the vestibuloinfraglottic duct is visible (see Figure 48–2, C). The ventricles of the larynx begin to appear as right and left laterally projecting epithelial buds. The right and left leaves of the epithelial lamina are beginning to separate, but at

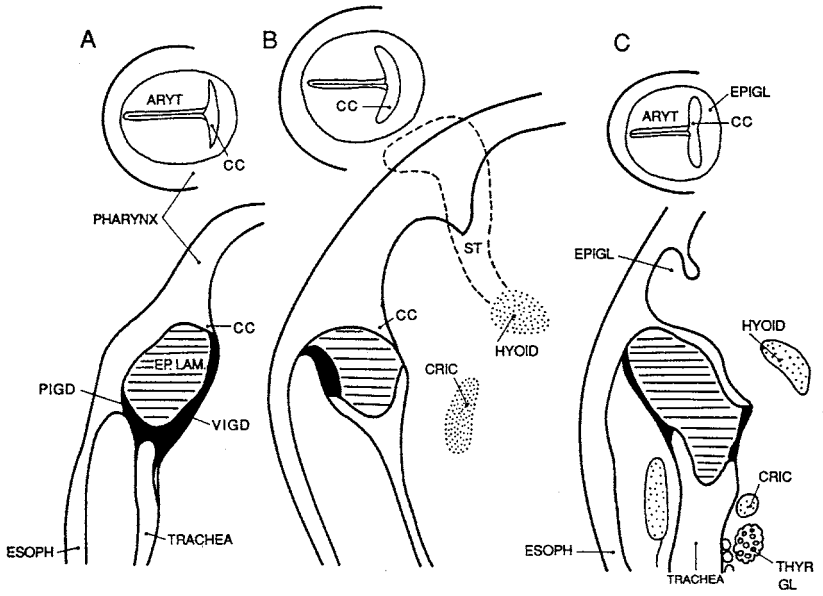

FIGURE 48–2. Development of the epithelial lamina and the first skeletal elements of the larynx in stages 16 to 21 (5½ to 7 weeks). The *upper row* shows the larynx as seen from above, and the *lower row* provides median sections at the corresponding stages (16, 17, and 21). ARYT = arytenoid swelling; CC = coronal cleft; CRIC = cricoid condensation; EPIGL = epiglottis; ESOPH = esophagus; PIGD = pharyngoinfraglottic duct; THYR GL = thyroid gland; VIGD = vestibuloinfraglottic duct.

the end of the embryonic period (stage 23), areas of fusion generally persist rostrally and caudally. The pharyngeal lumen, however, is continuous with the infraglottic cavity and hence with the trachea. Cavitation is beginning in the ventricles.

By the end of the embryonic period (stage 23; Figure 48–3), the hyoid cartilage consists of the body and greater horns, the lesser horns being distinct nodules separated from the styloid processes. The cartilaginous thyroid laminae, which may show a foramen, are united below by mesenchyme ("copula"). The superior horns may or may not be continuous with the laminae, but they arise in common with the greater horns of the hyoid. The cricoid cartilage is a continuous ring that comprises an arch and a lamina. Each arytenoid cartilage possesses a cartilaginous muscular process and a mesenchymal vocal process.

Most of the major laryngeal muscles (cricothyroid, posterior and lateral cricoarytenoids, thyroarytenoid, transverse arytenoid) are now present (although not yet striated), and their innervation follows the adult pattern closely.[7] Motor fibers penetrate the muscles. The vocalis is beginning to differentiate.

The laryngeal cavity now comprises (as in the adult) the vestibule, the ventricles and the part between them, and the infraglottic cavity. The ventricles are not at the level of the future glottis, which lies more caudally. The sensory innervation is well established, although most fibers do not yet reach the epithelium. In the laryngopharynx, however, receptors are present.[8]

FETAL PERIOD

Much information concerning the fetal larynx is available from Soulié and Bardier.[5]

During trimester 1 (Figure 48–4, A), the larynx increases in size from about 3 to 7 mm. The thyroid laminae become fused, and the cricothyroid membrane develops. The vocal ligaments begin to form early (33 mm), and the ventricular ligaments and glottis become increasingly apparent. The ventricles acquire their saccules. The cricoarytenoid joints undergo cavitation, in which they are followed by the cricothyroid joints. By 90 mm, the laryngeal cavity has its adult form.[5]

During trimester 2 (see Figure 48–4, C), the larynx increases in size from about 8 to 15 mm. The thyroid cartilage becomes a single structure. The epiglottis begins to chondrify. The hyoid cartilage commences ossification. The corniculate and cuneiform cartilages develop. The joints acquire ligaments. Glands become well developed. Elastic fibers have been detected in the epiglottis.[14]

During trimester 3, the larynx increases in size to about 15 to 20 mm, and the inlet is about 5 mm in diameter. Laryngeal connective tissue compartments in trimesters 2 and 3 have been studied.[15]

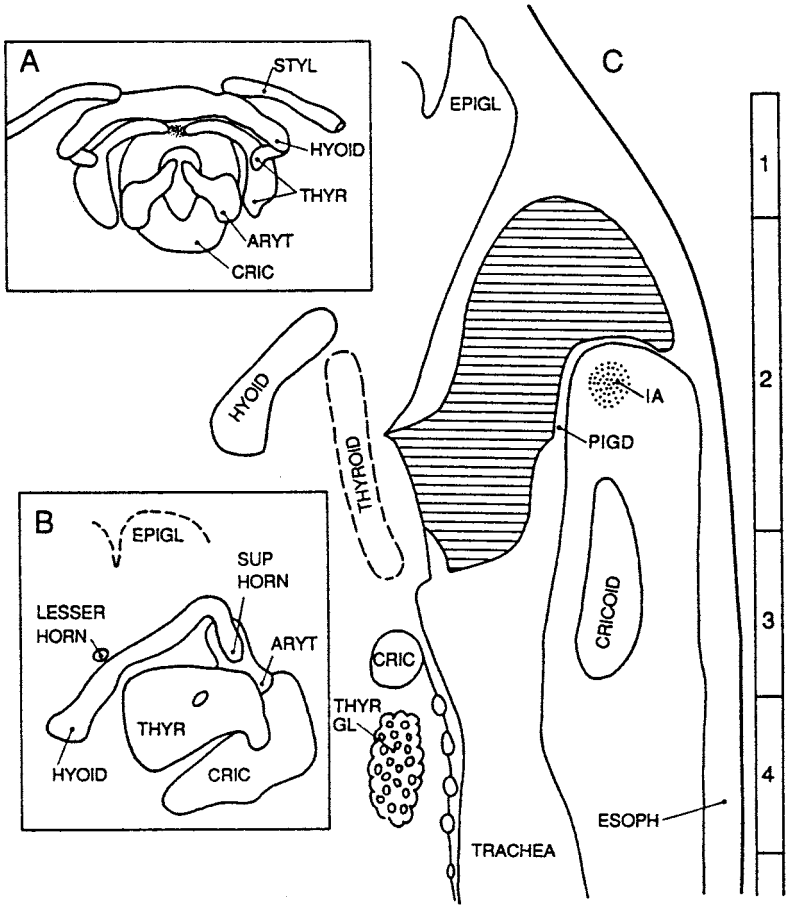

FIGURE 48–3. Larynx at the end of the embryonic period (8 weeks), showing reconstructions of three embryos at stage 23. *A*, Skeletal elements from above. *B*, Lateral view of skeleton. Note the foramen in the thyroid cartilage, through which nerve fibers of the external laryngeal nerve and an artery may enter; the opening can be found as a variation in the adult. The hyoid is remarkably ventral with regard to the thyroid cartilage. *C*, Median section. The numbers 1 to 4 indicate vertebral levels. STYL = styloid process; ARYT = arytenoid cartilage; CRIC = cricoid cartilage; EPIGL = epiglottis; ESOPH = esophagus; IA = interarytenoid muscle; PIGD = pharyngoinfraglottic duct; THYR = thyroid cartilage; THYR GL = thyroid gland.

Measurements of the developing larynx are available: embryonic and fetal,[5] fetal and infantile,[16] infantile,[17] infantile and child's,[18] and prepubertal and pubertal.[19] The larynx, as indicated by the tip of the epiglottis, the hyoid, and the lower border of the cricoid, descends from embryonic and fetal life to adulthood (Figure 48–5). Vertebral levels are available: embryonic,[4] fetal,[20] fetal and child's,[21] and child's.[22] The infantile larynx has been studied,[23,24] and detailed views have been published.[25]

Ossification in the thyroid cartilage frequently begins from about 20 years onward in the posterior

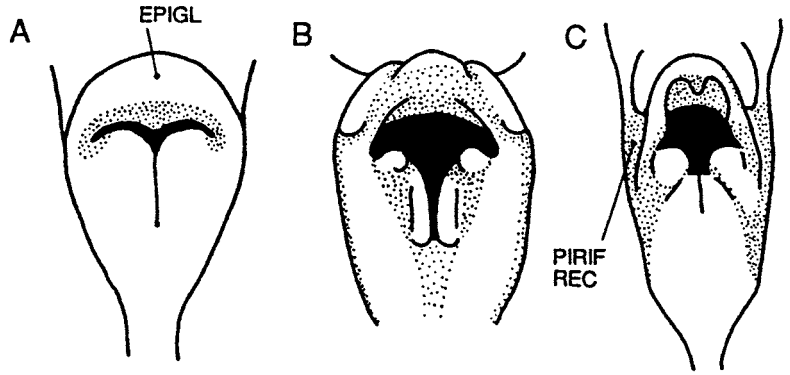

FIGURE 48–4. Dorsal view of the prenatal larynx at (*A*) 32 mm (8 weeks), (*B*) 55 mm (10 weeks), and (*C*) 160 mm (18 weeks). Note the appearance of the corniculate tubercles, the aryepiglottic folds, and the piriform recess (PIRIF REC). Adapted from Soulié A and Bardier F.[5]

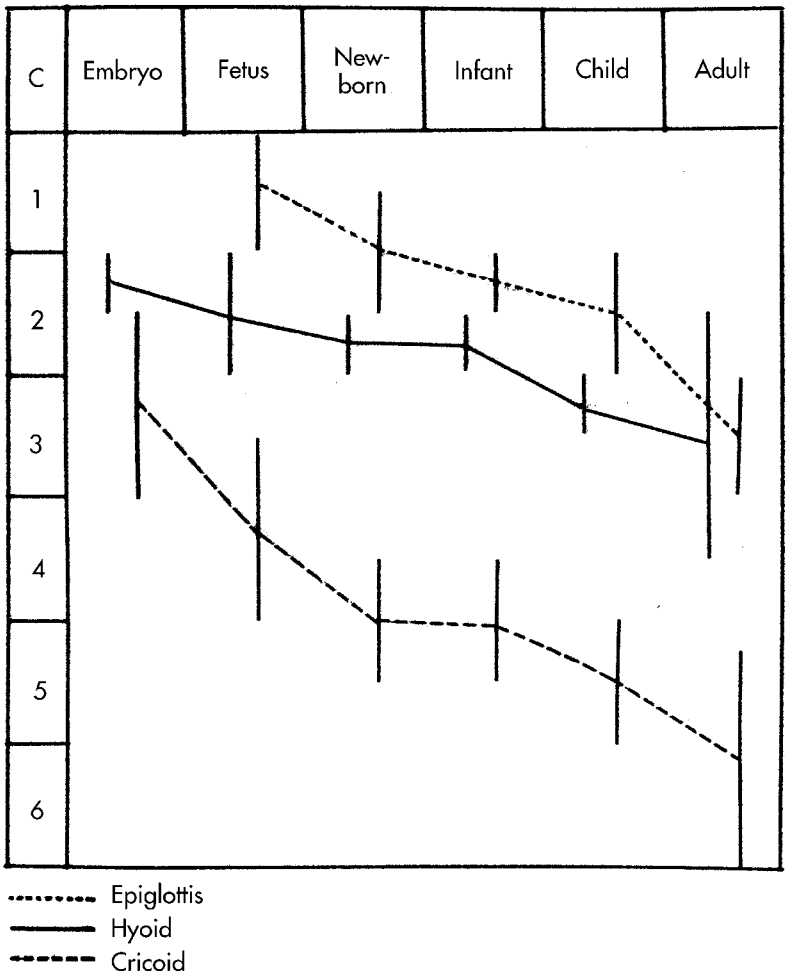

FIGURE 48–5. Graph showing the prenatal and postnatal descent of the hyoid, cricoid, and epiglottis with reference to cervical vertebrae 1 to 6.

border of each lamina. It would be imprudent, however, to attempt to estimate age from the extent of the ossific process.[26]

Function begins in the fetal larynx early in trimester 2, when the larynx opens for the inhalation of amniotic fluid into the lungs, and the diaphragm descends. Phonatory vibrations commence later in the trimester.[27]

CONGENITAL ANOMALIES

Only some congenital anomalies of the larynx are currently amenable to interpretation in developmental terms.

Some laryngeal anomalies are part of a more widespread disturbance. Thus, congenital webs may be accompanied by subglottic stenosis, and structures far removed are affected in some instances, such as anomalies of the limbs. Similarly, cleft larynx may be associated with a congenital cardiac defect or cleft lip and palate and has been considered a median developmental field defect that can occur in causally different syndromes.

Laryngomalacia, said to be the most frequent congenital laryngeal anomaly, produces partial obstruction of the supraglottic airway, but its cause is unclear and cannot be merely immaturity and alterations of the cartilaginous and muscular components.[28]

Laryngeal clefts, which may extend to the trachea and even to the carina, are rare.[29] Interarytenoid clefts develop as a consequence of lack of development of the interarytenoid and aryepiglottic muscles.[30] Cricoid clefts, which may be partial or total, may arise from incomplete dorsal fusion of the limbs of the single ventral chondrific center.[30] Com-

plete clefts, those that involve the trachea, probably develop during separation of the trachea and esophagus at 4 to 5 weeks (stage 13), as suggested by the frequent association with tracheoesophageal fistulae.

Congenital laryngeal atresia probably arises between 6 and 10 postovulatory weeks, the more extensive examples representing embryonic stages and the less severe forms being fetal. They are supraglottic rather than infraglottic.[30] Complete atresia, which is probably the least frequent of congenital laryngeal anomalies, is associated with polyhydramnios.[28] It resembles closely the normal appearance of the larynx at 6 weeks (stage 18) and may be basically a persistence of the embryonic condition when the epithelial lamina has reached its full expansion (see Figure 48–2, C). Incomplete atresia arises later; hence, the vestibule has already developed to a variable degree. Glottic atresia, the most frequent type, probably arises early during the fetal period, when the epithelial lamina has failed to undergo further delamination.

Congenital laryngeal webs, situated ventrally and extending dorsally to a variable degree, are also thought to result probably from a localized failure of splitting of the epithelial lamina into two walls, most likely early in the fetal period. A special instance is a web at the vocal folds, namely at the lower border of the epithelial lamina. It presents, early in the fetal period, as a perforated membrane that obstructs the glottic opening.[30]

Infraglottic (subglottic) stenosis is not associated with the persistence of the epithelial lamina, but some instances seem to be produced by deformities of the cricoid cartilage. Cartilaginous and membranous types would differ in origin.

Congenital laryngeal cysts may be ventricular or infraglottic. They are usually in the region of the saccule but do not communicate with the laryngeal lumen. They probably indicate disturbed development in fetal life.

Nonrecurrent laryngeal nerve is associated with an abnormal origin of the right subclavian artery, usually from the dorsal aspect of the arch of the aorta. The condition is believed to arise from an embryonic failure of the right aortic arch 4, allowing the nerve to proceed directly to the larynx.

CHAPTER 49

Disorders of Voice, Speech, and Language

Fred D. Minifie, PhD

Disorders of voice, speech, and language comprise an important category of problems faced by the physician because treatment of these disorders can have a large influence on vocational, social, and emotional adjustments of the patient. Many otolaryngologists are properly reluctant to provide rehabilitation for communicative disorders beyond the treatment of disease because they believe they are not qualified. Patients, however, inevitably seek answers to questions about communication disorders and, while attempting to be helpful, the physician often finds it necessary to play the role of a part-time speech-language pathologist and counselor. One of the purposes of this chapter is to provide current information about disorders of voice, speech, and language and their remediation.

This chapter is organized around three major categories of communication disorders: disorders of voice, speech, and language. Each category will be discussed separately. Communication disorders stemming from hearing impairments are discussed in Chapter 5.

VOICE DISORDERS

Normal Voice Production

Voiced sound during speech production is called phonation. Depending on the length, tension, and thickness adjustments of the vocal folds, the tone produced by normal vibrating vocal folds can vary in frequency (perceived as variations of the pitch of the voice), intensity (loudness), duration, or quality. Such parameters contribute to changes in intonation and stress during speech production and perception.

Pitch The pitch of sound produced during normal phonation is directly related to the frequency at which air pulses are released through the glottic aperture owing to vocal fold vibration, a rate determined primarily by the mass and elasticity of the vocal folds in relation to their length. Large folds produce a lower pitch than smaller folds because the greater mass causes them to vibrate more slowly. This is why adults have lower vocal pitches than do infants and young children; vocal pitch is inversely related to the size of the vocal folds. However, each talker also has the ability to change the frequency of vocal fold vibration. When the folds in any normal larynx are shortened, their cross-section becomes larger, and their myoelasticity is reduced. Such folds tend to move more slowly. Conversely, when the vocal folds are elongated, they become thinner, and their elasticity is increased. As a result, when the air stream pushes tightened and thinned vocal folds apart, they return to their approximated positions more quickly. This reaction results in increased frequency of vocal fold vibration (higher pitch). Frequency of vibration may also be altered by isotonic tension in the muscles of the vocal folds. This type of contraction increases the stiffness of the folds and consequently causes them to vibrate more rapidly.

Loudness Loudness of the voice is related to the sound pressure created by the released pulsations of air through the glottis. Sound pressure is directly proportional to the volume-velocity of airflow in the glottis. By increasing the thickness and stiffness of the vocal folds, increased resistance can be offered to the flow of air from the lung as the folds remain closed for a longer percentage of time during each cycle of vibration. The longer closed period allows greater subglottal air pressure to build up to overcome the increased resistance offered by the folds. With increased subglottal driving pressure on opening of the glottis, increased volume velocities of air-

flow occur. Moreover, because increased stiffness and thickness of the vocal folds increase the elasticity of the vocalis or internal thyroarytenoid muscles, they snap back to the midline with increased velocity. The rapidly changing volume-velocity of the escaping train of pressure pulses increases the amplitude of sound waves generated, causing greater excursions of the tympanic membrane in the ear of a listener and a sensation of louder sound.

Quality Both vocal fold vibration and resonance determine the quality of voice. The phonatory aspect includes the manner of air pulse release at the glottis. Opening, closing, and closed phases of the glottal cycle can vary in relation to each other. For example, laryngeal lesions can influence the pattern of movement of the vocal folds, independently and in combination (to be discussed later in this chapter). These factors can influence the number and relative intensity of harmonic partials composing the complex vocal sound and, consequently, the quality of the voice. Modification of sound as it travels through the pharynx, mouth, and nose (resonance) results from selective emphasis and damping of the overtones and other partials in the complex sound generated in the larynx.

The contribution of voice to a normal communication process is demonstrated succinctly by its absence; speech without phonation is whispering. In whispered speech, the vocal folds do not vibrate, and the laryngeal sound is aphonic. When this condition is present, the speaker can produce speech and language but has no vocal pitch in the musical sense. The sound is a relatively weak noise composed of breath sounds produced when the air becomes turbulent as it rushes past the irregularities that jut from the walls of the respiratory tract (particularly at the true and false vocal folds). This turbulent air noise constitutes a sound source that is acted on by the resonances of the mouth, pharynx, and nose much as resonance occurs when vocal sound arises at the glottis. When the vocal folds vibrate, there is vocal sound that has pitch and many of the distinguishing vocal qualities that identify individual voices, whereas in whisper they are absent.

Causes of Voice Disorders

Voice disorders always have causes. Something must be abnormal or atypical in the way in which the vocal folds function to produce disordered voice. A clinical appreciation of vocal fold vibration can begin with the concept of an ideal larynx. In such an organ, the two vocal folds would have the same dimensions, they would move symmetrically and regularly, and each vibratory cycle would include three phases: glottal opening, glottal closing, and closed glottis. The vocal sound from this ideal larynx would be judged "excellent"; it would be smooth and free of all hoarseness, have an appropriate pitch range for the age and gender of the talker, and would be capable of wide pitch and loudness variation. When vibration of the vocal folds varies from the ideal, the characteristics of the voice also vary from the ideal—the extent of vocal difference depending on the type and amount of alteration in the vibratory pattern.

The assumption that no two faces are exactly alike is commonly accepted. Observation of living and dissected larynges leads to a parallel assumption that no two larynges are exactly alike. Each larynx reflects its uniqueness in its behavioral physiology, yet most larynges are capable of producing a normal voice that is judged to be within the accepted ranges of pitch, loudness, and quality found in a majority of individuals of the same age and sex.

Abnormal vocal fold vibration takes many forms, most of them not visible to the unaided eye. Ultra–slow-motion films of abnormal voices reveal that one fold may move faster than the other, one may have a greater lateral excursion, vibration may be limited to one vocal fold, there may be no glottal closure or incomplete glottal closure, closure may occur at a paramedian position, vibratory patterns may be dissimilar at different regions along one or both folds, and the vibratory periods and amplitudes may be randomly variable in consecutive glottal openings.[1] Acoustic indicators of such patterns may include pitch period perturbations (jitter), amplitude perturbations (shimmer), decreased signal-to-noise ratio (more glottal noise), altered fundamental frequency (F0), increased standard deviations of F0, and many others. The potential complexity of vibratory patterns resulting from combinations of these cyclic abnormalities and sequential irregularities is almost endless.

Pitch Disorders Pitch disorders are present when the voice is consistently higher or lower (in relation

to the musical scale) than would be expected for an individual of a given gender and age or when the sound is tremulous, monotonous, or bizarre (eg, when the pitch patterns do not convey the ideas being expressed). An involuntary, high-pitched voice in males does not necessarily interfere with communication, and if a woman produced it, it would probably not be considered unpleasant. A similar example could be provided for women with very low-pitched voices. The "voice disorder," therefore, is not the sound itself, which may be quite appropriate for the size and shape of the larynx that produced it, but the inappropriateness of the sound to the circumstances (the age and gender of the talker).

Functional Pitch Problems. In contrast to the foregoing example, high-pitched male voices frequently have functional origins. Verdolini described mutational falsetto as "the continued use of a high pitched (falsetto) voice by a postpubertal male, without any apparent physical basis. For some patients, psychological conflict is implied as a basis for the disorder. In other patients, the disorder may simply reflect a learned pattern."[2] To tell a person with this type of voice that he has nothing wrong with his larynx and that he should go home and speak normally may reassure him, but it does not help him, and usually it serves only to increase his frustration. He is already speaking "normally" and needs to be taught how to phonate in a way that is "abnormal" for him. Most of these patients respond readily to voice therapy and adopt the new voice after a brief period of self-consciousness. Those with normal structure who voluntarily maintain the high pitch reflect an abnormal self-image and should be referred to a psychiatrist or clinical psychologist.

Another form of functional pitch problem is ventricular phonation wherein the talker produces a low-pitched, gravely voice through vibration of the false vocal folds. This type of phonation most often develops as a compensatory mechanism.

Organic High-Pitch Problems. Although most abnormally high-pitched voices are probably caused by functional problems, cases with organic causes are not uncommon and may be classified into four categories: underdeveloped larynx, laryngeal web, structural asymmetry, and swelling in the anterior commissure.

Underdeveloped Larynx. The underdeveloped larynx has small vocal folds that vibrate more rapidly than larger folds and consequently create a high pitch. The small larynx may accompany a general structural retardation or may be part of a hereditary familial body size. The clinician should be particularly sensitive to genetic syndrome effects from various forms of dwarfism, short neck, an abnormality associated with syndromes of short stature, and other possible syndromic effects when an underdeveloped larynx is observed.[3] The larynx may also fail to develop as a result of hormonal imbalance, which is usually revealed in simultaneous retardation of other secondary sex characteristics.

Laryngeal Web. Another organic cause of high-pitched voice is a laryngeal web, which may be congenital or cicatricial. When this structure is small enough not to interfere with breathing or when it does not contribute to stridor, it may go undetected until the voice is observed as abnormal. A web need not extend far along the borders of the vocal folds to create a voice problem. Its effect is to shorten the free portions of the folds and thereby produce faster vibration and a resulting higher pitch. The vocal tone in children with webs resembles falsetto and tends to be weak. Hoarseness may be present also, accompanied by the audible evidence of vocal strain, particularly with men who have attempted to force a lower pitch.

Structural Asymmetry. A third organic cause for chronic high pitch is abnormal approximation of the vocal folds. In this condition, a structural asymmetry may cause the vocal process of one arytenoid cartilage to slide on top of its opposite member in such a manner that posterior parts of the membranous folds are pressed together, thereby effectively shortening their vibrating portions. The adjustment approximates that which is often observed in the male larynx when a high-pitched, falsetto voice is produced.

Swelling of the Anterior Commissure. A fourth condition, and one that may be overlooked or ignored as a cause of excessively high pitch, is enlargement of the glottal margin of one or both vocal folds adjacent to the anterior commissure. A localized protrusion no more than l mm high and 2 mm long on the glottal margin is sufficient to shorten the vibrating length of the folds and to produce a higher than normal pitch. This lesion can be

seen only when the anterior commissure is visualized, while the folds are widely abducted. During adduction, the protruding areas are compressed into the underlying tissue and create the illusion of a prominent commissural attachment without significance. The location of the offending lesion at the anterior attachment where the folds converge enables it to modify the vibratory pattern more extensively than it would if it were located more posteriorly. When a protruding mass is located where it is not pinched between the vocal folds, it usually does not shorten the vibrators and consequently does not raise vocal pitch; instead, it often causes a lower pitch accompanied by hoarseness or breathiness.

Organic Low-Pitch Problems. Defects of vocal pitch can also encompass the abnormally low voice. Excessively low pitch in both men and women is usually associated with organic change; however, functional disorders are observed in persons who attempt to speak at a pitch below that which is optimum for the structures involved. The most common organic origins of low-pitched voices are Reinke's edema, virilization, glottalization or "vocal fry," and tremulousness.

Reinke's Edema. Verdolini suggested that

> Reinke's edema involves the widespread accumulation of fluid or swelling, usually in both vocal folds, in the layer of tissue right below the vocal fold epithelium. Although the causes for this edema are not entirely clear, some clinicians think that chronic exposure to irritants such as smoke may play a role in the development of the condition. The most obvious effect of Reinke's edema on voice typically is an extremely low speaking pitch (due to the increased mass of the folds) and loss of the ability to produce high notes. The voice is also described as raspy.[2]

Virilization. An abnormally low pitch or masculine type of voice in a woman is as distressing to the woman possessing it as high pitch is in the male, and for the same kinds of psychosocial reasons. Virilization of the female voice after hormone therapy in young women has been reported with increasing frequency.[5,6] Recovery of normal pitch in these patients does not occur with interruption of medication, and at present, no specific counteragent seems to exist. The larynges of women with virilized voices appear to be normal in all aspects except perhaps for some general enlargement of the vocal folds toward their glottal margins. The effects of compensatory vocal adjustments on size and condition of the folds are not known.

Glottalization or "Vocal Fry." A form of excessively low pitch characterized by a low-frequency popping or ticking sound is referred to as vocal fry or glottalization. It is produced normally when only a little breath pressure is exerted against the vocal folds, such as during the ending of a phrase. This low-pitched voice is adopted occasionally by adolescent boys and young men in an effort to sound "more masculine." Although glottalization is often functional, it also has organic causes. Edematous vocal folds from whatever cause are frequently associated with this voice. Other alterations of the vocal folds, such as dry mucosa following irradiation therapy, or absence of a flexible covering membrane, may be observed.

Tremulousness. Vocal pitch deviation such as persistent tremulousness and its opposite, extreme monotony, are rare in young persons and are usually considered psychogenic. In older individuals, however, these vocal characteristics may be symptomatic of deterioration or injury to the nervous system.[7] In instances of brainstem involvement, such vocal changes may appear among the early symptoms and consequently deserve careful consideration in diagnosis.[8,9] On the other hand, when either tremulousness or monotony develops as a secondary symptom, other impairments are usually so prominent that the voice, as an entity, is relatively unimportant as a priority in therapy.[10,11] One of the most common diseases of the extrapyramidal system is Parkinson's disease, in which chemical deficiencies (specifically a lack of dopamine) produce a generalized movement disorder characterized by small movements (hypokinesia) and slow movements (bradykinesia) that impose low-frequency variations on voice production.[2,12]

Loudness Disorders Disorders of loudness may also be classified into categories that parallel those used with pitch deviations; some are functional and some are organic. The voice may be too loud or not loud enough in relation to the place and circumstances, or there may be loudness variations that are not appropriate for conveying the meaning of the utterance. Moreover, any generalized swelling of the

glottal margins that improves approximation without stiffening the folds contributes to glottal closure and sound generation. Patients whose voices become louder when they have laryngitis or mild edema illustrate this fact.

Functional Loudness Problems. Personal Adjustment. Atypical loudness is often an indicator of personality aberrations (eg, overly aggressive, shy, or socially insecure persons). Voices may be too loud or too soft depending on the personality. Fortunately, these adjustment problems are amenable to counseling procedures by a speech-language pathologist or clinical psychologist. Voice improvement is usually enhanced by direct training of voice production along with counseling.

Environmental Stress. Some persons are required to speak loudly in their occupations. This vocal requirement often creates laryngeal trauma, subsequent changes in the vocal organs, and consequent voice disorders. Excessively loud speaking and loud cheering at sports events are recognized as principal types of vocal abuse. These causes create difficult problems to manage when the basic occupational conditions persist. Voices can be retrained, however, if the patient is willing to learn how to use the voice. An adjunct to voice training and a substitute when circumstances are not conducive to such therapy is the use of a speech aid. Small, portable amplifying systems consisting of a clip-on microphone, amplifier, and loudspeaker are available and, when used properly, can provide adequate loudness of voice in noisy environments. The focal problem with the occupational voice disorder, when work requires daily vocal abuse, is the lack of opportunity to recover from traumatic effects and to institute a period of training to prepare the voice for unusual demands. Such patients benefit from periods of complete vocal rest (silence) prior to participating in vocal retraining therapy. Ideally, it is helpful to the professional speaker as well as to workers in noisy environments to acquire "big voices" during therapy. Fortunately, amplification can satisfy the job needs and reduce the vocal abuse for some patients.

Organic Loudness Problems. Paralysis or Paresis. When a slowness, weakness, or absence of complete glottal closure occurs, the voice is weak and breathy. The basic causes are as follows: impaired neural control from cerebral cortex lesions (stroke) or peripheral factors such as local trauma (including surgery), viruses, and heart disease; myasthenia gravis; arthritis; or general debility from anemia or other diseases. In the larynx, peripheral paralyses and pareses usually affect only one vocal fold. The unaffected vocal fold usually compensates to some degree by crossing the midline of the glottal space to achieve closure during phonation.[2] When the disease and organic conditions permit, direct therapy for voice improvement often produces good results. Suggestions about therapy are presented later in this chapter.

Bowed Vocal Folds. This muscular deformation stems from long-term heavy use of the voice, particularly in elderly patients. Patients produce a weak voice because of an impaired ability to develop closure of the vocal folds during voicing.

Sulcus Vocalis. A groove parallel to the vocal fold margin may be present in one or both vocal folds as a result of congenital or possibly developmental causes. Although this condition is not well understood because data are limited, the weak voice may result from an inability to achieve adduction of the vocal fold along its entire length.[2]

Hearing Impairment. When a loss of hearing is sufficient to cause an individual to speak more loudly than circumstances warrant, a hearing problem is usually evident, and the offending vocal symptoms (similar to those described above under the topic of functional loudness problems) are approached through treatment of the hearing loss.

Voice Quality Disorders

Voice quality disorders encompass resonance and phonatory components. The phonatory deviations can be placed along an auditory continuum extending from aphonia to hoarseness, with such intervening and intermixing qualities as breathiness and harshness. In this chapter, phonatory disorders are presented under five headings: aphonia, breathiness, harshness, hoarseness, and spasmodic dysphonia. Authors reporting in the medical literature tend to classify all voice disorders under the headings of aphonia and hoarseness. These terms are useful but not adequate for a discussion of the variety of existing phonatory defects.

Aphonia and Its Causes. Aphonia, the absence of phonated sound, is revealed as a whispered voice,

which indicates that the vocal folds are not vibrating. One should be careful not to confuse aphonia with elective mutism, in which the patient has the potential to phonate but simply chooses not to speak. Aphonia exists when the folds do not approximate sufficiently to be activated by the air stream or when the folds themselves are not capable of vibrating even when approximated. Causal factors in aphonia include lateral positioning of the arytenoid cartilages with the associated open glottis, massive intrusion of some neoplasm, atrophy or absence of vocal fold tissue, excessively stiff folds, or nonflexible mucosal covering of the folds. Aphonia can also result from organic disease. The associated organic diseases range from paralyses and other neural impairments to various tumors, inflammatory disease, scarring, and other localized laryngeal lesions. Aphonia also may be indicative of a functional disorder of psychogenic origin, most commonly conversion aphonia/dysphonia. Treatment of such functional disorders must be sensitive to the underlying psychogenic bases of the disorders. Aphonia may be present continuously but is more frequently intermittent. Intermittent aphonia varies considerably, sometimes even within the speech of a single patient. Some persons whisper most of the time; others may be aphonic momentarily within words or parts of sentences.

Breathiness. Chronic breathiness can be recognized by excessively audible breath-flow noise that is accompanied by a relatively low vocal loudness level (a low vocal signal-to-noise ratio). The problem is common and varies from scarcely discernible levels of breathiness in the voice to the almost aphonic. The vocal folds vibrate during the production of a breathy voice but do not impede the airflow sufficiently to allow much increase in subglottal pressure. Air flows alternately more and less but is not completely interrupted during the vibratory cycle. Several organic conditions modify the glottal configuration sufficiently to create incomplete glottal closure associated with a breathy voice. Muscular tension dysphonia (simultaneous contraction of laryngeal adductor and abductors) can create incomplete closure during each glottal cycle and produce a breathy voice.[2] Moreover, various conditions of paralysis (unilateral or bilateral) as well as growths protruding into the glottal space (these include discrete mass lesions such as nodules, sessile polyps, peduncular polyps, cysts, papillomas, keratosis, leukoplakias, cancers, contact ulcers, and edema) can prevent the glottal borders from touching firmly during the vibratory cycle. Even complete closure of the muscular borders of the glottis can be associated with a breathy voice if glottal resistance is markedly reduced (eg, when flaccid vocal folds result from a lower motoneuron disease such as myasthenia gravis), or in the presence of hypokinetic neurologic disorders such as Parkinson's disease, or if a chronic posterior glottal chink (intercartilaginous portion) is observed.[13]

In many respects, the causes of a breathy voice are similar to, or may be the same as, those of aphonia. This fact stresses the observation that the voice is not a reliable indicator of the type or extent of laryngeal impairment or disease. At any given moment, the degree of vocal fold approximation that can be achieved is influenced by the vowel sound that is being produced,[14] the vocal effort used by the talker,[15] and the muscle tension in the larynx. These factors can determine whether the voice is normal, aphonic, breathy, or hoarse. Although many attempts have been made to identify laryngeal disease based on acoustic measurements of the vocal signal-to-noise ratio, particularly by investigators in Japan, such measures appear to be more related to perceived levels of breathiness than to specific diseases of the larynx.[16–20]

Breathy voice has been associated traditionally and sometimes exclusively with the availability of breath. This association is not valid apart from a consideration of the concurrent condition of the larynx. Breath supply may be expressed in two ways: the amount of air available and the force with which it is expelled. Observation reveals that a reduced air supply, such as that resulting from the removal of one lung, is not in itself a cause of breathiness. Substantial clinical evidence also indicates that reduced breath pressure alone is not a cause of breathiness. If low pressure produced the defect, a person with a normal voice would necessarily have a breathy voice whenever a tone of low intensity was produced. Many persons with low vital capacity have normal voices.

Harshness. Harshness is a physiologic opposite of breathiness. When the vocal folds remain in contact for a disproportionately long time in the vibratory cycle, a voice quality known as harshness results.

This vocal problem is usually functional. Harshness is accompanied by increased air pressure and tighter glottal closure. When the harsh voice is produced loudly, as it is sometimes by hyperactive, aggressive individuals, the speech is staccato, and the listener perceives hyperactive contraction in the entire respiratory, phonatory, and articulatory musculature. This behavior is called hyperfunctional voice production. Organic causes of harshness include edematous vocal folds, neoplasms, and any other structural alteration that may prolong the closed phase of the vibratory cycle.

Hoarseness. Hoarseness and harshness are often confused with each other, partly because both terms are relatively imprecise. Hoarseness varies from mild to severe and is so common in the population as a result of acute upper respiratory infections that it evokes little concern unless it is severe or chronic. The differentiating, audible feature of hoarseness is a roughness that results from random variations in the periodicity of the glottal waveform and/or random variations in the intensity of consecutive sound. Such variations may contribute to, or be accompanied by, noise in the phonation. Consequently, it is understandable that the perceptual conditions of hoarseness and breathiness often coexist.

Normal vocal sound results from repetitive vibrations that are similar to each other in time and intensity or that vary progressively as pitch or intensity shifts upward or downward. Vocal sound is generated by the motions of the folds in conjunction with the breath stream that activates them, and any condition that alters their regular, repetitive, synchronous vibration, causing randomly timed or randomly intense pressure pulses, creates a voice quality called hoarseness. Physical conditions that cause random aperiodicity probably result from a combination of transient and interference factors and may include any disease or condition in the larynx that changes the size, stiffness, or surface characteristics of one or both vocal folds (laryngitis or any of the discrete mass lesions, eg, nodules, polyps, cysts, papillomas) or that causes excessive squeezing of one fold against the other (eg, pressed phonation by a patient with contact ulcers). Any of these factors may create the conditions for hoarseness. Enlargements caused by tumor or edema, reductions resulting from surgery or atrophy, flaccidity subsequent to neural involvement, and functional hypercontraction of the adductor muscles represent the kinds of changes to which reference has been made. Under certain circumstances, swollen tissue or secretions above or on the vocal folds may be set into more or less independent vibration and may thereby create hoarse or rough sounds. Descriptions of the many laryngeal diseases and anomalies potentially related to hoarseness occupy much of this volume. The possible effects of some of these conditions are summarized in a later section on voice therapy.

Spasmodic Dysphonia. The term spasmodic dysphonia (sometimes called spastic dysphonia) designates one of the most disabling of communication disorders. It is probably an organic movement disorder with an unknown cause. It prevents or seriously limits the person who has it from holding positions in which speaking is required. The problem originates in the larynx and is heard most frequently as a sudden, momentary interruption of the voice caused by brief, spasmodic glottal closure. In some patients, instead of closing, the glottis spasmodically opens to allow air to escape, as in a whisper.[21] The closure form of the disorder is often referred to as adductor spasmodic dysphonia and the open form as abductor spasmodic dysphonia.[22] In addition to these symptoms, some patients describe difficulty with breathing in the adductor type. Also, as patients attempt to "speak through" the spasmodic closure, the voice may be described as "squeezed," "effortful," or "struggle strained." Occasionally, when a vowel sound is prolonged, as in singing, a prominent intermittent pulsing occurs, suggesting a tremor. The adductor form is more common than the abductor, but both may be heard in a single patient. The spasmodic episodes occur most frequently on vowel sounds, particularly at the beginning of words. The abductor form is most prominent on vowels that follow unvoiced fricative sounds. Almost without exception, persons with spasmodic dysphonia can whisper normally without interruption in the flow of speech. Superficially, spasmodic dysphonia resembles stuttering, but significant differences exist between these disorders. One of the puzzling features of this type of dysphonia is that the severity and type of symptoms can vary within as well as among patients. Inconsistency of symptoms undoubtedly contributes to the traditional assumption that spasmodic dysphonia is psychogenic.[23,24] Indeed, it may be, but research evidence indicates

the possibility of a neural etiologic component.[25–27] A discussion of the several theories is not appropriate here but may be explored through references at the end of the chapter.[28–31] Differing concepts are mentioned simply because the neurogenic theory has led to surgical therapeutic procedures that have been more successful in treating the adductor type than other approaches.[32] The tenacious persistence of spasmodic dysphonia has caused patients to seek help from psychiatry, clinical psychology, speech therapy, hypnosis, drugs of many varieties, and bizarre remedies of every type, all unsuccessfully.[33]

The observed freedom from spasmodic dysphonia during whispering, and almost complete fluency by patients when they produce a breathy voice, demonstrates that the spasmodic adductory speech symptom is absent when glottal closure does not occur. Short-term clinical relief of the dysphonia can be achieved by chemically blocking one recurrent laryngeal nerve to create a temporary unilateral vocal fold paralysis. This injection procedure is also useful in diagnosis because it demonstrates the effect of a unilateral paralysis on the speech symptoms. When the injected anesthetic results in immediate elimination of both the tight glottal closure and the symptoms of spasmodic dysphonia, the diagnosis of the disorder is strongly supported. The resulting voice is not normal, although it is useful for communication purposes.

Patients with spasmodic dysphonia usually have had the disorder for many years and have become frustrated with the uniform lack of assistance from various therapies. They are generally eager to prolong the fluent speaking they experience during the nerve block and request some way to accomplish that end. The three options that are available are (1) the creation of a permanent unilateral paralysis by sectioning of one of the recurrent laryngeal nerves, a therapy that has become rather widely used[34–36]; (2) the establishment of a temporary unilateral paralysis by crushing one recurrent laryngeal nerve[37]; and (3) the production of another temporary laryngeal nerve paralysis by the injection of botulinum toxin.[38] The crushing and toxin procedures are usually followed in 3 to 6 months by a return to pretreatment function. The underlying rationalization for the temporary paralysis procedures is that if spasmodic dysphonia is psychogenic, the fluent speech practiced during the period of paralysis should persist after recovery from the paralysis. Unfortunately, the speech symptoms tend to recur with return of function. When unilateral paralysis is permanent after section of one recurrent nerve, the voice is almost always normally fluent for at least the first year, but as time passes, more and more patients report recurrence of their symptoms.[39–41] The several reported failures signal the need for increased caution with the surgical approach and careful assessment of the conditions associated with the occurrences.[42] In contrast, some patients are known to have maintained normal fluency for more than 10 years. These varying results lead to the speculation that spasmodic dysphonia symptoms are probably the result of multiple causes.

The abductor type of spasmodic dysphonia is not helped by intentional unilateral vocal fold paralysis. This procedure simply exaggerates the undesired glottal opening. Patients with this problem report considerable variation in symptoms, with the disorder worsening with anxiety and worry.[43] Psychiatry, clinical psychology, speech-language pathology, medicine, and many exotic approaches have been as unsuccessful with this form of spasmodic dysphonia as with the adductor form. Unfortunately, there is no known temporary alleviation of the abductor symptoms that parallels the anesthetic blocking of one recurrent laryngeal nerve used with the adductor form of the disorder. There is substantial evidence of neurogenic disorder with the abductor as well as the adductor form of the dysphonia. Support for neural involvement has been found in electromyography,[44] electroencephalography,[45] magnetic resonance imaging,[46] auditory brainstem response,[47] and various clinical neurologic tests.

Resonance and Resonance Disorders When the shapes and adjustments of the resonance spaces do not conform to the customary configurations, resonance disorders are apt to be present. The two most common resonance defects are too much nasal resonance (hypernasality) and insufficient nasal resonance (hyponasality). The first is caused by incomplete closure of the velopharyngeal valve or by a fistula in the structures separating the oral and nasal spaces, and the second is caused by blockage of the nasal passageway. Incomplete velopharyngeal closure results from one or more of five possible causes: (1) congenital deformity, such as cleft palate, submucous cleft, excessively deep pharynx, or short palate; (2) paralysis of pharyngeal or palatal mus-

cles; (3) destructive disease; (4) surgical procedure in which adenoidal tissue vital to velopharyngeal closure has been removed; and (5) imitation of hypernasal speech.

The second general condition, blockage of the nasal passageway, causes denasality (cold-in-the-head speech), which also results from one or more of five causes: (1) growths such as adenoid tissue, papillomas, polyps, and nasal spurs; (2) hypertrophy resulting from chronic disease; (3) swollen mucosa associated with allergies; (4) trauma to the nose; and (5) imitation. A blockage situated anteriorly in the nasal passageway may contribute to hypernasality instead of hyponasality because the posterior nasal areas act as resonators if an opening is present at the velopharyngeal valve. This form of hypernasality can be demonstrated by pinching the nose closed and trying to speak "through the nose."

A resonance disorder identified as muffled quality or "hot potato speech" is often difficult to identify because it is similar to some rural dialects. It results from space-occupying lesions such as masses of lymph tissue or tumors in the valleculae between the epiglottis and the base of the tongue. Confusion with dialects occurs because some speakers habitually retract the base of the tongue into the pharynx on sounds that customarily do not use that adjustment.

Combined Sources of Voice Quality Disorders. The two separate sources of voice quality disorders, the larynx and resonance cavities, are capable of functioning independently; consequently, quality deviations can be generated in either one separately or in both concurrently. This possibility provides the means by which many combinations of phonatory and resonance problems may be produced simultaneously and presents a basis for the variety of voice quality disorders that exist. The potential array of vocal problems may be compounded by the simultaneous presence of both organic and functional deviations. It is apparent that vocal disorders deserve careful evaluation and diagnosis; it is equally clear that vocal rehabilitation may require more than one type of therapy.

Summary of Conditions Affecting Laryngeal Health and Function

To stress the need for careful and complete medical evaluation and treatment of the individual who has a voice disorder is probably redundant. Otolaryngologists, particularly, are aware that voice problems are among humankind's most subtle disorders; they reflect certain aspects of the patient's thinking, behavior, health, and diseases. The causes of voice disorders may be arbitrarily grouped into the following nine categories:

1. Structural modifications that result from misuse of the voice, such as thickened vocal fold tissue, myasthenia laryngis, vocal nodules, and contact ulcer. Furthermore, vocal abuse combined with infection may cause such chronic conditions as laryngitis, corditis with hypertrophic and hyperplastic laryngitis, and atrophic laryngitis.
2. Anxiety, emotional turmoil, frustration, and similar psychogenic problems that cause excessive contraction of the laryngeal, thoracic, and associated musculature during speech but do not cause observable organic disease
3. Diseases and growths, including infections not related to vocal abuse; paralyses of central, peripheral, and myopathic origin; cysts; and both benign and malignant tumors
4. Mechanical and chemical irritants affecting the mucosa: fumes, irritating vapors and gases, dry air, dusts, allergens, caustic fluids, and gastric reflux
5. Substances causing noninflammatory edema, such as internal medicaments, mechanical compression of venous blood flow, endocrine imbalance, and allergy
6. Irradiation therapy, antihistamines, and other medications that cause drying of the mucosa
7. Congenital anomalies
8. Destruction of laryngeal tissue by surgery, trauma, or disease
9. Systemic disorders leading to chronic fatigue, such as anemia, metabolic disturbances, malnutrition, and inadequate rest, can also affect the voice adversely

Therapy for Voice Disorders

The long history of medicine has demonstrated that medical and surgical treatment may eliminate some types of voice disorders, but such treatment cannot always restore normal function. Nonmedical rehabilitative measures may be necessary to help compensate for altered anatomic and physiologic

conditions, and re-educative procedures are usually indicated in the treatment of habitual or functional disorders. The preceding descriptions of voice disorders and their causes have indicated the potential complexity of voice problems. Rehabilitative measures used in the management of such problems follow the approved convention of adapting the therapy to the specific patient and his or her disorder. Because this presentation must play a relatively minor role in a volume on otorhinolaryngology, suggestions for therapy have been limited to basic or universal recommendations that can be used by the physician who cannot devote much time to vocal rehabilitation. When greater depth is needed, one should refer to detailed books and extensive reports in the periodical literature to support systematic therapy. The purpose of this volume is best served by directing the physician's attention to the following four aspects of diagnosis and voice therapy: (1) conditions affecting the patient's general health and the function of the larynx, (2) environment, (3) psychological adjustment, and (4) voice.

Environmental Factors A program of voice therapy that does not recognize the demands of the environment on the communication needs of the patient is incomplete and may be doomed to failure. The person who must talk more or less continuously in a noisy environment may develop detrimental vocal habits and may also abuse the larynx and create tissue changes. In some families, excessive and harmful use of the voice is so common or so subtle that the persons involved are not aware of the excess and do not associate the behavior with the voice problem. Therapy for a voice disorder that is generated and nourished within an environment often encompasses complex personal management problems. Frequently, the patient cannot move to another job or otherwise modify his/her living situation; when such changes can be made, however, the restoration of the voice is simplified. When the environmental conditions cannot be altered, the voice therapy must include a review of the situation with the patient, or with the parents if children are involved, to provide insight and a rationale for adjustment to the environment. To ignore the patient's work setting, recreation routines, and living patterns is to invite failure.

Psychological Factors An individual's attitude toward self and the environment is reflected in such vocal elements as the rate of speaking, choice of words, vocal pitch, loudness of the voice, and vocal quality.[48] These factors often indicate the degree of poise, anxieties, emotional states, feelings of friendship or hostility, and belief about acceptance or rejection. When these concepts cause the individual to use an unpleasant, inadequate, or defective voice, any successful modification of the problem must include a consideration of the person's concepts about self, the environment, and his or her speech. In Western culture, the low-pitched male voice seems to be identified strongly with concepts of masculinity, and unless the young man realizes that a tenor voice is just as masculine as a bass one, he is apt to develop detrimental vocal habits that are carried into adulthood. Children as well as adults sometimes use loud voices or rough-sounding, hoarse voices to dominate, control, or compete in their family or social groups. The focus of attention here is on the fact that the attitudes and needs of the individual that led to vocal nodules or thickened vocal fold tissue must be considered in any program of vocal rehabilitation. Individuals occasionally demonstrate overwhelming anxieties in vocal disorders (eg, hysterical aphonia, intermittent dysphonia, and tremulousness). In these conditions, psychiatric assistance is usually desirable, and if any work on the voice is recommended, it is carried on as a supporting activity in close cooperation with the psychiatrist. The preceding paragraphs have suggested that psychogenic factors of many degrees of severity may cause voice disorders. It follows that successful vocal rehabilitation must include appropriate psychotherapeutic procedures when indicated.

Analysis of the Voice Problem Defective voices are usually not consistently abnormal in the same degree under all circumstances. A voice that is hoarse at a low pitch may be completely clear in falsetto. The vocal sound may vary during the production of different vowels, and the characteristics of vocal defects often change with loudness or vocal effort. The individual who provides voice therapy must know the capacities and limitations of the patient's voice because this information not only provides diagnostic data but also determines the pattern of rehabilitation. To determine the dimensions of a voice disorder, the clinician should evaluate systematically and individually the pitch, loudness, and quality characteristics of the voice.

The patient should be asked to sing a vowel, such as /a/, up and down a musical scale to the limits of the individual's range. It may be necessary to provide a tone to imitate because many patients with voice disorders have poor pitch discrimination. The adequacy of the pitch range should be noted, as well as any changes in vocal quality that occur at different positions on the scale. The patient should also be required to read a few paragraphs of simple material to reveal typical vocal habits. Generous samples of the patient's vocal production should be recorded during the evaluation process. Recordings are essential for objective listening to the voice and serve as a basis for determining improvement or regression during the course of therapy. The vocal evaluation should answer the following questions: Is the pitch of the voice that the patient uses in conversation and while reading aloud normal for a person of that age, sex, and size? Are there any unusual inflections or atypical pitch variations? Is the pitch range satisfactory, such as a minimum of five to six tones? Can the patient match the pitch of a given tone and voluntarily go up and down a scale? Is the loudness of the voice appropriate to the circumstances? Is there any evidence of a hearing loss? Is the quality of the voice predominantly normal? Is it aphonic? Breathy? Harsh? Mildly hoarse? Severely hoarse? Does the quality change when the pitch is high or low? Does the speaker appear to be using too much or too little effort during speaking? Does too much sound seem to come out through the nose? Does too little sound pass through the nose on the /m/, /n/, and /ng/ sounds? Is there any tremulousness? Is the speech commensurate with the socioeconomic background of the patient? Under what conditions of pitch, vowel sounds, and loudness levels does the subject produce the best vocal sound?

Patient's Evaluation of the Voice Problem Two basic premises support the concept that one must evaluate one's own voice problem if one wishes to modify it. First, an individual does not hear his or her own voice as others hear it; second, the clearer and more specific a goal or task can be made, the faster it will be reached. A corollary to these concepts is that unless an individual can recognize the voice problem and can form a clear concept of the improved vocal sound, remedial efforts will be relatively ineffective. The process by which a person evaluates his or her own voice is systematic listening, sometimes called "ear training." Samples of the patient's voice should be recorded at appropriate intervals during therapy, and these should be studied carefully with frequent comparison of the changing vocal features over time. The clinician should choose one vocal element at a time for special attention and must avoid both discouraging and overwhelming the patient with the re-educative task. This purposeful listening requires great clinical skill to make it meaningful and to keep the patient motivated. Inexperienced listeners do not hear many of the elements of vocal sound, particularly their own, until they are instructed; this is the function of the clinician. The temptation to send the patient home to listen to a voice recording as a therapeutic measure should be resisted until one is assured that the patient can identify specific faults. Another aspect of evaluative listening is detailed analytic study of the vocal characteristics of other persons with both good and poor voices. This exercise improves the patient's ability to identify specific vocal features and use them in production through imitation and experimental variations.

Voice Therapy *Direct Voice Therapy.* Two types of instruction relate specifically to direct voice therapy: the first can be classified as recovery, the second as training. Recovery procedures presume a need for healing, for a return of the structures to normal. They are based on the premise that the vocal organs will restore themselves if abusive behavior is discontinued. Recommendations commonly given to achieve these goals include complete vocal silence for a week or two (or sometimes longer) with no whispering, limited vocal use in which speaking is allowed only when absolutely necessary, reduced vocal intensity, elimination of all singing, limitation of physical exercises and activities that cause the breath to be impounded by the closure of the glottis, and avoidance of coughing and clearing of the throat whenever possible. These recommendations are essentially passive but are often desirable early in therapy. However, if recovery procedures have allowed the larynx to become more normal, the resumption of habitual patterns of phonation ordinarily causes a relapse. To be successful with these patients, voice therapy must include a period of training that modifies previous habit patterns and replaces them with more efficient phonatory behavior.

Imitation and Experimentation. Soon after learning to hear specific flaws in the voice, the patient should

be encouraged to experiment with voice production in an effort to modify specific faults and also to develop greater control over the voice. It is often helpful to use computer software that permits two voice samples to be displayed at once. One channel can display a previously recorded voice sample or the clinician's live voice sample and the other displays the patient's efforts to match the model.

Relaxation. With voice disorders in which vocal abuse is present, the patient usually has excessive tension in the muscles of the larynx as well as elsewhere throughout the body. Unless this tension can be controlled, vocal therapy cannot progress. The patient needs to relax. The term relaxation commonly has two meanings: it may refer to the absence of muscle contraction, or it may signify coordination in which the opposing sets of muscles exert just enough reciprocal tension on each other to accomplish a desired movement with perfect control. Both types of relaxation can be, and sometimes must be, learned for the successful alleviation of a voice disorder. Learning to relax involves both muscle training, which can be approached directly through exercise, and emotional control, which is managed through modification of attitudes, anxiety, worry, and comparable problems.

Pitch Adjustment. Many persons, particularly men, attempt to use a vocal pitch that is lower than that which is normal for their laryngeal structures. This behavior not only produces an unpleasant voice but also traumatizes the laryngeal structures. If this vocal tendency is observed, its inadequacy should be explained and assurance provided that a more normal pitch will supply a satisfactory masculine image. Subsequently, direct instruction can be given to establish a habitual pitch that averages four or five musical notes above the lowest tone that the patient can produce. An average shift of as little as one tone upward "feels" much higher to the patient and causes reluctance to accept the change. Furthermore, the patient is usually surprised to discover little change in the recording and is startled when the average listener does not recognize a change of as much as several tones in his speaking pitch.

Speech Articulation in Patients with Voice Disorders. Although articulatory disorders are discussed later in this chapter, a close relationship exists between disorders of articulation and certain voice problems that need attention in a discussion of voice therapy. Two types of phonatory problems are effectively treated through the management of articulation. One of these is observed when generalized excessive muscle tension is chronic during speaking, and the other is found in indistinct speech caused by imprecise or inaccurate movements of the lips and tongue. Where excessive muscle tension exists, mouth opening is usually minimal, talking is of the "clenched jaw" variety, and the vocal sound may be hoarse, harsh, or hypernasal. Easier, more efficient speaking usually accompanies increased opening of the mouth, reduction of rate, and relaxation of the muscles of the head and neck. When imprecise, inaccurate, or lax speech exists, the tongue and lips do not make firm contact with their opposing structures, that is, movements are often incomplete in a phonetic sense. The speech is frequently called "slurred" or "careless." Actually, the atypical sounds are usually learned in an environment where such speech is typical. When speakers with these habits are requested to talk so that they can be more easily understood, they attempt to comply by speaking more loudly and by increasing laryngeal and respiratory muscle contraction. Training in more appropriate production of speech sounds usually increases intelligibility and reduces the detrimental, excessive effort.

Vocal Practice. If the physician finds it necessary or desirable to direct the vocal practice of a patient, the focus should be on the use of a quiet voice. More specifically, practice sessions of 5 to 10 minutes should be advised in which vowel sounds are prolonged gently at various pitches, and short selections from magazine stories and other sources are read aloud. If the subject has experimented successfully with various voice qualities and is able to relax adequately, such practice will prove beneficial. If the patient uses detrimental vocal behavior when he/she reads aloud, however, this practice should be postponed. Vocal practice requires patience and constancy. Patients are often disturbed when they are told that they may not detect much improvement in 3 months or more and that 6 months may be required to achieve some skill in the use of new vocal habits. Persons preparing their voices for singing or acting accept the concept of lengthy training, but those correcting voice defects seem to expect a mag-

ical change. Consequently, one of the most difficult and important aspects of voice therapy is motivation of the patient.

Laryngeal Cancer and Vocal Rehabilitation

Hoarseness, laryngeal cancer, and speech rehabilitation are intimately related. The sound of the voice is often the first evidence of disease and consequently is important in diagnosis. The choice of medical treatment for the disease, whether it be irradiation, chemotherapy, partial laryngectomy, total laryngectomy, or combinations of these procedures, influences the type and amount of speech therapy to be used after control of the disease. Although cancer in the larynx may not influence the voice, in more than half of the patients, hoarseness is present and is accompanied frequently by pitch change and reduction of loudness. A retrospective study of 260 patients with laryngeal carcinomas by Lowry and others reported that "hoarseness was the predominant symptom in all four stages of glottic and supraglottic lesions."[49] In 1974, the American Cancer Society anticipated 9,500 new cases of laryngeal cancer for that year: 8,300 expected in men and 1,200 in women.[50] In 1988, the estimate was 12,200 new cases, with 9,900 in men and 2,300 in women.[51] The estimated new cases in 1994 totaled 12,500: 9,800 men and 2,700 women. A slight downturn in the number of laryngeal cancers was estimated for the year 2000: 10,100 new cases, with 8,100 men and 2,000 women.[52] These data have not been adjusted to general population growth. There appears to be little change in the proportion of cases in the general population over the 25-year period, but the female-to-male ratio has increased progressively from 0.144 in 1974 to 0.246 in 2000.[53] A report by Gates and associates in 1982 revealed that "of 103 people with clinical diagnosis of laryngeal cancer studied by the authors, 53 eventually were treated by total laryngectomy and, in some cases, radical neck dissection (43 cases), preoperative radiation therapy (15 cases), postoperative radiation therapy (29 cases), and postoperative chemotherapy (7 cases)."[54] The implication of these reports is that in approximately half of the cases, laryngeal cancer will be treated by total laryngectomy. Subtotal laryngectomy and irradiation will be used with the other half, only a relatively small number of whom will require extensive vocal rehabilitation. Training in communication skills is almost always desirable for patients who have had a total laryngectomy.

Presurgical Considerations Presurgical management of the person who must have the larynx removed is extremely important in the total therapy and should be handled with great care. Most laryngeal surgeons have developed effective procedures for informing and advising their patients about the surgery and its sequelae. A study by Snidecor of approximately 150 laryngectomees, however, indicated that presurgical management could be improved.[55] Of the patients studied, 85% believed that they had been counseled well and at the right time, but the majority of these patients also stated that they would have benefited from more specific counseling for themselves and their spouses about the operation, the postsurgical physical conditions, and the impending speech impairments. Only 53% learned from their surgeons about the kinds of devices available for replacement of voice. The remainder obtained their information from other laryngectomees, speech-language pathologists, and the American Cancer Society. At the time when the diagnosis of laryngeal cancer was reported to the patients, about three-fourths of them were accompanied by their spouses, which was considered helpful and desirable, but more than half of the spouses were "shocked, anxious, and deeply concerned."[55] The same study confirmed what most laryngologists know: that patients who have been told they have cancer and need surgery are filled with anxiety and many fears. They fear the cancer and the possibility of death, the surgery, and the loss of voice and its consequences, and they are distressed about the potential effects of vocal impairment on their work, family life, and social relationships. Such fears and anxieties are to be expected, but the sensitive counselor who acknowledges such feelings and whose experience allows anticipation of the postsurgical conditions can often reduce the patient's apprehension. The importance of patient attitudes and their improvement as part of the counseling of patients was revealed also in a study by Gates and associates.[56] In their second article showing an analysis of factors related to success or failure in rehabilitation, they stated, "Factors that correlated with successful rehabilitation were less postoperative radiotherapy, more vigor, greater imaginativeness, independence and

self-assuredness, and absence of denial."[57] The latter four factors are amenable to counseling and reflect the importance of this process in both the pre- and postsurgical periods.

Presurgical Speech Training Some laryngeal surgeons regularly introduce a skilled laryngectomized speaker to the patient before surgery. Others believe this practice to be unwise. Gates and associates stated that "… a preoperative visit by a laryngectomee is not associated with success in learning esophageal speech or in rehabilitation and in fact, is statistically significantly correlated with a poorer outcome."[56]

Reliable estimates of the prevalence of presurgical speech training are not available, but few speech-language pathologists currently seem to advise this practice. Perhaps the most satisfactory way to plan for postsurgical speech in the presurgical period and to handle the many questions about work, family, and social relationships is to introduce a mature speech-language pathologist who has had extensive experience with laryngectomized persons. The speech-language pathologist's function is to encourage and to motivate the patient to make plans for the postsurgical period. The speech-language pathologist does not promise fluent speech or that the learning will be easy but expresses confidence that verbal communication is usually possible with esophageal speech, a tracheoesophageal prosthesis, or an artificial larynx.

Early Postsurgical Period Within a few days after surgery, the patient begins to assess the new condition. The patient is relieved that the operation is successfully past and is glad to be alive but discovers new problems and fears to add to those that linger. The patient is bothered somewhat by breathing and coughing through the stoma and is dismayed by the reality of voicelessness. Attempts to whisper are frustrating. During convalescence, anxieties often grow about employment, personal appearance, family relationships, and association with friends. If the patient or the patient's associates have impaired hearing, communication becomes doubly difficult. The inability to talk leads to depression and withdrawal from social situations, a condition that becomes progressively more difficult to reverse. The distinction between vocal tone production and speech sound formation is clearly illustrated by the laryngectomized person. Without the larynx (voice generator), the patient can simply mouth the words. The removal of the larynx usually leaves the articulatory mechanism intact. Consequently, when the patient substitutes some other sound for the missing laryngeal tones, speech is possible. The options open to the laryngectomized person to develop a new voice are discussed later in this chapter. If the person who loses the larynx could resume talking immediately after the laryngectomy, concern would be no greater than that associated with any other major surgery. Unfortunately, when the means of communication is disrupted, the patient feels isolated and at a great disadvantage. The early restoration of the ability to communicate is a major consideration in successful rehabilitation. Every possible effort should be made while the patient is still in the hospital to establish communication by computer, writing, picture boards, signing, or the use of an artificial larynx. In addition, plans should be made during this period for instruction at home. This program should include direct work with the patient. Of equal importance is instruction of the spouse and other family members. Because individuals vary greatly in their ability to understand alaryngeal speech, the problem listeners in the family group should be identified and taught to comprehend. Some of the instruction will include speech reading skills and the use of hearing aids where indicated.[58]

Hospital care of laryngectomees, whether in the immediate postsurgical period or at some later admission for any reason, deserves special attention from all service levels. The inability of the patient to communicate creates serious problems, especially when specialized nursing care is not available. Many horror stories have been related by laryngectomized persons, ranging from aides splashing water into the stoma during bathing and application of oxygen to the nose to failure to open a plugged stoma. The International Association of Laryngectomees recommends that a special "warning" sign at the bed and on the patient's chart identify every hospitalized laryngectomee and that the care providers be given specific instructions.[59]

Restoring Speech Communication Following Laryngectomy It is a truism that any form of substitute voice is inferior to that produced normally. Similarly, any usable speech is superior to mutism, whispering, writing, or signing. Clinicians must

search for the best substitute voice sources in relation to the needs and capacities of the individual patient. Because structural adjustments above the larynx regulate the acoustic filtering of the laryngeal sound source, they are primarily responsible for creating the sounds of spoken language. Thus, any complex sound that can be put into the upper airway can be substituted for the laryngeal sound source and molded into speech. The need to restore speech to the laryngectomized patient has enabled engineers, surgeons, speech-language pathologists, and others to devise various means for producing sound that can substitute for the normal voice.

Engineering Approach. The engineering approach involves the development of artificial sound generators. These can be separated into two general types according to the driving force used in the production of sound: one is powered by the breath stream, the other by electricity from batteries.

Breath-Activated Instruments. The various forms of breath-activated instruments have three elements in common: (1) a flexible tube that conveys the breath from the tracheal stoma to a small capsule held in one hand; (2) the capsule, which contains a reed or membrane that is vibrated by the breath, thereby generating the sound; and (3) a second, smaller tube that carries the sound from the capsule into the mouth, where it is articulated into speech. Breath-powered, handheld artificial larynges are inexpensive and offer the patient an early means of talking with little or no special instruction. The speech sound can be relatively loud, phrasing and sentence length are normal, and speech is intelligible, even though it has a monotonous pitch. Unfortunately, the disadvantages attending the use of these simple instruments are substantial; consequently, few of them are currently in use. The problems can be listed as follows: moisture from the exhaled breath condenses relatively quickly at the vibrator, causing malfunction and the necessity of draining or drying it; the tube conveying air from the stoma to the vibrator becomes congested with mucus from the trachea, causing both hygienic and esthetic problems; and saliva seeps into the sound-conducting tube, contributing to vibrator problems and necessitating frequent changes and washing of the tube to keep it clean. Because the unit is held by one hand, it interferes with two-handed activities; furthermore, because it must be transported by the user and kept readily available for speaking, it becomes a nuisance.

Electrical Artificial Larynges. Two major types of electrical instruments are in common use. In one, the sound is generated by a battery-powered buzzer, about the size of a hearing aid phone, that is held in the hand and from which the sound travels by way of a tube into the mouth. The sound is formed into speech by articulatory movements as it is with the breath-powered unit. The second type of instrument has several forms, but basically it is a handheld unit, about the size of a two-cell flashlight, that transmits a buzzer type of sound through the tissues of the neck into the pharynx, mouth, and nose, where the sound is articulated into speech in the customary manner. The vibrating element of these units is a disk that is placed against the skin of the neck. It is activated by a battery and controlled by a switch similar to that on a flashlight. Battery-powered artificial larynges share with the breath-activated units such advantages as low cost, early and easy restoration of speech, and good intelligibility. The electrical tissue-vibrating instruments have the additional positive features of freedom from hygienic problems, moisture condensation, and instrument care that accompany the breath-powered units. On the negative side, electrical artificial larynges require one hand for operation and must be carried continuously by the user. Furthermore, the vibrating disk models generate a field noise that is transmitted directly to the surrounding air, where it competes with the sound that comes from the speaker's mouth. The ambient noise and the monotonous speech sound produce an artificial, machine-like utterance. Breathing and phrasing are interrelated in normal speech. When the basic sound is produced more or less continuously, as with the electrical instruments, utterance tends to become "mechanical." Experienced users of these units, however, learn to start and stop the sound to approximate the appropriate phrasing of the sentences.

Surgical Approach. Surgical efforts to produce substitute vocal sound have extended over many years and can be classified into three forms.

Tracheoesophageal Shunts. A primary surgical approach to the construction of a substitute sound source is the formation of a tracheoesophageal shunt.[60,61] Basically, the shunt is a small channel extending from

the upper, posterior wall of the trachea through the anterior wall of the esophagus. When the tracheal stoma is closed with a finger, exhaled air passes through the shunt into the esophagus, where it vibrates the pharyngoesophageal sphincter or other esophageal tissue to create a sound. At least four advantageous features are associated with the surgical creation of a shunt for the production of voice. When the air resistance in the shunt is relatively small, the manner of speaking is almost effortless; the voice is produced on the exhalation of pulmonary air as in ordinary speaking; phrases and pauses occur at linguistically appropriate places; occasionally, slight pitch variation is achieved; and little training in the use of the method is needed. The Blom-Singer and Panje prostheses are comfortable, reliable, and relatively unobtrusive.[62] Detailed descriptions of these prostheses and the procedures for placing them are presented in Chapter 54. Additional information appears in the literature.[63,64] The major limitation, from a speech standpoint, is that a finger must be used to close the tracheal stoma whenever sound is produced unless the patient is able to wear a tracheostoma valve.[65] Vocal intensity is usually reduced from that of normal speech, and the prosthesis must be removed, cleaned, and reinserted. The new prostheses have greatly reduced problems of leakage, infection, and stenosis.[66] Patients must be selected carefully and motivated to want to improve their speech and must be capable of managing the hygienic care of the prosthesis as well as having the dexterity to remove and replace it.

Construction of a Pseudoglottis. Theoretically, the ideal solution to the loss of voice through the removal of the larynx would be the construction of a living tissue substitute that would produce sound and have no detrimental sequelae. In this approach, the surgeon constructs a pseudoglottis at approximately the location of the original larynx. Muscle and cartilage that can be spared are formed into an airway continuous with the trachea. At the junction with the pharynx or esophagus, a vibrator "buttonhole" is formed that can generate a sound when the breath is exhaled through it. Some success has been achieved through this approach by highly skilled surgeons with carefully selected patients. Unfortunately, the pseudoglottis is usually not a liquid-tight valve. Fluids leak from the pharynx or esophagus into the trachea, leading to pneumonia and other diseases. In patients with whom the procedure has been successful, the voice has been good. When a tracheal stoma has been maintained, however, the patient has the disadvantage of using a finger to cover the opening to divert the air stream.

Combined Surgical and Artificial Devices. In this approach, an artificial, breath-powered, sound-generating reed is mounted in a small box and is activated by air conducted through a tube from the tracheal stoma to the box. The sound is discharged through a second tube that extends from the generator to a surgically created fistula that passes through the skin and deeper structures at the side of the neck into the pharynx. The small enclosure containing the sound source lies on the patient's chest just below the stoma.[67] The surgical creation of a fistula into the pharynx, permitting the connection of an external, artificial sound source, appeals to some laryngectomized persons, particularly those who have been unable to learn esophageal speech and who do not want to use one of the handheld artificial larynges. The advantages of the surgical fistula and attached mechanical device include the capacity to produce highly intelligible, fluent speech with customary phrasing and the utterance of sentences of normal length. Both hands are freed for normal activity. The disadvantages of this system are (1) the obvious esthetics, the hygienic and clothing annoyances caused by a device attached at both the tracheal stoma and the fistula; (2) the special surgical procedure that is necessary to create the fistula; (3) occasional rupture of a neck artery when the fistula is located incorrectly; (4) the hygienic care of the fistula and instrument; and (5) the need to insert a stopper into the fistula to prevent leakage when the tube that passes through the fistula is removed for sleeping or other reasons.

Esophageal Speech Approach. The third approach to speech recovery for laryngectomees is the development of esophageal speech. This procedure allows the patient to control and refine the natural eructation sound as the basis for speech. The advantages of esophageal speech are that (1) natural physiologic structures and functions are used, thereby obviating the need for an artificial device; (2) both hands are free for normal activities during speech; and (3) the good esophageal speaker presents a relatively normal appearance and speaking manner. The disadvantages of esophageal speech are that (1) it is often dif-

ficult to learn (according to Gardner, approximately 30% of laryngectomized patients do not learn to speak well with esophageal speech[68]), and frequently, 3 months or more are required to achieve fluency; (2) phrasing is usually changed, so fewer words than normal are uttered in a sequence without pause for phonatory air; and (3) the voice lacks sufficient loudness to be heard easily over common environmental noise. All of the substitute methods of creating voice, except the battery-powered, disk-type artificial larynges, encounter maximal problems when the patient eats. Swallowing food and the stimulation of salivary secretion complicate speaking and frequently embarrass the patient in social situations. Esophageal voice production and the artificial larynges with oral tubes are probably more adversely affected while eating than with the other methods discussed.

The air used in ordinary eructation comes from the stomach, and the sound usually does not result from voluntary acquisition and expulsion of air. Many persons, however, can learn to take air into the esophagus and expel it without allowing it to reach the stomach. In this method, air in the esophagus is put under slight pressure by respiratory movements and escapes in vibratory pulses through the sphincter mechanism at the upper end of the esophagus. This organ does not produce sound as effectively as the larynx, but its phonation function is similar, and it is subject to considerable regulation. The ability to control the air charge and consequently the moment of sound production is the primary problem in learning esophageal speech. Before air can be expelled from the esophagus, it must be taken in. If it is allowed to enter the stomach, it cannot be returned readily for voice; consequently, the air charge must not be swallowed in the sense that water is swallowed. Instead, it must either be "inhaled" or "injected" into the esophagus. Experience proves that either of these procedures is serviceable for each has been used by good esophageal speakers. Indeed, many of these speakers use both methods interchangeably.

INHALATION METHOD. If the esophagus were held open as the trachea is, the ordinary respiratory expansion of the thorax would draw air into the esophagus as readily as into the lungs. Many laryngectomized persons can learn to relax the upper esophageal sphincter at the moment of inhalation and thereby allow air to be pulled into the esophagus. In the initial stages of learning this procedure, however, before the laryngectomee is able to relax the esophageal valve readily, he or she can facilitate the intake of air by momentarily covering the stoma with a finger. This action suddenly decreases the pressure in the thorax, causing the air in the pharynx to be drawn into the esophagus. As soon as the air has been taken in, it can be expelled by increasing the thoracic pressure, as in exhalation. This return flow is interrupted intermittently by the vibration of the tissues of the pseudoglottis, thereby producing sound.

INJECTION METHOD. The "injection" method of putting air into the esophagus uses a different principle from that used in the inhalation procedure just described. In injection, the air is forced, pumped, or squeezed from the mouth and pharynx into the esophagus. Injection is accomplished by closing the lips and the velopharyngeal valve to provide an airtight oropharyngeal area while simultaneously thrusting the back of the tongue upward from the /d/ position. This movement pumps the air out of the mouth (oral cavity) into the pharynx, and because it is not permitted to escape through the nose and no longer has access to the larynx and trachea, it passes into the esophagus. Squeezing the air from the mouth into the esophagus can also be achieved by compressing the lips and buccal spaces, as in making a /b/ sound, and simultaneously lifting the mandible.

Several manuals and instructional booklets are also available through local cancer societies. It is often necessary for the person working with a laryngectomee to help with suggestions about everyday hygiene and appearance. The instructor should be able to advise on such items as care of the tracheal tube and prostheses, cleanliness, coverings for the stoma, suitable neckwear for men and women, precautions related to bathing, difficulties of speaking while eating, and similar personal problems. The clinician should also be able to help the laryngectomee join a "Lost Cord Club" for instruction, practice, and recreation. Addresses can be obtained from the International Association of Laryngectomees* or from a local chapter of the American Cancer Society.

*International Association of Laryngectomees, 8900 Thornton Road, Box 99311, Stockton, CA 95209, USA.

Selecting a Method of Speech Rehabilitation
The welfare of the patient is, of course, the first consideration in the rehabilitation process. The laryngologist, speech-language pathologist, and others involved in restoration of communication should assess the patient's needs and potential for rehabilitation as early as possible, preferably while the patient is still in the hospital. If the team determines that a shunt with a Blom-Singer or Panje prosthesis is appropriate, the steps toward spoken communication are clearly evident. When surgery is not indicated, attention can be given immediately to the use of an artificial larynx. Subsequently, when healing and the effects of postsurgical irradiation have progressed satisfactorily, esophageal speech instruction can be introduced. Most clinicians agree that good esophageal speech is more desirable than speech with artificial devices. The rehabilitation team, however, can determine when or whether such instruction should be introduced. If the decision is made to use an artificial larynx, either temporarily or permanently, the patient should be taught how to manipulate it most effectively and how to care for it.[69] Manufacturers customarily include printed instructions, but usually these need to be supplemented by demonstration and personal experimentation.

DISORDERS OF SPEECH

Speech-language pathologists recognize that substantial segments of the adult population as well as younger groups have serious speech, language, and voice defects, the problems that involve otolaryngologists most directly. Prevalence of communication disorders in children is high, with a gradual decline through adolescence. At least 5% of school-age children (up to age 17) have significant speech impairment, although most professionals consider this estimate extremely conservative. Some researchers have reported a prevalence as high as 10% for certain samples of children.[70] Most of these difficulties in children involve functional articulation disorders; faulty language formulation and dysfluency (stuttering) comprise the remainder. The presence of communication problems appears to stabilize during adulthood and tends to increase after the age of 40 years. There seems to be a higher percentage of disorders in men than women. Fewer disorders are assumed to occur among adults than among children. The ever-increasing size of our geriatric population, however, with its associated communication disorders, may require us to change that assumption. In addition, many neurogenic speech and language disorders, unlike stuttering and many articulatory disorders, develop in adulthood.

Speech and language disorders can be divided into three major categories. First and most common are the *articulation disorders*. These problems involve the production of defective speech sounds and sound combinations that may be distorted, omitted, substituted, or added as accessory sounds. Sometimes articulatory disorders are the result of neurogenic disorders, the dysarthrias. A second type of disorder is the *impairment of speech fluency*, called *stuttering* or *stammering*. Repetition of sounds, syllables, words, or phrases; sound prolongations; atypical pauses (hesitations); word substitution; and use of word fillers characterize dysfluent behavior. A third category is variously labeled *language impairment, linguistic disability,* or *faulty symbolization*, which refers to disorders in both expression of thought through verbal language and its comprehension. The category includes various disorders, ranging from delayed/deviant language development to neurogenic disorders known as aphasia.

Normal Speech Development in Children

The normal acquisition of speech may be expected to follow much the same pattern as the motor, adaptive, and personal-social behavior of the child. As in all other types of learned behavior, speaking depends on the process of maturation. A "speech readiness period" extends from birth to the fifth year of life, when the child acquires the ability to develop speech as a method of communication. This capacity, however, represents the cumulative learning of many bits and pieces of language that begin within the first few weeks of life.[71] Although endowed by nature with the capability of learning language, it appears that a child learns to talk only because people in the immediate environment speak to each other and to the infant. In the first few months of life, infants are capable of perceptually differentiating a wide variety of speech sound contrasts, giving children the capability of learning any of the languages of the world.[72,73] However, by 6 months of age, children have already begun to lose some of the capability of perceptually differentiating among sound contrasts that are not used by talkers within their immediate language environ-

ment.[74] Also, by 6 months of age, infants show an enhanced ability to distinguish perceptually those sounds used by talkers within their native language environment.[75] Infants and young children are typically "bathed in language" by their caregivers during the first months of life. Such stimulation, often called motherese, serves to nurture proper language development.[76] This potential for language learning is graphically highlighted by cases of abandoned, nonstimulated children who manifest severe language impairments. Before the child can learn to use oral symbols as a form of social behavior, he or she normally lives through a series of prelinguistic overlapping stages of sound production. The child's physical, emotional, and intellectual needs are served and expressed in each stage.[77] Furthermore, the emergence of speech in the "normal" child serves as an excellent index of his or her physical, intellectual, and emotional status. From a body systems perspective, the general sequence of speech development involves attaining proficiency with breath control, then laryngeal control, and finally articulatory control.[78] The development of speech can be classified into a sequence of five stages, each of which has distinctive characteristics that blend cumulatively.

The Cry The first stage is crying, which includes both undifferentiated and differentiated cry. During the first month or two, the cry does not differentiate sensations of hunger or pain, heat, cold, or other kinds of discomfort. Differentiated crying appears within the first few months, and the mother soon learns to interpret variations in the cry as signals of immediate needs or desires.[79]

Babbling In the second stage, babbling, the infant does not abandon differentiated crying but usually by the third or fourth month produces a variety of sounds at random and may appear to be "listening" as well as responding to sounds in the environment. Most of these are "cooing" sounds that are like vowels. Prosodic features (pitch, stress, and duration) begin to develop. Later the child begins to use the lips and tongue to make consonant-like sounds that combine with those vowels, producing what we call babbling.[80] Because the child's sensory feedback loop (primarily auditory) is beginning to develop now, the child's babbling becomes progressively imitative of the prosodic and phonemic aspects of the input (adult) language. Children at 3 to 10 months of age progressively play with adult forms of speech.

Reduplicated Babbling Reduplicated babbling (repeated syllables such as pa, pa, pa, ba, ba, ba, ku, ku, ku, etc) begins during the second 6 months. At first, the sounds produced are carried over from babbling, but later the infant appears to be responding more selectively to the sounds of others, as well as to those he or she has just produced. Reduplicated babbling appears to be a good index of normal development. Virtually all normal-hearing children produce reduplicated babbling before 12 months of age, whereas children with significant hearing impairments rarely do.[81] The speech development of the congenitally deaf child differs from that of the child with normal hearing beyond the babbling stage. The deaf child does not continue babbling for as long as the hearing child, and speech development usually follows a different pattern from that of a hearing child.[82]

Echolalia Echolalia, the name given to the fourth stage, begins somewhere around the ninth to tenth month, when the baby repeats sounds that he or she hears in the environment. The child seems to produce sounds that are pleasurable and repeats sounds that another individual produces. This is the stage when the child demonstrates that speech and language comprehension are emerging. Up to this stage, the baby has been acquiring an inventory of sound complexes that later will be used in learning to speak and in developing a vocabulary. The ages at which children typically master the sounds of English are shown in Table 49–1 (after Sander[83]).

Intentional Speech The fifth stage is the acquisition of speech as a practical tool for communication. Before entering this final but ever-expanding stage, the child must have established a functional understanding of conventionalized speech patterns. Providing meaningful time sequences for the mastery of speech sounds is difficult because many factors influence and regulate their acquisition. Girls generally surpass boys in learning speech sounds and tend to be accelerated in articulation skill from about $4\frac{1}{2}$ years on. Girls normally approximate mature articulation by the age of 7, whereas boys usually take an additional year to reach the same degree of proficiency. Whereas development of articulation skills is nearly complete for most normal children by age 8 years, subtle performance differences still exist for several years. Research evidence emphasizes that the accuracy of speech motor control continues to improve until age 11 or 12 years, at which point,

TABLE 49–1. Guidelines of Normal Acquisition of Consonant Sounds

	Customary Articulation	
Sounds	*50% of Children (yr)*	*90% of Children (yr)*
p, m, h, n, w, b	1.5	3.0
k, g, d	2.0	4.0

j	4.0	7.0
v	4.0	8.0
th	4.5	8.0
zh	6.0	8.0+

Adapted from Sander EK.[83]

adult-like articulation performance is achieved.[84] In general, research indicates that the average child of 36 months should have acquired a vocabulary of approximately 1,000 words and should be using short, meaningful sentences.[72] Errors in the articulation will probably occur; nevertheless, 80 to 90% of conversational speech should be intelligible to an interested listener. If a child is not speaking acceptably by the age of 7 years, it may be because of any one or a combination of the following: (1) defective hearing, (2) poor motor coordination, (3) physical defects, (4) poor speech models in the family environment, (5) insufficient language stimulation, (6) mental retardation, or (7) emotional disturbance. As Table 49–1 highlights, however, occasional difficulty with later developing sounds should not prompt undue concern by parent, clinician, or physician.

Since the mid-1970s, a major shift has occurred regarding the theory behind speech sound development. Rather than tracking the developmental timetable of individual speech sounds, contemporary researchers investigate the emergence and disappearance of phonologic processes (eg, cluster reduction, unstressed syllable deletion, stop for fricative substitutions, etc).[85,86] A detailed discussion of the chronology of phonologic processes is beyond the scope of this chapter, but developmental charts/graphs are available to the interested reader in the professional literature.[78,87,88]

Articulation Disorders

Disorders of speech articulation may be described as faulty or atypical production of sounds in the spoken language. These problems encompass many kinds of articulatory defects, both functional and organic, and constitute the most frequent type of speech disorder observed within the population.

Functional Articulation Disorders When a disorder is designated functional, it does not necessarily indicate that it is a simple problem. Some functional articulation disorders are truly psychogenic, but most represent problems stemming from faulty learning and/or habits of misuse. Because successful therapy may depend on discovering causal factors, however, one must explore certain aspects of the individual's physical and social development. Habit-strength is a learning theory concept that relates to the automaticity of both appropriate

and inappropriate behavior. Applied to speech, habits can account for the persistence of a problem and the resistance to its successful treatment.

The child's mental age or intelligence must also be considered when articulation is being evaluated. Intelligence, reflected in cognitive functioning, underlies one's ability to learn. Because learning is fundamental to speech and language acquisition, intelligence factors can influence speech performance. It is not surprising, then, that numerous studies have demonstrated that children of low mentality produce more articulation errors than children of normal intelligence. Moreover, children with severe articulation defects frequently have depressed scores in reading and spelling, which may help to explain their low scores on verbal intelligence tests.

The word delay implies normal sound development as a reference, and impairment of this type is manifested as (1) a delay in onset, (2) slowness of development, and/or (3) termination of development before the average adult skills are achieved.[78,89] Furthermore, delay assumes that between the onset and termination of a particular child's development, the course of events will follow the developmental sequence observed with children who are acquiring speech normally.[90]

Answers to the following questions may supply useful insight into the problems: Did the child follow a normal pattern in sitting, walking, eating, talking, and using the toilet? Did the child have any periods of extreme illness or temporary hearing loss? Did the child have extended absences from the family environment? Did emotional conflicts arise between the mother and father or between the parents and the child? Did any undue penalties and frustrations occur that may have been associated with the speech readiness period? Did or do persons in the environment have similar speech problems that could have been imitated?

In summary, a child with a delay profile demonstrates performance similar to that of a normal but younger speaker. In contrast, deviant speech refers to an articulation profile unlike that of a normally developing child, even a younger one.[78] Although both appropriate and delayed characteristics may still persist in the speech of these children, the deviant speaker's articulation reveals error patterns that cannot be accounted for on the basis of a "delayed" concept.

The traditional way of describing the nature of articulation disorders is in terms of the following four classic error types:

Substitutions. One standard sound is substituted for another in the initial, medial, or final position within the word. For example, the sound *w* is frequently substituted for *r,* producing *wed* for *red; t* or *d* may replace *th,* and *mother* becomes *mudder* and *something* changes to *someting; th* may substitute for *s,* and *miss* becomes *mith.* The most frequently misarticulated sounds are often those that are mastered later in the course of speech development: */s, z, r, 1, th, ch, sh, zh/.*

Omissions. Sounds are omitted in a word and are not replaced by a substitute. The child may produce *tep* for *step, air* for *where,* or *daw* for *dog.*

Distortions. The target sounds are produced but are modified so that the perceptual result is inaccurate. A distortion might be considered a special case of substitution error in that a standard sound is replaced by a nonstandard sound. The /s/ and /z/ are among the most misarticulated speech sounds because adjustments of the tongue, teeth, and bite relationships during normal growth and development during the preschool and primary years are so exacting that minor deviations easily occur. A common form is lisping, when one or more of the sibilant consonants /s, z, *sh, zh/* is distorted.

Additions. Extra sounds are added that are not part of the word: examples are *warsh* for *wash* or *plass* for *pass.* Additions are not as common as substitutions, omissions, and distortions.

Organic Articulation Disorders in Children

Many speech-language pathologists now approach the subject of organic articulation disorders cautiously. As Bernthal and Bankson stated,

> Although individuals with oral structural deviations frequently experience articulation problems, the relationship between structural deficits and articulation skills is not very predictable. The literature cites many instances of individuals with structural anomalies who have developed appropriate compensatory gestures to produce acoustically acceptable speech. Why some individuals are able to compensate for relatively gross abnormalities and others are

unable to compensate for lesser deficits has not been resolved.[91]

These observations clearly emphasize that the relationship between oral structure and articulation proficiency is neither simple nor automatic. The remarkable compensatory potential of the oral-peripheral mechanism seems to account for the clinically observed inconsistencies in speakers whose performance is relatively better than would be expected from the individual's structural status. In general, structural deviations can affect articulation by interfering with articulatory contact points, breath stream flow (force and direction), oral breath pressure, and oral-nasal cavity coupling. Disorders such as cleft lip and palate can involve all of these aspects, whereas the normal loss of front teeth in a growing child might create involvement of only the first two factors. As Carrell pointed out, a good rule of thumb is to "consider any structural deviation a possible cause of misarticulation provided the nature of the speech defect is consistent with the deviation."[92]

Structural and Syndrome-Related Speech Disorders. Many structural deviations (eg, clefts of the lip and/or palate) are associated with speech, hearing, and language disorders. The physician should be sensitive to the possibility that structural anomalies concomitant to speech disorders can result from dysmorphisms of genetic origin, commonly referred to as syndromes, or a "pattern of things that run together."[3] When multiple dysmorphisms appear in the same patient, consultation with a medical geneticist is prudent to determine whether evaluation and treatment of the family as well as the patient are necessary. Shprintzen identified some syndromic patterns commonly associated with language and speech disorders. Contiguous gene disorders give rise to Prader-Willi, Beckwith-Wiedemann, velocardiofacial, and Rubinstein-Taybi syndromes.[3] Mechanically induced syndromes that cause deformations from tearing or mutilation of the embryo include sequences in which multiple anomalies stem from a single factor. Such sequences that result in speech and language disorders include ADAM sequence (amniotic deformations, adhesions, and mutilations—the craniofacial complex and limbs are particularly susceptible to amniotic adhesions resulting in cleft lip, facial clefts, and anencephaly), Pierre Robin syndrome (micrognathia, large U-shaped cleft palate, and upper airway obstruction), and Stickler's syndrome (clefting of palate, micrognathia, and perhaps Robin sequence). Other teratogenic disorders are associated with multiple anomalies. Examples include the effects of thalidomide, German measles virus, and fetal alcohol syndrome. Myotonic dystrophy (Steinert's disease), neurologic diseases associated with lysosomal storage diseases (Hunter's syndrome), cleft of the larynx (Opitz syndrome), and vocal cord atrophy (owing to Werner's syndrome) can have specific consequences on the voice and speech production capabilities of the patient. Although a discussion of these syndromes is well beyond the scope of this chapter, interested readers should consult the excellent references provided.[3,93–95]

Tongue-tie (Ankyloglossia). Parents frequently take children with articulatory defects to physicians to determine whether the child is "tongue-tied." The term "tongue-tied" (ankyloglossia) is used when the lingual frenum appears to be abnormally short or taut, restricting the movement of the tongue so that it cannot move upward to the alveolar ridge. Although this condition is known to exist, its interference with articulation is considered comparatively rare. McEvery and Gaines examined 1,000 children who had short frenums and found only 4 with articulatory defects.[96] They recommended that the frenum not be clipped because of possible infection, hemorrhage, and residual scar tissue. A more recent study confirmed the minimal relationship between ankyloglossia and articulation disorders, finding that an individual who presents a tongue-tie and an associated articulatory problem can usually be re-educated successfully without surgical removal or clipping of the frenum.[97] The exception is when the tip of the tongue is almost completely immobilized. Even in these cases, however, surgical intervention does not independently remedy the speech problem. The freedom of the tongue that results from clipping the frenum provides a potential for improvement, but the tongue habits that have developed will persist during speaking until the individual has been retrained.

Dental Abnormalities and Tongue Thrust. Normally, the teeth serve an important function in the production of speech sounds. Research and clinical observations have indicated, however, that many

individuals with dental abnormalities are able to make compensatory adjustments that produce acceptable speech. Professional debate related to the developmental nature of swallowing (normal and abnormal), the impact of tongue thrust on dentition and articulation, and the efficacy of speech and/or myofunctional therapy has created an ongoing controversy that is still unresolved. Review of the various positions in the literature led Bernthal and Bankson to the following conclusions[91]:

1. Currently, no data support the existence of a distinct clinical entity sometimes referred to as "tongue thrust." Behavior so identified is probably "normal," especially in preadolescent children.
2. Speech sound errors, particularly sibilant distortions, are present in greater number in those who evidence reverse swallow patterns than in those who do not.
3. The speech-language pathologist should focus on the correction of speech sound errors. On the basis of developmental data, techniques designed to change swallow patterns as part of an overall remediation program appear ill advised before a client has reached adolescence.

Treatment of Articulation Disorders in Children The complexity of speech production requires awareness of many factors that could influence speech sound learning/monitoring/modification and performance. One must evaluate the articulation problem in terms of (1) the degree of sound variation, (2) the consistency of misarticulation, (3) the effect of the disorder on intelligibility, and (4) the total number of sounds affected. This clinical strategy naturally results in capturing an essential component of any treatment plan; it must be prescriptive. The goal in treating articulation disorders is to identify and correct defective sounds. Most treatment is directed at improving performance accuracy and consistency. The four general steps of remediation are (1) training the speaker's perceptual skills (phonologic process or sound identification and discrimination), (2) establishing the new response (correct sound production), (3) strengthening and generalizing the correct sound production or phonologic process to connected speech levels, and (4) carrying over the new response to conversational speech both within and outside the clinical setting. The last three stages are really designed to habituate the new response.[78] Although the steps are straightforward, the complexity of the behavior and the clinical process dictate that treatment be guided by a professional speech-language pathologist rather than by the client or parents attempting a self-improvement program. Additionally, the parents should guard against continually correcting the child in his or her speech production. When proper therapy for articulatory problems is administered, the prognosis is good.

Disorders of Speech Motor Control

"Neuromotor speech disorders are disturbances of movement of the speech production system that result in someone being imperfectly understood or creating the impression that something is unusual or bizarre about his or her speech pattern."[98] The two major types of neuromotor speech disorders are dysarthria and apraxia.

Dysarthria Dysarthria may be defined as a defect of articulation resulting from a lesion in the central or peripheral nervous system, which directly regulates the muscles used for speaking. It involves an impairment in the control and execution of speech movements because of muscle weakness, slowness, incoordination, or altered muscle tone.[98] Depending on the type of damage to the neuromuscular control system, dysarthria can result in impaired respiration, phonation, articulation, resonance, and prosodic aspects of speech. Largely through the work of Darley and his colleagues at the Mayo Clinic in the 1970s, differential diagnosis of the types of dysarthrias can now be made.[99] Table 49–2 presents a list of recognizable dysarthria types along with the neurologic conditions or level of brain damage associated with them. Dysarthrias associated with Parkinson's disease[7,9,11–13,100,101] and amyotrophic lateral sclerosis[10,102–106] have probably received more research attention during the past 5 years than other types of speech disorders.[107,108]

Apraxia In contrast, apraxia of speech represents an impairment in the programming of speech movements in the absence of muscle impairments associated with dysarthria.[98] Apraxia is considered to involve damage to the speech programming area of the brain in the left frontal lobe (Broca's area).[109] With both

TABLE 49–2. Types of Dysarthrias

Dysarthria Type	*Neurogenic Condition or Level of Damage*	*Speech Deviations*
Flaccid	Brainstem, lower motoneuron	Hyponasality, breathiness, poor articulation
Spastic	Bilateral motor strip	Strained-strangled voice, low pitch, very poor articulation
Ataxic	Cerebellum	Irregular speech and syllable repetition
Hypokinetic	Basal ganglia, parkinsonism	Reduced loudness, rushes of speech
Hyperkinetic	Many levels of extrapyramidal motor system	Unsteady rate, pitch, loudness; sudden or slow variations in speech or voice; stoppages; tics; grunts

conditions, dysarthria and apraxia, articulation proficiency of the speaker is adversely affected. As would be expected, the degree to which speech intelligibility is compromised depends on the type and severity of the underlying neuromuscular impairment. Darley and associates suggested that a comparison of dysarthria and apraxia of speech reveals distinctive performance profiles.[99] According to their extensive study of these clinical entities, the "most characteristic error made by dysarthric patients is imprecise production of consonants, usually in the form of distortions and omissions." These are considered errors of "simplification." In contrast, the patient demonstrating apraxia of speech reveals errors of "complication" and relatively few simplification errors. These complication errors include "substitutions of other phonemes, often unrelated substitutions, as well as additions of phonemes, repetitions of phonemes, and prolongations of phonemes."

Treatment of the Motor Speech Disorders
Although distinctive articulation profiles can be described for both motor speech disorders, differential diagnosis between these two clinical entities is usually difficult to make with confidence. The prognosis for improvement with therapy for both of these motor speech disorders should be guarded, but judgment varies with the type and severity of the underlying neuromuscular impairment.[110] Because patients with either disorder may benefit from a formal, structured remediation program, rehabilitation should be provided. According to Darley and associates,[99] any treatment program should incorporate five fundamental principles: (1) the patient must be assisted to develop functional compensation from the healthy body systems; (2) the patient must develop the perspective that speech production must now become a highly conscious, deliberate effort; (3) the patient must develop the ability to monitor speech performance continuously; (4) remediation must begin as soon as possible because waiting is not beneficial; and (5) the patient must receive continued support and reassurance. In an attempt to enumerate various treatment options with neurogenic speech disorders, LaPointe and Katz included medical (alleviate cause), behavioral (modify neuromuscular and aerodynamic events), palliative (make the behavior, as well as the reaction to it, more moderate), and alternate mode (implement alternative communication systems) intervention strategies.[111] Typically, the speech-language pathologist uses one or all of the final three options in conjunction with the appropriate medical intervention.

Defects of Fluency (Stuttering)

The terms stuttering and stammering are used synonymously around the world, although the term stuttering is preferred in the United States. Stuttering is one of the most enigmatic speech defects encountered by the speech-language pathologist. This phenomenon is difficult to define because "no two stutterers are alike" and no single stutterer is the same from one time until the next. A workable def-

inition of stuttering that has been acceptable to all speech-language pathologists has not yet been formulated. Wingate, however, provided a useful description of the disorder that enumerates behaviors common to all stutterers and indicates kinds of accessory behaviors shown only by some:

> I. (a) Disruption in the fluency of verbal expression, which is (b) characterized by involuntary, audible or silent, repetitions or prolongations in the utterance of short speech elements, namely: sounds, syllables, and words of one syllable. These disruptions (c) usually occur frequently or are marked in character and (d) are not readily controllable. II. Sometimes the disruptions are (e) accompanied by accessory activities involving the speech apparatus, related or unrelated body structures, or stereotyped speech utterances. These activities give the appearance of being speech-related struggles. III. Also, there are not infrequently (f) indications or report of the presence of an emotional state, ranging from a general condition of "excitement" or "tension" to more specific emotions of a negative nature such as fear, embarrassment, irritation, or the like. (g) The immediate source of stuttering is some incoordination expressed in the peripheral speech mechanism; the ultimate cause is presently unknown and may be complex or compound.[112]

Although no conclusive prevalence figures currently exist, it has been estimated that stuttering has its highest occurrence in the preschool years (above 4%), declining thereafter to an unstable value of less than 1%. This declining pattern appears to relate to two factors, successful therapy and spontaneous recovery. Research has confirmed the clinical observation that stuttering is more common among boys than girls in a ratio of approximately 3 to 1.[113] The literature presents a variety of theories regarding the origin of stuttering; unfortunately, none represent professional consensus. Based on extensive case study, Van Riper concluded that one cannot determine or account for the onset of stuttering in terms of the conditions surrounding it for the vast majority of cases studied soon after onset.[114] At a basic physiology level, however, Van Riper stated that it seems reasonable to attribute stuttering to the "difficulty some children are bound to experience in mastering the synchronized timing of the motor coordinations required for speech." Van Riper's conclusion has current consensus in light of the emerging research evidence that differences in speech physiology do exist between stutterers and nonstutterers.[115–117] In fact, research into the nature of stutterers' *fluent* utterances indicates subtle motoric differences (not auditorily perceptible) that suggest some underlying difficulty with motor control and timing.[118] Substantial agreement exists on the general "facts" regarding the onset and development of stuttering. The typical onset occurs during the preschool years, usually 1 or 2 years after the child first learns to speak (onset is rare in adulthood). The onset is usually gradual and most often characterized by an excessive amount of repetitive speech (sounds or syllables), usually without tension or effort. Although the exact nature of development varies among stutterers, virtually all demonstrate a change of behavior as long as the disorder persists. The initial speech characteristics of part-word repetitions are often supplemented with sound prolongations and hesitations, usually associated with increasing struggle and avoidance behavior. Reactions by listeners, important "others," and the stutterer tend to create fear, anxiety, and self-doubt. These observations tend to confirm the accuracy and utility of Wingate's "definition" presented earlier. Moreover, the stability of these behaviors is not observed until the advanced stage of the disorder. Until that time, the severity of stuttering has been described as cyclic, changing from better to worse with no apparent logic. Despite differences in severity and symptom profile, there is clear evidence that as long as the disorder persists, the stutterer must face exposure of the disability to an ever-growing number of situations that come with social and professional growth in adulthood. Stuttering is truly a disorder of social living, not just a speech impediment.

Research regarding the development of speech and language skills makes it clear that most children experience periods of "normal nonfluency" during their early years that look and sound similar to the behaviors described as onset characteristics of stuttering. The number and duration of such episodes vary among children, but their occurrence does *not* automatically confirm the existence of stuttering. Therefore, great caution should be exercised to avoid the unnecessary stigmatizing effect of labeling a child's nonfluencies as clinically significant (stuttering) when they could be variations of *normal* speech development. Although differentiation between normal nonfluencies and those reflective of incipient stuttering is difficult, research has gener-

ated behavior guidelines to assist the speech-language pathologist in making these clinical distinctions.[114,119,120] Almost all stutterers have periods of relative freedom from hesitancies, repetitions, blocks, or prolongations. Stutterers can usually sing or speak in unison without disruption in their flow of speech and usually have no difficulty when speaking aloud to themselves or to a pet. The degree of communicative stress in a speaking situation appears to govern the degree of stuttering severity.

Common Questions about Stuttering What is primary stuttering? This term is sometimes used to describe a child's speech when it is marked by effortless repetitions or prolongations of words, phrases, or syllables without an awareness on the child's part that these mannerisms are different or abnormal. Johnson stated that "practically all stutterers are originally diagnosed (regarded as "stutterers," "not talking right," or "having difficulty saying words," and so forth) by … their parents, more often than not the mother being the first to become concerned."[121] Is stuttering hereditary? No clear evidence supports the view that stuttering is a characteristic that can be transmitted, in a biologic sense, from one generation to another. Does stuttering run in families? Research studies pertaining to the families of stutterers and nonstutterers indicate that, to a limited extent, stuttering does tend to run in families. The reason appears to involve tradition more than heredity. When parents have had a background of experience with stuttering, they appear to react to the speech imperfections of their children differently from parents who are unfamiliar with the condition. Parents with stuttering in their background may be so conditioned in attitude, policies, and concern that they view their child's normal speech imperfections as stuttering. Is stuttering caused by imitation? Parents are frequently concerned about the possibility of a child becoming a stutterer if their child associates with a stuttering child. Imitation in and of itself does not cause stuttering. If this were true, the incidence of stuttering would be considerably higher than that currently reported. Children have been exposed to stuttering for years in public and private schools, and no "epidemic" has ever been recorded.

Why do more boys stutter than girls? Studies have shown that male stutterers outnumber female stutterers by about 3 to 1. From a physical standpoint, the sex ratio might reflect a less stable neuromuscular control system for speech in boys, at least during the early years of development.

Treatment of Stuttering Parents of a young child who demonstrates minor hesitations and repetitions in his or her speech should remain unemotional about these speech patterns to prevent the development of undue awareness and concern on the part of the child. Being an attentive, thoughtful listener is the best response. The young child with incipient stuttering should not be subjected to direct speech therapy or any type of therapy related to speech production. According to Shames, the family is a critical factor in dealing with the young child because "the family can either reinforce or counteract the efforts of the speech-language pathologist."[122] An advanced, or secondary, stutterer should seek the assistance of a qualified speech-language pathologist. The stutterer or the family should be warned against treatment employing unethical procedures, such as gimmicks, devices, pills, or the guarantee of a "cure for stuttering." The treatment should always be conducted by individuals who have had academic training and experience in the areas of speech-language pathology, clinical psychology, or psychiatry. A multitude of different therapy strategies are currently available, and each reflects a theoretic view of the cause and nature of stuttering. Recent theories and treatment strategies have centered on fluency disorders as a motor speech disorder. In general, however, clinical management of stuttering involves changing the stutterer's attitude, method of talking, and/or environment. The advanced or secondary stutterer must perceive the need for therapy. Frequently, the family of the secondary stutterer is also in need of appropriate treatment.

DISORDERS OF SYMBOLIZATION (LANGUAGE)

Language may be defined as an organized symbolic representation of thought and action used as a means of communication on an abstract level by human beings. Therefore, preceding the act of speaking is the process of symbolization, which involves the comprehension and formulation of language. When this process is disturbed, the result may be classified as a communication disorder that is manifested in the inability, or limited ability, to use linguistic symbols as a means of oral communication. This difficulty is

common to many different types of children (including children with "specific language impairment," children with aphasia, mentally retarded children, children with autistic-like characteristics, and hearing-impaired children) and markedly influences normal language acquisition. Language disorders are also central to the adult aphasic patient.

Children with Specific Language Impairment

Children with specific language impairment generally have a disorder profile limited to the area of language. The particular difficulty may be in some or all of the following components of language: (1) lexicon (the concepts and labels of our vocabulary), (2) syntax (word order), (3) morphology (word forms), (4) semantics (word meaning), and (5) pragmatics (use of language in social contexts). According to Leonard's description of children with specific language impairment, "the most notable feature of these children's language is that the large majority of the linguistic features reflected in their speech are slow to emerge and to develop."[123] This is descriptive of a delay profile. Although no consensus exists on the causes underlying the problems of this group of children, causes most often cited are perceptual difficulties, cognitive development problems, environmental and personal interaction difficulties, and brain damage. In many respects, language intervention is similar to that used for other disorders of communication. A prescriptive program, based on comprehensive language testing, should be directed to the necessary area of oral language production and/or comprehension.

Children with Acquired Aphasia

The general term aphasia (dysphasia) refers to the difficulty experienced in the comprehension (receptive-sensory) and the use of linguistic symbols (expressive-motor) in verbal communication. A useful operational definition, presented by Myklebust, is as follows:

> Childhood aphasia refers to one or more significant deficits in essential processes as they relate to facility in use of auditory language. Children having this disability demonstrate a discrepancy between expected and actual achievement in one or more of the following functions: auditory perception, auditory memory, integration, comprehension, and expression. The deficits referred to are not the result of sensory, motor, intellectual, or emotional impairment, or of the lack of opportunity to learn. They are assumed to derive from dysfunctions in the brain, though the evidence for such dysfunctioning may be mainly behavioral, rather than neurological, in nature.[124]

Leonard emphasized that children with acquired aphasia differ from other language-disordered children in that they have an initial period of normal language development.[123] They then lose that ability, usually because of some known brain damage caused by either illness or trauma. The most prominent disorder feature has been described as a noticeable reduction in the amount of speech generated, sometimes approaching mutism.[125] Apraxia of speech and word retrieval problems are not uncommon; however, comprehension deficits are less severe. In general, language recovery is usually more rapid and complete than for adult aphasics, particularly when focusing on production-side symptoms. The age of damage onset and location of the lesion are two critical factors that dictate the impairment profile and the prognosis. For example, if the damage occurs before age 9 and is limited to one cerebral hemisphere, the child often demonstrates normal or near-normal language development and performance. In general, the best prognosis is associated with a discrete lesion of late onset, whereas the worst prognosis emerges with a widespread lesion early in life. Parents frequently seek professional assistance after their child has been "diagnosed" erroneously as mentally retarded, deaf, or emotionally disturbed. The child may appear mentally retarded because of poor performance on standardized intelligence tests; the label deaf may be applied because of an inability to use verbal symbols that require hearing for response. The emotionally disturbed classification may seem appropriate because of exhibited behavioral problems, yet more inclusive evaluation of all of the data usually differentiates several problems and identifies the aphasic child. Diagnosing aphasia in children is a complex process requiring the united efforts of many specialists, including the neurologist, pediatrician, psychologist, otologist, audiologist, speech-language pathologist, and educational consultant. Only through the combined efforts of these specialists, using a systematic, diag-

nostic approach, will the child be led to a more prescriptive type of educational training.

Because many aphasic children recover quickly after head injury or illness, the role of the speech-language pathologist and other professionals may be minimal. When residual deficits persist, however, a formal remediation program appears justified.[126] Holland and Reinmuth remind us that for an unfortunate minority of these children, the prognosis is not good.[127] Extensive residual problems require intensive, specialized, interdisciplinary remediation available only through special rehabilitation centers or special schools. In those settings, "restitution of linguistic, cognitive and physical skills is the primary goal." The diagnosis and prescribed training program for the aphasic child would be woefully incomplete if the emotional factors of the family environment were not considered. The family may protect or shield the child excessively, or else coerce or reject the child. The presence of an aphasic child in the family unit may be deeply disturbing; the situation requires a thorough appraisal of both the family structure and the need for therapeutic counseling.

Aphasia (Dysphasia) in Adults

Aphasia is associated with cortical disturbances or lesions resulting from vascular impairment (thrombosis, embolism, and hemorrhage), tumors, degenerating and infectious disease, and trauma. Holland and Reinmuth stated that aphasia is a general term applied to different but related syndromes that impair the ability to formulate, retrieve, and/or decode the symbols of language.[127] As a common adult disorder of communication, it disrupts speech and verbal output, comprehension of speech, and reading and writing skills. The onset of aphasia is usually abrupt and typically occurs in adults with no previous speech or language difficulty. According to Holland and Reinmuth, most syndromes of aphasia share several concepts:

1. Aphasic symptoms are not bizarre but rather are extreme extensions of language problems demonstrated daily by normal speakers (ie, losing one's train of thought, forgetting how to spell a word, not understanding a spoken word or concept).
2. All aphasics have some fundamental difficulty with both comprehension and word retrieval, regardless of the presence of other deficits.
3. There is a continuum of severity within each syndrome.

The linguistic disturbances of the aphasic have been classified in numerous ways that reflect the clinical experience of the classifiers and their concepts of cortical function related to language.[128] These classifications have also attempted to recognize the major types and specific forms of language disturbance. One classification system presently in wide use is the one developed by a Boston-based group of professionals that highlights fluent versus nonfluent types.[129] The six options were summarized by Boone as follows[70]:

1. Broca's or motor aphasia—marked reduction in speech output, common oral-verbal apraxia, relatively good speech comprehension, word retrieval problem, writing performance matches speech output
2. Transcortical motor aphasia—a fairly rare type with significant struggle in producing an utterance, telegraphic speech is common, relatively good speech comprehension, impaired writing skills
3. Anomic aphasia—word retrieval problems predominate for both speech and writing, nearly normal comprehension for speech and reading
4. Wernicke's or jargon aphasia—significant comprehension deficit for speech and reading, fluent but jargon-like verbal output, writing parallels speech patterns
5. Conduction aphasia—nearly normal comprehension for speech and reading, marked deficit in speech repetition, fluent speech output with numerous sound and word errors
6. Global aphasia—the most severe and most common type; profound problems with both verbal output and comprehension, and both reading and writing functions are poor

The emotional language of the adult aphasic is usually better than his or her propositional language. The patient may find it easier to swear, count, or use other forms of automatic speech or nonpropositional forms of speech but is at a loss when requested to develop this emotional language into abstract or propositional language situations. The patient experiences difficulty in combining simple linguistic symbols into more complex linguistic units. The patient is not without words but rather cannot

quickly command the response that is appropriate to the situation. Boone emphasized that the brain damage (regardless of its cause) can produce other deficits or symptoms.[70] These include hemiplegia (gross motor paralysis), hemianopsia (visual field defect), intellectual deficits, seizures, dysarthria (motor speech impairment), and apraxia (inability to execute voluntary movement).

Prognosis for the recovery of the aphasic patient must be based on many factors, including the site and extent of the lesion, general health, attitude toward self and environment, age and educational attainment, vocation and avocations, family attitude, and degree of cooperation. Assuming that these and other factors are relatively positive, considerable recovery may be expected from the overall linguistic and physical impairments. Spontaneous improvement may be noted during the first few months after the onset without structured training. This may give false hope to the patient and family for additional recovery without seeking professional assistance. Depending on the degree of involvement, the family, with the physician's guidance, should enlist the services of a physical therapist, occupational therapist, speech-language pathologist, psychologist, and vocational counselor in formulating a personalized rehabilitation program. Ideally, the adult aphasic should be started on a program of rehabilitation as soon after the traumatic episode as possible.

CHAPTER 50

Airway Control and Laryngotracheal Stenosis in Adults

Joseph C. Sniezek, MD, Brian B. Burkey, MD

The successful management of the airway is of paramount importance. Airway control requires a logical and systematic approach guided by the principles of basic and advanced life support techniques and a working knowledge of relevant pharmacology. Most importantly, the health professional must possess a mastery of the anatomy and physiology of the upper aerodigestive tract. The airway surgeon is also uniquely responsible for the diagnosis and treatment of airway lesions such as laryngotracheal stenosis and arytenoid fixation.

ANATOMY

Successful airway intervention necessitates an understanding of the anatomy of the laryngotracheal complex (Figure 50–1). The hyoid bone allows muscular attachment from the lingual muscles and mandible as well as the extrinsic muscles of the larynx and serves as a laryngeal anchor via the thyrohyoid membrane. This membrane is pierced bilaterally by the superior laryngeal neurovascular bundles. Embryologically, the hyoid bone is derived from mesodermal cells in the second and third branchial arches. The greater horn of the hyoid bone is derived from the third branchial arch, whereas the lesser horn is of second branchial arch origin.

The major cartilages of the larynx include the thyroid, cricoid, epiglottis, and paired arytenoids (Figure 50–2). These cartilages develop from mesenchymal tissue originating in the fourth, fifth, and sixth branchial arches. The thyroid cartilage is a shield-shaped structure whose central prominence tends to be more acutely angled in men than in women. The inferior horns of the thyroid cartilage articulate with the posterior facets of the cricoid cartilage and form the important cricothyroid joints, which are synovial and allow a hinge motion between the cartilages.

The cricoid cartilage is the only complete ring of the airway, which accounts for the association between prolonged or traumatic endotracheal intubation and subglottic stenosis occurring in this area. The cricoid is composed of hyaline cartilage that often calcifies later in adult life. It tends to be broader posteriorly and tapers to a smaller arch anteriorly, mimicking the shape of a signet ring. The thyroid and cricoid cartilages are attached anteriorly by the cricothyroid membrane.

The epiglottis serves a protective function for the airway and is composed of elastic cartilage. It attaches to the thyroid cartilage via the thyroepiglottic ligament (Figure 50–3). The arytenoid cartilages provide the posterior attachments of the vocal cords, the anterior attachment being on the thyroid cartilage at Broyle's ligament. The arytenoids articulate with facets on the posterosuperior aspect of the cricoid cartilage and form synovial joints.

The trachea begins at the lower border of the cricoid cartilage and is composed of incomplete, C-shaped "rings" of hyaline cartilage. The rings are open posteriorly and connected on this aspect by fibroareolar connective tissue and smooth muscle fibers. The larynx and trachea are lined with a pseudostratified, ciliated columnar epithelium interspersed with mucus-secreting cells, except at the glottis, which is lined with a stratified squamous epithelium. The trachea bifurcates at approximately the sternal angle, forming the two bronchi. The right bronchus is wider, shorter, and more vertically oriented than the left bronchus. When using an open bronchoscope, one may most easily examine both bronchi by passing the instrument through the right side of the mouth, thus allowing the best view of the obliquely angled left bronchus while preserving visualization into the right bronchus.[1]

CLINICAL EVALUATION OF THE AIRWAY

The clinical evaluation of the airway must begin with a rapid assessment of the patient's ventilatory and respiratory status. If the patient is in impending airway distress, prophylactic measures to prevent deterioration of the airway must be employed. If the patient does not appear to be ventilating adequately, the airway must be definitively secured through either medical or surgical techniques. If medical control of the airway fails and intubation is impossible owing to an airway injury or upper airway obstruction, an urgent tracheostomy or cricothyroidotomy must be performed. The technique and advantages of each are discussed in this chapter. The symptoms and signs that indicate upper respiratory obstruction include hoarseness; dyspnea; stridor; intercostal, suprasternal, and supraclavicular retractions; restlessness; cyanosis; and drooling. The signs of trauma to the airway include bloody sputum, subcutaneous emphysema, and palpable laryngotracheal fractures.

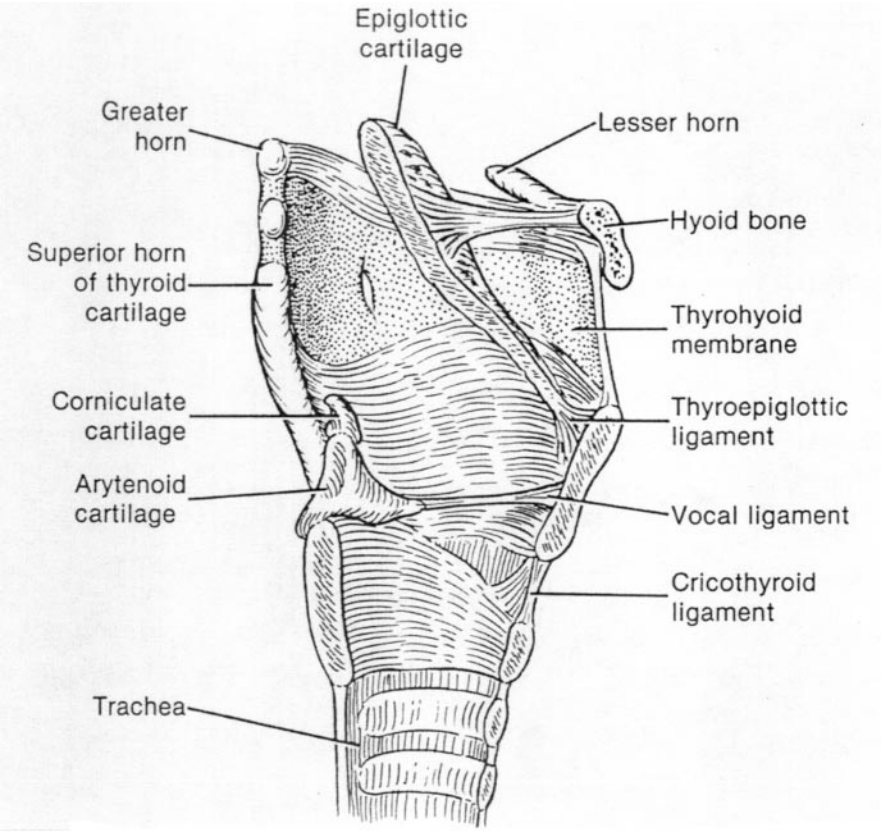

FIGURE 50–3. Sagittal section of the larynx. Reproduced with permission from Graney DO, Flint PW. Anatomy. In: Cummings CW, et al, editors. Otolaryngology-head and neck surgery. 2nd ed. St. Louis: Mosby Year Book; 1993. p. 1694.

If the patient does not require an immediate airway intervention, the caregiver may proceed with a diagnostic assessment. This assessment should include a complete history and a physical examination of the upper aerodigestive tract. If the patient is seen in the clinic setting, a mirror indirect laryngoscopy may be performed. Perhaps the most valuable study is a direct fiber-optic examination via nasopharyngoscopy. This technique allows unparalleled visualization of the upper airway and larynx and may allow for video documentation (Figure 50–4). The fiber-optic endoscopes and light sources are now portable and may be used in the emergency department, intensive care unit, and nursing unit. A blood gas determination, chest radiograph, and airway evaluation with radiography or computed tomography may also be indicated.

While remaining cognizant of the general status of the patient, the surgeon must accurately assess the nature and level of the airway obstruction and establish airway control below the lowest level of the obstruction. Once the airway has been controlled, a complete airway evaluation may be performed in the operating room through direct laryngoscopy and tracheoscopy. This mission must be accomplished while respecting the possibility of other injuries such as cervical spine dislocation, vascular injuries, or other associated medical conditions.

AIRWAY MANAGEMENT

Although the management of the airway in the controlled environment of the operating room is straightforward, patients presenting in the emergency department pose unique problems such as cervical spine injuries, closed head injuries with the possibility of increased intracranial pressure, laryngotracheal disruption, airway hemorrhage, and facial deformities. The intensive care unit setting also offers challenges such as confounding medical issues. These complicating factors can be handled only through an individualized approach that is guided by a stepwise progression of techniques aimed at controlling the increasingly difficult airway.

Supplemental oxygen is the most simple measure of airway support and should be given almost universally to patients with airway distress. After this intervention, the clinician should evaluate for airway

FIGURE 50–4. Flexible fiberoptic examination of the larynx with video documentation.

obstruction from foreign bodies such as displaced teeth or tongue and soft tissue collapse into the pharynx. Because of its efficacy and lack of cervical movement, the jaw thrust is the most appropriate positioning maneuver.[2] Lifting the chin and extending the neck may be successful in improving the airway but risks cervical spinal cord injury in a trauma patient. An oropharyngeal airway may relieve soft tissue obstruction of the airway (Figure 50–5). It serves to displace the tongue anteriorly, providing an unobstructed airway. A nasopharyngeal airway (trumpet) may be placed transnasally into the posterior hypopharynx, thus relieving soft tissue obstruction of the posterior oropharynx. Nasopharyngeal airways tend to be less stimulating than oral airways in awake patients but risk epistaxis. Nasopharyngeal trumpets should not be used in patients with known or suspected basilar skull fractures owing to the risk of inadvertent intracranial placement.[3]

A laryngeal mask airway is a nondefinitive technique sometimes employed by emergency med-

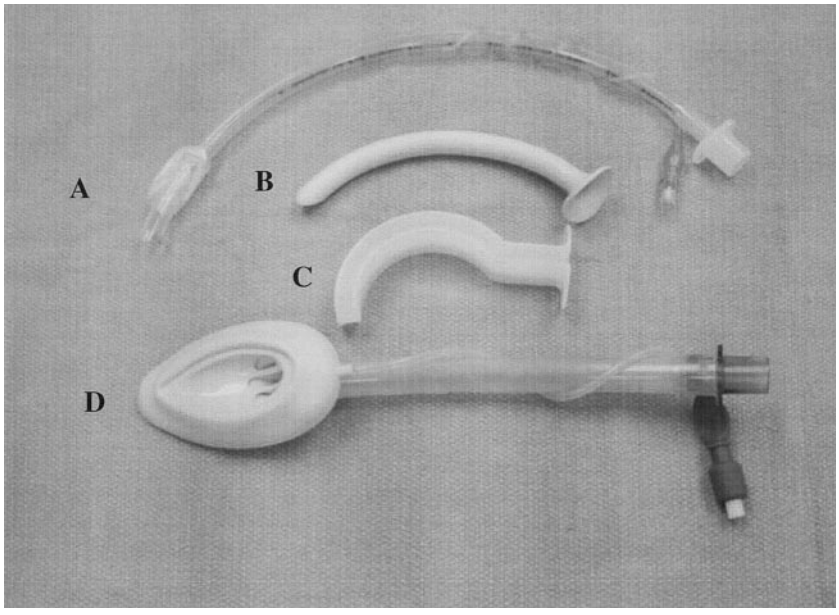

FIGURE 50–5. *A*, Endotracheal tube; *B*, nasopharyngeal trumpet; *C*, oral airway; *D*, laryngeal mask airway. Courtesy of Dr. Michael S. Higgins.

ical technicians or anesthesiologists to obtain a temporary airway for positive pressure ventilation. This device forms a "seal" over the larynx and provides a route for oxygen flow into the trachea. If a definitive airway is required, endotracheal intubation is the quickest and most successful option whenever possible. It allows ventilatory control with the ability to deliver high levels of oxygen and temporarily protects against aspiration. Endotracheal intubation may be achieved through either an oral or a transnasal route. In the case of head and neck trauma, transoral intubation may be achieved while holding in-line cervical traction and maintaining cervical stabilization. Manual in-line immobilization is the optimal method of stabilization and results in significantly less cervical spine movement than stabilization in a Philadelphia collar.[4]

The most common technique employed for oral intubation in the emergent situation is the rapid sequence induction. This uses preoxygenation and denitrogenation followed by a short-acting hypnotic agent such as thiopental or midazolam followed by a neuromuscular blocking agent. An assistant may hold cricoid pressure to prevent aspiration if the patient is unconscious. If a cervical spine injury is suspected, a second assistant maintains in-line stabilization during the intubation. A fiber-optic endoscope may also be placed inside an endotracheal tube to facilitate the localization of the airway. The tube can be passed over the endoscope after the airway has been identified and entered. One disadvantage of this endoscopic technique is that the presence of blood and secretions may obscure visualization through the endoscope.

A more invasive method of providing oxygenation to a patient who cannot be intubated or ventilated is the technique of percutaneous transtracheal ventilation. This procedure involves a caudally directed puncture of the cricothyroid membrane with a 14-gauge intravenous catheter. One must ensure that the catheter is within the trachea and not lodged in the subcutaneous tissue, in which case, subcutaneous emphysema may result and make further attempts at tracheal intubation more difficult. After the catheter has been placed into the trachea, the needle is removed and oxygen is provided via a jet injector, ventilating bag, or gas outlet of an anesthesia machine. This technique is merely a temporizing measure until a definitive surgical airway can be obtained.

Cricothyroidotomy

If the airway cannot be controlled through endotracheal intubation or other medical maneuvers, a surgical airway must be obtained. Cricothyroidotomy is a surgical method of airway management that was reintroduced to the medical community by Brantigan and Grow in 1976.[5] The technique simply involves the creation of an opening into the cricothyroid membrane followed by the placement of a stenting tube. Cricothyroidotomy is often considered the preferred method of obtaining an emergent surgical airway.[6–8] The procedure begins with the identification of the cricothyroid space between the thyroid and cricoid prominences. Local anesthesia may be infiltrated into the area if time permits. A horizontal incision is made over the middle third of the membrane and is carried directly into the airway. A dilating instrument is inserted next to the scalpel to secure the airway opening. Mayo scissors are used to enlarge the opening, and every effort is made not to damage the cricoid or thyroid cartilages. An endotracheal tube may be placed through the cricothyroidotomy and ventilation begun through the lumen of the tube. Once the airway has been secured, the patient may be taken to the operating room and the cricothyroidotomy may be repaired and converted to a tracheostomy.

Although cricothyroidotomy has been used for long-term airway management, it is most useful in the emergency setting, where a surgical airway must be rapidly gained.[9] Cricothyroidotomy is faster and usually easier to perform than a tracheostomy, especially in the hands of a nonsurgeon, requiring little surgical skill other than a knowledge of anatomy. Reported complications of cricothyroidotomy include bleeding, tube displacement, infection, true vocal cord damage, subcutaneous emphysema, and the development of subglottic or tracheal stenosis.[10,11] Hawkins et al confirmed the safety of emergency cricothyroidotomy in their series of 5,603 consecutive adult trauma patients, of whom 66 required cricothyroidotomy.[7] No significant morbidity or complications were noted in this series.

Tracheostomy

Tracheostomies have been performed for over 2,000 years. Until the early 1900s, however, the procedure was reserved for essentially moribund patients owing to high rates of morbidity and mortality. Attitudes

toward tracheostomy changed in 1909, when Chevalier Jackson described the modern tracheostomy.[12] Jackson then addressed the high rate of laryngeal and tracheal damage and stenosis that had previously been associated with tracheostomies in his landmark article of 1921, "High Tracheotomy and Other Errors: The Chief Cause of Chronic Laryngeal Stenosis."[13] In this treatise, the author hypothesized that the unacceptably high rates of laryngeal and tracheal stenosis associated with tracheostomies preceding his description were attributable to damage to the thyroid and cricoid cartilages incurred during the performance of "high" tracheostomies. Jackson implored that tracheostomies be performed below the second tracheal ring, thereby avoiding these dreaded complications. This dictum has been followed to the present day.

Technique A tracheostomy is generally begun with a horizontal skin incision approximately midway between the sternal notch and cricoid cartilage, although some surgeons prefer a vertical skin incision. The incision is carried down through the skin, subcutaneous tissue, and platysma to the level of the strap muscles. After identifying the strap muscles, the sternohyoid and sternothyroid muscles are separated in the midline by incising the fascia that connects them. Retractors are used to pull the muscles laterally, revealing the thyroid isthmus. The cricoid cartilage is palpated and identified at this point. The isthmus of the thyroid gland is dissected off of the trachea in a bloodless fascial plane just superficial to the trachea. The thyroid isthmus is transected and suture-ligated. A cricoid hook is used to pull the trachea superiorly to stabilize the airway and improve exposure of the anterior tracheal wall (Figure 50–6). The fine fascia overlying the trachea is carefully separated.

Although horizontal and vertical incisions into the tracheal wall have been proposed, an inferiorly based Bjork flap consisting of several tracheal rings is a superior option for adults. Following Jackson's principle, a horizontal incision is made between the second and third tracheal rings and carried inferiorly with Mayo scissors to fashion an inferiorly based flap. The space between the rings may be calcified in older patients. The Bjork flap is sewn to the subcutaneous tissue of the inferior skin margin with

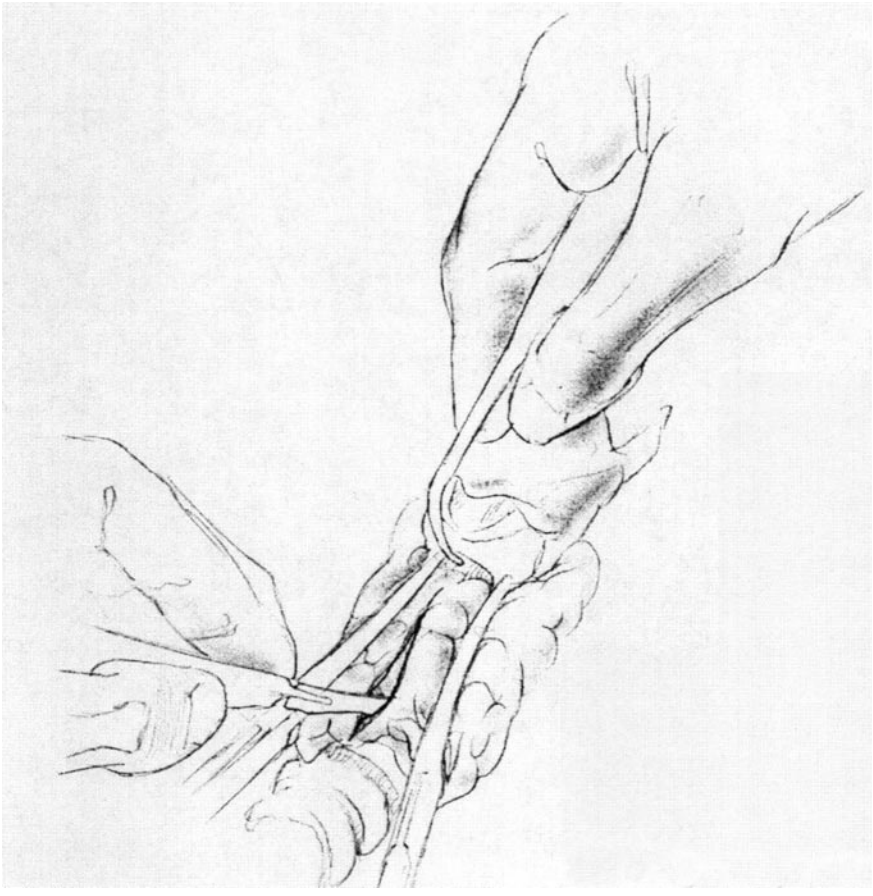

FIGURE 50–6. Stabilization of the trachea with a cricoid hook and division of the thyroid isthmus. Reproduced with permission from Bailey BJ, et al, editors. Head and neck surgery-otolaryngology. Philadelphia: JB Lippincott; 1993. Copyright Lippincott Williams & Wilkins. p. 716.

an absorbable suture (Figure 50–7). This tracheal flap makes reintubation safer in the event of accidental extubation but does lead to a slightly increased risk of tracheocutaneous fistula. For this reason, a horizontal H incision based on the third tracheal ring or the removal of an anterior section of a single tracheal ring may be preferable in patients who are expected to require a tracheostomy only for a short period of time.

When a tracheostomy is permanent or of long duration, the surrounding skin may be surgically defatted and sutured to the tracheostoma circumferentially. This is particularly useful in obese patients, in whom a semipermanent tracheostoma can be fashioned that is less prone to maceration or the formation of granulation tissue and stenosis because the skin directly abuts the respiratory mucosa of the trachea. The creation of a semipermanent tracheostoma in this fashion also serves to decrease the length of the tract of the tracheostomy, thereby facilitating removal and reinsertion of the tracheostomy tube.

The tracheostomy incision should never be closed tightly and must allow the passive egress of air from the wound to prevent subcutaneous emphysema, which could potentially lead to pneumomediastinum, pneumothorax, or infection.

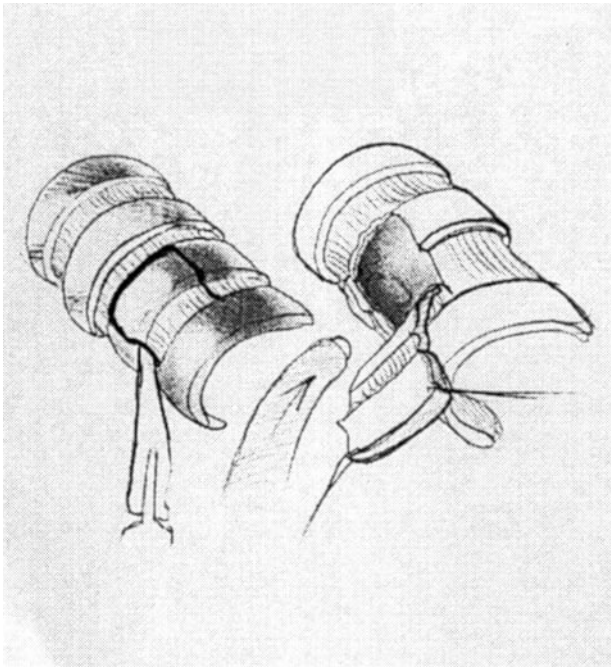

FIGURE 50–7. Creation of an inferiorly based Bjork flap. Reproduced with permission from Bailey BJ, et al, editors. Head and neck surgery-otolaryngology. Philadelphia: JB Lippincott; 1993. Copyright Lippincott Williams & Wilkins. p. 716.

Complications of Tracheostomy The complications of tracheostomy are often divided into two main categories: early and late. Early complications include hemorrhage, tube obstruction, tube displacement, subcutaneous emphysema, and pneumothorax. Late complications include innominate artery rupture, infection, aspiration, granuloma formation, and laryngeal or subglottic stenosis.[14]

Early Complications. Hemorrhage. Mild bleeding is the most common early complication of tracheostomy, occurring in about 5% of cases. The hemorrhage is usually from veins or the incised thyroid isthmus. Mild bleeding can generally be controlled by raising the head of the patient to decrease venous pressure or by placing hemostatic gauze over oozing areas. Major hemorrhage is unusual and most often involves a branch of the superior thyroid artery. Arterial bleeding is an indication for immediate surgical exploration for bleeding control and vessel ligation.

Tube Obstruction. Tube obstruction is the most common cause of ventilatory insufficiency in a posttracheostomy patient and most often results from a mucous plug. Dried mucus and secretions in and around the tracheostomy tube can form crusts that may become large enough to obstruct the lumen of the tube. Audible airflow and difficulty passing a suction catheter through the tube are signs of impending tube obstruction. Adequate humidification, irrigation, frequent suctioning, and cleaning of the inner cannula help to reduce the risk of plugging and obstruction. If the tracheostomy tube becomes obstructed and cannot be recannulized, the patient and care staff should be instructed to remove the entire tube.

Tracheostomy Tube Displacement. Displacement of the tracheostomy tube or dislocation of the tube from the tracheostomy tract poses a considerable risk to the patient who has recently undergone a tracheostomy. Displacement of the tube is most likely to occur in the early postoperative period before a stable tract has matured between the tracheal lumen and the skin. Displacement most often occurs owing to the tube being inadequately secured to the patient with sutures or ties. Excessive tension applied on the

tube from the ventilatory apparatus also poses a risk of tube dislodgment.

Tracheostomy tube replacement in the early postoperative period and during the first tube change should be done under direct vision with the surgeon in attendance. Blind reinsertion risks creating a false passage into the paratracheal tissues.

Subcutaneous Emphysema. Subcutaneous emphysema results from the forced entrance of air into the fascial planes of the neck and usually results from closing the tracheostomy incision too tightly. Tube obstruction or displacement can also lead to the escape of air into the fascial planes. Crepitus and soft tissue swelling can involve the neck, face, and upper torso. Minor amounts of subcutaneous emphysema usually resolve spontaneously without significant sequelae, whereas massive amounts may progress to pneumomediastinum and pose an increased risk of infection through bacterial contamination.

Pneumothorax. Pneumothorax occurs in less than 5% of tracheostomies and can result from damaging the pleural apices during dissection that veers away from the midline. Pneumothorax may also be caused by excessively forceful ventilation that prevents the passive exhalation of air. This air trapping can lead to alveolar rupture and the entrance of air into the pleural space. A misplaced tracheostomy tube can also introduce air into the pleural space or mediastinum. Decreased breath sounds may indicate a pneumothorax, although this complication is usually asymptomatic and noted incidentally on the postoperative chest radiograph. A small pneumothorax is generally observed with serial chest radiographs, whereas a large or symptomatic pneumothorax may require a chest tube for lung re-expansion.

Late Complications. Innominate Artery Rupture. Innominate artery rupture is perhaps the most dreaded tracheostomy complication and, although rare, results in only a 10 to 25% survival rate.[15] Innominate artery rupture is heralded by a "sentinel bleed," which is a brief episode of bleeding occurring minutes to hours prior to a massive hemorrhage. Rapid peristomal bleeding, even when it resolves, should trigger a fiber-optic examination of the trachea to rule out innominate artery involvement. When massive bleeding does occur, the tracheostomy tube should be rapidly replaced with a longer cuffed endotracheal tube to allow oxygenation while digital pressure is applied to compress the innominate artery against the manubrium. The patient should be taken immediately to the operating room for median sternotomy and vessel ligation. Many surgeons feel that the Bjork flap technique of tracheostomy lessens the risk of this potentially fatal complication.

Infection. Although bacterial colonization of the trachea and peristomal area is unavoidable owing to the moist, open nature of the tracheostomy wound, significant infections rarely occur after a tracheostomy. Local cellulitis can generally be managed with aggressive local cleaning measures and topical antibiotics. Uncontrolled local infection can rarely lead to serious complications such as mediastinitis or predispose a patient for innominate artery rupture or peristomal tissue loss. Local infection that does not respond to aggressive local wound care should be treated with systemic antibiotics.

Aspiration. Aspiration following tracheostomy is a phenomenon that is often overlooked. Although a tracheostomy is generally thought to "protect" the airway, tracheostomies have actually been shown to decrease the protective glottic closure reflexes of both the true and false vocal cords.[16] Loss of this protective mechanism does predispose the tracheostomized patient to aspiration and concomitant pneumonia. Prophylactic measures include a soft, solid diet, which poses a decreased risk of aspiration when compared to liquids, and maintaining the patient in a somewhat upright position. Although inflating the tracheostomy tube cuff can afford temporary airway protection, hyperinflation of the cuff actually exacerbates aspiration owing to compression of the esophagus. Consultation with a speech and swallowing therapist is advisable for any patient who requires a tracheostomy.

Granuloma Formation. Granulation tissue may form in the peristomal area owing to chronic mucosal and skin irritation by an inadequately fixed or improperly fitted tracheostomy tube. Granulation tissue may also form inside the tracheal lumen. Early and small granulomas may be managed with local débridement. Mature, fibrotic lesions generally require endoscopic laser excision.

Subglottic Stenosis. Tracheostomies may contribute to subglottic stenosis by causing chronic irritation to the tracheal mucosa while also providing a route of bacterial contamination that causes

increased inflammation in the damaged area. This inflammation results in the formation of scar tissue and subsequent subglottic stenosis. Gastroesophageal reflux is also felt to increase the risk of subglottic stenosis by providing additional mucosal irritation that contributes to granulation and scar tissue formation. The risk of this complication underscores the importance of minimizing extraneous motion of the tracheostomy tube, managing gastroesophageal reflux, and removing a tracheostomy tube when it is no longer required for airway support and protection.

Percutaneous Tracheostomy

Although percutaneous tracheotomy was first described in 1955,[17] it experienced a resurgence in popularity after its reintroduction by Ciaglia and colleagues in 1985.[18] The technique involves the transcervical insertion of a guidewire into the airway followed by blunt dilation of the guidewire tract. The tracheostomy tube is inserted over the guidewire using a modified Seldinger technique. The advantage of the procedure is that it can be performed at the bedside in the intensive care unit.[19] Visualization of the guidewire insertion, dilation, and tracheostomy tube placement may be achieved via a flexible fiber-optic laryngoscope inserted at the time of the procedure. This improved visualization decreases airway complications by preventing improper placement of the guidewire or esophageal perforation by the inserting device or guidewire itself.[20] The proper level of tracheostomy placement may also be confirmed with airway visualization at the time of the procedure.

One major disadvantage of percutaneous tracheostomy is that only a narrow, dilated tract, rather than a formal stoma, is created during the procedure. This results in an increased rate of tube displacement and difficult tube reinsertion with percutaneous tracheostomy as compared with a standard tracheostomy.[21] An increased rate of postoperative death owing to tube dislodgment has been described with the percutaneous technique.[22] The surgeon may wish to consider this factor in planning a tracheostomy procedure on a patient who is known to be difficult to intubate translaryngeally. Likewise, a patient with morbid obesity or cervical anatomic anomalies is not a good candidate for percutaneous tracheostomy and should likely undergo a standard tracheostomy performed in the controlled environment of the operating room.

An additional disadvantage of percutaneous tracheostomy is the risk of tracheal or subglottic stenosis. Unlike soft tissue, cartilage is rigid and incapable of changing shape and conforming to the shape of a dilator. Because of the progressive dilations performed during percutaneous tracheostomies, the tracheal cartilages are at high risk for crush injury during the procedure. Damaged cartilage poses a risk of scar tissue formation and subsequent tracheal or subglottic stenosis.

Since a percutaneous tracheostomy must sometimes be converted to a standard open tracheostomy, a surgical tracheostomy tray and someone with the ability to perform a standard tracheostomy should be present at the time of the percutaneous procedure. With these precautions and adequate training, percutaneous tracheostomy can be a safe and efficient procedure.

Open Bedside Tracheostomy

A tracheostomy can also be performed in the intubated patient as an open procedure at the bedside in the intensive care unit setting.[23] The only advantage of performing a tracheostomy at the bedside is that operating room costs are defrayed and the procedure is generally less expensive than a percutaneous tracheostomy. Obvious disadvantages are that lighting, surgical assistance, and equipment are inferior to that available in a standard operating room. Patients with unfavorable anatomy such as cervical mass lesions or morbid obesity are not good candidates for an open bedside tracheostomy and should proceed to the operating room for a standard tracheostomy.

LARYNGEAL AND TRACHEAL STENOSIS IN THE ADULT

The management of laryngeal and tracheal stenosis in adults is both challenging and intriguing. The diagnosis and evaluation of these lesions requires a complete mastery of the anatomy and physiology of the upper aerodigestive tract. The incredible variability of stenotic areas in the adult larynx and trachea requires the head and neck surgeon carefully to individualize treatment and provide unique strategies for the management of these diverse lesions.

Etiology

There are many factors that can lead to laryngotracheal stenosis (LTS) (Table 50–1). Most cases of adult LTS result from external trauma or prolonged endotracheal intubation. External trauma causes cartilage damage and mucosal disruption with hematoma formation. These hematomas eventually organize and result in collagen deposition and scar tissue formation. Endotracheal intubation can cause mucosal damage through pressure necrosis and direct injury resulting from the pressure of the endotracheal tube or cuff. Mucosal ulceration also leads to healing through collagen deposition, fibrosis, and scar tissue formation. Lesions from endotracheal intubation are usually located in the posterior part of the glottis, where the tube most often contacts mucosa, or in the trachea, where the cuff or tube tip causes mucosal damage. Low-pressure endotracheal tube cuffs have somewhat reduced the rate of cuff-induced damage. The length of intubation, tube movement, tube size, and gastroesophageal reflux can also contribute to LTS.

Classification

Since areas of LTS are so variable in their size, consistency, and location, a rigid classification scheme is essentially impossible, and the surgeon must describe and document the lesion in a way that is widely understandable and reproducible. The classification of LTS in adults begins with the anatomic location of the lesion as glottis, subglottis, trachea, or a combination of these. These stenotic segments may then be further described as anterior, posterior, or circumferential. The size and length of the stenotic area are critical in classifying the lesion as well.

Diagnostic Assessment

The evaluation of LTS must begin with a meticulous history and physical examination. Since most cases of LTS result from laryngotracheal trauma or endotracheal intubation, the timing of the predisposing incident should be recorded. Any previous airway evaluations or attempts at repair should also be noted. The patient should be questioned regarding the onset, duration, and severity of symptoms such as exercise intolerance, disruption of lifestyle, and tracheostomy dependence. Patients who do require a tracheostomy should be questioned as to how often

the tube may be plugged. Symptoms of aspiration, voice change, or dysphagia may indicate the degree of glottic involvement.

The entire upper aerodigestive tract must be carefully examined in a patient with suspected LTS. Indirect laryngoscopy and flexible fiber-optic laryngoscopy offer critical information regarding the supraglottic airway and mobility of the true vocal folds. In extreme abduction, areas of subglottic stenosis may be visible using these techniques. Video documentation of these procedures offers a valuable method of treatment planning and patient education.[24]

Although imaging studies such as airway radiographs, computed tomography, and magnetic resonance imaging occasionally provide useful information, the most valuable diagnostic assessment stems from the examination of the patient by endoscopy. After the patient has been examined by indirect laryngoscopy and flexible fiber-optic techniques, rigid endoscopic evaluation under general anesthesia should be performed in all patients with symptomatic airway abnormalities. Direct measurement and documentation of the diameter and length of stenotic areas are critical steps in the management of these lesions. Measurement of the diameter of stenotic segments is best evaluated by passing an endoscope, with a known diameter, that just fits through the stenotic area. Measurement of stenosis length may be performed by placing the endoscope at the distal end of the stenotic segment and marking the instrument at the incisors. The endoscope is withdrawn to the proximal aspect of the stenosis and remarked. The length of stenosis may be measured on the endoscope.

Treatment of Laryngotracheal Stenosis

Medical Most surgeons who treat LTS recommend the use of antibiotics, local and/or systemic corticosteroids, and histamine$_2$ antagonists or omeprazole when treating mild or acute subglottic injuries. In mature areas of laryngotracheal fibrosis and scarring, these medical treatments are unlikely to result in any clinical improvement.

Endoscopic Some areas of LTS are amenable to endoscopic treatment techniques such as laser vaporization and dilation, excision using a microtrapdoor technique, or serial dilation with radial incisions of the stenotic segment. Intralesional corticosteroids may also be injected under endoscopic guidance.[25] Lasers allow the precise treatment of tissue throughout the airway while avoiding external incisions and providing an excellent method of cutting, coagulating, or vaporizing tissue. Hemostasis may be achieved, and perioperative edema is often decreased with the use of lasers owing to smaller amounts of tissue sustaining thermal damage when compared to electrocautery.

The ideal laser for any particular case depends on the type of tissue and lesion that requires treatment. Owing to its precision (the small spot size) and availability, the carbon dioxide laser, which produces light in the mid-infrared region, remains the instrument of choice in the endoscopic management of LTS. Although the carbon dioxide laser is very precise, it is not a good instrument for coagulation and can only be used to coagulate vessels up to 0.5 mm in diameter. If the area of stenosis is thought to be very vascular, a laser with better hemoglobin absorption, such as a KTP or Nd:YAG laser, would be recommended. One further disadvantage of the carbon dioxide laser is that it lacks a good fiber-optic delivery system and must generally be controlled via a micromanipulator system mounted on a microscope.

Laser ablation of stenosis is a useful technique that may be combined with dilation of the stenotic segment or placement of an intraluminal stent. This procedure is most successful in the management of early lesions composed mostly of granulation tissue that have not yet evolved into a mature scar. Stenotic segments less than 1 cm in length may also be addressed with this method.

The microtrapdoor technique is used to debulk stenotic areas confined to a single quadrant of the airway. The procedure is somewhat more technically demanding than simple ablation of the stenosis. First, a laser incision is made on the superior aspect of the stenotic shelf (Figure 50–8). Once the incision has been made, a microelevator is used to elevate a mucosal flap over the area of scar tissue. The laser may be used to vaporize the scar tissue forming the stenosis. Once the scar tissue has been adequately vaporized, the flap is repositioned into its original location. The laser may be defocused and milliwatt power settings used to weld the edges of the incision together.

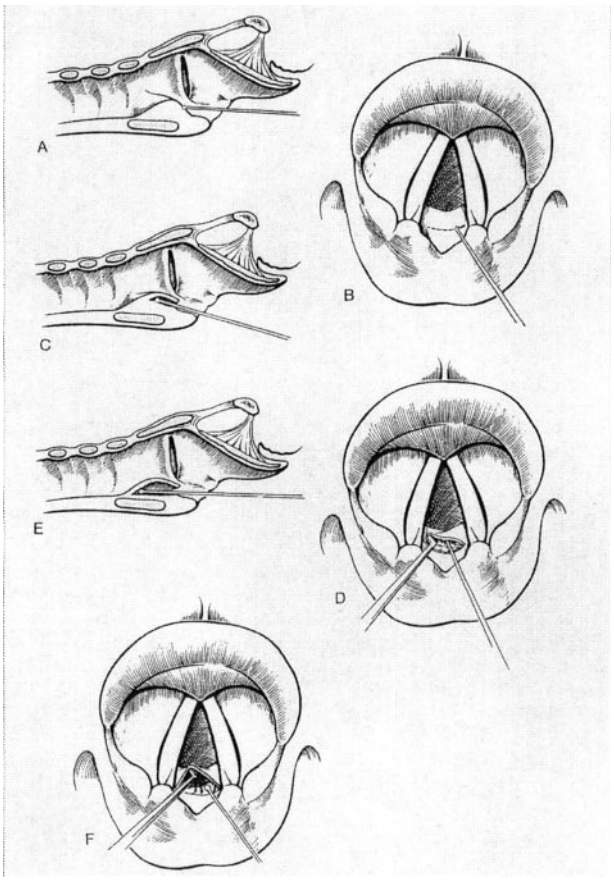

FIGURE 50–8. Microtrapdoor technique used to debulk areas of stenosis. *A* and *B*, The laser is used to make an incision on the superior aspect of the stenotic shelf. *C* and *D*, The flap is elevated distally. *E* and *F*, The scar tissue is vaporized in a submucosal plane. Reproduced with permission from Coleman JA et al.[25]

Areas of circumferential stenosis may be addressed endoscopically by making radial incisions in the scar tissue with a laser and dilating the treated area with a bronchoscope or dilating instrument. The laser is used to create radial incisions in the scar tissue in four to six areas (Figure 50–9). The laser may be coupled to a ventilating bronchoscope if the patient is not tracheostomy dependent. The incisions break up the circumferential scar band and leave islands of intact mucosa. Leaving areas of intact mucosa is critical to prevent circumferential areas denuded of mucosa that would ultimately reform scar tissue similar to the original lesion or possibly even make the scarring worse. The stenotic segment may be sequentially dilated. The procedure generally needs to be repeated at several 3- to 4-week intervals before an adequate airway is achieved. Local applications of corticosteroids or mitomycin-C may be used with any of the endoscopic techniques in an attempt to prevent the reformation of the cicatrix.

Open Surgical Techniques Severe areas of LTS that do not respond to endoscopic techniques require an open surgical procedure. Open techniques attempt either to excise the stenotic segment and reanastomose the airway or to augment the circumference of the stenotic segment with transplanted tissue. Stenoses that are longer than 1 cm, have glottic or extensive tracheal involvement, have failed endoscopic treatment, and have near-complete stenoses are candidates for an open technique. In patients with diabetes or severe systemic illnesses, open approaches must be considered with great care. Such patients suffer from poor wound healing, have a high risk of perioperative complications, and have a lower rate of successful outcome after open procedures. In these high-risk patients, a tracheostomy may be the most prudent choice of management.

Laryngotracheoplasty is often used to repair segments of LTS more than 1 cm in length.[26] The procedure begins with a transverse cervical incision in a natural skin crease at the level of the cricoid cartilage. Subplatysmal flaps are elevated superiorly to the thyroid notch and inferiorly to the sternum. The strap muscles are separated in the midline and retracted laterally. The thyroid isthmus is divided and ligated. The anterior cricoid ring is divided vertically with a knife or saw. The incision is extended superiorly and inferiorly based on the exact location and extent of the stenosis (Figure 50–10). The goal is to open the entire stenotic segment. To prevent voice damage, the incision is not extended to the anterior commissure unless this area is involved by the stenosis. If the cricoid cartilage cannot be opened sufficiently owing to calcification or extensive scarring, a posterior cricoid cartilage split may be performed to gain the needed mobility. If a posterior cricoid cartilage split is performed, the surgeon must be careful not to damage the underlying esophagus.

Although it is tempting to remove scar tissue at this point in the procedure, the surgeon must remember that the goal of the procedure is to open the area of stenosis widely rather than to remove tissue. Resection of scar tissue and mucosa risks scar regeneration and recurrent stenosis. Submucosal

Reproduced with permission from Coleman JA et al.[25]

resection of scar tissue, however, is generally safe and does not increase the risk of restenosis.

A posterior graft, if it must be used, is placed next. Posterior grafts usually contain a flange that is tucked behind the posterior lamina of the cricoid cartilage bilaterally to prevent extrusion into the airway. An airway stent, if one is to be placed, is inserted after placement of the posterior cricoid graft. The anterior cartilage graft is generally cut in a fusiform or boat-shaped fashion with beveled edges to prevent the graft from slipping into the airway. The graft is sutured into place while taking great care to ensure that the sutures remain extraluminal. The strap muscles are reapproximated in the midline, and the platysma and skin are closed over a passive drain to allow air egress and prevent subcutaneous emphysema. The success rate of primary laryngotracheal reconstruction in adults is in the 60 to 70% range.[27]

Cartilage grafts for laryngotracheoplasty may be harvested from the costal cartilage or nasal septal cartilage. Costal cartilage is the most commonly used source of grafts. The fifth or sixth costal cartilage is harvested with the anterior perichondrium intact. The grafts are carved to the appropriate shape, with the perichondrium facing the airway lumen. The hyoid bone may also be harvested through the existing cervical incision and used as an interposition graft, which offers the advantage of avoiding the need to prepare a second operative area. The central portion of the hyoid bone between the lesser cornua may be used as a free graft and fixed into place. The hyoid bone has also been used as a pedicled graft based inferiorly on the sternohyoid muscle.[28]

Tracheal Resection and Reanastomosis Areas of cervical tracheal stenosis up to about 5 cm can generally be excised, and the proximal and distal tracheal segments reanastomosed primarily. A suprahyoid laryngeal release may be required to allow for closure under minimal tension. When performing this procedure, the surgeon must keep in mind the age and body habitus of the patient. Older patients

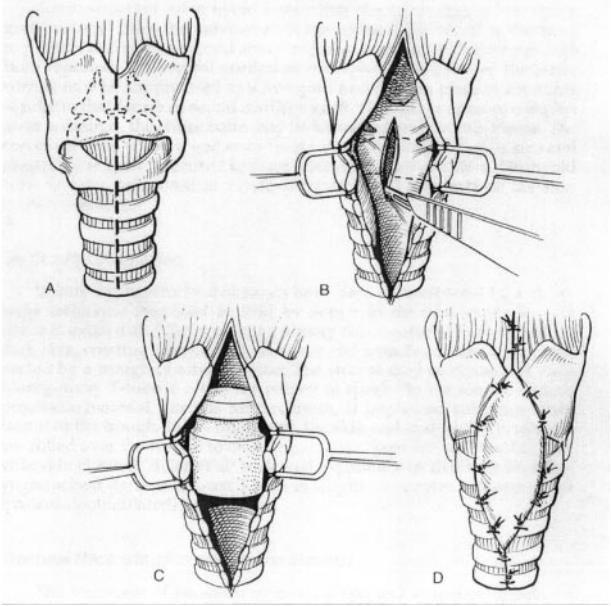

FIGURE 50–10. *A*, Vertical splitting of the cricoid cartilage during laryngotracheoplasty. *B*, Splitting of the posterior cricoid. *C*, Laryngeal stent in place. *D*, Graft sutured in place. Reproduced with permission from Duncavage JA and Koriwchak MJ.[24]

tend to have calcifications between the tracheal rings, resulting in decreased tracheal elasticity. Patients with large, thick necks and older patients with cervical kyphosis also tend to lack tracheal mobility.

Prior to the procedure, the patient is generally positioned with the neck extended on a shoulder roll. If a tracheostomy is present, the skin of the tracheostomy site is included in the incision planning and is excised. After a transverse skin incision has been made, subplatysmal flaps are raised superiorly to the thyroid cartilage and inferiorly to the manubrium. The strap muscles are separated in the midline and retracted laterally. The thyroid isthmus is divided and ligated, if necessary. The area of stenosis is then located and can be confirmed endoscopically. Care is taken to preserve the lateral blood supply to the trachea proximal and distal to the site of stenosis. The dissection around the area of stenosis must proceed directly on the trachea to prevent injury to the recurrent laryngeal nerves.

The esophagus is identified and carefully dissected away from the membranous trachea. The trachea may be incised above and below the stenotic segment. The endotracheal tube is placed transorally into the distal tracheal segment. The closure always begins posteriorly. Vicryl sutures are placed in an extraluminal fashion through the perichondrium of the proximal and distal tracheal segments (Figure 50–11). The neck is flexed prior to tying the sutures. Additional sutures may be placed around a tracheal ring above and below the site of anastomosis to decrease tension on the closure. The strap muscles are reapproximated in the midline. The platysma and skin are closed after placement of a passive Penrose drain that allows the egress of air and prevents subcutaneous emphysema.

It is essential to minimize the tension on the closure after tracheal reanastomosis. Surgical techniques that decrease tension include mobilization of the trachea through blunt anterior and posterior dissection and release of the suprahyoid muscular attachments. A cardiothoracic surgeon may also perform a division and reattachment of a bronchus, which allows further superior mobility of the distal trachea. Positioning maneuvers such as neck flexion also decrease tension on the site of anastomosis. Some surgeons place a stitch between the chin and manubrium (Grillo stitch) to prevent the patient from extending the neck during the postoperative period.

The patient may be extubated at the conclusion of the procedure or remain intubated overnight and extubated on the first postoperative day at the discretion of the surgeon. The success rate for this procedure generally exceeds 90%.[29]

Several new techniques have been described and applied in the treatment of segmental tracheal stenosis. Cryopreserved, irradiated tracheal homograft transplantation has been used to treat tracheal stenosis. This technique requires the harvest of tracheal tissue from donor cadavers within 24 hours of death. The grafts are placed in a –70°C chamber prior to irradiation to 25 kGy and are stored at –70°C until transplantation. Kunachak et al reported that three of four patients treated with this technique were successfully decannulated and display a near-normal tracheal lumen with histologic evidence of normal respiratory epithelium at the grafted site.[30]

The technique of microvascular free tissue transfer has also been applied to the challenging problem of LTS. Esclamado and Carroll reported the use of a fibular osseocutaneous free flap in the

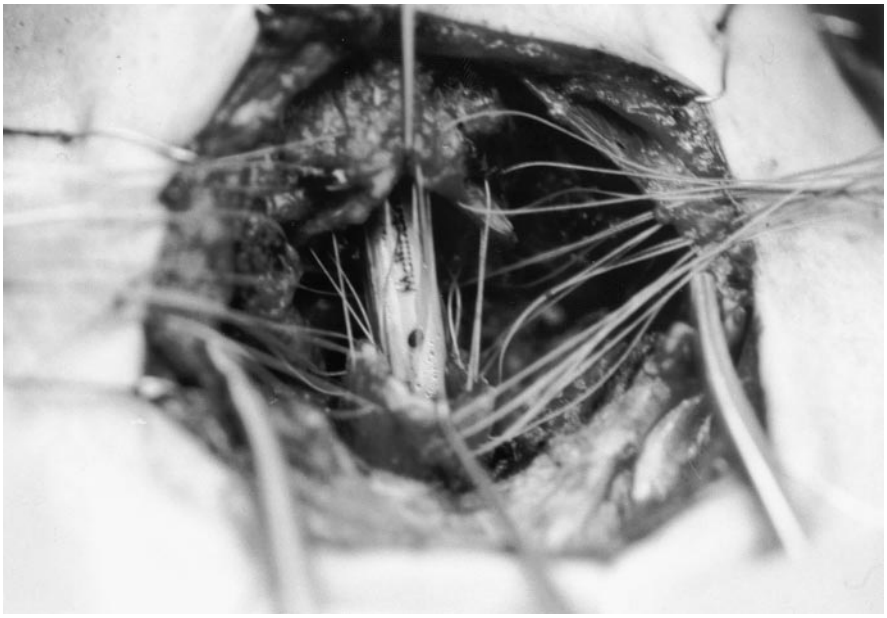

FIGURE 50–11. Tracheal anastomosis intraoperative photograph after the excision of a stenotic tracheal segment. Sutures have been placed but not tied. Courtesy of Dr. James L. Netterville.

reconstruction of a complex LTS.[31] At this point, the usefulness of microvascular free flaps appears to be limited to a subset of complex cases not amenable to more conventional surgical techniques.

CRICOARYTENOID JOINT FIXATION

The cricoarytenoid joint is a synovial joint formed by the articulation of the arytenoid cartilage with the posterosuperior aspect of the cricoid cartilage. The vocal process of the arytenoid cartilage is usually free to rotate in three dimensions to allow proper apposition of the true vocal folds. This normal mobility of the arytenoids can be impaired by several factors. Dislocation of the arytenoid cartilage may occur due to either external trauma or intubation. The arytenoid may be dislocated anteriorly or posteriorly, with anterior dislocation being slightly more common owing to the force vector exerted by the blade of a laryngoscope. Several inflammatory disorders such as rheumatoid arthritis and gout may also involve the cricoarytenoid joint and result in an abnormal "fixation" of the joint. Inflammatory disorders can result in unilateral or bilateral cricoarytenoid joint dysfunction. With cricoarytenoid arthritis, the patient generally presents with symptoms of stridor and dyspnea with a variable degree of dysphonia.[32] The dysfunction results from fixing of the vocal cords in the paramedian position and the inability to achieve normal apposition of the true vocal folds on phonation or normal abduction with inspiration. However, denervation of the larynx may also limit the normal mobility of the arytenoids.

In the patient with suspected cricoarytenoid joint dysfunction, the differential diagnosis is threefold. First, the posterior cricoarytenoid muscle may be denervated. Second, the arytenoid cartilage may be dislocated. A history of trauma should be carefully elicited in this group of patients. Finally, the joint may be fixed because of an inflammatory condition. The proper location and mobility of the cricoarytenoid joint are best assessed under general anesthesia by gently rocking the arytenoid cartilage back and forth. A "fixed" cricoarytenoid joint can be diagnosed with this method. An electromyogram of the intrinsic laryngeal musculature can determine if the immobility is caused by denervation or is secondary to fixation of the cricoarytenoid joint. A careful history aids in the diagnosis of a systemic inflammatory condition.

The treatment of cricoarytenoid joint dysfunction must be carefully individualized to the patient and the disease process. A patient with an inflammatory disease should be treated medically with the aid of a rheumatologist. Stable patients who are able to phonate, breathe, and swallow well without aspiration may be safely observed. Unstable patients or patients who do not improve on medical and rehabilitative strategies must be treated surgically. Patients with inadequate ventilation may undergo a tra-

cheostomy, which would likely result in maintenance of an excellent voice owing to the medial position of the vocal cords. Patients who wish to be decannulated can be offered a cordectomy or arytenoidectomy, but they must be carefully counseled that a more patent airway will result in an inferior voice. A successful treatment strategy requires excellent communication between the surgeon and the patient and intensive patient education and counseling.

Cordectomy and Arytenoidectomy

A carbon dioxide laser endoscopic posterior partial transverse cordotomy can sometimes provide an adequate airway and allow decannulation in a patient whose true vocal folds are in a medial position, cannot be abducted, and prevent adequate airflow through the glottis.[33] The cause of the medialized vocal folds may be either bilateral cricoarytenoid joint fixation or bilateral vocal fold paralysis. The procedure of laser cordotomy involves excising a transverse wedge of tissue from the posterior portion of one vocal fold just anterior to the vocal process of the arytenoid cartilage. The technique may also be performed bilaterally. The excision of this tissue in the posterior glottis allows a portal for airflow through an otherwise constricted airway. Complications of the procedure include granulation or scar tissue formation at the site of the cordotomy, requiring a repeat procedure, and decreased voice quality. The patient must be counseled that improving the airway necessarily decreases the quality of voice and that a balance between the two must be struck.

Excision or lateralization of the arytenoid cartilage is a second option for improving the patency of the airway when the vocal cords are adducted and airflow through the glottis is inadequate. The arytenoid cartilage may be removed surgically and the true vocal fold sutured laterally to improve the airway. Likewise, an endoscopic laser partial arytenoidectomy may be performed.[34] The goal of both techniques, as with laser posterior cordectomy, is to improve airflow through the posterior portion of the glottis while minimally affecting the anterior two-thirds of the glottis, which is largely responsible for phonation. Successful outcomes may result from each of the three procedures, and the technique of choice must be tailored to the experience of the surgeon and the individual patient.

CONCLUSION

The successful management of the airway requires a complete understanding of the structure and function of the upper aerodigestive tract. Likewise, a systematic and progressive algorithm must be employed in cases of airway distress. Several options exist for the management of patients who require a surgical airway, and the correct technique must be individually matched to the needs and situation of the patient.

Laryngotracheal stenosis poses a formidable challenge to the airway surgeon owing to the variability in the location and degree of stenotic segments. Areas of stenosis must be carefully evaluated prior to planning any treatment regimen. Once again, the treatment must be individualized to the patient, taking into account the etiology and anatomy of the lesion as well as the medical status of the patient.

CHAPTER 51

Trauma to the Larynx

Peak Woo, MD, Philip Passalaqua, MD

ETIOLOGY

The position of the larynx in the neck, protected by the mandible superiorly and the clavicles and sternum below, shields it from falls and blows. The lateral mobility of the larynx within the neck also serves to prevent the severe effects of compression injuries. The ossification centers of the larynx do not develop until young adulthood and are more pronounced in the male. This makes laryngeal fractures a rare condition, one more often seen in men than in women.

Although the cartilaginous framework provides protection to the larynx, once this framework has been violated by trauma, the tight space defined by the laryngeal skeleton makes rapid airway compromise possible. The tight adherence of the soft tissue to the laryngeal framework and the potential spaces that can be easily expanded at the expense of the airway make rapid changes in the airway status possible in patients with laryngeal trauma.

External laryngeal trauma is a relatively uncommon injury. Jewett et al reported an incidence of blunt trauma to the larynx of 1 in 137,000 in an analysis of 54 million inpatients over a 5-year period in 11 US states.[1] Laryngeal trauma accounts for about 1 in every 25,000 emergency department visits. In addition to the obvious possibility of acute airway obstruction, the complications of late diagnosed or undiagnosed laryngeal injuries can be severe, including glottic insufficiency, aspiration, and laryngeal stenosis. Furthermore, studies have demonstrated that early diagnosis and surgical management result in improved functional outcomes.[1,2]

BIOMECHANICS OF LARYNGEAL TRAUMA

The larynx may be injured by blunt and penetrating wounds and may be traumatized by intubation and foreign bodies. In motor vehicle trauma, the head is often in extension. During deceleration, the larynx and neck are pulled forward while the thorax is held in restraint. The larynx is decelerated against blunt objects, such as the steering wheel and dashboard, and is crushed against the vertebral column. Similar mechanisms of injury may occur in sporting accidents (ie, karate, hockey, basketball, Frisbee throwing, water skiing). In laryngeal trauma, the severity of the injury is dependent on the velocity and site of injury. In mild cases, the patient may not report the injury for many days. Severe injuries may result in catastrophic asphyxia in the field.

The other major causes of blunt trauma to the larynx are of the "clothesline" type. The injury may be caused by a clothesline, chain, or tree branch. Injures of this type occur when the anterior part of the neck strikes one of these objects while bicycling, snowmobiling, or riding in all terrain vehicles. Clothesline injuries tend to be more severe because of the high impact of the force and therefore require special attention. In clothesline injuries, the possibility of cricotracheal separation is a special concern.

It appears that the larynx cannot be fractured by concussion unless it is supported to some extent by the vertebral column. Furthermore, a blow to the neck will do relatively little damage to the laryngeal skeleton if the laryngeal cartilage is soft and pliable. The cartilage may spring back into position without fracture. Such injury will result in soft tissue edema and hematoma. Soft tissue disruption may result in edema and hematoma severe enough to interrupt the airway or cause dysphonia and stridor. Rapid acceleration and deceleration of the soft tissue of the larynx may result in arytenoid cartilage dislocation and mucous membrane tears and disruption of the laryngeal ligaments.

TYPES OF LARYNGEAL TRAUMA

Soft tissue injuries to the larynx from blunt trauma include laryngeal edema, hematoma, and mucosal tears. Often edema or hematoma involves the

aryepiglottic folds and false vocal cords owing to the supraglottic submucosal distensibility.[3] Fluid or blood accumulations can occur rapidly, resulting in acute laryngeal obstruction.

During the course of a laryngeal trauma, the posterior ends of the thyroid cartilage alae may be compressed against the vertebral column. This pressure against the thyroid cartilage will splay the angle of the thyroid cartilage to a more obtuse angle. Therefore, most fractures of the thyroid cartilage occur in the midline with loss of the normal acute angulation of the thyroid alae (Figure 51–1). A similar force applied to the cricoid cartilage against the vertebral column will result in a comminuted fracture of the signet ring–shaped cartilage.

Most blunt injuries resulting in laryngeal trauma are caused by an anterior to posterior striking force. In strangulation injuries, the larynx may be injured by lateral to medial compressive forces. It is likely that because of the greater ossification of the cartilages and the greater development in both acute thyroid alae angulation and size, the male larynx is more brittle and more subject to fracture under the influence of violent impact. Because of the prominence of the thyroid cartilage and its thyroid notch, it is the cartilage most usually fractured. The cricoid cartilage is generally more protected. With the exception of isolated trauma to the lower part of the neck by a thin object, cricoid fractures are usually combined with thyroid fractures. When cricoid fractures are combined with thyroid cartilage fractures, they are usually more extensive and dangerous. A wide array of fractures, dislocations, and nerve injuries are also possible. Table 51–1 lists the various fractures and other trauma possible.

Gunshot and knife wounds account for the majority of penetrating injuries. Gunshot wounds produce a greater degree of soft tissue injury depending on the velocity and mass of the bullet. The higher-velocity bullets will result in greater injury to the surrounding soft tissues. Knife injuries

usually result in less soft tissue damage but can be associated with injuries of vessels and nerves at some distance from the wound of entrance. During a knife injury, the larynx is often displaced without serious injury owing to the great lateral movement. A slash to the neck may result in lacerations of the cricothyroid membrane. Penetrating injuries of the larynx and trachea may occur in isolation but are usually part of more complex penetrating neck trauma that requires greater workup.

Laryngeal trauma in children tends to be less severe because of the higher position of the larynx in the neck in the pediatric population. Furthermore, owing to the pliable cartilage of a child's larynx, there is a lower incidence of laryngeal fractures. In addition, there is a lower incidence of laryngotracheal separation in the pediatric population because of the narrow cricothyroid membrane.[4]

Intubation injuries to the larynx usually result in soft tissue trauma to the posterior part of the larynx caused by an endotracheal tube or cuff. The most common occurrence is ulceration of the mucous membrane overlying the vocal process of the arytenoid cartilage. More severe injuries may be caused by prolonged intubations. These may take the form of intubation granuloma, posterior synechia, glottic stenosis (Figure 51–2), cricoarytenoid joint ankylosis, and subglottic stenosis. The factors contributing to poor outcomes in intubated patients include prolonged intubation, infection, gastroesophageal reflux, movement, pressure necrosis, and chondritis. The arytenoid cartilage can be dislocated by traction of the endotracheal tube that can cause a tear of the posterior cricoarytenoid ligament. In addition, an endotracheal tube pushed into the larynx without direct guidance through the glottis may result in a posterior vector against the cricoarytenoid joint, resulting in a posterior, lateral dislocation of the arytenoid cartilage. This may be associated with a tear of the anterior cricoarytenoid ligament.

DIAGNOSIS

The symptoms and signs depend on the cartilage involved and the extent of the soft tissue injury. Patients with laryngeal trauma may present to the emergency department with multiple injuries to other organ systems. Therefore, the laryngeal injury that has not caused acute airway obstruction may be missed. One should have a high index of suspicion for laryngeal injury in any patient presenting with blunt neck trauma. Diagnosis of subtle laryngeal injury in a timely manner is important for both treatment and prognosis.

All patients with injury to the anterior part of the neck should be carefully evaluated for the existence of laryngeal trauma. The symptoms suggestive of laryngeal injury include cough and expectoration. Pain is present in nearly every patient with laryngeal injury and is accentuated by phonation or deglutition. Tenderness and swelling may be quite marked. Swelling of the neck may be accompanied by loss of laryngeal landmarks in the anterior part of the neck. Dyspnea is often present in varying degrees owing to edema of the soft tissue or blood in the trachea. Hemoptysis may be present but is usually not severe. Stridor and voice change are other signs that suggest laryngeal trauma. Although dysphagia may be present with endolaryngeal trauma, it may also be suggestive of esophageal or hypopharyngeal injury. Emphysema of the neck suggests a perforation of a

viscus such as the larynx or hypopharynx. Soft tissue injuries may be accompanied by ecchymosis of the skin. In more severe injuries of the larynx in which the airway compromise is marked, asphyxiation and massive hemoptysis may occur. Crepitation of the neck secondary to subcutanous air may be elicited (Figure 51–3).

WORKUP FOR LARYNGEAL TRAUMA

The field management of the patient with suspected laryngeal injury consists of stabilization of the cervical spine and establishment of an airway. In the event of life-threatening airway compromise, intubation or tracheostomy in the field may be necessary.

After the patient has been stabilized and other potential life-threatening injuries are under control, the physical examination and assessment of the neck may commence for evaluation for laryngeal trauma. The workup for laryngeal trauma consists of physical examination of the neck, fiber-optic laryngoscopic examination, radiologic examination, and operative laryngoscopy.

Stridor is the most common sign in patients with upper airway compromise. The type of stridor may be indicative of the location of the injury. Combined inspiratory and expiratory stridor suggests some degree of obstruction at the level of the glottis. Expiratory stridor is more consistent with a lower airway injury. On the other hand, inspiratory stridor is indicative of supraglottic airway obstruction.[5] The presence of both stridor and hemoptysis has been associated with severe laryngeal trauma, displaced fractures of laryngeal cartilage, significant endolaryngeal or laryngopharyngeal edema or hematoma, or large mucosal tears exposing cartilage.[6]

A thorough physical examination must be performed with special attention to the presence of neck tenderness, crepitus owing to subcutaneous emphysema, soft tissue swelling, and loss of thyroid cartilage prominence. Fiber-optic laryngoscopy in the stable patient is an essential element of the physical examination and should focus on vocal cord mobility, tears, mucosal edema, hematoma, and dislocated or exposed cartilage. If limited range of motion of the vocal cords is noted, a structural deformity or arytenoid dislocation is likely. On the other hand, immobility of the vocal cords suggests recurrent laryngeal nerve injury.[5]

The patient presenting with soft tissue injury alone will often display edema, submucosal hemorrhage, and ecchymosis. Laceration of the mucosa, exposed cartilage, arytenoid cartilage dislocation, and disruption of the laryngeal architecture are highly suspicious of laryngeal framework injury. Despite the above generalizations, some patients

FIGURE 51–3. Axial computed tomographic scan showing massive subcutaneous emphysema in a patient with a laryngeal fracture.

with minimally displaced fractures of the larynx will present with a benign appearance of the larynx, and the fracture will be missed until the laryngeal edema has subsided, leaving the dislocation or laryngeal framework abnormality to be manifest as persistent hoarseness or dysphagia.

RADIOLOGIC EVALUATION

If cervical spine injury is suspected, it must be evaluated with cervical films prior to movement of the head. Chest radiography should be done to rule out a pneumothorax. Conventional neck radiographs can be used to screen for subcutaneous emphysema, whereas, historically, fluoroscopy was used in assessment of vocal function. With the advent of computed tomographic (CT) scanning, this study has supplanted laryngograms and laryngeal tomography. The laryngeal CT scan is the most useful radiologic examination for evaluating laryngeal injury. There is some debate regarding the utility of CT scans in cases at the ends of the disease spectrum. Stringer and Schaefer do not recommend CT scan in those individuals with minimal cervical trauma and a normal physical examination as the scan will not change the management. They also do not recommend CT scans in individuals who have penetrating injuries, obvious fractures, and large lacerations and in those who will require open exploration. They do note that there are exceptions for which the CT scan can serve as a roadmap for structural repair.[5] Bent et al routinely used CT scans to evaluate severe injuries that required operative management. They found that CT scans assisted in anticipating specific injuries and aided with the planning of the operative procedure.[7] In the vast majority of laryngeal trauma cases, CT scans offer better visualization of the subglottic and anterior commissure areas, can help identify clinically unapparent cartilage fractures, and can verify laryngoscopic findings.[8] Provided that the radiographic facilities are present and the patient is stable, a 2 mm CT scan or a spiral CT scan through the larynx offers the maximal detail as to the extent of laryngeal framework injury. More recently, with the use of spiral CT scans and three-dimensional reconstruction, virtual laryngoscopy and bronchoscopy have become possible. Their role in laryngeal fracture diagnosis and management has yet to be confirmed.

Carotid arteriography may be indicated in penetrating injuries to help reveal vascular injuries. If esophageal or pharyngeal tears are suspected, a Gastrografin (meglumine diatrizoate) swallow may be indicated. Gastrografin is the preferred agent over barium owing to the possibility of a fistula. In these cases, Gastrografin is less irritating to the soft tissues.

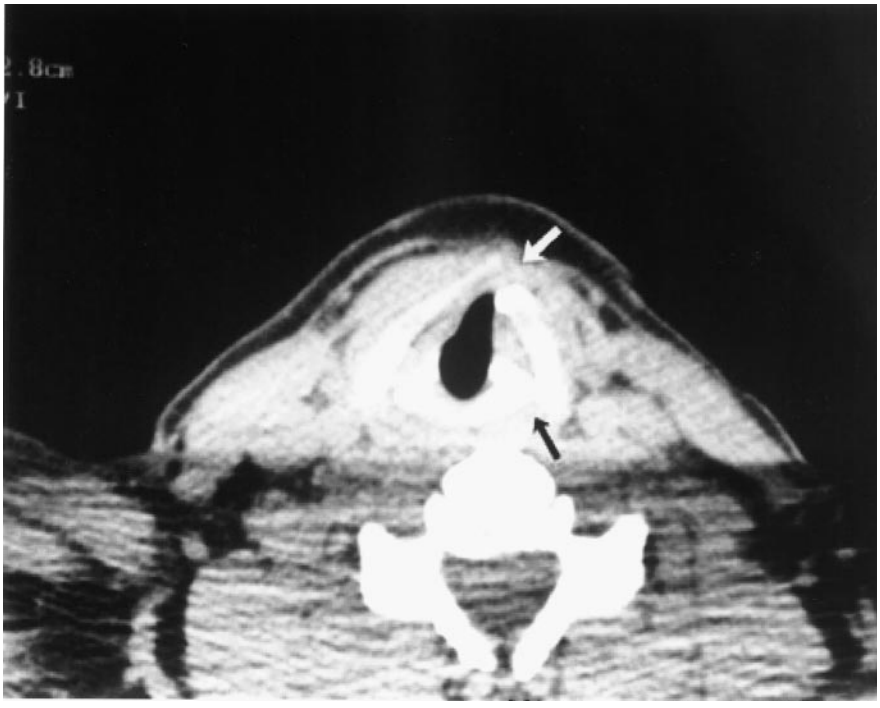

FIGURE 51–4. Axial computed tomographic scan showing a thyroid cartilage fracture (*white arrow*) and left arytenoid cartilage dislocation (*black arrow*) laterally and inferiorly.

OPERATIVE ENDOSCOPIC EVALUATION

Operative endoscopic examination by direct operative laryngoscopy, esophagoscopy, and bronchoscopy allows the treating surgeon to assess fully the extent of mucosal injury and disruption of the laryngeal framework. Direct visualization of laryngeal structures has advantages over flexible laryngoscopy or radiographic examination in that palpation of the structures may be performed. Subglottis and tracheal injuries may be missed by fiberoptic examination; injuries to these areas are better defined by operative laryngoscopy. Mucosal tears and cartilage exposure that appear as soft issue injuries or edema by CT scan can be mapped without difficulty. Provided that the operative risks are minimal, the managing physician should have a low threshold for operative endoscopic evaluation of the patients with suspected laryngeal trauma.

EMERGENCY MANAGEMENT

In the initial management of laryngeal trauma, securing and stabilizing the airway are of paramount importance. However, there is controversy regarding the optimal method of establishing a patent airway. Oral intubation in the setting of laryngeal trauma can be precarious owing to the possibility of further damaging the larynx, the creation of false passages, and precipitating loss of a tenuous airway. For these reasons, it is recommended that if intubation is necessary, it is to be done after cervical spine injuries have been ruled out and the laryngeal anatomy has been defined by prior fiber-optic laryngoscopy and that it be done in a setting with access to direct visualization with operative bronchoscopes and with equipment and personnel required for a tracheostomy. A clinician experienced in airway management should carry out the procedure of intubation.

Owing to the inherent risks of intubation in the setting of laryngeal trauma, many authors recommend a tracheostomy under local anesthesia.[7,9,10] A tracheostomy provides a method of stabilizing the airway with less risk of loss or further injury of the airway.[5] Optimally, tracheostomies for laryngeal trauma should be performed at the fourth to fifth ring of the trachea. By performing the tracheostomy lower than usual, further damage to existing injuries can be avoided. A vertical incision also affords better exposure so that, in the case of laryngotracheal separation, the trachea may be better accessed if it has retracted inferiorly.[11] Cricothyrotomy should be used only as an emergency method of airway establishment and should be converted to a standard tracheostomy as soon as possible. The possible sequela of not recognizing a cricothyrotomy in the setting of laryngeal injury include (a) the subsequent development of perichondritis and necrosis of the cricoid cartilage, (b) the development of subglottic stenosis, and (c) injury to the conus elasticus and the vocal cords. Therefore, any tracheostomy done in the field or in the emergency setting should be carefully evaluated for the possibility that it is a cricothyrotomy or that it has caused cricoid injury. In the event that a high tracheostomy or a cricothyrotomy is present, the airway access should be converted to a conventional tracheostomy below the second tracheal ring. The preferred time for revision tracheostomy after cricothyrotomy is within 24 hours after the initial operation.

CONSERVATIVE MANAGEMENT

After the initial evaluation and management of emergent airway issues, further treatment is divided into nonoperative and operative management. A conservative approach can be taken in patients with minimal soft tissue swelling or small hematomas who are stable and without evidence of respiratory compromise. Conservative management should be reserved for soft tissue injuries and nondisplaced laryngeal fractures. Hematoma and edema of the larynx often resolve spontaneously if there is no evidence of other injury. Conservative management is also appropriate in small mucosal lacerations or avulsions that do not involve the free edge of the vocal cord or anterior commissure. Observation is also appropriate when there is a nondisplaced single thyroid cartilage fracture without exposed cartilage and mucosal laceration.

Endoscopic evaluation of the larynx and trachea should be carried out if there is suspected laryngeal fracture, mucosal laceration, or emphysema of the neck. If there is extensive soft tissue swelling with airway compromise but no evidence of framework injury or mucosal laceration, the surgeon may elect to perform a tracheostomy without open surgical exploration of the larynx. Putting the larynx

at rest with conservative treatment will allow the optimum chance for edema to subside while safeguarding the airway.

Conservative management consists of observation, bed rest, voice rest, humidification of inspired air, antacids, and antibiotics. If a tracheostomy is not necessary, the patient is observed for 24 hours in an inpatient setting. During the 24 hours of observation, the patient should be followed for evidence of airway compromise from progressive swelling. In an effort to prevent further swelling and reduce the edema present, bed rest with elevation of the head is indicated. Similarly, the goal of voice rest is to reduce swelling. Corticosteroids have been used for their anti-inflammatory properties and anecdotally prevent the progression of edema. Humidification of inspired air is thought to prevent crust formation if mucosal damage is present.[12] Koufman has suggested that antacid use may be beneficial by decreasing the incidence of mucosal irritation and possible laryngeal stenosis from gastroesophageal reflux.[13] Antibiotics are indicated, especially in patients with multiple fractures in whom there is an increased risk of infection and perichondritis. Furthermore, a clear liquid diet may be beneficial initially. A nasogastric tube should be avoided if possible owing to the risk of further injury during placement. In addition, with extended placement of a nasogastric tube, there is risk of mucosal ulceration in the postcricoid region.[3]

SURGICAL MANAGEMENT

Injuries requiring surgical intervention include those with (1) exposed cartilage, (2) large mucosal lacerations, (3) lacerations involving the free edge of the vocal cord, (4) vocal cord immobility, (5) dislocated arytenoid cartilages, (6) displaced cartilage fractures, and (7) any neck injury with airway obstruction. The timing of surgical repair has been debated in the past, with some authors arguing that delaying surgery 3 to 5 days allowed resolution of edema and therefore better recognition of the anatomy. However, the current consensus is that outcomes are improved with early intervention. In one study, significantly better outcomes were noted in the group that was surgically repaired within 24 hours when compared with the group that was treated within 2 to 7 days.[2] A delay of greater than 24 hours to surgical repair has also been found to be associated with an increased incidence of wound infections, especially with supraglottic injuries.[14] Similar results have been reported in several studies with regard to the voice. Waiting longer than 48 hours for surgical repair is associated with increased laryngeal dysfunction.[3] Early intervention may help reduce "uncontrolled healing" of lacerations that result in scar formation.[7]

The immediate goals of surgical repair may be guided by the extent of the deficit and the needs of the patient. Clearly, intervention in a laryngeal fracture may have to be delayed in an unstable patient with multiple trauma. In contrast, the patient with a laryngeal fracture who is a voice professional will want to have everything possible done to restore voice function despite a stable airway. The early goals of surgical intervention should be to establish a safe airway, document the injury, repair cartilage injuries and restore the laryngeal framework, repair soft tissue lacerations, and promote early healing of the injury by prevention of infection and tissue necrosis. In the repair of laryngeal trauma, the long-term goals should be optimum functional restoration of voice, airway, and swallowing.

Although not a common injury, surgical management of laryngeal fractures has many possible variations. Some of these variations depend on the method of fracture reduction, whereas others depend on the method of stabilization and stenting technique used. Another variation depends on the site of fracture. Fractures of the thyroid and cricoid cartilages may be repaired by open reduction and rigid fixation, whereas arytenoid cartilage dislocation and laryngotracheal separation are more often treated by repair followed by endolaryngeal stenting. Table 51–2 outlines some of the types of injuries to be considered in the repair of laryngeal trauma.

In an effort to optimize the outcomes in laryngeal fractures, unique aspects of the laryngeal anatomy and function must be considered. The following factors are worth detailing: (a) laryngeal cartilages without great blood supply are in contact with mucosa; (b) the mucosal surface is in contact with contaminated upper airway secretions, making infection after injury possible; (c) the larynx is subject to great movement during normal deglutition and respiration, making stabilization difficult; and (d) the relatively small laryngeal cartilages have a great number of intrinsic and extrinsic muscles attached, making functional outcomes uncertain after laryngeal fracture. To counter these unique

TABLE 51–2. Types of Laryngeal Injuries: Causes, Manifestations, and Treatment

Type of Injury	*Causes*	*Symptoms and Signs*	*Treatment*
Fracture of the cricoid cartilage	MVA, closed injury Emergency tracheostomy	Dysphonia, odynophagia, +/– airway obstruction	ORIF with or without stenting
Fracture of the thyroid cartilage	MVA, closed injury Penetrating injury	Dysphonia, odynophagia, +/– airway obstruction	ORIF with or without stenting
Arytenoid cartilage dislocation	Closed injury Intubation	Hoarse voice, aspiration, dysphagia, +/– airway obstruction	Arytenoidpexy, stenting
Laryngotracheal separation	Vehicular trauma	Airway obstruction	Operative repair or resection, stenting
Complex fractures	High-speed MVA, GSW	Airway obstruction	Operative repair or resection, stenting

MVA = motor vehicle accident; GSW = gunshot wound; ORIF = open reduction internal fixation.

problems in the repair of laryngeal fractures, the laryngeal surgeon should (a) strive to reduce the amount of mucosal loss and hasten mucosal healing, (b) improve cartilage survival by rigid fixation and movement reduction, and (c) if necessary, prevent cicatrix formation during healing by the use of endolaryngeal stenting.

The first step in any planned surgical treatment of a laryngeal fracture is a rigid direct laryngoscopy to evaluate the extent of mucosal injury and to palpate the arytenoid cartilages for dislocation or immobility. Laryngeal exploration is performed through a horizontal incision at the level of the cricothyroid membrane. Subplatysmal flaps are elevated from the level of the hyoid bone to the sternal notch. The strap muscles are separated vertically at the midline raphe and retracted laterally. The larynx is entered, depending on the site of injury, through a midline thyrotomy or through the thyroid cartilage fracture if the fracture line runs within 2 to 3 mm of the midline of the thyroid cartilage. Care is taken to avoid injury to the anterior commissure. This can be accomplished by horizontally dividing the cricothyroid membrane prior to performing the midline thyrotomy and directly viewing the undersurface of the vocal folds from below. If there is disruption of the anterior commissure tendon, the surgeon must carefully search for and reattach it to the thyroid cartilage.

After exposure of the endolarynx, any mucosal lacerations are approximated with fine absorbable sutures. Fast-absorbing mild 4-0 chromic sutures are used. If possible, knots should be placed outside the lumen to prevent formation of granulation tissue. In most instances, mucosal injuries can be repaired with adjacent mucosa. When mucosal injuries are large, as may be present in an arytenoid cartilage avulsion, a piriform sinus mucosal flap may be used to cover any exposed cartilage. If there is extensive mucosal damage in the membranous portion of the vocal fold, re-establishment of mucosa may be accomplished by the use of free buccal mucosal or dermal grafts. A careful examination of the repair should show that all of the exposed cartilage is covered without tension. Pedicled mucosal flaps and mucosal or dermal grafts are used if there is not enough adjacent mucosa within the larynx to cover all exposed cartilage. These free grafts are of second choice because there is a greater likelihood of scar formation with their use compared with local mucosal flaps. In addition, these free grafts carry the morbidity associated with additional incisions.[5] The importance of restoring the lining of the larynx is attributable to the inherent tendency of exposed cartilage to facilitate the formation of granulation tissue, subsequently leading to fibrosis and laryngeal stenosis. There is also an increased risk of perichondritis when cartilage is left exposed. Care should be exercised to avoid aggressive débridement of soft tissue or mucosa. Because of the unique nature of the laryngeal framework and the attached mucosa, only devitalized tissue should be removed. Any removed tissue should be replaced by local adjacent tissue

transfer or soft tissue grafts. This is to prevent late glottal incompetence.

Another basic principle of laryngeal trauma surgery is to preserve as much cartilage as possible. Even free fragments of cartilage can be used to provide a scaffolding and stability, provided that they are covered with viable mucosa. If free cartilage fragments are used, they should be fixated with suture or miniplates.

Mildly displaced simple fractures can be repaired with nonabsorbable sutures through the outer perichondrium. Displaced fractures of laryngeal cartilage are reduced and immobilized. To prevent chondritis, very small pieces of cartilage without intact perichondrium are débrided. Fractures can be fixated with wire, nonabsorbable suture, or miniplates. If suture is used, fracture-site sutures should not be tightened until all fractures are reduced to avoid further damage to the mucosa by tearing. Internal fixation of laryngeal fractures may be performed if there are multiple fractures or fractures with displacement, or it may be used instead of internal laryngeal stenting. Titanium miniplates offer the advantage of superior alignment of displaced fractures because of the three-dimensional nature of miniplates (Figure 51–5).[15]

Reconstruction plates used in facial fracture repair may be used in laryngeal fracture repair. These plates are bioimplants made of titanium, stainless steel, or polyglycolic acid. Being malleable, these plates can be used as an internal scaffold for sutures or screws to fix the laryngeal fracture fragments into position. The three-dimensional contour of the laryngeal skeleton may be re-established with a single reconstruction plate bent to the shape of the thyroid cartilage. For the cricoid cartilage, it may be used to stabilize comminuted fragments and provide rigid fixation to the fragments. The screws and plates are best used in ossified cartilages but may be used with care in nonossified cartilage. Because of the soft nature of the cartilage, surgical tapping and drilling of the cartilage are not necessary. In general, four to six 5.0 mm by 2.0 mm screws serve to fix the laryngeal skeleton. Although we have also tried microplates, the smaller screws and the tendency to strip the smaller holes make the miniplate system more useful. In the rare adolescent or pediatric patient in whom the cartilage is thin, sutures alone are used to fixate the fragments onto the miniplate scaffold, thereby achieving stabilization without the need for screws.

In situations in which rigid internal fixation or immobilization cannot be achieved, laryngeal stenting will be necessary. Stents are also indicated when there is injury to the anterior commissure or when extensive soft tissue injury is present. If mucosal

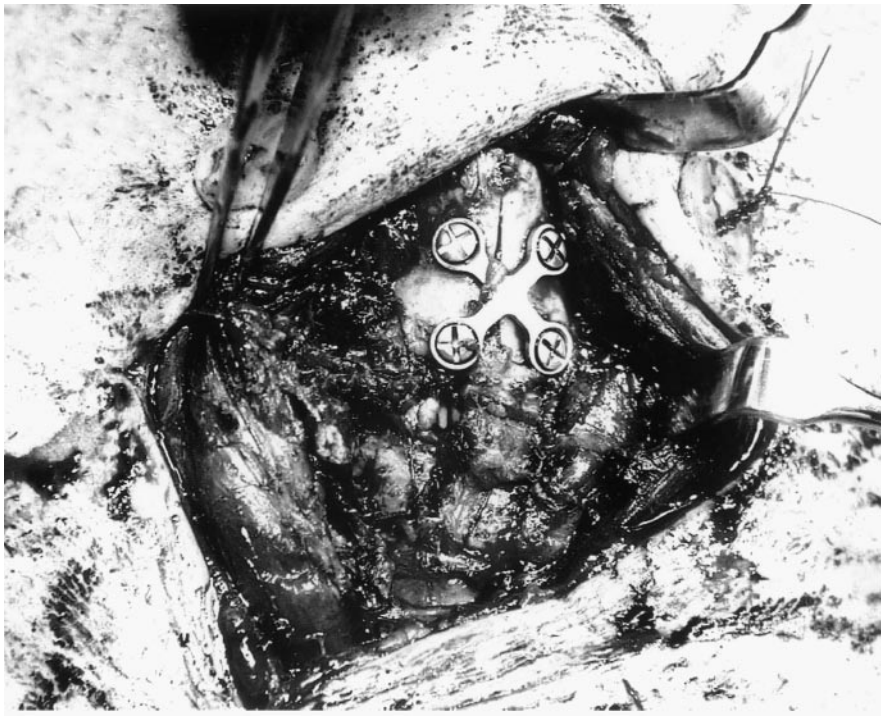

FIGURE 51–5. Miniplate used to fixate a thyroid cartilage fracture rigidly.

grafting is required, the internal stent serves to hold the graft in approximation to the raw surface to be grafted. The goal of stenting is to provide stability and prevent mucosal adhesions and subsequent laryngeal scarring. The type of stent to be used is controversial. Soft stents may be made of a finger cot packed with antibiotic-impregnated cotton gauze. Soft semirigid stents made of Silastic are commercially available in different sizes, from child to female to male. These can be inserted and modified according to need. Theoretically, "soft stents" result in less damage to surrounding tissue than firmer stents. However, many authors have found an increased risk of infection and formation of granulation tissue with "soft stents."[7,16] Firm stents are usually made of silicone, Silastic, or Portex. They are secured in a similar fashion as soft stents.

The stent is fixed with heavy nonabsorbable suture so that the superior end is at the aryepiglottic folds and the inferior end is above the tracheostomy site. The stent should be placed so that it moves with the larynx during swallowing. It can be secured with two mattress sutures through the skin, then through the thyroid cartilage below the level of the glottis, and then through the stent and out the cartilage and skin on the opposite side. The sutures can be fastened to buttons on the skin. Regardless of the method of suturing, the stent should be easily removed at endoscopy. Furthermore, the stent should be fixed in such a manner that if a suture breaks, the stent may still be recoverable.[5]

There has been controversy regarding the optimal time period that stents should remain in place. The beneficial effects of laryngeal stabilization and prevention of scar formation should be weighed against the risk of infection and irritation leading to granulation tissue and scar formation with subsequent laryngeal stenosis. Previously, longer periods of time, up to 6 weeks, were favored for stent placement. Currently, most authors recommend that stents be removed after about 2 to 3 weeks, providing that fractures have been stabilized and lacerations closed effectively.[2,5] After the stent is removed at direct laryngoscopy, the need for additional removal of granulation tissue can be assessed. If granulation tissue requires removal, a carbon dioxide laser can be used.[5]

Despite controversy regarding the management of severe laryngeal trauma involving comminuted fractures and significant endolaryngeal injury, there is consensus that neither grafts nor stents are substitutes for meticulous primary closure of mucosal wounds and diligent reduction and internal fixation of fractures.

Some specialized injuries from laryngeal trauma may occur as a consequence of closed or open injuries. These merit individual discussion below.

Dislocation of the Cricothyroid Joint

Usually with trauma, the inferior aspect of the thyroid cartilage is displaced posteriorly. As a result of this displacement, the recurrent laryngeal nerve may be compromised near the cricothyroid joint, resulting in vocal cord paralysis. Vocal fold paralysis owing to cricothyroid joint avulsion is often temporary, and function usually returns in 3 to 4 weeks. If no recovery of function is noted after 8 to 12 weeks, spontaneous function is unlikely to return. At this point, decompression of the nerve by resection of the inferior cornu of the thyroid cartilage may be considered since the cause of paralysis in many cases is neuropraxia. Electromyographic (EMG) studies of the vocal cord may be useful in assessing the utility of decompression. If the vocal cord is paralyzed longer than 9 months, the long-term prognosis is poor.[3]

Supraglottic Injuries

Supraglottic injuries require a more aggressive surgical approach owing to the high incidence of infection and fibrosis. In some isolated supraglottic injuries, the epiglottis may be avulsed from its anterior attachments, thereby allowing the epiglottis to prolapse posteriorly into the laryngeal lumen. In these instances, the epiglottis may be resected with no alteration in swallowing function. If the trauma is more extensive, a portion of the thyroid cartilage and false vocal cords can be resected in addition to the epiglottis as in a standard horizontal supraglottic laryngectomy.[3] Generally, supraglottic injuries result in horizontal fractures of the superior aspect of the thyroid alae, resulting in avulsion of the epiglottis superiorly and posteriorly. The epiglottis is then prone to fixation in the posterior position owing to scarring. In addition, fixation of the arytenoid cartilages can occur in untreated injuries, leading to eventual laryngeal stenosis. One exception to the above approach is when there is associated vocal cord paral-

ysis or glottic trauma. With vocal fold paralysis or concomitant glottic injuries, supraglottic resection should not be done owing to the increased incidence of aspiration. Rather, the supraglottic region should be reconstructed and the epiglottis removed.[3]

Glottic Injuries

With glottic injuries, fractures of the thyroid cartilage often occur at the level of attachment of the true vocal cords. Dislocation of one or both arytenoid cartilages with resultant vocal cord immobility is common (Figure 51–6). Dislocated arytenoid cartilages are realigned in their correct position with relation to the other laryngeal structures. These cartilages should not be fixated or removed. As with mucosal tears in other areas, primary reapproximation of the tissue should be attempted. If the mucosa cannot be closed primarily, advancement flaps of mucosa of the piriform sinus area can be used. If vocal cord immobility is present and is secondary to nerve injury, no corrective action should be taken since spontaneous return of vocal cord function is common.

Cricotracheal Separation

Cricotracheal separation is a devastating injury with unique characteristics that require close attention. Unfortunately, most of these patients do not survive the acute airway obstruction that occurs. If they do make it to the hospital alive, the airway is often tenuous owing to the loss of cricoid support. There is also a high likelihood of injury to the recurrent laryngeal nerves. Once an airway is secured through tracheostomy, definitive repair can be planned. These patients are at high risk of development of subglottic stenosis.

Cricoid Cartilage Fracture

Often the cricoid cartilage is fractured in two sites laterally, resulting in a telescoping of the cricoid cartilage anteriorly to posteriorly. If this is the case, the cartilage fractures should be exposed, reduced, and fixated, often requiring a laryngeal stent (Figure 51–7). Care should be taken to avoid injury to the cricothyroid muscle when repairing cricoid cartilage fractures. When the cricoid cartilage is intact, mucosa should be approximated with absorbable suture. To lessen the tension on this repair, sutures can be placed from the upper border of the cricoid cartilage around the first or second tracheal ring.[5] In situations in which the cricoid cartilage fracture is comminuted, internal fixation must be performed to offer stabilization during restructuring of the cricoid. As much as one-third of the anterior part of

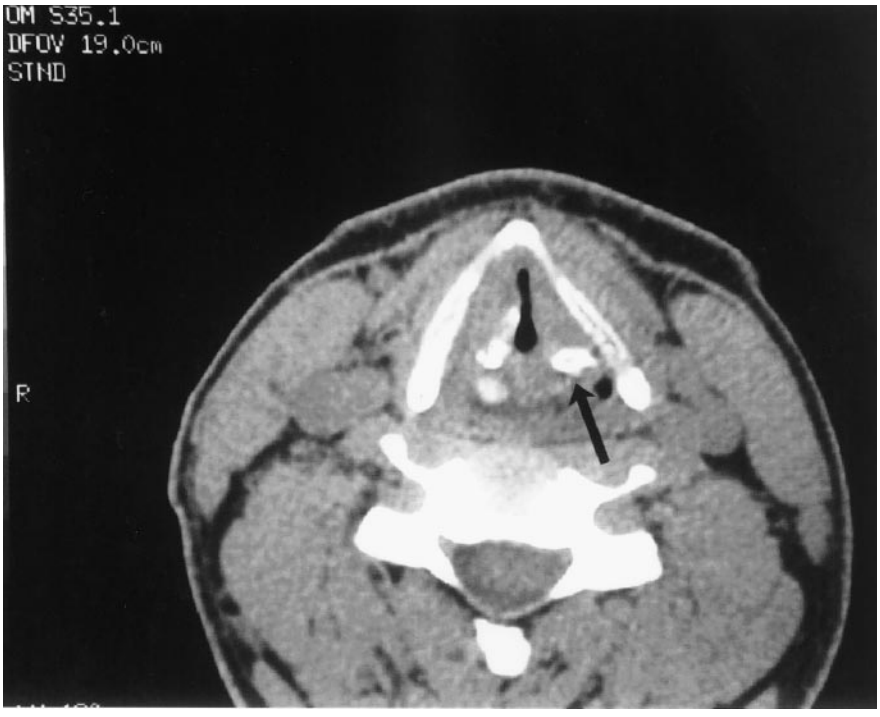

FIGURE 51–6. Axial computed tomographic scan showing arytenoid cartilage dislocation (*arrow*).

FIGURE 51–7. Axial computed tomographic scan showing cricoid cartilage fracture. *Arrows* indicate fracture sites.

the cricoid cartilage can be repaired using the sternohyoid muscle and its overlying fascia.[17] In patients with combined compromise of the trachea and the cricoid cartilage, sleeve resection and primary repair may be performed.[18]

Recurrent Laryngeal Nerve Injury

If the recurrent laryngeal nerve is severed and this is recognized at the time of exploration, the best approach is to reanastomose the transected nerve. Although vocal fold mobility may not be regained, muscle atrophy can be minimized through nerve regeneration, thereby improving the quality of the voice.[5]

Penetrating Laryngeal Injuries

The basic principles of management of blunt laryngeal injuries apply to penetrating injuries to the larynx. Owing to the especially destructive nature of high-velocity gunshot wounds, these injuries deserve special comment. With gunshot wounds, tissue viability is difficult to assess initially. The high energy that the bullet imparts to the soft tissue leads to a wider area of significant injury than simply the path of the missile. Furthermore, the course of the bullet is often erratic. Some authors recommend delaying definitive surgical repair so that the extent of nonviable tissue becomes apparent.[3,6] Other authors do not suggest delaying surgical intervention but rather emphasize that a wide area must be excised because the extent of devitalized tissue is not evident initially.[2,9,17] In either situation, all viable structures should be conserved. However, owing to the severe structural disruption of this type of injury, stenting is often necessary. At times, the injury is so massive that partial or total laryngectomy is indicated.

Unlike gunshot wounds, knife injuries do not impart a significant force to soft tissue distant from the course of the penetrating object. Therefore, the risk of nonviable soft tissue distant from the penetrating course of the knife is not present.

Pediatric Laryngeal Trauma

The same basic management principles discussed for the adult population also apply to the pediatric population, with a few additional caveats regarding securing a child's airway. Owing to the rapid oxygen desaturation of a child compared with an adult, efficiency in obtaining and stabilizing the airway is paramount. Furthermore, tracheostomy with local anesthesia is not a reasonable option in a scared, injured child. The airway should be stabilized under direct visualization with bronchoscopy; if needed, a

tracheostomy may then be performed over the bronchoscope.[4] During endoscopy following the tracheostomy, the laryngeal injuries can be assessed.

COMPLICATIONS

Even with the prompt recognition of laryngeal injuries and appropriate management, complications including granulation tissue, laryngeal stenosis, vocal cord paralysis, and aspiration are possible. Untreated displaced fractures may heal with dystrophic chondrification (Figure 51–8). Chondronecrosis with prolonged granulation tissue and progressive cicatrix formation is a feared complication of laryngeal fracture. Factors that increase the formation of granulation tissue include the presence of cartilage without mucosal covering and the presence of a stent. Granulation tissue increases the risk of fibrosis, which subsequently leads to stenosis. The primary closure of lacerations and the careful covering of all exposed cartilage with mucosa are of paramount importance. Other techniques have been attempted to reduce the formation of granulation tissue. These methods include intralesional and systemic corticosteroids, splinting, and irradiation. However, none of these treatment options have proven to be beneficial. Therefore, the optimal methods of preventing granulation tissue are the initial complete mucosal closure over cartilaginous structures and maintaining a stent in place the shortest period of time required for fixation.

Laryngeal stenosis may develop despite meticulous care after injury. In the case of supraglottic stenosis, the scar tissue may be excised with the carbon dioxide laser. If needed for wound coverage, local mucosal flaps or buccal mucosal grafts can be used. Similarly with glottic stenosis, posterior or interarytenoid scarring can be excised and local advancement flaps used if necessary. In the case of thin webs, a laser may be used to divide the web. If the glottic stenosis is severe, a laryngofissure with direct excision of the stenotic area is likely necessary. In these severe cases, a stent with a tissue graft is often placed to facilitate re-epithelialization.[12] In late or repeat reconstructions of the larynx in which laryngeal stenosis is an ongoing issue, the use of a conforming laryngeal prosthesis is invaluable. This application is described by Montgomery and Montgomery.[19]

Laryngeal stenosis in the subglottic area is more difficult to treat effectively. With limited subglottic stenosis, excision of fibrotic tissue with a carbon dioxide laser and repeated dilations of the stenotic area may be adequate. In cases of more severe subglottic stenosis, cricoid splits with cartilage grafting are required. To stabilize the restructuring postoperatively, a stent is often needed.

FIGURE 51–8. Axial computed tomographic scan showing dystrophic calcification several months after a missed thyroid cartilage fracture. *Black arrow* indicates dystrophic calcification. *White arrow* indicates thyroid cartilage fracture.

Tracheal stenosis of up to 4 cm can be resected with subsequent end-to-end tracheal anastomosis.[12] Late reconstructions of the larynx using pedicled and autogenous grafts have been used with good results in adults suffering from laryngeal stenosis after laryngeal trauma.[20–23]

In addition to laryngeal stenosis, another possible complication is paralysis of the vocal cords. The cause of an immobile vocal cord must be determined to make appropriate management decisions. To evaluate whether an injured recurrent laryngeal nerve or a cricoarytenoid joint fixation is responsible for vocal fold dysfunction, direct laryngoscopy is performed. During the laryngoscopy, the arytenoid cartilage is palpated to evaluate mobility. If the arytenoid cartilage is mobile, injury of the recurrent laryngeal nerve is the probable cause. If any question still exists, laryngeal EMG can also be performed. Electromyography is a valuable way to evaluate if the laryngeal muscles are denervated or the recurrent laryngeal nerve is intact. If the recurrent laryngeal nerve is severed, the EMG will show total denervation of the muscles. If the nerve is injured but recovering, the EMG will show signs of electrical recovery. If the EMG shows that the muscle activity is intact, the vocal cord immobility is likely secondary to cricoarytenoid joint fixation.

Bilateral vocal fold fixation or bilateral laryngeal nerve paralysis is especially challenging in the management of late effects of laryngeal trauma. Reinnervation procedure using the ansa cervicalis to the recurrent laryngeal nerve has been reported with success by Crumley. In all reinnervation procedures, the duration of reinnervation process and aberrant reinnervation with synkinesis continue to be problems in the optimal restoration of function in patients with bilateral vocal fold paralysis.[24,25]

Patients with bilateral cricoarytenoid joint ankylosis owing to intubation or laryngeal fracture are tracheostomy dependent unless additional surgery can be done. The surgery for bilateral cricoarytenoid ankylosis varies from open surgical arytenoidectomy to arytenoidpexy to endoscopic arytenoidectomy or transverse cordectomy. All have their advantages and disadvantages.

Beside laryngeal stenosis, laryngeal incompetence may result in disabling aspiration or dysphonia. Glottic incompetence is most obvious after the laryngeal edema and hematoma have fully resolved. Unfortunately, this is often when a previously unrecognized fracture is found with misalignment of the fracture, resulting in glottal incompetence. The cause of late glottic incompetence may be attributable to loss of soft tissue, vocal fold paralysis, and laryngeal ankylosis as well as inadequate repair and reconstruction of the normal endolaryngeal volume or inadequate approximation of the laryngeal fragments. These problems may result in inadequate soft tissue needed for glottic closure during deglutition or phonation. Since spontaneous recovery of vocal cord function with injury of the recurrent laryngeal nerve is likely unless the nerve is severed, observation for up to 8 months is indicated. However, if dysphonia or aspiration is caused by laryngeal ankylosis or anatomic deficits, repair of laryngeal incompetence by laryngoplasty is indicated. Using modern phonosurgery techniques, the vocal folds can be medialized as a temporizing measure with Gelfoam or fat injection.[26] In situations in which the paralysis does not resolve, vocal cord medialization by laryngoplasty with or without arytenoid cartilage adduction may be performed.[27]

RADIATION INJURY

External beam radiation has been used successfully for the treatment of laryngeal carcinoma for many decades. Full-course therapeutic radiation always causes temporary laryngeal edema. In addition, radiation therapy can cause permanent morbidity of the larynx. The spectrum of injury ranges from edema to perichondritis and cartilage necrosis. The incidence of radiation-induced soft tissue injuries has decreased from 5% in 1970 to 1% in 1990.[28] However, owing to the recent trend in treating advanced-stage laryngeal carcinoma with organ-preservation protocols, more patients are receiving high-dose radiation and are therefore at risk for developing radiation-induced complications. Although most cases of radiation-induced chrondronecrosis occur within the first year after treatment, the changes in the vasculature are permanent, and necrosis has been reported to occur 50 years after treatment.[29]

Pathology

The first effects of radiation therapy are in the epithelium. There is loss of glandular secretions, and ciliary function is damaged. This leads to dry, irritated mucosa that is prone to infection. Radiation induces

fibrosis of the submucosal layer, thereby reducing venous outflow that, in turn, causes acute edema. With higher doses, the perichondrium degenerates, and a lymphocytic infiltration occurs. When the dose exceeds 1,000 to 1,200 cGy, irreversible vascular and lymphatic injury occurs. Subintimal fibrosis and proliferation of the endothelium cause obstruction of small arterioles. These changes in the endothelium are permanent and are the main cause of subsequent perichondritis and chondronecrosis.

Clinical Presentation and Management

Clinical symptoms and signs of radiation injury to the larynx include dysphonia, dysphagia, cough, pain, odynophagia, weight loss, aspiration, upper airway obstruction, malodorous breath, and sepsis. Chandler described a clinical grading system for radiation-induced changes in the larynx.[30] Grades I and II include moderate hoarseness, moderate dryness, moderate edema and erythema, and mild impairment of vocal fold mobility. These symptoms and signs are expected in all patients receiving radiation therapy. These patients can often be successfully treated with humidification, antireflux medication, and sialagogues.

Grade III consists of severe hoarseness, dyspnea, moderate dysphagia, and odynophagia. On examination, there is fixation of the vocal folds with marked edema and erythema. Treatment consists of humidification, antireflux medication, antibiotics, and corticosteroids. A 2- to 3-week course of this treatment often results in marked improvement in symptoms.

If there is no response or recurrent episodes, the patient is likely progressing to frank chondronecrosis. Grade IV involves respiratory distress, severe pain, dehydration, and fever. There is evidence of airway obstruction and fetid odor with possible skin necrosis. Treatment is the same as for grade III reactions except that tracheostomy is often needed for airway control and gastrostomy is often needed for adequate nutritional support.

Often patients with radiation-induced changes in the larynx become a diagnostic dilemma for the clinician. It is often impossible to distinguish between recurrent carcinoma and radiation reaction, particularly in the face of increasing edema and impairment of vocal fold mobility. If a patient fails to respond to conservative management (corticosteroids, antibiotics, antireflux medication, and humidification), direct laryngoscopy and biopsy are necessary. If tumor is present at biopsy, total laryngectomy is performed. If no tumor is demonstrated, conservative measures can be continued for several weeks, with frequent follow-up to detect recurrent carcinoma. In addition, hyperbaric oxygen has been used successfully in preventing the need for laryngectomy and tracheostomy in patients with grade IV laryngeal radionecrosis. If after a few months the larynx remains nonfunctional (tracheostomy dependence, severe pain, aphonia, and aspiration), total laryngectomy should be considered even if no tumor is present at biopsy.[31]

Many clinicians are reluctant to biopsy a radiated larynx unless their index of suspicion for recurrent tumor is very high. The already compromised laryngeal cartilage will suffer further ischemia and potential salivary contamination at biopsy, thus increasing the risk of irreversible necrosis. The problem arises in distinguishing who is at high risk for recurrent carcinoma. Computed tomographic scanning and magnetic resonance imaging have not consistently been useful in distinguishing between radiation changes and tumor. Positron emission tomographic scanning has shown some promise in this area by appropriately distinguishing tumor from radiation changes.[32]

LARYNGEAL BURNS

The most common type of thermal injury to the larynx occurs with inhalation of hot gases or smoke in burning buildings. Rarely are thermal injuries secondary to ingestion of hot liquids or foods. When ingestion of a hot liquid or solid is the cause, the burn is usually confined to the supraglottis and posterior part of the larynx. Often there are oral cavity burns as well. Owing to reflexive glottic closure, there is almost never subglottic injury. Isolated burns to the supraglottis can mimic acute infectious epiglottitis. If this occurs, the airway should be controlled by either tracheostomy or intubation in the operating room. The edema secondary to hot liquid or solid burns usually resolves rapidly, and decannulation or extubation can be accomplished in a short time. Rarely do hot liquids or solids cause long-term sequelae in the larynx.

In contrast, inhalation injuries frequently cause severe and potentially life-threatening acute and long-term complications. Both heat and irritant inhalation produce severe tracheobronchitis with

sloughing of mucosa. If the basal cell layer of the epithelium is intact, early repair with minimal complications is expected. If the basal cell layer is lost owing to the original insult or subsequent local trauma, delayed repair will result in granulation tissue formation and potential airway stenosis.[33]

Thermal inhalation injury most commonly occurs in patients with concomitant cutaneous burns. The incidence of inhalation burns increases as the extent of the cutaneous burn increases. The location of maximal injury within the airway depends on the size of the inhaled particles. Large particles mainly affect the trachea and larynx, whereas small particles mainly affect the alveoli. Thermal injury induces rapid edema that can cause airway obstruction.

Patients with inhalation injury have a wide variability of presenting symptoms and signs. These range from cough, to stridor, to respiratory arrest. Some authors have advocated elective intubation of all patients with suspected inhalation injury. Others argue that this leads to many unnecessary intubations, and expectant management of the airway can be safely performed for stable patients.[34] Most authors agree that if a patient presents with stridor, loss of consciousness, or massive burns, immediate intubation should be carried out.

If the patient is stable, the decision regarding intubation can be deferred until fiber-optic laryngoscopy and bronchoscopy have been performed to assess the airway. Some centers use flow-volume loops and ventilation-perfusion nuclear medicine scans to assess the damage to the lower airways and predict who requires intubation. If on fiber-optic laryngoscopy and bronchoscopy soot or mucosal injury is found, intubation should be performed. Patients who require intubation are at risk for late laryngeal and tracheal complications because their mucosas have already been damaged by the burns. No definitive improvement in outcome has been demonstrated with empiric treatment with antibiotics and corticosteroids in inhalation burns.

There is some controversy regarding the indications for tracheostomy in the patient with inhalation injury. Some argue that tracheostomy should be avoided to prevent bacterial contamination of the lower airway. Others state that early tracheostomy will "put the larynx at rest" and prevent possible laryngeal stenosis. Overall, the management of the airway in the patient with inhalation injury should be individualized based on the patient's clinical situation.

CONCLUSION

External laryngeal trauma is a rare injury in which morbidity is significantly decreased by early and accurate diagnosis and management. Stabilization and maintenance of the airway are paramount concerns. Tracheostomy is the preferred method of airway stabilization. If endotracheal intubation is to be performed, it should be done under direct visualization by an experienced clinician and with a tracheostomy kit at hand. The history, physical examination, and diagnostic imaging provide information regarding the severity of the injury. If displaced cartilaginous fractures and mucosal lacerations are present, the goal is realignment and fixation of the fractures and primary closure of all lacerations so that all exposed cartilaginous structures are covered. In some cases, stents and miniplates must be used to provide adequate stabilization of structures. With appropriate management, complications such as laryngeal stenosis can be minimized.

CHAPTER 52

Infectious and Inflammatory Diseases of the Larynx

James A. Koufman, MD, Peter C. Belafsky, MD, PhD

The majority of patients with disorders of the larynx and voice suffer from infectious and noninfectious inflammatory conditions. It is important to remember that the term *inflammation* implies a local response to tissue injury, characterized by capillary dilation and leukocyte infiltration. The typical symptoms and signs of inflammation are swelling, redness, and, sometimes, discomfort or pain. The term *laryngitis* is synonymous with laryngeal inflammation, although not with hoarseness. Laryngitis (laryngeal inflammation) may result from infection by an invading microorganism or from irritative, traumatic, metabolic, allergic, autoimmune, or idiopathic causes.

Acute and chronic laryngitis are very common in otolaryngologic practice, and the causes (differential diagnoses) in pediatric and in adult patients are different. In infants and children, for example, the most common cause of laryngitis is acute infection, whereas in adults, laryngitis generally tends to have a chronic, noninfectious cause.

Within the last 20 years, laryngopharyngeal (gastroesophageal) reflux has been discovered to be a far more important cause of laryngeal inflammation than was previously recognized. In addition, primarily because of acquired immune deficiency syndrome (AIDS), infecting microorganisms that were rarely encountered in the practice of otolaryngology just a few years ago are re-emerging. Thus, the otolaryngologist today must again become familiar with the clinical manifestations of infection by a wide spectrum of microorganisms.

Laryngeal inflammatory disorders are unusual in that often more than one causative factor or condition can be identified. For example, patients with Reinke's edema are frequently smokers who also misuse their voices and have reflux. Such patients may also develop laryngeal carcinoma.

Each of the underlying causes must be identified and corrected if treatment is to be successful. As more has been learned about the larynx, environmental influences, and the effects of systemic disorders on the larynx, imprecise diagnostic terms, such as *nonspecific laryngitis*, have appropriately begun to disappear from the otolaryngologic literature.

The differential diagnosis of the (infectious and noninfectious) causes of laryngitis is shown in Table 52–1.

LARYNGOPHARYNGEAL (GASTROESOPHAGEAL) REFLUX DISEASE

It has been estimated that 10% of Americans have heartburn on a daily basis, and an additional 30 to 50% have it less frequently.[1] Of all of the causes of laryngeal inflammation, gastroesophageal reflux disease (GER, GERD) is the most common cause, and as many as 10 to 50% of patients with laryngeal complaints have a GER-related underlying cause.[2,3]

The term *reflux* literally means *back flow*. Reflux of stomach contents into the esophagus is common, and many patients with GERD have symptoms such as heartburn and regurgitation related to inflammation of the esophagus by acid and digestive enzymes. When refluxed material escapes the esophagus and enters the laryngopharynx above, the event is termed *laryngopharyngeal reflux* (LPR). Although the terms *gastroesophageal reflux* and *laryngopharyngeal reflux* are often used interchangeably, the latter is more specific. Laryngopharyngeal reflux is the preferred term for use in otolaryngology because the patterns, mechanisms, and manifestations of LPR differ from classic GERD.

Laryngopharyngeal reflux affects both children and adults and may be associated with an acute,

    2. Muscle tension dysphonias
    3. Contact ulcer and granuloma

chronic, or intermittent pattern of laryngitis, with or without granuloma formation. Indeed, LPR has also been implicated in the development of laryngeal carcinoma and stenosis, recurrent laryngospasm, and cricoarytenoid joint fixation, as well as with many other otolaryngology-related conditions, including globus pharyngeus, cervical dysphagia, and subglottic stenosis.[3–10]

The symptoms of LPR are quite different from those of classic GERD as seen in the gastroenterology patient, who characteristically has heartburn, regurgitation, and esophagitis. Patients with "reflux laryn-

gitis" (LPR) present with hoarseness, but almost two-thirds deny ever having heartburn.[3,6] Other throat symptoms, such as globus pharyngeus (a sensation of a lump in the throat), dysphagia, chronic throat clearing, and cough, are often associated with LPR.[6] Gastroenterologists call reflux patients who deny gastrointestinal symptoms *atypical refluxers*, but these patients are quite typical of those encountered in otolaryngologic practice.[11] The symptoms and laryngeal conditions that have been reported to be associated with LPR are summarized in Table 52–2, and the differences between the LPR patient and the typical GERD patient are summarized in Table 52–3. We have developed and validated a nine-item reflux symptom index (RSI) to quantify patient symptoms of LPR and evaluate treatment efficacy (Table 52–4). This outcome instrument has displayed excellent reproducibility and criterion-based validity.[12]

Laryngeal Findings

Physical findings of LPR can range from mild, isolated edema and/or erythema of the area of the arytenoid cartilages to diffuse laryngeal edema and hyperemia with granuloma formation and airway obstruction. We have validated an eight-item reflux finding score (RFS) to document the severity of the clinical findings of LPR (Table 52–5).[12,13] Use of the RFS not only helps physicians identify subtle findings of reflux, it also assists in evaluating the severity of laryngeal tissue injury, as well as documenting treatment efficacy. Figure 52–1 displays the physical findings of LPR, which are discussed in detail below.

Pseudosulcus vocalis refers to a pattern of subglottic edema that extends from the anterior commissure to the posterior part of the larynx; it appears like a groove or sulcus. It can easily be differentiated from a true sulcus (*sulcus vergeture*), which is the adherence of the vocal fold epithelium to the vocal ligament secondary to the absence of the superficial layer of lamina propria. True sulcus is related to scarring of the vocal fold(s) in the phonatory striking zone. Whereas true sulcus stops at the vocal process and is in the midportion of the striking zone, pseudosulcus vocalis extends all the way to

TABLE 52–2. Symptoms and Laryngeal Conditions Reported to be Associated with Laryngopharyngeal Reflux

Symptoms	*Conditions*
Chronic dysphonia	Reflux laryngitis
Intermittent dysphonia	Subglottic stenosis
Vocal fatigue	Carcinoma of the larynx
Voice breaks	Endotracheal intubation injury
Chronic throat clearing	Contact ulcers and granulomas
Excessive throat mucus	Posterior glottic stenosis
"Postnasal drip"	Arytenoid cartilage fixation
Chronic cough	Paroxysmal laryngospasm
Dysphagia	Paradoxical vocal fold movement
Globus	Globus pharyngeus
Intermittent airway obstruction	Vocal nodules
Chronic airway obstruction	Polypoid degeneration
	Laryngomalacia
	Pachydermia laryngis
	Recurrent leukoplakia
	Sudden infant death syndrome

GERD = gastroesophageal reflux disease; LPR = laryngopharyngeal reflux.

the back of the larynx. Its presence contributes 2 points to the RFS.

Ventricular obliteration is a frequent finding that may be identified in up to 80% of patients with LPR. Swelling of the true and false vocal folds causes this space to become obliterated and thus poorly visualized. With partial ventricular obliteration, the space is reduced, and the false vocal fold edge is indistinct. With complete ventricular obliteration, the true and false folds appear to touch, and there is no true ventricular space. Partial obliteration contributes 2 points and complete obliteration contributes 4 points to the RFS.

Laryngeal erythema/hyperemia is a nonspecific finding that is dependent on the available endoscopic equipment. Subtle changes in erythema are difficult to quantify and vary depending on the quality of the fiberscope, video monitor, and light source. Nonetheless, isolated erythema of the area of the arytenoid cartilages contributes 2 points and diffuse laryngeal erythema contributes 4 points to the RFS.

True vocal fold edema is graded as mild (1 point) if only slight swelling exists and moderate (2 points) when it becomes more perceptible. Edema is graded as severe (3 points) when swelling of the cord becomes sessile. Finally, polypoid degeneration of the true vocal fold contributes 4 points to the RFS.

Diffuse laryngeal edema is judged by the size of the airway relative to the size of the larynx. It is graded as mild (1 point) to obstructing (4 points). Hypertrophy of the posterior commissure is another frequent finding of LPR. It is graded as mild (1 point) when there is a mustache-like appearance of the posterior commissure mucosa and moderate (2 points) when the posterior commissure mucosa is swollen

enough to create a straight line across the back of the larynx. Posterior commissure hypertrophy (PCH) is graded as severe (3 points) when there is bulging of the posterior part of the larynx into the airway and obstructing (4 points) when a significant portion of the airway is obliterated. The final two items on the RFS are granuloma/granulation and thick endolaryngeal mucus. Patients get 2 points when these entities are present and 0 points otherwise.

Diagnosis

Ambulatory 24-hour double-probe (simultaneous esophageal and pharyngeal) pH monitoring (pH-metry) is the current gold standard for the diagnosis of LPR.[3,14,15] The distal probe is placed 5 cm above the lower esophageal sphincter (LES), and the proximal probe is placed in the hypopharynx 1 cm above the upper esophageal sphincter (UES), just behind the laryngeal inlet (Figure 52–2). The traditional technique of probe placement is to place both the proximal and distal pH probes under manometric guidance. A manometer is inserted through the nasal cavity and advanced through the esophagus into the stomach. It is then slowly withdrawn, and the locations of the LES and UES are determined. The correct pH catheter is then chosen based on these measurements. An alternative technique involves placing the proximal probe just above the UES under direct fiber-optic visualization. The distance between the proximal and distal

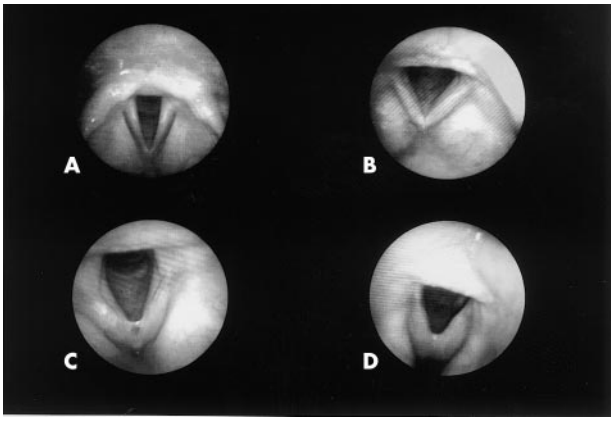

FIGURE 52–1. Findings of laryngopharyngeal reflux. I: *A*, Bilateral pseudosulcus vocalis. Notice that the subglottic edema extends past the vocal process (*arrow*). Also present are mild posterior commissure hypertrophy and vocal fold edema. *B*, True sulcus vocalis (adhesion of overlying vocal fold epithelium to underlying vocal ligament) (*arrow*). II: *A*, Open laryngeal ventricles (*arrowhead*). Also present are small prenodules. *B*, Near-complete ventricular obliteration. Also present are mild posterior commissure hypertrophy and moderate vocal fold edema. III: Granuloma of left vocal process. IV: *A*, Mild vocal fold edema. *B*, Moderate vocal fold edema. Pseudosulcus, mild posterior commissure hypertrophy, and partial ventricular obliteration are also present. *C*, Severe vocal fold edema. Sessile changes are noted. *D*, Polypoid degeneration of the vocal folds. V: *A*, Normal posterior commissure. Cuneiform cartilages can be visualized. *B*, Mild posterior commissure hypertrophy. Mustache-like configuration of posterior larynx. Cuneiform no longer visualized. *C*, Moderate posterior commissure hypertrophy. Straight bar across posterior larynx. *D*, Severe posterior commissure hypertrophy. Protrusion of posterior commissure into airway.

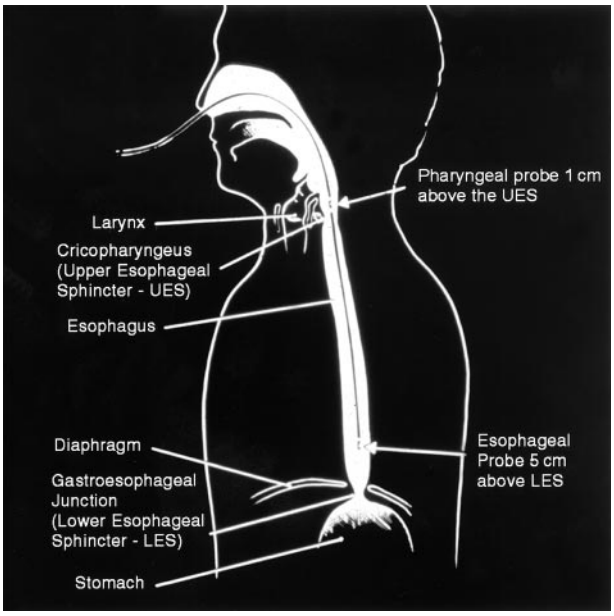

FIGURE 52–2. Technique of ambulatory 24-hour double-probe pH monitoring. The distal probe is placed 5 cm above the lower esophageal sphincter (LES), and the proximal (pharyngeal) probe is placed 1 cm above the upper esophageal sphincter (UES).

pH probes is fixed at 15 cm. This technique is easier, less time consuming, and less costly than using manometric guidance. Placement of the proximal probe above the UES can be performed accurately using this method. This technique, however, is unable to estimate precisely interprobe distances.[16] Thus, the exact location of the distal probe is uncertain, and the esophageal data are often grossly inaccurate using this technique.

pH-metry has been available for many years, and standards (normal values) have been established in many laboratories.[2,17] In general, the most important parameter used to evaluate the presence of GERD at the distal probe is the percentage of time that the pH is less than 4. This measurement is usually recorded for time in the *upright position*, time in the *supine position*, and the *total time* of the study. For the upright period, the upper limit of normal is approximately 8.0%, and for the supine period, approximately 2.5%.[17]

The proximal pharyngeal probe is invaluable in patients with LPR because it is placed behind the larynx just above the cricopharyngeus; thus, reflux recorded by it is diagnostic of LPR (Figure 52–3). In addition, it has been found that without the proximal (pharyngeal) probe, the diagnosis of LPR will be missed in approximately 30 to 50% of patients.[18]

It is also advisable to evaluate the esophagus of patients with LPR. This may be accomplished by performing a barium esophagram[19] or, more recently, transnasal esophagoscopy. Although the prevalence of esophagitis in patients with LPR is only 20%, the percentage of other esophageal

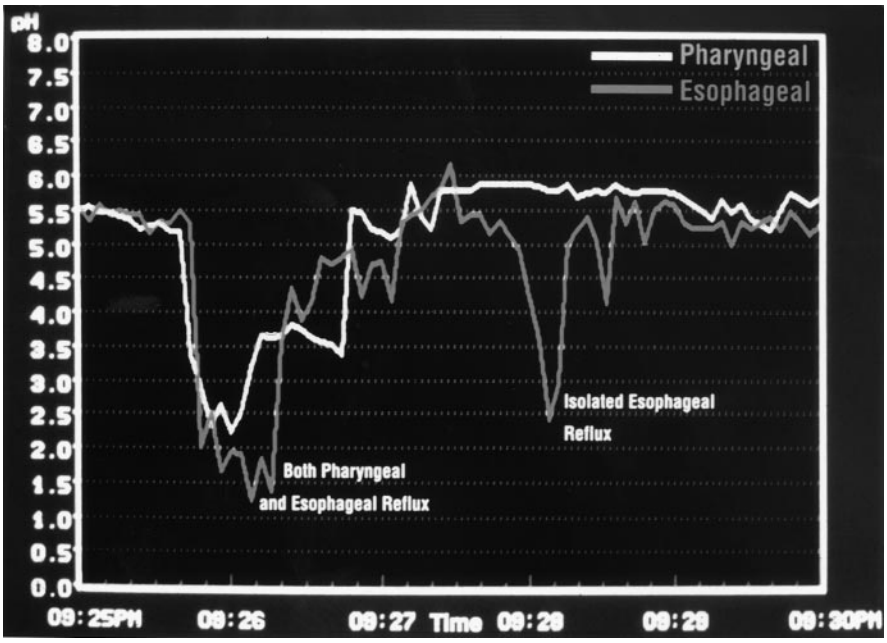

FIGURE 52–3. Example of an abnormal double-probe pH study. The *darker tracing* is the esophageal pH, and the lighter tracing is the pharyngeal pH. A combined esophageal and pharyngeal reflux event (pH < 4) is demonstrated at 9:26. An isolated esophageal reflux event is demonstrated at 9:28.

abnormalities such as Barrett's metaplasia (7%) may be high (JA Koufman and PC Belafsky, unpublished data).

Treatment

There are three levels of antireflux treatment: *level I*—dietary and lifestyle modification plus antacids, *level II*—level I plus use of a histamine H_2-receptor antagonist (such as cimetidine, ranitidine, or famotidine), and *level III*—antireflux surgery (eg, fundoplication) or proton pump inhibitor (PPI) therapy (eg, omeprazole, esomeprazole, lansoprazole, pantoprazole, or rabeprazole). The details of each of the three levels are listed in Table 52–6.

Clinical experience with LPR suggests that treatment must be individualized, with the level of treatment depending on the severity of the patient's condition. For many patients with LPR, level I or level II treatment is appropriate initial therapy, but both forms will fail in up to 35% of patients.[2,15,20] If level II treatment fails, level III treatment with a PPI is indicated. In patients who present with severe LPR or complications of LPR (laryngospasm, obstructing

TABLE 52–6. Treatment ("Levels") for Reflux Laryngitis

Level I—Antireflux therapy (ART)

- A. Dietary modification
  1. No eating or drinking within 3 hours of bedtime
  2. Avoid overeating or reclining right after meals
  3. No fried food; low-fat diet
  4. Avoid coffee, tea, chocolate, mints, and soda pop
  5. Avoid other caffeine-containing foods and beverages
  6. Avoid alcohol, especially in the evening
  7. Avoid other foods that cause you problems
- B. Lifestyle modification
  1. Elevate the head of the bed 4 to 6 inches
  2. Avoid wearing tight-fitting clothing or belts
  3. If you use tobacco, quit!
- C. Liquid antacids qid (1 tablespoon 1 hour after each meal and at bedtime)

Level II—Medication plus ART

- A. Level I (above), plus B or C (below)
- B. Initial treatment
  1. Histamine H_2-receptor antagonists bid
- C. Escalation for treatment failures
  1. Increase histamine H_2-receptor antagonist dose up to double-dose qid or
  2. Use a proton pump inhibitor (PPI)

Level III—Proton pump inhibitors or antireflux surgery

- A. Level I (above) minus antacids, plus B or C (below)
- B. Proton pump inhibitor bid (first dose in the morning, second at 5 pm; the duration of initial treatment should be 6 months; large patients may require larger doses. Patient symptoms should improve by 2 months.)
- C. Antireflux surgery (fundoplication)

granuloma, subglottic stenosis, etc), initial treatment with twice-daily PPI is indicated.

At present, the PPIs are the most effective antireflux medicine available because, unlike the H_2-antagonists, they can achieve total acid suppression.[20,21] Unlike treatment for GERD that usually responds to once-a-day dosing, complete resolution of tissue injury to the larynx may require higher doses of medication. Our approach to the patient with severe or complicated LPR is to begin therapy with twice-daily PPI. Research suggests that patient symptoms will achieve maximal relief by 2 months. Laryngeal reflux findings resolve more slowly, however, and may take 6 months or longer to reverse.[12] If patients are still symptomatic at 2 months, or if the laryngeal findings have not significantly improved by 6 months, repeat pH testing is indicated to ensure reasonably complete acid suppression (efficacy study). The failure of adequate acid suppression on twice-daily PPIs is significant, and a low threshold for obtaining an efficacy study on medication should be maintained.[22,23] In some patients who face a lifetime of antireflux treatment, or in patients who fail medical therapy, referral for a fundoplication is warranted.

Potentially Life-Threatening Manifestations of Laryngopharyngeal Reflux

Paroxysmal Laryngospasm Laryngospasm is an uncommon complaint, but patients who experience it usually are able to describe the event in vivid detail. If the clinician mimics severe inspiratory stridor, the patient will confirm that his or her breathing pattern during attacks was indeed similar. Laryngospasm is often paroxysmal and usually occurs without warning. For some patients, the attacks awake them from sleep; for others, the attacks occur during the day. The attacks may have a predictable pattern (eg, occurring postcibal or during exercise), and some patients are aware of a relationship between reflux and the attacks (others are not). Loughlin and Koufman have studied 12 patients with recurrent paroxysmal laryngospasm, 11 of whom had documented LPR by pH-metry and all of whom responded to treatment with PPIs by a cessation of laryngospastic episodes.[24]

Laryngeal Stenosis Excluding trauma, LPR is the primary cause of laryngeal stenosis, including subglottic stenosis and posterior laryngeal stenosis;[2,4,5,10] pH-metry-documented LPR has been found in 92% of patients.[2] Treatment with PPIs or fundoplication will result in subsequent decannulation of the vast majority of patients with such stenosis, in some cases without surgery.[2,10]

The traditional dichotomy between mature and immature stenoses probably represents an oversimplification. *Immature* implies that massive edema and granulation tissue are present and that the inflammatory process is ongoing; *mature* implies that acute inflammation has resolved and that the stenosis is composed of mature fibrotic tissue with thin (normal) overlying epithelium. Surgical attempts to correct immature stenoses usually fail unless the LPR is controlled. Conversely, mature stenoses usually can be corrected surgically. In reality, however, many cases are neither mature nor immature but somewhere in between. The same may also be true of many acquired laryngeal webs.

pH-metry and aggressive antireflux therapy should be used in all patients with laryngeal stenosis. As the database grows, this admonition will probably become dogma. Meanwhile, treatment with PPIs or fundoplication should be considered adjuncts to surgical therapy.

Laryngeal Carcinoma The risk factors for the development of laryngeal carcinoma include LPR.[7,8] Koufman reported a series of 31 consecutive patients with laryngeal carcinoma in whom abnormal reflux was documented in 84%, but only 58% were active smokers.[2] The relationship between LPR and malignant degeneration remains unproven, but the available pH-metry data suggest that most patients who develop laryngeal malignancy both smoke and have LPR. In addition, apparently premalignant lesions may resolve with appropriate antireflux therapy.[2]

The previously identified risk factors for laryngeal carcinoma, tobacco and ethanol, also strongly predispose one to reflux.[2] Tobacco and alcohol adversely influence almost all of the body's antireflux mechanisms; they delay gastric emptying, decrease LES pressure and esophageal motility, decrease mucosal resistance, and increase secretion of gastric acid. Routine pH-metry, followed by PPI treatment, is recommended for all patients with laryngeal neo-

plasia, with or without other risk factors for the development of carcinoma of the larynx.

Laryngopharyngeal Reflux Disease in Infants and Children

Laryngopharyngeal reflux is ubiquitous and pernicious in pediatric otolaryngology patients. The diagnosis may be particularly difficult to make because infants and children almost never complain of heartburn or other reflux symptoms. Laryngopharyngeal reflux has been clearly established to be associated with the development of childhood laryngeal and tracheal stenosis, as well as with reactive airway disorders (laryngospasm, asthma, sudden infant death syndrome, laryngomalacia, bronchopulmonary dysplasia, and aspiration pneumonia).[9,10,25,26]

A high index of suspicion is necessary for the diagnosis of LPR to be considered; currently, only prolonged pH-metry is diagnostic. Other tests, such as barium esophagography, radionuclide scanning, and the lipid-laden macrophage test, lack sufficient sensitivity and/or specificity to be of value in the majority of cases.

PEDIATRIC LARYNGITIS

Pediatric patients with laryngeal inflammation and edema present with one or more of the following symptoms: dysphonia, odynophonia, cough, dysphagia, odynophagia, stridor, and dyspnea. Airway obstruction from inflammatory laryngeal edema is more common in children than in adults owing to the small size of the pediatric larynx. Equivalent amounts of mucosal swelling may result in critical narrowing and obstruction in a child, while causing only minimal symptoms in an adult. Table 52–7 shows the effects of 1 mm of edema on the cross-sectional (subglottic) area of a small neonate, an average child, and an adult male. The magnitude of the difference between the effect in each explains why laryngeal inflammation is more often a life-threatening illness requiring airway management in infants and children than it is in adults.

TABLE 52–7. Effect of 1 mm of Edema on the Cross-sectional Area of the Subglottic Larynx in the Neonate, Child, and Adult (Area = πr^{2*})

	Neonate	*Child*	*Adult*
Normal			
Subglottic diameter (mm)	4	8	14
Subglottic radius (mm)	2	4	7
Subglottic area (mm^2)	12	48	147
Effect of 1 mm of edema			
Subglottic diameter (mm)	2	6	12
Subglottic radius (mm)	1	3	6
Subglottic area (mm^2)	3	27	108
Percent reduction of airway area	75	44	27

*For the sake of simplicity, for these calculations $\pi = 3$.

Laryngotracheitis (Croup)

Viral laryngotracheitis is the most common laryngeal inflammatory disorder of childhood. It is responsible for 15% of respiratory disease seen in pediatric practice. Usually, this condition is self-limited, occurs in children under the age of 3 years, and has a seasonal peak, with most cases occurring during the winter. Typically, for several days prior to presentation, the child's history is compatible with that of a viral upper respiratory infection with rhinitis, cough, and low-grade fever. When symptoms of hoarseness, dyspnea, stridor, and a barking cough develop, the diagnosis of laryngotracheitis is made. The characteristic cough gives laryngotracheitis its common name, croup. Parainfluenza viruses (types 1, 2, and 3) account for more than half of croup cases. Other viruses frequently implicated in the disorder include rhinovirus, respiratory syncytial virus, and adenovirus. Less common causes of laryngotracheitis are influenza, measles, mumps, pertussis, and chickenpox.[26]

When airway obstruction is caused by laryngotracheitis, the stridor is characteristically inspiratory, or biphasic. Although the diagnosis of laryngotracheitis is generally based on the history, examination of the larynx, although not necessary, shows erythematous and edematous mucosa with normal vocal fold mobility. Radiographs, which reveal a narrowing of the subglottic lumen, the "steeple sign," may be used to differentiate this condition from supraglottitis.

The need for inpatient hospitalization depends on the degree of airway obstruction. Treatment is

aimed at decreasing laryngeal edema and preventing stasis and crusting of secretions within the airway. Therapy usually includes hydration, humidification of inspired air, and treatments with nebulized racemic epinephrine. Antipyretics, decongestants, and parenteral corticosteroids are often administered. Although the value of corticosteroids remains controversial, many experienced clinicians use them because they believe that the anti-inflammatory effect can obviate the need for intubation when the airway is marginally adequate. Artificial airway support (eg, intubation) is necessary in a relatively small proportion of patients with laryngotracheitis. When needed, however, intubation should be carried out by experienced personnel, preferably in the operating room, where maximum airway control can be achieved.

Endoscopy with cultures of the airway surfaces and secretions should be considered for patients with atypical or severe laryngotracheitis, particularly those who cannot be extubated successfully. Secondary bacterial infection of the airway (membranous croup) is more serious and is usually suspected when the patient experiences high temperature spikes and exudative, purulent drainage. Bacterial tracheitis may ensue. Radiographically, the lumen of the upper airway will appear narrowed, shaggy, and irregular. The organisms most commonly involved are *Haemophilus influenzae*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and hemolytic streptococci. Antibiotic therapy is indicated and is directed at the causative microorganisms.

Supraglottitis (Epiglottitis)

Acute supraglottitis is a life-threatening infection of the supraglottic larynx traditionally caused by *H. influenzae* type B. Since childhood immunization against type B *H. influenzae* has become commonplace, however, the disease is significantly less prevalent, and epidemiologic data suggest that non–type B *H. influenzae* is more frequent among those vaccinated children who are affected.[27] Other organisms causing supraglottitis include *Streptococcus pyogenes, S. pneumoniae*, and *S. aureus*. The infection is a true medical emergency. Children aged 2 to 4 years are the most frequently affected group, and cases are more frequent in the winter and spring months. The illness begins rapidly over 2 to 6 hours with the onset of fever, sore throat, and inspiratory stridor. The voice tends to be muffled, and there is no barking cough, as in croup. As the supraglottic structures become more edematous, airway obstruction develops.

The child is generally ill-appearing, stridulous, sitting upright, and drooling because swallowing is painful. The diagnosis is usually based purely on the history and clinical findings. Examination of the epiglottis (in the emergency room) may precipitate airway obstruction and thus is not recommended. Lateral soft tissue radiographs may reveal the classic "thumb sign" of the edematous epiglottis with a dilated hypopharynx. Occasionally, the epiglottis itself is not enlarged, but the supraglottic region still appears hazy and indistinct owing to edema of other supraglottic structures. In severe cases, treatment should not be delayed to obtain radiographs. If radiographs are deemed necessary, the study should be carried out in the presence of personnel capable of immediately intubating the patient should airway obstruction occur.

The child with suspected epiglottitis should be taken to the operating room immediately to establish the diagnosis and secure an airway. The child is transported to the operating room by the parents, an otolaryngologist, and an anesthesiologist. Direct laryngoscopy usually will show the epiglottis to be very swollen and cherry red, as are the aryepiglottic folds and the false vocal folds. The true vocal folds and subglottis typically appear to be normal or to be only minimally involved.

Treatment is directed at airway maintenance and then toward providing antimicrobial and supportive care. Drawing blood, starting intravenous lines, obtaining a rectal temperature, or otherwise disturbing the patient should be postponed until the airway is secured.

After the child is anesthetized and the diagnosis is made, the child should be orally intubated to secure the airway. The oral endotracheal tube can then be converted to a nasotracheal tube, with direct visualization of the glottis as the orotracheal tube is removed. Instruments necessary for rigid bronchoscopy and tracheostomy should be available and ready in the operating room in case the airway is lost before intubation.[28] In institutions without a highly skilled pediatric intensive care staff, a tracheostomy may be preferable to endotracheal intubation. It is easier to secure and to re-establish the airway if a tracheostomy tube is in place.[29]

Cultures of the epiglottis and blood are obtained after the airway is secured. Empirically,

antimicrobial therapy is initiated against *H. influenzae* and group A streptococcus and classically consists of a second- or third-generation cephalosporin (cefuroxime, cefotaxime, or ceftriaxone). Ampicillin/sulbactam and trimethoprim/sulfamethoxazole are alternatives. Chloramphenicol is highly effective but should not be used because of the availability of less toxic alternative agents. Extubation is usually possible after 48 to 72 hours, at which time the edema has subsided sufficiently to allow an air leak around the endotracheal tube. Transnasal fiberoptic laryngoscopy is the most reliable and most commonly employed technique to ensure resolution of the edema before extubation. Differentiating acute epiglottitis from laryngotracheitis is not always easy, but it is of paramount importance. Some of the differentiating signs and symptoms are shown in Table 52–8.

Diphtheria

Worldwide, diphtheria is an uncommon laryngeal infection, although a report from India suggests that outbreaks still occur there.[30] Laryngeal diphtheria is caused by *Corynebacterium diphtheriae* and generally affects children over the age of 5 years. A febrile illness of slow onset associated with sore throat and hoarseness is then followed by progressive airway obstruction.

The microorganism causes an inflammatory response in the mucous membranes, which results in a thick, grayish-green, plaque-like membranous exudate over the tonsils, pharynx, and laryngeal structures. Characteristically, the exudate is difficult to dislodge and bleeds when removed. The diagnosis requires that the clinician have a high index of suspicion confirmed by observing the typical oropharyngeal findings. Cultures and smears are obtained for confirmation.

Treatment consists of establishing a safe airway via a tracheostomy (intubation is contraindicated because it may dislodge a portion of the plaque and cause airway obstruction) and administering diphtheria antitoxin and penicillin or erythromycin to eradicate the microorganisms. Mortality results largely from the neuropathies that develop secondary to the diphtheria toxin. Even in the patient immunized against diphtheria, the disease may still occur but will tend to be mild.

Spasmodic Croup

Spasmodic croup, or "false croup," is a noninfectious form of laryngeal inflammation associated with a mild, chronic-intermittent, croup-like pattern. Spasmodic croup generally affects children 1 to 4 years of age and may be associated with a mild respiratory tract infection but not with a febrile illness. An

TABLE 52–8. Some of the Distinguishing Characteristics of Laryngotracheitis (Croup) and Supraglottitis (Epiglottitis)

Feature	*Croup*	*Epiglottitis*
Age	Less than 3 y	Over 3 y
Onset	Gradual (d)	Rapid (h)
Cough	Barky	None
Posture	Supine	Sitting
Drooling	No	Yes
Radiograph	Steeple sign, narrowed subglottis	Thumb sign, enlarged epiglottis, dilated hypopharynx
Etiology	Viral	Bacterial
Treatment	Supportive (croup tent, corticosteroids)	Airway management (intubation or tracheostomy) and antibiotics

affected child generally awakes at night with a barking cough, stridor, and mild dyspnea of sudden onset. Nocturnal attacks may occur as isolated events or recur over two to three nights, but generally the child is asymptomatic during the day.

Typically, each episode subsides spontaneously, within a few hours. Examination may show mildly erythematous laryngeal mucosa, with boggy mucosal edema present in the subglottis. Humidified oxygen is generally recommended as the principal treatment. Awareness of spasmodic croup is important in helping to differentiate it from viral laryngotracheitis.

Owing to the pattern of the affliction, allergy was once assumed to be the underlying cause of spasmodic croup. Currently, although the etiology of spasmodic croup remains uncertain, recent evidence suggests that extraesophageal reflux may frequently be the cause.[9] When spasmodic croup is suspected, 24-hour pH monitoring may be diagnostic. If, after a positive pH study, the patient's condition is alleviated by antireflux therapy, it may be concluded appropriately that reflux was the cause.[25]

Traumatic Laryngitis

Traumatic laryngitis is most commonly caused by vocal abuse, such as excessive shouting or yelling, but it also can result from persistent coughing, inhalation of toxic fumes, or direct endolaryngeal injury. Such patients present with varying degrees of hoarseness and odynophonia. The mucosa of the true vocal folds is hyperemic from dilated vessels present on the superior and free surfaces. Edema within Reinke's space develops and submucosal hemorrhage may occur. This form of laryngitis is self-limited and subsides within a few days when treated with voice conservation and humidification.

Vocal nodules may become chronic in children who continually abuse their voices. Nevertheless, for two reasons, surgical treatment is rarely indicated: first, it is difficult to modify the vocal behaviors of such children, and when such nodules are removed, they usually promptly recur. Second, the nodules resolve spontaneously in most children before puberty. One notable exception is female cheerleaders, who may still have nodules in adulthood.

ACUTE LARYNGEAL INFECTIONS OF ADULTS

Viral Laryngitis

Laryngitis Owing to Viral Upper Respiratory Infection Acute viral laryngitis in adults is common and is generally less serious than in children because of the larger adult airway, which is able to accommodate more swelling without compromise of the airway. The typical type of acute laryngitis seen in adults is almost always viral. Influenza and parainfluenza viruses, rhinoviruses, and adenoviruses are the most common causative agents, although many other viruses have been implicated. Adult patients with viral laryngitis do not usually seek medical attention unless they are professional voice users, in which case, the laryngitis may be of great significance to the patient's ability to earn a living. Such patients present with symptoms of a generalized viral syndrome (low-grade fever, malaise, rhinitis) and hoarseness. The dysphonia is characterized by voice breaks, episodic aphonia, and a lowering of pitch. Often a hoarse cough is present.

Characteristically, the laryngeal mucosa is diffusely erythematous and edematous, especially over the true vocal folds. The disease is self-limited and is best treated symptomatically with humidification, voice rest, hydration, cough suppressants, and expectorants. Antibiotic treatment is not usually necessary. In the professional vocalist, corticosteroids are sometimes used to reduce the vocal fold edema, particularly during the recovery phase. However, the physician's administration of such anti-inflammatory medications does not imply that the vocalist with laryngitis can or should perform.

Laryngotracheitis Adult infectious croup is uncommon; when it does occur, it is quite similar to the laryngotracheitis seen in children. The viral prodrome lasts 1 to 7 days, followed by the development of a barking cough and sometimes inspiratory stridor. Throat cultures are usually negative. On fiber-optic laryngoscopy, adults with laryngotracheitis demonstrate subglottic edema and erythema. It has been reported that a relatively large proportion of adults with this syndrome require airway intervention.[31]

Herpes Simplex Herpes simplex infection is ubiquitous, may affect any age group, and, uncom-

monly, may infect the larynx. Most cases of herpetic laryngitis have been reported in very young or debilitated patients. At the time of delivery, a neonate passing through the birth canal may contract genital herpes from a mother with active disease. Subsequent herpes infection in the infant may involve the upper airway and, if the larynx is involved, may cause acute airway obstruction.[32] Therefore, when a child develops stridor in the neonatal period, herpetic infection should be one of the diagnoses considered. Today, laryngeal herpes is most commonly seen in the immunocompromised patient, although herpetic epiglottic infection, causing airway obstruction in otherwise healthy adults, has been reported.[33]

Herpes infection should be suspected whenever a patient presents with a painful vesicular mucosal eruption. After the vesicles rupture, ulceration and tissue necrosis may occur, and the surrounding inflammatory response may be intense. The diagnosis of a primary herpetic infection may be made by serologic testing; however, swab, culture, and polymerase chain reaction detection of viral deoxyribonucleic acid (DNA) are the most reliable diagnostic tests. Symptomatic treatment depends on the site of involvement; topical or systemic acyclovir, or another specific antiherpetic medication, may hasten recovery.

Bacterial Laryngeal Infections

Bacterial laryngitis may develop secondary to purulent rhinosinusitis or tracheobronchitis and generally is less commonly diagnosed in adults than in children. Supraglottic involvement, as in pediatric patients, is the most common form of bacterial laryngitis.

Supraglottitis in the Adult In adults, supraglottitis is manifest by fever, sore throat, a muffled voice, dysphagia, and odynophagia. The onset of symptoms prior to presentation is typically longer than that seen in children (usually more than 24 hours). The diagnosis of supraglottitis is made by observing the swollen, bright-red epiglottis and/or supraglottic structures by fiber-optic laryngoscopy or a swollen epiglottis and dilated hypopharynx on a lateral neck radiograph.

Supraglottitis in adults has a slightly different clinical picture. In adults, the infectious etiology is less likely *Haemophilus* and more likely group A streptococcus. The clinical course appears less severe, with less seasonal variation and airway compromise. Although one must never be complacent with management of the airway, conservative airway management in an intensive care setting is often successful, and tracheostomy is rarely required.[34,35] Conservative measures include oxygenation, humidification, hydration, corticosteroids, and intravenous antibiotics.

In adults, there appear to be two relatively useful clinical predictors of the need to establish an airway. Patients who present to the emergency department less than 8 hours after the onset of a sore throat and patients who are drooling at presentation (in preference to swallowing because of severe odynophagia) almost always require airway intervention.[36]

Laryngeal Abscess Laryngeal abscess is a complication of perichondritis and a recognized sequela of bacterial laryngeal infection. It is more common in adults than in children, even though epiglottic abscess occurs most often as a complication of supraglottitis. Often the adult patient who develops a laryngeal abscess has a preexisting, predisposing laryngeal condition, such as prior irradiation for cancer.

In the preantibiotic era, typhoid fever was a frequent cause and was usually fatal. Other less frequently associated infections include measles, scarlet fever, erysipelas, gonorrhea, syphilis, tuberculosis, and diphtheria. Laryngeal abscess may also be a complication of prolonged nasogastric or endotracheal intubation.[37]

The symptoms of laryngeal abscess are similar to those of supraglottitis. Localizing tenderness to palpation over the laryngeal framework is its hallmark. Fluctuance in the anterior neck, although uncommon, denotes necrosis of the thyroid cartilage. The diagnosis of laryngeal abscess may be made by computed tomographic scanning of the larynx and by fiber-optic or direct laryngoscopy. No current radiographic method accurately predicts the condition of the laryngeal cartilages unless there is obvious widespread destruction.

When abscess is suspected and the patient's airway is marginal, a tracheostomy should be performed under local anesthesia prior to direct laryngoscopy. If the airway is not compromised, direct laryngoscopy, with laser-assisted incision and drainage of the abscess, may suffice as initial treat-

ment. Granular mucosa should be removed, and an attempt should be made to determine if necrotic cartilage is exposed within the endolarynx. Infection of the laryngeal framework can lead to severe laryngeal stenosis.

Gram stain and bacteriologic cultures of the abscess contents or necrotic debris should be obtained routinely, and the results should influence the choice of antibiotic. In cases not complicated by necrotic cartilage, conservative management is usually successful. When necrotic cartilage is present, the combination of surgical débridement, prolonged parenteral antibiotic therapy, and hyperbaric oxygen therapy may enhance recovery and preserve laryngeal function. When all other alternatives have failed, laryngectomy may be considered.

Gonorrhea Gonorrhea is a sexually transmitted genital and sometimes oropharyngeal infection caused by the bacteria *Neisseria gonorrhoeae*. The genital infection may be asymptomatic, so carriers can unknowingly infect their sexual partners. Pharyngeal gonorrhea is transmitted by orogenital contact and is manifested as a diffuse and severe exudative pharyngitis that may directly or indirectly involve the larynx. The infection may produce a pseudomembranous inflammation, which may be confused with diphtheria or streptococcal pharyngitis. Diagnosis is made by culture and identification of the *N. gonorrhoeae* microorganism from swabs of the pharynx (and of the genitalia). Today, most cases of laryngopharyngeal gonorrhea are treated with a single intramuscular dose of ceftriaxone or a course of oral cefixime.

CHRONIC INFECTIONS (GRANULOMATOUS DISEASES)

Granulomatous infections (eg, tuberculosis and syphilis) were recognized long ago and continued to be common afflictions throughout the world in the preantibiotic era. During the twentieth century, these conditions appeared to be on the decline, and some of them had all but disappeared until relatively recently. With the advent of effective anticancer chemotherapy, organ transplantation, and human immunodeficiency virus (HIV) infection, it was discovered that the microorganisms causing many of the granulomatous diseases thrive in the immunocompromised host.

Granulomas are nodular histopathologic lesions characterized by a central mass of epithelioid cells and giant cells surrounded by lymphocytes and other inflammatory cells. Central necrosis (caseation) is seen in many granulomatous conditions and is conspicuously absent in others.

Unlike children, adults have many chronic forms of granulomatous laryngitis, and these may go unrecognized for many years. Chronic granulomatous conditions involving the larynx may be attributable to numerous different types of microorganisms (bacteria, fungi), to an autoimmune process, or to an idiopathic cause. Although not included in this section, some parasitic infections may also cause laryngeal granulomas.

Granulomatous lesions of the larynx may appear as smooth, diffuse swellings of the affected tissues; diffuse cobblestone mucosa; well-defined, discrete nodules; or an ulcerating inflammatory mass. Sometimes, granulomatous diseases mimic laryngeal carcinoma, so the necessity of biopsy is obvious. However, even when the suspicion of malignancy is low, biopsy is frequently necessary to make a diagnosis. Some of the distinguishing features of the most frequent laryngeal granulomatous conditions are shown in Table 52–9.

Granulomatous Diseases Caused by Bacteria

Tuberculosis In 1900, laryngeal tuberculosis was very common, occurring in approximately half of patients with advanced pulmonary disease. With the discovery of effective antituberculous drugs, the incidence of both pulmonary and laryngeal tuberculosis rapidly declined. Nevertheless, tuberculous laryngitis remains one of the most common granulomatous diseases of the larynx, and, today, it is frequently unassociated with advanced active pulmonary disease. In 1993, Ramadan et al reported 16 patients with laryngeal tuberculosis, only 5 of whom had active cavitary lung disease.[38] Because persons with laryngeal tuberculosis often have no simultaneous or previous pulmonary involvement, the clinical presentation may often be similar to that of a neoplastic process.[39] A biopsy is necessary to obtain an accurate diagnosis.

Patients with laryngeal tuberculosis commonly present in their third to fourth decade of life with varying symptoms, including hoarseness, odynopha-

TABLE 52–9. Some Distinguishing Characteristics of Granulomatous Conditions That Commonly Affect the Larynx

Tuberculosis	Posterior third of larynx involved
Leprosy	Supraglottic involvement
Scleroma	Catarrhal stage; Mikulicz's cells
Actinomycosis	Draining sinuses; sulfur granules
Syphilis	Painless ulcers; positive syphilis serology
Candidiasis	Leukoplakia-like lesions; identifiable on Gram stain
Blastomycosis	Painless ulcers; microabscesses
Histoplasmosis	Anterior laryngeal involvement; pseudocarcinoma
Coccidiomycosis	Painless abscesses; spores seen on histology
Sarcoidosis	Supraglottic swelling, nodules, granulomas
Wegener's granulomatosis	Subglottic involvement; necrotizing vasculitis; pulmonary and/or renal involvement

gia, and otalgia. Respiratory obstruction may develop in later stages of the disease, and approximately one-quarter of patients with laryngeal tuberculosis have airway obstruction at the time of their initial presentation.

Laryngeal examination may reveal diffuse edema and hyperemic, hypertrophic mucosa involving the posterior third of the larynx, or the process may be diffuse, nodular, and ulcerative. In the nodular, ulcerative (later) stages, tuberculosis may easily be confused with laryngeal carcinoma.

It is a misconception that interarytenoid (posterior commissure) involvement, alone, is the most commonly observed pattern.[40] In the modern era, the true vocal folds appear to be the most commonly involved site.[41]

The diagnosis is made by demonstrating typical caseating granulomas on histology and acid-fast staining microorganisms by smear and/or culture. Treatment with antituberculous drugs usually resolves both the pulmonary and the laryngeal disease. If tuberculous laryngitis is left untreated, cicatricial laryngeal stenosis with vocal fold fixation may develop, necessitating surgical correction or tracheostomy.

Leprosy (Hansen's Disease) Leprosy is caused by infection with the bacillus *Mycobacterium leprae*. The disease usually affects the skin and peripheral nerves but may affect other organ systems. Cutaneous nodules may become disfiguring and will eventually cause peripheral neurologic damage and muscular weakness. In 2000, 738,284 cases of leprosy were identified worldwide. In 1999, 108 cases were reported in the United States. Over one-third of the global cases are limited to India.[42]

The larynx is involved in approximately one half of patients with leprosy, and it most consistently involves the epiglottis. As the disease progresses to involve the glottis, hoarseness develops, and later destruction of the cartilaginous laryngeal framework may occur, as well as lepromatous nerve involvement, which may cause laryngeal paralysis.[43,44] With lepromatous laryngitis, odynophagia, odynophonia, and referred otalgia are uncommon, but they do occur.

In patients with lepromatous leprosy, direct laryngoscopy typically reveals a nodular, edematous supraglottis with ulceration. Diagnosis is made by biopsy, which reveals a chronic inflammatory cell infiltrate with foamy leprous cells that contain the bacillus *M. leprae* (Hansen's bacillus). Nasal smears for the intracellular microorganisms may be diagnostic. Treatment consists of the long-term use of diaminodiphenylsulfone (dapsone). Tracheostomy may be required if laryngeal stenosis develops.

Scleroma Scleroma, previously called "rhinoscleroma" because of its predilection for the nose, is a chronic infection caused by *Klebsiella rhinoscleromatis*. Scleroma remains endemic today in Europe, Mexico, Central America, South America, and Egypt. Most cases found in the United States occur in recent immigrants.[45–47]

The disease primarily involves the mucosa and submucosa of the nasal cavity but may also involve the larynx, especially the subglottic region, and the trachea. Laryngeal involvement has been reported in approximately 15 to 80% of cases.[48]

The disease has three distinct stages: (1) *the catarrhal stage,* characterized by persistent puru-

lent rhinorrhea, with nasal crusting and obstruction; (2) *the granulomatous stage,* characterized by small, painless granulomatous nodules within the upper respiratory tract, including the larynx; and (3) *the sclerotic stage,* in which the glottis and subglottis are usually involved and hoarseness and respiratory obstruction may develop. The progression through these three stages usually takes many years.

The diagnosis is made by isolating the microorganism from the tissues, although positive complement fixation and agglutination tests are highly suggestive. Foamy vacuolated histiocytes (Mikulicz's cells) and bloated plasma cells with red birefringent inclusions (Russell bodies) are seen histologically.

Treatment consists of intravenous aminoglycosides, tetracycline, or cephalosporins. Laryngeal dilatation, endoscopic resection, and tracheostomy may be required during the sclerotic phase. Untreated rhinoscleroma may cause death owing to airway obstruction. Progression of laryngeal scleroma to laryngeal carcinoma has been suggested in some affected persons.[49]

Actinomycosis Cervicofacial actinomycosis is a chronic suppurative disease caused by the anaerobic bacterium *Actinomyces bovis* or *Actinomyces israelii.* Initial involvement of the cervical or mandibular region leads first to paralaryngeal and then to laryngeal disease. Pain is the most common initial manifestation, followed by hoarseness, cough, and, eventually, airway obstruction.

The larynx appears diffusely erythematous and swollen with draining sinuses; its consistency is firm and woody.[50] Diagnosis is made by identifying the typical "sulfur granules" in biopsy material and by culturing the microorganism. Long-term therapy with penicillin or tetracycline is effective. Stenosis and laryngeal fixation secondary to deep ulcerations and chondritis may develop if the disease is left untreated. Laryngeal dilatation, arytenoidectomy, or tracheostomy may be required.

Nocardia species of the *Actinomyces* family are soil saprophytes that are widely distributed throughout the world. Like other *Actinomyces*, *Nocardia* may infect humans by inhalation or through a break in the skin. Nocardiosis is characterized by diffuse microabscesses that, on histologic examination, show a neutrophilic predominance; sulfur granules are atypical. Aerodigestive tract involvement is common. The diagnosis is made by culture and isolation of the *Nocardia* microorganism, and treatment is with systemic sulfisoxazole.

Tularemia Tularemia, also called "rabbit fever" and "deer fly fever," is caused by the bacterium *Francisella tularensis.* It is found only in the northern hemisphere (Europe, Asia, and North America). Most cases occur from contact with rabbits or squirrels, but many other wild and domesticated animals have been reported to carry the disease. Transmission to humans can also occur by a bite from a tick or a deer fly, which are the intermediate hosts and insect vectors.

In humans, the most common portal of entry is through the skin or mucous membranes. Headache, myalgia, and malaise are common symptoms. Oropharyngeal tularemia, which occurs in approximately 1% of cases, produces an intense exudative pharyngitis associated with lymphadenopathy.[51] Diagnosis is made by serologic tests since the microorganisms are difficult to identify on culture or histologic examination. Treatment is with streptomycin or gentamicin for 7 to 10 days.

Glanders At one time in history, glanders was "the plague of horses," and, secondarily, it affected man. Today, glanders is rare around the world but still occurs in Asia, Africa, and South America. The disease is caused by infection by the bacterial organism *Pseudomonas mallei* (*Burkholderia mallei*). Transmission is still by contact with an infected horse or by inhalation or inoculation of contaminated material, and infected humans are almost exclusively horse handlers.[52]

Infection by inoculation of broken skin causes systemic infection characterized by fever, malaise, prostration, pneumonia, and lymphadenopathy. Truly systemic (septicemic) involvement may be fatal. Infection by inhalation produces an intense, ulcerative mucopurulent granulomatous reaction in the mucous membranes of the aerodigestive tract and pneumonia. Treatment is with sulfonamides.

Syphilis Syphilis is a sexually transmitted spirochetal infection caused by *Treponema pallidum.* Syphilitic chancres do not usually involve the larynx, and, most commonly, the larynx becomes involved during the secondary and tertiary stages. However, tertiary syphilis may not develop until years after the

initial infection. Diffuse erythematous papules, painless superficial ulcers, and cervical lymphadenopathy are seen during the secondary stage and generally clear without treatment within several weeks. Gumma formation during the tertiary stage can lead to laryngeal fibrosis, chondritis, and stenosis.

The typical laryngeal findings are diffuse erythema and edema, with necrotic ulcers that mimic carcinoma or tuberculous laryngitis. Serologic tests for syphilis are diagnostic, and a lumbar puncture should be performed to rule out central nervous system involvement. Penicillin is still the treatment of choice.[53]

Although very rare, congenital syphilitic laryngitis can occur in infants born to mothers with syphilis. This diagnosis should be considered in the differential diagnosis of neonates with laryngeal stenosis. Treatment should be instituted if there is serologic evidence of active disease.[54]

Mycotic (Fungal) Granulomatous Diseases

Candidiasis Although laryngeal candidiasis (usually infection by species, *Candida albicans*) is infrequently reported, its occurrence is not rare in laryngologic practice. Laryngeal candidiasis virtually never occurs in the absence of identifiable (local and/or systemic) predisposing factors, but it does sometimes occur in reasonably healthy patients who are not severely immunocompromised.

Among the risk factors for development of laryngeal candidiasis are the use of corticosteroids and broad-spectrum antibiotics, diabetes, burns, alcoholism, endotracheal intubation, and previous (viral or bacterial) laryngeal infection. *Candida* laryngotracheitis, for example, may occur as a complication of treatment in previously healthy children hospitalized for laryngotracheitis and treated with systemic corticosteroids and broad-spectrum antibiotics.[55]

Cases of laryngeal *Candida* infection may occur in ambulatory patients as well. A relatively benign, isolated form of laryngeal candidiasis (without the involvement of any other contiguous anatomic structures) occurs in some patients who use corticosteroid inhalers. Typically, such patients have used them on a daily basis for years. (The most common indication for the chronic use of corticosteroid inhalers is asthma.) This form of isolated laryngeal candidiasis has a distinctive appearance: intense, diffuse laryngeal erythema with an irregular, friable, white exudate (occurring most notably on the true vocal folds). The infection is superficial, and no ulceration or necrosis is seen (Figure 52–4). Patients with this particular condition usually complain of hoarseness but no other symptoms. The diagnosis is usually made on the basis of the history and clinical findings. A 2-week course of treatment with nystatin (swish and swallow) or an oral antifungal agent, such as ketoconazole or fluconazole, is effective treatment for most patients with this type of *Candida* laryngitis; however, in some cases, treatment must be continued for several weeks to eradicate the disease. Candidal esophagitis should be considered in a patient with laryngeal involvement and dysphagia.

Severe immunosuppression (owing to chemotherapy or AIDS) is more often associated with the development of invasive laryngeal candidiasis, and, as expected in such patients, the infection is often more serious and sometimes can be life-

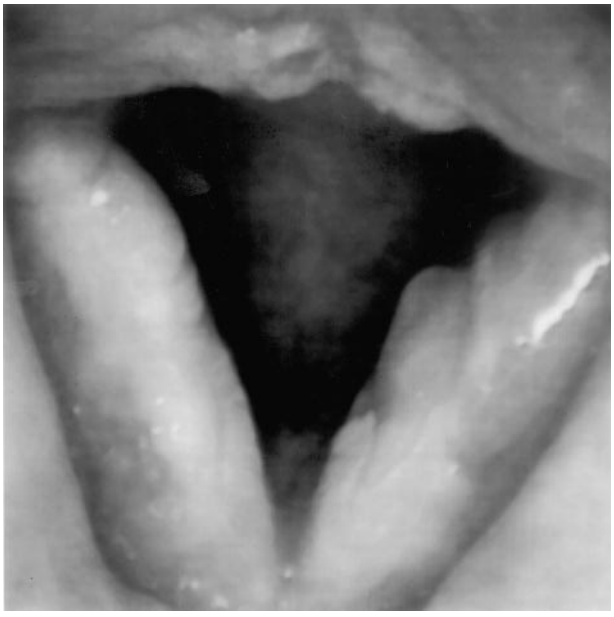

FIGURE 52–4. Candidiasis of the larynx. This is the appearance of the larynx of a 45-year-old woman with lifelong asthma who had been using corticosteroid inhalers for many years. This appearance is different from that usually seen in immunocompromised patients, the latter group having a more invasive, necrotizing form of candidiasis.

threatening owing to bleeding or airway obstruction. In the immunocompromised patient, laryngeal candidiasis may be caused by local aerodigestive tract infection, which can subsequently give rise to widespread systemic candidiasis. The converse, secondary involvement of the larynx by disseminated candidiasis, is uncommon. However, infection is rarely confined to the larynx but usually involves adjacent areas of the airway and esophagus as well.

Sometimes the esophagus is involved but, initially, not the larynx. When a patient presents with dysphagia and barium esophagography or transnasal esophagoscopy reveals *Candida* esophagitis, the clinician should suspect that the patient has AIDS. Indeed, aerodigestive tract candidiasis may be the first presenting manifestation of AIDS.

Invasive *Candida* laryngitis in the immunocompromised host produces painful, ulcerative lesions and deep tissue necrosis and may progress rapidly. In addition to hoarseness, patients with this type of infection complain of sore throat, dysphagia, and odynophagia. For the diagnosis to be made, it must be suspected. Unlike other fungi, *Candida* species can easily be identified on Gram stain.[56] Confirmation of the diagnosis is made by the histopathology and culture of biopsied tissue. Invasive laryngeal candidiasis is treated with parenteral amphotericin B and, when necessary, airway support.[57]

Blastomycosis North American blastomycosis is a chronic pulmonary infection caused by the fungus *Blastomyces dermatitidis*. Laryngeal involvement occurs in 2 to 5% of cases.[56,58] The microorganism is generally found in damp areas where decaying wood is present. Its distribution in the United States and Canada is concentrated around the Great Lakes and along the Mississippi, Ohio, and St. Lawrence rivers. Primary laryngeal blastomycosis has been reported.[59]

Patients typically present with multiorgan systemic involvement and severe hoarseness and cough when the larynx is involved. The microorganism produces erythematous, granular, mucosal lesions in the larynx, which progress to small, painless abscesses and ulcerations. Histologically, caseous necrosis with abundant acute inflammatory cells and microabscesses are seen, as well as giant cells in the surrounding tissue. Pseudoepitheliomatous hyperplasia is a characteristic change seen in the epithelial layer. The fungus in yeast form may be seen in the region of the microabscesses and is periodic acid–Schiff positive. Treatment is with long-term oral itraconazole, with amphotericin B being reserved for very severe or recalcitrant cases. In the absence of treatment, progressive fibrosis with vocal fold fixation develops, as do pharyngocutaneous fistulaes.

Histoplasmosis Histoplasmosis is a systemic mycotic disease caused by *Histoplasma capsulatum* and may involve the larynx (Figure 52–5). Nodular superficial granulomas that may ulcerate and become painful involve the anterior portions of the larynx and epiglottis. Esophageal involvement may occur (Figure 52–6). Histologic examination shows granulation tissue composed of plasma cells, microorganism-laden macrophages, lymphocytes, and giant cells, which may be confused with the granulation tissue of carcinoma or tuberculosis. Diagnosis is made by culture and the complement fixation test.

Amphotericin B is the treatment of choice. Laryngeal stenosis may develop when extensive ulceration leads to chondritis. In this instance, laryngeal dilatation, arytenoidectomy, or tracheostomy may be required to provide a safe airway.

Coccidioidomycosis Coccidioidomycosis, also called "desert fever" (or "San Joaquin Valley fever" in the United States), is caused by the microorganism

FIGURE 52–5. Histoplasmosis of the larynx. Note pedunculated lesion of the left true vocal fold.

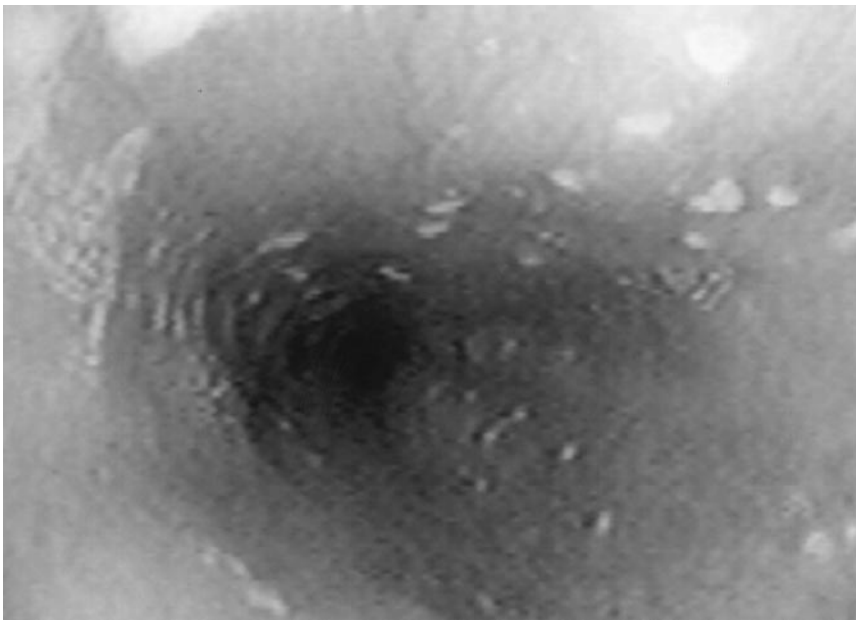

FIGURE 52–6. Diffuse esophageal histoplasmosis.

Coccidioides immitis, which is found in desert soil. It is primarily a pulmonary fungal infection that is endemic to the southwestern United States, Mexico, and central South America. Reportedly, 60% of people with this infection are asymptomatic; 40% develop a flu-like illness, and among those, 0.5% develop a systemic, disseminated, more severe form of the disease. Patients with the disseminated form may develop hoarseness, cough, and airway obstruction owing to laryngeal coccidioidomycosis.[60] Disseminated extrapulmonary disease is far more common in males and in blacks.[61]

Laryngeal disease usually develops during the acute phase of the primary infection. Laryngeal involvement can, however, develop in patients who have had granulomatous lung disease for months or years. In addition to the laryngeal findings of intense, diffuse laryngeal erythema (with or without focal ulceration), most patients with *C. immitis* have cervical lymphadenopathy. Histology reveals caseating granulomas with multinucleated giant cells and pathognomonic, double-walled endospores. The diagnosis is made by serologic testing and biopsy of affected tissue. Treatment is with amphotericin B. When death occurs, it is usually owing to meningeal involvement.

Aspergillosis Aspergillosis is generally an infection of immunocompromised patients, and respiratory tract involvement is common. When the larynx is involved, patients complain of hoarseness, dysphagia, and, sometimes, symptoms of airway obstruction.

In the immunocompromised patient, *Aspergillus* infection is usually necrotizing, invasive, and associated with a poor prognosis. Despite aggressive antifungal treatment with amphotericin B and attempted wide surgical excision (including laryngectomy), most such patients with this infection die of progressive disease.[62]

Sporotrichosis Sporotrichosis, an uncommon fungal infection of the skin or airway, is caused by *Sporothrix schenckii* and occurs worldwide. The causative fungus is most commonly found in sphagnum moss and wood. People who work with wood usually get the cutaneous form of sporotrichosis, whereas most cases of laryngeal sporotrichosis occur in people working with the moss.[63]

The more common cutaneous form of sporotrichosis causes granulomas in the subcutaneous layer of the skin and in regional lymph nodes. If the mucous membranes of the upper airway are damaged or abraded for any reason, inhalation of the fungus may result in laryngopharyngeal infection. Hoarseness and cough are the most common symptoms, and the lesions appear granulomatous. Diagnosis is made by biopsy and by culturing the microorganism. Oral potassium iodide is sufficient

treatment for cases with superficial involvement; deep tissue involvement requires a course of amphotericin B therapy.[64]

Idiopathic Granulomatous Diseases

Sarcoidosis Sarcoidosis is a slowly progressive, rarely fatal, systemic granulomatous disease of unknown cause. The disease afflicts blacks 10 times more commonly than whites. The lungs and skin are most commonly involved, and laryngeal sarcoidosis occurs in 1 to 5% of cases.[65,66] When the skin of the nasal rim is affected, upper respiratory sarcoidosis involvement is seen in approximately 75% of cases[67] (Figure 52–7). Rarely, the larynx may be involved without clinical or radiographic evidence of lung involvement.[68]

Laryngeal sarcoid usually involves the supraglottic larynx and sometimes the subglottis but typically spares the true vocal folds. Characteristically, the entire supraglottis appears pale pink and massively edematous, sometimes obscuring visualization of the vocal folds. The turban-like appearance of the epiglottis is virtually pathognomonic.[65] Less commonly, some laryngeal sarcoidosis patients present with a few discrete, sometimes hemorrhagic, nodules (up to 1 cm in diameter) on the epiglottis or other supraglottic structures.

Laryngeal sarcoidosis is a diagnosis of exclusion based primarily on finding noncaseating granulomas and diffuse edema with miliary nodules involving mainly the supraglottic structures and on excluding tuberculosis and other fungal diseases. Patients may present with hoarseness and varying degrees of airway obstruction; however, ulcerative lesions and pain are rare.

The use of systemic and intralesional corticosteroids generally results in improvement or apparent resolution of the lesions. In severe cases, however, endoscopic dilatation and laser resection of involved supraglottic tissues, or tracheostomy, may be necessary.

Wegener's Granulomatosis Wegener's granulomatosis is a systemic disease of unknown etiology, characterized by necrotizing granuloma with vasculitis involving the upper respiratory tract, lungs, and kidneys. On presentation, its laryngeal involvement may resemble acute laryngitis, but the eventual development of granulomatous ulcers throughout the larynx may lead the clinician to suspect the diagnosis. Subglottic stenosis occurs in approximately 20% of cases and can lead to significant airway obstruction, requiring tracheostomy and surgical correction of the stenosis.[69] Diagnosis is based on typical histologic findings of necrotizing granulomas and vasculitis. The anticytoplasmic autoantibody test (C-ANCA) is highly specific for Wegener's granulomatosis. Recommended treatment includes cyclophosphamide with corticosteroids.

FIGURE 52–7. Sarcoidosis of the nasal rim.

ALLERGIC, IMMUNE, AND IDIOPATHIC DISORDERS

Hypersensitivity Reactions

The term *hypersensitivity* implies an overzealous response of the immune system to an antigenic stimulus. Hypersensitivity reactions include conditions such as allergic rhinitis, contact dermatitis, and urticaria, but these conditions do not produce life-threatening, obstructive edema within the airway.

Anaphylaxis, an acute and profoundly life-threatening immune-mediated allergic response, is made up of a triad of clinical manifestations: (1) flushing, pruritus, and/or urticaria; (2) airway obstruction (angioedema, laryngospasm, and/or bronchospasm); and (3) circulatory collapse (shock).

Angioedema Angioedema, which may occur with or without anaphylaxis, is an acute, allergic, histamine-mediated, inflammatory reaction characterized by acute vascular dilation and capillary permeability. This reaction can occur in many parts of the body; when the airway is acutely affected, the condition is potentially life-threatening. Oral and laryngopharyngeal structures are frequently affected.

In susceptible patients, angioedema can be precipitated by medications (eg, penicillin, aspirin, other nonsteroidal anti-inflammatory drugs, and angiotensin-converting enzyme inhibitors), by food additives and preservatives, and by blood transfusions, infections, or insect bites. In addition, the condition may be associated with a coexisting connective tissue disorder.[70]

Hereditary angioedema is an autosomally dominant inherited deficiency of C1 esterase inhibitor that leads to recurrent attacks of mucocutaneous edema. An acquired form of C1 esterase deficiency has also been reported in patients with angioedema who have occult lymphoma.

Diagnosis is made primarily from the history, although the offending agent may not be readily apparent. Patients present with edema that may involve the face, oral cavity, oropharynx, or larynx. The onset is rapid and may be associated with pruritus. Hoarseness is common when the larynx is involved.

Treatment of both types of angioedema must be prompt and aggressive. Epinephrine, corticosteroids, antihistamines, and aminophylline are the mainstays of therapy. If progressive airway obstruction develops, intubation or tracheostomy may be required. Chronic "pretreatment" of hereditary angioedema with danazol appears to elevate levels of functional C1 esterase inhibitor and to help prevent recurrent episodes.

Stevens-Johnson Syndrome Stevens-Johnson syndrome is a mucocutaneous hypersensitivity reaction (at the severe end of the erythema multiforme spectrum) usually triggered by medications (eg, sulfonamides, phenobarbital, and carbamazepine). It is an acute febrile illness characterized by conjunctivitis, rash, and severe oropharyngeal mucositis. The mucosal and skin lesions rapidly progress to bullae formation and desquamation of the skin in sheets. The most severe form of this syndrome is called toxic epidermal necrolysis, and this variant may involve the larynx.[71] Diagnosis is made by biopsy, and treatment is primarily supportive, including tracheostomy when the airway is compromised. If death occurs, it usually is owing to sepsis from bacterial superinfection.

Immune and Idiopathic Disorders

Infections of the Immunocompromised Host Immunocompromised patients, whether immunocompromised from diabetes, long-term corticosteroid therapy, chemotherapy, or AIDS, are at risk of developing opportunistic infections of the aerodigestive tract. The most commonly reported opportunistic infections that affect the larynx are shown in Table 52–10. Of those listed, laryngeal candidiasis, tuberculosis, and herpes infections are the most commonly encountered in patients with AIDS.

When any immunocompromised patient develops even slight hoarseness, dysphagia, or odynophagia, the otolaryngologist should suspect infection of the laryngopharynx. Even microorganisms that are usually considered indolent may aggressively invade tissue and cause acute inflammation, massive tissue destruction, and rapid obstruction of the airway. When new throat symptoms arise in the immunocompromised patient, the clinician should perform an examination promptly, and if there is evidence of infection, the clinician should aggressively attempt to obtain material for culture and for histologic examination.

TABLE 52–10. Common Laryngeal Infections of the Immunocompromised Host

Viral
Herpes simplex
Herpes zoster
Cytomegalovirus
Papova (papilloma)
Toxoplasmosis
Bacterial

Atypical mycobacteria
Actinomycosis
Fungal
Candidiasis
Aspergillosis
Histoplasmosis
Coccidioidomycosis

Rheumatoid Arthritis Rheumatoid arthritis is a systemic autoimmune disorder of unknown cause that can affect any organ in the body. Its most common manifestation is symmetric polyarthritis, but it also can cause inflammation in nonjoint structures, vasculitis, and pulmonary changes.[72] Rheumatoid arthritis may affect the larynx both directly and indirectly.

Rheumatoid involvement of the cricoarytenoid joints may cause hoarseness or airway obstruction. At postmortem examination, up to 87% of patients with rheumatoid arthritis have cricoarytenoid joint changes, but, based on laryngoscopy, only 17 to 33% of patients have clinical signs of laryngeal involvement, namely posterior laryngeal inflammation and decreased arytenoid cartilage mobility.[73]

Rheumatoid nodules may occur anywhere in the larynx or within the substance of the vocal fold itself, leading to hoarseness. The gross appearance of rheumatoid laryngeal nodules is variable. They may appear as white submucosal nodules, as ulcerated friable polypoid lesions, or as ill-defined masses deep within the substance of the vocal fold. Occasionally, unsuspected rheumatoid nodules are discovered during direct laryngoscopy by palpation of the nodule.

Histologically, these lesions show a central area of fibrinoid necrosis surrounded by histiocytes, plasma cells, and lymphocytes. They can be highly vascularized and hyalinized and may have a fibrous capsule. Frequently, rheumatoid nodules of the larynx are misdiagnosed as pyogenic granulomas.[74]

Rheumatoid arthritis, like other collagen vascular diseases, often involves the esophagus, causing esophageal dysmotility and reflux disease. Thus, patients with rheumatoid arthritis may have reflux laryngitis, but it is not known whether such reflux contributes to the arytenoid fixation.

The choice of treatment for rheumatoid airway obstruction secondary to arytenoid cartilage fixation depends on the patient's overall medical condition. Since surgical rehabilitation of arytenoid cartilage function is not possible, endoscopic arytenoidectomy is usually the treatment of choice. This procedure leaves the patient with an adequate airway and a somewhat breathy, dysphonic voice. Sometimes the rheumatoid arthritis so severely affects the neck that endoscopic exposure of the larynx is not possible. In such cases, an open surgical procedure, or simply a tracheostomy, may be performed.

Because rheumatoid nodules of the larynx frequently lie within the substance of the vocal fold and may be inflamed, the vocal fold may be scarred after their removal. As a consequence, most patients with this type of rheumatoid involvement of the larynx have persistent hoarseness following nodule removal.

Systemic Lupus Erythematosus Lupus is a systemic, autoimmune disease of unknown etiology. It affects women more commonly than men and usually presents in the second and third decades of life. Patients with this condition may have autoantibodies to a variety of different tissues, and head and neck manifestations are common. Although the most common manifestations of lupus are arthritis, malar rash, and photosensitivity, up to 40% of patients have mucosal lesions of the aerodigestive tract as well.

The lesions may be varied, for example, petechiae, ulcerations, or raised nonulcerated lesions with erythematous borders. The palate and nose are commonly involved. Painless nasal septal perforations may occur. The larynx may also be involved by these mucosal lesions or, on occasion, by cricoarytenoid arthritis.[72]

Laryngeal involvement usually occurs at times of acute exacerbation of the systemic disease. Airway compromise is uncommon but does occur. Biopsy reveals a mononuclear cell infiltrate. Positive fluorescent antinuclear antibody tests are important for diagnosis and are a key part of ARA criteria. Corticosteroids and symptomatic therapy are the treatment.

Cicatricial Pemphigoid Pemphigus and pemphigoid are idiopathic, autoimmune epithelial disorders. There are several clinical variations; however, in common, they share subepithelial bullae inflammation. The primary distinctions between the two entities are the clinical patterns and histologic features: in pemphigus, there is suprabasilar separation (cantholysis), and in pemphigoid, the bullae are subepidermal. Clinical variations, that is, the manifestations and sites of involvement, are believed to be the result of autoimmunity to distinct basement membrane antigens. Pemphigus and pemphigoid also may be associated with systemic lupus erythematosus. Of this group of uncommon bullous diseases, only cicatricial pemphigoid appears to involve the larynx with any frequency (9 to 20% of cases).

Cicatricial pemphigoid is a painful, unremitting, chronic-inflammatory, vesiculobullous disease. Cicatricial formation may occur at any site of involvement, including the nose, nasopharynx, pharynx, larynx, and esophagus. Cicatricial pemphigoid affects women twice as often as men, and most patients are over 50 years of age. The oral cavity and eyes are most commonly involved; the aerodigestive tract is sometimes involved. The largest series reported in the otolaryngology literature reported 13 (9%) of 142 patients with laryngeal involvement, 3 of whom required airway intervention.[75] All 13 had involvement of other areas of the aerodigestive tract as well, but isolated laryngeal involvement has been reported. The primary symptom of laryngeal pemphigoid is severe odynophagia, and the most common findings are ulcers of the epiglottis and aryepiglottic folds.

Diagnosis is dependent on biopsy, which shows inflammatory subepithelial bullae surrounded by a mixed cellular inflammatory infiltrate. Immunofluorescent studies usually reveal linear deposition of immunoglobulins (IgG and IgM) along the basement membrane.[75] Long-term treatment is with the anti-inflammatory medication dapsone, with systemic corticosteroids and/or immunosuppressive therapy being reserved for dapsone treatment failures. Intralesional corticosteroids are ineffective. Stenosis of the larynx and other sites usually requires surgical intervention.

Relapsing Polychondritis Relapsing polychondritis is a rare, idiopathic, generally progressive, autoimmune disease that causes inflammation of cartilage. It can mimic rheumatoid arthritis and sometimes occurs in patients with other autoimmune diseases, such as Sjögren's syndrome, systemic lupus erythematosus, and psoriatic and rheumatoid arthritis.

Relapsing polychondritis occurs in all age groups, having a bell-shaped distribution and a peak incidence in the fourth decade. Although only 10% of patients present with respiratory tract involvement (larynx and trachea), more than 50% eventually develop such involvement, and 20% require tracheostomy. Of the 20 to 30% of patients who eventually die of the disease, most die of respiratory complications.[76]

This disease is characterized by episodes of inflammation with subsequent destruction of the cartilage of the ears, nose, and larynx. Arthritis involving the large joints is also common. Laryngeal involvement is manifest by hoarseness, dyspnea, stridor, cough, and, sometimes, pain and hemoptysis. On examination, therefore, a clinical diagnosis is confirmed by cartilage biopsy, although most patients with this disorder also have autoantibodies to type II collagen.

Initially, most patients present with bilateral involvement of the ear cartilage. Typically, the ears suddenly become red, swollen, and tender. With or without treatment, the condition may subside within 5 to 10 days. The next most common sites of involvement are the nose and the costal cartilages; there can be involvement of the eye.

Histologically, the normal cartilage is replaced by an eosinophilic material, and acute and chronic infiltrates of lymphocytes and plasma cells are present. The usual basophilic appearance of the cartilage matrix is lost, lacunae are interrupted, and fibrous tissue replaces cartilage. As the disease progresses, fibrosis and chondronecrosis become marked.

Treatment includes corticosteroids and anti-inflammatory medications such as dapsone. Corticosteroid and immunosuppressive medications are used for patients with severe, recalcitrant, or rapidly

progressive disease, especially when the larynx or other airway structures are involved. Tracheostomy may be necessary in the later stages of the disease.

Sjögren's Syndrome Sjögren's syndrome is an idiopathic autoimmune disorder characterized by the clinical triad of xerostomia (dry mouth), conjunctivitis sicca (dry eyes), and rheumatoid arthritis. Patients with Sjögren's syndrome have a relatively high incidence of developing lymphoma. There is also a "limited" form of the disease, occurring without the arthritis, called "sicca syndrome."

Although the cause (or causes) of these syndromes is unknown, both the limited and the full-blown forms have in common autoantibodies to glandular tissue in the eyes, nose, oral cavity, and laryngopharynx. In addition to the lacrimal glands and the major salivary glands, minor salivary and seromucinous glands are usually affected throughout the aerodigestive tract.

The diagnosis is made clinically using a Schirmer's test to document the dryness of the eyes and by salivary gland biopsy. In the major salivary glands, the histologic picture demonstrates (1) an intense lymphoid infiltrate, especially in periductal areas; (2) glandular atrophy; and (3) myoepithelial hyperplasia. Although the salivary glands are virtually always affected, biopsy of a major salivary gland is rarely necessary. Instead, biopsy of minor salivary gland tissue (lip biopsy) is usually sufficient to make the diagnosis. The histopathologic features seen in minor salivary glands are similar to those seen in the major salivary glands, although the myoepithelial hyperplasia is absent.

The seromucinous glands of the larynx may be involved, leading to inflammation of the larynx similar to that seen in the salivary glands. Clinically, this involvement produces edema, erythema, dryness, crusting, and, hence, chronic hoarseness. Laryngeal Sjögren's syndrome, however, does not occur in isolation; that is, patients with laryngeal symptoms and signs of Sjögren's syndrome also have other manifestations of the disease.[77]

In some cases, the mucosa of the posterior commissure appears so hypertrophic that the clinician must consider the possibility of tumor. The larynx in Sjögren's syndrome usually exhibits intense erythema and hypertrophy of the posterior commissure with dry, tenacious mucus between the vocal folds.

Biopsies of the larynx reveal histologic findings similar to those seen in the salivary glands. In addition, patients with Sjögren's syndrome often have impaired esophageal function and gastroesophageal reflux. Treatment is symptomatic, and antireflux and anti-inflammatory medications are sometimes prescribed.

Amyloidosis Amyloidosis is a dysproteinemia in which a characteristic, amorphous, eosinophilic substance is deposited in the tissues of various organs. Amyloidosis is classified as being either "systemic" or "localized." The systemic types are familial, primary (with or without myeloma), and secondary (usually associated with chronic inflammatory disease). Primary amyloidosis has a 5-year survival of only 20%, with the patients dying of renal, central nervous system, or cardiac involvement.[78] The "localized" type of amyloidosis is almost never fatal and is the type that most commonly involves the larynx. On rare occasions, however, the larynx may become involved by either primary or secondary systemic amyloidosis. In other words, most cases of laryngeal amyloidosis occur in isolation, although simultaneous involvement of the trachea and, to a lesser extent, the bronchi occurs in about one-third of those cases.

On laryngoscopy, amyloidosis appears as diffuse mucosal thickening or subepithelial nodules, localized mainly to the anterior part of the subglottis. Patients are usually asymptomatic until the deposits involve the vocal folds or critically narrow the airway. When amyloidosis is suspected, biopsy specimens should be stained with Congo red, which, when viewed with polarized light, shows a pathognomonic apple-green birefringence.

Laryngeal amyloidosis usually has a benign course. Symptomatic cases are best treated by endoscopic carbon dioxide laser excision of the lesions; laryngeal dilatation and tracheostomy are rarely necessary.[79]

MISCELLANEOUS INFLAMMATORY CONDITIONS

Parasitic Infections

Trichinosis Trichinosis in humans is caused by ingesting meat contaminated with the helminthic roundworm *Trichinella spiralis*. Trichinosis is relatively common worldwide. About 30 cases occur

each year in the United States. In the past, contaminated pork was the most common source of infection, but today, most cases are caused by eating feral meat, such as bear or wild boar.

Humans are particularly susceptible to trichinosis infection. Soon after ingestion, the larvae penetrate the intestinal wall, where copulation and multiplication occur. The next generation of larvae then enters the bloodstream, is distributed throughout the body, and finally enters and grows in skeletal muscle. The muscles of the diaphragm, eyes, tongue, chest, shoulders, and calves are often affected. Laryngeal involvement is uncommon.

In tissue, the larvae elicit an eosinophilic and lymphocytic inflammatory response. The severity of the clinical manifestations depends on the location and density of the larvae. The first symptoms occur within 2 days of ingestion. During the initial stage of infection, diarrhea, nausea, and malaise are common. During the muscle invasion stage (lasting 1 to 6 weeks), fever, weakness, skin rash, myalgia, muscle tenderness, and facial and periorbital edema are usually present. Some cases are complicated by urticaria, splinter hemorrhages, and angioedema. The primary symptom of laryngeal involvement is hoarseness. Trichinosis should be suspected by the history and eosinophilia. Diagnosis can be made by serologic testing and muscle biopsy. Treatment is with a 7-day course of thiabendazole. The disease can be prevented by cooking meat products to an internal temperature of 170°F.

Leishmaniasis Leishmaniasis, although uncommon in the United States, is indigenous throughout the rest of the world. It is estimated that there are 1.5 to 2 million cases each year worldwide. The vast majority of the world's cases occur in India, Bangladesh, Nepal, Sudan, and Brazil. The organism infects rodents and dogs, and transmission to humans is usually from an animal, although the bite of an intermediate host, the sandfly, may cause the disease as well. Although there are several clinical forms of the disease, the mucocutaneous form, caused by *Leishmania braziliensis* and *Leishmania mexicana*, is the one that most commonly involves the airway. Espundia, the form caused by *L. mexicana*, is endemic in south-central Texas.

Usually, one or more skin lesions on the lower extremity begin as sores that slowly enlarge and ulcerate over a period of months. These untreated lesions seldom heal. Months or years later, metastatic lesions appear on the lips, nose, and pharynx. Leishmaniasis involves the larynx in approximately one-third of cases.[80]

Fever, anemia, weight loss, and hoarseness are common symptoms. As time passes, extensive soft tissue destruction may lead to grotesque facial disfiguration, as well as progression of the laryngeal disease. Examination of the larynx may reveal a localized, polypoid, inflammatory lesion or diffuse, granular, spongy mucosa throughout the larynx. The lesions may be ulcerated, and airway obstruction may occur. These lesions are often mistaken for laryngeal cancer, tuberculosis, histoplasmosis, or blastomycosis.

Biopsy reveals a chronic granulomatous pattern, with a predominance of lymphocytic and histiocytic cells. The diagnosis can be made by identification of the parasite in biopsy specimens, but, in some cases, the parasites may be difficult to find. A specific agglutination test for leishmaniasis and the leishmaniasis skin test are diagnostic. The mucocutaneous form of leishmaniasis should be treated with antimonials for at least 30 days.

Schistosomiasis Endemic in the tropics and subtropics, schistosomiasis ("bilharziasis" in Egypt) is widespread in 72 countries of the world and infects an estimated 5% of the world's population—200 million people. It is the most prevalent helminthic infection in the world.

There are three *Schistosoma* species parasitic in man: *S. mansoni, S. japonicum*, and *S. haematobium*. *Schistosoma mansoni* and *S. japonicum* inhabit the mesenteric veins; the eggs are found along the wall of the intestine and in the liver and are passed in the feces. *Schistosoma haematobium* invades the veins of the pelvic plexus, and the eggs are passed in the urine. Ectopic lesions occur in 18% of cases and may be found in any part of the body. How the parasite reaches other parts of the body, outside the gastrointestinal and urinary tracts, is unknown.

Humans contract schistosomiasis from water infested by cercariae, the microscopic infective stage. Cercariae penetrate the intact skin, and *schistosomules* form in the skin. After several days, the schistosomules migrate to the lungs and portal veins, where the male and female species mate. Weeks later, depending on the species and the time of transit,

eggs are deposited in the infected organs.

To complete the life cycle, organisms excreted by humans must contaminate water because the snail is the intermediate host. The cercariae grow in the soft tissue of the snail, and after 1 to 2 months, they are released back into the water, where they can again enter the human body, thus completing the organism's life cycle.

Schistosomiasis in the aerodigestive tract is characterized by intense inflammatory granulomas around deposits of schistosome eggs. Granulomas may be as small as a pinhead or as large as an orange. Histologically, coagulation necrosis occurs around the egg deposits, and eosinophils, plasma cells, and lymphocytes predominate in the cellular response.[81]

Patients with laryngeal schistosome granulomas present with hoarseness. The laryngeal lesion has the appearance of a pink-gray, cauliflower-like granuloma, with surrounding inflammation. Ipsilateral paralysis may be present.[81,82] The degree of surrounding fibrosis is determined by the egg density and the duration of the infection.

Diagnosis may be suspected by the histologic examination; however, confirmation of the diagnosis is made by identification of parasitic ova in the urine or feces. Treatment is with antihelminthic medication (praziquantel or oxamniquine).

Syngamosis *Syngamus laryngeus* is a unique gapeworm indigenous to Brazil, Puerto Rico, Martinique, Trinidad, British Guiana, the West Indies, and the Philippines. It invades the upper respiratory tract of cattle, water buffalo, and (very rarely) humans. Transmission to humans is believed to be through consumption of contaminated vegetables. Once ingested, the adult worms migrate to the larynx and upper trachea and firmly attach themselves to those mucosal surfaces.

The primary symptoms of syngamosis are cough, a foreign body sensation in the throat, and, occasionally, hemoptysis. The diagnosis may be suspected if the patient coughs up worms in copula or if they are seen on laryngoscopy. Removal of the worms by direct laryngoscopy is the only known treatment.[83]

Inhalation Laryngitis

When nebulized, radiolabeled, acidic fog is inhaled and scanned, the density of aerosol deposit in the larynx is greater than in any other site in the aerodigestive tract.[84] The size and anatomic configuration of the larynx (having the narrowest and most convoluted lumen of the upper airway) may explain this phenomenon. Perhaps for this reason, the larynx is especially susceptible to the effects of tobacco smoke, dust, and other airborne environmental contaminants. Table 52–11 lists some of the commonly reported substances associated with acute and chronic inhalation injuries of the larynx.

Acute (Thermal) Injury Thermal and toxic injuries of the airway are often seen in patients with facial burns. In this regard, thermal injury usually plays a greater role than chemical injury in the larynx. Intense heat produces excessive vasodilation, capillary permeability, massive edema, and, thus, airway obstruction. The edema usually peaks at 8 to 24 hours following injury and resolves within 4 to 5 days.

The severity of permanent damage depends on the severity of the burn. Complete laryngeal stenosis can occur. Treatment consists of providing humidified oxygen and maintaining the airway. In most cases, corticosteroids and antibiotics should be avoided. Weeks after the acute injury has resolved, laryngeal dilation and surgical procedures to re-establish the airway, if necessary, may be performed.

Pollution and Inhalant Allergy The common clinical manifestations of allergy to inhalants are well known to otolaryngologists: sneezing, watery rhinorrhea, nasal congestion, and obstruction. The most common offending allergens are dusts, pollens, molds, and chemicals. Allergic reactions of the larynx, similar to those seen in the nose, are uncommon but do occur. The diagnosis is made by the history, clinical findings, and intradermal skin testing. Treatment should be removal of the offending allergen(s), if possible, and desensitization. Corticosteroid inhalers are ineffective in laryngeal allergy and should be avoided.

Carcinogens Tobacco and several other carcinogens (see Table 52–11) cause chronic inflammation of the larynx. These substances can cause mucosal thickening, submucosal edema, hyperkeratosis, dysplasia, and, eventually, carcinoma. In the larynx, leukoplakia, pachydermia, and Reinke's edema (polypoid degeneration) should be viewed as precursors to the development of carcinoma.

TABLE 52–11. Causes of Inhalation Laryngitis (Substances Associated with Acute and Chronic Laryngeal Inflammation)

Acute inhalation injury
Steam
Hot dry gases
Smoke
Common allergens
Dusts
Animal danders
Formaldehyde
(Plus the list of pollutants below)
Pollutants
Dusts
Ozone
Ammonia
Chlorine
Nitrous oxide
Hydrogen disulfide
Sulfur dioxide
Carbon monoxide
Sulfuric acid
Hydrochloric acid
Kerosene (heaters)
Insecticides
Pesticides
Known carcinogens
Tobacco
Asbestos
Radon
Nickel
Sulfuric acid
Isopropyl oils
Mustard gas

Leukoplakia, which means "white plaque," is histologically hyperkeratosis. This is a typical metaplastic response of epithelium to chronic irritation, regardless of the cause. When the laryngeal mucosa becomes diffusely thickened (and also usually diffusely hyperkeratotic) to the point of narrowing the lumen of the endolarynx, the condition is termed *pachydermia laryngis*. Pachydermia ("elephant skin") is frequently found in the larynges of patients who have smoked cigarettes for many years.

Reinke's edema also results from chronic laryngeal irritation over a period of many years. It is almost always bilateral, and although it occurs most frequently in elderly female smokers, it is also seen in nonsmoking patients with reflux disease and hypothyroidism.

Leukoplakia, pachydermia, and Reinke's edema may improve with cessation of smoking and antireflux therapy (when the patient has reflux disease), but often patients with these lesions require surgical treatment.

Radiation Injury

Radiation Laryngitis Radiation therapy for laryngeal carcinoma, as well as for tumors in other head and neck sites, may deliver significant radiation doses to normal laryngeal tissue. The initial effects produce an intense inflammatory response, characterized by increased capillary permeability, edema, neutrophilic infiltration, vascular thrombosis, and obliteration of lymphatic channels.

Patients undergoing radiation treatment complain of a globus sensation, dysphagia, odynophagia, dysphonia, and odynophonia. On examination, the larynx appears red and swollen, and a fibrinous exudate may be present. The symptoms tend to worsen as the treatment progresses; they are worst at the completion of treatment and gradually abate thereafter.[85]

Late tissue sequelae consist of degenerative changes and fibrosis in adipose, connective, and glandular tissues and a pronounced obliterative endarteritis of small blood vessels. These changes may take place over a period of years, and the symptoms of many patients worsen with time.

Atrophy of glandular elements of the larynx leads to *laryngitis sicca*, a dry larynx. This, in turn, increases the susceptibility of the larynx to infection and to damage from LPR. Patients often complain about the effects of dryness, including hoarseness, crusting, globus, and cough. Treatment is symptomatic, consisting of hydration, administration of expectorants, and environmental humidification.

Radionecrosis Like laryngitis sicca, radionecrosis is a late complication of laryngeal irradiation, being the result of ischemia of the cartilaginous framework. Patients with laryngeal radionecrosis usually present with dysphagia, weight loss, *fetor oris* (foul breath), severe dysphonia, impaired vocal fold mobility, and relative airway obstruction; the last three depend on the amount and location of swelling. Massive edema of the larynx with airway obstruction is not uncommon.

When a patient presents after radiation therapy with increasing symptoms and laryngeal edema, the clinician must determine the cause or causes. The differential diagnosis of laryngeal radionecrosis also includes tumor recurrence and reflux. Known as "the three R's" (radionecrosis, recurrence, reflux), which of these has caused the patient's increasing symptoms will determine the treatment. Each patient must be evaluated for each of the three possibilities.

Computed tomographic scanning of the larynx may reveal tumor recurrence; however, unless there is relatively massive destruction, scans are notoriously unreliable for evaluating the laryngeal cartilages. Tumor recurrence is usually treated by surgical salvage, and reflux is usually treated with PPI.

Treatment for radionecrosis should be individualized. In some cases, necrotic cartilage and soft tissue can be removed through an endoscopic approach. Often, however, an open surgical procedure is needed. The larynx may then be stented for 2 to 4 weeks. If the necrotic sequestration has been adequately removed, the larynx may heal in a satisfactory manner, even if much of the cartilaginous framework is resected. When available, hyperbaric oxygen treatment may be of significant benefit, completely obviating surgery in selected cases.[86] Laryngectomy should be a last resort and should be considered only when all conservative measures have failed.

Vocal Abuse and Misuse Syndromes

Vocal Fold Hemorrhage Screaming and other forms of vocal abuse can lead to acute submucosal hemorrhage of the vocal folds. By history, such hemorrhage occurs abruptly and produces severe dysphonia. On examination, the appearance of hematoma is unmistakable. Voice rest is the usual treatment, although some laryngologists recommend surgical drainage in selected cases.

Muscle Tension Dysphonias *Muscle tension dysphonia* is a generic term for any "functional" voice disorder caused by chronic vocal abuse or misuse. Patients with vocal nodules, contact ulcers, and granulomas or the Bogart-Bacall syndrome all fit into this category, as do patients with psychogenic voice disorders.[87,88] We classify laryngeal muscle tension into primary and secondary categories. Primary muscle tension dysphonia is owing to nonorganic vocal fold pathology. The behavior may be learned or entirely psychogenic. Secondary, or compensatory, muscle tension dysphonia is a result of an underlying glottal insufficiency. Among a community cohort (N = 100), persons with vocal fold bowing were 17 times more likely to display abnormal muscle tension patterns (MTPs) (predominantly MTP II and III in Figure 52–8) than individuals without vocal fold bowing ($p < .001$).[88,89] The glottal incompetence may be owing to presbylaryngis, vocal fold paralysis, or vocal fold paresis. These findings suggest that supraglottic hyperfunction may be a physiologic attempt by the glottis to compensate for underlying glottal closure problems. Muscle tension dysphonias are common in professional voice users and are frequently initiated or complicated by reflux

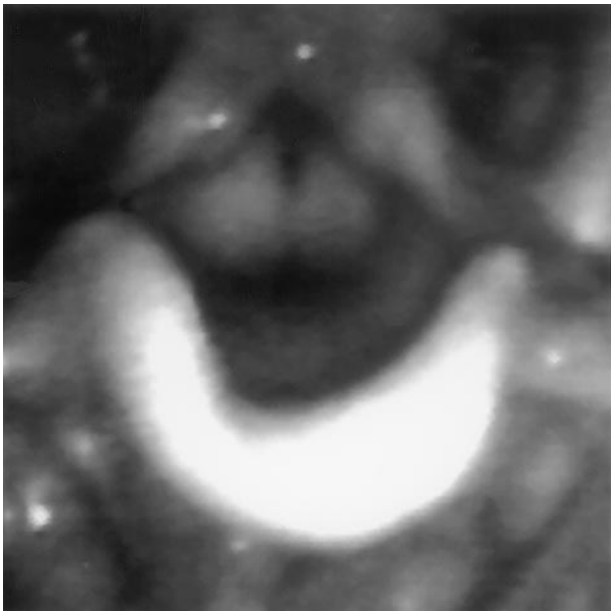

FIGURE 52–8. Muscle tension pattern II—lateral to medial approximation of the false vocal folds. The true vocal folds are completely obscured. Muscle tension pattern III—anterior to posterior contraction of the larynx. The anterior third of the true vocal folds is obscured.

laryngitis. Treatment with voice therapy, surgery, and, when appropriate, antireflux therapy often successfully resolves the problem.

Contact Ulcers and Granulomas Anatomically, only a thin layer of mucosa and perichondrium overlies the vocal processes of the arytenoid cartilages, so ulceration over a vocal process can occur from a variety of insults, including vocal abuse, coughing, viral infection, GER, and endotracheal intubation.[90–92] Because of the shape of the larynx, endotracheal tubes reside in the posterior commissure and thus have contact with the vocal processes. Examination of 99 postintubation laryngeal specimens obtained at autopsy showed that those intubated for less than 12 hours demonstrated pale, oval areas on the mucosa of the vocal processes, which under microscopic examination revealed complete or focal loss of surface epithelium. Those intubated for 12 to 48 hours almost uniformly demonstrated ulcerations over the vocal processes.[93]

Granulomas over the vocal process are five times more common than ulcers. Chronic ulcers over the vocal processes are uncommon because most either heal or go on to form granulomas.[94] The most common sequence of granuloma formation is as follows. First, the mucosa overlying the vocal process is acutely damaged. Then, owing to continued trauma (eg, throat clearing, cough, or LPR), ulceration may occur. Next, as the ulcer attempts to heal, secondary infection and/or reflux perpetuates the inflammation, and a granuloma forms (Figure 52–9).

As recently as 25 years ago, contact ulcers and granulomas were believed to be exclusively caused by vocal abuse; consequently, prolonged periods of voice rest were prescribed. Such treatment was, however, usually unsuccessful. Today, regardless of the inciting cause, patients with these lesions should initially be treated with "voice modification" (not voice rest), to reduce continual vocal process trauma, and antireflux therapy (preferably with a PPI). This regimen will result in healing in the majority of cases within 6 months.

Although surgical removal of a vocal process granuloma is seldom indicated, there are three instances when it should be considered: (1) when the clinician is concerned about the possibility of carcinoma, (2) when the lesion has matured and taken on the appearance of a fibroepithelial polyp, and (3) when the airway is obstructed. The carbon dioxide surgical laser is useful in removing granulomas.[94] Finally, in carefully selected cases, if traumatic vocal behaviors persist and cannot be corrected, a "one-time" botulinum toxin injection may be used "to put the larynx to rest" long enough for recalcitrant granulomas to heal.

CHAPTER 53

Neurogenic and Functional Disorders of the Larynx

Christy L. Ludlow, PhD, Eric A. Mann, MD, PhD

Normal speech requires the complex integration of peripheral and central motor control mechanisms. The voice component of speech requires (1) neural control of the intrinsic and extrinsic laryngeal muscles to shape the glottis and (2) a steady stream of airflow from the respiratory system to support regular, symmetric, and synchronous vibration of the vocal folds. Thus, the central nervous system must coordinate the respiratory, phonatory, and speech mechanisms to produce normal phonation during speech.

Effects of Speech on Laryngeal View during Endoscopy

The larynx does not function in isolation from other structures in the vocal tract. Muscles shaping the pharynx and oral cavity, particularly those controlling the tongue, lip, and jaw, alter laryngeal tension as they change vocal tract posture. In normal speech, the vocal tract moves rapidly between different target shapes for specific speech sounds.

Valving at the glottis, velum, tongue, lips, and jaw amplifies certain harmonics of the fundamental frequency of vocal fold vibration, based on the posture and shape of the vocal tract. Depending on the shape of the tract, harmonics in the region of certain resonant frequencies are amplified, resulting in sound energy in formants. The frequency regions of the formants are responsible for the vowel sounds. A simple example is illustrated in Figure 53–1. Sagittal sections show specific vocal tract configurations for the vowels /i/ (labeled "iy"), /u/ (labeled "uw"), /æ/ (labeled "ae"), and /a/ (labeled "aa"). In high-frequency vowel sounds such as /i/ or "ee," the posture of the tongue is high and forward, exerting tension from the tip to the base of the tongue. Coupling between the hyoid bone and suspended thyroid cartilage distributes tension to extrinsic and intrinsic laryngeal musculature that may tilt the thyroid cartilage. During /i/, the pharyngeal cavity is large, making conditions for airflow different than for production of /a/ or "ah," which is characterized by a constricted pharyngeal cavity because of the low and posterior placement of the tongue.

These differences in pharyngeal constriction also affect videoendoscopy; the vowel /i/ allows a better view of the larynx because the tongue is forward and high, opening the pharynx and bringing the epiglottis forward. In contrast, during /a/, the larynx is much less visible because the tongue is back; consequently, the epiglottis covers the larynx, obstructing the view.

Multidimensional Aspects of Voice Function and Disorders

Pharyngeal and/or laryngeal constriction can produce turbulence in airflow in the case of neurogenic disorders. Conversely, reduced vocal fold adduction can produce breathiness because of air escaping and not being modulated to produce voice. The acoustic product is thus affected by changes in constriction and air pressures in the pharynx and oral cavity. Both peripheral and central neurogenic disorders, therefore, may alter the voice by changing the configuration of the larynx and vocal tract. In functional voice disorders, changes in vocal tract tension can also alter voice to a similar degree as in neurogenic voice disorders. Abnormalities in vocal tract tension owing to voluntary or involuntary muscle contractions occur in neurogenic and/or functional disorders. The origins may by traumatic, neoplastic, vascular, infectious, degenerative, or idiopathic. They are often present in conjunction with disease processes that alter not only the laryngeal musculature but also lip, tongue, and jaw control and other motor systems such as respiration.

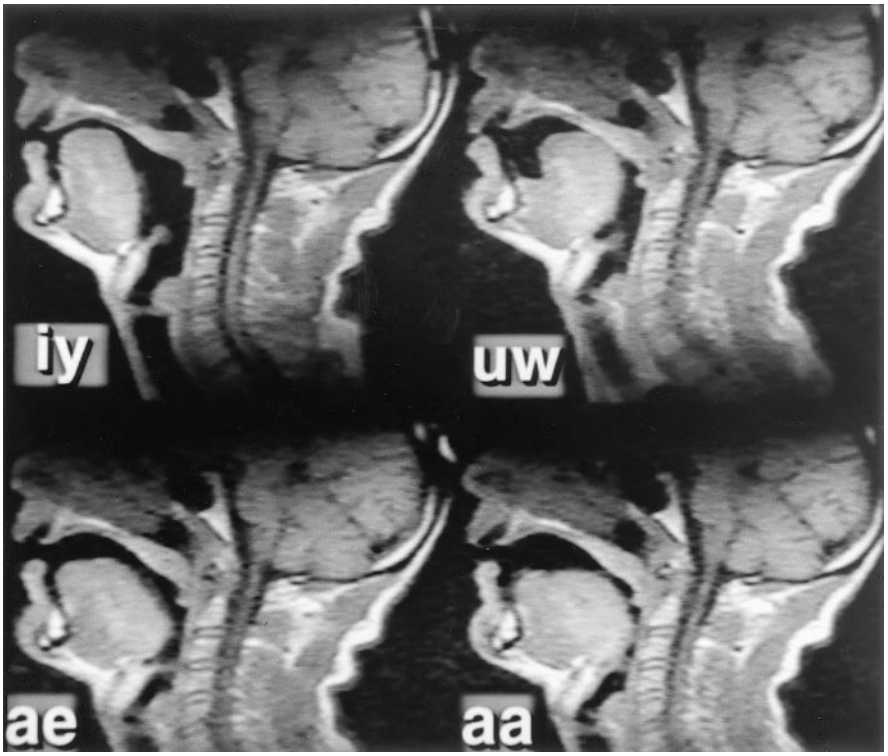

FIGURE 53–1. Sagittal sections from magnetic resonance images of the vocal tract illustrate vocal tract shape during production of four vowels. Adapted from Baer T, Gore JC, Gracco LC, Nye PW. Analysis of vocal tract shape and dimensions using magnetic resonance imaging: vowels. J Acoust Soc Am 1991;90:799–828.

In addition to the degree of motor impairment, the diagnostic process must also take into account the body's capacity for reorganization and compensation that may alter the perceived severity of speech disturbance. Perceptual voice parameters such as pitch, loudness, voice quality, and their variability may help to characterize neurogenic and functional voice disorders. Quantification of acoustic and perceptual characteristics of voice and speech may be useful based on a variety of instrumental techniques.[1,2] Computer-assisted quantification of the acoustic product may be a valuable adjunct to the perceptual parameterization of voice; however, the two are not synonymous.[3] Measures based on pressure and flow transduction during phonation provide information about the functional relationship between the respiratory and phonatory systems. Further, the use of diagnostic imaging techniques, including rigid and flexible fiber-optic videoendoscopy, allows observation of laryngeal and pharyngeal movement. Flexible fiber-optic examination is required when the voice disorder occurs more during connected speech, such as in spasmodic dysphonia (SD). Stroboscopic examination is useful in assessing the vibratory characteristics of the vocal folds.[4] High-speed photography, ultrasonography, videofluoroscopy, and magnetic resonance imaging are other imaging tools that have value in the diagnostic protocol.[5,6] Use of electromyography (EMG) accompanied by magnetic stimulation of the laryngeal nerve may be valuable in differentiating peripheral and central neurogenic dysfunction.[7] The goal of instrumental and perceptual techniques has been to characterize vocal fold movement control in terms of timing, speed, and accuracy of movement of vocal tract structures and to quantify these parameters for the documentation of the status and progression of disease for therapeutic purposes.

NEUROGENIC DISORDERS

Dysphonia can appear as the first sign of neurogenic disease, whereas the other speech symptoms (dysarthria) may become evident only as the disease progresses. Therefore, caution should be used in the treatment of neurogenic voice symptoms until it can be ensured that the laryngeal disorder is focal and not part of a progressive neurodegenerative disease. For example, what may initially appear to be a unilateral idiopathic vocal fold paralysis might later progress to become a bilateral vocal fold paralysis as part of a peripheral neuropathy[8] or multiple systems atrophy.[9] A unilateral thyroplasty could be detrimental if bilateral vocal fold paraly-

sis developed subsequently resulting in airway compromise. For this reason, a complete neurologic examination is important before planning intervention in these disorders.

Functionally, neurogenic disorders resulting in dysphonia may be divided into the following categories:

1. Consistent neurogenic voice disorders are characterized by constant vocal quality, loudness, or pitch deviations during speech and sustained vowels. Examples include flaccid dysarthria owing to lower motoneuron disease loss, a peripheral neuropathy, or laryngeal nerve injury. These can produce paralysis or paresis of the adductor and/or abductor muscles, causing asymmetries in movement. On the other hand, tension in the vocal folds may be altered when either the cricothyroid muscle or the thyroarytenoid muscles are affected as both contribute to vocal fold tension.[10]
2. Spastic dysarthria, including dysphonia, is associated with upper motoneuron disease involving the corticobulbar tracts. For example, hypertension of the vocal tract, including the vocal folds, may be seen in multiple sclerosis (MS).
3. Arrhythmically fluctuating neurogenic voice disorders are most frequent. These are characterized by unpredictable, irregular variations in quality, loudness, and pitch during speech. Sustained vowel production may accentuate irregularities in some cases. Ataxic, choreic, and dystonic dysphonias, including the SDs, display this type of irregularity.
4. Rhythmically fluctuating neurogenic voice disorders include palatopharyngolaryngeal myoclonus and essential voice tremor. These dysphonias are marked by regular or rhythmic fluctuations in voice, pitch, and loudness. Paroxysmal neurogenic voice disorders exhibit bursts of dysphonic voice, as in Tourette's syndrome.
5. Neurogenic voice disorders associated with loss of volitional control of voice production, including apraxia of phonation, respiration, or speech and akinetic mutism, usually follow a cerebrovascular accident or cortical injury.

Upper Motoneuron Disorders

Upper motoneuron diseases with characteristic voice components include Parkinson's disease and related syndromes. Parkinsonism is a pathophysiologic state reflecting failure of the nigrostriatal dopaminergic neuronal system owing to degeneration or destruction of the substantia nigra. This can occur by depleting neuronal dopamine, inhibiting its synthesis, or blocking the striatal dopamine receptors.[11] The basal ganglia modulate cortical control via the thalamus. Neural activity at the cortex, in turn, controls the lower motoneurons. Hence, damage to the basal ganglia can release inhibition of nerve impulses affecting the lower motoneurons, resulting in rigidity and reduced rate of movement (bradykinesia).

Hypophonia in Parkinson's Disease Although parkinsonism can be described as a syndrome of diverse origins, distinct syndromes are recognized from clinical features and secondary or associated manifestations, although differentiation is often difficult. Parkinson's disease can occasionally be familial, and genetic predisposition can be both mendelian or a complex interaction of a genetic predisposition with environmental factors.[12] Onset is typically in the sixties or later, but the disease may appear as early as the middle thirties. Rare cases have been reported as early as 15 years of age.[11]

Reduced loudness and breathy vocal quality, referred to as hypophonia, are the hallmark of voice disorders in early Parkinson's disease. An essential feature is a voice quality that fades into breathiness in contextual speech. The patient may have difficulty with production of glottal stops or voice onset after voiceless consonants such as /s/. For this reason, persons with early onset of Parkinson's disorder may have voice symptoms similar to abductor SD.[13] There may be reduced range and speed of vocal fold movement, particularly on the more affected side. Distinctions between voiceless and voiced sounds become reduced owing to impaired ability to produce glottal stops to mark word boundaries. Patients tend to maintain sounds as all voiced or all voiceless.[14] In later stages of the disease, the patient may be unable to produce phonation even with instruction. In advanced disease, severe "on-off" drug-related phenomena may occur, during which patients may experience breathy voice followed by periods of propulsive speech with a strained quality. Vocal fold imaging studies in Parkinson's disease often illustrate a glottic gap and bowing of the vocal folds[13] associated with breathiness and reduced loudness. Asymmetries have also been demonstrated

in vocal fold closure, thinning of the mucosa, and vocal fold bowing.

Patients can increase voice intensity on demand,[15] and voice therapy aimed at increasing vocal intensity can improve speech intelligibility and voice when combined with dopaminergic enhancement therapy.[16] Focus on upper articulator (lip, tongue, and jaw) movement produces little in the way of increased intelligibility for this population. Recently, percutaneous collagen augmentation of the vocal folds has been used to improve the breathy hypophonia of Parkinson's disease in persons with vocal fold bowing and glottic insufficiency.[17] Collagen therapy does not, however, improve overall speech intelligibility in patients with preexisting dysarthria producing speech intelligibility and articulatory precision problems.

Parkinson Plus Syndromes: Progressive Supranuclear Palsy Progressive supranuclear palsy (PSP) is a rare degenerative disorder characterized by supranuclear ophthalmoplegia, complaints of falling backward, nuchal dystonia in extension, moderate axial dystonia, pseudobulbar palsy, difficulty in swallowing, dysarthria, bradykinesia, masked facies, nonspecific changes in personality, lability, sleep disturbance, and performance decrements on various neuropsychological tasks. Progressive supranuclear palsy may be differentiated from Parkinson's disease in that supranuclear ophthalmoplegia is characteristic of PSP, and the tremor present in parkinsonism is typically absent in PSP. Patients with PSP may have voice symptoms similar to those in parkinsonism, with the possible exception of vocal tremor. Dysphagia is a major problem for these patients. Hypophonia is present, with unilaterally reduced vocal fold range and speed of movement. The associated dysarthria may include palilalia (uncontrolled syllable repetition) and oral motor rigidity.[18]

Multiple Systems Atrophy Multiple systems atrophy is another disease that is included as a Parkinson plus syndrome. This is a rare degenerative movement disorder with lesions in the cerebellum, brainstem, and basal ganglia.[19] Three clinical variants are recognized: (1) spinocerebellar degeneration (olivopontocerebellar atrophy), (2) progressive autonomic failure (Shy-Drager syndrome), and (3) atypical parkinsonism (striatonigral degeneration).[20]

Olivopontocerebellar atrophy is characterized by progressive cerebellar ataxia, and coordination of the laryngeal muscles is affected, as in ataxic dysarthria. One sees loss of muscle coordination (dyssynergia), loss of ability to gauge range of motion (dysmetria), and tremor during voluntary movement (intention tremor). The degree of laryngeal impairment depends on the severity of the ataxia. Dysphonia may take one of several forms: sudden bursts of loudness, irregular increases in pitch and loudness, or coarse voice tremor.[21]

In Shy-Drager syndrome, voice symptoms typical of Parkinson's disease are present, along with progressive autonomic dysfunction.[22] Voice may be more severely affected owing to reduced range and speed of abduction of the vocal folds. Speech is slowed, with a reduction in vocal intensity, and there is an absence of glottal stops and poor voicing contrasts. Patients may also be predisposed to laryngospasm. The most prominent feature is airway compromise secondary to bilateral abductor paresis, and patients often require tracheostomy in the late stages of the disease.[23]

Voice treatment for these syndromes largely depends on the stage of disease and may include compensatory strategies as well as supportive nonverbal communication alternatives in end stages.

Pseudobulbar Palsy Pseudobulbar palsy results from neuronal loss above the level of the nucleus ambiguus involving the corticobulbar tracts bilaterally. It can occur with vascular and degenerative lesions involving the cortical motor areas bilaterally, vascular lesions and tumors of the internal capsule or brainstem, degenerative lesions involving the entire corticobulbar tract system, or infections. Dysphonia associated with these types of lesions is characterized by a strained-strangled, harsh voice, likely the result of hyperadduction of true and false vocal folds. This is thought to be the result of loss of inhibition of excitation of vagal nuclei. Individuals with pseudobulbar palsy have a breathy voice with vocal fold asymmetry.[21]

Multiple Sclerosis Multiple sclerosis is a progressive demyelinating disorder, having sensory and motor impairments, cognitive problems, spasticity, and tremor. Although MS is one of the most common causes of ataxia, patients with MS usually have evidence of central nervous system disease outside the cerebellum and its pathways.[23] For example,

optic nerve and corticospinal tract involvement are usually present. Dysarthria, tremor, and decomposition of movement are frequently associated with gait and limb ataxia in MS.

Essential features include staccato speech and harsh voice quality with intermittent hyperadduction of the vocal folds. Spasticity and tremor may affect all or some regions of the vocal tract, thereby reducing speech intelligibility and making speech effortful. Breathy voice and vocal fold asymmetry are common findings. Depending on the systems involved, voicing may or may not be affected in some stages of this disease. Given the predominant ataxia that may influence speech motor systems, voicing is characteristic of other ataxic dysarthrias (see the section of this chapter on cerebellar degeneration). In one case of vocal fold paralysis associated with MS, botulinum toxin injection into the abductor musculature appeared to result in improved vocal fold mobility and voice,[24] presumably by allowing "rebalancing" of the forces with the intralaryngeal musculature.

Myoclonus Myoclonus is a sudden, brief, shocklike involuntary movement caused by active muscular contractions.[25] The distribution may be focal, multifocal, or generalized, with the presentation spontaneous, active, and stimulus sensitive. The source of the neural discharge may be cortical, brainstem, or spinal. Four main pathophysiologic categories of myoclonus have been described: cortical, subcortical, cortical-subcortical, and spinal myclonus differ in the location of neurons involved in producing myoclonus.[25] Sometimes these jerks are produced in response to external stimuli, but most occur both at rest and during purposeful movements.

Palatal myoclonus is focal, affecting the movements of the palate either unilaterally or bilaterally at 1.5 to 3 Hz. It is frequently accompanied by synchronous movements of adjacent muscles such as the extraocular muscles, tongue, larynx, face, neck, or diaphragm.[26] When the soft palate is involved, abrupt, rhythmic, anteroposterior, and vertical movements occur. Pharyngeal muscle contractions can open and close the eustachian tube, thereby producing a bruit or clicking sound transmitted by the tympanic membrane and sometimes heard by others. The constant clicking sounds are often the patient's primary complaint and can be benefited by injection of the tensor veli palatini muscles with small dosages of botulinum toxin.[27] Movements are often present during sleep and may occur without the patient's knowledge. Myoclonus may be idiopathic or may be seen in association with stroke, MS, tumors, trauma, or metabolic encephalopathy.[28] Pathology affecting the inferior olivary nuclei may be the origin of palatal myoclonus.[29] When the pharynx and larynx are involved, rhythmic adductor movements of the vocal folds and gross upward and downward movements of the larynx cause momentary and rhythmic phonatory interruptions. Voicing deficits are not often perceived during connected speech but will be apparent on vowel prolongation.

Lower Motoneuron Disorders

Amyotrophic Lateral Sclerosis Amyotrophic lateral sclerosis, a motoneuron disease, may produce a mixed dysarthria because of both upper motoneuron involvement and some lower motoneuron involvement, particularly in the late stages of the disease (flaccid-spastic paralysis). Amyotrophic lateral sclerosis is a degenerative disease of the corticobulbar tracts and lower motoneuron nuclei. The speech and voice symptoms may vary depending on the predominance of spastic or flaccid components. Flaccid symptoms present as hypoadduction of one or both vocal folds and pooling of saliva in the piriform sinuses on laryngeal examination. Voicing is characterized by breathy, hypernasal quality with reduced intensity range. A "wet" phonation is the result of poor management of secretions owing to flaccidity. Dysphagia is common. If spastic components prevail, voicing will be strained and harsh because of hyperadduction of the true and false vocal folds. A mixed form of dysphonia may result in voicing characterized by both flaccid and spastic components.

Amyotrophic lateral sclerosis occurs in the fifth to seventh decade of life and may present with primarily pyramidal tract signs or lower motoneuron signs of progressive muscular atrophy. Fasciculations are more common in the pyramidal tract form. When the disease affects the brainstem rather than the spinal cord, it may progress more rapidly. Speech symptoms may be the first signs in the bulbar type.[30] Facial muscle weakness, palatal weakness, and lip, tongue, and jaw weakness with tongue fasciculations are predominant and cause poor speech intelligibility. Voicing is weak and breathy because of flaccidity of the vocal folds.

Myasthenia Gravis Myasthenia gravis is a disorder of acetylcholine transfer at the myoneural junction, characterized by weakness and fatigability of striated muscle. Muscle contraction, dependent on stimulation of the motor end plate by acetylcholine, is weakened or reduced by the reduction of acetylcholine receptors. This disorder causes a flaccid dysphonia, characterized by breathy, weak phonation. Sometimes stridor can develop with bilateral abductor muscle weakness.[31] The voice intensity range is reduced, and sustained effort causes progressive weakness. This disorder may affect phonation (larynx), resonation (velum), and articulation (lip, tongue, and jaw), and these systems may be affected separately or serially as the disease progresses. The larynx is less frequently affected, whereas the extraocular muscles are usually the first affected. Dysphagia can be severe.[32] This and other early disorders of neurogenic origin may present with reduced movement range and speed of the vocal folds on laryngoscopic examination and are often mistaken for psychogenic voice disorders. Flaccid dysphonia may be an early symptom of neurogenic disease.[30]

Wallenberg's Syndrome Occlusion of the posterior inferior cerebellar artery may produce infarction of the lateral medulla, resulting in Wallenberg's syndrome, also known as lateral medullary syndrome. The medial and descending vestibular nuclei are usually included in the zone of infarction consisting of a wedge of the dorsolateral medulla just posterior to the olive. This syndrome is marked by dysarthria and dysphagia, ipsilateral impairment of pain and temperature sensation on the face, and contralateral loss of pain and temperature in the trunk and extremities. Major symptoms include vertigo, nausea, vomiting, intractable hiccupping, ipsilateral facial pain, and diplopia. Unilateral vocal fold paralysis and flaccid dysphonia occur when the nucleus ambiguus or corticobulbar tracts leading to it are affected.[33] If the paralysis persists past 1 year, both voice and swallowing can sometimes be benefited by a thyroplasty to augment the paralyzed side.

Postpolio Syndrome Of the 250,000 survivors of the poliomyelitis epidemics, approximately 25% experience progressive muscle weakness known as postpolio syndrome. Postpolio patients who complain of swallowing difficulties are at risk for laryngeal dysfunction. This syndrome is characterized by the new onset of progressive muscle weakness, fatigue, and pain. This may occur 30 to 40 years after the initial infection with polio. Electrodiagnosis of neuronal dropout or axonal loss in these patients is consistent with neurogenic change. Patients with previous bulbar symptoms show evidence of neurogenic change. The course of this disease is variable. In some cases, patients may develop progressive vocal fold involvement leading to bilateral vocal fold paralysis and acute respiratory distress. Patients with active swallowing complaints require thorough laryngeal and voice assessment to evaluate the coexistent laryngeal pathologic process in addition to appropriate therapy for dysphagia.[34]

Disorders of the Peripheral Nervous System

The recurrent laryngeal nerves (RLNs) and external branches of the superior laryngeal nerves (SLNs) supply motor innervation to the laryngeal muscles, providing support for fine control, as described in Table 53–1. The conduction velocity is high, and the innervation ratio per motor unit is low, estimated at 100 to 200 cells per motor unit. This represents a smaller innervation ratio than the hand, indicating a very fine degree of contraction and ability to control precisely phonatory parameters such as fundamental frequency.[35]

Lesions of the tenth cranial nerve at any point along its pathway from the nucleus ambiguus in the brainstem to the musculature cause paresis or paralysis of the laryngeal muscles, resulting in dysphonia or even aphonia. The extent of weakness and the degree of dysphonia depend on the location of the lesion along this pathway (Table 53–2).

Evaluation of Voice Function

Clinical evaluation of dysphonia includes diagnostic procedures to determine the cause of the voice disorder, the degree of phonatory deficit, and the prognosis for recovery of function. Based on these assessments, therapeutic recommendations may involve behavioral, medical, or surgical treatment. The most effective treatment plan often includes a multidisciplinary approach, using complementary techniques. For example, patients who present with vocal fold paralysis may require medialization surgery. To optimize the surgical effects on phonation,

however, voice therapy is often recommended pre- and postoperatively to help the patient to undo the previous compensatory techniques before surgery and to learn to use the "new vocal instrument" after surgery. Some diagnostic parameters measure the degree and nature of vocal impairment to determine appropriate intervention. Monitoring the patient's progress throughout treatment is essential to successful outcome. Because phonosurgery does not always result in a normal voice, the speech-language pathologist or laryngologist must decide whether difficulties in ease of phonation are structurally or behaviorally based. This is best accomplished with a combination of instrumental and perceptual tests.

Videostroboscopy The importance of adequate visualization of the larynx during phonation and respiration cannot be overestimated. These observations are easily made using laryngeal videostroboscopy, which allows viewing of the vibratory characteristics of the vocal folds, as well as opening and closing gestures. A description of vibratory characteristics of the vocal folds should include basic information about the (1) symmetry of bilateral movements, (2) regularity, (3) glottal closure, (4) amplitude, (5) mucosal wave, (6) extent of nonvibratory portions, and (7) the opening-closing pattern.[36]

Acoustic and Perceptual Measures Perceptual assessment and objective acoustic measures are also useful in documenting the progress and success of treatment. The degree of impairment is necessarily reflected in the nature and degree of vocal control available to the patient. Measures of frequency and intensity characteristics of phonation should include mean, range fluctuation, extent, and periodicity. Fundamental frequency is the acoustic correlate of pitch, measured in hertz. Intensity, measured in decibels, is the acoustic correlate of loudness. The range in each of these parameters indicates the limits of laryngeal movement dynamics available to the subject. Instrumental assessment of these factors as well as noise and harmonic structure in the voice signal is now available in a variety of computer-based systems designed specifically for voice analysis. Measures of the irregularity in frequency and intensity of the voice signal, also known as perturbation measures, may be useful in monitoring vocal performance[1] in normal voices but often cannot be accurately used in dysphonia because of tracking difficulties for an abnormal signal. Jitter refers to cycle-to-cycle variation in time or period of vibration (frequency). Shimmer refers to variation in amplitude from cycle to cycle (intensity). Harmonics-to-noise ratio is often used to assess the degree of energy contained in harmonics of the fundamental frequency compared to turbulent noise between harmonics present during phonation. These values are thought to reflect abnormalities or asymmetries in mass, neural control, tension, and biomechanical characteristics of the vocal folds.

Aerodynamic Measures Some measure of airflow or volume velocity is useful in determining how rap-

idly the air passes through the glottis. Mean airflow may be obtained from averaged measures over several glottal cycles. Mean airflow rates are useful in documenting change following phonosurgery, especially in RLN paralysis, because preoperative airflow is high. These measures may be made using a pneumotachograph.[1,2] A spirometer is used to determine flow volume loops, which are altered by glottal narrowing.

Subglottal pressure is important for vocal fold vibration and for modulation of vocal intensity. Subglottal pressure may be measured indirectly by a pressure transducer placed in the oral cavity.[37] During production of the sound "p," requiring lip closure, the vocal tract is a closed tube with equal pressure throughout. Pressure measured in the oral cavity reflects pressure beneath the glottis. In a related measure, glottal resistance is calculated by dividing subglottal pressure by mean airflow. Glottal resistance increases with vocal intensity and is thought to be low in case of RLN paralysis. Phonation threshold pressure is the lowest subglottal pressure that a person can use to achieve phonation and, as such, can be used as a measure of vocal fold stiffness.[38] These and other quantifiable measures are currently routinely used in the evaluation of voice deficits, including vocal fold paralysis. The acquisition of perceptual and objective data is key in the treatment program of patients with neurogenic voice disorders.[2,4]

Neurophysiologic Measures of Voice and Laryngeal Function Electromyography is a useful adjunct in the assessment of neuromuscular disorders and is often used in prognostic judgments about patients with those disorders. Electrical silence, fibrillation potentials, polyphasic potentials, high-amplitude potentials, and percentage of normal potentials are the basis for interpretation of such examinations. Electromyography may be useful in differentiating a variety of voice disorders: peripheral and central vocal fold paralysis, functional disorders, and arytenoid joint fixation (Table 53–3).[2,39] Others have suggested the use of neuromyographic assessment that involves the direct stimulation of a laryngeal nerve in conjunction with the use of EMG to monitor resulting muscle activity.[40] During this examination, the contraction of laryngeal muscles is monitored with EMG, while the skin surface is stimulated in the area of the SLN. This produces a short latency response that is brainstem mediated and effected by the RLN to the thyroarytenoid muscle. This method is thought to be one means of obtaining an early estimate of the type and degree of RLN injury. Compared with standard EMG, this technique may offer some advantage in monitoring the reinnervation of paralyzed laryngeal muscles following different reinnervation techniques.[39,40]

Phonosurgery for Vocal Fold Paralysis

The glottis must remain closed for airway protection during swallowing, be patent for respiration, and oscillate for vocalization.[41–43] Neither of the first two vital functions can be compromised in surgery aimed at improving phonation. Because speech requires effective motor coordination of muscles of respiration and the pharynx, mouth, and tongue as well as the larynx, if these other functions are impaired, surgery for vocal fold paralysis for speech may not be warranted, such as in patients with severe dysarthria.

The vocal fold has three functional layers: (1) the cover, which consists of the epithelium and the superficial layer of the lamina propria, or Reinke's space; (2) the vocal ligament, which consists of the confluence of the intermediate and deep layers of the lamina propria; and (3) the vocalis muscle. The cover is the most compliant layer and vibrates most during phonation. Scarring within this layer must be avoided because it can severely disturb the mucosal wave and thus the quality of the voice. The mechanical relationships between these layers determine the vibratory properties of the vocal fold and the quality of the phonation. Any proposed phonosurgery must take into account not only the effect on the position of the vocal fold as a whole but also the effect on the mechanical relationships between the layers. This becomes particularly important in the selection of locations for vocal fold injections aimed at augmentation. The movement of the vocal folds during phonation is at least two-dimensional and includes both lateral-medial and superior-inferior motion during vibration. The shape of the vocal fold changes during vibration as the wave in the mucosa travels from the inferior to the superior level as well as from the medial to lateral surface. New methods of high-speed imaging are now showing that vibration can involve much of the laryngeal tissue during phonation in three dimensions. It is not yet known

TABLE 53–3. Electromyographic Patterns in Relation to the Duration of Vocal Fold Paralysis

Muscle	*Duration EMG*	*–2W*	*2W–1M*	*1M–2M*	*2M–3M*	*3M–6M*	*6M–12M*	*12M+*	*Total*

VOC = vocalis; W = weeks of paralysis; M = months of paralysis; S = electrical silence; F = fibrillation potential; P = polyphasic potential; H = high-amplitude potential; n = normal potential (reduced in number); N = normal potential; LCA = lateral arytenoid; PCA = posterior arytenoid. When two or more different patterns were observed within a given muscle, the categorization in this table was made according to the following rule: F + S → F, P + x → P (x: any pattern), H + x → H, n + S and/or F → n, N + S and/or F → N.
From Hirano M.[2]

to what degree the vibration of other parts of the sound propagation.

Perioperative Management Numerous disease processes can negatively influence the results of phonosurgery. Because phonosurgery is elective, these conditions must be treated before surgery is performed. Preoperatively, all patients should discontinue tobacco use. Many patients benefit from an appropriate program of aerobic or vocal exercise. It is also important to optimize management of nutrition; diabetes; pulmonary disease, especially in patients with chronic obstructive pulmonary disease (COPD); chronic allergy; and gastroesophageal reflux disease (GERD). The benefits of the most technically superb phonosurgery are likely to elude patients with either (1) inability to sustain phonation because of active COPD, vocal edema owing to chronic allergy or smoking, or continued inflammation in the larynx owing to persistent reflux or (2) a postoperative wound infection owing to uncontrolled diabetes and poor nutrition. Postoperatively, many surgeons recommend a short period of complete voice rest (less than 1 week), although the benefit from complete vocal rest has not been proven. Alternatively, modified voice rest can be recommended for which extended speaking without adequate rest and loud phonation are avoided. Whispering can be damaging and is not indicated after any phonosurgery.

Unilateral Paralysis Before phonosurgery, a careful search must be made for the primary cause of the dysfunction. Vocal fold immobility may be attributable to surgical damage to the RLN, such as during thyroid or cancer surgery, or may result from invasion of the nerve by tumor, from neuromuscular disorders or neurodegenerative disease, or from trauma to or disease of the cricoarytenoid joint. Procedures that are appropriate to perform while waiting for recovery and compensation include medialization thyroplasty, collagen, and Gelfoam or fat injection, which have less chance of causing permanent damage. Voice and swallowing therapy should be initiated during this period.[44] For patients with known terminal or unresectable disease, such as advanced cancer invading the RLN, time should not be wasted, and phonosurgery, if desired, should proceed at once.

Surgery for Glottic Incompetence Glottic closure is essential not only for phonation but also for airway protection. Procedures to correct glottic insufficiency are of three major types: augmentation, medialization, and reinnervation. With all techniques, a delicate balance must be reached: providing sufficient glottic closure for phonation and airway protection while leaving an adequate opening to allow respiration.

Augmentation. Vocal fold injection places material within or lateral to the vocal fold to move it medially or to smooth its medial edge. It is best performed under direct laryngoscopy with the patient awake to allow for intraoperative assessment of results. Topical lidocaine anesthesia and intravenous sedation are sufficient for most patients.[45] Injection is accomplished with a Bruening syringe, which delivers about 0.2 mL of material with each click of its ratcheted piston. One or two injection sites are usually sufficient.

Polytetrafluoroethylene paste (Teflon) has been widely used in the past for the treatment of vocal fold paralysis since its introduction by Arnold in 1962.[46] It was injected lateral to the thyroarytenoid muscle to prevent extrusion and to minimize alteration of the mechanical properties of the vocal fold layers. Many patients have achieved initially good voice results following Teflon injection, but local inflammatory responses to this foreign material (ie, Teflon granulomas) are now well documented[47] and believed by some authors to occur in all cases over time.[48] Overinjection or misplaced injection of Teflon appears to increase the risk for development of granuloma.[49] Enlargement of the granuloma may cause the free edge of the vocal fold to become irregular and stiff, resulting in worsening dysphonia. Airway obstruction can also occur owing to progressive enlargement. Surgical management of laryngeal Teflon granuloma is still evolving but includes endoscopic laser vaporization[50] or resection of the granuloma via an open approach.[51] Unfortunately, these procedures may result in persistent dysphonia owing to vocal fold scarring. Other disadvantages of Teflon are related to its irreversible nature, potential interference with the mucosal wave if injected superficially, paste migration, and, most importantly, exclusion of future motor recovery. Many laryngologists now perform Teflon injections only infrequently because of these disadvantages and owing to the availability of newer techniques of vocal fold medialization without these disadvantages.[51]

Gelfoam paste can be injected when return of vocal fold function is anticipated and only temporary medialization is desired.[52] An effect lasting 6

weeks to 3 months is typical. Although scarring and deformation of the vocal fold can occur, this material is usually absorbed, and no permanent damage occurs if normal function returns to the vocal fold.

Autologous fat injection for treatment of vocal fold paralysis was first reported by Mikaelian et al in 1991.[53] Cited advantages include the lack of foreign body inflammatory response, the availability and ease of harvesting graft material, and the soft, pliable texture of fat that does not impair the normal vibratory characteristics of the vocal fold. It must be carefully harvested to prevent fat cell destruction and is injected into two to three locations within the thyroarytenoid muscle.[53] Problems with resorption of the injected fat over time have led most surgeons to overinject the vocal fold by 30 to 50%. Rosen reported no noticeable resorption of fat beyond that which occurs within the first postoperative month.[45] Several techniques of fat harvesting have been proposed to enhance long-term graft survival.[54,55]

Collagen injection is a preferred technique for correction of gaps caused by vocal fold atrophy and other small defects. Collagen should be injected superficially, into the deep layer of the lamina propria to prevent rapid resorption. If this rule is followed, the correction present after 3 months tends to persist.[56] Over time, collagen has a softening effect on the tissues, so reinjection at a later date is usually easy. Earlier studies used injectable bovine collagen preparations,[56,57] which carry the risk of hypersensitivity reactions or transmission of infectious agents. Autologous collagen has been proposed as a safer alternative to the bovine preparation.[58–60] Autologous fascia may also prove to be useful for vocal fold augmentation in the future.[61]

Vocal fold injection is a simple technique but is not without pitfalls. The ideal material for injection has not yet been found. Nonetheless, vocal fold injection can provide marked benefit for patients with glottic insufficiency causing aspiration, weak or absent cough, short maximum phonation time, breathy voice, insufficient loudness, and limited pitch range.

Medialization Thyroplasty. Laryngeal framework surgery provides methods to medialize, separate, shorten, or lengthen the vocal folds. These procedures, referred to as thyroplasty types I through IV, respectively, were popularized by Isshiki and bear his name. If the preoperative laryngeal examination reveals contact of the mobile vocal process with the paralyzed vocal process during phonation, then type I thyroplasty alone usually results in significant improvement.[62] If a wide posterior glottal gap is noted during phonation, a concomitant arytenoid adduction procedure (described below) may be required to achieve an optimal voice result. The lateral compression test is sometimes useful for preoperative assessment of these patients. In this maneuver, the examiner uses the thumb and forefinger to compress the thyroid alae medially while the patient sustains a vowel sound. Subjective and objective measures (ie, maximum phonation time, videostroboscopy, acoustic analysis) of change, if any, are noted. If improvement is noted with the lateral compression test, then type I thyroplasty is usually successful. However, it may still be successful even if no improvement is noted on manual compression, especially in older patients with ossified, inflexible thyroid cartilages.

Like vocal fold injection, thyroplasty is best performed with the patient awake to allow intraoperative monitoring of results. The patient is placed supine on the operating room table. Intraoperative flexible fiber-optic laryngoscopy is used to verify the side of paralysis. The entire procedure is accomplished under local anesthesia consisting of 1% lidocaine and 1:100,000 epinephrine. A 3 to 4 cm transverse incision is made along a skin crease overlying the involved thyroid ala from a point on the anterior cervical midline extending laterally (Figure 53–2). Superior and inferior subplatysmal flaps are raised, and the retraction of the strap muscles exposes the outer perichondrium of the thyroid cartilage ala.

Using a caliper, a horizontal midline of the thyroid ala is determined. The size of the alar window measures approximately 6×13 mm. The window is carefully positioned below the horizontal midline 5 to 7 mm from the anterior commissure (Figure 53–3). The window should be as close to the inferior border of the thyroid ala as possible while leaving a sufficiently strong inferior cartilage strut to support the implant (3 mm).[62] The exact placement and size of the window should take into account the anticipated shape and size of the implant and the overall size of the larynx.[63]

An inferiorly based perichondrial flap is raised according to the calculated window dimensions. The cartilage window is cut with a 2 to 3 mm otologic bur. Care is taken to avoid violating the inner alar perichondrium. The cartilage window is then

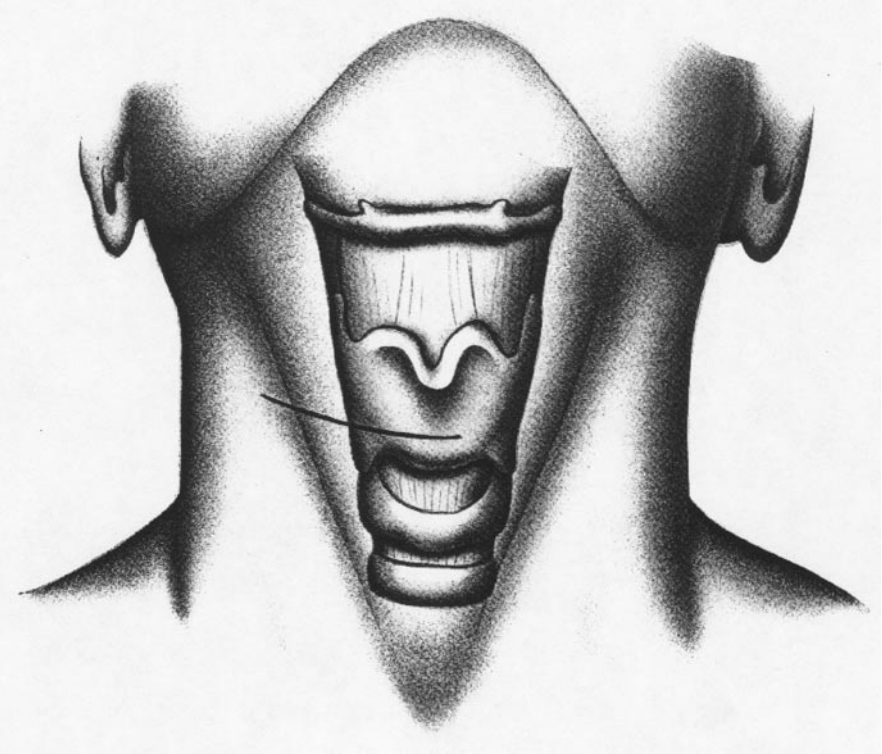

FIGURE 53–2. The incision is outlined in a cervical crease overlying the thyroid cartilage extending more to the side of the paralysis. If indicated, simultaneous procedures such as arytenoid adduction or reinnervation can be performed through one incision. Reproduced with permission from Wanamaker JR et al.[62]

removed, and the inner perichondrium is carefully elevated from the medial surface of the thyroid cartilage surrounding the window using a Woodson elevator. Too high an elevation from the horizontal midline may lead to perforation at the laryngeal ventricle. Some authors recommend creation of an anteriorly based flap of the inner perichondrium to enhance the accuracy and effectiveness of medialization (Figure 53–4).[62] The Silastic prosthesis is fashioned and placed into the alar window. When optimal medialization has been established, the prosthesis is scored flush with the outer perichondrium and is cut across with a scalpel to result in an embedded edge (Figure 53–5). The inferior perichondrial flap is sutured back to its anatomic position with interrupted 5-0 nylon sutures, and the wound is closed in a two-layer fashion over a quarter-inch Penrose drain.

McCulloch and Hoffman introduced the use of expanded polytetrafluoroethylene (Gore-Tex) as an alternative to Silastic for medialization.[64] Cited advantages of this material include the ability to make incremental and easily reversible adjustments in medialization, the lack of precision required in creating the cartilage window or shaping the implant, and the lack of special instrumentation required.[65]

Advantages of type I thyroplasty over Teflon injection include easy intraoperative adjustability and the ability to remove the implant if vocal fold movement returns. Thus, in patients who may spontaneously recover neuromuscular function, corrective surgery can be performed before the usual 6- to 8-month waiting period. Type I thyroplasty allows the medialization of the entire fold rather than an isolated or uneven segment sometimes observed following injection techniques. Following successful type I thyroplasty, an immediate improvement is seen both in breathiness and maximum phonation time. Over time, reductions in voice strain are also common.

Poor or suboptimal voice results most commonly from placing the window too far superiorly or anteriorly. This may result in excessive convex displacement of the anterior part of the vocal fold and diminished voice quality. Of even more concern, excessive anterior placement predisposes to penetration of the ventricular mucosa, granuloma formation, and implant extrusion.[58,63,66]

Arytenoid Adduction. In 1978, Isshiki et al described the arytenoid adduction procedure for patients in whom vocal fold paralysis resulted in a

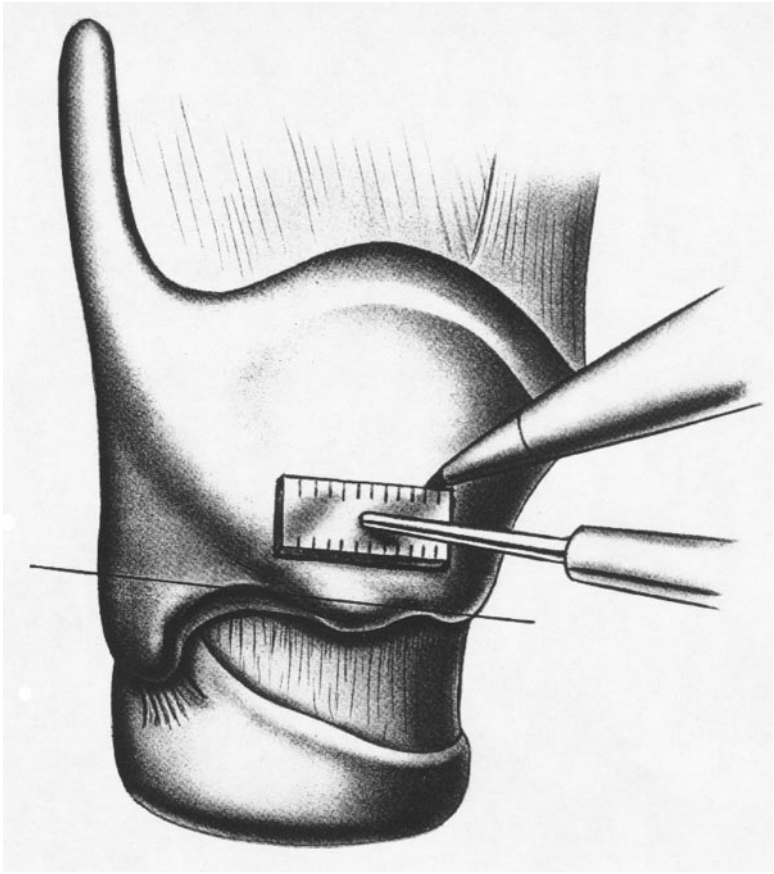

FIGURE 53–3. The window is outlined using the 6 × 13 mm window template parallel to the lower border of the thyroid cartilage. When outlining the lower border, one must elevate both anterior and posterior to the muscular process of the attachment of the cricothyroid muscle. This process is quite variable in size. The true parallel line is obtained by lining up the anterior part of the lower border of the thyroid cartilage with the ridge in the cartilage posterior to this process. The window is outlined as low as possible while leaving an inferior strut (3 mm) that is strong enough to support the implant. Reproduced with permission from Wanamaker JR et al.[62]

large posterior glottal chink or a difference in the level of the vocal folds during phonation.[67] The goal of the procedure is to approximate the physiologic position of the arytenoid during phonation. Under local anesthesia, the cricoarytenoid joint is exposed through dislocation of the cricothyroid joint and subperichondrial dissection around the posterior border and inner surface of the thyroid ala. Careful superior elevation of the piriform sinus mucosa exposes the posterior cricoarytenoid (PCA) muscle and the palpable arytenoid muscular process. The cricoarytenoid joint is opened, and two 3-0 nylon sutures are tied across the muscular process. The sutures are then passed anteromedially through the paraglottic space, through the anterior part of the thyroid ala, and are tied on the outer surface of the ala. The vector of force of these sutures causes a medial-inferior rotation of the arytenoid cartilage, which mimics the action of the lateral cricoarytenoid and lateral thyroarytenoid muscles.

Netterville et al facilitate exposure of the muscular process through removal of a cartilaginous window on the posterior border of the thyroid ala.[68] The fixation suture is then placed through the lateral surface of the muscular process without disrupting the cricothyroid or cricoarytenoid joints. Arytenoid adduction appears to enhance the aerodynamic parameters and perceptual voice quality of many patients undergoing type I thyroplasty, and some laryngologists now routinely expose the muscular portion of the arytenoid cartilage as part of their laryngeal framework surgery to assess the benefit of arytenoid adduction in conjunction with Silastic or Gore-Tex medialization.[69] Arytenoid adduction reduces the posterior glottic aperture (ie, the ventilatory portion of the glottis), and this procedure should be used with caution, if at all, in patients with COPD, with paresis of the contralateral vocal fold, or who require a wide glottal aperture for intensive aerobic activities.

Arytenoid Arytenopexy. Noting the excessively inferior displacement of the vocal fold that may result from the classic arytenoid adduction procedure, Zeitels et al designed the adduction arytenopexy procedure to reflect more closely the simultaneous, three-dimensional effects of the lateral cricoarytenoid, PCA, interarytenoid, and thyroarytenoid

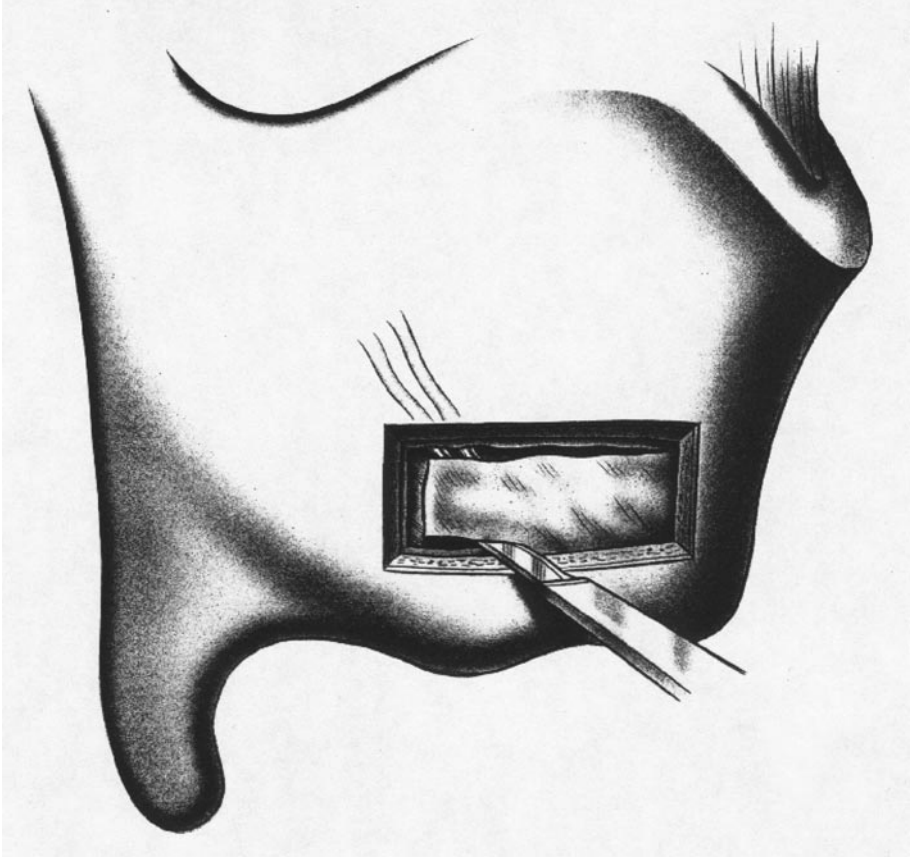

FIGURE 53–4. The perichondrium is carefully incised along the superior, inferior, and posterior margins of the window. Care is taken to minimize injury to the underlying thyroarytenoid fascia, which protects the muscle and the distal branches of the superior laryngeal vessels. Reproduced with permission from Wanamaker JR et al.[62]

muscles on arytenoid position and stabilization during phonation.[70,71] Following exposure and opening of the cricoarytenoid joint, a 4-0 polypropylene suture is placed through the posterior plate of the cricoid cartilage medial to the joint facet. The suture is then passed through the body of the arytenoid cartilage and back out underneath the facet through the posterior plate of the cricoid cartilage where it is tied following endoscopic verification of proper arytenoid position. Silastic medialization (type I thyroplasty) is then performed to optimize the position of the membranous vocal fold. The addition of a cricothyroid subluxation suture has also been proposed to increase the length and tension of the paralyzed fold as needed to enhance the final voice result.[72]

Reinnervation. Reinnervation techniques succeed to the degree that they can reproduce the normal tone and action of the intrinsic laryngeal muscles. Tucker described use of a nerve muscle pedicle from the omohyoid muscle to restore adductory function to the thyroarytenoid muscle in nine patients.[73] All patients had a unilateral vocal fold paralysis with involvement of both SLNs and RLNs, resulting in a large posterior glottal defect and bowing of the affected fold. After creating a window in the lower half of the ipsilateral thyroid ala, the nerve muscle pedicle was sutured to the lateral portion of the thyroarytenoid muscle. Between 2 and 12 weeks postoperatively, some observable return of adductory function and improvement in voice was noted in all patients. Four of the nine patients achieved appropriate adduction and tensing of the affected fold during phonation. Since the ipsilateral recurrent nerve is not disturbed during the dissection, this procedure does not preclude any spontaneous reinnervation that may occur by the RLN.

Crumley et al reported excellent voice quality in patients undergoing ansa cervicalis nerve transfer (NT) to RLN for unilateral RLN paralysis.[74] The ansa's branch to the sternothyroid is sutured to the distal end of the transected RLN using 10-0 monofilament nylon sutures. The best results were seen in patients without prior medialization procedures and in whom the paralysis had occurred within 24 months of NT. Although adductory or abductory movements of the operated side were not observed, NT is thought to impart static tone and mass to the

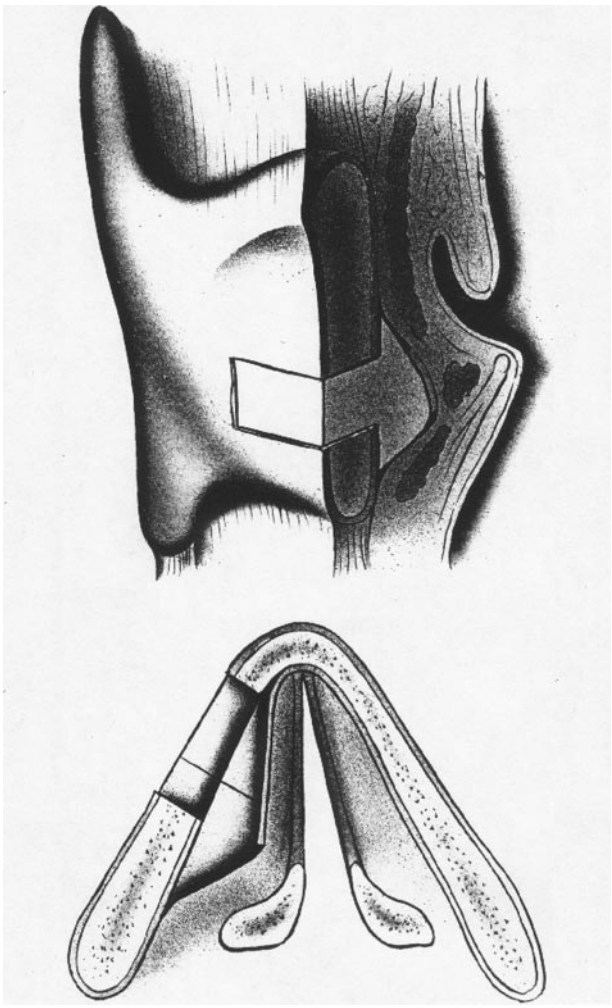

FIGURE 53–5. The final position of the implant (*above*) shows the plane of maximal medialization at the lower margin of the window. This helps to prevent medialization of the false vocal fold and the ventricular mucosa. The posterior extension of the implant (*below*) medializes the vocal process of the arytenoid as well as the mobile true vocal fold. This results in some adduction of the arytenoid cartilage. Reproduced with permission from Wanamaker JR et al.[62]

intrinsic laryngeal muscles, thereby stabilizing the arytenoid cartilage into a more symmetric position compared with the opposite side. The jerky, synkinetic movements sometimes seen following RLN injury have not been observed following NT; the sternothyroid branch of the ansa appears to provide weak, tonic innervation, which maintains vocal fold tone without producing spasms. Crumley et al recommended NT as the procedure of choice in younger patients and voice professionals because the voice quality results, in their experience, are superior to those achieved with Teflon or thyroplasty. The disadvantages of the technique include a waiting period of up to 6 to 12 months postoperatively until improvement is seen, and transection of the RLN disrupts any spontaneous reinnervation that has occurred. Despite these promising results, NT is infrequently performed in the general otolaryngology community for the treatment of unilateral vocal fold paralysis.[75]

Bilateral Vocal Fold Paralysis

Patients with bilateral vocal fold paralysis usually require treatment because of loss of abductor function leading to airway obstruction. Not only is the glottic chink narrowed by the resting position of the vocal folds, but also, with inspiration, the Bernoulli effect causes the folds to move medially as the velocity of the airflow increases. Surgical treatment of this problem usually involves one of three strategies: bypassing the site of obstruction, increasing the caliber of the airway, or attempting to restore abductor function. In weighing treatment options, points to consider include effectiveness, preservation of vocal quality, and possible complications.

Tracheostomy Tracheostomy bypasses the site of obstruction, providing immediate, effective treatment. Although long-term tracheostomy may be less appealing than other treatments, it often plays a role in the treatment of acute bilateral vocal fold paralysis by stabilizing the patient. When quick recovery of function is expected, it may be possible to avoid this operation altogether with the use of continuous positive airway pressure to splint the airway.[76] In other cases, tracheostomy may be useful as an interim treatment, allowing other techniques to be performed under less pressing circumstances.

Increasing Airway Caliber Techniques for enlarging the airway usually involve lateralization of one of the vocal folds and/or the removal of tissue, particularly from the posterior glottis. Work by Hirano and colleagues has shown that the posterior glottis accounts for 50 to 65% of the area of the total glottis.[77] Thus, enlarging the posterior glottis has a greater effect on the airway while preserving vocal quality. These techniques have been applied using both transcervical and endoscopic approaches.

Transcervical Approaches. Chevalier Jackson in 1922 used the midline thyrotomy to resect the vocal fold and ventricle, resulting in a satisfactory airway but a poor-quality voice.[78] Subsequent techniques that used a laryngofissure included cordopexy,[79] submucous resection of the vocal fold,[80] and arytenoidectomy with cordopexy.[81] Later this approach was used to perform arytenoidectomy alone,[82] without lateralization, which was successful in expanding the airway while preserving voice.[83] In 1946, Woodman modified a lateral open approach to perform arytenoidectomy, avoiding laryngofissure.[84] While the arytenoid was excised, the vocal process was preserved and used to lateralize the cord by suturing it to the lesser cornu of the thyroid cartilage. Although this procedure was widely used for many years and resulted in a predictably good airway, the voice results were often poor.

Endoscopic Approaches. Thornell introduced the endoscopic arytenoidectomy in 1948.[85] Good results have been reported with this procedure, and it has been widely used. El Chazly et al reported better airway results when posterior cordectomy was added to arytenoidectomy, although vocal quality was reportedly impaired.[86] Problems with hemostasis during traditional endoscopic arytenoidectomy were overcome with the introduction of the carbon dioxide laser arytenoidectomy by Ossoff et al in 1984.[87] They reported a success rate of 86% for this procedure, which includes vaporization of a portion of the vocalis muscle as well as the arytenoid.[88] In contrast, a procedure that involves vaporization of only the medial portion of the arytenoid has been described in patients with more moderate airway compromise.[89] This procedure is reportedly superior in preserving voice and can be done as a staged bilateral procedure if necessary. Benninger et al stressed the importance of maintaining a medial mucosal flap for coverage of remaining exposed cartilage to reduce postoperative granuloma formation.[90] Temporary stitch lateralization of the operated vocal fold has also been used to ensure an adequate airway until postoperative edema resolves in patients without tracheostomy.[90]

Some endoscopic techniques do not involve arytenoidectomy. Kirchner described a procedure in which he resected a portion of the thyroarytenoid muscle and then lateralized the vocal fold with temporary sutures.[91] Success has also been reported for endoscopic lateralization with permanent sutures without any tissue resection.[92] Other techniques have made use of the carbon dioxide laser. Linder and Lindholm described using the laser to reduce the bulk of the vocal fold laterally, followed by fibrin glue to maintain it in the lateral position.[93] The laser has also been used to remove a portion of the posterior vocal fold (posterior cordectomy), most recently by Dennis and Kashima,[94] who created a crescent-shaped 3.5 to 4 mm defect anterior to the vocal process. Even less tissue was removed with the subsequent development of transverse cordotomy, in which the incision anterior to the vocal process leads to the development of a wedge-shaped defect as the thyroarytenoid muscle retracts.[95] Transverse cordotomy may also be combined with anterolateral arytenoidectomy.[90]

Restoration of Function The techniques described previously often involve a trade off between airway and vocal quality. Thus, the ideal treatment of bilateral vocal fold paralysis remains restoration of function via reinnervation. Direct repair of the injured RLN has not led to satisfactory results; vocal fold motion tended to be uncoordinated and synkinetic.[96,97] Better results were obtained in animals with selective reinnervation of the laryngeal abductor muscle, the PCA.[98] Use of a cable graft directly to the PCA was not successful in humans, however.[99] A more successful procedure has been the use of a nerve muscle pedicle based on the ansa hypoglossi to reinnervate the PCA.[100] In 1989, Tucker reported a long-term success rate of 74% in more than 200 patients with bilateral vocal fold paralysis, with success based on the rate of decannulation.[101] Other centers have not been able to achieve this success rate, however.

Another promising strategy for restoring function in bilateral RLN paralysis involves the use of electrical pacing devices.[102] Electrical stimulation of the PCA using an implantable nerve stimulator has been shown to abduct the vocal folds sufficiently to permit decannulation in five of seven patients implanted worldwide thus far.[103] Presently, the device is turned on by the patient as needed and supplies a programmed schedule of stimulations to which the patient must entrain his/her breathing pattern. Ultimately, a pressure-sensing device may be added to the system to coordinate PCA stimulation with inspirations. The technology and surgical approaches for laryngeal pacing are currently

undergoing improvements and refinements, which will hopefully lead to functional rehabilitation of the paralyzed larynx.

In summary, tracheostomy and endoscopic procedures, particularly those that make use of the carbon dioxide laser, are currently the mainstays of treatment for bilateral vocal fold paralysis. Because of the tradeoff often involved between airway and vocal quality, however, much research continues to focus on the development of techniques to restore function to the larynx.

Laryngeal Paralysis and Aspiration

Vocal fold paralysis alone, whether unilateral or bilateral, rarely results in aspiration. When vocal fold paralysis occurs in conjunction with other motor or sensory dysfunction, however, the combination may significantly impair the protective function of the larynx, leading to aspiration. Neurogenic causes of aspiration may include cerebrovascular accidents, degenerative diseases, neuromuscular disorders, peripheral nerve disorders, intracranial neoplasms, and anoxic or traumatic brain injury.[104]

Evaluation of the patient with aspiration begins with a thorough history and physical examination and requires multidisciplinary evaluation.[105] The history should elicit information about symptoms of any associated neurogenic disorder as well as information about respiratory symptoms that may indicate the degree of severity of aspiration. Physical examination should include visualization of the larynx. Other testing should include chest radiography and modified barium swallow[42] using contrast material of different consistencies performed with the guidance of a speech-language pathologist.

Nonsurgical management of the patient with aspiration usually consists of discontinuing oral intake and providing alternative methods of alimentation. Enteral alimentation is preferable and may be provided with a nasogastric feeding tube. For long-term feeding, however, gastrostomy or jejunostomy may be performed. Attention should also be given to pulmonary toilet. Tracheostomy may be helpful in caring for patients with copious secretions; however, the presence of a tracheostomy may also contribute to problems with aspiration.[42,43]

Specific surgical treatment of the patient with significant aspiration and vocal fold paralysis includes a variety of procedures to medialize the vocal fold discussed elsewhere in this chapter.[43] In patients in whom recovery of function is expected, procedures that are temporary or reversible are indicated, such as Gelfoam paste injection[106] or thyroplasty.[107]

Other surgical techniques are not specifically directed at treatment of vocal fold dysfunction; rather, they involve separation of the upper digestive tract from the upper respiratory tract. Unfortunately, patients undergoing such procedures frequently lose the ability to phonate and may also require permanent tracheostomy. Such procedures can be performed with low morbidity, however, and some of these procedures are at least theoretically reversible should function return.

Narrow-field laryngectomy remains the oldest and one of the most effective surgical treatments of aspiration. Tracheoesophageal puncture can be used to restore phonation. Reluctance to sacrifice an otherwise normal larynx has led to the development of other procedures to close the larynx. Montgomery described a glottic closure technique in which the true and false vocal cords were approximated.[108] Closure was improved by Sasaki and associates with the interposition of a sternohyoid muscle flap.[109] This procedure was extremely effective but did not permit phonation, which was sometimes possible with supraglottic laryngeal closure methods. Since first being described in 1972,[110] the epiglottic flap closure technique has undergone certain modifications, including intentionally leaving an opening posteriorly to permit phonation.[111] Successful reversal of this procedure has been reported by an endoscopic approach.[112] Biller and colleagues have also described a supraglottic closure technique, vertical laryngoplasty, intended for use in patients undergoing total glossectomy.[113] This method also permits speech.

Efforts to devise a procedure that is completely reversible have led to the development of different endolaryngeal stents. Weisberger and Huebsch used a solid Silastic stent in conjunction with a tracheostomy,[114] whereas Eliachar and Nguyen devised vented silicone stents that permit phonation.[115] The advantages of stenting include the use of the endoscopic approach and ease of reversibility. Successful control of aspiration has not been uniform, however, and long-term use of stents carries the risk of endolaryngeal injury, limiting their utility.

Tracheoesophageal diversion was developed by Lindeman with the goal of controlling aspiration

definitively while preserving the larynx and RLNs and thus the potential for reversal.[116] In this procedure, the trachea is divided at the level of the fourth or fifth ring. The proximal trachea is anastomosed to the esophagus, whereas the distal trachea is anastomosed to the skin. Thus, aspirated secretions are diverted back into the gastrointestinal tract. In the modified laryngotracheal separation procedure, the proximal segment is instead closed as a blind pouch.[117] Both techniques have provided good control of aspiration, and both have been successfully reversed.[118] Because no current method is completely satisfactory, investigations continue in an attempt to find a safe, effective means of controlling aspiration without disrupting respiratory or phonatory function. One possibility for the future may be implantable electronic systems now being developed in animals that can produce tight glottic closure during swallow.[119]

FUNCTIONAL VOICE DISORDERS

The term "functional voice disorder" is used to designate a voice disorder resulting from difficulties with the use of the larynx for voice production. There are no structural abnormalities and no peripheral nerve injuries to account for abnormalities in laryngeal function. The disorder occurs only when the person attempts to use their larynx for a particular function such as vocalization or breathing. These disorders are thought to be owing to abnormalities in central nervous system control or behavior.

Functional voice disorders may be (a) idiopathic, (b) attributable to misuse of the larynx for voice production (eg, the development of compensatory behaviors for voice production), or (c) psychogenic, owing to psychological difficulties interfering with normal voice production.

As knowledge and understanding of these disorders progress, fewer will be considered functional after an underlying abnormality has been identified. For example, the SDs are currently classified as idiopathic disorders but are also classified as laryngeal dystonias, a motor control disorder.[120] Until the underlying defect is identified, however, these are considered idiopathic disorders.

Most of these disorders have distinctive symptom patterns, allowing them to be recognized as separate disorders. Further, they usually respond differently to various treatment approaches. Identification depends on the person's voice symptoms.[121] Because diagnosis is based on voice characteristics, consensus has not yet been reached, and diagnoses may differ even among specialized voice centers. Because treatments for controlling symptoms in some of the functional voice disorders are invasive and may alter the larynx, accurate diagnosis is important before such intervention is warranted.

Idiopathic Disorders

In these voice disorders, volitional control of vocal fold movement during the specific laryngeal functions is affected, such as speaking in the SDs and respiration in paradoxical vocal fold movement.

Spasmodic Dysphonias The SDs include *adductor* SD (uncontrolled closing of the vocal folds),[122] *abductor* SD (prolonged vocal fold opening for voiceless sounds extending into vowels),[123] or *vocal fold tremor* (modulations in phonatory pitch and loudness most evident during prolonged vowels). These disorders are characterized by involuntary changes in the ability to maintain voicing during speech either because of intermittent glottal catches (voice breaks) in the adductor type or breathy breaks owing to prolonged vocal fold abductions for voiceless consonants in the abductor type. Often the problem first appears with a very specific task,[124] gesture or posturing of the larynx, such as vowel production during speech, and then may progress to interfere with other tasks or postures such as singing and speaking using falsetto. In mild to moderate forms of SD, patients may have uncontrolled spasms affecting only the speaking voice, with normal singing and falsetto phonation.

Onset often follows an upper respiratory infection, laryngeal injury or inflammation, a period of excessive voice use, or occupational or emotional stress.[125] Increased effort is one of the major patient complaints, along with loss of control and an increased difficulty with prolonged voice use or stress. Onset is between 30 and 50 years of age, and at least 60% of those affected are women. The characteristics of these disorders include the following:

1. They are specific to a particular task, gesture, or posture of the larynx.
2. They are action induced, that is, they appear only with voluntary movement and are not usually apparent at rest.

3. They become worse with prolonged speaking, practice, or performance.
4. Onset is usually gradual, often following some upper respiratory infection, inflammation, or stressful event.
5. Reflexive and emotional aspects of voice function are unaffected, such as coughing, crying, shouting, and laughter.
6. In professional voice users, they may appear during busy professional schedules or following injury.

In some patients, particularly those with abductor SD, some degree of vocal fold asymmetry may be apparent within the first 6 to 12 months, suggesting injury.[126,127] With time, this asymmetry often disappears, but the disorder remains.

Movement abnormalities occur when the patient attempts specific gestures such as phonation of vowels in adductor SD, voiceless consonants (such as s, h, f, t, k) followed by vowels in abductor SD, or using a modal speaking voice in vocal tremor.

No information is available on the etiology of these disorders. Sometimes they occur in persons with a family history of dystonia.[120] However, in clinics specializing in voice disorders, few patients with SD have a positive family history for dystonia.

Diagnosis and Assessment. Diagnosis and management of SDs are best accomplished by a voice team including an otolaryngologist, a speech pathologist, a neurologist, and, in some cases, a psychologist. Because these movement disorders affect the larynx, diagnosis depends on observing the vocal folds during speaking and nonspeech gestures. In addition, the larynx must be visualized to rule out other disorders that could account for the symptoms. The laryngologist rules out vocal fold nodules, polyps, carcinoma, cysts, contact ulcers, inflammation (laryngitis), vocal fold paresis, or paralysis using fiber-optic laryngoscopy. A neurologic examination is necessary to rule out amyotrophic lateral sclerosis, Parkinson's disease, or supranuclear palsy, which can all produce vocal fold movement abnormalities.[128] Some patients may also have concomitant focal dystonias such as writer's cramp or blepharospasm, which can be successfully managed by a neurologist. Many patients may have some degree of laryngeal tremor in addition to spasmodic hyperadduction or hyperabduction. These patients are usually included as a subtype of the SDs[129,130] and may have a more severe disorder.[131]

An extensive history, a trial of voice therapy, and a psychosocial interview may be needed to rule out psychogenic dysphonia.[132,133] Patients may have psychosocial reactions as a result of their voice disorder, confounding the ability to differentiate idiopathic SD from psychogenic disorders through history and interview. For example, many patients will no longer use the telephone and avoid social gatherings as a result of having a speech disorder. Voice disorders have not been found to produce mental illness, however.[134]

Tasks To Be Examined During Fiber-optic Laryngoscopy. Both speech and nonspeech tasks must be sampled to identify (1) movement control abnormalities during vocal fold abduction (opening) and adduction (closing) in speech and (2) movement during nonspeech items such as respiration, sniffing, throat clearing, whistling, and singing. For example, in the paradoxical vocal fold movement disorder, vocal fold abnormalities appear only during inspiratory breathing but not talking (Table 53–4).

Fiber-optic laryngoscopy is useful when examining dysphonia associated with many of the neurogenic disorders to determine how vocal fold movement is affected for adduction and abduction and the speed of motion. Usually, stroboscopy is less helpful because patients with tremor or spasms do not have a regular phonatory cycle that can be tracked from the contact microphone or electroglottographic signal. Further, in patients with other functional voice disorders such as muscular tension dysphonia, the constant hoarseness similarly interferes with tracking. The emerging use of kymography and eventually high-speed video will be particularly useful for examining such patients.

Speech Testing. Voice symptoms should be compared during three tasks to discriminate among adductor SD, abductor SD, and vocal tremor:

1. Prolonged vowel phonation usually manifests tremor if it is present; prolonged vowel production is affected only in the more severe forms of adductor and abductor SD.
2. Production of sentences in which all of the sounds are voiced and frequent glottal stops are at word boundaries (eg, "We mow our lawn all

TABLE 53–4. Movement Characteristics Observed during Fiber-optic Laryngoscopy in Various Types of Functional Voice Disorders

Task	*Movement Examined*	*Adductor SD*	*Abductor SD*	*Tremor Adductor*	*Tremor Abductor*	*Paradoxical Vocal Fold Movement Disorder*	*Muscular Tension Dysphonia*
Deep inhalation	Abduction range	Normal abduction	May be increased	Normal	May have tremor	Vocal fold adduction	Normal
Prolonged vowel "ee"	Adduction for voice	Normal or intermittent hyperadductions	Normal	Repetitive hyperadductions (5 Hz)	Repetitive abductions (5 Hz)	Normal	Constant hyper-adduction
Throat clear 3 times	Adduction	Normal	Normal	Normal	Normal	Normal	Normal
Whisper	Vocal fold partial abduction	May have hyperadduction	May have increased abduction	Normal	May have tremor	Normal	May have constant adduction
Whistling	Vocal fold abduction and adduction	Normal	Normal	Normal	Normal	Normal	Normal
Repeated and quick sniffs	Speed of abduction	Normal	May be increased in range	Normal	May have tremor on abduction	Adduction on sniff	Normal
Alternating between sniff and vowel "ee"	Speed and range of abduction and adduction	Intermittent hyperadduction on vowel	Normal	Tremor on vowel	Tremor on vowel	May have hyper-adduction on sniff	Constant hyper-adduction on vowel

TABLE 53–4. *Continued*

Task	*Movement Examined*	*Adductor SD*	*Abductor SD*	*Tremor Adductor*	*Tremor Abductor*	*Paradoxical Vocal Fold Movement Disorder*	*Muscular Tension Dysphonia*
Rapid repetition of vowel "ee" 6 times	Phonation offset owing to glottal stop	Prolonged glottal stops	Normal	Tremor on vowel	Tremor on vowel	Normal	Constant hyper-adduction with antero-posterior squeeze
Rapid repetition of "see" 6 times	Speed of abduction and adduction	Normal or intermittent adductions on vowel	Prolonged abductions during "s"	Adductor tremor on vowel	Abductor tremor on vowel	Normal	Constant hyper-adduction
Ascending and descending glides	Controlled lengthening and shortening of folds	Normal or intermittent adductions on low end	Normal	Adductor tremor on low end	Abductor tremor	Normal	Constant hyper-adduction
Sentences: "We eat eels everyday"	Glottal stops in sentences	Prolonged glottal stops	Normal	Adductor tremor	Abductor tremor	Normal	Constant hyper-adduction
"The waves were rolling along"	Constant voicing in sentences	Intermittent spasms in vowels	Normal	Adductor tremor	Abductor tremor	Normal	Constant hyper-adduction
"He will keep the keys"	Voiceless consonants in sentences	Normal	Prolonged voiceless consonants "he," "k"	Adductor tremor	Abductor tremor	Normal	Constant hyper-adduction

SD = spasmodic dysphonia.

year" and "We eat eels everyday") is usually most difficult and demonstrates frequent breaks or voice arrests in adductor SD.

3. Production of sentences with voiceless consonants (s, t, p, k, h) ("She speaks pleasingly," "Keep Tom at the party," and "When he comes home, we'll feed him") is usually most difficult in abductor SD. Sentences with predominantly voiced sounds are much easier to produce and smoother for these patients.

Electromyography. The laryngeal muscle activation abnormalities that can produce problems differ greatly across patients and can account for the wide variety of symptoms manifested.[135] The laryngeal muscles should be examined to determine which muscles contain spasms concurrent with a patient's voice symptoms during speech. In adductor SD, the thyroarytenoid is the most often affected.[136] In abductor SD, spasms can be seen in the cricothyroid in some patients[123] and in the posterior cricoarytenoid in others, or heightened activity can be seen on one side in the thyroarytenoid muscle.

In vocal tremor, a variety of muscles can be involved.[137] Most often the thyroarytenoid is affected, but other muscles, including the strap muscles, can be affected, including the thyrohyoid, the sternothyroid, and, in some patients with abductor tremor, either the cricothyroid or PCA or both.

By using a concentric EMG electrode connected to an amplifier with a dual-channel storage oscilloscope, one channel for the EMG and another for the speech waveform, at a slow sweep speed, quick identification can be made of the muscles having spasms during voice breaks. Descriptions of EMG techniques are provided in greater detail in Hirano and Ohala.[138]

For the thyroarytenoid and lateral cricoarytenoid muscles, items to be examined for spasmodic bursts concurrent with voice breaks include prolonged "ee," repeated "ee," and all voiced sentences, such as "We mow our lawn all year." When examining abductor SD, while recording from the cricothyroid or PCA, speech should include "see-see-see," "pea-pea-pea," "he-he-he," "Kathy took a potato," and "Keep Tom at the party." Muscles with bursts of activity before and during voice breaks can be considered for injection with botulinum toxin injection.

Treatment. In the last 15 years, the following treatments have been used for managing symptoms in adductor SD.

Voice Therapy. This can assist mildly affected patients but may not have long-lasting effects. When uncertain of the diagnosis of a patient's voice disorder, a trial of voice therapy is recommended. Usually within three sessions, a speech pathologist experienced in voice therapy will report whether voice therapy might be beneficial for a patient. Voice therapy may also be helpful after botulinum toxin injection by prolonging the benefit period.[139]

Inhalation Voice Therapy. Speaking on inhalation is sometimes helpful in mild to moderate cases but may not have long-lasting effects. This technique is difficult for some patients to learn given that they often have respiratory control problems in addition to their voice problems.

Recurrent Laryngeal Nerve Section. Dedo first described unilateral removal of a 1 cm segment of the RLN below the thyroid isthmus for the treatment of adductor SD in 1976.[140] The procedure resulted in an initial dramatic reduction or elimination of voice spasms, but symptoms may recur in up to 64% of patients.[141] Recurrence of symptoms has been attributed to reinnervation of the operated side based on EMG and histologic studies. Those patients failing surgery may still respond to botulinum toxin injections.[142] Owing to the high rate of symptom recurrence, the permanent alteration in laryngeal function, and the requirements for subsequent medialization surgery in some patients with excessive breathiness, RLN section is less preferred to botulinum toxin injections at the present time.

Recurrent Laryngeal Nerve Avulsion. Netterville and his colleagues proposed a more extensive removal of the recurrent nerve in an effort to reduce the risk of reinnervation into the distal stump of the sectioned RLN.[143] After mobilization of the ipsilateral thyroid lobe, all branches of the RLN are identified, traced, and avulsed from their muscular insertions deep to the cricopharyngeus muscle. The total length of RLN removed averages 9 cm, in contrast to an average of 2 cm reported in previous RLN section studies. Long-term follow-up (3 to 7 years) on 18 patients following RLN avulsion revealed that 16 patients (89%) were free of SD symptoms at 3-

year follow-up.[144] Two of these patients, however, later developed recurrent spasms following medialization laryngoplasty for treatment of weak voice. Thus, an overall success rate of 78% (14/18) was reported for the series, which compares favorably to long-term recurrence rates for RLN section.[141] Weed et al recommended that RLN avulsion be reserved for patients who do not benefit from or do not tolerate botulinum toxin injections or have failed prior RLN section.[144]

Selective Laryngeal Adductor Denervation-Reinnervation. Berke et al published preliminary results with selective bilateral denervation of the laryngeal adductor muscles in an attempt to achieve a permanent bilateral adductor weakness that mimics the transient effects of botulinum toxin.[145] The new procedure involves bilateral section of the adductor RLN branches to the thyroarytenoid and lateral cricoarytenoid muscles with intentional reinnervation of the proximal thyroarytenoid branches using branches of the ansa cervicalis nerve. The aim of this directed reinnervation is to prevent unwanted reinnervation by RLN efferents and to preserve adductor muscle tone.

The study presented 1- to 5-year follow-up on 21 patients with adductor SD who underwent the procedure. In general, the symptoms and overall severity of SD improved from moderate to severe ratings preoperatively to mild to absent ratings postoperatively. All patients experienced severe vocal fold bowing and breathiness in the early postoperative period that improved after 3 to 6 months. Aspiration of greater than 2 weeks duration was noted in two patients, one of whom required hospitalization for aspiration pneumonia. Additional treatments (botulinum toxin, voice therapy, collagen injection, thyroarytenoid myotomy) were also performed in several patients to enhance the postoperative voice result. As noted by the authors, long-term follow-up in a larger patient population will be required to define the role of this procedure in the treatment of adductor SD. In particular, the effects of bilateral denervation on airway protection and fine motor control of the larynx (pitch variability, loudness range) require further careful assessment. Because the procedure is technically difficult and produces permanent structural and functional changes in the larynx, it should be reserved for patients with relatively severe disease. However, the authors reported promising results with normal conversational voice intensity and good inflection in most adductor SD patients treated thus far.

Thyroplasty. This surgical approach pushes the thyroid keel posteriorly, thus shortening and adducting the vocal folds.[146] In most cases, this can be detrimental to the voice, resulting in pitch lowering. This surgery cannot be easily reversed owing to the long-term effects of fibrosis and scarring. Because other more successful approaches are available, it is not recommended for patients with adductor SD.

Botulinum Toxin. This approach was developed in 1987[147] and has been evaluated using unilateral or bilateral thyroarytenoid injections in adductor SD.[148] The results seem excellent, with restoration of normal voice in 70% of patients for up to 3 months, followed by gradual symptom return within 4 to 5 months. Because the effect is temporary, it can be used on a trial basis in certain muscles in a particular patient. At 3-month intervals, injections can be administered in different muscle combinations to identify the correct muscles and dosage to be used for a particular patient.

The most commonly used method of injection is the percutaneous EMG-guided approach through the cricothyroid membrane.[149] The injection needle is Teflon coated, except for the bared tip, which serves as a monopolar EMG electrode when the bared hub is connected to a physiologic amplifier. This allows monitoring for a characteristic physiologic signal to determine that the needle tip is located in muscle before injecting. However, because the monopolar electrode has a large recording field and may pick up signals from any of the laryngeal adductor muscles in the region, such monitoring is not necessarily specific for the targeted thyroarytenoid muscles.[7]

To approach the thyroarytenoid percutaneously, the needle is angled superiorly and slightly laterally to approximate the mediolateral aspect of the vocalis portion of the TA muscle.[138] However, the needle tip can easily be placed more posteriorly than intended, medial to the lateral cricoarytenoid muscle and medial-superior to the cricothyroid muscle.[150] This can be seen in coronal sections of the adult human larynx.[151] From this, it is apparent that posteriorly placed injections may denervate portions of the lateral cricoarytenoid and cricothyroid muscles, in addition to the thyroarytenoid,

either by direct injection of these muscles or by diffusion across fascial planes.[152] This could account for the variability in response that is often seen (a) among patients and (b) in the same patient from consecutive EMG-guided injections several months apart, even though the same technique and dosages are used.

Two approaches have been used: large unilateral injections producing unilateral vocal fold paralysis[153] or small bilateral injections not altering the range of vocal fold movement on either side.[154] The advantage of the unilateral injection technique is that muscles on only one side of the larynx are affected by botulinum toxin. The long-term effects of repeated needle insertion and repeated denervation by botulinum toxin on laryngeal muscles are as yet unknown. Muscle biopsies in blepharospasm patients treated repeatedly with botulinum toxin injection have demonstrated significant muscle scarring and atrophy.[155] Similar changes in both thyroarytenoid muscles could have long-term effects on airway protection. The disadvantage of the unilateral injection approach is that a large dosage of toxin must be administered and that immobility of the injected fold often results.[153]

The advantage of the bilateral approach is that much smaller dosages of botulinum toxin can be used, reducing the cost. Further, effective symptom control can be obtained without any observable change in range of motion. Partial denervation seems to be effective in reducing the degree of hyperadduction, resulting in less interference with phonation. The disadvantages are that injections and needle insertions are performed on both sides of the larynx. With repeated injections every 4 to 6 months over many years, damage might result to both sides of the larynx, reducing airway closure and protection during swallowing.[156] Another difficulty with the bilateral approach is that if symptom control is not obtained with the usual dosage of 2.5 U on each side, further bilateral injections have the risk of causing bilateral adductor paralysis. With unilateral injections, repeated injection at higher dosages on the same side can be administered without danger of aspiration.

Other injection techniques that use visualization of the vocal folds rather than EMG to guide placement of the injection needle are the indirect laryngoscopic peroral method[157] and the transcartilaginous method.[158] Recently, the availability of the flexible fiber-optic nasolaryngoscope with a working channel has made possible an endoscopic method of injecting the thyroarytenoid muscle using a flexible catheter needle.[159] The usual dosages used by each technique are presented in Table 53–5.

Within 5 days of thyroarytenoid botulinum toxin injection, the number of breaks in phonation on vowels is reduced, the presence of voice roughness or hoarseness is reduced on spectrographic analyses, and speech rate is increased.[153] Patients' subjective reports include a reduction in speech effort and tension, reduced number of breaks, and greater voice control.[160] Two major side effects are reported: breathiness and swallowing difficulties. These side effects do not occur in all patients but can be significant in males following bilateral injections.[160]

Caution should be exercised in the use of botulinum toxin, particularly in undiagnosed patients with functional voice disorders. In such patients, the injections should be as small as possible (see Table 53–5) and combined with voice training. The injections should be only in those muscles demonstrated to be affected through a thorough EMG study during patient performance of affected and unaffected tasks.

Botulinum toxin injections have been employed in abductor SD in both the cricothyroid muscles[123] and the PCA.[161] Only about two-thirds of persons with abductor SD are benefited and to a lesser degree than those with adductor SD following thyroarytenoid muscle injections.[160]

The effects of vocal tremor on voice production can also be reduced by botulinum toxin injection[160]; however, the outcome is less predictable, and not all persons with vocal tremor are benefited.[162,163] In those patients with tremor affecting only the vocal folds and involving just the thyroarytenoid muscles, this treatment can be as effective as in adductor SD. However, many patients with this disorder have involvement of the strap muscles and have limited benefit even when these additional muscles are injected.

Paradoxical Vocal Fold Movement Paradoxical vocal fold movement is the adduction of the vocal folds during the inspiratory phase of respiration producing either a complete stoppage of air or stridor. These patients have normal vocal fold movement during speech, however, and often can inspire

TABLE 53–5. Dosages Used for Unilateral and Bilateral Injection of the Thyroarytenoid Muscle in Adductor Spasmodic Dysphonia

Unilateral/Bilateral	*EMG Guided*[149] *(U)*	*Injection Technique Peroral*[157] *(U)*	*Transcartilaginous*[158] *(U)*	*Endoscopic*[159] *(U)*

between phrases while speaking. There are several different categories of patients with these disorders: (1) as an idiopathic focal dystonia or part of Meige's syndrome,[164] (2) associated with or masquerading as asthma,[165] (3) exercise-induced stridor,[166] (4) psychogenic,[167,168] and (5) associated with gastroesophageal reflux.[169]

These movement disorders are very rare but have become increasingly recognized in the last 5 years.[170,171] Most patients were previously diagnosed as psychogenic,[165] although it is becoming increasingly apparent that some are not.[164,172] The first presentation of this as a focal laryngeal dystonia specific to inspiration suggested that in some patients this is not psychogenic but rather caused by involuntary spasmodic bursts in the thyroarytenoid muscle.[164] Patients with a focal dystonia report that the symptoms are not present during sleep but that the symptoms are often present during the daytime, when they may become exacerbated by exercise and stress. Treatment with botulinum toxin is difficult because swallowing problems can be experienced as a result.[173] Some success has been reported in selected cases not responsive to speech therapy, psychotherapy, and pharmacotherapy.[164,174]

Patients with Meige's syndrome, an orofacial dyskinesia, can develop pharyngeal spasms producing intermittent airway obstruction, either because of pharyngeal constriction or obstruction at the epiglottis. Often the cricopharyngeus muscle is overly active in such patients. Again, the symptoms are absent during sleep, almost always present during the day, but exacerbated by stress.

Patients with chronic asthma can have laryngeal vocal fold adduction during asthmatic attacks.[166,175] However, it is not known whether this is owing to psychological overlay, might be a learned response, or is a dystonic reaction following many years of use of inhalants for symptom management. Exercise-induced asthma has also been reported to have a laryngeal adduction component.[166]

Most cases in the literature of paradoxical vocal fold dysfunction causing stridor or episodes of airway obstruction have been reported as psychogenic. In such cases, the symptoms abate following psychotherapy and speech therapy.[176]

Koufman has suggested that gastroesophageal reflux is a common cause of paroxysmal laryngospasms.[169] He reported 12 patients who presented with intermittent, sudden-onset, noisy, obstructed breathing that some termed choking episodes. These attacks of stridor often occurred following a meal, after the start of exercise, or after bending over. Sometimes they occurred at night. Some had them up to twice a day, others much less frequently, only a few a year. These attacks usually lasted only a few minutes. All complained of symptoms of reflux such as a lump in the throat, chronic throat clearing, cough, intermittent hoarseness, and difficulty swallowing. He reported that all responded well to lifestyle modification and omeprazole 20 mg twice daily.

However, caution must be exercised in diagnosis and treatment of this group of disorders,[171] which can be life threatening.[170]

Disorders of Vocal Misuse

Disorders of vocal misuse are often thought of as psychogenic; however, these disorders are best conceptualized as disorders of muscle misuse.[177]

Muscular Tension Dysphonia Muscular tension dysphonia is a complex first described by Morrison and colleagues[177,178] as dysphonia resulting from increased muscular tension in the larynx and neck associated with (1) palpably increased phonatory muscle tension in the paralaryngeal and suprahyoid muscles, (2) elevation of the larynx in the neck on increasing vocal pitch, (3) an open posterior glottic chink between the arytenoid cartilages on phonation, and (4) variable degrees of mucosal changes such as vocal nodules or chronic laryngitis. Morrison et al have now named this "laryngeal isometric" to denote the high level of generalized muscle tension in all of the laryngeal muscles.[177] These patients often have a high level of anxiety and may have learned an abnormal pattern of laryngeal muscle use. Aronson included these patients as psychogenic voice disorders and recommended laryngeal maneuvering, progressive relaxation, and voice training, going through several stages from simple to more complex voice production.[122] Roy and colleagues have shown that manual laryngeal manipulation is an effective intervention for this disorder.[179]

Other variants of vocal misuse owing to muscle tension include lateral-to-medial hypercontraction, which produces a tense harsh voice with high laryngeal resistance. This posture of the larynx may be triggered by an infection or chronic reflux and is often associated with erythema or diffuse thickening of the mucosa. Morrison and colleagues have termed this "irritable larynx," suggesting that peripheral inflammation may be the basis for the disorder.[180] Poor vocal habits can be reversed by therapy working directly on changing vocal posture and technique. Fiber-optic videotaping can be an instructive feedback tool.

Supraglottic hyperconstriction is a third variant of muscular tension. Hyperadduction of the ventricular folds along with the vocal folds produces a squeaky voice with a great deal of effort. Very rarely, phonation is produced at the ventricular folds, but most often both the vocal folds and ventricular folds are involved in voice production.

Anteroposterior supraglottic contraction produces a "pinhole"-type larynx in the most severe form with no voice or an anteroposterior shortening in milder forms, which results in a rough, hoarse, low-pitched voice.

The etiology of these misuse disorders is unknown; rarely are these patients' voice production abnormalities helped by psychological counseling alone. Usually, they respond to voice re-education and life management counseling to change their patterns of voice use.

The distinction between these patients and adductor SD patients is the degree to which the abnormal laryngeal posture is used consistently for voice production (see Table 53–4). In muscular tension dysphonia and other variants of vocal misuse, the abnormal vocal fold positioning seen on fiber-optic videoendoscopy is consistent regardless of the type of speech. In the SDs, the abnormalities are intermittent, depending on the voicing gesture required, and contain irregular rapid adductor or abductor movements causing intermittent voice breaks on particular types of speech sounds, vowels in adductor SD and prolonged voiceless consonants in abductor SD. In benign essential tremor, these intermittent voice breaks are regular, usually around 5 Hz. However, in some of the more extreme forms of SD and/or muscular tension dysphonia, the differentiation can be difficult because the spasmodic involuntary movement abnormalities may be difficult to identify when patients have extreme muscular tension. Whenever a possibility of either diagnosis exists, a trial of voice therapy by a speech pathologist experienced in treatment of these disorders is recommended before considering botulinum toxin. If botulinum toxin is employed, a combined regimen of voice therapy following injection can be helpful in training patients to eliminate those abnormal postures that may be contributing to their voice disorder in addition to the spasmodic involuntary movements.

Voice Fatigue Syndrome Voice fatigue syndrome is diagnosed only after other disorders have been excluded, including myasthenia gravis, Parkinson's disease, amyotrophic lateral sclerosis, and muscle atrophy associated with aging, Epstein-Barr virus, and sulcus vocalis. When a misuse disorder is present, patients use excessive muscular tension in one muscle group that interferes with voice production for extended periods. Often patients must use their voice for authority or change their use for special demands such as classroom teaching. Patients then complain about their loss of voice and fatigue by the end of the day. Fiber-optic videotaping can be beneficial in retraining normal voice production.

Voice fatigue can also be associated with aging when an apparent loss of muscle bulk can become

apparent. If neurogenic disease can be excluded, then a regimen of increased physical exercise may be beneficial in increasing vocal function.

Abnormal Loudness Abnormal loudness can be identified as a misuse disorder when patients employ increased and excessive intensity, often when they have experienced a rapid diminution in their hearing or that of a family member. These patients may have assumed abnormal voice production patterns with excessive tension similar to the variants of muscular tension dysphonia.

Abnormal Pitch The continuation of a high pitch sometimes occurs in males following pubescent voice change. It can also be referred to as puberphonia or mutational falsetto. The misuse of a tense elongated vocal fold position during voicing can be seen. Often when this condition continues into adulthood, it is difficult to reverse because the misuse has become part of the voicing gesture. Laryngeal maneuvering can sometimes be successful in reducing the abnormal posturing.[122,177] The combination of an initial treatment with botulinum toxin into the cricothyroid muscles in association with voice retraining can be beneficial in the most resistant cases.[181]

False Vocal Fold Phonation (Dysphonia Plicae Ventricularis) This was described above as a variant of muscular tension dysphonia in which there is excessive lateral-to-medial approximation. Phonation involving only the ventricular folds is extremely rare and usually occurs following injury to the true vocal folds from intubation, radiation, vocal fold atrophy owing to vocal fold paralysis, or surgery for carcinoma. In most functional cases, hyperadduction of both the glottis and ventricular folds is involved. When this condition occurs with functional vocal folds, it is best treated using fiber-optic videoendoscopy to demonstrate gestures such as throat clear, humming, and sighing when glottal phonation is most likely independent of ventricular adduction.

Psychogenic Voice Disorders

These voice disorders are related to psychological processes in the patient resulting in inappropriate use of a normal vocal mechanism for speech communication. A psychogenic origin should be considered only when all other possible structural, neurogenic, or functional voice disorders have been excluded. Sometimes patients can have a psychological history similar to that usually found in patients with a psychogenic voice disorder but have an unrelated voice disorder, for example, a neurogenic disorder. Many of the other functional disorders, such as the SDs, were considered psychogenic voice disorders until recently. Only the behavioral characteristics are available for differentiating among these disorders.[129,182–186] In general, psychogenic voice disorders do not produce chronic habitual abuse or overuse of the peripheral vocal mechanism and rarely produce secondary peripheral tissue abnormalities. Sometimes the abnormal voice production can be intermittent with normal periods of voice production.

At least five types of psychogenic voice disorders can be identified and are described below: conversion reaction dysphonia, malingering, psychogenic dysphonia, elective mutism, and psychological overlay. Patients with vocal misuse are sometimes classified as having psychogenic voice disorders, and successful management can include vocal retraining alone. In psychogenic voice disorders, management is most successful when vocal retraining, psychological or psychiatric counseling, and life situation change are simultaneously employed; otherwise, the voice symptoms may return intermittently.

Most psychogenic dysphonias are hypofunctional vocal behaviors, "whispering" or "aphonic" dysphonia, but they may also appear as falsetto or hyperfunctional behaviors or as a variable mix of the two.

Conversion Reaction Dysphonia The essential feature of conversion reaction dysphonia is the experience of severe psychological or emotional trauma that is closely associated in time with the onset of the dysphonia.[187] The traumatic experience may be concrete and easily identified, such as the loss of a loved one or the experience of a direct threat to the patient or a loved one, or it may be more subtle and difficult to identify, such as the experience of psychological or physical abuse or the patient's fear of losing a loved one.

Voice quality in conversion reaction dysphonia is typically, but not exclusively, hypofunctional, or aphonic.[188] Sometimes the voice can be tremorous as

well.[189] Laryngeal function for vegetative purposes (eg, swallowing, coughing) is within normal limits. Fiberoptic evaluation of the larynx is remarkable for lack of vocal fold adduction during attempts to produce voicing for speech without evidence of vocal fold paresis, paralysis, arytenoid fixation, or other movement difficulties. Vocal fold adductions for coughing and Valsalva's maneuver are within normal limits.

In some cases, conversion reaction dysphonia occurs as hyperfunctional dysphonia and may accompany complaints regarding inconsistent, mild respiratory distress. Conversion disorders most frequently affect young women in their twenties and thirties. Vocal symptoms appear in their final form rather than gradually increasing in severity.

Because diagnosis requires the confirmation of a sudden onset of vocal symptoms closely associated with the experience of an event that may have caused severe psychological trauma, the patient's history, provided either by the patient or others in the patient's environment, is essential.[190] In some cases, the patient is aware of the event and talks about it freely. Sometimes, however, extensive interview and counseling may be required before the patient may be willing or able to talk about the event directly. Interviews with close relatives or friends may be important in such cases, along with referrals for professional psychological evaluation and counseling.

In hypofunctional cases, weak, breathy voice quality with complete or near-complete absence of vocal fold contact or vibratory activity is common. In hyperfunction, however, vocal fold tension is increased such that vocal fold vibration for speech is difficult or impossible to achieve. Such tension is frequently associated with palpable tension in the extrinsic laryngeal muscles.[177] In some cases, symptoms may be more noticeable during formal testing situations than during informal communication.

Malingering Dysphonia Although the presentation is very similar to conversion reaction dysphonia in symptoms, malingering dysphonia involves a conscious intent on the part of the patient to simulate a voice disorder for some gain, often financial or emotional. The patient may be pursuing a medical malpractice suit, an injury or accident case, a legal redress against an employer, or special disability assistance. Other agendas may be less concrete although no less motivating for the patient, such as attempting to avoid communication with an individual or attempting to avoid an experience that the patient considers objectionable. A carefully obtained, complete patient history and interview are the most useful tools for identifying a malingering dysphonia from conversion reaction dysphonia.

Voice quality in malingering dysphonia is usually hypofunctional or aphonic for speech communication purposes, although hyperfunctional or variable cases may be found. Voice quality associated with vegetative functions such as coughing or throat clearing is usually normal. No evidence of laryngeal physiologic abnormality is present. Cognitive distracters, such as counting backwards in sevens or reading difficult material, are often important in eliciting voice production inconsistencies.

Psychogenic Dysphonia In most psychogenic dysphonias, patients exhibit inconsistent voice symptoms, such as intermittent aphonia, abnormal vocal pitch, or periods of severe or markedly abnormal voice may be interspersed with periods of normal voice. These symptoms may be in reaction to psychosocial stresses either in the intermediate or distant past. Symptoms range from a noticeable voice abnormality in pitch to stuttering-like voice breaks to complete aphonia disrupting all attempts to communicate. Often patients express a lack of responsibility for their voice problem and poor insight into their voice difficulties. These patients usually have a history of frequent somatic complaints and are unable to take responsibility for their life situations. They may respond to symptom-oriented voice therapy early in their course or may become resistant to voice therapy and require psychosocial management. They often become dependent on others for communication; in fact, the voice abnormalities may be used unconsciously by the patient to avoid certain social or occupational situations that they find stressful.[188]

Diagnosis may depend on identifying significant psychosocial trauma or physical/sexual abuse, a dissociative personality, or a history of frequent somatizations. An inconsistency of the voice symptoms is often noted by others in the patient's environment. Often the voice symptoms become less exaggerated during distraction such as reading difficult material orally and counting backwards or during examinations such as fiber-optic nasolaryngoscopy. The disorder is more often seen in females who are unable to control their environment.

In cases of aphonia, the patient does not adduct vocal folds for speech but has normal Valsalva's maneuver and swallow. Although patients may have secondary gains from their disorder, they are usually not conscious of the secondary gain. Symptoms may range from periods of intermittently abnormal pitch or hoarseness with strained voice to a consistent aphonia with an absence of vocal fold adduction only for speech.

Elective Mutism Although rare, this usually appears in young children immediately following a traumatic event or in extreme anger. It is characterized by a complete withholding of oral communication in the presence of normal laryngeal structure and function and language skills. It frequently occurs with psychosocial problems relating to the family situation (abuse, conflicts within the family or with the community). This appears most often at preschool or kindergarten age, and the child becomes mute on entering school. It may occur at other times during the school-age years in response to traumatic events and sometimes in adults. Without intervention, it can persist for several years. The withholding of vocal communication is related to issues of control, emotional disengagement, manipulation, secondary gain, and low self-esteem and indicates maladaptive psychosocial development. The family may have a history of frequent somatizations, hostility toward school or community, and disturbed interpersonal relationships.

The child may be described as shy and cooperative and attentive in class. Normal results on tests of receptive language, reading, writing, and other school-related abilities are found, as are normal results when the structure and function of the larynx are visualized. The parents may minimize the problem, suggesting that there is no difficulty at home and that the child does not like to talk at school. The child may have a continuous and consistent refusal to talk in almost all situations (eg, school, school bus, playground) but demonstrates the ability to comprehend spoken language and read and speak appropriately when not observed. A team approach including voice therapy, psychosocial counseling, and intervention is beneficial.

Psychogenic Overlay Frequently, patients have complex voice disorders; they may develop emotional complaints as the result of having a voice disorder, which may then appear psychogenic in origin,[191] or they may either consciously or unconsciously exaggerate their symptoms to draw attention, receive sympathy, or receive further secondary gains resulting from their voice disorder. Management is most effective by combining appropriate treatment of the primary voice disorder (phonosurgery, voice therapy, pharmacotherapy) with counseling to emphasize the advantages of recovery.

Conclusions

Because of the complexity and diagnostic uncertainty of most of the functional voice disorders, caution must be exercised. Usually, the disorder is not acute or life threatening, except in the case of acute airway obstruction in paradoxical vocal fold adduction. Therefore, a trial of voice therapy is often warranted before embarking on phonosurgery, botulinum toxin injections, pharmacologic management techniques, or psychological counseling.

CHAPTER 54

Neoplasms of the Larynx and Laryngopharynx

Robert A. Weisman, MD, Kris S. Moe, MD, Lisa A. Orloff, MD

BENIGN TUMORS

Benign neoplasms are uncommon in the larynx and laryngopharynx, compared with their malignant counterparts. They are presented in the order of their frequency of occurrence. Other mass lesions, such as laryngoceles, nodules, polyps, cysts, and varices, may simulate a benign neoplasm and are discussed in Chapter 66.

Papillomas

Papillomas are verrucous lesions, often with multiple warty excrescences that occur primarily on the true vocal folds (Figure 54–1). They may extend beyond the true vocal folds to the supraglottis, the subglottis, and, rarely, the tracheobroncheal tree.

Neuroendocrine Tumors

Neuroendocrine cells, derived from the neural crest, have been demonstrated in the larynx.[1] Two types of tumors, paragangliomas and carcinoids, are thought to arise from these cells. Laryngeal paraganglia are associated with the superior and recurrent laryngeal nerves. Carcinoid tumors are discussed later in this chapter.

Paragangliomas These tumors arise from the paired paraganglia associated with the internal branch of the superior laryngeal nerve and the posterior branch of the recurrent laryngeal nerve (sensory branches of Galen's anastomosis). Rarely, they may be found anteriorly in the cricothyroid membrane. Laryngeal paragangliomas are histologically identical to carotid body tumors, glomus vagale tumors, and glomus jugulare tumors and may be part of a multifocal pattern seen in some patients. The lesion is most often associated with the superior laryngeal nerve, has a dumbbell shape, and may be partially within and outside the larynx, resembling a laryngocele. Differentiation from a laryngocele is best made by computed tomography (CT), magnetic resonance imaging (MRI), and angiography. As with other "glomus" tumors, treatment can involve observation, embolization, excision, or radiation therapy, depending on the individual patient characteristics.

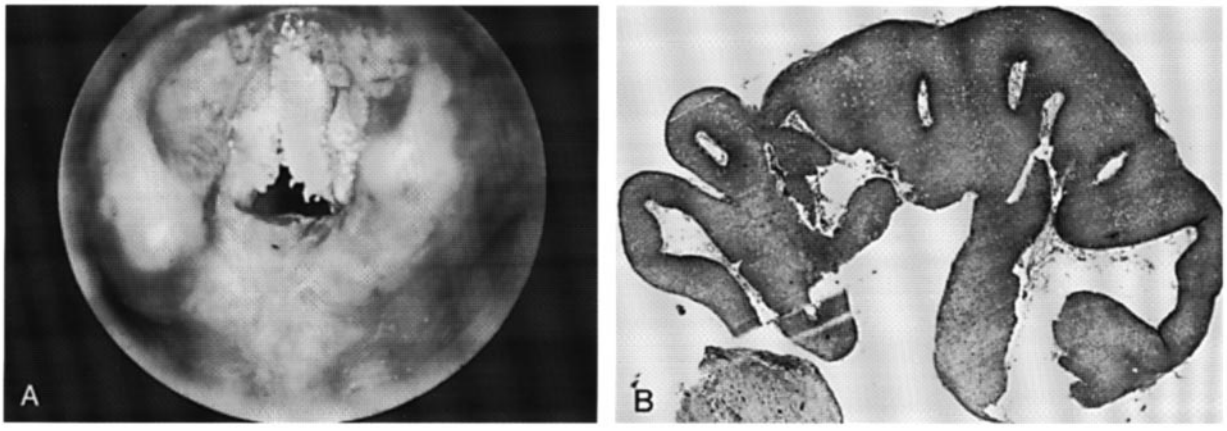

FIGURE 54–1. *A*, Papilloma involving the true vocal folds. The lesion is typically raised and verrucous. *B*, Histologic appearance of pedunculated papilloma (hematoxylin and eosin stain; original magnification × 40).

Schwannomas

This benign nerve sheath tumor arises most frequently in the head and neck region and has been reported in the larynx in over 100 patients. Most of the laryngeal tumors arise around the superior laryngeal nerve and may be found in the aryepiglottic fold. There is a slight female preponderence, and most occur in the fifth and sixth decades of life. Most are small enough to be removed endoscopically, whereas larger tumors may require a lateral pharyngotomy. Malignant degeneration is very rare but has been reported.[2]

Neurofibromas

Neurofibromas contain a mixture of neural axonal or dendritic fibers and Schwann cell elements.[3] They are rare in the larynx and usually appear in the extrinsic portion. They are frequently associated with von Recklinghausen's disease, as part of a generalized neurofibromatosis. They are most frequently encountered in children and young adults and frequently present with stridor. The lesion is submucosal, occurs most often in the supraglottis, and is not encapsulated. Surgical cure is usually associated with a neural deficit, either sensory or motor.

Granular Cell Tumors (Myoblastomas)

Although frequently referred to in the literature as a "myoblastoma," this neoplasm is actually of Schwann cell origin. Approximately 50% arise in the head and neck region, most commonly in the tongue. About 10% arise in the larynx, where they most commonly arise at the junction of the vocal ligament and the vocal process of the arytenoid cartilage as a submucosal mass. These lesions can be removed endoscopically or by thyrotomy and are not well encapsulated. They are sometimes multifocal[4] and are most frequently encountered in the fourth and fifth decades of life. Incomplete excision has been noted to result in apparent long-term cure in some cases.

Vascular Tumors

Hemangiomas Angiomas may be simple (capillary) or cavernous in the larynx and pharynx. The most common symptom is bleeding, which may be severe. On inspection, these lesions are bluish masses and, when exophytic, may resemble a "bag of blue worms." Biopsy of such lesions may be hazardous in an uncontrolled setting and is often nondiagnostic. Treatment consists of endoscopic excision for small lesions and external approaches for larger tumors, where proximal and distal vascular control is optimal.

Cavernous hemangiomas occur most frequently in the false vocal folds, and capillary hemangiomas may occur in both the supraglottis and the vocal folds. Congenital hemangiomas, usually detected in infancy, occur mostly in the subglottis. First described by Phillips and Rush in 1913,[5] subglottic hemangioma is considered a distinct clinical entity. It occurs twice as frequently in males as in females. There is a common association with multiple cutaneous or other capillary hemangiomas of the skin and oral mucosa (Figure 54–2). There is a 5% association with other congenital anomalies, and over 70% occur in the posterior part of the larynx or posterior tracheal wall. Management is discussed in Chapter 45.

Lymphangiomas Lymphangiomas are generally synonymous with cystic hygromas of infancy. In the laryngopharynx, they are most frequently found in

FIGURE 54–2. Male infant with subglottic congenital hemangioma and facial and mucosal capillary hemangiomas.

the supraglottis and the hypopharynx, and patients with them often present with airway obstruction. In the supraglottis, extensive infiltration throughout adjacent structures is common.[6]

Hemangiopericytomas Hemangiopericytomas arise from the pericytes lining the walls of vessels. The majority are benign and arise in the supraglottis. They are most often encountered in elderly patients and may bleed easily when manipulated.

Myogenic Tumors

Leiomyomas Leiomyomas of the larynx are rare. They occur most often in the false vocal folds, aryepiglottic folds, and ventricles. A vascular form called angioleiomyoma has been described in older men. They are most often submucosal and occasionally pedunculated, arising from the vocalis muscle. Lancinating pain is noted in some cases. Incomplete excision has been associated with significant bleeding.[7]

Myomas and Myoblastomas Myomas and myoblastomas are benign tumors that originate over the arytenoid areas. They appear as red swellings with smooth surfaces. Excision can be performed endoscopically but may require an open procedure if there is extension to deeper tissues or if they are broadly based in the larynx or pharynx.

MALIGNANT NEOPLASMS

Squamous Cell Carcinoma

Incidence The incidence of laryngeal cancer is relatively low compared with that of carcinomas of all sites, comprising about 2 to 5% of all cancers worldwide.[8] The relative incidence is similar to that for all sites in the oral cavity as a group and is similar to that of thyroid cancer (12,000 cases in the United States per year).[8] According to the American Cancer Society, 10,000 new cases of laryngeal cancer and 4,000 deaths related to laryngeal cancer were expected to occur in the United States in the year 2000.[8] In addition, 2,500 new cases of hypopharyngeal cancer were expected. Over the years, there has been a male predominance noted (about 5:1 in the United States). As more women have taken up smoking in recent decades, a shift in this ratio can be expected. In the United States, a study at Ben Taub General Hospital revealed that comparing the two 15-year periods 1959 to 1973 and 1974 to 1988, the ratio of male-to-female incidence of laryngeal cancer dropped from 5.6 to 1 to 4.5 to 1.[9] Another study revealed an increase in the incidence of supraglottic lesions in women.[10]

There is an increased reported incidence of laryngeal cancers in industrialized areas (up to 6 to 8% of all cancers). In the Connecticut Tumor Registry, the incidence of carcinoma of the larynx was recently reported to be 12% of all tumors diagnosed. About 3,700 deaths related to laryngeal cancer were reported in 1989, with an overall mortality probability of 32% for those newly diagnosed with the disease. At the time of diagnosis, 25% had regional metastases, and 8 to 10% had distant metastases. These statistics were similar in 2001.

The greatest incidence of laryngeal cancer occurs in the fifth, sixth, and seventh decades (more than 80%). The largest number of cases occurs in the sixth decade (approximately 40% of all cases), with the average age for the occurrence of laryngeal carcinoma appearing to be approximately 59 years. In Scandinavian countries, the peak age of occurrence appears to be older, with a peak between 70 and 74 seen in Norway. Worldwide, the peak incidence appears to be between 55 and 65. In age-corrected data, the incidence continues to rise until age 75. Laryngeal cancer in children and adolescents is rare and tends to be papillary-lymphocytic and nonkeratinizing.

Laryngeal and laryngopharyngeal cancers continue to be the most common malignant tumors of the head and neck in the US, despite relative increases in the incidence of oral cavity and oropharynx tumors in recent decades. In contrast, both incidence and mortality have doubled in Italy over the last few decades.[11] Similar findings have been reported in the Scandinavian countries, Uruguay, and Puerto Rico. Among the countries with the lowest reported incidences of these cancers are Japan, Singapore, Syria, Armenia, and Australia. Within individual countries, inhabitants of urban, highly industrialized areas have a laryngeal cancer risk two to three times that of rural inhabitants.[12] Certain religious groups, such as Mormons, Seventh-Day Adventists, and Parsis, which forbid drinking ethanol and smoking tobacco, have low rates of laryngeal cancer.

Etiologic Factors By far, smoking tobacco has been implicated as the prime factor in causing laryn-

geal cancer. Cigarette, pipe, and cigar smoking are all considered risk factors, with cigarette smoking posing the greatest risk. Only about 1% of larynx cancer occurs in nonsmokers. Nicotine has not been clearly shown to be carcinogenic, but there is abundant evidence that tars and polycyclic hydrocarbons found in tobacco smoke are strong carcinogens in the larynx. Epidemiologically, larynx cancer risk increases with younger age at onset of smoking behavior, number of years smoking, and average quantity of tobacco smoked per day.[13]

Other etiologic factors have been suggested. There are conflicting reports on the role of alcohol in the development of laryngeal cancer, although the preponderance of evidence suggests a promoting effect of alcohol in the pathogenesis of laryngeal cancer, especially in smokers who drink heavily.[14] Alcohol use appears to correlate better with the occurrence of supraglottic cancers rather than glottic tumors.[15] Alcoholics who smoke are thought to carry a 25- to 50-fold increase in risk of laryngeal cancer over nonsmokers. Other etiologic factors include gastroesophageal reflux[16] and exposure to wood dust, asbestos, volatile chemicals, nitrogen mustard, and ionizing radiation. Persons with various types of immunodeficiency states are also thought to be at higher risk for developing laryngeal cancer. An underlying genetic susceptibility to this type of cancer may also exist and has been theorized as a potential cofactor in oncogenesis. A growing body of evidence from molecular genetic studies supports this hypothesis.[17–23] Such a theory might explain why some individuals smoke heavily and never develop cancer, whereas others may smoke lightly or not at all and develop laryngeal cancer. The role of "passive smoking" in the development of laryngeal cancer remains unknown. Human papillomavirus (HPV) is also considered to be an important cofactor in the development of laryngeal cancers. The strain HPV 16 has been most frequently demonstrated in laryngeal squamous carcinomas by using probes for HPV deoxyribonucleic acid (DNA).[24] In addition, the capsid antigen for HPV has been identified in as many as 70% of all laryngeal cancers.[25] A multifactorial model for the development of laryngeal cancer has been proposed by Koufman and Burke and is shown in Figure 54–3.

Variations in the occurrence of laryngeal cancers are seen among countries and ethnic groups but generally reflect the prevalence of tobacco use in

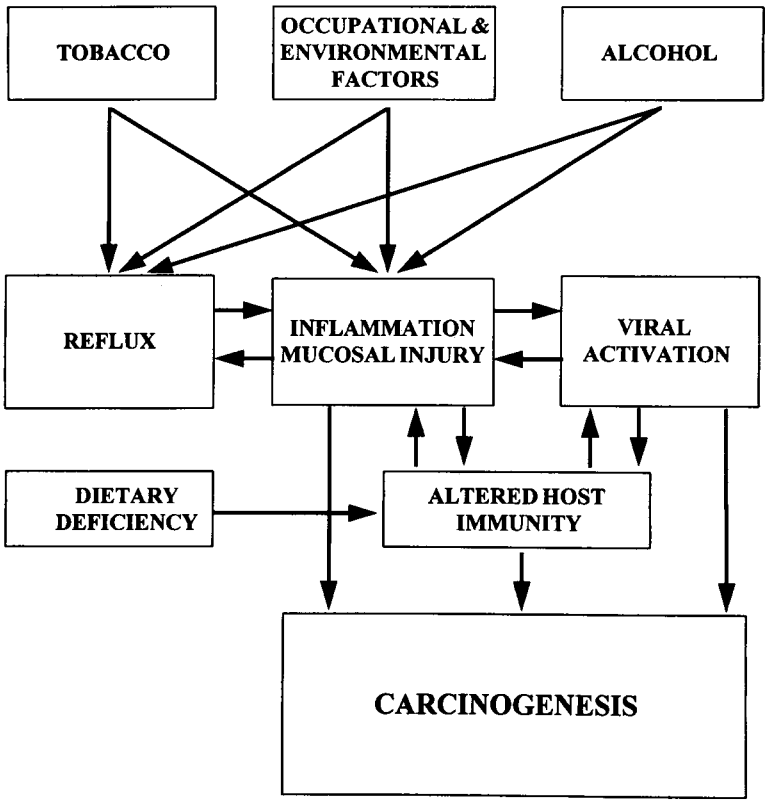

FIGURE 54–3. Schematic model of multifactorial development of squamous cell carcinoma of the larynx. Reproduced with permission from Koufman JA, Burke AJ. The etiology and pathogenesis of laryngeal carcinoma. Otolaryngol Clin North Am 1997;30:1–19.

those countries. There are also wide variations geographically in the distribution of laryngeal cancers among the various subsites. In some countries (eg, Finland), supraglottic cancers predominate, whereas in neighboring countries (Sweden), glottic tumors are in the majority. In the United States, African Americans have a 50% higher rate of laryngeal cancer compared with whites.[26] Clearly, genetic influences are important in determining the occurrence and site of involvement. However, this is a complex issue, and other factors, such as general nutrition, are important. Deficiencies in certain nutrients, particularly the B vitamins, vitamin A, beta-carotene, and retinoids, are considered to be important in the development of squamous cell cancer in general. Heavy alcohol use and lower socioeconomic class may predispose to these nutritional deficiencies or to a higher incidence of gastroesophageal reflux disease and could account for some of the differences noted between different countries, cultures, and ethnic groups.

Verrucous carcinoma of the larynx has been studied extensively with regard to its etiology. Tobacco use is not as highly correlated with this variant of squamous cell carcinoma, but there is a very strong association with HPV.[27] In situ hybridization studies have demonstrated the presence of DNA from the HPV 16 strain, almost exclusively.[24] Human papillomavirus DNA has not been demonstrated in normal mucosa adjacent to these cancers.[28] As in other aerodigestive tract squamous cell cancers, the virus is thought to act as a promoter in the process of carcinogenesis.[29]

Oral herpes simplex infections are also thought to be possible predisposing causes of laryngeal cancers. Elevated levels of circulating carcinoembryonic antigen have been demonstrated in this group of patients. Furthermore, affected patients are postulated to have depressed cellular immunity, which could lead to failure of immune surveillance and progression of a developing cancer.

An increased risk of laryngeal cancer has been noted with certain anatomic conditions. Laryngoceles, or cystic dilations of the laryngeal ventricles, are found in 2% of adult larynges but can be identified in as many as 18% of laryngeal cancers. The incidence of laryngoceles increases with age, especially in males. Whether the laryngocele precedes the cancer and is a causative factor or whether it is secondary to obstruction of the ventricle by tumor is debatable. Another anatomic condition, sulcus vocalis, an indentation along the free edge of the vocal fold, has been reported to occur with greater than expected frequency in patients with laryngeal cancer.[30]

Plummer-Vinson syndrome (sideropenic dysplasia with atrophic gastritis, achlorhydria, and glossitis) is reported to be associated with an increased incidence of postcricoid carcinoma. Most of these patients are older women living in northern latitudes. The exact mechanism by which the carcinomas are induced is not known, but iron deficiency, vitamin deficiencies, and genetic and nutritional factors may all play a role. Up to 30% of affected individuals will develop the carcinoma.[31]

Ionizing radiation is thought to induce some laryngeal cancers, just as it is thought to play a role in thyroid and salivary gland cancers. Workers exposed to radioactive sources were noted as early as the 1930s to have an increased rate of laryngeal cancer. Reports have also appeared linking therapeutic doses of radioactive iodine to subsequent laryngeal neoplasia. Patients who received external beam radiation in relatively low doses for such conditions as acne, scrofula, and skin cancer have been noted to have a slightly increased risk of laryngeal cancer. In juvenile laryngeal papillomatosis, reports of malignant degeneration after therapeutic external beam radiation suggest that the radiation may have induced the malignant change. However, many of the patients who were treated in this fashion had advanced, aggressive, recurrent, and disseminated papillomas that may have already begun to undergo malignant change. It has also been suggested that when second primary tumors appear many years (usually 15 to 20) after previous external beam radiation treatment for cancer of the head and neck, the second tumor was induced by the radiotherapy.[32] This association is difficult to prove because most of these patients have risk factors for head and neck cancer, and there is roughly a 4% per year risk of developing a second head and neck primary in this population.

Association with Second Primary Malignant Tumors Second primary tumors occur synchronously in about 1% of laryngeal cancers and metachronously in 5 to 10%. This occurrence seems to be greater with supraglottic compared with glottic primaries. Some series have indicated a three-fold

increase in supraglottic cancers.[33] Laryngeal cancer is one of the tumors with one of the highest rates of associated second primary cancers. The most common second primary tumor is bronchogenic carcinoma. Of these second primaries in the lung, 10% are synchronous, 30% occur in the first year, another 30% by 5 years, and the rest within the first 20 years. The risk of a second lung tumor is directly proportional to the duration and degree of smoking and continuation of smoking after definitive therapy for the laryngeal cancer.[34] Eighty percent of the patients developing second lung primary tumors have carcinoma in situ (Cis) or T1 laryngeal tumors.[35]

Although annual plain chest radiographs are used to screen for second primary tumors (and metastatic disease) and are useful in detecting asymptomatic lung primaries, the effect on outcome may be small. A study by Engelen and associates revealed a malignant lung primary in 12.4% of patients being followed for laryngeal cancer.[36] They noted 69% of the patients to be asymptomatic when the lung primary was detected. The survival time for these patients was longer than for those whose lung primary was detected after symptoms appeared, but overall survival was not significantly impacted. The role of chest CT in screening for second primaries and metastatic disease is not clear since the test is very sensitive and not very specific. Small nodules of indeterminate significance are often found on chest CT, with the minority of the nodules being malignant. Positron emission tomography (PET) may prove to be more effective as a screening procedure for secondary primary tumors in laryngeal cancer, and in head and neck cancer in general, because of early reports of its sensitivity and specificity for malignant deposits. Concurrent PET and CT or MRI may provide anatomic detail regarding areas of abnormal functional activity, allowing targeted biopsy of small areas to determine whether a new lesion is a second primary. Investigations are currently in progress to determine if this is a cost-effective modality to screen for second primary tumors and for metastatic disease.

Pathology Over 95% of all malignant laryngeal tumors are squamous cell carcinomas. These tumors arise from the surface epithelium, which is a stratified squamous lining, except at the free edge of the vocal fold, where the mucosa consists of a pseudostratified squamous layer. Areas of hyperkeratosis, dysplasia, and Cis are often found adjacent to the primary invasive lesion. With proper orientation, it is usually possible to define a transition from normal epithelium, to dysplastic epithelium, to invasive carcinoma (Figure 54–4). Islands, tongues, and clusters or cords of invasive atypical cells within the underlying stroma characterize the tumor. The cells show squamous differentiation, including keratinization of individual cells, keratin pearl formation, or intercellular bridging.

When hyperkeratosis is present, a characteristic white lesion is seen on the vocal fold. Generally,

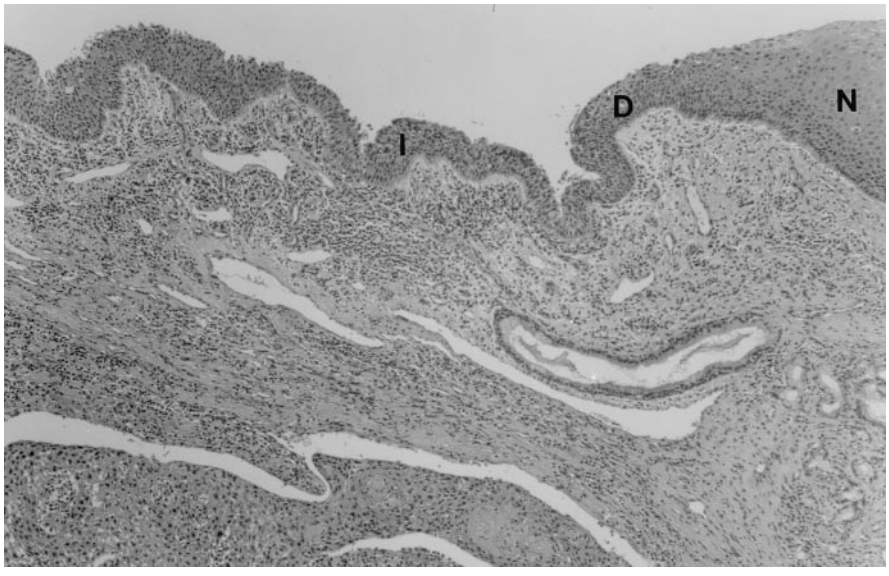

FIGURE 54–4. Photomicrograph depicting transition from normal epithelium (N) to dysplasia (D) to in situ carcinoma (I) (hematoxylin and eosin stain).

such lesions exhibit thickening of the epithelial layer and abnormal keratinization of the superficial layers. The generic term leukoplakia is often used to describe such a finding, although both benign and malignant lesions can have this appearance (Figure 54–5). This lesion may be solitary or multifocal. Histologically, most of these lesions are benign, but there is thought to be an approximately 3% risk of malignancy for leukoplakia of the vocal fold.[37]

Erythroplasia or erythroplakia refers to a red lesion of the vocal fold. Most of these lesions are raised and irregular, with increased vascularity and abnormally engorged U-shaped vessels on the surface. These lesions are thought to carry even greater risk of harboring malignancy than white lesions.[38] Both lesions require biopsy to establish their nature. Recently, contact endoscopy with vital staining has been introduced,[39] with reports indicating that benign and malignant lesions can be distinguished by this method without biopsy.[40]

It is important for clinicians to understand the meaning and significance of certain pathologic terms that are used to describe changes in the vocal fold epithelium that precede the development of true cancer. *Hyperplasia* is merely a thickening of the epithelial layer owing to an increased number of cells. This finding is often seen in areas of irritation or trauma. Metaplasia refers to a change in the histology of a tissue from one benign form to another. *Hyperkeratosis* is an increase in the keratin layer of squamous epithelium. *Keratosis* and *keratotic* are terms that more accurately describe this change in the vocal fold since the normal epithelial layer there is nonkeratinized. *Dysplasia* is a truly premalignant change and describes disorder in the usual progressive maturation of cells from the basal layer to the outer layer of the squamous epithelium, usually in association with changes in individual cells on a spectrum from benign to malignant. Dysplasia (some pathologists prefer the term *atypia*) is usually graded mild, moderate, or severe, depending on the degree of these changes. Most pathologists agree that severe dysplasia is synonymous with Cis. In Cis, the carcinoma is limited to the epithelial layer, and the basement membrane remains intact (Figure 54–6). The tumor can involve a seromucinous gland and still be considered in situ. Only when the basement membrane is crossed by the tumor is the term *invasive* carcinoma used. Since Cis and invasive carcinoma are often found on the vocal fold surrounded by areas of dysplasia of varying degrees, one school of thought suggests that carcinoma occurs after an orderly progression from mild to moderate to severe dysplasia (Cis).[41] Others have disputed this theory since some carcinomas appear to be surrounded by only mild dysplasia, and some patients have focal Cis in the basal layers without dysplasia of the surrounding epithelial cells. It is possible that more than one mechanism exists.

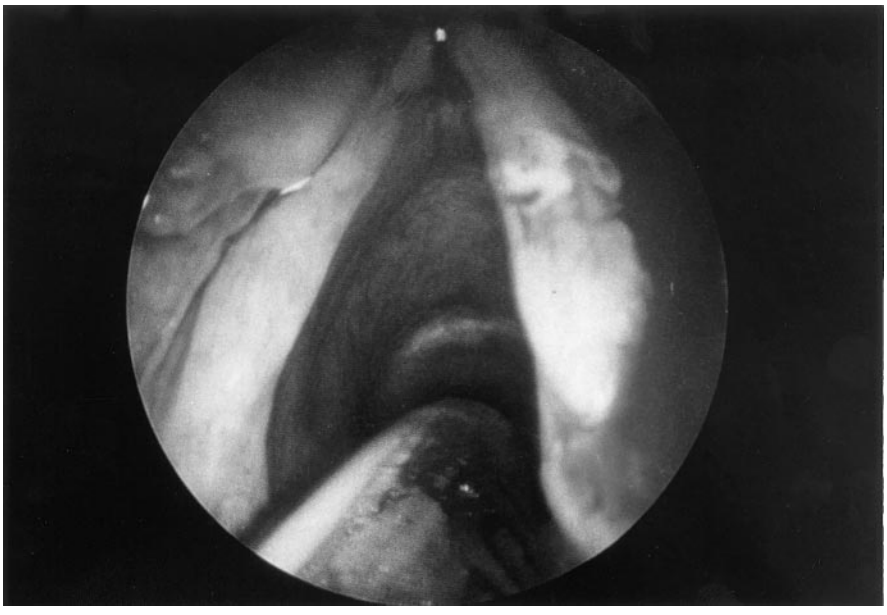

FIGURE 54–5. Leukoplakia of the true vocal fold. The malignant potential of these lesions warrants biopsy.

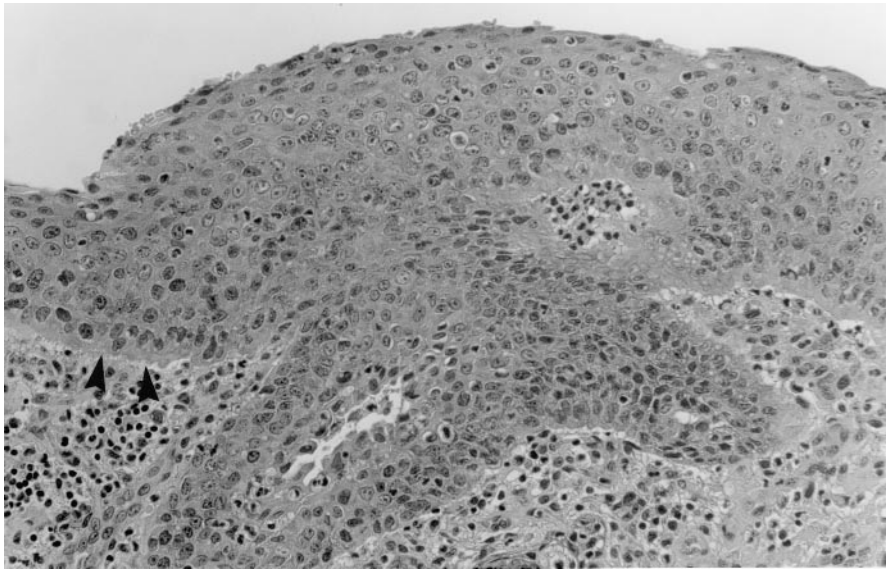

FIGURE 54–6. Photomicrograph of carcinoma in situ of the true vocal fold. Although the individual epithelial cells are clearly malignant, the basement membrane is intact (*arrows*) (hematoxylin and eosin stain).

These lesions have clinical relevance since 3% of hyperkeratoses without dysplasia, 7% of mild dysplasias, 18% of moderate dysplasias, and 24% of severe dysplasias of the vocal folds have been shown to ultimately develop invasive carcinoma.[37] Since these lesions begin on the vocal fold and cause hoarseness early, they are often detected early, in contrast to many other primary sites. It is important to understand the impact of these pathologic descriptions to counsel the patient regarding cancer risk and to institute appropriate plans for close follow-up.

Other pathologic features of laryngeal cancers are relevant to prognosis. Supraglottic cancers tend to be less differentiated than glottic cancers and exhibit earlier and more extensive local invasion as a group. Although grading of cellular differentiation does not correlate strongly as an independent variable with regard to outcome in most series, more poorly differentiated tumors have a greater likelihood of lymphatic metastasis,[42] which has a major impact on survival.[43] Other microscopic features, such as presence of a pushing versus an infiltrating border, the presence or absence of a local host inflammatory reaction to the tumor, and presence or absence of vascular or perineural invasion, have been noted as important prognostic indicators in laryngeal cancers and in head and neck cancers in general. The thickness of the lesion or depth of invasion may be an important prognostic indicator, as has been shown in other head and neck cancer primary sites (eg, floor of mouth), but this correlation has not been demonstrated in the larynx.

Besides the gross and microscopic appearance of vocal fold lesions, genetic and molecular biologic characteristics of these abnormal areas are being studied to determine their malignant potential. Cell cycle and flow cytometry techniques have been used to study the DNA content of laryngeal neoplasms. Dysplastic lesions that are aneuploid have a high risk of progressing to invasive carcinoma.

Variants of Squamous Cell Carcinoma. Verrucous Carcinoma. Verrucous carcinoma is a subtype of squamous cell carcinoma that comprises between 1 and 4% of all malignant tumors of the larynx.[44] Grossly, it is characterized by an exophytic, keratotic mass with a distinct edge. Lymph node metastases do not occur.[45] Typically, multiple biopsies and observation of the clinical behavior of the lesion are necessary before a definite diagnosis of malignancy is made. Histologically, these tumors are extremely well differentiated, invade the underlying stroma with a pushing border, and have very few mitoses (Figure 54–7). The differential diagnosis includes verruciform squamous cell carcinoma, verruca vulgaris, and verrucous hyperplasia.

Basaloid Squamous Cell Carcinoma. This variant of squamous cell cancer is seen more frequently in

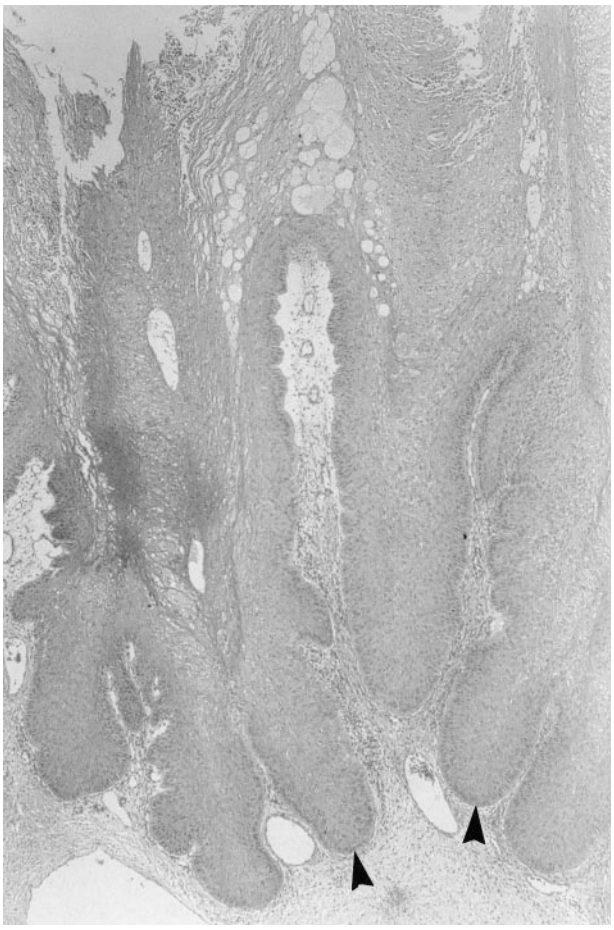

FIGURE 54–7. Photomicrograph showing a well-differentiated tumor with a "pushing" margin (*arrows*), typical of verrucous carcinoma (hematoxylin and eosin stain).

larger lesions that exhibit aggressive behavior.[46] It is more frequently encountered in the hypopharynx than the supraglottic or glottic larynx. Histologically, nests of small, basaloid cells that stain predominantly blue because of their high nuclear-to-cytoplasm ratio characterize the tumor. Comedonecrosis and stromal hyalinization are frequently encountered. Pseudopalisading of the tumor cells is occasionally seen (Figure 54–8). The differential diagnosis includes adenoid cystic carcinoma (solid variant). Whereas some studies have indicated a poorer prognosis for this subtype compared with other squamous cell cancer, others have shown no difference in survival when subjects are matched for stage, site, and type of treatment.[47] Interestingly, DNA analysis showing aneuploidy in basaloid variants predicts an improved survival.[48]

Spindle Cell Variant. Spindle cell squamous carcinoma is also called pseudosarcoma, carcinosarcoma, and sarcomatoid carcinoma of the larynx. Grossly, the lesion is usually polypoid, but about one-third of cases exhibit ulceration and endophytic growth.[49] Histologically, these tumors show a pleomorphic spindle cell component associated with invasive cancer or Cis. Occasionally, the associated squamous cancer cannot be identified. Rarely, but particularly after radiation therapy, the spindle cell portion of the tumor undergoes osteocartilaginous differentiation.[49] Using immunohistochemical stains and electron microscopy, the spindle cells can often be shown to be of epithelial origin, leading to speculation that the spindle cell portion represents an area of malignant metaplasia.[50] The differential diagnosis includes soft tissue sarcoma, malignant melanoma, and unusual reaction to radiation therapy in exuberant granulation tissue. Despite its aggressive appearance and worse prognosis than spindle cell tumors at most sites, glottic spindle cell tumors have an excellent (90%) survival rate. These tumors are radioresistant, and surgery is favored as the mainstay of treatment.

Nonsquamous Tumors. Adenoid Cystic Carcinoma. This tumor is rare in the larynx and probably arises from minor salivary glands or seromucinous glands. Reflecting this origin, most of these tumors are either subglottic or supraglottic.[51] As at other sites, the tumor can exhibit a cribriform, tubular, or solid growth pattern, with the latter being associated with a somewhat worse prognosis. As at other sites, the neoplasm has a strong proclivity for perineural invasion and spread and often presents with pain. Pulmonary and osseous metastases are fairly common, and lymph node metastasis is infrequent enough that elective treatment of the neck is not indicated.

Neuroendocrine Carcinoma. There are three distinct subtypes in this group of unusual neoplasms. Since they behave differently and have different treatments, correct histologic diagnosis is essential.

Typical carcinoid of the larynx is extremely rare and is seen almost exclusively in males. Histologically, the tumors contain islands, nests, and cords of cells that lack nuclear atypia, mitotic figures, or necrosis. Surgery is usually curative.[52]

Atypical carcinoid is more common than typical carcinoid in the larynx. Differing from typical

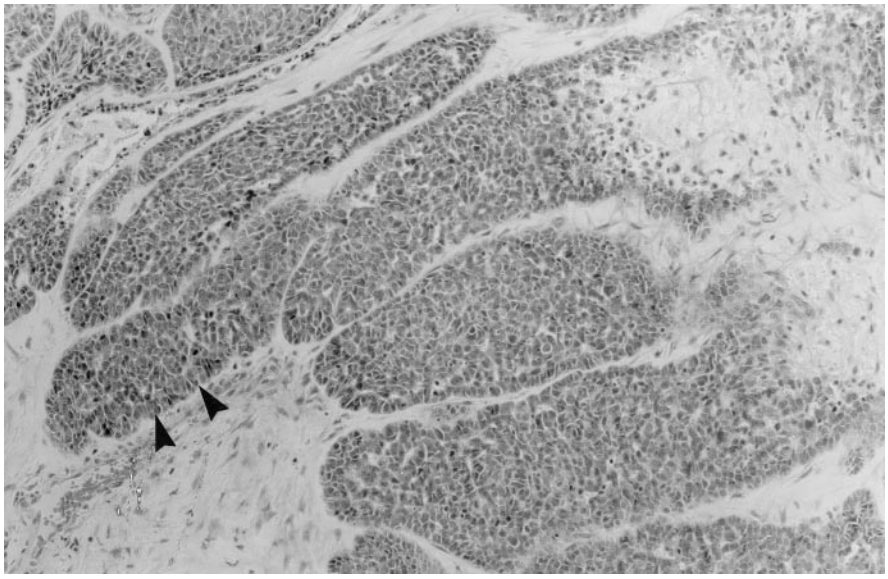

FIGURE 54–8. Photomicrograph of basaloid squamous cell carcinoma. The basaloid cells are small and dark, with pseudopalisading (*arrows*); this is a squamous cell cancer (hematoxylin and eosin stain).

carcinoid, the tumor cells exhibit mild to moderate nuclear atypia, occasional mitotic figures, and individual cell necrosis. Microscopically, these tumors strongly resemble medullary thyroid carcinoma and often stain positive for calcitonin, even though serum calcitonin levels are rarely elevated. Atypical carcinoids are more biologically aggressive than typical carcinoids, with regional and distant metastases being common. Surgery with or without adjuvant radiation and chemotherapy is the treatment of choice, yielding a survival rate of about 60%.[53]

Small cell carcinoma of the larynx is quite rare, comprising 0.5% of all laryngeal malignancies.[52] Histologically, it is identical to small cell carcinoma of the lung, and a metastasis from a lung primary should be considered when this lesion is encountered. Like small cell lung cancer, the prognosis is poor. Surgery is ineffective, and treatment consists of chemotherapy and radiation therapy.

CHONDROSARCOMA. Chondrosarcoma is rare but is the most common sarcoma arising in the larynx.[54] Clinically, the tumor is slow growing and submucosal and most commonly arises from the cricoid cartilage. Biopsy can be problematic because of the location of the lesion and its firm consistency and because a large tissue sample is needed to establish the grade of the neoplasm. Histologically, the tumor exhibits hypercellularity, nuclear atypia, and double nucleated cells, all of which distinguish the tumor from a benign chondroma. Surgery is the main treatment, and lymph node metastasis is rare.

Anatomic Subsites and Patterns of Spread of Laryngeal Tumors The spread of cancers arising in the larynx follows fairly predictable patterns. The pathway of spread is determined by several factors, among them the presence of anatomic barriers to spread (eg, perichondrium and cartilage) and the density of local vessels and lymphatic channels. Because the supraglottis arises from a different embryologic source than the glottis and subglottis, its lymphatic drainage patterns are significantly separate and different. This separation is often referred to as compartmentalization of the larynx, as described by Pressman.[55] A schematic diagram of the anatomic subsites used to classify laryngeal tumors is shown in Figure 54–9.

SUPRAGLOTTIC TUMORS. Supraglottic cancers involve the region bounded superiorly by the free border of the epiglottis and inferiorly by the false vocal folds and the laryngeal ventricles (Figure 54–10). Laterally, the medial aspect of the aryepiglottic folds defines the border. These neoplasms tend to spread by local extension. The majority start on the epiglottis and from there can extend to the aryepiglottic folds, false cords, and ventricle. The epiglottic perichondrium and cartilage are initial barriers to anterior spread. The thyroepiglottic ligament is the last

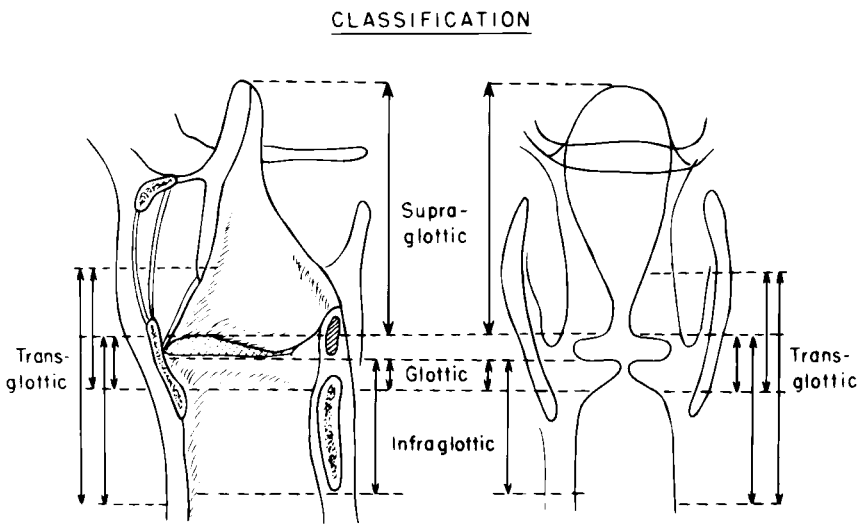

FIGURE 54–9. Schematic representation of the anatomic classification of laryngeal tumors.

barrier to spread anteriorly into the preepiglottic space. Anterior to the soft fibrofatty tissue of the preepiglottic space, the inner perichondrium of the thyroid cartilage and the cartilage itself and the outer perichondrium are the final barriers to spread into the neck. Extension through the vallecula allows tumor spread directly into the base of the tongue. In the aryepiglottic fold, the quadrangular membrane is a moderate barrier to spread of tumors superiorly and laterally from the epiglottis or the false vocal fold.

There is a strong tendency for supraglottic tumors to spread via lymphatics. Numerous reports estimate that 39 to 65% of patients with T2 to T4 supraglottic cancers present with overt lymph node metastasis, whereas 32 to 34% of such patients staged N0 have pathologically positive nodes.[56,57] This observation is consistent with the rich lym-

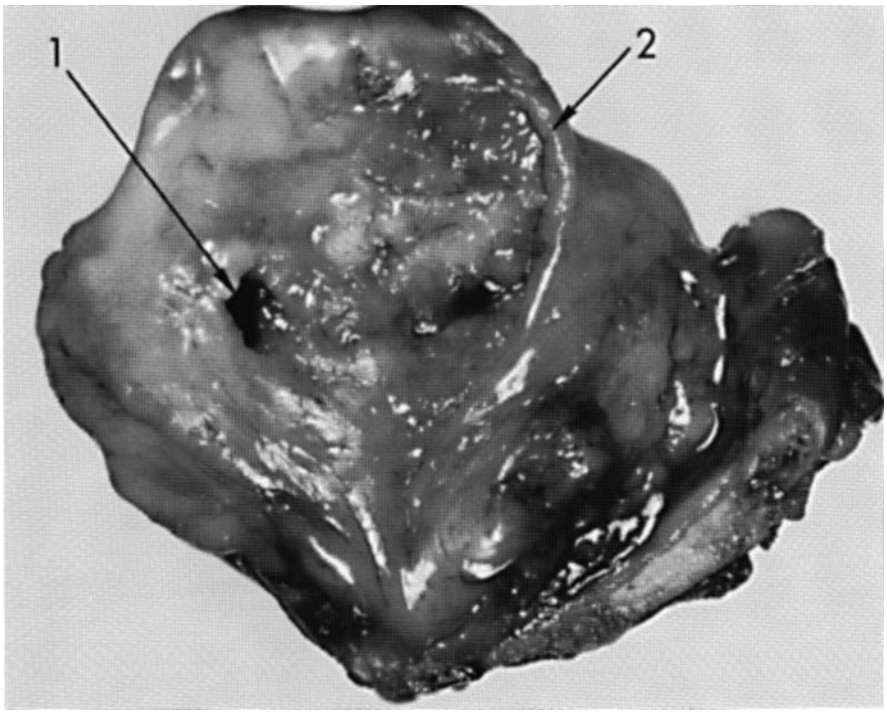

FIGURE 54–10. Specimen from a subtotal supraglottic laryngectomy demonstrating gross appearance of the tumor. Note infiltrating and spreading margins (2) and central area of necrosis with epiglottic foraminal invasion of the cartilage (1).

phatic network found in the supraglottic submucosa. From the epiglottis, lymph channels drain bilaterally to the false vocal folds. The drainage from the false vocal folds and the remainder of the supraglottic larynx is superior and lateral. Most of these lymph channels exit the larynx via the thyrohyoid membrane in parallel with the superior laryngeal veins. The primary nodal beds draining the supraglottis are in levels II and III in the neck (Figure 54–11).

Cancers arising on the edge or margin of the aryepiglottic fold are subclassified as "marginal tumors" and are considered by some to be separate from supraglottic lesions. Their biologic behavior resembles that of piriform sinus cancers. They therefore have a very high rate of submucosal spread, early lymphatic metastasis, and greater propensity for distant metastasis than supraglottic lesions.

Glottic Tumors. Glottic tumors involve the true vocal folds. The inferior limit of this region is generally thought to be 10 mm below the free edge of the true vocal fold, although there is some debate over this distance. The intrinsic muscles of the larynx extend about 10 mm below the true vocal folds. Some contend that the glottis extends up to 20 mm below the vocal fold, whereas others choose 5 mm as the limit. The anterior limit of the glottis is the anterior commissure, and the posterior limit is the vocal processes of the arytenoid cartilages.

The true vocal folds are unusual in that they have very sparse lymphatic drainage. Glottic neoplasms, therefore, tend not to spread via lymphatics until the tumor has extended beyond the vocal fold into an area richer in lymph vessels. The main means of spread of glottic tumors is by local extension (Figure 54–12). Primary vocal fold neoplasms tend to stay confined to the vocal fold for a relatively long period of time and are detected at that stage frequently because patients develop hoarseness early in the course of their disease and seek medical attention. When glottic tumors spread, they tend to

extend laterally and inferiorly, respecting the embryologic compartmentalization of the larynx. When vocal fold tumors extend laterally, they enter the paraglottic space and have access to spread either superiorly or inferiorly along the thyroid cartilage. Direct invasion of the thyroarytenoid muscle and spread to the cricoarytenoid area occur, resulting in vocal cord fixation or paralysis.

Superior spread in the paraglottic space results in tumor invasion of the preepiglottic space or even the thyrohyoid membrane. Inferior spread results in extension to and through the cricothyroid membrane into the thyroid gland or other neck structures. Such extension can also result in spread along the conus elasticus into the subglottic space. Extension of tumors onto the undersurface of the true vocal fold can also result in extension to the subglottis, either on the surface or submucosally. Another important pathway of spread from the glottis occurs at the anterior commissure. The anterior vocal ligament and associated vessels perforate the thyroid cartilage at that point, creating a preformed pathway for spread of cancers that involve the anterior commissure. This mode of spread has been used to explain treatment failures of relatively small lesions at the anterior commissure treated with either radiation or endoscopic resection. Direct invasion of the thyroid cartilage at other locations is usually seen only in tumors that are very advanced locally.

Subglottic Cancers. The subglottic region begins 10 mm below the vocal folds and extends inferiorly to the level of the inferior border of the cricoid cartilage. Primary tumors in the subglottis are rare, comprising only 1% of all laryngeal cancers. They tend to spread downward, either on the surface or submucosally in the upper trachea or anteriorly through the cricothyroid membrane. Exit through the cricothyroid membrane results in spread into adjacent neck structures, as noted above for glottic lesions. The risk of lymphatic spread in these tumors is probably intermediate between supraglottic and glottic tumors and ranges between 10 and 34% in the small series that have been reported.

Transglottic Tumors. These cancers cross the ventricle from either the true cord upward or the supraglottis downward. Structures of both the supraglottic and glottic larynx are involved. This term can also be applied to cancers arising on the true vocal folds that extend greater than 10 mm below the edge of the vocal fold to involve the subglottis or to tumors that involve all three major subdivisions of the larynx. Patterns of spread follow those for all of the affected subsites.

Superior Hypopharyngeal Tumors. Cancer that involves the lingual surface of the epiglottis, vallecula, or base of the tongue falls into this category. The lateral boundaries are the glossoepiglottic folds.

Inferior Hypopharyngeal Tumors. These are mainly piriform sinus tumors. They are found in an area bounded superiorly by the glossoepiglottic fold, medially by the aryepiglottic fold and medial wall of the piriform sinus, laterally by the mucosa over the thyroid lamina, and posteriorly by the lateral wall of the hypopharynx. Postcricoid tumors arise from the mucosa over the posterior cricoid lamina and are bounded superiorly by the arytenoids and inferiorly by the entrance to the esophagus. Posterior pharyngeal wall tumors arise from the posterior wall of the hypopharynx. All of the inferior hypopharyngeal tumors tend to spread by local infiltration on the surface and submucosally, spread via lymphatics early in their course, and have a high rate of distant metastasis. Posteriorly, the prevertebral fascia is the main important barrier to spread.

Distant Metastasis. Distant spread of primary laryngeal tumors is usually a late event, when tumors have recurred locally and/or regionally after treatment. At presentation, 25% will have regional nodal metastasis, and only 8 to 10% have distant metastasis. Overall, 50% of all laryngeal cancers remain locally confined, whereas 35% have regional spread, and 15% develop distant metastases. The lung, liver, and bone are the most frequently involved sites for metastatic disease.

Clinical Evaluation Assessment of the patient with laryngeal cancer begins with a thorough history and physical examination. Patients with supraglottic cancers often remain asymptomatic until a relatively large tumor bulk is present. Nodal metastasis is often the initial complaint. Patients with glottic tumors tend to present early, with hoarseness as their chief complaint. Subglottic tumors are rare and may present with stridor or hemoptysis. Several key symptoms should be noted in the history.

Hoarseness is the major presenting symptom in patients with glottic cancer. The examiner must determine the duration of this symptom, its progression, and associated symptoms. The degree of voice alteration is related to the extent of the lesion. On the true vocal fold, even a small tumor on the surface epithelium may alter the voice by interfering with the normal mucosal wave and by adding mass to the vocal fold. More extensive lesions that invade below the surface epithelium tether the surface, interfering with normal propagation of the mucosal wave of the vocal fold. This subtle disturbance is best appreciated on videostroboscopy. More extensive invasion involves the vocalis muscle, leading to diminished lateral movement of the vocal fold, even to the point of complete fixation.

Hoarseness is commonly present for 3 months or longer in patients who present with vocal fold cancer. As many as 30% have been hoarse for a year or more. In supraglottic tumors, hoarseness tends to occur later, when tumors have become bulky and overhang the glottis or spread through the paraglottic space to fix the vocal fold. The voice change seen with supraglottic lesions tends to be more of a muffled voice, somewhat similar to the "hot potato" voice of epiglottitis. Some patients with supraglottic tumors have no hoarseness at all and may be asymptomatic or have other complaints. Hypopharyngeal tumors rarely cause hoarseness until they become quite extensive, causing either vocal fold fixation or effects on the voice caused by sheer bulk.

Other symptoms that should be sought in the interview of a patient suspected of having laryngeal cancer include dyspnea, dysphagia, and pain, particularly ear pain. Dyspnea occurs in glottic tumors when the airway is compromised by tumor bulk or by unilateral or bilateral vocal fold fixation. Edema associated with tumor invasion of local lymphatics may also contribute to airway narrowing. In supraglottic tumors, dyspnea is a late finding, when tumor bulk is so great that the oropharyngeal or hypopharyngeal portion of the airway becomes obstructed. Dysphagia is not frequently encountered with glottic tumors until tumor size has increased enough to cause arytenoid dysfunction. Supraglottic tumors are more likely to cause dysphagia or odynophagia because the tumor is frequently on the epiglottis, where base of tongue invasion or movement of the tumor with swallowing may elicit pain and cause swallowing dysfunction. Dysphagia is most often seen in tumors that involve the hypopharynx, such as piriform sinus, posterior pharyngeal wall, or the postcricoid area.

Pain is a late finding in glottic cancers and usually denotes extension of the tumor through cartilage and into extralaryngeal structures. Supraglottic tumors may present with pain earlier, in the form of a sore or scratchy throat. As supraglottic lesions enlarge, pain increases with involvement of the base of tongue, cartilage invasion, and extension into the superior laryngeal nerves and the soft tissues of the neck. Ear pain is considered "referred pain" and is considered to be a sign of glossopharyngeal or vagus nerve involvement, usually by extension of tumors into the base of the tongue or the piriform sinus. Primary tumors of the piriform sinus commonly present with referred ear pain, often before any other symptoms are present.

Other symptoms less frequently reported by patients with laryngeal cancer include cough, hemoptysis, bad breath, and weight loss. Cough is generally a sign of low-grade aspiration owing to loss of laryngeal sphincteric function and is most commonly seen in glottic tumors. Hemoptysis is seen mainly in patients with large, fungating, friable supraglottic neoplasms. Occasionally, blood loss can be insidious, causing severe anemia. Foul odor is seen in larger tumors, mainly in the supraglottis, that exhibit significant necrosis. Weight loss is usually an omen of a poor prognosis, indicating an advanced lesion, possibly already exhibiting distant metastasis. Tenderness to touch over the larynx or loss of the external landmarks of the larynx on palpation is also worrisome and usually indicates a tumor that has extended through the laryngeal cartilages.

Other historical items are of importance. The general health status of the patient should be sought in detail, including comorbidities that may have an impact on choice of treatment. The patient's use of tobacco should be documented. Patients often stop smoking shortly before presentation to a physician and may answer "no" if asked if they smoke. Asking if the patient has ever smoked will usually reveal the smoking history. Alcohol consumption should be documented in a similar manner. Learning the patient's occupation through the social history can also be important and may have an impact on decision making later. As with other cancer patients, it is important for the caregiver to be aware of the

patient's social circumstances and to develop an idea of what kind of support the patient will have in the post-treatment period out of the hospital setting. Proper discharge planning will ensure a smooth transition from hospital to home and maximize the patient's psychological well-being.

Physical Examination. All patients with hoarseness of 2 weeks or longer without a clear-cut diagnosis should undergo evaluation by a head and neck specialist. The larynx should be assessed by all means available to the physician until he/she is satisfied that an adequate examination has been achieved. Indirect mirror laryngoscopy in a cooperative patient can be quite adequate and gives an undistorted view of the larynx. Flexible or rigid fiber-optic laryngoscopy should be used in most cases in which cancer is suspected. Video documentation is useful for patient teaching, for review by the examiner, for presentation to other consultants not present at the endoscopy, and for comparison to the treated larynx after radiation or organ-conserving surgery.

Videostroboscopy adds another dimension to the evaluation of early glottic cancers. This technology focuses on the movement of the epithelial layer of the vocal fold relative to the underlying stroma, vocal ligament, and musculature. During phonation, the vocal fold epithelium moves freely over the fibroelastic cushion of the lamina propria in Reinke's space. A surface cancer on the vocal fold that invades the basement membrane, by definition, tethers the mucosa to the underlying stroma, causing dyskinesis of the mucosal wave on that vocal fold and loss of synchrony between the vocal folds. Deeper invasion, with tethering of the mucosa to the intrinsic muscles of the larynx, produces even greater distortion of the mucosal wave. These subtle changes are not apparent on naked eye or routine fiber-optic examination. However, such findings may be of critical importance when deciding whether to radiate a patient or use microsurgical excision for early vocal fold cancer.[58,59] Others have challenged this concept, pointing out that thick keratoses and scarring from previous vocal fold trauma can produce alterations similar to invasive tumors.[60] These authors suggest that stroboscopy may be more important in evaluating the vocal fold not involved with cancer since its status may be the best predictor of voice outcome after treatment.

Neck examination is always performed when a diagnosis of laryngeal cancer is suspected. Lymph nodes are rarely detected on physical examination with most glottic cancers, even when the primary is relatively advanced. Supraglottic cancers and tumors of the laryngopharynx are much more likely to present with nodal metastasis. When lymph nodes are detected, their size, character, number, and position in the neck should be recorded. In supraglottic cancers, levels II and III are most likely to harbor metastases, whereas in glottic cancers, levels II, III, and IV are the likely sites (see Figure 54–11). For cancers in the upper laryngopharynx, lymphatic drainage is similar to that for supraglottic cancers, and for those in the inferior region, levels III and IV are most often involved.

Imaging Studies. Several modalities are currently available to the clinician for evaluating the larynx and neck. Earlier methods such as plain radiographs, laryngograms, xeroradiography, and laminography have been completely replaced by CT and MRI in the United States. The newer modalities show fine anatomic detail and provide useful information on cartilage invasion (Figure 54–13), subglottic extension, extralaryngeal spread, base of tongue invasion, preepiglottic space invasion, and the status of lymph nodes, usually with greater accuracy than physical examination. Both CT and MRI should be considered complementary to physical examination, office endoscopy, and operative endoscopy. Neither modality delineates small or superficial primary lesions well, for example.

Neck staging is enhanced with both modalities, which have similar sensitivities and specificities for detecting nodal metastases. Both types of imaging still miss a significant percentage of occult metastatic disease in necks staged N0 clinically. Both modalities have sensitivities in the 60 to 80% range, whereas specificity ranges from 72 to 89%. Features such as size greater than 1 cm (1.5 cm for level II lymph nodes), evidence of central necrosis, irregular lymph node margins, loss of fat planes around lymph nodes, round rather than oval shape, and clusters of lymph nodes that do not individually meet size criteria are considered positive for metastatic disease radiographically.[61]

Positron emission tomography scanning is a relatively new development that images cancers differently than CT and MR. Positron emission tomography is a functional study based on the differential uptake of radioactive [18^{F}]fluorodeoxyglucose by

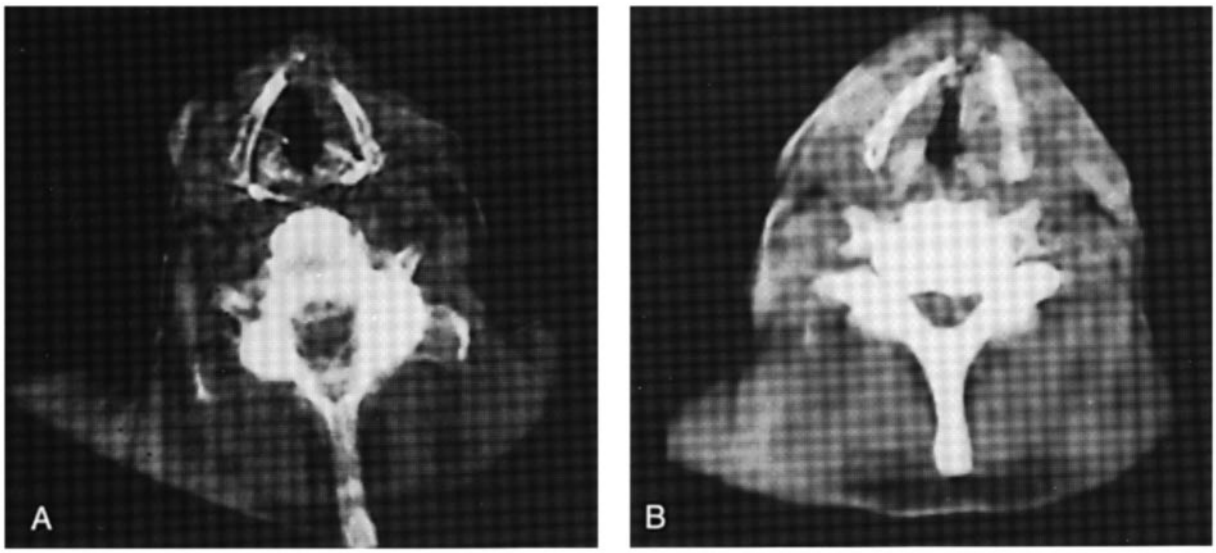

FIGURE 54–13. Computed tomographic scans of two vocal fold tumors. *A*, Anterior commissure and thyroid cartilage invasion. *B*, Left vocal fold carcinoma with vocalis muscle, anterior commissure, and thyroid cartilage invasion.

different tissues. Tumors tend to have a greater metabolic demand than normal tissues and take up the radionuclide more rapidly. This property of malignant tissues shows up as a "hot spot" on a PET scan (Figure 54–14). Positron emission tomography has been shown to be highly specific, sensitive, and accurate (up to 100%) in detecting occult nodal disease in the N0 neck and promises to be more helpful in staging the neck than the current standard of CT or MRI.[62–64] Assessment of primary tumors of the larynx with PET alone is not likely to be helpful, but newer technology combining PET and CT or MRI gives both functional and anatomic information about a tumor's size and location and may prove to be very valuable in the precise delineation of the extent of laryngeal cancers.[65] Positron emission tomography does appear to have promise in detecting recurrent tumors and in finding second primary lesions in the head and neck.[66,67] Caution may be necessary in interpreting the results of PET scans of the larynx since false positives are thought to occur in patients who talk extensively just prior to examination.

Panendoscopy. The next step in diagnostic evaluation of patients with laryngeal cancer is panendoscopy. This diagnostic procedure is sometimes referred to as triple endoscopy and includes direct laryngoscopy, esophagoscopy, and bronchoscopy. The purpose of the operation is to assess the extent of the laryngeal tumor by direct laryngoscopy, obtain representative tumor tissue by biopsy, and assess the respiratory tract and upper digestive tract for synchronous primary tumors. The procedure is performed under deep general anesthesia with paralysis to allow a thorough, safe examination of the larynx, esophagus, and tracheobronchial tree. The relative merits of esophagoscopy and bronchoscopy compared to imaging studies for the detection of multiple primary tumors are a subject of debate. However, panendoscopy remains the standard by which other modalities are measured. Esophagoscopy and bronchoscopy should be performed prior to laryngoscopy so that bleeding from the more proximal laryngeal lesion will not distort the examiner's view of the esophagus or tracheobronchial tree.

Direct laryngoscopy, although appearing to be a relatively simple procedure, requires technical skill and experience to be performed effectively, with minimal trauma to the patient. A variety of laryngoscopes are available for this procedure, although the technology has not changed greatly in the last 100 years. The older laryngoscopes, such as those introduced by Jackson and Hollinger, provide adequate lighting and access and permit monocular viewing. Biopsy is performed through the open tube of the laryngoscope. The larger laryngoscopes introduced

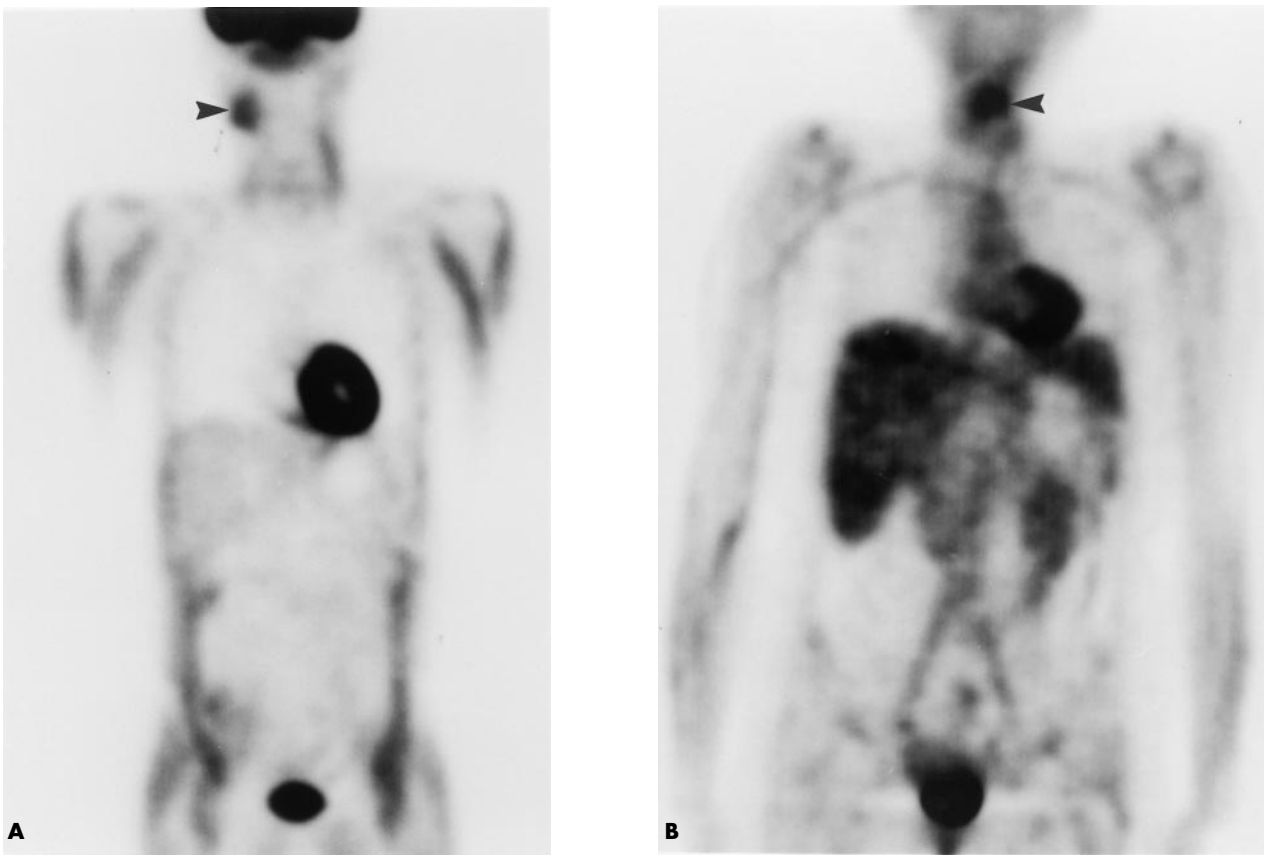

FIGURE 54–14. *A*, Positron emission tomographic scan showing uptake in the neck in a mass (*arrowhead*) thought to be radiation fibrosis. Fine-needle aspiration was negative on multiple passes. Open biopsy showed viable cancer cells. *B*, Positron emission tomographic scan showing uptake in the larynx (*arrowhead*) in a patient treated with radiation therapy for piriform sinus cancer. Office endoscopy and computed tomography were negative, but biopsy was positive.

by Jako, Dedo, and others permit binocular viewing and can be coupled with the operating microscope to provide a magnified view of early glottic lesions. Bivalved endoscopes were introduced in Europe in the last decade, provide wide exposure of supraglottic lesions in particular, and are useful in providing the wide access needed for endoscopic resection of small tumors. Zeitels recently introduced a modified laryngoscope with a triangular rather than oval tip, which is thought to improve exposure of the anterior commissure.[68] All of these laryngoscopes can be suspended to free both of the surgeon's hands for manipulation of the microscope and use of surgical instruments.

It is important to perform direct laryngoscopy gently. Great care should be taken to avoid injury to the anterior maxillary teeth, preferably by using a standard or custom-made tooth guard. The laryngoscope should be inserted gently, using the examiner's nondominant hand, so that instruments can be introduced with the dominant hand. When suspension is used, both hands can control instruments. The laryngoscope should be advanced slowly, following landmarks such as the uvula, epiglottis, and endotracheal tube to find the glottis. When examining supraglottic tumors, a broad, flat-tipped laryngoscope, modeled after the standard Jackson laryngoscope, should be used. Since supraglottic tumors bleed easily, the laryngoscope should be placed in the vallecula first to allow viewing of the epiglottis. Even with the best equipment, supraglottic tumors can be difficult to assess. They arise from and extend to structures that are relatively mobile and compressible. Glottic lesions remain more stable during examination and can be more accurately evaluated.

Microlaryngoscopy, in which the operating microscope is coupled with direct laryngoscopy, is highly useful in examining early cancers of the true vocal fold. The magnification provided by the microscope allows accurate determination of the extent of most small tumors. Biopsy using microinstrumentation can be very precise, limiting damage to adjacent normal portions of the vocal fold. Subglottic extension can be assessed with the microscope, although this is sometimes better evaluated by inserting a 0-degree rigid telescope between the vocal folds. Spatulas and vocal cord retractors used in laser surgery can be used to displace a vocal fold to examine its undersurface or to allow better visualization of the subglottic space or the laryngeal ventricle.

Adequate specimens are obtained for biopsy using cup forceps. Sufficient viable-appearing tissue should be obtained for pathologic examination. Excessive biopsies are not warranted and should be avoided. In the case of bulky tumors that intrude on the airway, an argument can be made for debulking at the time of biopsy to decrease the need for tracheostomy at the end of the endoscopy. Such patients need to be observed closely in the hospital since delayed bleeding and swelling can lead to airway obstruction, usually several hours after the procedure.

In patients with a marginal airway, a decision has to be made whether endotracheal intubation will be attempted or whether a tracheostomy under local anesthesia will be performed prior to direct laryngoscopy. Consultation between the surgeon and the anesthesiologist is critical to avoiding airway emergencies in such patients. The decision will be influenced partly by the skill and experience of the anesthesiologist in intubating the partially obstructed airway. Such patients should be intubated awake, with fiber-optic guidance. It is safer to perform a tracheostomy under general anesthesia with the airway already secured; if there is any doubt that the anesthesiologist will be able to pass an endotracheal tube into the airway without precipitating obstruction, a tracheostomy should be performed under local anesthesia. In some cases, patients with partial airway obstruction from a laryngeal tumor will not tolerate the supine position, and the tracheostomy has to be performed with the patient in the sitting position.

In certain patients, the risk of general anesthesia or other factors may preclude operative direct laryngoscopy. It is possible in some patients to obtain biopsy specimens without general anesthesia, usually to facilitate nonsurgical management or in the palliative setting. Fine-needle aspiration of cervical metastases is often sufficient. In the absence of clinically positive lymph nodes, some tumors can be sampled by performing a biopsy through a flexible bronchoscope introduced under topical anesthesia. Supraglottic tumors are fairly easy to access in this fashion. Glottic lesions on the side of a fixed vocal fold can also be accessed for biopsy in this manner. This technique should be avoided in patients with marginal airways. In certain cases, CT-guided needle biopsy can be employed to sample a laryngeal primary. Hypopharyngeal lesions can usually be sampled safely by either method.

Tumor Staging. The staging of laryngeal cancer in the United States follows the guidelines set forth in the tumor, node, metastasis (TNM) classification system created by the American Joint Committee on Cancer. The current classification system is presented in Table 54–1. It is important to remember that this is a clinical staging system, based on all types of clinical information available (physical

TABLE 54–1. TNM Staging for Carcinoma of the Larynx

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
Stage IVa	T4	N0	M0
	T4	N0	M0
	Any T	N2	M0
Stage IVb	Any T	N3	M0
Stage IVc	Any T	Any N	M1

examination, endoscopy, biopsy, imaging) prior to institution of therapy. Like all staging systems, the purpose is to stratify patients according to extent of disease in such a way that groups are defined that can be predicted to have a range of outcomes from excellent to poor. The TNM system does this based on morphologic and functional findings and does a fairly good job of separating patients into four groups (stage I to IV) such that increased stage is associated with decreased survival. Nevertheless, some patients in stage I die, and some in stage IV survive, and prediction of outcome based on tumor extent alone lacks precision.

A modified staging system for cancer of the larynx was proposed by Piccirillo et al,[69] in which patient characteristics were combined with the description of tumor extent. Severity of symptoms related to cancer was combined with comorbidity factors to create a functional severity index. Three functional severity classes were defined based on this index, with survival rates of 83%, 58%, and 15%. These functional severity indices were combined with the TNM stage to derive a clinical severity index. Survival rates for the four stages of the clinical severity index were 88%, 80%, 63%, and 28%. This system proved to be significantly better than the TNM system alone at predicting outcome. The author have subsequently proposed a similar staging system for all head and neck cancer sites that includes comorbidity as a major component.[70]

Although these clinical staging systems are useful and are frequently employed to make decisions when recommending treatment to patients and for comparing outcomes in clinical trials, precise prediction of outcome remains elusive. In the future, analysis of molecular markers and gene expression is likely to provide a better prediction of prognosis than purely clinical staging. Furthermore, even though staging systems may predict outcome in terms of survival, quality of life issues are of great importance to head and neck cancer patients and especially to patients with laryngeal cancer. Measurement of treatment outcomes has already started to focus on quality of life after treatment as well as quantity of life (survival), and quality of life measures are included in most clinical trials of head and neck cancer today. Future staging may also include the likelihood of achieving a good quality of life after treatment as well as survival.

TREATMENT OF CANCERS OF THE LARYNX AND LARYNGOPHARYNX

General Principles

Optimal treatment of cancers of the larynx and laryngopharynx should result in the highest probability possible for cure of a given stage of disease, while either preserving normal functions as much as possible or allowing for post-treatment rehabilitation of the patient to as high a level of function as possible. For patients at every stage of disease, it is no longer sufficient to simply design treatment with survival as the only end point. To this end, there has been a trend over the last 20 years to improve all treatment modalities for laryngeal cancer, such that the impact of treatment on the patient's social and economic circumstances is minimized without compromising survival. The following sections of this chapter review the various treatment options for patients with laryngeal cancer, ranging from small, early lesions to large, advanced lesions. Rehabilitation of speech after treatment will also be discussed.

Management of Early Glottic Cancer

The vocal fold is the most common primary site of laryngeal cancer in the United States. Since minor alterations in its function cause symptoms very early in the course of the disease, early detection occurs often and results in a high rate of cure. Effective management of the disease depends on a thorough understanding of the anatomy, histology, and lymphatic drainage of the glottis.

As stated, the larynx is lined by respiratory epithelium except at the vocal cords. Here the tissue is pseudostratified squamous epithelium situated over the lamina propria, a gelatinous fibroelastic layer, which, in turn, covers the vocalis muscle. The lamina propria allows for a sliding mucosal wave over the muscle. Any invasive process through this layer will cause an abnormal wave and hoarseness. The area between the vocalis muscle and mucosa is Reinke's space. Deep to vocalis muscle is the paraglottic space, and after invasion into this space, the disease process is no longer "early," and vertical growth may proceed over the entire lateral aspect of the larynx.

The anatomic compartmentalization of the larynx adds to the favorable prognosis of early glot-

tic carcinoma. The conus elasticus may inhibit progression of a tumor. If the lesion remains superficial and caudal to the free edge, it will grow onto the undersurface of the vocal fold and then to the subglottis. If it progresses cephalically over the conus elasticus into the vocalis muscle and laryngeal ventricle, it is free to spread into the paraglottic space.

"Early" carcinoma refers to a heterogeneous group of tumors, including Cis and T1 and T2 lesions. These tumors are grouped together and designated as early because the largest drop in patient survival occurs with tumor progression from stage II to stage III.

Overall, early glottic carcinoma is understaged clinically in 40% of cases. True Cis is rather rare; most of these tumors have an invasive component and are actually T1 lesions. It is important to consider that although an anterior commissure lesion may appear quite innocuous, it is located in an area that may be difficult to visualize, where the barrier to spread through the perichondrium is violated by Broyle's tendon. Thus, a tumor that grossly appears to be T1 might have microscopic invasion of the cartilage, making it in reality a T4 lesion.

The management of early glottic cancer focuses on the primary site since lymph node metastasis is uncommon with T1 or T2 lesions. There is some debate regarding the best management for early glottic cancers. There are numerous reports regarding both radiotherapy (XRT) and surgery as highly successful modalities for treating early glottic cancers. Primary XRT is delivered as photons in an average dose of 6,600 cGy to a field limited to the larynx, usually 6×6 cm. The treatment is delivered in 6 to 7 weeks in single fractions in the range of 180 to 200 cGy, 5 days a week. With this approach, cure rates for T1 cancers range from 80 to 91%.[75] Many studies include surgical salvage in their results, whereas others do not. Similar cure rates are reported for surgical treatment of early-stage glottic cancers. The choice of which modality to use is frequently influenced by the expected voice outcome. Until recently, it was generally accepted that XRT produced a better voice result than surgery for all early-stage glottic cancers, and in the United States and most of the world, XRT was the preferred initial treatment for early vocal fold cancers.

Radiation Therapy Virtually all of the data on radiation treatment of early glottic cancer are based on retrospective analyses or on single-institution reports of consecutive patients treated. One extensive review of 38 reported series for T1 vocal fold cancer found an overall cure rate of 83.7%.[71] Others have reported a range from 80 to 91%. Local control rates as high as 95% and as low as 67% have been reported.[72] Male gender and bilateral vocal fold involvement portend a worse outcome.

T2 glottic carcinomas are reported to have a lower cure rate than T1 cancers. A study evaluating the results of treatment of T2 glottic cancer with primary XRT reported in 25 series indicated an overall cure rate of 64%.[73] There is wide variation in the reported success rate for treating T2 lesions, which may reflect selection of more favorable lesions at some centers compared with others. T2 lesions are often described as heterogeneous, and some propose dividing them into T2a (normal mobility) and T2b (impaired mobility).[74] Wang reported local control rates of 86% for T2a lesions and 63% for T2b lesions treated with primary XRT.[75] To improve the accuracy of staging of lesions that may involve the anterior commissure, Zeitels recommended resection of the anterior vestibular folds and infrapetiole region to allow inspection of Broyle's tendon. This can be done without disturbing the voice and will demonstrate if there is cartilage invasion in this potentially dangerous area.

Surgical Treatment of Early Glottic Cancer Surgeons have devised many operations for early glottic cancer over the last two centuries. Brauers introduced partial laryngectomy in the form of cordectomy via vertical laryngofissure (thyrotomy) in 1834. Early results with this approach were poor, probably because of a lack of adequate lighting, instrumentation, general anesthesia, antibiotics, and blood replacement. It was long held that partial resection of the larynx was dangerous and that only a total laryngectomy could be considered as surgical treatment for cancer. In the 1940s and 1950s, procedures were introduced that provided adequate tumor removal while preserving some degree of vocal communication, swallowing function, and breathing without a tracheostomy. In the modern era, hemilaryngectomy techniques have replaced cordectomy. Patient selection is critical to success in these procedures. The procedures are based on the knowledge that early glottic tumors remain confined to the vocal fold, tend to be well differentiated with a well-

demarcated leading edge, and rarely spread to lymphatics.

The following criteria should be met for patients to be candidates for partial laryngectomy of any type:

1. The patient should be in good general health. Elderly, debilitated, or mentally impaired patients who would not be able to tolerate a temporary tracheostomy and/or temporary aspiration with eating should not be candidates for conservation procedures.
2. The patient should have a good understanding of the procedure and the possibility that prolonged rehabilitation of speech and swallowing may be required.
3. Adequate pulmonary function is most critical for supraglottic laryngectomy. Poor exercise tolerance, either by history or demonstrated on pulmonary function tests, excludes most patients from open partial laryngeal surgery, particularly supraglottic laryngectomy. If doubt exists, a formal consultation with a pulmonary specialist should be obtained.

For glottic lesions, vertical, frontolateral, and anterior approaches are commonly used. The vertical hemilaryngectomy is most commonly used and is illustrated in Figure 54–15. Absolute control of the vocal fold margins by frozen section must be obtained to achieve maximum success rates. A margin of 1 mm on the vocal fold is considered adequate. Numerous variations on this basic surgical approach have been described. Up to one entire arytenoid, one-third of the contralateral vocal fold, and up to one half of the vertical height of the anterior part of the cricoid cartilage can be removed. If more than one-third of the contralateral vocal fold must be removed, a keel should be placed through the thyrotomy and secured to the skin with button fixation for 3 to 6 weeks (Figure 54–16). Others have described rotation of an epiglottic flap to reconstruct the loss of the anterior parts of the vocal folds[76] (Figure 54–17). Another option for extensive involvement of both true vocal folds is the CHEP procedure (cricohyoidoepiglottopexy), described later in this chapter and shown in Figure 54–18.

Endoscopic Excision of Early Vocal Fold Cancers

With the introduction of the operating microscope and its coupling to the carbon dioxide laser by Strong and Jako in 1972,[77] interest in endoscopic treatment of vocal fold cancer increased. In Western Europe over the last 10 years, a number of investigators have published relatively large series of patients treated by either laser or cold steel excision of early vocal fold cancers. Like partial laryngectomy techniques in the past, acceptance was initially slow in the United States and elsewhere. Doubts were raised concerning the oncologic safety of such techniques and about the voice outcomes compared to XRT. However, detailed reports from centers in Europe and the United States have documented local control and survival outcomes as good as or better than those achieved for XRT for Cis, T1, and T2 vocal fold cancers,[78–83] with local control rates ranging from 88 to 93% and laryngeal preservation rates ranging from 93 to 100% for T1 lesions. Voice results are quite good for early lesions with minimal invasion of

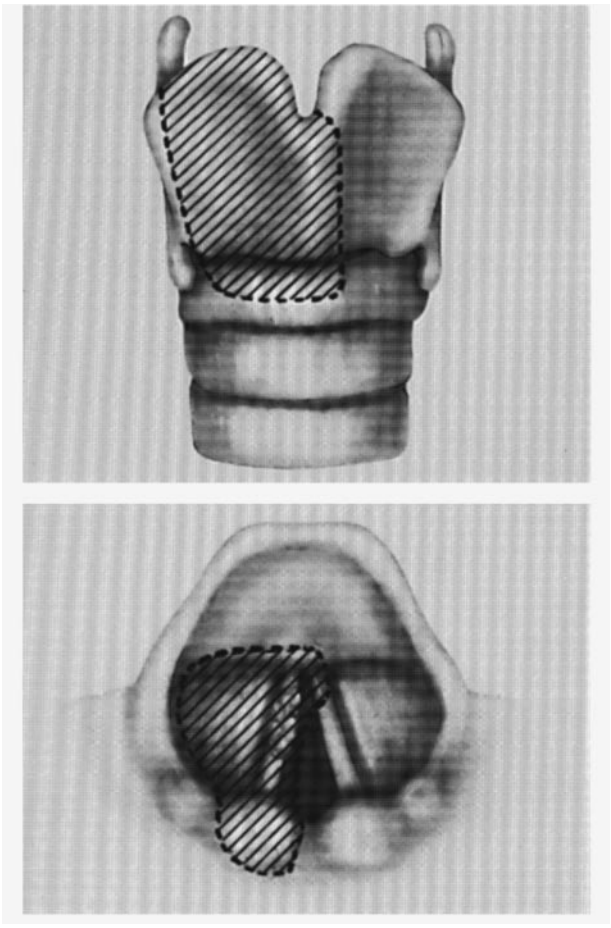

FIGURE 54–15. Schematic diagram of vertical hemilaryngectomy. The *outlined shaded areas* indicate the resected tissue.

Reinke's space and approach those observed after XRT. Furthermore, 40% of Tis to T2 patients whose cancer recurs can be salvaged with laryngeal conservation surgery.[83]

Patients with no or minimal disturbance of the mucosal wave on videostroboscopy are the best candidates for this procedure. Some debate exists over whether carbon dioxide laser or cold steel techniques should be used. Both methods allow precise microscopic control of the excision, but some argue that the heat from the laser–tissue interface results in more scarring after healing than in cold steel techniques, resulting in a worse voice outcome. Distortion of the margins by the laser is also noted as a potential disadvantage. Excision of the false vocal fold on the side of tumor involvement greatly aids visualization during surgeries for larger early lesions and also provides a wider field of view for following the patient endoscopically after treatment.[84]

There are several advantages proposed by advocates of endoscopic treatment of vocal fold cancers. First, cure rates are at least as good as seen with XRT. Second, voice results in selected patients are probably similar to those achieved with XRT. Third, since XRT is not used, it will still be available should the patient develop a second primary tumor or a

recurrence at the primary site that cannot be salvaged with endoscopic surgery. The high rate of laryngeal preservation noted with this approach supports this assertion. Fourth, the procedure is cost effective. A report by Myers et al confirmed that endoscopic management of T1 glottic cancer was less expensive and equally as effective as XRT.[85] Finally, treatment is accomplished quickly, with little morbidity, and may be suitable for those patients who wish to avoid daily treatment with XRT over a protracted course of several weeks. A typical endoscopic resection of an early vocal fold cancer is shown in Figure 54–19.

Based on available information, it seems reasonable to employ XRT as initial treatment for most T1 vocal fold lesions, except for those that appear to have minimal invasion of the subepithelial layer of the vocal fold, as determined by videostroboscopy or by examination at the time of direct microlaryngoscopy. T2a lesions are probably best treated by XRT, whereas T2b lesions should be considered for primary surgery, with XRT as the second option. Lesions defined as Cis based on biopsy are best managed by excision until they involve areas that cannot be followed adequately by office endoscopy, at which time XRT should be considered.

Management of Early Supraglottic Cancer

Early supraglottic cancer is rarely encountered. Even T1 and T2 primaries have a significant rate of lymph node metastasis. Management of the neck is critical since uncontrolled neck disease is the major reason for failure to control supraglottic carcinomas. For the purposes of this discussion, early supraglottic cancers are defined as T1 or T2 primary lesions, and discussion of neck management is similar to that

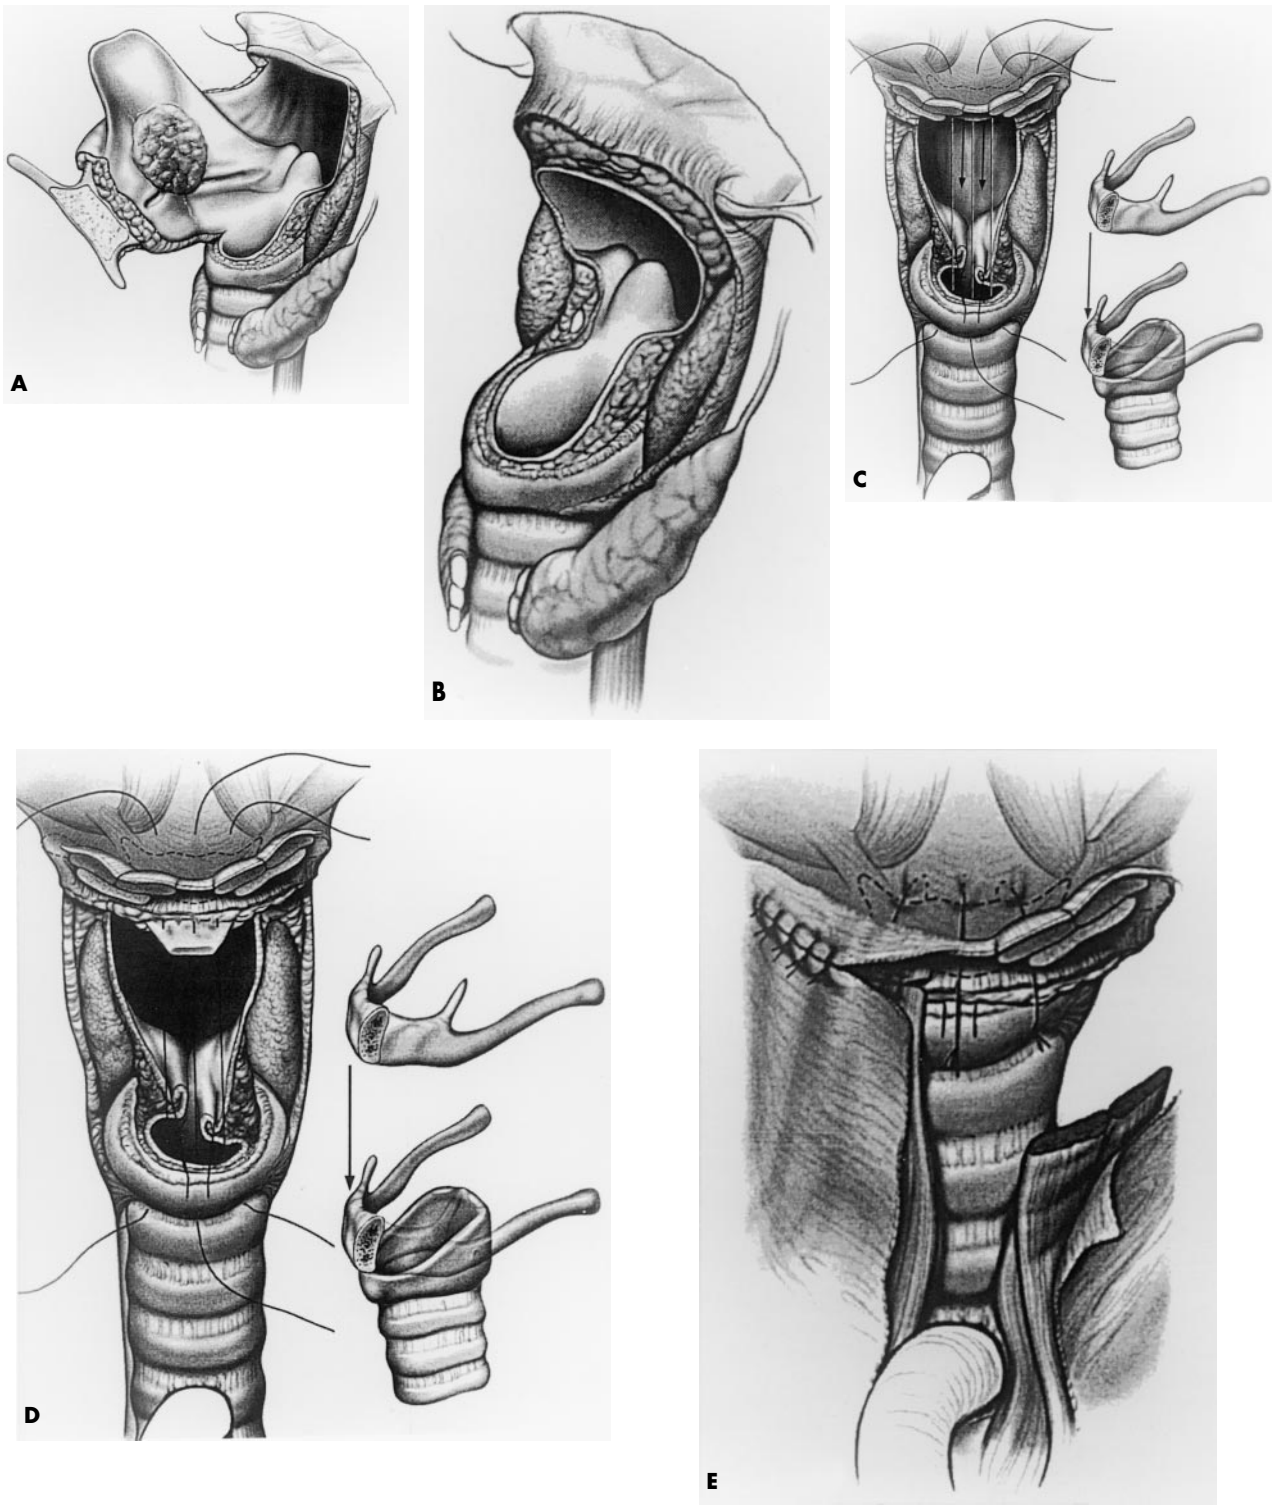

FIGURE 54–18. Schematic diagram of cricohyoidoepiglottopexy (CHEP) and cricohyoidopexy (CHP) procedures. *A*, Exposure and tumor cuts are shown for CHP. *B,* The defect after resection is shown for CHP. *C*, The vocal fold remnants are sutured to the anterior part of the cricoid cartilage to maintain their position and tension. Heavy sutures (eg, 2-0 polyglactin) are used to approximate the cricoid cartilage to the hyoid bone. *D*, In CHEP, sutures are passed through the epiglottis and base of the tongue to prevent epiglottic prolapse, but the closure is otherwise similar. *E*, The wound after closure of the larynx is complete.

discussed in the section on advanced supraglottic cancers later in this chapter.

Early supraglottic cancers can be managed either with surgery alone or radiation alone, although neck node involvement may mandate combined modality therapy. T1 primary tumors are rare since they usually remain silent as isolated lesions on the epiglottis. The limited reported experience with these lesions indicates that local control can be achieved with either surgery or radiation in over 90% of patients. T2 lesions involve two subsites of the supraglottis, without vocal fold fixation. Such tumors often involve the epiglottis and one aryepiglottic fold or other subsite combinations. Most reports, even though retrospective, indicate excellent local control with surgery that compares very favorably to conventional XRT. A study comparing primary surgery with primary XRT for T1 to 4N0 supraglottic carcinomas yielded identical 5-year survival rates for T categories 1 to 3, with an improved survival for T4 tumors treated surgically (56 versus 14%).[73] Local control rates for T2 lesions treated with XRT vary widely, from 53 to 89%,[86,87] but are generally similar to or slightly less than local control rates for surgery.

Surgery for Supraglottic Cancer Partial supraglottic surgery was performed as early as 1920 via transhyoid pharyngotomy. Alonso described a two-stage procedure for supraglottic resection that was performed through a lateral pharyngotomy. Ogura combined this approach into a one-stage procedure that has been widely used since the late 1950s. This supraglottic laryngectomy or horizontal partial laryngectomy encompasses the epiglottis, aryepiglottic folds, and false vocal folds and is illustrated in Figures 54–20 and 54–21. It can be extended to include one arytenoid cartilage, part of the tongue base, and the vallecula. If the arytenoid cartilage is excised, the true vocal fold is pexed in the midline to the posterior part of the cricoid cartilage to facilitate glottic closure for speech and swallowing. Closure of the defect created is almost always under tension. The preserved outer perichondrium of the thyroid cartilage and strap muscles are sutured to the base of the tongue anteriorly, and the cut edge of the aryepiglottic fold is sutured to the lateral part of the base of the tongue and pharynx. Some surgeons keep the patient's neck flexed postoperatively for 10 to 14 days, in some instances suturing the chin to the chest to prevent neck extension. Contraindications to the procedure have been cited as vocal fold fixation, tumor extension to 5 mm or less from the anterior commissure (often difficult to evaluate by preoperative endoscopy or imaging), and thyroid cartilage invasion. Patients must have excellent pulmonary function to be candidates for the operation.

For tumors that extend to the posterior parts of the aryepiglottic folds and the glottis, an extended or "three-quarter" laryngectomy has been described. It combines a supraglottic laryngectomy with a ver-

tical hemilaryngectomy. Reconstruction requires rotation of either the saved superior cornu of the thyroid cartilage or the posterior edge of the thyroid ala to reconstruct a stable pseudocord pedicled on the inferior constrictor muscle and covered with mucosa advanced from the hypopharynx (Figure 54–22).

If a cancer involves the piriform sinus by extension from the supraglottis, an oblique extension of the standard supraglottic laryngectomy can be made to encompass the lesion (Figure 54–23). Involvement of the piriform apex, the thyroid or cricoid cartilage, the glottis or subglottis, or an anatomic site beyond the laryngopharynx is a contraindication to this procedure. The defect created is usually too large for primary closure, and a pedicled myocutaneous flap (pectoralis major, latissimus dorsi) or a free flap (radial forearm) is the best means of reconstruction. The free flap usually retains vibratory properties owing to its pliability and minimal thickness, resulting in better voice results than myocutaneous flaps.[88]

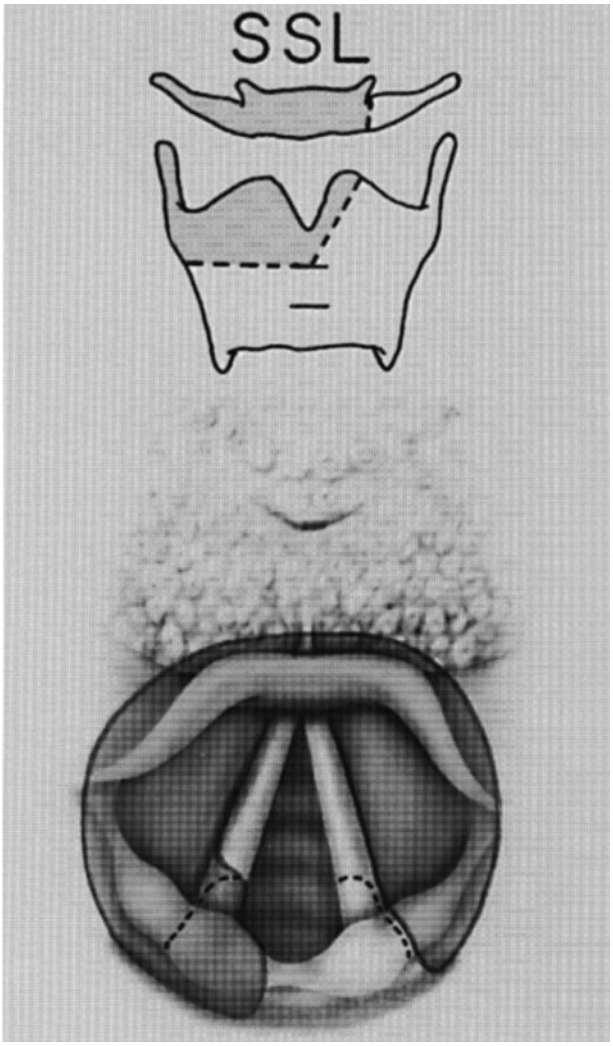

FIGURE 54–20. Schematic view of a subtotal supraglottic laryngectomy (SSL). The cartilage and bone cuts are shown above. The true vocal folds and at least one arytenoid cartilage are spared.

Cricohyoidoepiglottopexy and cricohyoidopexy should be kept in mind as alternatives to traditional open supraglottic laryngectomy techniques. These approaches are applicable to selected T2 supraglottic cancers thought not to be amenable to supraglottic partial laryngectomy because of ventricular invasion, glottic extension, and/or impaired motion of the vocal fold.

Transoral Carbon Dioxide Laser Resection of Supraglottic Cancers

The slow acceptance of endoscopic techniques for supraglottic cancers bears similarities to the delayed acceptance of open partial laryngectomy techniques 40 to 50 years ago. New developments in instrumentation, particularly the introduction of "split" or bivalved laryngoscopes, have enhanced exposure that is needed for this kind of surgery (Figure 54–24). Reports of relatively large series from Europe[89–91] and the United States[92,93] indicate excellent local control rates for T1 and T2 supraglottic lesions. For T1 lesions of the suprahyoid epiglottis, there is little controversy that this technique is effective. Proponents of transoral carbon dioxide resection cite low local recurrence rates for T2 lesions, similar to those for open supraglottic laryngectomy approaches, as support for their method.[94] Even T3 lesions based on preepiglottic space invasion can be managed endoscopically since the entire inner perichondrium of the thyroid cartilage and preepiglottic fat can be removed (Figure 54–25). If limited invasion of the thyroid cartilage is found, the procedure can be converted to an open approach, or the area can even be resected endoscopically with the laser or cold steel instrumentation.

The technique for larger lesions that cross the midline is quite different than those used in open techniques. The tumor is split vertically in the midline and is removed in at least two segments. Splitting the tumor actually allows the surgeon to see with the operating microscope and feel with instru-

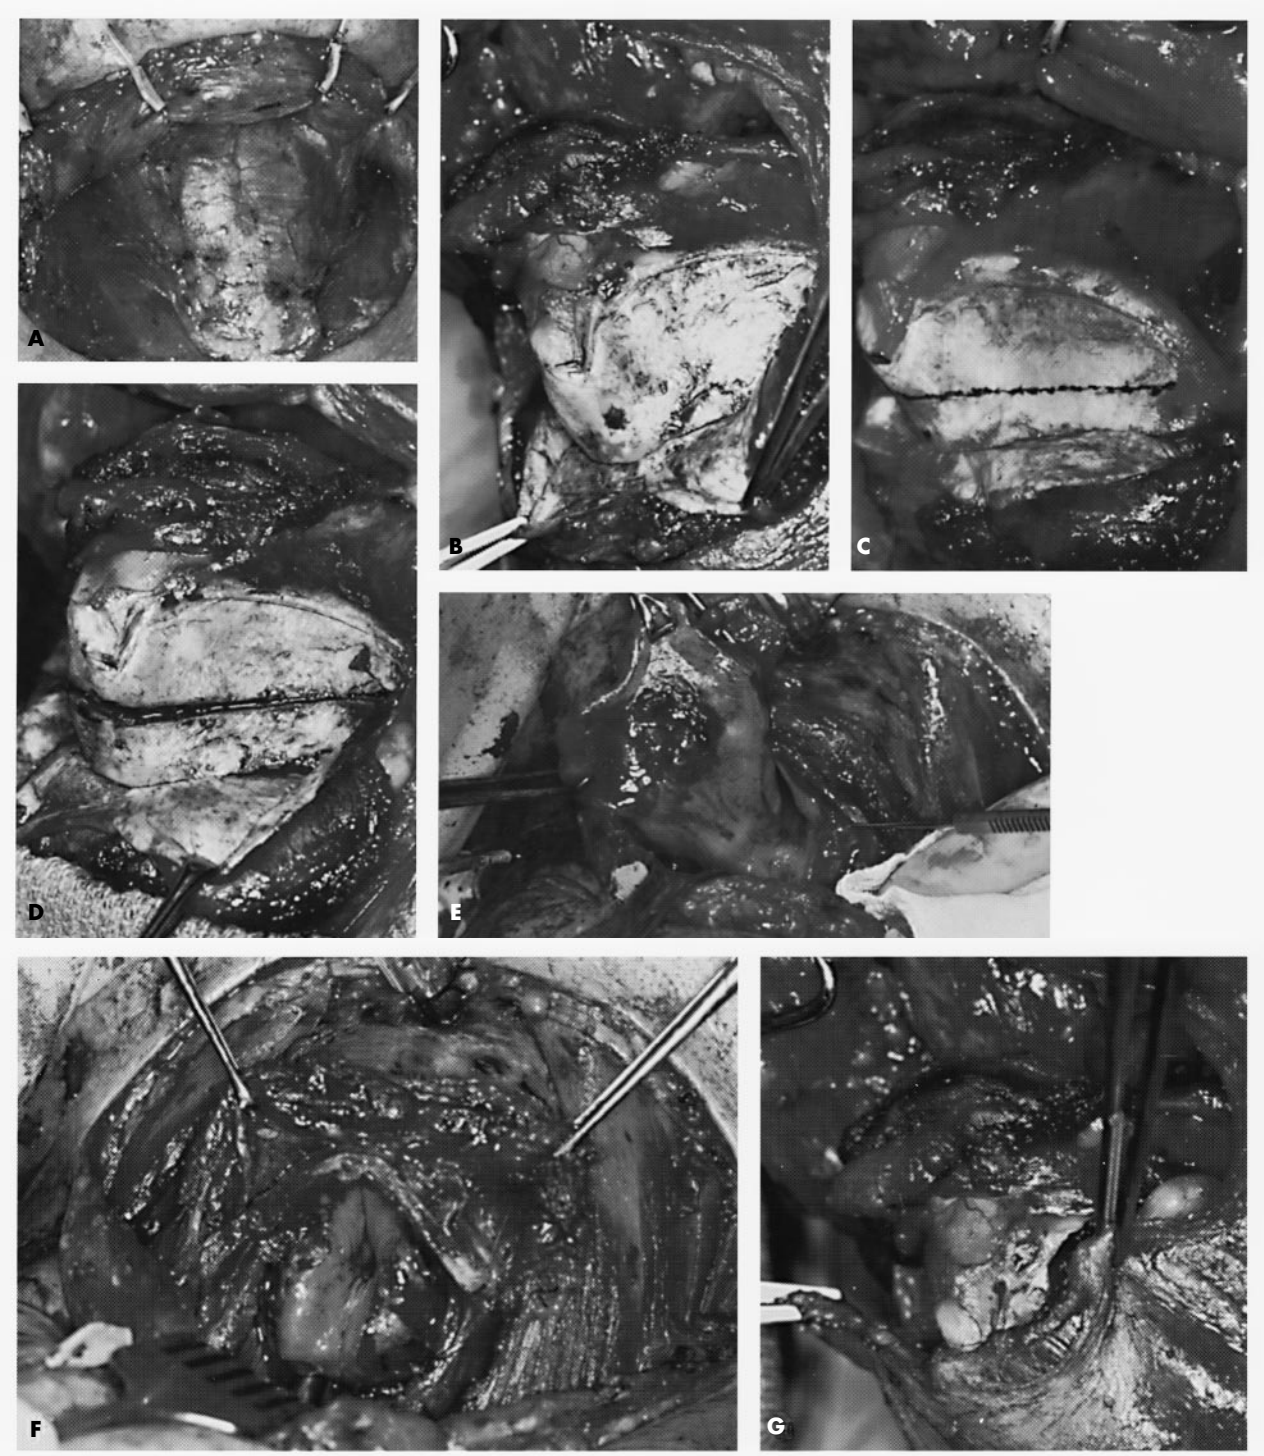

FIGURE 54–21. Subtotal supraglottic laryngectomy. *A*, Anterior neck exposure. *B*, Perichondrial elevation. *C*, Horizontal subperichondrial incision outlined. *D*, Incision completed with oscillating saw. *E*, Resection of the supraglottis with direct vocal fold visualization. *F*, View of defect after resection. *G*, Strap muscles and perichondrium are elevated; closure of perichondrium and strap muscles to base of tongue.

ments where the interface is between tumor and normal tissue. Debulking the tumor can also facilitate exposure without compromising the resection. Frozen sections are obtained after tumor removal is completed. Proponents of the endoscopic laser resection point out that their patients have less morbidity than those treated by open techniques in that tracheostomy is usually avoided, hospital stay is dramatically shorter, and time to resumption of speech and swallowing is considerably shortened.[92] Many patients require nasogastric tube feedings for only a few days, and some can swallow shortly after surgery and do not require a feeding tube. It seems likely that this technique will gain popularity in the United States in the future and will probably be used more frequently than open supraglottic laryngectomy procedures.

It would appear that early supraglottic cancers can be managed well with either radiation or surgery. In patients who are N0, single-modality therapy that includes both sides of the neck, as well as the primary site, is often sufficient. Surgery has the advantage of providing information on the adequacy of primary treatment (margins) and true pathologic staging of the neck. Whereas XRT may be less morbid, voice results are similar with surgery, and newer, less invasive surgical techniques may make the cost and morbidity of the two approaches equivalent. Patients with N+ necks almost always require combined surgery and radiation, particularly for advanced (N2 and N3) neck disease. In such cases, XRT for the primary site and combined treatment for the neck seems rational since XRT tends to adversely impact the functional results of conservation surgery of the supraglottic larynx.

Other Methods for Treating Early Laryngeal Cancers

Photodynamic therapy has been used to treat early vocal cord cancers, particularly recurrences after radiation failure. This method employs a photoactive drug that is administered systemically to the patient up to several days in advance of treatment, depending on the kinetics of the drug. The lesion is viewed endoscopically and is treated with a laser of appropriate wavelength to activate the drug to a toxic form in tumor cells that have been exposed to the laser light. Although a number of photoactive drugs have been investigated, most patients have been treated with hematoporphyrin derivative (HPD). The advantage of this approach is that there is little damage to nontumor tissue if precautions are taken to limit laser exposure to the tumor only. Another advantage is that unlike radiation, the treatment can be repeated as many times as needed, either for incomplete response

or for recurrence. For Cis and T1 glotttic cancers, complete responses approached 90% with a single treatment, and a cure rate of 95% was seen with a 79-month follow-up period.[95] The effect on tissue is superficial, but that is all that is required on the true vocal fold in most cases. The disadvantage is that, after the photoactive drug is administered (4 days before photoactivation for HPD), the patient must avoid exposure of the skin, eyes, and mucous membranes to light for an extended period of time (about 1 month for HPD). Severe burns have occurred in patients when adequate precautions were not taken. The photoactive drugs are also very expensive, and the laser used is proprietary and does not employ a wavelength found in other commonly used lasers. If a photoactive drug with a short half-life can be developed at a competitive cost, this technique will probably gain wider acceptance.

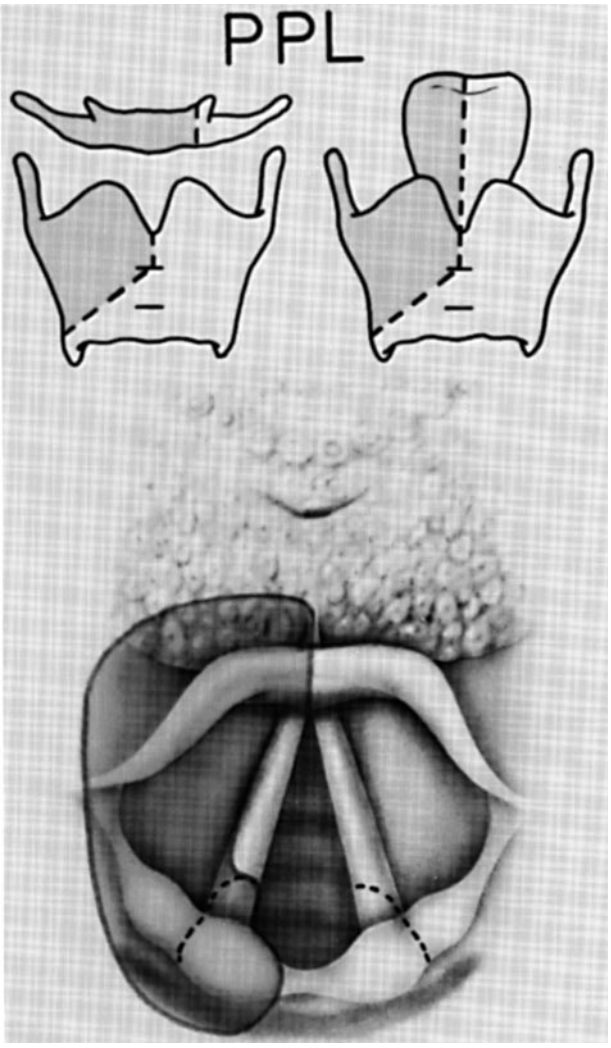

FIGURE 54–23. Schematic drawing showing the extent of cartilage and soft tissue resection for a partial laryngopharyngectomy. An oblique cartilage resection is performed to include the piriform sinus. PPL = partial pharyngolaryngectomy.

Chemotherapy for Early Glottic Cancer

There is little experience with chemotherapy as the sole treatment for early laryngeal cancer. One intriguing report of 21 patients with T1 to 3N0 glottic cancers who exhibited a complete response to *cis*-platinum/5-fluorouracil chemotherapy had a 5-year survival rate of 95%, local control rate of 71%, and metachronous second primary incidence of 14%. None of these patients developed regional or distant metastases. All local recurrences were salvaged with either partial laryngectomy or XRT.[96] Such an approach may merit further investigation, but the potential toxicity of treatment must be weighed against the excellent results that are already available with the many approaches described above.

Management of Advanced Laryngeal Cancer

Advanced cancer of the larynx includes stage III and IV tumors. Most such tumors are T3 or T4 at the primary site. Any size primary tumor that presents with a neck metastasis is considered advanced. It is fairly uncommon to see neck metastasis at presentation with a T1 or T2 glottic tumor or a T1 supraglottic tumor, but in such patients, management of the primary tumor is usually straightforward, with the neck metastasis being of greater concern and having the greatest impact on survival. For practical purposes, advanced cancer will be defined here as T3 or T4 disease, with or without cervical lymph node metastases.

Surgical management for laryngeal cancer is suggested in reports in the medical literature as early as 1801. It is not clear whether these early operations were for cancer or for benign lesions. In 1874, Billroth reported the first total laryngectomy. Although there was initial resistance to this procedure, other surgeons subsequently confirmed the safety and efficacy of this procedure. Numerous operations less radical than a total laryngectomy were described before and after its introduction. Most of these "conservation" procedures were designed for smaller (T1 and T2) primaries.

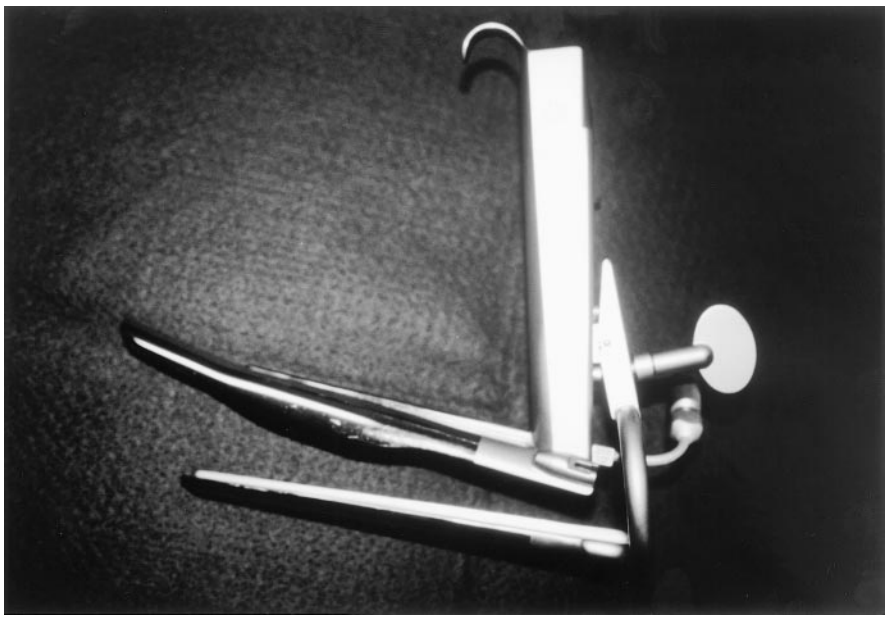

FIGURE 54–24. Bivalved laryngoscope essential for exposure needed to perform endoscopic carbon-dioxide laser resection of supraglottic cancers.

Other surgical procedures have been developed for larger laryngeal tumors with the goal of preserving and reconstructing enough of the larynx to allow retention of speech, swallowing, and breathing functions while providing tumor control rates comparable to total laryngectomy. Several types of "subtotal" laryngectomy have been described, most notably that of Pearson in 1981.[97] Piquet and associates[98,99] and Weinstein and Laccourreye[100] published extensive experience with supracricoid laryngectomy techniques that allow resection of selected advanced laryngeal and laryngopharyngeal cancers with primary closure of the defect. The cricoid cartilage is sutured to the retained hyoid bone or epiglottis, with preservation of one functioning cricoarytenoid unit being a prerequisite.

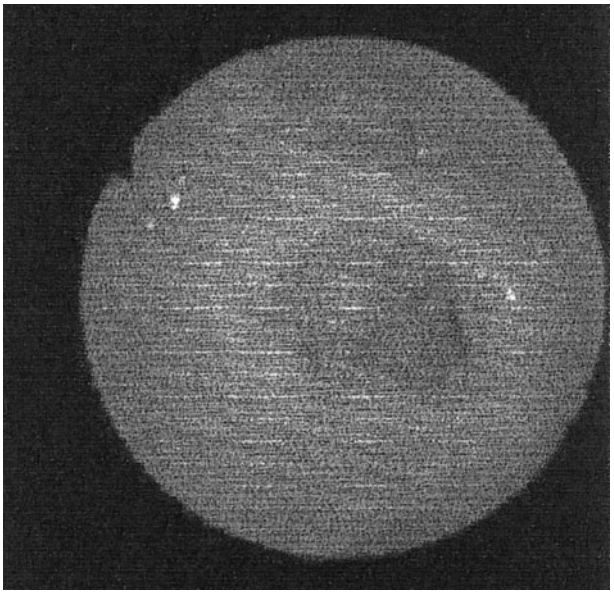

FIGURE 54–25. Postoperative view showing surgical defect after transoral endoscopic carbon-dioxide laser resection of a T2 supraglottic cancer. Part of the preepiglottic space was included in the specimen.

Primary radiotherapy has been used extensively to treat advanced laryngeal cancers, particularly in centers outside the United States. When radiation is used as single-modality therapy, surgery is kept in reserve for salvage of treatment failures. In general, when this approach has been analyzed critically, radiation alone has not fared as well as surgery for resectable lesions.[101–104] Vocal fold fixation is considered a relative contraindication for radiation because it portends a high failure rate. As newer radiation technology and hyperfractionated treatment schedules have been introduced, some have challenged this concept.[105]

Management of Specific Subtypes of Advanced Cancers

Advanced Supraglottic Cancer T3 supraglottic cancer, by definition, involves the preepiglottic space, invades cartilage, extends to the medial wall of the

piriform sinus, or causes vocal fold fixation. There is also a very high probability of lymphatic metastasis. Treatment options include surgery alone, surgery combined with preoperative or postoperative radiation therapy, primary radiotherapy, or a combination of chemotherapy and radiotherapy, with surgical salvage for failures of the latter two options. Controversy exists over the best treatment, and planning tends to be individualized according to tumor size and location, age and general health status of the patient, presence or absence of vocal fold fixation, estimated pulmonary function, other patient parameters, and the wishes of the patient. Preservation of laryngeal function without compromising survival should be attempted whenever possible.

T3N0 supraglottic cancers can be treated by supraglottic laryngectomy as long as patient selection criteria are strictly followed. The operation should not be attempted if there is vocal fold fixation, extensive involvement of the piriform sinus, thyroid or cricoid cartilage invasion, or extensive involvement of the base of the tongue (to or beyond the circumvallate papillae). Preepiglottic space invasion is not an absolute contraindication to supraglottic laryngectomy. Surgical management of properly selected patients results in a 3-year disease-free survival of 75%.[106–108] Local recurrences occur in only 10% of patients at this stage undergoing this procedure. Because of the high rate of lymphatic metastasis, elective treatment of the neck is indicated. Bilateral supraomohyoid neck dissection is advocated as therapeutic (in pathologically N0 necks) and as a staging procedure in patients who are pathologically lymph node positive. Patients with more than one positive lymph node or with any lymph node exhibiting extracapsular spread should probably receive postoperative radiotherapy.

A major requirement for selection for supraglottic laryngectomy is adequate pulmonary function. Almost all patients exhibit some degree of aspiration after supraglottic laryngectomy, even those performed for T1 and T2 lesions endoscopically by carbon dioxide laser excision. Patients with poor exercise tolerance can be expected to be at high risk for aspiration pneumonia after supraglottic laryngectomy. Pulmonary function studies should be performed preoperatively in all patients being considered for this operation. Forced expiratory volume in 1 second of at least 75% is considered by many to be a requirement.

Even in properly selected patients, approximately 5 to 10% will eventually require a completion laryngectomy for intractable aspiration.[109] About 20% will require a prolonged tracheostomy (more than 3 months), most of whom are patients who have received postoperative radiation therapy. Rates of prolonged dysphagia after surgery are low but are directly proportional to the extent of surgical resection, with the highest rates observed in patients who have had part of the base of the tongue or piriform sinus removed. Reports from Europe on carbon dioxide laser endoscopic resection of large supraglottic cancers describe lower rates of dysphagia and aspiration than those observed for open procedures for similar-size lesions. Less tissue destruction and removal, absence of tension associated with wound closure in open procedures, and less damage to the superior laryngeal nerves are probable explanations for these observations. A high degree of technical training, skill, and experience is necessary to achieve good results with such endoscopic techniques.

Voice results for patients treated with supraglottic laryngectomy without postoperative radiation are equivalent to those for similar patients treated with primary radiotherapy.[110] Voice results after transoral laser excision of larger supraglottic cancers have not been systematically studied but are thought to be at least as good, if not better than, those achieved by open supraglottic laryngectomy. It is noteworthy that patients with supraglottic cancers amenable to supraglottic laryngectomy who are treated with total laryngectomy have survival rates that are no higher than similar patients treated with supraglottic laryngectomy.

Advanced supraglottic cancers that exhibit vocal fold fixation, postcricoid extension, cartilage invasion, or extension outside the larynx are usually treated with total laryngectomy and postoperative radiation. However, several organ-preserving strategies are applicable to such lesions and are discussed later in this section. Most advanced supraglottic cancers have positive neck lymph nodes or have a high risk of neck metastasis in the N0 neck. It is fair to say that the neck should be treated in all cases of advanced supraglottic cancer. Because most of the supraglottic subsites have bilateral lymphatic drainage, both sides of the neck require treatment. For the N0 neck, bilateral selective neck dissection encompassing levels II, III, and IV is considered suf-

ficient by most surgical oncologists. Although some argue that such surgery does not impact survival,[111] valuable pathologic staging information is gained, which certainly impacts the decision whether to use postoperative radiation. Patients with greater than one positive lymph node and those with any lymph node exhibiting extracapsular spread should receive postoperative radiation. Patients with N+ neck disease should have a more extensive neck operation, usually a modified radical or radical neck dissection on the involved side(s). Neck structures spared in such operations depend on the size and location of the involved lymph nodes. All such patients should receive postoperative radiation.

Radiation Therapy. Standard, once-daily radiation therapy has been investigated as single-modality treatment for advanced supraglottic cancers that are considered resectable by supraglottic laryngectomy. Higher local failure rates, lower survival rates, and lower rates of laryngeal preservation have been reported for patients treated with radiation for cure, with surgery reserved for salvage of treatment failures.[101–104] In most of those patients, surgical salvage consists of total laryngectomy, and salvage surgery is usually possible in only 50% of such patients.[112] Twice-daily or hyperfractionated radiation therapy schedules have been reported to produce improved local control rates for advanced supraglottic cancers compared with standard, once-daily fractionation schedules.[113] This radiation approach will be discussed in greater detail in the section on advanced glottic cancer.

Advanced Glottic Cancers Until the last decade, advanced glottic cancers were treated either by total laryngectomy or by radiation therapy for cure, with total laryngectomy in reserve for surgical salvage. Although the merits of the two approaches were debated extensively in the medical literature, a prospective, randomized, controlled study was never performed. Proponents of surgery as primary therapy claimed higher survival rates, whereas those espousing radiation first pointed out the advantage of voice preservation in those individuals who did not relapse after radiation. Many studies were retrospective, and survival rates for T3 lesions ranged from 49 to 80%[73,114,115] and for T4 lesions from 32 to 63%.[73,115]

The technique of total laryngectomy has changed very little in the last century. A radical, en bloc resection of the larynx is performed. The hyoid bone is included in the resection, and the trachea is transected at the highest level that is oncologically feasible to facilitate creation of a tracheostoma of sufficient size that can be sutured to the skin with as little tension as possible. The operation can be extended to include adjacent involved areas of the base of the tongue and hypopharynx. When a partial or total pharyngectomy is added to a standard total laryngectomy, some sort of flap reconstruction is usually required. The main flaps used are the pectoralis major myocutaneous flap and the radial forearm free flap, especially when a strip of intact normal hypopharyngeal mucosa can be maintained between the oropharynx and the esophagus. When total pharyngectomy and/or esophagectomy are performed, visceral reconstruction is usually achieved with either a jejunal free flap or, more commonly, gastric pull-up. For piriform sinus tumors and for tumors with greater than 10 mm of subglottic extension, a thyroid lobectomy or subtotal thyroidectomy should be performed, depending on the extent of spread in relationship to the midline.

Radiation treatment for laryngeal cancer dates to 1903. As the technology involved in radiation treatment has improved and as our understanding of radiobiology has increased, so has the methodology advanced in delivering radiotherapy to patients. Today, there are numerous radiation fractionation strategies and schedules that are used for treating advanced laryngeal cancer.

It was initially felt that radiation was effective against cancer because tumor cells were more sensitive to ionizing radiation than normal cells of the same tissue type. Although this has been found not to be the case from tissue culture studies, it is clear that tissues with a large portion of proliferating cells (high growth fraction) are more susceptible to the lethal effects of radiation. The percentage of cells in the proliferative phases of the cell cycle is one determinant of radiation sensitivity. The ability of cells to repair DNA damage caused by radiation is now recognized as an important factor in determining the effect of radiation and chemotherapy on cancer cells. Depending on the degree of damage and the cell's ability to repair the damage, the cell will either go into growth arrest (to repair damaged DNA) or go on to apoptosis (programmed cell death). Certain

strategies, such as twice-daily radiation (hyperfractionation), are designed to kill more cancer cells by treating in more fractions, over a shorter interval, to confer lethal damage to cells that might otherwise repair themselves. Chemotherapy concurrent with radiotherapy may act as a radiation sensitizer in the same manner or by forcing more of the tumor cell population into phases of the cell cycle in which they are more susceptible to the effects of radiation.

A prospective trial concerning XRT only for laryngeal cancer was conducted at the Princess Margaret Hospital in Toronto.[113] Patients with advanced head and neck cancer were randomized to either once-daily XRT to a total dose of 51 Gy in 20 fractions delivered in 4 weeks at 2.55 Gy per day or twice-daily XRT to a total dose of 58 Gy delivered in 40 fractions in 4 weeks at 1.45 Gy twice a day at least 6 hours apart. Of the 336 patients entered, 116 had T3 or T4 laryngeal cancers, of which 30 were glottic and 86 supraglottic. Fifty-one were T3 and 65 were T4. Local control at 3 years was achieved in 50% of the once-a-day treatment arm and 54% in the twice-daily treatment group. Overall survival was 47% for once-daily XRT and 69% for twice-daily XRT, a significant difference. A number of other trials comparing once-a-day with twice-a-day radiation schedules have been reported, most indicating improved locoregional control with twice-daily XRT but mixed results in terms of any impact on survival.[116-121] Most of these studies have involved large numbers of patients from all head and neck subsites and have not focused specifically on the larynx.

Organ Preservation Approaches Today the emphasis has shifted to organ-preserving strategies, both surgical and nonsurgical, for managing advanced glottic (and supraglottic) cancers. Perhaps the major impetus for this trend was the Department of Veterans Affairs (VA) Laryngeal Cancer Study Group, which initiated a multicenter, randomized, prospective trial to evaluate a laryngeal preservation strategy in patients with locally advanced, resectable laryngeal cancer.[122] The majority of the patients entered had advanced glottic cancers, but some supraglottic cancers were also included. All patients entered would normally have been candidates for total laryngectomy. Patients were randomized to one of two treatment arms. One arm was standard therapy with total laryngectomy and postoperative radiation. The other arm was induction chemotherapy with *cis*-platinum and 5-fluorouracil for two to three cycles. Patients exhibiting at least a partial response were then treated with radiation therapy. Patients who did not exhibit a major response to chemotherapy were treated with laryngectomy followed by radiation therapy. At 60 months median follow-up, there was a similar survival rate in the two treatment arms (68%). Patients in the chemotherapy arm had a higher rate of local recurrence, whereas those in the standard therapy arm had a higher rate of distant metastasis. Survival was equivalent for chemotherapy responders and nonresponders.

The results from this trial are important because they showed in a randomized prospective study that survival was equivalent between an organ preservation strategy and standard therapy that included laryngectomy. Laryngeal preservation occurred in 64% of the survivors in the chemotherapy arm without compromising survival. It should be noted that 65 of the 166 patients entered in the chemotherapy arm (40%) actually were alive with a larynx at the end of the observation period.

There have been a number of criticisms aimed at the VA study. First, there was no treatment arm in which patients were randomized to radiation only. A number of centers have reported survival rates and laryngeal preservation rates with radiation alone that are similar to those achieved in the two arms of the VA study. The role of chemotherapy in this study has also been questioned. Was the chemotherapy beneficial as a therapeutic agent, or did it just select those patients who would be likely to do well with radiation alone? Some studies, including meta-analyses, have even shown a negative effect of induction chemotherapy on survival in head and neck cancer.[123] Another criticism of the study is that the quality of speech and swallowing in the patients treated in the two arms was not compared. Even though many patients retained their larynx in the chemotherapy arm, the functionality of the preserved organ was not addressed, nor was it compared to the results after total laryngectomy with a tracheo-esophageal puncture (TEP) or other means of speech rehabilitation.

Despite these criticisms, it is clear that laryngeal preservation strategies are worth considering since some larynges can be saved without compromising overall survival. Even though the original VA trial is open to criticism, many community practitioners

have adopted the sequential chemotherapy and radiation strategy of the VA study in their management of advanced laryngeal cancer. Guidelines from the National Comprehensive Cancer Network list induction chemotherapy as an option for T2 and T3 hypopharyngeal cancer and for laryngeal cancers that would require total laryngectomy.[124] This is of concern since standard and hyperfractionated radiation-only approaches result in reported cure rates similar to those in the VA study.[125,126] Furthermore, there is a definite trend emerging from the results of a number of trials of concurrent chemotherapy and radiation therapy that indicate results superior to sequential chemotherapy and radiation. So far, there have been no trials published evaluating concurrent chemoradiation exclusively in advanced laryngeal cancers. However, a second VA trial is under way in which there are three arms: the previously used induction chemotherapy arm, a radiation-only arm, and a radiation and concurrent single-agent chemotherapy arm. The results of this trial will soon be available and should provide important information on the relative merits of these organ preservation strategies.

Surgeons have also been active in the area of organ preservation for advanced laryngeal cancers. Pearson described the subtotal laryngectomy in the early 1980s.[97] Although some natural phonatory function without an artificial device could be achieved, a permanent tracheostomy was required. This procedure did not seem to offer a great advantage over a total laryngectomy with adequate voice rehabilitation. Supracricoid laryngectomy was introduced by Piquet and associates[98,99] and has been popularized by others.[100] The two main procedures, CHEP and cricohyoidopexy, overcome the need for a permanent tracheostomy and are illustrated in Figure 54–18. In these procedures, at least one functioning cricoarytenoid unit, the hyoid bone, and an intact cricoid ring are required. Survival rates of 80 to 85% have been reported for patients with T3N0 cancers using these techniques.[127,128] Proper surgical technique and patient selection are important for success with these procedures.

Others have used induction chemotherapy to downstage laryngeal primary lesions so that partial laryngectomy can be performed rather than total laryngectomy. Brasnu et al reported a series of 60 patients with T3 and T4 supraglottic and transglottic carcinomas managed this way.[129] They reported 5-year survival of 72.7%, with local and regional failure rates of 8.3 and 9.2%, respectively. Another study reported on a series of 69 patients who were initially candidates for total laryngectomy who were treated with induction chemotherapy. Thirty-three patients were selected for partial laryngectomy (n = 14) or radiation (n = 19) and had their larynx preserved. Rudert and others have even reported successful application of transoral carbon dioxide laser resection to selected T3 laryngeal cancers, particularly supraglottic cancers with extension to the central portion of the preepiglottic space.[130]

In summary, great controversy continues to surround the choice of treatment for advanced cancer of the larynx. Insufficient objective data exist to differentiate between standard therapy (laryngectomy with postoperative XRT), altered fractionation XRT, chemoradiation protocols, and the newer, function-preserving operations for selected advanced lesions. Treatment continues to be individualized, with such factors as the patient's age and general health, occupation, ability to use alternative means of communication, and the patient's own wishes all coming into play. Quality of life concerns, in addition to survival data, will increasingly be used to aid in the decision-making process.

Voice Results after Treatment for Laryngeal Carcinoma

When survival outcomes for different treatment regimens for the same stage of disease are similar, voice quality after treatment becomes an important factor in choice of therapy. Measurement of voice can be done using objective mechanical or physical parameters (shimmer, jitter, signal-to-noise ratio, fundamental frequency, intensity), aerodynamic properties (subglottic pressure, maximal airflow), and general phonatory measures (eg, maximum phonation time). Such measures are quantifiable, but voice quality is perceptual and therefore subjective. Most studies comparing voice outcomes employ assessments by trained listeners.

Early Lesions For Cis and microinvasive carcinoma, videostroboscopic examination is critical. If there is any propagation of the mucosal wave through the lesion, then microsurgical excision with margins can usually be performed with an excellent voice result.

The voice results reported after endoscopic carbon dioxide partial cordectomy for early cancers not invading the anterior commissure, vocal process, ventricle, or subglottis are surprisingly good. McGuirt et al reported that 83% of 15 patients so treated achieved normal glottic closure, 61% had a demonstrable mucosal wave, and all were rated as either normal or mildly abnormal by a panel of expert listeners.[131] A more recent study resulted in lower rates of mucosal wave preservation, but voice results were generally very acceptable.[132] Based on the few reported studies comparing radiation to laser resection for T1 lesions limited to the middle third of the vocal fold, subjective assessment reveals similar results for the two modalities. Objective measures tend to be better in the patients receiving radiation. The quality of the voice after laser excision appears to decline in proportion to the amount of vocalis muscle resected.[132]

The voice results reported after endoscopic carbon dioxide cordectomy for early cancer not involving the anterior commissure, vocal process, ventricle, or subglottis are surprisingly good. The entire vocal fold is removed from the anterior commissure to the vocal process and laterally to the inner perichondrium of the thyroid cartilage. The postoperative voice in patients treated this way is breathy, weak, and harsh, and complete glottic closure rarely occurs.[133] The voice results when radiation is used for similar lesions are almost always superior.

Hemilaryngectomy produces variable voice results, but almost all patients experience harsh, breathy voices and incomplete glottic closure. Voicing often is accomplished by recruitment of supraglottic structures to achieve laryngeal closure.[134] Although there are no data comparing the voice results of the many reconstruction methods used for the hemilaryngectomy defect, it appears that the postoperative voice is better in those patients who undergo reconstruction than in those who are left to heal by secondary intention. There are no studies comparing voice results between patients having hemilaryngectomy and those receiving XRT for similar lesions. Since the majority of patients who undergo hemilaryngectomy are radiation failures, it would be difficult to conduct such a trial. Subtotal or near-total laryngectomy techniques result in a voice that is variable and unpredictable, with a higher fundamental frequency than that of normal speakers.[135]

Alaryngeal Speech There are several rehabilitative options available to individuals who have undergone total laryngectomy. The three major categories are electronic devices, esophageal speech, and TEP. These techniques are complementary and are not mutually exclusive. Most patients ultimately use only one of these forms of communication.

Electrolarynx. Electronic devices can be used shortly after laryngectomy and are often the initial method of oral communication. The instrument is battery powered and handheld and produces vibratory energy that is transmitted to the mouth and/or pharynx by placing the vibrating end against the submandibular area or cheek or via a plastic tube placed directly in the mouth. Although this option has the advantage of allowing early voicing after laryngectomy, the mechanical voice quality is a disadvantage. All consonants are voiced when the instrument is used, making intelligibility difficult at times.

Esophageal Speech. This form of alaryngeal speech does not involve artificial devices. The speaker swallows or "injects" air into the stomach and esophagus and expels it through the pharynx, speaking while the pharyngoesophageal segment vibrates. A minority of all laryngectomees actually master this technique, and maximum phonatory time (MFT) is short, requiring frequent gulping of air. Fundamental frequency is lower than in normal speakers. Nevertheless, motivated individuals who achieve esophageal speech can be excellent speakers who do not depend on mechanical devices and who can speak with both hands free.

Tracheoesophageal Puncture. This surgical/prosthetic type of voice restoration was introduced in 1980 by Singer and Blom[136] and rapidly became accepted as a means of voice restoration after laryngectomy. The technique consists of creating a tract between the superior aspect of the tracheal stoma and the neopharynx. The procedure is usually performed under general anesthesia, using a rigid esophagoscope to visualize the puncturing instrument as it enters the lumen of the pharynx, protecting the posterior wall of the pharynx from injury. A stent (often a 16 Fr. feeding tube) is placed in the puncture tract, is secured to the skin with sutures, and is left in place for 5 to 10 days after the procedure to allow the tract to mature. The stent is removed,

and a prosthesis is inserted (Figure 54–26, A). Several companies make excellent prostheses.

When the stoma is occluded, air is forced into the prosthesis, and a vibratory sound is made in the pharynx, allowing the patient to voice during exhalation. In principle, this approach is similar to esophageal speech since expelled air creates a vibrating sound in the pharyngoesophageal segment. However, the volume of air that can be expelled from the lungs is much greater than that expelled from the esophagus, allowing greater volume and much longer MFT and providing some ability to modulate intensity.

Experienced listeners consistently rate the voices of TEP recipients superior to those of esophageal speakers.[137,138] Objective parameters of TEP more closely resemble normal speech than do those of either esophageal speakers or those using an electrolarynx. Maximum phonatory time for TEP speakers averages 12 seconds, compared with 1.9 seconds for esophageal speakers and 25 seconds for individuals with a normal larynx.[139]

Tracheoesophageal puncture can be performed as a primary procedure during laryngectomy or as a secondary procedure after the tracheal stoma is well healed. Voice results and complication rates are similar for primary and secondary TEP. Success and complication rates appear to be similar in radiated and nonradiated patients. Tracheoesophageal puncture can also be performed successfully in patients requiring free flap reconstruction of the pharynx in conjunction with laryngectomy. Voice quality is reduced compared with standard TEP but is still rated as good by the patients themselves.[140]

Some patients with TEP can wear an external valve over the stoma that allows them to phonate with their hands free. The flutter valve is secured to the skin with an adhesive (Figure 54–26, B). Patients with a flat neck contour around their stoma seem to have the most success with this device since adhesion to the skin is facilitated. It has been noted that some TEP users who do not use the external valve and have to use one hand to cover their stoma will return to esophageal speech because they prefer the hands-free advantage over the improved voice quality of the TEP.

Complications of TEP include bleeding, infection, aspiration, and failure to achieve speech. Many of the voice failures after TEP are thought to be owing to spasm in the pharyngoesophageal segment. Pharyngeal plexus lysis or cricopharyngeal myotomy has been shown to overcome this type of failure in a high percentage of patients.[141] Performing only a two-layer closure and avoiding closure of the constrictor muscles during the repair of the pharynx after laryngectomy is thought to reduce the incidence of pharyngoesophageal spasm and improve the chance for successful TEP after laryngectomy.[142]

Management of Cancer Recurrence

The means of managing recurrence of cancer of the larynx are determined by the extent of the original lesion and its treatment. Recurrence of early lesions after XRT can often be salvaged by surgery, either conservation procedures, where indicated, or by total laryngectomy. Recurrence after initial conser-

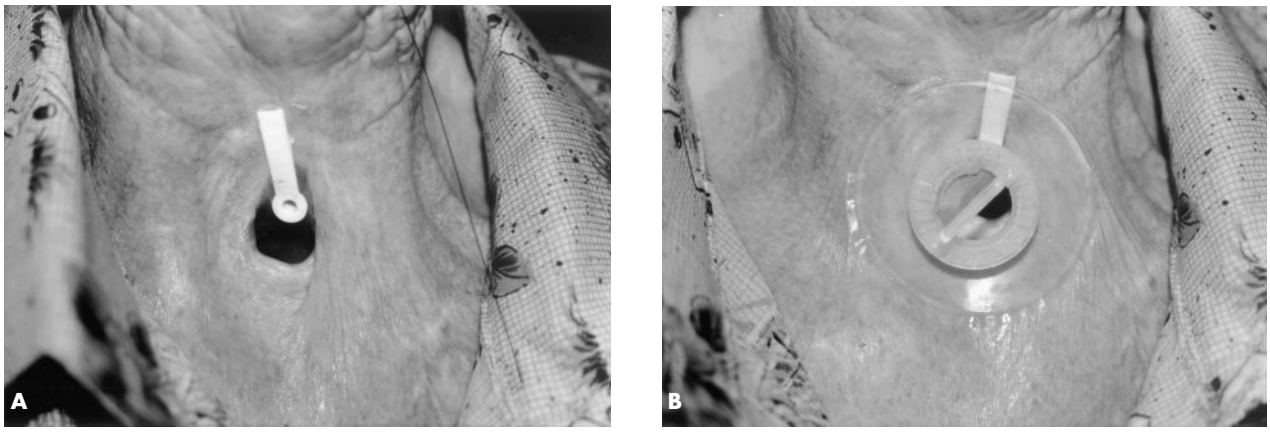

FIGURE 54–26. *A*, Blom-Singer voice prosthesis in place in tracheal stoma. *B*, External valve covering stoma, allowing hands-free phonation.

vation laryngeal surgery can be salvaged either by surgery (usually completion laryngectomy) or by radical radiation therapy if radiation was not used previously. Failure after radiation for larger primary tumors can be salvaged by total laryngectomy in 30 to 60% of patients. Failure in the neck can sometimes be salvaged by further surgery and/or XRT but usually portends a poor outcome, often with distant metastases.

Parastomal recurrence is a specific clinical entity in which tumor recurrence takes place near the tracheal stoma (Figure 54–27). Risk factors for this type of recurrence are thought to be pretreatment tracheostomy, subglottic extension greater than 10 mm, large tumor volume, and paratracheal lymph node involvement. Some have reported that survival is 0% with paratracheal lymph node involvement and have recommended elective unilateral or bilateral dissection of these lymph nodes in patients at risk for stomal recurrence.[143] Although some have devised aggressive surgical procedures, including en bloc resection of the stoma with mediastinal lymph node dissection, operative morbidity is high, and the salvage rate is very low (17 to 45%).[144] Recurrences confined to the area above the equator of the stoma, without involvement of the esophagus, appear to be the group amenable to salvage surgery. Computed tomography and MRI are very helpful in determining tumor extent prior to attempted salvage.

Complications of Treatment of Laryngeal Cancer

Radiotherapy Complications Complications similar to other sites are encountered, such as skin desquamation, tanning, or slough; mucosal ulceration and dryness; loss of taste function; hoarseness; dysphagia; and esophageal stricture. Another important complication is chondroradionecrosis of the laryngeal cartilages, which is similar to osteoradionecrosis of bone. Ulceration of mucosa over cartilage, either secondary to radiation itself or after biopsies or other instrumentation of the airway, leads to bacterial infection of radiated cartilage. Pain is the hallmark of this complication, often associated with increased swelling over the laryngeal cartilage landmarks. Low-grade fever may be present, and odynophagia is common. Differentiating this condition from recurrent tumor may be difficult, and biopsies and imaging studies are often inconclusive. Diagnosis is clinical, after attempts have been made to determine if there is tumor recurrence. Treatment consists of high-dose parenteral antibiotics and hyperbaric oxygen, usually 30 to 40 treatments. Failure to respond to treatment usually results in laryngectomy, and it is not unusual to find occult cancer in such specimens.

Surgical Complications The complications seen after surgery for laryngeal cancer are similar to those for most major head and neck cancer operations.

FIGURE 54–27. Parastomal recurrence after laryngectomy. Even with radical surgery in selected patients, prognosis is poor.

Bleeding, infection, fistula formation, aspiration pneumonia, stomal stenosis, and pharyngeal and esophageal stenosis are known to occur with total laryngectomy. Similar complications, plus glottic or supraglottic stenosis, can occur with hemilaryngectomy or supraglottic laryngectomy operations. Fistula formation occurs in 6 to 66%, with a lower incidence occurring in glottic tumor resections (6 to 15%). Higher rates of fistula formation occur with large supraglottic primaries, in all patients who have undergone previous XRT with or without chemotherapy for cure, and when the surgery is not done at a planned interval (usually 3 to 6 weeks) after completion of radiation. Fistulae after laryngectomy are especially dangerous since the carotid artery lies adjacent to the resection bed and is subject to rupture. Fistulae that leak around the stoma are also dangerous since direct aspiration via the tracheostoma is likely.

Distant Metastases

Patients with glottic primaries are the least likely to develop distant metastases, whereas supraglottic tumors that extend to the hypopharynx, especially the piriform sinus, are most likely to spread distantly. Lung, liver, and bone are the most common distant metastatic sites. Distant metastatic disease is also most likely to occur in patients with advanced (N2 or N3) neck disease and in patients who have recurred after initial treatment.

A dilemma arises with a solitary pulmonary lesion that is suspected to be metastatic in a patient with a laryngeal primary cancer since a second primary in the lung is a possibility. If there are no other metastatic deposits detected and the pulmonary lesion is resectable, the laryngeal tumor is treated first, followed by thoracotomy for the lung lesion. If the lung lesion is not resectable, the laryngeal tumor is treated with palliative XRT as needed.

The lung is the most commonly detected site for metastasis from laryngeal cancer, with 50 to 80% occurring there. Lung metastasis is usually associated with a mean survival of 12 months. Bone metastases make up 10 to 35% of laryngeal cancer metastases and portend a poor prognosis, with a mean survival of less than 4 months. The lesions are often lytic and painful and occur most often in the thoracolumbar vertebrae and the ribs. Liver metastases are quite common at autopsy, occurring in 80% of patients with distant metastases. They are often asymptomatic and undetected during life. Skin metastases, often to the neck, are common in preterminal patients.

Palliative Care of Laryngeal Cancer

Occasionally, patients present with such advanced disease and in such poor general health that curative treatment is either not possible or is too dangerous to undertake. About 7 to 12% of patients with laryngeal cancer will present with distant metastases. In such cases, palliative treatment with XRT may be useful. Symptoms of airway obstruction, pain, and dysphagia can often be improved by a course of XRT characterized by larger fraction size, fewer treatments per week, and shorter overall treatment time. In other patients, airway obstruction can be relieved by tracheostomy, and dysphagia and malnutrition can be ameliorated by placement of a gastric feeding tube.

Recurrent disease leading to death occurs in about 25 to 35% of patients with laryngeal cancer. Local and regional recurrence can be palliated with appropriate chemotherapy. A variety of drugs possess significant activity against squamous cell cancer and include *cis*-platinum, carboplatinum, the taxanes, 5-fluorouracil, etoposide, and methotrexate, to name a few. Palliative treatment regimens should be designed to produce as little toxicity as possible, while holding out a reasonable chance for amelioration of symptoms. Such treatment should not be offered or given to patients who are not having major symptoms (pain, dysphagia, dyspnea) and should be held in reserve until needed. As with all cancer patients, the patient and his/her family need to be included in the decision-making process when palliative care is considered. Entry into an accredited hospice program is appropriate when medical interventions have been exhausted or have been refused by the patient and survival beyond 6 months is unlikely.

CHAPTER 55

Cancer Immunology

Scott E. Strome, MD, Ray O. Gustafson, MD, H. Bryan Neel III, MD, PhD

At the beginning of the twentieth century, microbiologists established the foundation for the science of immunology and described the process of host resistance to infectious disease. The field of tumor immunology grew out of speculation that immune mechanisms might be involved in host defense against malignancy.

In the laboratory, when biologists harvested tumor tissue from one animal and attempted to propagate it in a second animal, the tumor transplant was rejected quickly. This phenomenon stimulated intense interest and investigation, but the nascent field of tumor immunology was arrested in the 1930s by the demonstration that rejection of transplanted tumors was simply a manifestation of the general phenomenon of rejection of foreign tissues. Although this observation led to the study of major histocompatibility complexes (MHCs), formed the basis for organ transplantation, and resulted in the discovery of cell-mediated cytotoxicity, it impeded the search for an immune basis of tumor resistance for many years.

Renewed interest in the field of tumor immunology in the 1940s and 1950s resulted from the work of Gross,[1] Foley,[2] Prehn and Main,[3] and Klein et al[4] after the development of highly inbred (syngeneic) strains of mice. In experiments using the chemical carcinogen methylcholanthrene to induce murine sarcomas, these investigators conclusively demonstrated the ability of tumors to elicit a tumor-specific immune response.

As outlined in a review by Ritts and Neel,[5] resistance to subsequent transplantation of grafts of the same tumor could be induced by tumor excision or amputation, use of subtake tumor dose or cells that had been damaged irreversibly in their reproductive capacity by irradiation or chemicals, or necrosis in situ by ligation release,[6,7] cryosurgery,[8–11] or electrocoagulation. In a series of classic experiments, mice from which tumors had been excised showed a reduced rate of tumor growth at the challenge site compared with that of controls, indicating existence of immunity after excision. Mice from which tumors had been eradicated in situ by cryosurgery, ligation release, or electrocoagulation showed a reduced rate of tumor take and growth at the challenge site compared with controls and with mice subjected to tumor excision, indicating even greater immunity after necrosis of tumor in situ. The pattern of differential immunity is seen consistently after challenge with graded doses of tumor cells and in other tumor-host systems.[12]

All of these experiments strongly suggested that tumor cells must express unique surface determinants that can be recognized by the immune system as nonself, and these determinants were termed "tumor-specific antigens." Tumor immunologists subsequently have been concerned with the identification and characterization of tumor-associated antigens, processing and presentation of tumor-associated antigens, subsequent humoral and cellular immune responses, and manipulation of the immune system in the diagnosis of and therapy for malignant disease. A thorough understanding of the basic science of immunology is a prerequisite for the study of cancer immunology (see Chapter 28.)

SIGNIFICANCE OF THE IMMUNE RESPONSE

Although tumor immunology is a young field, it has stimulated a great deal of research; however, the actual clinical significance of the immune response to malignant disease remains unclear. In 1959, Thomas suggested that the host possessed a normal homeostatic cellular mechanism that was active in preventing establishment of "nonself,"[13] and Burnet later termed this homeostatic mechanism "immunosurveillance."[14]

Among the more impressive indirect data establishing the phenomenon of surveillance in cancer are the observations that the frequency of neoplasia ranges from 10 to 15% in patients who have cellular immunodeficiency diseases—10,000 times that of an actuarially matched population[15]—and is 0.7% in patients who have received selective immunosuppressive therapy, primarily at the cellular level, for kidney transplantation. The neoplasia observed in children with T-cell deficiency syndromes is most often (more than 60%) of the reticuloendothelial system. Spontaneous, complete regression of established tumors is uncommon, but cases are well documented. On the other hand, most physicians have observed patients who were apparently "cured" for many years only to discover metastases as many as 20 years after ablation of the primary neoplasm. Lymphocyte infiltration of solid tumors, including squamous cell carcinoma of the head and neck, is associated with a better prognosis.[16] Surgeons, particularly those working with diseases of the head and neck, know that identification of viable tumor cells in wound washings or in circulation does not reliably predict local recurrence or survival.[17] Finally, immune mechanisms are weak at the extremes of age, early childhood and late adulthood, and these are the times when the incidence of malignancy is greatest.

According to the theory of immunosurveillance, response against malignancy in the host has been attributed primarily to mature, specifically immune T cells. Accordingly, it was anticipated that T-cell–deficient laboratory animals, such as the congenitally athymic nude mouse, would lack resistance against malignancy and would be subject to a significantly higher incidence and more rapid progression of malignancy than its immunocompetent counterpart. Several reports have taken the failure to demonstrate such a significantly higher incidence of malignant change in the nude mouse as convincing evidence against the theory of immunosurveillance.[18–21] Studies of cell-mediated immunity, however, have provided additional information that diminishes the controversy surrounding immunosurveillance.

First, the nude mouse possesses high natural killer (NK) reactivity, which offers a potential explanation for its low incidence of spontaneous malignancy and its resistance to growth of malignant tissue transplants.[22] Second, Talmadge and associates have shown that malignant cells that are highly susceptible to natural killing in vitro grow poorly in normal mice but disseminate rapidly in the NK-deficient beige mouse.[23] In humans, depressed to absent NK reactivity has been found in patients with Chédiak-Higashi syndrome and a hereditary form of malignant melanoma.[24] Furthermore, Takasugi et al[25] and Pross and Baines[26] compared in vitro NK reactivity of a large number of cancer patients with various controls and demonstrated a correlation between increased tumor burden and depressed NK reactivity. Thus, there are several lines of evidence to associate the role of immunosurveillance with the NK phenomenon. Although NK activity may not be a critical factor in host defense against established tumors, evidence is accumulating to support the role of the NK cell in the control of metastatic disease.[27]

Lymphocytic blastogenic transformation induced by phytohemagglutinin and by specific antigens, as an in vitro correlate of delayed cutaneous hypersensitivity, is impaired in some patients with cancer. Because the end point of such studies is unrelated to the inflammatory response, it is concluded that there is a cellular immune defect or diminution in cell-mediated immunity. At least on an operational level, the failure to manifest cellular immunity in cancer is caused by a deficit or a malfunction, or both, of T lymphocytes.

Immunologic testing, performed at diagnosis and clinical staging and before treatment has been instituted, can provide information that predicts or assists in predicting patients in whom cancer is most likely to recur. Testing could also serve as a basis on which adjuvant forms of therapy can be instituted. In a prospective study of squamous cell carcinomas of the head and neck,[28] patients were categorized into two groups: those who remained tumor free and those who had cancer recurrence. Pretreatment phytohemagglutinin and concanavalin A–induced blastogenesis were more often depressed in patients in whom clinically apparent recurrence eventually developed than in patients without recurrence. This finding is consistent with the hypothesis that cellular immune function, as measured in the laboratory by nonspecific blastogenesis, can identify, within the staging system, subpopulations of patients who are less likely to survive after conventional therapy (Table 55–1). In this study, T-lymphocyte and B-lymphocyte enumerations had no predictive value. However, some studies have demonstrated consistently reduced T-cell numbers and activity in patients with advanced head and neck cancers.[29,30]

TABLE 55–1. Pretreatment Test Results (Mean) by Stage of Disease in Patients Who Remained Tumor Free and in Patients in Whom Cancer Recurred

	Tumor Free			*Cancer Recurrence*		
Variable	*Stage I*	*Stage II*	*Stage III*	*Stage I*	*Stage II*	*Stage III*
T cells						
N	2,213	1,537	2,342	2,876	1,881	1,824
%	79	75	74	65	77	71
B cells						
N	458	413	537	720	448	592

Other studies reported increased levels of suppressor T cells in the peripheral blood and regional lymph nodes of patients with head and neck cancer,[31–33] whereas another study reported increased ratios of helper T cells to suppressor T cells in patients with head and neck cancer.[34] These findings suggest that complex changes in cellular immune regulation may be more important than total T-cell number in explaining the failure of immunosurveillance and that ineffective cytotoxic responses may be caused by inappropriate stimulation of suppressor cell activities. In a detailed series of experiments, Wolf et al have shown that (1) T lymphocytes are the major lymphocyte component infiltrating head and neck carcinomas; (2) suppressor T cells are the dominant cell type in tumor parenchyma, but helper and suppressor T cells are equally represented in tumor stroma; and (3) extent of helper cell parenchymal infiltration correlates directly with clinical outcome in patients who have head and neck cancer.[35] In a subsequent flow cytometry study of T-cell subsets in patients with previously untreated head and neck cancers, this group of investigators provided firm evidence that decreased proportions of cytotoxic or suppressor cells are associated frequently with advanced head and neck cancers and portend a poor prognosis.[36]

The humoral immune system may interfere with the host response to tumor, contributing to a failure of immunosurveillance. Elevated titers of immunoglobulin A (IgA) have been demonstrated in the sera of patients with head and neck cancer,[37,38] and it has been proposed that the IgA functions as a blocking factor of lymphocyte-mediated cytotoxicity, at least in unique forms of nasopharyngeal carcinoma (NPC).[39,40] Furthermore, Seder et al reported successful palliative treatment of advanced head and neck cancers by plasmapheresis and hypothesized mediation of the beneficial response by a reduction of circulating immunosuppressive factors.[41]

CLINICAL APPLICATIONS OF TUMOR IMMUNOLOGY

The orchestrated activity of the immune system is capable of providing a natural defense against malignant disease, and a significant aspect of tumor immunology is concerned with manipulation of the immune system in the diagnosis and treatment of cancers that evade surveillance. Current emphasis is on tumor markers, monoclonal antibodies, and cell-based strategies for mediating the regression of established disease.

Tumor Markers

Oncogenesis is associated frequently with detectable changes in the serum content of various substances, which are referred to as tumor markers.[42] Many different types of tumor markers have been described. One scheme[43] groups them as (1) markers indicat-

ing a predisposition to malignant changes, (2) markers indicating inflammation or tumor necrosis, (3) markers relevant to tumor metabolism, (4) hormone receptors,[44] and (5) oncogenic virus antigens. The three basic uses for tumor markers include screening of high-risk populations, distinguishing among malignant tumors or between benign and malignant processes, and following the course of a tumor over time.[45]

Although there is growing evidence for the existence of tumor-specific antigens in squamous carcinomas of the head and neck,[18] two of the most widely used markers in the practice of head and neck oncology are calcitonin and Epstein-Barr virus (EBV)-associated antigens. Jackson et al demonstrated the value of serum calcitonin levels as a screening test for family members of patients with medullary carcinoma of the thyroid and for post-treatment surveillance for recurrent disease.[46]

A wealth of biologic, biochemical, and immunologic evidence supports an association between EBV and NPC. Immunologic studies have identified antibodies against certain EBV-associated antigens and support the concept that these markers are of value in the diagnosis and management of patients with NPC.[47–50] The most specific tests are those that measure the IgA antibody response to EBV-induced viral capsid antigen and the IgG antibody response to early antigen; the viral capsid antigen (IgA) is the more specific of the two tests.[49] The viral capsid antigen (IgA) and early antigen tests complement the process of diagnosis of NPC and are of special value in directing attention to the nasopharynx in patients with occult or small NPCs.[50–52]

The antibody-dependent cellular cytotoxicity assay titrates sera for antibody to the EBV-induced membrane antigen complex and predicts the clinical course and prognosis of patients with World Health Organization (WHO) types 2 and 3 NPC.[53] High titers at diagnosis signify a better prognosis. It is a significant risk factor and has been incorporated into a new staging (scoring) system for NPC.[54]

A striking relationship exists between the antibody titers and the histopathologic type of NPC. In a prospective collaborative study of NPC in North American patients,[49,51,55] antibody titers were consistently increased in cases of WHO types 2 and 3, averaging 85% positive. In cases of WHO type 1, however, the incidence of positive test results was similar to that for control groups.[49] Further refinement of these tests may lead to their use in screening programs in areas of the world with a high incidence of NPC.

The striking correlation between EBV and certain types of NPC led investigators to seek other viral associations in patients with head and neck malignancies. The recognized relationship between human papillomavirus (HPV) and cervical carcinoma has resulted in efforts to define the presence of HPV in malignant and premalignant lesions of the head and neck.[56] Recent studies of premalignant lesions have focused primarily on laryngeal papillomas and inverted papillomas of the nasal cavity. Garcia-Milian et al analyzed the presence of HPV in normal laryngeal mucosa, laryngeal carcinoma, and laryngeal papilloma by using polymerase chain reaction.[57] This study demonstrated an 82% and 48.5% association between the presence of HPV and laryngeal papillomas and carcinomas, respectively, significantly different from the 16% detection of HPV in normal controls.[57] In addition to the association of HPV with respiratory tract papillomas, there are several anecdotal reports of squamous cell carcinoma developing in the presence of respiratory papillomatosis without coexisting risk factors.[58,59]

Similar studies of the relationship between malignant degeneration of inverted papillomas and the presence of specific HPV subtypes are inconclusive. A study by Beck et al evaluating archival specimens of inverted papilloma demonstrated a significant correlation between the degree of dysplasia and specific HPV subtypes.[60] Other studies have failed to show an association between HPV and the presence of inverted papilloma or in the progression of this disease toward malignancy.[61,62] Resolution of this controversy will most likely require a prospective study using fresh tissue to avoid the limitations of DNA extraction from paraffin.

Interestingly, recent studies from our laboratory at the Mayo Clinic (A Savva, AE Brissett, SE Strome, B Gastout, JC Lewis, R McGovern, AM Weaver, D Persing, JL Kasperbauer, unpublished data, 2000; AE Brissett, A Savva, SE Strome, BS Gastout, JE Lewis, JL Weaver, RM McGovern, JL Kasperbauer, unpublished data, 2000) evaluating malignant and normal tonsillar tissue from age-matched controls demonstrated a significant increase of specific HPV subtypes, with a statistically significant improvement in disease-specific survival in patients with HPV. Several mechanisms have been postulated to characterize the potential pathophysi-

ologic relationship between the presence of HPV and the development of malignancy, including the ability of the HPV E6 protein to bind p53 and indirectly increase its rate of degradation.[63] A direct causal relationship between the presence of HPV and the development of squamous cell carcinoma has not been demonstrated conclusively.

Monoclonal Antibodies Antigen-specific monoclonal antibodies are products of hybridomas; they typically result from the fusion of immune-stimulated murine spleen cells and an appropriate B-cell tumor. Although this technology was first reported as recently as 1975,[64] it has generated an explosion of research on the diagnostic and therapeutic applications of monoclonal antibodies.[65]

In the diagnosis of malignant disease, monoclonal antibodies have been labeled with a radionuclide, injected into the patient's bloodstream, and then visualized with a radiation scanner, radioimmunodetection (RAID). The potential clinical applications for RAID in malignant disease include presurgical staging of the extent of the disease, postsurgical evaluation of residual disease, confirmation of viable tumor identified by other methods, identification of disease recurrence in patients with increasing serum tumor-marker titers, and confirmation of tumor targeting by antibody for immunotherapy. The best current indications for RAID are the detection of occult tumors and the confirmation of tumor sites revealed by other radiologic methods. Most studies of RAID have used ovarian and colorectal cancers, and with several thousand patients studied, between 60 and 90% of known lesions have been identified correctly. With the use of pancarcinoma antibodies and monoclonal agents with greater specificity, the tumor indications for RAID are expanding.

Several strategies have been followed in the therapeutic application of monoclonal antibodies. One strategy has involved administration of unconjugated, naked monoclonal antibody to produce complement-dependent or antibody-dependent cell-mediated cytotoxicity, to interfere directly with the growth or differentiation of tumor cells by binding to them, and to enhance the activities of other agents such as interferon and interleukin-2.

Another monoclonal antibody therapeutic strategy has involved the coupling of conventional cytotoxic agents to a tumor-seeking monoclonal antibody, with the expectations of decreased host toxicity and increased antitumor efficacy. Similarly, the conjugation of biologic toxins with carrier antibodies to produce potentially therapeutic immunotoxins has been explored. Despite their theoretic appeal, both of these approaches have been hampered by problems of conjugating the agent to a monoclonal antibody and the production of human antibodies against the murine monoclonal antibody and agent. Finally, with advances in the chemistry of antibody radiolabeling, many radionuclides are being investigated for radioimmunotherapy, with the prospect of sparing normal tissues from intensive radiation. Despite its theoretic appeal, radioimmunotherapy presents formidable obstacles, including bone marrow toxicity, a low dose of radiation delivered to the tumor, and limited use of multiple treatment courses because of mouse monoclonal antibody antigenicity. Monoclonal antibodies are not yet "magic bullets," but they do hold exciting prospects for enhanced oncologic selectivity and efficacy. In head and neck oncology, monoclonal antibodies have been used primarily in the laboratory for characterization of tumor-associated antigens and study of lymphocyte subpopulations.[18,35]

ACTIVE AND PASSIVE IMMUNOTHERAPY

Cellular Immunity to Malignant Tumors

Fundamental to the understanding of the role of cellular therapy in tumor immunology is an appreciation of the methods of antigen presentation and the role of the cellular immune response in mediating tumor growth in vivo. Both $CD8^+$ cytotoxic T lymphocytes and $CD4^+$ T cells are considered important effector arms of the cellular immune response to malignancy.[66] The initial signal for T-cell activation depends on antigen presentation in the context of appropriate MHC molecules. Subsequent nonspecific secondary signaling of the antigen-primed T cell by a group of glycoproteins, termed "costimulatory molecules," dictates antitumor reactivity.

Costimulatory molecules play diverse roles in regulating the antitumor T-cell response. Certain costimulatory molecules mediate T-cell proliferation and inhibit activation-induced cell death.[67] This is best evidenced by the interaction of B7-1(CD80)/B7-2(CD86) ligands on antigen-presenting cells with the CD28 receptor molecule constitutively expressed on

T cells.[68] Recently, a new group of costimulatory molecules has been characterized as belonging to the tumor necrosis factor family by virtue of primary, secondary, and tertiary structural homology. Certain members of this family, such as 4-1BB, are inducibly expressed on activated T cells and act in concert with B7/CD28 to enhance T-cell proliferation and antitumor reactivity.[69] Other tumor necrosis factor family members, such as LIGHT, act in a CD28-independent fashion to stimulate T-cell proliferation through the herpes virus entry mediator and lymphotoxin beta-receptor.[70]

In contrast to their stimulatory function, specific receptor–ligand interactions from both the tumor necrosis factor and B7 family are recognized to result in T-cell apoptosis. This is best evidenced by the Fas/Fas ligand interaction.[71] Interestingly, specific molecules have different costimulatory function, dependent on the status of T-cell activation. For example, B7-H1, a recently cloned member of the B7 family, is thought to provide stimulatory activity to naive T cells but to induce apoptosis in activated cells.[72] This suggests that costimulatory molecules play an essential role in maintaining the delicate balance between T-cell protective function and autoimmunity.

Recently, a specialized class of professional antigen-presenting cells (APCs), termed "dendritic cells" (DCs), has been recognized as essential for antigen processing and presentation in the presence of appropriate costimulation. Dendritic cells exist in two forms: an immature form in which antigen uptake is high and a mature form that expresses high levels of class I and II MHC molecules with a broad spectrum of constitutive and inducible costimulatory motifs. Dendritic cells have a migratory function and are detected in lymphoid and nonlymphoid organs. Perhaps most importantly, DCs with prior exposure to antigen can effectively educate naive APCs, resulting in priming of the immune response postulated to overcome effectively tumor-induced tolerance.[73,74]

Mechanisms of Tumor Escape

An understanding of the tumor's ability to evade the host immune response is premised on a working knowledge of two fundamental concepts: immune ignorance and immune tolerance.[75] A simple analogy for immune ignorance is lack of vision, whereas tolerance is characterized by the inability to respond to what is seen. Tumors have developed several mechanisms to prevent immune recognition, including down-regulation of major histocompatibility and transport-associated protein molecules necessary for antigen presentation. Additionally, in cancer patients, T cells are tolerized, or improperly activated, which might be caused by down-regulation of the zeta chain of the T-cell receptor and P56LCK signaling molecule.[76] Thus, at the most basic level, immunologic strategies for the treatment of malignancy can be conceptualized as breaking ignorance and overcoming tolerance. Because both ignorance and tolerance are important physiologically for the maintenance of immunologic homeostasis and the prevention of autoimmunity, any therapeutic strategy that alters this intricate balance has the potential to elicit an autoimmune response.

Cellular Strategies for the Treatment of Malignancy

Cellular strategies for cancer therapy can be broadly divided into two separate categories: active and passive. Active strategies are vaccines, which stimulate the host's cellular and humoral effector arms and ultimately depend on intact host immunity. Passive immunotherapy is defined as the transfer of tumor-specific effector cells to mediate the regression of established tumor. Because passive immunotherapy, also termed "adoptive immunotherapy," relies on effector cell transfer, these approaches may be therapeutic in the absence of functional host antitumor immune response.

Recent advances in the active immunotherapy of cancer have relied primarily on the use of DC vaccines. These DC approaches are premised on the knowledge that antigen presentation in the absence of appropriate costimulation results in activation-induced cell death.[77] When tumor cells serve as APCs, they may effectively induce tolerance by providing initial T-cell–specific antigenicity without costimulation. By presenting tumor antigens in the context of requisite costimulatory motifs, DCs loaded with tumor-associated antigens and tumor-specific antigens might overcome tolerance.[78]

Several methods of antigen loading of DCs are undergoing evaluation to determine therapeutic efficacy and clinical practicality. The primary approaches include the use of tumor lysates, tumor-specific peptides, tumor-specific ribonucleic acid (RNA), and

DC–tumor cell fusion.[78–84] Two recent studies documented the potential therapeutic efficacy of these strategies for the treatment of solid malignancies. Nestle et al, using DCs loaded with tumor lysates from melanoma patients, demonstrated a clinically effective antitumor immune response in 5 of 16 patients.[74] More recently, Kugler et al used allogeneic DCs fused with autologous tumor for the treatment of patients with metastatic renal cell carcinoma.[84] This strategy relied on autologous tumor cell antigen presentation, with allogeneic DCs providing appropriate costimulation and a nonspecific alloimmune response. In this trial, 17 patients had a 41% overall response rate at a mean follow-up of 13 months. Despite these initial encouraging results, several basic issues, including methods of DC generation and cytokine priming, utility of specific DC subsets (DC1 versus DC2) for initiating an immune response, and timing of antigen loading, require further characterization before broad clinical application.[85]

Unlike vaccine strategies, passive immunotherapy approaches may be successful in treating patients with large tumor burdens who have a poorly functional immune effector arm. In fact, adoptive immunotherapeutic approaches have demonstrated the greatest overall therapeutic efficacy of any immunologic treatment strategy.[86] Recent studies by Plautz et al documented the utility of tumor-specific activated effector T cells in mediating the regression of established tumor in human tumor models.[87,88] This improved therapeutic efficacy has resulted from subtle changes in lymph node priming and culture technique, including vaccine priming of lymph nodes with tumor in the presence of granuloma granulocyte-macrophage colony-stimulating factor, superantigen stimulation of pre-effector T cells in vitro, and shorter culture duration.[87,88]

Further improvement of these passive immunotherapy strategies will most likely rely on the identification and characterization of subpopulations of tumor-specific effector T cells within tumor-draining lymph nodes. One such example is the identification of a population of lymph node cells characterized by low levels of expression of the L-selectin molecule, which have been demonstrated to mediate all of the antitumor immune reactivity in mouse models.[89] Translation of these data in human squamous cell carcinoma models has demonstrated phenotypic and functional differences of L-selectin cells in vitro, which will improve our understanding of antitumor T-cell immunity and might further existing passive immunotherapy strategies for the treatment of solid malignancies.[66]

Monitoring of the Immune Response in Immunotherapy Trials

Further understanding and development of immunotherapy for the treatment of solid tumors will rely on the ability to create effective immunologic monitoring strategies. Specifically, functional gains will likely be made when we can identify and track the population of antigen-specific T cells responding to tumor and characterize the recovery of broad arrays of T-cell subsets as determined by specific Vα and Vβ chains of the T-cell receptor. Two recent developments, tetramers and T-cell spectrotyping, are critically important in this regard.

Tetramers are created by the fusion of four class I major histocompatibility receptors loaded with specific peptides. These molecules are used to identify T cells with T-cell receptors specific for the loaded peptide. When tetramers are conjugated with specific fluorochromes, they are effective in labeling peptide-specific T cells whose frequency can subsequently be determined by flow cytometry.[90] This technique allows accurate monitoring of the peptide-specific T-cell response in situations in which the antigen of interest is characterized and is unique (eg, peptide-loading strategies for DCs with a defined tumor-specific antigen). In certain circumstances, this technique may be used to replace the mixed lymphocyte response, which is labor intensive and experience dependent, allowing accurate monitoring of peptide-specific immunologic response.

T-cell spectrotyping relies on specific RNA primers to the variable regions of the T-cell receptor, Vα and Vβ, to define the presence of T-cell subsets within blood or tissue.[91] Although this technique does not demonstrate T-cell specificity for individual antigens, it defines the role of specific T-cell subsets in the antitumor immune response and characterizes changes that occur as a result of therapy. Tetramers and spectrotyping are becoming more widely available and serve as primary examples of the integral role of monitoring in the evolution of tumor immunotherapy.

CHAPTER 56

Molecular Biology of Squamous Cell Carcinoma

Carter Van Waes, MD, PhD

Head and neck squamous cell carcinoma (HNSCC) is the most common cancer that affects both human communication and survival. It accounts for 90% of the cancers arising in the upper aerodigestive tract, making it the most common type of cancer and cause of cancer deaths among patients with head and neck cancer. It accounts for over 40,000 new cancer cases and 11,000 deaths annually in the United States.[1] Despite progress in refinement of surgery, radiation, and chemotherapeutic approaches that have enhanced organ preservation, there has been no improvement in survival of patients with HNSCC over the past 25 years.[1] Recent advances in determining the identity and function of molecular events involved in the pathogenesis of HNSCC have provided a foundation for development of new methods for screening, prevention, and therapy in the new century.

Progress in understanding the molecular biology of HNSCC has been made possible through advances in technology that have permitted detection and mapping of deoxyribonucleic acid (DNA) sequences and genes throughout the human genome.[2] *Cytogenetic analysis* is a method that has enabled detection of chromosomal abnormalities that are large enough to be seen with special stains and light microscopy. Abnormalities such as deletions, amplifications, and translocations have been detected in certain chromosomal regions with increased frequency in HNSCC and other cancers. In some cases, these abnormalities have led to the identification of specific genes whose deletion, amplification, or truncation is involved in development of cancer. *DNA polymorphism analysis* is another important tool made possible by identification of differences in DNA sequence fragments between individuals at chromosomal locations throughout the genome. With this method, different-size DNA fragments cut by enzymes from the DNA contributed by each parent are identified with electrophoresis, allowing the detection of two copies (alleles) in normal cells from the patient. In cancer cells, loss of one marker, called a *loss of heterozygosity* (LOH), has been used to detect nearby alterations in DNA. DNA polymorphism and LOH analyses have permitted the detection and mapping of molecular alterations in DNA that were too small to be detected by cytogenetic analysis, thereby resulting in finer maps and detection of additional submicroscopic DNA abnormalities. Further mapping and sequencing of these regions have been made possible by development of methods for cloning large fragments of chromosomal DNA and methods for high through-put DNA sequencing, resulting in the positional cloning of many of the mapped genes. The recent development of a rough draft of the sequence of the human genome from high throughput DNA sequencing should rapidly result in the identification of genes remaining to be discovered.

The identification of genes and gene fragments has enabled studies of differences in expression in HNSCC of messenger ribonucleic acids (RNAs) using Northern blot and polymerase chain reaction methods and of proteins with immunoassays. Recently, technology has enabled reduction of these assays into *microarrays*, which have the capability to compare simultaneously and detect differences among thousands of different messenger RNAs or proteins in samples from normal and malignant tissue. Studies to determine the relative expression and function of genes in the cell are leading to a better understanding of the pathways involved in the pathogenesis of cancer and their potential usefulness for molecular diagnosis and therapy. As a result of these advances, it seems likely that in the next two decades, prevention and treatment of HNSCC will

increasingly involve use of molecular assays for prediction of prognosis and response to therapy and targeted prevention and therapy using molecular medicine and "gene surgery."

Carcinogenesis of Head and Neck Squamous Cell Carinoma

Development of HNSCC has been associated with repeated exposure to and injury by chemical carcinogens contained in tobacco and alcohol[2] or chronic infection by human papillomavirus (HPV)[3] or Epstein-Barr virus.[4] Several physical and viral causative agents associated with the development of HNSCC can cause defined molecular changes that result in malignancy. Worldwide, tobacco and alcohol products are the leading risk factors for development of HNSCC. Tobacco contains aromatic hydrocarbons that can cause DNA damage, most commonly resulting in G:C to T:A base-pair transversions and G:C to A:T base-pair transitions.[5] Alcohol appears to increase risk when used in combination with tobacco. Other physical agents that appear to contribute to the incidence of HNSCC at specific subsites can cause DNA damage. The increased incidence of lip and skin cancer in regions nearer the equator such as in Australia and the southwestern United States is associated with sun exposure. The ultraviolet spectrum in sunlight can cause thymidine dimer formation, resulting in C to T base transitions.[5]

Certain viruses have been associated with HNSCC, and these viruses can commandeer vital cellular control pathways and cause DNA disruption on integration. Human papillomavirus type 16, which is the subtype that causes cervical carcinoma in women, has recently been shown to be prevalent in oropharyngeal carcinomas, including nonsmokers.[3] Cells infected with HPVs express proteins encoded by viral genes called E6 and E7 that can inactivate the p53 and retinoblastoma proteins that help regulate cell proliferation and death. Epstein-Barr virus has been associated with nasopharyngeal carcinoma, particularly in Asia.[4] It encodes viral proteins that can promote immortalization and proliferation of epithelia and lymphocytes. Epstein-Barr virus also carries a gene that encodes a homologue of human interleukin-10 (IL-10), an immune hormone that can suppress development of cytotoxic T-lymphocyte immunity, which is needed for immune destruction of cancer cells.

Critical Events in the Development of Cancer

Tumor development following exposure to carcinogenic agents involves molecular changes that affect key cellular functions necessary for malignant behavior. These changes include overriding the normal program for cell differentiation and death and favoring an increase in cell proliferation and life span.[6] Malignant tumor progression involves additional changes that result in establishment of a blood supply, migration, invasion, and metastasis within the patient host.

Weinberg has shown that molecular alteration in expression or function of a minimum of three genes is required to alter important cellular functions and cause transformation and tumor development from normal human cells under experimental conditions.[7] One important requirement for neoplastic transformation and tumor formation is an increase in *cell proliferation*. He showed that increased cell-cycle progression and proliferation can result from activation of a signaling kinase called Ras. Ras may be activated by mutation or by activation of growth factor receptors. However, Ras activation and increased proliferation alone are not sufficient as such cells eventually reach the end of their life span, undergoing "crisis" and death. Thus, a second requirement is an increase in *cell life span*, or *immortalization*. Cells normally stop proliferating and reach the end of their life in a finite number of cell divisions. The life-span limit of normal cells has been shown to be associated with a gradual shortening of the telomeres, which are the ends of chromosomes. In contrast, cancer cells do not exhibit shortening of the telomeres, and this has been found to be attributable to increased expression of an enzyme called telomerase. Experimental expression of telomerase in normal cells transformed with Ras provides a second event needed to extend cell life span. Third, cancer cells exhibit a decrease in the rate of programmed cell death, called *apoptosis*. Weinberg showed that inactivation of mechanisms that prevent apoptosis, such as by a viral gene, is a requirement for transformation and tumor development. Inactivation of certain genes in the cell, by viruses, mutation, or loss, can affect the cell-death program. Inactivation or loss of one such gene called p53, which encodes a 53,000 kDa

protein, can reduce the ability of the cell to undergo cell-cycle arrest, repair damaged DNA, or undergo apoptosis when DNA damage cannot be repaired. Because inactivation of p53 may result in replication of cells with DNA mutations and damage, changes in expression of additional genes may occur, leading to further increases in malignant behavior. Genes that encode proteins necessary for normal behavior that stop uncontrolled growth or are necessary for death of aging or damaged cells, such as p53, are termed *tumor suppressor genes*.[7] When abnormal expression of genes "turns on" transformation and growth, these genes have been called *oncogenes*.[7] Genes expressed by viruses, such as E6 and E7, are called *viral oncogenes*. Genes such as the signal kinase Ras are termed *cellular oncogenes*. Altered expression of different combinations of oncogenes and tumor suppressor genes may result in increased proliferation and life span and decreased cell death, leading to tumor formation.

Cellular Pathologic Changes during Development of Head and Neck Squamous Cell Carcinoma

The initial development of HNSCC involves a series of progressive pathologic changes in behavior of cells in squamous cell mucosa and underlying stroma of the upper aerodigestive tract, as illustrated in Figure 56–1, A. Cells injured by exposure to physical or viral agents may undergo irreversible damage and cell death or undergo repair and survive. The surviving cells often acquire increased cellular resistance and proliferate and migrate, healing the area of injury. With repeated injury, increased numbers of cells may accumulate to produce a thickened epithelium, termed *hyperplasia*. With repeated exposure to mutagenic agents, irreversible genetic mutations may occur, with changes in cell behavior that include a partial- or full-thickness increase in proliferating and morphologically atypical cells called *dysplasia* or *carcinoma in situ* (Cis), respectively. Dysplasia and Cis lesions are premalignant. Invasion and migration into the stroma are the hallmark of *invasive carcinoma*, which is the stage of malignant tumor development. Hyperplasia, dysplasia, or Cis may be accompanied by hyperkeratinization, which may be visible clinically as *leukoplakia*. Dysplasia, Cis, or microinvasive carcinoma is accompanied by a progressive increase in inflammation, vascularity, and proliferation of fibrous stroma, which may be visible clinically as induration and vascular erythema, called *erythroplasia*.

Molecular Pathologic Changes during Development of Head and Neck Squamous Cell Carcinoma

Early Expression of Epidermal Growth Factor Receptor and Transforming Growth Factor α in Head and Neck Squamous Cell Carcinoma The histopathologic cellular changes that occur during the stages of tumor development of HNSCC have been associated with an accumulation in molecular changes, as highlighted in Figure 56–1, B. One of the earliest events identified in development of HNSCC is overexpression of a growth factor receptor called epidermal growth factor receptor (EGFR) and one of its stimulatory factors, transforming growth factor-α (TGF-α)[8] (see Figure 56–1, B). Grandis and colleagues have demonstrated that over 90% of HNSCCs overexpress EGFR and TGF-α.[8,9] Increased expression of TGF-α and EGFR has been detected in tumor cells and mucosa from patients with HNSCC, when compared with normal mucosa from controls, indicating that TGF-α and EGFR expression may be an early event in carcinogenesis of HNSCC.[8,9] Increased expression of both TGF-α and EGFR occurs with progression to carcinoma (see Figure 56–1, B). Epidermal growth factor receptor and TGF-α appear to be overexpressed owing to transcriptional activation of the genes for this receptor and ligand in most HNSCC.[8] Patients with carcinomas expressing higher levels of these factors have been shown to have a shortened disease-free survival, independent of cervical lymph node stage.[9]

Production of TGF-α and expression of EGFR establish a potential autocrine signal pathway for continuous stimulation of proliferation of squamous cells, and the importance of TGF-α and EGFR expression in growth of HNSCC has been established. Inhibition of either TGF-α or EGFR expression or function using antisense oligonucleotides[10,11] or pharmacologic inhibitors in combination with radiation[12,13] was found to decrease proliferation and growth of HNSCC cells in vitro and of xenografts in mice in vivo. The effects of EGFR activation may be mediated through several signal pathways, which include Ras, mitogen-activated protein kinase, phosphatidylinositol-3-kinase, and signal transduc-

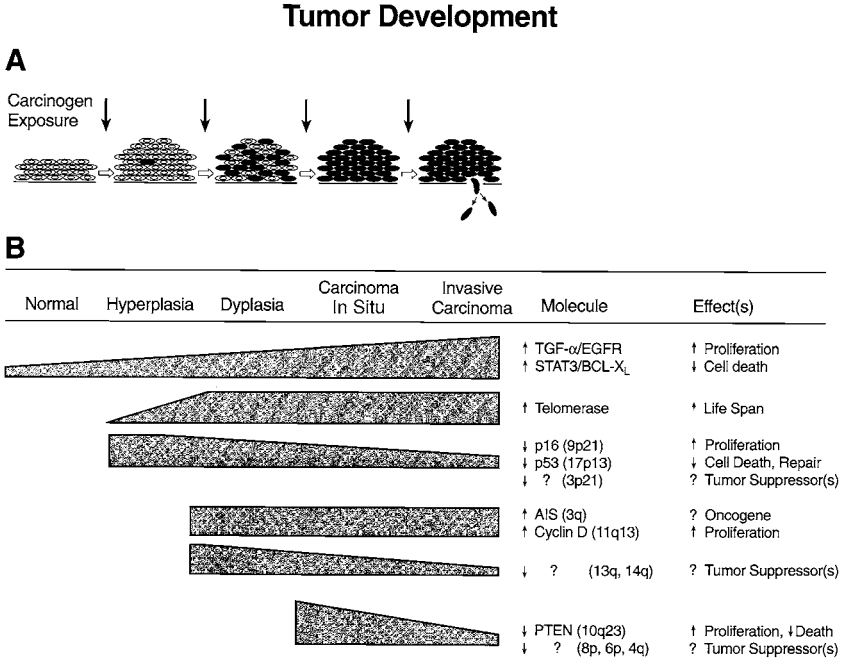

FIGURE 56–1. Model of histopathologic and molecular changes with tumor development of head and neck squamous cell carcinoma (HNSCC). *A*, Histopathologic changes during tumor development of HNSCC occur following repeated carcinogen exposure, as described in the text. *B*, Molecular changes with tumor development. ers and activators of transcription 3 (STAT3). Grandis et al have shown that EGFR activation of STAT3 prevents HNSCC cells from undergoing cell death (apoptosis) and stimulates proliferation.[14] Thus, overexpression of EGFR appears to contribute to the increase in proliferation as well as decrease in cell death involved in tumorigenesis.

Early Activation of Telomerase in Head and Neck Squamous Cell Carcinoma Early activation of telomerase has been detected in HNSCC. Mao et al reported that although telomerase is not detected in normal mucosa, increased telomerase activity is detected with development of squamous hyperplasia, dysplasia, and invasive carcinoma.[15] Califano et al have also shown that increased telomerase activity may be detected in dysplasia and invasive carcinoma and, with lower sensitivity, in shed cells in oral rinses from patients.[16] The increased expression of telomerase observed in HNSCC is consistent with the requirement for immortalization of cancer cells in a study of carcinogenesis by Weinberg.[7]

Tumor Suppressor Genes and Oncogenes in Development of Head and Neck Squamous Cell Carcinoma There is evidence for inactivation of tumor suppressor genes and activation of oncogenes at several chromosomal loci during development of HNSCC. Califano et al have shown that the LOH at several chromosomal loci occurs with increasing frequency with different stages of development of HNSCC[17] (see Figure 56–1, B).

A locus on the short (p) arm of chromosome 9 located at 9p21 has been found to exhibit LOH at an early stage during development of hyperplasia.[17] Chromosome 9p21 has been found to encode a protein called p16, which is a cyclin-dependent kinase called CDKN2/MTS-1/INK4A that normally inhibits cell-cycle progression. p16 was found to be inactivated in the majority of HNSCC by homozygous deletion, by methylation of the regulatory promoter region of the gene, or by mutation,[18] thereby releasing squamous cells to proliferate. Re-expression of p16 in HNSCC cells by gene transfer suppressed cell growth in vitro.[19] Loss of p16 in HNSCC may be detected by immunostaining as well as molecular methods.

A locus on the long (q) arm of chromosome 11 located at 11q13 demonstrates LOH in increasing frequency during the Cis stage[17] and is associated with amplification of a cell-cycle regulatory protein called cyclin D1.[20] Increased expression of cyclin D1 is prevalent in HNSCC. Cyclin D1 is required for progression of cells through the cell cycle, thereby stimulating squamous cells to proliferate. Inhibition of cyclin D1 results in inhibition of growth of HNSCC in vitro.

Chromosome 3p is altered with increasing frequency with development of dysplasia in HNSCC

and lung cancers and contains at least three putative loci, the identity of which remain to be determined.[17,21] Recently, a homologue of p53 has been identified on 3q, and this protein, designated p40AIS (amplified in squamous cell carcinoma), was found to occur with high frequency in HNSCC and lung squamous cell carcinoma.[22] Amplified in squamous cell carcinoma is a homologue of the p53 tumor suppressor gene but lacks the tumor suppressor function of p53. Expression of AIS was found to promote growth of rat cells in soft agar and in mice, indicating that it may play an early role in transformation as an oncogene. Increased p40 expression appears to be correlated with loss of p53, and p40 may interact and inhibit normal p53 function.

Chromosome 17p13 encodes the p53 gene, which is deleted or mutated with relatively low frequency in dysplasia and Cis and with increased frequency in primary carcinomas.[17] A variety of functions have been attributed to the p53 gene,[23] which are thought to result primarily in tumor suppression. p53 is expressed in response to DNA damage, resulting in cell-cycle arrest for the repair of DNA damage or induction of cell death when damage is irreversible.[23] Loss of p53 presumably eliminates mechanisms by which cancer cells undergo repair or cell death.

Chromosome 13q21 has been shown to exhibit increasing LOH with Cis and invasive carcinoma.[17] It includes the region encoding the retinoblastoma gene, another tumor suppressor gene. However, mutation of the retinoblastoma gene occurs relatively infrequently in the HNSCC studied, indicating the possible presence of another gene at this location.

Loss of heterozygosity of loci on 4q occurs with increased frequency in invasive carcinomas, suggesting that the gene(s) located therein are associated with later stages of primary tumor development. To date, the identity of genes and predictive value of alterations of these loci in prognosis have not been demonstrated.[24]

Loss of heterozygosity involving chromosomes 8p and 6p is observed in invasive HNSCC, and a locus on chromosome 8p23 is associated with poor prognosis.[25] The putative tumor suppressor genes at the chromosome 8p loci remain to be identified. A p53 regulated growth inhibitory gene that is a member of the tumor necrosis factor–related apoptosis-inducing ligand (TRAIL) family has been mapped to the chromosome 8p21 region in HNSCC and infrequently undergoes mutations that result in loss of function.[26]

Loss of heterozygosity at chromosome 10q23 is detected with intermediate frequency in primary HNSCC and has been found to reflect deletion or inactivation of a gene called phosphatase and tensin homolog deleted on chromosome 10 (*PTEN*).[27] *PTEN* functions in the inactivation of Akt, a protein kinase. Akt is activated by EGFR and other cytokine and growth factor receptors. Early activation of Akt by overexpression of EGFR, and later by loss of *PTEN*, could lead to increased survival and growth of HNSCC and other cancers.

In summary, HNSCCs have been found to accumulate a series of genetic changes during the histopathologic stages of tumor development. The functions of the affected genes identified to date are consistent with the changes required for development of cancer, namely genes involved in regulation of cell-cycle progression and proliferation, cell life span, and cell death. The early occurrence of multiple events and detection of events at different stages in individual cancers from different patients suggest that different combinations of multiple genes affecting cell-cycle progression and proliferation, cell life span, and cell death can contribute to the common histopathologic stages of tumor development observed in HNSCC.

Tumor Progression and Metastasis of Squamous Cell Carcinoma The late stages of cancer involve progressive tumor invasion and metastasis, which are the stages that ultimately affect vital functions and cause death in patients. Figure 56–2 highlights some of the important histopathologic and molecular events associated with tumor progression and metastasis.

Development of *invasive carcinoma* is associated with focal dissolution of the basement membrane and extracellular matrix (ECM), detachment, and migration of cells into the submucosal tissue (see Figure 56–2, A). Head and neck squamous cell carcinomas that exhibit a streaming pattern of small clusters of cells through the ECM are associated with more aggressive behavior and poor prognosis.[28] *Tumor progression* to a size that becomes visible and has an effect on adjacent structures requires an increase in supply of oxygen and nutrients and removal of waste. Folkman is largely responsible for establishing the concept that new blood vessel for-

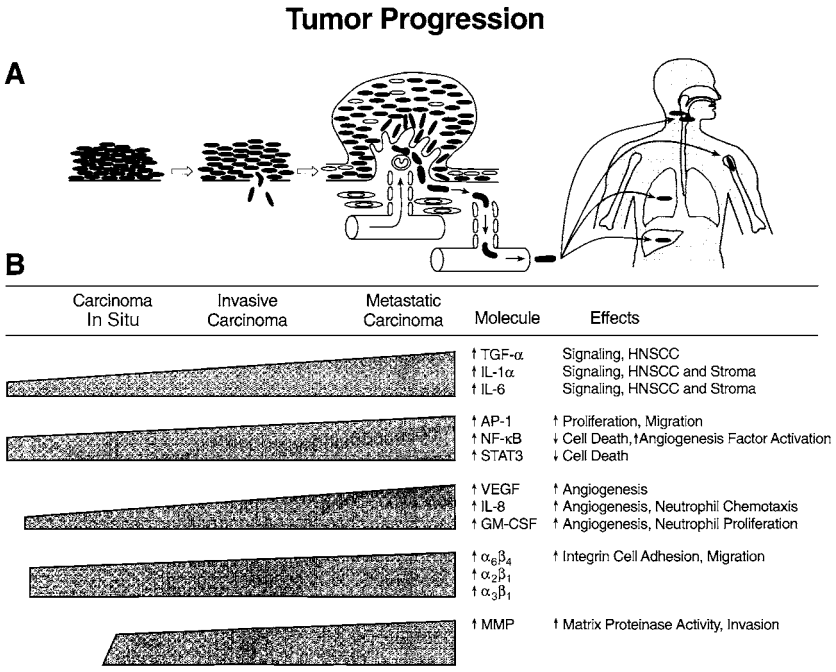

FIGURE 56–2. Model of histopathologic and molecular changes with tumor progression and metastasis of head and neck squamous cell carcinoma (HNSCC). *A*, Histopathologic changes during tumor development of HNSCC as described in the text. *B*, Molecular changes with tumor progression. TGF = transforming growth factor; IL = interleukin; AP = activator protein; NF-κB = nuclear factor-kappa B; STAT = signal transducers and activators of transcription; VEGF = vascular endothelial growth factor; GM-CSF = granulocyte-macrophage colony-stimulating factor; MMP = matrix metalloproteinase.

mation is critical in cancer.[29] Enlargement of tumors to a size beyond 0.5 cm exceeds the range for diffusion of oxygen from existing vessels and necessitates new blood vessel formation, called *neoangiogenesis*. Such new vessel formation has been demonstrated in all cancers and is commonly associated with an increase in inflammatory cells. Increased vessel density and inflammation within tumors have been associated with more rapid growth, metastasis, and a decrease in prognosis, suggesting that the increase in vessels may somehow relate to increased access for metastasizing cancer cells. Invasion of the lymphatics and blood vessels and *circulation* of cells are necessary for regional and distant spread of HNSCC.

Growth of the tumor epithelia and angiogenesis is also accompanied by increased infiltration of inflammatory cells and proliferation of fibrous stroma. Several studies have suggested that tumor cells that induce host inflammatory and stromal cell responses grow, invade, and metastasize more rapidly. Chen et al have shown that during progression, squamous cell carcinomas undergo additional changes needed for growth and metastasis that depend on the host.[30] Young and colleagues have shown that inflammatory cells infiltrating human and murine squamous cell carcinomas are one of the host components that promote growth and metastasis.[31] These inflammatory cells bear a stem cell marker called CD34 and appear to differentiate into granulocytes and the endothelial cells that form new blood vessels. Young[32] and Pekarek and colleagues[33] have shown that the granulocytes promote increased growth and metastasis. Granulocytes from the host can release growth factors[33] and proteases[34] that stimulate growth and invasion of tumor cells. Squamous cell carcinomas also induce proliferation of stromal fibroblasts. Fibroblasts also secrete factors and ECM substances that can promote growth.[35] The establishment of *metastases* requires cell arrest and vessel formation in a new location. Head and neck squamous cell carcinoma shows a predilection for metastases to the lymphatics, lungs, liver, and bone marrow, suggesting that the cells and substrate of the reticuloendothelial system provide a favorable environment for arrest and formation of squamous cell carcinoma metastases.

Molecules Involved in Cell Adhesion, Migration, and Invasion by Head and Neck Squamous Cell Carcinoma Head and neck squamous cell carcinomas exhibit alterations in expression of a repertoire of cell adhesion molecules and ECM substances that function in attachment and migration. Increased expression of cell adhesion molecules called *integrins* has been detected in HNSCC by Van Waes et al.[36] The integrins are heterodimers comprised of α and β subunits that form a superfamily of cell surface receptors involved in cell-cell and cell-

ECM adhesion and recognition. The integrin α6β4, α2β1, and α3β1 heterodimers are normally expressed among proliferating layers of squamous cell epithelium but are expressed in suprabasilar layers of many squamous cell carcinomas in association with increased proliferation and immortalization that occur during early tumor development.[36] Increased suprabasilar expression of α6β4, as detected by monoclonal antibody A9, was found to be correlated with a poorer prognosis in a prospective study of 80 patients with HNSCC.[37] Expression of integrin α6β4 has been shown to promote aggressive tumor behavior.[38] The α6β4, α2β1, and α3β1 integrins have been found to be receptors for ECM laminin, and α2β1 and $\alpha_3\beta_1$ integrins also bind to collagen. Head and neck squamous cell carcinomas secrete the basement membrane component laminin in vitro and in situ, and blockade of α6β4, α2β1, and α3β1 completely inhibits attachment of HNSCC to laminin.[39] Monoclonal antibody to the α6 integrin also has been shown to reduce binding to activated endothelial cells. Thus, HNSCCs exhibit constitutive alterations in expression of a repertoire of integrin cell adhesion molecules, and expression of integrin α6β4 in particular is linked with aggressive tumor behavior.

Increased expression and activation of enzymes involved in remodeling of the ECM have been detected in HNSCC and are associated with increased invasiveness and pathogenicity. The matrix metalloproteinases (MMPs) comprise a family of proteases that digest ECM, which are up-regulated in HNSCC (see Figure 56–2, B). Head and neck squamous cell carcinoma exhibits increased expression of urokinase-type plasminogen activator (uPA) and uPA receptor as well as the MMPs membrane-type MMP-1, collagenase 1, stromelysin 1, and gelatinase B.[40] Expression of these factors and invasiveness appears to be inducible by epidermal growth factor (EGF) or scatter factor (SF).[40–42] Invasion of EGF- or SF-stimulated cells is completely suppressed by recombinant and synthetic MMP inhibitors.[40] These studies suggest that MMPs may be more important than the plasminogen activator-plasmin system in mediating EGF- or SF-induced tumor cell invasion of interstitial matrix barriers. Inflammatory cells infiltrating tumors also can express MMPs. Matrix metalloproteinase-9 may be expressed by host-derived neutrophils, macrophages, and mast cells attracted to the tumor site. Matrix metalloproteinase-9 expressed by bone marrow–derived cells appears to promote malignant tumor progression of squamous cell carcinoma in vivo.[43]

Cytokine and Growth Factors Involved in Inflammatory and Angiogenesis Responses to Head and Neck Squamous Cell Carcinoma The demonstration of the role of host inflammatory and angiogenesis responses in progression and metastasis of squamous cell carcinoma has led to efforts to identify the molecules involved. Head and neck squamous cell carcinomas have been found to express a number of cytokines and growth factors that mediate inflammatory and angiogenesis responses (see Figure 56–2, B). Squamous cell carcinomas produce a repertoire of factors in vitro and in situ that include IL-1α, IL-6, IL-8, granulocyte-macrophage colony-stimulating factor (GM-CSF), growth-regulated oncogene-α (GRO-α), and vascular endothelial growth factor (VEGF).[44,45] Tumor fibroblasts have been shown to produce SF/hepatocyte growth factor (HGF).[35] Interleukin-6, IL-8, GRO-α, VEGF, and HGF are of sufficient stability and are produced at high enough concentrations that they have been detected in the serum of patients.[44]

Interleukin-1 is a cytokine that can regulate expression of several of the other factors detected in squamous cell carcinoma. Interleukin-1 serves as an autocrine factor to stimulate HNSCC to produce IL-8, GM-CSF, and VEGF [46] and as a paracrine factor to stimulate production of HGF by fibroblasts. In addition, IL-1 has important systemic regulatory effects as an important mediator of acute-phase reactions, increased catabolic state and cachexia often observed in patients with aggressive HNSCC. Interkeukin-1 and IL-6 both have direct effects as autocrine factors that can stimulate proliferation of HNSCC cells.[46,47]

Interleukin-8 and GRO-α are both members of a related family of chemoattractant and proliferative factors that contain a cysteine-X-cysteine (C-X-C) amino acid motif. Interleukin-8 and GRO-α have been shown to serve as chemoattractants for granulocytes and endothelial cells, which are major constituents of the inflammatory response in HNSCC. Loukinova et al have shown that expression of the murine homologue of GRO-α and IL-8 promotes aggressive growth and metastases, angiogenesis, and inflammatory cell infiltration in squamous cell carcinoma.[45] The aggressive pattern of growth is reversed in knockout mice deficient in CXC receptor

2, the receptor for the chemokine. These results provide direct evidence that tumor factors and the host response induced by them are critical in tumor progression and metastasis of squamous cell carcinoma. Kitadai et al have shown that IL-8 has similar effects on growth of other histologic types of human tumors as xenografts in mice.[48] Young et al have shown that GM-CSF produced by squamous cell carcinoma may also play a role in activity of CD34 progenitors of granulocytes and endothelium, which they reported are associated with metastasis.[31] Vascular endothelial growth factor also promotes angiogenesis and stimulates expression of αvβ3 and αvβ5 integrin heterodimers that are involved in migration of endothelial cells during angiogenesis. Inhibition of αv integrins inhibits tumorigenesis of squamous cell carcinomas in mice.[49]

Activation of Oncogenic Signal Pathways and Transcription Factors in Head and Neck Squamous Cell Carcinoma Identification of growth factors, cytokines, and other molecules that contribute to pathogenesis of squamous cell carcinoma has facilitated characterization of mechanisms of activation and potential targets for molecular therapy of HNSCC. Cytokines as well as integrins and MMPs expressed by HNSCC are also frequently expressed during the early response to injury, and these so-called "early response" genes are regulated by a group of transcription factors, which are proteins that usually bind DNA in the upstream (5′) noncoding portion of each gene. Transcription factors regulate expression of genes through transcription of messenger RNA. Transcription factor binding sequences in the regulatory region of cytokine genes expressed by HNSCC include nuclear factor-kappa B (NF-κB), activator protein-1 (AP-1), and nuclear factor IL-6 (NF IL-6), and these transcription factors were found to be activated in HNSCC.[50] Grandis et al have identified another transcription factor, called STAT3, which is activated and appears to regulate expression of BCL-XL, a molecule that prevents apoptosis of HNSCC cells.[14]

Studies performed to determine the effects of activation of transcription factors NF-κB and STAT3 in HNSCC have shown that they are important in the pathogenesis of HNSCC. Activation of both NF-κB and STAT3 appears to be important for preventing HNSCC cells from undergoing apoptosis.[14,51] Head and neck squamous cell carcinoma cells in which activation of NF-κB and STAT3 has been blocked by genetic methods exhibit increased cell death and inhibition of tumorigenesis in immune-deficient mice.[14,51] Inhibition of NF-κB also sensitizes HNSCC cells to cell death induced by radiation treatment and immune killing by tumor necrosis factor.[52,53] Molecular inhibitors of signal pathways that activate NF-κB, AP-1, and STAT3 are in development as potential agents for pharmacologic therapy of HNSCC.

Several of these transcription factors identified in HNSCC can be activated by signal receptors expressed on the surface of HNSCC, as illustrated in the model in Figure 56–3. Autocrine activation of TGF-α/EGFR, IL-1/IL-1 receptor, and IL-6/IL-6 receptor can potentially induce activation of NF-κB, AP-1, and STAT3.[47] In addition, squamous cell carcinomas have also been shown to express c-Met, which is a tyrosine kinase receptor for SF,[40,41] a factor produced as a result of paracrine activation of stromal fibroblasts by tumor cell–derived IL-1[35] (see Figure 56–3). c-Met may activate genes in HNSCC through the Ets oncogene family transcription factor or E1AF.[41] Together, these various signal pathways and transcription factors activate expression of many of the genes that have been shown to contribute to pathogenesis in HNSCC (see Figure 56–3). New drugs that target these receptors or intermediate kinase pathways are the subject of intensive preclinical and clinical development.

Molecular Diagnosis of Head and Neck Squamous Cell Carcinoma

Progress in the determination of molecular mechanisms involved in the pathogenesis of development and progression of HNSCC, together with sensitive molecular assay methods, has expanded opportunities for use of molecular diagnosis in patients with HNSCC. Using polymerase chain reaction–based methods for amplification of DNA, LOH of specific markers associated with HNSCC has been shown to occur in biopsy specimens of lesions prior to development of invasive malignancy.[17] Mutant p53 detected in surgical margins from patients has been shown to predict positive margins and sites of future recurrence.[54] Overexpression of telomerase and mutant p53 has been detected in tissue biopsies as well as in saliva,[16,23] opening possibilities for screening. Recently, detection of microsatellite and methylated DNA, which are markers for inactivated tumor

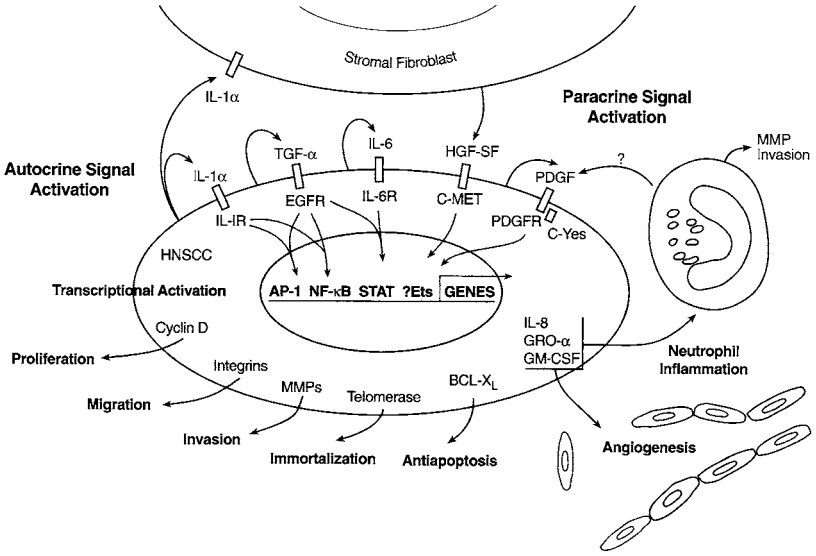

FIGURE 56–3. Summary of molecular changes affecting tumor and host cells that promote tumor development and progression of head and neck squamous cell carcinoma (HNSCC). Factors produced by tumor and host cells result in autocrine and paracrine signals that activate HNSCC transcription factors and genes. Genes activated by transcription factors cause cellular changes in HNSCC that lead to tumor development and host inflammatory and angiogenesis responses that promote malignant tumor progression and metastasis. TGF = transforming growth factor; EGFR = epidermal growth factor receptor; IL = interleukin; HGF-SF = hepatocyte growth factor-scatter factor; PDGF = platelet-derived growth factor; AP = activator protein; NF-κB = nuclear factor-kappa B; STAT = signal transducers and activators of transcription; GRO = growth-regulated oncogene; VEGF = vascular endothelial growth factor; GM-CSF = granulocyte-macrophage-colony-stimulating factor; MMP = matrix metalloproteinase.

suppressor genes, has been assayed in blood[55,56] and may eventually be useful for diagnosis and detection of recurrence. Detection of overexpressed proteins in blood, such as cytokines and angiogenesis factors, may also eventually prove useful in predicting behavior and recurrence.[44] These studies have established the feasibility of using molecular methods to screen patients for diagnosis, prognosis, and detection of recurrence. Further understanding of the "anatomy" of activation of pathways and target genes, as in Figure 56–3, will eventually offer the possibility of determining susceptibility or resistance of HNSCC to different therapies.

Molecular Therapy of Head and Neck Squamous Cell Carcinoma

The determination of molecular mechanisms involved in pathogenesis of development and progression of HNSCC has enabled the development and testing of specific molecular therapies. Replacement of mutant p53 by gene transfer inhibits growth of experimental tumors, and p53 gene therapy in patients with advanced HNSCC has established the feasibility of gene therapy in HNSCC.[57] Limited expression of genes administered within the tumor and the tendency of cancer cells lacking p53 to survive and become dominant provide obstacles to successful treatment of cancer by replacement of a normal gene. Identification of the role of EGFR in HNSCC and other cancers has led to testing of therapy with DNA antisense sequence to the target gene. Grandis et al and He et al have shown that EGFR and STAT3 antisenses inhibit growth of HNSCC,[10,11] and a clinical trial is under way to determine safety in patients and effects of expression of antisense DNA on tumor gene expression. Antibodies that inhibit activation of EGFR have been shown to inhibit growth of squamous cell carcinomas when given concurrently with radiation.[12,13,58] Small molecule inhibitors of EGFR and of components of the NF-κB and AP-1 pathways have been developed and are under study for use in patients with HNSCC.

CHAPTER 57

Chemotherapy for Head and Neck Cancer

Bruce Brockstein, MD, Janardan D. Khandekar, MD

Head and neck cancer (HNC) accounts for only 5% (or 40,000 patients) of malignancies in the United States, but the associated pronounced cosmetic and functional morbidities resulting from both the disease and its treatment heighten its relative importance. As a result, these tumors require the multidisciplinary care and expertise of head and neck surgeons, radiation and medical oncologists, prosthodontists, speech and swallowing therapists, pathologists, radiologists, dietitians, physiatrists, nurses, and social workers.

Multimodality care has led to clear improvements in the outcome for HNC patients. Chemotherapy has assumed an increasing role in HNC in both the curative and palliative settings. In just the last decade, it has been demonstrated that larynx preservation is possible in up to two-thirds of stage III and IV larynx and hypopharynx patients who receive chemotherapy prior to radiation therapy (RT).[1,2] Concomitant chemotherapy and RT (CRT) have recently been definitively shown to improve survival compared with RT alone for patients with unresectable HNC.[3–5]

Chemotherapy plays a diverse role in the many diseases for which it is used. The ultimate objective of chemotherapy is to cure the patient of a malignant disease. In practice, cure has been realized for only a few types of metastatic malignancies, and most patients with metastatic solid tumors cannot be treated with curative intent. Chemotherapy as a single modality has the potential to cure patients with testicular cancer, small cell lung cancer, ovarian cancer, lymphoma, leukemia, and sarcomas of children or young adults. In most disseminated solid tumors, cure is not yet possible, although significant palliation and lengthening of survival can be achieved.

The use of chemotherapy in treating malignancies aims at the eradication of systemic cancer or the increase of locoregional control when used with surgery or RT. Patients are treated with chemotherapy for either "macroscopic" or "microscopic" metastases or as an adjunct in the management of primary, localized tumors. In the setting of macroscopic metastases ("metastatic disease"), patients have clinical or radiologic evidence of tumor spread. Microscopic metastasis refers to clinically unrecognizable small metastatic tumor deposits, which, if untreated, will become macroscopic. It is in this setting that *adjuvant* or *neoadjuvant* chemotherapy is used.

Traditionally, chemotherapy had been used only after the failure of irradiation and/or surgery to control head and neck tumors. These local therapeutic modalities, however, fail to cure a sizeable percentage of patients. Although patients with limited disease (T1–2, N0, M0) can be treated effectively with local modalities such as surgery and radiation, with 60 to 90% cure rates, over 70% of patients with extensive disease (T3–4, N1–3, M0) have recurrence at 2 years after these treatments. This formed the impetus for clinical trials of chemotherapy in the primary treatment of HNC in the 1970s to 1990s that have demonstrated that chemotherapy is an important adjunct to surgery and/or radiation.

This chapter reviews the principles of chemotherapy and describes its uses in HNC. The understanding of molecular biology and genetics is exploding and is beginning to have an impact on therapy of HNC. These topics are also briefly touched on.

CELL CYCLE

Malignant tissues are largely made up of dividing cells, which synthesize deoxyribonucleic acid (DNA) at some point in their life cycle, and nondividing

cells. The dividing cells pass through four different phases (Figure 57–1). Mitosis occupies a discrete phase (M) of the cell cycle. Following the division, the cell enters the G_1 phase. This phase is then followed by DNA synthesis, which is termed the S phase. After completion of the DNA synthesis, the cell then enters a phase of apparent rest (G_2) before the initiation of the next mitosis.

In most dividing cells, the periods for S, G_2, and M phases are of relatively constant duration. Variation of the length of the cell cycle generally occurs in the G_1 phase. When the proliferating cells stop dividing, they do so in the G_1 phase. This phase seems to hold the key to the proliferative activity of the tissue. When the cell-cycle time (time taken for a proliferative cell to move from one mitosis to another) is short, and thus the proliferative activity is high, the G_1 phase is of brief duration. When proliferative activity is slow, the G_1 phase is long.

It is not clear at present how a mammalian eukaryotic cell decides to leave the G_1 phase and to start DNA synthesis. Based on the differences in ribonucleic acid (RNA) content, two distinct subcompartments, G_{1A} and G_{1B}, have been recognized. It is postulated that, after the mitosis, cells reside in the low RNA G_{1A} compartment and that an increase in RNA above this critical level is required for G_1 cells to be able to initiate DNA replication. The G_1 cells with high RNA values are in G_{1B}. During the S phase, biosynthesis of enzymes essential for pyrimidine and nucleic acids is accentuated, and the DNA content of the cell doubles. The phase of DNA synthesis is then complete, and the cell enters G_2 phase. None of the phases is quiescent, and RNA and protein synthesis occurs throughout each of them.

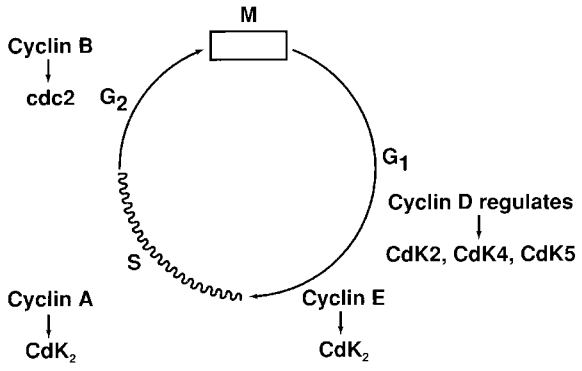

FIGURE 57–1. The cell-cycle phases: M = mitosis; G_1 = preceding DNA synthesis; S = DNA synthesis; G_2 = premitotic resting.

The molecular mechanisms controlling cell cycle are being rapidly elucidated. Cell-cycle control is based on two key families of proteins. The first is the family of cyclin-dependent protein kinases (CdK for short), which phosphorylates selected proteins. The second is a family of specialized activating proteins called cyclins that bind to the CdK molecules and control their ability to phosphorylate appropriate target proteins. Thus, there are two checkpoints in the cell cycle, namely at G_1/S and G_2/M. These checkpoints are controlled by various genes such as the retinoblastoma and p53 genes.

In addition to differences in the biochemical mechanism of action, discussed later, antineoplastic agents also differ in the point in the cell cycle at which they act. The drugs can be grouped as follows on the basis of their effects on phases of the cell cycle[6–8]:

1. *S phase specific.* These are the agents that inhibit the DNA synthesis that occurs in the S phase of the cell cycle. Drugs such as methotrexate (MTX) inhibit not only DNA but also RNA and protein synthesis and are called S phase specific.
2. *Non S specific.* Alkylating agents and antitumor antibiotics exert a direct effect on DNA; thus, their activities are not dependent on the phase of the cell cycle.
3. *Antimitotics.* Plant alkaloids such as vincristine arrest mitosis during metaphase.

Studies of the cell kinetics indicate that the often-held belief that all malignant tumors are rapidly proliferating is not necessarily true. The mean doubling time of human tumors (time taken by a tumor to double its volume) can be as short as 1 week in Burkitt's tumor or as long as several years in some adenocarcinomas.

Malignant tumor formation occurs when any of the following three events occur together or separately: (1) the growth fraction, defined as a proportion of tumor cells in the mitotic cycle at a given time, may become large; (2) the cell-cycle time may become shorter (on average, the cell-cycle time of tumors is 2 days, which is not faster than normal cells); (3) normally, renewal of normal cells is accompanied by cell loss, an active process known as "programmed" cell death or apoptosis. When this cell loss is reduced, tumor formation can occur. This

seems to be the major factor in the production of most tumors.

Epidermoid neoplasms have about 35% growth fraction (dividing cells) in contrast to 3 to 5% in breast cancer and virtually 100% in embryonal tumors. Because most of the chemotherapeutic agents act on these dividing cells, epidermoid cancers would be intermediate in their response to drugs. Recent work suggests that, at the metastatic site, a tumor may still be proliferating rapidly, whereas the parent neoplasm has a low growth fraction. This suggests that chemotherapy given to these patients may still be useful. Methods for measurement of cell kinetic parameters in patients are cumbersome, however. The results of therapy based on these considerations are also at present not much different from those with conventional therapy. Nevertheless, newer advances in this field may considerably alter the present practice of chemotherapy.

MODE OF ACTION OF ANTINEOPLASTIC AGENTS

Traditional Chemotherapy Drugs

The DNA synthesized during the S phase of the cell cycle acts as a selective template for the production of specific forms of messenger, ribosomal, or transfer RNA. The specific sequences of the messenger RNA determine which enzymes will be synthesized in the cell. The enzymes, in turn, are responsible for the structure, function, metabolism, and proliferative rate of the cells.

Most of the clinically useful antineoplastic drugs appear to work by inhibition of synthesis of either enzymes or substrates essential for the nucleic acid synthesis and/or function. Based on the mechanism of drug action, agents that are useful in HNC can be classified as follows:

1. *Antimetabolites*. These drugs inhibit purine or pyrimidine biosynthesis. Methotrexate, for example, inhibits formation of reduced folates, which are essential for thymidine synthesis.
2. *Drugs that interfere with the structure or function of the DNA molecule*. Alkylating agents such as cyclophosphamide change the structure of DNA, thereby arresting cell replication. On the other hand, antibiotics such as dactinomycin and doxorubicin bind and intercalate with nucleotide sequences of the DNA molecule and thereby block messenger RNA (mRNA) production.
3. *Mitotic inhibitors*. Vinca alkaloids, such as vincristine and vinblastine, and the taxanes paclitaxel and docetaxel arrest cell division by disrupting the microfilaments of the mitotic spindle.

New or Investigational Classes of Chemotherapy

A major focus of drug development in academia, industry, and government is drugs that work via different, nonclassic mechanisms. There is hope, and already proof of principle, that some of the drugs from these new classes will improve outcomes or cure rates in HNC and other cancers:

1. *Monoclonal antibodies and vaccines*. These agents target specific cell antigens. Monoclonal antibodies targeted against a single antigen are already approved by the US Food and Drug Administration (FDA) and are in clinical use. These monoclonal antibodies may be used alone or in combination with chemotherapy or RT. They may be linked to radioactive substrates ("radioimmunoconjugates") or may be "bispecific" to an antigen and another target such as an immune effector cell. Trastuzumab (Herceptin) combined with chemotherapy improves outcome for patients with advanced breast cancer who overexpress Her2, a transmembrane receptor protein. Rituximab (Rituxan), directed against the B-cell antigen CD-20, is approved for use in low-grade lymphomas and is being investigated in aggressive B-cell lymphomas. The epidermal growth factor receptor (EGFR) is overexpressed in most HNCs and is one of the most common molecular abnormalities. Upon ligand binding, the receptor undergoes conformational change and dimerizes with another EGFR molecule or another member of the EGFR family of receptors. This then initiates a cascade of signal transduction that is mitogenic and may be antiapoptotic. Epidermal growth factor receptor has become a target for therapy in HNC and other cancers. C225 is a chimeric human-mouse monoclonal antibody directed against EGFR, which is currently in phase III trials. The antibody binds to EGFR, preventing binding of the natural ligands

so that activation does not occur.[9] The antibody has antitumor effects as well as radio-sensitizing effects.[10] The antibody is currently in phase III trials.

2. *Signal transduction modulators*. A variety of these drugs are in clinical trials, and one has recently gained FDA approval for the treatment of chronic myelogenous leukemia. STI-571 (Gleevec) is a tyrosine kinase inhibitor that has shown unprecedented activity in refractory chronic myelogenous leukemia and gastrointestinal stromal tumors. This drug is likely to lead the way in the approval of many other drugs in this class. Head and neck cancer will likely also be a target of such therapies, with targets such as EGFR and downsteam molecules.
3. *Angiogenesis inhibitors*. This broad term refers to drugs that target the synthesis or integrity of tumor neovasculature. It is an attractive target for cancer therapy since vascular biosynthesis is much more active in tumors than normal tissue and may thus provide a more rational target for therapy. No drugs from this class are yet approved, but many are in clinical trial.
4. *"Gene therapy/gene transfer."* Head and neck cancer is a prime target for gene therapy. Head and neck cancer trials of the drugs ONYX-015 and RPR/INGN-201 are among the first gene therapy trials in oncology. ONYX-015 uses an adenovirus with the *E1B* gene deleted. This modification renders it unable to replicate in cells with normal p53 but allows for selective replication and cell lysis in p53 mutant cells.[11] This drug is being extensively studied as a single agent and in combination therapies, and via several routes of delivery.[12,13] One interesting study was recently reported with preliminary results. Thirty-seven patients with recurrent HNC received intratumoral injections of p53 in combination with cisplatin and 5-fluorouracil. Almost all patients had prior surgery and RT. The complete response (CR) rate was 27%, and the overall response rate (RR) was 63%. More impressively, none of the 19 injected tumors that responded to therapy had progressed at the time of an early report (5-month median follow-up).[14]

   RPR/INGN 201 (Ad5CMVp53) uses a replication-deficient adenovirus to deliver a wild-type *P53* gene driven by a cytomegalovirus promoter. Early studies in over 200 patients have shown intratumoral injections to be tolerable, with some evidence of activity of this drug. Phase III studies are ongoing.
5. *Photosensitizers*. Photosensitizers such as porfimer sodium (Photofrin) are used in photodynamic therapy. Given systemically, these drugs are preferentially taken up in tumor cells, rendering them more sensitive to light-mediated cell killing than their surrounding tissues. Although not approved specifically for HNC, these drugs have been used for palliation in advanced HNC or the treatment of early-stage HNC.
6. *Inhibitors of invasion and metastasis.* An important step in the invasion and metastasis process is the disruption of the epithelial basement membrane. This step is integrally related to the angiogenesis process. A number of such drugs have been tested or are currently in clinical trial, although none are yet approved.
7. *Antisense oligonucleotides.* Once the gene sequence of a cancer-related gene or oncogene is identified, an exogenous, complementary oligodeoxynucleotide (oligo) can be synthesized against the gene or oncogene mRNA. Oligos of large enough base-pair size can be synthesized to be uniquely complementary to the target mRNA. The antisense oligo, by formation of an mRNA-DNA duplex, could specifically prevent translation of that mRNA into protein. These drugs continue in the developmental and clinical trial phase.
8. *Biologics*. Drugs such as interleukin-2 and interferon-α have an established role in the therapy of malignant melanoma and renal cell carcinoma. The role of interferon in HNC has diminished, but research in this field is continuing.

CHEMOTHERAPY-RELATED ISSUES

General Toxicity of Antineoplastic Agents

Most of the approved chemotherapy agents act on the proliferative fraction of cells. Therefore, an undesirable consequence of these drugs is the damage inflicted on the normal cells undergoing rapid cell division. This correlation between proliferative activity and toxicity is most notable in the hair follicles, skin, gastrointestinal mucosa, and normal bone marrow elements. Clinically, then, damage to these tis-

sues is manifested as alopecia, stomatitis, nausea, vomiting, anemia, leukopenia, and thrombocytopenia. In addition to these effects, specific problems can occur with each drug, and these are discussed below.

Chemotherapy Drug Resistance

Resistance to chemotherapy drugs, either inherent or acquired, remains a major problem in cancer chemotherapy. Resistance to natural product drugs, known as *multidrug resistance*, has been shown to be acquired by the tumor cells to drugs that are structurally and functionally unrelated. Initially, this type of drug resistance was shown to be owing to the presence of a P-glycoprotein encoded by the human multidrug resistance (*MDR*) gene. Subsequently, it was shown that the gene product, P-glycoprotein, is inserted in the plasma membrane and acts as an adenosine triphosphate–driven drug efflux pump. Other proteins, such as multidrug resistance–associated protein, have also been implicated in this drug resistance. Many other mechanisms, such as altered blood delivery of drugs and activation of target enzymes as well as modulation of DNA, may also confer drug resistance.

Organ Preservation

A major goal of combined chemotherapy and radiation is that of decreasing morbidity. The organs in the head and neck area are of paramount importance for normal daily function; therefore, organ preservation has assumed an important role. An important emerging concept not only in the chemotherapy of cancer in general but also in all of cancer treatment is the impact that the disease and/or treatment may have on the quality of life. Full consideration of organ preservation strategies must consider the maintenance of normal organ anatomy and function, as well as global quality of life. Assessment of function outcome is a major goal in organ preservation trials. Specific issues of organ preservation are discussed below.

SPECIFIC CHEMOTHERAPEUTIC AGENTS

US Food and Drug Administration–approved chemotherapy drugs used, but generally not specifically approved for HNC, are described below. Mechanisms, RRs to the drug as a single agent, and toxicities are described. The definition of RR or clinical benefit in HNC requires special consideration.

Definition of Clinical Benefit

Clinical benefit from systemic chemotherapy in patients with HNC or other cancers can be defined by the *objective RR* in measurable disease, the *time to progression*, the impact on *overall survival*, or the success of *organ preservation strategies*. Objective responses are defined as partial or complete. Partial response is generally defined as a $\geq 50\%$ decrease in the sum of the product of the perpendicular diameters of all tumors. Complete response is defined as 100% shrinkage. Most commonly, objective RRs are used, although they may not be the best assessment of clinical benefit. When comparing objective RRs between various regimens in HNC, certain caveats apply. Objective RRs may vary greatly between studies, and a number of factors can account for these discrepancies. Prior chemotherapy can greatly alter (decrease) the RR to a subsequent regimen. Neoadjuvant chemotherapy for patients with locoregional disease generally results in two-fold higher RRs than those achieved in patients with recurrent and metastatic disease who have received no prior chemotherapy. Response rates in multi-institutional phase III trials are generally lower than those reported in single-institution or phase II trials. The definition of response is variable among studies; some use computed tomographic (CT) scans for evaluation, whereas others rely on clinical examination for tumor measurement. Defining objective response, particularly for patients who have had prior locoregional therapy, is difficult in HNC. Head and neck cancers tend to form less well-defined, discrete lesions than are seen in other sites (eg, lung, liver, or brain), making precise measurement difficult and introducing a variable in response reporting. Despite these difficulties, most clinicians use the objective RR as the primary end point in metastatic disease.

The reported objective response of various drugs in head and neck cancer is shown in Table 57–1.

Multiple other drugs (eg, mitomycin, cyclophosphamide, doxorubicin, vinblastine, hydroxyurea) have shown RRs in smaller studies of 10 to 40% but are rarely used in HNC. Newer, approved

Bleomycin	28

*Combined results of clinical trials (phases II and III) of single-agent chemotherapy for head and neck cancer. Trials took place in different settings and in different eras, using different evaluation techniques. Therefore, no direct comparisons regarding efficacy can be made from this table.

drugs such as irinotecan-11, gemcitabine, and vinorelbine have activity in HNC, but their role is undefined.

Specific Drugs

Methotrexate *Methotrexate* was the first active chemotherapeutic agent for patients with HNC. The biochemical effects of MTX have been extensively studied. Methotrexate acts primarily by inhibiting the activity of the enzyme dihydrofolate reductase, which converts dihydrofolate to tetrahydrofolate. The reduced folates are required for the formation of thymidylate, which then becomes incorporated into DNA. Other evidence suggests that the drug also inhibits purine biosynthesis.

Methotrexate has been administered by and studied in multiple doses, routes (oral, intravenous, intra-arterial), and schedules. In multi-institutional phase III studies using standard-dose MTX (usually 40 mg/m^2 per week) as the control arm, objective RRs ranged from 12 to 35% (average 22%).[15–20] The disparity in reported RRs of this one drug is an example of the difficulty in comparing RRs across trials in HNC. The superiority of high-dose MTX with leucovorin rescue versus standard dose has not been demonstrated. Response durations to MTX are comparatively short-lived because of development of resistance to the drug. There are several mechanisms of resistance to MTX. These include decreased transport of the drug across cell membranes and amplification of the gene for dihydrofolate reductase (gene amplification results in more copies of the gene and thus the enzyme, and increased enzyme level results in decreased inhibition by MTX). Additionally, decreased formulation of polyglutamates may result in decreased inhibition of DNA synthesis. The main side effects of MTX, when given weekly or biweekly, include bone marrow suppression, stomatitis, mucositis, and sometimes nausea, vomiting, and diarrhea.

Randomized trials have shown that, compared with single-agent cisplatin, single-agent MTX has a lower RR (12 versus 28% and 24 versus 29%), a shorter overall survival, but a better toxicity profile.[15–20] Because MTX is easy to administer and has manageable toxicities, some experts still consider MTX the standard single agent for comparison in HNC trials.

Cisplatin Cisplatin is an alkylating agent that exerts its effect by the formation of intrastrand and interstrand DNA cross-links. Cisplatin has been extensively studied in a variety of doses, routes, and schedules for patients with advanced HNC. In large phase II and multicenter phase III trials, the single-agent RR is about 20%.[16,21,22] In randomized trials, single-agent cisplatin appears to produce a superior RR when compared to MTX. Survival was also significantly better in one of these studies. As a single agent, it may be superior to single-agent bleomycin and appears to be equivalent to 5-fluorouracil (5-FU) alone. Cisplatin has not been directly compared to paclitaxel (Taxol) or docetaxel (Taxotere).

Higher than standard doses of cisplatin have been studied in advanced HNC. However, the incremental benefit may not be sufficient to warrant the added toxicity. If given without forced hydration and diuresis, nephrotoxicity is extremely common. Severe nausea and vomiting are at least partly ameliorated by the serotonin receptor antagonist antiemetics such as ondansetron or granisetron. After multiple doses, peripheral neuropathy and ototoxicity become increasingly common.

Carboplatin Carboplatin is an analogue of cisplatin that causes less nephrotoxicity, ototoxicity, and neuropathy, although it is more myelosuppressive. The single-agent RR of carboplatin is 25%, similar to that of cisplatin.[23] Although single-agent randomized comparative studies are lacking, extrap-

olation from combination studies combining each agent with 5-FU suggests a marginal superiority of cisplatin over carboplatin.[24,25]

Taxanes In advanced squamous cell HNC, the taxanes, paclitaxel and docetaxel, have emerged as perhaps the most active of all single agents. Both drugs act by stabilization of microtubules against depolymerization, blocking mitosis. Paclitaxel was originally isolated and supplied from the bark of the Pacific yew *Taxus brevifolia*; however, both drugs are now manufactured using a semisynthetic process from natural precursors.

Paclitaxel In two phase II studies of patients with advanced HNC, single-agent paclitaxel was associated with an RR between 35 and 40%.[26,27] The major toxicity is hematologic. An ongoing EORTC (European Organization for Research and Treatment of Cancer) Head and Neck Cancer Cooperative Group trial is comparing two schedules of paclitaxel to bolus MTX. Preliminary analysis shows a lower RR for paclitaxel compared with that seen in the earlier studies.

Docetaxel Docetaxel has been evaluated in four phase II trials of 144 patients, about one half of whom had received prior chemotherapy. The RR ranges from 21 to 42%, with a median response duration of 11 weeks in one study.[28–31] There are no randomized trials directly comparing docetaxel with paclitaxel for patients with advanced HNC.

Side effects of the taxanes include myelosuppression, peripheral neuropathy, nail damage, skin rash, and fluid retention (docetaxel).

5-Fluorouracil 5-Fluorouracil and its deoxynucleoside, floxuridine, are both prodrugs that require intracellular metabolism for cytotoxicity. Three different targets are known to be affected by these fluorpyridimines. The metabolite of 5-FU, known as 5-fluorodeoxyuridine monophosphate, forms a stable complex with thymidylate synthetase, inhibiting de novo thymidylate synthesis and thus causing cell death by thymidine starvation. Further, 5-FU may induce DNA damage by two distinct mechanisms: fraudulently being incorporated into DNA, which causes DNA fragmentation and cell death, and inhibiting DNA repair. The degree of inhibition of thymidylate synthetase can be augmented by exogenous folates. This forms the basis for using leucovorin with 5-FU.

5-Fluorouracil, despite its extensive use as a radiosensitizer and widespread experience in combination with cisplatin (see below), has not been well studied as a single agent for HNC. An older study reported a 15% objective RR in patients with HNC. In a more contemporary randomized phase II study, 5-FU alone (1,000 mg/m^2 per day $\times$ 4 days) had a RR of 13%, compared with 17% for cisplatin and 32% for cisplatin plus 5-FU.[22] The side effects of 5-FU are schedule dependent but include nausea, vomiting, myelosuppression, diarrhea, and stomatitis.

Ftorafur and Uracil UFT, a 1:4 molar mixture of ftorafur (which is converted to 5-FU in the liver) and uracil (which inhibits the catabolism of 5-FU), is an oral drug that has been predominantly developed in Japan and Spain. In phase II trials of patients with advanced HNC, the overall RR exceeded 30%.[32]

In the United States, several other oral fluorinated pyrimidines, including Orzel, which combines UFT and oral leucovorin, and capecitabine, a 5-FU prodrug, are undergoing investigation in HNC. In a preliminary report of 29 patients with advanced HNC, the overall RR with single-agent Orzel was 28%, including three CRs.

Ifosfamide Ifosfamide is a prodrug that requires hepatic activation to an active alkylating agent. There are at least eight trials evaluating ifosfamide as a single agent in advanced HNC. In these reports, the objective RR has ranged from 4 to 53%.[33,34] Some but not all of this difference may be accounted for by a dose-response relationship. One of the highest RRs, 43%, was from a study using 17.5 g/m^2 ifosfamide; in contrast, the lowest RR (4.3%) was noted with a lower dose (1.5 g/m^2 per day for 5 days). However, this same regimen was used in a third trial that reported the highest RR of 53%. The side effects of ifosfamide include nausea, vomiting, myelosuppression, hemorrhagic cystitis, a generally reversible central nervous system toxicity, and proximal renal tubule damage.

Bleomycin Bleomycin has modest activity when used as a single agent for HNC. In multicenter phase II trials, objective RRs range from 6 to 56% (average 28%). [35,36] Despite minimal myelosuppression with this agent, nonhematologic toxicity (eg, pneumonitis, stomatitis, and skin changes) has precluded its widespread use in patients with HNC.

Cyclophosphamide, Doxorubicin, and Hydroxyurea Cyclophosphamide, doxorubicin, and hydroxyurea have been studied in a wide variety of doses and schedules. Many of these reports predated CT scanning, complicating the interpretation of RRs. In five trials, the objective RR with single-agent cyclophosphamide was 36%. The single-agent RR has ranged from 13 to 23% with doxorubicin and from 32 to 39% with hydroxyurea. The main utility of hydroxyurea in HNC has been as a radiosensitizer. Despite these "high" RRs from older studies, these drugs are probably less active than those above and are not commonly used for HNC.[37,38] Newer drugs such as vinorelbine, gemcitabine, and irinotecan have shown activity against HNC in small studies, and their roles continue to be defined.

COMBINATION CHEMOTHERAPY

For most cancers, drug combinations give better results than single agents. These results may be explained on the basis of a number of theoretical and practical considerations. Drugs with multiple mechanisms of action may kill cells resistant to only one drug or may prevent the emergence of resistant tumor cells. Similarly, by acting on different phases of the cell cycle, the drugs may have additive or synergistic effects. Finally, with the combination of drugs with different spectrums of clinical toxicity, administration of full or nearly full doses of each of the active agents is possible.

In HNC, most combinations have been based on cisplatin or methotrexate. At least six large randomized studies comparing cisplatin-based com-

*Minority of patients on this trial had no prior therapy and no metastases.

bination regimens to single-agent chemotherapy have demonstrated superior RRs for combination therapy compared with monotherapy in patients with metastatic or recurrent disease (Table 57–2).[16–18,20–22,39] However, survival duration, at least within the power of these studies, has not been improved by the use of multidrug regimens in the palliative setting. These studies attempted to increase RRs by combining, to achieve additive or synergistic activity, drugs with proven single-agent activity, such as cisplatin, 5-FU, MTX, and bleomycin. Cisplatin combined with 5-FU is one combination that is synergistic in vitro, and, clinically, cisplatin followed by a 4- to 5-day continuous intravenous infusion of 5-FU is a very active combination. For patients with recurrent disease, it has reproducibly yielded RRs ranging from 30 to 40%.[15] In the neoadjuvant (prior to chemotherapy or radiation) setting with locally advanced, nonmetastatic disease, RRs are about 80%, with 10 to 40% CR rates.[1,2,40,41]

The combination of cisplatin and 5-FU has been compared with each of these drugs delivered separately as single agents in a three-arm randomized trial. Although the RR of the combination (32%) was significantly higher than that of cisplatin (17%) or 5-FU alone (13%), there was no significant difference in the median survival, 5 to 6 months, for all groups.[22] A randomized trial by the Southwest Oncology Group (SWOG) compared cisplatin and 5-FU with a combination of carboplatin and 5-FU (postulated to be equally active but less toxic) and single-agent MTX.[27] Both cisplatin and carboplatin combined with infusional 5-FU resulted in an improved RR as compared with methotrexate alone. Both combinations were more toxic, and survival was not affected.

The taxanes are now commonly used in combination regimens.[42–47] A recently completed trial compared cisplatin plus 5-FU versus cisplatin plus paclitaxel for recurrent and metastatic HNC. Both regimens were essentially equivalent in RR and survival, although cisplatin with paclitaxel may be slightly less toxic. Several other three- or four-drug combination regimens containing taxanes have shown high RRs and continue under development.

The following conclusions can be made about combination chemotherapy:

1. Combinations produce statistically significantly higher RRs than the single agents with which they have been directly compared.
2. Cisplatin and infusional 5-FU and taxane combinations generally produce higher RRs than other combinations.
3. In no direct comparison has survival been meaningfully increased when comparing combinations with single agents. No well-conducted studies have been performed to ascertain a survival benefit of chemotherapy versus best supportive care.
4. The toxicities of cisplatin and infusional 5-FU (especially nausea and vomiting) are significantly higher than with single agents.

Clinical research now focuses on the identification of new agents and combinations with activity in HNC. In particular, the new agents paclitaxel, docetaxel, irinotecan, topotecan, and gemcitabine have only begun to be tested in combinations for HNC. Drugs with novel mechanisms, such as monoclonal antibodies, gene transfer agents, angiogenesis inhibitors, and other inhibitors of invasion and metastasis, are currently under investigation in combination. The role of retinoids, selenium, and other molecules in the reversal of premalignant lesions and prevention of primary or second malignancies is also under active investigation.[48]

In summary, chemotherapy for recurrent or metastatic HNC may be palliative in some patients, although the impact on survival duration is small. Methotrexate in weekly low doses, cisplatin or carboplatin, infusional 5-FU, paclitaxel, and docetaxel remain the most active single agents, producing RRs of approximately 20 to 30% that last for 2 to 6 months. Combination chemotherapy, particularly the combination of cisplatin and 5-FU and cisplatin (or carboplatin) and paclitaxel, produce higher RRs, although long-term survival is rarely achieved. Because cure is unlikely to occur as a result of any of these drugs or combinations in the previously treated patient population and in view of the poor outcome with standard single agents and combinations, whenever possible, patients should be treated on a clinical trial.

COMBINED MODALITY THERAPY

Neoadjuvant Chemotherapy

In the 1980s and 1990s, enormous enthusiasm was generated for neoadjuvant chemotherapy for HNC. Through early clinical trials, it quickly became clear

that tumors treated with chemotherapy prior to surgery or radiotherapy usually shrank substantially.[49] This concept was, therefore, extensively studied on the following theoretical grounds: untreated tumors with intact vascular supply have better drug delivery, as compared with tumors previously treated with radiation or surgery in which normal vasculature and drug delivery are disrupted; regression of primary and lymph nodal tumors may permit subsequent local therapies such as surgery and radiation to have enhanced efficacy; the extent of surgical resections can be reduced to more conservative procedures; reducing the bulk of initially unresectable lesions may allow eventual surgical removal; eradication of subclinical micrometastasis at the earliest possible time can reduce the risk of systemic relapse; tolerance of intensive combination chemotherapy is better in patients with better performance and nutritional status (which generally worsen after chemotherapy and RT); a subpopulation of patients can be identified who might further benefit from additional adjuvant chemotherapy following local treatments.

The outcome of two decades of clinical research in neoadjuvant chemotherapy in HNC was disappointing and can be summarized as follows:

1. Overall RRs (at least 50% tumor shrinkage) exceeding 80% are frequently achieved.
2. Complete RRs usually range from 20 to 40%, with most trials reporting approximately 30%. Many of the clinical CRs are confirmed histologically at surgery.
3. Toxicity is usually moderate to severe, but the administration of subsequent standard local therapy is not compromised (although a small percentage of patients with CRs will refuse subsequent planned local therapy).
4. The rate of development of distant metastases is decreased.
5. Patients achieving CRs have a better prognosis, particularly if the responses are histologically confirmed. This observation, though, does not establish that chemotherapy is responsible for better results as chemotherapy-responsive patients may have an intrinsically favorable course.
6. *Organ preservation is made possible, at least in laryngeal and hypopharyngeal carcinoma.*
7. *Survival, assessed in randomized studies, is generally not improved (with the possible exception of patients receiving neoadjuvant cisplatin plus 5-FU); thus, the use of* neoadjuvant *chemotherapy today is very limited.*

This last observation was made by analyzing the randomized trials comparing standard local therapy given with or without neoadjuvant chemotherapy. A large number of such randomized trials have been conducted, allowing for conclusions to be drawn, despite the patient heterogeneity, by analyzing aggregate trials. Most individual trials have been too small or poorly designed to be conclusive. About 10 studies, however, have entered large numbers of patients. The most important of these are summarized in Table 57–3.[1,2,40,41,50–53] In none of these 10 studies was overall survival prolonged. In all 8 studies reporting rates of distant metastases as a site of first failure, the rate of distant metastases was decreased among the patients receiving chemotherapy.[54] Unfortunately, most patients still died of locoregional disease complications; therefore, the decreased rate of distant metastases did not translate into a survival benefit. These negative results have been confirmed by three recent meta-analyses.[3–5] In the individual patient meta-analysis performed by the MACH-NC (Meta-analysis of Chemotherapy on Head and Neck Cancer) Cooperative Group, however, it was noted that in the subset of patients receiving neoadjuvant cisplatin plus 5-FU, there was a significant survival benefit (hazard ratio 0.88, 95% confidence interval [CI] = 0.79 to 0.97).[3] Additionally, since metastases are decreased using neoadjuvant chemotherapy, it is possible with improved locoregional treatment modalities that neoadjuvant chemotherapy may further improve survival rates.

As mentioned, organ preservation may be possible with the use of neoadjuvant chemotherapy. This has been demonstrated in two well-conducted randomized trials. One is the randomized trial conducted by the Veterans Administration Cooperative Study Program. In this study, patients with advanced laryngeal cancer were randomized to standard therapy with surgery and postoperative RT or to three cycles of neoadjuvant cisplatin and 5-FU followed by RT.[1] Response was assessed after two cycles of chemotherapy. Partial and complete responders continued with a third cycle of chemotherapy. Only patients who failed to respond to the first two cycles of chemotherapy or had residual disease after RT proceeded with surgery on the experimental study arm. Two goals were pursued in this study: improved survival and larynx preservation. The 2-year actuar-

ial rates of overall survival were identical in the two groups at 68%. The most important finding was the high rate of larynx preservation. Sixty-four percent of patients on the chemotherapy arm had their larynges preserved, with a median follow-up of 33 months. Thirty-nine percent of patients remained disease free with an intact larynx. Only two salvage laryngectomies were performed after the first year. A similar

rate of disease-free survival with larynx preservation (28%) was achieved in another study with similar design in hypopharyngeal cancer.[2]

Generally, based on these two studies, all patients with laryngeal or hypopharyngeal carcinoma who would otherwise be required to have total laryngectomy or pharyngolaryngectomy should be offered organ preservation therapy. The protocol used in the Department of Veterans Affairs larynx trial is acceptable at a minimum, although the addition of concomitant chemotherapy to RT is likely to further improve survival and organ preservation. It should be noted that in the MACH-NC meta-analysis, the inclusion of a third small larynx preservation study has created a nonsignificant negative effect of chemotherapy, although a similar outcome continues to exist in the two major studies. An ongoing Intergroup study is currently aimed at determining optimal larynx preservation strategy and compares RT alone versus RT with neoadjuvant or concomitant chemotherapy. It is notable that several new aggressive multiagent neoadjuvant chemotherapy regimens, given prior to RT, are showing promise at improving survival further.

Neoadjuvant chemotherapy has not conclusively improved survival, and its use remains investigational for sites other than the larynx and hypopharynx. Ongoing roles include organ preservation in larynx and hypopharynx cancer and a possible role in the treatment of nasopharyngeal cancer. Finally, the neoadjuvant setting may serve as an appropriate time to test promising new chemotherapy agents or drug combinations.

Adjuvant Chemotherapy

Adjuvant chemotherapy generally refers to the postoperative (or post-RT) use of chemotherapy to reduce the risk of recurrence. This strategy is clearly effective in breast and colon cancer, along with several other malignancies. In HNC, this strategy has been difficult to implement and not very successful and is therefore rarely used today.

Combined Radiation and Chemotherapy

Concomitant, or simultaneous, chemotherapy and RT (CRT), as opposed to neoadjuvant chemotherapy, does have a large and growing role in the treatment of locoregionally advanced HNC. Because HNC manifests clinically predominantly as a *locoregional* disease, concomitant chemoradiotherapy is valuable because it focuses early treatment on the site that determines prognosis. Clinical trials have proven the utility of CRT, which was hypothesized as useful for some of the following reasons: chemotherapy drugs and RT may be active against different tumor cell populations, based on factors such as cell-cycle specificity, pH, or oxygen supply. Cells that are resistant to one modality of treatment may respond to the other. Some chemotherapy drugs may "recruit" cells from the G_0 phase of the cell cycle to the more RT-responsive cell-cycle phases. Chemotherapy may shrink tumors, allowing for improved efficacy of RT by decreasing tumor interstitial pressure and increasing blood flow and oxygen delivery. Early eradication of tumor cells in the radiation field may prevent the emergence of drug or RT resistance; early treatment of microscopic tumor spread outside the RT field may allow for the eradication of microscopic metastases. Chemotherapy may prevent inherent causes of resistance to RT such as tumor cell repopulation between RT fractions and sublethal radiation damage and may inhibit recovery from potentially lethal radiation damage.[54,55]

Although a number of drugs can enhance the efficacy of RT, most also increase the damage to normal tissue. Thus, the balance of efficacy and toxicity with respect to the patient and tumor characteristics is a determining factor for the use of a particular CRT regimen. A large number of chemotherapeutic drugs and combinations have been used in conjunction with radiation.[54–69] A brief overview of the results will be considered.

There are several clinical settings in which CRT may be used, and these will be addressed individually. Unresectable locoregionally advanced HNC is clearly better treated with CRT than RT alone in most settings. In the postoperative setting, several studies suggest that CRT, for high-risk patients, confers an advantage over RT alone.[57,62] For patients with resectable disease who, for medical reasons or refusal of surgery, are to receive nonsurgical treatment, CRT is generally superior to RT alone. Chemoradiotherapy has not been directly compared to surgery and RT for resectable and operable patients; however, comparison with phase II and phase III CRT arms of other studies suggests that appropriately administered intensive CRT may be at least equivalent to surgery plus RT.[56,58,64,69]

TABLE 57–4. Randomized Studies of Concomitant Chemoradiotherapy versus Radiotherapy Alone

Authors/Year	*Patients (N)*	*Chemotherapy (+ RT in All)*	*Overall Survival (%) Chemotherapy/ Control*	*Comments*
Single-agent cisplatin or 5-FU				
Browman et al[60]	175	5-FU infusion	(2 y) 63/50 ($p = .08$)	
Lo et al[65]	151	5-FU bolus	(5 y) 32/14 ($p < .05$)	
Jeremic et al[63]	130	Cisplatin, daily	(5 y) 46/25 ($p = .008$)	Hyperfractionated RT
Bachaud et al[57]	83	Cisplatin, weekly	(5 y) 38/13 ($p < .01$)	
Combination chemotherapy				
Taylor et al[67]	214	Cisplatin, 5-FU	(2.5 y) 41/36	CRT was "split course," control group was neoadjuvant cisplatin/5-FU→RT
Merlano et al[66]	157	Cisplatin, 5-FU	(3 y) 41/23 ($p < .05$)	Chemotherapy alternated with RT
Brizel et al[58]	116	Cisplatin, 5-FU weeks 1, 6	(3 y) 55/34 ($p = .07$)	Hyperfractionated RT
Wendt et al[69]	270	Cisplatin, 5-FU weeks 1, 4, 7	(3 y) 48/24 ($p < .0003$)	Hyperfractionated RT
Adelstein et al[56]	100	Cisplatin, 5-FU weeks 1, 4	(5 y) 50/48	Far less salvage surgery needed in chemotherapy arm
Calais et al[61]	226	Carboplatin, 5-FU, weeks 1, 4, 7	(3 y) 51/31 ($p = .02$)	
Al-Sarraf et al[74]	295	Arm A, RT; Arm B, cisplatin; weeks 1, 4, 7, or Arm C, cisplatin, 5-FU weeks 1, 5, 9	(3 y) 20/37/29 (for RT/cisplatin/ cisplatin, 5-FU) ($p = .016/.13$)	Arm C had 4-week RT break (weeks 5 to 8)

RT = radiotherapy; 5-FU = 5-fluorouracil; CRT = chemotherapy and radiation therapy.
All studies used cisplatin, 5-FU, or the combination of cisplatin (or carboplatin) and 5-FU. Several principles are demonstrated, including the superiority of CRT over RT for unresectable patients and the superiority of CRT (hyperfractionated) over hyperfractionated RT alone.

Representative randomized studies in which cisplatin (or carboplatin) and/or 5-FU were used concomitantly with RT are detailed in Table 57–4.

Unresectable Head and Neck Cancer

There is great variability on the definition of resectability, which is highly dependent on the surgeon's and patient's opinion and preferences. This is, of course, an important factor in interpreting the outcome in trials of patients with "unresectable" HNC. Despite these problems, historically, long-term survival with RT alone for unresectable HNC has been 10 to 30%. Numerous trials have been performed over the last two to three decades in which patients with unresectable

HNC have been randomized to receive RT with or without concomitant chemotherapy. Multiple different drugs have been used, alone or in combination, on various schedules with respect to timing of chemotherapy, dose of radiation, etc. Some general conclusions can be drawn from these studies, particularly from three recent, large-scale meta-analyses.[3–5] In general, CRT using most single-agent chemotherapy drugs studied have produced locoregional control and survival superior to RT alone. Comparisons have not been directly made between the various radiosensitizing chemotherapy drugs. The most frequently used and perhaps best single-agent chemotherapy drugs are 5-FU and cisplatin. Although they have not been directly compared to RT alone, paclitaxel and docetaxel are also commonly used. Several other drugs are effective but less commonly used because of concerns about side effects or inferior efficacy. Many combination regimens have been used, the most effective of which appears to be the combination of cisplatin and 5-FU. The combination of carboplatin and paclitaxel is undergoing rigorous study based on its potential efficacy and relative tolerability.[70] The combination of 5-FU and hydroxyurea has been extensively studied at the University of Chicago and appears to be a synergistic regimen, which may be as effective or more effective than cisplatin and 5-FU.

Results from the three mentioned meta-analyses have mostly involved unresectable patients. In the summary meta-analysis by El-Sayed and Nelson of 11 studies of concomitant CRT for which there were adequate survival data, a relative reduction in the hazard of death of 22% was found (95% CI = 8 to 33%, $p < .005$).[5] Another meta-analysis by Munro of 16 trials found an absolute benefit of 12% (95% CI = 5 to 19%).[4] More recently, the MACH-NC Cooperative Group performed an individual patient meta-analysis involving over 10,000 patients.[3] The hazard ratio of death in the concomitant group was 0.81 (95% CI = 0.76 to 0.88), representing an improvement in survival from 32 to 40% at 5 years. The subset of trials using multiagent chemotherapy demonstrated a hazard ratio of 0.69! The benefit of CRT must be weighed against the increased toxicity that occurs with its use. Acute mucositis, dermatitis, and chemotherapy-specific side effects are greater. Short-term gastric feeding devices are needed more frequently, and although few data exist, long-term pharyngeal dysfunction may be more common with CRT.

The latest generation of studies continues to show improved survival with aggressive CRT. This advantage is maintained even when chemotherapy is added to hyperfractionated RT,[58,63,69] so the benefit of chemotherapy is not solely owing to more intensive treatment but rather to a true radioenhancing effect.

Postoperative Adjuvant Chemoradiotherapy Only a few studies have prospectively assessed postoperative use of CRT versus RT alone in a randomized setting. In one study of 83 patients with stage III or IV HNC who had surgery but had extracapsular lymph node spread, patients were treated with RT alone or with RT plus weekly cisplatin. The combined-modality group experienced improved locoregional control as well as improved overall survival (36 versus 13% 5-year overall survival, $p < .01$).[57] In a second trial from Yale University, over 200 patients were treated with RT or RT plus mitomycin.[62] Sixty percent of patients were treated postoperatively. The combined-modality group experienced improved locoregional control and cause-specific survival. Other studies are currently completing accrual and will be published in the next few years.

Chemoradiotherapy in Resectable Head and Neck Cancer Until quite recently, CRT has had a lesser role in resectable HNC. It is now becoming more widely accepted that at least some intensive CRT programs, when used to treat patients who are appropriately medically fit, can yield results that appear to be comparable and in some cases better than definitive surgery plus RT. As of the time of the writing of this chapter, however, this concept had not yet gained universal acceptance. It should be noted that even when primary site surgery is not initially used, the head and neck surgeon still plays a major role in diagnostic procedures, follow-up, neck dissection in some patients, and surgical salvage for CRT failures.

No randomized data have compared concomitant CRT to surgery ± RT. Several indirect comparisons suggest CRT as an alternative to surgery. Adelstein et al randomized 100 patients, mostly stage IV, to RT alone or RT plus concomitant cisplatin and 5-FU on weeks 1 and 4 of RT.[56] In the CRT arm, 5-year survival was 50%. Eleven patients required

surgical salvage, which was successful in 8. Overall survival with primary site preservation was 42%. Although survival was equivalent in the RT-only arm, 27 patients required surgical salvage, which was successful in 17. Brizel et al randomized 116 stage III and IV patients to hyperfractionated RT alone or chemotherapy (cisplatin and 5-FU) plus hyperfractionated RT.[58] The 3-year survival was 55% in the CRT arm, which is comparable to or better than most surgical series. Although the survival in the subset of patients with resectable disease (47% of patients) was not reported, it was likely as good as or better than the group as a whole. In a similar study, 130 mostly stage IV patients received hyperfractionated RT ± daily cisplatin.[63] Again, 47% of CRT patients were resectable and likely had an overall survival better than the 46% 5-year survival experienced by the group as a whole. Several phase II trials have also examined this issue. Kies et al administered three cycles of induction chemotherapy using cisplatin, 5-FU, leucovorin, and interferon-α followed by CRT with 5-FU, hydroxyurea, and radiotherapy to 93 stage IV HNC patients.[64] Although not specifically reported, a large number had potentially resectable disease. The 5-year survival of the group as a whole was 62%. Since, in general, resectable patients have less biologically aggressive disease, it is likely that the resectable patients, not specifically reported on, had an even better survival. Several other studies have yielded similar results.

Based on these and other data, it is our belief that stage III or IV patients with resectable disease, who are likely to have significant functional or cosmetic sequelae from their surgery and who will require postoperative RT anyway, can be offered an aggressive definitive CRT regimen if they are medically fit.

Three published trials randomized patients into either concomitant radiation and combination chemotherapy or induction chemotherapy (using the same drugs) followed by radiation. The groups receiving concomitant therapy generally had a better disease-free and overall survival.

In summary, randomized clinical trials have shown survival benefits by combining single-agent or combination chemotherapy with radiation. However, treatment is intensive, with potential acute and chronic side effects that need to be considered in ongoing and future studies.

TREATMENT OF OTHER RARE TUMORS OF THE HEAD AND NECK

Salivary Gland Tumors

These tumors are usually treated with surgery and radiation. Chemotherapy has a palliative role only. The role of chemotherapy as a radiosensitizer for salivary gland tumors is not well studied. Because of the rarity of these tumors, as well as their heterogeneity, the entire spectrum of chemotherapy drugs has not yet been tested. The combination of cyclophosphamide, doxorubicin, and cisplatin (the "CAP" regimen) is the most active known combination.

Nasopharyngeal Carcinoma

Chemotherapy plays a crucial role in nasopharyngeal cancer. Because of the location of these tumors and the existence of other treatment options, surgery is generally not used. Early-stage nasopharyngeal tumors are generally treated for cure with RT alone. Stage III or IV tumors can be cured with RT alone, but the combination of chemotherapy and RT nearly doubles the cure rate. The most compelling study results are from an Intergroup trial in the United States that randomized 147 patients to RT alone or concomitant cisplatin and post-RT cisplatin and 5-FU. The study was stopped early when a significant difference in 2-year survival was noted in favor of the chemotherapy arm. The 3-year survival rates in the chemotherapy and nonchemotherapy groups, respectively, were 78 and 47% ($p = .005$).[71] Early follow-up of another study of 321 patients in an endemic area of Asia confirmed similar results.[72]

Metastatic undifferentiated carcinoma, or lymphoepithelioma, of the nasopharynx is highly sensitive to chemotherapy. In four consecutive studies of a total of 165 patients treated with cisplatin-containing regimens for metastatic lymphoepithelioma, 19% achieved a CR, and 64% responded with at least a partial response.[73] Twelve percent of patients were free of disease at 3 years after chemotherapy, and 14 of 165 were still disease free at least 82 months. Chemotherapy plays an important role in nasopharyngeal cancer and should now be considered a standard part of treatment for all but the few early-stage cases. The optimal timing and role of chemotherapy remain to be determined.

PREVENTION

Head and neck cancers are primarily caused by smoking and chewing tobacco. Primary prevention, therefore, continues to be of paramount importance. It has also been seen that patients with HNC who continue to smoke during RT have a lower RR and survival than those patients who quit, even at that stage. Patients with HNC treated successfully with surgery or radiation develop second primary cancer (mostly in the head and neck or lung) at an annual rate of 3 to 7%. Strategies have been devised to prevent the second primary cancers by administration of chemicals that suppress carcinogenesis and thus prevent invasive cancer. This strategy, known as chemoprevention, has assumed great importance in recent years. Lippman and Matrisian recently reviewed the dynamics of progression from normal cells to invasive oral cancers and pointed out the molecular changes that occur during progression and identified targets for chemoprevention.[48]

The premalignant lesion of HNC is usually leukoplakia. Several studies have examined the ability of synthetic (such as 13-*cis*-retinoic acid) and natural retinoids in reversing leukoplakia. Initial studies indicated a high RR but also a rapid relapse when therapy is stopped. Likewise, randomized studies to date have not demonstrated the success of retinoids in preventing the progression of premalignancy to malignancy.

High-dose 13-*cis*-retinoic acid has also been shown in some studies to reduce the development of second cancer after treatment of primary head and neck tumors. A large randomized study is currently under way to evaluate the role of retinoids in secondary prevention in this disease.

SUMMARY AND CONCLUDING REMARKS

In the past several years, chemotherapy has assumed an expanded and important role in the management of HNC. Once used purely, and relatively ineffectively, for palliation, chemotherapy now has diverse roles. Given concomitantly with RT, chemotherapy enhances cure rates in comparison with RT alone. Chemotherapy can be used prior to definitive RT for larynx or hypopharyngeal cancer without sacrificing survival opportunity and allowing for possible larynx preservation. For metastatic or incurable HNC, chemotherapy continues to be palliative. Several new chemotherapy drugs with novel mechanisms of action are in various stages of clinical trials and may provide an additional chance to increase cure rates for HNC.

CHAPTER 58

Nutrition of the Head and Neck Patient

Laurence J. DiNardo, MD, Elizabeth G. Miller, RD

Malnutrition has been reported in 30 to 50% of head and neck cancer patients.[1] Four factors are generally responsible for calorie and protein malnutrition in these individuals. First, the tumor itself may present a barrier to deglutition through obstruction or pain. Second, tumor metabolism remains constant despite changes in nutritional status. Consequently, starvation responses such as lipolysis are not used by tumor cells, and glucose is continuously derived from protein catabolism. Third, recent evidence suggests that cancer cachexia may be induced by catabolic factors secreted by tumor cells.[2] Finally, tumor treatment may induce anorexia through discomfort, obstruction, and loss of taste. Accelerated radiotherapy has been associated with grade 3 to 4 reactions necessitating nasogastric (NG) or percutaneous gastrostomy feedings in 26% of patients with a median weight loss of 4.1 kg.[3] Difficulties are not limited to high-dose, large-field radiation treatments. A significant decrease in body mass index (BMI) has been observed in 80% of patients undergoing radiation therapy for early laryngeal carcinoma despite dietetic consultation and protein/calorie supplementation.[4] Tables 58–1 to 58–3 list the possible consequences of cancer treatment—surgery, radiation, and chemotherapy—that may impact a patient's nutritional status.[5]

Conversely, complications resulting from modern, aggressive treatment regimens for head and neck cancer are exacerbated by poor nutrition. Patients receiving accelerated fraction radiation therapy, chemoradiation, or extended resection with free flap reconstruction are particularly at risk. Preoperative weight loss of greater than 10% has been identified as the most prominent nutrition-related factor in the development of postoperative complications.[1] In addition, preoperative weight loss of greater than 5% has been associated with higher mortality rates for men with head and neck cancer.[6]

Recent work has identified relationships among immune function, nutritional status, and postoperative wound infection. Malnourished head and neck cancer patients demonstrate a significantly lower human leukocyte antigen (HLA)-DR expression on monocytes than well-nourished, matched controls.[7] Theoretically, this places these patients at a higher risk for postoperative infection. Intervention with immune-enhancing formulas has resulted in a significant decrease in the incidence of postoperative infectious complications.[8]

ASSESSMENT OF NUTRITIONAL STATUS

Recognition and assessment of nutritional status are important to the management of the head and neck cancer patient. The initial nutritional assessment includes anthropometric, biochemical, clinical, and dietary history data.

Anthropometric Measurements

The percentage of weight loss (% wt loss) that a patient has experienced is the most common estimate of malnutrition. The patient's usual body weight (UBW) is defined as his or her weight 6 months prior to the assessment. Actual, or current,

TABLE 58–1. Surgery Related Nutritional Consequences

Nausea
Vomiting
Diarrhea
Cheilosis, glossitis
Pharyngitis
Esophagitis
Anorexia

body weight is then measured. The % wt loss is calculated as follows:

$$\% \text{ wt loss} = (\text{UBW} - \text{current wt})/\text{UBW} \times 100$$

Severe malnutrition is defined as greater than 10% weight loss in 6 months.[9]

A patient's height is needed to allow determination of ideal body weight (IBW), percent IBW (%IBW), and additional anthropometric measurements. Ideal body weight may be determined using reference values for a given height and frame size[10] or by the Hamwi method[11]:

- For men: 106 pounds for the first 5 feet, with an additional 6 pounds for each inch over 5 feet
- For women: 100 pounds for the first 5 feet, with an additional 5 pounds for each inch over 5 feet

Percent IBW is then calculated as follows:

$$\%\text{IBW} = \text{actual (current) wt}/\text{IBW} \times 100$$

The extent of malnutrition is then estimated as follows[9]:

- Mild malnutrition = 80 to 90% IBW
- Moderate malnutrition = 70 to 79% IBW
- Severe malnutrition = < 69% IBW

Another method for assessing weight status is by determination of BMI:

$$\text{BMI} = \text{wt (kg)}/\text{ht}^2\,\text{(m)}$$

Once calculated, the patient's BMI is compared to reference values:

- Underweight: BMI < 18.5
- Adequate weight: BMI = 18.5 to 24.9
- Overweight: BMI = 25 to 29.9
- Obese: BMI > 30

Further assessment of a patient's nutritional status using anthropometric data can be performed through measurement of triceps skinfold thickness and mid-arm muscle circumference using skinfold calipers and a measuring tape. These determine the adequacy of a patient's fat and somatic protein, or skeletal muscle status. Given inconsistency in measurements among clinicians and the influence of hydration on results, these are now uncommonly performed tests. Body fat, lean body mass, and total body water can be calculated from bioelectrical impedance analysis and may be used as a bedside measurement of a patient's fluid status.[12]

Biochemical Assessment

Assessment of laboratory data comprises another facet of the nutritional status evaluation. The serum proteins that are often used to assess nutritional status include albumin, transferrin, and prealbumin or transthyretin. Each have different synthesis rates and half-lives; therefore, these parameters vary in their reflection of alterations in nutritional status.

The general availability of albumin measurement renders it a useful test. It reflects visceral protein status. Since it has a long half-life of approximately 20 days, however, it does not detect early protein deficiency. Various levels of depletion have been defined[9]:

- Adequate = > 3.5 g/dL
- Mild depletion = 2.7 to 3.5 g/dL
- Moderate depletion = 2.1 to 2.6 g/dL
- Severe depletion = < 2.1 g/dL

Albumin is influenced by many non-nutritional variables, including hydration status, liver or renal

disease, sepsis, trauma, surgery, and congestive heart failure, as well as infusion of albumin, fresh frozen plasma, or whole blood. Unfortunately, this necessitates cautious interpretation of albumin values.

In protein-calorie malnutrition from cancer-related cachexia, there appears to be an insufficient supply of amino acids for liver protein synthesis, resulting in a decline in serum albumin. A decline in serum albumin is correlated with cachexia and is a predictor of mortality. In cancer patients, postoperative complications are more frequent with serum albumin < 3.0 g/dL. Decreased tube feeding tolerance has also been observed with a serum albumin < 2.5 g/dL.

Transferrin is more useful than albumin as a measure of visceral protein status. Owing to its relatively short half-life (8 days), it is more sensitive to short-term changes in nutrient intake. The degree of malnutrition relative to serum transferrin levels is as follows:

- Adequate = 200 to 400 mg/dL
- Mild malnutrition = 180 to 200 mg/dL
- Moderate malnutrition = 160 to 180 mg/dL
- Severe malnutrition = < 160 mg/dL

As with albumin, transferrin can be impacted by non-nutritional variables. Levels may be increased with iron deficiency anemia, some malignancies, acute hepatitis, oral contraceptive use, and pregnancy. Levels may be decreased with chronic infection, cancer, iron overload, liver disease, and protein-losing enteropathy. Despite its shorter half-life, transferrin is not as commonly used as albumin or prealbumin in evaluating malnutrition and visceral protein status.

Prealbumin, also named transthyretin or thyroxine-binding globulin, has a half-life of 2 to 3 days and therefore has replaced the transferrin assay in many institutions. Its shorter half-life makes it a sensitive indicator of visceral protein status. It is most useful when assessing a patient for acute changes in nutritional status and short-term response to nutritional support through weekly measurements. Assessment of visceral protein status based on the serum transthyretin value is estimated as follows:

- Adequate = 18 to 42 mg/dL
- Mild depletion = 13 to 17 mg/dL
- Moderate depletion = 8 to 12 mg/dL
- Severe depletion = ≤ 7 mg/dL

Prealbumin levels are also impacted by non-nutrition factors. Levels can be increased with renal dysfunction, dehydration, and blood transfusions. Levels may be decreased by stress, surgery, inflammation, cirrhosis, hepatitis, and hyperthyroidism.

Retinol-binding protein, with a half-life of 10 hours, measures acute protein deprivation or minor stress. Normal values range from 2.6 to 7.6 mg/dL.

Evaluation of immune function can also provide information relevant to the patient's nutritional status and serves as a predictor of postoperative complications. In the past, intradermal antigen challenge for the detection of delayed hypersensitivity was used as a measure of immune competence. It has fallen out of favor owing to its lack of specificity. Total lymphocyte count (TLC) is currently the most frequently employed test of immune status in the head and neck cancer patient. It is calculated as follows[1]:

$$\text{TLC} = \frac{[\%\ \text{lymphocytes} \times \text{white blood count (WBC)}]}{100}$$

Immune competence is then evaluated as follows[9]:

- Adequate immunocompetence = > 1,800 mm^3
- Mild depletion = 1,500 to 1,800 mm^3
- Moderate depletion = 900 to 1,500 mm^3
- Severe depletion = < 900 mm^3

The use of TLC as an indicator of nutritional status is limited since marked changes can occur in the WBC and differential counts on a day-to-day basis. Also, numerous non-nutrition-related factors can alter the value, such as severe stress, infection, corticosteroid therapy, cancer, renal failure, surgery, and cancer treatments such as radiation therapy and chemotherapy.

Several parameters have been combined to create the prognostic nutritional index (PNI), which has been defined by various formulas.[1] An example:

$$\text{PNI} = [0.14 \times \text{alb (g/dL)}] + [0.03 \times \%\text{IBW}] + [0.73 \times \text{TLC } (10^9/\text{mm}^3)] - 8.90$$

A correlation between the PNI and surgical risk in patients with head and neck cancers has been observed. A value less than 1.31 is considered below normal.

Clinical Data and Dietary History

The physical examination is an important component of the nutritional status assessment. Physical

findings that imply vitamin, mineral, and protein-calorie deficiencies and excesses are listed in Table 58–4. However, most of the physical findings are not specific for individual nutrient deficits and must be considered together, along with diet history, anthropometric data, and laboratory results.

A diet history is used to identify underlying risks for nutrition depletion or excess. Causes include inadequate intake, compromised metabolism (altered absorption, decreased use, or increased losses), and heightened requirements for nutrients. Patients with the characteristics included in Table 58–5 have increased susceptibility for nutritional problems.[13]

The diet history of the head and neck cancer patient should include questions about alcohol consumption. When alcohol is substituted for good nutrition, malnutrition owing to inadequate nutrient intake occurs. Alcoholic persons are prone to develop malabsorption of nutrients owing to inflammation of the gastrointestinal tract. Altered absorption or metabolism of thiamin, folic acid, pyridoxine, vitamin A, vitamin B_{12}, sodium, potassium, magnesium, calcium, phosphorus, zinc, and selenium can result. Long-term alcoholism can also induce cirrhosis, with the potential development of ascites and/or hepatic encephalopathy. Glucose intolerance may be observed in alcoholics secondary to pancreatic inflammation or injury.

Commonly used methods for obtaining a diet history include the 24-hour recall, a 1- to 7-day food intake record, and a food frequency questionnaire. A number of computer programs allow rapid estimation of nutrient intake based on these records or questionnaires. It is important to remember that in the course of the complete medical history, information elicited from the patient in all of the areas noted in Table 58–6[13] will aid in identifying possible nutrient deficits not gathered from the dietary recall.

ASSESSMENT OF NUTRITIONAL NEEDS

The assessment of nutritional needs must include calorie, protein, lipid, vitamin, mineral, and water requirements. Calorie and protein needs vary depending on several factors: (1) a patient's current nutritional status, (2) whether the need is for maintenance or repletion, (3) whether a patient is at risk for refeeding syndrome, and (4) whether a patient is in a catabolic state. Adult daily calorie requirements are estimated at 30 to 35 kilocalories per kilogram of body weight (kcal/kg).[14] As many as 10 kcal/kg body weight may be added to regain lost weight and compensate for surgical stress. The Harris-Benedict equation was derived to estimate more accurately a patient's basal energy expenditure (BEE), the energy expended at rest[15]:

$$\text{For men: BEE} = 66.47 + [13.75 \times \text{wt (kg)}] + [5.0 \times \text{ht (cm)}] - [6.76 \times \text{age (y)}]$$

$$\text{For women: BEE} = 665.10 + [9.56 \times \text{wt (kg)}] + [1.85 \times \text{ht (cm)}] - [4.68 \times \text{age (y)}]$$

In general, to calculate the total calorie need of a head and neck cancer patient, the BEE is multiplied by a stress and activity factor totaling 1.3 to 1.5, with the higher number used for sepsis or other hypermetabolic states. If weight gain or nutritional repletion is desired, approximately 500 to 1,000 calories/day is added to the total calorie need. Since these calculations are estimates and not based on actual measurement of caloric expenditure, frequent monitoring of a patient's response to the nutrition regimen is required.

Acceleration in protein turnover and derangements in protein metabolism have been observed in cancer patients. In contrast to simple starvation, protein use increases when a cancer patient is under metabolic stress. Protein needs are usually calculated based on actual or adjusted body weight. The approximate protein need can then be adjusted based on the degree of protein depletion and metabolic stress factors. Under normal conditions with no stress, protein requirements are estimated at 1.0 g/kg/day. For the well-nourished, mildly stressed cancer patient, the protein need may only be 1.2 g/kg/day. However, with mild to moderate depletion along with metabolic stress, up to 1.5 g/kg/day may be necessary. If a head and neck cancer patient undergoes surgery with reconstruction, protein needs for healing may be up to 2.0 g/kg/day. The amount of protein provided may require further adjustments if renal or liver disease is present.

The best method to determine if protein needs are met in the malnourished patient is by monitoring for gradual weight gain and positive nitrogen balance. In the well-nourished patient, weight maintenance and nitrogen equilibrium are the goals.

TABLE 58–4. Physical Findings and Associated Nutrient Deficiencies/Excesses

Finding	*Deficiency*	*Excess*
Hair and nails		
Transverse hair depigmentation	Protein	
Sparse hair	Protein, biotin, zinc	Vitamin A
Corkscrew hair	Vitamin C	
Transverse nail ridging	Protein	
Skin		
Scaling	Vitamin A, zinc, fatty acids	Vitamin A
Cellophane appearance	Protein	
Cracking dermatitis	Protein	
Follicular hyperkeratosis	Vitamins A, C	
Petechiae	Vitamin C	
Purpura	Vitamins C, K	
Pigmentation, desquamation of sun-exposed areas	Niacin	
Yellow pigmentation-sparing sclerae		Carotene
Eyes		
Papilledema		Vitamin A
Night blindness	Vitamin A	
Perioral		
Angular stomatitis	Riboflavin, pyridoxine, niacin	
Cheilosis	Riboflavin, pyridoxine, niacin	
Oral		
Atrophic lingual papillae	Riboflavin, niacin, folate, vitamin B_{12}, protein, iron	
Glossitis	Riboflavin, niacin, pyridoxine, folate, vitamin B_{12}	
Hypogeusia, hyposmia	Zinc	
Swollen, retracted, bleeding gingiva	Vitamin C	
Neurologic		
Headache		Vitamin A
Drowsiness, lethargy, vomiting		Vitamins A, D
Dementia	Niacin, vitamin B_{12}, folate	
Confabulation, disorientation	Thiamin	
Ophthalmoplegia	Thiamin, phosphorus	
Peripheral neuropathy	Thiamin, pyridoxine, vitamin B_{12}	Pyridoxine
Tetany	Calcium, magnesium	
Other		
Parotid enlargement	Protein (consider bulimia)	
Heart failure	Thiamin, phosphorus	
Hepatomegaly	Protein	Vitamin A
Edema	Protein, thiamin	
Poor wound healing, decubitus ulcers	Protein, vitamin C, zinc	

TABLE 58–5. Patients at High Risk for Nutritional Deficits

Underweight: less than 80% standard and/or recent loss greater than 10% usual body weight
Poor intake: anorexia, nothing by mouth more than 5 days
Protracted nutrient loss: malabsorption, enteric fistulae, draining abscesses or wounds, renal dialysis
Hypermetabolic state: sepsis, fever, extensive burn, or trauma
Chronic alcohol/drug use: corticosteroids, antimetabolites, immunosuppressants
Impoverishment, isolation, advanced age

Weekly serial monitoring of a patient's prealbumin or transthyretin level is another method for tracking protein supplementation.

Ideally, ≤ 30% of nonprotein calories should be derived from fat. The appropriate administration of essential fatty acids helps to blunt the insulin response by decreasing the need for infusions rich in glucose. Deriving calories from fat also has a protein-sparing effect.[16] Using greater amounts of fat in combination with less glucose is especially important in patients with diabetes mellitus in whom fat can provide as much as 60% of nonprotein calories.

Although recommended daily doses of vitamins, minerals, and trace elements exist,[17] requirements for nutritionally depleted cancer patients have not been established. It is recommended that patients requiring prolonged parenteral nutrition receive regular doses of multivitamins and trace elements. More definitive guidelines will likely evolve as knowledge is gained regarding the role of vitamins, minerals, and trace elements in critically ill patients. Experimental evidence exists in mice, for example, which demonstrates increased survival in endotoxin shock with the administration of vitamin D analogues.[18]

NUTRITIONAL SUPPORT

Whenever possible, nutritional support should be provided through the enteral route. The use of an intact gastrointestinal tract is not only more cost effective, safer, and more practical than parenteral nutrition, it also maintains the integrity of the gut mucosal barrier and immune function.[19] In addition, no survival advantage or reduction in treatment toxicity has been demonstrated with the routine administration of total parenteral nutrition in cancer patients.[20]

Oral alimentation should always be considered first. Simple interventions such as the eradication of oral candidiasis or the treatment of mucositis may facilitate oral intake. Nutrition counseling and provision of nutritional supplements can further support oral intake in head and neck cancer patients. Nutritious liquid formulas can be taken by mouth when other foods cannot be tolerated. The administration of appetite stimulants such as megestrol acetate has been advocated in patients with cancer-related anorexia or cachexia. The risk of side effects such as adrenal suppression, hyperglycemia, and thromboembolic events must be considered with this medication.[21] However, if surgery, radiation, or chemotherapy side effects prevent a patient from taking oral liquids, nutritional support can be provided via a feeding tube. Despite the ability to take some oral nutrition, the seriously malnourished patient should be considered for early feeding tube placement owing to the impending side effects of cancer therapy. A review of head and neck cancer patients who were treated with radiation therapy found that early initiation of enteral nutrition lowered the need for treatment breaks and possibly led to enhanced treatment efficacy.[22]

Types and Selection of Feeding Tubes

Enteral feeding involves the administration of nutrient solutions through a tube into the upper gastrointestinal tract. There are two major routes for tube placements: those entering the gastrointestinal tract via the nose (NG and nasointestinal) and those entering the gastrointestinal tract through the abdominal wall (gastrostomy, duodenostomy, jejunostomy). Occasionally, a feeding may be given through a tube inserted in the mouth (orogastric) or esophagus (cervical esophagostomy).

The timing and type of enteral tube feeding are largely dependent on the anticipated duration of nutritional supplementation. Placement of a pliable red rubber or Dobbhoff tube for feeding is preferred if short-term nutritional support is expected. Nasogastric tube feeding should be restricted to short-term use owing to nasopharyngeal and laryngeal

TABLE 58–6. Nutrition History Survey

Mechanism of Deficiency	*History*	*Deficiency to Suspect*
Inadequate intake	Alcoholism	Calories, protein, thiamin, niacin, folate, pyridoxine, riboflavin
	Avoidance of fruit, vegetables, grains	Vitamin C, thiamin, niacin, folate
	Avoidance of meat, dairy products, eggs	Protein, vitamin B_{12}
	Constipation, hemorrhoids, diverticulosis	Dietary fiber
	Isolation, poverty, dental disease, food idiosyncrasies	Various nutrients
	Weight loss	Calories, other nutrients
Inadequate absorption	Drugs (especially antacids, anticonvulsants, cholestyramine, laxatives, neomycin, alcohol)	Varies, dependent on drug
	Malabsorption (diarrhea, weight loss, steatorrhea)	Vitamins A, D, and K; calories; protein; calcium; magnesium; zinc
	Parasites	Iron, vitamin B_{12} (fish tapeworm)
	Pernicious anemia	Vitamin B_{12}
	Surgery Gastrectomy Intestinal resection	Vitamin B_{12} (if distal ileum), iron, others as in malabsorption
Decreased utilization	Drugs (especially anticonvulsants, antimetabolites, oral contraceptives, isoniazid, alcohol)	Varies, dependent on drug
	Inborn errors of metabolism (by family history)	Various nutrients
Increased losses	Alcohol abuse	Magnesium, zinc
	Blood loss	Iron
	Paracentesis (ascitic, pleural)	Protein
	Diabetes, uncontrolled	Calories
	Diarrhea	Protein, zinc, electrolytes
	Draining abscesses, wounds	Protein, zinc
	Nephrotic syndrome	Protein, zinc
	Peritoneal dialysis or hemodialysis	Protein, water-soluble vitamins, zinc
Increased requirements	Fever	Calories
	Hyperthyroidism	Calories
	Physiologic demands (infancy, adolescence, pregnancy, lactation)	Various nutrients
	Surgery, trauma, burns, infection	Calories, protein, vitamin C, zinc
	Tissue hypoxia	Calories (inefficient utilization)
	Cigarette smoking	Vitamin C, folate

irritation as well as potential for necrosis of the nasal alae. With the placement of an NG tube, the patient can be weaned quickly from intravenous hydration after surgery, receive adequate nutrition postoperatively, and have access for medications. If there is difficulty transitioning to complete oral intake, then the patient is considered for placement of a percutaneous endoscopic gastrostomy (PEG), which is more appropriate for long-term feeding. If it is anticipated that the patient will require long-term tube feeding postoperatively, a PEG tube can be placed intraoperatively. Intraoperative PEG tube placement has been associated with fewer complications than preoperative insertion.[23] Open or laparoscopic gastrostomy tube placement is considered in cases for which PEG placement is not feasible.

Intestinal feedings are indicated when gastric reflux results in aspiration, with depressed gastric motility and emptying, with significant pulmonary disease, or when ulcer disease, cancer, or surgery involves the stomach. Tube feeding into the intestine may be provided via a nasointestinal tube, PEG-jejunostomy, or a surgical jejunostomy tube. If a patient is dependent on a feeding jejunostomy tube for medication administration, an 8 French tube or larger should be used to prevent clogging.

Tube Feeding Formulas

Numerous oral and tube feeding solutions are available. Some are intended for general nutrition; others are designed to meet specific metabolic or clinical needs. Occasionally, blenderized foods can be used for the provision of adequate nutrition by oral or feeding tube routes.

The majority of head and neck cancer patients are administered commercially available polymeric formulas. Polymeric formulas consist of macronutrients in the form of isolates of intact protein, fats, and carbohydrate polymers. In most of these solutions, protein makes up 12 to 20% of total calories; carbohydrates, 40 to 60%; and fats, 30 to 40%. In the standard formulas, the ratio of nonprotein calories to nitrogen is approximately 150 to 1. In the high-nitrogen formulas, this ratio is much lower, approximately 75 to 1. Table 58–7 provides an overview of these formulas.[24]

Polymeric formulas contain whole proteins isolated from casein, whey, lactalbumin, and egg white. The source of carbohydrate is usually glucose polymers from starch and its hydrolysates. The fats are from vegetable sources. Essential vitamins and minerals are present in sufficient amounts so that 100% of the United States Recommended Daily Allowance for each nutrient is met through a daily intake of 1,500 to 2,000 calories of the formula. The amounts of minerals such as sodium and potassium vary greatly, allowing for adjustment based on requirements.

Polymeric formulas are lactose free with a caloric density between 1 and 2 cal/mL. The higher-calorie formulas allow for more calories in a smaller volume and are therefore suitable for patients requiring fluid restriction. These high-osmolality formulas often are best initiated at half strength and advanced as tolerated to full strength while maintaining appropriate hydration. Modified, more costly, polymeric formulas have been devised to suit the needs of patients with renal failure, liver failure, and diabetes.

Monomeric formulas require less digestion than do regular foods or polymeric solutions. They are suitable for patients with impaired digestion. These formulas are rarely used in head and neck cancer patients with the exception of extremely low-fat preparations administered in the presence of a chylous fistula. Formulas with medium-chain triglycerides are also useful in the presence of a chyle leak since they enter the systemic circulation without passing through the thoracic duct.

Tube Feeding Administration

With an NG tube, placement in the stomach must be verified prior to each feeding and the head of the patient's bed elevated. Initiation of bolus feeding may range from 100 to 200 mL every 3 to 4 hours, with the final feeding provided to the patient no later than 11:00 pm. Feedings should be administered by gravity drip over 30 to 60 minutes. Advancement of feedings by 50 to 100 mL every shift (8h) or daily are performed as tolerated, and residuals are monitored until the tube feeding volume goal is attained.

Initiation of tube feeding through a surgically placed gastric tube is similar to NG tube feeding except a delay of as much as 48 hours after insertion is required to allow for maturation of the stoma and return of bowel function.

After PEG or percutaneous radiologic gastrostomy feeding tube placement, feeding can often be initiated within 12 hours. If bowel sounds are present, continuous delivery of water at 50 mL/hour can

begin within a few hours of insertion. If water is tolerated, feeding is initiated using a full-strength, isotonic formula infused at 50 mL/hour. Residuals should be monitored every 4 hours, and feeding is advanced as with an NG or gastric tube.

Feeding into the intestine requires an intermittent or continuous pump-assisted delivery of formula since bolus amounts and hyperosmolarity can lead to diarrhea. After placement of a nasointestinal (nasoduodenal or nasojejunal) tube, feedings are administered over a 12- to 24-hour period and should be started at an isotonic level (300 mOsm) or at a low rate (10 to 15 mL/hour). The rate of infusion may be increased every 8 to 24 hours as tolerated until the desired volume is reached. The rate and concentration of the formula should not be increased simultaneously.

Administration of formula through a feeding jejunostomy tube is identical to a nasointestinal feeding tube except feeding initiation may not begin for 12 to 24 hours after tube placement. With a PEG/jejunostomy, initiation is the same as for a PEG except a continuous infusion of formula is required.

Feeding Tube Complications

Tube Clogging If a feeding tube becomes clogged, any enteral solution remaining in the tube should be withdrawn. To remove any obstruction, the following steps are attempted: (1) Inject 5 mL of warm water into the tube and clamp for 5 minutes. Flush with water until clear; if the tube remains clogged, then (2) inject a bolus (20 to 30 cc) of air to dislodge the clog. If the air seems to free the obstruction, follow it with 30 to 50 mL of warm water, cola, or cranberry juice to cleanse the tube. If the tube remains clogged, (3) crush one 324 mg sodium bicarbonate tablet. Mix the powder with the contents of one pancrelipase (Cotazym or Viokase) capsule and 5 mL of sterile water. Inject the alkalinized enzyme mixture into the tube and clamp it for 5 minutes. Flush the tube with water until clear. If the aforementioned techniques fail, the tube should be replaced.

Formula–Drug Interactions Formula–drug interactions resulting in delayed or diminished drug absorption are outlined in Table 58–8.[25] In addition, physical incompatibilities between enteral formulas and medications may result in tube obstruction, as detailed in Table 58–9.[25]

Diarrhea Diarrhea is defined as an increase in the quantity and/or frequency of bowel movements. Diarrhea has been reported to occur in approximately 30% of patients receiving tube feeding.[26] However, tube feeding itself is often not the cause.[27] Potential causes of diarrhea include (1) an inappropriate rate of formula infusion, (2) impaired functional capacity of the gastrointestinal tract, (3) hypoalbuminemia, (4) the concurrent use of antibiotics and other medications, (5) altered bacterial flora, and (6) enteral formula contamination.

The healthy gastrointestinal tract can handle intermittent feedings of as much as 500 mL given over 10 to 15 minutes. This feeding method has routinely been used with success in patients with dysphagia owing to cancer of the head and neck.[28] If diarrhea occurs, slower delivery of intermittent feedings or a change in the tube feeding product to one that is isotonic or contains fiber may be helpful.

Enteral nutrition-related diarrhea is often secondary to an osmotic effect, which is the result of the small intestine's inability to absorb specific nutrients. This condition is frequently associated with a decline in intestinal blood flow and absorptive capacity. Hypoalbuminemia, which is associated with poor water absorption by the colon, can also contribute to diarrhea. This is observed in patients with edema and fluid overload. Switching the enteral solution to a more calorie-dense product (1.5 to 2.0 cal/mL) will decrease free water intake and may help correct fluid balance. When serum albumin is severely low, intravenous infusion of albumin may be indicated to correct fluid balance and promote protein repletion.

The diarrhea resulting after tolerance to an enteral formula has been achieved may be attributable to bacterial overgrowth. This overgrowth is often caused by long-term antibiotic use. If suspected, stool cultures for *Clostridium difficile* should be performed and the patient treated with oral vancomycin or metronidazole as indicated. The use of a fiber-containing formula has been helpful in correcting loose stools in these cases. Antidiarrhea medications should be used with caution if an infectious cause of diarrhea is suspected.

Another potential cause of diarrhea is fecal impaction in which loose stool can leak around the area of impaction until the bowel is cleared. Medications, especially antacids, can also induce diarrhea and should be considered.

TABLE 58–8. Significant Drug–Nutrient Interactions

Medications	*Interaction*	*Possible Outcome*
Antibiotics		
Tetracycline	Decreased bioavailability with milk and dairy products	Treatment failure
Quinolones (ciprofloxacin/ norfloxacin)	Decreased bioavailability with milk and dairy products	Treatment failure
Azithromycin	Decreased bioavailability with food	Treatment failure
Antifungal		
Itraconazole	Increased bioavailability with food	Possible treatment failure if not administered with meals
Antiviral		
Didanosine Indinavir	Food decreases bioavailability	Treatment failure
Saquinavir	Food increases bioavailability	Increased antiviral activity if administered with meals
Warfarin	Vitamin K–rich foods antagonize the anticoagulant effect	Decreased anticoagulation
Cyclosporin	Food and grapefruit juice increase plasma levels	Possible toxicity, lower doses may be efficacious
Alendronate	Food decreases bioavailability	Treatment failure

Refeeding Syndrome Refeeding syndrome is a serious metabolic disturbance that may occur with the initiation of aggressive nutrition support in a patient with severely depleted nutrition stores. Significant compartmental shifts in phosphorus, magnesium, and potassium can be induced. These shifts, as well as sodium retention with resultant expansion of the extracellular space and associated increased circulatory demands, may prove disastrous.

Hypophosphatemia is potentially the most serious single consequence in refeeding syndrome.[29] In starvation, there is a slowing of the overall metabolic rate and, in particular, glucose oxidation. The need for phosphorus is low. When carbohydrates and glucose are reintroduced, this need dramatically rises and may surpass the rate at which phosphorus can be mobilized from bone. Cardiopulmonary failure and death may occur within days of feeding a previously starved but stable patient.

In patients at risk for refeeding syndrome, normal levels of phosphorus, potassium, and magnesium should be present prior to initiating nutrition support. Calorie repletion begins at less than 50% of need and is advanced over the course of a week to a goal of 30 cal/kg/day or less. If adequate renal and hepatic function exists, 1.5 g of protein/kg/day can also be administered. A daily multivitamin, mineral supplement, thiamin (100 mg/day), and selenium (50 μg/day) are recommended. Careful monitoring of vital signs, weight, and input and output, as well as electrolytes, is necessary during nutrition support of at-risk individuals.

Parenteral Nutrition

Parenteral nutrition is the intravascular administration of carbohydrates, protein, fat, vitamins, and minerals. Total parenteral nutrition involves nutrient administration into the superior vena cava, thereby allowing for the infusion of hypertonic solutions. Hyperalimentation solutions typically contain 25% glucose given at a gradually increasing infusion rate

TABLE 58–9. Mediations Incompatible with Enteral Nutritional Formulas

Product	*Incompatibility/Interaction*
Vitamin B elixir	Forms large particle clumping
Brompheniramine elixir	Forms adhesive gelatinous material
Brompheniramine phenylpropanolamine elixir	Enteral food breakdown
Calcium glubionate syrup	Adhesive gelatinous mass created
Chlorpromazine concentrate	Granulation occurs at point of mixing
Doxepin liquid	Feeding separates slightly with no clogging
Ferrous sulfate elixir	Completely gels and clogs feeding tubes
Guaifenesin expectorant	Viscous precipitate forms
KCl 10% and 20% liquid	Incompatible at mixing interface
KCl syrup	Enteral products become viscous and gelatinous
Lithium syrup	Enteral products form granular film
Medium-chain triglyceride oil	Immiscible with enteral products
Methenamine mandelate suspension forte	Mixture becomes gelatinous
Metoclopramide	Some feedings form thin granular formulation
Opium liquid	Separation, globular particle formation
Phosphosoda	Results in heavy or granular feedings
Pseudoephedrine syrup	Viscous gelatinous mass forms on mixing
Sucralfate	Solidifies formula
Thioridazine solution	Granule formation
Zinc sulfate capsules	May induce gelatinous or hard mass formation

toward a goal of 5 mg glucose/kg/minute. Insulin requirements must be closely monitored. Amino acids are administered in 2.5 to 5.0% solutions in sufficient quantity to ensure positive nitrogen balance. The remainder of noncarbohydrate calories is derived from fat emulsions. Peripheral partial nutrition supplements enteral feeding with the administration of a 10% glucose solution, amino acids, and fat emulsion through a peripheral vein.

Complications from parenteral nutrition are significantly higher than for enteral feeding and include sepsis, hyperglycemia, hypoglycemia, hyperlipidemia, hepatic dysfunction, electrolyte imbalance, and thrombophlebitis. The indications for parenteral nutrition in the head and neck patient are limited to gastrointestinal dysfunction or intractable aspiration of tube feedings. Occasionally, total parenteral nutrition is used to treat a chyle fistula not responsive to medium-chain triglyceride formulas.

Conclusion

Several factors conspire to induce malnutrition in the head and neck patient. It is necessary to identify and quantify nutritional deficits to replete losses adequately. Enteral feeding is desired with a functioning gastrointestinal tract, and various maneuvers exist to use an intact gut better. Nutrition repletion should be carefully monitored to allow the patient the potential benefits of increased treatment tolerance and perhaps improved survival.

CHAPTER 59

Imaging of the Oral Cavity, Pharynx, Larynx, Trachea, Salivary Glands, and Neck

Mahmood F. Mafee, MD

See Chapter 31 for the theoretical basis of computed tomography (CT) and magnetic resonance imaging (MRI).

ORAL CAVITY, OROPHARYNX, AND UPPER NECK

Imaging Anatomy

The detailed anatomy of the oral cavity and oropharynx can be found in Chapter 43. For the purpose of this chapter, the cross-sectional anatomy visible on CT and MR images will be reviewed and defined. Several CT and MR images of the normal oropharynx and upper neck are shown in Figure 59–1, A through H. For the purpose of uniformity, the scans are all spin density– or proton-weighted MRIs (see Figure 59–1). In axial CT sections or MRIs taken at the level of the floor of the mouth and tongue (see Figure 59–1, A through D), the oropharynx, palatine tonsils, submandibular glands, extrinsic and intrinsic muscles of the tongue, external and internal carotid arteries, internal jugular veins, and parts of the mandibles are among the many structures that are visualized clearly (see Figure 59–1). In axial CT or MRI sections taken at the level of the alveolar process of the maxilla, the soft palate is shown blending with the upper portion of the oropharynx (see Figure 59–1, G and H). The hard palate is limited laterally by the alveolar process of the maxilla. The medial pterygoid muscle is seen as a distinct quadrilateral image occupying a position on the inside of the ramus of the mandible (see Figure 59–1, E through H). Medial to the medial pterygoid muscles, the symmetric low-density (lucent) parapharyngeal spaces are shown. Also visualized are the masseter muscle, retromandibular vessels, parotid gland, styloid process, and retrostyloid neurovascular structures (see Figure 59–1). The differential enhancement of the vascular structures of the neck versus other structures is best demonstrated with the incremental CT dynamic technique. On spin echo MRIs, the vascular structures (arteries) are demonstrated as hypointense images (signal void). On magnetic resonance angiogram (MRA) and magnetic resonance venogram (MRV) without need for contrast injection, the vascular structures are seen as hyperintense images.

ORAL CAVITY, OROPHARYNX, HYPOPHARYNX, LARYNX, AND NECK

Imaging Pathology

Benign and malignant lesions of the oral cavity and oropharynx can be readily visualized with CT and MRI. Figure 59–2 shows a lymphangiohemangioma of the tonsillar region, and Figure 59–3 shows a carcinoma of the tonsil and soft palate with bilateral lymph nodal metastases. With MRI or CT, a primary tumor and metastatic lymph nodal involvement can often be readily identified (Figures 59–3 and 59–4). Figure 59–5 demonstrates the value of MRI, including MRA, in the evaluation of a recurrent tonsillar cancer and thrombosis of the internal jugular vein. Tumors of the tongue and floor of the mouth (Figure 59–6), posterior pharyngeal wall (Figure 59–7), and hypopharynx (Figure 59–8) are readily evaluated with CT and MRI.

Infection, trauma, congenital malformation, and benign and malignant tumors in this region are evaluated adequately by clinical examination, plain films, barium swallow, cine-esophagram, and ultrasonography. The ability of MRI and CT to provide superficial and deep soft and hard tissue information and tissue identification (fat, muscle,

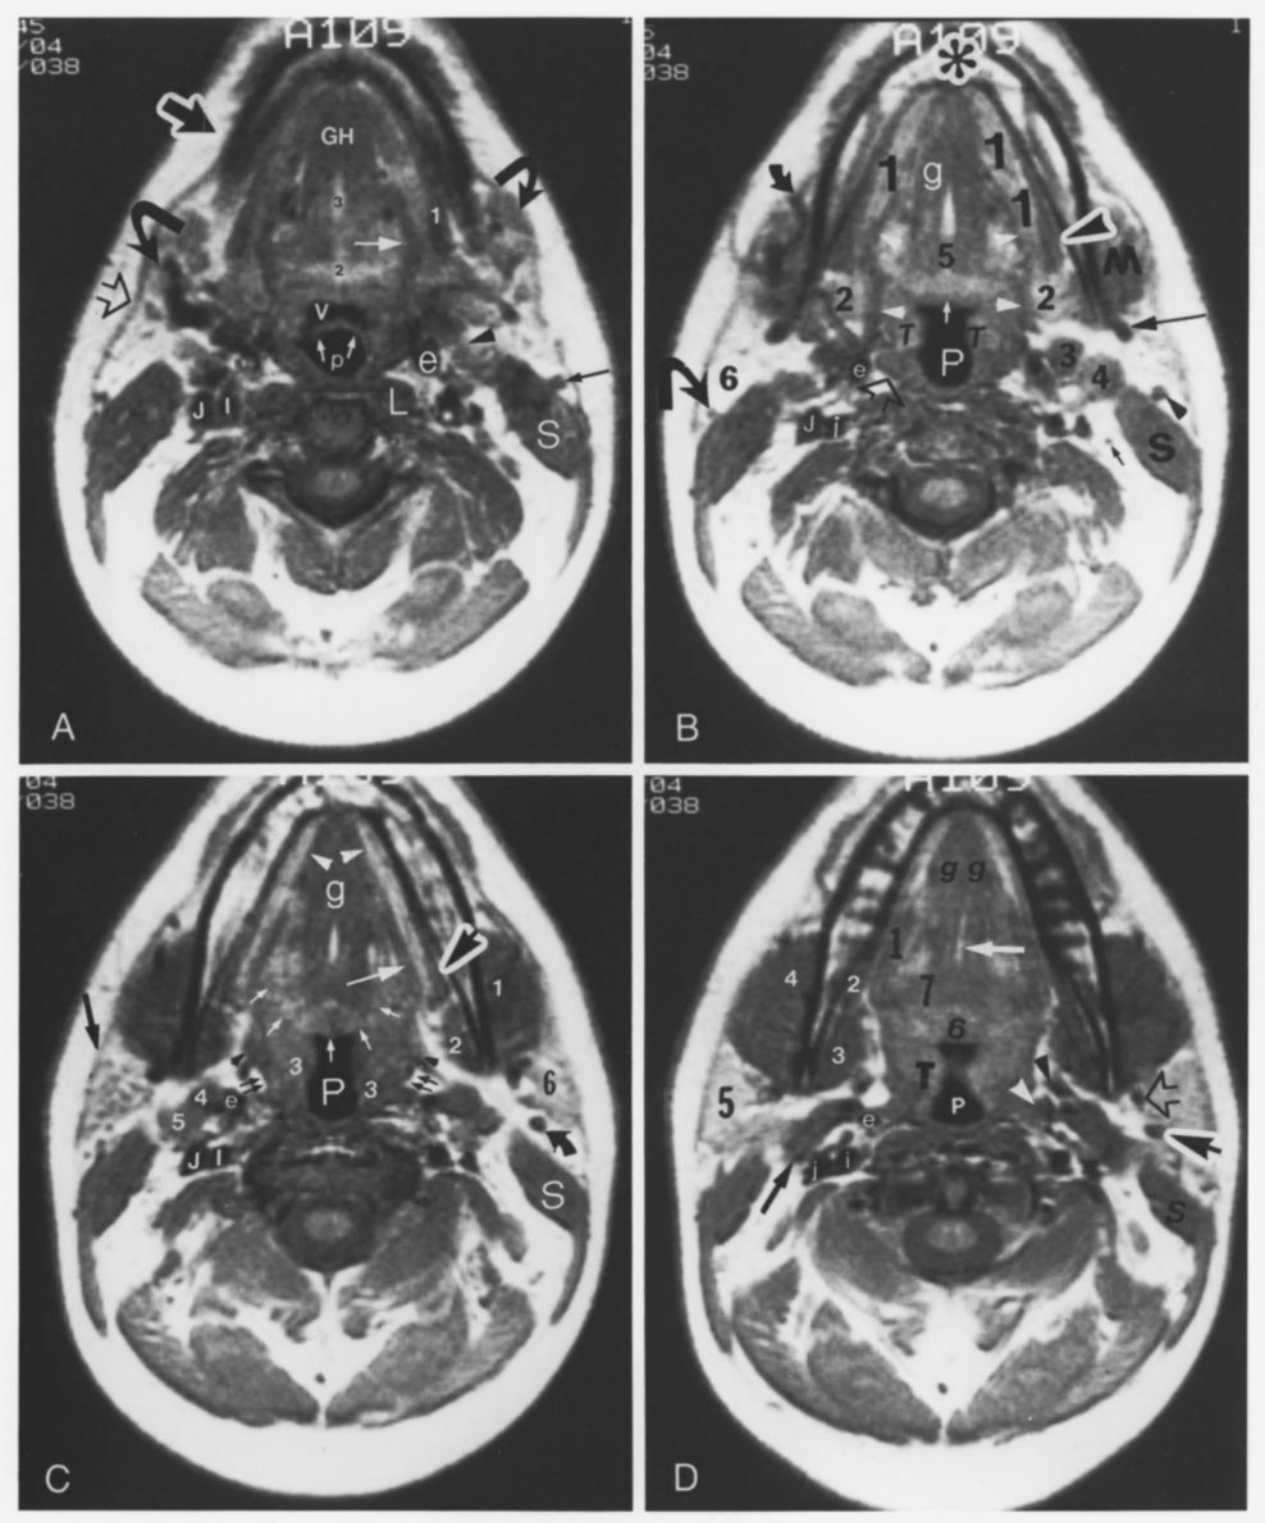

FIGURE 59–1. All except *H* are proton-density 2000/20 magnetic resonance images of the same normal subject. *A*, This section is through the lower margin of the mandible (*black and white arrow*) and through the body of the third cervical vertebra. The section passes through the lower part of the tongue and through the oral portion of the pharynx (p), just above the epiglottis (*small white arrows*). The submandibular glands (*curved arrows*) are cut through their middle portions. The platysma (*open arrow*) and external jugular vein (*black arrow*) are seen. The hyoglossus muscle (*white arrow*),

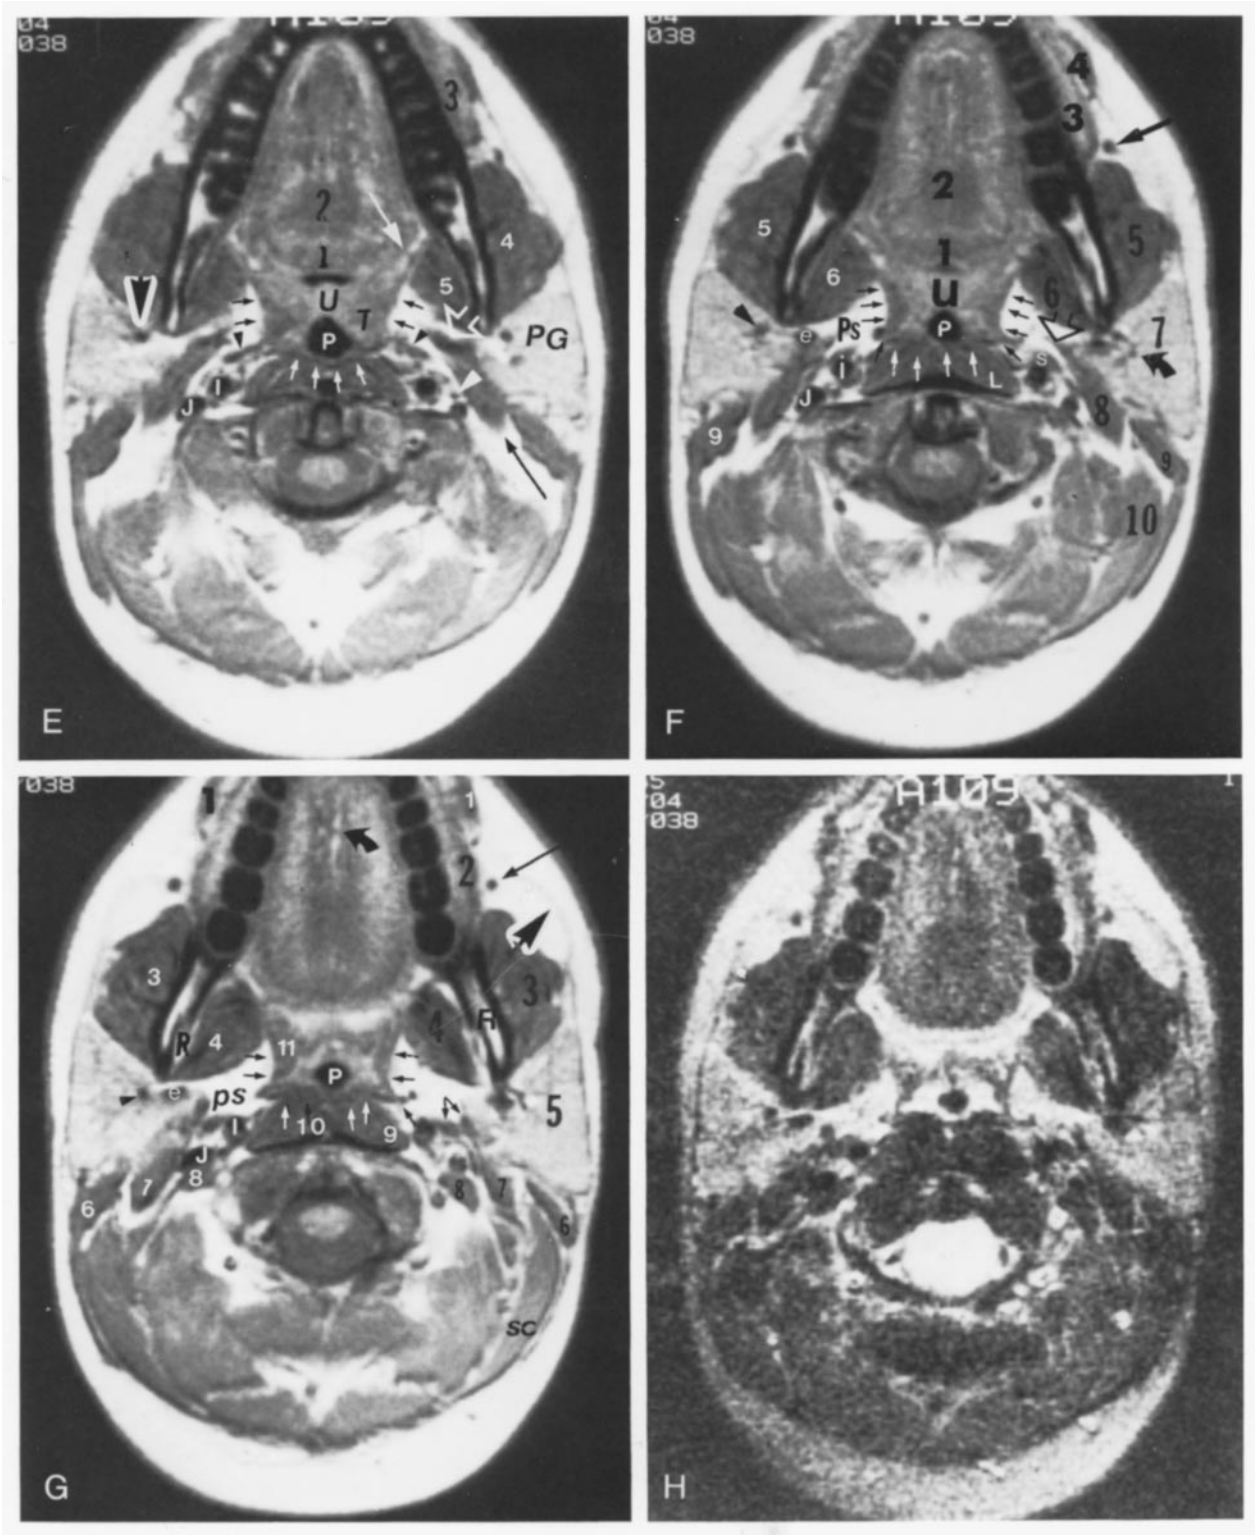

the stylohyoid muscle (*arrowhead*), and the tendinous portion of the digastric (lateral to the styloid process) muscle are seen medial to the submandibular gland. 1 = mylohyoid muscle; 2 = intrinsic muscle of the tongue with associated intermuscular fat; 3 = median raphe; e = external carotid artery; GH = geniohyoid muscle; I = internal carotid artery; J = internal jugular vein; L = longus colli muscle; S = sternocleidomastoid muscle. *B*, This section passes through the body of the mandible, just above the mental foramen, and through the lower margin of the axis. It passes through the tongue just

above the level of the foramen cecum (*small white arrow*) and the inferior margins of the palatine tonsils (T). Little of the parotid gland (6) is seen in this section. The maximal anteroposterior extensions of the sublingual glands are seen (1), and the submandibular glands (2) are also demonstrated. Note the intrinsic muscle of the tongue (5); the genioglossus muscle (g); the pharynx (P); masseter (M), mylohyoid (*white and black arrowhead*), stylohyoid, and digastric (3) muscles; a possible lymph node and digastric muscle (4); sternocleidomastoid muscle (S); spinal accessory nerve (*small black arrow*); auricular nerve (*long black curved arrow*); external (e) and internal (i) carotid arteries; internal jugular vein (J); retromandibular vein (*black arrow*); anterior facial vein (*short black curved arrow*); styloglossus muscles posterior to the hyoglossus muscles (*white arrowheads*); and pharyngeal constrictor muscles (*open arrow*). *C*, This section passes through the mandible, near the junction of the ramus and the body and the tongue at the level of the upper portions of the sublingual glands (*white arrowheads*). The high-density image medial to the mandible is caused by the sublingual gland and fat in the fascial planes. This section passes through the pharynx (P) at the level of the middle portions of the tonsils (3). The tongue shows the following muscles: genioglossus (g), hyoglossus (*white arrow*), and styloglossus (*black arrowheads*). Note the mylohyoid (*black and white arrowhead*), platysma (*black arrow*), parotid gland (6), digastric muscle (5), stylohyoid muscle (4), external jugular vein (*curved arrow*), and sternocleidomastoid muscle (S). *D*, This section is 3 mm superior to *C* and shows various structures: genioglossus muscles (gg); septum linguae (*white arrow*); stylohyoid muscle (*black arrowhead*); stylopharyngeus muscle (*white arrowhead*); tonsils (T); oropharynx (P); longitudinal (6) and transverse (7) muscle fibers of the tongue; hyoglossus (1), mylohyoid (2), internal pterygoid (3), and masseter (4) muscles; parotid gland (5); posterior belly of the digastric muscle (*black arrow*); sternocleidomastoid muscle(s); retromandibular vein (*open arrow*); external jugular vein (*black and white arrow*); external (e) and internal (i) carotid arteries; and internal jugular vein (j). *E*, This section is 3 mm superior to *D* and passes through the upper portion of the tongue and shows the uvula (U), palatine tonsil (T), oropharynx (P), and posterior belly of the digastric (*black arrow*), stylohyoid (*open arrow*), and stylopharyngeus (*black arrowheads*) muscles. The styloglossus and stylopharyngeus muscles are seen medial to the stylohyoid muscle and lateral to the internal carotid artery (I). Note the palatoglossus muscle (*white arrow*), parotid gland (PG), spinal accessory nerve (*white arrowhead*), superior longitudinal muscle fibers of the tongue (1), transverse muscle fibers of the tongue (2), buccinator muscle (3), masseter muscle (4), internal pterygoid muscle (5), pharyngeal constrictor muscle (*small black and small white arrows*), retromandibular vein (*black and white arrow*), and internal jugular vein (J). *F*, This section is 3 mm superior to *E* and shows the superior longitudinal muscle fibers of the tongue (1); transverse muscle fibers of the tongue (2); buccinator muscle (3); orbicularis oris muscle (4); masseter muscle (5); internal pterygoid muscle (6); parotid gland (7); posterior belly of the digastric (8), sternocleidomastoid (9), splenius capitis (10), and superior pharyngeal constrictor (*small white and small black arrows*) muscles; uvula (u); pharynx (P); parapharyngeal space fat (Ps); external (e) and internal (i) carotid arteries; internal jugular vein (J); anterior facial vein (*black arrow*); intraparotid facial nerve (*curved arrow*); retromandibular vein (*black arrowhead*); and stylopharyngeus (s) and stylohyoid (*open arrow*) muscles. *G*, This section is 3 mm superior to *F* and passes through the lower part of the alveolar process of the maxilla and just below the palatine process of the maxilla. The section passes through the upper part of the ramus of the mandible (R). The following structures are seen: quadratus labii superioris (1), buccinator (2), masseter (3), and internal pterygoid (4) muscles; parotid gland (5); sternocleidomastoid (6), splenius capitis (sc), digastric (7), rectus capitis lateralis (8), rectus capitis anterior (9), longus capitis (10), and palatopharyngeus (11) muscles; superior pharyngeal constrictor muscle (*small white and small black arrows*); styloid muscle group (*joined arrows*); platysma muscle (*white and black arrow*); anterior facial vein (*long black arrow*); retromandibular vein (*black arrowhead*); external (e) and internal (I) carotid arteries; internal jugular vein (J); and the mucous membrane of the hard palate, which shows the medial raphe (*curved arrow*) and numerous mucous glands, which are represented by small white areas. *H*, This is the T_2-weighted magnetic resonance image of *G*. Note the hypointensity of all muscles and hyperintensity of mucosal linings.

lymph node, bone, air, fluid, calcium, and blood) makes them the most complete technique for the diagnosis of pathologic conditions in these regions.[1–13] Branchial cleft cysts (Figure 59–9), ranula (Figure 59–10), cystic hygroma (Figure 59–11), thyroglossal duct cysts (Figure 59–12), dermoid and epidermoid cysts, vascular malformations, cellulitis, and abscesses are all well suited for MRI and CT.[1–11] Deep soft tissue edema and hematoma can be readily recognized in trauma patients. The total extent of deeply seated malignant tumors, associated lymphatic chain involvement, and vascular

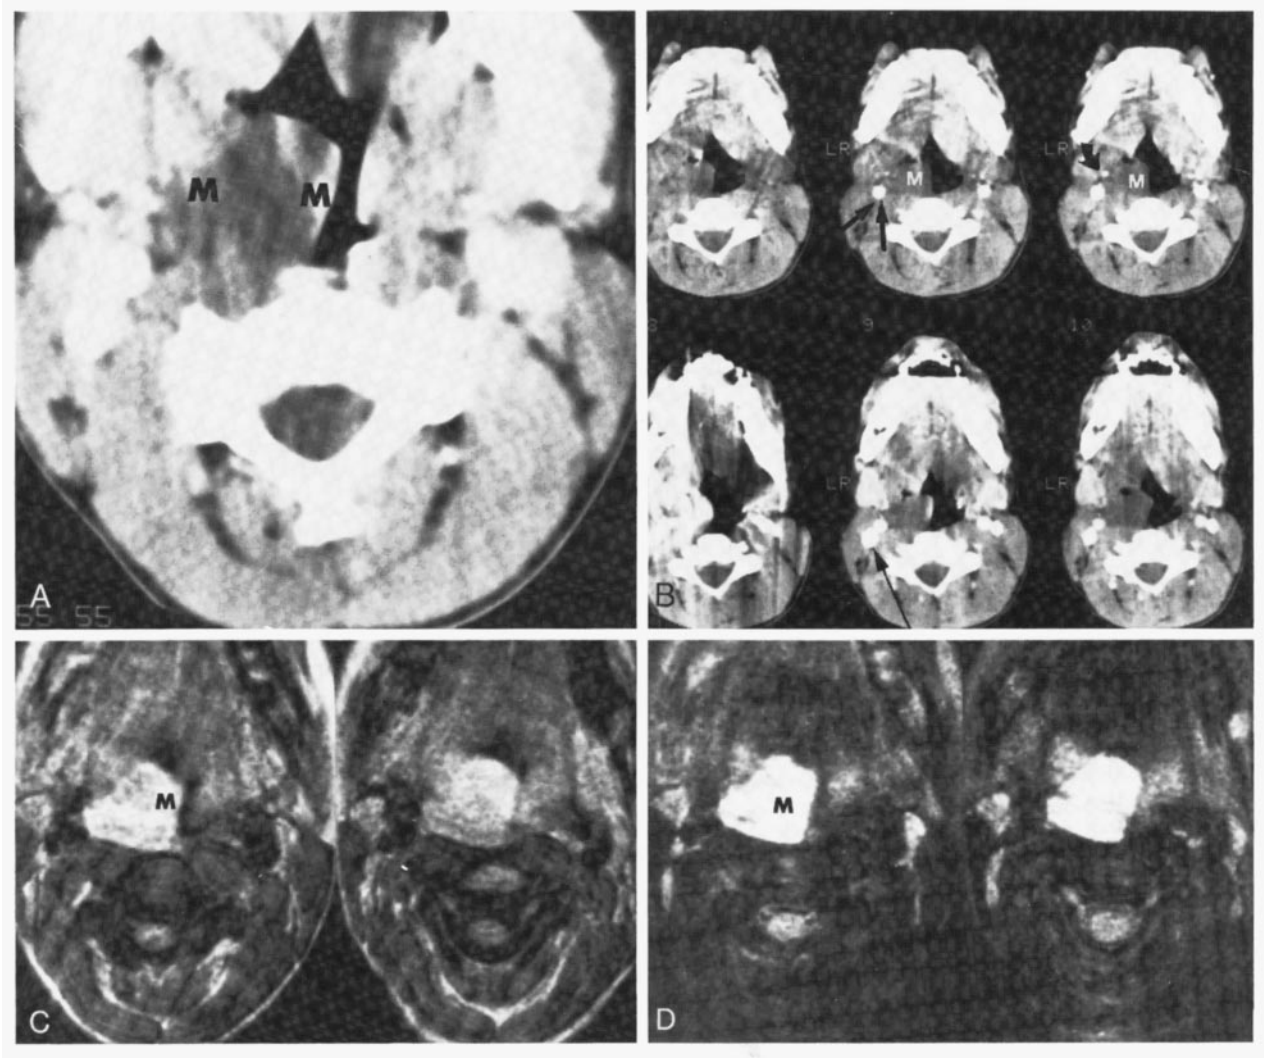

FIGURE 59–2. Cavernous lymphangiohemangioma of the oropharynx. *A*, Axial contrast computed tomographic (CT) scan shows a low-density mass (M) involving the right tonsil and posterolateral wall of the oropharynx. *B*, Serial dynamic CT scans show sequential enhancement of the external (*curved arrow*) and internal (*arrows*) carotid arteries and internal jugular vein (*long arrow*). Note that the mass (M) is not enhanced. Artifacts are seen in the fourth section. *C*, Proton-weighted magnetic resonance images (MRIs) showing the cavernous lymphangiohemangioma (M). *D*, T_2-weighted MRIs, showing the lymphangiohemangioma (M). Reproduced with permission from Mafee MF, Compos M, Raju S, et al. Head and neck: high field magnetic resonance imaging versus computed tomography. Otolaryngol Clin North Am 1988;21:513–46.

encasement can be better determined with contrast-enhanced CT examination (see Figure 59–7).[1,5] The carotid body and glomus vagale tumors and neurogenic tumors, although uncommon, are considered frequently in the differential diagnosis of cervical masses.[8–11] With infusion CT, at times the differential enhancement of these lesions from adjacent muscles and vascular structures may not be sufficiently diagnostic to distinguish them from a vascular tumor (Figures 59–13 through 59–15), lymph node, or other abnormal solid lesion (see Figure 59–13).[7,8] Dynamic CT clearly visualizes the sequential enhancement of the carotid arteries and internal jugular veins, and the

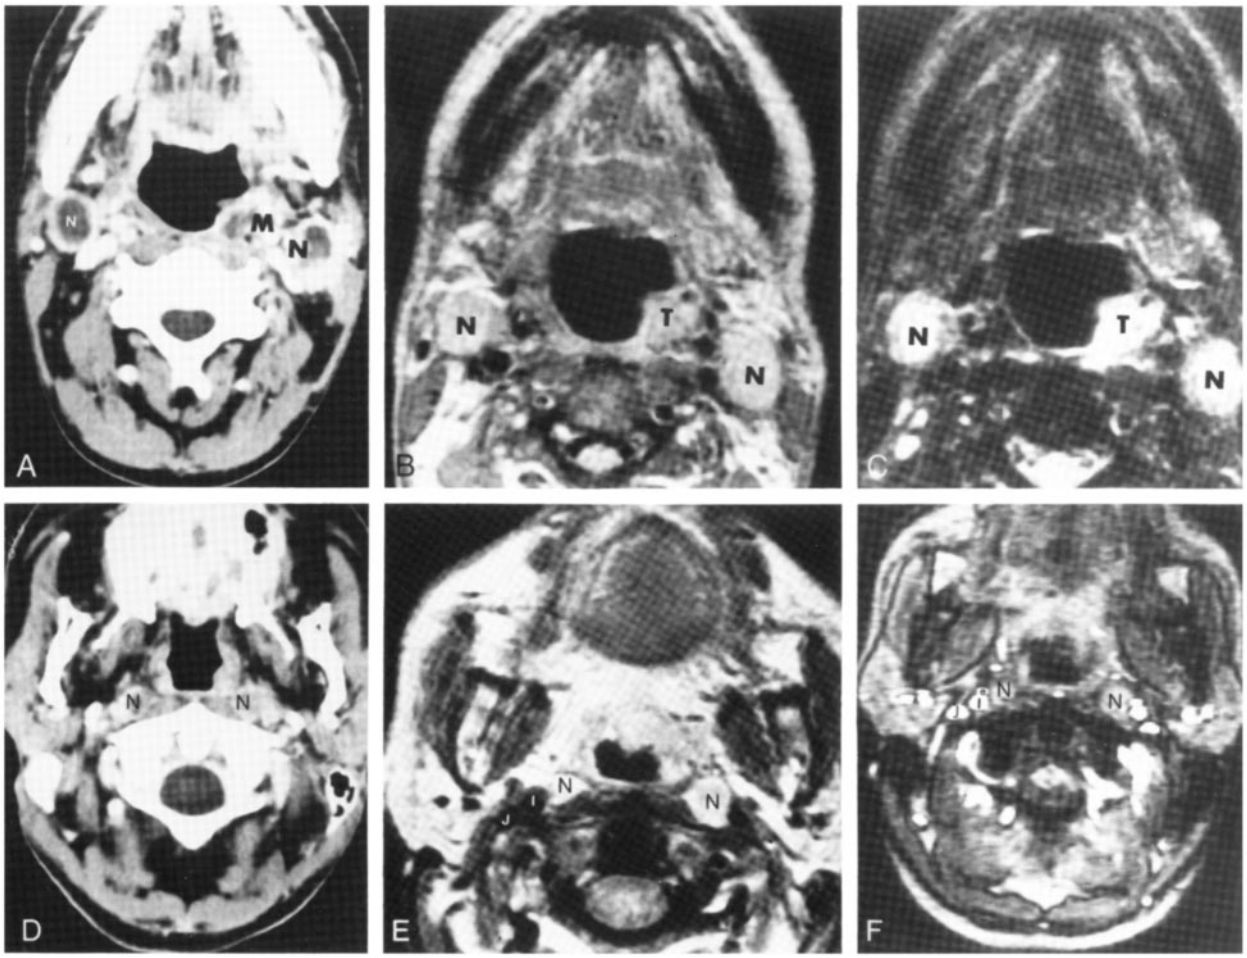

FIGURE 59–3. Squamous cell carcinoma of the left tonsil and soft palate. *A*, Contrast-enhanced computed tomographic (CT) scan shows a left tonsillar mass (M) and bilateral necrotic lymph nodes (N). Proton-weighted (*B*) and T_2-weighted (*C*) magnetic resonance images (MRIs) show tumor (T) and enlarged lymph nodes (N). The necrotic nature of the lymph nodes is better appreciated on CT scan (*A*). Notice that tumor and nodal metastases have identical signal characteristics in this patient. *D*, Axial CT scan obtained superior to *A* showing bilateral retropharyngeal lymph nodes (N). *E*, Proton-weighted MRI shows bilateral retropharyngeal lymph nodes (N). Note hyperintensity of all vascular structures. e = external carotid artery; I = internal carotid artery; J = internal jugular vein. Reproduced with permission from Mafee MF, Compos M, Raju S, et al. Head and neck: high field magnetic resonance imaging versus computed tomography. Otolaryngol Clin North Am 1988;21:513–46.

tumor becomes densely opacified for a short time as the intravenously injected bolus of contrast material traverses the vascular bed of the tumor (see Figures 59–13 and 59–14). With MRI, glomus vagale and carotid body tumors (see Figures 59–14 and 59–15) can be distinguished from other lesions such as neurofibromas (Figure 59–16). Glomus complex tumors are highly vascular (Figure 59–17); therefore, on standard angiography and dynamic CT or MRA, this increased vascularity can be demonstrated, allowing differentiation of them from other lesions (see Figures 59–14 and 59–17).

Larynx and Hypopharynx

Computed tomography and MRI of the neck represent a major advance in laryngology.[14–26] The ability of CT to show accurately mucosa, deep laryngeal tissues, and laryngeal cartilages and the speed of new-generation spiral CT make it an ideal radiologic

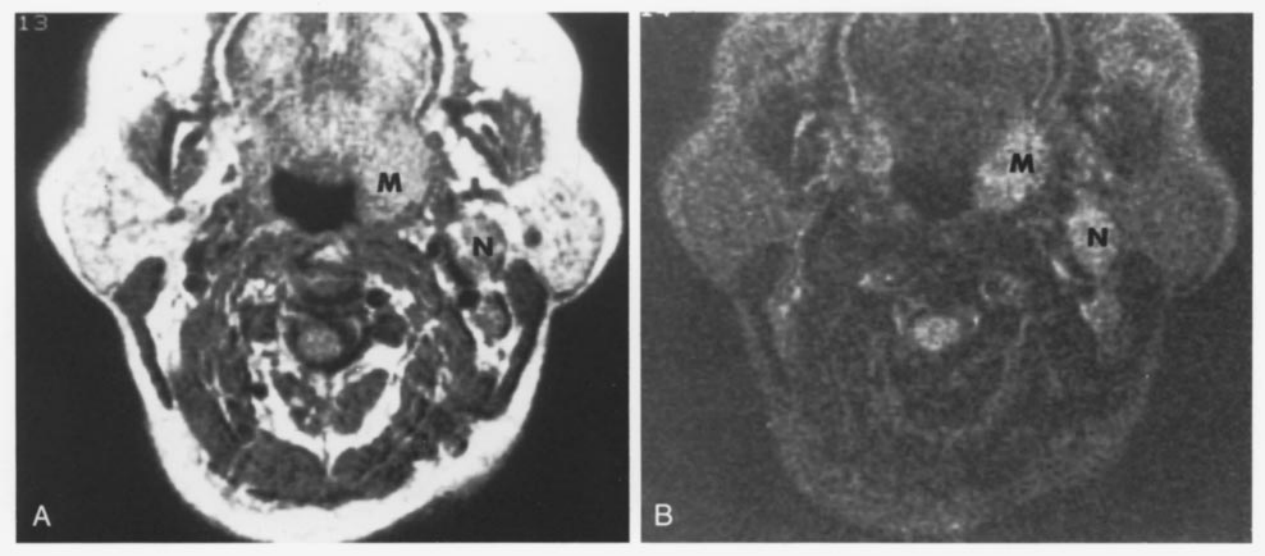

FIGURE 59–4. Non-Hodgkin's lymphoma of the tonsillar region. Proton-weighted (*A*) and T_2-weighted (*B*) axial magnetic resonance images show a tonsillar mass (M) and a deep enlarged lymph node (N). Reproduced with permission from Mafee MF, Compos M, Raju S, et al. Head and neck: high field magnetic resonance imaging versus computed tomography. Otolaryngol Clin North Am 1988;21:513–46.

imaging method for evaluation of the larynx. The characteristic configurations of the hyoid bone and the thyroid, cricoid, and arytenoid cartilages greatly facilitate the orientation of CT scanning.[15,16,22] A section taken at the level of the hyoid bone (Figure 59–18) demonstrates the free portion of the epiglottis, valleculae, glossoepiglottic folds, pharyngoepiglottic folds, and superior portion of the piriform sinuses. In scans taken caudally, the preepiglottic space, epiglottis, aryepiglottic folds, piriform sinuses, thyroid cartilage, false cords, corniculate cartilages, true vocal cords, arytenoid cartilages, cricoid cartilage, cricothyroid articulation, conus elasticus, trachea, thyroid gland, and vascular structures can be visualized (Figures 59–19 through 59–24).

On CT scans, the preepiglottic space (see Figure 59–19) is seen anterior to the epiglottis as a low-density (lucent) image because of its high fat content.[15,16,22] On T_1-weighted MRI, this space is seen as a hyperintense image. The epiglottis is rarely calcified (Figure 59–25). Therefore, in an axial section, it is imaged as a sharply delineated anteriorly convex curved image, separating the preepiglottic space from the laryngeal vestibule (see Figure 59–25). The aryepiglottic folds make the posterolateral limit of the laryngeal vestibule[16] and separate the laryngeal vestibule from the posteriorly and laterally located piriform sinuses lying between the aryepiglottic folds and thyroid cartilage (see Figure 59–19). The ventricular folds (false vocal cords) are two thick folds of mucous membrane that contain both fat and minor salivary gland structures.[16] At the level of the false vocal cords, the airway is pear-shaped (see Figure 59–20). The soft tissues of the false cords are less dense on CT scans than the true vocal cords. The level of the false cords will always be apparent because of the shape of the airway and the fact that the corniculate and arytenoid cartilages (in their upper portions) are usually imaged with the false cords. At this level, the upper portion of the thyroid gland is imaged overlying the thyroid cartilage (see Figure 59–23). The remainder of the gland is seen on CT scans as a triangular, dense image (owing to iodine content) in the lower sections taken down to the upper tracheal rings. The junction of the false and true vocal cords (laryngeal ventricle) reveals a diamond-shaped contour if contiguous thin sections are obtained.[16]

True Vocal Cords and the Rima Glottidis When the transition is made to the glottis, the airway assumes a triangular appearance (see Figure 59–21). The rima glottidis is a fissure between the vocal

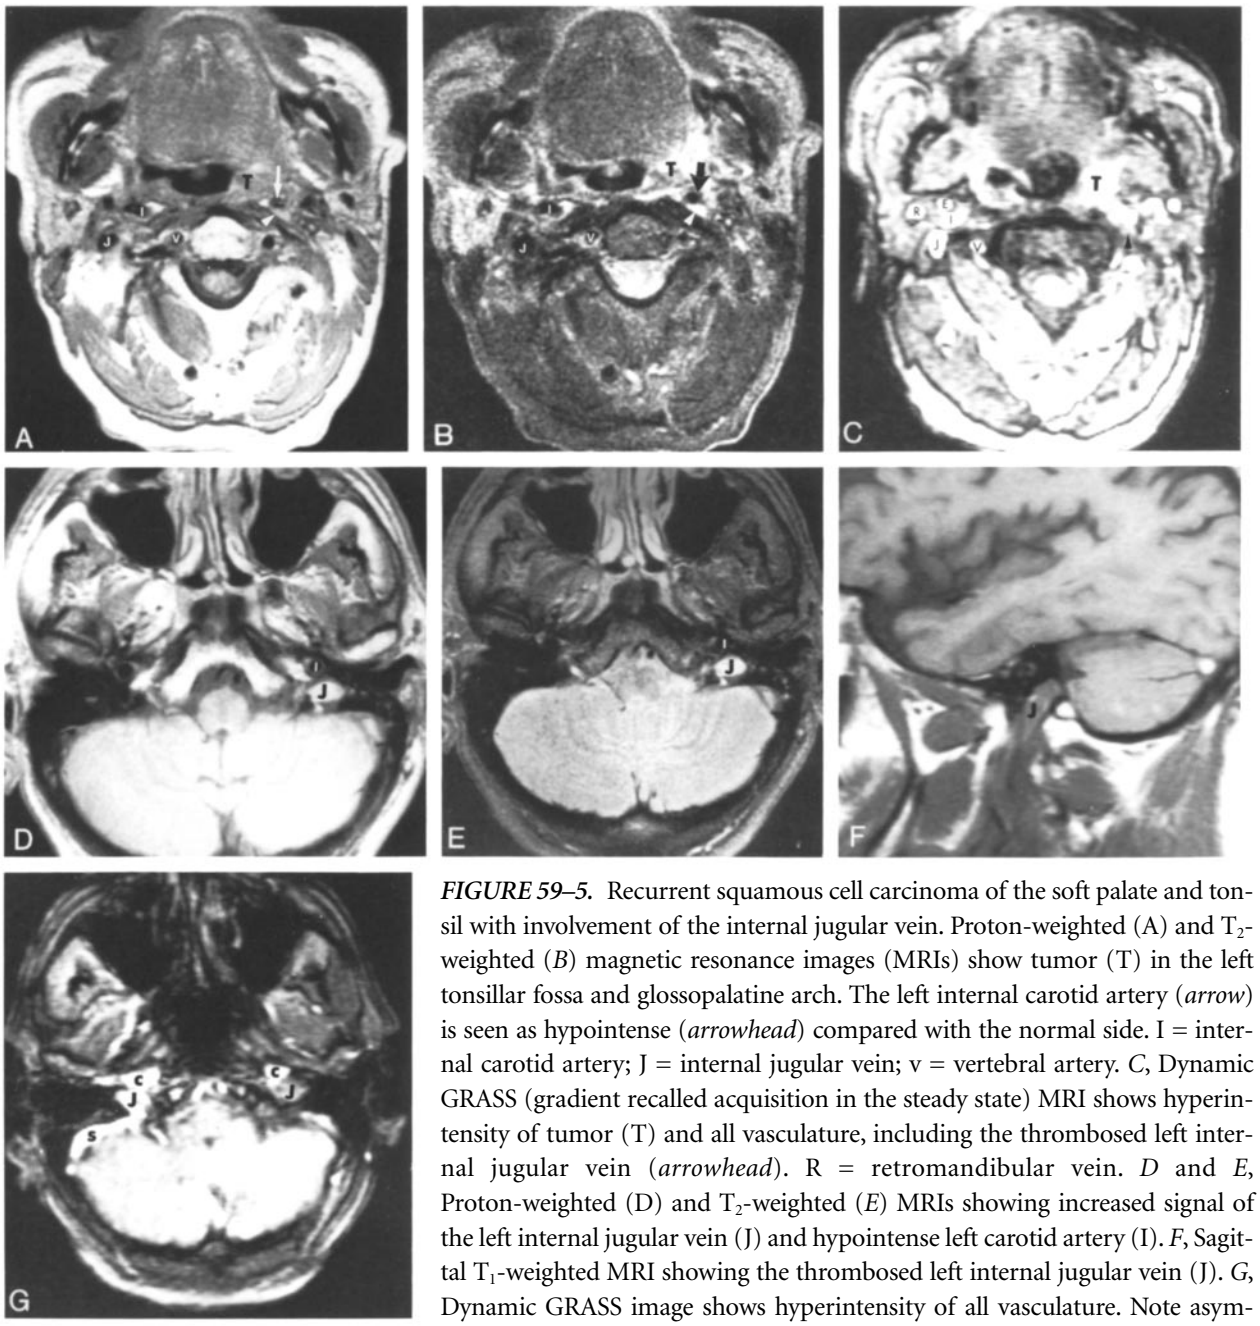

FIGURE 59–5. Recurrent squamous cell carcinoma of the soft palate and tonsil with involvement of the internal jugular vein. Proton-weighted (A) and T_2-weighted (*B*) magnetic resonance images (MRIs) show tumor (T) in the left tonsillar fossa and glossopalatine arch. The left internal carotid artery (*arrow*) is seen as hypointense (*arrowhead*) compared with the normal side. I = internal carotid artery; J = internal jugular vein; v = vertebral artery. *C*, Dynamic GRASS (gradient recalled acquisition in the steady state) MRI shows hyperintensity of tumor (T) and all vasculature, including the thrombosed left internal jugular vein (*arrowhead*). R = retromandibular vein. *D* and *E*, Proton-weighted (D) and T_2-weighted (*E*) MRIs showing increased signal of the left internal jugular vein (J) and hypointense left carotid artery (I). *F*, Sagittal T_1-weighted MRI showing the thrombosed left internal jugular vein (J). *G*, Dynamic GRASS image shows hyperintensity of all vasculature. Note asymmetry of signal of internal jugular vein (J). c = internal carotid artery; s = sigmoid sinus. Reproduced with permission from Mafee MF, Compos M, Raju S, et al. Head and neck: high field magnetic resonance imaging versus computed tomography. Otolaryngol Clin North Am 1988;21:513–46.

cords and includes the vocal process of the arytenoid cartilages. It is limited dorsally by the mucous membrane, passing between the arytenoid cartilages at the level of the true vocal cords (see Figure 59–21).[16,20] The true vocal cords can be seen arising from the vocal process of the arytenoids and extending to the midpoint of the thyroid cartilage as they attach to the anterior commissure region of the larynx immediately subjacent to the point fusion of the paired thyroid alae (see Figure 59–21).[16,20] The true

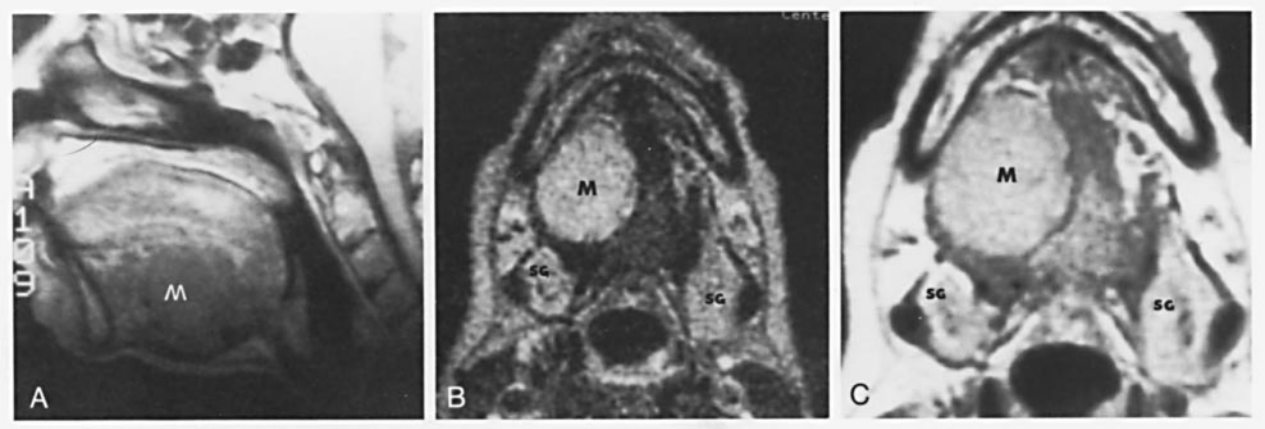

FIGURE 59–6. Pleomorphic adenoma of right submandibular region. *A*, T_1-weighted sagittal scan shows a hypointense mass (M) in the submandibular region. *B*, Proton-weighted magnetic resonance image (MRI) showing a mass (M) of intermediate signal intensity, which is isointense to the submandibular gland (SG). *C*, T_2-weighted MRI showing the mass (M), which is slightly hyperintense to normal submandibular gland (SG). This tumor was thought to arise from a minor salivary gland of the floor of the mouth. Reproduced with permission from Mafee MF, Compos M, Raju S, et al. Head and neck: high field magnetic resonance imaging versus computed tomography. Otolaryngol Clin North Am 1988;21:513–46.

vocal cords have a dense vocal ligament along their free margin (see Figure 59–21, C).[16,20] At its widest, the true vocal cord measures 5 mm in thickness[16] and tapers to a thickness of 1 to 2 mm anteriorly where it meets with the contralateral true vocal cord to form the anterior commissure (see Figure 59–21). If the neck is not positioned properly, slight asymmetry of the true vocal cords will be present (see Figure 59–22).

The anatomy of the rima glottidis and its function can be evaluated by obtaining CT scans and MRIs during quiet breathing, forced inspiration,

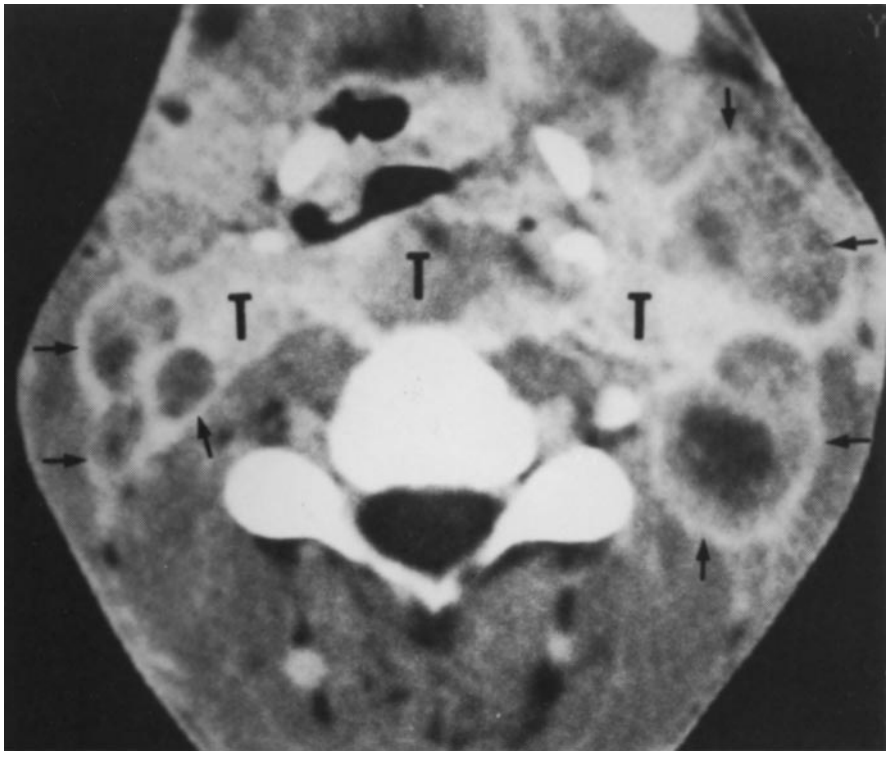

FIGURE 59–7. Pharyngeal carcinoma. Postinfusion contrast-enhanced computed tomographic scan showing a large enhanced, partially necrotic (low-density areas) tumor (T) involving the posterior pharyngeal wall, left tonsillar fossa, left side of the epiglottis, and left side of the base of the tongue, extending beyond the midline, involving the right side of the upper part of the hypopharynx. Note multiple, well-circumscribed ring-like enhancing lesions caused by necrotic lymph nodes (*arrows*). The carotid sheath vessels are engulfed by the metastatic lymph nodes at this level.

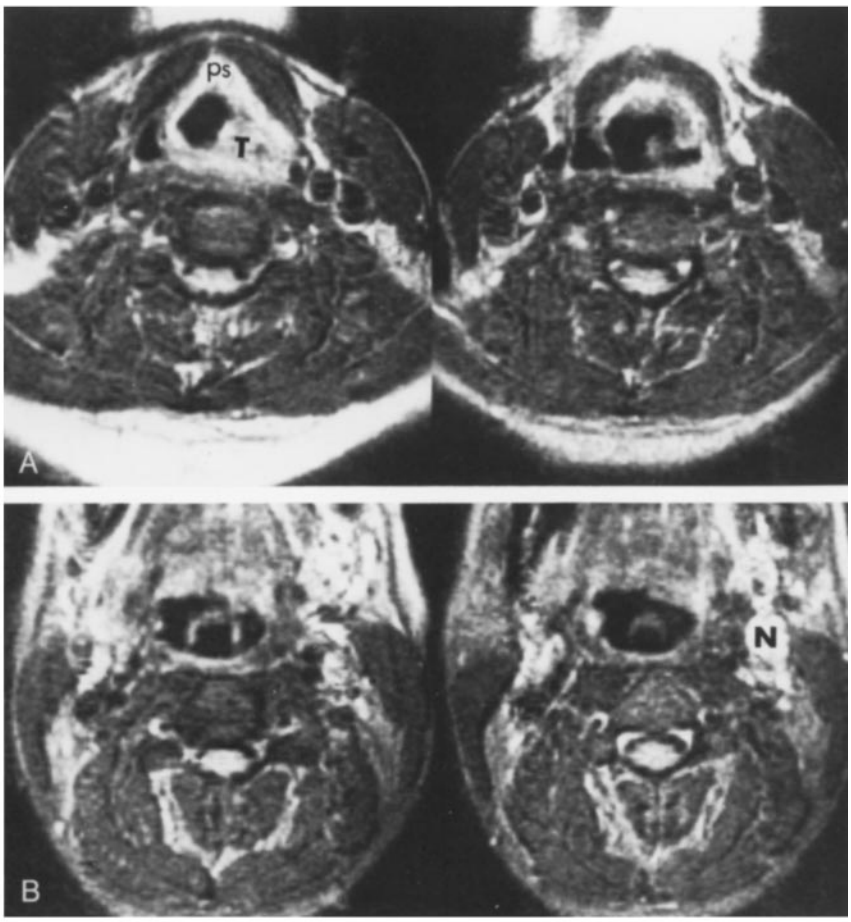

FIGURE 59–8. Squamous cell carcinoma of the piriform sinus. *A*, Proton-weighted magnetic resonance image (MRI) showing the tumor (T) and the fatty-areolar tissue in the preepiglottic space (PS). As seen, the tumor boundaries cannot be distinguished from normal fatty tissues in these MRIs. T_2-weighted MRI is needed for the distinction. *B*, Proton-weighted MRIs obtained superior to *A* showing enlarged lymph node (N).

phonation, and Valsalva's and modified Valsalva's maneuvers.[16,20] The rima glottidis has two parts: intermembranous, the ventral three-fifths between the cords (glottis vocalis), and the intercartilaginous, the dorsal two-fifths between the arytenoid cartilages (glottis respiratorial). It is the narrowest part of the larynx, but its width and shape vary with the movements of the vocal cords and arytenoid cartilages during respiration and phonation.[20] In a state of rest (eg, in quiet respiration), the intermembranous part of the rima is triangular (see Figure 59–21), its apex is ventrally located at the anterior commissure, and its base is represented by a line between the arytenoids (see Figure 59–22).[16,20] The intercartilaginous part is somewhat semicircular in shape (see Figure 59–21) and should be smooth and symmetric on a CT scan and MRI.[16,22] During closure of the rima glottidis (eg, when Valsalva's or modified Valsalva's maneuver is employed), both the true vocal cords and the arytenoid cartilages are adducted (see Figure 59–21, D). During force inspiration, the vocal cords undergo extreme abduction; the arytenoid cartilages are rotated laterally, and their vocal processes move widely apart. During phonation, the intermembranous and intercartilaginous space of the glottis is reduced owing to adduction of the vocal cords and adduction and medial rotation of the arytenoid cartilages (see Figure 59–21).[16,20]

Subglottis and Cricoid Cartilage The subglottis is well imaged by CT and MRI. The undersurface of the true vocal cords forms the superior limits of the subglottis (see Figure 59–22). The cricoid cartilage and the membrane and ligaments that attach to it make up the remaining boundaries of the subglottic space.[16,20] It must be remembered that the cricoid cartilage, which has a signet-ring shape, slopes inferiorly as it is followed anteriorly. The cricothyroid distance approximates 1.5 cm anteriorly, although the cricoid rises to the level of the vocal cords at the cricoarytenoid articulations posteriorly.[16] This is a critical transition point as anterior soft tissue exten-

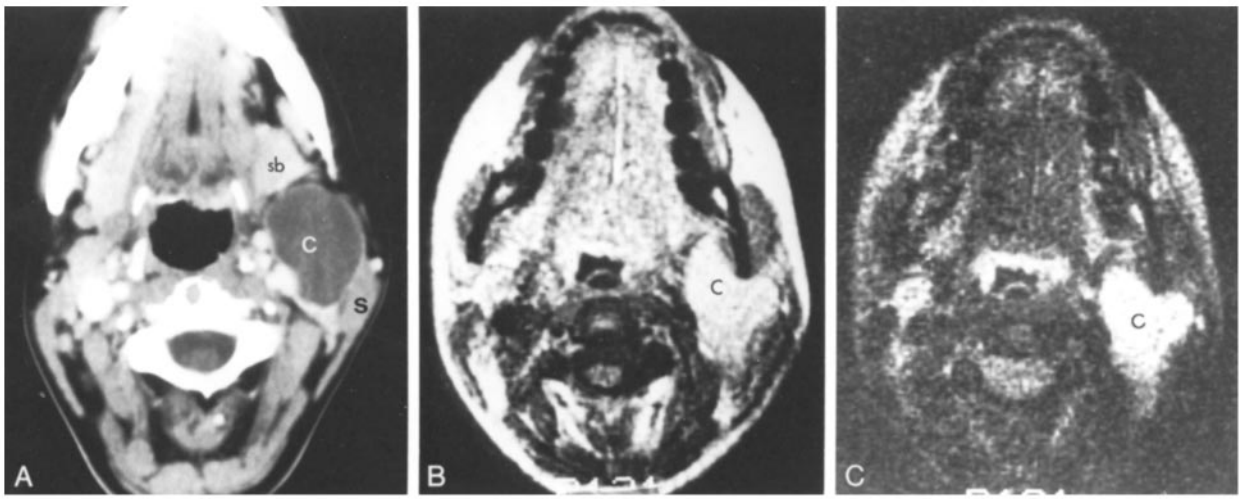

FIGURE 59–9. Second branchial cleft cyst. *A*, Axial computed tomographic scan showing the branchial cyst (c), sternocleidomastoid muscle (S), and submandibular gland (sb). *B*, Proton-weighted axial magnetic resonance image (MRI) showing the cyst (c). *C*, T_2-weighted MRI showing the cyst (c) as a hyperintense image.

sion of glottic carcinoma in the subglottis does not produce cartilage involvement until it has made the full inferior infiltration to the level of the cricoid cartilage. However, posterior extension of glottic cancer provides easy access to the high-rising cricoid signet. When the transition is made to the subglottis, the airway first assumes an ovoid and then a circular appearance (see Figures 59–22 and 59–23). The mucosa in the subglottic region is thin and should be smooth and symmetric in all sections. Increased soft tissue thickening in this area always suggests the presence of some abnormality.

Measurements of the transverse and anteroposterior diameters of the subglottis and the postcricoid-prevertebral, soft tissue thickness in 20 individuals (26 to 73 years of age) who were scanned for possible herniated disk or cervical cord lesion have been made. At the level of the undersurface of the true vocal cords and at the widest area (at the level of the posterior undersurface of the true vocal cords), the transverse diameter measured 1.38 to 1.58 cm, with an average of 1.47 cm. The anteroposterior diameter measured 2.20 to 2.40 cm, with an average of 2.24 cm. The prevertebral soft tissue (from the anterior margin of the vertebra to the posterior margin of the cricoid lamina) measured 0.82 to 0.96 cm, with an average of 0.87 cm. The transverse and anteroposterior diameters of the subglottic region, measured in a section obtained at the cricothyroid articulation, were as follows: the transverse diameter, at the widest area (midportion), measured 1.60 to 1.76 cm with an average of 1.64 cm, and the anteroposterior diameter measured 2.08 to 2.36 cm with an average of 2.12 cm. The prevertebral soft tissue measured 0.70 to 0.98 cm, with an average of 0.85 cm. When the transition is made to the trachea, the airway shows a posterior indentation because of the esophagus, which appears as a round soft tissue image posterior to the trachea (Figure 59–26).

The calcification and ossification of the thyroid cartilage may be occasionally uniform; therefore, on CT, its boundaries are delineated clearly (see Figure 59–21). Frequently, however, its calcification and ossification are irregular and asymmetric. Therefore, care must be taken in evaluating thyroid cartilage involvement by CT.[14–16] The paralaryngeal fat planes marginate the internal cortices of the thyroid cartilage (see Figure 59–22) and are seen as low-density fatty regions that are actually inferior and lateral extensions of the preepiglottic space (see Figure 59–22).[16,20] Obliteration of the paralaryngeal fatty planes usually indicates tumor infiltration.[20] The cricoid cartilage (see Figure 59–23), however, is frequently well calcified and its boundaries clearly delineated (see Figures 59–22 and 59–23). Characteristically, it has a dense cortex and a lucent medullary portion (see Figures 59–22

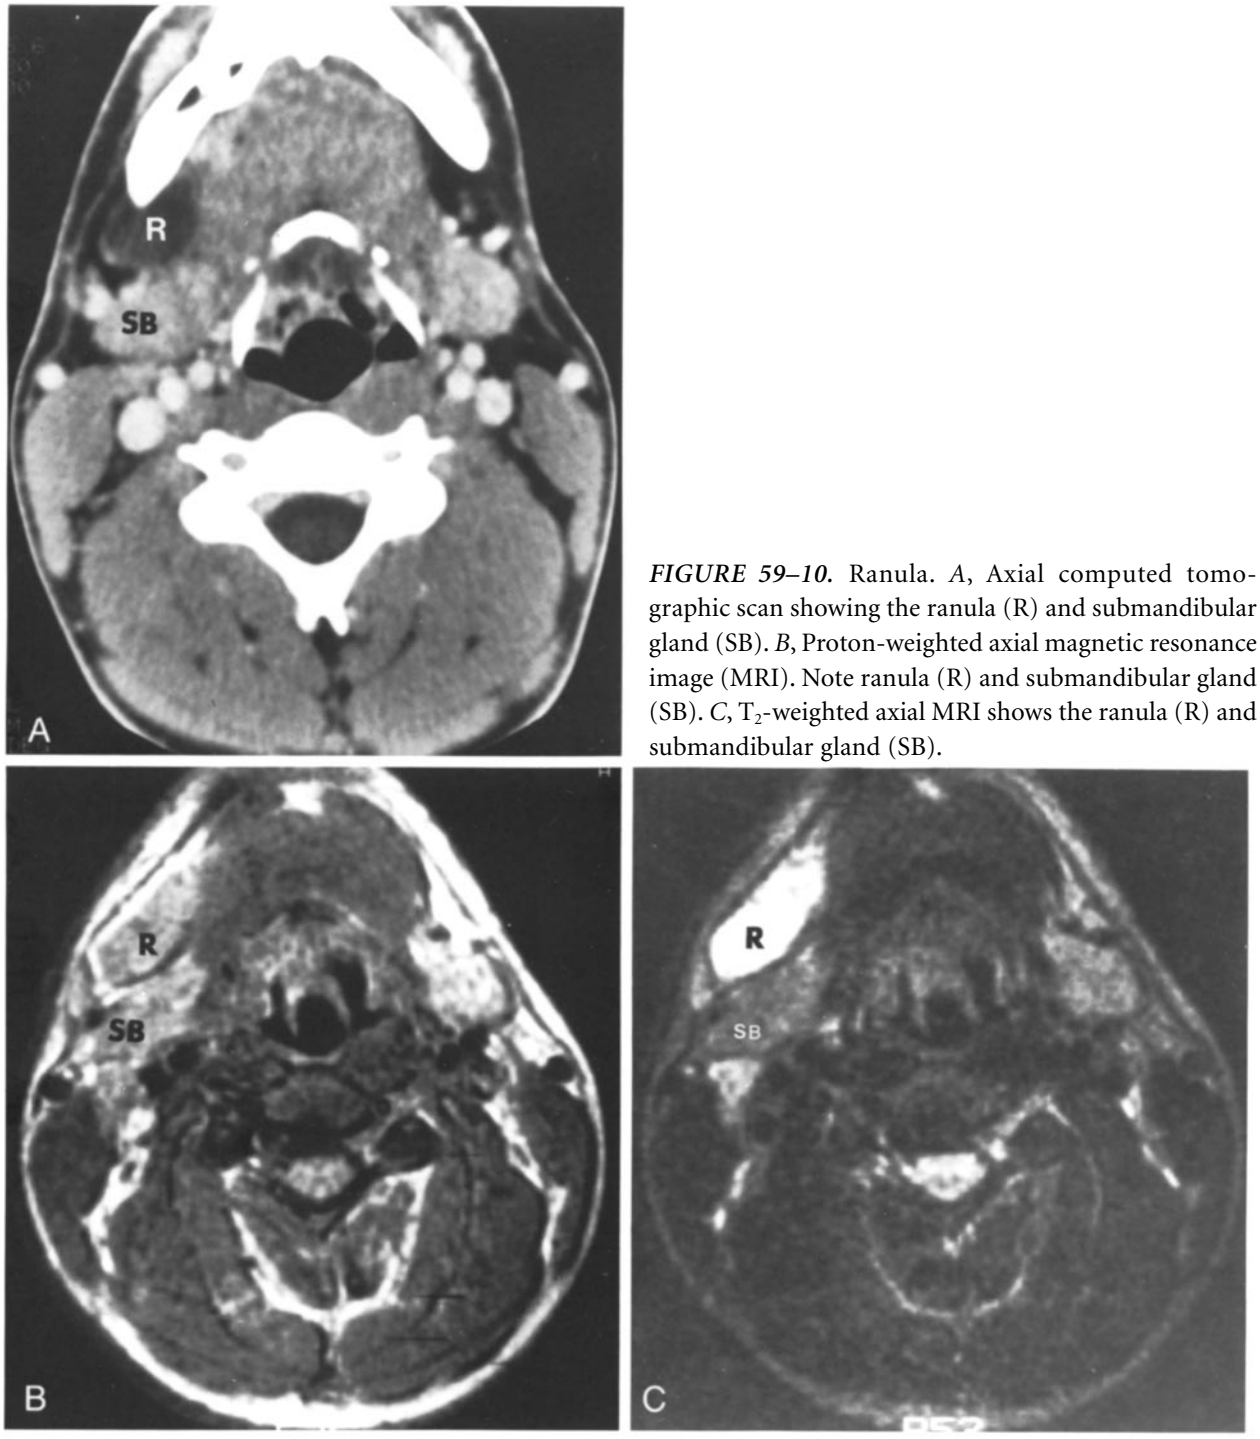

FIGURE 59–10. Ranula. *A*, Axial computed tomographic scan showing the ranula (R) and submandibular gland (SB). *B*, Proton-weighted axial magnetic resonance image (MRI). Note ranula (R) and submandibular gland (SB). *C*, T_2-weighted axial MRI shows the ranula (R) and submandibular gland (SB).

and 59–23). The arytenoid cartilages are frequently calcified and often appear symmetric (see Figure 59–21). Asymmetric calcification of the arytenoid cartilages should not be mistaken for tumor involvement.[16,20,25,26] Increased density (sclerosis) of arytenoid cartilage adjacent to laryngeal carcinoma may be related to tumor involvement; however, it not infrequently represents inflammatory reaction rather than tumor involvement.[25,26]

Magnetic resonance imaging, because of its superior spatial resolution and three-dimensional capability, is superior to CT for delineating the

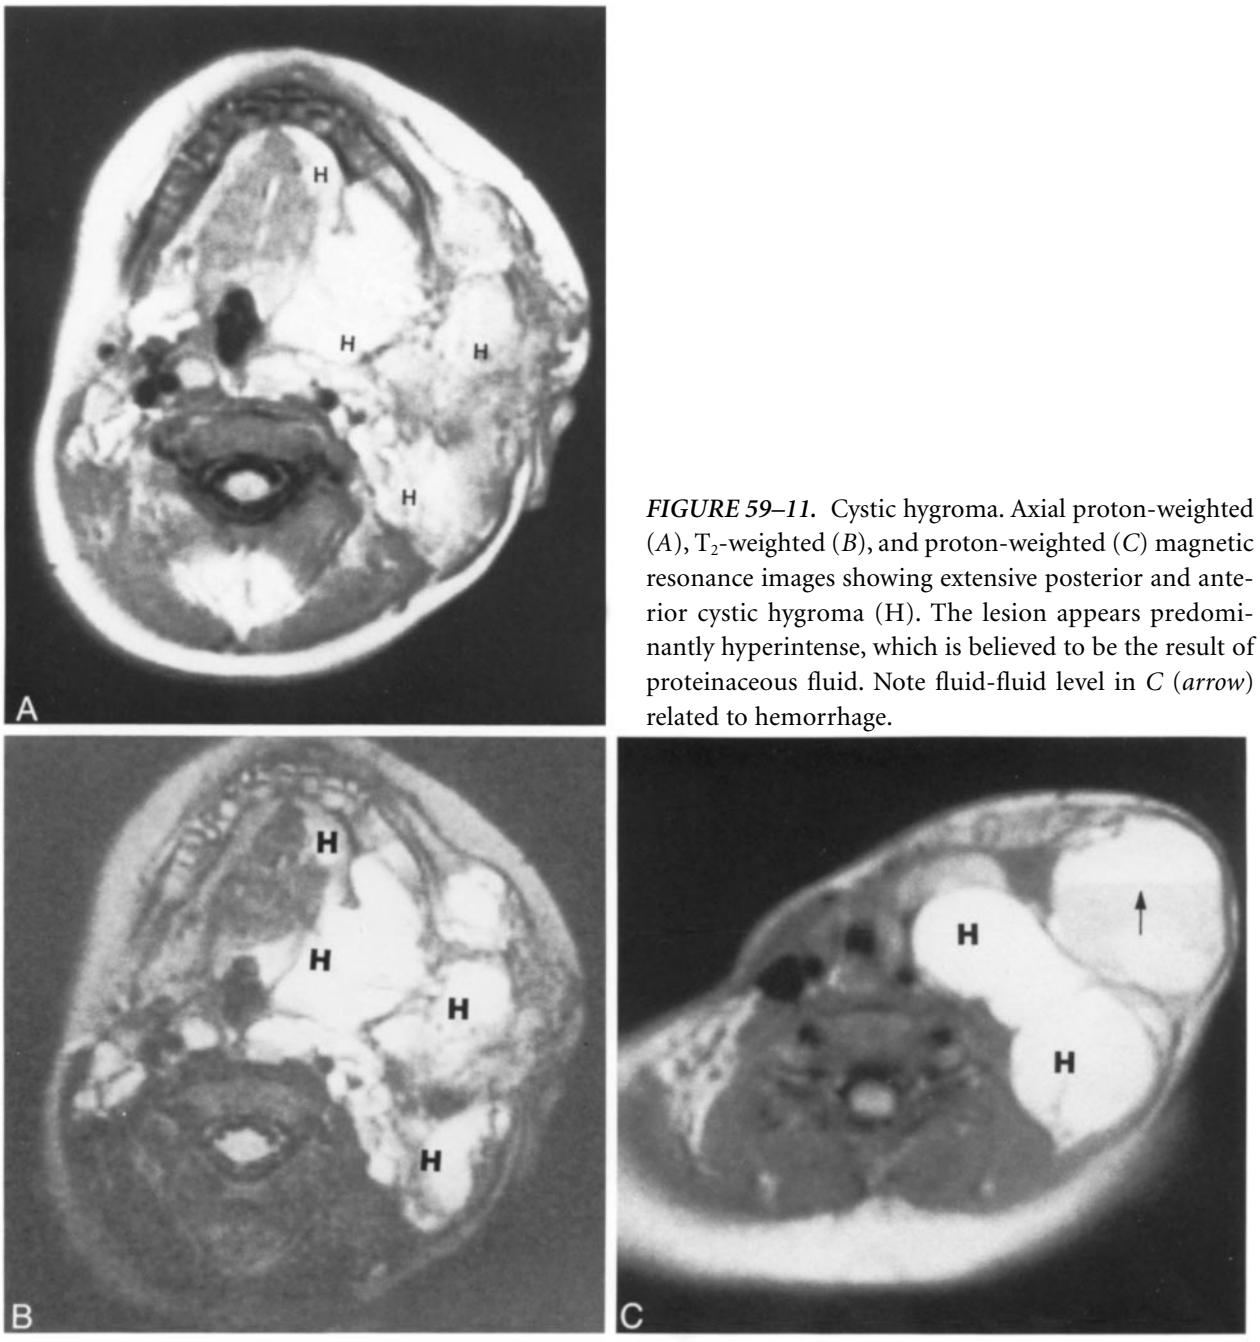

FIGURE 59–11. Cystic hygroma. Axial proton-weighted (*A*), T_2-weighted (*B*), and proton-weighted (*C*) magnetic resonance images showing extensive posterior and anterior cystic hygroma (H). The lesion appears predominantly hyperintense, which is believed to be the result of proteinaceous fluid. Note fluid-fluid level in *C* (*arrow*) related to hemorrhage.

anatomy and pathology of the larynx (see Figure 59–25). Magnetic resonance imaging provides maximum information on the extent of the tumor. The disadvantages of MRI are as follows: (1) MRI frequently requires 45 to 60 minutes scanning time, during which time any patient motion, including heavy breathing, swallowing, and coughing, can degrade the image; (2) MRI is contraindicated in patients with cardiac pacemakers, cochlear implants, and those with ferromagnetic objects in the body; and (3) MRI is, unfortunately, the most expensive of all diagnostic imaging modalities.

Laryngeal Pathology Computed tomography has made a major contribution to the radiologic evaluation of the largynx.[14–23] It is the procedure of choice in the investigation of laryngeal trauma,[19] especially in the acute phase, because it

provides evidence of mucosal disruption, hematoma formation, fracture and cartilage displacement, and an axial display of the airway[19] (Figures 59–27 and 59–28). Benign lesions of the larynx are generally diagnosed by clinical examination rather than radiologic techniques. Laryngeal cysts and laryngoceles are well suited for CT and MRI. Computed tomography is able to define the extent of the laryngocele more precisely than either clinical examination or conventional radiographic techniques. Using CT, a laryngocele appears as a well-circumscribed air-filled enlargement that represents extension and elongation of the laryngeal appendices (saccules) of the laryngeal ventricle (Figure 59–29). When the laryngocele is filled with fluid (complicated laryngocele),

FIGURE 59–12. Thyroglossal duct cyst. Arch Otolaryngol 1983;109:691–6.

it appears on CT and MRI as a smoothly marginated mass along the lateral wall of the larynx, and it may be difficult to differentiate it from an aryepiglottic fold cyst.

Malignant Tumors of the Larynx The vast majority of laryngeal and hypopharyngeal tumors are squamous cell carcinomas. Except for skin cancer, cancer of the larynx is the most common malignant tumor of the head and neck region. Only 5 to 10% of malignant neoplastic lesions of the larynx and hypopharynx are non–squamous cell tumors. Cancers of the larynx and hypopharynx are by far the most common indications for imaging of this region. Involvement of the preepiglottic space or paralaryngeal space and subglottic extension can be detected by both CT and MRI. Detection of cartilage invasion if it is less than 6 mm constitutes a serious challenge. Areas of increased cartilage sclerosis may be seen on CT scans adjacent to the tumor. This is most often related to inflammatory changes in the immediate tumor vicinity rather than tumor invasion. The ability of CT and MRI to demonstrate accurately mucosal, deep laryngeal tissue and associated lymphatic chain involvement makes either of them an ideal imaging method for evaluation of laryngeal tumors (Figures 59–30 through 59–32).[15,20,21,25,26] Computed tomography and MRI have their major value in the pretreatment tumor, node, metastasis staging of laryngeal cancer.[20,25] Tumor involvement of the anterior and posterior commissures (see Figure 59–32, C), subglottic region (see Figures 59–32, E, and 59–32, F), and trachea is best evaluated by CT. Cartilage involvement (see Figure 59–30) and extension of the tumor in the paralaryngeal and paraglottic spaces can be demonstrated in a manner not available before the introduction of CT. Computed tomography is very helpful in the evaluation of tumor extension, specifically in the axial dimension.[16,20] Its primary application is in the evaluation of T3 and T4 laryngeal cancer.[20,21] Magnetic resonance imaging of the larynx can provide valuable information (see Figure 59–32).[25,26] With

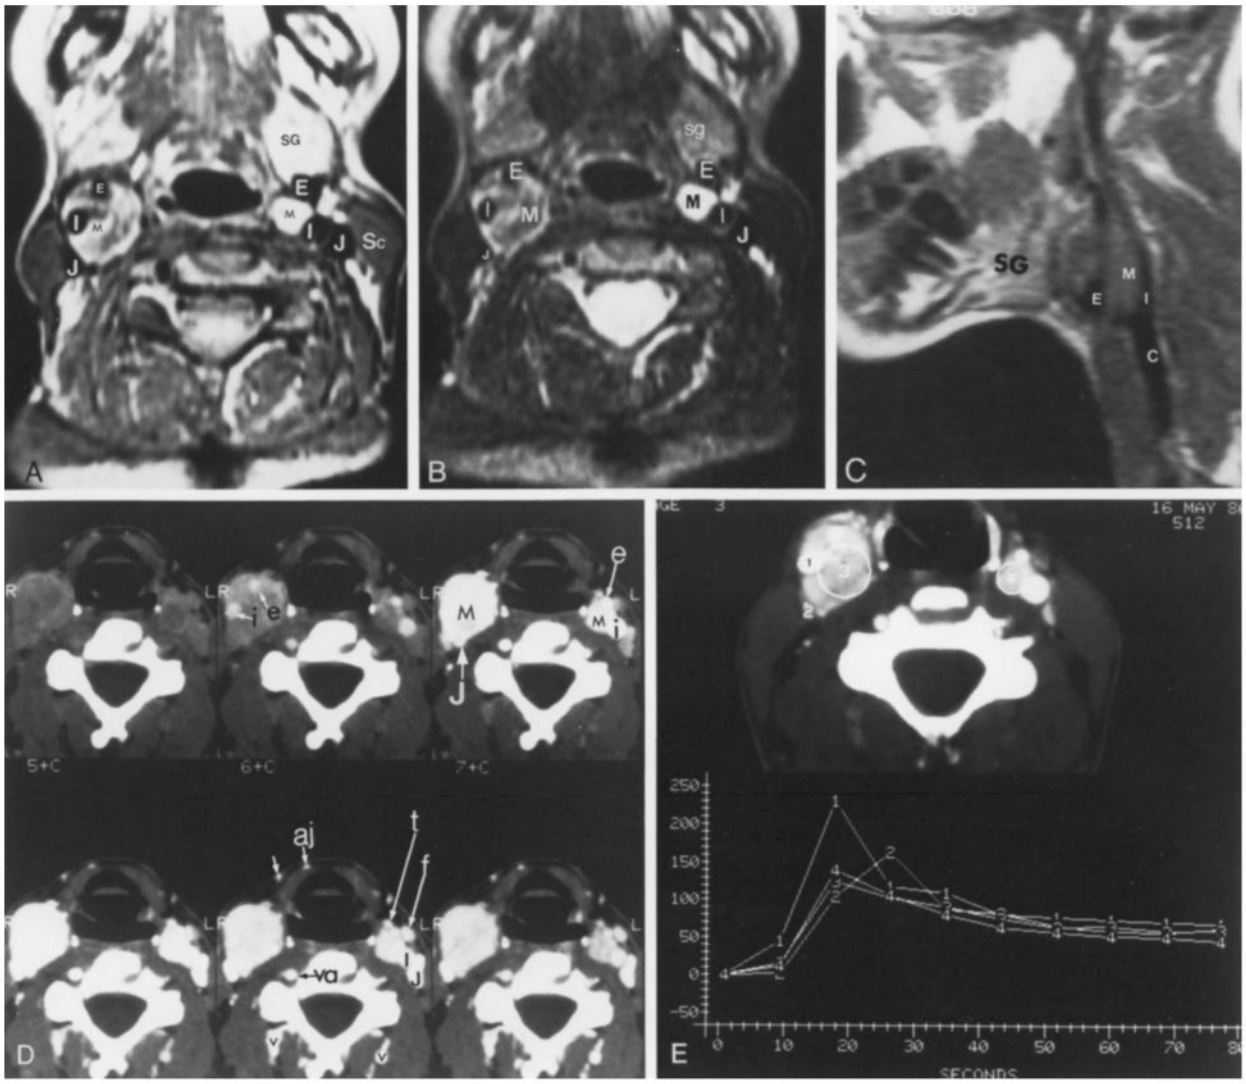

FIGURE 59–14. Bilateral carotid body tumors. Proton-weighted (*A*) and T_2-weighted (*B*) axial magnetic resonance images (MRIs) showing bilateral masses (M), submandibular gland (SG), sternocleidomastoid muscle (Sc), external (E) and internal (I) carotid arteries, and internal jugular vein (J). *C*, T_1-weighted sagittal MRI showing the right carotid body mass (M); common (C), external (E), and internal (I) carotid arteries; and submandibular gland (SG). *D*, Dynamic computed tomographic scans showing the sequential enhancement of external (e) and internal (i) carotid arteries and internal jugular vein (J). Notice intense enhancement of the carotid body tumors (M). On the left side, the tumor has widened the neuroforamen (*curved arrow*). 1 = internal jugular vein; 2 = internal carotid artery; 3 = anterior jugular vein. *B*, Dynamic GRASS (gradient recalled acquisition in the steady state) axial MRI shows the neurofibromas (*arrows*). Notice the hyperintensity of the vascular structures.

mesodermal origin may be seen in larynx and hypopharynx. These unusual tumors comprise about 2 to 5% of all laryngeal tumors.[2] These tumors include hemangiomas (Figure 59–33, A); chondrogenic tumors (chondromas, chondrosarcomas) (Figure 59–34); osteoblastomas; lymphomas, including plasmacytomas; minor salivary origin tumors (pleomorphic adenomas, adenoid cystic carcinomas); tumors of fatty tissue; neurogenic tumors[2,27]; myogenic tumors; fibrohistiocytic tumors; leiomyomas (Figure 59–35); paragangliomas; myxomas; synovial sarcomas; and metastases.

TRACHEA

Subglottic and tracheal airways can be evaluated by standard radiography, CT, and MRI. Subglottic tracheal stenosis can be best evaluated by CT and, in particular, spiral CT. Congenital anomalies and inflammatory, traumatic, and neoplastic conditions of the trachea can be evaluated by plain radiography, CT, and MRI.[28,29] Computed tomography is the study of choice for laryngeal and tracheal trauma. Magnetic resonance imaging is the study of choice for inflammatory and neoplastic conditions of the trachea (Figure 59–36). The extent of tracheal stenosis, tracheal invasion by thyroid carcinoma, and primary tumors of the trachea is best evaluated by MRI (Figure 59–37).

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING OF NECK LYMPH NODES

Computed tomography and MRI will permit the consistent detection of lymph nodes greater than 1.5 cm in diameter (see Figure 59–32, A and F),[20] and they are almost always tumor bearing. Lymph nodes between 1 and 1.4 cm may represent tumor or reactive hyperplasia.[30,31] Any modality that could show abnormal lymph nodes accurately would have great impact in the management of patients with head and neck cancers.[31,32] The treatment of patients at high risk but without clinical evidence of neck (lymph node) tumors has long been a source of confusion and controversy.[31,32]

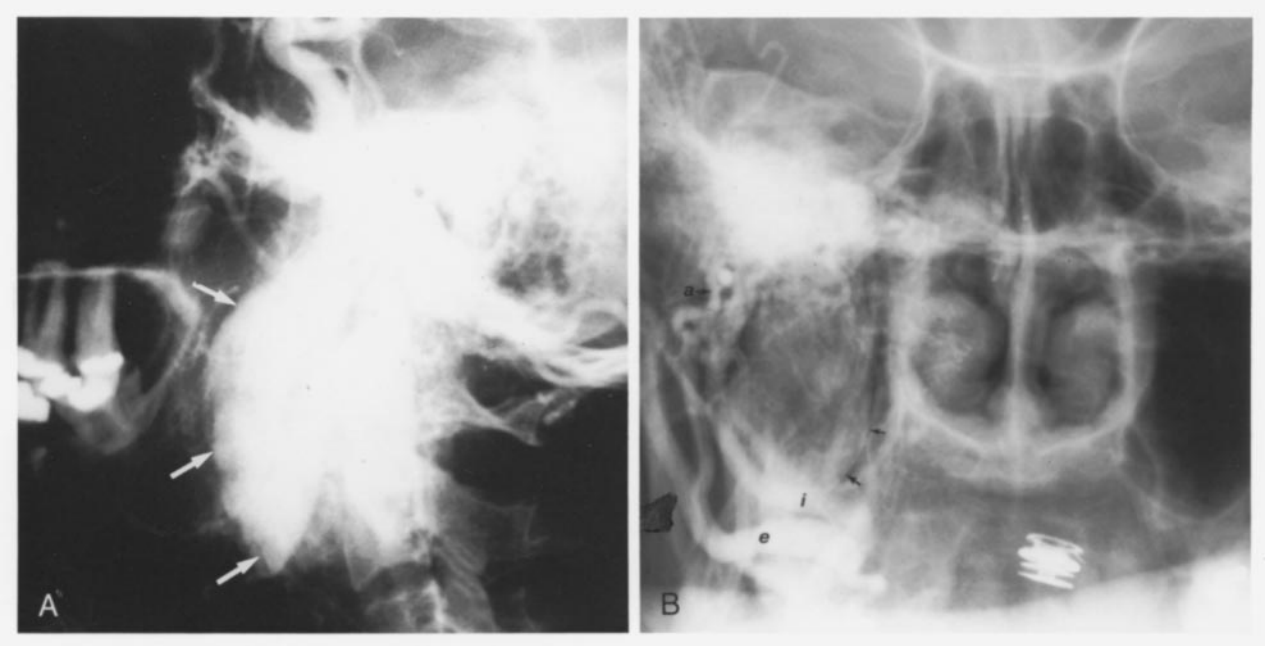

FIGURE 59–17. Carotid body tumor. *A*, Lateral angiogram shows marked tumor blush of a large carotid body tumor (*arrows*). *B*, Frontal angiogram of another patient with a large glomus jugulare tumor showing the tumor blush and involvement of the internal jugular vein (*arrows*). Notice the displaced internal (i) and external (e) carotid arteries. Notice also a large ascending pharyngeal artery (a).

The size of normal lymph nodes varies and may measure up to 15 mm in the upper deep cervical jugular chain, to which most head and neck tumors first metastasize.[32,33] Theoretically, lymph nodes become positive at a nondetectable size. As many as 1 billion cells are necessary to produce a mass of 1 cm.[3,34] The CT and MRI malignancy criteria should include the following: (1) lymph nodes of any size with clear evidence of central low density on CT or abnormal intensity on MRI, evidence of

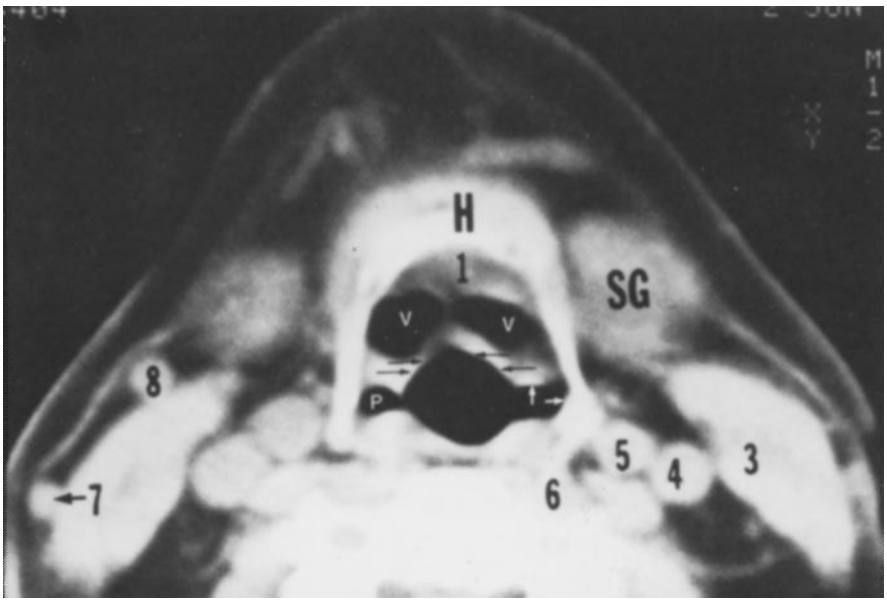

FIGURE 59–18. Axial computed tomographic scan of the oropharynx showing the hyoid bone (H), base of the tongue (1), and, posterior to that, the valleculae (V). Note the epiglottis (*black arrows*), pharyngoepiglottic folds (*white arrows*), upper part of the piriform sinuses (p), submandibular glands (SG), sternocleidomastoid muscles (3), internal jugular veins (4), common carotid arteries (5), longus colli muscles (6), and external jugular veins (7). The platysma muscle is overlying the lateral facial vein (8).

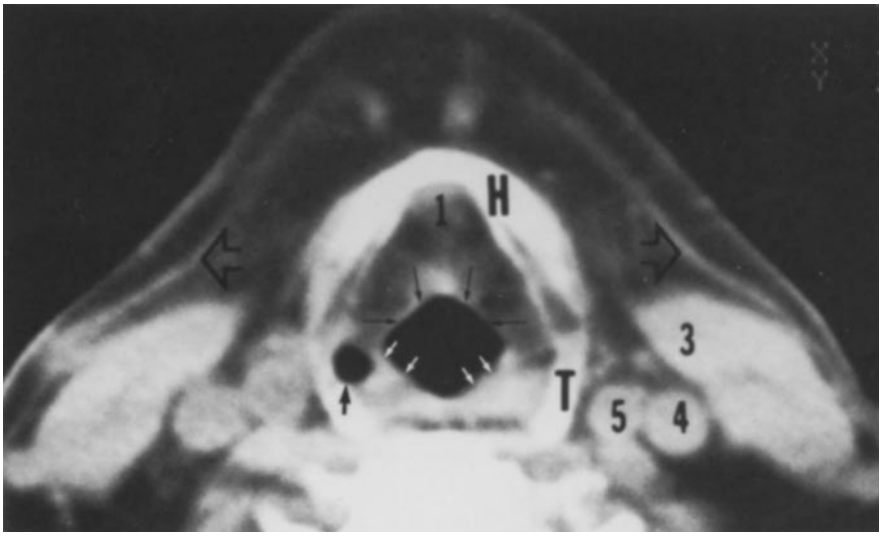

FIGURE 59–19. Axial computed tomographic scan of the larynx and hypopharynx at the level of the superior cornua of the thyroid cartilage (T), showing the inferior part of the hyoid bone (H), preepiglottic space (1), epiglottis (*black arrows*) and aryepiglottic folds (*white arrows*), platysma muscles (*open arrowheads*), sternocleidomastoid muscles (3), internal jugular veins (4), and common carotid arteries (5). Air is seen in the right piriform sinus (*arrow*).

central neurosis; (2) diameter of more than 15 mm for lymph nodes located in levels I and II and more than 10 mm for lymph nodes located in other levels; (3) groups of three or more borderline lymph nodes; (4) loss of tissue planes around any enlarged lymph node; (5) any size lymph node with calcification in a patient with papillary carcinoma of the thyroid gland, which should be considered metastatic unless proven otherwise; (6) any size lymph node in a patient with mucocutaneous malignant melanoma should be considered suspicious for metastases, particularly if it behaves differently on imaging from the contralateral side. Although CT and MRI provide improved clinical staging, they have major limitations. For example, small areas of necrosis may not be depicted clearly, particularly with MRI. In addition, adipose metaplasia in the hilum of a lymph node or an area of hypovascularity can mimic necrosis.[35] More importantly, as Crile pointed out almost 100 years ago, some large lymph nodes may be inflammatory, whereas nonpalpable lymph nodes may be carcinomatous.[36] Although CT and MRI have some limitations in detecting metastatic lymph nodal disease, they are valuable

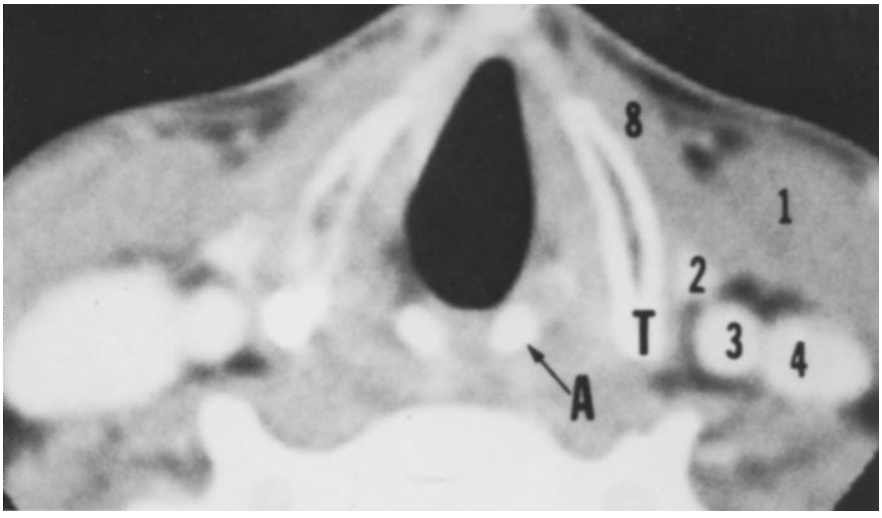

FIGURE 59–20. Axial computed tomographic scan of the larynx at the level of the false vocal cords showing the superior portion of the arytenoid cartilages (A), thyroid cartilage (T), thyroid gland (2), common carotid arteries (3), internal jugular veins (4), sternocleidomastoid muscles (1), and infrahyoid strap muscles (8). Note asymmetry of the internal jugular veins, with the right being larger than the left.

FIGURE 59–21. *A*, Rima glottidis in quiet respiration. Note the symmetry and smooth appearance of the true vocal cords and arytenoid cartilages (a). Notice that the widest part of the glottic aperture is opposite the vocal processes of the arytenoid cartilages. The intermembranous part of the rima glottidis is triangular, and the intercartilaginous part is semicircular in shape. Notice the symmetry in the distances between the thyroid (t) and arytenoid (a) cartilages. c = upper part of the cricoid cartilage. *B*, Normal true vocal cords. Axial computed tomographic (CT) scan obtained during quiet breathing, showing the thyroid cartilage (T) and arytenoid cartilages (a) and their vocal processes. Notice the slight asymmetry of the true vocal cords, which is caused by the asymmetric position of the cords in the section. *C*, Normal true vocal cords. A CT scan of the larynx during expiratory phonation showing the cricoid lamina (c) and the vocal (v) and muscular (m) processes of the arytenoid cartilages. The adducted true vocal cords and partially volumed laryngeal ventricles (*arrows*) are shown. *D*, Closure of the rima glottidis. This is the same patient and the same CT scan level as in *A*; however, during scanning, the patient was requested to hold his breath. Notice closure of the glottic aperture caused by approximation of the true vocal cords. The true vocal cords and arytenoid cartilages (a) are adducted. Notice rotation of the arytenoid cartilages as compared with *A*. The cricoarytenoid articulation (*arrow*) is demonstrated in this breath-holding scan. P = piriform sinus; T = thyroid cartilage. Reproduced with permission from Mafee MF, Schild JA, Valvassori GE, Capek V. Computed tomography of the larynx: correlated anatomy and pathologic macrosection studies. Radiology 1983;147:123–8.

adjuncts to clinical evaluation alone and especially valuable in those head and neck sites that are not accessible to palpation, such as retropharyngeal, intraparotid (deeply seated), parapharyngeal, paratracheal, and mediastinal nodes.[33,37,38] Some lymph nodes, such as the retropharyngeal (adults), intraparotid, suboccipital, periauricular, and superficial lymph nodes, particularly Delphian nodes, are so

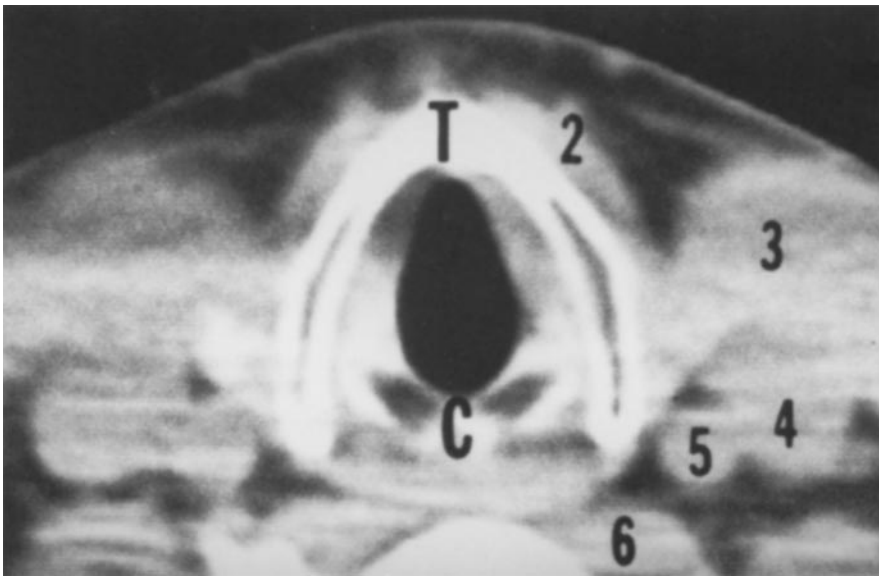

FIGURE 59–22. Normal axial computed tomographic scan at the level of the undersurface of the true vocal cords showing the thyroid cartilage (T), infrahyoid strap muscles (2), sternocleidomastoid muscles (3), internal jugular veins (4), common carotid arteries (5), longus colli muscles (6), and the cricoid cartilage lamina (C).

small that they are rarely detected on CT and MRI. Whenever these lymph nodes are detected by CT and MRI, they should be considered highly suspicious for pathologic lymph nodes.

Newer imaging modalities are currently under investigation and hopefully may further improve the diagnostic accuracy of metastatic lymph nodal disease. Positron emission tomography (PET) has been shown to be sensitive for detecting lymph node metastasis with a higher accuracy rate than MRI.[37–41] The MRI has been widely used for detection of metastatic lymph nodes. The signal intensity of metastatic lymph nodes often does not differ from that of normal lymph nodes. A central necrosis is seen as an area of low signal on T_1-weighted and high intensity on T_2-weighted MRIs. At times, central necrosis may not be appreciated on MRI. It is not unusual to find borderline-sized lymph nodes without central necrosis in CT or MRI. Recent development in MRI contrast material and new contrast agents, such as superparamagnetic iron oxide, has increased the accuracy of MRI.[42,43] Micrometastases are unlikely to be detected by MRI or CT. Localization and imaging of radiolabeled monoclonal antibodies for the detection of cervical metastasis have been successfully investigated in mice.[44]

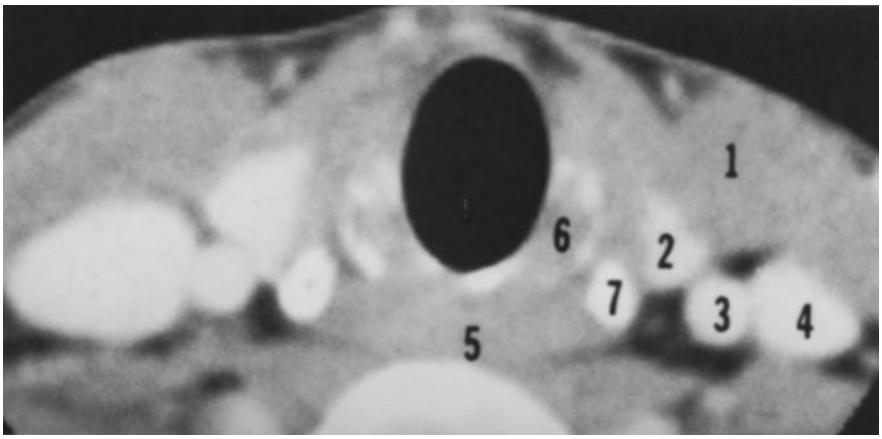

FIGURE 59–23. Normal axial computed tomographic scan at the level of the upper subglottic region. The cricoid cartilage is partially calcified (6). Notice the sternocleidomastoid muscles (1), thyroid gland (2), common carotid arteries (3), internal jugular veins (4), postcricoid region (5), and inferior cornua of the thyroid cartilage (7).

SALIVARY GLANDS

Parotid Gland

The parotid gland, which lies immediately inferior and anterior to the external ear, is divided into a superficial lobe and a deep lobe that curves around the posterior margin of the ramus of the mandible and extends deeply inward toward the lateral parapharyngeal wall (see Figure 59–1, E through H).[45] The main portion of the gland is superficial and is connected to the deep lobe by an isthmus. On a CT scan, the parotid gland is seen as a relatively low-density image with its superficial lobe somewhat flattened and quadrilateral in form in children and young adults. Its density is lower but may be the same as the submandibular gland. It is placed between the ramus of the mandible, mastoid process, and sternocleidomastoid muscle. Not uncommonly, a prominent indentation by the sternocleidomastoid muscle is seen on CT scans or MRIs over the posterior aspect of the gland (see Figure 59–1, E through H). The superficial lobe is broad and can reach nearly to the zygomatic arch. Stensen's duct crosses the masseter muscle, pierces the buccinator muscle and mucous membrane of the mouth, and opens in the cheek opposite the second upper molar tooth. The main duct and intraglandular ductal system can be visualized with standard or CT contrast sialography as well as magnetic resonance sialography. The parotid glands demonstrate an intermediate signal intensity on T_1-weighted and proton-weighted MRIs that enables the clinician to define the gland–muscle interface (see Figure 59–1, E through H).

Submandibular Gland

The submandibular gland is situated in the submandibular triangle, reaching anteriorly to the anterior belly of the digastric muscle and posteriorly to the stylomandibular ligament, which intervenes between it and the parotid gland.[45,46] It extends superiorly deep to the inferior border of the mandible, in the submandibular fossa to the medial side of the body of the mandible, opposite the second and third molar teeth (see Figures 59–1, A, and 59–38). The mylohyoid muscle indents the anterior surface of the gland. The lower part of the gland is covered by the skin, superficial cervical fascia, platysma, and deep cervical fascial. The submandibular duct (Wharton's duct) runs anteriorly between the mylohyoid, hyoglossus, and genioglossus muscles and the sublingual gland to open in the caruncula sublingualis. The entire gland and duct can be visualized with CT sialography (Figure 59–39). Both submandibular and sublingual glands are visualized distinctly on MRI or CT, particularly after intravenous infusion of iodine contrast (Figure 59–40).

Sublingual Gland

The sublingual gland is situated beneath the mucous membrane of the floor of the mouth, at the site of the frenulum of the tongue, in contact with the sublingual depression on the inner surface of the mandible close to the symphysis.[24] Its excretory ducts are multiple. The larger one (Bartholin's duct) opens into the submandibular duct.[45] Sometimes the sublingual gland can be visualized during sialography of the submandibular gland (see Figure 59–39). Because of marked enhancement, both the submandibular and sublingual glands are visualized with CT incremental dynamic study (see Figure 59–40). The parotid, submandibular, and sublingual glands are seen on MRIs with exquisite anatomic details (see Figure 59–1).

Parotid Gland Pathology

Acute infection of the parotid gland manifests itself as diffuse swelling of the gland. An abscess is seen on a CT scan as a discrete low-density (lucent) image (Figure 59–41). The inflammatory processes of adjacent structures, such as an abscess of the masseter and sternocleidomastoid muscles, can be diagnosed and differentiated from a parotid abscess. The diagnosis of chronic parotitis, which results from ductal obstruction because of a stone and recurrent parotitis and chronic punctate sialadenitis (benign lymphoepithelial disease, Mikulicz's syndrome, Sjögren's syndrome) of the parotid or submandibular gland, can be accomplished more readily with conventional sialography.[21,24] Computed tomography of the parotid gland performed with or without contrast infusion (Figure 59–42) and CT contrast sialography (Figure 59–43) can locate parotid masses. Magnetic resonance imaging, similar to CT, is extremely useful and has replaced CT in the evaluation of salivary gland masses. The differentiation of extrinsic mass versus intrinsic parotid tumor is a simple matter if MRI or CT is used,[24,45,46]

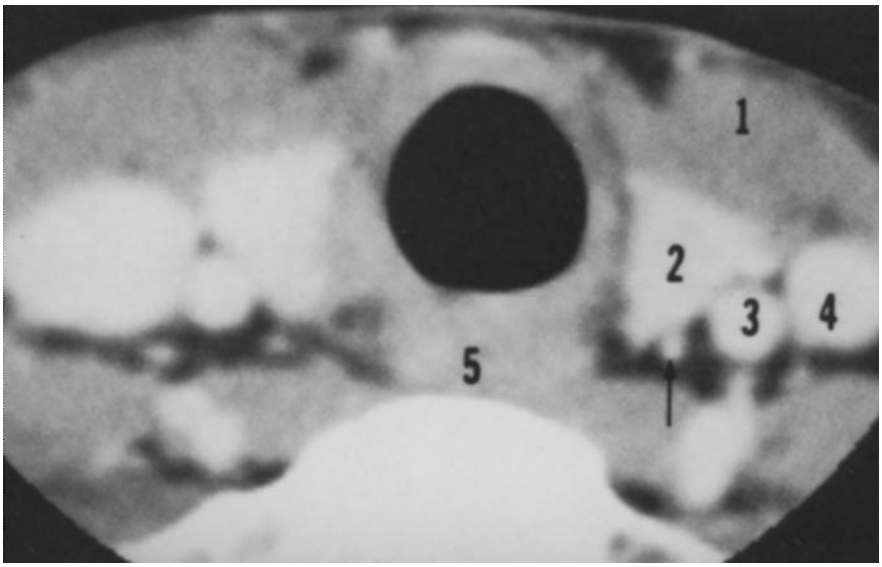

FIGURE 59–24. Normal axial computed tomographic scan at the lower subglottic region showing the sternocleidomastoid muscles (1), thyroid gland (2), common carotid arteries (3), internal jugular veins (4), postcricoid pharyngeal musculature (5), and inferior thyroid artery (*arrow*).

whereas this problem can be extremely difficult to resolve by conventional sialography.[24]

Tumors that are 1 cm in diameter or less are exceedingly difficult to demonstrate by conventional sialography, especially if they are peripherally located.[24] On CT scans, small mass lesions can be seen because they have a different CT appearance in noncontrast and contrast infusion CT as compared with normal parts of the gland.[24] On CT sialography, they appear as filling defects. Magnetic reso-

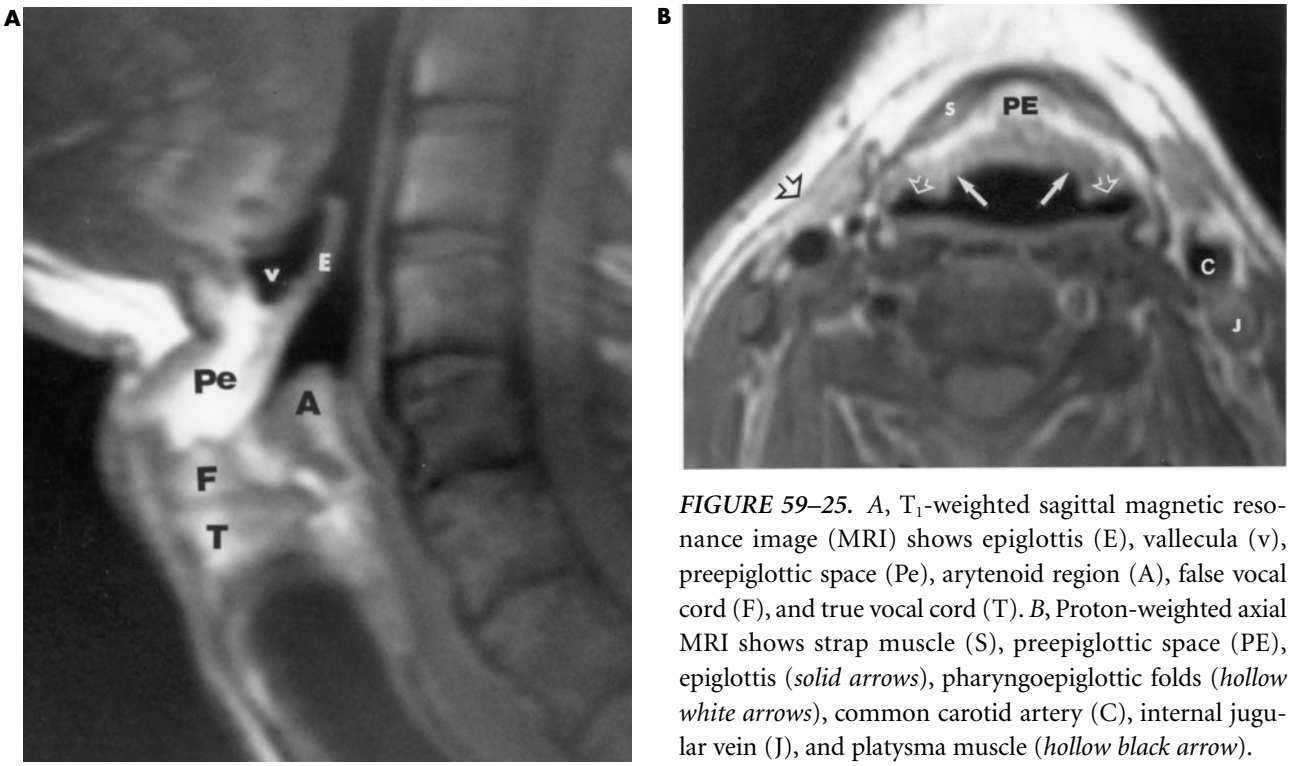

FIGURE 59–25. *A*, T_1-weighted sagittal magnetic resonance image (MRI) shows epiglottis (E), vallecula (v), preepiglottic space (Pe), arytenoid region (A), false vocal cord (F), and true vocal cord (T). *B*, Proton-weighted axial MRI shows strap muscle (S), preepiglottic space (PE), epiglottis (*solid arrows*), pharyngoepiglottic folds (*hollow white arrows*), common carotid artery (C), internal jugular vein (J), and platysma muscle (*hollow black arrow*).

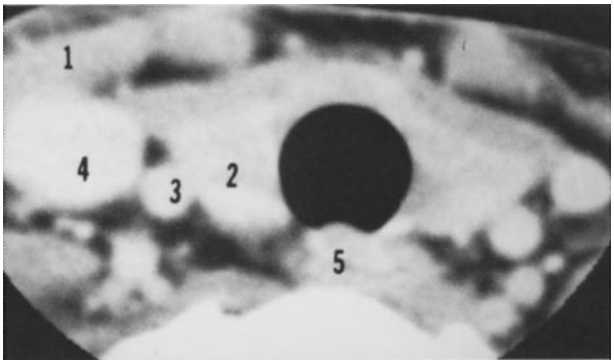

FIGURE 59–26. Normal axial computed tomographic scan at the level of the first tracheal ring showing the sternocleidomastoid muscle (1), thyroid gland (2), common carotid artery (3), internal jugular vein (4), and esophagus (5).

nance imaging, because of its superior contrast resolution, is more sensitive than CT scan and sialography for the evaluation of salivary gland tumors. Conventional sialography is the study of choice for the evaluation of chronic sialopathy, including Sjögren's syndrome.

Tumors of the Parotid Gland The primary neoplastic disorders of the salivary glands may be divided as follows: (1) neoplasms of supporting tissue origin such as hemangioma, lymphangioma, lipoma, schwannoma, fibroma, malignant lymphoma, and various sarcomas and (2) neoplasms of epithelial tissue origin that can be classified as follows:

1. Benign lesions, which include mixed tumors (pleomorphic adenoma), papillary cystadenoma lymphomatosum (Warthin's tumor), and acidophilic cell adenoma (oncocytoma, oncocytosis), and the monomorphic tumors, which include basal cell adenoma, glycogen-rich adenoma, clear cell adenoma, and myoepithelioma.[45,46] Other benign tumors of the salivary gland include papillary ductal adenoma (papilloma), benign lymphoepithelial lesion, sebaceous gland adenoma, and lymphadenoma.[45]
2. Malignant lesions of the salivary glands, which include malignant mixed tumor, malignant

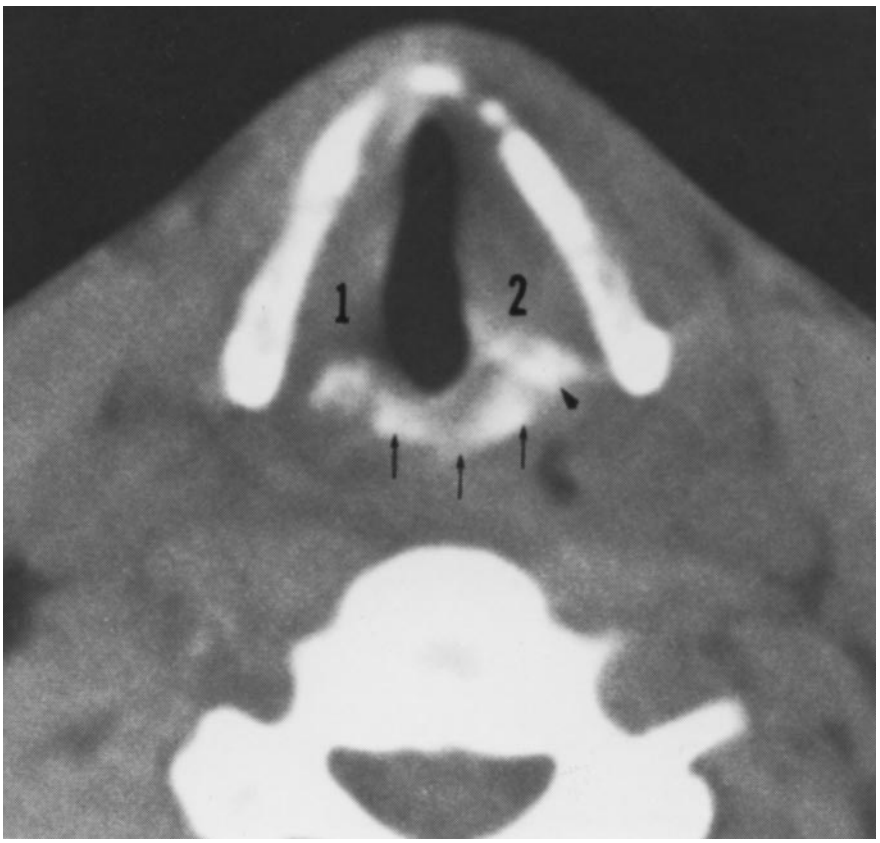

FIGURE 59–27. Computed tomographic scan, showing enlargement (hematoma) of the left true vocal cord (2). The left arytenoid cartilage (*arrowhead*) is rotated medially. The signet portion of the cricoid cartilage (*arrows*) and right true vocal cord (1) appear normal.

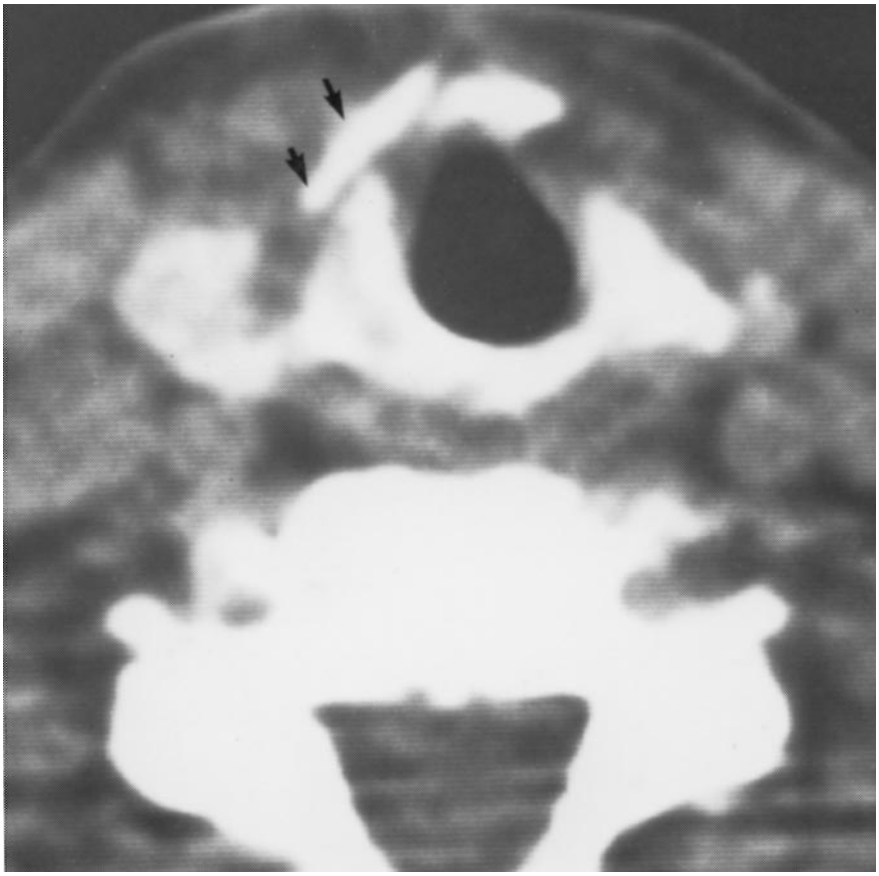

FIGURE 59–28. Computed tomographic scan at the level of the inferior margins of the true vocal cords showing a displaced fragment of the fractured thyroid cartilage (*arrows*).

ex-pleomorphic adenoma (carcinoma arising in a benign mixed tumor), primary squamous cell carcinoma, adenoid cystic adenocarcinoma, mucoepidermoid carcinoma (low grade, high grade), acinic cell (acinous) adenocarcinoma (low grade, high grade), oncocytic carcinoma (malignant oncocytoma), adenocarcinoma (mucus producing), clear cell adenocarcinoma (nonmucinous and glycogen containing or nonglycogen containing), and other adenocarcinomas; and miscellaneous, which include sebaceous adenocarcinoma, Stensen's duct tumors, melanoma, carcinoma lymphoepithelial lesion, metastasis, carcinosarcoma, undifferentiated carcinoma, and unclassified lesions.[45,46]

Cystic lymphoid hyperplasia in acquired immune deficiency syndrome (AIDS) involves the parotid gland lymph nodes. The changes are identical to those of persistent generalized lymphadenopathy in association with gross epithelial cysts in the lymph nodes. The cystic spaces are lined by the tonsil-like, invaginating squamous epithelium.[45]

Computed Tomography and Magnetic Resonance Image Appearance of Salivary Gland Tumors In general, differentiation of benign and malignant tumors by CT or MRI is not the primary goal of CT and MRI. Rather, CT and MRI become important in showing total extent of disease, local lymphadenopathy, and distant metastasis.[45] The CT appearance of cysts is similar to that of cysts in other organs of the body.[45] Generally, cysts have thin walls, are well circumscribed, and contain water-density material, or if they contain proteinaceous fluid, the cyst may appear rather dense. Hemangiomas may have a characteristic CT appearance, demonstrating intense enhancement on dynamic

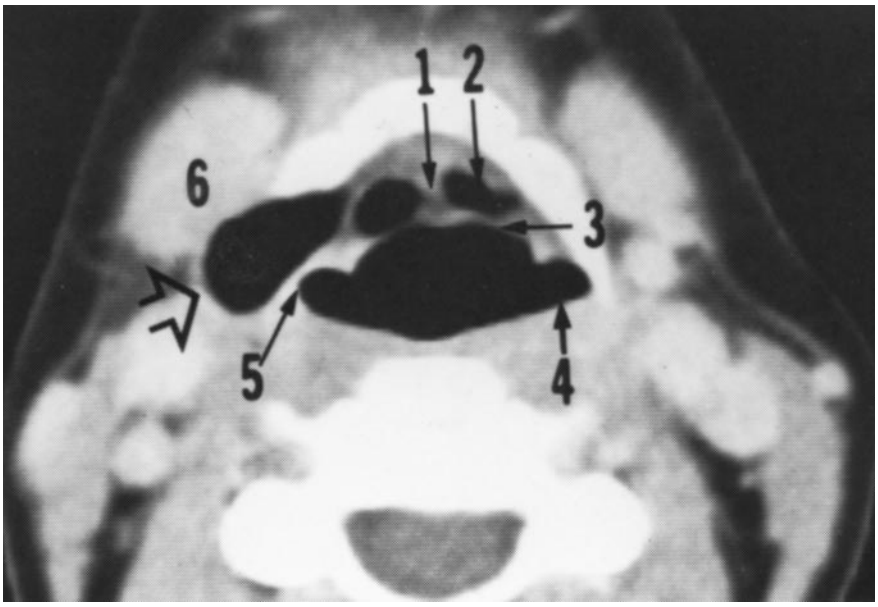

FIGURE 59–29. Laryngocele. The laryngocele bulges outside the larynx laterally (*open arrow*). 1 = median glossoepiglottic fold; 2 = vallecula; 3 = tip of the epiglottis; 4 = upper portion of the piriform sinus; 5 = pharyngoepiglottic fold; 6 = submandibular gland.

CT scans. Benign mixed tumors are typically sharply circumscribed, lying in an otherwise normal gland (Figures 59–44 and 59–45).[45]

Intraparotid facial neuroma may not be differentiated from benign mixed tumor (see Figure 59–42). In the parotid, most tumors are usually of higher density than the general low-density parotid gland. Some parotid glands may be relatively dense; therefore, the mass may be isodense with gland tissue. Identification may then require CT sialography or MRI to outline the tumor mass. Submandibular masses have similar CT appearances to those of the parotid; however, the normally high density of the submandibular gland at times necessitates MRI and

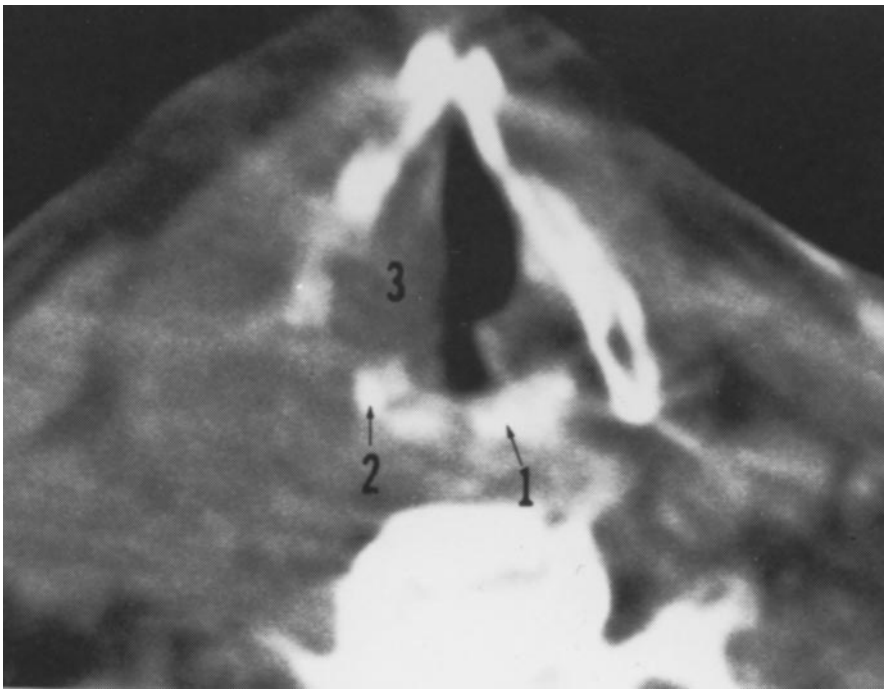

FIGURE 59–30. Computed tomographic scan showing a large tumor involving the right true vocal cord that is fixed in the paramedian position (3). Note extension of the tumor between partially destroyed thyroid cartilage and partially destroyed right arytenoid cartilage (2). Note tumor extension outside of the larynx into the neck. 1= left arytenoid cartilage.

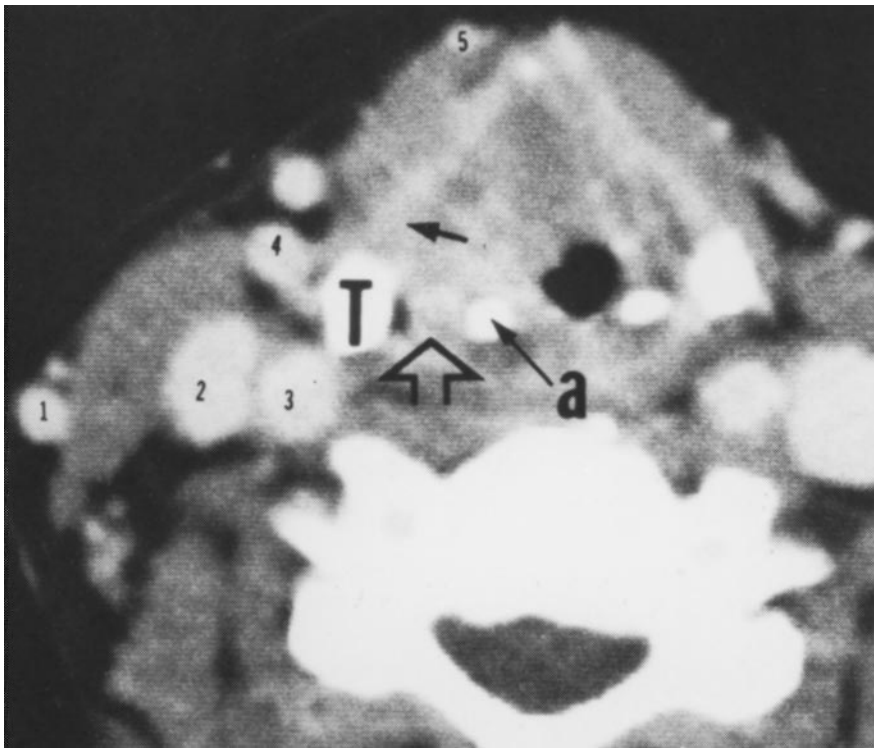

FIGURE 59–31. Postcontrast computed tomographic scan showing a large tumor involving the right false vocal cord and epiglottis and extending beyond the midline involving the left false vocal cord. The thyroid cartilage (T) is partially calcified, and the thyroid alae are seen as faint increased density with the tumor involving the right ala (*arrow*) and extending into the paraglottic space (*open arrowhead*) between the thyroid cartilage and right arytenoid cartilage (a) that is displaced medially. 1 = external jugular vein; 2 = internal jugular vein; 3 = common carotid artery; 4 = posterior facial vein; 5 = anterior jugular vein.

occasionally may necessitate CT sialography. The CT appearance of Warthin's tumor or papillary cystadenoma lymphomatosum, the second most common benign tumor in the parotid gland, is nonspecific, usually appearing as a well-circumscribed mass within or on the surface of the parotid gland.[45] Although, histologically, these tumors often have cystic components and some mucoid fluid within, the CT characteristics are not specific because the cystic spaces are very small.[45] At times, Warthin's tumors tend to have multiple lobules, may originate from relatively small intraglandular components with larger extraglandular components, with or without foci of calcifications, and have the appearance that has been compared to a branch of grapes.[45] Malignant tumors may be similarly sharply circumscribed (Figure 59–46) or may have indistinct margins. Invasive tumors are poorly marginated and extend beyond the glandular tissue into the fat and fascial planes. These tumors invade adjacent anatomic structures and may extend into the external auditory canal, middle ear, base of the skull, lateral pharyngeal space, and infratemporal fossa. Localized inflammatory lesions within the salivary glands may mimic mass lesions. Inflammatory disease usually results in a relatively diffuse, irregular, radiodense lesion in an enlarged gland.[45] It is not possible by CT alone to differentiate a benign lesion from a malignant one whenever a well-defined tumor is present in the salivary glands. Although an infiltrating mass is most likely to be a malignant lesion, an inflammatory reaction around a benign mass can have the same appearance as a malignant tumor. It should also be noted that masses arising in a salivary gland may be entirely or almost entirely surrounded by salivary tissue, or they may extend outside the salivary gland and be only partly buried in the gland.[45] In this situation, the intraglandular component abuts the salivary gland tissue directly without an intervening fat layer.

Magnetic resonance imaging and CT are both useful in the evaluation of salivary gland masses.[45,46] They can help to differentiate intrinsic from extrinsic lesion such as a cervical lymph node and a parapharyngeal mass from a parotid mass. The MRI may give some indication of the relationship of a parotid mass to the facial nerve. Although the MRI, like the CT scan, cannot give a histologic diagnosis, it can

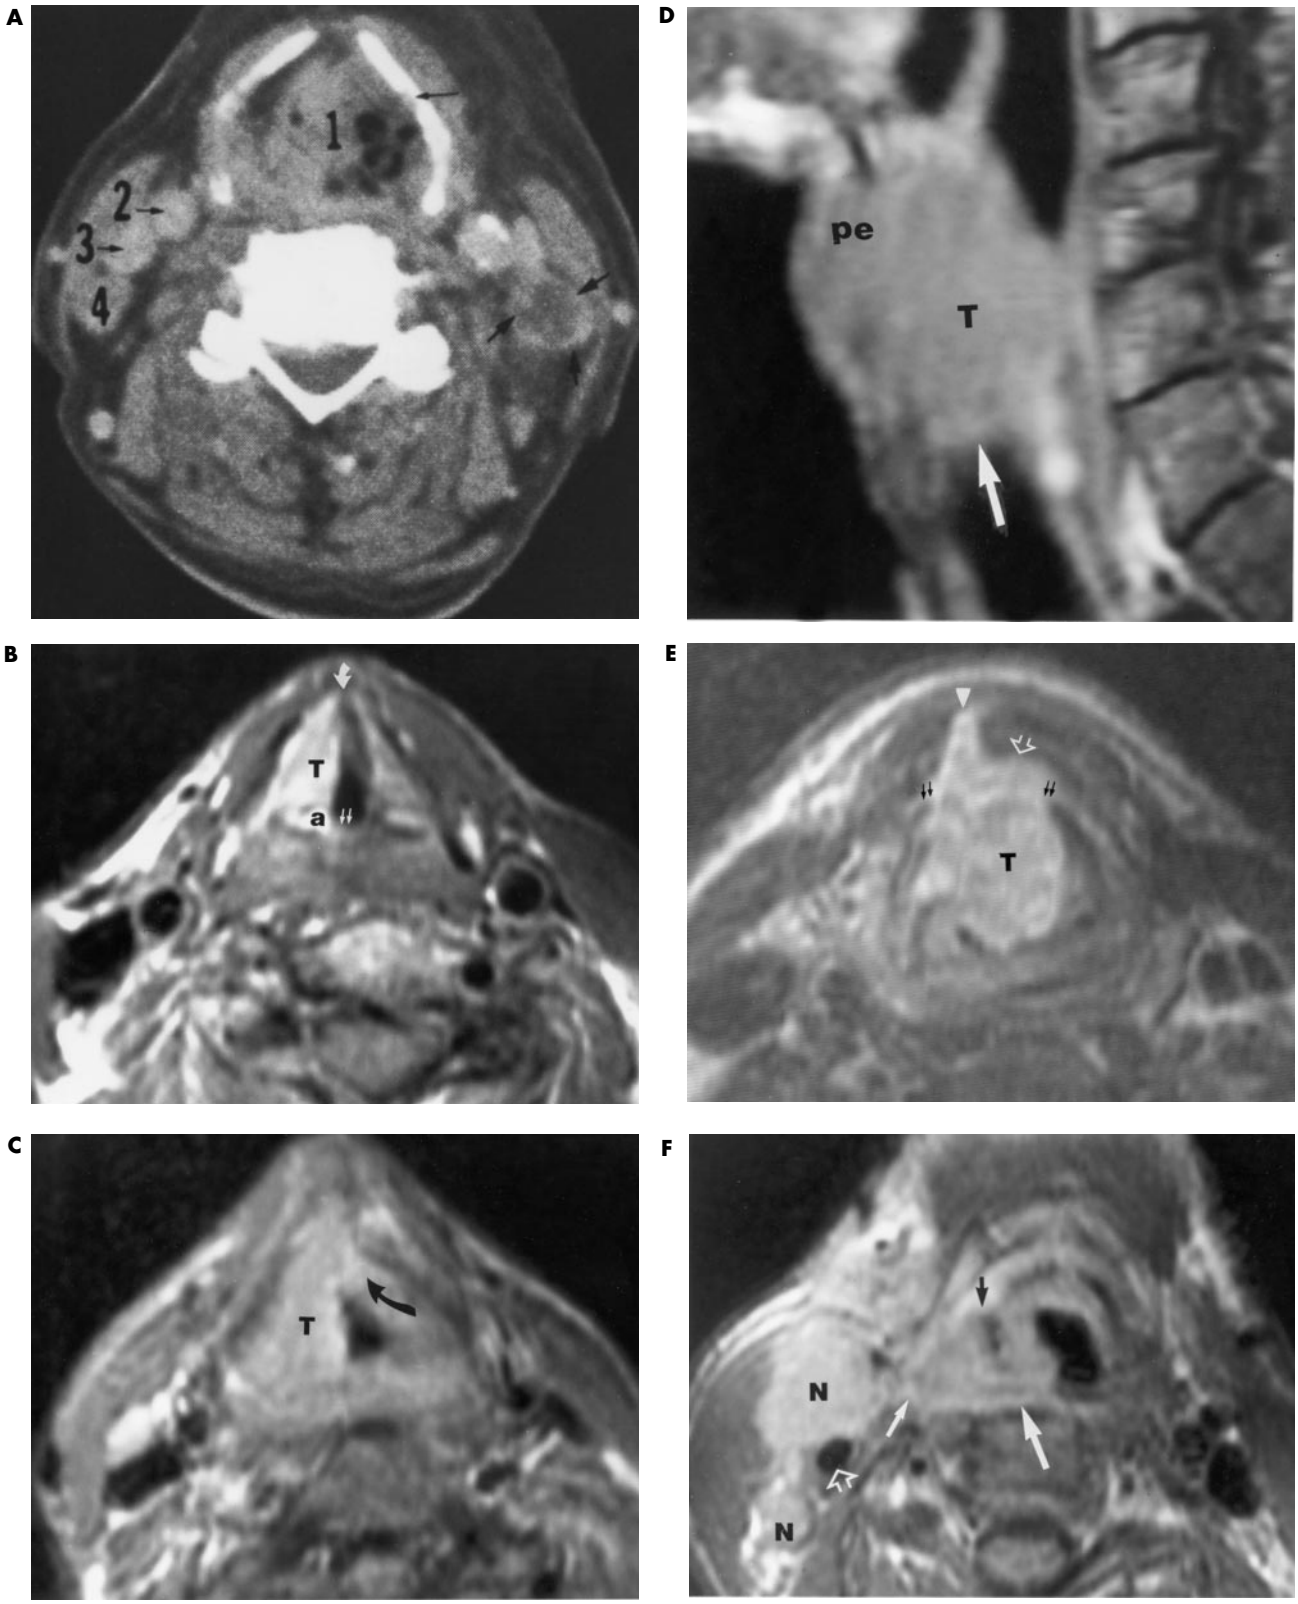

FIGURE 59–32. A, Computed tomographic scan showing a large necrotic exophytic tumor arising from the left aryepiglottic fold (1). Note tumor involvement of the left thyroid ala (*arrow*) and epiglottis and extension beyond the midline with involvement of the right aryepiglottic fold and destruction of the posterior aspect of the right thyroid ala. Note large left necrotic lymph node (*arrows*) and large right lymph node (4). 2 = common carotid artery; 3 = internal

jugular vein. *B*, Glottic carcinoma. Proton-weighted axial magnetic resonance image (MRI) shows tumor (T) involving the entire right true vocal cord. Note normal anterior (*curved arrow*) and posterior (*arrows*) commissures. The arytenoid cartilage (a) is normal. *C*, Supraglottic carcinoma. Proton-weighted axial MRI shows tumor (T) involving the right false vocal cord and extending beyond the midline to involve the left false vocal cord (*curved arrow*). *D*, Supraglottic carcinoma. T_1-weighted sagittal MRI, same patient as in *C*, shows large supraglottic tumor (T) with involvement of the preepiglottic space (pe) and extension into the immediate subglottic space (*arrow*). *E*, Supraglottic carcinoma. T_2-weighted axial MRI shows large tumor (T) with involvement of the thyroid cartilage (*small arrows*), extending into the preepiglottic space (*hollow arrow*) and strap muscles (*arrowhead*). *F*, Carcinoma of the right piriform sinus. Proton-weighted axial MRI shows a large mass (*arrows*) involving the right side of the hypopharynx. Note multiple metastatic lymph nodes (N). The common carotid artery (*hollow arrow*) is intact.

give an indication of the general morphology of the tumor. Rounded, sharply marginated, well-capsulated tumors tend to be benign (see Figure 59–45), whereas irregular and diffuse tumors tend to be malignant. Lipomas, lymphangiomas, and hemangiomas may be specifically differentiated from other salivary tumors. Most salivary gland tumors are seen on MRI as intermediate or low signal intensity on T_1- and proton density–weighted images and as high signal intensity on T_2-weighted images (see Figures 59–42 and 59–45). The tumors, when they are small, have a homogeneous appearance. Mixed signal

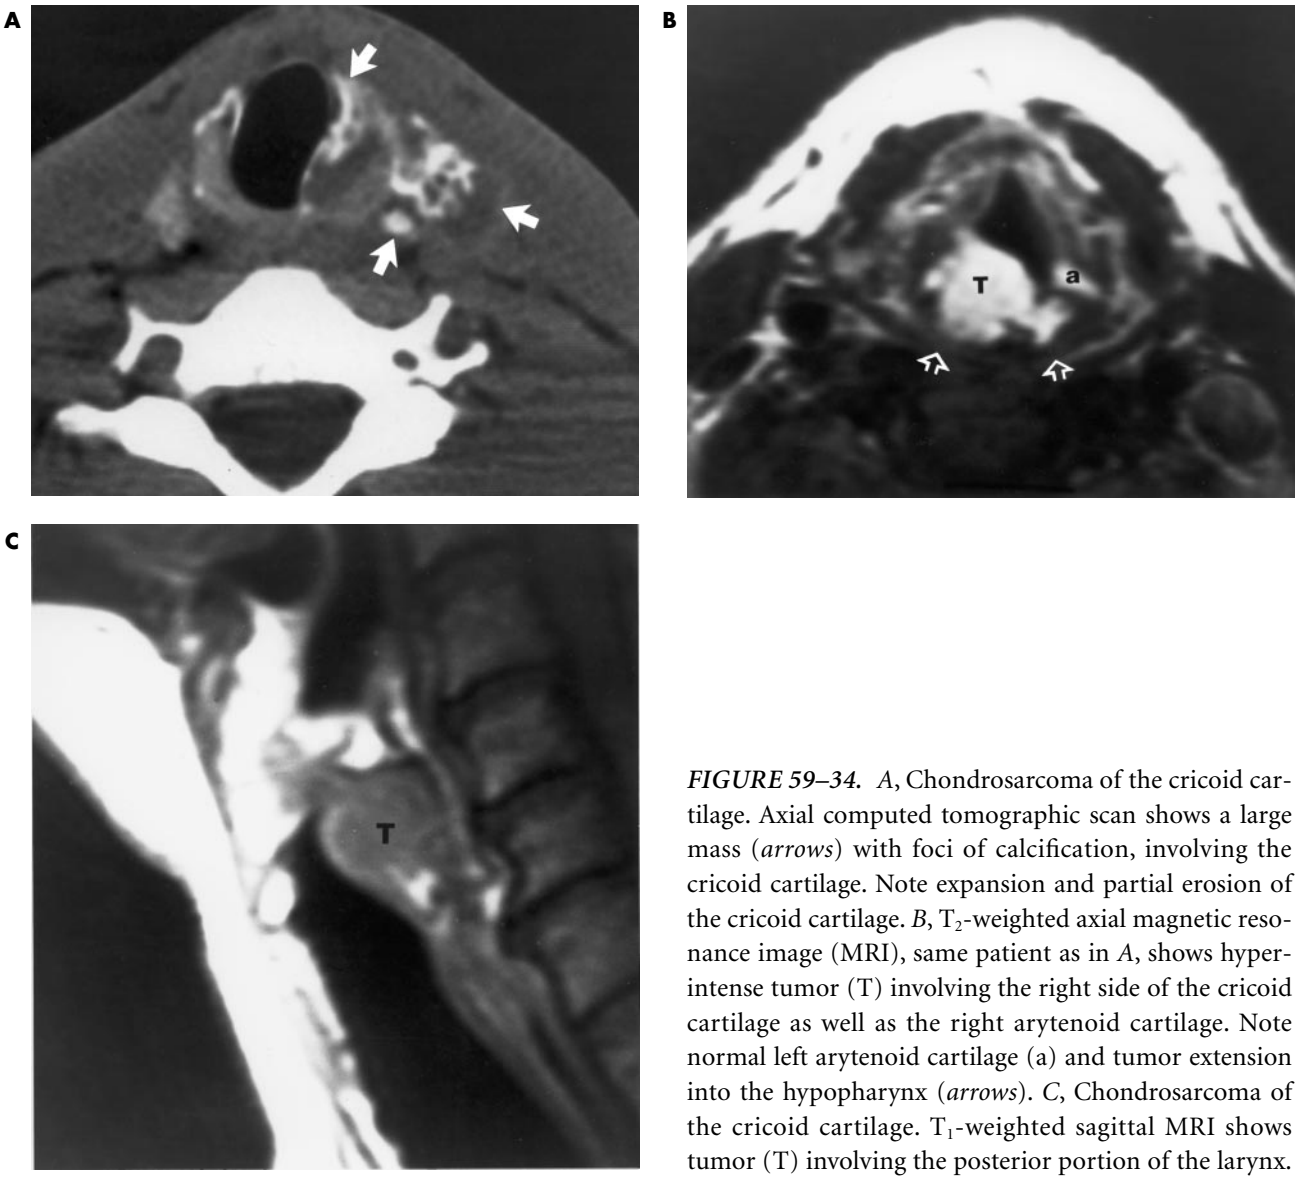

FIGURE 59–34. *A*, Chondrosarcoma of the cricoid cartilage. Axial computed tomographic scan shows a large mass (*arrows*) with foci of calcification, involving the cricoid cartilage. Note expansion and partial erosion of the cricoid cartilage. *B*, T_2-weighted axial magnetic resonance image (MRI), same patient as in *A*, shows hyperintense tumor (T) involving the right side of the cricoid cartilage as well as the right arytenoid cartilage. Note normal left arytenoid cartilage (a) and tumor extension into the hypopharynx (*arrows*). *C*, Chondrosarcoma of the cricoid cartilage. T_1-weighted sagittal MRI shows tumor (T) involving the posterior portion of the larynx.

intensities may be present particularly when they are larger than 3 cm. The serous- and mucus-filled spaces are common in benign mixed tumors.[45] In Warthin's tumor, they are more likely to be related to areas of frank cystic degeneration. In general, mixed signal intensities may be present in inflammatory lesions, benign tumors, and malignant tumors on both T_1- and T_2-weighted images.[45] Malignant salivary gland tumors may show intermediate to low signal intensity on T_2-weighted images. The more cellular and more aggressive a tumor is, the less likely it is that it will be hyperintense on T_2-weighted images. Calcification may be present in Warthin's tumor and acinic cell tumor. Calcification is rare in mixed tumors. Irregular calcifications in a mixed tumor, associated with pain or rapid growth, should raise the possibility of malignant sarcomatous (osteochondrogenic) degeneration.

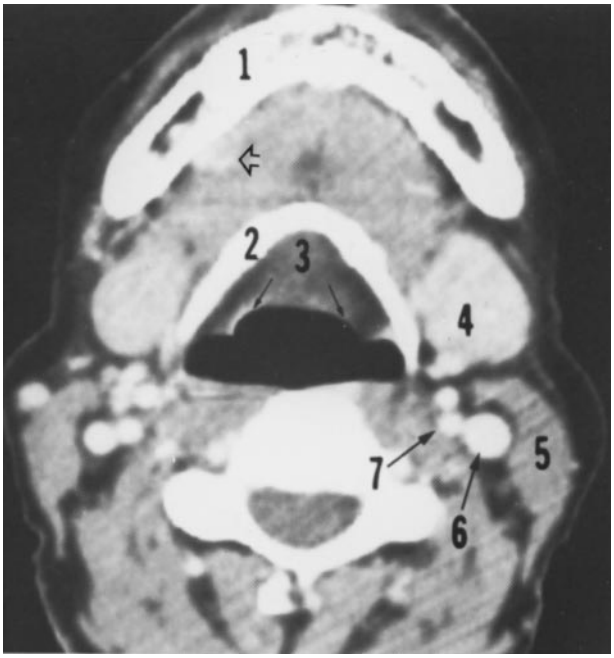

FIGURE 59–38. Axial computed tomographic scan of the oropharynx, showing the mandible (1), hyoid bone (2), base of the tongue (3), epiglottis (*arrows*), submandibular gland (4), sternocleidomastoid muscle (5), internal jugular vein (6), internal carotid artery (7), and, anterior to that, external carotid artery. The submandibular (4) and sublingual (*open arrow*) glands are intensely enhanced during rapid infusion of iodine contrast material.

Benign Mixed Tumors The most common benign tumor of salivary gland origin is the benign mixed tumor. A solitary mass in the parotid glands is a benign mixed tumor in 60 to 65% of the cases.[2,45] In the parotid, they are found most often in the lateral portion but may occur in any portion of it. [45] The CT and MRI appearance of these tumors represents a well-circumscribed mass, lying in an otherwise normal gland (see Figure 59–45). The CT and MRI appearance of an intraparotid facial neuroma (see Figure 59–42) may be identical to a benign mixed tumor. A characteris-

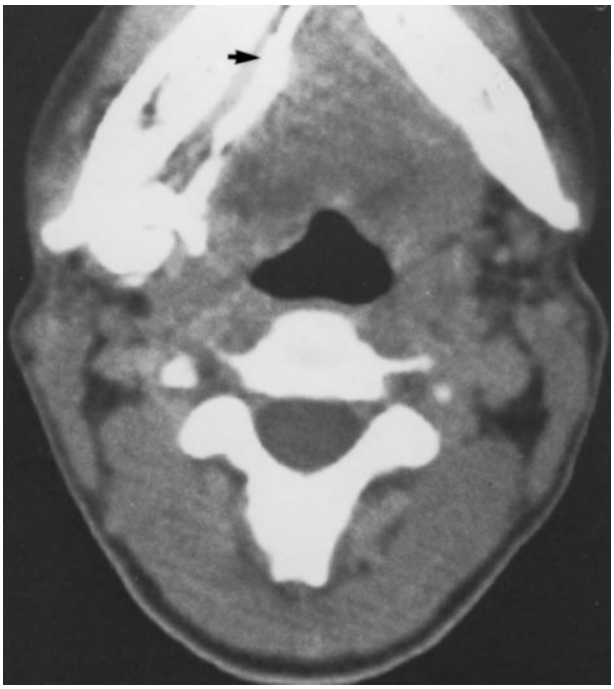

FIGURE 59–39. Computed tomographic sialogram showing the right submandibular gland and Wharton's duct (*arrow*). Note atrophic submandibular gland on the left side.

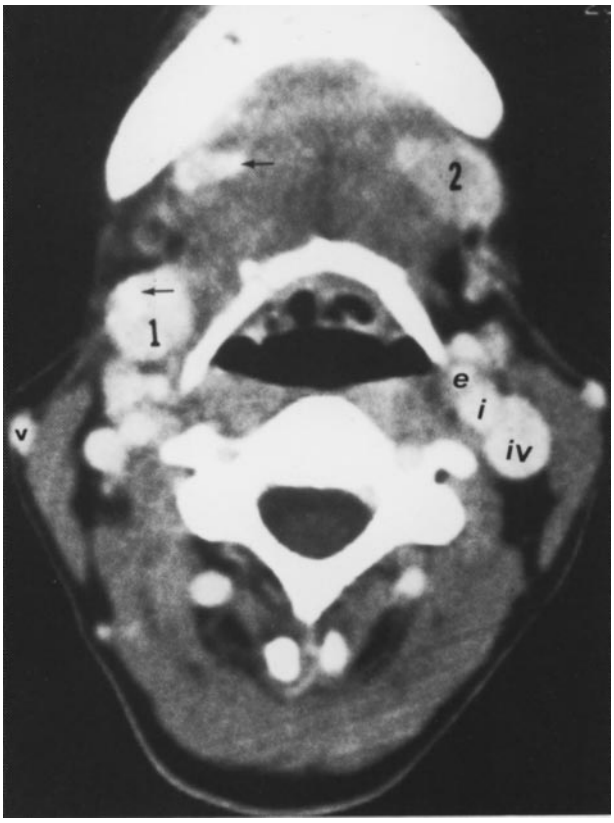

FIGURE 59–40. Axial computed tomographic (CT) scan of the oropharynx showing marked enhancement of the submandibular (1) and sublingual (2) glands. *Arrows* point to the residual pantopaque in the glands from previous CT pantopaque sialography. Note atrophic left submandibular gland (compare with Figure 59–38) and intense enhancement of the external (e) and internal (i) carotid arteries and external (v) and internal (iv) jugular veins.

tic but not pathognomonic feature of benign mixed tumors is that they become more heterogeneous in appearance on postcontrast T_1-weighted MRIs.

Papillary Cystadenoma Lymphomatosum. Papillary cystadenoma lymphomatosum (Warthin's tumor) occurs almost exclusively in the parotid gland and affects males more frequently than females.[2,45,46] It accounts for approximately 6 to 8% of the parotid tumors.[45] The mass usually occurs in the tail of the gland and is characterized by a painless, slow-growing asymptomatic mass. The tumor occasionally occurs in both parotid glands. Histologically, its characteristics include a double-layered epithelium having a tubulopapillary cystic pattern within lymphoid tissue or a lymph node.[45] The CT and MRI appearance of a Warthin's tumor is nonspecific, usually appearing as a well-marginated mass. At times, frank cystic degeneration may be present. There may be foci of fine or coarse calcifications present. These tumors characteristically concentrate technetium 99.[45]

Acidophilic Cell Adenoma. Acidophilic cell adenoma (oncocytoma, oncocytosis) is a benign lesion believed to arise from ductal epithelium.[45] The characteristic cell of the oncocytoma is the oncocyte. This cell is characterized by an excessive number of mitochondria that is best determined with electron

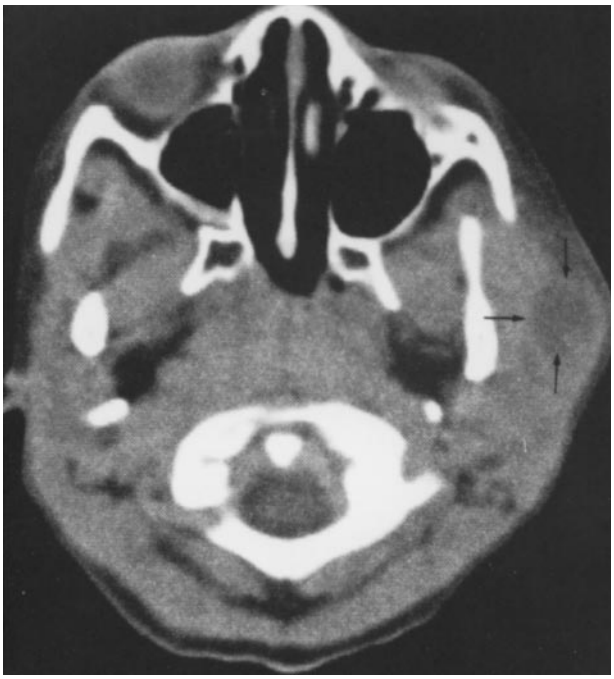

FIGURE 59–41. Parotid gland abscess. Computed tomographic scan of the parotid glands showing a round low-density image (*arrows*) caused by an abscess.

microscopy.[45] Oncocytoma such as Warthin's tumor has the ability to concentrate technetium 99; therefore, a "hot" area on radioisotope technetium 99 will indicate the possible presence of either a Warthin's tumor or an oncocytoma.

Gland Cell Carcinoma (Adenocarcinoma) *Adenoid Cystic Carcinoma.* Adenoid cystic carcinoma is uncommon in the parotid gland and common in the submandibular gland and the minor salivary glands of the oral cavity.[45] This tumor is also variously named adenocystic adenocarcinoma, cylindroma, pseudoadenomatous basal cell carcinoma, and adenocarcinoma.[2] These tumors occur more frequently in women in early middle age.[45] Pain is common and may be a prominent symptom. The mass grows slowly, and encapsulation of the lesion is not common. This tumor is unique in its strong tendency to invade nerves and perineural lymphatics.[45,46]

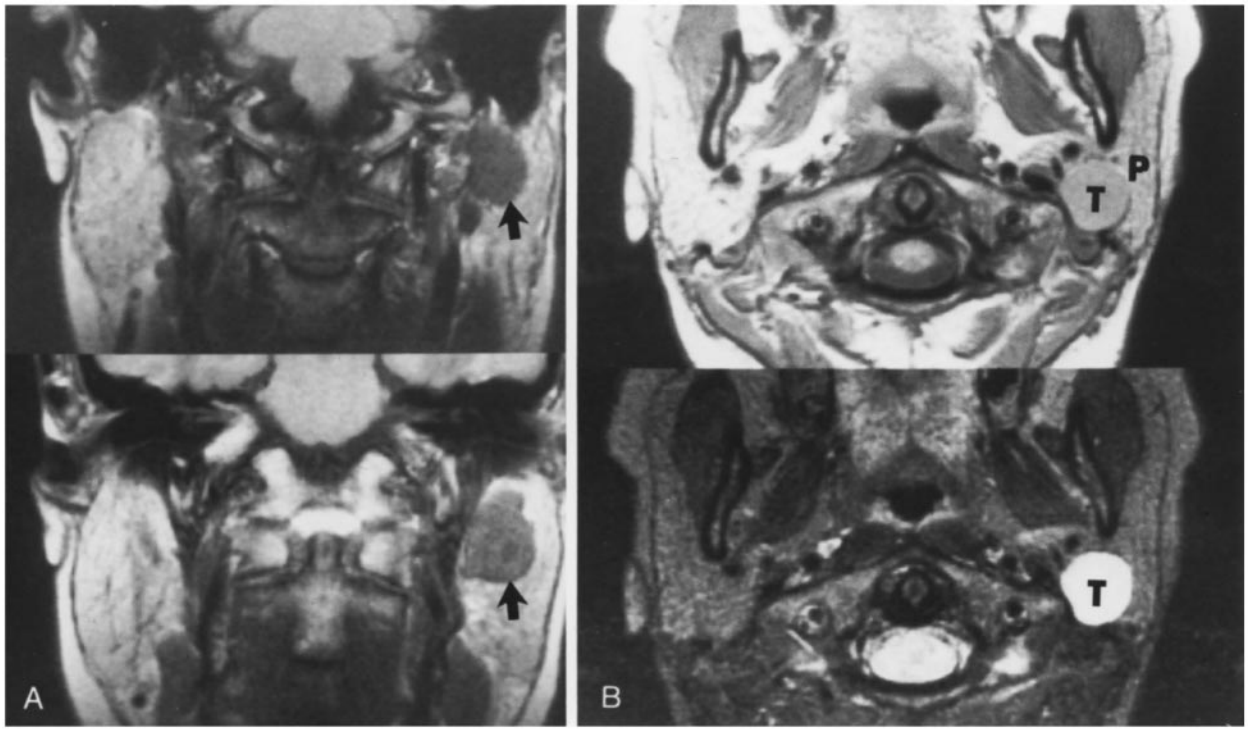

FIGURE 59–42. Facial neuroma arising within the parotid gland. *A*, T_1-weighted magnetic resonance images (MRIs) showing a hypointense mass (*arrows*). *B*, Proton-weighted (*top*) and T_2-weighted (*bottom*) axial MRIs showing the tumor (T) within the parotid gland (P). Notice hyperintensity of the tumor in the T_2-weighted image.

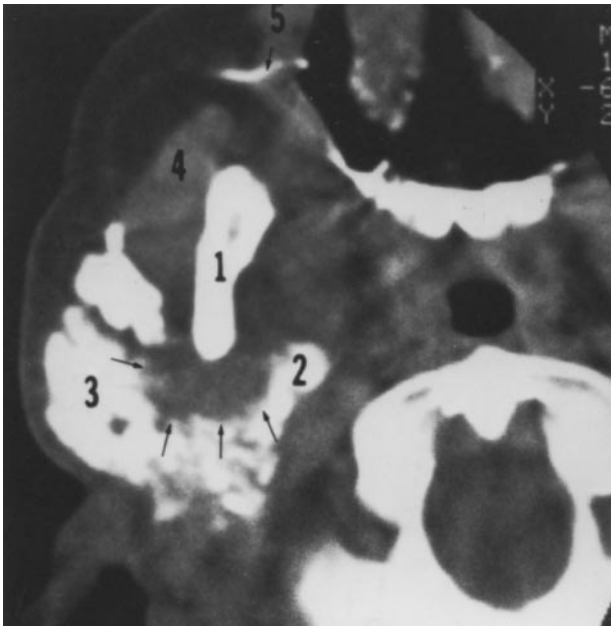

FIGURE 59–43. Axial computed tomographic sialogram of a parotid tumor. A large tumor (*arrows*) is seen involving the superficial and deep lobes of the right parotid gland. The lesion is sharply delineated from the surrounding gland tissue that is filled with contrast. 1 = mandible; 2 = deep lobe of parotid gland; 3 = superficial lobe of the parotid gland; 4 = masseter muscle; 5 = contrast in Stensen's duct.

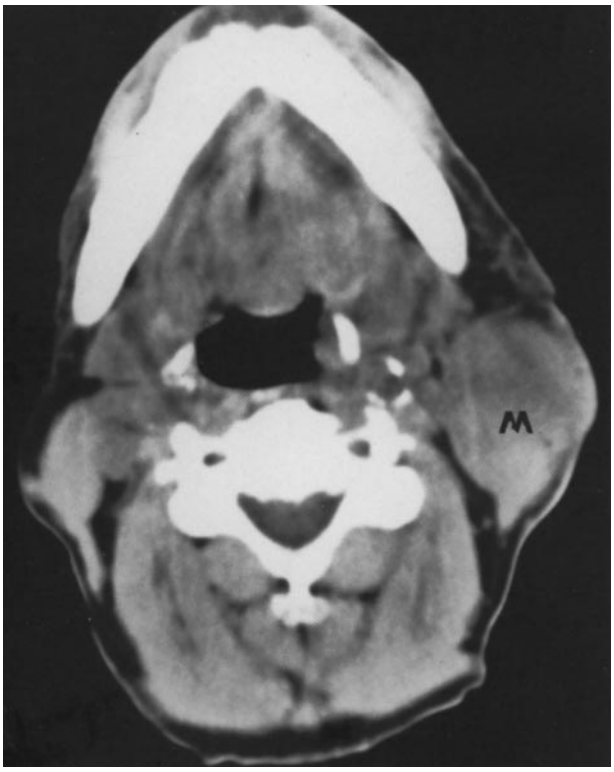

FIGURE 59–44. Parotid tumor. Axial computed tomographic scan shows a large mass (M) involving the left parotid gland.

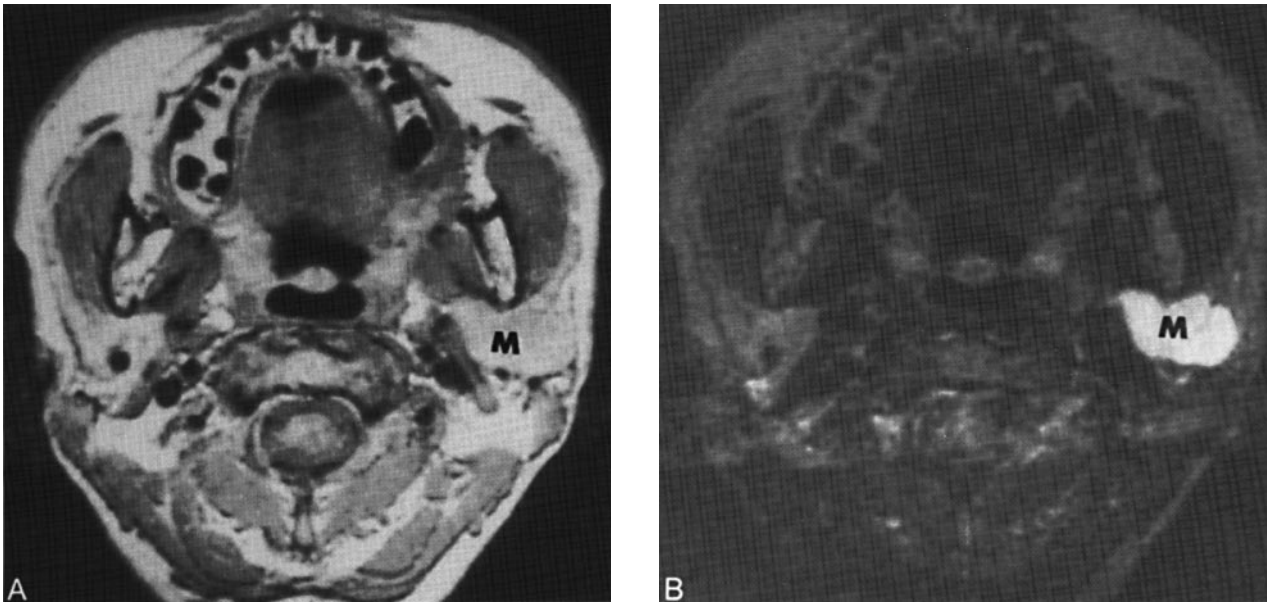

FIGURE 59–45. Pleomorphic adenoma. Proton-weighted (*A*) and T_2-weighted (*B*) axial magnetic resonance images show a well-defined mass (M) involving the left parotid gland.

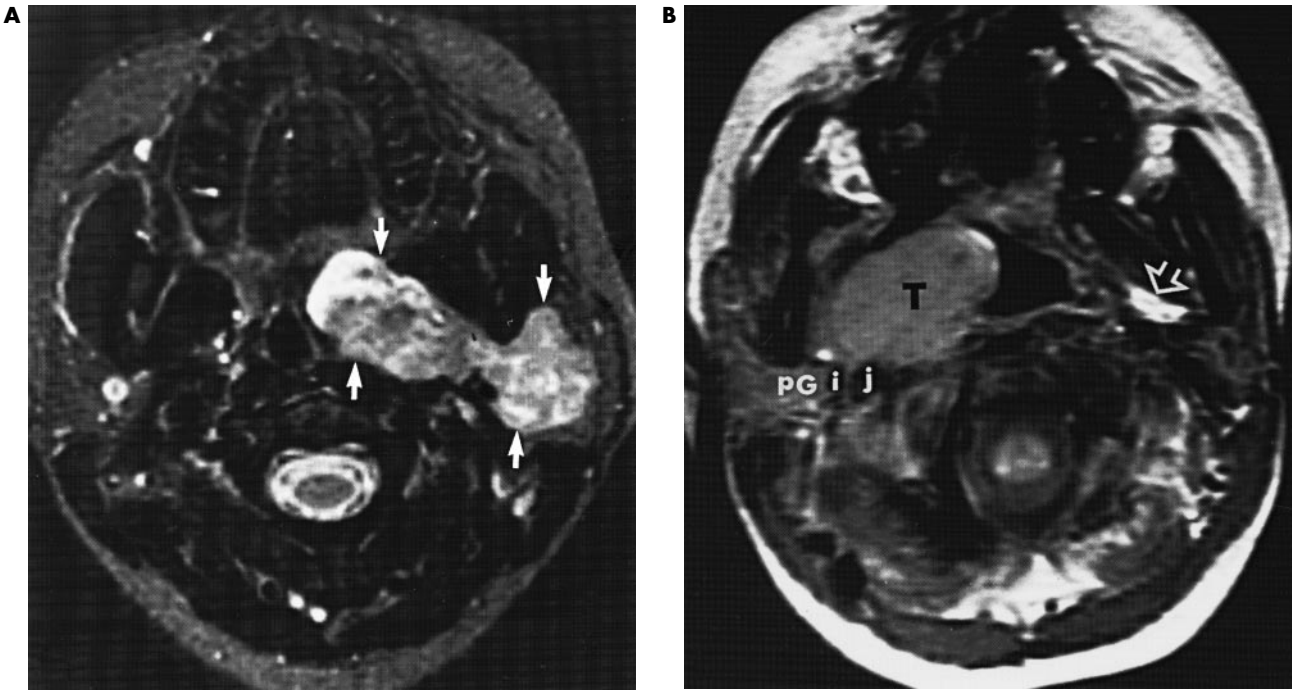

FIGURE 59–46. *A*, Malignant tumor of the parotid gland. T_2-weighted axial magnetic resonance image (MRI) shows a large mass involving the deep lobe of the left parotid gland, extending into the parapharyngeal space (*arrows*). This was reported as being compatible with liposarcoma. *B*, Parapharyngeal adenocarcinoma. Proton-weighted axial MRI shows a large tumor (T) involving the right parapharyngeal space. Notice normal left parapharyngeal space (*arrow*). i = internal carotid artery; j = internal jugular vein; PG = parotid gland.

CHAPTER 60

Neoplasms of the Nasopharynx

Frank G. Ondrey, MD, PhD, Simon K. Wright, MD

ANATOMY

Optimal interpretation of the clinical symptoms and natural history of patients with malignant processes in the nasopharynx requires a basic understanding of the anatomy of this structure. The nasopharynx is an open cuboidal chamber that lies beneath the base of the skull at the posterior aspect of the nasal fossa. It measures 4.0 to 5.5 cm transversely and 2.5 to 3.5 cm in the anteroposterior dimension and is roughly 4.0 cm in height. Anteriorly, it borders the posterior nares, within which lie the posterior ends of the middle and inferior turbinates. The roof is a sloping concave surface formed by the posterior body of the sphenoid, basilar component of the occipital bone, and anterior arch of the atlas. The nasopharyngeal tonsil lies in the midline in the roof and posterior wall. The superior pharyngeal constrictor and fascia complete the posterior wall. The floor of the nasopharynx is composed of the soft palate.

The lateral walls contain important structures such as the pharyngotympanic tube, situated 10 to 12 mm behind and slightly below the level of the posterior part of the inferior turbinate. The lateral walls consist of only two layers: the mucous membrane and the pharyngeal aponeurosis. The cartilaginous eustachian tube passes through this aponeurosis, opening into the fossa of Rosenmüller. Lateral to the lateral wall, the mandibular nerve exits the foramen ovale into the infratemporal fossa. Posterior to the eustachian tube is the retroparotid space, which contains the pharyngeal lymph nodes, internal carotid artery, internal jugular vein, and glossopharyngeal, vagus, spinal accessory, and hypoglossal nerves as well as the cervical sympathetic nerve.

Understanding the relative contents and locations of the foramina surrounding the nasopharynx allows the clinician to predict the extent of tumor spread based on cranial nerve examination. Six foramina are adjacent to the wall of the nasopharynx: (1) foramen lacerum, (2) foramen ovale, (3) foramen spongiosum, (4) carotid canal, (5) jugular foramen, and (6) hypoglossal canal. The foramen lacerum and the foramen ovale offer little resistance to tumor spread into the cranium, and their close proximity to the cavernous sinus and cranial nerves II, III, IV, and VI explains the frequency of cranial nerve palsies at diagnosis.

The lymphatics of the nasopharynx drain either through direct efferent channels to the deep lymph nodes of the posterior triangle or first through the lateral pharyngeal wall to the retroparotid or lateral pharyngeal lymph nodes and then on to the upper jugular chain. Some channels may pass directly to the jugulodigastric chain. Lymphatic channels often cross the midline and offer ready access to both sides of the neck.[1]

NASOPHARYNGEAL CARCINOMA

Natural History

Epidemiology Nasopharyngeal carcinoma (NPC) is unique among squamous cell carcinomas of the head and neck in its geographic epidemiologic profile. Although it is a rare tumor in most parts of the world, in regions of southeastern Asia, its incidence soars to 27.3 in 100,000. The highest incidence occurs in Taiwan, where 98% of the population is Chinese, 90% of whom originate from the Guangdong province. There is a decrease in incidence in northern China, falling to 3 in 100,000 in northern provinces. The Japanese, who trace their origins to the Mongoloid region, have an incidence of just 1 in 100,000 for both men and women. In Europe and North America, the incidence is 1 in 100,000. In China, the disease rate rises after age 20 years and falls after age 60; the mean age is 40 to 50 years. The male to female ratio is 3 to 1.

Dietary Associations. Because of the strikingly high incidence of NPC among the "boat people" of southern China (54.7 in 100,000), speculation about their unique environmental exposures led to the examination of salted fish as a risk factor. Salted fish has been shown to contain strong carcinogens and mutagens. Animal studies support the association: 5 of 22 rats fed with low doses of Cantonese-style salted fish developed malignant tumors of the nasal or paranasal sinus cavities, whereas no similar tumors developed in controls.[2] This finding was confirmed by Yu et al in 1989, who demonstrated a dose-dependent relationship between salted fish intake and tumor development in rats.[3] The amounts of salted fish fed to rats were in the range of human consumption.

Yu reviewed seven case-control studies examining the connection between diet and NPC,[4] four of which were conducted in the Cantonese ethnic group. All of these studies demonstrated a significant positive association between salted fish intake and risk of NPC. In two longitudinal studies, childhood exposure, in particular exposure from the time of weaning, was found to be more strongly related to the risk of developing NPC than adult exposure alone. Salted fish is a diet staple in these populations, and the process of preserving fish instills a variety of potential carcinogens into the food. Low levels of several volatile nitrosamines are detected in salted fish, most of which can induce nasal and paranasal tumors in animals. Bacterial mutagens are also present. Substances activating the Epstein-Barr virus (EBV) have also been identified in salted fish. Together, these factors may combine to explain the findings of these case-control studies.

Epstein-Barr Virus Associations. Epstein-Barr virus is a double-stranded DNA virus that, in addition to being the cause of infectious mononucleosis, is implicated in a variety of lymphoid neoplasms: endemic Burkitt's lymphoma, post-transplantation lymphoproliferative disorders, subsets of Hodgkin's disease, and nasal T-cell lymphoma.[5] The connection between EBV and NPC was first made in the late 1960s, when serologic studies demonstrated elevated immunoglobulin (Ig)A and IgG titers against viral antigens. Two major lines of evidence for the role of EBV have been elucidated: serologic studies and nucleic acid studies.

Serologic Studies. Elevated levels of IgA and IgG antibodies directed against the viral capsid antigen and early antigen in patients with NPC have been documented by many studies. Immunoglobulin A can be detected in 80 to 85% of patients with NPC. These profiles are uncommon in patients with carcinomas in other parts of the head and neck. Response to treatment yields a corresponding decrease in levels; increasing titers are associated with progression of disease. Anti-EBV nuclear antigen-1 IgA has also proven to be a sensitive indicator of the presence of NPC: levels are present in 90% of patients with NPC compared with 7% of normal controls and 14% of patients with non-NPC cancers. These serologic tests have implications for screening in high-risk areas and for monitoring the progression of the disease. Although serologic studies paint a convincing picture for the involvement of EBV in NPC, they do not provide direct evidence for EBV in the pathogenesis of the disease.

Nucleic Acid Studies. Direct evidence of the role of EBV in the pathogenesis comes from studies of EBV ribonucleic acid (RNA) in NPC cells, the presence of which indicates infection with the virus. In a study of 120 cases of NPC, including 31 with World Health Organization (WHO) type I histology (keratinizing squamous cell carcinoma), in situ hybridization demonstrated EBV RNA in all samples.[6] Similar studies have also demonstrated EBV-encoded RNA in carcinoma in situ and areas of dysplasia whether or not associated with a primary invasive lesion.[7] These findings are in distinction to patients without NPC. The consistent presence of EBV in preinvasive lesions strongly supports EBV infection as an early event in the malignant transformation of nasopharyngeal epithelial cells.

Clonality. The role of EBV in the pathogenesis of NPC has been proven one step further by the demonstration of a clonal population of EBV DNA in invasive lesions.[7] The mechanism of transformation, however, is not well understood. Epstein-Barr virus elaborates several proteins; one candidate is latent membrane protein (LMP)-1, which is found in 65% of invasive lesions. This protein is required for EBV-mediated transformation of B lymphocytes; transfection of the protein in epithelial cells causes keratin down-regulation and morphologic changes toward spindling of cells. Taken together, the role of EBV in NPC is convincing.

Immunity *Biomarkers.* Epstein-Barr Virus Antigens. Given the close association of EBV and NPC, it is not surprising that considerable attention has been focused on EBV antigens as biomarkers to predict the NPC clinical course. Serologic studies can be useful in this regard: response to therapy is indicated by declines in titers of IgA anti–viral capsid antigen and early antigen. Conversely, disease progression correlates to rising titers of IgA.[8] Epidermal growth factor and its receptor (EGFR) have been associated with malignant progression in squamous cell carcinomas. Additionally, the tumor proliferation marker Ki67 has similar associations with malignant progression. Increased expression of EGFR and elevated numbers of Ki67-positive cells have been correlated with expression of EBV LMP-1 and were more frequently seen in cases of advanced NPC.[9]

Growth Factors Vascular endothelial growth factor (VEGF) is a potent angiogenic growth factor elaborated by many malignant tumors. Elevation of this growth factor has been shown to predict poor prognosis in several tumor types. Serum VEGF was found to be elevated in patients with metastatic NPC but not in patients with nonmetastatic NPC. This correlates with findings of increased tumor microvessel density in tumor from patients with metastatic NPC.[10] Because VEGF is elevated only in metastatic NPC, it is of limited value in early diagnosis of the disease. Other growth factors are currently under investigation and may prove useful as additional therapies are developed for NPC.

Histology

World Health Organization Classification and Outcomes The WHO has classified NPC into three histopathologic groups based on light microscopy. WHO type I is a keratinizing squamous cell carcinoma similar to others of the head and neck. It exhibits abundant keratin formation with intercellular bridges and various degrees of differentiation. It can be subdivided into well-differentiated (G1), moderately differentiated (G2), or poorly differentiated (G3) grades. WHO type II is a nonkeratinizing form with greater pleomorphism, scant keratin formation, and a variety of patterns. It exhibits a pavemented or stratified pattern with clear cell margins. WHO type III is an undifferentiated tumor originally described as lymphoepithelioma by Schmincke and Regaud. It is characterized by greater heterogeneity of cell size, indistinct cell borders, and prominent nucleoli. Types II and III both typically demonstrate lymphocytic infiltration; in contrast, it is less commonly seen in type I. Types II and III are endemic forms of NPC and are classically associated with EBV (Figure 60–1).

The clinical implications of the differential types are considerable. In a National Cancer Data Base study of 5,069 patients diagnosed with NPC in the United States between 1985 and 1989, there were substantial differences between 5-year survivals of keratinizing (37%) versus nonkeratinizing (65%) and undifferentiated (64%) NPC[11] (Figure 60–2). Furthermore, differential survival of various patient origin groups correlated tightly with the respective proportion of keratinizing NPC. Origin groups with the best survival had the highest proportion of radioresponsive nonkeratinizing and undifferentiated NPCs; likewise, worst survival groups had the highest proportion of poorly responsive keratinizing carcinomas. Ironically, the more differentiated unilateral tumors had poorer outcomes. This study was performed in the United States; the translatability of results to endemic areas is not known (Figure 60–3).

Staging Systems

The epidemiologic idiosyncrasy of NPC is reflected in the controversies surrounding the staging of this disease. All staging of NPC begins with a thorough physical examination, including endoscopy. Imaging studies, including computed tomography (CT) and magnetic resonance imaging (MRI), are performed to define soft tissue and bony extension. Ho developed a staging system based on his extensive experience treating NPC in endemic areas of southeastern Asia. His system divides all disease into three tumor categories that do not account for nasopharyngeal subsite involvement. Ho's staging system divides the neck into three zones with increasing node status from superior to inferior.

The fourth edition of the American Joint Committee on Cancer (AJCC) staging was developed and applied in the United States, where NPC is nonendemic. It divides all disease into four tumor categories, including T2 accounting for multiple

nasopharyngeal subsite involvement. The neck is treated similarly to other head and neck cancers.

The fifth edition of the AJCC staging system sought to combine the value of each staging system by including components of the Ho and AJCC systems, producing a system that simplifies the nasopharyngeal subsites and preserves the vertical stratification of lymph node involvement. This staging system was applied to 107 patients in the United States and compared with the two previous staging

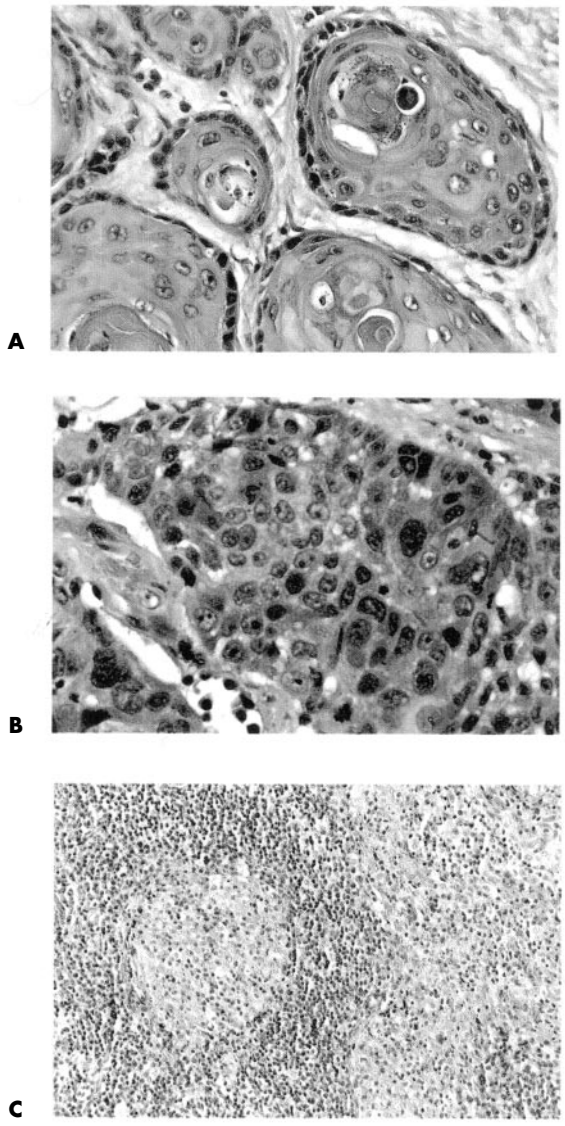

FIGURE 60–1. Nasopharyngeal carcinoma histology. *A*, WHO type I—well-differentiated nasopharyngeal cancer. Note keratin pearls, intracellular bridges, and increased nuclear-to-cytoplasmic ratios but consistent sizes of the nuclei. *B*, WHO type II—Note decreased level of differentiation characterized by increased nuclear pleomorphism. Also note increasing inflammatory infiltrate compared with WHO type I tumors. *C*, WHO type III—classic appearance of a lymphoepithelioma with difficult to distinguish squamous cancer cells in a background of lymphocytes.

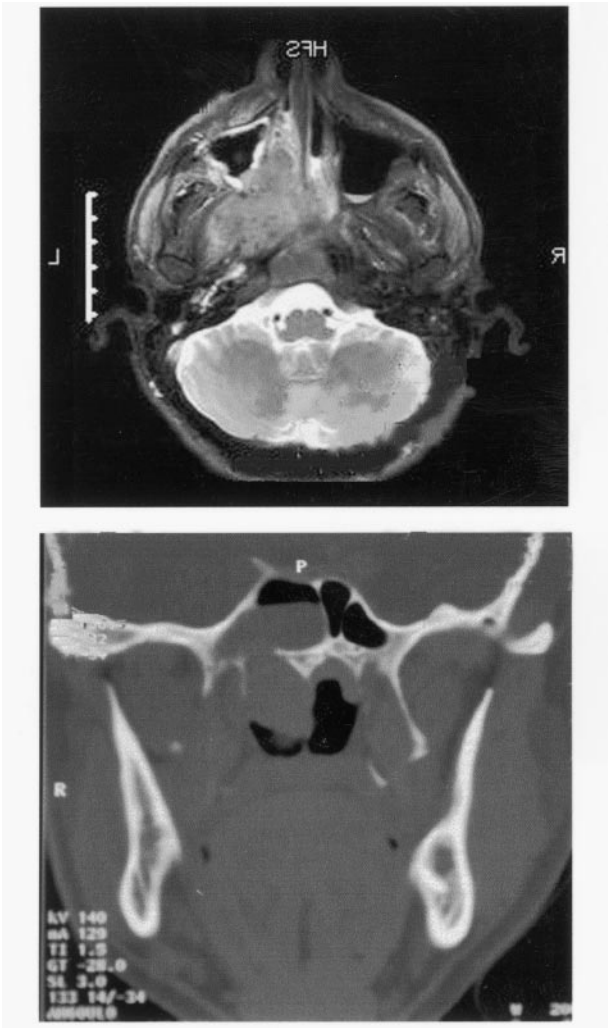

FIGURE 60–2. Magnetic resonance imaging and computed tomographic appearance of invasive nasopharyngeal cancer of the skull base. In the *upper panel*, note the appearance of the tumor in the nasopharynx with extensive invasion into the nasal cavity bilaterally with erosion of the posterior part of the nasal septum and the posterior wall of the maxillary sinus. Note the difference in density of the tumor and the water density of the maxillary sinus mucosa on this T_2-weighted image. Posteriorly, the tumor invades the clivus and area surrounding the brainstem. Laterally, the tumor extends into the pterygoid musculature. In the *lower image*, sphenoid sinus invasion is demonstrated with erosion of the bony floor of the sphenoid sinus.

classifications,[12] and it was found to be superior. A similar study was performed in Singapore on 677 patients with primarily endemic NPC. The revised 1997 AJCC staging was applied and found to be prognostically useful. A direct comparison was not performed.[13] The new staging system should help to standardize staging and facilitate comparison of patient groups undergoing clinical trials around the world (Table 60–1).

Clinical Presentation

The early diagnosis of NPC is impeded by the poor accessibility of the site to routine physical examination. The early symptoms of the disease are often confounding to physicians and empirically treated as non–life-threatening entities for some time before the diagnosis is made. Generally, symptoms fall into one of four general areas of complaint: aural, nasal, neck, and miscellaneous accounted for by cranial nerve involvement (facial pain, diplopia). The classic presentation at the time of diagnosis is a neck mass and conductive hearing loss, often with bloody drainage. Nasopharyngeal carcinoma often arises from the lateral wall of the nasopharynx, near the fossa of Rosenmüller. As the mass enlarges, it obstructs the eustachian tube orifice and induces a serous otitis media.

Site of first symptom in 151 NPC patients was analyzed by Neel et al.[14] The sites were the neck (36%), ear (29%), and nose (21%). Symptoms at the time of admission were compiled by Dickson.[15] A neck mass was present in 60 to 70% of patients, hearing loss in 44 to 53%, nasal obstruction in 27 to 32%, and epistaxis in 34 to 46%. Cranial nerve palsies were present in 3.9 to 15.1 of patients, the most common being cranial nerve VI. Sites of origin in descending order were lateral wall (35.9%), posterior superior wall (27.8%), too extensive to determine (14.4%), and not well described (15.2%).

Facial sensory deficits or facial pain suggests involvement of the foramen lacerum. Invasion of the cavernous sinus is indicated by cranial nerve deficits of cranial nerves III, IV, and VI. Because cranial nerve VI crosses lateral to the carotid artery, this is the first intracavernous cranial nerve encountered. Unilateral deficits of cranial nerves III, IV, VI, and V1 define the superior orbital fissure syndrome, which suggests involvement of the orbit. Deficits of cranial nerves IX, X, and XI indicated extension of tumor through the carotid canal caudad toward the jugular foramen or hypoglossal foramen. Cervical sympathetic involvement may cause Horner's syndrome, ptosis, miosis, and anhidrosis, often seen with lower cranial nerve deficits.[15]

The parapharyngeal space is involved in 75 to 80% of patients by CT. Invasion of local areas is common. The oropharynx is involved in 15% of patients, the nasal cavity in 20%. The bony base of the skull is involved in more than one-quarter of patients, and brain involvement occurs in 3 to 12%. Cranial nerves IV and V are commonly involved; cranial nerve XII may be affected by bulky upper cervical nodes. Cranial nerves IX, X, and XI often reflect jugular foramen involvement; involvement of the cavernous sinus will affect cranial nerves III and IV.[16,17]

Nodal involvement is extremely common in NPC, occurring in 75 to 90% of WHO type II and III histologies at the time of diagnosis. In type III, nodal involvement is bilateral in 60% of patients. Distant dissemination is reported by most major series to be between 5 and 11% at the time of pres-

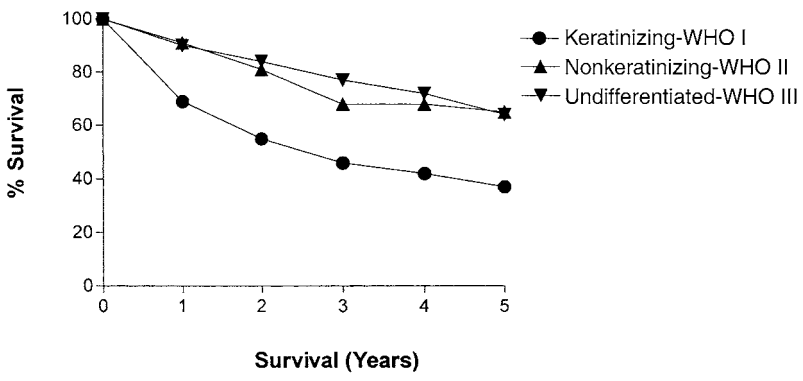

FIGURE 60–3. Five-year survival of patients with nasopharyngeal cancer by WHO classification. Note that the poorer differentiation status portends improved survival.

entation. The most common sites are bone, lung, liver, and extraregional lymph nodes.[18]

Diagnosis

The diagnosis of NPC begins with an accurate history and complete physical examination, including endoscopic visualization of the nasopharynx. This is followed by endoscopic examination of the nasopharynx under general anesthesia for the purpose of tumor staging. Patients who present with neck metastases with unknown primaries should have NPC ruled out by direct biopsy. Imaging studies are done to define the extent of the primary lesion as well as neck metastasis. Magnetic resonance imaging is useful for evaluation of muscle, nerve, or intracranial invasion, whereas CT demonstrates bony involvement more reliably. Olmi et al demonstated that CT can upstage 50% of T2 and T3 lesions.[19] Chest roentgenogram, bone scan, complete blood count, serum chemistries, and liver function tests are recommended. Nutritional support should be instituted when appropriate (Figure 60–4).

TABLE 60–1. Fifth Edition of AJCC Staging Sytem

T1	Tumor confined to the nasopharynx		
T2	Tumor extends to soft tissue of oropharynx and/or nasal fossa T2a: Without parapharyngeal extension T2b: With parapharyngeal extension		
T3	Tumor invades bony structures and/or paranasal sinuses		
T4	Tumor with intracranial extension and/or involvement of cranial nerves, infratemporal fossa, hypopharynx, or orbit		
N0	No regional lymph node metastasis		
N1	Unilateral metastasis in lymph node(s) measuring ≤ 6 cm in greatest dimension above the supraclavicular fossa		
N2	Bilateral metastasis in lymph node(s) measuring ≤ 6 cm in greatest dimension above the supraclavicular fossa		
N3	Metastasis in a lymph node(s): (a): > 6 cm in greatest dimesion (b): Extension to the supraclavicular fossa		
M0	No distant metastasis		
M1	Distant metastasis		
Stage I	T1	N0	M0
Stage IIA	T2a	N0	M0
Stage IIB	T1	N1	M0
	T2b	N0–1	M0

TREATMENT

External Beam Radiotherapy Historically, radiotherapy has been the standard of treatment for locoregionally confined NPC. In such patients, it is administered with the intent to cure. The location of primary disease with respect to vital structures, the propensity for bilateral lymphatic metastases, and the inherent radiosensitivity of NPC have made radiation therapy the primary treatment modality, although surgery is sometimes employed for local recurrences after radiotherapy failure. Neck dissection may be performed to address bulky advanced neck disease.

The entire nasopharynx and bilateral retropharyngeal, jugulodigastric, low neck, posterior chain, and supraclavicular lymph nodes are included in the initial radiotherapy target. At least 45 to 50 Gy at 1.8 to 2.0 Gy per fraction (day) are delivered. The primary tumor dose is usually boosted to 66 to 70 Gy based on tumor stage. Because NPC is generally more radiosensitive than other squamous cell carcinomas of the head and neck, moderate-dose radiotherapy followed by neck dissection is not recommended. However, proven residual disease after full-course radiotherapy should be addressed with neck dissection 6 to 8 weeks following completion of radiotherapy.[18] M. D. Anderson Cancer Center has reported survival on a consecutive series of 378 patients. Respective actuarial survival rates at 5-, 10-, and 20-year follow-up were 48%, 34%, and 18%.[20] Local control rates with radiation alone for T1, T2, T3, and T4 tumors are 85 to 95%, 80 to 90%, 60 to 75%, and 40 to 60%[18]; most failures are isolated, and nearly all occur within 5 years of therapy.

The treatment of the N0 neck is guided by two principles. First, the high probability of neck involvement is unrelated to the stage of the primary disease, and bilateral involvement is frequent. Thus, it is not possible to predict reliably a side of disease or which patients may have subclinical local metastases. Second, although salvage surgery of the untreated neck is effective in 80 to 90% of patients, the appearance of disease in the untreated neck is strongly associated with distant metastasis.[21,22] Because patients without subclinical metastases cannot be distinguished from those with subclinical metastases, coupled with the fact that close surveillance and salvage surgery are associated with adverse outcomes, the elective treatment of the necks of all patients is warranted, even though, inevitably, some patients will be receiving treatment unnecessarily. Regional control rates with radiation alone are good: reported 5-year regional control rates for N0, N1 and N2, and N3 categories are 90 to 100%, 80 to 90%, and 60 to 80%, respectively. It is unclear whether local recurrence increases the risk of distant metastasis.

Timing of radiation delivery is important. It is well established that a prolonged course of radiation

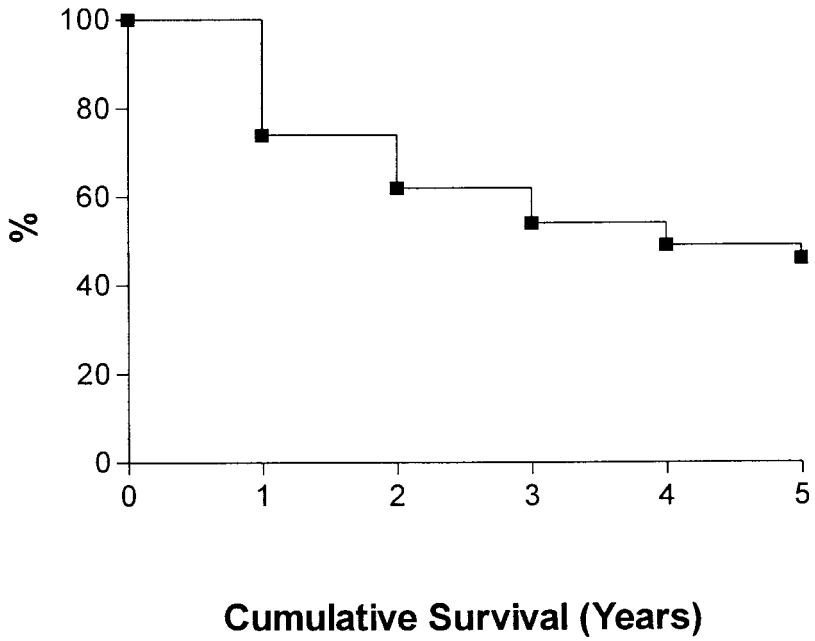

FIGURE 60–4. Five-year survival of non-Hispanic/non-Asian US citizens across all histologic types. All types and stages are shown in this cross-sectional graph.

delivery portends a poorer prognosis. Hyperfractionation involves the use of a smaller dose per fraction given; accelerated fractionation reduces overall treatment time. Hyperfractionation allows a higher total dose to be delivered without increasing the rate of late complications. This is based on the differential response of acute-reacting tissues, such as tumor, compared with late-reacting tissues. This differential reaction is inversely related to fraction size. By decreasing the total duration of treatment, accelerated fractionation reduces the opportunity for tumor clones to proliferate. Phase II studies indicate mixed results. Interestingly, an interval of at least 8 hours between fractions appears to be necessary to prevent brain or spinal cord injury.[18]

The ability to achieve focal exposure and relative ease of access to the nasopharynx have generated interest in endocavitary radiotherapy (brachytherapy) as a means of boosting dose to the primary tumor site following external beam radiotherapy. No phase III studies have been performed to evaluate this modality. However, in a study by Chang et al, the best actuarial survival occurred in a group of patients receiving a total combined external and endocavitary dose of 72.5 to 75 Gy.[23] It was better than the survival of the second experimental arm receiving a > 75 Gy total dose. The authors also concluded that fraction size should be decreased to reduce complications. Fractionated high-dose brachytherapy delivered as a boost to external beam radiotherapy was delivered on an outpatient basis to 29 T1 to T3 patients and 13 T4 patients.[24] The results were compared with matched retrospective controls. Multivariate analysis demonstrated hazard ratios for brachytherapy versus no brachytherapy of 0.24 for time to local failure, 0.35 for time to distant failure, 0.31 for disease-free survival, and 0.44 for cause-specific survival. Doses of 73 to 95 Gy were administered with minimal morbidity. Definite indications for endocavitary radiotherapy await further clinical trials.

Predictors of Radiotherapy Failure. The ability to predict which patients are at greatest risk of failure would make it possible to focus more aggressive or adjuvant therapy on those who have the worst prognosis, while sparing those with a favorable outlook the morbidity of aggressive treatment. As expected, tumor category and node category are well-established predictors of survival. Interestingly, tumor category is unrelated to risk of distant metastasis; its impact on survival can be attributed to increasing risk of local failure. Conversely, node category exerts its influence on survival through increasing risk of distant metastasis, recognizing that, overall, the risk of neck failure is low. Other strong predictors of failure include more differentiated tumors (WHO type I) and cranial nerve involvement (Table 60–2).[18,20]

Management of Radiotherapy Failures. Reirradiation of local failures has been examined. Teo et al treated 103 of 123 isolated local failures with reirradiation using mainly external beams as salvage after failure of contemporary high-dose primary radiotherapy.[25] Twenty were treated with nasopharyngectomy with/without radical neck dissection with/without postoperative radiotherapy. With a 20-month median follow-up, reirradiation to high dose achieved a 5-year overall survival of 7% and 5-year local control of 15%, with significant late complications. Surgical salvage was associated with earlier recurrent tumor categories and better survival and local control than the reirradiation group. This relation persisted even when controlling for recurrent T1 and recurrent T2 size lesions.

Photodynamic therapy (PDT) has been used for the treatment of locally recurrent NPC.[26] In a pilot study, five patients with recurrent NPC with a depth less than 10 mm by CT and with no clinical recurrent neck disease underwent PDT with intravenous hematoporphyrin derivative in four and porfimer sodium in one activated by a 630 nm laser light under local anesthesia. Three of five patients were reported to be disease free at 51, 52, and 60 months; the longest survival time was in a patient who had failed reirradiation to a total dose of 136 Gy. There were no complications related to treatment. At the Prince of Wales Hospital in Hong

Kong, where NPC is endemic, Tong et al reported their experience with the same agent and light in the treatment of 12 patients with recurrent disease after radiotherapy. All 12 patients demonstrated dramatic response by CT and MRI at 6 months post-PDT. Of the 8 patients for whom cure was sought, 3 remained disease free at 9 to 12 months following a single treatment; the remaining patients achieved useful palliation. Minimal morbidity occurred. Further study of this modality is warranted.[27]

Complications of Radiotherapy. In modern clinical trials, mucositis is the most frequent radiotherapy acute toxicity, occurring in 18 to 84%. Grade 3 mucositis (< 50%) occurs in 20 to 28% of patients.[20] The most common long-term complications of radiotherapy are skin or subcutaneous fibrosis, osteoradionecrosis, radiation myelitis, brain necrosis, temporomandibular joint ankylosis, hypopituitarism, sensorineural hearing loss, and bone atrophy (Table 60–3). In a cohort of patients undergoing radiotherapy for T4 NPC, severe late complications occurred in 23.5% of patients. Neck fibrosis, massive bleeding, and trismus accounted for 71% of the complications in 42 patients.[28]

Chemotheraphy and Radiotherapy. Since NPC is considered both radiosensitive and chemosensitive, it stands to reason that treatment with chemotherapy and radiotherapy protocols would be tried. Problems with overlapping toxicities had precluded such treatments in the past. However, with advances in radiotherapy delivery, chemotherapeutic agents, and supportive care, chemoradiotherapy protocols have been made possible. Although radiotherapy has been effective for treating early-stage disease, patients with bulky lymphadenopathy or supraclavicular metastases are at greater risk of distant metastases and experience a 5-year survival rate of 10 to 40% with radiotherapy alone. The high incidence of distant metastasis combined with the chemosensitivity of NPC makes this malignancy an ideal candidate for the addition of chemotherapy to the treatment regimen.[29]

TABLE 60–3. Long-Term Complications of Radiotherapy

The goal of chemoradiotherapy is to enhance local control of tumor and to address distant metastases that are not included in the field of radiation. To obtain optimal local control results, the two modalities should be delivered as close in time as possible to achieve a synergistic effect. Toxicity becomes the limiting factor in this setting, and drugs with minimal overlapping toxicities with radiotherapy and each other are favored. As for control of distant metastases, there is no synergistic effect, and the timing of administration is unrelated to radiotherapy. The earlier the treatment, however, the smaller will be the micrometastatic tumor deposits.

Neoadjuvant Chemoradiotherapy. Radiation for stage I and II NPC generally does well. For patients with locoregionally advanced NPC in whom bulky lymph node metastases, local failure, and distant metastasis rates are high, the 5-year survival ranges from 10 to 40%. Knowing that NPC is chemosensitive, it is logical to add chemotherapy to the treatment regimen in this patient population. Early studies of neoadjuvant chemotherapy using three cycles of cisplatin-containing regimens yielded encouraging results with acceptable toxicities.[29] The M. D. Anderson Cancer Center performed a matched cohort study of neoadjuvant chemotherapy consisting of three cycles of 5-fluorouracil (5-FU) and cisplatin followed by radiotherapy. Sixty-one patients were accrued and matched based on tumor category, node category, histology, and level of cervical lymph metastasis. With a median follow-up of 4.9 years, a significant difference in distant metastasis was observed favoring the chemoradiotherapy group (19%) versus radiotherapy alone (34%). This was reflected in the disease-free survival (64 versus 42%) and the overall survival (69 versus 48%). There were no significant differences in acute toxicity between the two groups.

The Institute Gustave Roussy initiated a phase III international multicenter randomized trial com-

paring neoadjuvant chemotherapy given as three cycles of bleomycin, epirubicin, and cisplatin followed by radiotherapy with radiotherapy alone. A total of 339 patients with undifferentiated NPC with N2 and N3 (AJCC) were accrued and randomized to the treatment arms. With a median follow-up of 49 months, a significant difference in disease-free survival favoring the chemotherapy arm was observed (54.7 versus 32.7%, $p < .01$). An excess of treatment-related deaths occurred in the chemotherapy arm (8 versus 1%). No difference in overall survival was seen; this was ascribed to the better postrelapse survival in the radiotherapy-alone arm.[30] A prospective randomized trial comparing combined neoadjuvant and adjuvant chemoradiotherapy with radiotherapy alone was conducted at the Prince of Wales Hospital in Hong Kong. Eighty-two patients with Ho's N3 staging or any node stage with nodes > 4 cm were randomized to receive two cycles of cisplatin and 5-FU prior to radical radiotherapy followed by four cycles of postradiotherapy chemotherapy. The overall response rate to neoadjuvant chemotherapy was 80% (19% complete response, 62% partial response). With a mean follow-up of 28 months, there were no statistically significant differences between the two arms in terms of acturarial survival, disease-free survival, locoregional relapse rate, distant metastatic rate, and median time to relapse.[31] The absence of difference between the two arms may be explained by the low number of patients enrolled in the study combined with the good overall survival of the radiotherapy control group (80% at 2 years). The low levels of chemotherapy used in this trial may also explain the lack of survival benefit with the experimental arm.

Thus, although neoadjuvant and adjuvant chemoradiotherapy may alter the natural history of locoregionally advanced NPC by prolonging disease-free survival, no randomized trials offer evidence of improving overall or disease-specific survival.

Concurrent Chemoradiotherapy. The use of concurrent chemoradiotherapy was limited by concerns for overlapping toxicity, as experienced in earlier head and neck trials using 5-FU, bleomycin, and mitomycin-C. Two concurrent chemoradiotherapy phase II studies not using cisplatin did not suggest any benefit in overall survival.[32,33] Cisplatin is a good candidate for concomitant treatment because its toxicities do not overlap with those of radiotherapy: myelosuppression is uncommon. Because cisplatin is independently one of the most active agents against NPC, it was employed in a series of 27 patients treated in a concurrent manner resulting in superior disease-free survival, overall survival, and incidence of distant metastasis compared with historical controls.[34]

Based on this, a Head and Neck Intergroup study for patients with stage III/IV NPC was initiated; it randomized patients to a standard radiotherapy control arm (2 Gy/fraction to 70 Gy over 7 weeks) or to a concurrent cisplatin and adjuvant cisplatin and 5-FU in which cisplatin was given every 3 weeks, totaling three doses during radiotherapy. This was followed by cisplatin and 5-FU for three cycles. After the first planned interim analysis with 138 evaluable patients, the trial was closed. About 25% of patients had WHO type I histologies. At a mean follow-up of 2.7 years, 3-year overall survival rates are 78% and 47% for the chemoradiotherapy and radiotherapy arms. The median progression-free survival was 13 months in the radiotherapy arm compared with 52 months in the chemoradiotherapy arm. No fatal toxicity events related to planned treatment occurred; however, grade 3 to 4 toxicity occurred more frequently in the chemoradiotherapy arm (76 versus 50%). Both progression-free survival and 2-year overall survival were statistically significant in favor of concurrent chemoradiotherapy followed by adjuvant chemotherapy.[35] Because of the rarity of this disease, all stage III and IV patients were included, thus representing a heterogeneous group with respect to tumor and node categories. Forty-four percent of patients in the radiotherapy arm and 45% of patients in the chemoradiotherapy arm exhibited type III histologies. The applicability of this heterogeneous study population to treatment of patients in endemic areas, where up to 90% of histologies can be expected to be type III, is unknown. Type 1 and types 2 and 3 differ in their association with EBV as well as in their reported response to radiotherapy,[31] which confound the applicability of this study to populations from endemic areas. A further limitation of this study is the combination of concomitant cisplatin and adjuvant cisplatin and 5-FU. The contribution of concurrent and adjuvant chemotherapy treatment cannot be separated in this study.[35]

Radiotherapy-Chemotherapy Summary. The addition of chemotherapy to standard radiotherapy in

patients with advanced NPC has been supported by clinical studies. Neoadjuvant chemotherapy has been shown to have an impact on preventing distant metastasis,[20] although its efficacy in preventing locoregional recurrence is not clear. To date, no randomized trial has demonstrated definite improvement in overall survival from either neoadjuvant or adjuvant chemotherapy.

Concomitant chemotherapy offers more promising results; however, the only phase III study contains both concomitant and adjuvant chemotherapy in its only experimental arm; thus, definite conclusions regarding the contribution of concomitant chemotherapy cannot be definitively assessed. Further, the heterogeneity of histologic types in this North American study cannot be assumed to be applicable to patient populations in endemic areas. Still, the high response rate to cisplatin-based regimens is encouraging, and reports of patients with distant metastasis achieving long-term disease-free survival warrant further investigation. The benefit of high-dose chemotherapy with autologous bone marrow or peripheral stem cell support has not been investigated.

Overall Treatment Summary. Radiotherapy as a single-modality treatment remains the standard of reference for NPC clinical trials. This may be augmented by brachytherapy in selected patients. Chemotherapy may be added in patients with advanced locoregional disease or recurrent disease or in those with distant metastases in the context of clinical trials, but chemotherapy remains investigational. Other modalities for treatment of recurrent disease include PDT, which remains in its infancy with respect to treatment of NPC.

Further clinical trials are needed to assess the role of chemotherapy in early-stage NPC and to define the optimal time of administration of chemotherapy with respect to radiotherapy. Also, the applicability of North American concomitant chemoradiotherapy trials to patient populations from endemic countries remains to be defined. Additional treatment approaches such as PDT hold promise in selected patients but await clinical evaluation.

Summary

Nasopharyngeal carcinoma is a common malignancy in certain populations but represents less than 1% of the malignancies in the United Stated. Dramatic improvements in survival with the delivery of platinum-based therapies in conjunction with external beam radiotherapy for advanced disease has replaced radiation-only treatment regimens. Advances in imaging modalities of the skull base have allowed for the more accurate staging of this malignancy. Efforts in examining viral serologies have not resulted in predictable biomarkers of survival or response. Efforts in molecular medicine are continuing.

JUVENILE NASOPHARYNGEAL ANGIOFIBROMA

A clinical presentation of epistaxis and nasal obstruction in an adolescent male patient classically represents a juvenile nasopharyngeal angiofibroma (JNA) until proven otherwise. This is a relatively rare sporadic neoplasm that represents approximately 0.05% of all head and neck neoplasms. Clinically, this tumor may be locally invasive, even eroding adjacent skull base bone. This tumor is nonencapsulated and is highly vascular but has not been shown to be metastatic. Incomplete excision of JNA may result in its recurrence, but often microscopic disease is left after excision, and in the majority of individuals, the neoplasms do not recur. Spontaneous regression of the neoplasm has been identified after incomplete gross excision, but untreated angiofibromas have not been shown to regress spontaneously.[36] Several hypotheses regarding the source of this mass have been advanced, but the origin of this tumor as an anomaly of embryology or as part of a genetic syndrome has never been substantiated. The anatomic site of origin in nearly all cases appears to be in the nasopharynx at the superior aspect of the sphenopalatine foramen. The tumor develops and remains submucosal in a complicated anatomic compartment that defies simple surgical extirpation with generous margins.

Natural History

Over time, JNAs increase in size and may involve extensive regions adjacent to the nasopharynx. Anteriorly, the tumor can extend submucosally to involve the posterior aspect of the septum and roof of the nasal cavity at the choanae. The lesion may then extend further anteriorly into the nasal cavity. Superiorly, the tumor will cause flattening of the floor

and posterior aspect of the sphenoid sinus and may enter the sinus and fill it. Tumors usually invade the sphenopalatine foramen and will involve the pterygopalatine fossa. Rarely, anterior invasion into the maxillary sinus will occur after erosion of the pterygoid plates and invasion of the posterior wall of the maxillary sinus. Juvenile nasopharyngeal angiofibroma may also extend laterally into the area of the cheek and extend into the infratemporal fossa. If involvement of the pterygopalatine fossa occurs, tumors may extend into either orbital fissure and gain access to the cavernous sinus. Approximately 10% of tumors will have invaded intracranially at the time of diagnosis, but they typically remain extradural. Intracranial tumor may also be encountered after nasoethmoidal extension up to the level of the cribriform plate.

Differential Diagnosis and Staging

The differential diagnosis of lesions within the nasopharynx in the age group affected by JNA includes both benign and malignant processes. Other benign conditions associated with nasal obstruction include adenoid and turbinate hypertrophy, nasal polyposis, antral choanal polyps, and nasopharyngeal cysts. Other benign neoplasms of the nasopharynx include chordomas, angiomatous polyps, teratomas (eg, dermoids), fibromas, hemangiomas, gliomas, fibrous dysplasia, chondromas, and rhabdomyomas.[37] Soft tissue malignancies in the differential diagnosis include rhabdomyosarcoma, NPC, and lymphomas.

There have been at least three staging systems proposed for JNA since the 1970s, but Radkowski et al proposed the most recent update in 1996.[38] This system appears to reflect a multi-institutional consensus of lesions grouped similarly and also reflects current treatment strategies for this tumor on a stage-dependent basis (Table 60–4).

Clinical Presentation

The average and median ages for the presentation of JNA are 12.5 and 14 years, respectively. Earlier-stage lesions will present with epistaxis and nasal obstruction, and, clearly, symptoms and signs at the initial patient encounter will have predictive value for the anatomic extent of the disease. For example, significant lateral extension of the disease may cause serous otitis media and conductive hearing loss, facial deformity including a cheek mass, and proptosis. Cranial nerve findings are rare but may exist and be attributable to involvement of cranial nerves I to VI.

Diagnostic Workup

Once the clinical presentation suggests a possible differential diagnosis, the radiologic workup is performed. Presently, there is little utility in any plain film analysis of the intricate anatomy of the nasopharynx. Typically, a contrast-enhanced CT and MRI with gadolinium would be the gold standard radiographic evaluations for JNA. The CT scan is advantageous for delineating the extent of any skull base encroachment or invasion that would help the surgeon determine the extent of resection necessary based on bony compartmentalization of the skull base. Additionally, in the differential diagnosis of JNA, other potential benign and malignant processes exist that would have radiographic appearances different from JNA (eg, osteosarcomas or an NPC with extensive bony skull base invasion). The MRI is particularly helpful in identifying soft tissue characteristics of the lesion that would increasingly suggest that it is JNA as opposed to another neoplasm. The lesion will demonstrate contrast enhancement on both studies, and any vascular flow voids within the lesion will be identified on MRI. The usual nearly

TABLE 60–4. Staging of Juvenile Nasopharyngeal Angiofibroma

Stage	*Description*
IA	Limited to nose/nasopharyngeal vault
IB	Extension into one or more sinuses
IIA	Minimal extension into pterygopalatine fossa
IIB	Occupation of whole pterygopalatine fossa with or without orbital bone erosion
IIC	Infratemporal fossa extension with or without posterior extension to pterygoid plates
IIIA	Erosion of skull base, minimal intracranial extension
IIIB	Erosion of skull base, extensive intracranial involvement with/without cavernous sinus involvement

Adapted from Radkowski et al.[38]

uniform enhancement of this lesion radiographically distinguishes it from other vascular entities such as arteriovenous malformations. Additionally, other accompanying features of the soft tissue, including reactive inflammation of the sinus or nasal mucosa or postobstructive sinusitis, will be well delineated on MRI (Figure 60–5).

Because of the characteristic clinical presentation and radiographic appearance, few clinicians would feel compelled to obtain tumor biopsies as part of the workup. Clearly, a biopsy of this lesion could lead to massive hemorrhage and is discouraged. However, there are lesions reported in the literature that resemble JNA by all of the above criteria

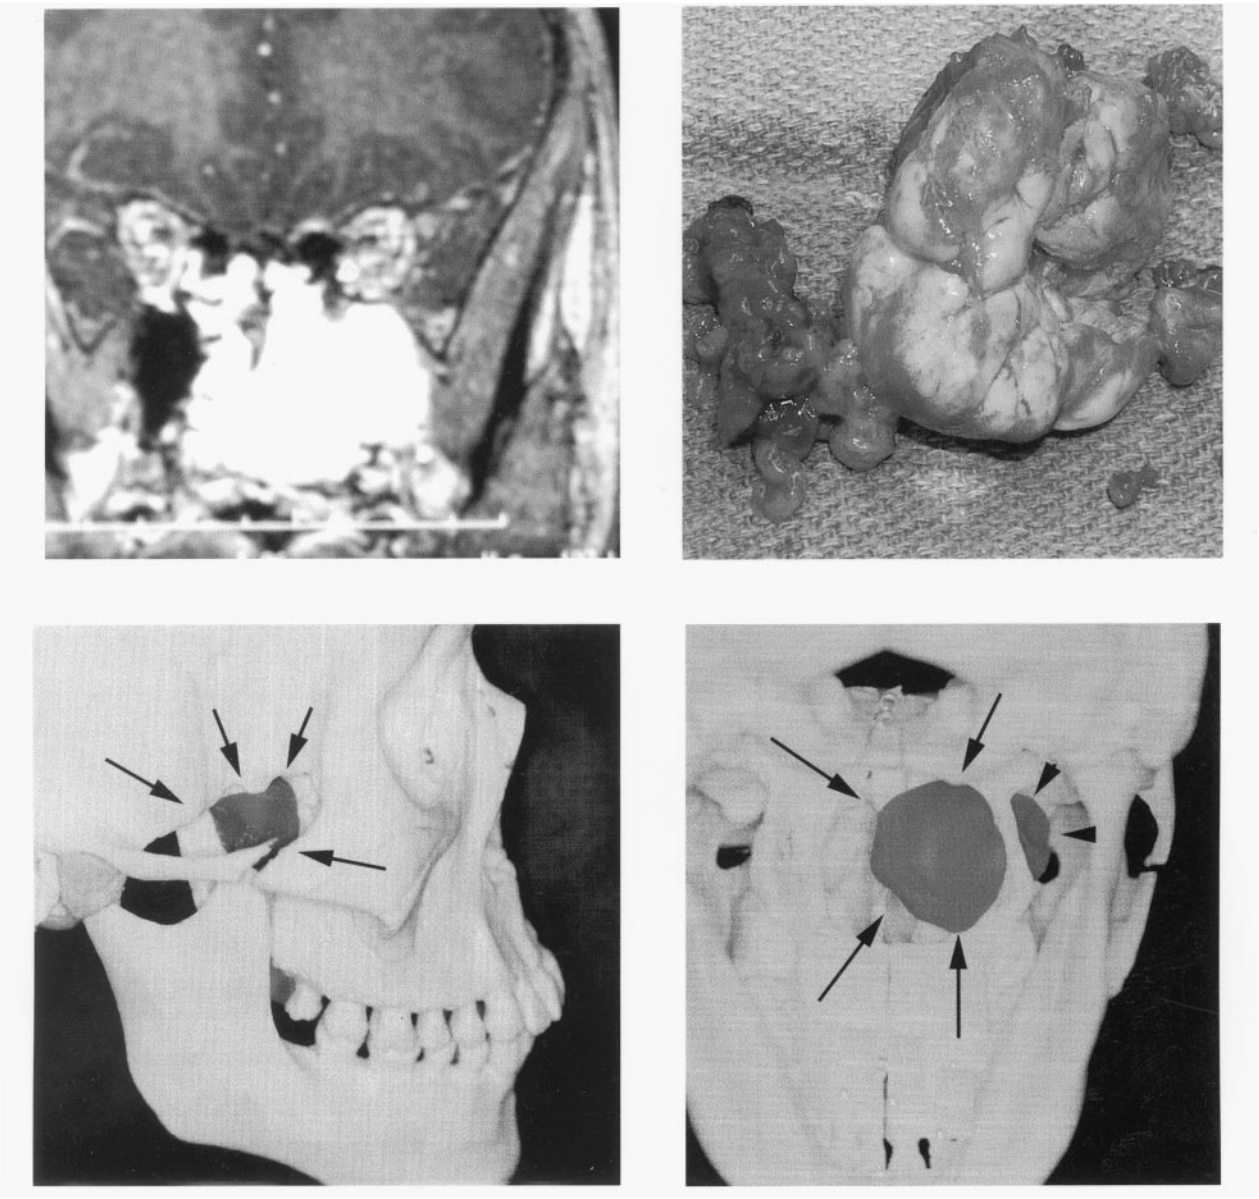

FIGURE 60–5. Juvenile nasopharyngeal angiofibroma. *Upper left*, Coronal magnetic resonance imaging (MRI) appearance of a juvenile nasopharyngeal angiofibroma occupying the nasopharynx with extension into the maxillary and ethmoid sinuses with lateral extension into the infratemporal fossa. *Upper right*, Gross anatomic view of the juvenile nasopharyngeal angiofibroma in the MRI. Note the pseudoencapsulated appearance of the tumor. *Lower left*, Lateral view depicting extension of tumor into infratemporal fossa from the nasopharynx. *Lower right*, Base view of depiction of tumor originating in the nasopharynx with lateral extension into the skull base region with involvement of the pterygoid plates and the infratemporal fossa.

but turn out to be other histologic diagnoses, including rhabdomyosarcoma.[37] Originally, angiography was a diagnostic test of JNA confirmation, but both CT and MRI eliminate the need for this test as part of the workup in most cases. However, lesions currently undergo preoperative embolization with carotid angiography at many major centers. This technique allows for a decrease in blood loss during surgery by 60 to 80%. Typically, embolization agents are directed via the external carotid circulation through the internal maxillary artery, but significant blood supply can be derived directly from the internal carotid artery and ethmoidal arteries.

Treatment

Surgery Because JNAs can involve multiple anatomic sites at the skull base, surgical treatment options can be applied on a more or less stage-specific basis. Additionally, the experience and surgical preference of the otolaryngologist or skull base team may affect which approach is chosen for a particular tumor. Endoscopic approaches have been suggested for small tumors at least for the smallest stage I tumors, and this has become a preferred approach for selected tumors at some institutions.[39] Transpalatal approaches have been used to remove JNA from the nasopharynx when there is limited lateral extent of the tumors since the 1960s. Typically, this resection involves an approach to the soft palate with removal of the third molar, hard palate, and pterygoid plates with a bur or bone punches. This has allowed access to the primary tumor and its lateral extent behind the maxillary sinus. This approach, however, does not allow further lateral access, and excision of the tumor is without a surgical margin. However, several authors agree that residual microscopic disease is associated with involution. Other surgeons approach lesions of limited extent transfacially through a lateral rhinotomy and medial maxillectomy approach. Midfacial degloving techniques may also be used. Lesions with extension into areas outside the nasopharynx will often require a combination of skull base approaches to gain adequate exposure.[40–44] Clearly, lateral approaches to the infratemporal fossa are required in resecting lesions with lateral extensions to that region.[45]

Other Modalities Juvenile nasopharyngeal angiofibromas are known to have recurrence rates up to 25%, and extension of disease into extranasopharyngeal sites correlates with increased rates of recurrence. For these reasons, several investigators have considered additional modalities of treatment for extensive JNA. Some institutions will employ radiation therapy as standard care for intracranial disease extension and when there is significant blood supply to the tumor from the internal cartoid artery system. Typically, 30 to 40 Gy are used in standard fractions to gain control of the lesion.[46] Significant further growth of tumor is not noted, but lesions do not completely regress after treatment. Intensity-modulated radiotherapy (IMRT), using multileaf collimators, has been employed in recurrent JNA. In a limited number of patients, response to 3,400 to 4,500 cGy of IMRT was demonstrated on physical examination and radiographically.[47] Because these tumors are associated with puberty in young males, considerable effort has been expended in hormonal therapies as primary or adjunctive treatment for these tumors. Hormonal therapies for this lesion have included the use of diethylstilbestrol and flutamide.

Summary

Juvenile nasopharyngeal angiofibroma is a benign but locally invasive tumor of the anterior skull base. The natural history of the disease in young males strongly suggests a gonadotropic hormonal contribution to the growth of this neoplasm, but this concept has not been fully exploited in the treatment of this neoplasm. Advances in invasive neuroradiology, imaging, and skull base surgery have allowed for approaches to this neoplasm that have resulted in improved outcomes with decreased morbidity.

CHAPTER 61

Neoplasms of the Oral Cavity and Oropharynx

Dennis H. Kraus, MD, John K. Joe, MD

The list of neoplasms potentially involving the oral cavity and oropharynx is extensive and diverse. The focus of this chapter is on squamous cell carcinoma (SCC), also called epidermoid carcinoma, the most common malignant neoplasm of the oral cavity and oropharynx. Tumors affecting these regions have significant effects on respiration, deglutition, and speech. The propensity for locoregional recurrence of advanced cancers of the oral cavity or oropharynx necessitates combined therapy, usually surgery and adjuvant radiotherapy. Appropriate treatment planning, therefore, is most effective using a multidisciplinary approach, encompassing the head and neck surgeon, radiotherapist, medical oncologist, prosthodontist, and speech pathologist.

ANATOMY

Both the oral cavity and the oropharynx are composed of distinct anatomic subsites.[1] Malignancy arising at different subsites may vary in behavior, so recognition of this anatomic classification allows for prognostic evaluation and appropriate treatment planning.

Oral Cavity

The oral cavity is defined as the region from the skin–vermilion junction of the lips to the junction of the hard and soft palate above and to the line of the circumvallate papillae below. As illustrated in Figure 61–1, the oral cavity includes the lips, buccal mucosa, upper and lower alveolar ridges, retromolar trigone, hard palate, floor of the mouth, and anterior two-thirds of the tongue (oral tongue).

The lip begins at the junction of the vermilion border with the skin and includes only the vermilion surface or that portion of the lip that comes into contact with the opposing lip. The upper and lower lips form the anterior boundary of the oral cavity and are joined at each lateral end at the oral commissure. The mental branch of the mandibular nerve (V3) exits from the mandible at the mental foramen to provide sensory innervation to the lower lip and may serve as an important pathway for cancer spread into the mandible.

The buccal mucosa includes the membranous lining of the inner surface of the cheeks and lips from the line of contact of the opposing lips to the line of attachment of mucosa of the alveolar ridge (upper and lower) and pterygomandibular raphe. The buccal mucosa forms the lateral wall of the oral cavity. Tumors of the buccal surface may penetrate through the mucosa to involve deeper structures such as the buccal fat pad or subcutaneous tissues of the cheek.

The upper alveolar ridge refers to the mucosa-covered alveolar process of the maxilla, which extends from the line of attachment of mucosa in the upper gingival buccal gutter to the junction with the hard palate. Its posterior margin is the upper end of the pterygopalatine arch. Cancer of the upper alveolar ridge may extend superiorly to involve the floor of the nasal cavity or the antrum of the maxilla.

The lower alveolar ridge refers to the mucosa-covered alveolar process of the mandible, which extends from the line of attachment of mucosa in the buccal gutter to the line of free mucosa of the floor of the mouth. Posteriorly, it extends to the ascending ramus of the mandible. The inferior alveolar nerve is a branch of the mandibular nerve (V3) providing sensory innervation to the gingiva of the lower alveolar ridge. The course of the mandibular nerve may serve as a route of spread for tumors of the lower alveolar ridge to the skull base.

The retromolar trigone (pterygomandibular raphe) is the triangular region from the level of the posterior surface of the last molar tooth to the apex superiorly, where it is attached to the pterygoid

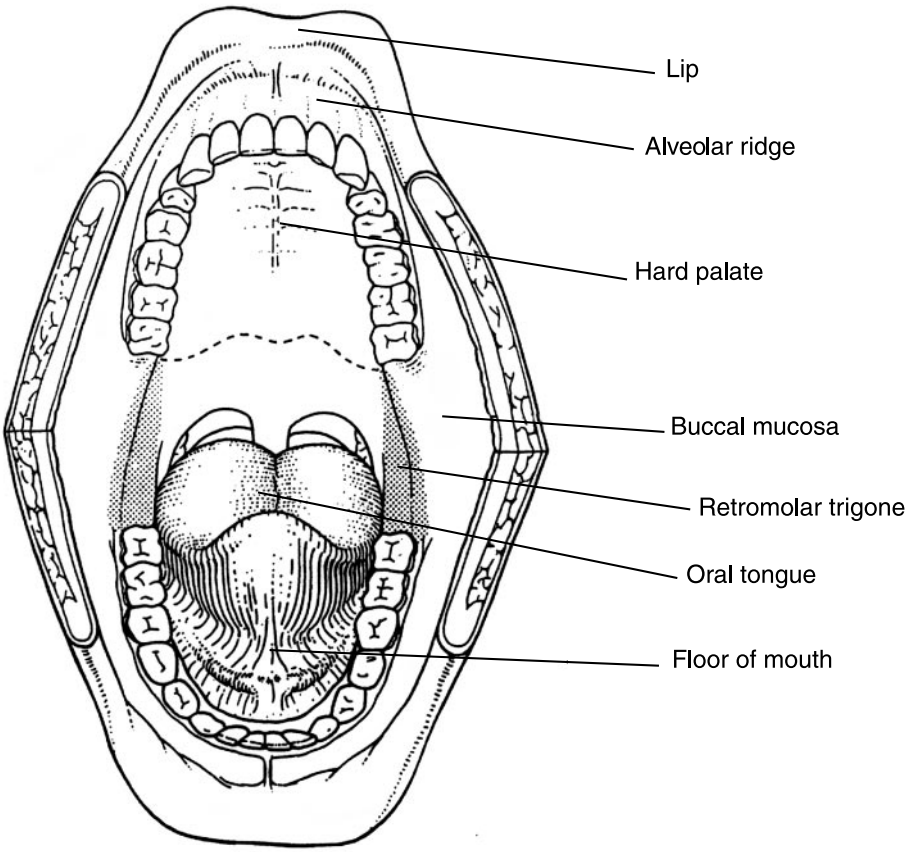

FIGURE 61–1. Anatomic sites of the oral cavity. Adapted from Alvi A, Myers EN, Johnson JT. Cancer of the oral cavity. In: Myers EN, Suen JY, editors. Cancer of the head and neck. 3rd ed. Philadelphia: WB Saunders; 1996. p. 321.

hamulus of the sphenoid bone. Mucosa of the retromolar trigone is tightly adherent to the underlying tendon between the buccinator and superior pharyngeal constrictor muscles and is separated from the periosteum of the ascending ramus of the mandible by the buccal fat pad. Tumors in this region frequently invade the mandible. The site of entry of the inferior alveolar nerve into the mandibular foramen places it at risk for involvement by tumors of the retromolar trigone. Branches from the glossopharyngeal (IX) nerve provide sensory innervation to the retromolar trigone, so cancer of this site often presents with referred pain in the ipsilateral ear.

The hard palate is the semilunar area within the upper alveolar ridge and includes the mucous membrane–covered palatine processes of the maxillary bones and the horizontal parts of the palatine bones. It extends from the inner surface of the superior alveolar ridge to the posterior edge of the palatine bone, forming the roof of the oral cavity. The palatine foramina are located near the junction of the hard palate and soft palate and contain the descending palatine arteries and the anterior, middle, and posterior palatine nerves. Although the mucosa and the periosteum of the hard palate are tightly adherent, the palatine foramina serve as potential routes of spread of cancer from the hard palate to the pterygopalatine fossae and the skull base. In a similar fashion, the incisive canals transmit the nasopalatine nerves and branches of the maxillary nerves (V2) and allow for tumor extension from the hard palate into the nasal cavities.

The floor of the mouth is the semilunar space over the mylohyoid and hyoglossus muscles, extending from the inner surface of the lower alveolar ridge to the undersurface of the anterior two-thirds of the tongue. Its posterior boundaries are the bases of the anterior pillars of the tonsils. The floor of the oral cavity is divided into two sides by the frenulum of the tongue and contains the openings of the ducts of the submandibular and sublingual salivary glands. The lingual nerve provides

sensory innervation to the floor of the mouth and may provide a conduit for tumor extension. The lingual nerve is a branch of the mandibular nerve (V3), as is the auriculotemporal nerve, which provides sensory innervation to the auricle, external auditory canal, and tympanic membrane. Therefore, cancer of the floor of the mouth may present with referred pain in the ipsilateral ear. Likewise, the submandibular duct may serve as a potential route for tumor spread. Cancer of the floor of the mouth may involve the mandible or tongue by direct extension.

The anterior two-thirds of the tongue are referred to as the oral tongue and include the freely mobile portion of the tongue that extends anteriorly from the line of the circumvallate papillae to the undersurface of the tongue at the junction of the floor of the mouth. It is composed of four areas: the tip, lateral borders, dorsum, and undersurface (nonvillous ventral surface of the tongue). The anterior two-thirds of the tongue or oral tongue are part of the oral cavity, and the posterior one-third or base of the tongue is part of the oropharynx. The hypoglossal nerve (XII) provides motor innervation to the tongue. The oral tongue receives sensory innervation from the lingual branch of the mandibular nerve (V3) and taste sensation from the chorda tympani branch of the facial nerve (VII). As with the floor of the mouth, cancers of the oral tongue may present with referred pain in the ipsilateral ear owing to involvement of the mandibular nerve (V3).

Lymphatics As illustrated in Figure 61–2, regional lymph node groups in the neck are grouped into various levels for ease of description.[1] Level I contains the submental and submandibular triangles bounded by the posterior belly of the digastric muscle, the hyoid bone inferiorly, and the body of the mandible superiorly. Level II contains the upper jugular lymph nodes and extends from the level of the hyoid bone inferiorly to the skull base superiorly. Level III contains the middle jugular lymph nodes from the hyoid bone superiorly to the cricothyroid membrane inferiorly. Level IV contains the lower jugular lymph nodes from the cricothyroid membrane superiorly to the clavicle inferiorly. The posterior limit of levels II, III, and IV is the posterior border of the sternocleidomastoid muscle (SCM). Level V contains the lymph nodes in the posterior triangle bounded by the anterior border of the trapezius posteriorly, the posterior border of the SCM anteriorly, and the clavicle inferiorly.

Metastasis to regional lymph nodes occurs in a predictable fashion through sequential spread. Regional lymph nodes at highest risk for metastases from primary SCCs of the oral cavity include those at levels I, II, and III, collectively known as the supraomohyoid triangle.[2,3] Tumors of each anatomic site have their own predictable first-echelon lymph nodes of involvement.[1] Nodal metastasis of SCC of the lip is uncommon but tends to involve initially adjacent submental and submandibular nodes and then jugular nodes. Tumors of the buccal mucosa tend to spread first to submental and submandibular nodes. Cancer of the upper and lower alveolar ridges involve buccinator, submandibular, jugular, and, occasionally, retropharyngeal nodes (Figure 61–3). Lymphatic drainage of the retromolar trigone involves upper jugular nodes, as well as subparotid and retropharyngeal nodes. Like tumors of the alveolar ridges, tumors of the hard palate do not commonly metastasize to regional lymph nodes, but

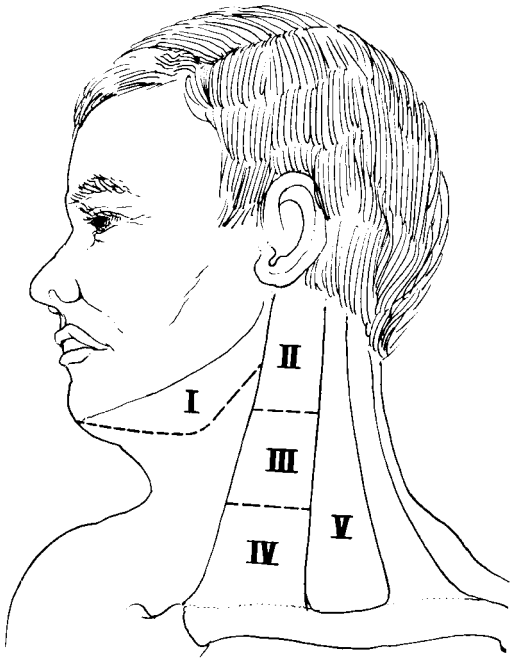

FIGURE 61–2. Cervical lymph node levels. Reproduced with permission from Alvi A, Myers EN, Johnson JT. Cancer of the oral cavity. In: Myers EN, Suen JY, editors. Cancer of the head and neck. 3rd ed. Philadelphia: WB Saunders; 1996. p. 322.

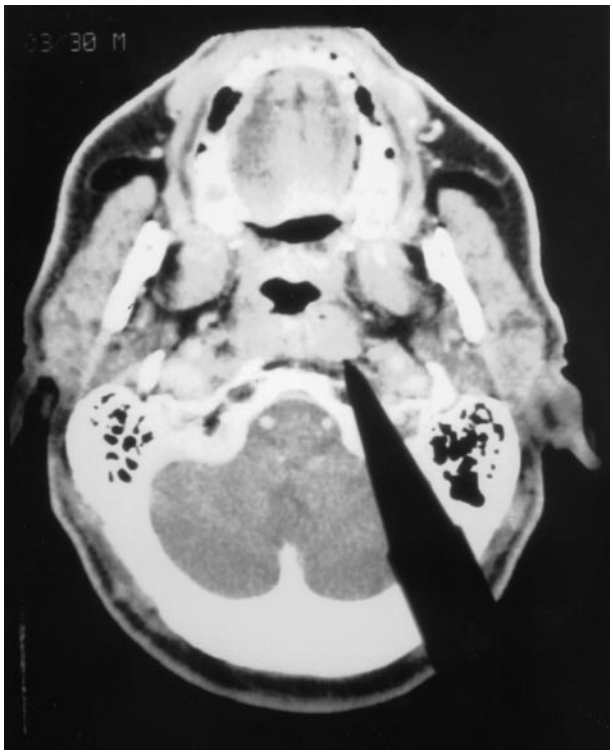

FIGURE 61–3. Axial computed tomographic scan of the neck demonstrating metastasis to a retropharyngeal lymph node (*pointer*).

lymphatic spread may involve buccinator, submandibular, jugular, and, occasionally, retropharyngeal nodes. Cancer of the floor of the mouth tends to spread first to submandibular and jugular nodes. Lymphatics of the tongue involve submental, submandibular, and jugular nodes. Lesions of the midline of the lip, floor of the mouth, or tongue commonly drain to lymphatic channels in both sides of the neck.

Oropharynx

The oropharynx is the midportion of the pharynx connecting the nasopharynx above with the hypopharynx below. The oropharynx extends from the plane of the inferior surface of the hard palate to the plane of the superior surface of the hyoid bone and opens anteriorly into the oral cavity. The oropharynx includes the base of the tongue, soft palate, tonsillar regions, and lateral and posterior pharyngeal walls. The anatomy of the oropharynx and divisions of the pharynx are illustrated in Figure 61–4.

Lymphatics The primary routes of lymphatic spread from primary tumors of the oropharynx, hypopharynx, and larynx involve deep jugular chain lymph nodes at levels II, III, and IV.[2,3] Midline structures such as the base of the tongue, soft palate, and posterior pharyngeal wall commonly drain to lymphatic channels in both sides of the neck. The soft palate, tonsillar region, and lateral and posterior pharyngeal walls drain to retropharyngeal lymph nodes.

EPIDEMIOLOGY

In the United States, the incidence of oral cavity and pharyngeal cancer is estimated to number approximately 30,200 new cases in 2000, representing 2.5% of all new cases of cancer.[4] Approximately 7,800 deaths from oral cavity and pharyngeal cancer are anticipated in 2000, accounting for 1.4% of the cancer mortality in the United States.

Patients with cancer of the oral cavity and pharynx in the United States remain predominantly male. The estimated incidence in men compared with women is approximately 2 to 1. This gender disparity, however, continues to narrow as tobacco use among women becomes relatively more prevalent.

The relative proportion of cancer of the oral cavity and oropharynx worldwide is significantly higher than that in the United States, representing greater than 30% of cancers in parts of India and Southeast Asia. This higher incidence worldwide is likely related to geographic differences in tobacco consumption, as described in the following section.

ETIOLOGY

The majority of patients with cancer of the oral cavity and oropharynx have a significant history of tobacco and alcohol consumption. Both tobacco and alcohol abuse independently contribute to the development of cancer of the oral cavity and oropharynx.[5,6] The cancer risk has been shown to be significantly elevated both for smokers who did not drink alcohol and for nonsmokers who abused alcohol.[6] When present together, however, the combined effects of tobacco and alcohol abuse in the development of oral and oropharyngeal cancer are multiplicative rather than simply additive.[7,8] These multiplicative effects of smoking and alcohol abuse are shown in Figure 61–5. The synergistic effect of

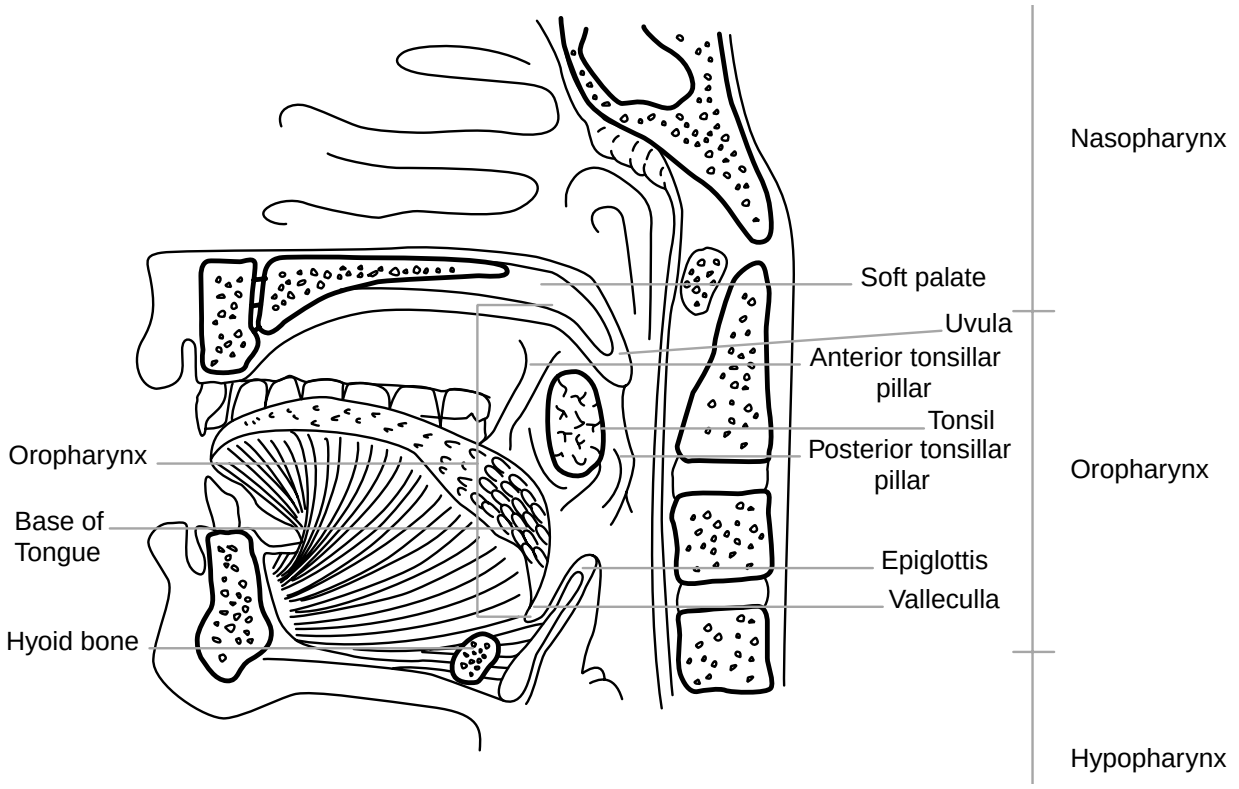

FIGURE 61–4. Anatomy of the oropharynx and divisions of the pharynx.

tobacco and alcohol is shown in the elevation of cancer risk more than 35-fold for men who smoke two or more packs of cigarettes and consume more than four alcoholic drinks per day.[9]

As previously mentioned, the geographic differences in tobacco consumption may explain the higher proportion of cancers arising from the oral cavity and oropharynx worldwide. In Southeast Asia, cultural practices such as reverse smoking, in which the lighted end of the cigarette is held within the mouth, have been shown to produce dysplastic changes at the hard palate.[10] Similarly, betel, a compound chewed regularly throughout Southeast Asia and the western Pacific basin, has been implicated in oral carcinogenesis. Composed of the nut of the areca palm (*Areca catechu*), the leaf of the betel pepper (*Piper betle*), and lime (calcium hydroxide), betel is chewed for its mild psychoactive and cholinergic effects.[11] Other practices common in Southeast Asia include bidi smoking, composed of tobacco rolled within a betel leaf, and consumption of paan, a quid of *Piper betle* leaf containing areca nut, lime, condiment, sweeteners, and sometimes tobacco.[12]

In nearly any form, tobacco consumption has been associated with oral cancer. For example, chronic snuff dipping, in which smokeless tobacco is held at the gingivobuccal sulcus, has been associated with a nearly 50-fold increase in cancers of the gum and buccal mucosa.[13] Pipe smoking and cigar smoking are other types of tobacco consumption linked to cancer of the oral cavity and oropharynx.

The mechanisms through which tobacco contributes to the development of carcinogenesis likely involve deoxyribonucleic acid (DNA) damage from tobacco-related nitrosamines and polycyclic aromatic hydrocarbons. The deleterious effects of these initiators and promoters of carcinogenesis may be partially reversible as cessation of smoking is associated with a sharply reduced risk of cancer, particularly for those who have quit for periods greater than 10 years.[9]

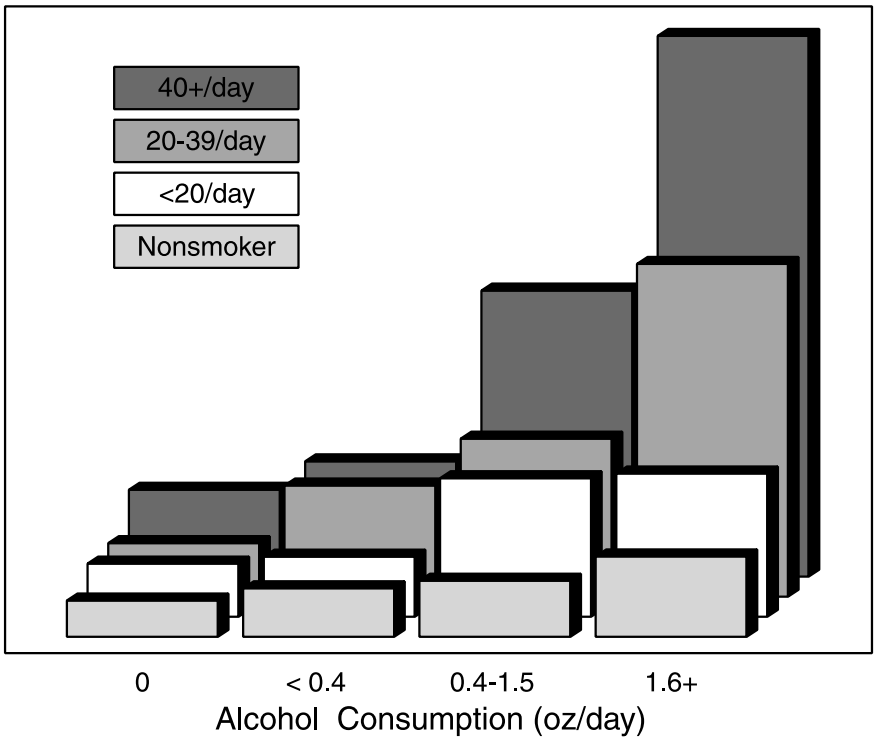
The mechanisms through which alcohol induces cancer development are less well characterized. The increased risk of cancer of the oral cavity and pharynx associated with frequent use of mouthwash high in alcohol content suggests that the etiology involves topical exposure.[14] The specific agent responsible has yet to be identified as experimental studies with laboratory animals have not demonstrated a causal effect between alcohol and carcino-

genesis.[15] Possible mechanisms proposed include alcohol possibly enhancing the metabolism of other carcinogens or enhancing nutritional deficiencies, thus promoting neoplastic change in oral and pharyngeal mucosa. The synergistic effects of combined tobacco and alcohol abuse multiplying the risk of cancer underscore the need for programs to encourage abstinence and cessation from these habits.

Viral infection has been correlated with the development of head and neck cancer. Human papillomavirus (HPV) is a well-established cause for benign recurrent oral and laryngeal papillomas. Genomic DNA sequences of HPV type 16 have been detected in SCCs of the tongue, tonsil, and pharynx.[16] The presence of HPV in the oral cavity has been associated with an increased risk of cancer of the oral cavity or oropharynx (odds ratio = 3.70; 95% confidence interval = 1.47 to 9.32), independent of exposure to tobacco and alcohol.[17] Similar to HPV, infection with human immunodeficiency virus (HIV) appears to confer increased risk for neoplasia. Kaposi's sarcoma is a common manifestation of acquired immune deficiency syndrome (AIDS). Squamous cell carcinoma in patients infected with HIV appears to assume an accelerated course. Squamous cell carcinoma of the upper aerodigestive tract in patients infected with HIV who also exhibited tobacco and/or alcohol abuse occurred at an earlier

Relative risk* of oral cancer according to level of exposure to smoking and alcohol

		Smoking (cigarette equivalents/day)			
		0	< 20	20-39	40+
Alcohol (oz/day)	0	1.00	1.52	1.43	2.43
	< 0.4	1.40	1.67	3.18	3.25
	0.4-1.5	1.60	4.36	4.46	8.21
	1.6+	2.33	4.13	9.59	15.5



*Risks are expressed relative to a risk of 1.00 for persons who neither smoked nor drank.

Essentials of head and neck oncology. New York: Thieme Medical Publishers; 1998.

age and resulted in a significantly poorer disease-specific survival.[18]

Poor socioeconomic status, neglected oral hygiene, recurrent trauma from ill-fitting dentures, vocal abuse, and gastroesophageal reflux are other factors associated with an increased risk of carcinoma of the oral cavity and oropharynx. Outdoor occupations requiring prolonged exposure to ultraviolet B radiation in sunlight pose a greater risk of carcinoma of the lower lip.[19] Ionizing radiation has been implicated in the development of minor salivary gland malignancy of the oral cavity and pharynx. Certain dietary habits have been linked to an increased risk for oral cancer, including dietary deficiencies of vitamin A or riboflavin. Achlorhydric iron deficiency anemia associated with Plummer-Vinson syndrome has been shown to be a risk factor for cancer of the oropharynx in Scandinavian women.

PATHOLOGY

Slaughter et al proposed the concept of "field cancerization," a theory predicated on the notion that carcinogen-induced cytologic changes throughout the mucosal lining of the upper aerodigestive tract result in the persistent risk for multiple primary cancers.[20] This theory is supported by the rate of second primary tumors in patients with oral and pharyngeal cancer, approximately 4% annually.[21] The risk of second primary tumors for SCC of the head and neck is approximately 4% annually, up to 25% at 10 years. Both tobacco and alcohol consumption contribute independently to the risk of second primary tumors, with the effects of smoking more pronounced than those of alcohol.[22] The risk of developing subsequent primary tumors in patients who cease smoking after control of the first cancer is one-sixth the risk of those who continue to smoke.[23]

Molecular Events

There have been significant advances recently in our understanding of the cascade of molecular events responsible for carcinogenesis. The development of malignant tumors appears to be the result of multiple accumulated genetic alterations.[24] These genetic mutations must occur in the correct number and sequence for cancer to develop, a progression of genetic events first described in colorectal tumorigenesis.[25] A genetic progression model for head and neck cancer has been established demonstrating that field cancerization seems to involve the expansion and migration of clonally related preneoplastic cells.[26] Microsatellite-based genetic analysis of chromosomal alterations demonstrates that recurrent premalignant lesions arise from a common clonal progenitor with subsequent outgrowth of clonally divergent populations.[27] Phenotypically benign mucosa in the upper aerodigestive tract may harbor foci of clonal, preneoplastic cells that are genetically related to sites of cancer.[28] This observation may explain the incidence for local recurrence following surgical resection of cancers in the oral cavity and oropharynx with margins seemingly adequate by gross and microscopic examination.

Attempts to characterize the genetic events that occur during the progression to a malignant phenotype have focused much attention on determining potential candidates to serve as predictors of behavior or targets for therapy. Genetic alterations in the progression to carcinogenesis include activation of proto-oncogenes and the inactivation of tumor suppressor genes. *P53* is a tumor suppressor gene that plays an important role in arresting cell growth in the presence of genetic damage to permit DNA repair or lead to apoptosis. Mutations in and subsequent inactivation of the *P53* tumor suppressor gene may result in accumulation of DNA damage and uncontrolled cellular growth. It has been shown that the incidence of *P53* mutations increases throughout the progression from premalignant lesions to invasive carcinomas.[29] A history of tobacco and alcohol use is associated with a high frequency of *P53* mutations in patients with SCC of the head and neck, providing an important link between these etiologic factors and the molecular progression to carcinogenesis.[30] Consistent with the aforementioned clonal, preneoplastic cells described in seemingly benign oral and pharyngeal mucosa, *P53* may play a role in the concept of field cancerization. Previous reports have examined pathologic specimens for *P53* mutations in patients undergoing surgery for SCC of the head and neck.[31] Among tumor resection margins and regional lymph nodes initially judged to be negative for cancer on light microscopy, a substantial percentage was positive for *P53* mutations specific for the primary tumor of the head and neck. Patients with these margins positive for *P53* mutations appeared to demonstrate increased risk of local recurrence. In addition to an

association with local recurrence following surgery, mutations in *P53* have also been implicated in locoregional failure in patients with SCC treated with radiation therapy.[32] The precise relationship of *P53* and other specific genetic targets involved in malignant transformation has yet to be fully delineated; however, their study continues to further our understanding of the complex cascade of molecular events that result in carcinogenesis.

Precancerous Lesions

Akin to the progression of genetic events leading to phenotypic evidence of malignancy, various precancerous lesions affect the oral cavity and oropharynx with the potential for malignant degeneration. Leukoplakia is a clinical descriptive term for a white patch in the oral cavity or pharynx that does not rub off. The most common histologic change is epithelial hyperplasia in approximately 80% of lesions, but the prevalence of premalignant or malignant transformation is variable. A review of over 3,000 specimens clinically diagnosed as leukoplakia over a 13-year period revealed mild to moderate epithelial dysplasia in 12.2%, severe epithelial dysplasia or carcinoma in situ in 4.5%, and infiltrating SCC in 3.1%.[33]

Oral lichen planus is a white, lacy, striated lesion of unknown etiology most commonly occurring on the buccal mucosa. Malignant change in oral lichen planus is rare and likely prompted by carcinogenic cofactors.[34]

Erythroplasia appears as a red, slightly raised, granular lesion in the oral cavity and oropharynx. In contrast to the variable incidence of cancer in patients with leukoplakia, erythroplasia has a much higher correlation with concurrent or subsequent malignancy.[35] Minimal size of erythroplastic lesions does not preclude invasiveness, mandating biopsy at times of clinical suspicion.[36]

Oral submucous fibrosis is a precancerous lesion predominantly seen among people from India and Pakistan. It is a chronic disease of the oral mucosa characterized by inflammation and progressive fibrosis of the lamina propria and deeper connective tissues.[37] Bands of oral submucous fibrosis are commonly found in the posterior part of the oral cavity in mild cases and, as the disease increases in severity, are found anteriorly as well.[38] The malignant transformation frequently associated with oral submucous fibrosis is likely multifactorial in origin.[37] After adjusting for other risk factors in a study in Pakistan, patients with oral submucous fibrosis were 19 times more likely to develop oral cancer than those without it.[12]

Histopathology

Squamous cell carcinoma constitutes more than 90% of the malignant neoplasms of the oral cavity and oropharynx. The gross morphologic growth patterns of SCC include exophytic, ulcerative, and infiltrative. The ulcerative type is the most common form of SCC in the oral cavity and demonstrates proclivity for rapid invasion.

Histologically, SCC may be classified into the following categories: keratinizing, nonkeratinizing, spindle cell, adenoid squamous, and verrucous carcinoma. Keratinizing SCCs generally arise from ectodermally derived tissue, tend to be ulcerative or fungating, have less tendency for submucosal spread, and have infiltrating margins. Nonkeratinizing carcinomas typically arise from endodermally derived mucosa, spread submucosally, and have "pushing" margins. Spindle cell carcinoma is a rare variant of SCC demonstrating spindle-shaped mesenchymal cells resembling highly anaplastic sarcoma admixed with components of epidermoid carcinoma.[39] Adenoid squamous carcinoma is a rare variant of SCC in which adenoid transformation appears to arise within preexisting SCC.[40]

Described by Ackerman, verrucous carcinoma presents as a slowly growing exophytic or warty neoplasm in the oral cavity.[41] A well-differentiated variant of SCC, verrucous carcinoma has the histologic appearance of keratinized epithelium arranged in long, papillomatous folds with a "pushing" border. Verrucous carcinoma typically affects the buccal mucosa of elderly patients with a history of tobacco exposure or poor oral hygiene.[42] True verrucous carcinoma does not have metastatic potential.[43] The recommended treatment for verrucous carcinoma is wide surgical excision, although irradiation may be considered in selected patients.[44] Anaplastic transformation of verrucous carcinoma has been reported to occur following treatment with radiation therapy,[45] but this theory is controversial. Foci of less differentiated SCC have been observed to coexist within verrucous lesions, and recurrent lesions tend to be in the form of less differentiated

carcinomas.[44] There is a high rate of recurrence following single-modality treatment with either surgery or irradiation, so combined therapy may be considered for extensive lesions.[46] The histologic change in recurrent lesions to a less differentiated form may explain prior reports of malignant transformation following radiotherapy.

MECHANISMS OF CANCER SPREAD

Local Spread

Primary tumors of the oral cavity and oropharynx spread along tissue planes of least resistance, initially extending superficially along surface mucosa. As lesions enlarge, deeper structures may become involved, including the submucosa, underlying muscle, cartilage, or bone. Squamous cell carcinoma of the head and neck typically extends from its epicenter by irregular fingerlike projections, frequently with microscopic tumor as far as 1 cm beyond tumor margins apparently clear by inspection or palpation.[47] This insidious microscopic course of SCC may provide a mechanism for local recurrence in the presence of apparently negative surgical margins.

As previously mentioned, the risk of developing second primary cancers is approximately 4% per year, up to 25% at 10 years, mandating the need for regular, comprehensive follow-up. Both tobacco and alcohol have each been shown to contribute independently to the formation of multiple primaries. The concept of field cancerization demonstrates the potential of multifocal carcinogenesis through the accumulation of genetic alterations from chronic exposure to mutagenic agents. Multiple primary malignancies are described as simultaneous if diagnosed at the same time as the primary tumor, synchronous if diagnosed within 6 months of the primary tumor, or metachronous if diagnosed later than 6 months after the primary tumor.

Primary tumors may track along the course of nerves and spread outside the oral cavity and oropharynx. The negative prognostic implications of perineural spread are multifactorial. Tumor may spread to the base of the skull, making it less amenable to surgical resection and intensive radiotherapy. Tumors with perineural extension raise the question as to what constitutes an adequate margin of excision in the presence of possible discontinuous spread along the course of the nerve. Microvascular invasion has been demonstrated to have a negative impact on survival for oral and pharyngeal cancers, correlating with higher rates of locoregional recurrence and distant metastases.[48]

Regional Spread

Metastasis to regional lymphatics by carcinoma of the oral cavity and oropharynx is related to tumor size and location, depth of invasion, and the extent of lymphatic drainage from the primary site. Previous surgery, radiation, or inflammation may result in aberrant lymphatic drainage secondary to fibrosis of lymphatic channels. The metastatic potential of primary tumors of the lip, alveolar ridge, and hard palate is less than that of tumors arising elsewhere in the oral cavity. In general, lesions in the posterior part of the oral cavity have a higher predilection of regional lymph node metastases than those lesions situated more anteriorly in the oral cavity.[49] There is an increased risk for bilateral or contralateral metastases from primary tumors arising from midline structures, such as the midline lip, floor of the mouth, oral tongue, base of the tongue, soft palate, and posterior pharyngeal wall. The 5-year survival rate of patients with cervical metastases is approximately 50% that of patients without regional metastases.[50]

Extracapsular spread of carcinoma in cervical lymph nodes portends a poor prognosis. Extracapsular extension has been associated with increased rates of regional recurrence[51] as well as significantly decreased survival rates.[52] Other negative prognostic factors with regard to regional metastases include an increased number of involved nodes, as well as spread of tumor to lymph node levels more inferiorly in the neck.

Distant Spread

Distant metastases from cancers of the oral cavity and oropharynx generally do not occur until advanced stages of disease. Distant metastases typically involve first the lungs or bones.[53] Surveillance chest radiographs, therefore, are essential as part of the routine follow-up for a patient treated for head and neck SCC.

Previous studies have demonstrated that although up to 20% of patients who succumb to head and neck cancer develop metastases to distant

sites, only 4% had distant spread without antecedent failure in the head and neck.[54] Treatment efforts have therefore traditionally concentrated on locoregional control of disease above the clavicles.

CANCER OF THE ORAL CAVITY AND OROPHARYNX IN YOUNG ADULTS

Squamous cell carcinoma of the oral cavity and oropharynx tends to affect patients around the sixth decade of life. A topic of much debate concerns the biologic behavior of cancer of the oral cavity and oropharynx in the younger adult population. Although relatively infrequent, SCC of the oral cavity is observed in increasing numbers in patients younger than 40 years in age.[55] It has been previously reported that SCC of the tonsil arising in patients younger than 40 years resulted in poorer 5-year survival rates.[56] Molecular differences in tumor biology have not been demonstrated in the younger population, and the theory of a more aggressive behavior in the younger population is controversial. Three-year disease-free survival in patients with SCC of the tongue who were less than 40 years in age was not statistically different from that of patients older than 40 years with similar extent of disease.[57] It has been further demonstrated that although adults younger than 40 years with SCC of the tongue had higher rates of local recurrence than did older patients, this difference did not translate into poorer survival rates.[58] It should be noted that studies on both sides of this debate used small patient samples in light of the relatively infrequent occurrence of oral or pharyngeal cancer in the younger adult. However, the rising incidence of malignancy in this subset of the population warrants further efforts toward prevention and cessation of tobacco and alcohol abuse.

OTHER MALIGNANT TUMORS OF THE ORAL CAVITY AND OROPHARYNX

Squamous cell carcinoma accounts for greater than 90% of the malignancies of the oral cavity and oropharynx. Other malignant tumors affecting this region include Kaposi's sarcoma, extranodal non-Hodgkin's lymphoma, mucosal melanoma, and minor salivary gland cancer.

Kaposi's sarcoma is a common manifestation of AIDS and clinically presents as nonpruritic violaceous macules of the mucosa of the upper aerodigestive tract. These tumors grow slowly and may be treated with radiation, laser excision, cryotherapy, or intralesional injection of vinblastine.

Extranodal non-Hodgkin's lymphoma may present as a painless mass along the palate or gingiva or as an asymptomatic enlargement of one tonsil.

Mucosal melanoma of the head and neck is rare, representing only 3% of all melanomas.[59] The palate is the most common site of involvement in the oral cavity, with intralesional lymphatic and blood vessel invasion frequently seen. Surgical excision is the recommended method of treatment, although the ultimate prognosis is typically poor owing to distant dissemination.[60]

The most common minor salivary gland tumor of the oral cavity and oropharynx is adenoid cystic carcinoma, although mucoepidermoid carcinoma and adenocarcinoma may also be present in this region. The incidence of minor salivary gland cancer in this region is increased following previous therapeutic irradiation.

EVALUATION

History and Physical Examination

The first step when evaluating a patient with cancer of the oral cavity or oropharynx is a thorough history and comprehensive examination of the head and neck. The patient should be asked about symptoms of dysphagia, odynophagia, dysarthria, globus sensation, difficulty breathing, hemoptysis, otalgia (possibly referred), weight loss, or other constitutional symptoms. One component of a complete history is an adequate social history establishing risk factors for cancer of the head and neck. The patient should be asked about consumption of tobacco and alcohol, occupational exposures (including exposure to sunlight), and previous radiation exposure.

During the comprehensive examination of the head and neck, assess thoroughly the patient's oral cavity and oropharynx. Look for pigmentation changes or ulcerations of the oral mucosa. Assess the state of dentition for gingival disease and missing or loose teeth. Test the patient's maximal interincisor distance on mouth opening to rule out trismus (indicating possible involvement of the pterygoid musculature). A thorough examination includes visual inspection and palpation of all sites in the oral cavity and oropharynx for mucosal lesions or masses. Bimanual palpation is particularly useful to

evaluate the buccal surfaces and the floor of the mouth. Assess voluntary movement of the oral tongue. Do not neglect to palpate the base of the tongue. Indirect mirror laryngoscopy or fiber-optic laryngoscopy may assist inspection of the oropharynx. Test the patient's somatosensory function of the lower divisions of the trigeminal nerve (V2 and V3) for asymmetry. The patient's neck should be palpated for masses at all five levels. Palpable masses should be assessed for size, location, consistency, mobility, and tenderness.

The necessity for a systematic, comprehensive approach to the history and physical examination cannot be overemphasized. Tumor location is one factor influencing the time of presentation for patients complaining of symptoms. It has been shown that the delay in diagnosis for primary tumors of the oral cavity is greatest for floor of the mouth cancer and shortest for tongue cancer.[61] A number of other factors are involved in patient presentation, including tumor size; bleeding; pain; nodal metastases; interference with speech, breathing, or eating; and tendency to seek treatment. In light of the variable stage of disease at time of presentation, a complete examination of the head and neck is critical. The concept of field cancerization lends credence to the adage that finding one lesion in the oral cavity or pharynx does not preclude the presence of others.

Imaging Evaluation for Regional Metastases

When evaluating for nodal metastases, errors may occur in the clinical assessment of regional lymph nodes by palpation alone. It may be difficult to appreciate lymphadenopathy in patients with a short, stout neck, fibrotic changes secondary to previous radiotherapy, and metastatic lymph nodes at sites typically inaccessible by routine physical examination, such as the parapharyngeal space.[62] There is no substitute for a systematic, comprehensive examination of the neck, but imaging techniques provide valuable supplemental information regarding the status of regional lymph nodes. The sensitivity of CT and magnetic resonance imaging (MRI) for accurately detecting nodal metastases has been reported as 84% and 92%, respectively.[63] Although the presence of metastatic involvement of a lymph node is a pathologic and not a radiologic diagnosis, there are characteristic changes apparent on CT and MRI that suggest the presence of carcinoma, including rim enhancement, central necrosis, and a nodal size in excess of 1 cm in diameter. Positron emission tomography (PET) has also been shown to be useful in detecting regional metastases, with a sensitivity reported as 82%.[64] The utility of fluorine-18-fluorodeoxyglucose (FDG) PET in detecting primary and metastatic SCC of the oral cavity and oropharynx is demonstrated in Figure 61–6. Both physical examination and imaging are techniques prone to false-positive and false-negative errors in assessing for metastases to regional lymph nodes.[65] Pathologic confirmation by fine-needle aspiration (FNA) biopsy is therefore critical for any suspicious neck mass. Fine-needle aspiration is a highly sensitive procedure with minimal morbidity that allows cytologic examination of the aspirate. Repeat FNA should be considered following an initial nondiagnostic FNA. Open neck biopsy is a procedure with extremely limited indications and should be considered only when both the surgeon and the patient are prepared to proceed immediately with a neck dissection if indicated.[62]

Imaging Evaluation of the Mandible

Computed tomography and MRI provide useful adjuvant information regarding soft tissue and bony invasion of advanced oral and oropharyngeal tumors, particularly with extension toward the nasal cavity, maxillary sinus, parapharyngeal space, and larynx. An area of controversy, however, has surrounded the optimal evaluation of mandibular involvement by cancer.

Patterns of spread of SCC within the mandible include spread along the inferior alveolar nerve as well as direct extension through the cancellous bony trabeculae.[66] Clinical evaluation by physical examination has been studied in comparison to panoramic radiographs (panorex) and to CT scans for assessing mandibular invasion by tumor.[67] Clinical evaluation was found to be the most accurate modality to determine the extent of bony invasion and to decide the optimal method of mandibular resection. Panoramic films were found to be helpful in evaluating gross extent of mandibular invasion but not helpful for assessing minimal bony invasion or cortical invasion. The utility of CT scans was reported to be limited owing to the presence of irregular dental sockets and artifacts. Computed

tomographic scans demonstrating mandibular invasion from SCC of the oral cavity are shown in Figure 61–7. DentaScan software provides imaging of the mandible and maxilla in three planes of reference: axial, panoramic, and oblique sagittal. DentaScan imaging minimizes dental restoration artifact, and the multiple planes of visualization improve evaluation of cortical bony margins.[68,69]

ENDOSCOPY

Endoscopic examination of the upper aerodigestive tract under anesthesia provides both thorough inspection of the primary tumor and evaluation for second primary tumors, with the ability to biopsy suspicious sites. The oropharynx, hypopharynx, larynx, and esophagus should be examined in a systematic fashion. The routine use of bronchoscopy is controversial owing to its low yield of synchronous carcinoma of the lung, in the presence of a normal chest radiograph and in the absence of clinical symptoms.[70]

STAGING

Staging systems for cancer provide a standardized measurement for assessing the extent of disease. Staging allows estimation of prognosis, assistance in

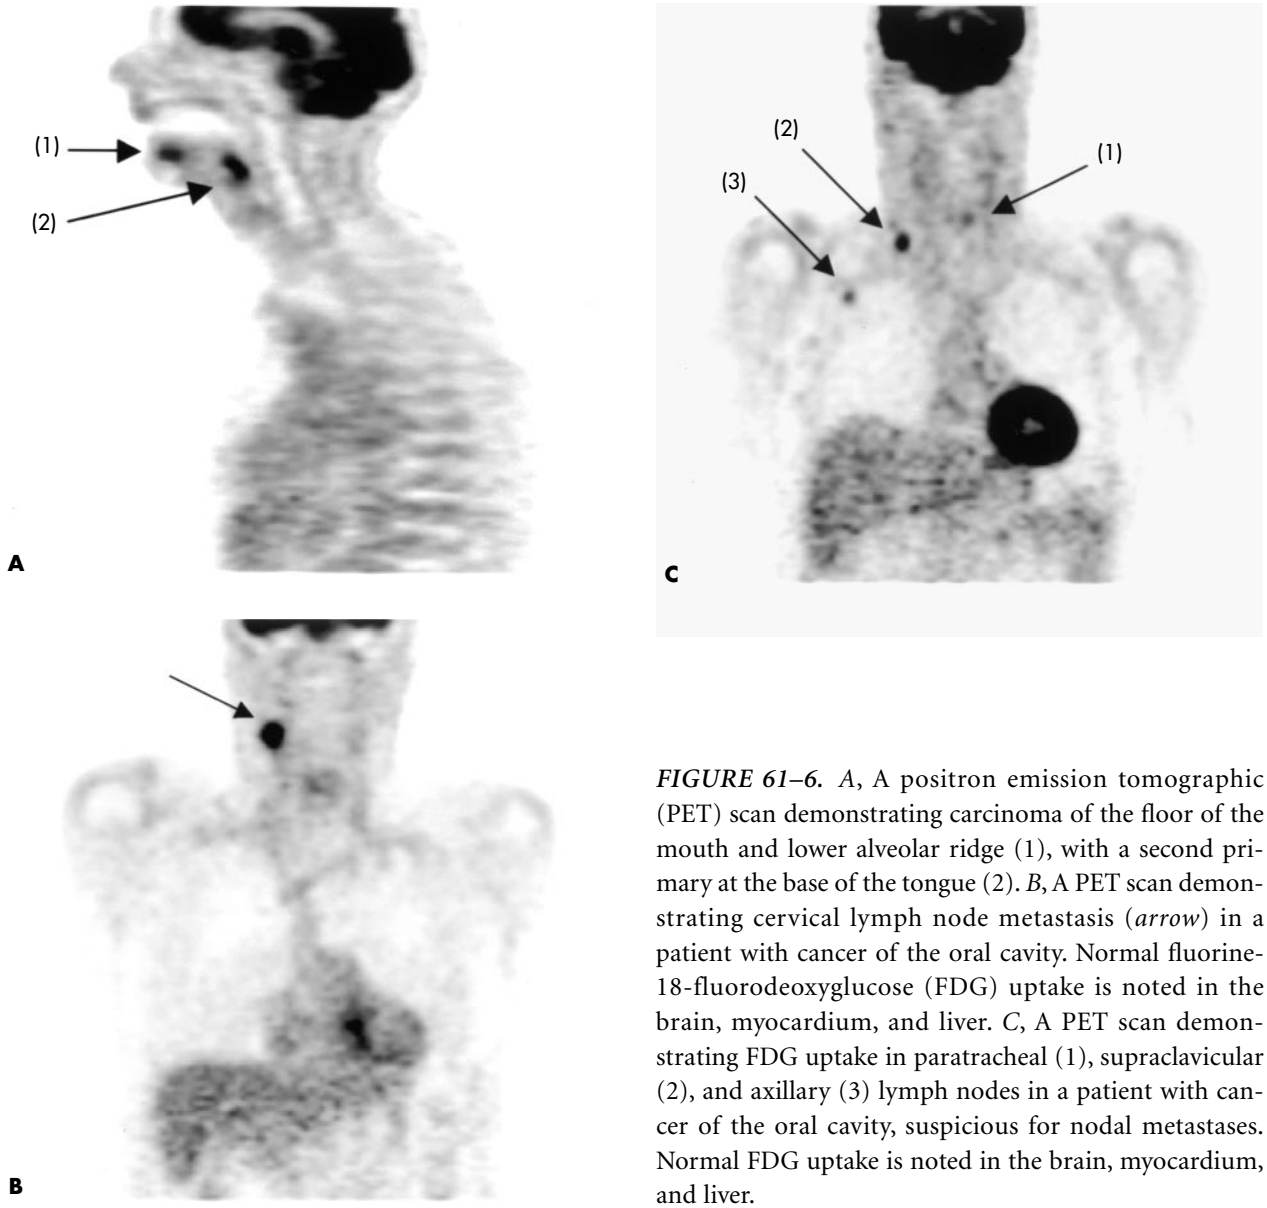


FIGURE 61–6. A, A positron emission tomographic (PET) scan demonstrating carcinoma of the floor of the mouth and lower alveolar ridge (1), with a second primary at the base of the tongue (2). *B*, A PET scan demonstrating cervical lymph node metastasis (*arrow*) in a patient with cancer of the oral cavity. Normal fluorine-18-fluorodeoxyglucose (FDG) uptake is noted in the brain, myocardium, and liver. *C*, A PET scan demonstrating FDG uptake in paratracheal (1), supraclavicular (2), and axillary (3) lymph nodes in a patient with cancer of the oral cavity, suspicious for nodal metastases. Normal FDG uptake is noted in the brain, myocardium, and liver.

planning treatment options, evaluation of the effectiveness of treatment modalities, and promotion of a uniform comparison of treatment results. The staging system of the American Joint Committee on Cancer is based on the TNM staging system in which T category refers to the primary tumor, N category refers to regional cervical lymph node metastases, and M category refers to distant metastases (Tables 61–1 and 61–2).[1] Patient factors such as comorbidity[71,72] and molecular characteristics of tumors are not incorporated in the current staging system, but such variables may provide useful information regarding prognosis and outcomes analysis.

TREATMENT

The primary objective in treating patients with SCC of the oral cavity or oropharynx should focus on rendering the patient free of disease. In general, early-stage lesions may be treated by surgery or radiation with comparable results, and more advanced cancers are best approached with combined therapy. The proclivity of these tumors, particularly late-stage disease, for locoregional failure, however, mandates recognizing the specific prognostic factors associated with each case. Tailoring the most appropriate therapy involves considering patient characteristics, including comorbidity and motivation; physician resources, including experience and facilities; and tumor presentation, including location, grade, and extent of disease. Further, important principles that must be reconciled with tumor eradication include optimizing esthetic form and preserving proper function, including respiration, swallowing, and speech.

SURGERY

In light of the comparable results for early-stage lesions treated with either surgery or radiation therapy, factors in favor of surgical resection include the pathologic staging of local invasion and avoiding complications associated with radiotherapy, including xerostomia and osteoradionecrosis. The primary limitation of surgery involves functional impairment, particularly when resection involving the mandible or tongue is necessary.

Surgical Approaches Different surgical approaches to the oral cavity and oropharynx exist, depending on tumor location and extent. Peroral excision is a suitable approach for small lesions of the oral cavity, including those arising from the floor of the mouth or oral tongue. A cheek flap, either upper or lower, may be constructed for larger lesions in the oral cavity. A visor flap may be used for anterior lesions in the oral cavity to avoid external facial incisions but at the expense of bilateral mental nerve sacrifice.

Tumors arising at or extending to the posterior part of the oral cavity or oropharynx may require mandibulotomy for adequate exposure. A paramedian mandibulotomy approach with paralingual extension (mandibular swing), illustrated in Figure

61–8, offers more versatility and less morbidity than mandibulotomy through a lateral approach.[73] The mandibular swing procedure provides the option for surgical resection with adjuvant radiotherapy as an alternative to single-modality high-dose irradiation to treat oropharyngeal cancer.[74] Placing the mandibulotomy anterior to the inferior alveolar (mental) foramen is ideal to preserve the integrity of the inferior alveolar nerve and to exclude the osteotomy from the portals employed for adjuvant external beam radiotherapy.[75]

One evolution in the surgical approach to cancers of the oral cavity and oropharynx is the attempt to spare the mandible in the absence of bony invasion.[76] Mandibular preservation stems from several principles. Oncologically, it was recognized to be no longer necessary to remove a portion of the mandible simply to keep contents from a neck dissection in continuity with resection of a primary oral tumor.[77] Functionally, resection of the anterior arch of the mandible results in disabilities, including drooling and interference with eating, directly related to the amount of bone removed. Esthetically, this "Andy Gump" deformity results in an inferior cosmetic appearance. Segmental mandibulectomy is illustrated in Figure 61–9.

Instances of bony invasion by tumor mandate resection of that portion of the mandible. The amount of bone to be resected is predicated on the location and extent of bony involvement. Marginal mandibulectomy, shown in Figure 61–10, has been recommended for lower gingival cancers if erosive bony defects did not extend beyond the inferior alveolar (mandibular) canal or if invasive bony defects were confined to a superficial area of alveolar bone.[78] Rim mandibulectomy may be effective, provided that there is preservation of at least 1 cm thickness of bone inferiorly to prevent mandibular fracture.[79]

Surgical Margins An important concept in the surgical management of cancer of the oral cavity and oropharynx concerns the importance for adequate margins of resection. Local recurrence in patients with positive surgical margins following resection of SCC from the oral cavity was twice as high as those with negative margins.[80] Furthermore, local recurrence rates and 5-year survival rates of patients with "close" surgical margins (less than

5 mm) were comparable to those with microscopically positive margins.[81]

In light of the impact of histologically "close" or positive margins on local recurrence and survival, it is critical at the time of surgery to ensure resection margins of adequate size. Another factor to consider at the time of surgery is the reported change in tissue margins before and after pathologic fixation. In an animal model, oral cavity margins shrank from approximately 30 to 50% from the in situ measurement of the surgeon at the time of resection to final pathologic evaluation on the microscopic slide after formalin fixation.[82]

Radiation Therapy

General principles of radiotherapy summarized by Wang include the generally favorable radioresponsiveness of most early-stage head and neck SCCs; a well-oxygenated environment provides an ideal setting for therapeutic radiation; invasion of bone or deep muscle portends a poorer response to radiotherapy; and neck dissection, with or without adjuvant irradiation, is the preferred treatment for large cervical metastases.[83]

Modalities for primary irradiation include external beam radiation therapy, interstitial implantation, or a combination of the two. Definitive radiotherapy shares comparable results with surgical treatment for early-stage oral or oropharyngeal cancers. Radiation therapy is typically favorable for tonsillar carcinoma, which is particularly responsive to radiation therapy, and is preferred for early-stage lesions in the oral cavity or oropharynx in patients who pose an anesthetic risk.

Radiation dose depends on the extent of disease and the tolerance of the surrounding normal tissues. Definitive radiotherapy may be delivered with doses of 60 to 65 Gy over 6 weeks for smaller tumors. Larger tumors may require 65 to 70 Gy delivered over 7 weeks. Adjuvant radiotherapy following surgery may be delivered with doses of 60 to 65 Gy over 6 weeks for microscopic residual disease. Greater doses may be required for gross residual disease.

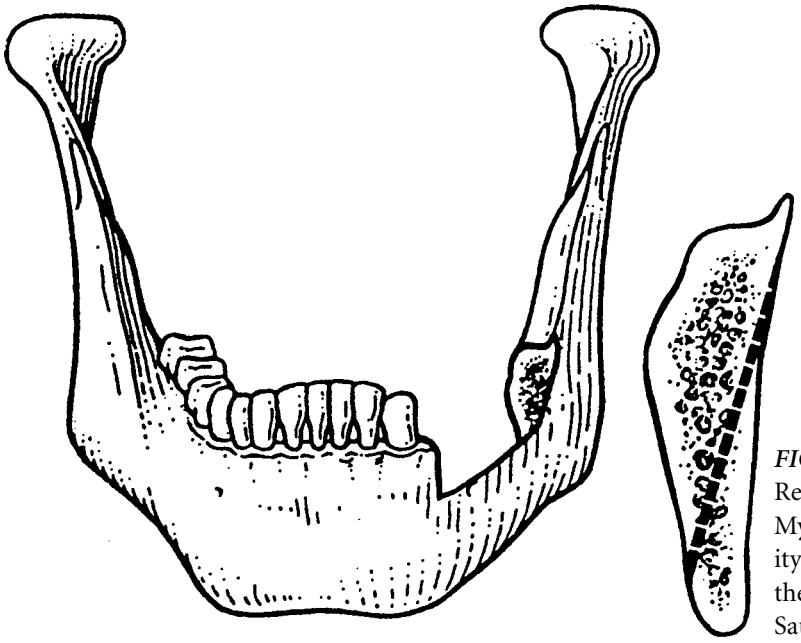

FIGURE 61–10. Marginal mandibulectomy. Reproduced with permission from Alvi A, Myers EN, Johnson JT. Cancer of the oral cavity. In: Myers EN, Suen JY, editors. Cancer of the head and neck. 3rd ed. Philadelphia: WB Saunders; 1996.

Improvement continues in the mode of delivery of radiotherapy. Improved 5-year local control rates and disease-specific survival rates have been reported for T1 to T3 base of tongue and faucial tonsillar lesions using an accelerated hyperfractionated radiotherapy twice-daily program compared with conventional once-daily radiation therapy.[84] A phase III randomized trial 9003 of the Radiation Therapy Oncology Group (RTOG) has reported improved locoregional control of locally advanced head and neck cancer using hyperfractionation or accelerated fractionation with concomitant boost compared with conventional once-daily fractionation.[85] Interstitial brachytherapy has been demonstrated to be effective for carcinoma of the oral cavity and oropharynx.[86]

In addition to side effects of mucositis and xerostomia, major complications of definitive radiotherapy for SCC of the oral cavity and oropharynx have been reported, including osteoradionecrosis, pathologic fracture, or ulceration of mucous membranes.[87] The risk of osteoradionecrosis necessitates comprehensive dental care prior to the initiation of radiotherapy.[88]

Combined Therapy

A combination of surgery and radiation therapy is recommended for advanced cancers of the oral cavity and oropharynx in light of the high propensity for locoregional failure. The timing of irradiation in relation to surgery has been a matter of debate. The advantages of preoperative radiotherapy include reduction of tumor volume in a better-oxygenated environment and possible sterilization of the surgical field. The disadvantages of preoperative radiotherapy include possible surgical wound complications and possible obscuring of tumor margins at the time of resection. The advantages of postoperative (adjuvant) radiotherapy include the safer administration of higher radiation doses, improved patient compliance, and irradiation of potential microscopic disease rather than gross, bulky tumor. The disadvantages of postoperative radiotherapy include the possibility of surgical complications delaying the initiation of radiation treatments. The final report of study 73-03 of the RTOG did not detect statistically significant differences in locoregional control or overall survival between preoperative radiotherapy and postoperative radiotherapy for carcinoma of the oral cavity and oropharynx.[89]

At the present time, combined treatment for advanced carcinoma of the oral cavity typically involves surgical resection and postoperative radiation therapy. Indications for adjuvant radiotherapy include multiple positive nodes, extracapsular lymph node extension, and positive margins of

resection. Adjuvant radiation therapy has been shown to improve locoregional control in the presence of extracapsular spread or positive resection margins following surgery.[90] Postoperative radiotherapy, however, should not be construed as a panacea for an inadequate operation. Adjuvant radiotherapy does not appear to decrease the risk of local recurrence in patients with positive margins to a level similar to that in comparable patients with negative margins not treated with radiotherapy.[80]

The ideal timing of postoperative radiotherapy has been recommended as starting treatments within 6 weeks following surgery. For stage III and IV SCC of the head and neck, locoregional recurrence was 5.5% when adjuvant radiotherapy was initiated within 6 weeks following surgery. Locoregional recurrence was 31.5% when postoperative radiation therapy was delayed longer than 6 weeks.[91] This increase in nodal recurrence rate when adjuvant radiotherapy was delayed longer than 6 weeks was observed whether nodal metastases were confined to a single nodal level or whether multiple levels were involved. Furthermore, this higher recurrence rate with delayed radiotherapy was not abrogated by using higher doses of radiation.[92]

Neck dissection is the preferred modality for salvage. Irradiation for surgical failure in the neck is associated with worse survival rates compared to salvage neck dissection following failed radiotherapy.[93]

Chemotherapy

The effect of using chemotherapy to treat head and neck SCC has been studied in a variety of settings. Chemotherapy administered prior to definitive local therapy is referred to as neoadjuvant (induction) chemotherapy. Adjuvant chemotherapy describes chemotherapy delivered after definitive local therapy. Concomitant chemotherapy refers to chemotherapy administered simultaneously with irradiation.

A multi-institutional prospective randomized trial of the Southwest Oncology Group demonstrated no survival advantage with the addition of neoadjuvant chemotherapy, administered prior to surgery and postoperative radiotherapy, for advanced resectable head and neck cancer.[94] Jacobs et al found no demonstrable difference in 5-year survival rates between neoadjuvant and adjuvant chemotherapy using cisplatin and 5-fluorouracil (5-FU) for advanced, resectable head and neck cancer.[95] Another study using adjuvant cisplatin and 5-FU following surgery with postoperative radiotherapy demonstrated a decreased incidence of distant metastases but no difference in 4-year locoregional control, overall survival, or disease-free survival.[96] In light of the effective treatment of concomitant chemotherapy and irradiation for advanced laryngeal cancer,[96,97] a randomized trial of concomitant carboplatin and 5-FU combined with radiotherapy was performed for stage III and IV oropharyngeal carcinoma.[96,98] These results demonstrated greater 3-year overall actuarial survival and disease-free survival rates than conventional radiotherapy alone. Locoregional control was improved in concomitant chemotherapy and radiation therapy compared with radiation therapy alone. However, mucositis and hematologic toxicity, measured by neutrophil count and hemoglobin level, were higher for the concomitant treatment group.

Further investigation into the benefit of chemotherapy for carcinoma of the oral cavity and oropharynx is warranted as it currently plays a supplemental role to the established treatment modalities, surgery and radiation. Chemotherapy, however, is frequently employed in the palliation of advanced head and neck cancer not amenable to the primary methods of treatment or in the setting of recurrent disease.

Chemoprevention

Recent efforts to expand our armamentarium to treat cancer of the oral cavity and oropharynx have included investigation of chemopreventive agents. As the genetic events leading to carcinogenesis are further elucidated, attempts have been made to identify potential agents that can prevent DNA damage or enhance DNA repair. A prospective randomized trial has demonstrated effective treatment of oral leukoplakia with a 6-month trial of isotretinoin (13-*cis*-retinoic acid), with significant reduction in lesion size and reversal of dysplasia.[99] Relapse, however, occurred in 56% 2 to 3 months following cessation of treatment. A follow-up prospective randomized study used a 12-month trial of isotretinoin following primary treatment for SCC of the oral cavity, pharynx, or larynx.[100] After a median period of 32 months, no significant differences were found in local, regional, or distant recurrences of the

primary cancers. However, patients treated with isotretinoin had significantly fewer second primary tumors. The response to chemopreventive agents may include genetic alterations not readily apparent on phenotypic presentation. This discordance suggests the need to consider not only phenotypic changes, such as lesion size and differentiation, but also genotypic response, using critical genetic markers, when evaluating the effect of chemopreventive agents.[101]

Management of the Neck

An issue of ongoing controversy concerns the management of the neck in patients without clinical evidence of regional nodal metastases (the N0 neck). Lymphatic metastases from primary tumors of the oral cavity and oropharynx occur in a predictable fashion through sequential spread. Although previous surgery or irradiation may result in aberrant lymphatic drainage, there are well-established first-echelon lymph nodes at highest risk for metastases depending on the primary site of cancer. Pathologic evidence of micrometastases has been observed on gross section in up to 33% of elective neck dissection specimens. More sensitive detection methods such as serial sectioning or polymerase chain reaction may result in an even higher prevalence. In light of the propensity for various sites of the oral cavity and oropharynx to spread to regional lymphatics and the high risk of nodal recurrence, what constitutes the ideal approach to the N0 neck? Is the best approach observation or treatment? If treatment is chosen, is elective neck dissection or elective neck irradiation the optimal modality?

Elective Neck Dissection It has been previously reported that there is no survival advantage offered by elective neck dissection when compared to observation.[102] However, when observation is used for the neck at risk for metastasis, patients tend to fail with advanced nodal disease, even with close follow-up.[103] Elective neck dissection has been shown to improve locoregional control and may therefore positively impact on the quality of patient's survival.[104]

One criticism of elective neck dissection has focused on potential complications from the procedure. Initially described by Crile in 1906[105] and popularized by Martin et al,[106] the so-called radical neck dissection or comprehensive neck dissection, with sacrifice of the spinal accessory nerve (XI), SCM, and internal jugular vein, is associated with significant morbidity. Significant compromise of shoulder function results from sacrifice of nerve XI, and cosmetic deformity with platysmal banding occurs from resection of the SCM.[107] Removal of the internal jugular vein risks significant edema of the face and occasional neurologic deficit, particularly following bilateral neck dissection or when radiotherapy is employed.

In light of the morbidity associated with radical neck dissection, there has been a trend toward selective, rather than comprehensive, neck dissection, based on the predictable pattern of cervical lymph node metastases. Selective neck dissection has been demonstrated to be an oncologically sound procedure, providing effective treatment for the N0 neck.[108] Supraomohyoid neck dissection (SOHND), selective lymphadenectomy clearing cervical nodal levels I, II, and III, has been recommended for N0 patients with primary SCCs of the oral cavity.[3,109] Other reports have extended the indication for SOHND for primary tumors in the oral cavity to include not only N0 necks but also N1 necks without evidence of extracapsular spread.[110,111] A proposed limitation of the SOHND for primary tumors of the oral tongue concerns the potential for "skip metastases," or metastases to inferior cervical nodes at level III or IV in the absence of demonstrable involvement at levels I and II.[112] Although clearing level IV during a SOHND adds little in terms of morbidity and operative time, the risk of isolated level IV involvement in the absence of other cervical metastases may be sufficiently low as to obviate the need for routine addition of level IV to the SOHND for the N0 neck with an oral cavity primary tumor.[113]

Based on the predictable spread of cervical nodal metastases, SOHND may not be sufficient for the N0 neck with a primary arising in the oropharynx. The risk for level IV spread is higher from primary tumors of the oropharynx compared with those arising from the oral cavity. Thus, an anterolateral neck dissection encompassing levels II, III, and IV of the deep jugular chain has been advocated for N0 necks with an oropharyngeal primary.[3]

For primary tumors of the oral cavity or oropharynx, the risk of level V involvement has been shown to be minimal when only one level is involved, unless level IV is the involved level or multiple levels are involved.[114] Level V, therefore, is not

routinely included in the selective lymphadenectomy of N0 necks for primaries of the oral cavity or oropharynx.

In this era of more selective neck dissections, the utility of lymphoscintigraphy with nodal sampling, clinically useful for treatment of cutaneous melanoma, has been investigated for primaries of the oral cavity. The fundamental principle behind determining the sentinel lymph node of a primary cancer is based on the well-established patterns of cervical lymph nodes at highest risk for metastasis. Given the potential savings of time, cost, and morbidity, the detection of the sentinel node by lymphoscintigraphy has been shown to be a feasible procedure for selected patients with oral cancer and clinically negative necks. However, the ability to detect metastases reliably has not been established.[115] Previous neck dissection has been demonstrated to result in modified lymphatic drainage in patients with tongue cancer, thereby possibly further complicating accurate detection by lymphoscintigraphy.[116] The applicability of lymphoscintigraphy-assisted sentinel lymph node sampling may be limited in oral cavity cancer, secondary to the technical challenges of accurate detection, as well as the risk of associated morbidity that may not be significantly different from that of a SOHND.

Elective Neck Irradiation The theoretical advantages of treating the N0 neck with surgical lymphadenectomy include pathologic staging information, preparation of donor and recipient vessels for microvascular reconstruction, and avoidance of the morbidity associated with radiotherapy. However, elective neck irradiation has been shown to provide lymph node failure rates of less than 5% when the primary lesion has been adequately controlled.[117] In fact, no significant differences in regional recurrence have been demonstrated following treatment with elective neck irradiation compared to elective neck dissection.[118]

The modality chosen to address the clinically negative neck may be largely influenced by philosophy of the treating physician. Nevertheless, as a general rule, the treatment modality for the primary tumor of the oral cavity and oropharynx may be used concurrently to address occult metastases in the clinically negative neck. Recognizing that some sites of the oral cavity have less propensity to spread to regional lymphatics (hard palate, alveolar ridge, and nonmidline aspects of the lip), the risk of regional failure with primaries of the oral cavity and oropharynx is sufficiently high to warrant elective treatment of the neck in most instances.

Therapeutic Neck Dissection For the clinically positive neck, the traditional surgical procedure of choice has been comprehensive neck dissection with preservation of nerve XI when technically feasible. The continuing evolution of a more selective approach to the neck, however, has included the clinically positive neck as well. Comprehensive neck dissection, with preservation of nerve XI, the SCM, and the internal jugular vein, may be performed for N1, N2a, or N2b disease when technically feasible. Supraomohyoid neck dissection may be acceptable for N1 disease without extracapsular extension arising from primaries of the oral cavity, particularly when the involved node is at level I.

SPECIFIC SITES IN THE ORAL CAVITY

Lip

Squamous cell carcinoma of the lip, by virtue of its location, tends to present at an early stage. The lower lip is affected more commonly, presumably secondary to sunlight exposure, with origin at the commissure occurring in less than 1% of cases.[119]

Comparable cure rates have been reported for small tumors using either surgery or radiation therapy, but surgical excision is the treatment of choice in most instances owing to its lower morbidity and better cosmetic result.[120] Advantages of surgery over irradiation include the ability to assess tumor margins, avoidance of the complications associated with radiotherapy, and rapid rehabilitation.[121] Lesions up to one-third the lip length may be resected with primary closure, and a number of options exist for flap reconstruction for larger lesions.

An important consideration for advanced lesions is possible involvement of the mental branch of the mandibular nerve (V3), which provides sensory innervation to the lower lip. Surgical salvage for local recurrence is successful in greater than 70% of cases.[120]

Metastases from carcinoma of the lip are uncommon except in advanced lesions, recurrent lesions, or lesions arising at the oral commissure. When lymphatic spread arises from midline lip

lesions, bilateral nodal metastases are more prevalent. Depth of invasion is an important prognostic factor for regional lymph node metastasis, particularly for lesions greater than 6 mm thick.[122]

Overall survival rates reported for stages I to IV are approximately 90% when using surgery for stages I and II and combination treatment of surgery plus adjuvant radiotherapy for stages III and IV.[120]

Buccal Mucosa

Cancers of the buccal mucosa are characteristically locally aggressive, spreading to adjacent gingiva in approximately 38% of cases and involving the retromolar trigone or pterygoid region in approximately 13%.[123] The intraoperative photograph in Figure 61–11 depicts an advanced-stage SCC of the right buccal mucosa extending through the external skin.

Surgical resection is recommended for stage I and II tumors, with combination therapy using surgery and postoperative radiotherapy for stage III and IV tumors.

Using this treatment approach, the following 5-year survival rates have been reported: stage I, 77%; stage II, 65%; stage III, 27%; and stage IV, 18%.[123]

Upper and Lower Alveolar Ridges

Tumors of the alveolar ridge typically present with soreness or gum pain, ulceration, intraoral bleeding, loosening of teeth, or ill-fitting dentures. Patients tend to present with symptoms within 3 months duration.[124]

Cancer of the upper alveolar ridge may extend superiorly to involve the floor of the nasal cavity or the maxillary sinus. Carcinoma of the alveolar ridge more commonly arises from the lower alveolus, and cancers of the lower gum may spread along the course of the inferior alveolar nerve toward the skull base.

Based on 2-year survival rates, marginal mandibulectomy has been demonstrated to be a sound oncologic procedure for stage I and II disease of the lower alveolus.[125] Marginal mandibulectomy is an effective procedure for lower alveolar carcinoma but is contraindicated if the mandible is enveloped by tumor, if there is tumor invasion through the cortical plate, or if there has been recent tooth extraction in proximity to the tumor.[124] The use of adjuvant radiotherapy has been advocated for inadequate margins of surgical resection, perineural invasion, or extensive nodal metastases,[126] although regional metastases to cervical lymphatics are uncommon in carcinoma of the alveolar ridge.

Using surgery as the primary treatment modality, with the addition of postoperative radiotherapy for advanced lesions, the following 5-year survival rates have been demonstrated: stage I, 77%; stage II, 70%; stage III, 42%; and stage IV, 24%.[124]

FIGURE 61–11. Advanced-stage squamous cell carcinoma of the right buccal mucosa penetrating through the skin.

Retromolar Trigone

Branches from the glossopharyngeal (IX) nerve provide sensory innervation to the retromolar trigone, so patients with carcinoma of the retromolar trigone may present complaining of pain referred to the ipsilateral ear. Numbness in the distribution of the inferior alveolar nerve may be observed if tumor invades the mandible. Trismus may result from invasion of the pterygoid musculature. Extension into the pterygopalatine fossa may lead to disease at the skull base. The proximity of the structures of the oropharynx, including the base of the tongue, soft palate, and tonsil, places them at risk for tumor involvement by direct extension. Proximity to the ramus of the mandible often necessitates resection of the ascending portion of the mandible.

Hard Palate

Although relatively rare in the United States, carcinoma of the hard palate is more prevalent in places of the world where reverse smoking is practiced. The heat generated from holding the lit end of the cigarette near the hard palate has been demonstrated to result in malignant transformation. Presenting symptoms of cancer of the hard palate include pain, bleeding, improper denture fit, or altered speech. Biopsy may be necessary to distinguish carcinoma of the hard palate from other disease entities, such as necrotizing sialometaplasia. One confounding factor in establishing a diagnosis of hard palate cancer is the considerable delay before patients present complaining of symptoms. One study showed that 58% of patients had had symptoms for at least 12 weeks before seeking treatment, and 38% had a delay of more than 6 months.[127] Advanced tumors may extend into the nasal cavity through the incisive foramen or may approach the skull base via the greater palatine foramina.

For early-stage lesions, no differences have been shown between single-modality treatment using either surgery or irradiation, so selection of therapy should be based on the anatomic location and extent of disease, the presence of second primaries, and associated patient comorbidities.[127] Surgery followed by adjuvant radiotherapy is recommended for advanced-stage disease.

Regional lymphatic drainage from the hard palate is sparse, so metastases to cervical lymph nodes are uncommon.

Floor of the Mouth

By virtue of their location, cancers of the floor of the mouth may remain undetected until they progress to advanced disease. Large bulky tumors may affect normal speech and deglutition. Patients may complain of pain referred to the ipsilateral ear from tumor involvement of the lingual nerve extending to the main trunk of the mandibular nerve (V3). Advanced tumors may invade the tongue or mandible by direct extension. Second primary tumors are particularly common with floor of the mouth cancer.[128]

Elective treatment of the neck is warranted in carcinoma of the floor of the mouth owing to the significant incidence of occult nodal metastases, even with T1 lesions.[129] Patients with high-stage primary cancers are at high risk for advanced nodal metastases as approximately one-third of patients with T4 tumors present with N3 disease.[128] The risk of contralateral nodal metastases is significant with floor of the mouth cancer,[130] and multiple levels are often involved.[128]

The following 5-year survival rates, using surgery as primary therapy with postoperative radiotherapy for stage III and IV disease, have been reported: stage I, 88%; stage II, 80%; stage III, 66%; and stage IV, 32%.[128]

Figure 61–12 illustrates the surgical management of a patient with biopsy-proven SCC of the floor of the mouth invading the ventral surface of the oral tongue. The patient underwent resection of the lesion at the floor of the mouth and ventral surface of the tongue, with marginal mandibulectomy, bilateral SOHND, and tracheostomy. Repair of the surgical defect was accomplished through radial forearm free flap reconstruction.

Oral Tongue

Common presenting symptoms and signs for carcinoma of the oral tongue include localized pain and the presence of an ulcer, frequently at the middle third of the tongue. Patients may report dysarthria or pain with eating. As with the floor of the mouth, cancers of the oral tongue may present with referred pain in the ipsilateral ear owing to involvement of the mandibular nerve (V3).

Second primary tumors are common in cancers of the tongue, occurring in approximately 24% of patients.[131]

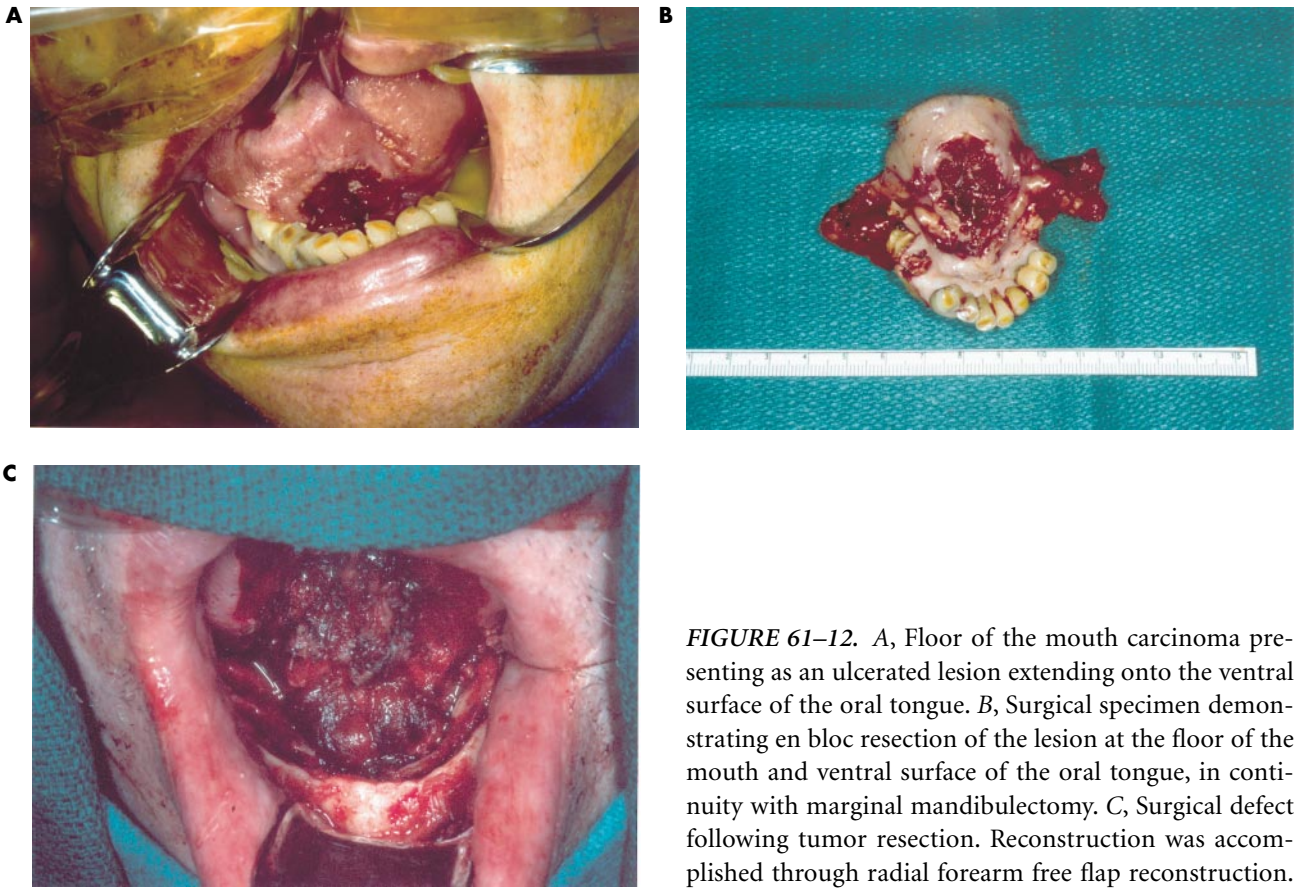

FIGURE 61–12. *A*, Floor of the mouth carcinoma presenting as an ulcerated lesion extending onto the ventral surface of the oral tongue. *B*, Surgical specimen demonstrating en bloc resection of the lesion at the floor of the mouth and ventral surface of the oral tongue, in continuity with marginal mandibulectomy. *C*, Surgical defect following tumor resection. Reconstruction was accomplished through radial forearm free flap reconstruction.

There have been no demonstrable differences in rates of locoregional control or survival between surgery and irradiation for T1 and T2 lesions.[132] Surgical resection is typically employed for stage I and II lesions, whereas combined therapy using surgery and postoperative radiotherapy is indicated for stage III and IV disease.[131]

Occult metastases in regional lymphatics are common with carcinoma of the tongue, particularly when the depth of the primary tumor is greater than 2 mm thick.[133] The risk of regional metastases approaches 40% in this group of patients, necessitating elective treatment of the N0 neck with carcinoma of the oral tongue. The rates of both locoregional control and survival are improved with elective neck dissection, even for T1 and T2 lesions.[134] The N0 neck may be treated with selective neck dissection as no differences in survival or locoregional control have been demonstrated between comprehensive and selective neck dissection for elective lymphadenectomy[131,135]

Improvements in observed rates of overall 5-year survival have been attributed to a more aggressive approach to the neck in patients with early-stage (stages I and II) tumors and the addition of postoperative radiotherapy in patients with advanced-stage (stages III and IV) disease. Reported 5-year survival rates for cancer of the tongue using surgery has primary treatment with adjuvant radiotherapy: stage I, 90%; stage II, 72%; stage III, 54%; and stage IV, 34%.[131] The increasing use of mandible-sparing procedures and selective neck dissections may result in improved quality of survival as well.

RECONSTRUCTION OF THE ORAL CAVITY

Following resection of cancers of the oral cavity, defects may be approached in a variety of ways. Select small intraoral defects may be closed primarily, covered with a local flap or split-thickness skin graft, or left to heal by secondary intention. Larger defects may require more complex flap reconstruction. A number of factors affect the type of reconstruction, if any, used, including tumor extent and location; possible dysfunction of breathing, swal-

lowing, or speech; patient comorbidity; and the surgeon's experience and preference.

A comprehensive description of the variety of reconstructive techniques for soft tissue and bony defects following ablation of oral cavity cancers is beyond the scope of this chapter (see Chapters 40 and 41). Nevertheless, two key developments in the evolution of head and neck reconstruction that deserve special mention include pedicled flaps and microvascular free tissue transfer.

The pectoralis major myocutaneous flap provides well-vascularized soft tissue for reconstructing oral cavity defects in a single stage.[136] It is one example of a pedicled flap, receiving its blood supply from the thoracoacromial artery, and is useful for reconstructing intraoral as well as external defects. Its reliable vascularity, proximity to the head and neck region, and availability for harvest with the patient in a supine position led to its wide acceptance for reconstruction of head and neck defects. The pectoralis major myocutaneous flap, however, does have several disadvantages in intraoral reconstruction, including hair-bearing skin, soft tissue bulk inappropriate for smaller defects, and limitation in the arc of rotation.

Microvascular free tissue transfer revolutionized head and neck reconstruction, providing flaps and their nutrient vessels to repair complex defects with uniformly perfused tissue. The radial forearm free flap and rectus abdominis free flap are two types of free tissue transfer useful for intraoral soft tissue reconstruction.

Mandibular defects may be successfully reconstructed with composite bone flaps, including the fibular osteocutaneous free flap or iliac crest osteocutaneous free flap. Such vascularized composite bone flaps provide reliable bone stock for optimal esthetic contour and masticatory function. Figure 61–13 illustrates the surgical management of a patient with biopsy-proven SCC of the floor of the mouth involving the anterior part of the mandible and anterior part of the tongue. The patient underwent resection of the floor of the mouth, subtotal glossectomy, segmental mandibulectomy, tracheostomy, and bilateral modified radical neck dissection incorporating cervical nodal levels I through IV. Mandibular reconstruction was accomplished using fibular free flap, with soft tissue coverage provided by radial forearm free flap reconstruction.

SPECIFIC SITES IN THE OROPHARYNX

Base of the Tongue

Typical of cancers of the oropharynx, base of the tongue cancers often present at an advanced stage of disease. Overall, 62% of patients present with nodal metastases,[137] and contralateral or bilateral nodal involvement is frequently seen.

A variety of treatment options for base of the tongue cancer have been proposed, including surgery with or without postoperative radiotherapy, primary external beam radiotherapy, external beam radiation therapy with brachytherapy implantation with or without neck dissection, and induction chemotherapy with external beam radiation therapy with or without brachytherapy. Given the proximity of the larynx to lesions of the base of the tongue, an important consideration in planning therapy is optimizing functions of speech and swallowing while eradicating disease.

Table 61–3 illustrates 5-year overall survival rates for patients with base of the tongue carcinoma treated with different treatment modalities.

Using surgery as definitive treatment with postoperative radiotherapy for advanced disease, 5-year survival rates for patients with stage I and II lesions were found to be 77%, whereas that for stage III lesions was 64% and for stage IV disease 59%.[137] In this study, mandible continuity was maintained in 86%, and the larynx was preserved in 80%.

Combination therapy using external beam radiotherapy and implantation of iridium 192 has been employed for T1 to T4 base of the tongue cancers. Using irradiation alone for N0 necks and treating N+ necks with irradiation and neck dissection, overall 5- and 10-year survival rates have been reported at 86% and 52%, respectively.[138]

Five-year overall and disease-free survival rates for patients treated with continuous-course external beam irradiation (with or without neck dissection) who did not receive interstitial implantation were reported to be 43% and 58%, respectively.[139] This study found improved local control for T4 tumors treated with twice-a-day fractionation compared with once-a-day fractionation.

Finally, in light of the favorable results using induction chemotherapy followed by irradiation in the treatment of advanced laryngeal cancer, similar regimens have been studied for carcinoma of the

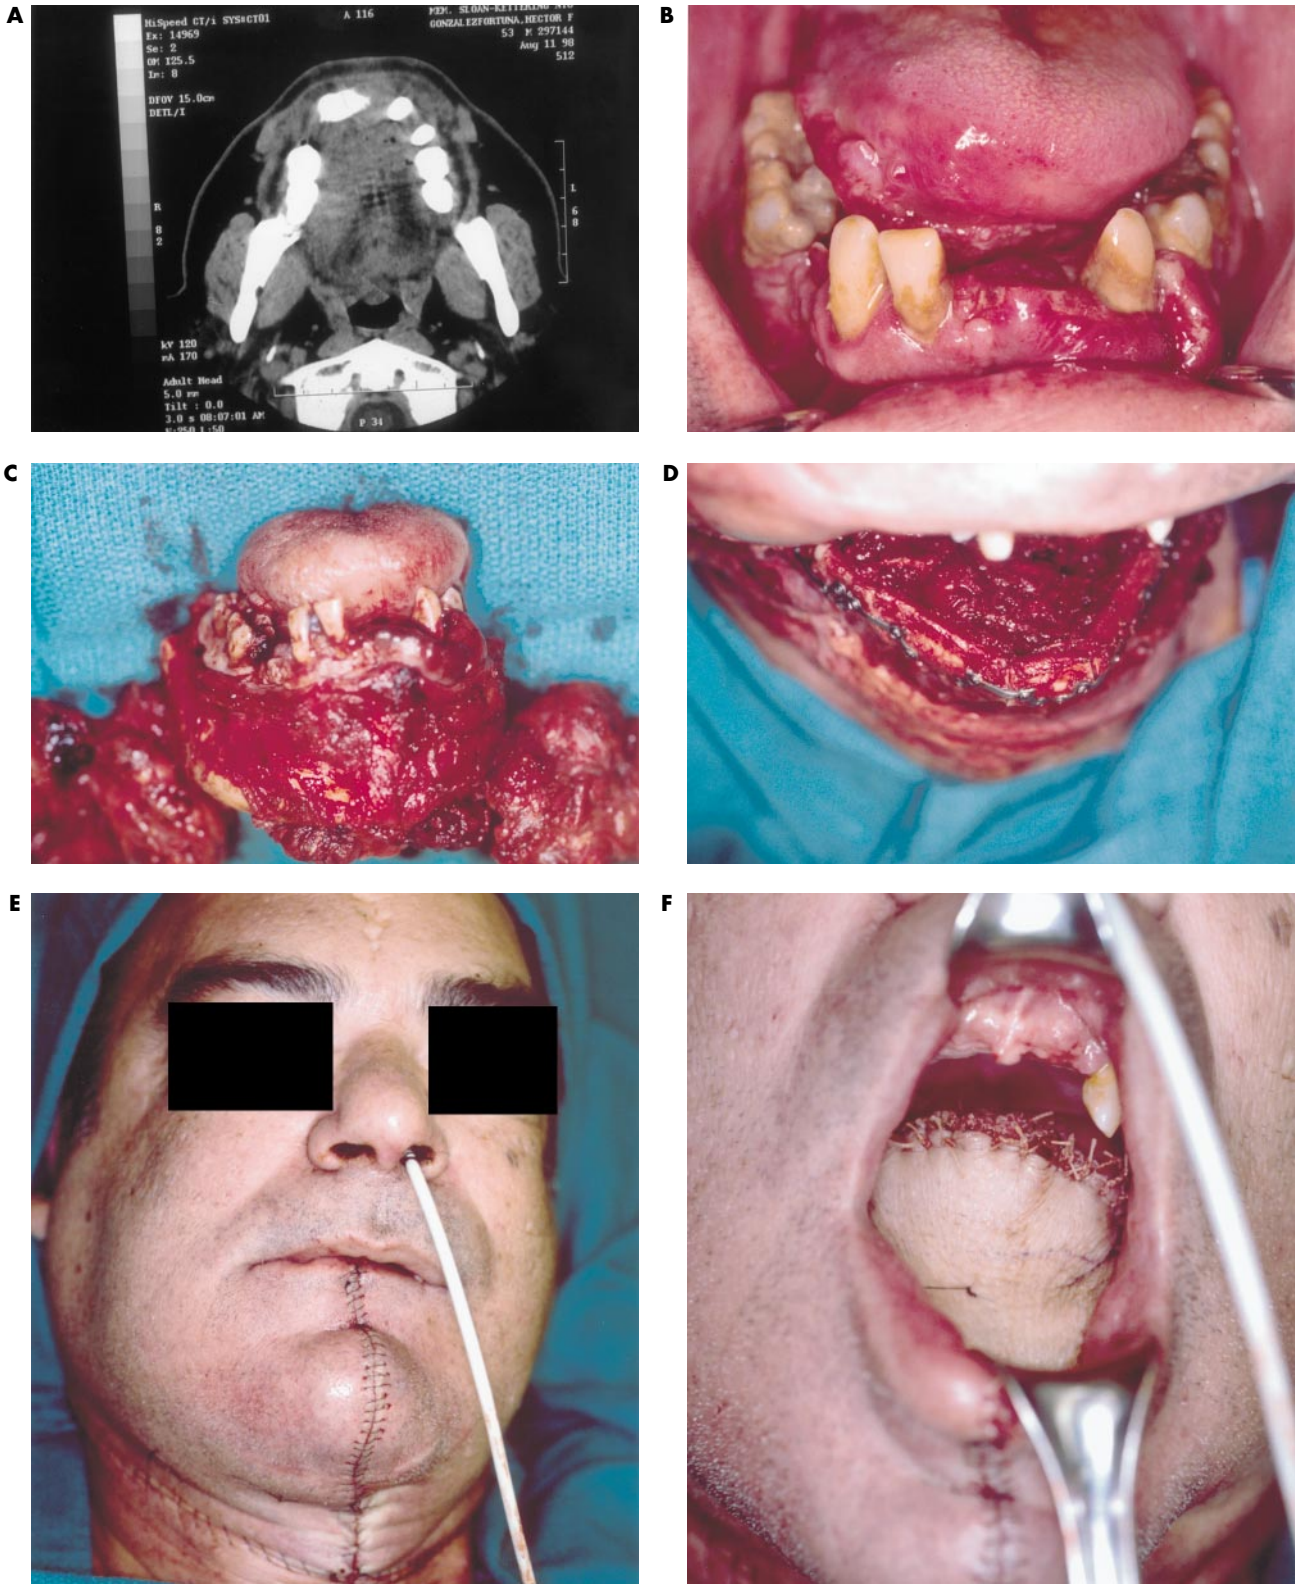

FIGURE 61–13. *A*, Axial computed tomographic scan of the neck demonstrating extensive squamous cell carcinoma of the floor of the mouth. *B*, Tumor extended through the dental alveoli of the anterior part of the mandible, as well as into the anterior portion of the oral tongue. *C*, Surgical specimen demonstrating en bloc segmental mandibular resection, in continuity with the oral tongue, floor of the mouth, and contents of bilateral modified radical neck dissections. *D*, Reconstruction of the anterior part of the mandible using contoured fibular free flap. *E*, Closure of the midline lip split incision. *F*, Soft tissue reconstruction using radial forearm free flap.

TABLE 61–3. 5-Year Overall Survival for Base of the Tongue Squamous Cell Carcinoma

Surgery with postoperative radiotherapy (137 patients): 55%
External beam radiotherapy (138 patients): 43%
External beam radiotherapy with brachytherapy (139 patients): 86%
Chemotherapy with radiotherapy (140 patients): 41%

base of the tongue. Patients in one study with advanced SCC of the oropharynx were given one to three cycles of cisplatin, followed by definitive radiotherapy, for a complete or partial response at the primary site. External beam radiotherapy was administered with or without interstitial implant and with or without accompanying neck dissection. Five-year overall and failure-free survival rates were reported as 41% and 42%, respectively.[140]

Comparing the results of different treatment modalities is difficult owing to the inherent diversity of patient samples and extent of disease included in reported studies. Primary radiotherapy is associated with favorable rates of local control and overall survival, but large, deeply invasive tumors may not be as radiosensitive as exophytic lesions. Larger, well-defined tumors can often be resected with preservation of the mandible and larynx, with satisfactory function of speech and swallowing.[137] Further investigation is necessary to compare functional results following surgery versus those following radiotherapy. Regardless of the modality chosen for the primary tumor, the propensity for base of the tongue carcinoma to spread to regional lymphatics mandates an aggressive approach to the neck. Neck dissection should be considered for clinically evident nodal metastases, recognizing the potential for bilateral involvement.

Soft Palate

Surgery or radiotherapy provides good local control and survival rates in early-stage (stages I and II) tumors, but combination therapy, using surgical resection followed by adjuvant radiation therapy, is recommended for stage III and IV tumors. Resection of large cancers of the soft palate may be complicated by postoperative velopharyngeal insufficiency, best treated with a palatal obturator.

Tonsil

Of all of the tumors in the oral cavity and oropharynx, cancers of the tonsil are the most radiosensitive, particularly exophytic lesions. Diagnosis at an early stage (stages I and II) is uncommon in light of the disease being present for some time before the patient presents complaining of symptoms. Stage I and II tumors may be best approached with primary radiotherapy, recognizing the potential for occult nodal metastases. Treatment planning for stage III and IV tumors is slightly more complicated as the method of choice may differ depending on the particular situation. A small tonsil primary with extensive nodal metastases may be treated with primary radiotherapy with consideration for neck dissection. In contrast, a large primary tumor at the tonsillar region without regional lymph node metastases could be approached with combination surgery and postoperative radiotherapy or with combination chemotherapy and irradiation. The following 3-year survival rates, using radiotherapy for stage I and II tumors and combined therapy with surgery and postoperative radiation therapy for stage III and IV disease, have been reported: stage I, 89%; stage II, 83%; stage III, 58%; and stage IV, 49%.[141]

Posterior Pharyngeal Wall

Cancers of the posterior pharyngeal wall commonly present with dysphagia and odynophagia. Alternatively, the patient may complain of a globus sensation or change in voice.

Second primary tumors are common, affecting 37%, most commonly arising in the oral cavity or larynx.[142] Spread to retropharyngeal lymph nodes may occur in 30 to 40% of cases.

Both surgery and radiation have been singly employed, often with disappointing results. Overall 5-year survival rates using surgery were reported at 32%, ranging from 44% for favorable lesions to 15% for extensive tumors.[142] Posterior pharyngeal wall resection with laryngeal preservation and radial forearm free flap reconstruction may be appropriate for selected lesions. This approach, however, is not recommended for patients with significant comor-

bidities owing to the potential for postoperative complications.[143] Previously reported single-modality radiation survival rates have been dismal, with approximately 3% surviving to 5 years.[144] Although the data are sparse, it appears that combination therapy of surgery and postoperative radiotherapy or chemoradiation may be indicated, particularly for advanced disease.

RECONSTRUCTION OF THE OROPHARYNX

As in the oral cavity, surgical defects in the oropharynx may be approached in a variety of ways. Certain lesions may not require complex reconstructive efforts, being amenable to primary closure or healing by secondary intention. Larger defects may require split-thickness skin graft coverage, local or regional flap reconstruction, or microvascular free tissue transfer. As in the oral cavity, the need for reconstruction is based on a variety of factors, including tumor extent and location; possible dysfunction of breathing, swallowing, or speech; patient comorbidity; and the surgeon's experience and preference.

Kraus has previously reported on reconstruction following resection of cancers of the oropharynx.[145] The majority of cases involving resection of a base of the tongue primary may be closed primarily. Early-stage (stage I and II) cancers of the tonsil may heal by secondary intention following peroral resection. More advanced lesions of the tonsil may require flap reconstruction, depending on the size of the mucosal defect and the need to resect portions of the mandible. Tension-free primary closure is often possible following segmental mandibulectomy. Advanced lesions necessitating a mandibulotomy approach with mandibular preservation may require flap reconstruction to resurface the inner portion of the mandible. The thin, pliable nature of the radial forearm free flap makes it a preferable choice over the pectoralis major myocutaneous flap for reconstruction in this region. Similarly, the radial forearm free flap may be a suitable choice for reconstruction of extensive soft palate defects. For posterior pharyngeal wall defects, laryngeal preservation with radial forearm free flap reconstruction should be reserved for patients with high performance status in the hope of minimizing postoperative morbidity.

CHAPTER 62

Diseases of the Salivary Glands

William R. Carroll, MD, C. Elliott Morgan, DMD, MD

The spectrum of diseases involving the salivary glands includes congenital anomalies, infections, localized and systemic inflammatory conditions, and benign and malignant neoplasms.

ANATOMY

Parotid Gland

The parotid gland is located in the space between the ramus of the mandible and the external auditory canal and mastoid tip. The anterior portion of the gland overlies the masseter muscle, and the posterior portion overlies the sternocleidomastoid muscle. The deep, medial portion of the gland is adjacent to the parapharyngeal space. The styloid process is adjacent and deep to the gland. The carotid artery and internal jugular vein are medial to the styloid process.

The parotid gland is covered by the parotid fascia. This layer is an extension of the superficial layer of the deep cervical fascia that splits to envelop the gland. On its inferomedial surface, the condensation of the fascial envelope suspended between the styloid process and the mandible is termed the stylomandibular ligament. This ligament separates the inferior portion of the parotid gland from the posterior portion of the submandibular gland. The parotid duct (Stensen's duct) exits the superficial part of the gland anteriorly and passes across the masseter muscle at a location halfway between the zygoma and the oral commissure. As the duct reaches the anterior portion of the masseter muscle, it turns medially to pierce the buccinator muscle and enters the buccal mucosa of the oral cavity opposite the second upper molar tooth. Lymph nodes may be found within the capsule of the parotid gland. These lymph nodes drain the scalp, forehead, eye, cheek, and oral commissure.

Surgeons often speak of superficial and deep lobes of the parotid gland and suggest that the facial nerve lies in a true cleavage plane between these two lobes. Most anatomists conclude that there is no true anatomic division between the superficial and deep lobes. These terms simply refer to the presence of tissue both lateral and medial to the facial nerve.

The position of the facial nerve is the dominant consideration in surgery of the parotid gland. As the nerve exits the stylomastoid foramen, it enters the posterior and medial portion of the gland, usually as a single trunk. Its primary bifurcation occurs at the pes anserinus with subsequent secondary division into five facial and cervical branches. The nerve lies within the substance of the gland and is not simply covered by folds of the gland. Numerous variations in the branching pattern of the facial nerve occur, and the surgeon must be observant during approach and dissection of the nerve.[1]

Parotid gland secretions are stimulated by parasympathetic fibers originating in the inferior salivatory nucleus of the brainstem. These fibers join the glossopharyngeal nerve and then the lesser petrosal nerve before joining the otic ganglion just outside the foramen ovale. The auriculotemporal nerve picks up these parasympathetic fibers and distributes them to the parotid gland.

Submandibular Gland

The submandibular gland is located within the submandibular triangle of the neck. Like the parotid gland, it is covered with a fascial capsule, which originates from the superficial layer of the deep cervical fascia. At the posterior border of the gland, the stylomandibular ligament separates the submandibular gland from the parotid gland. The anterior

border of the submandibular gland is folded over the posterior border of the mylohyoid muscle, creating portions of the gland both superficial and deep to the mylohyoid muscle. The submandibular gland duct (Wharton's duct) arises from the medial aspect of the gland and proceeds submucosally in the floor of the mouth medial to the sublingual gland to reach its papilla at the side of the frenulum of the tongue. The vascular supply to the submandibular gland is from the facial artery, which enters the gland just superior to the posterior belly of the digastric muscle. Small branches from the facial artery enter the gland directly. The lingual nerve is located just medial and superior to the gland within the sublingual space. The hypoglossal nerve courses between the medial portion of the submandibular gland and the hyoglossus muscle deep to the digastric muscle. The marginal mandibular branch of the facial nerve often overlies the lateral aspect of the submandibular gland. It is positioned in a plane deep to the platysma muscle but superficial to the submandibular gland fascia. Protection of these nerves during surgery of the submandibular gland will be discussed in more detail.

Parasympathetic stimulation of the submandibular gland causes formation and release of saliva. The responsible parasympathetic fibers originate in the superior salivatory nucleus in the brainstem. These fibers travel with the seventh cranial nerve and enter the chorda tympani nerve as it branches from the facial nerve within the mastoid. After traversing the middle ear and entering the infratemporal fossa, the chorda tympani joins the lingual nerve just below the foramen ovale. The parasympathetic fibers run with the lingual nerve to the submandibular ganglion, which is suspended from the lingual nerve just superior to the gland.

Sublingual Glands

The sublingual glands are located submucosally in the floor of the mouth. They are paired structures and nearly meet in the anterior part of the floor of the mouth. Typically, there is no single duct draining the submandibular glands. Rather, there are 10 to 12 smaller ducts that pass directly into the mucosa of the floor of the mouth. The sublingual glands are innervated by parasympathetic fibers of the chorda tympani nerve.

Minor Salivary Glands

There are hundreds of small, unnamed minor salivary glands distributed throughout the upper aerodigestive tract. These glands are both mucus and serous producing, and each has its own small duct draining directly to the mucous membrane. The minor salivary glands are most prominent in the oral cavity and are located in the hard and soft palate, lips, buccal mucosa, floor of the mouth, and tongue. As is discussed, many of the diseases involving the major salivary glands may also be found within the minor salivary glands. The neoplasms arising in the minor salivary glands are very often malignant.

HISTOLOGY

Microscopically, the salivary glands are composed of acini, secretory tubules, and collecting ducts (Figure 62–1). The acinar cells are responsible for producing the secretions, which may be either serous or mucinous. The acinar cells within the parotid gland are primarily serous. The acinar cells in the sublingual glands are mostly mucinous. The submandibular gland and minor salivary glands contain a mixture of serous- and mucus-producing cells. As will be discussed, neoplasms of the salivary glands arise from the different histologic components of the secretory apparatus (see Figure 62–1).

PHYSIOLOGY

Saliva has several important functions, including initiation of digestion of food, lubrication of food, protection of dental structures, control of oral cavity bacterial counts, and immune system function. When stimulated, the acinar cells of the salivary glands produce a transudate of fluids; proteins and other organic substances are actively excreted. The flow of saliva results from release of stored saliva as well as production and secretion of newly formed saliva. Chemically, normal saliva typically includes 99% water, electrolytes, and organic compounds including proteins, urea, lipids, and amino acids.[2] Included in the protein portion of saliva are amylase, albumin, immunoglobulin A (IgA), and lysozyme. The submandibular glands account for approximately 70% of the total volume of saliva. The parotid glands produce approximately 25%, and the

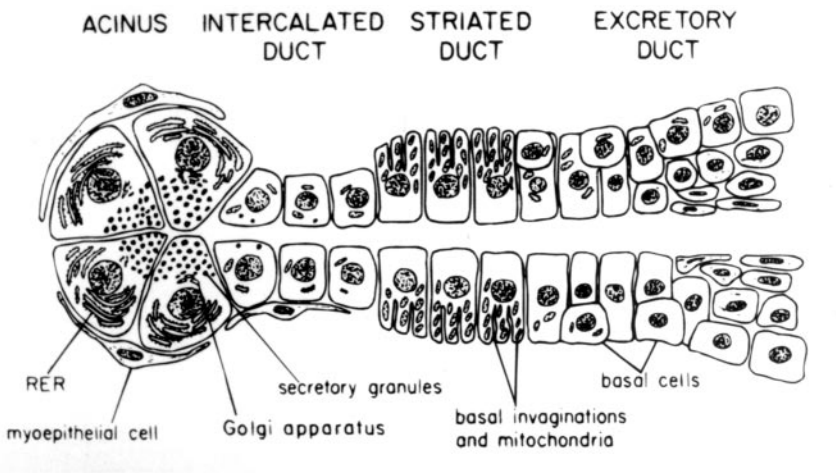

FIGURE 62–1. The salivary gland acinus and duct system. RER = rough endoplasmic reticulum.

sublingual and minor salivary glands are responsible for the balance. There is a baseline secretion rate of saliva that occurs to lubricate and protect the oral cavity and pharynx.

INFLAMMATORY DISEASES OF THE SALIVARY GLANDS

Viral Infections (Mumps)

Mumps (epidemic parotitis) is a disease of viral origin most commonly occurring in the pediatric age group. Viral parotitis is usually caused by a paramyxovirus (specifically the *Rubulavirus*), but many viral pathogens may cause acute infections within salivary glands.

In contrast to bacterial sialadenitis, viral infections of the salivary glands are systemic from the outset. There is a 2- to 3-week incubation period after exposure when the virus multiplies in the upper respiratory tract or parotid gland. A 3- to 5-day period of viremia follows, and the virus localizes in the parotid gland, germinal tissues, and central nervous system. Typical symptoms include fever, malaise, and headaches, followed by tenderness and enlargement of the parotid glands. As the parotid glands enlarge, trismus and dysphagia may develop. Typically, the disease involves the parotid glands primarily, but the submandibular and sublingual glands may be involved on occasion. The disease is usually self-limited and uncomplicated. The swelling of the glands characteristically subsides within 2 weeks.

Complications of viral parotitis may occur owing to the systemic nature of the infection. The most common complication from paramyxovirus parotitis is orchitis, occurring in 20 to 30% of males. Oophoritis occurs in 5% of females. Involvement of the germinal tissues does not usually cause sterility. Aseptic meningitis is a complication in about 10% of patients with viral parotitis. Pancreatitis occurs in 5%.

Sensorineural hearing loss occurs in 0.5 to 4% of patients with mumps syndrome. The hearing loss progresses rapidly and occurs in the later stages of parotitis. Tinnitus, vertigo, and aural fullness develop with the onset of hearing loss. The hearing loss is usually profound, permanent, and unilateral in the majority of cases.

Diagnosis of viral parotitis can be confirmed with viral serology. Complement-fixing antibodies appear following exposure to paramyxovirus. Complete blood count usually shows leukocytopenia with relative lymphocytosis. Amylase levels are increased in the early stages of infection.

Treatment of viral salivary gland infection is supportive. Live attenuated mumps vaccine as part of mumps-measles-rubella immunization is given to children after 12 months of age. Antibody titers are elevated in 90% of recipients. There have been no deaths and very few side effects from the vaccine.[3,4]

Sjögren's Syndrome

Sjögren's syndrome is a chronic autoimmune disorder of the exocrine glands, which affects predominantly, but not exclusively, the salivary glands. It is the second most common autoimmune disease, trailing only rheumatoid arthritis. The signs and symptoms of Sjögren's syndrome were first described by Haddu in 1883. Sjögren, a Swedish ophthalmologist, published a monograph in 1933

describing Sjögren's syndrome as a distinct clinical syndrome with systemic manifestations.

Sjögren's syndrome is now classified in two forms: primary (confined to exocrine glands) or secondary (systemic involvement in extraglandular sites). In 80% of primary and 35% of secondary cases, unilateral or bilateral salivary gland swelling occurs. The pathogenesis of Sjögren's syndrome remains unclear; viral infection is a possible trigger. Sjögren's syndrome has been seen in various ethnic groups. Women with the onset in the fourth to fifth decades of life constitute 90% of cases.

The salivary gland enlargement associated with Sjögren's syndrome is often bilateral and diffuse. The parotid or submandibular glands may be involved, and the swelling in the glands may be episodic and fluctuating. The salivary gland enlargement is typically painless, with firmness throughout the gland.

The most common symptom of Sjögren's syndrome is xerostomia (dry mouth). The decreased salivation causes difficulty with swallowing, altered taste, and speech difficulties. Long-term xerostomia causes an increase in dental caries and tongue atrophy. Ocular involvement in Sjögren's syndrome is characterized as keratoconjunctivitis sicca. Symptoms include pain, burning, and photophobia. Long-term xerophthalmia may cause corneal abrasions, scarring, and vision loss.

The secondary form of Sjögren's syndrome may progress to multisystem involvement. The systemic symptoms are linked to connective tissue disease. Rheumatoid arthritis occurs in 50% of patients with Sjögren's syndrome. Other diseases associated with the secondary form include lupus, vasculitis, scleroderma, dermatomyositis, Crohn's disease, pulmonary interstitial fibrosis, interstitial nephritis, pancreatitis, thyroid disease, and peripheral neuropathy. A high prevalence of sensorineural hearing loss occurs in secondary Sjögren's syndrome.

Asymmetric enlargement of the parotid that persists or is rapid in onset should raise suspicion of lymphoma. Patients have 44 times greater risk of developing lymphoma after developing Sjögren's syndrome. Parotid enlargement in the presence of splenomegaly, lymphadenopathy, immunosuppression, or previous radiation should raise suspicion for lymphoma.

The most appropriate diagnostic test for Sjögren's syndrome is controversial. Schirmer's test is used to document decreased lacrimation. Slit lamp examination can identify corneal ulcerations and keratosis. Sialometry is not of practical use to document xerostomia owing to variable results.

Laboratory tests for Sjögren's syndrome are of limited benefit. SS-A (anti-Ro) and SS-B (anti-La) autoantibodies are found in 38 to 60% and 25 to 40% of patients with primary Sjögren's syndrome, respectively. Enzyme-linked immunosorbent assay techniques may reveal SS-A and SS-B antibodies in 95% and 87% of patients, respectively, but also in 10 to 15% of healthy individuals. Unfortunately, SS-A and SS-B antibodies may be found in other autoimmune diseases. The occurrence of SS-A and SS-B antibodies correlates with earlier onset and longer duration of disease.

Salivary tissue biopsy is the most commonly employed method for diagnosing Sjögren's syndrome. The minor salivary glands of the lower lip are most commonly biopsied owing to ease of access and minimal complications. At least four minor salivary glands should be present in the specimen for a representative biopsy. Histologic diagnosis is based on the presence of more than one cluster of greater than 50 lymphocytes per 4 mm^2. Lip biopsy has the highest specificity (95%), sensitivity (58 to 100%), positive predictive value, and negative predictive value of all tests for Sjögren's syndrome.[5–12]

Human Immunodeficiency Virus

Patients infected with the human immunodeficiency virus (HIV) may develop a spectrum of salivary gland disorders, including diffuse infiltrative lymphocytosis, benign lymphoepithelial lesions, lymphoepithelial cysts, and malignant salivary gland tumors, including lymphoma, Kaposi's sarcoma, and adenoid cystic carcinoma.

Diffuse infiltrative lymphocytosis is very much like Sjögren's syndrome with bilateral parotid enlargement, xerostomia, xerophthalmia, and arthralgia. SS-A, SS-B, and rheumatoid factor serology are negative, but salivary gland biopsy has characteristics of Sjögren's syndrome.

Lymphoepithelial cysts may occur unilaterally or bilaterally in the parotid glands. Multiple lymphoepithelial cysts are so characteristic of HIV infection as to be considered almost pathognomonic. The pathogenesis of the cysts is unknown, and they can occur at any stage of the disease. Needle biopsy of the cysts should be done along with HIV testing.

Patients with HIV with parotid swelling should be evaluated for parotid tumors like uninfected patients. Patients with HIV have a higher incidence of lymphoma, general lymphadenopathy, and Kaposi's sarcoma associated with parotid enlargement than the general population. Fine-needle biopsy is often useful in patients with HIV with parotid enlargement.[13]

Sarcoidosis

The salivary glands are involved in 6 to 10% of patients with sarcoidosis. The parotid gland is involved most commonly. Heerfordt's syndrome (uveoparotid fever) results from sarcoidosis and includes uveitis, lacrimal and salivary gland inflammation, and facial paralysis. The diagnosis is one of exclusion because the noncaseating granulomas are not pathognomonic for the disease. Anemia, thrombocytopenia, leukopenia, eosinophilia, decreased albumin, and hyperglobulinemia support the diagnosis. Elevated angiotensin-converting enzyme levels, sedimentation rates, and calcium levels may also be present. Hilar adenopathy may be present on a chest radiograph.

The most common neurologic manifestation of sarcoidosis is facial paralysis, occurring in 50% of patients with nervous system involvement. The paralysis is bilateral in one-third of patients and usually resolves spontaneously but may recur. Corticosteroids are used to treat patients with more advanced forms of sarcoidosis.[14]

Wegener's Granulomatosis

Wegener's granulomatosis is a systemic disorder often involving the respiratory tract from the nose to the lungs, as well as the kidneys. Wegener's granulomatosis affects both sexes equally, occurs in all ages, and is usually seen in Caucasians. Histologically, Wegener's granulomatosis is characterized by vasculitis of medium and small vessels.

More than 70% of the features associated with Wegener's granulomatosis are related to the ears, nose, and throat. Symptoms develop insidiously, with sinusitis being the most frequent presentation. Salivary gland enlargement may accompany the nasal and sinus symptoms, with the parotid or submandibular glands, or both, being affected. Subglottic stenosis commonly occurs. In the lower airway, pulmonary infiltrates or cavitary nodules are also noted. Renal involvement indicates systemic Wegener's granulomatosis and is the most frequent cause of death.

Laboratory evaluation of Wegener's granulomatosis includes complete blood count, sedimentation rate, autoimmune serology, creatinine level, chest radiograph, and sinus computed tomographic (CT) scan. Elevated levels of antineutrophil cytoplasmic antibody (C-ANCA) are indicative of Wegener's granulomatosis. The sensitivity of C-ANCA is 40 to 90%, depending on the activity of the disease, with a specificity of 90%.

Intranasal biopsies should be taken with a generous section of viable nasal mucosa. These can be taken from the turbinate, septum, or lateral nasal wall. The specimen should be examined for fungal microorganisms as well. Wegener's granulomatosis must be differentiated from other granulomatous diseases including polymorphic reticulosis, Churg-Strauss syndrome, lymphoma, sarcoidosis, scleroma, tuberculosis, relapsing polychondritis, and fungal disease.

The "gold standard" for treatment of Wegener's granulomatosis is cyclophosphamide and glucocorticoids. Methotrexate has been used with corticosteroids in milder forms of Wegener's granulomatosis. Upper airway involvement responds well to trimethoprim and sulfamethoxazole used in combination with cyclophosphamide and glycocorticoids.[15–17]

Acute and Chronic Bacterial Infections of the Salivary Glands

Acute bacterial sialadenitis may involve any salivary gland, although the parotid gland is affected most frequently. Suppurative infection of the salivary glands may be an isolated, acute event or chronic with recurrent acute exacerbations.

Acute bacterial infection of the salivary glands may occur either by retrograde transmission of bacteria from the oral cavity or by stasis of salivary flow. Saliva contains lysozyme and IgA, which protect the salivary glands from infection. Stone formation (sialolithiasis) may cause mechanical obstruction of the salivary duct, causing stasis of flow with resultant bacterial infection. Elderly patients are at high risk for salivary gland infection owing to medications that decrease salivary flow. These medications

include diuretics, antidepressants, beta blockers, anticholinergics, and antihistamines. Patients with chronic, debilitating conditions, patients with compromised immune function, HIV-positive patients, and anorexic and bulimic patients, as well as depressed patients, are at an increased risk for acute bacterial salivary gland infection. Xerostomia of any cause increases the risk for bacterial parotitis.

Staphylococcus aureus is the most common microorganism causing acute bacterial parotitis. Other microorganisms include beta-hemolytic streptococcus, *Haemophilus influenzae*, pneumococcus, and, less frequently, gram-negative microorganisms.

Symptoms of acute bacterial sialadenitis include rapid onset of pain, swelling, induration, and fever. The symptoms may worsen during eating. Examination reveals induration, erythema, edema, and tenderness over the gland and purulence at the ductal orifice.

Bacterial sialadenitis may progress to abscess formation. Pitting edema of the skin overlying the involved gland is said to be indicative of abscess formation. Needle aspiration of the gland may confirm abscess formation. Cultures are done on all aspirated material. Failure to improve after 48 to 72 hours of antibiotic therapy may also indicate abscess formation. Radiographic scans followed by incision and drainage are indicated.

Patients who do not respond to standard therapy for bacterial infection should be evaluated for other disease processes that may mimic bacterial sialadenitis. Lymphoma, cat-scratch disease, Sjögren's syndrome, and Wegener's granulomatosis may mimic acute bacterial sialadenitis. Appropriate imaging and laboratory studies should be done to rule in or out these diseases.

Treatment of acute sialadenitis is directed at improving salivary flow, reversing any underlying conditions responsible for the onset of the infection, and appropriate antibiotic therapy. Antibiotic therapy should be directed toward the gram-positive and anaerobic microorganisms commonly involved. Oral antibiotic therapy can be given if no other systemic illness is present. Incision and drainage are reserved for localized abscesses.

Facial nerve paresis may rarely occur in acute sialadenitis. Because of their location, submandibular and parotid infections may spread into the deep neck spaces. Hematogenous spread of infection can also occur, causing sepsis or even shock and multisystem organ failure in debilitated patients.

Chronic Sialadenitis

Patients with chronic sialadenitis experience recurrent, low-grade inflammation and edema of the gland, minor pain, and sialorrhea that may be slightly purulent. *Streptococcus viridans* is the usual infecting microorganism. Measures to increase salivary flow should be instituted and appropriate antibiotics given. Benign lymphoepithelial lesions may develop from chronic parotitis. Attempts to identify stones or duct strictures should be made. Sialography may reveal a stone or ductal stenosis. The inflammatory process may wax and wane, with symptom-free periods. Conservative therapy usually manages the recurrent inflammation.

Surgical incision is reserved for refractory recurrent infections or in cases with a suspicion of malignancy.[18–25]

IMAGING

Plain radiography, ultrasonography, sialography, radionuclide scanning, CT scanning, and magnetic resonance imaging (MRI) have all been employed to image the salivary glands.

Plain Radiography

Salivary calculi can be detected within the ducts of the major salivary glands on occasion using plain radiographs. Stones occur much more commonly in the submandibular duct and are opaque 80 to 94.7% of the time. Parotid stones are more likely radiolucent, but by using high-quality intraoral plain films, up to 70% of parotid stones may be visualized.

Ultrasonography

Ultrasonography is an inexpensive, noninvasive way to evaluate for submandibular or parotid stones. Up to 90% of stones greater than 2 mm in size can be detected. Ultrasonography also shows the location of the stone and can be used in acute sialadenitis when sialography is contraindicated.

Contrast Sialography

Contrast sialography has been the mainstay for detecting sialolithiasis. Sialography is also used to detect chronic inflammatory changes in the ductal systems. Among the changes seen are dilation of terminal ducts and acini and strictures. Sialography has been replaced by CT and MRI for evaluation of neoplastic parotid masses.

SALIVARY GLAND NEOPLASMS

Salivary gland neoplasms can occur at any site where salivary tissue is found. The most common benign and malignant neoplasms occurring in salivary tissue are discussed below. The predilection of these tumors to occur in specific subsites is highlighted for each tumor type. The common surgical techniques to deal with neoplasms in the parotid, submandibular, and sublingual glands are discussed in detail.

Histogenesis

There is no universal agreement on the cell of origin for salivary gland neoplasms. The two most common theories of origin are the "stem cell" theory and the "multicellular" theory.[26,27] The stem cell theory proposes that the intercalated duct cells and myoepithelial cells of the salivary glands arise from one type of stem cell, and, in turn, these cells give rise to the group of tumors including pleomorphic adenomas, oncocytomas, acinic cell carcinoma, and adenoid cystic carcinoma. The other type of stem cell gives rise to the excretory ducts, and from this lineage, the epidermoid tumors such as mucoepidermoid carcinoma arise.

The multicellular theory attempts to pair each type of parotid neoplasm with a particular cell of origin within the salivary apparatus. Hence, squamous cell and mucoepidermoid carcinomas arise from excretory duct cells, pleomorphic adenomas arise from intercalated duct cells, and Warthin's and oncocytic tumors arise from striated ductal cells. There is no consensus currently whether the stem cell theory or the multicellular theory best explains the histogenesis of salivary gland neoplasms. Recent evidence seems to be swinging more toward the unicellular, stem cell theory.[26]

Benign Salivary Gland Neoplasms

Pleomorphic Adenoma Pleomorphic adenoma or benign mixed tumor is the most common salivary tumor, accounting for up to two-thirds of all salivary gland neoplasms.[28] Approximately 85% of all pleomorphic adenomas are located in the parotid glands, 10% in the minor salivary glands, and 5% in the submandibular glands.[26] Pleomorphic adenomas contain both mesenchymal and epithelial cells. Grossly, the tumors appear encapsulated but, on close inspection, have pseudopod extensions into the surrounding tissues. This growth pattern is thought to be responsible for the high rate of local recurrence (approximately 30%) when these tumors are enucleated.

Within the parotid gland, the majority of pleomorphic adenomas arise in the superficial lobe. Adequate surgical therapy involves nerve identification and protection with removal of the tumor and an adequate cuff of surrounding parotid gland parenchyma. A complete superficial parotidectomy has been recognized for years as the standard procedure in dealing with parotid gland neoplasms. However, most head and neck surgeons now recognize that an "adequate" parotidectomy can be tailored to the size and location for a given parotid tumor.

Genetic alterations associated with the formation of pleomorphic adenoma have been identified. Tumor deoxyribonucleic acid (DNA) has been shown to have chromosome abnormalities involving chromosome 8q12. This region is the site of the pleomorphic adenoma gene *PLAG-1*.[29] In a series of pleomorphic adenomas, loss of heterozygosity at the loci 8q and 12q were detected in 47% and 27%.[30] Carcinoma ex-pleomorphic adenoma has been noted to have some of the same genetic alterations. Investigators have noted a higher expression of p53 in patients with carcinoma ex-pleomorphic adenomas than in benign pleomorphic adenomas.[31]

Warthin's Tumor Warthin's tumor, or papillary cystadenoma lymphomatosum, is the second most common benign neoplasm of the salivary glands. The tumor is named for the University of Michigan pathologist who first reported two cases in the United States. Interestingly, Warthin's tumor occurs almost exclusively in the parotid glands. It typically involves the lower pole of the parotid gland and may be bilateral in up to 10% of cases. The most popular etiologic theory suggests that Warthin's tumor arises in salivary ducts that are trapped within intraparotid

lymph nodes. Because the parotid gland is encapsulated relatively late during development, it is the only salivary gland with lymphoid tissue located within the substance of the gland.

The recommended treatment for Warthin's tumor is complete surgical excision similar to that described for pleomorphic adenomas. In elderly or debilitated patients, a fine-needle aspirate, which is diagnostic of Warthin's tumor, coupled with a consistent clinical picture, may be grounds for expectant, nonsurgical management. No definite etiologic factors or genetic alterations have yet been identified in Warthin's tumor. It is felt that the lymphoid component of Warthin's tumor is benign and derived from a preexisting lymph node.[26,27] Recent DNA studies suggest that no clonal expansion is seen in the cells of Warthin's tumor. In other words, the tumor may eventually be proven to be a reactive process.

Monomorphic Adenomas Monomorphic adenomas include basal cell adenoma, clear cell adenoma, and glycogen-rich adenoma among other less common tumors. The most common monomorphic adenoma is the basal cell adenoma, which comprises 1 to 3% of salivary gland neoplasms.[32] The monomorphic adenomas may be separated into basaloid and nonbasaloid types. The basaloid types occur more commonly in the major salivary glands, particularly the parotid gland.[33] Treatment of monomorphic adenomas includes wide surgical excision with an adequate cuff of normal surrounding tissue.

Oncocytomas Oncocytomas comprise less than 1% of all salivary gland neoplasms. These rare tumors are typically found in the superficial lobe of the parotid gland. Oncocytomas are grossly encapsulated, single lesions. Histologically, the tumors are composed of large cells with round nuclei. The cytoplasm is filled with mitochondria.[26,27] Treatment of oncocytoma, much like the other benign salivary tumors discussed above, involves wide local excision with a cuff of surrounding gland parenchyma. Because they most commonly occur in the parotid gland, a superficial parotidectomy with facial nerve preservation is usually required. Rarely, malignant oncocytomas are detected. Cytologic differentiation from benign oncocytoma can be difficult, and malignancy is usually defined by invasive clinical and histologic features.[26]

Hemangiomas Hemangiomas are the most common tumor arising in the salivary gland from the connective tissue elements. They are the most common salivary gland tumor of any type in children and are often detected within the first year of life. Hemangiomas often occur over the angle of the mandible, and the overlying skin may contain a bluish discoloration. Engorgement of the lesion with crying or straining is often also seen.[28] Most hemangiomas in the salivary glands undergo spontaneous resolution. Nonsurgical therapy may be indicated for massive lesions that are interfering with the aerodigestive tract or causing hematologic complications. Surgical treatment is only rarely recommended.[28]

Malignant Tumors of the Salivary Glands

Salivary gland malignancies make up a relatively small percentage of all cancer occurring in the head and neck region. Benign salivary gland tumors outnumber malignant salivary tumors by approximately 3 to 1 overall.[34]

As a general rule, residents and medical students are taught that 20% of parotid tumors are malignant, 50% of submandibular gland tumors are malignant, and 80% of minor salivary gland and sublingual gland tumors are malignant. Spiro and Spiro analyzed over 7,000 reported salivary gland neoplasms. Seventy-eight percent of the parotid neoplasms were benign, 54% of submandibular neoplasms were benign, and 35% of minor salivary gland neoplasms were benign.[35]

Malignant salivary gland tumors often present in a similar fashion to their benign counterparts. Pain is present in 10 to 29% of patients with cancer in the parotid gland, and facial paralysis is detected in 10 to 15% of parotid gland malignancies.

Because malignant salivary gland tumors are reasonably rare, characteristic genetic alterations, oncogene markers, and predisposing factors are still being determined. A brief synopsis of these factors will be presented with each tumor type. The etiology of malignant salivary gland tumors is not well defined. The clear association with smoking and alcohol use found in many other head and neck carcinomas has not been documented. Radiation exposure is one known risk factor, and there seems to be a dose-response relationship for the development of malignant tumors.[36,37] Of 2,807 salivary gland neo-

plasms presented by Spiro, 35% of the malignant neoplasms were mucoepidermoid carcinomas, 23% were adenoid cystic carcinoma, 18% were adenocarcinoma, 13% were malignant mixed tumor, and 7% were acinic cell carcinoma.[38] Most authors comment on the difficulty encountered in classifying salivary gland tumors, and, indeed, the classification schemes have changed from time to time.

Mucoepidermoid Carcinoma Mucoepidermoid carcinoma is the most common malignant salivary gland tumor. Approximately one half of all mucoepidermoid carcinomas occur in the parotid gland, with the majority of the remainder occurring in minor salivary glands. As the name implies, mucoepidermoid carcinomas are composed of both mucus and epidermoid cells. Pathologists also describe the presence of intermediate and clear cells. Histologic grading of mucoepidermoid carcinoma has correlated with prognosis. Most surgeons recognize high- and low-grade subtypes of mucoepidermoid carcinoma. Some authors include an intermediate grade as well. Clearly, the prognosis with high-grade tumors is worse with respect to local recurrence and distant metastases, and overall survival is diminished. For high-grade lesions, the local recurrence rates following surgery approach 60%. Nodal metastases may develop in 40 to 70% of patients, and 30% develop distant metastases. Five-year survival rates are typically 30 to 50% for high-grade lesions.[38] In contrast, low-grade mucoepidermoid carcinomas have 5-year survival rates in the 80 to 95% range. They are much less likely to develop nodal or distant metastasis. Most patients with mucoepidermoid carcinoma present with an asymptomatic mass at the primary site. Pain, facial paralysis, and neck masses are also seen and are usually associated with high-grade and highly malignant mucoepidermoid carcinomas.

Surgical treatment for mucoepidermoid carcinoma is influenced by histologic grading. For low-grade mucoepidermoid carcinoma, treatment usually involves wide surgical excision. Neck dissection or adjuvant irradiation is used only when clinically evident metastases are detected or when there is evidence of bone, nerve, or extraglandular invasion. In contrast, high-grade mucoepidermoid carcinomas are treated more like squamous cell carcinomas. Wide surgical excision combined with regional lymph node dissection and adjuvant radiation therapy is commonplace. The issue of facial nerve preservation in the presence of high-grade mucoepidermoid carcinoma is controversial. Some surgeons prefer a wide block excision of the parotid gland (radical parotidectomy) with no attempt at facial nerve preservation. Others feel that if the tumor can be easily separable from the nerve and there is no histologic evidence of perineural invasion, the nerve can be preserved. No one recommends preserving the facial nerve when it is clearly invaded by tumor.

Five-year survival rates for low-grade mucoepidermoid carcinoma are 80 to 95% overall. Five-year survival rates for high-grade tumors are 30 to 50%.[38]

Adenoid Cystic Carcinoma Adenoid cystic carcinoma is the second most common malignancy of the salivary glands. It is the most common malignancy in the submandibular glands and minor salivary glands. The most common clinical presentation for adenoid cystic carcinoma is a painless, slowly enlarging mass. However, paresthesias and paralysis are more common with adenoid cystic carcinoma than other salivary malignancies. Indeed, perineural invasion and spread is a hallmark of adenoid cystic carcinoma.[36] There are three common histologic patterns for adenoid cystic carcinoma: tubular, cribriform, and solid. Low-grade adenoid cystic carcinomas typically contain a mixed tubular and cribriform pattern. The solid pattern is more common in high-grade malignancies.[39] The prognosis of adenoid cystic carcinoma may be related to histologic grade. Those patients with low-grade tumors have slow disease progression and infrequent distant metastasis. Patients with high-grade malignancies experience much more rapid growth, with higher frequency of distant metastasis and decreased survival.[39] In the Sloan Kettering series, however, the early trend toward better survival with low-grade lesions disappeared as the patient follow-up exceeded 10 years. In other words, disease progression was slower and less fulminant but relentless and equally deadly. Fifteen- to 20-year survival rates are in the 30% range regardless of histologic grade.[38]

Treatment of adenoid cystic carcinoma includes wide local excision of primary disease and therapeutic lymph node dissection. Elective node dissections are not typically recommended. Full-course radiation therapy is usually recommended

postoperatively.[36] For adenoid cystic carcinoma of the parotid gland, some surgeons have recommended wide-field radical parotidectomy with transection of the facial nerve within the mastoid to best control perineural spread. Fast neutron radiotherapy has proven effective for recurrent or unresectable adenocystic carcinoma. In the University of Washington series, when patients were able to undergo surgical resection (even if microscopic margins were not clear) and there was no direct skull base involvement, 5-year regional control rates of 80% were achieved. The authors concluded that fast neutron radiotherapy is effective for locally advanced adenoid cystic carcinoma but that overall survival is unlikely to be improved without improvement in control of distant metastatic disease.[40]

Polymorphous Low-Grade Adenocarcinoma Polymorphous low-grade adenocarcinoma (PLGA) was first described in 1983 by Batsakis et al and was initially termed "terminal duct adenocarcinoma."[41] In 1984, the term polymorphous low-grade adenocarcinoma was proposed.[26,42]

Polymorphous low-grade adenocarcinoma typically arises from the minor salivary glands and is frequently seen in the oral cavity. The palate is the most common location for PLGA. The lesions typically present as a circumscribed, slow-growing, painless mass. These minor salivary gland malignancies may be confused with pleomorphic adenoma on the benign side and with adenoid cystic carcinoma on the more malignant side.[43] Proper treatment of PLGA is surgical. The tumors are considered low grade, and in a review of over 200 cases, a 17% recurrence rate and 9% regional metastatic rate were noted. Elective node dissection is not recommended.[26,44]

Acinic Cell Carcinoma Acinic cell carcinoma is reasonably rare and comprises roughly 1 to 3% of all salivary gland tumors. In the past, acinic cell carcinoma was known as acinic cell tumor. Most investigators now believe that all of these tumors are malignant. Most acinic cell carcinomas are found in the parotid gland, where they comprise 12 to 17% of parotid malignancies. Bilateral parotid gland involvement has been reported in up to 3% of cases. The biologic behavior may range from slow, indolent, local growth to a more aggressive form with rapid growth and the potential for distant metastasis.

Treatment of acinic cell carcinoma is wide surgical excision. Determinate survival rates were reported by Spiro et al to be 76%, 63%, and 55% at 5, 10, and 15 years, respectively.[26,45] Radiation is not typically used for primary treatment. Adjuvant radiation is often recommended in the face of lymphatic or perineural invasion. The role of elective neck dissection has not been established. As with most parotid malignancies, the authors often perform a selective neck dissection of levels 2 and 3 when resecting acinic cell carcinoma.

Malignant Mixed Tumors This somewhat confusing group of tumors contains at least three distinct tumor types: (1) carcinoma ex-pleomorphic adenoma, (2) malignant mixed tumor (carcinosarcoma), and (3) benign metastasizing pleomorphic adenoma. Carcinoma ex-pleomorphic adenoma is the more common of these three. This tumor represents malignant transformation of the epithelial component of a pleomorphic adenoma. The risk of malignant transformation increases from 1.5 to approximately 9.5% over 5 to 15 years duration of the pleomorphic adenoma.[36,46] The biologic behavior of carcinoma ex-pleomorphic adenoma is generally more aggressive than other salivary gland malignancies. Treatment is wide local excision with consideration of lymph node dissection and postoperative radiation therapy. Five- and 10-year survival rates are 40 and 24%, respectively.[38]

Malignant mixed tumor is less common and contains malignant epithelial and mesenchymal components. This is a true carcinosarcoma, and both components of the malignancy are evident in metastatic sites. The sarcomatous component is often differentiated as a chondrosarcoma, but other types of sarcoma are also described.[43] Treatment is wide surgical excision and radiation. Distant metastases are common, and the prognosis is poor.

Metastasizing pleomorphic adenoma represents an unusual lesion in which benign-appearing pleomorphic adenoma appears in regional lymph nodes. A 22% mortality rate associated with this finding has been reported. There is a suggestion that the risk of developing metastasizing pleomorphic adenoma increases with the longevity of the original tumor and with local recurrence.

Squamous Cell Carcinoma Primary squamous cell carcinoma of the salivary glands is rare and probably occurs only in the parotid and submandibular glands. Squamous cell carcinoma is much more commonly metastatic to the parotid gland parenchyma or intraparotid lymph nodes. The diagnosis of squamous cell carcinoma within the salivary gland should always trigger an intensive search for a primary lesion.

Primary squamous cell carcinoma of the parotid typically presents as a firm, fixed mass. Treatment is aggressive wide surgical excision with consideration of regional lymph node dissection. Adjuvant radiation therapy would usually be recommended. Five-year survival is estimated at 45%.[36]

SURGERY OF THE MAJOR SALIVARY GLANDS

Surgery of the Submandibular Glands

The incisions for approach to the submandibular gland vary somewhat depending on the pathology. For benign neoplasms and inflammatory processes, a reasonably short, transverse incision in a natural skin crease two fingerbreadths below the angle of the mandible is used. If there is malignancy within the submandibular gland and a neck dissection is also anticipated, the preferred incision for neck dissection is used.

The skin and subcutaneous tissues are elevated in the subplatysmal layer. At the inferior border or the gland, flap elevation using cold dissection with scissors or scalpel is preferred to avoid damage to the underlying marginal mandibular nerve. The marginal mandibular nerve lies between the platysma/superficial musculoaponeurotic system (SMAS) layer and the superficial layer of the deep cervical fascia (capsule of the submandibular gland). The nerve lies superficial to the facial vein at the posterior border of the gland as well. If the skin flaps have been elevated in a proper plane, the nerve is often easily seen. It is typically small (1 to 2 mm in diameter) and often is accompanied by a small vasa nervorum, which runs along the superficial surface. If desired, the nerve can be isolated along its inferior border and raised out of the field at this point. Another method for preserving the nerve involves incising the capsule of the submandibular gland inferiorly. The facial vein is also divided, and these two structures are lifted to the inferior border of the mandible, elevating the nerve out of the field.

With the gland exposed and the marginal mandibular nerve protected, removal of the gland begins. The facial artery and vein are identified at the superior edge of the gland, where it lies adjacent to the inferior border of the mandible. There is rarely any consequence to complete ligation of the facial artery and vein. Nonetheless, the authors typically preserve these vessels for benign disease, choosing to ligate the three or four tributaries into the gland instead. The vessels are followed posteriorly and inferiorly to the digastric tendon. Attention is then turned to the anterior aspect of the gland. As the anterior aspect of the gland is elevated, staying close to the gland capsule, the mylohyoid muscle comes into view. The mylohyoid muscle is then mobilized along its posterior border from hyoid bone to the junction with the mandible. A retractor is placed under the mylohyoid muscle, exposing the tissues of the deep floor of the mouth. Any gland attachments to the inferior border of the mandible can be quickly taken down to this same plane without any risk of damage to neural structures.

Once the plane of the floor of the mouth is reached, the lingual nerve is identified as it arcs downward into the field. The submandibular ganglion carrying parasympathetic fibers into the gland is located at the apex of the arc and is divided. The submandibular duct is then identified at the anterosuperior aspect of the gland. It is isolated, teased downward from the floor of the mouth, and ligated and divided.

At this point, the gland is free from all important vascular and neural attachments. The gland can simply be rotated from superior to inferior, lifted off the digastric tendon, and removed. Care should be taken to keep the plane of dissection in the areolar tissue adjacent to the medial capsule of the gland. In doing so, the surgeon will stay superficial to the mylohyoid and hyoglossus muscles and avoid damage to the hyoglossal nerve. If any doubt regarding the position of the hypoglossal nerve exists, it can usually be identified in the deeper tissues just superior to the tendon of the digastric muscle.

In cases of malignancy, or when the submandibular gland is removed as part of a neck dissection, the perifacial lymph nodes along the superior and posterior aspects of the gland should

be removed as well. These are the cases in which damage to the marginal mandibular nerve is most commonly seen. The procedure can be modified by identifying the marginal mandibular nerve, dissecting down onto the inferior border of the mandible, and dividing the facial artery and vein as they cross the mandible. Rather than hugging the superior border of the gland, as in benign disease, the entire gland and the perifacial nodal tissue are removed by this modification.

Surgery of the Parotid Gland

Surgery of the parotid gland is challenging. Even with normal anatomy and normal surrounding parotid tissue, dissection of the branches of the facial nerve requires patience and great attention to detail. When the parenchyma of the gland is altered by an inflammatory process or the course of a nerve is distorted and attenuated by tumor, preservation of the facial nerve fibers can be very difficult. Schedule plenty of time to perform parotidectomies. Be patient, insist on careful hemostasis, and use loupe magnification if available.

Surgical preparation and draping of the patient are important in parotidectomy. The authors prefer to be able to see the entire side of the face during the operation to monitor for facial stimulation. An Io-Ban drape is used on the anterior half of the face for this purpose. For unusual cases, intraoperative facial nerve monitoring can be very helpful.

The operation begins with proper exposure. A modified Blair incision or a modified facelift incision is acceptable for parotidectomy. Skin flaps are elevated in the subplatysmal and sub-SMAS plane. The parotid gland, like the submandibular gland, is encapsulated by the superficial layer of the deep cervical fascia. The plane of flap elevation should be between the platysma/SMAS layer and the gland capsule. The tail of the gland is sharply separated from the sternocleidomastoid muscle. Often electrocautery is used for this portion of the dissection. The external jugular vein is divided. The anterior branch of the greater auricular nerve is divided while preserving the posterior branch if at all possible. The digastric muscle is identified and exposed from the submandibular triangle back to the mastoid tip. The posterior part of the parotid gland is then separated sharply from the ear structures from the zygoma superiorly down to the mastoid tip. Dissection can proceed rapidly down to the level of the lateral aspect of the mastoid tip and to the cartilaginous portion of the ear canal.

At this point in the operation, the main trunk of the facial nerve is identified. There are four or five common ways of identifying the facial nerve. In our opinion, the most reliable is by identification of the tympanomastoid suture. Looking at a skull, the tympanomastoid suture extends medially along the skull base until it ends at the stylomastoid foramen. The stylomastoid foramen is almost always within the suture line and, with the exception of congenital otic deformities, provides a safe and consistent guide to the facial nerve. The second common method uses the position of the tragal pointer cartilage. However, as elsewhere in the body, the shape and size of the cartilage vary. Previous experience has determined that the adage "one centimeter deep and one centimeter inferior to the tragal pointer" is much less reliable than the tympanomastoid suture.

Once the main trunk of the facial nerve is identified, only limited dissection of the parotid gland is completed until the pes anserinus is seen. The majority of neoplasms of the parotid gland lie within the superficial lobe. The direction of dissection is determined by the location of the tumor. For tumors in the lower portion of the gland, the upper division or perhaps one of the buccal branches can be followed anteriorly, maintaining an adequate cuff of parotid tissue superior to the tumor. Once the superior border has been established, the lower branches are subsequently exposed while rotating the tumor from superior to inferior. When palpating parotid glands, preoperatively, one is often tempted to simply perform wide local excision without facial nerve identification. Experience shows that most of these tumors lie directly adjacent to at least one branch of the facial nerve, and rarely, if ever, will the surgeon feel that the nerve has been dissected needlessly.

For deep lobe tumors, malignancies of the parotid gland, and chronic inflammation involving the entire gland, a more complete parotidectomy is necessary. For total parotidectomy, exposure of all of the nerve branches is accomplished. Sharp dissection frees the nerve from the main trunk to the periphery, exposing the underlying deep lobe. The deep lobe is then separated from the masseter muscle anteriorly, the zygoma and mandibular condyle superiorly, and the parapharyngeal structures medially. The superficial temporal artery at its ori-

gin from the internal maxillary artery is adjacent to the deep lobe of the parotid gland. This should be approached and controlled carefully. Impressive arterial bleeding from the internal maxillary artery can occur, and rapid application of clamps to control the bleeding can result in damage to the overlying facial nerve network.

A complete parotidectomy leaves a significant depression in the posterior lateral aspect of the face. There are differing opinions whether this should be camouflaged. Some surgeons feel that filling in the defect makes detection of recurrent disease more difficult. Others feel that in this day of advanced head and neck imaging, recurrence can be picked up easily by imaging techniques. The authors infrequently surgically fill these defects. In patients who are very concerned about appearance, however, camouflage of the defect is used. Options include fat grafts, sternocleidomastoid muscle rotation flaps, acellular dermal grafts, or free vascularized fascial grafts.

CHAPTER 63

Diseases of the Thyroid and Parathyroid Glands

Robert A. Hendrix, MD

THYROID GLAND

The thyroid gland (from Greek *thyroeides*, meaning shield-like) is a brownish-red, highly vascular, ductless gland situated anteriorly in the visceral compartment of the neck at the level of the fifth, sixth, and seventh cervical and first thoracic vertebrae. The normal adult gland weighing 20 to 25 g is slightly larger in women. It enlarges further during puberty, menstruation, and pregnancy. It consists of right and left cone-shaped lobes 5 cm in length, connected by a narrow region of gland termed the isthmus. The base of each lobe lies on a level with the fourth or fifth tracheal ring, with the apex oriented laterally and superiorly to the level of the oblique line of the thyroid cartilage. The pyramidal lobe is a variable tail of thyroid tissue trailing superiorly from a paramedian attachment to the isthmus. A true capsule of fibrous connective tissue contains the parenchyma and sends fine septae between lobules of the thyroid gland.

PHYSIOLOGY

The thyroid gland contains two types of functioning endocrine cells of different origins. The follicular cells secrete L-thyroxine (T_4) and 3,5,3′-triiodo-L-thyronine (T_3), which influence a wide range of metabolic processes. The parafollicular cells or C cells influence calcium metabolism by secretion of calcitonin.

The lumina of follicles of the thyroid contain thyroglobulin as a colloid. This glycoprotein is produced only by follicular cells. Production of active thyroid hormone begins with energy-dependent uptake and transport of extracellular iodide across the follicular cell membrane. Following oxidation of iodide and repeated iodinations of tyrosine residues on newly synthesized thyroglobulin at the cell–colloid interface, T_3 and T_4 are produced and stored in the follicular lumen bound to thyroglobulin.

Liberation of active thyroid hormone requires uptake of colloid droplets from the lumen by pinocytosis and transport through the follicular cell with hydrolysis of thyroglobulin and release of free T_3 and T_4. Thus, normal secretion of thyroid hormone requires not only an adequate rate of hormone synthesis but also the capacity to hydrolyze thyroglobulin to liberate T_4.

The follicles secrete only 20% of serum T_3; dehalogenation of circulating T_4 produces the remainder. The concentration of unbound T_3 is about 10 times greater than unbound T_4 because of different affinities for thyroid-binding globulin and other plasma proteins. Nonetheless, plasma proteins reversibly bind almost all of the serum T_3 and T_4, leaving only 0.3% of T_3 and 0.03% of T_4 (or one-tenth the level of T_3) free to act on receptor sites.

The metabolic effects and the regulation of thyroid hormone depend solely on the concentration of free or unbound T_4 and T_3 in plasma. Approximately one-third of the T_4 is deiodinated to T_3, and *T_3 is three times more potent than T_4*. Thus, T_4 exerts most of its metabolic effects through its conversion to T_3. The weaker binding of T_3 to plasma protein carriers may also contribute to the more rapid onset and shorter duration of its action.

Thyrotropin (thyroid-stimulating hormone [TSH]) is a glycoprotein secreted by basophilic (thyrotropin) cells of the anterior pituitary gland. Thyroid-stimulating hormone mediates suprathyroid regulation of thyroid hormone secretion. It acts on the follicular cell receptor to increase all aspects of follicular cell metabolism, including synthesis of hormone and thyroglobulin and hormone secretion. The thyrotropin receptor belongs to the large and diverse family of G protein–coupled receptors,

which all share a common molecular structure: an extracellular amino terminal, seven transmembrane loops, and an intracytoplasmic carboxyl terminal. Of the subfamily of glycoprotein hormone receptors, binding specificity arises from an especially long amino-terminal extracellular domain. The gene for the thyrotropin receptor is encoded by 10 exons spread over 58 kilobases on chromosome 14. The first 9 exons encode the large extracellular domain, and the tenth exon encodes the carboxyl terminus. The thyrotropin receptor is coupled to a subunit of guanine-nucleotide-binding protein that activates adenylate cyclase and increases intracellular levels of cyclic adenosine monophosphate (cAMP). Follicular cell growth and function are both stimulated by the "second messenger" cAMP. Further, expression of thyroglobulin and thyroid peroxidase genes is indirectly regulated by cAMP. Were a single thyroid epithelial cell to contain a somatic mutation that caused chronic stimulation of the cAMP pathway, that cell would be stimulated to grow and clonal proliferation would result, giving rise to an autonomously functioning thyroid adenoma and eventually to hyperthyroidism. In contrast, blocking autoantibodies to the thyrotropin receptor would inhibit the molecular cascade and cause hypothyroidism. Similarly, hypothyroidism could arise from an inherently defective thyrotropin receptor.

With higher thyrotropin concentrations, coupling of the thyrotropin receptor to yet another G protein leads to activation of phospholipase C. Further, growth factor I, transforming growth factor ß, platelet-derived growth factor, epidermal growth factor, fibroblast growth factor, and cytokines stimulate growth of thyroid follicular cells, mainly acting through the protein tyrosine kinase signal transduction pathway.[1]

Hypothalamic secretion of thyrotropin-releasing hormone (TRH) controls TSH secretion. Free thyroid hormones in serum exert negative feedback at the level of the pituitary by inhibiting TSH secretion and antagonizing TRH by decreasing the number of receptors on the thyrotropin cell. At the level of the thyroid gland, iodine depletion enhances the responsiveness to TSH, whereas iodine enrichment inhibits the TSH response. The biosynthesis and secretion of T_3 and T_4 can be affected, not only by deficiency of dietary iodide but also by drugs such as lithium, propylthiouracil, sulfonamides, phenytoin, and nitrophenols.

Deiodination of approximately 40% of T_4 produces inactive T_3 or reverse T_3 (rT_3). Certain conditions (eg, starvation) increase the T_4 conversion to rT_3, thereby requiring occasional measurement of rT_3.

Calcitonin is a 32 amino-acid polypeptide transcribed from a locus on chromosome 11p, which is tightly linked with the gene for parathyroid hormone (PTH), parathormone. Three peptides are encoded by the calcitonin gene: calcitonin, a 21 amino-acid carboxy-terminal flanking peptide (katacalcin), and a calcitonin gene–related peptide. The action of calcitonin is independent of PTH and vitamin D. The main endocrine effect is to decrease the number and activity of osteoclasts, thereby reducing bone resorption, which is the basis for its use in the treatment of Paget's disease. Extrathyroid calcitonin synthesized in the pancreas, gastrointestinal tract, pituitary, and brain probably acts as a locally inhibitory neurotransmitter. Calcitonin is present in high circulating levels in the fetus, probably owing to the high fetal serum levels of calcium. Apparently, calcitonin affects fetal bone metabolism and skeletal growth and remains at high levels in cord blood as well as in young children. Levels are very low in older children and adults, in whom it has little consequence to metabolism. Even with very high levels in patients with medullary carcinoma of the thyroid, hypercalcemia is not observed.[2]

Laboratory Assessment of Thyroid Function

Serum Tests Related to Thyroid Hormone The most widely used serum assays of thyroid hormone are the T_4 radioimmunoassay (RIA), T_3 uptake of resin, and free T_4. Thyroxine RIA, as a measure of total serum thyroxine, has a normal range of 5 to 13 mg/dL.

States of altered thyroxine binding affect available thyroid hormone. Adequate assessment requires T_4 RIA measurement in combination with the T_3 uptake of resin as an indirect measure of T_4-binding protein. The T_3 uptake of resin test is performed by incubating serum with radioactive, labeled T_4 or T_3 in the presence of insoluble particles of resin or charcoal that absorb any labeled hormone not bound by serum protein. After removal of the serum, the percentage of radioactive hormone not taken up by serum proteins is measured in the precipitate. The result varies inversely with the concen-

tration of unoccupied sites on serum protein carriers of thyroid hormone. Triiodothyronine uptake of resin may vary in certain conditions such as pregnancy, when the T_4 is increased and the T_3 uptake is low because of increased thyroid-binding globulin.

The "free" T_4 determination (FT_4) measures the metabolically effective fraction of circulating T_4. Free T_4 provides the best assay of thyroid hormones in regard to function because it is not affected by thyroid-binding globulin. Free T_4 may be estimated from the more commonly available free T_4 index, equal to the product of the T_4 and the T_3 uptake of resin. This calculation is used to correct for abnormalities of T_4 binding. Nonetheless, this is unnecessary if the free T_4 test is available.

Thyroxine-binding globulin (TBG) RIA is a direct and specific test for T_4-binding abnormalities and is unaffected by changes in other serum proteins.

Triiodothyronine assessments made by RIA can be valuable in the diagnosis of thyrotoxicosis with normal T_4 values (T_3 thyrotoxicosis) and in some cases of toxic nodular goiter.

The measurement of serum TSH concentration by RIA is useful to evaluate hyperfunction of the thyroid gland. Most evaluations of thyroid function should start with a sensitive thyrotropin assay. In a patient with little clinical probability of thyroid dysfunction, a normal TSH screen requires no further testing. If TSH is elevated, an FT_4 and possibly a thyroid antibody should be performed to evaluate for hypothyroidism. If TSH is low, then an FT_4 and possibly a T_3 should be performed to evaluate for hyperthyroidism. However, in elderly patients, a low TSH assay may not be associated with hyperthyroidism. This approach to testing provides an efficient way to assess thyroid hormone function (Table 63–1).[3]

Direct Tests of Function The most commonly used direct test of gland function is the thyroid radioactive iodine uptake (RAIU). Historically, the RAIU involved in vivo administration of iodine 131 (^{131}I), but ^{123}I has become the agent of choice because of lower radiation dosages. It is administered orally in capsule form 24 hours before measurement of thyroid accumulation of isotope. The RAIU is also used in the thyroid suppression test, in which the RAIU is repeated after 7 days of daily administration of T_3. A decrease in the RAIU is evidence of the presence of thyroid suppression. This is of value in the assessment of glandular hyperfunction. Similarly, the thyrotropin stimulation test (RAIU performed following TSH administration) is useful to differentiate primary thyroid insufficiency from thyroid hypofunction caused by pituitary hypofunction.

Imaging of the Thyroid Gland

Closely related to the RAIU is the thyroid scintiscan by gamma camera 24 hours after administration of ^{123}I. To evaluate metastatic thyroid cancer or a substernal thyroid, ^{131}I should be used to overcome photon attenuation by bone. Several radionuclides have been studied that concentrate in thyroid tissue, including gallium 67, thallium 201, and technetium 99m-methoxy-isobutyl isonitrile (^{99m}TCMIBI) also called 99m TC-sestamibi and ^{99m}Tc tetrofosmin. Nonetheless, it is not generally possible to differentiate benign from malignant thyroid nodules by this modality alone.[4]

TABLE 63–1. Summary of Interpretations to be Drawn from the Results of a "Serum Thyroid Panel"

Results of Serum Testing	*Interpretation of Thyroid Function*
Normal TSH and no clinical suspicion of thyroid disease	Normal
Normal TSH and normal FT_4	Normal
Elevated TSH and low FT_4	Primary hypothyroidism
Elevated TSH and elevated FT_4	Secondary (pituitary) hyperthyroidism or inappropriate thyroxine ingestion
Low TSH and high FT_4	Primary hyperthyroidism
Low TSH and low FT_4	Pituitary insufficiency

TSH = thyroid-stimulating hormone; FT_4 = free thyroxine.

The thyroid also concentrates monovalent ions such as sodium ^{99m}Tc pertechnetate. Because ^{99m}Tc has a short half-life and is not organically bound, its presence in the thyroid is only transient. Thus, if radioactive iodine uptake is blocked or contraindicated, ^{99m}Tc, at a dose of approximately 5 mCi, may be administered intravenously, with a scan performed at 20 minutes. Either technique adequately assesses thyroid enlargement or cold nodules. Increased sensitivity to the planar ^{99m}Tc scan has recently been reported using single-photon emission computed tomography (SPECT) for preoperative localization of occult medullary carcinoma of the thyroid gland.[5]

In traditional management following total thyroidectomy for thyroid cancer, thyroid hormone supplement is withheld to render the patient hypothyroid with a consequential increase in TSH level. This stimulates residual thyroid tissue and functioning metastatic cells to take up radioactive iodine for diagnostic scanning or ablation. Recombinant thyrotropin has been shown effective, although not as sensitive as thyroid withdrawal, in evaluation of patients with thyroid cancer. Recombinant human thyrotropin appears more sensitive than thyroid hormone withdrawal in causing an elevation of quantitative thyroglobulin levels in metastatic thyroid cancer. Instead of discontinuing thyroid hormone, recombinant human thyrotropin can be given on two consecutive days with a scanning dose administered on the third day. On the fifth day, the scan and quantitative thyroglobulin are obtained. Recombinant human thyrotropin is still under investigation for use in the treatment of metastatic thyroid cancer but is approved for use in treatment of hypopituitarism and in patients with so much functioning residual thyroid tissue as to prevent elevation of TSH. The advantage of recombinant human thyrotropin in this setting prevents the long period of hypothyroidism that can be very symptomatic for the patient.[6]

B-mode (two-dimensional) ultrasonography is a useful adjunctive tool for the evaluation of thyroid masses.[7] This method is particularly recommended in children or pregnant women, in whom radioactive isotopes are undesirable. The chief role of this modality is to distinguish between cystic and solid lesions, particularly in goiter. However, ultrasonography and thyroid scan are complementary tools for evaluation of thyroid nodules, and some argue that both are necessary for adequate assessment.[8]

Computed tomography (CT) and magnetic resonance imaging are useful to evaluate thyroid anatomy and relationships with adjacent structures, particularly in preoperative planning. Computed tomographic scan with iodinated contrast interferes with performance of the radioactive iodide uptake and scan for up to 6 weeks. Thyroid scans and RAIU should therefore be performed before CT with contrast.

Positron emission tomography (PET) is a promising modality for investigation of thyroid lesions. Measuring uptake of [18^{F}]-2-deoxy-2-fluoro-D-glucose (FDG) in thyroid nodules, increased uptake was seen in malignant lesions, distinguishing benign from malignant disease in each of 19 cases.[9] Further evaluation of this imaging modality in larger series provides an important future research direction.

Fine-Needle Aspiration Biopsy

Fine-needle aspiration (FNA) biopsy has become the diagnostic study of choice for all solitary thyroid nodules, for nodules within multinodular goiters that grow rapidly or steadily or have a worrisome texture, or for diffusely enlarged thyroids with localized nodules. The goal set by the Papanicolao Society of Cytopathology for laboratories is to aim for a standard for FNA diagnosis of thyroid nodules of a false-negative rate of less than 2% and a false-positive rate of less than 3%.[6] Fine-needle aspiration is currently performed by 88% of otolaryngologists for evaluation of thyroid masses and by 12% for evaluation of parathyroid masses.[10] This office procedure requires a 10 mL syringe with a fine needle (21 or 22 gauge) passed through alcohol-prepared skin to a palpable nodule or area of interest in the thyroid during continuous aspiration. The specimen may be smeared on a slide and sprayed immediately with fixative or submitted in appropriate media (eg, Carbowax) for later examination. The validity of this technique depends largely on the expertise and experience of the individual cytopathologist. Reportedly, sensitivity ranges from 75 to 93.5% and specificity from 75 to 100%.[11,12] However, malignancy can be present in up to 15% of indeterminate specimens and 11% of negative specimens. Comparison of diagnostic signs with biopsy-proven malignancy

shows an association with tumor size (> 4 cm), irregular borders, fixed lesions, or heterogeneity on ultrasonography. Close follow-up with repeat FNA in 6 months is recommended in patients with any of these features despite negative FNA.[13] Beyond well-differentiated thyroid tumors, FNA enables earlier diagnosis of rare but highly malignant neoplasms such as teratoma of the thyroid, characterized by small, round cells with neuroepithelial differentiation and metastases to lymph nodes.[14]

The gross appearance of aspirated fluid often yields diagnostic information: crystal-clear fluid is suggestive of a parathyroid cyst; yellow fluid is suggestive of a transudate; chocolate, green, or turbid fluid suggests degeneration; and bloody fluid from a palpable mass can suggest a rapidly growing vascularized tumor or aspiration of a vessel. Complications of this procedure include hematoma formation and recurrent laryngeal nerve injury, and the risk of infection is low.

Embryology

The parafollicular cells of the thyroid gland are part of the amine precursor uptake and decarboxylation (APUD) cell population, which is derived from neuroectodermal or neural crest cells.

The primordium of thyroid follicles arises from endoderm in the floor of the pharynx between the first and second pharyngeal pouches. This area evaginates to form a median diverticulum by the end of the fourth week. It grows caudally as a tubular thyroglossal duct through the midline of the primordium of the hyoid bone, eventually to bifurcate and develop into the isthmus, pyramidal lobe, and lateral lobes of the thyroid gland. The foramen cecum marks the site of origin of the thyroglossal duct, often identified in examination of the dorsum of the tongue. Maldevelopment of the thyroglossal duct can result in midline cervical ectopic thyroid or even lingual thyroid. Lingual thyroid is an irregular base-of-tongue mass that may interfere with aerodigestive function as it increases in size. Remnants of the thyroglossal duct that persist can give rise to midline cysts without sex predilection and usually prior to the third decade. Because of the developmental course of the thyroid gland, effective surgical extirpation requires complete excision of the cyst and any tract up to the foramen cecum including resection of 1 to 2 cm of the central portion of the hyoid bone (as described by Sistrunk in 1920). Although anomalies of the thyroid-hyoid apparatus are rare, fusion of the thyrohyoid interval (thyroid cartilage to hyoid bone) has been reported and can render the standard Sistrunk procedure impossible.[15]

The fetal thyroid begins to collect and organify iodine by about 10 weeks gestation. Adequate fetal thyroid function becomes necessary because maternal-fetal transfer of T_3 and T_4 is minimal. By the end of the first trimester, colloid follicles are visible, and both T_4 and TSH are detectable in the fetal blood. Fetal thyroid function increases in the second trimester associated with increasing thyroid secretion and TBG. Further, an increase in fetal TSH occurs as the fetal hypothalamus matures and produces TRH. Maternal TRH crosses the placenta and may contribute to the fetal pituitary activity, but, otherwise, the fetal pituitary-thyroid axis is a functional unit distinct from the mother.

Disorders of the Thyroid Glands

Goiter Goiter (from Latin *guttur*, meaning throat) is an enlargement of the thyroid gland resulting in swelling in the front of the neck. The term struma (from Latin *struere*, to build) is occasionally applied to describe this condition. A diffusely enlarged thyroid gland becomes palpable when the volume of the gland is doubled, and a visible goiter is usually at least three times the normal thyroid mass of 20 g.

Simple (Nontoxic) Goiter During puberty and pregnancy, the thyroid gland normally undergoes a diffuse enlargement. This is related in part to increased estrogens and subsequent increase in TBG. Colloid goiter can thus arise and is typified histologically by large colloid spaces and flattened follicular epithelium. This condition is usually self-limited and rarely requires treatment.

The term endemic goiter is applicable when 10% or more of the population has generalized or localized thyroid enlargement. It generally reflects a dietary deficiency of iodide particular to a geographic region, causing insufficient thyroid hormone secretion. Five percent of the world's population have goiter or associated disorders (cretinism, impairment of growth and mental development, etc). Of these, 75% live in less developed countries, where iodine deficiency is prevalent.[16] Twenty-five percent of goiters occur in more devel-

oped countries. These so-called "sporadic goiters" arise largely from iodine-sufficient conditions including autoimmune thyroiditis, hypo- or hyperthyroidism, and thyroid carcinoma. Histologically, endemic goiter is identical with colloid goiter.

Nodular Goiter The cause of nodular goiter is poorly understood but may be related to varying levels of TSH over a lifetime. The percentage of individuals with nodular goiter increases with advancing age. Multinodular goiter has a prevalence of 4% in the United States (with a female-to-male ratio of 6.4 to 1.5). Histologically normal parenchyma is interspersed between nodules of varying size and consistency. Nodules smaller than 2 cm are rarely noticed by patients, although with quick growth or painful hemorrhage into a cyst, the patient may seek attention. Large multinodular goiters are usually asymptomatic. They can, however, cause compression of neck structures, resulting in dysphagia, cough, or respiratory distress or a feeling of constriction in the throat. This may necessitate subtotal or total bilateral thyroidectomy. Overall, the recurrence rate for multinodular goiter treated by nontotal bilateral thyroidectomy is 21%, with the average time to recurrence at 8.75 years.[17]

The molecular biology of follicular cell growth in thyroid nodules is incompletely understood. However, distinct molecular pathogenetic mechanisms exist in hyperfunctioning and nonfunctioning follicular thyroid adenomas. Activating or "gain of function" mutations of the TSH receptor gene (*TShR*) or Gs alpha genes occur with hyperfunctioning thyroid adenomas, in which case, activation of the cAMP cascade leads to proliferation but maintains differentiation. Nonfunctioning follicular adenomas probably arise from oncogenes other than the *TShR* and Gs alpha genes.[18]

Medical therapy is indicated if a goiter is a cosmetic problem or if it becomes symptomatic because of compression and displacement of vital structures. Exogenous thyroid hormone is given to suppress TSH secretion. Radioiodine is usually effective for more extensive cases.

Substernal goiter can develop from downward growth of the thyroid gland into the superior mediastinum. This can potentially cause serious symptoms from compression of tracheal or venous and arterial structures. Substernal goiter not responsive to thyroid hormone suppression is generally managed by thyroidectomy, usually through a standard cervical incision.

Thyroid cancer has reportedly been found in 4 to 17% of patients with multinodular goiter; however, this likely represents bias in selection of patients for operation. The incidence of carcinoma is probably closer to 0.2%. For multinodular goiters with behavior or findings suggestive of malignancy, evaluation by FNA biopsy cytology may be useful. In the event of sudden, continued growth of a hard nodule, whole-goiter progression, symptoms related to compression or displacement, or severe cosmetic deformity despite medical treatment, a subtotal thyroidectomy is appropriate.

Hypothyroidism Hypothyroidism results from insufficient thyroid hormone secretion. In adults, this appears as myxedema characterized by weakness, lethargy, nonpitting edema, coarse dry skin, and possibly hearing loss. Hypothyroidism is present in approximately 1 in 5,000 neonates, although cretinism may not become evident until after several months of extrauterine life. This may arise from inadequate iodide intake in the maternal diet, thyroid agenesis, or administration of propylthiouracil or radioactive iodide during pregnancy. In infants, hypothyroidism causes cretinism with lethargy, stunted growth, mental retardation, and hearing loss. Hypothyroidism during pregnancy apparently can harm the neuropsychological development of the fetus. Mild maternal hypothyroidism alone has been associated with lower IQ scores in offspring. For women of childbearing age who are hypothyroid or who undergo thyroidectomy, it is important that they maintain a euthyroid state should they become pregnant. This is an exceedingly important responsibility of the thyroid surgeon to provide proper patient education in this regard.[6]

Hypothyroidism is not in itself an indication for thyroidectomy, but it can arise from surgical or medical intervention. In particular, surgical extirpation of a lingual thyroid or a thyroglossal duct cyst without preoperative thyroid scan may unexpectedly remove all functioning thyroid tissue. Although congenital hypothyroidism can affect hearing, no auditory effects of short-term (8 weeks) T_4 depletion are detectable.[19] Patients at high risk for myxedema coma require effective teaching regarding the signs and symptoms of hypothyroidism as well as annual thyroid function tests (including serum TSH).[20]

Careful monitoring of patients on thyroid replacement is prudent. Specifically, subclinical hyperthyroidism is associated with reduced bone density in the pelvis and axial skeleton in postmenopausal women. A three-fold increase in the incidence of atrial fibrillation is seen in elderly with hyperthyroid states. Therefore, in the absence of metastatic thyroid cancer, TSH suppression only to low normal is recommended. Given the deleterious effects of iatrogenic hyperthyroidism, treatment of cold nodules and euthyroid multinodular goiter with TSH suppression is generally out of favor.[6]

Thyrotoxicosis Thyrotoxicosis is the clinical and physiologic response of the tissues to an excess supply of active thyroid hormone. Causes of this syndrome fall into one of three main categories. The most important category includes diseases in which the gland sustains overproduction of thyroid hormone. This can arise in the presence of an unregulated thyroid stimulator of extrapituitary origin, as in Graves' disease or in patients who develop hyperthyroidism in association with Hashimoto's thyroiditis.[8] Rarely, excessive secretion of TSH from a pituitary tumor causes thyrotoxicosis.[21]

The second category involves the development of thyrotoxic states secondary to subacute (de Quervain's) thyroiditis or in the syndrome of chronic thyroiditis with spontaneously resolving thyrotoxicosis. In the presence of an inflammatory process, preformed hormone leaks from the gland in excess. The gland, however, fails to produce new hormone because of the suppression of TSH by feedback inhibition; this process is therefore self-limited. This often results in a transient insufficiency of thyroid hormones.

The third category is unusual and arises when a source of excess hormone arises from other than the thyroid gland, as in the case of a community-acquired outbreak of transient thyrotoxicosis arising from ingestion of ground beef contaminated with bovine thyroid gland.[22] Rarely, functioning metastatic follicular carcinoma can account for thyrotoxicosis. Up to 25% of patients with multinodular goiter may develop Jod-Basedow disease, which is thyrotoxicosis in response to the use of exogenous iodine (eg, radiographic contrast dye or iodide expectorants). This disorder is self-limited and is treated principally by discontinuing iodide use.

Hyperthyroidism If sustained hyperfunction of the thyroid gland leads to thyrotoxicosis, the condition is properly termed hyperthyroidism. Thus, not all thyrotoxic states are associated with hyperthyroidism. In true hyperthyroidism, an increased radioactive iodine uptake is found. In contrast, nonhyperthyroid thyrotoxic states have a decreased RAIU. Furthermore, in conditions with sustained hyperfunction of the thyroid gland, the use of treatments to decrease hormone synthesis (antithyroid agents, surgery, or radioiodine) is appropriate. In the absence of a true hyperthyroid state, however, these are inappropriate and ineffective methods for treatment of thyrotoxicosis. Young patients more commonly develop thyrotoxicosis from Graves' disease, whereas older patients develop toxic nodular goiter.

Graves' Disease Graves' disease is a relatively common disorder of unknown origin consisting of a triad of hyperthyroidism with diffuse goiter, ophthalmopathy, and dermopathy. All aspects of the triad need not appear together. Graves' disease is more frequent in women and has a definite familial predisposition. The basic disorder is a disruption of homeostatic mechanisms caused by the presence of an abnormal thyroid stimulator in the plasma. This long-acting thyroid stimulator is present in the IgG class of immunoglobulins. Long-acting thyroid stimulator, however, does not appear to be the antibody responsible for ophthalmopathy. Thus, Graves' disease appears to be an autoimmune process in which an antibody to the thyroid TSH receptor is produced by the patient's own lymphocytes. Subtle variation in immunoregulatory genes may be associated with autoimmune disease states. A complex interaction between genetic and environmental factors influences susceptibility to autoimmune thyroid diseases, Graves' disease and autoimmune hypothyroidism. Human leukocyte antigen and cytotoxic T-lymphocyte–associated-4 regions appear to influence susceptibility to disease to some degree, although other genes remain unknown. As crucial factors in the regulation of inflammatory and immune responses, cytokines are also potential candidate genes for autoimmune thyroid disease.[23]

The symptoms of Graves' disease include nervousness and tremors with mood swings, tachycardia, hypertension, diarrhea, insomnia, and heat intolerance, particularly in younger patients. In older patients, weakness, dyspnea, and even cardiac

failure can arise. Thyrotoxicosis may lead to degeneration of skeletal muscle fibers, enlarged heart, fatty infiltration and fibrosis of the liver, and bony decalcification.

Ocular signs include a characteristic stare with infrequent blinking and lid lag owing to sympathetic overstimulation. In contrast to the infiltrative ophthalmopathy, these findings subside when thyrotoxicosis is treated. The ophthalmopathy of Graves' disease is caused by an inflammatory infiltrate of the orbit that spares the globe. Edema and inflammation of the muscles, with infiltration by lymphocytes, mast cells, and plasma cells, account for the increased volume of orbital contents and proptosis. Eventually, muscle fibers degenerate and fibrose.

The dermopathy of Graves' disease is characterized by a thickened dermis caused by a lymphocytic infiltration.

In the triad of Graves' disease, diffuse toxic goiter is the most common presentation. In a severe case, Graves' disease is a straightforward diagnosis. Increased radioactive iodide uptake, serum T_4 radio immuno assay (RIA), and T_3 resin uptake serve more as baseline than diagnostic aids.

The treatment of hyperthyroidism in Graves' disease has two approaches, both of which are directed to limit thyroid hormone production by the gland. The first approach uses antithyroid agents to blockade hormone synthesis chemically. The second approach is ablation of thyroid tissue either by surgery or by means of radioactive iodine.

A trial of antithyroid therapy is desirable in children and patients under 40, including pregnant women, but it may also be employed in older patients. This includes propylthiouracil or methimaxole. Propylthiouracil is preferred in pregnancy because it has less transference across the placenta. Furthermore, the drug is not excreted in breast milk. Iodide inhibits release of hormones from the thyroid gland in hyperfunction. This is useful in treatment of thyrotoxic crisis, although the response is often incomplete and transient. Large doses of glucocorticoids such as dexamethasone help to reduce the serum T_4 concentration and can contribute to management of thyrotoxicosis as well as oculopathy.

In the past, a major cause of mortality in Graves' disease was thyroid storm, characterized by hyperthermia, tachycardia, hypertension, profuse sweating, intense irritability, extreme anxiety, and eventual prostration with irreversible hypotension and death.[20] This phenomenon represents an acute adrenergic crisis caused by thyroid hormone augmentation of the effects of catecholamines, particularly by induction of additional myocardial catecholamine receptors. Treatment with sympatholytic drugs including reserpine, guanethidine, and β-adrenergic blockers (propranolol), as well as oxygen, intravenous glucose, iodide, and adrenal steroids, has brought this serious problem under control for the surgeon.

Surgical ablation of the thyroid gland in Graves' disease is recommended in patients who have had a relapse or recurrence after drug therapy, in patients with a large goiter or drug toxicity, and in patients who fail to follow a medical regimen or to return for periodic examinations.

Although a radioiodide has no known carcinogenic effects as a β-emitter in adults treated for hyperthyroidism, many physicians prefer to reserve therapy for patients over 30 years of age who are unlikely to bear children. Hypothyroidism occurs with insidious onset in 40 to 70% during the 10-year period following treatment with ^{131}I. Patients treated for Graves' disease are particularly vulnerable to serious complications of myxedema. Some clinicians recommend treatment with large doses of ^{131}I followed by permanent physiologic replacement with exogenous thyroid hormone. In younger patients or in those for whom radioiodide is contraindicated, a subtotal thyroidectomy can be performed as described in a later section of this chapter. Surgical patients must attain a stable euthyroid state through antithyroid agents before any operation.

Toxic Adenoma Thyrotoxicosis caused by thyroid hormone secreted by an autonomous follicular adenoma is termed toxic adenoma. This can follow a long period of euthyroid function in which suppression of normal gland balances the hyperfunctioning adenoma. In regions with adequate dietary iodine, hyperthyroidism owing to Graves' disease is 50 times more prevalent than hyperthyroidism owing to autonomously functioning thyroid adenoma. However, hyperthyroidism arises from different mechanisms in iodine-deficient areas. For instance, in areas of Denmark, hyperthyroidism is attributable to Graves' disease in only 39%, with autonomously functioning thyroid adenoma responsible for 10% and toxic multinodular goiter (discussed below) accounting for 48%. It appears that iodine deficiency

promotes the development of autonomously functioning thyroid nodules.[1]

Radioiodide is generally an effective treatment for toxic adenoma, often sparing the normal remaining gland, which has low uptake of iodide. Thyroid lobectomy is appropriate for patients at risk, as discussed later in this chapter in relation to the solitary nodule.

Toxic Multinodular Goiter Toxic multinodular goiter (Plummer's disease) is a disease of aging that arises in a simple (nontoxic) goiter of long standing. The development of thyrotoxicosis with slow progression of multinodular goiter is usually caused by an autonomous functioning adenoma. Approximately 10% of solitary palpable nodules have autonomous function. In multinodular goiters over 100 g, two-thirds have autonomous secretion of thyroid hormone. Treatment is primarily medical, consisting of antithyroid drugs (propylthiouracil or methimaxole), sympatholytic therapy, and radioiodide. In the absence of symptoms caused by mass effects of goiter, surgery is reserved for toxicity not controlled medically.

Thyroiditis Rarely, the thyroid gland may have a bacterial infection. Of much greater significance are the inflammatory diseases of the thyroid that do not become manifest in the acute phase. Among these is subacute (de Quervain's granulomatous) thyroiditis, a febrile disease in which the thyroid becomes acutely congested, edematous, and mildly tender, often after an upper respiratory infection. The disease is characterized by repeated remissions and exacerbations over several months without hypothyroidism or evidence of stimulating antibodies. Thyroid microsomal and thyroglobulin antibodies, however, do appear in low titers in subacute thyroiditis. Histologically, an inflammatory infiltrate with large, multinucleated giant cells containing vesicles of colloid suggests a foreign body reaction. This condition is not treated by a surgical procedure.

Hashimoto's disease (struma lymphomatosa) is the most common type of thyroiditis. This goitrous form of autoimmune thyroiditis and its variant, lymphocytic thyroiditis, appear mostly in women as symmetric, rubbery enlargement of the gland. Although microsomal and thyroglobulin antibodies are present, tissue damage appears to be cell mediated. T cells from patients with autoimmune thyroiditis react with iodinated thyroglobulin, but with the addition of iodine, they react with the noniodinated form. Addition of iodine to thyroglobulin generates or exposes epitopes. Further, thyroglobulin-reactive autoantibodies exhibit proteolytic activity on thyroglobulin.[24] Histologically, a lymphocytic infiltrate tending to form lymphoid follicles with plasma cells is seen. Follicles are progressively compressed and distorted into fused masses of cells without a colloid space. Follicular cells may eventually be transformed into Hürthle cells, which appear as nests of large pink cells with abundant granular cytoplasm packed with mitochondria. Although this condition is associated with mild thyrotoxicosis in the early stages because of release of stored hormone from damaged follicles, most patients have depressed thyroid function (RAIU low to normal). In the later and chronic stage, hypothyroidism commonly develops. Fine-needle aspiration biopsy cytology can assist in the diagnosis. Open biopsy or procedures to alleviate compression of the trachea or esophagus are sometimes necessary.

Riedel's struma (invasive fibrous thyroiditis) is a rare presentation of thyroiditis characterized by irreversible, profound hypothyroidism and a stony hard, irregular, fibrous gland. Symptoms can include cough, dyspnea, and difficulty in swallowing. Replacement thyroid hormone is the principal treatment.

Management of Thyroid Neoplasia

Solitary Nodule of the Thyroid The most common indication for thyroidectomy (50% of cases) in the United States is the presence of a solitary thyroid nodule, defined as a discrete mass, greater than or equal to 1 cm in diameter, discovered by palpation of a thyroid gland otherwise of normal size and consistency. Solitary nodules may occur in up to 4% of the population and are most often found in patients 30 to 50 years of age, with a four-fold increase in frequency in women. With ultrasonography, nodules occur in up to 50% of individuals over 50 years of age. It is important to distinguish clinically between the solitary nodule and a multinodular thyroid gland because the latter has a low incidence of malignancy. One series reports spontaneous disappearance as the most common outcome for an untreated, long-standing nodule (38.3%); on the other hand, 13% of nodules in this series were enlarging. Needle biopsy demonstrated malignancy in 26.3% of enlarging nodules, compared with 6.4%

of nodules that were of stable size.[25] In another series, interval examination at 5 years of patients with incidental findings of abnormalities on thyroid ultrasonography revealed that 12% had new nodules (all benign), 12% had grown but all were benign, 24% were diminished or disappeared, and one had a benign adenomatous nodule. They concluded that incidental ultrasonographic abnormalities of the thyroid are generally benign and clinically inconsequential.[26]

Increased risk of malignancy is associated with prior neck irradiation, and a thyroid nodule with enlarged lymph nodes or fixation of nodule to overlying strap muscles suggests malignancy.[27] The most common cause of solitary thyroid nodules in children and adolescents is follicular adenoma, although malignancy is reported in 25.5% of cold nodules in children.[28] A neck mass is the most common presenting symptom of papillary or follicular thyroid carcinoma in patients under 20 years of age.[29]

The evaluation of patients with thyroid nodules should include an assessment of laryngeal motor function, serum thyroid hormone levels, radioactive iodide uptake, and scintiscan. If a hot nodule is demonstrated by ^{99m}Tc scanning, reexamination with radioiodide is recommended. Ultrasonography to differentiate between cystic and solid thyroid nodules is accurate in 82 to 95% of cases. Fine-needle aspiration biopsy cytology often provides an accurate diagnosis and is used by some practitioners to treat cystic lesions. The reported incidence of carcinoma in solitary nodules ranges from 1.3 to 20.3%.

The series with the highest yield of carcinomas on thyroidectomy had stringent selection of patients based on risk factors. Thus, using known risk factors, patients with solitary nodules at increased risk for malignancy can be identified and selected for surgical procedures.[30] Increased risk is found in the following situations:

1. Thyroid nodules associated with vocal cord paralysis (infrequently, benign nodules can cause paresis or paralysis by compression, which is usually alleviated by excision of the mass)[31]
2. Solitary nodules in men
3. Solitary nodules in patients under 20 years old or over 50 years old
4. Solitary nodules in patients with a history of head and neck irradiation
5. Palpable lower or midcervical lymph nodes and apparently normal thyroid glands in young patients
6. Functioning or cold nodules on scintiscan or radionuclide uptake outside the thyroid gland
7. Solid or partially cystic lesions by ultrasonography
8. Recurrent cystic lesions following needle aspiration
9. Abnormal cytologic findings on needle aspiration biopsy
10. Solitary nodules that fail to disappear in response to thyroid hormone suppression therapy

In patients with chronic thyroid disease, high-risk patients who are candidates for surgery may be identified by the following criteria:

1. Multinodular goiter containing cold nodules that enlarge in response to suppression with thyroid hormone
2. Rapidly enlarging nodules in chronic goiters with or without suppression
3. Goiters with vocal cord paralysis
4. A history of head and neck irradiation
5. A history of neoplasia of the thyroid gland

Thyroid adenomas are benign, encapsulated neoplasms with a glandular cellular structure. These lesions may be classified as follicular adenomas, Hürthle cell adenomas, and papillary adenomas. If a "hot" or hyperfunctioning adenoma is demonstrated by technetium scan and this finding persists on a thyroid suppression test, this lesion can be treated with radioactive iodide. Benign teratoma can also occur in the thyroid gland.

Malignant Lesions

Malignant tumors of the thyroid include papillary adenocarcinoma, follicular adenocarcinoma, Hürthle cell carcinoma, medullary carcinoma, and undifferentiated carcinomas (small cell carcinoma and giant cell carcinoma). Various miscellaneous malignant lesions include lymphoma, sarcoma, and teratoma.

Papillary Adenocarcinoma Thyroid carcinomas comprise approximately 1% of all malignant tumors in the United States. Of these, 60 to 70% are papillary carcinomas. These account for 80 to 90% of radiation-induced thyroid carcinomas. The demonstration of G protein or thyrotropin receptor gene mutations in the presence of a synergistic,

activated *RAS* gene supports the multistep model of thyroid carcinogenesis in differentiated carcinoma.[1] Of children aged 10 to 15 years exposed to fallout in the Chernobyl accident, rearrangements of the *RET* oncogene were found in 44%. The majority of *RET* rearrangements identified arose from inversion of part of chromosome 10 involving papillary thyroid cancer genes 1 and 3 (*PTC1* and *PTC3*). *PTC1* rearrangements were associated with classic papillary carcinoma and histologically diffuse sclerosing variants, whereas *PTC3* apparently gave rise to tumors with a solid/follicular morphology.[32] Dietary iodine in childhood is also regarded as an etiologic factor. Although usually sporadic, papillary thyroid carcinoma can occur in familial form (fPTC) and is sometimes associated with nodular thyroid disease. Studies of the fPTC susceptibility gene by genetic linkage and sequence analysis reveal *MET* as the proto-oncogene of isolated fPTC.[33]

Approximately 25% of papillary carcinomas are occult, discovered incidentally at surgery, and of questionable clinical significance. The peak incidence is in the third and fourth decades, with a three-fold increase in frequency in women. Study of a large population in Taiwan with papillary thyroid carcinoma over a 15-year period found the mean age of onset at 40.4 ± 14.6 years and a 5-year survival probability of 0.9817%. The survival was improved over time, apparently owing to more aggressive surgical and medical management and, especially, earlier detection of disease.[34]

One variant of papillary carcinoma, referred to as Warthin-like tumor of the thyroid gland, has been described. These neoplasms are characterized by prominent T- and B-cell lymphocytic infiltration in stalks of papillae and oxyphilic epithelial metaplasia suggestive of Warthin salivary tumor. However, nuclear features are reminiscent of papillary thyroid carcinoma, and tumor cells are strongly positive for Leu M1 and epithelial membrane antigen, although less for thyroglobulin and negative for calcitonin. The *RET* proto-oncogene encodes a receptor tyrosine kinase for transforming growth factor-β–related neurotrophic factors. Expression of the *RET* proto-oncogene has been detected in numerous tissues, including neural crest–derived cell lines. More recently, *RET* expression has been demonstrated in papillary and follicular thyroid cancer cells.[35] Further evidence for the papillary carcinoma of this variant, Warthin-like tumor of the thyroid gland, lies in expression of the *RET/PTC* fusion gene in these tumors as evidenced by strong reactivity with antibodies against *RET/PTC*.[36]

Among several unique histologic subtypes of papillary carcinoma is tall cell variant, constituting 5 to 10% of all papillary thyroid carcinomas. In patients over 50 years old, it is associated with a more aggressive clinical course as evidenced by a higher rate of recurrence and tumor-related mortality. Tall cell variant tends to present at an advanced stage owing principally to extrathyroid invasion.[37]

Thyroglossal duct cysts are second in incidence only to enlarged cervical lymph nodes as the cause of pediatric neck masses. One percent of thyroglossal duct cysts are malignant, and 81.7% of these are papillary carcinomas.[38]

Although two-thirds of papillary thyroid carcinomas have follicular elements, their behavior is determined by the papillary aspect. These are unencapsulated tumors that tend to invade lymphatic vessels as well as normal surrounding thyroid parenchyma directly. Multicentricity of the primary neoplasm is a common feature, seen in 20 to 80% of patients.

This lesion generally has a prolonged course, and the overall mortality is estimated at 10% or less. The patient's age at diagnosis is the most important prognostic factor. The prognosis is excellent in children and young adults, even in the presence of advanced primary disease or lymph node metastases.[39] Despite the good prognosis, almost 50% of patients who die of papillary carcinoma do so because of local invasion.

Various surgical procedures have been recommended, ranging from subtotal lobectomy to total thyroidectomy. Microscopic disease in the contralateral lobe has been reported in 8 to 88% of cases by various investigators. Total ipsilateral lobectomy, isthmusectomy, and subtotal contralateral lobectomy probably comprise the most common procedure for papillary carcinoma confined to the thyroid gland. For more extensive well-differentiated disease, improved survival requires aggressive management of the primary and cervical node disease by surgery, followed at 6 weeks by thyroid scan and high-dose ^{131}I administration for ablation of the remnant.[40]

With the application of excellent surgical skills, a complete extirpation of the thyroid gland can be performed without recurrent laryngeal nerve injury

or the reported 2% incidence of permanent hypoparathyroidism. Recurrent neck disease must be treated by neck dissection. The concept of "node plucking" is controversial.[41]

Follicular Adenocarcinoma Follicular carcinoma accounts for approximately one of five thyroid cancers, peaking in the fifth decade of life with a 3 to 1 female preponderance. Like papillary carcinoma, it is well differentiated, despite a worse prognosis. These tumors can be encapsulated, or they can invade vasculature. Distant metastases, especially to lung and bone, are found commonly. Of deaths from follicular carcinoma, 75% arise from distant metastases.

For patients under 40 years of age with encapsulated follicular carcinoma, isthmusectomy and lobectomy are performed, with total thyroidectomy reserved for patients over 40 years old. Some surgeons prefer to perform total thyroidectomy for all patients because follicular carcinoma, unlike papillary carcinoma, can undergo late anaplastic transformation. For invasive follicular carcinoma, total thyroidectomy is recommended, followed by ablative radioiodine, because of the potential for distant metastases. In the presence of palpable lymph nodes in the neck, modified radical neck dissection is recommended with preservation of the eleventh cranial nerve and the sternocleidomastoid muscle. Some surgeons do remove the ipsilateral internal jugular vein.

A major difficulty is distinguishing between follicular adenoma and follicular carcinoma. In up to one-third of cases, a frozen-section diagnosis of follicular adenoma is changed to follicular carcinoma. The extent of resection with indeterminate lesions must take this into account with consideration of prognostic factors such as the patient's age and sex and the size of the lesion.[42]

Thallium 201 scintigraphy with serum thyroglobulin provides a basis for follow-up of well-differentiated thyroid cancer. Others use whole-body ^{131}I (WBI) scan at 6 months after thyroidectomy with an ablative dose of ^{131}I. One group reported detection of metastatic tumor based on whole-body ^{99m}Tc-sestamibi scan (WBMIBI) with serum thyroglobulin levels in several patients with negative WBI scans.[43] Moderate elevations in thyroglobulin may be attributable to inadequate thyroid suppression therapy and may require assessment by careful assay of TSH levels. Patients with elevated thyroglobulin levels despite adequate suppression therapy following definitive treatment of a well-differentiated carcinoma are at increased risk of recurrence.[44] Whole-body ^{99m}Tc-sestamibi scan is a potentially valuable tool not only in WBI-negative patients but also in the presence of antithyroglobulin antibodies. Another group recommends use of the FDG PET scan as the study of choice for detection of ^{131}I-negative recurrences and metastases.[45]

Hürthle Cell Carcinoma Hürthle cells observed in thyroid gland atrophy of Hashimoto's disease are a benign entity. Hürthle cells occur in clusters as a degenerative transformation of the follicular cells. Hürthle cell carcinoma can occur as a malignant thyroid neoplasm composed of this cell type; however, this is sometimes classified as a variant of follicular carcinoma. This disease behaves clinically as an intermediate between low-grade and angioinvasive follicular carcinoma. It is difficult to confirm malignancy of a Hürthle cell mass on a pathologic basis alone; therefore, any isolated nodule should be considered malignant on clinical grounds.

Treatment of Hürthle cell carcinoma involves at least an isthmusectomy and lobectomy.[46] If Hürthle cell carcinoma appears as a solitary thyroid nodule exceeding 2.0 cm, or if it is bilateral, total thyroidectomy is recommended. Radical neck dissection is further recommended in the event of cervical nodal metastases.

Medullary Carcinoma with Amyloid Stroma Medullary carcinoma accounts for 5 to 10% of thyroid carcinomas. Lesions are capable of local invasion, spread to regional lymphatic vessels, or distant metastases. They are derived from C cells of the thyroid gland and are capable of producing calcitonin. Calcitonin is an important tumor marker in medullary carcinoma, with the chemoluminescence immunoassay of monomeric calcitonin being more sensitive than nonspecific RIA.[47]

A variant of medullary carcinoma is seen in thyroid carcinoma with mixed follicular and C-cell differentiation patterns and highly heterogeneous patterns of growth. These are referred to as mixed medullary thyroid carcinomas, and their clinical behavior is the same as ordinary medullary carcinoma. Analysis of the two cell types shows that they do not arise from a common precursor as remarkable differences in the genetic profile (*RET* muta-

tions and allelic losses) are displayed. In some cases, the follicular component is oligo-/polyclonal and, thus, probably hyperplastic rather than neoplastic. The morphology of this variant may arise from follicular cells growing into the medullary carcinoma after acquiring some molecular defect. Management of mixed medullary thyroid carcinomas is determined by the true neoplastic component as medullary carcinoma.[48]

Multiple endocrine neoplasia type I (MEN-I) is characterized by parathyroid chief cell hyperplasia with pancreatic islet cell and pituitary adenomas.[49] Two further familial syndromes, multiple endocrine neoplasia type IIa (MEN-IIa) and the rarer type IIb (MEN-IIb), were found in association with medullary carcinoma of the thyroid after its first description in 1959.[50,51]

Multiple endocrine neoplasia type IIa (Sipple's syndrome) consists of medullary thyroid carcinoma with associated pheochromocytoma and parathyroid hyperplasia. Metachronous development of each aspect of Sipple's syndrome can occur. Multiple endocrine neoplasia type IIb is characterized by medullary carcinoma of the thyroid, pheochromocytoma and multiple mucosal neuromas, ganglioneuromatosis, and a Marfan's habitus. Further, a familial non-MEN (FN-MEN) is recognized in which hereditary medullary carcinoma of the thyroid occurs without associated endocrinopathy. Each of these clinical syndromes, MEN-IIa, MEN-IIb, and FN-MEN, is inherited as an autosomal dominant trait. Kindred should be screened by detection of increased serum calcitonin, either basally or following pentagastrin stimulation. Patients with medullary carcinoma or C-cell hyperplasia as a premalignant precursor require prompt and thorough surgical intervention because this malignant lesion is biologically aggressive, with onset at a young age.[52] Children with MEN-IIb should be studied shortly after birth, and those with MEN-IIa should be evaluated by the age of 1 year.[53]

The basis for these familial syndromes associated with medullary carcinoma lies in the common embryologic origin of the parafollicular cell and the adrenal medullary cell. Both are members of the APUD cell population, derived from neural crest cells. The presence of abnormal (nondiploid) DNA as determined by flow cytometric analysis of nuclear suspensions appears to be associated with a worse prognosis in sporadic and familial medullary thyroid carcinoma.[54]

Although papillary thyroid carcinoma is not a characteristic of MEN-II, the diseases have associated genes. The proto-oncogene *RET*, which has been demonstrated to be rearranged in papillary cancer, has been mapped near the predisposition locus for MEN-II, with apparent tight linkage between loci. *RET* is expressed in medullary thyroid carcinoma and pheochromocytoma, making it a candidate gene for MEN-II. The variations in expression of the MEN-II syndrome may be attributable to structural alteration of several contiguous genes in the MEN-II chromosomal region.[55] Techniques of molecular biology will likely provide the means to assess and control this form of malignant disease in the foreseeable future.

Medullary carcinoma does not take up radioiodide, so this treatment is not recommended. Because of the propensity of medullary carcinoma for local microvascular invasion, late recurrence (up to 20 years after treatment), and metastatic disease, aggressive surgical intervention is recommended. Furthermore, external ionizing radiation and chemotherapy are of limited value. A total thyroidectomy is generally recommended because of the high incidence of bilaterality, especially in familial syndromes. Most clinicians favor a radical neck dissection on the side of the primary neoplasm with a modified neck dissection on the contralateral side in the event of bilateral thyroid gland involvement. The incidence of bilateral disease in the gland or neck is especially high in familial disease. Attention to family history and evaluation for other endocrinopathies are imperative. As with well-differentiated thyroid adenocarcinomas, medullary carcinomas can eventually degenerate to anaplastic carcinoma.

Anaplastic Carcinoma Anaplastic carcinoma, largely a disease of the elderly, accounts for less than 10% of malignant thyroid tumors. This disease has shown a three-fold to four-fold decline in incidence internationally over the past 45 years, relating inversely to the increase in extirpative thyroid procedures.[56] Foci of differentiated thyroid cancer are commonly observed, suggesting a degenerative origin, based on "clonal evolution." Chromosomal aberrations 5p, 8p, and 8q, rarely found in differentiated thyroid carcinoma, are found in anaplastic carcinoma. These chromosomes may harbor gene loci affecting aggressiveness of neoplastic growth

and, thus, could play an important role in carcinogenesis.[57] Up to 20% of patients have a history of a previously treated well-differentiated carcinoma of the thyroid.

Anaplastic carcinoma is an often rapidly fatal, aggressive, enlarging, bulky mass that distorts the anterior neck and often obstructs the aerodigestive tract. In many cases, the patient undergoes biopsy by needle aspiration or open biopsy, and the neoplasm is deemed inoperable. Palliative radiation therapy and chemotherapy may prolong life.[58] Patients with the small cell type may have a slightly longer survival than those with large cell anaplastic carcinoma.

Other Malignant Lesions Sarcomas comprise less than 1% of malignant tumors of the thyroid. They have a poor prognosis despite aggressive surgical intervention. All varieties of lymphoma arise in the thyroid gland, most frequently non-Hodgkin's lymphoma. This lesion may appear as a rapidly enlarging goiter in an elderly person. Treatment usually involves lobectomy or total thyroidectomy followed by external beam radiation. A wide range of thryoid neoplasms representing metastases from distant sites has been reported.

Surgical Anatomy

In the medial aspect, the thyroid gland is deep to the sternohyoid and underlying sternothyroid (strap) muscles. Inferiorly, the sternocleidomastoid muscle overlaps the strap muscles, whereas more superiorly, it overlaps the lateralmost extent of the thyroid gland. The anterior surface of the thyroid gland faces the pretracheal layer of the deep cervical fascia, which extends around posteriorly to envelop the trachea, esophagus, and recurrent laryngeal nerves.

The deep or medial surface of the thyroid gland is adapted to the larynx and trachea. At the superior pole of each lateral lobe, the medial surface is in contact with the inferior pharyngeal constrictor and the posterior portion of the cricothyroid muscle. The medial aspect of the thyroid gland is also intimately related to the parathyroid glands and the recurrent laryngeal nerves. The correct level of dissection for dorsal mobilization is anatomically defined as lying anterior to the lamella that covers the vessel- and nerve-containing plane of the neck.[59] On occasion, the gland may extend posterior to the trachea. Appreciation of these relations contributes to surgical technique and understanding of the symptoms of thyroid masses.

Suspension of the Thyroid Gland The thyroid gland is suspended in the neck from the cricoid and thyroid cartilage by two ligaments: the anterior suspensory ligament and the surgically more important posterior suspensory (Berry's) ligament.

The anterior suspensory ligament attaches the superior border of the isthmus and superomedial aspect of each lateral lobe to the cricoid cartilage and cricothyroid muscle.

The posterior suspensory ligament is distinct from the anterior suspensory ligament and becomes a pedicle for the thyroid gland in the course of thyroid lobectomy. Berry's ligament extends from the medial and deep portions of each lateral lobe of the thyroid to the lateral surface of the cricoid cartilage as well as the posterior lateral aspect of the first and second tracheal rings. It is an important surgical landmark because the recurrent laryngeal nerve passes either deep to this ligament or between leaves of the ligament in its cephalic course. The recurrent laryngeal nerve often divides into two branches inferior to this ligament; therefore, all branches must be visualized to avoid injury. Furthermore, a portion of the lateral thyroid lobe extends deep to the ligament. In some patients, the ligament may actually be embedded in glandular tissue, demanding meticulous surgical dissection.

An occasional anomaly observed is a unilateral or paired bilateral muscle, the levator glandulae thyroideae muscle, inserting into the thyroid gland and originating from the hyoid bone.

Blood Supply The blood flow to the thyroid gland is on the order of 100 mL/minute, reflecting the importance of thyroid hormone to whole-body metabolism. The thyroid gland receives this abundant blood supply through paired inferior thryoid arteries as well as an occasional unpaired lowest thyroid artery of variable size (Figure 63–1).

The dominant artery to the thyroid is usually the inferior thyroid artery, although it can be of variable origin and relationship. Typically, it ascends along the medial side of the anterior scalene muscle behind the prevertebral fascia. Thereafter, it loops down onto the anterior surface of the longus colli to pass behind the common carotid artery in variable relation to the middle cervical ganglion of the sym-

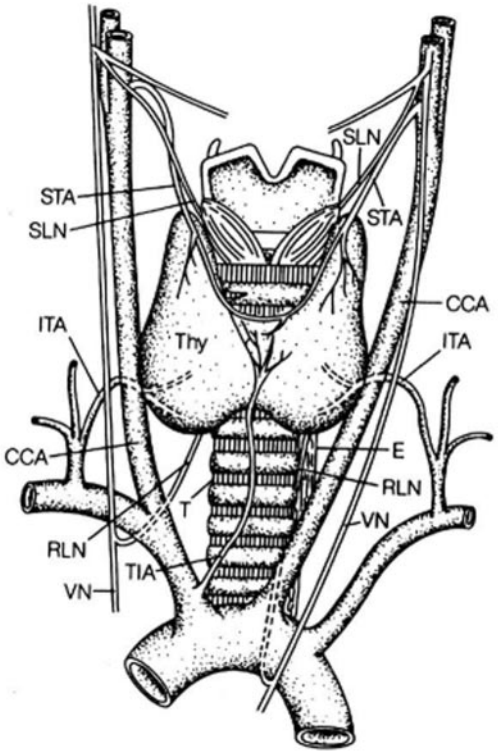

FIGURE 63–1. Arteries of the thyroid and the laryngeal nerves, anterior view. Dissection of the recurrent laryngeal nerve (RLN) begins in the triangle bounded by the trachea (T), the common carotid artery (CCA), and the thyroid gland (Thy). Branches of the inferior thyroid artery (ITA) can run close to the recurrent nerve. The esophagus (E) runs somewhat to the left of the trachea. The superior thyroid artery (STA) is closely related to the external branch of the superior laryngeal nerve (SLN). The vagus nerve (VN) courses parallel to the carotid artery. The thyroid ima artery is labeled TIA.

pathetic trunk. Medial to this point, it penetrates the prevertebral fascia and, in variable relationship to the recurrent laryngeal nerve, divides into a dominant upper branch to just below the midportion of the lateral thyroid lobe and a lower branch to the inferior border of the lobe. Small branches of the inferior thyroid artery cross deep to Berry's ligament and along its inferior edge, where clamping for hemostasis may injure the recurrent laryngeal nerve. Duplication of the inferior thyroid artery has been observed; in this case, both inferior thyroid arteries arise from the subclavian artery on one side. In the occasional absence of an inferior thyroid artery, the ima thyroid artery may replace it, or it may simply be an accessory vessel. Most commonly, the ima thyroid artery arises from the innominate (brachiocephalic) artery.

The superior thyroid artery is the first anterior branch of the external carotid artery, although it can arise from the bulb of the common carotid artery. In its descent toward the apex of the thyroid lobe, the artery is closely related to the course of the external branch of the superior laryngeal nerve. This nerve is therefore a potential source of complication in thyroid surgery. On approach to the gland, the superior thyroid artery divides into an anterior and a posterior branch. The anterior branch runs close to the medial aspect of the lobe and across the isthmus superiorly, often anastomosing with the superior thyroid artery from the opposite side. The course of the superior thyroid artery is the most constant of the arteries to the thyroid gland.

Venous drainage of the thyroid gland is by two or three pairs of veins that anastomose freely in the gland. These vessels are named by location: superior, middle, and inferior thyroid veins (Figure 63–2).

The superior thyroid vein emerges from the upper portion of the thyroid gland and accompanies the superior thyroid artery to empty into the internal jugular vein or lower end of the common facial vein at the level of the carotid bifurcation.

The middle thyroid vein is variable in presence and size and arises from the lateral surface of the thyroid, crossing in front of the common carotid artery to drain into the internal jugular vein. It may be torn in dissecting the gland from the carotid sheath. The middle thyroid vein is present in roughly 50% of patients.

The inferior thyroid vein drains the lower portion of the gland to the brachiocephalic vein of the same side. The inferior thyroid veins form the plexus thyroideus impar, a rich anastomosis in front of the trachea, which can produce troublesome bleeding in a tracheostomy. Occasionally, the inferior thyroid veins join inferiorly to drain by way of a common trunk to the left brachiocephalic vein, which is referred to as a thyroidea ima vein.

Neural Input Neural fibers reach the thyroid gland from the superior cervical ganglion of the sympathetic trunk and the superior laryngeal branch of the vagus. It is generally accepted, how-

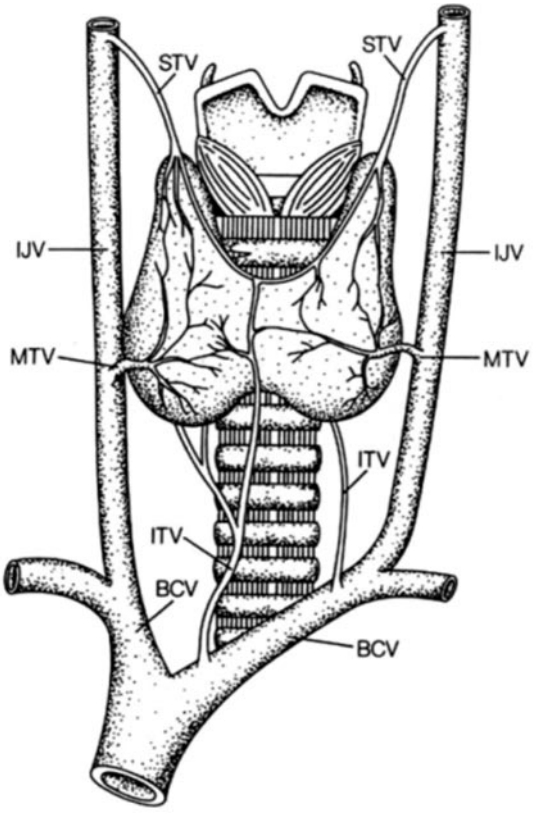

FIGURE 63–2. Venous drainage of the thyroid gland, anterior view. The superior thyroid vein (STV) closely approximates the course of the superior thyroid artery. The middle thyroid vein (MTV) occurs variably, draining into the internal jugular vein (IJV). The inferior thyroid veins (ITV) drain into their respective brachiocephalic veins (BCV).

ever, that these nerves are related functionally to blood vessels only and not directly to the function of glandular tissue.

Lymphatics Lymphatic drainage of the thyroid is chiefly by inferior and superior lymphatic vessels accompanying the arterial blood supply. The isthmus is mostly drained by inferior lymphatic channels, as are the lower portions of the lateral lobes. The lower channels then distribute to the lower deep cervical lymph nodes, the supraclavicular lymph nodes, and the pretracheal and paratracheal lymph nodes, as well as the prelaryngeal lymph nodes just above the isthmus. The Delphian node is a median prelaryngeal lymph node often palpable in the presence of thyroid disease. Drainage also occurs to the brachiocephalic lymph nodes, which are related to the thymus in the superior mediastinum. Lymph vessels from the thyroid gland may enter into the thoracic duct directly. Superior lymphatic channels drain the superior and medial surfaces of the lateral lobes as well as the superior surface of the isthmus. The upper channels empty into the upper cervical lymph nodes.

PARATHYROID GLANDS

The parathyroid glands consist of four small, ovoid, yellowish-brown structures located between the posterior border of the thyroid lobes and its capsule. These endocrine glands produce PTH, which acts to increase serum calcium. They are named anatomically with respect to laterality and superior or inferior position. Each gland is normally about 50 mg and measures on the order of 6 mm by 4 mm by 2 mm, with the least dimension in the anteroposterior orientation. Adenomas of the parathyroid glands can weigh from 120 to 800 mg. Generally, PTH production is proportional to the mass of the gland.

The parathyroid glands are endoderm derivatives of the third and fourth pharyngeal pouches. Like the thymus, the *inferior* parathyroid glands (IPGs) are derivatives of the *third* pharyngeal pouch. Therefore, IPGs are also referred to as *parathyroids III*. Similarly, the *superior* parathyroid glands (SPGs), derived from the *fourth* pharyngeal pouch, are referred to as *parathyroids IV.*

The parathyroids have a rich blood supply from the inferior thyroid artery and the anastomotic artery that connects the superior to the inferior thyroid arteries. This anastomotic artery can serve as a guide in locating parathyroid glands. Dense lymphatics drain the parathyroids in close association to lymphatics of the thyroid gland and thymus. Neural input to the parathyroids is sympathetic, arising from the superior or middle sympathetic ganglion for vasomotor control, although glandular function is controlled by serum calcium rather than bloodflow.

The SPGs are more constant in position than the IPGs. The SPGs are usually located around the middle of the posterior border of the lateral lobe of the thyroid gland. The inferior glands have more varied positions. Inferior parathyroid glands can occur within the thyroid capsule below the inferior thyroid artery near the inferior pole of the lateral thyroid lobe. Tumors arising from the IPGs in this

relation tend to grow down the inferior thyroid veins, anterior to the trachea, and into the superior mediastinum. Inferior parathyroid glands can also present posterior to the thyroid capsule and above the inferior thyroid artery, and tumors arising from these can develop posteriorly and inferiorly to grow behind the esophagus and into the posterior mediastinum. Inferior parathyroid glands can also occur within the thyroid lobe itself near the inferior aspect of the posterior border. However, parathyroid glands can exist as diffusely scattered collections of parathyroid tissue in connective tissue or fat, or represented as only three distinct glands. Generally, SPGs are *deep* and IPGs are *superficial* to the recurrent laryngeal nerves on each side.

In children, parathyroid glands consist of cords or columns of cells called chief cells with fine connective tissue septae extending from a thin capsule into the gland. Around 6 years of age, other cells appear, the oxyphil cells, which are probably derived from chief cells. The oxyphil cells are larger than chief cells with a greater volume of eosinophilic, granular cytoplasm. The oxyphil cells apparently have high metabolic activity with abundant mitochondria and glycogen particles but sparse endoplasmic reticulum. Lipid deposits accumulate progressively in parathyroids with aging. Large sinusoidal capillaries are distributed between the columns. Chief cells vary in cytoarchitecture, with the most active staining darker with more granular endoplasmic reticulum, a prominent Golgi complex, and numerous membrane-bound secretory vesicles. The chief cells secrete PTH from the cytoplasm into the pericapillary spaces by exocytosis.

Calcitonin and PTH-related peptide (PTHrP) are important for calcium regulation in the fetus. In adults and children, calcium-phosphorous homeostasis is regulated principally by vitamin D and PTH.

Parathyroid hormone–related peptide is homologous to PTH in the first 13 amino acids of the amino terminus, of which 8 amino acids are identical. There is no homology with the mid or carboxyl regions. Parathyroid hormone–related peptide is transcribed from a gene on the short arm of chromosome 12, whereas the gene for PTH is located on the short arm of chromosome 11. Parathyroid hormone–related peptide acts on PTH receptors in bone and kidney cells, increases urinary cAMP and production of 1α-hydroxylase involved in production of 1,25-dihydroxycholecalciferol ($1,25[OH]_2D_3$). Parathyroid hormone–related peptide is vital to normal fetal development, and production of PTHrP occurs in nearly every cell type, including every embryonic tissue at some point in development. For instance, production in keratinocytes is important in keratinocyte differentiation and development of hair follicles. Parathyroid hormone–related peptide gene deletion is a lethal error in animal models. Parathyroid hormone–related peptide produced by fetal parathyroids is present in cord blood at three-fold higher levels than that found in adult serum. Parathyroid hormone–related peptide is critical to maternal-fetal calcium transfer, providing the fetal requirement of 30 g of calcium, and is essential for normal fetal skeletal development and maturation. Particularly during the second trimester, maternal absorption of calcium should increase from around 150 to 400 mg daily. Parathyroid hormone–related peptide levels are also increased in lactation. Pasteurized bovine milk, as well as human breast milk, contains PTHrP at levels 10,000 times greater than normal serum.[2]

Whereas PTHrP is increased in benign breast hypertrophy, PTHrP is the most important of tumor-derived factors that act to increase renal reabsorption of calcium and increase osteoclastic bone resorption. Parathyroid hormone–related peptide can be overexpressed in squamous cell carcinomas of the head and neck. Increased circulating PTHrP derived from tumor is associated with paraneoplastic syndrome humoral hypercalcemia of malignancy, occurring in 2 to 10% of all cancer patients, although infrequently reported with head and neck cancer. Attempts to use PTHrP as a tumor marker have not been successful.[60]

The biologic activity of PTH lies in the first 34 residues of its 84 amino-acid chain (9,500 daltons). Secretion of PTH is increased in response to falling serum calcium levels. Parathormone acts on target cells of the kidney and bone via specific transmembrane receptors, activating a transduction pathway involving a G protein coupled to the adenylate cyclase system. In the kidney, PTH stimulates activity of 1α-hydroxylase involved in production of $1,25(OH)_2D_3$. Increased $1,25(OH)_2D_3$, in turn, induces synthesis of calbindin-D, a calcium-binding protein of the intestinal mucosa required for absorption of calcium. 1,25-Dihydroxycholecalciferol is also required for PTH to mobilize calcium by increasing resorption of bone.

Parathormone is synthesized in the parathyroid glands from an initial 115 amino-acid chain, pre-pro-PTH. This is converted to a 90 amino-acid chain, pro-PTH, which is hydrolyzed to PTH as the main secretory product. Once released, PTH is rapidly broken down in the liver and kidney into three smaller fragments, of which the 1 to 34 amino-terminal chain has biologic activity, although present in very small serum concentrations. The existence of these three derivatives is the basis for numerous assays. The carboxyl-terminal chain is more slowly cleared through glomerular filtration and is present at serum levels 50- to 500-fold greater than active hormone. Assay of the carboxyl-end fragment is useful in testing for hyperparathyroidism, although less applicable to evaluate for secondary hyperparathyroidism in patients with renal failure. Differentiation of subnormal concentrations that occur in hypoparathyroidism requires certain specific sensitive RIAs for PTH. Of particular importance is a sensitive 15-minute immunochemiluminometric assay that has been developed for intraoperative use.[2]

With inadequate serum levels of PTH (hypoparathyroidism) and consequential hypocalcemia, convulsive spasms of muscles (tetany) ensue. If laryngeal and respiratory musculature become involved, tetany can cause death. Treatment involves administration of intravenous or enteric calcium and calcitriol or vitamin D, and possibly magnesium.

The most common cause of surgical hypercalcemia is primary hyperparathyroidism, excessive PTH production from a primary defect of the parathyroid glands. Parathyroid adenoma is the cause of primary hyperparathyroidism in 80 to 85% of cases.[61] Symptoms arise from effects on several systems: renal, with polyuria, and renal colic owing to lithiasis; rheumatic, with bone and joint pain; neuronal, with fatigue, memory loss, and depression; and gastrointestinal, with dyspepsia, anorexia, and nausea. Thus arises the medical student's memory aid, rhyming the symptoms: "aching bones, renal stones, mental moans, abdominal groans." In hyperparathyroidism, excessive PTH causes demineralization of bone from calcium ionization. The resultant hypercalcemia may be associated with metastatic or aberrant calcification in vital organs including the kidneys.[2]

Calciphylaxis is a rare disorder typically affecting renal failure patients. This condition manifests in vascular calcification with subsequent skin necrosis, gangrene, and often death from sepsis. Skin lesions arise from acute local calcification beginning with mottled discolorations that indurate. Skin biopsy can establish diagnosis early. Dry gangrene of fingers and toes can occur, and a case of lingual necrosis has been documented. Parathormone is thought to act as a tissue sensitizer leading to soft tissue changes. Survival is 65% when parathyroidectomy is used to control this complicated condition compared with 35% without surgery.[62]

Management of Hyperparathyroidism

The majority of patients in the United States with primary hyperparathyroidism are asymptomatic. The usual treatment is surgical removal of the abnormal parathyroid gland(s). There is currently no effective medical treatment. Oral phosphate administration is dangerous with the risk of metastatic calcification. Estrogen therapy in postmenopausal women with mild hyperparathyroidism decreases serum calcium concentrations slightly without changing PTH levels. Although bisphosphonates can inhibit bone resorption, they have had, at most, a transient effect. Parathyroid cells have a calcium-sensing receptor that regulates synthesis and secretion of PTH. When stimulated by increased extracellular calcium, the activated receptor signals the cell via a G protein–transducing pathway that raises intracellular calcium concentration and inhibits secretion of PTH. This has encouraged a search for calcimimetic drugs that might serve to inhibit parathyroid cell function by activating the calcium receptor. One such molecule is phenylalkylamine (R)-N-(3-methoxy-alpha-phenylethyl)-3-(2-chlorophenyl)-1-propylamine or R-568. This drug inhibits secretion of PTH in postmenopausal women with mild primary hyperparathyroidism with a consequential decrease in serum calcium. There is also an associated hypercalciuric response, presumably from alleviation of parathormone-driven, renal tubular resorption of calcium.[63] Such drugs may lead to medical treatments, which can lower serum calcium and PTH secretion without surgery.

Indications for parathyroidectomy with hypercalcemia include serum calcium levels consistently greater than 1 to 1.4 mg/dL above normal in patients under 50 years of age (eg, serum calcium

12.0 mg/dL); calcium renal calculi, urinary calcium greater than 400 mg/24 hours, or reduced renal function; bone density greater than 2 standard deviations from normal; or coexisting disease that would make observation inappropriate. Assessment of bone density has become more accurate, and bone density improves up to 20% after parathyroidectomy. Certainly, parathyroidectomy prior to development of serious bone demineralization is beneficial. Improvement in glucose control attendant to parathyroidectomy suggests that diabetic patients with hyperparathyroidism should have surgery. Surgical treatment for nonspecific symptoms such as weakness and fatigability is debatable.[64]

Preoperative scanning with ^{99m}Tc-sestamibi scintigraphy has become the preferred localization study. Sestamibi scan can also be done intraoperatively, as described in more detail below.[65] These scans are low cost, specific, and sensitive. Accurate localization allows parathyroidectomy of the specific abnormal gland. This diagnostic tool has not reduced the failure rate of parathyroidectomy as sestamibi scans can miss multiglandular disease and have a small rate of false-positive results. Nonetheless, sestamibi scans are necessary for unilateral or focused parathyroidectomy and useful in patients with thyroid disease or previous thyroidectomy.

Parathyroid Masses

There have been relatively few clinically significant though nonfunctional cysts of the parathyroid glands. Typically, these solitary masses average 4 cm in diameter and present in the region of the inferior aspect of either lateral thyroid lobe, which is pushed forward by the cyst. Generally, these cysts are relatively avascular and "shell out" surgically. They can occur in all ages after childhood and without sexual predilection. Such cysts may be asymptomatic or may cause tracheal deviation, symptoms of respiratory restriction, or even hoarseness owing to pressure on the recurrent laryngeal nerve. It is fairly rare for benign, noncystic parathyroid lesions to present as palpable masses; however, up to 45% of parathyroid carcinomas are reportedly palpable.[66] Parathyroid carcinoma is rarely encountered but can be associated with uncontrollable hypercalcemia with metastases. Only 0.017% of cases of hyperparathyroidism arise from parathyroid carcinoma.[64] Parathyroid carcinoma should be surgically excised with appropriate margins of normal tissue and regional dissection as necessary.

Surgical Techniques

Total Thyroid Lobectomy and Isthmusectomy

The patient is placed in a supine position on a shoulder roll with hyperextension of the neck. A transverse incision is made through skin and platysma muscle in the anterior neck within 3 cm above the suprasternal notch and extended laterally as necessary. Hereafter, meticulous hemostasis should be maintained throughout the procedure. By subplatysmal dissection, skin flaps are developed vertically from the sternoclavicular border to the eminence of the thyroid cartilage and laterally from the midline to the anterior border of the sternocleidomastoid muscle. The strap muscles, sternohyoid and sternothyroid, are divided vertically in the midline as needed for exposure; dissection progresses in the plane of the pretracheal fascia, allowing retraction of the strap muscles to expose the true capsule of the isthmus and entire lateral lobe on the superficial surface. Superiorly and laterally, this requires dissection underneath the sternocleidomastoid muscle (Figure 63–3). The middle thyroid vein, if present, may be divided and ligated at the lateral border of the lateral lobe of the thyroid gland at this time. Dissection of the deep surface of the thyroid gland begins inferiorly and laterally with exposure of the main trunk of the recurrent laryngeal nerve. This is bounded by a triangle consisting of the trachea and esophagus medially, the common carotid artery laterally, and the inferior border of the thyroid gland superiorly. The apex of this triangle faces inferiorly, and blunt dissection begins at this area. The recurrent laryngeal nerve is at a depth at or just anterior to the tracheoesophageal sulcus and may lie in the sulcus or several centimeters lateral to it. Occasionally, the right laryngeal nerve enters the triangle laterally from behind the common carotid and passes superiorly and medially in an oblique course. Because the esophagus lies to the left of midline, the left recurrent laryngeal nerve may be close to the esophagus.

The parathyroid glands should now be identified. They appear as vascular, brownish fat. Whereas the inferior parathyroid glands have a variable location, the superior parathyroid glands are located more consistently at the midportion of the deep sur-

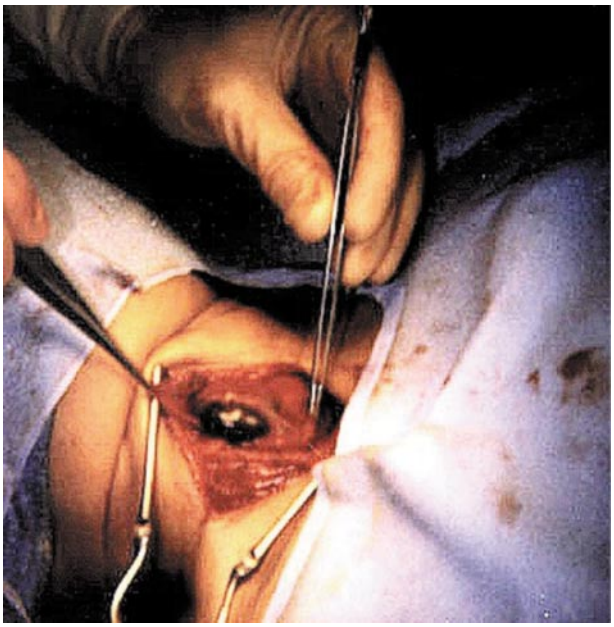

FIGURE 63–3. Photograph from hemithyroidectomy for a predominantly right-sided goiter displacing the trachea to the left and causing dysphagia. Cephalad is toward the left edge of the image. The transverse skin incision has been made and skin-platysma flaps are held back with a self-retaining retractor. The strap muscles have been divided in the midline, and the goiter has just become visible as a dark, largely cystic mass.

face of the thyroid lobe. As the dissection progresses, the inferior thyroid vein is divided and ligated. With the recurrent laryngeal nerve identified, the inferior thyroid artery is now divided and ligated close to the gland to avoid damaging the blood supply to the parathyroid gland.

The isthmus is now transected on the contralateral side and oversewn with a running 0 silk suture. The anterior suspensory ligament is transected, freeing the superior border of the isthmus and superior pole medially from the cricoid cartilage (Figure 63–4). With the course of the recurrent laryngeal nerve exposed nearly to the superior border of the thyroid lobe, the posterior suspensory ligament is identified by lateral retraction of the lobe. The recurrent laryngeal nerve runs between leaves of this ligament or deep to it (Figure 63–5). As with dissection of the facial nerve, the recurrent laryngeal nerve should be exposed and in full view when dividing any tissue.[67] The posterior ligament is sharply transected close to the trachea and cricoid cartilage. The gland may be adherent in this area,

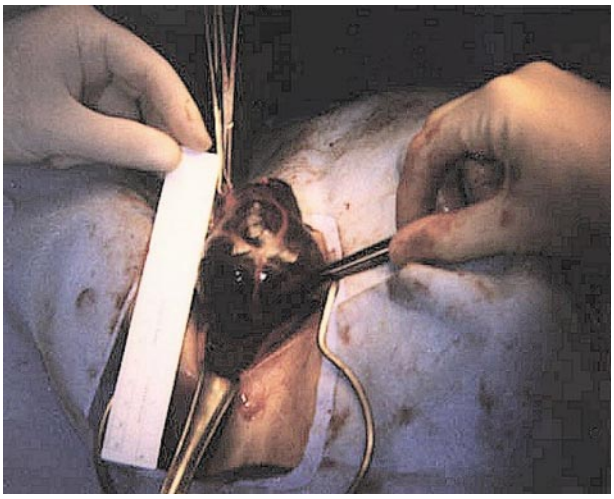

FIGURE 63–4. The right thyroid lobe has been dissected laterally and inferiorly and an isthmusectomy has been performed. Cephalad is toward the left edge of the image. The lobe is still attached by Berry's ligament and the pedicle of the superior thyroid artery and vein. At this point, the tumor is nearly delivered from the field, although injury to the superiormost aspect of the recurrent laryngeal nerve could occur until release from Berry's ligament.

and a postoperative scan often reveals uptake from residual gland.

The parathyroid glands may be superficial to the recurrent laryngeal nerve in the plane of dissection or even attached or contained by the thyroid capsule; therefore, it is prudent to examine the capsule after removal of the thyroid lobe. Parathyroid glands may appear as dark tissue suggestive of a subcapsular hematoma. Parathyroid tissue sinks in saline, which provides an intraoperative means to test suspect tissue. Frozen section of a small portion of the tissue in question should be used to confirm the presence of a parathyroid gland. If a parathyroid gland is unintentionally removed, reimplantation, as described later, is recommended.

At this point, the superior thyroid artery and vein should be skeletonized by blunt dissection while held on tension with slight downward traction of the thyroid lobe. The veins and arteries should be ligated separately with free ligatures to avoid superior laryngeal nerve injury and arteriovenous fistula. To avoid injury, some recommend that the superior laryngeal nerve be skeletonized with periapical dissection in the visceroverterbral angle.[68] It is possible

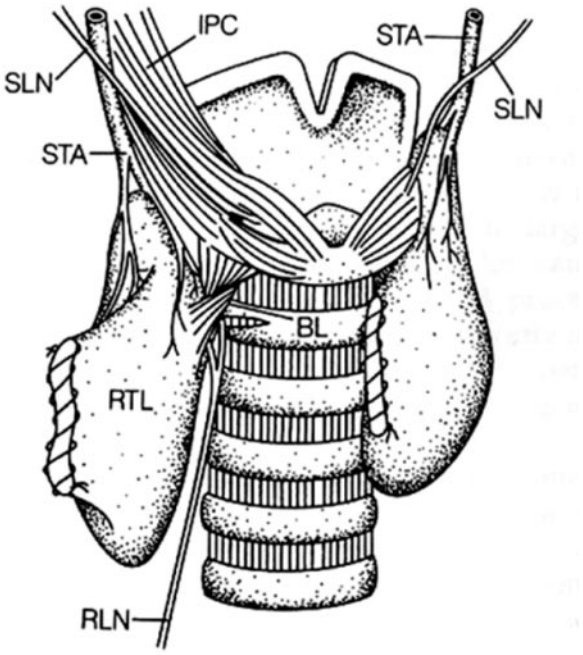

FIGURE 63–5. Total thyroid lobectomy and isthmusectomy, oblique view. The right thyroid lobe (RTL) and isthmus are under traction laterally and inferiorly, which tends to separate the superior thyroid artery (STA) from the external branch of the superior laryngeal nerve (SLN). Note the relation of the superior pole of the lateral lobe to the inferior pharyngeal constrictor (IPC). The recurrent laryngeal nerve (RLN) often branches as it runs deep to or through the posterolateral suspensory (Berry's) ligament (BL).

to find thymus tissue attached to the superior pole of the thyroid gland. The lateral lobe and isthmus are then removed from the surgical field.

Figure 63–6 demonstrates the right recurrent laryngeal nerve following hemithyroidectomy to remove a right-sided goiter (Figure 63–7). In certain situations, the recurrent laryngeal nerve is appropriately sacrificed. These situations include ipsilateral vocal cord paralysis with reasonable certainty of malignant disease grossly invading the nerve, so the patient's life would be compromised by preserving the nerve.

Assuming that the parathyroid glands have either been preserved or reimplanted, the wound is closed in layers, with good cosmetic technique. Suction drainage of the surgical field is practiced by most surgeons, usually through a separate stab incision. Postoperative management without drainage of the surgical field has been reported in large numbers without evidence of increased risk, however.[69,70] Some surgeons perform flexible fiberoptic endoscopy in the operating room immediately following extubation to document intact laryngeal motor function.

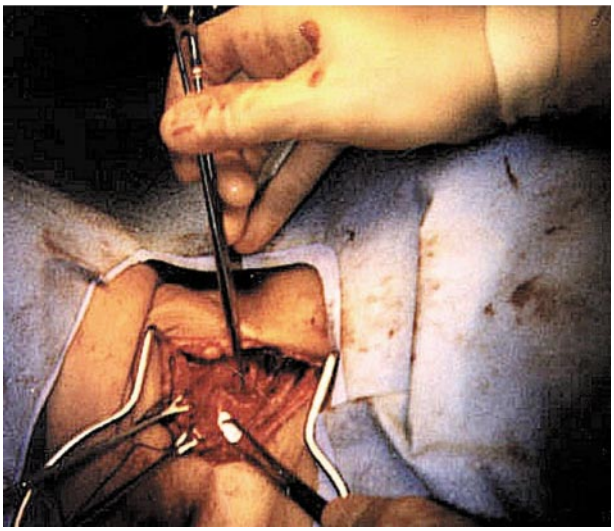

FIGURE 63–6. The lobectomy and isthmusectomy are completed. Cephalad is toward the left edge of the image. The trachea is being retracted slightly with a hemostat, and, near its tip, the right recurrent laryngeal nerve is demonstrated in the tracheoesophageal groove.

FIGURE 63–7. The dark, largely cystic right thyroid lobe and isthmus after excision, longitudinal dimension approximately 8 cm. Were parathyroid glands not identified, a search for them by subcapsular exploration of the posterior aspect of the specimen would be appropriate, and reimplantation would be performed.

Although cervical incision is usually adequate, in operations for recurrent goiter, very large posterior goiters, or carcinoma requiring mediastinal dissection, sternotomy may be indicated. Recurrent laryngeal nerve injury is more easily avoided in these more challenging cases by the following: systematic identification of the recurrent nerve (see Figure 63–6), avoidance of enucleating the intrathoracic side of the goiter first, and meticulous dissection to avoid stretching the nerve, especially on the left side. Rarely, tracheomalacia secondary to prolonged compression of the trachea by the goitrous mass requires careful postoperative observation.[71]

Technique for Reimplantation of Parathyroid Tissue Parathyroid glands removed inadvertently should be cleaned carefully in saline and diced into small pieces measuring approximately 1 × 1 mm.[72] Up to 40 pieces of parathyroid grafting material may be obtained by this technique. The parathyroid gland may be implanted into the sternocleidomastoid muscle[73] or into the volar surface of the previously prepared and draped nondominant forearm. Small pieces of parathyroid tissue can be implanted into the brachial, radialis, or flexor muscle group, closing the overlying muscle and fascia with interrupted suture of 5-0 mersilene to prevent extrusion and further to serve as a marker for the implantation site. Bleeding in the implantation site should be carefully avoided. The total surface area of the parathyroid transplantation site is generally 5 × 5 cm. This is closed in standard fashion. In the immediate postoperative period, PTH levels can be undetectable but generally recover to preoperative levels within about 2 weeks.[74]

Techniques of Parathyroidectomy Currently, two markedly different techniques of parathyroidectomy are practiced: bilateral, open neck exploration and minimally invasive radioguided parathyroidectomy (MIRP).[75]

Traditionally, surgery for biochemically proven primary hyperparathyroidism involved bilateral neck exploration following the general approach described earlier for thyroidectomy. This technique is still appropriate for parathyroid hyperplasia or clinical situations in which MIRP is contraindicated. At least 97% of parathyroid glands can be reached through the neck, so mediastinal dissection is seldom necessary. The safest neck exploration is performed in a highly controlled, bloodless surgical field. The inferior thyroid artery is usually preserved and often provides the main blood supply to adenomas. The lateral thyroid lobe is reflected medially and anteriorly to gain access to the posterior capsule and prevertebral fascia.

For management of solitary parathyroid adenoma, unilateral, focused parathyroidectomy is a rapidly advancing and appealing alternative. Currently, only about 50% of patients are candidates for focused parathyroidectomy. Several important technological tools have become available to the parathyroid surgeon that make unilateral surgery feasible: imaging of parathyroid tissue by ^{99m}Tc-MIBI scintigraphy,[76] use of an intraoperative gamma probe,[75] and intraoperative rapid PTH assay.

By 1997, endoscopic approaches to neck exploration and parathyroidectomy had been developed in animal models and were applied to human cadavers.[77] In early 1998, successful endoscopic parathyroidectomy with resection of 3^1/$_2$ parathyroid glands for hyperplasia was reported.[78] Published 1 month earlier was a report of four patients with parathyroid adenoma removed by unilateral endoscopic parathyroidectomy. In each patient, preoperative localization imaging techniques had been applied, and endoscopic exploration took place through one 11 mm and two 5 mm ports. The adenoma was endoscopically located and successfully removed in each case with rapid correction of hypercalcemia. The patients did not require analgesics, and the scars were cosmetically minimal, with excellent patient acceptance.[79] Subsequently, there has been a plethora of reported experience worldwide with endoscopic parathyroidectomy by various techniques, including "pure" endoscopic approaches using constant gas insufflation and video-assisted gasless techniques, unilateral approaches via neck or extracervical (thoracic or axillary) ports, and bilateral endoscopic explorations by anterior chest incisions. The postoperative pain is generally very limited. Cosmetically, visible surgical scars are minimized or essentially avoided.[80] Application of intraoperative sestamibi scans by gamma probe further facilitates endoscopic localization of adenoma with or without video imaging in minimally invasive surgical fields. Focused parathyroidectomy and, in particular, MIRP have made outpatient parathyroidectomy possible for

many patients.[81] Operating time by MIRP is comparable to that of open parathyroidectomy, with a typical report stating mean duration of 65 to 84 minutes with a range from 30 to 180 minutes.[82,83]

The following situations may present contraindications to MIRP: presence of coexisting nodular thyroid disease, previous neck surgery or irradiation, suspicion of parathyroid hyperplasia, history of familial primary hyperparathyroidism, or other anatomic or medical contraindications. In one report, one in six patients undergoing MIRP required conversion to open parathyroidectomy.[84] Other authors reported greater success, however, emphasizing it to be a feasible surgical procedure with normal postoperative serum calcium and PTH levels in all cases, reduced postoperative pain compared to conventional parathyroidectomy, and an acceptable length of operating time and cosmetic results.[82,83]

Strictly speaking, MIRP involves use of a handheld intraoperative detector such as the Navigator miniature handheld probe, which can be used for endoscopic procedures to guide the surgeon to a parathyroid adenoma. This requires injection of 20 mCi ^{99m}Tc sestamibi 2 hours preoperatively and performing a parathyroid scan. If the scan confirms a single adenoma, patients are taken to the operating room straight away, and a general anesthesia or local anesthesia with sedation is administered.[85]

The procedure by a lateral neck approach begins with a 15 mm transverse skin incision on the anterior border of the sternocleidomastoid muscle. The fascia connecting the thyroid lobe and lateral aspect of the strap muscles is divided adequately to permit visualization of the prevertebral fascia. After the surgical field is adequately opened, three trocars are inserted: a 12 mm trocar through the incision and two 2.5 mm trocars, one above and one below the larger trocar. Carbon dioxide is insufflated at 8 mm Hg. Unilateral, parathyroid exploration is performed through a 10 mm 0-degree videoendoscope. Magnification afforded by the fiber-optic system is excellent for identifying structures in the neck. The working space in an endoscopic surgical field is usually adequate as long as good hemostasis is maintained. Endoscopic mobilization of the lateral thyroid lobe for access to the tracheoesophageal groove can be technically difficult. The handheld probe is used to guide the surgeon to the adenoma. With the adenoma identified, trocars are withdrawn. Working directly through the skin incision, the lateral thyroid lobe is retracted medially and the adenoma is excised, clipping its pedicle.[83] Review of the literature suggests that most surgeons conclude the procedure once the adenoma is excised. However, one recommends identification and biopsy of the second gland on the same side and, if normal, concluding the operation. If the second nonadenomatous gland is histologically abnormal or if the ^{99m}Tc sestamibi scan suggests multiple lesions, then bilateral neck exploration is recommended.[86]

Although expensive, intraoperative rapid PTH assay is helpful in focused parathyroidectomy. Excision of sufficient abnormal parathyroid tissue is correlated with assays performed prior to incision, and at 5 and 10 minutes after excision, that demonstrate a measured decrease of 59%. Intraoperative rapid PTH assay is most reliable in treatment of a single adenoma but is not as reliable in parathyroidectomy for hyperplasia.[6]

Sestamibi has good affinity for hyperfunctioning parathyroid lesions as *hot nodules*. A two-phase protocol with early (10 minutes) and late (120 minutes) imaging is used. Lesions with mass greater than 250 mg are detected with this scintigraphy (sensitivity 85 to 90% with a specificity of nearly 100%), although hyperplastic glands are not imaged as effectively as adenomas. This modality is better than ultrasonography (sensitivity 82.9%) to detect ectopic parathyroid tissue and recurrent disease. It is also superior to imaging by other radionuclide tests such as subtraction thallium 201 (sensitivity 84.6%), ^{99m}Tc pertechnetate, or tetrofosmin scanning.[61,87,88] A reduced time-window scan is recommended for patients with a high degree of suspicion for parathyroid adenoma not visualized by a standard sestamibi scan. In one study in which 3 of 31 patients with adenomas had negative ^{99m}Tc-sestamibi scans, reduced time-window scans, single-view scans at 15, 30, 45, and 120 minutes, and tomograms at 60 minutes revealed two of three adenomas that would otherwise have escaped detection.[89] Whereas preoperative localization can be achieved in 85 to 90% of cases, sensitivity can be boosted to 95% using the ^{99m}Tc-sestamibi SPECT technique and a three-dimensional, volume-rendered reprojection for visualization.[76]

In one experience, 44% of patients were discharged on the day of MIRP and 83% within 23

hours after the neck exploration.[75] Another author reported 65% of MIRP patients discharged within 5 hours of surgery compared to a mean stay of 1.35 days in traditional, open parathyroidectomy.[85] Further, comparison of charges for traditional open neck exploration revealed lower costs for MIRP owing to decreased duration of the operation, anesthesia, and hospitalization and elimination of the need for histologic evaluation of frozen sections by use of intraoperative rapid PTH assay. Numerous authors concluded that MIRP is a logical approach to primary hyperparathyroidism owing to solitary adenoma.[85,90,91]

In one study of previously operated necks, preoperative ^{99m}Tc-sestamibi scanning and ultrasonography localized only 64% of hyperfunctioning glands. Intraoperative ^{99m}Tc-sestamibi scanning was found in several studies to localize correctly at least 91% of hyperfunctioning glands. Intraoperative sestamibi scan was recommended as a helpful and effective guide for exploration in necks with previous parathyroidectomy.[65,75]

Recently, intraoperative assessment of adequacy of parathyroidectomy has been made by intraoperative radioactivity ratios. Sestamibi injection is administered 3.5 to 1.5 hours preoperatively. After excision, tissue samples are counted, and a simple percentage of background radioactivity is calculated. Whereas other tissues contained at most 2% of background, hyperplastic parathyroids contained 7.5% ± 0.8%, with a maximum of 16%. Adenomas contained 59% ± 9%, with a range from 18 to 136%. This method eliminates the necessity of histopathologic evaluation of frozen sections of specimens.[92]

With successful localization, minimally invasive surgery with or without video assistance can be performed feasibly under local or general anesthesia with a high success rate. For multiglandular disease, however, neither rapid intraoperative PTH assay nor the sestamibi scan is as accurate. Even in difficult cases of reoperation, the overall success rate has not improved despite these techniques. Nonetheless, it appears that MIRP will remain important as an established though evolving technique for parathyroidectomy, especially for parathyroid adenomas.[6,92]

Complications of Thyroid Surgery

Complications of thyroid surgery and parathyroidectomy are best avoided by a thorough working knowledge of the anatomy and embryology of the visceral compartment of the neck, careful preoperative planning, and excellent surgical technique.[93] Although numerous reports advocate subtotal thyroidectomy, total lobectomy (uni- or bilateral) is recommended in most situations. Although improved local control of disease is achieved with more radical procedures, no convincing evidence of improved survival exists.[94] General anesthesia is most commonly used, and it is important for the surgeon to be present at induction to secure an airway by emergency open bronchoscopy or tracheostomy if the patient has respiratory embarrassment owing to a large goiter. A trend exists toward increased use of local anesthesia and outpatient surgery for thyroid procedures. No significant difference is found in the rate of major complications for hemithyroidectomy performed under local anesthesia as compared with general anesthesia.[95]

Thyroid operations including total thyroidectomy have been performed in large numbers as outpatient or short-stay procedures in several centers in the United States and Europe. Extensive perioperative patient teaching is required for the layperson to recognize and react properly to the symptoms and signs of surgical complications. More complex procedures such as reoperation, neck dissection, and sternal splits are more safely managed on an inpatient basis.[96]

Good exposure is an absolute necessity. Collar incisions allow the best cosmetic result for the exposure needed. In some cases, exposure is improved by division of the strap muscles approximately halfway between the hyoid bone and the sternum. This avoids injury to their innervation from the ansa cervicalis. Early in the operation, the trachea should be exposed caudal to the isthmus so emergency access to the airway can be obtained in the event of obstruction.

Exposure of the recurrent laryngeal nerve is mandatory when a lateralized procedure is performed. The nerve should be preserved from the thoracic inlet to its entry into the larynx at the cricothyroid membrane. Unilateral laryngeal nerve injury is reported in 2.3% of cases, largely because of lack of nerve identification.[97] One must remember that at least 1 in 400 cases may not have a recurrent nerve. An anomalous inferior laryngeal nerve occurs almost always on the right and is always associated with an anomalous retroesophageal subclavian

artery, that is, a right subclavian artery arising from the left descending aorta. In these cases, the inferior laryngeal nerve passes directly from the vagus to the larynx. Digital subtraction angiography can confirm this anomaly and is recommended in any reoperation on the right side of the thyroid, especially if the nerve was not identified in the previous surgery.[98]

Iatrogenic injury to the superior laryngeal nerve occurs in 2.4% of patients undergoing surgery in the thyroid periapical region. Such injury can cause temporary or permanent change in voice quality or deglutition. Mobilization of the viscerovertebral angle can provide access to the superior laryngeal nerve, and use of a nerve stimulator can be made in difficult situations to minimize the risk of this complication.[68]

If reoperation is required within 2 weeks, anatomic landmarks will be obliterated because of the inflammatory response. Blunt dissection should be used, although if the reoperation is months to years later, fibrosis often requires sharp dissection. Operating away from the primary site of surgery is recommended. The risk of morbidity is roughly doubled in a second thyroidectomy procedure.

Hemorrhage is usually not a problem. The lowest thyroid artery is divided and ligated first and then the middle thyroid vein if present. The inferior thyroid artery is best divided near the capsule of the gland to prevent injury to the sympathetic trunk (with a resultant Horner's syndrome) and to preserve blood supply to the parathyroid glands. On the left, the thoracic duct can be injured, with resulting chyle fistula. The safest way to divide the superior laryngeal artery and vein is with careful downward traction and skeletonization of the vessels. Caution is advisable if retraction stretches or places pressure on the carotid artery because this has been associated with embolic occlusion of the retinal artery.[99]

Infection occurs in less than 1% of thyroidectomies; however, suction drainage is traditionally recommended to prevent hematoma. Some surgeons have experienced no increased risk by not placing drains or using drainage only in select cases.[69,70] Tracheostomy may be necessary because of tracheal malacia or injury to the recurrent laryngeal nerves. If necessary, a suture can be placed in the second tracheal ring and brought out through the wound as a quick guide to the anterior tracheal wall. Rarely, pneumothorax can occur, and a postoperative chest radiograph is recommended.

Postoperative hemorrhage occurs in fewer than 1% of patients. The resulting hematoma remains in the midline below the strap muscles, creating an increasing pressure and causing collapse of the airway and respiratory embarrassment. In this event, the wound must be opened immediately "wherever you are." Thereafter, the patient can return to the operating room for re-exploration, control of the bleeding vessel, and repeat closure of the wound. Subsequently, edema of the airway can be expected and may require tracheostomy. Tracheostomy may also be necessary in the presence of marked tracheal malacia secondary to large goiter or for incomplete resection of cancer with anticipated postoperative radiation therapy, as in patients with anaplastic carcinoma. The need for elective tracheostomy to prevent postoperative airway obstruction occurs in less than 1% of patients.

During thyroidectomy, the parathyroid glands should be looked for and protected when found. In one-fourth of thyroidectomies, the patient has a transient mild decrease in serum calcium, which is generally asymptomatic. This is probably caused by trauma to the glands and their blood supply. Transient hypocalcemia can be severe in 8% of patients over the first 96 hours postoperatively.[100] Thus, the critical period for calcium monitoring is 24 to 96 hours postoperatively. If calcium infusion is not required within the first 72 hours, it will probably be unnecessary. It is also important to monitor serum magnesium levels postoperatively and correct as necessary.[101] Permanent hypoparathyroidism occurs in up to 8% after total thyroidectomy.[97]

Tetany with hypocalcemia can be treated with calcium gluconate intravenously or calcium carbonate orally in patients without achlorhydria. In patients with achlorhydria, calcium lactate in water and often vitamin D are required.

Myxedema can occur in 4 to 6 weeks after a thyroidectomy, particularly if the gland has been totally ablated. Hashimoto's disease also progresses to hypothyroidism eventually. This can be treated with a variety of drugs for thyroid replacement. Some of these include 2 to 3 g of desiccated thyroid extract, up to 0.2 mg of tetraiodinated levothyroxine sodium (Synthroid), or 25 to 75 μg of triiodinated liothyronine sodium (Cytomel) daily. Treatment by thyroid replacement may be achieved with T_4 alone. However, it has been suggested that partial substitution of T_3 may actually improve

mood and neuropsychological function, especially in patients who still do not feel well despite apparently adequate levels of T_4. Administration of 10 μg of T_3 to enough T_4 to ensure a euthyroid state is recommended.[6] The greatest cause of death in the past was thyroid storm, which can now be effectively controlled. The mortality rate of thyroidectomy today is approximately 0.1%.

Complications of Parathyroid Surgery

Complications of open exploration-type parathyroidectomy are essentially the same as those described for thyroidectomy except for problems arising from ablation of thyroid tissue. For MIRP, regarded as a safe and effective method of parathyroidectomy, the complication rate is described as low. One author reported only minor local complications occurring in 8% of patients.[75] Problems associated with MIRP can include hemorrhage or hematoma, infection, scarring, subcutaneous emphysema (although this is less likely with a gasless endoscopic approach), recurrent laryngeal nerve injury, failure to locate the parathyroid gland of interest (eg, in a previously operated neck), and, conceivably, pneumothorax.

CHAPTER 64

Laser Surgery in the Head and Neck

Lou Reinisch, PhD, Robert H. Ossoff, MD

The use of lasers in otolaryngology has resulted in the addition of new surgical procedures and the refinement of conventional surgical procedures. The carbon dioxide laser is still the most commonly used laser for surgery of the upper aerodigestive tract. The use of the carbon dioxide laser for treating lesions of the oral cavity, pharynx, larynx, and tracheobronchial tree has been facilitated by previous experience with the techniques of endolaryngeal microsurgery.[1] The introduction of the microspot for carbon dioxide laser microsurgery has further refined the use of the carbon dioxide laser for endoscopic surgery.[2,3] The superpulsed carbon dioxide laser and the argon and the potassium titanyl phosphate/532 (KTP/532) lasers are being used for stapedotomy with increasing frequency.

The neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, with and without contact probes, continues to be used for obstructing lesions of the tracheobronchial tree[4,5] and for cavernous hemangiomas of the head and neck.[6] The use of the Nd:YAG contact probes for head and neck surgery is still being explored. The KTP/532 laser has been used by many otolaryngologists for pharyngeal tonsillectomy, although there appear to be no major benefits of using the laser over conventional techniques in routine tonsillectomies.[7–10] The continuous and flash-pumped yellow dye lasers are used to treat port-wine stains with excellent results.[11–13] The concept of photodynamic therapy (PDT) to treat malignancies of the upper aerodigestive tract is still under active investigation.[14–34]

It is apparent that many lasers are being used in otolaryngology for a wide variety of surgical diseases. This chapter focuses on these lasers and their potential uses. The laser is not a panacea, but when it is used to advantage for a specific disease process, an improvement in patient care may be expected.

LASER BIOPHYSICS

LASER is an acronym for light amplification by the stimulated emission of radiation. A laser is an optical device containing three fundamental parts. First, there is the laser medium. In the first laser made, the laser medium was a ruby crystal.[35] Second, there is an excitation source. In the first laser made, the excitation source was the flash from a camera. Third, one needs two mirrors to provide the optical feedback, involving a laser medium, an excitation source, and a resonant cavity.[36,37]

What happens in the lasing process can be explained in the following series of steps. The lasing medium (eg, the ruby crystal) is placed between two parallel mirrors facing each other, as shown in Figure 64–1. The lasing medium is then excited. The excitation, perhaps from the flash lamp or from an electrical arc, will promote the molecules or atoms in the lasing medium from the ground state up to an excited state.

Atoms or molecules in an excited state will return to the lower energy state in the process that is called "spontaneous emission." In spontaneous emission, the excited atoms or molecules spontaneously decay from their excited state to their lower energy states. The energy is emitted as light. The emission is in all directions, and some of the emission can be reflected back into the laser medium.

If the light is reflected by the mirror and reenters the laser medium, the light can then stimulate additional radiation. In other words, as the light travels through the lasing medium, if it finds a mol-

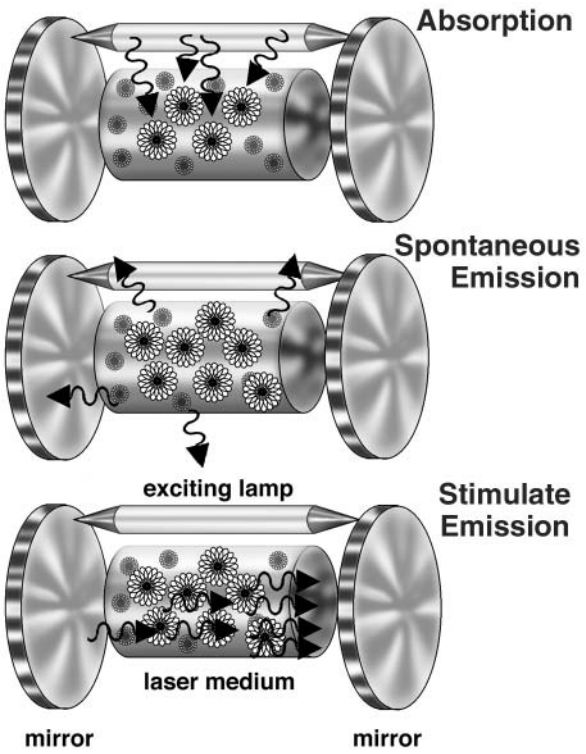

FIGURE 64–1. Schematic illustration of the laser, showing the mirrors, the laser medium, and the exciting lamp. Light from the lamp can excite atoms in the medium through the process of absorption. The excited atoms can return to their ground state and emit the absorbed energy as light in a process called spontaneous emission. If emitted light interacts with other atoms in the excited state, it will stimulate them to return to their ground states and emit light in a process called stimulated emission. The amplification of the light by stimulated emission is the basis for the laser.

ecule or an atom in an excited state, it will tickle or stimulate that atom to release its energy and make the transition to the ground state. So one wave of light becomes two waves of light. Both of these waves of light continue to propagate through the lasing medium. To achieve a net amplification of the light, more atoms or molecules must be in the excited state than those in the ground state. This is termed a "population inversion."

The stimulated emission continues as the light reaches the front mirror and then is reflected back through the laser medium yet another time. The stimulated light is emitted in the same direction as the incident light, so all of the rays of light are parallel. The light continues to be amplified by the stimulated emission as long as more atoms or molecules are in the excited state than the ground state. The "population inversion" is crucial to the lasing process. These events provide the origin of the laser acronym.

The laser light is then released from the resonant cavity by a partially reflecting mirror. A fraction of the light is transmitted out of the laser cavity while the remaining fraction of the light stays in the cavity to maintain the lasing process. The lasing process continues in the resonant cavity as long as the excitation source keeps the molecules or atoms in the laser medium excited. This light is emitted either as a continuous wave or as a pulse depending on whether the excitation is continuous or pulsed.

Typically, surgical lasers have an optical resonating chamber (cavity) with two end mirrors; the space between these mirrors is filled with a lasing medium such as argon, Nd:YAG, or carbon dioxide.[38] The radiant energy emitted is extremely intense and unidirectional or collimated.[39] The light is coherent, both temporally and spatially. Temporal coherence means that the photons alternate sinusoidally in phase with one another, whereas spatial coherence means that the photons are equal and parallel across the wave front. These properties of monochromaticity, intensity, collimation, and coherence distinguish the organized radiant energy of a laser from the disorganized radiant energy of a light bulb.

After emission of the radiant energy through the partially reflective mirror, the laser beam can be passed through a fiber. The fiber allows transmission of the laser energy at the distal end of the fiber. The total internal reflection of the optical fiber causes the collimation of the laser beam to be lost. The result is a divergent beam at the fiber tip.

The laser beam can also be passed through a lens that focuses the radiant energy to a small beam waist, or spot size, ranging from approximately 0.1 to 2.0 mm. The focusing lens is usually treated with special optical coatings to allow the helium-neon aiming beam and the invisible carbon dioxide beam to be focused coplanar. This lens is characterized by a specific focal length that determines the distance from the lens to the target tissue for focused use.

Surgical lasers typically permit end-user control of three variables: (1) focal length spot size

(mm), (2) power (watts), and (3) exposure time (seconds). Power, measured in watts, may be kept constant with widely varying effects, depending on the spot size and duration of exposure. For example, if the time of exposure is kept constant, the relationship between power and depth of tissue injury becomes logarithmic as the spot size is varied.

Power density or irradiance, on the other hand, is a useful way of monitoring the surgical effects of the laser. It is a measure of the power output of the laser in watts over the cross-sectional area of the laser beam in square centimeters (in the equation below, r is the radius of the spot):

$$\text{Power density} = \text{Power (watts)}/\pi \times r^2\ (\text{cm}^2)$$

Furthermore, power density is a measure of the concentration of radiant energy of the laser beam. Here, if the time of exposure is kept constant, the relationship between power density and depth of injury is linear as the spot size is varied. Therefore, surgeons should calculate the appropriate power density for various procedures; such calculations allow the surgeon to control tissue effects predictably when changing from one focal length to another or when using different surgical lasers.

Radiant exposure (RE) or fluence expressed as joules/cm^2 is equal to the power density (watts/cm^2) multiplied by the time of exposure in seconds:

$$\text{RE} = \text{power density} \times \text{time}$$

This is a measure of the total amount of laser energy per unit area of exposed target tissue.

Carbon dioxide lasers can emit radiant energy with different beam configurations that ultimately determine the depth of tissue damage and vaporization across the spot size. Transverse electromagnetic mode (TEM) refers to the intensity distribution over the spot area and determines the shape of the focused laser spot. The most fundamental TEM is TEM_{00}. In this mode, if the laser beam is cut in cross-section, it appears circular, with the power density of the beam following a gaussian distribution (Figure 64–2, A). In other words, the power density is greatest at the center of the beam and diminishes progressively toward the periphery. Thus, the center of the beam can be used for vaporization and the periphery for coagulation.

$TEM_{01}{}^{\star}$ (Figure 64–2, B) and $TEM_{11}{}^{\star}$ (Figure 64–2, C) have a more complex distribution of energy and cause characteristic variations in tissue ablation depth. In fact, there are cold spots in the center of their beams. Additionally, they cannot be focused to as small a spot size as TEM_{00} lasers. Most carbon dioxide surgical lasers manufactured in the last 10 years produce a TEM_{00} beam profile.

Although simple ray diagrams normally show parallel light to be focused to a point, the actual situation is more complicated. A lens will focus a gaussian beam to a beam waist or a finite size. This beam waist is the minimum spot diameter, d, and can be written as

$$d \sim \frac{2 f \lambda}{D}$$

where f is the focal length of the lens, λ is the wavelength of light, and D is the diameter of the laser beam incident on the lens (Figure 64–3). The beam waist occurs not at one distance from the lens but over a range of distances. This range is termed the depth of focus and can be written as

$$\text{depth of focus} \sim \frac{\pi d^2}{2 \lambda}$$

We realize the depth of focus every time we focus a camera. With a camera, a range of objects is in focus, and we can set the focus without carefully measuring the distance between the object and the lens. Notice from the above equations that a long focal length lens (a large f) leads to a large beam waist. A large beam waist also translates as a large depth of focus.

The size of the laser beam on the tissue (spot size) can therefore be varied in two ways. Since the minimum beam diameter of the focal spot increases directly with increasing the focal length of the laser-focusing lens, the surgeon can change the focal length of the lens to obtain a particular beam diameter. As the focal length becomes smaller, there is a corresponding decrease in the size of the focal spot; also, the smaller the spot size is for any given power output, the greater the corresponding power density. The second way the surgeon can vary the spot size is by working either in or out of focus. The minimum beam diameter and highest power concentration occur at the focal plane, where much of the precise cutting and vaporization are carried out (Figure 64–4, A). As the distance from the focal plane increases, the laser beam diverges or becomes defocused (Figure 64–4, B). Here the cross-sectional

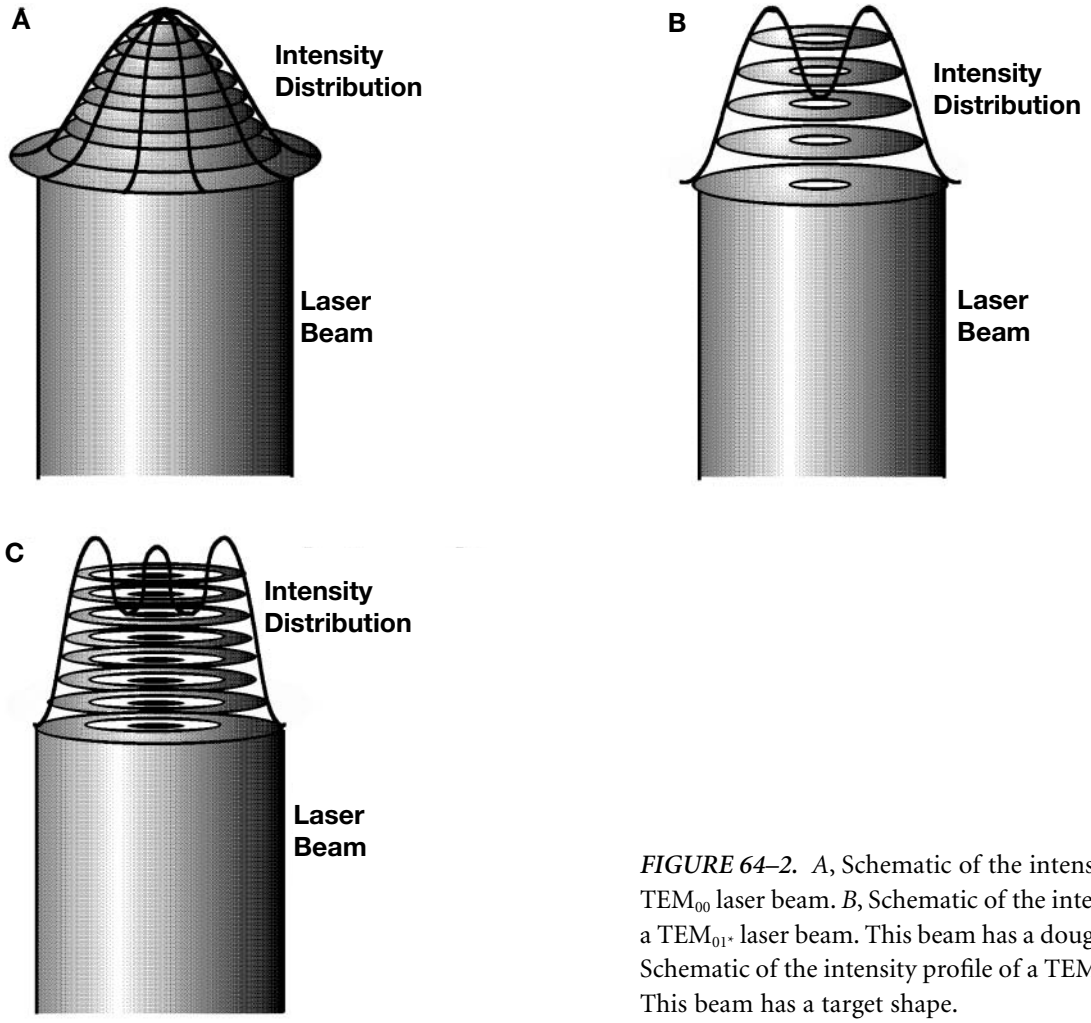

FIGURE 64–2. *A*, Schematic of the intensity profile of a TEM_{00} laser beam. *B*, Schematic of the intensity profile of a TEM_{01^*} laser beam. This beam has a doughnut shape. *C*, Schematic of the intensity profile of a TEM_{11^*} laser beam. This beam has a target shape.

area of the spot grows larger and thus lowers the power density for a given output. As one can readily see, the size of the focal spot depends on both the focal length of the laser lens and whether the surgeon is working in or out of focus.

Figure 64–5 demonstrates these concepts using arbitrary ratios accurate for a current model TEM_{00} carbon dioxide laser. The laser lens setting (focal length) and working distance (focus/defocus) combinations shown here determine the spot size of the laser beam. The height of the various cylinders represents the relative fluence of the light incident on the tissue.

The equations for power density and radiant exposure demonstrate that the surgeon can vary the amount of energy delivered to the target tissue by varying the power output, cross-section area of the beam, and time of exposure. The power output of the typical medical carbon dioxide laser can be varied between 1 and 100 watts. Tissues with less water content require a greater power output to achieve the desired effect.

The use of a fiber to deliver the laser energy to tissue causes the laser beam to lose its collimation (unidirectionality). The result is that the closer the fiber tip is to the tissue, the smaller is the spot size or area of laser energy distribution. As the fiber is moved away from the tissue, the spot size will increase, causing a dilution of the laser energy over the larger area.

The third means by which the surgeon can vary the amount of energy delivered to the target tissue is by varying the exposure time. The longer the tissue is exposed to the laser beam, the greater the amount of radiant exposure (joules/cm^2) that is delivered to the target tissue. The time can be varied by working in either the continuous or the pulsed mode, with the pulse duration ranging from 0.05 to 0.5 second.

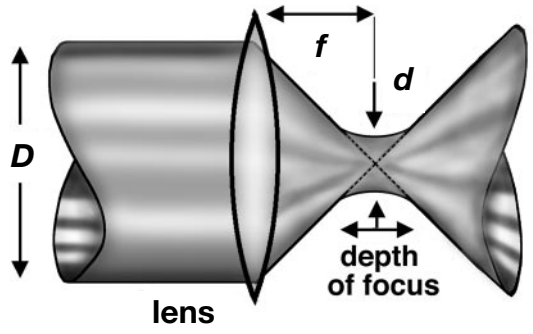

FIGURE 64–3. Schematic of the diffraction limited spot size or beam waist, d, of a parallel beam of light of diameter, D, focused by a lens with a focal length of f.

Laser energy can also be delivered over a short time duration, from milliseconds to femtosecond ranges. A continuous-wave laser can be "pulsed" in the millisecond range. A noncontinuous or pulsed laser can deliver true pulses of laser energy in a duration as short as several femtoseconds (10^{-15} seconds) (Table 64–1). The pulsed laser delivers energy with high peak powers. One needs to visualize a train of pulses with high peaks but short time durations (Figure 64–6). The high peaks are the peak intensities in watts that can be obtained by pulsed lasers. The average power delivered to tissue is expressed by the pulses/second times peak power times the pulse width. On a continuous-wave laser, the meter reads in watts. On a pulsed laser, however, the meter reads in joules (watts times seconds). Pulsed lasers and superpulsing of a continuous-wave laser permit the laser to produce a high peak power. A pulsed Nd:YAG ophthalmologic laser can produce 6.7×10^6 watts per pulse. The pulse duration can be as short as 30×10^{-12} seconds. If we remember that power density or irradiance is the number of watts divided by the area, we can see that the pulsing of the laser permits high wattage with resultant very high-power densities. These high-power densities can cause nonthermal tissue interactions. The flash-pumped yellow dye laser is an example of a pulsed laser used in otolaryngology to treat port-wine stains. Some carbon dioxide lasers and the KTP/532 laser deliver laser energy in a quasicontinuous wave or pulsed mode.

In summary, by varying the power output of the laser unit, the spot size or cross-sectional area of the beam, or the time of exposure, the surgeon can adjust the laser to incise, coagulate, or vaporize the target tissue.

TISSUE EFFECTS

The actual tissue effects produced by the radiant energy of a laser vary with the specific wavelength of the laser used. The interaction of laser energy with

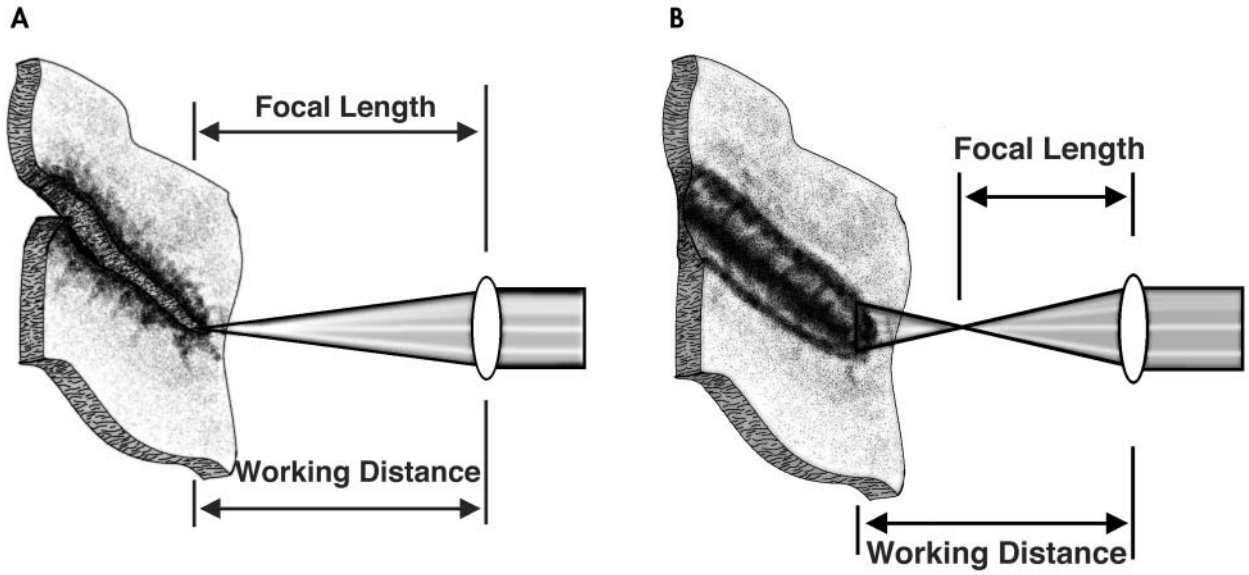

FIGURE 64–4. A, Schematic illustration of the laser incising tissue with the working distance equal to the focal length of the lens. *B*, Schematic illustration of the laser excising tissue with the working distance not equal to the focal length of the lens.

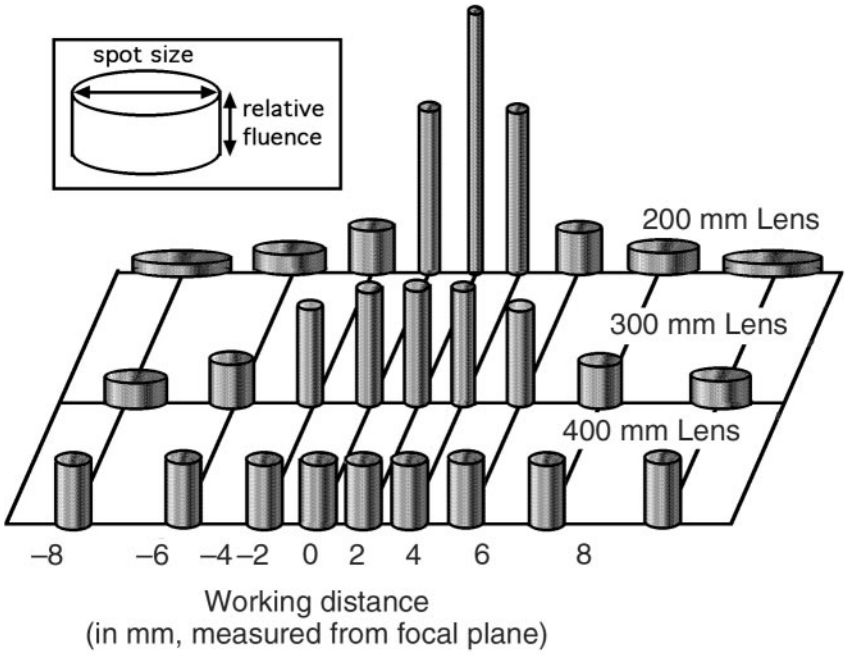

FIGURE 64–5. Graph of the fluence and spot size for three different focal length lenses, working at and near the focal length of the lens. The cylinder diameter is proportional to the spot diameter for a current model carbon dioxide laser. The height of the cylinder is proportional to the fluence of the laser. The lowest fluence has arbitrarily been set equal to one.

living tissue can produce three distinct reactions. First, the laser energy can be absorbed by chromophores within the tissue. The resulting effect can be the production of heat. This is the thermal effect seen in most conventional laser systems in use today.

Second, the radiant energy of a laser can stimulate or react with specific molecules within a cell. This reaction can cause a chemical change to occur within the cell. This effect is termed photochemical. An example is the reaction that occurs with injection of a photosensitizing drug into tissue and the biochemical effect that is produced when the drug is activated by the stimulating effect of radiant laser energy.

Third, the use of short pulses of high-wattage laser energy can disrupt cellular architecture because of the production of sound waves or photoacoustic shock waves.[40–42] The mechanical disruption of tissue is an example of a nonthermal tissue effect.

The radiant energy of a laser can interact with tissue in four ways. The radiant laser energy can be transmitted through the tissue with little of the energy absorbed by the surrounding tissue. The first interaction is transmission. The transmission of laser energy can be understood by remembering the effect of argon laser energy on water. The energy of the argon laser passes through or is transmitted through clear liquids without being absorbed significantly. The second interaction is absorption. The absorption of laser energy by tissue is a complex process depending on the laser wavelength and the color of the tissue. The length of the laser wavelength and the amount of color have an effect on energy absorption. The carbon dioxide laser is essentially colorblind. The visible lasers, however, are color dependent in energy absorption. The third interaction is scattering. Laser energy is also scattered for-

TABLE 64–1. Time Scales

1 second (s)					
1 millisecond (ms)	10^{-3} s				
1 microsecond (μs)	10^{-3} ms	10^{-6} s			
1 nanosecond (ns)	10^{-3} μs	10^{-6} ms	10^{-9} s		
1 picosecond (ps)	10^{-3} ns	10^{-6} μs	10^{-9} ms	10^{-12} s	
1 femtosecond (fs)	10^{-3} ps	10^{-6} ns	10^{-9} μs	10^{-12} ms	10^{-15} s

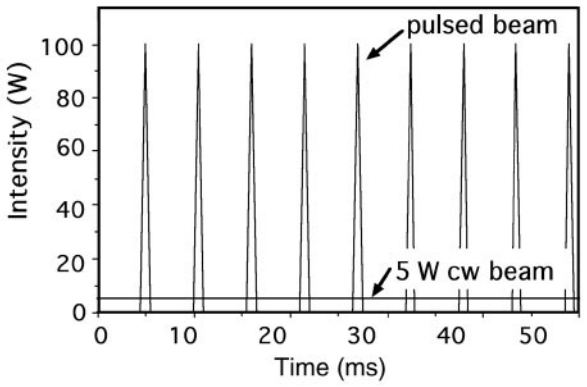

FIGURE 64–6. Schematic of the temporal profile of a continuous-wave laser and a pulsed laser. The continuous-wave laser produces a constant 5 W laser output. The pulsed laser produces pulses of light, each 100 W in peak intensity and on for 5 ms with a repetition rate of approximately 18 Hz.

ward into tissue and backward away from tissue. The scattering coefficient depends on the wavelength. The shorter the wavelength, the more strongly scattered is the laser energy. Therefore, the laser energy of visible lasers is more strongly scattered than for lasers in the infrared region of the electromagnetic spectrum. The last laser tissue effect is reflection of laser energy from the tissue surface in addition to limiting the penetration of the laser into the tissue.

The radiant energy of a laser produces a thermal effect when it is absorbed by the tissue and converted to heat.[43–45] When the target absorbs a specific amount of radiant energy to raise its temperature to approximately 60° to 65°C, protein denaturation starts to occur. Blanching of the tissue surface is readily visible, and the deep structural integrity of the tissue is disturbed. When the absorbed laser light heats the tissue to approximately 100°C, vaporization of intracellular water occurs. This causes vacuole formation, cratering, and tissue shrinkage (Figure 64–7). Carbonization, disintegration, smoke, and gas generation with destruction of the laser-radiated tissue occur at several hundred degrees Celsius.

If the radiant energy is poorly absorbed by the target tissue, excess thermal damage to adjacent tissues occurs.[44,45] Reflection of the energy at the tissue surface or transmission of poorly absorbed energy through the target tissue makes it necessary to prolong the time of exposure of the target tissue to the laser energy to achieve the desired ablation. This prolonged exposure of the target tissue causes an increased thermal effect with resultant damage to the surrounding nontarget tissue.

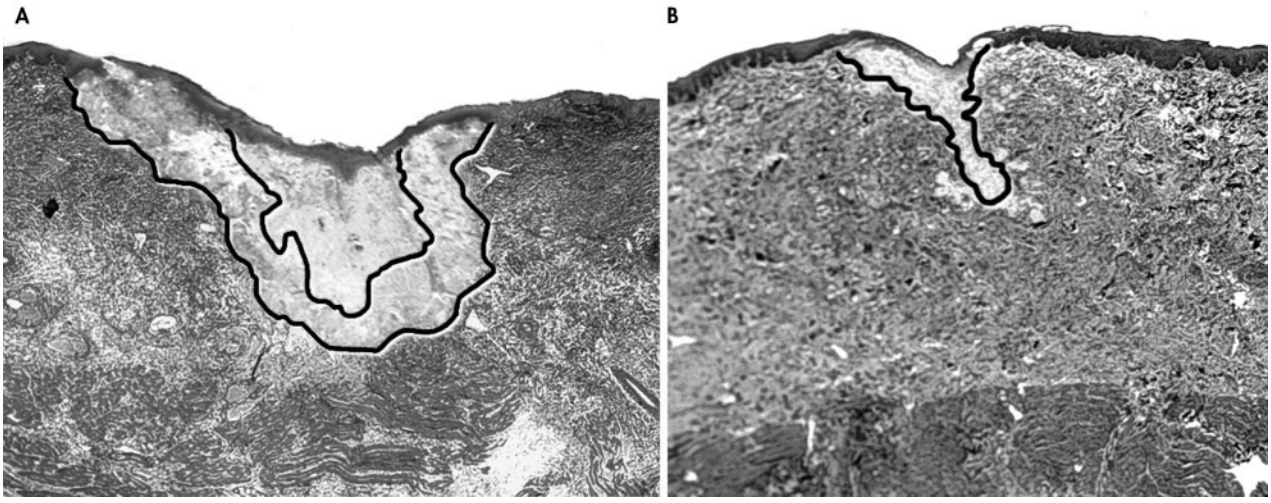

FIGURE 64–7. Laser incisions of the oral mucosa of a dog 1 week after the incisions were made. *A* shows the incision that was made with a continuous-wave carbon dioxide laser (5 W, 0.2 s repeat pulses). The large area outlined is thermally denatured collagen. The central outlined area is a region containing neutrophils still within the inflammatory phase of wound healing. *B* shows the incision that was made with the pulsed carbon dioxide laser (60 μs, 0.5 J/pulse, 10 Hz repetition rate). There is no thermally denatured collagen still present. The outlined area is a region containing neutrophils still within the inflammatory phase of wound healing. The stain is Masson trichrome.

In the center of the wound is a volume of tissue vaporization; here just a few flakes of carbon debris are noted. Immediately adjacent to this volume is a zone of thermal necrosis measuring approximately 100 μm wide. Next is a volume of thermal conductivity and repair, usually 300 to 500 μm wide. Small vessels, nerves, and lymphatics are sealed in the zone of thermal necrosis; the minimal operative trauma combined with the vascular seal probably accounts for the notable absence of postoperative edema characteristic of laser wounds.

Studies comparing the histologic properties of healing and the tensile strength of the healing wound after laser- and scalpel-produced incisions in experimental animals have been performed. In 1971, Hall demonstrated that the tensile strength in a carbon dioxide laser–produced incision was less up to the twentieth day of healing and became the same by the fortieth day.[46] In 1981, Norris and Mullarry studied the healing properties of carbon dioxide laser incisions in pigs histologically.[47] They showed that scalpel-produced incisions exhibited better tissue reconstruction than laser-produced incisions up to the thirtieth day, after which time both incisions exhibited similar results.

In 1982, Finsterbush et al measured the tensile strength of carbon dioxide laser incisions in rabbits and compared them to scalpel wounds.[48] They gently removed the charring and debris on the wound edges before closure. The laser beam–produced wounds were significantly stronger than those made with a scalpel for the first 19 days. In 1983, Buell and Schuller created carbon dioxide laser incisions in pigs and compared them with scalpel incisions.[49] They found the laser wound to be weaker in tensile strength than the scalpel wounds for the first 3 weeks. Research on wound healing from lasers has confirmed the delay in the healing of laser incisions.[50,51] Analysis of the healing process and the effect of the laser on components of the healing process is beginning to provide details about the laser wound-healing delay.[52,53]

Studies in our laboratory have shown that the delay in wound healing is secondary to thermal damage to tissues surrounding the incision and thus produces debris that must be removed before wounds can be repaired.[54–60] This delay has been observed through the first 30 days of wound healing. During the ablation process, some of the thermal energy is conducted to surrounding tissues and can damage the cellular and extracellular structures. Additionally, some of the tissue at the perimeter of the laser beam is exposed to low levels of laser energy, and this subablative energy also damages surrounding tissue. This excess thermal damage can be observed at the borders of laser incisions. The thickness of this thermal damage has been correlated with the delay in wound healing.[51,54]

The laser pulse structure and duration have been shown to be an important parameter in minimizing thermal damage. These studies identified the importance of the pulse length in relation to the thermal relaxation time, a time constant that is the amount of time required for thermal energy to diffuse to surrounding tissues, thus heating and injuring them. This time has been estimated by several models as ranging from 7 to 700 μs.[56,57,60] Thus, a shorter pulse duration should show less thermal damage because the laser energy is delivered so quickly that it cannot diffuse to surrounding tissues. Studies in canine oral mucosa have shown decreases in wound healing delays when using a 60 to 100 μs pulse duration.[57]

By developing lasers that have more favorable wound-healing properties, the major disadvantage of laser incisions could be minimized while still offering the unique advantages that the laser affords for surgery.

LASER TYPES AND APPLICATIONS

Six types of lasers are currently in use in otolaryngology-head and neck surgery, and many more are in various states of development. The characteristic potential for the clinical application of a particular surgical laser is determined by its light emission paradigm, that is, pulse character and wavelength, and by its absorptive characteristics in tissue. The surgeon should therefore consider the properties of each wavelength at the time that he or she chooses to use a particular laser. This facilitates the accomplishment of his or her surgical goal with minimal morbidity and maximal efficiency.

Argon Lasers

Argon lasers produce a visible blue-green light with discrete wavelengths of 488 and 514 nm. The radiant energy from an argon laser is readily transmitted through clear aqueous tissues such as those of the

cornea, lens, and vitreous humor because it has a low water absorption coefficient. Certain tissue pigments, such as melanin and hemoglobin, effectively absorb the argon laser light. When low levels of this blue-green laser light interact with highly pigmented tissues, a localized coagulation within these tissues takes place. The clinician uses this selective absorption of the argon laser by pigmented tissue to photocoagulate pigmented lesions such as port-wine hemangiomas and telangiectasias.[61–65] Used in this application, the radiant energy from the argon laser passes through the overlying skin with some absorption by melanin and beta-carotene and reaches the pigmented target tissue, causing protein coagulation. A second-degree burn occurs in the overlying epidermis. Gradual blanching of the laser-photocoagulated area occurs over several months.

Focusing the argon beam to a small spot size causes its power density to increase sufficiently to result in vaporization of the target tissue. Otologists have used this laser to perform stapedotomies because of its ability to be focused into a very small beam. This procedure was popularized by Perkins.[66] Because bone reflects most visible light, including the blue-green radiant energy of argon laser, it becomes necessary to place a small drop of blood on the stapes to initiate absorption. Other middle ear applications of the argon laser include lysis of middle ear adhesions, ossicle sculpturing, and spot welding of grafts in tympanoplasty.[67–73] Advances in fiber-optic technology have allowed development of a series of handheld argon laser microprobes, which have been called Endo-Otoprobes (HGM Medical Laser, Salt Lake City, Utah).[74–76] The optical fiber-transmitting laser energy is contained within the Endo-Otoprobe, which is handheld like a surgical instrument in the operative field. Because Endo-Otoprobes are handheld and available in a variety of angles, use of these probes allows the surgeon to use the laser in a direction different from the visual field of the microscope, facilitating aiming the laser beam around a corner without having to use an expensive and delicate micromirror.

The advantages of using the argon laser with the Endo-Otoprobes in otology include permitting the surgeon to vaporize or coagulate tissue while avoiding excessive mobilization of the ossicular chain. The blue-green color of the laser light also decreases the risk of damage to the facial nerve and inner ear structures.[77]

Because the blue-green light from the argon laser readily penetrates the eye to the retina, special amber-colored safety glasses are required for all personnel in the operating room.

Neodymium:Yttrium-Aluminum-Garnet Lasers

Neodymium:yttrium-aluminum-garnet lasers produce light that has a wavelength of 1064 nm and is therefore invisible. Because the water absorption coefficient of this laser is low, its radiant energy can be transmitted through clear liquids, which facilitates its use in the eye or other water-filled cavities, such as the urinary bladder or synovial capsule. The absorption of its energy by tissue depends on pigment; therefore, most of the energy is scattered both forward and backward through the tissue. The zone of damage produced by impact with the Nd:YAG laser is not limited as with the carbon dioxide laser. A homogeneous zone of thermal coagulation and necrosis may extend 4 mm from the impact site, and precise control is not possible.

These characteristics make the Nd:YAG laser an excellent surgical tool for tissue coagulation. Vaporization and incision can be performed with this wavelength, but precision is lacking, and tissue damage is difficult to control. Attachment of synthetic sapphire contact tips to the end of the quartz fiber-optic delivery system allows the Nd:YAG laser to be used for incision and vaporization with increased precision and diminished tissue damage.[6,78,79]

The Nd:YAG laser beam can be transmitted through flexible fiber-optic endoscopes. A separate fiber passed down the biopsy channel of the endoscope transmits the laser beam. Extruded quartz or sapphire tips in many shapes are also available.[78,80,81] These are sometimes called sculpted tips, and they are used once and discarded. They appear to be reasonably effective in delivering the laser light to a small volume and providing some limitation to the lateral thermal damage. The major applications for Nd:YAG lasers to date are treatment of acute gastrointestinal hemorrhage[82] and palliation of obstructing bronchial carcinomas[83–85] and esophageal carcinomas.[86–89] Other applications include photocoagulation of hemangiomas[90,91] of the head and neck and intranasal hereditary hemorrhagic telangiectasia.[65,92]

Laser-induced interstitial thermotherapy (LITT) is a technique whereby laser energy is directly applied into tumors with flexible Nd:YAG laser optical fibers passed through needles placed into the tumor. This technique is attractive since it is minimally invasive and carries a low morbidity. It may also allow the treatment of deep and difficult to reach tumors in the head and neck and other areas as improved noninvasive monitoring techniques of laser–tissue interactions are developed. The treatment is enhanced with ultrasonography and magnetic resonance imaging for real-time interstitial needle placement in tumors, identification of vessels, and monitoring and quantifying laser-induced tissue damages. Additionally, laser-induced tissue photoablation can be monitored using real-time color flow Doppler ultrasonography.[93]

Lymphangiomas of the tongue and neck are vascular lesions that are difficult to treat and frequently recur. Magnetic resonance–controlled LITT with the Nd:YAG laser has been shown to be a safe treatment. Real-time monitoring of tissue temperature with thermosensitive sequences allows controlled coagulation necrosis.[94]

It has also been shown in a group of 121 patients with symptoms of nasal obstruction owing to hypertrophied inferior turbinates that an endonasal laser technique, the wedge turbinectomy using the Nd:YAG laser, is effective and safe. A steady improvement in nasal patency was observed in 104 patients (85.9%). Additionally, 65% of the patients who experienced long-term failure in this study were affected by allergic rhinitis.[95]

Neodymium:yttrium-aluminum-garnet lasers are typically available in 15- to 110-watt units. Because the invisible light from the Nd:YAG laser can easily cause retinal damage, specially colored safety glasses are required for all personnel in the operating room.

Pulsed Yellow Dye Laser

The pulsed yellow dye laser operates at a visible wavelength of 585 nm. The laser beam is pulsed to deliver energy for only 360 μs. This laser was specifically developed for use in treating port-wine stains.[11–13,49,96] Oxyhemoglobin has an absorption peak near 577 nm. Although this absorption peak is less than at 418 nm, it does permit deeper laser penetration into tissue. Tan et al showed that at 585 nm there is maximal hemoglobin absorption with a minimum of scattering and minimal absorption by melanin and other pigments.[97] When the duration of the laser pulse is shorter than the time for the heat energy to be conducted away to adjacent tissues, the thermal relaxation time, excessive tissue heating can result. It was found for cutaneous microvessels that 20 μs pulses from a pulsed dye laser cause vessel wall fragmentation and hemorrhage. Garden et al found that longer pulse widths caused no significant hemorrhage.[11] The pulse width of 360 μs caused thermal denaturation of the vessel, producing a more desirable clinical outcome. The epidermis in their study showed no evidence of damage when the laser was used at recommended threshold exposures.

The flash pump dye laser has also been used for the treatment of laryngeal papillomas. In a trial comparing flash pump dye laser to the carbon dioxide laser treatment of laryngeal papillomas in a children's hospital, none of the patients described major discomfort, and five patients described their voice as being the same as or better than it was after prior carbon dioxide laser procedures. A treatment effect was noted in all patients and was similar to the results noted on the carbon dioxide laser–treated side. Because the flash pump dye laser coagulates rather than vaporizes tissue, potential advantages may include decreased scarring relative to carbon dioxide laser treatment and improved patient and operator safety.[98]

An innovative use for the flashlamp pumped dye laser tuned to slightly shorter wavelengths was suggested by Ito and Baba.[99] An in vivo study was performed to evaluate the use of pulsed dye laser beam for the fragmentation of salivary calculi. Optimal fragmentation was achieved with a wavelength of 504 nm. Under continuous endoscopic monitoring, laser-induced shock wave lithotripsy is performed. Laser lithotripsy of salivary stones with endoscopic monitoring permits treatment on an outpatient basis with little inconvenience to the patient.

The yellow dye laser has special electrical and plumbing requirements. Special safety eye wear is required.

Argon Tunable Dye Laser

The argon tunable dye laser system works on the principle of the argon laser, making a high-intensity

beam that is focused on dye that is continuously circulating in a second laser optically coupled to the argon laser. The argon laser beam energizes the dye, causing it to emit laser energy at a longer wavelength than the pump beam. By varying the type of dye and using a tuning system, different wavelengths can be obtained. The laser energy from this dye laser can then be transmitted through flexible fiber-optics and delivered through endoscopic systems or inserted directly into tumors. The major clinical use of this laser is with selective PDT of malignant tumors following the intravenous injection of a photosensitizer, typically, hematoporphyrin derivative.[18–25] The argon tunable dye laser is normally tuned to emit laser light at 630 nm.

After the intravenous injection, the photosensitizer disseminates to all of the cells of the body, rapidly moving out of normal tissue but remaining longer in neoplastic tissue. After a few days, a differential in concentration exists between the tumor cells and the normal cells. When the tumor is exposed to red light (630 nm), the photosensitizer absorbs the light; the absorption of this red light causes a photochemical reaction to occur. Toxic oxygen radicals, such as singlet oxygen, are produced within the exposed cells, causing selective tissue destruction and cellular death. Since there is less photosensitizer in the normal tissues, a much less severe or no reaction occurs. The main technical problem is getting enough light to the target area. Here the argon tunable dye laser system has helped to solve this problem. Additional research to increase the laser intensity and simplify the sometimes cumbersome setup is being conducted with gold vapor lasers.[21,25]

Results obtained by many investigators in this country demonstrate that the premise of treating selected neoplasms with a photosensitizer followed by activation with light is valid. The overall potential and exact place of maximum value of this form of treatment remain to be established. Areas that appear to be very promising include carcinoma of the urinary bladder,[27] endobronchial lesions of the lung,[28] selected carcinomas of the upper aerodigestive tract,[29] skin cancers,[30] and cutaneous metastases of breast cancers.[31] Trials are now being conducted in certain specialties on intraoperative PDT in conjunction with conventional surgery.[28]

Manyak et al reported in 1988 that patients who underwent PDT for recurrence of a primary head and neck neoplasm generally did not have improved survival despite successful local tumor eradication.[19] Photodynamic therapy may be indicated for either curative or palliative treatment of endobronchial malignancies. Prospective studies are under way to examine the efficacy of PDT for endobronchial neoplasms.

Photodynamic therapy has also been used as a palliative treatment for recurrence (after chemotherapy, external beam irradiation, and surgery) or in elderly patients to avoid inappropriately extensive and mutilating surgery.[33] The photosensitizing dye was Photosan 3. The light source was an argon dye laser with a wavelength of 630 nm and a power of 100 mW/cm^2, coupled with a cylindrical or spherical applicator and a lens fiber tip. It has been used for patients suffering from cancer of the palatine arch, tonsil, nasal septum, and glottis.

In many instances, PDT is used as an adjuvant therapy with surgery to reduce tumor recurrence in the head and neck. It is given intraoperatively after resection. A concern with the use of intraoperative PDT is the possible effect on wound healing, especially on the healing of myocutaneous flaps, which are widely used to reconstruct defects following resections for head and neck cancer. In a laboratory study, rats receiving porfimer sodium (Photofrin) and laser irradiation had serous effusion, epidermal necrosis, and weaker tensile strength of the healing of a flap based on the inferior epigastric artery.[34] These results should be considered when contemplating the use of PDT as adjuvant intraoperative therapy for tumor surgery requiring flap reconstruction after ablative surgery.

The argon dye laser requires special electrical and plumbing installation. Special eyewear is required. In addition, prolonged photosensitivity is the most common side effect encountered by the patients.

KTP/532 Laser

The KTP/532 laser is an optically pumped, solid-state laser that produces a visible 532 nm beam with an emerald green color. This laser is a frequency-doubled Nd:YAG laser producing all of its output at 532 nm. The Nd:YAG laser rod is continuously pumped with a krypton arc lamp and Q-switched. The Nd:YAG laser wavelength is frequency-doubled by placing a KTP crystal in the beam path, which halves the wavelength, producing the characteristic

532 nm output. Like the argon laser, the radiant energy from the KTP laser is readily transmitted through clear aqueous tissues because it has a low water absorption coefficient. Certain tissue pigments, such as melanin and hemoglobin, absorb the KTP laser light effectively. When low levels of green laser light interact with highly pigmented tissues, a localized coagulation takes place within these tissues. The KTP/532 laser can be selected for procedures requiring precise surgical excision with minimal damage to surrounding tissue, vaporization, or photocoagulation. The power density chosen for a given application determines the tissue interaction achieved at the operative site.

The KTP/532 laser is transmitted through a flexible fiber-optic delivery system that can be used in association with a micromanipulator attached to an operating microscope or freehand in association with various handheld delivery probes having several different tip angles. These handheld probes facilitate use of the KTP/532 laser for benign and malignant oral cavity applications,[10,100] functional endoscopic sinus surgery and other intranasal applications,[101,102] and otologic applications.[73,103–106] Examples of handheld KTP/532 laser applications include tonsillectomy, turbinectomy, stapedotomy, excision of acoustic neuroma, and excision of benign and malignant laryngeal lesions. Use of the micromanipulator facilitates middle ear and microlaryngeal laser surgery because it is more conventionally performed using a carbon dioxide laser.

Different dyes are being tested for PDT that absorb strongly in the visible region of the spectrum. The KTP/532 laser becomes the obvious light source. It was reported that cultured human P3 squamous cells incubated 2 hours with daunomycin exhibited enhanced cytotoxicity after exposure to the monochromatic 532 nm green light from a KTP laser.[107] When the KTP laser output was varied from 0 to 120 joules in daunomycin-sensitized tumor cells, a linear phototherapy response was seen with energy as low as 12 J inducing drug phototoxicity.

The KTP/532 laser is typically available as a unit that delivers between 0.5 and 20 watts with fiber diameters of 200, 400, and 600 microns. Because the visible green light from the KTP/532 laser can penetrate the eye and cause retinal damage, special wavelength-specific safety glasses must be worn by the surgeon and all personnel in the operating room.

Other Lasers

In an effort to have a more controlled laser effect with less damage to adjacent tissue, several lasers in the near- to mid-infrared region are being investigated. These include the erbium:YAG and the holmium:YAG. The erbium:YAG lases at the infrared peak of water absorption at 2.94 μm. Here the extinction length in water is less than 2 μm. The laser produces very clean incisions with a minimal amount of thermal damage to the adjacent tissue.[108] The erbium:YAG laser has been quite successful in ablating bone and cartilage in laboratory investigations.[109,110] There are some concerns about the negative consequences of the photoacoustic signal that accompanies the ablation.[111-116] There are two negative aspects to this laser. The wavelength is too long to be transmitted through normal optical fibers. This gives a distinct advantage to lasers that produce light that can be transmitted through fibers. More importantly, the thermal propagation is so short that there is practically no tissue coagulation and no hemostasis. This laser is therefore unsuitable to use in highly vascular tissue.

The holmium:YAG laser operates at 2.1 μm. This wavelength can be effectively transmitted through fibers. The extinction length in water is about 0.4 mm, which suggests that this laser light should interact with tissue very similar to the carbon dioxide laser. The holmium:YAG has been combined with the fiber-optic endoscope for sinus surgery.[117,118] The hemostasis is good, and the soft bone ablation is readily controlled.[119–121] Adjacent thermal damage zones vary from 130 to 220 μm.

A study demonstrated the clinical efficacy of the holmium:YAG laser for endoscopic sinus surgery.[122] In a prospective, randomized, controlled, single-blinded study, 32 patients underwent endoscopic sinus surgery using the holmium:YAG laser on one side of the nose and conventional endoscopic instrumentation on the other side. Patients were followed for 2 years after surgery. The mean intraoperative blood loss was 24.6 mL less on the laser-treated side of the nose than on the conventionally treated side ($p < .001$). Improvements in symptoms of pain, congestion, and drainage were equivalent for both treatment modalities. Microscopic analysis demonstrated the ability of the holmium:YAG laser to remove tissue in relatively thin layers with ablation depths of 260 to 340 microns per pulse.

A study also demonstrated the utility of the holmium:YAG laser in the management of pediatric airway disorders. In the study, safety, precision, hemostasis, bone-cutting properties, and accessibility to the lesion of the equipment were compared to standard therapies. Additionally, postoperative outcomes were compared to standard therapies. It was concluded that the holmium:YAG laser is a safe, effective tool in the treatment of pediatric airway disorders and offers the advantage of a flexible fiber-optic system, good hemostasis, and better bone-cutting characteristics than the carbon dioxide laser.[123]

There is also work with other materials that emit light in the near-infrared region of the spectrum, such as the cobalt:magnesium fluoride laser (tunable from 1.8 to 2.14 μm).[124] Alexandrite lasers (750 nm)[125] and titanium sapphire lasers (tunable from 0.6 to 1.0 μm) have also been considered.[126]

The diode laser (600 to 1,000 nm) has also been used for various surgical applications. The diode laser is small and lightweight, and the light is delivered by an optical fiber. The interaction of the diode laser light is similar to the Nd:YAG or the KTP/532 laser. There is moderate absorption by melanin and hemoglobin. It has been considered for turbinate reduction,[127] laser-assisted stapedectomy,[128] and mucosal intact laser tonsillar ablation[129] and is to be used with laser welding techniques to prevent fistula formation.[130]

Ultimately, many parameters such as cost, reliability, and size, in addition to the tissue response, will influence choice of lasers in medicine.

Carbon Dioxide Laser

Carbon dioxide lasers produce light with a wavelength of 10.6 μm in the mid-infrared, and therefore invisible, range of the spectrum. The site where the invisible carbon dioxide laser beam will impact the target tissue is indicated by a built-in coaxial helium-neon laser beam that is red. To increase the visibility of the aiming beam, some lasers have a green aiming beam. The carbon dioxide laser has a high water absorption coefficient, is independent of tissue color, and is well absorbed by all soft tissues that are high in water content; the thermal effects of adjacent nontarget tissue are minimal. The extinction length of this wavelength is about 0.03 mm in water and in soft tissue; reflection and scattering are negligible. These properties make the carbon dioxide laser versatile for use in otolaryngology-head and neck surgery.

At present, the invisible radiant energy emitted from the optical resonating chamber of a carbon dioxide laser can be mechanically conveyed by means of a series of mirrors through an articulating arm to the target tissue.[131] Transmission through rigid nonfiber-optic endoscopes facilitates use of the carbon dioxide laser for bronchoscopy, laparoscopy, and arthroscopy. Hollow and flexible waveguides are available for clinical use, but there is considerable loss of energy and limitations on maximum incident energy. However, these flexible waveguides are shown to be effective in a number of procedures.

Carbon dioxide surgical lasers can operate in both continuous and pulsed modes. They can be used freehand for macroscopic surgery, adapted to the operating microscope for microlaryngoscopy, or adapted to a bronchoscopic coupler for rigid bronchoscopy.[132–135]

Carbon dioxide lasers are typically available in 25- to 100-watt units. They are self-contained and have no special electrical or plumbing requirements.

Although the beam cannot penetrate the eye to the retina, it can cause corneal or scleral burns.[136,137] Therefore, protective glasses are required; ordinary glass or plastic correctional lenses have been satisfactory. Clear plastic safety glasses have also provided adequate protection. Hard contact lenses stop the beam, but all of the uncovered portions of the eye are unprotected from any misdirected laser radiation.

Macroscopic Applications Macroscopic applications of the carbon dioxide laser are numerous. In the oral cavity, benign tumors can be excised or ablated with the laser.[138-143] A one-stage tongue release can be effectively performed; this procedure is helpful in rehabilitating patients following composite resection with tongue flap reconstruction.[144] Speech and deglutition can be improved in selected cases. Multiple areas of leukoplakia can be precisely excised and ablated[29,138,145–148]; in most instances, a graft is not necessary to resurface the operative field. Selected superficial carcinomas can be excised with the use of the laser, and large recurrent or inoperable tumors can be debulked for palliation.[88,143,149,150]

Within the nasal cavities and paranasal sinuses, the carbon dioxide laser is used to treat choanal atresia, hypertrophic inferior turbinates, squamous

papilloma, recurrent inverted papilloma, and hereditary hemorrhagic telangiectasia.[151–156] For this last condition, we believe the Nd:YAG laser to be a more efficacious instrument. The optical waveguides have improved the treatment for hypertrophic inferior turbinates[157] and have permitted a laser partial epiglottidectomy to be performed in those patients who have not been improved with uvulopalatopharyngoplasty.[158] Also, the Swiftlase scanner for the continuous-wave carbon dioxide laser has been used in the management of 387 patients with hypertrophy of the inferior turbinate mucosa. The 1-year postoperative follow-up revealed good results in 261 (81%) of 321 patients.[159] In at least one study, patients preferred the carbon dioxide laser to the Nd:YAG laser for treatment of the inferior turbinates.[160]

Laser surgery of the inferior turbinates has been used as an effective surgical treatment for patients with allergic rhinitis, particularly for those who have persistent nasal obstruction and do not respond well to pharmacologic therapy. There is evidence that the expression of local inflammatory cytokines can be attenuated by carbon dioxide laser treatment.[161] This may be closely related to the clinical effectiveness of this procedure. Treatment with the carbon dioxide laser has been shown to be more effective with a laser output of 5 W than with an output of 3 W. Additionally, treatment was judged less effective in patients aged 15 years or less than in older patients.[162]

Lingual tonsillectomy, excision of tonsillar neoplasms, serial excision of the palatine tonsils, and excisions of neoplasms of the posterior pharyngeal wall can be performed with the help of this laser.[139,163,164] Peritubal adenoid tissue and recurrent papilloma in the nasopharynx can be ablated by reflecting the radiant energy of the carbon dioxide laser off the front surface of a stainless steel mirror.

Facial plastic surgical applications include excision of rhinophyma,[165–168] excision of benign and malignant skin tumors,[169] and ablation or dermabrasion of nevi and tattoos.[170–173]

Procedures have been introduced to the United States from Europe that allow a serial ablation of the uvula and soft palate to treat patients with snoring problems successfully.[174] Performed in an ambulatory setting under local anesthesia, this procedure is associated with much less pain and perioperative morbidity for the patient than with conventional surgery. Additionally, there is no risk of airway obstruction, no hospitalization, and no lost time from work. For these reasons, it has become very popular. The treatment was shown to be nearly five times more effective in patients with a body mass index (see Chapter 58) less than 28 kg/m^2.[175]

A handheld otoscope has been combined with a flashscanner of the carbon dioxide laser for pressure equalization tube insertion in an office setting.[176] Laser-assisted tympanic membrane fenestration was performed with the laser set at single pulse. Insertion of grommets was accomplished using the otomicroscope and an "alligator" microforceps. Although the data indicate high parent and physician satisfaction, along with strong incentives for physicians to use this technique, there are few data that compare this technique to general anesthesia and surgical insertion of tubes.

Microscopic Applications *Benign Laryngeal Disease* The carbon dioxide laser has been used more in microlaryngeal surgery than in any other area of interest to the otolaryngologist-head and neck surgeon. This laser has universal applications in microscopic surgery of benign laryngeal disease.[134] Its advantages of increased precision and decreased postoperative edema must be weighed against the disadvantages of risks of laser-associated complications and increased operating time. With experience, the drawbacks become limited, and the advantages open new horizons. Although knowledge of its use permits the otolaryngologist to apply the carbon dioxide laser in practically all microlaryngeal procedures for benign laryngeal disease in a safe and effective manner, it is not the only surgical tool to be used for any given operative procedure.

Surgery for recurrent respiratory papillomatosis has advanced with the use of the laser.[153,154,177] Initial disappointment in its inability to cure the disease has been tempered by its effectiveness in preserving normal laryngeal structures and maintaining the translaryngeal airway with an efficiency previously unattained.[178,179] Surgery in children for webs, subglottic stenosis, capillary hemangiomas, and other lesions is also significantly enhanced by the precision, preservation of normal tissue, and predictable minimal postoperative edema associated with judicious use of the carbon dioxide laser.[180–184]

Although laryngeal hemangiomas in adults are uncommon, there have been four cases reported in

2000.[185] All masses were detected at endoscopy, and all were biopsied and ablated uneventfully with a carbon dioxide laser. Laryngeal hemangiomas that affect only the glottic area can be treated endoscopically with a carbon-dioxide laser with little to no risk.

Surgery in adults for polyps, nodules, leukoplakia, papillomas, cysts, and other benign laryngeal conditions also finds an advantage with this laser.[186–188] In fact, the laser has created an era of conservation surgery for benign disease. Classically, laryngeal surgery has consisted of vocal cord stripping with healing by remucosalization. Now more normal tissue can be preserved and more limited spot ablations performed; even flaps of mucosa may be mobilized and advanced in the larynx with endoscopic laser techniques.[134] The laser has lowered the risks to the integrity of the anterior commissure of the larynx during one-stage operations on both cords by its ability to ablate areas and to leave adjacent tissue 0.1 mm away undisturbed by mechanical or other effects.

Biopsy may be performed with the laser, even with a small spot size machine, although there is some tissue vaporization. Scissors and cup forceps still have a role for small lesion biopsy. Surgical judgment is obviously important. In extensive areas of suspicious disease, the laser (with a small spot size) is appropriately used for excisional biopsy.

Webs and subglottic stenoses are also effectively incised with the laser.[189–192] Fewer than 50% of anterior commissure webs recur after laser resection. Yet some lasers have such large spot sizes that their use is inappropriate for the procedure. Stenosis can also be treated as long as treatment requires simple tissue ablation with minimal associated edema. If skeletal support is needed, the laser does not provide this, and other techniques should be used.

Endoscopic arytenoidectomy has been performed for many years.[193–196] The addition of the laser allows the surgeon to vaporize the mucosa and underlying arytenoid cartilage layer by layer precisely in a dry field. The precision associated with its use facilitates performance of this operation even by surgeons who had difficulty in mastering the conventional techniques of endoscopic arytenoidectomy. Other microscopic applications of the carbon dioxide laser include excision of internal laryngoceles and excision of hypopharyngeal diverticula.[197–201] In the latter application, a specially designed endoscope facilitates performance of the operation.

The introduction of the adult subglottiscope has extended the microscopic control and delivery of the carbon dioxide laser radiation to the subglottis and upper trachea.[202] Selected stenoses in this area have been successfully treated using microtrapdoor flaps.[203,204]

In summary, the carbon dioxide laser has proved to be a tool with numerous applications for microscopic laryngeal surgery. As the instrument becomes more familiar and friendly to the operating team, the results will continue to improve.

Malignant Laryngeal Disease. Endoscopic management of malignant laryngeal disease is not a new concept. In 1920, Lynch reported 39 patients with early glottic cancers that he successfully treated with transoral excision.[205] In 1941, New and Dorton reported a 90% cure rate with transoral excision and diathermy.[206] In 1973, Lillie and DeSanto reported 98 patients with early glottic carcinoma who were treated with transoral excision; all were cured, although 5 of these patients required further treatment.[207] Hemostasis was achieved with electromicrocautery.

In carcinoma in situ, the tumor's malignant cells have not penetrated the basement membrane and therefore have no metastatic potential. In a study reported in 2000, 29 patients with glottic carcinoma in situ with a minimum follow-up of 2 years were treated initially with transoral carbon dioxide laser surgery.[208] A complete removal of the tumor was possible with superficial laser cordectomy in 21 patients and with subligamental laser cordectomy in 8 cases. There was no tumor-related death in this series. Repeated laser resections were performed in 4 patients for local recurrences. No patient required total laryngectomy or radiotherapy during a follow-up ranging from 25 to 143 months. The local control rates were superior to those previously reported with conventional surgery and similar to those after radiotherapy. The ultimate rate of larynx preservation was seven times higher than reported after radiotherapy. Carbon dioxide laser surgery is an option for the treatment of carcinoma in situ of the larynx.

The transoral treatment of squamous cell carcinoma of the larynx using the carbon dioxide laser is therefore an obvious extension of the application of this surgical instrument.[209–211] The advantages of precision, hemostasis, and decreased postoperative edema allow the laryngologist to perform exquisitely

accurate and relatively bloodless endoscopic surgery of the larynx. The laser has facilitated a renaissance in the endoscopic management of early vocal cord carcinomas.[212,213]

Three distinct advantages exist with this modality of treatment. First, with the laser, it is possible to remove bulky tumors of the anterior commissure area or vocal fold to obtain an accurate assessment of its extent for purposes of staging and treatment. Additionally, previously biopsied tumors of the vocal cord may represent a diagnostic problem with respect to their extent. Here the laser may be used to excise the area surrounding the biopsy site.

Inexact staging after direct laryngoscopy is fairly common. By definition, a T1 carcinoma of the true vocal cords requires cord mobility as defined by the indirect examination. This implies that the tumor is confined to the surface epithelium and has not deeply invaded the vocalis muscle. Vocal cord mobility by itself is a poor indicator of tumor invasion of the underlying muscle.[214] Deep invasion of the vocalis muscle by the cancer has been found after excisional biopsy in many patients who were staged T1 by the indirect examination. These patients should realistically be reclassified as T3 squamous cell carcinoma.

Airway re-establishment is a second advantage of the carbon dioxide laser in treating patients with laryngeal carcinoma. The laser can be used to reduce the amount of tumor obstructing the airway, thereby avoiding the need for a preoperative tracheostomy.

The third advantage of using the carbon dioxide laser in the treatment of laryngeal cancers is that endoscopic excision of laryngeal carcinoma using the carbon dioxide laser may be curative. The experience of Strong et al,[143] Ossoff et al,[214] Blakeslee et al,[215] and Hirano et al[216] appears to support the previous work of Lillie and DeSanto,[207] New and Dorton,[206] and Lynch.[205]

Our current treatment plan for the endoscopic management of T1 vocal cord carcinoma includes an excisional biopsy with the carbon dioxide laser.[214] Supravital staining with toluidine blue can be performed as a diagnostic aid before biopsy. The surgical specimen is labeled and sent for frozen-section examination. Any questionable margins are controlled by frozen section. If the tumor is found to be histologically T3 or T4, the patient is later treated by conventional surgical techniques (partial or total laryngectomy).

Advantages of Carbon Dioxide Laser Surgery. The greatest advantage of the carbon dioxide laser is precision, which allows the surgeon to make accurate lesions. When the carbon dioxide laser is coupled to the operating microscope with a micromanipulator, it becomes possible to achieve surgical accuracy within 0.1 mm. The smallest spot sizes are in the range of 0.10 (200 mm objective) to 0.3 mm (400 mm objective) with current technology. This control, provided by the micromanipulator, is significantly more than is available with handheld microlaryngeal cupped forceps. The second major advantage of the carbon dioxide laser is hemostasis. Characteristically, the laser coagulates vessels up to 0.5 mm in diameter but has the ability to coagulate larger vessels up to 2 mm in diameter under certain circumstances. Vessels larger than 2 mm must be clamped and ligated. The third advantage of the carbon dioxide laser is decreased postoperative edema. A fourth advantage is decreased postoperative pain. Pain has been reported to be reduced or absent after use of the carbon dioxide laser. This probably results from the thermal sealing of nerve endings in the operative wound. Other advantages that have been attributed to the carbon dioxide laser include decreased postoperative scarring and uncomplicated wound healing.

Cold Steel versus the Carbon Dioxide Laser. We are increasing our preference for cold steel over the carbon dioxide laser for critical surgery that involves the vocal folds and can affect the voice. Both tools are effective. However, we find that with sufficient training and skill, the cold steel can yield a slightly better voice, probably owing to the lack of lateral thermal damage.

A similar conclusion was found by a group in Germany.[217] They reported on a prospective randomized study to examine the postoperative functional results after laser phonosurgery in comparison with cold phonosurgery. Conventional cold phonosurgery was performed in 23 patients, and 21 patients were treated by laser phonosurgery. To determine vocal function, examinations included direct videolaryngoscopy, determination of maximal phonation, speech voice field, and assessment of their singing voice. The results 4 months after surgery showed an improvement of vocal function in both treatment groups in comparison with the

preoperative findings. However, the improvement is only statistically significant after cold surgery.

Otosclerosis. The carbon dioxide laser has been shown to possess ideal tissue interaction characteristics for surgery in the oval window for the performance of primary stapedotomy and revision stapedectomy.[218] A small spot size microscopic coupler should be used in these cases.

Bronchoscopic Applications. Successfully coupling the carbon dioxide laser to a ventilating bronchoscope represented a logical extension of the clinical application of the carbon dioxide laser.[149,219] Specifically, use of the carbon dioxide laser coupled to a ventilating bronchoscope allows the surgeon to perform hands-off endoscopic surgery through the relatively long and narrow operative field of a ventilating bronchoscope. The advantages of precision and hemostasis facilitate visualization, and decreased postoperative edema and scarring facilitate control over the final result of the operation.

Current indications for bronchoscopic carbon dioxide laser surgery include management of recurrent respiratory papillomatosis[153,154,177,178] or granulation tissue involving the trachea[220] and resection of selected areas of tracheal stenosis.[162,191,192,221,222] Tracheal and proximal endobronchial adenomas and webs can also be resected using the carbon dioxide laser.[223] Finally, patients with selected obstructing tracheal and proximal endobronchial cancers can have their airways reestablished as a means of palliation using the laser bronchoscope.[224] The major contraindication to this procedure is extraluminal compression of the trachea by an extrinsic tumor. The Nd:YAG laser is preferred over the carbon dioxide laser for this latter application.[225,226]

Anesthetic Techniques for Carbon Dioxide Laser Surgery. Optimal anesthetic management of patients for laser surgery of the larynx must include attention to the safety of the patient, the requirements of the surgeon, and the hazards of the equipment.[227,228]

Because of the time required to align accurately and manipulate the laser, most patients require general anesthesia for this type of operation. Any nonflammable general anesthetic is suitable, and both halothane and enflurane fall into this category. Because of the fire hazard, the inspired concentration of oxygen is important. Mixtures of helium, nitrogen, or air plus oxygen are commonly used to maintain the FIO_2 below 40% but also to ensure adequate oxygenation. Intravenous supplementation of inhalation anesthesia with small doses of narcotic and/or tranquilizers is commonly used to shorten the emergence period following anesthesia. Total intravenous anesthesia with reversible short-acting narcotics and tranquilizers plus jet ventilation is another acceptable anesthetic technique for microlaryngeal laser surgery. The use of the adult subglottiscope requires the use of jet ventilation and total paralysis.

Precautions for Carbon Dioxide Laser Surgery. Certain precautions are necessary when using the carbon dioxide laser. First, to reduce the risk of ocular damage, the patient's eyes should be protected by a double layer of moistened eye pads, and all operating room personnel should wear protective glasses. Additionally, a sign should be placed outside the operating room door warning all persons entering the room to wear protective glasses because the laser is in use. Corneal damage can occur from direct or reflected laser beam irradiation to the eyes. Second, all exposed skin and mucous membranes of the patient outside the surgical field should be protected by a double layer of moistened surgical towels.

Protection of the endotracheal tube from either direct or reflected laser beam irradiation is of primary importance.[229–233] Should the laser beam strike an unprotected endotracheal tube carrying oxygen, ignition of the tube could cause a catastrophic, intraluminal, blowtorch-type airway fire. Red rubber endotracheal tubes wrapped circumferentially with reflective tape have been used successfully in the past to reduce the risk of intraluminal fire. Metallic endotracheal tubes and silicone endotracheal tubes specially designed for use in microlaryngeal laser surgery also reduce the risk of intraluminal fire.[234–240] The cuff of the endotracheal tube should be filled with methylene blue–colored saline to act as a heat sink. The placement of water-saturated neurosurgical cottonoids below the vocal cords to protect the cuff of the endotracheal tube further reduces this risk. These cottonoids need to be moistened frequently during the procedure. The

development of the operating platform placed in the subglottic larynx can minimize the possibility of an airway fire even further. Should the cuff become deflated by an errant hit of the laser beam, the tube should be removed and replaced with a new one. The cottonoids must be counted like surgical sponges at the completion of the procedure. Perhaps the single most important safety precaution related to reducing the risk of an intraluminal endotracheal tube fire is using mixtures of oxygen (FIO_2 40% or less) and helium for ventilating the patient during microlaryngeal laser surgery.

Additional precautions must be taken to provide for adequate smoke evacuation from the laryngoscope, bronchoscope, or oral cavity to allow for safety as well as visualization of the operative field.[241–244]

Complications of Carbon Dioxide Laser Surgery. Many of the possible complications of carbon dioxide laser surgery have been mentioned in the general discussion of precautions for laser surgery. These include corneal burns, skin burns, misdirected burns from direct or reflected energy, and endotracheal tube ignition.[245–247]

Other complications associated with the use of the carbon dioxide laser include trauma to the vocal cords during intubation with the aluminum foil–wrapped endotracheal tube, intraoperative airway obstruction secondary to a foreign body (aluminum foil tape or cottonoids), tracheal perforation, acquired glottic web, subglottic stenosis, vocal cord fibrosis, arytenoid perichondritis, delayed bleeding, and delayed postoperative airway obstruction.[248–253]

Great care must be exercised when wrapping the red rubber endotracheal tube circumferentially with the reflective metal tape. We recommend using quarter-inch tape because it wraps better than larger sizes with fewer subsequent folds, kinks, or rough spots. Additionally, the endotracheal tube should be inspected for areas of possible dislodged aluminum tape.

Tracheal perforation is a distinct possibility when performing laser bronchoscopy. Using the laser in the single- or repeat-pulse mode should allow the surgeon to differentiate among mucosa, perichondrium, and tracheal cartilage. Using the laser in the continuous mode often makes that necessary distinction rather difficult.

Acquired glottic web can occur if laser surgery is performed bilaterally at the anterior commissure.[254,255] Subglottic stenosis can result from accidental laser irradiation to the subglottic larynx while working at the anterior or posterior commissure.[256] We recommend using the operating platform to protect the mucosal tissues of the subglottis. Vocal cord fibrosis results from vaporizing vocalis muscle during the process of laser surgery to the true vocal cords.[254,257] This complication can be avoided by proper control of the power density while working on the true vocal cords. Close observation also aids in the prevention of this complication; a small amount of tissue retraction occurs within the laser impact point when the vocalis muscle is penetrated by the laser beam. Arytenoid perichondritis can occur after deliberate or accidental cartilage exposure during endoscopic laser surgery. Parenteral antibiotics help to minimize this complication.

Delayed postoperative bleeding often occurs if vessels larger than 1 mm are treated by laser coagulation. In dealing with bleeding vessels, those that would ordinarily need to be clamped and ligated if the laser were not being used should still be clamped and ligated. Only vessels less than 1 mm should be coagulated with the carbon dioxide laser. Although delayed postoperative airway obstruction associated with using the carbon dioxide laser is rare, it can occur within 18 hours of the operative procedure. The most frequent time for airway edema to occur in our experience has been between 1 and 6 hours postoperatively. We do not recommend performing outpatient endoscopic microlaryngeal laser procedures. When performing laser surgery in the oral cavity under local anesthesia, we keep our patients in the day surgery suite for up to 6 hours postoperatively to observe them for edema or possible airway obstruction before discharge.

CHAPTER 65

Introduction to Peroral Endoscopy

Ellen S. Deutsch, MD, Jane Y. Yang, MD, James S. Reilly, MD

Aerodigestive endoscopy offers a privileged and exciting view into structures and functions that are vital for the survival of human beings. It provides precise anatomic information about intraluminal anatomy, as well as details about mucosal characteristics and dynamic processes not obtainable by any other method of evaluation. Advances in optics, instruments, and anesthesia, employed in conjunction with equipment and techniques developed by innovative and observant pioneer endoscopists, allow us extraordinary capabilities to evaluate the aerodigestive system.

Although it is important to have appropriate equipment, Chevalier Jackson also stated that

> Endoscopic ability cannot be bought with the instruments. As with all mechanical procedures, facility can be obtained only by educating the eye and the fingers in repeated exercise of a particular series of maneuvers. As with learning to play a musical instrument, a fundamental knowledge of technic, positions, and landmarks is necessary, after which only continued manual practice makes for proficiency.[1]

Aerodigestive endoscopy should be methodical, thorough, and timely. Repetition of a standardized protocol will improve efficiency, but the clinician should also continuously endeavor to improve the quality and ease of the procedure, incorporating improvements in equipment, techniques, or theories of disease pathogenesis.

The topics in this section have been arbitrarily divided, but principles addressed in discussing the selection or use of one instrument or technique may also be applicable to other instruments or techniques. Similarly, dividing diseases into categories defined by anatomic boundaries may provide a framework for methodical evaluation, but the potential for complex relationships between different anatomic areas should also be considered.

HISTORY OF AERODIGESTIVE ENDOSCOPY

Early attempts at aerodigestive endoscopy were hampered by primitive sources of light. In 1806, Bozzini fashioned an angled speculum with a mirror insert for examination of various body cavities, including the larynx, using a single wax candle for illumination.[2,3] In 1829, Babbington described a glottiscope, a three-bladed device including a stainless steel mirror and tongue retractors.[2] Desmoreaux, the "father of endoscopy," redesigned Bozzini's endoscope in 1853 by attaching a gaslight and condensers to project a beam of light down the tube; however, this was cumbersome and not widely accepted.[2] In 1854, Manuel Garcia, a voice teacher preoccupied with the possibility of observing the movements of the vocal cords, noticed sunlight flashing on the window panes of a house and considered the idea of light from one mirror reflected to another. Using a dental mirror, a hand mirror, and sunlight, he was able to visualize his own larynx and vocal cords.[2]

Turck, Czermak, and Morell MacKenzie refined the instruments and techniques for endoscopy,[2] but MacKenzie's reputation suffered following a consultation by German royal physicians to give an opinion about the hoarseness of Crown Prince Frederick William of Prussia, who was married to Queen Victoria's oldest daughter. MacKenzie's biopsy specimen from a tumor of the prince's vocal cord was interpreted by Professor Rudolf Virchow as a benign lesion. It was not until 9 months later, after additional

biopsies, that its malignant nature was identified. Meanwhile, the prince had been crowned emperor but died only 3 months after his coronation.[2]

Killian devised a different approach to the larynx, developing a direct laryngoscope as well as an apparatus for suspending the laryngoscope and using a headlight for illumination. In 1897, he used a rigid endoscope to examine the airways[4] and was the first to remove a foreign body in the bronchial tree using direct upper bronchoscopy without tracheostomy under local anesthesia.[5]

In the early 1900s, Chevalier Jackson refined the rigid bronchoscope,[4] invented distal lighting for endoscopic equipment,[2] and designed a variety of endoscopic instruments. He chronicled his observations with dramatic paintings and drawings.[2] His book, *Bronchoscopy and Esophagoscopy*, first published in 1922, remains a comprehensive treatise on the techniques of peroral endoscopy almost a century later.[1]

The use of magnification to enhance endoscopy was developed by Brunings in Germany and Jackson in the United States in the early 1900s.[2] The addition of the Zeiss operating microscope in the mid-1950s, with appropriate laryngoscopes such as those designed by Jako, allowed binocular magnification.[2]

Advances in illumination and optics have also facilitated the development of rigid esophagoscopy; however, an understanding of optimal patient positioning derives from the insight of physicians working in collaboration with sword swallowers. Similar to the development of laryngoscopy, Bozzini's initial theories of esophagoscopy involved esophagoscopes with a curve for the pharynx where light would be reflected by a mirror.[3] Adolf Kussmaul was the first to use a straight tube, with lighting developed by Desmoreaux using a gasoline lamp; light was reflected by two mirrors passing through a lens for concentration.[3] After studying the techniques of sword swallowers, he was able to look into the stomach using a 47 cm tube but was disappointed as he saw only bubbling,[3] and he never published his technique.

Leiter, an instrument maker, constructed a light source using a platinum wire heated to a white glow by electricity and a cooling system of circulating water. He visited Kussmaul and convinced Johann von Mikulicz-Radecki of the importance of the straight-tube esophagoscope. Von Mikulicz was also inspired by sword swallowers.[3] Huizinga quoted from von Mikulizc's 1881 publication, *Zur Technik der Gastroskopie und Oesophagoskopie*: "The first thing to do was to examine if this masterpiece was the result of an abnormal anatomy or if every normally built man could imitate it with a more innocent straight instrument. So Leiter induced several young men to exercise with rubber sticks and mostly they succeeded in introducing it into the stomach."[3] The two "crucial moments" during sword swallowing occur during passage of the sword at the upper and lower esophageal sphincters.[3] During modern rigid esophagoscopy, the position of the patient's head and neck is changed as insertion of the esophagoscope progresses, but this is not feasible for a sword swallower. The sword swallower must optimize the position of the proximal esophagus by voluntary anterior displacement of the lower jaw, hyoid bone, and tongue base, as well as simultaneously accommodating the forward direction of the distal esophagus.[3]

In the 1960s, flexible fiber-optic bronchoscopes were developed and introduced into clinical use by Shigeto Ikeda[4]; fiber-optic esophagoscopes, shortly thereafter, came into use. Fiber-optic telescopes comprise a bundle of flexible fibers, some carrying light to the object to be examined and others carrying the image back to the viewer.[6] The guidable lens tip allows flexible positioning of the scope, and wide angle and zoom lenses are available.[6] At approximately the same time, rod lens telescopes were invented by Professor H. H. Hopkins, providing improved optics and light transmission via rigid telescopes, with a capability for angled and wide-angle lenses.[7] Modern endoscopy also uses endoscopic cameras and recording equipment, allowing video or digital recording and slow-motion replay, multiple observers, and ease of photographic documentation.[8] Endoscopists continue to refine instruments, the understanding of disease, and patient management.[9]

INDICATIONS FOR LARYNGOSCOPY IN THE OFFICE

Laryngeal examination should be performed when signs and symptoms indicate the possibility of isolated benign or malignant vocal fold lesions, neurologic disease including motoneuron disorders, systemic disease, and hyperfunctional disorders (Table 65–1). Laryngoscopy can contribute to defin-

ing the extent and number of lesions, obtaining a biopsy, and establishing and maintaining an airway.[10] In adults and adolescents, a complete laryngeal examination can usually be accomplished in an office setting. In young children, dynamic or mass lesions of the supraglottis and glottis, such as laryngomalacia, vocal fold paralysis, and vocal fold papillomas, can often be evaluated. Awake laryngoscopy performed in the office is useful if the findings would be likely to obviate the need for endoscopy under general anesthesia. Examples include diagnosing vocal fold nodules, vocal fold paralysis, or laryngomalacia when the history and endoscopic findings are classic. In young patients,[11] patients with significant anxiety or certain anatomic abnormalities, or those who are developmentally or neurologically impaired, examination may be more difficult, and only sporadic glimpses of anatomy and function may be obtained. Visualization of the airway in the operating room may be preferable if there is a need to evaluate the airway below the level of the vocal folds in children, if there is significant airway distress, or if the patient is very ill or uncooperative.

Superimposed on the question of whether to proceed with airway endoscopy is the question of how urgently the endoscopy should be performed. Proceed urgently if there is significant respiratory distress, the patient appears uncomfortable or fatigued, or the patient is newly cyanotic or has a new supplemental oxygen requirement that cannot be explained solely by other organ system problems. Proceed urgently if the stridor is of acute onset, such as from foreign-body aspiration; if certain infections are suspected, such as exudative tracheitis or epiglottitis; or if there has been mechanical or thermal trauma to the airway. Proceed urgently if there is significant dysphonia, which suggests lesions at the level of the vocal folds, such as papilloma, exudative infections, and foreign bodies, which can progress to complete airway obstruction.

TECHNIQUES FOR EXAMINATION OF THE LARYNX IN THE OFFICE

Most adults and older children will tolerate examination of the larynx in an office setting, particularly when the patient is approached with adequate psychological preparation and gentle technique. It may be useful to both explain and then demonstrate that particular instruments are not threatening by touching them to a less vulnerable portion of the patient's body, such as his or her arm. When a camera and monitor are being used, the capability of the telescope can be demonstrated by "examining" a button or detail of the patient's clothing or jewelry, etc. Infants and young toddlers may require restraints.

The larynx should be viewed at rest, during respiration, and during vocalization, noting details of symmetry, motion, surface architecture, evidence of inflammation, and abnormal masses or growths.[12]

Mirror

Advocates of mirror or "indirect" examination of the larynx espouse the glare-free lighting of laryngeal structures, allowing observation of subtle color variations (Figure 65–1). The patient sits erect, facing the endoscopist, in the "sniffing" position, with the neck flexed on the chest and the head extended on the neck. The patient opens his mouth and protrudes his tongue. The endoscopist grasps the tongue, wrapped in gauze, between his or her thumb, on the dorsal surface, and third finger, on the

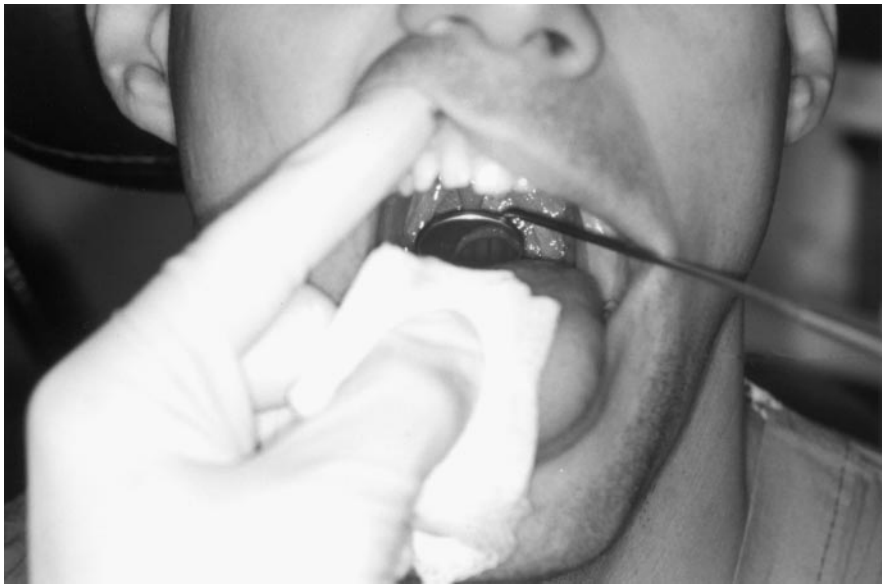

FIGURE 65–1. Mirror examination of the larynx. Note the epiglottis visible within the mirror's image and the vocal folds posterior to the epiglottis.

ventral surface, essentially rolling the tip of the tongue over the endoscopist's finger. The endoscopist's second finger can be used to retract the upper lip superiorly. A mirror on an angled handle is grasped, near the mirror end, in the endoscopist's right hand and placed in the posterior part of the pharynx, lifting the uvula. Encouraging the patient to "breathe through your mouth" or "pant like a puppy" may facilitate placement of the mirror. Warming the mirror or applying soap or a defogging solution will minimize fogging of the mirror as the patient breathes. A concave mirror on a headband, coordinated with an external light source, or a headlight is positioned so that the light is deflected from the mirror onto the pharynx and larynx and the image of the larynx is reflected back to the endoscopist. Having the patient phonate a prolonged, high-pitched /ee/ lengthens the vocal folds and moves the larynx upward vertically[6] to improve visualization of the entire vocal folds, including the anterior commissure.

Mirror examination requires a significant amount of endoscopic skill, as well as patient cooperation. Many patients have a sensitive gag reflex, allowing only brief glimpses into the laryngopharynx that may not be sufficient for proper diagnosis. Limitations include anatomic variations, such as a large tongue, micrognathia, and trismus, that preclude adequate examination and the inability of the patient to speak in a normal manner because of the requisite positioning.[6]

Fiber-optic Telescopes

Fiber-optic telescopes are frequently the preferred tools for laryngeal examinations in the office. The fiber-optic examination is often more comfortable for the patient and allows the otolaryngologist longer intervals to examine the hypopharynx and larynx (Figure 65–2). Fiber-optic nasopharyngoscopes (rather than bronchoscopes) are often of sufficient length but do not contain a suction channel so cannot be used to apply topical anesthesia or to suction excess secretions.[8] Guidable fiber-optic telescopes are available with outer diameters as narrow as 2.2 mm, allowing atraumatic passage through the nares of a normal neonate. Although smaller telescopes are more comfortable for patients, larger lenses provide better quality images. The patient may be examined sitting erect and facing the examiner or supine, with the endoscopist at the patient's head or side. As the fiber-optic telescope is passed through the nose, almost the entire upper aerodigestive tract from the nares to the larynx may be visualized. A limited view of the subglottis may also be obtained but can be deceptive, particularly in children, as the normal narrowing of the cricoid is accentuated by the angle of visualization, and this may give a false impression of subglottic stenosis. The fiber-optic telescope can be passed through the mouth, but a bite block or other device may be necessary to prevent the instrument from being bitten, and the nasal portion of the examination will not be obtained. Folded gauze or preformed plastic bite

FIGURE 65–2. Fiber-optic laryngoscopy demonstrated by a left-handed endoscopist.

blocks can be used. In an edentulous infant, the endoscopist's finger can be used as a bite block. Among techniques for examination in an office setting, fiber-optic telescopes require the least amount of patient cooperation and cause the least interference with normal speech and voice production. During fiber-optic laryngoscopy, the larynx may be observed while the patient speaks, sings, whistles, plays a wind instrument, or demonstrates a particular voice disturbance[6] as the telescope does not interfere with positioning of the tongue, teeth, lips, etc. The apices of the piriform sinuses may be visualized during a Valsalva's maneuver. Fiber-optic examination is useful for evaluating dynamic lesions, such as laryngomalacia or vocal fold paralysis. Fiber-optic telescopes are also useful in the occasional circumstance when a rigid telescope cannot be safely placed or the larynx is difficult to visualize with a laryngoscope because of anatomic abnormalities such as micrognathia, cervical spine rigidity or instability, or immobility of the temporomandibular joint. In children and some adults, passage of the fiber-optic telescope through the glottis can cause laryngospasm; prophylactic application of local anesthesia may be indicated. Application of an anesthetic may interfere with assessments of sensation.

70- or 90-Degree Telescope

A rigid telescope with an angled lens of 70 or 90 degrees can be passed through the mouth to the oropharynx to view the larynx (Figure 65–3). Twenty centimeters are often a comfortable telescope length for the endoscopist. Patient positioning and the technique for inserting the telescope are similar to that for mirror examination. Placement of the telescope in the mouth will limit the variety of speech sounds that can be elicited. Children as young as 6 or 8 years of age may be able to cooperate for this examination.

Stroboscope

Although stroboscopy for viewing the larynx was first described by Oertel in 1878, early equipment was bulky and expensive, and it has taken another century of technological advances to provide user-friendly equipment.[13] Modern stroboscopes emit rapid pulses of light at a rate that may be set by the examiner or, more commonly, synchronized with the vocal frequency of the patient during phonation. The stroboscope is coupled with a rigid or fiber-optic endoscope and a video recording device, as well as a microphone placed over the lateral aspect of the neck to measure the acoustic characteristics of the patient's voice. The fundamental frequency is the individual's lowest vocal frequency, measured in hertz, and referred to as pitch. If the frequency of the light pulse is the same as the vocal frequency, the resulting image will appear to be static. If the light pulse frequency is slightly longer or shorter than the vocal frequency, the image will

FIGURE 65–3. Laryngeal examination using an angled telescope. Note image of supraglottic structures visible on monitor.

appear to change slowly. Observation of the true vocal fold vibratory pattern may reveal subtle vocal fold pathology that could not otherwise be visualized.[6] Normal vocal folds vibrate symmetrically, that is, as mirror images of each other, during phonation. Successive vocal fold cycles should occur in a regular sequence; aperiodicity is abnormal. Glottal closure refers to the completeness of vocal fold apposition during phonation, and deficits in degree and configuration may occur. Vocal fold stiffness may cause disturbances in the mucosal wave or amplitude (extent of lateral motion). Abnormalities may result from presbyphonia, scarring, masses, or neurogenic lesions.

Fiber-optic Endoscopic Evaluation of Swallowing

Fiber-optic endoscopic evaluation of swallowing (FEES) has become an extremely useful adjunct to videofluoroscopic evaluation for patients with dysphagia or aspiration.[11] Videofluoroscopy provides information about the swallow mechanism during all phases of swallowing; however, FEES allows direct visualization of the velopharynx and larynx with better evaluation regarding sensory and neurologic status. Fiber-optic endoscopic evaluation of swallowing can be performed at bedside without radiation exposure. Recording the examination using a television monitor and videotape recorder allows repeated review, slow-motion review, and patient education. Application of topical anesthetic beyond the nasal cavity is not recommended as it may interfere with assessment of laryngopharyngeal sensation.

The first observation is made in the nasopharynx, where velopharyngeal competence is tested. Palatal closure is observed while the patient performs certain plosive speech tasks such as repeating "k, k, k" or "pick up the cupcake," and a palatal stress test can be accomplished by having the patient phonate a forced "ssss."[14]

The endoscope is passed beyond the nasopharynx to evaluate laryngopharyngeal anatomy. Pooling of secretions in the piriform sinuses or impaired mobility of the tongue base or vocal folds suggests a neurogenic or anatomic abnormality. Adequate pharyngeal squeeze is tested by asking the patient to phonate a high-pitched "/ee/."[14] In patients with pharyngeal paralysis, the inferior constrictors will not contract to close the piriform sinuses. In adults, a gross assessment of laryngeal and hypopharyngeal sensation may be accomplished by touching the tip of the endoscope to the piriform sinuses, supraglottis, and true vocal folds.

A more quantitative analysis may be obtained by positioning an endoscope with a suction channel about 5 mm from the surface of the aryepiglottic fold, delivering discrete pulses of air with pressures ranging from 2 to 10 mm Hg, and ascertaining the threshold pressure necessary to stimulate vocal fold adduction. Aviv et al have demonstrated a correlation between the degree of laryngopharyngeal sensory discrimination deficit and aspiration.[11]

Management of secretions or a food bolus in the hypopharynx and larynx are evaluated before, during, and after swallowing. Three consistencies of food are tested with food coloring added to improve visualization.[11] Pureed foods have the lowest risk of aspiration and are usually tested first. Management of particulate foods is tested using crackers. Water is evaluated last because it provides the greatest neurophysiologic challenge. Premature spillage and postswallow residue in the piriform sinuses or laryngeal vestibule (the area bounded anteriorly by the laryngeal surface of the epiglottis, laterally by the aryepiglottic folds, and posteriorly by the arytenoids) are abnormal. Laryngeal penetration, defined as passage of food below the false vocal folds, or aspiration, passage of food below the true vocal folds, is abnormal.[11] If penetration occurs, note the presence or absence of an appropriate cough reflex and adequate ability to expectorate the aspirated material. Assess compensatory strategies, such as positional alteration, altering the rate of administration or viscosity or texture of the food or liquid, or changes in feeding implements.[11] If the patient has a tracheostomy, the endoscope can be passed through the tracheostomy to further evaluate tracheal penetration.[14]

Local Anesthesia

The use of local anesthesia can contribute significantly to patient comfort and cooperation, as well as ameliorate the reflex response to mucosal stimulation, which includes tachycardia, hypertension, and laryngospasm.[15] Anesthesia can be accomplished by topical application of solutions or gels[16] or by local injection.[17] Local anesthesia can ablate the sensation of touch but may not be sufficient to alleviate discomfort from the traction forces required for suspension laryngoscopy.[15] Local anesthetics block the generation and the conduction of nerve impulses, presumably by increasing the threshold for electrical excitation in the nerve, slowing the propagation of the nerve impulse, and reducing the rate of rise of the action potential. Clinically, the order of loss of nerve function is (1) pain, (2) temperature, (3) touch, (4) proprioception, and (5) skeletal muscle tone.[18]

The internal branch of the superior laryngeal nerve provides sensory innervation to a small portion of the posterior aspect of the base of tongue, the laryngeal surface of the epiglottis, and the mucous membranes of the larynx down to, but not including, the true vocal folds.[17,19,20] The recurrent laryngeal nerve supplies innervation to the glottis and infraglottic portion of the larynx.[17] The remainder of the hypopharynx derives sensory innervation from the glossopharyngeal nerve.

Topical Anesthesia To anesthetize the nose and pharynx, topical anesthetics can be painted, dripped or aerosolized into the nose, gargled,[16] or sprayed onto the palate and posterior pharyngeal wall. A transmucosal superior laryngeal nerve block will anesthetize the hypopharynx and supraglottic larynx. To accomplish this, topical anesthetic agents are applied to the base of tongue and piriform sinuses using a moist cotton swab in a Jackson forceps[15] or are dripped or sprayed via a curved cannula or the side channel of a fiber-optic telescope.

Infiltration of Anesthetic Agents Glossopharyngeal nerve block has been advocated to eliminate the gag reflex and provide sufficient anesthesia for esophagoscopy. As with topical anesthetics, the glossopharyngeal nerve block can ablate sensation from tactile receptors in the mucosa of the lateral and posterior wall of the oropharynx, hypopharynx, and posterior third of the tongue. However, unlike topical anesthetics, it also ablates sensation from pressure receptors in the posterior third of the tongue. An angled 23-gauge tonsil needle is used to slowly inject lidocaine into the lateral oropharyngeal wall at a point 0.5 cm behind the midportion of the posterior tonsillar pillar. The needle is repositioned if blood is aspirated prior to injection, and injection is aborted if the patient complains of a headache. Reported complications include headache from intra-arterial injection and arrhythmias secondary to blocking carotid sinus afferent nerve fibers.[21]

A percutaneous superior laryngeal nerve block can be accomplished by injecting a local anesthetic agent in the region of the internal branch of the superior laryngeal nerve as it pierces the thyrohyoid membrane (Figure 65–4).[17,19,20] The greater cornu of the hyoid on the side to be anesthetized can be made prominent by pressing on the contralateral greater cornu with the forefinger. In adults, the needle is inserted 1 cm below and 2 cm anterior to the greater cornu. The needle is advanced posteriorly and slightly superiorly, as well as deep to the strap muscles. Before injecting, aspirate to ensure that the nee-

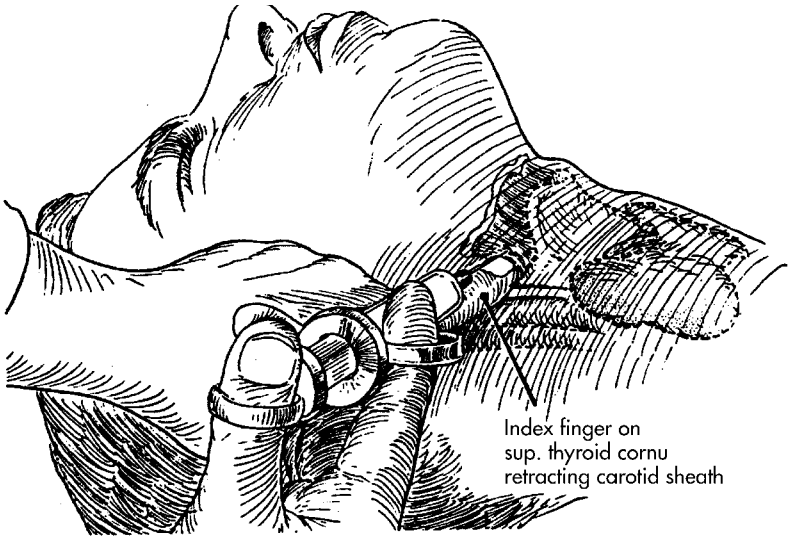

FIGURE 65–4. Technique for blocking the internal branch of the superior laryngeal nerve. Reproduced with permission from Gaskill JR, Gillies DR. Local anesthesia for peroral endoscopy. Using superior laryngeal nerve block with topical application. Arch Otolaryngol 1966;84:654–7. Copyrighted 1966, American Medical Association.

dle is not in an air-containing space or in the superior thyroid artery, which enters the larynx with the superior laryngeal nerve. One to 2 mL of 1% lidocaine or 0.5% bupivacaine should be infused slowly. Transcutaneous superior laryngeal nerve block is relatively contraindicated when the needle might pass through carcinoma or infected tissue.[20] Reported complications of superior laryngeal nerve block include hypotension and bradycardia.[22]

Local Anesthetic Agents *Lidocaine*, with or without epinephrine, is the most widely used topical anesthetic for awake endoscopy and can be used topically or via local infiltration (Table 65–2). *Cocaine* hydrochloride is unique among local anesthetic agents as it provides both topical anesthesia and vasoconstriction. It is rapidly absorbed by mucous membranes; high plasma levels owing to excessive and rapid absorption may lead to toxicity.[23–25] Although 1.2 g is estimated to be a fatal dose, toxicity occurs at variable doses, and severe toxicity from 20 mg has been reported.[23,24] *Tetracaine* is a relatively toxic topical anesthetic agent.[15] *Bupivacaine* is administered by injection; convulsions owing to systemic toxicity leading to cardiac arrest have been reported, presumably following unintentional intravascular injection.[25]

Precautions The lowest effective doses should be used. Appropriate doses should not be exceeded and should be carefully calculated in small patients, geriatric patients, children, and patients with cardiac or liver disease. Appropriate monitoring and resuscitation equipment and supplies and appropriately trained personnel should be available. After application of local anesthesia, patients should not eat or drink until adequate laryngeal sensation has returned.

Topical Decongestants Topical decongestants may be added to decrease nasal mucosal edema, congestion, or secretions during transnasal examinations (Table 65–3). They should be used with caution in children and patients with hyperthyroidism, cardiovascular disease, hypertension, diabetes mellitus, narrow-angle glaucoma, or benign prostatic hypertrophy.[23]

Bacterial Endocarditis Prophylaxis

Bacterial endocarditis usually develops in individuals with underlying structural cardiac defects that develop bacteremia with microorganisms likely to cause endocarditis. In these individuals, endocarditis prophylaxis is recommended for surgical operations that involve respiratory mucosa including bronchoscopy with a rigid telescope. Current criteria and regimens are available from the American Heart Association.[26]

EXAMINATION OF THE LARYNX IN THE OPERATING ROOM

Airway endoscopy entails cooperation among the endoscopist, anesthesiologist, nurses, and other support personnel to coordinate both the procedure and

TABLE 65–2. Local Anesthetic Agents

Anesthetic Agent	*Available Concentrations*	*Maximum Dose*	*Contraindications*	*Signs of Toxicity*
Lidocaine *without* epinephrine		4.5 mg/kg, not to exceed 300 mg	Hypersensitivity to lidocaine/amide-type anesthetics	Seizures, drowsiness, tremors, hypotension, bradycardia, respiratory depression
Lidocaine *with* epinephrine		7 mg/kg, not to exceed 500 mg	Hypersensitivity to lidocaine/amide-type anesthetics	Seizures, drowsiness, tremors, hypotension, bradycardia, respiratory depression
Tetracaine	0.25% or 0.5% topical solution	1 mg/kg	Hypersensitivity to tetracaine/ester-type anesthetics Should not apply to inflamed tissue	Hypo- or hypertension, respiratory arrest, hypersensitivity, nausea and vomiting
	Cetacaine spray™: 2% tetracaine hydrochloride and 14% benzocaine	Cetacaine spray: apply in adults for 1 second or less	Cetacaine spray should not be sprayed in excess of 2 s	
Cocaine	1%, 4%, 10% topical solution	1–3 mg/kg Generally 1 mg/kg sufficient	Hypersensitivity to cocaine products Systemic use contraindicated	Tachycardia, myocardial ischemia, seizures, anxiety, nervousness, restlessness, excitability, respiratory arrest

Cocaine hydrochloride; lidocaine; tetracaine (DrugPoints® System); cocaine (ToxPoints® System) [serial online]. 2000;106:http://hcs.mdx.com/ (accessed Dec 8, 2000) (a password from MICROMEDEX is needed to access the site and its databases).

the relevant equipment. Advice historically attributed to Chevalier Jackson is stated as "2 minutes of preparation, 2 hours of surgery; 2 hours of preparation, 2 minutes of surgery." Establishing a routine, organized approach with other members of the team will facilitate efficient and directed patient management if a component of the procedure becomes urgent. Review the anticipated sequence of events with any new members of the team, including the anesthesiologist, nurses, and residents. Anticipate management options if an adverse event should occur. In time, the process of the procedure may flow without formal discussion. Select, assemble, and test any equipment that is likely to be used and locate any additional equipment the use of which is less likely but still possible.

The operating room should be set up to optimize safe and ergonomic relationships among the patient, anesthesiologist, endoscopist, and nurse. Both the endoscopist and the anesthesiologist should be able to access the patient's airway emergently. The cephalad portion of the operating room table should protrude over the base so that the endoscopist can sit comfortably at the head of the table. The table should include a joint at the level of the patient's neck to

TABLE 65–3. Topical Decongestants

Agent	*Available Solution Concentrations*	*Signs of Toxicity*
Oxymetazoline	0.025% 0.05%	Somnolence, sweating, central nervous system depression with hypertension, bradycardia

allow adjustments in flexion or extension as endoscopy proceeds. Ideally, instruments are passed over the right shoulder of a right-handed endoscopist. The assistant guides the distal tip of the instrument to the proximal opening of the laryngoscope.

The patient is placed in a supine position, with the head reaching the proximal edge of the operating room table. The "sniffer" or Boyce-Jackson position provides the best visualization of the larynx, with the neck flexed on the shoulders and the head extended on the neck (Figure 65–5).[27] A gelatin pad, folded towel, or other support can be used to extend the head. A shoulder roll is useful in small children in whom the relatively large occiput may cause excessive neck flexion. Optimal patient positioning may entail the use of an assistant.

Commercial defogging agents, soap, or warm water can be used to minimize fogging of the lens or the telescope can be touched to mucosa to warm the distal tip. Lubricant applied to the upper lip allows instruments to glide gently; otherwise, the resistance of the instrument rubbing across the lip can be misinterpreted as resistance from the airway, giving a false impression of narrowing.

Eye protection is recommended for the endoscopist and may consist of the surgeon's own refractive eyeglasses, protective goggles, or laser-compatible lenses. Endoscopy is generally performed as a "clean" procedure. To prevent nosocomial infections as well as erroneous diagnostic results, instruments should be disassembled after each use and all surfaces and channels wiped or brushed to remove mucus or other contaminants prior to disinfection or sterilization.

MEDICATIONS

Corticosteroids are usually given preoperatively or intraoperatively to minimize edema, which may be an

intrinsic component of the airway lesion or may occur following airway manipulation (Table 65–4). Edema generally occurs at the expense of the lumen, contributing to airway obstruction. The incidence of harmful effects after short-term administration of even massive doses of corticosteroids is low.[28]

Local anesthetic agents and topical decongestants may also be useful; the anesthesiologist should be made aware of any medications administered preoperatively or intraoperatively. Both topical and submucosal vasoconstricting agents, such as phenylephrine or epinephrine, can cause hypertension and acute, severe, increased left ventricular afterload. Subsequent administration of beta-blocking agents, to treat the hypertension, may further compromise left-sided cardiac output and result in acute pulmonary edema, profound hypotension, and cardiac arrest.[29]

General Anesthesia

In children for whom examination of dynamic laryngeal lesions such as vocal fold paralysis and laryngomalacia is performed in the operating room, limited sedation can be useful to achieve patient comfort, but oversedation will interfere will the endoscopist's ability to discriminate subtle findings. Similarly, evaluation of dynamic laryngeal lesions may be difficult during emergence from general anesthesia.

General anesthesia is necessary for suspension microlaryngoscopy and facilitates rigid bronchoscopy and rigid esophagoscopy. General anesthesia is managed by the anesthesiologist using a variety of inhaled and/or intravenous agents to achieve hypnosis, analgesia, amnesia, and muscle relaxation.[15] Adequate anesthesia should relax the muscle tone of the mandible and pharynx and blunt the laryngeal and bronchial reflexes.[30] Antisialagogues are often given to decrease the amount of secretions[30]; among these, glycopyrrolate produces less tachycardia than atropine.[31] Monitoring heart rate and adequate pulmonary ventilation are mandatory.[30] Adequate lighting should be available to permit assessment of the patient's color and visualization of the chest.[30] Pulse oximetry should be used prior to induction through full recovery.

Endoscopy Equipment

A variety of laryngoscopes have been developed in attempts to facilitate visualization and instrumentation for diverse lesions and anatomic constraints.[27] Most laryngoscopes used for adults are tubular, not round, so that the laryngoscope itself helps to distract tissue that might interfere with visualization. Anterior commissure laryngoscopes, such as the Holinger laryngoscope, are flared at the distal tip to improve anterior exposure of the larynx and are particularly well adapted to patients with an "anterior" larynx, large tongue, or short obese neck.[32,33] Lindholm laryngoscopes are wide enough to permit binocular vision, particularly of supraglottic lesions. Laryngoscopes such as Jako, Ossoff, and Abramson-Dedo have been specially modified for laser surgery; they provide excellent exposure and contain suction channels for the evacuation of smoke produced during laser vaporization.[32] The Jackson sliding laryngoscopes allow removal of a side or inferior panel, opening the side or bottom of the laryngoscope to facilitate instrumentation, particularly intubation. In children, laryngoscope blades are often open along the side or bottom; intubating laryngoscopes, with blades such as the Miller, can also be used. Laryngoscopes may contain side channels for suction, ventilation, or light carriers; light clips can also be attached to the proximal end of the laryngoscope. Specialized laryngoscopes are available, such as subglottiscopes or bivalved scopes used in the management of Zenker's diverticula.

Hopkins Rod Lens Telescopes

Rigid Hopkins rod lens telescopes are the workhorses of the airway evaluation. The optics and images are superior to those of comparably sized fiber-optic telescopes. In adults, standard telescopes measure 5.5 mm in outer diameter. For pediatric endoscopy, a telescope with an outer diameter of 4 mm and a length of 20 cm, such as the 7200 A telescope (Storz™), is relatively sturdy, passes easily through

the vocal folds and subglottis of a normal neonate, and provides a good quality image. It is short enough to be handled easily yet long enough to visualize beyond the carina in most children through school age. Larger-diameter telescopes are sturdier, transmit more light, and have superior optical resolution.[33] Narrower telescopes are useful for evaluating stenotic airways. For pediatric endoscopy, a variety of telescopes are necessary to fit a variety of sizes of ventilating bronchoscopes, optical forceps, etc; rigid telescopes are less flexible than fiber-optic telescopes, but this is not usually a practical limitation. The telescope tip may be defogged with a commercial solution or soap, by warming in warm water, or by touching mucosa.

Optical forceps, comprised of peanut, biopsy, or cup forceps with double-action jaws and containing a telescope for distal illumination and magnification, enable the endoscopist to visualize the airway lesion during attempts at manipulation, improving the safety and precision of the procedure (Figure 65–6). Although optical forceps can be inserted unsheathed, they are very fragile and are generally passed through a ventilating bronchoscope. They allow only a limited peripheral view, so visualization of the sidewall ventilation ports as the optical forceps is passed via the bronchoscope indicates proximity to the distal opening of the bronchoscope. The expandable tip of the instrument should be passed beyond the distal opening of the bronchoscope before the jaws of the instrument are opened.

Suspension Microlaryngoscopy

Supraglottic, glottic, and some subglottic lesions may be visualized using suspension microlaryngoscopy; it may also facilitate bronchoscopic procedures. Suspension devices free the surgeon's hands and provide stable access for visualization. Procedures using lasers, microdébriders, or microlaryngeal instruments can be accomplished using intermittent apnea techniques. Many laryngoscopes are designed or can be retrofitted for attachment to suspension equipment. Visualization, magnification, and illumination can be accomplished with a microscope using a 400 mm focal-length lens or a telescope attached to the laryngoscope. External laryngeal pressure applied to the lower portion of the thyroid cartilage will maximize visualization of the anterior commissure. Occasionally, a proximal light clip is useful.

Additional Equipment

Suctioning is often necessary to remove secretions interfering with visualization. Flexible suction catheters can be useful for routine, atraumatic suctioning. After exposing the larynx with a laryngoscope, the suction catheter, with the suction inactivated, can be insinuated between the vocal folds (as if intubating the patient with the suction catheter) and advanced to the carina. The suction is then activated, and the catheter is withdrawn expeditiously. Rigid suction catheters may be used for precise suc-

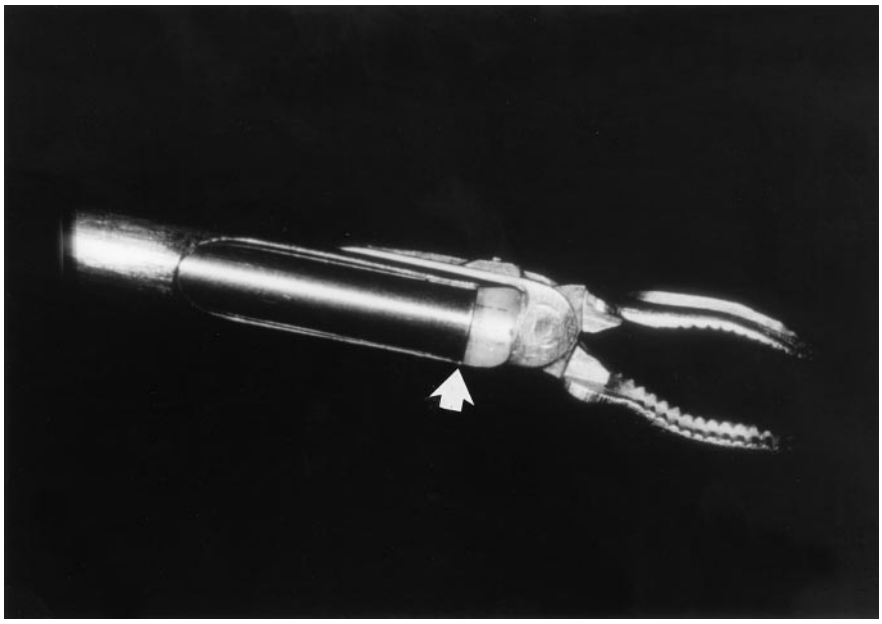

FIGURE 65–6. Distal end of "peanut" optical forceps, demonstrating proximity of telescope tip (*arrow*) to open jaws.

tioning; thumb controls are helpful. Large-bore catheters may be used to suction thick material but can cause trauma if not inserted gently. Placement is guided by feel and by listening for the tip of the catheter to contact the secretions. Small-caliber plastic suction catheters can be inserted via the side channel of ventilating bronchoscopes and allow simultaneous visualization while suctioning. It may be necessary to use a smaller-diameter telescope or larger bronchoscope to allow room for the suction catheter to pass adjacent to the telescope within the lumen of the bronchoscope.

A variety of microlaryngeal instruments are available, including straight and angled cup forceps, alligator forceps, straight and angled scissors, knives, retractors, and reflectors; some also contain aspiration tubes.[32] Older styles of laryngeal and endobronchial forceps are available in a great variety of configurations. Ring rotation forceps and rat-toothed forceps allow a grasped object to swivel in the plane of least resistance. A safety pin closer can be used to sheath the point of the pin within the keeper in situ (Figure 65–7). The lack of distal lighting and limitations of proximal magnification restrict the use of these instruments. In larger children, it is sometimes possible to pass a traditional instrument alongside a Hopkins rod telescope, but this can be very cumbersome and is not feasible in small children.

Although not widely used, contact endoscopy during microlaryngoscopy is a new tool that allows intraoperative examination of epithelial cells and the microvascular network of vocal fold mucosa that may provide in vivo and in situ diagnosis.[34] Magnification of 60 to 100 times is used in conjunction with methylene blue epithelial staining.[34]

Laryngoscopy Technique

Intubation prior to endoscopy is often avoided during evaluation for foreign-body aspiration or trauma as it may convert partial to complete airway obstruction, exacerbate trauma, or affect the endoscopic findings. However, intubation prior to endoscopy may be indicated in selected patients for safe airway management.

The introduction of the direct laryngoscope and exposure of the larynx comprises two stages: exposure and identification of the epiglottis and then elevation of the epiglottis and all of the tissues attached to the hyoid bone to expose the larynx to direct view. The laryngoscope is held in the left hand, and the spatular end is introduced in the right side of the patient's mouth, along the right side of the tongue, so the force necessary to elevate the powerful muscular tongue may be avoided by sweeping the tongue to the left. When the posterior third of the tongue is reached, the tip of the laryngoscope is directed toward the midline and the dorsum of the tongue is elevated by a lifting motion imparted to the laryngoscope. In adults,

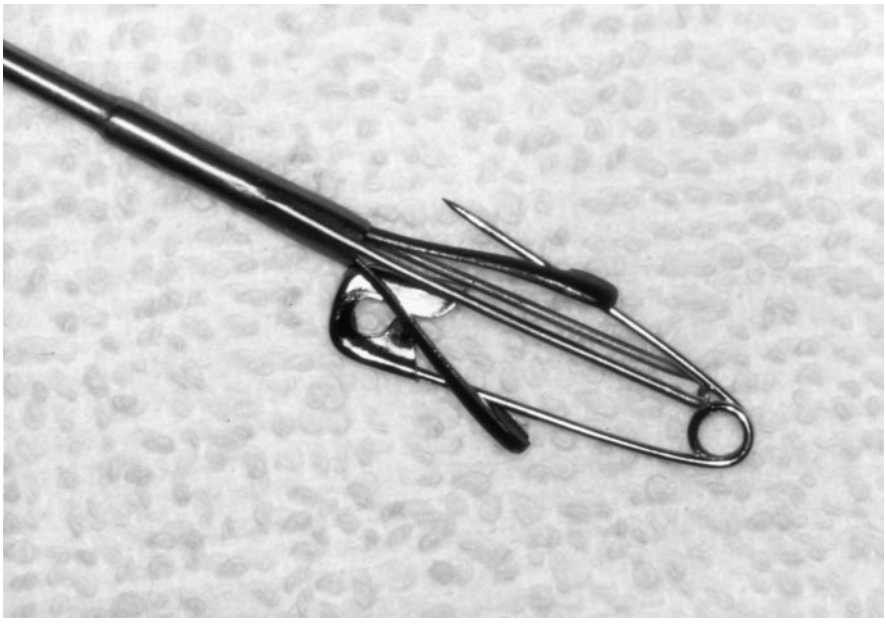

FIGURE 65–7. Safety pin closer. Note central rigid wire that abuts the ring of the spring, while two lateral components of the forceps engage the pointed and keeper branches of the safety pin. Withdrawing the lateral forcep components while maintaining the position of the ring will adduct the branches, closing the pin.

the spatular end of the laryngoscope is tipped back under the epiglottis and advanced about 1 cm. The larynx is now exposed by a motion that is best described as a suspension of the head and all of the structures attached to the hyoid bone on the tip of the spatular end of the laryngoscope. Particular care must be taken at this stage not to use the upper teeth as a fulcrum but rather to impart a lifting motion with the tip of the speculum.[1] The tip of the laryngoscope is lifted forward and upward ("toward the corner of the room, where the wall in front of you meets the ceiling"), exposing the vocal folds. If the anterior commissure of the larynx is not readily seen, the lifting motion and elevation of the head should be increased, or external pressure can be applied, depressing the thyroid cartilage.[1] Generally, the vocal folds are well seen before proceeding to insert a telescope or bronchoscope. A 0-degree telescope provides an excellent view of laryngeal structures; occasionally, an angled telescope may be used to visualize the ventricles, anterior commissure, or undersurface of the vocal folds.

In the pediatric patient, elevation of the occiput is not always necessary because the child has a proportionately large head and consequently already has the elevation of a "pillow" when the head, neck, and shoulders are in a neutral position on a flat surface.[35] The larynx is exposed using a rigid laryngoscope or an intubation laryngoscope with a straight blade, such as a Miller. The tip of the blade is passed along the right side of the tongue, sweeping the tongue to the left, and, instead of lifting the epiglottis, the tip of the blade is insinuated into the vallecula and then elevated. Elevating the base of the tongue and vallecula anteriorly provides an excellent view of the larynx that is easy to maintain for sustained periods of time.[35]

Despite appropriate technique and adequate anesthesia, rigid endoscopy may be difficult in patients with abnormal anatomy, such as morbid obesity, trismus or temporomandibular joint ankylosis, or inability to adequately flex or extend the neck, and fiber-optic endoscopy may be necessary.

Complications

Airway structures should be handled in a gentle, atraumatic manner to minimize the possibility of postoperative edema or mucosal abrasion, potentially progressing to scarring and subsequent stenosis. Edema may already be present or may be caused or exacerbated by manipulation of an inflamed or narrowed portion of the airway. In infants and small children, the subglottis is particularly at risk for injury and complications as it is the narrowest portion of the airway and is nondistensible. Whereas most of the larynx and trachea contains a membranous posterior component, the cricoid ring within the subglottis is a complete ring, so it cannot expand to accommodate the passage of instruments.

Bleeding, although generally minor, can interfere with visualization as well as ventilation and may be controlled by irrigation, application of neuropatties saturated with epinephrine, or tamponade.

Ventilation

Otolaryngologists and anesthesiologists have a unique relationship as they share responsibility for the airway during aerodigestive endoscopic procedures performed using general anesthesia. Selecting a safe and effective method of ventilation and oxygenation, while allowing adequate surgical exposure and access, requires planning and cooperation.

Standard endotracheal tubes, passed nasally or orally, provide good control of the airway and a closed ventilation system and are the most familiar to the anesthesiologist. They allow delivery of anesthetic gases and oxygen as well as removal of carbon dioxide. However, the tube will interfere with the surgeon's ability to see or work in the posterior part of the larynx[15] or subglottis. In addition, standard polyvinyl chloride endotracheal tubes are readily ignited by laser, producing an intense flame, scattering carbonaceous material through the endobronchial tree and releasing hydrogen chloride gas, which is a potent pulmonary toxin.[32]

With the increasing use of lasers in surgery, attempts have been made to develop tubes resistant to laser ignition. Silicone or red rubber tubes are fairly resistant to laser penetration; this resistance is increased if they are completely wrapped in an adhesive aluminum foil tape. Some tubes, including all-metal tubes, are "laser safe" but are fitted with separate rubber cuffs, which are not laser resistant; instilling saline into the cuff adds heat-sink protection. With any type of endotracheal tube, protection of the cuff and subglottic space is provided by saline-soaked cottonoids.[32]

Low-frequency subglottic jet ventilation can be accomplished using a narrow, self-centering tube designed to minimize interference with visualization of laryngeal structures. Potential complications include carbon dioxide retention,[36] pneumothorax, and pneumomediastinum, particularly if vocal fold adduction or mass lesions preclude adequate expiration of gases. The Hunsaker Mon-Jet subglottic tube (Tuta Labs, Sydney, Australia) is made of combustion-resistant fluoroplastic and allows periodic measurement of end-tidal carbon dioxide.[36] To prevent pneumothorax, a port allows continuous monitoring of end-expiratory and peak airway pressures, which will automatically stop insufflation if these pressures rise above a preset level.

Supraglottic jet ventilation is accomplished using a fireproof metal tube placed above the glottis. Adequate tidal volumes are accomplished by entrainment of room air ahead of the jetted oxygen, air, or anesthetic gas.[15] Precise positioning of tube and alignment along the central axis of the airway are critical.[15] Blood and debris can be blown into the trachea.[15] If the tube is misaligned or dislodged, submucosal emphysema, tension pneumothorax, or inadequate ventilation may occur.[15]

The *laryngeal mask airway* is an inflatable mask that is blindly inserted into the hypopharynx where it forms a low pressure, end-to-end seal with the glottis; a tube connects the mask to the breathing circuit.[37] A laryngeal mask airway may be useful in circumstances when cervical spine range of motion is limited. Laryngeal mask airways have been used to provide a conduit for blind intubation of a difficult airway or to facilitate passage of a fiber-optic bronchoscope.[37] The disadvantages include lack of protection against aspiration and the potential for airway obstruction owing to malposition, abnormal position of the epiglottis, or laryngospasm during induction or emergence. The laryngeal mask airway is contraindicated in patients at increased risk for regurgitation and aspiration. Contraindications relevant to otolaryngologists include pharyngeal pathology such as abscess, hematoma, tumor, or edema; airway obstruction at or below the larynx; inability to extend the neck or open the mouth more than 1.5 cm; and high airway resistance.[37]

Using intermittent apnea, the surgeon can work in the airway without the presence of tubes obstructing surgical access or distorting laryngeal anatomy. The risk of ignition by laser pulses is eliminated. Airway control and monitoring capabilities are limited,[15] and surgical procedures may be interrupted and rushed.[15] A facemask, endotracheal tube,[15] or jet ventilation can be used to provide oxygenation between episodes of apnea.

Spontaneous respiration requires a carefully balanced gas mixture to anesthetize the patient without significantly suppressing spontaneous respiration. Topical anesthesia may be necessary to suppress the laryngeal reflexes, that is, bradycardia, hypertension, and arrhythmias. This open system exposes operating room personnel to the anesthetic gases released into the room. Arrhythmias and inadequate ventilation can occur, depending on the anesthesiologist's success in maintaining adequate general anesthesia while allowing sufficient spontaneous respiration.[15]

Difficult Intubation

The otolaryngologist may be called on to secure the airway in emergent or nonemergent situations when anatomic abnormalities make intubation difficult. In these circumstances, the otolaryngologist's knowledge of abnormal anatomy and variations of normal anatomy is invaluable. If an elective intubation is expected to be difficult, appropriate equipment for endoscopic and surgical control of the airway should be available. Patients with morbid obesity, trismus or temporomandibular ankylosis, inability to flex or extend the neck adequately, suspicion of cervical vertebrae instability, possible traumatic laryngotracheal separation, or congenital or acquired oral, pharyngeal, laryngeal, or tracheal abnormalities may be difficult or even impossible to intubate. Patients who have undergone surgical laryngotracheal separation or diversion or laryngectomy cannot be intubated perorally or nasally; a tracheal stoma will be present but may be stenotic.

Several options are available to access the airway when standard methods are unsuccessful. After visualizing the larynx with a sliding laryngoscope, the side or bottom of the laryngoscope is removed so that an endotracheal tube can be passed adjacent to the laryngoscope lumen. Alternately, an endotracheal tube can be passed directly through the lumen of a Dedo-style laryngoscope. A stylet may be used to stiffen the endotracheal tube sufficiently to allow passage through a partially obstructing lesion. Intubation can also be accomplished during spontaneous ventilation using a fiber-optic bronchosope. An endotracheal tube, with the adaptor removed, is

placed proximally over the bronchoscope shaft, which is passed through the nose or mouth and advanced through the glottis to the carina. Application of lidocaine may be indicated. The endotracheal tube is then advanced over the bronchoscope; a rotating motion is used as the tube traverses the nose and larynx.[8] A 4.0 mm fiber-optic bronchoscope (standard adult size) can be used in endotracheal tubes larger than 6 mm, a 3.5 mm bronchoscope should be used in tubes from 4.5 to 6 mm, and the smallest of the ultrathin instruments with distal angulation (2.2 mm, Olympus PF22) will pass through 2.5 to 4 mm endotracheal tubes.[8]

If intubation attempts are unsuccessful in emergent situations, cricothyroidotomy or tracheostomy may be necessary. Mask ventilation can sometimes be used to temporize. If a tracheostomy stoma is present, cannulation may be accomplished with an endotracheal tube or a tracheostomy tube advanced with an obturator or over a suction catheter; serial dilatation may be required.

Patients who struggle to breathe spontaneously against a partially or totally obstructed airway may develop postobstructive (noncardiogenic) pulmonary edema.[38] Although the most common cause is postextubation laryngospasm,[38] postobstructive pulmonary edema can occur following acute airway obstruction of any cause and is estimated to occur in more than 10% of patients requiring active airway intervention for acute upper airway obstruction.[38] If reintubation is necessary, pink, frothy sputum may be appreciated; mechanical ventilation with positive end-expiratory pressures (PEEPs) may be indicated.[38]

Emergence and Postoperative Care

Emergence from general anesthesia can be accomplished using mask ventilation or intubation; the decision will depend on both the nature of the airway lesion and the preference of the anesthesiologist; however, minimizing airway manipulation is preferred when feasible. The level of care required after airway endoscopy is related to the severity of the airway lesion and the type of anesthesia used. Additional systemic corticosteroids and racemic epinephrine, with or without nebulized dexamethasone, may be indicated. Postoperative discomfort from the endoscopy itself is usually minor.

BRONCHOSCOPY

Bronchoscopy can be diagnostic or therapeutic, and interval examinations may be indicated to follow disease progression or response to treatment; additional indications are discussed in Chapter 67. During bronchoscopy, "all bronchial orifices must be identified seriatim; because this is the only way by which the bronchoscopist can know what part of the tree he is examining. Appearances alone are not enough. It is the order in which they are exposed that enables the inexperienced operator to know the orifices."[1]

Bronchoscopy can be accomplished using rigid or fiber-optic equipment. "Clearly rigid and flexible bronchoscopes neither duplicate or replace each other, rather they are complementary and should be used when appropriate for the particular problem."[39] Patient monitoring should be appropriate relative to the endoscopy technique, the lesion, and the patient's underlying medical status.

Rigid Bronchoscopy

Rigid ventilating bronchoscopes should be available during rigid airway endoscopy. They allow control of the airway, capability for ventilation and oxygenation, and a stable, protective conduit for manipulation and instrumentation. They are the instruments of choice for controlling massive pulmonary hemorrhage, removing tracheobronchial foreign bodies, dilating stenoses, excising granulation tissue, debulking large tumors, evaluating tracheoesophageal fistulae or laryngeal clefts, and performing laser therapy or inserting an airway stent[4,8,39] because of their rigidity and large caliber.

When Hopkins rod telescopes are used with rigid bronchoscopes, they provide better optical quality than comparably sized fiber-optic telescopes. The working channel of a rigid bronchoscope is larger than those of fiber-optic bronchoscopes, allowing passage of a greater variety and larger caliber of instruments, including large-bore suction catheters, various grasping or biopsy forceps, and devices to install stents. Larger biopsies and tumor debulking can be accomplished more efficiently. They can be used to shield, protect, and guide fragile instruments such as thin telescopes and optical forceps. The tactile sensation of fixation of structures is readily apparent with the rigid open-tube bronchoscope and seldom appreciated with a fiber-

optic instrument.[40] Rigid bronchoscopes are compatible with both carbon dioxide and flexible laser applications and are nonflammable. Pediatric bronchoscopes contain side-channel ports allowing passage of narrow-bore suction catheters, Dormia urologic stone baskets, or side-channel alligator or cup forceps while maintaining ventilation, visualization, and illumination during procedures such as biopsies or retrieval of foreign bodies.

The outer diameters of pediatric bronchoscope range from 4.2 to 8.2 mm and of adult bronchoscopes from 9.2 to 14 mm.[7] The number designated as the size of the bronchoscope does not necessarily directly correlate with the inner or outer diameter measurement of that instrument.

Although early rigid bronchoscopy was performed in conscious, awake patients, modern rigid bronchoscopy is usually performed using general anesthesia. Direct laryngoscopy is performed first to avoid missing a laryngeal or hypopharyngeal lesion. Rigid bronchoscopy can be performed using an open-tube bronchoscope containing a Hopkins rod telescope to provide magnification and distal illumination or a side-channel light carrier and a proximal magnification lens. Alternatively, an unsheathed Hopkins rod telescope can be used, providing excellent magnification and distal illumination. An unsheathed telescope is more fragile and does not provide access for ventilation. However, this optimizes the size of the telescope that can be inserted and, therefore, image quality, while limiting the outer diameter of instruments that may cause trauma in small children or narrowed airways.

The patient's head and neck are initially placed in a neutral position. A tooth guard is used in adults to prevent injury to the maxillary teeth. The bronchoscope is oriented so that the bevel is oriented vertically and the ventilation port is accessible to the anesthesiologist. The bronchoscope can be introduced directly into the oral cavity, or it can be passed through a Jackson slide laryngoscope. The bronchoscope is inserted into the oral cavity from the right side of the mouth; the endoscopist uses his or her left hand to hold the bronchoscope and his or her right hand to steady and maneuver the maxilla and retract the lips. The endoscopist's right hand will eventually be used for instrumentation while his or her left hand maintains stability and controls advancement of the bronchoscope. The bronchoscope is used to sweep the tongue to the left and is advanced until the tip of the epiglottis is visualized. At this point, the patient's head is extended relative to his neck. The tip of the bronchoscope is advanced in the midline until it passes through the laryngeal inlet and the vocal folds are visualized. The bronchoscope is positioned with the long end of the bevel parallel to the longitudinal axis of the vocal folds so that the long end of the bevel enters the glottis in the midline. The bronchoscope should pass gently through abducted vocal folds. Once beyond the glottis, the bronchoscope can be rotated in any desired direction, and the camera is rotated in a compensatory fashion to maintain an upright view on the monitor.

An alternate method, particularly useful in infants and children, is to first expose the vocal folds using a sliding laryngoscope or an intubating laryngoscope blade with an open back, such as a Miller. In adults, the laryngoscope is inserted under the epiglottis, and in children into the vallecula. Once the bronchoscope is passed through the vocal folds, the laryngoscope is gently removed. At this point,

> the bronchoscope is to be held by the left hand like a billiard cue, the terminal phalanges of the left middle and ring fingers hooking over the upper teeth, while the thumb and index finger hold the bronchoscope, clamping it to the teeth tightly or loosely as required. Thus the tube may be anchored in any position, or at any depth, and the right hand which was directing the tube may be used for the manipulation of instruments.[1]

Once the bronchoscope is within the trachea, the ventilation port can be used. As the bronchoscope is further inserted, the head must be positioned so that the tube corresponds to the axis of the lumen of the passage to be examined.[1] Examination of the trachea and bronchi should be performed in a routine sequence; the potential for bleeding, airway obstruction, or multiple lesions may affect the sequence in an individual patient. Mucosal characteristics are continuously examined as the bronchoscope is advanced and withdrawn. Mucosal abnormalities can be subtle because of small size, minimal surface effects, or obscure location. Slight surface irregularity or friability may be the only visual clue to a neoplasm. Often the best site for biopsy can be determined with telescopic magnification, but in vivo tissue staining has yielded diagnostic information in special circumstances. The

trachea and bronchi are also inspected for patency, deviation, configuration and intrinsic lesions, intraluminal lesions, or evidence of external compression. Subcarinal lymphadenopathy or other lesions may cause the carina or subcarinas to be blunted, broadened, displaced, or abnormally tethered during respiration and cardiac contractions.

As the bronchoscope approaches the carina, the patient's head is turned to the left to allow the bronchoscope to enter the right main bronchus. To enter the bronchi, the bevel of the bronchoscope should be turned in the direction of the bronchus to be explored.[1] The first orifice within the right main bronchus, on the lateral wall, is the opening to the right upper lobe bronchus (Figure 65–8). The bronchoscope can be stabilized just proximal to this subcarina and a 90-degree telescope passed through the bronchoscope, with its lens pointed laterally, to visualize the apical, posterior, and anterior segmental bronchi. As the bronchoscope is advanced through the bronchus intermedius, the head requires some left lateral deflection and a considerable degree of lowering[1] as the right middle lobe bronchus is identified anteriorly with its lateral and medial segments. The inferior lobe bronchus, located just posterior to the middle lobe bronchus, contains the superior, anterior basal, medial basal, lateral basal, and posterior basal segmental bronchi. A 0-degree Hopkins rod telescope may be passed through the bronchoscope to view the middle and lower lobe segments.

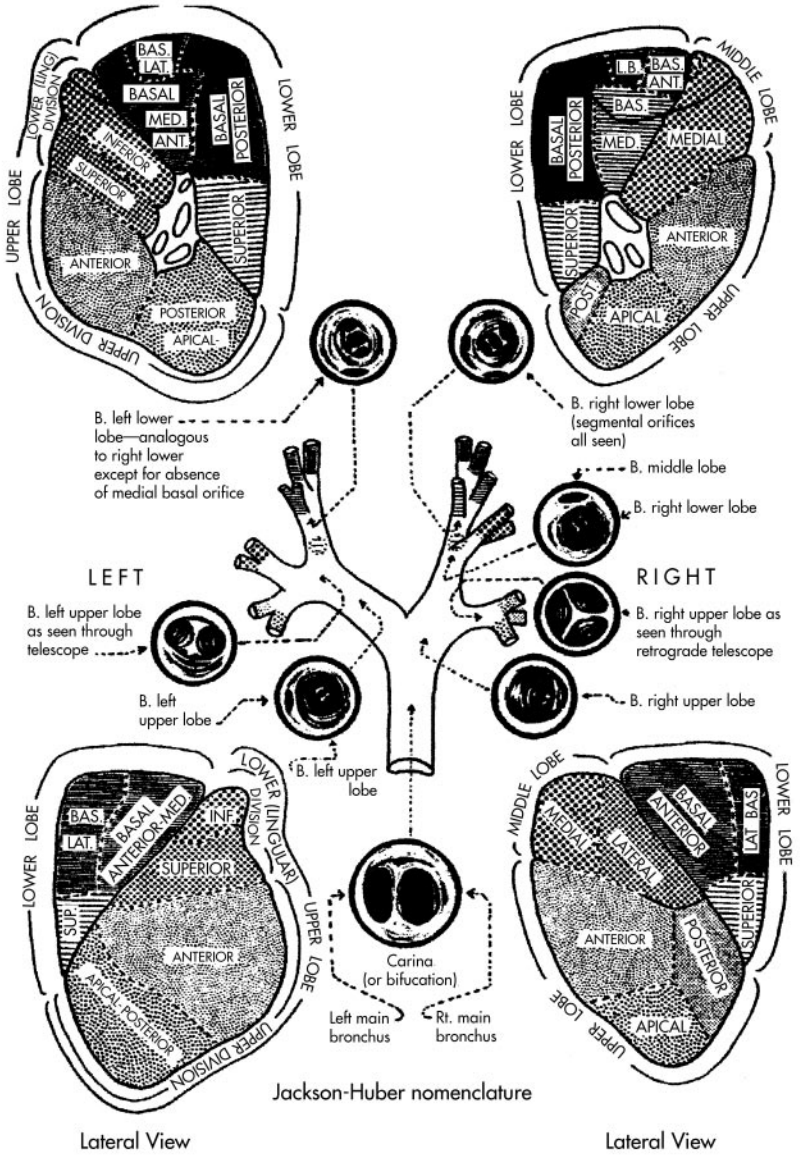

FIGURE 65–8. Schema showing the tracheobronchial tree, bronchopulmonary segments, and endoscopic landmarks.

The bronchoscope is then withdrawn just proximal to the carina, the patient's head is rotated to the right, and the bronchoscope is advanced into the left main bronchus. The left upper lobe bronchus, on the lateral wall, contains upper and lingular divisions, which can be visualized with a 90- or 120-degree telescope. The upper bronchus contains the apical, posterior, and anterior segmental bronchi; the lingular bronchus contains the superior and inferior segmental bronchi. Continuing distally, the lower lobe bronchus contains the superior segmental bronchus along its posterior wall and further distally the anterior, medial basal, lateral basal, and posterior basal segmental bronchi. As the bronchoscope is being withdrawn at the completion of bronchoscopy, careful retrograde examination should be performed.[41,42] During pediatric bronchoscopy, the telescope is connected to the ventilating bronchoscope by a locking bridge; the flexibility of the patient's neck and airway facilitate thorough examination using a 0-degree lens.

Mass lesions, including papillomas and granulation tissue, may be prudently biopsied or completely removed, particularly if obstructing and pedunculated. Removal of large sessile lesions, particularly if present in a circumferential distribution, may contribute to subsequent stenosis.

Limitations of rigid bronchoscopy include the requirement of adequate neck mobility and stability and the ability to open the patient's mouth; damage to teeth can occur.

Fiber-optic Bronchoscopy

Fiber-optic bronchoscopy is useful for examination of distal airway lesions, as a wedge for broncheoalveolar lavage, or as a conduit for fiber-optic lasers. Fiber-optic bronchoscopes can generally be inserted further toward the periphery of the lungs than rigid telescopes, particularly in the upper lobes. Fiber-optic endoscopy may be preferable in patients with cervical spine instability or limited mobility or trismus, for bedside examination, or when attempting to avoid the use of general anesthesia. Fiber-optic bronchoscopy can be performed in patients using topical or general anesthesia; however, it is more difficult to pass the bronchoscope through and beyond the glottis unless the patient is spontaneously ventilating. It may be performed using a conduit, such as an endotracheal or tracheostomy tube.

Fiber-optic bronchoscopy during spontaneous ventilation, with or without general anesthesia, is useful in evaluating dynamic lesions such as tracheomalacia or bronchomalacia.[8] Fiber-optic bronchoscopy may reveal significant airway collapse not evident during rigid bronchoscopy during general anesthesia; however, care must be taken to avoid overdiagnosis of airway dynamics. The presence of fiber-optic bronchoscope may increase airway resistance to the point that normal dynamics are exaggerated, particularly in infants whose airway structures are more compliant than those of adults.[8] Use of simultaneous fluoroscopic guidance[43] may facilitate intralesional placement of brushes, biopsy forceps, or catheters.

Equipment The outer diameter of adult fiber-optic bronchoscopes ranges from 3.4 to 6.2 mm, with side-channel diameters ranging from 1.2 to 3.2 mm; standard pediatric fiber-optic scopes have a 3.5 mm outer diameter and an operating channel of 1.2 mm.[39] Side channels can be used for suctioning, application of topical anesthetics or liquid radiographic contrast material, or passage of instruments such as biopsy forceps, balloon catheters, laser fibers, and wire brushes.[4] Fiber-optic bronchoscopes with tip angulation capability but without side channels are available with outer diameters as small as 2.2 mm.

Technique A sufficiently alert and cooperative patient can undergo fiber-optic bronchoscopy in a sitting position; the examination can also be performed supine. If the procedure is performed using local anesthesia, sedation and premedication with atropine may be used to reduce secretions and to prevent the vagovagal reflex. Anesthetizing the supraglottis and glottis prior to awake bronchoscopy, as described in the section on laryngoscopy, is helpful in preventing coughing and laryngospasm. Topical anesthesia of the trachea and subglottis, supplied by the recurrent laryngeal nerve,[17,20] can be accomplished by instilling anesthetic agents via the bronchoscope's instrument channel or by spraying the vocal folds and trachea at the beginning of each inspiration using a long, curved nozzle inserted perorally. Transtracheal injection of lidocaine can be performed via cricothyroid membrane puncture at the end of maximal expiration; subsequent coughing will spread anesthesia droplets from the carina to the inferior surface of the vocal folds.[17] Supplemental oxygen through the free

naris may be indicated in infants less than 5 kg or patients with diffuse lung disease or abnormal blood gas measurements.[39]

The bronchoscope's control unit and proximal lens are held with the endoscopist's left hand, leaving the right hand free to manipulate the bronchoscope or insert instruments. The endoscopist's thumb operates the angulation lever, which controls the angle of the distal tip, while the index finger is used to occlude the suction port as needed. Passing the bronchoscope through the nose is generally well tolerated and provides a stable, direct route to the vocal folds. A bite guard should be used to protect the bronchoscope if it is passed perorally. If the bronchoscope is inserted via the pharynx, it is advanced through the true vocal folds during inspiration; bronchoscopes may also be inserted through a facemask, laryngeal mask airway, or an endotracheal or tracheostomy tube. For patients receiving mechanical ventilation, various adapters can be used to minimize air leak and maintain mechanical ventilation and oxygen delivery.[43] When feasible in adults, the endotracheal tube size, based on the inner diameter, should be at least 1.5 mm larger than the external diameter of the fiber-optic bronchoscope.[44]

Pharyngeal hypotonia, from muscle or central nervous system disease, may make exposure of the larynx difficult. Techniques that may improve visualization include occluding the tracheostomy tube, if present; insufflating oxygen via the bronchoscope side cannel or a suction catheter or nasopharyngeal airway in the contralateral nasal cavity; or using a rigid laryngoscope.[8]

To obtain a biopsy, grasp the specimen with a cup forceps, then abruptly twist and withdraw the forceps. Aspirates or biopsy specimens obtained for culture should be placed in nonbacteriostatic saline; carinal biopsy specimens obtained in evaluation of ciliary motility abnormalities are placed in glutaraldehyde. If biopsy is performed for diffuse pulmonary disease, the specimen is obtained from the most gravity-dependent portion of lung to facilitate bleeding control.[16] After the biopsy is obtained, the fiber-optic bronchoscope is "wedged" to tamponade the bleeding for 3 to 5 minutes and then withdrawn without suctioning to avoid disturbing the clot.[16] In immunocompromised, thrombocytopenic patients undergoing evaluation for infections, broncheoalveolar lavage should be considered in lieu of biopsy.[16]

Although small forceps and baskets that will pass through the pediatric (or adult) flexible scope are available, foreign-body extraction is sufficiently difficult and risky that it should rarely, if ever, be attempted with a flexible bronchoscope unless attempts with a rigid instrument have failed and the flexible instrument offers some distinct advantage in the specific situation.[8]

Fiber-optic bronchoscopy is relatively contraindicated in patients who are hemodynamically unstable or who have unstable arrhythmias, increased intracranial pressure, severe hypoxemia, hypercapnia, systemic coagulopathy, or thrombocytopenia.[16]

Meduri and Chastre have defined factors affecting the risk of complications in mechanically ventilated adults undergoing fiber-optic bronchoscopy.[44] Criteria for high risk include active bronchospasm, PaO_2 of 70 mm Hg despite $FIO_2 > 70\%$, PEEPs of ≥ 15 cm H_2O, recent acute myocardial infarction (≤ 48 hours), unstable arrhythmia, mean arterial pressure < 65 mm Hg on vasopressor therapy, or platelet count < 20,000/mm^3.[44] Criteria for relatively high risk include PEEP > 10 cm H_2O, significant auto-PEEP (≥ 15 cm H_2O), prothrombin time or partial thromboplastin time greater than 1.5 times control, or increased intracranial pressure.[44]

Fiber-optic bronchoscopy can cause airway obstruction as the portion of the airway lumen occupied by the scope is not available for ventilation. The degree of obstruction is related to the outer diameter of the bronchoscope relative to the size of the narrowest portion of the airway; a 3.5 mm fiber-optic bronchoscope will nearly totally obstruct the airway of an infant less than 3,000 g in weight.[39] Other potential complications of rigid or fiber-optic bronchoscopy include drop in PaO_2, vagovagal reaction, fever, cardiac arrhythmias, bronchospasm, pneumonia, transient worsening in pulmonary infiltrates, and pneumothorax.[16,44] Suctioning and bronchial lavage may decrease effective tidal volume and decrease arterial oxygenation[43]; patients receiving mechanical ventilation may require compensatory changes in ventilator settings.[44]

Bleeding may occur at any site of manipulation, including the nose[45]; most resolve spontaneously.[16] The risk of bleeding is increased in patients with chest malignancies, pneumothorax,[44] immunosuppression, or coagulopathies.[16] Profuse bleeding, consisting of more than 100 mL of blood and lavage fluid in adults, can occur because of

trauma or underlying disease or following transbronchial, endobronchial, or brush biopsy.[16] Techniques helpful in controlling hemorrhage include intrabronchial instillation of 2 mL aliquots of 1:10,000 epinephrine; lateral decubitus positioning of the bleeding hemithorax; tamponade using the bronchoscope, Fogarty catheter, or a specially designed 200 cm long balloon catheter; bronchial artery embolization; open surgical procedures; or coagulation of endoscopically visible bleeding sites with a neodymium:yttrium-aluminum-garnet laser.[16] Compensatory strategies include selective intubation of the nonbleeding lung.[16] Fatal hemorrhage is uncommon.[16]

Limitations of Bronchoscopy

During rigid or fiber-optic bronchoscopy, care must be taken to minimize edema in distal airways as this may interfere with ventilation and oxygenation. Before manipulating a distal lesion or structure, it may be useful to review with the anesthesiologist how ventilation will be accomplished if the lesion is displaced or if edema occurs. Sometimes smaller telescopes can be passed beyond a lesion to view distal structures. Consider the risks of proceeding and the risk and availability of other avenues of investigation, such as medical imaging, to accomplish the intended objective.

ESOPHAGOSCOPY

Esophagoscopy provides details about esophageal anatomy and mucosal characteristics not obtainable by other methods. Specific indications for esophagoscopy are discussed in Chapter 67. As with bronchoscopes, rigid and fiber-optic esophagoscopes are complementary rather than rival instruments. Flexible instruments can be used in conscious patients, permitting assessment of function, as well as in patients with kyphoscoliosis, trismus, or cervical spine instability or rigidity, and for retrograde evaluation of the gastroesophageal junction. Endoscopy of the esophagus, stomach, and duodenum can be accomplished with a single instrument, and the use of general anesthesia may be avoided. Rigid instruments are superior for evaluation, biopsy, or management of the pharyngoesophageal segment and for particular lesions such as diverticula.[5]

Rigid Esophagoscopy

During rigid esophagoscopy, telescopes, light carriers, metal suction catheters, optical forceps, or other grasping instruments can be placed in the lumen of an open-tube esophagoscope. Pediatric esophagoscopes also contain a side channel oriented such that stiff plastic suction catheters, Dormia urologic stone baskets,[46] or narrow, flexible alligator or biopsy forceps can be inserted into the lumen alongside a Hopkins rod telescope, allowing simultaneous magnification, visualization, and distal illumination. Assembling the telescope within a pediatric esophagoscope with a locking bridge will result in the tip of the telescope protruding beyond the opening of the esophagoscope, limiting visualization. Alternatively, the telescope can be secured within the esophagoscope by inserting it through a cap with a rubber dam. This is less stable than a locking bridge but allows the tip of the esophagoscope to distend the esophageal lumen in advance of the telescope, improving visualization. Using this technique, the grip in the right hand must remain relaxed; clenching the fingers will cause the tip of the telescope to protrude beyond the tip of the esophagoscope. In a normal esophagus, straight and rigid tubes of 7 mm diameter should pass freely in infants and tubes of 10 mm in adults.[1]

The operating room table should have a joint under the patient's neck so the patient's neck and head position can be adjusted as the procedure progresses. The end of the table should protrude so that the endoscopist can sit comfortably at the head of the table as needed during the procedure.

Technique An experienced endoscopist may be able to retrieve a proximal esophageal foreign body during episodes of apnea, but generally patients undergoing rigid esophagoscopy are intubated, allowing control of the airway and minimizing time constraints. Following orotracheal intubation, taping the endotracheal tube to the left oral commissure facilitates passage of endoscopic instruments without inadvertent extubation.

The esophagus is a tubular structure that begins at the cricopharyngeus muscle, located about 20 cm from the teeth, and extends to the gastroesophageal junction at the diaphragmatic hiatus, about 40 cm from the teeth in adults. The cricopharyngeus muscle forms the upper esophageal sphincter, and thickening of the smooth muscle distally at the gastroesophageal junction creates the lower

esophageal sphincter. Normally, the lumen of the esophagus is collapsed in a flattened or stellate pattern, but it can be distended to at least 2 cm. The longitudinal mucosal folds flatten with distention. The wall of the esophagus is thin and lined by a shiny, pale pink mucosa.[1,41]

The diameter of the esophagus is reduced at four points: the cricopharyngeus, the crossing of the aorta at 25 to 30 cm from the incisors, the crossing of the left bronchus, and the hiatus for the esophagus at the diaphragm. The average distance to these points from the upper teeth, according to age, is shown in Figure 65–9. There is a definite fifth narrowing of the esophageal lumen not easily demonstrated endoscopically and not seen during dissection but readily shown functionally by the fact that almost all foreign bodies lodge at this point. This narrowing occurs just below the cricopharyngeus, at the superior aperture of the thorax, and is probably produced by the crowding of the numerous organs that enter or leave the thorax through this orifice.[1] In the spontaneously breathing patient, periodic relaxation and contraction of the cricopharyngeus muscle can be viewed via an esophagoscope placed posterior to the cricoid cartilage.

In the "high-low" technique described by Jackson, the position of both the endoscopist and the patient's head and neck relative to his body change as the endoscopy proceeds.[1] Jackson divides the procedure into four stages: entering the right piriform sinus, passing the cricopharyngeus, passing through the thoracic esophagus, and passing through the hiatus. Initially, to bring the cervical spine, and therefore the esophagus, into a straight line with the upper portion of the dorsal spine, the head is elevated into the "high" position.[1] The endoscopist stands cephalad to the patient. Jackson asserted that the services of a trained assistant to place the head in the proper sequential "high-low" positions are indispensable[1]; head position can also be maintained by flexing the neck joint of the operating room table or placing a firm support under the head.

Initially, the esophagoscope is nearly vertical, with the long end of the bevel positioned anteriorly. As the esophagoscope is advanced along the right side of the tongue and down the posterior pharyngeal wall, the long bevel is used to lift the tongue base, endotracheal tube, and arytenoid cartilages in advance of the esophagoscope, and the position of the esophagoscope will approach horizontal. The

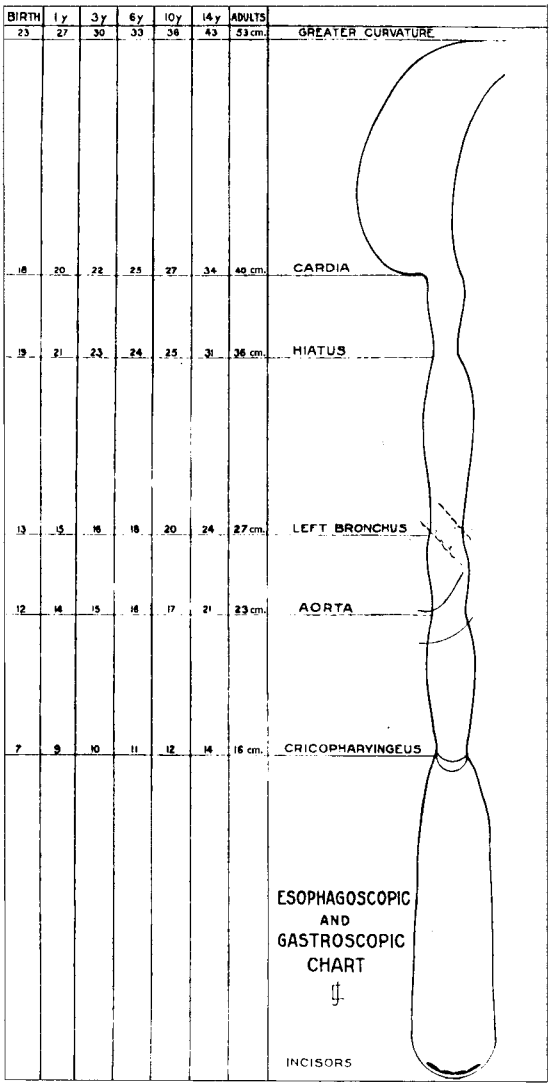

FIGURE 65–9. Jackson's chart of approximate distances of esophageal narrowings from the upper incisors at various ages. Reproduced with permission from Jackson C. Bronchoscopy and esophagoscopy. A manual of peroral endoscopy and laryngeal surgery. Philadelphia: WB Saunders; 1922.

esophagoscope follows the natural food passage; just as the epiglottis splits a bolus of food and the two portions drift laterally into the piriform sinuses, the esophagoscope is introduced via the right piriform sinus. "To insert the esophagoscope in the midline, posterior to the arytenoids, required a degree of force dangerous to exert and almost certain to produce damage to the cricoarytenoid joint or to the pharyngeal wall, or to both."[1] A lifting motion imparted to the tip of the esophagoscope by the left thumb will expose the rounded right arytenoid eminence. The tip

of the esophagoscope should now be directed somewhat toward the midline, following the funnel shape of the hypopharynx. The endoscopist's right hand remains at the proximal end of the esophagoscope to control the angle of insertion and progression of the esophagoscope, as well as the position of the telescope within the esophagoscope, and to manipulate side-channel suctions or other equipment. The endoscopist's left hand is positioned at the alveolar ridge or maxillary teeth. The fingers of the left hand advance the esophagoscope and maintain an awareness of a space between the esophagoscope and the patient's teeth, and the left thumb lifts the tip of the esophagoscope. The cricopharyngeus is entered without force.[1] "To prevent perforation the esophagoscope is to be passed only with ocular guidance."[1] Once the esophagoscope is introduced through the esophageal introitus and cricopharyngeus, the endoscopist sits and the head of the operating table is lowered below horizontal. At this point, the esophagoscope can be rotated so that the side-channel port is on the right, facilitating passage of suction catheters or instruments with the endoscopist's right hand. While instruments are manipulated with the right hand, the left hand maintains the appropriate position of the esophagoscope. The esophagoscope is gently advanced with the left hand, following the lumen.

If the patient's position is correct, the esophagoscope should glide easily through the thoracic esophagus. As the esophagoscope is advanced, the impression of the arch of the aorta and the left bronchus are usually seen only faintly, but pulsations can be felt readily through the endoscope.[1] After the levels of the aorta and the left bronchus are passed, the lumen of the esophagus seems to disappear anteriorly; the patient's head is lowered as required to maintain visualization.[1] As the esophagoscope passes through the hiatus for the esophagus of the diagphragm, the head is lowered and moved horizontally to the right so that the axis of the tube corresponds to the axis of the lower third of the esophagus. As the esophagus deviates to the left and turns anteriorly, the hiatus is usually apparent as an anteriorly placed narrowing. The head and shoulders at this time will be found to be considerably below the plane of the tabletop.[1] In addition to its anterior curvature, the lower third of the esophagus turns strongly to the left, so an esophagoscope inserted from the right angle of the mouth, when introduced into the stomach, points in the direction of the anterior superior spine of the left ileum.[1] As the hiatus is passed, the stellate pattern of the esophagus is replaced by the deeper red, velvety gastric mucosa with prominent rugal folds.

A side-channel suction can be used to aspirate secretions that interfere with visualization. The tip of the suction catheter should not be advanced beyond where it can be visualized so that the tip does not cause a perforation. During the procedure, the suction catheter can be left sheathed within the esophagoscope when not in active use. If the telescope is held in position by a rubber cap, then the length to which the telescope is inserted into the esophagoscope can by varied by the endoscopist. If the esophagoscope becomes flooded with secretions, the telescope can be partially withdrawn proximally and the suction catheter can be positioned with good visualization. Withdrawing the telescope a few centimeters also allows visualization of side-channel instruments as they are advanced before they project into the lumen of the esophagus.

Specular esophagoscopy comprises inspection of the hypopharynx and upper esophagus with an esophageal speculum or a long laryngoscope.[1] The larynx is exposed as in direct laryngoscopy, the right piriform sinus is identified, and the tip of the speculum is inserted therein and gently insinuated to the cricopharyngeal constriction. Too great extension of the head is to be avoided; slight flexion at the occipitoatloid joint is useful at times. Moderate anterior or upward traction pulls the cricoid away from the posterior pharyngeal wall and opens the lumen of the esophagus. The speculum has the disadvantage of limited length so that should the foreign body move downward, it cannot be followed with this instrument.[1]

Fiber-optic Esophagoscopy

Fiber-optic esophagoscopy can be performed under general or local anesthesia. For conscious patients, topical anesthetic agents are sprayed into the oral cavity and oropharynx, a bite guard is placed, and intravenous sedation may be useful. Because the primary complication of endoscopy is cardiopulmonary compromise, vital signs and oxygen saturation should be monitored during the procedure.

As with bronchoscopes, the flexible fiber-optic esophagoscopes have multiple accessories for diagnostic and therapeutic management of esophageal

pathology. Probes for Doppler, ultrasonography, and pH monitors as well as biopsy forceps, baskets, and cytologic brushes and needles are available.

The endoscopist controls the air, water, and suction valves and tip direction wheels. The right hand advances the instrument; rotating the instrument control handles applies torque to the esophagoscope, rotating the shaft and tip.

The esophagoscope can be inserted blindly, by feel, through the esophageal inlet. It can also be inserted under direct visualization; the tip of the endoscope is gently advanced into the hypopharynx to a distance approximately 18 cm from the incisors, reaching the level of the upper esophageal sphincter or muscle. The cricopharyngeus is closed at rest and opens during swallowing. The esophageal inlet is visualized, and the endoscope is gently advanced into the esophagus as the patient swallows. Difficulty passing the esophagoscope past the cricopharyngeus indicates obstruction, which may result from cervical spine spurs, tumors, postsurgical stenosis, or abnormal neural function. Examination is performed to a distance of 40 cm, where the ora serrata is located. This is also referred to as the squamocolumnar mucosal junction or Z line, demarcating the junction between pearly, esophageal, stratified squamous mucosa and the redder gastric columnar epithelium. Fiber-optic esophagoscopes are limited in their ability to visualize the region of the introitus and cricopharyngeus, which are common places for foreign-body lodgment.

Complications of Esophagoscopy

Potential complications of esophagoscopy include cricoarytenoid joint dislocation, bleeding, and perforation[1]; in addition, insufflation used during fiber-optic esophagoscopy can cause abdominal distention, contributing to respiratory compromise. Esophageal perforation may occur during or following esophagoscopy or surgical manipulation such as diagnostic biopsy, dilatation, and repair of tracheoesophageal fistula or hiatal hernia or as a consequence of ulceration or erosion of the esophageal wall from cancer, ectopic gastric mucosa, esophageal peptic ulcer, or foreign body.[47] Judicious choice of instrument diameter and length, maintaining visualization of the esophageal lumen, gentleness of touch, judicious biopsy of abnormal areas, avoidance of persistent attempts to pass the esophagoscope through a neoplastic area, and gentle dilation[47] will help prevent complications.

Perforations most commonly occur at the weakest points of the esophageal wall, such as the area just below the cricopharyngeus, the distal one-fifth, or the site of any local lesion that weakens the wall. The diagnosis is usually suggested by retrosternal or back pain, fever, or subcutaneous emphysema.[1,47] Following rigid or fiber-optic esophagoscopy, patients may be observed and not fed for varying lengths of time; a chest radiograph may be obtained to evaluate the possibility of free mediastinal air or pleural effusion, infiltrate, or pneumothorax. Either or both hemithoraces may be affected. Opaque media given by mouth can demonstrate the site of leakage.[47] Because the retrovisceral space and the superior mediastinum have practically no tissue barriers, infection following rupture spreads rapidly and extensively[47] and may result in septic mediastinitis.[1] Perforation caused by esophagoscopy or following esophageal surgery can often be managed by prohibiting oral intake and administering antibiotics and intravenous fluids; a feeding jejunostomy may be indicated. If the tear is large or there is evidence of infection in the pleural cavities or mediastinum, appropriate drainage should be established; fluid in the chest necessitates drainage.[47] Perforation resulting from cancer or ulceration requires repair of the rent, drainage, and antibiotics.[47] In a study of 24 cases of esophageal perforation, mortality was 25% if the perforation was recognized within 4 hours and 86% when recognition was delayed 24 hours or longer. Mortality was also higher in patients under 10 years and older than 60 years of age.[47]

CHAPTER 66

Laryngoscopy

Ellen S. Deutsch, MD, Jane Y. Yang, MD, James S. Reilly, MD

The larynx comprises the supraglottis, consisting of the epiglottis, aryepiglottic folds, false vocal folds, and laryngeal ventricle; the glottis or true vocal folds; and the subglottis, including the cricoid cartilage. Proctor described the laryngotracheal airway as "the bottleneck of the respiratory system. Whereas disease in the nose or in the bronchial airways will affect respiratory airflow in a limited way, laryngotracheal disease must always be considered potentially life threatening."[1]

LARYNGEAL DISEASE

Laryngeal disease generally presents with pain, stridor, or hoarseness. Hoarseness is a precise localizing feature, indicating that the abnormality involves, but is not necessarily limited to, the free margin of the vocal folds.

Benign Masses

Vocal fold nodules, polyps, and cysts generally occur at the junction of the anterior and middle third of the vocal fold and involve the epithelial and superficial layers of the lamina propria. Vocal fold nodules (Figure 66–1), generally bilateral and caused by voice abuse, are small, white, firm, sessile masses containing collagenous fibers and edema.[2] A nodule as small as 1 mm may impair the voice.[1]

Vocal fold cysts, usually unilateral, comprise epidermoid cysts and mucous retention cysts. Epidermoid cysts, caused by vocal trauma, arise from an infolding of the mucosa and are filled with caseous material. Mucous retention cysts arise from obstructed excretory ducts and are filled with mucoid material.[2] Posthemorrhagic cysts may contain blood products.

Polyps, caused by vocal trauma, are usually unilateral, pedunculated, or sessile and may have evidence of preceding hemorrhage. A prominent feeding vessel may be observed on the superior aspect of the vocal fold. Histologic analysis may reveal hyalin degeneration, thrombosis, edema, collagenous fibrous proliferation, and cellular infiltration.[2] Polyps are removed by grasping them with cup forceps and retracting them toward the midline. An incision is made through the mucosa into Reinke's space, and the polyp is separated from the underlying vocal ligament. Small mucosal tags can be vaporized or "spot welded" with a laser to provide a smooth surface.[3]

Reinke's edema, also known as polypoid corditis or polypoid degeneration of the vocal folds, is most commonly associated with tobacco use, although vocal misuse and extraesophageal reflux disease may contribute to this condition. The vocal folds have a sausage-shaped edematous appearance. Histologically, the superficial layer of the lamina propria is replaced by a myxomatous-appearing stroma.

Granulomas commonly occur on the vocal process or inner surface of the body of the arytenoid cartilage and can be large enough to obstruct the airway.[4] Primary etiologic factors include traumatic or prolonged intubation, vocal abuse or other trauma, or extraesophageal reflux disease. Allergy, infection, postnasal drainage, smoking, and psychosomatic factors may contribute.[5–7] Small lesions may be managed with voice and antireflux therapy,[5] but recurrence is common.[4] Adjunctive therapies include antibiotics, topical or systemic corticosteroids, and elimination of sources of chronic irritation.[4] Larger or persistent lesions may also require laser or other surgical resection.[3,4] Injection of botulinum toxin or intralesional corticosteroids may be successful for recalcitrant lesions.[6]

Benign neoplasms are less frequent causes of hoarseness. Laryngeal rhabdomyomas are benign but may recur if excision is incomplete. Despite the histologic resemblance to cardiac rhabdomyomas,

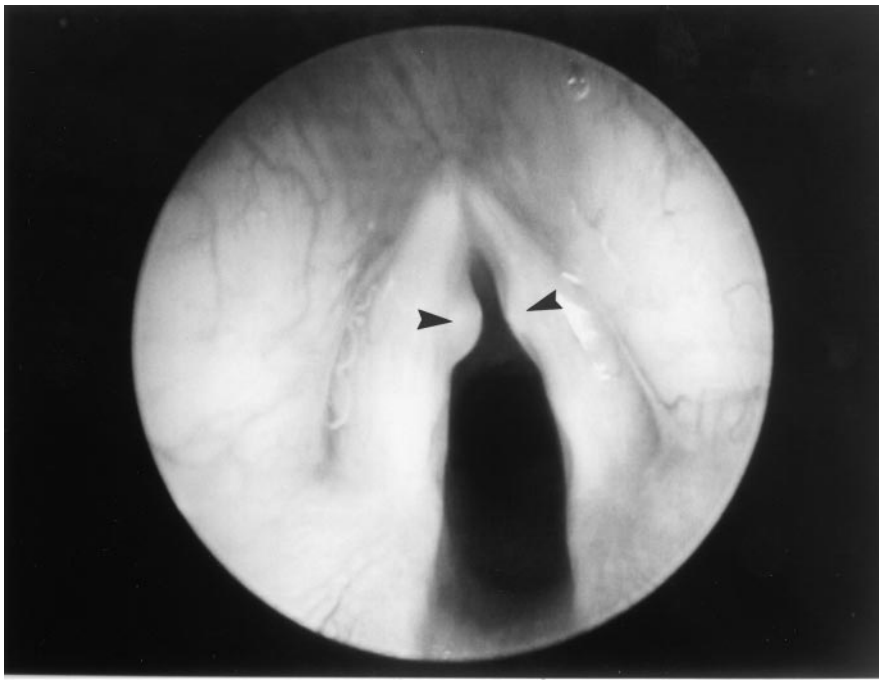

FIGURE 66–1. Vocal fold nodules (*arrows*).

extracardiac rhabdomyomas do not have the same association with tuberous sclerosis.[8]

Cartilaginous laryngeal neoplasms, such as chondromas, have a 5 to 1 male predominance; most occur in patients between the ages of 40 and 60 years. If located within the cricoid cartilage, dyspnea may be a more prominent symptom than hoarseness. Endoscopically, the lesions have a smooth, encapsulated appearance. Biopsy of hard masses, such as chondromas, may be difficult because the hardness of the lesion may permit removal only of overlying mucosa.[8]

Granular cell tumor, previously referred to as granular cell myoblastoma, is a benign, slow-growing neoplasm that can often be removed endoscopically.[8] The characteristic, but not pathognomonic, histologic feature is pseudoepitheliomatous hyperplasia. Immunohistochemical staining is positive for S-100, documenting neurogenic origin.

Neurofibromas and neurilemomas or schwannomas are histologically similar, benign, neurogenic tumors of the larynx originating from the aryepiglottic fold or from the false vocal folds. Reported age at presentation ranges from 3 months to 75 years of age; the lesions are smooth, with intact overlying mucosa. Biopsy may be difficult because the firmness and encapsulation of the mass resist the biopsy forceps; attempts to obtain adequate specimens may cause excessive bleeding. Extralaryngeal approaches may be required for resection of large lesions.[8]

Paragangliomas and atypical carcinoids may have similar clinical appearances. Paragangliomas present as red or blue submucosal masses most commonly located in the supraglottis. Atypical carcinoids may be similar in color but can also be polypoid, ulcerated, nodular, or pedunculated. Paragangliomas are the only laryngeal neoplasm with a female predominance; atypical carcinoid most commonly occurs in males. Both are of neuroendocrine origin, contain neurosecretory granules, and are distinguished by careful immunocytochemical and/or ultrastructural investigation. In contrast to other head and neck paragangliomas, such as chemodectomas, laryngeal paragangliomas do not secrete catecholamines. Treatment for atypical carcinoid is surgical. Regional metastases are common at the time of diagnosis; death usually occurs from distant metastases rather than local recurrence. Paragangliomas have an excellent prognosis and are managed with conservative surgery.[8–10]

Hemangiomas occur in both adult and infantile types. The infantile type typically presents as a compressible, sessile mass in the subglottis. They are usually unilateral but may be circumferential; histologically, they may be cavernous, simple, or capillary in appearance. Infantile subglottic hemangiomas generally increase in size and symp-

tom severity until 6 months of age, after which spontaneous regression occurs. The adult form occurs on or above the vocal folds and is often pedunculated, well demarcated, and reddish blue in color. Biopsy is generally considered both dangerous and unnecessary; diagnosis is based on clinical history and endoscopic appearances[8] and may be supported by radiologic studies. Kaposiform hemangioendothelioma is a rare, aggressive, vascular neoplasm, often associated with Kasabach-Merritt syndrome (platelet trapping associated with thrombocytopenia purpura), which is clinically and histologically distinct from the classic hemangioma of infancy (Figure 66–2).

Lipomas are usually solitary lesions found in men during the seventh decade of life; most can be removed endscopically.[8]

Extralaryngeal lesions may compress the airway and cause stridor by exerting a mass effect. Examples include retropharyngeal abscesses, adjacent tumors, or postcricoid foreign bodies (Figure 66–3).

Autoimmune, immune, and idiopathic diseases may have laryngeal manifestations. Sarcoidosis, discussed further in Chapter 67, is an idiopathic, chronic, noncaseating granulomatous disease that presents with dysphonia, dysphagia, globus sensation, and dyspnea.[11] Laryngeal sarcoidosis most commonly involves the supraglottis, particularly the epiglottis, which appears diffusely enlarged with occasional nodularity.

Scleroma (rhinoscleroma) is a chronic granulomatous infectious disease caused by *Klebsiella rhinoscleromatis*, which primarily occurs in the nose and nasopharynx but may involve the larynx.[12] Treatment includes antibiotics; surgical resection may be necessary for life-threatening airway obstruction.[12]

Wegener's granulomatosis is a necrotizing vasculitis typically involving a triad of organs: the sinuses, lungs, and kidneys. Nasal manifestations may include severe nasal crusting, epistaxis, ulcerations, and septal perforation. Glomerulonephritis may present with microhematuria, proteinuria, and red cell casts. Laryngeal involvement generally causes subglottic stenosis with dyspnea and stridor (Figure 66–4); progression may be followed endoscopically or radiographically.[13,14] Elevated antineutrophilic cytoplasmic antibodies are highly specific for Wegener's granulomatosis.[14] Diagnosis is supported by histology revealing necrotizing vasculitis involving small to medium-sized arteries and multinucleated giant cells or non-necrotizing granulomas.[12] Treatment consists primarily of corticosteroids and oral cyclophosphamide.[12]

Amyloidosis is a disease of unknown etiology characterized by deposition of extracellular, fibrillar protein. It is classified by the name of the fibrillar

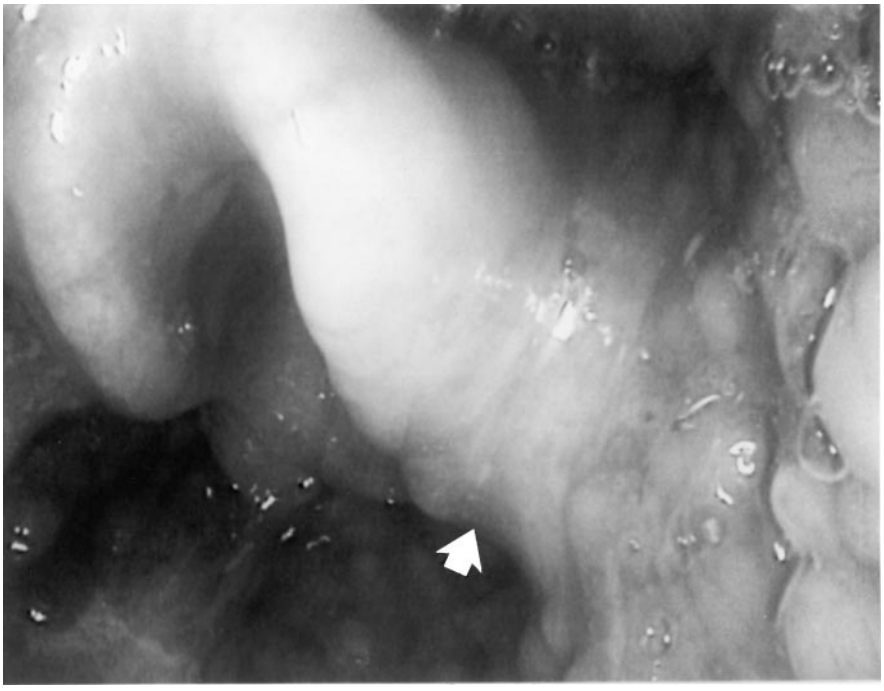

FIGURE 66–2. Kaposiform hemangioendothelioma involving the epiglottis, right pharyngoepiglottic fold (*arrow*), and hypopharynx in an infant. The subglottis and trachea were also affected, and radiologic study documented extensive mediastinal disease.

protein (AL, AA, ATTR, or AB2M), the precursor protein (kappa or lambda light chain, apoSSA, transthyretin, or β_2-microglobulin), and the clinical presentation (primary, secondary multiple myeloma associated, familial, or hemodialysis associated).[15] The larynx is the most common site of involvement in the upper aerodigestive tract. In the larynx, amyloidosis is usually localized, idiopathic, and primary,[15,16] presenting with insidious onset of hoarseness. Examination reveals a diffuse submucosal mass, which may cause vocal fold motion to appear sluggish. It is important to determine whether the disease is localized or systemic; systemic disease can involve any organ system and has a poor prognosis. Previously, rectal, lip, and gingival biopsies were obtained, but abdominal fat aspiration is a safe and better-tolerated procedure for identifying systemic disease.[17] Bone marrow biopsy may be necessary to determine whether the patient has multiple myeloma. Pediatric laryngeal amyloidosis is rare.[15]

Rheumatoid arthritis is an autoimmune disorder affecting 2 to 3% of the adult population.[18] Laryngeal involvement is believed to affect up to half of patients with rheumatoid arthritis.[19] Both adult and juvenile rheumatoid arthritis may involve the cricoarytenoid joint. During the acute inflammmatory stages, laryngeal manifestations may include throat pain, dysphagia, dysphonia, odynophagia, odynophonia, globus sensation, and referred otalgia. Examination of the larynx may reveal erythema of the mucosa overlying the joint, edema, and ulcera-

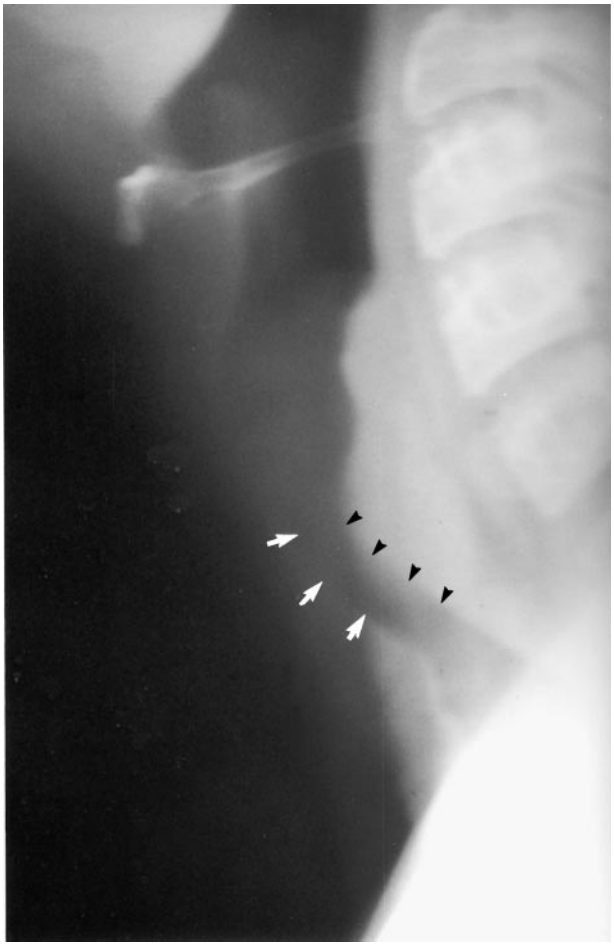

FIGURE 66–4. Lateral neck radiograph demonstrating subglottic narrowing (*arrows*) in an adolescent with Wegener's granulomatosis. (Courtesy of Eric Faerber, MD.)

tions.[1,18,20] Chronic rheumatoid arthritis may cause cricoarytenoid joint stenosis or fixation causing impaired vocal fold mobility; tracheostomy may be required for severe airway obstruction.[1] Rarely, rheumatoid arthritis causes submucosal nodules involving the true vocal folds, aryepiglottic folds, and postcricoid region.[18,20,21]

Relapsing polychondritis is a multisystemic autoimmune inflammatory disorder of obscure etiology characterized by progressive inflammation and degeneration of cartilaginous structures and connective tissues. One of the most prominent features is acute perichonditis of the pinna, sparing the noncartilaginous lobule. The disease is generally first characterized by perichondritis and cartilage dissolution in the nose and ears, but respiratory tract involvement may be the presenting symptom in as many as 26% of patients, and up to 50% of patients will eventually develop respiratory complications.[22] Symptoms of respiratory tract involvement include cough, hoarseness, aphonia, dyspnea, and tenderness over the thyroid cartilage and anterior trachea. Involvement of laryngeal cartilages can cause subglottic stenosis (Figure 66–5) or glottic aperture collapse. Laryngotracheobronchial involvement may cause life-threatening airway obstruction from acute inflammation, scarring, or airway collapse from cartilage dissolution.[1,23] McAdam et al's criteria for diagnosis require three or more of the following manifestations: bilateral auricular chrondritis, nonerosive seronegative inflammatory polyarthritis, nasal chondritis, ocular inflammation (uveitis, conjunctivitis, keratitis, episcleritis), respiratory tract (larynx, trachea, bronchi) chondritis, and audiovestibular damage (sensorineural hearing loss, vertigo, tinnitus); the ribs and heart can also be affected.[24] Laboratory studies may reveal normocytic, normochromic anemia, mild leukocytosis, and an elevated erythrocyte sedimentation rate. Medical management in the acute phases includes corticosteroids; dapsone and immunosuppresant agents, such as cyclophosphamide, may be helpful.[25]

Examination of supraglottic allergic edema reveals pale, watery swelling of the epiglottis and aryepiglottic folds.[26] The edema usually responds quickly to subcutaneous administration of 0.2 mL of epinephrine 1:1,000 for adults (0.01 mL/kg of body weight for children) plus 100 mg of intramuscular or intravenous hydrocortisone phosphate for adults[26]; antihistamines and inhaled racemic epinephrine may also be useful.[27–29] Fatal airway obstruction can occur when the larynx is affected[30]; endotracheal intubation or tracheostomy may be necessary. The acute edema usually subsides within 24 to 48 hours after initiation of treatment.

Hereditary angioedema results from an autosomal dominant deficiency of active C1 esterase inhibitor leading to recurrent attacks of localized

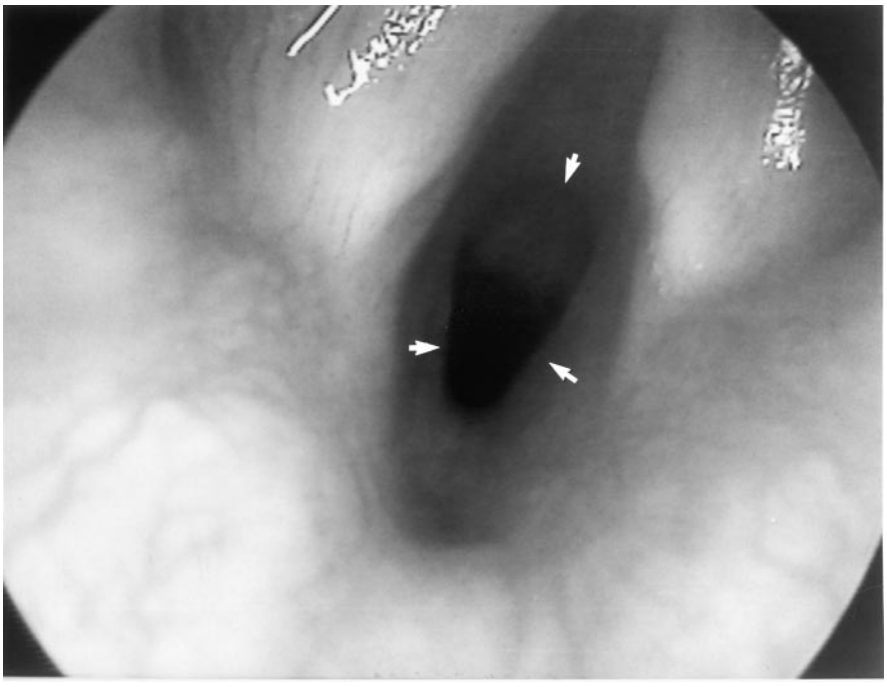

FIGURE 66–5. Endoscopic view of circumferential narrowing of the subglottis (*arrows*) in an 11-year-old boy with relapsing polychondritis.

edema or severe abdominal pain, precipitated by trauma or physical or emotional stress.[29,31] The onset is usually in childhood, and there may be a family or past medical history of self-limited attacks associated with a salmon-colored rash.[30] The deficiency of C1 esterase inhibitor protein is usually quantitative but can be qualitative.[31] Decreased levels of C4, another component of the complement activation cascade, may accompany both quantitative or qualitative C1 esterase inhibitor protein deficiencies; determination of C4 levels may be a useful screening test.[29,32] Airway occlusion is the most common cause of mortality.[31] Standard therapies for allergy-mediated angioedema, such as epinephrine, antihistamines, and corticosteroids, are less successful, and mechanical control of the airway may be needed.[31] Long-term prophylactic treatment may include attenuated androgens such as danazol or stanozolol; antifibrinolytic medications such as ε-aminocaproic acid and tranexamic acid; and C1-INH concentrate. Long-term use of attenuated androgens has been associated with hepatocellular carcinoma and should be used with caution in women, especially during pregnancy, and children. Antifibrinolytic medications are the drugs of choice for children; continuous use increases the risk of thromboembolic events.[33,34] C1-INH concentrate, effective within minutes of infusion, is used for acute management; fresh frozen plasma can also be used but is less efficacious. C1-INH concentrate or attenuated androgens are used for short-term prophylaxis before surgical and dental procedures.[29,34]

Acquired angioedema is less common and generally begins during adulthood.[31] Drug-induced angioedema most commonly occurs in patients taking angiotensin-converting enzyme (ACE) inhibitors, particularly captopril and enalapril maleate. The effects of kinase II, which stimulates the conversion of angiotensin I to the vasoconstrictive angiotensin II and inactivates bradykinin, a potent vasodepressor, are blocked by ACE inhibitors.[27]

Acute spasmodic laryngitis or nocturnal croup typically presents as a mild viral upper respiratory tract infection with nocturnal episodic wakening accompanied by inspiratory stridor and croupy cough in a toddler; it invariably subsides during the day. Examination is remarkable for the absence of severe laryngeal inflammation or fever. The etiology is unclear, but it may be related to an upper respiratory tract infection[30] or may be a manifestation of reactive airway disease.

Epiglottitis, or acute supraglottitis, is an acute bacterial infection of the epiglottis, aryepiglottic folds, and soft tissues of the arytenoid cartilages.[35] Features include the dangerously rapid onset of sore throat, high fever, muffled voice, and signs and symptoms of airway obstruction, including inspiratory stridor, inability to swallow, respiratory distress, and restlessness. The classic presentation is a pale, shocky, restless, drooling child in an upright position with head forward and tongue protruding. Examination, which is deferred until equipment and personnel are available to secure the airway, reveals fiery red edema of epiglottis and aryepiglottic folds.[26] Pediatric acute supraglottitis, now uncommon, was previously caused predominantly by *Haemophilus influenzae*. The disease is now more common in adults and may be life-threatening but is usually less severe, with slower onset and progression.

"Croup," or laryngotracheobronchitis, refers to a constellation of viral infections that may affect any or all segments of the pediatric airway. Croup is the most common illness affecting the airway in children and the most common cause of airway obstruction in children; the majority of patients are between the ages of 6 months and 4 years.[35] Patients usually have a characteristic "barking" cough, 60% have inspiratory stridor, and the voice may be hoarse but not muffled,[35] Most patients respond to medical and supportive therapy,[35] including humidification, nebulized racemic epinephrine, and systemic glucocorticoids[35]; uncommonly, intubation is necessary. Anteroposterior airway radiographs may demonstrate subglottic swelling, which changes the appearance of the square-shouldered space below the vocal folds to that of a steeple or pencil[35]; lateral neck radiographs may show subglottic haziness. Endoscopy is avoided during the acute phase of the illness but is indicated if the patient fails two extubation attempts[35] or does not improve as expected. Interval endoscopy is indicated if the patient has other risk factors for subglottic stenosis, more than three episodes of croup, onset of croup prior to 6 months of age, or an atypical course.

Recurrent respiratory papilloma is a benign but very rapidly proliferating tumor[30] that usually presents within the first few years of life with hoarseness, inspiratory stridor, and respiratory distress progressing over a period of weeks or months.[30] Human papillomavirus (HPV) subtypes 6 and 11 are most commonly found in juvenile recurrent respiratory

papilloma.[36] Treatment consists of repeated excision using carbon dioxide laser or a microdébrider.[3,36] A variety of adjunctive therapies have been tried, including interferon alpha-2a, cruciferous vegetables, indole-3-carbinol, acyclovir, ribavirin, mumps vaccine, isotretinoin, and photodynamic therapy.[36] Recent trials of cidofovir appear promising.[36] Tracheostomy may be necessary but may be associated with seeding of papillomas locally and distally.[30] Malignant degeneration of recurrent respiratory papilloma is uncommon, but the risk is greater for patients with subtypes 16/18 and 31/33[37] and those treated with radiation therapy.[38]

Bacterial or fungal laryngitis and tracheitis (Figure 66–6) can cause sudden airway obstruction.

Laryngopharyngeal reflux, or extraesophageal reflux, denotes the entry of gastric contents above the upper esophageal sphincter. More than 60% of adults with suspected laryngopharyngeal reflux do not have the classic gastroesophageal reflux symptoms of heartburn and reflux.[39,40] Otolaryngologic manifestations and sequelae of extraesophageal reflux include chronic intermittent hoarseness, vocal fatigue, sore throat, dysphagia, chronic cough, stridor, croup, subglottic stenosis, excessive mucus production, postnasal drip, globus sensation, a choking sensation resulting from laryngospasm, and frequent throat clearing.[40,41] Pulmonary conditions associated with reflux include asthma, pulmonary fibrosis, bronchiectasis, chronic bronchitis, and pneumonia.[42] Other oral cavity, nasal, and nasopharyngeal manifestations include chronic sinusitis, otalgia, and otitis media.[42] Laryngeal examination may reveal edema, which may be diffuse or limited to the vocal folds, obliteration of the ventricles, interarytenoid thickening, pseudosulcus, or vocal process granuloma. Effects within the posterior part of the larynx or trachea include erythema, edema, "cobblestoning," blunting of the carina, and friable mucosa.[39]

Two mechanisms of injury may coexist: reflex mechanisms may cause laryngospasm, bronchospasm, or apnea, and prolonged direct contact with the gastric fluid may cause mucosal damage. In infants, some gastroesophageal reflux is considered normal; however, it increases the risk of postintubation subglottic stenosis and should be controlled in candidates for laryngotracheal reconstruction and repair of cleft larynx.[35] Twenty-four-hour multichannel ambulatory esophageal pH monitoring is the most sensitive study for extraesophageal reflux; esophagoscopy with biopsy, barium esophagram, nuclear medicine scintiscan, and bronchoscopy with washings for fat-laden macrophages may be supportive.[35]

Treatment consists of a combination of antireflux behavioral and dietary modifications and acid-suppressive medications, including histamine H_2-receptor antagonists and proton pump inhibitors. Patients who are unable to tolerate the medications or those who continue to have acid reflux despite medications may benefit from surgical therapy such as Nissen fundoplication.[35]

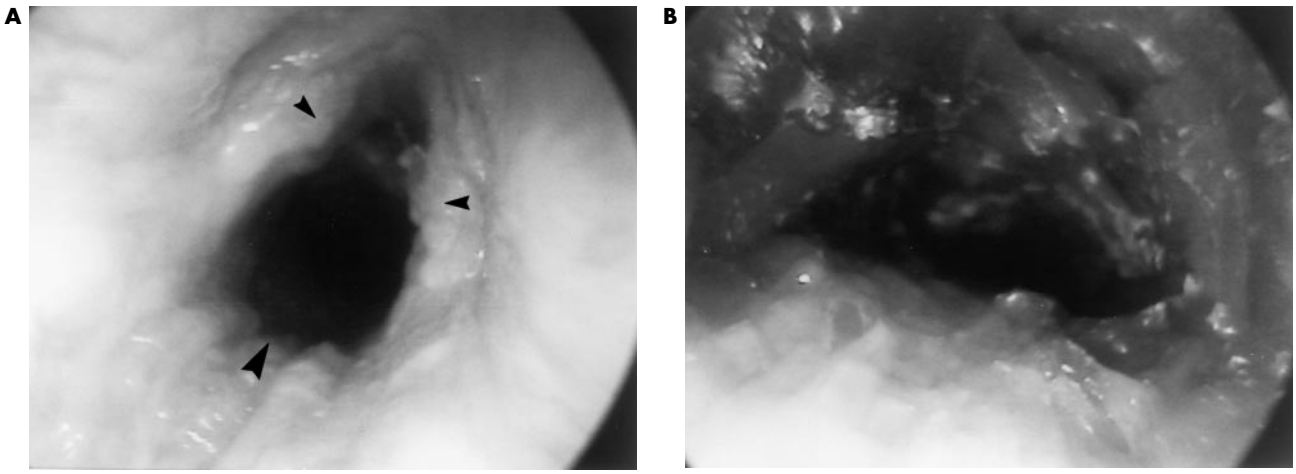

FIGURE 66–6. Endoscopic view of the larynx and trachea in a 4-year-old with diffuse *Candida* laryngitis (*A*) and tracheitis (*B*) with macrophage-activating illness. Note crusted lesions in the posterior commissure (*large arrowhead*) and obscuring the vocal folds anteriorly (*small arrowheads*) and massive crusts within the trachea.

Acute airway obstruction from laryngeal or tracheal edema is possible after ingestion of acid, alkali, or corrosive substances; following inhalation of hot air, smoke, steam, or chemical fumes[30,35]; or following direct mechanical trauma, such as a finger sweep maneuver. Traumatic epiglottitis may be treated with fluids, humidified supplemental oxygen, nebulized epinephrine, and parenteral administration of corticosteroids[30]; intubation may be necessary. Intraluminal trauma may occur from intubation or other causes and can result in acquired glottic or subglottic stenoses, subglottic cysts, synechiae, and webs. Pressure from endotracheal or tracheostomy tube cuffs may cause tracheomegaly (Figure 66–7).

External causes of laryngeal injury include blunt or penetrating trauma. The majority of blunt injuries result from motor vehicle crashes but may also occur from falls, sporting injuries, including "clothesline" injuries, or assaults. Penetrating injuries are most commonly caused by knives or bullets.[43] Minor injuries may consist of edema, hematoma, contusion, abrasion, and small lacerations; major injuries may include loss of soft tissue, large lacerations without approximation, fracture of cricoid or thyroid cartilages, displacement of the arytenoid cartilages or epiglottis, and impaired vocal fold mobility.[43] Cricoarytenoid joint dislocation, hematoma or soft tissue swelling, intralaryngeal edema, or fracture of the cartilaginous laryngeal framework[30] may cause acute respiratory obstruction. Airway obstruction may occur instantly, gradually over hours, or with great rapidity hours after the injury has occurred.[1] Computed tomography (CT) is the radiologic modality of choice; axial sections may demonstrate the extent of soft tissue edema and hematoma formation, the location of fractures, deformity of cartilaginous structures secondary to fractures, dislocation of the arytenoid cartilages, and disjunction of the cricothyroid joint.[44] Laryngoscopy is indicated when evidence of airway injury or obstruction occurs following trauma to the neck, as well as in patients sustaining high-risk injuries, even with minimal symptoms. Tracheostomy or intubation may be needed to maintain the airway.[30] The best airway and voice outcomes are achieved after penetrating injury and when treatment is instituted within 24 hours of injury.[43]

Congenital laryngeal abnormalities, including teratomas or hamartomas, laryngomalacia, subglottic stenosis, complete or partial laryngeal atresia including congenital laryngeal webs, laryngoesophagotracheal clefts, hemangiomas, and lymphangiomas, are discussed in Chapter 45.

Vocal fold paralysis may be congenital or acquired; the neural lesion may be central or peripheral. Central bilateral vocal fold paralysis may result from iatrogenic increased intracranial pressure[30] or congenital nerve compression, such as occurs with a Chiari brainstem malformation. Peripheral causes of paralysis are usually associated with injury to the recurrent laryngeal nerves, particularly during cardiovascular or thoracic surgery or operations on the

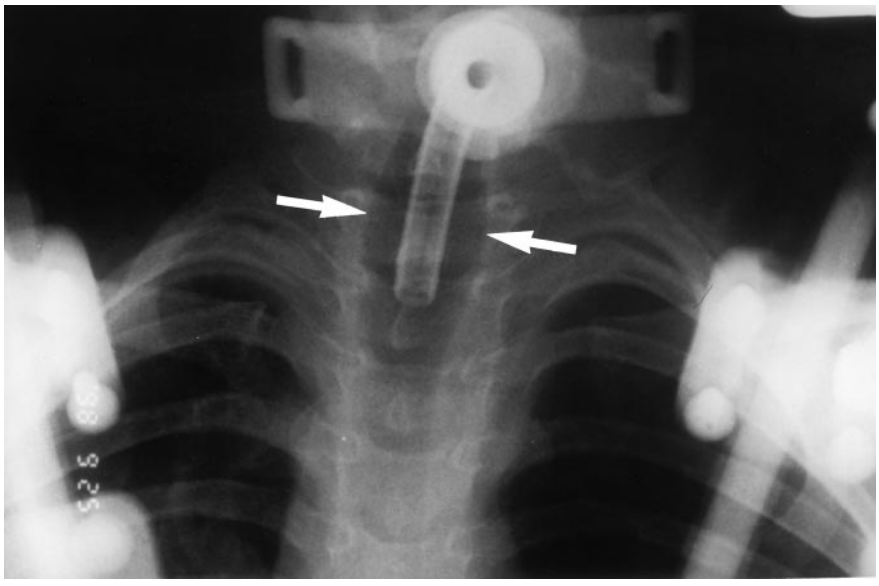

FIGURE 66–7. Chest radiograph demonstrating tracheomegaly (*arrows*) from a cuffed tracheostomy tube in a ventilator-dependent child.

neck such as thyroid surgery[30]; the left recurrent laryngeal nerve is more frequently injured. Other causes include involvement in benign or malignant tumors or inflammation in the neck or mediastinum; cardiovascular abnormalities, such as aneurysm; central nervous system disease; or neuromotor disorders such as myasthenia gravis and postpolio syndrome.[1]

Laryngeal nerve paralysis may result in a flaccid, shortened vocal fold that can be in a paramedian, intermediate, or lateral position relative to the midline and may result in loss of voice and aspiration from lack of adduction.[1,45,46] Medialization procedures may be performed for unilateral vocal fold paralysis to improve the vocal quality and decrease aspiration. Conversely, endoscopic laser arytenoidectomy or cordotomy, performed to improve the airway in bilateral vocal fold paralysis may result in a weaker voice.[3]

Speech and swallowing disorders, including dysarthria, dysphagia, or aspiration, may result from a combination of neurogenic, structural, cardiorespiratory, metabolic, and/or behavioral abnormalities.[47]

MALIGNANCIES

The larynx is the second most common site of cancer in the upper aerodigestive tract. A total of 12,500 new cases are diagnosed in the United States each year, with an estimated 5-year survival rate of 68% overall. Squamous cell carcinoma accounts for over 95% of all laryngeal malignancies, with a peak incidence in the sixth and seventh decades. Tobacco is the single most significant risk factor; ethanol is believed to have a synergistic effect with tobacco. Controversy exists as to whether ethanol alone is an independent risk factor.[48] Palliation and cure of laryngeal squamous cell carcinomas may be accomplished using radiation therapy, chemotherapy, laser,[3] or open surgical resection singly or in various combinations. Treatment decisions are based on the extent of local disease, results of previous treatment, and presence of metastases. Verrucous carcinoma, an exophytic, highly differentiated variant of squamous cell carcinoma, constitutes 1 to 3% of all laryngeal carcinomas. It rarely metastasizes, and surgical resection is the treatment of choice.[48] Laryngeal squamous cell carcinomas are rare in children.[38]

Pleomorphic carcinoma may histologically resemble other laryngeal supporting tissue neoplasms. Although treatment is predicated on the fact that the lesion is a squamous cell carcinoma, polypoid or pedunculated lesions portend a favorable outcome.[8]

Rhabdomyosarcomas are the most common type of malignant laryngeal tumor in children and adolescents.[38] Histologically, they are usually of the embryonal type and may be confused with benign lesions such as granular cell tumor and rhabdomyoma.[8] Treatment may include chemotherapy alone or with radiation therapy. Surgery is usually reserved for diagnostic biopsy or debulking lesions; extensive debilitating surgery is usually not indicated.[38]

Well-differentiated laryngeal fibrosarcomas usually do not metastasize, manifest a low recurrence rate, and have a low mortality rate. In contrast, poorly differentiated laryngeal fibrosarcomas are less common but more likely to metastasize or recur and are fatal in more than half of the reported instances.[8]

Primary tumors including adenocarcinoma, malignant fibrous histiocytoma, non-Hodgkin's lymphoma, malignant schwannoma, mucoepidermoid carcinoma, and primitive neuroectodermal tumor, as well as other sarcomas, such as synovial sarcoma, Ewing's sarcoma, chondrosarcoma, and "mixed" sarcoma, are rare.[38]

Metastases to the larynx are also rare and include metastases from testicular choriocarcinoma in adolescents;[38] additional evaluation may include a skeletal survey, bone scan, bone marrow aspirate or biopsy, CT of the chest,[38] and liver function tests.

RADIOLOGIC EVALUATION OF THE LARYNX

Routine radiologic evaluation comprises anteroposterior and lateral neck images. The lateral view of the neck provides useful information about the base of the tongue, vallecula, thyroid and cricoid cartilages, posterior pharyngeal wall, precervical soft tissues, and intralaryngeal structures including the epiglottis, aryepiglottic folds, arytenoids, false and true vocal folds, laryngeal ventricles, and subglottic space (Figure 66–8).

Fluoroscopy may be useful in assessing dynamic lesions. A cooperative patient can phonate /ee/ during inspiration to accentuate vocal cord motion and open the ventricles or breath-hold dur-

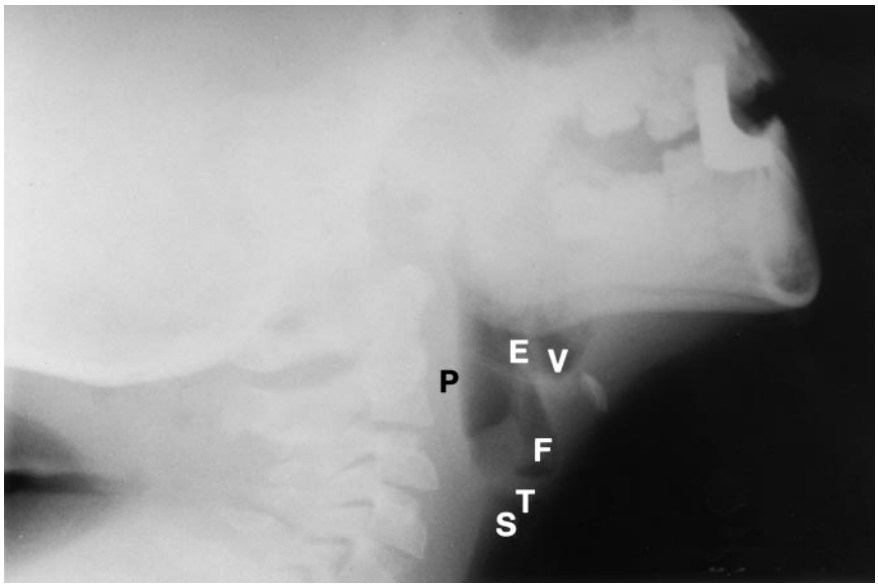

FIGURE 66–8. Lateral neck radiograph of a 6-year-old child with a large adenoid, demonstrating the valleculae (V), the epiglottis (E) crossed by the hyoid bone, the prevertebral soft tissue (P), the laryngeal ventricle between the false (F) and true (T) vocal folds, and the subglottis (S).

ing a modified Valsalva's maneuver to distend the piriform sinuses. Adding radiologic contrast agents such as barium or iohexol for tracheobronchography may enhance visualization and further define airflow dynamics and distal anatomy.[44,49]

Technological advances allow radiologic evaluation of deep tissue involvement by laryngeal disease. Spiral CT and fast magnetic resonance imaging techniques allow rapid acquisition of enhanced images of laryngeal structures, minimizing motion artifact. Direct spiral CT of the neck is performed in the axial plane; coronal, sagittal, and three-dimensional reconstruction can be computer generated. Magnetic resonance imaging has the advantage of multiplanar high-resolution imaging with an increased ability to separate various soft tissues and may be more sensitive for identifying early cartilage invasion[38,50] Both modalities are invaluable in preoperative malignancy staging, facilitating surgical planning. When possible, images should be obtained prior to biopsy to avoid artifact from postsurgical inflammation.[51]

CHAPTER 67

Bronchoesophagology

Jane Y. Yang, MD, Ellen S. Deutsch, MD, James S. Reilly, MD

BRONCHOLOGY

The trachea and bronchi usually function so well that their contribution to the respiratory process is taken for granted, but their critical importance in the function of the airway should not be underestimated. Heffner suggested that the compliant and noncylindrical structure of the trachea, comprising incomplete cartilage rings, allows for more than simple conduit function.[1] Enlargement of the lumen during inspiration may allow sufficiently decreased airflow velocity at the periphery of the air column so as not to impede the normal egress of the mucociliary blanket. In contrast, compression of the lumen at the beginning of a cough contributes to the increased driving pressure and increased airflow velocity that promote mucus expulsion; the abrupt noise of the cough results from suddenly increased airflow turbulence. Normal airflow in the trachea is laminar; masses or stenoses obstructing the lumen cause turbulent airflow evidenced as stridor. Adding low-density helium to oxygen can decrease turbulence and increase airflow in stenotic areas.[1]

Bronchoscopy

Bronchoscopy can be a diagnostic or therapeutic procedure, providing a direct view, tactile information, and the capability to manipulate the tracheal and bronchial lumina that cannot be obtained by any other method of investigation. Indications include obtaining tissue samples, placing treatment devices, removing foreign bodies, biopsy or removal of masses, and investigation of suspected pulmonary disease that does not respond to treatment as expected. Chest radiographs are usually obtained prior to endoscopy; they may narrow the differential diagnosis and direct the endoscopist's attention to a particular area.

Indications for Bronchoscopy

Hemoptysis The first step in hemoptysis management is control and protection of the airway. Although mild hemoptysis can be evaluated with fiber-optic telescopes, massive hemoptysis should be managed by rigid, open-tube endoscopy.[2] Options include using selective bronchial intubation or double-lumen endotracheal tube, allowing preferential ventilation of the uninvolved lung. Balloon tamponade can be accomplished using endoscopic guidance. Adjunctive methods include instillation of vasopressin, sodium bicarbonate, 1:20,000 concentrations of epinephrine, or cold saline lavages. Neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers may be used to control bleeding from airway neoplasms.[3] Thorough evaluation is required for patients with hemoptysis as the source may be located anywhere from the nares to the alveolar space, or even within the esophagus. Tracheobronchial causes of hemoptysis include tracheobronchitis, tracheobronchial tear, tracheal erosion, foreign body, endobronchial tumors, bronchiectasis, tuberculosis, lung abscess, and fungoma.[1] In patients with tracheostomies or endotracheal tubes, bleeding may result from suction trauma or granulation tissue.

Chronic Cough Bronchoscopy is indicated for patients with chronic cough; yield is increased if there is a history of tobacco use, chest radiograph abnormality, hemoptysis, or localized wheezing.[4] Other causes of chronic cough include asthma, evaluated with pulmonary function testing including methacholine challenge, and laryngopharyngeal (extraesophageal) reflux, evaluated with 24-hour multichannel pH monitoring and laryngeal examination. Medications, such as angiotensin-convert-

ing enzyme inhibitors, can also cause chronic cough.

Stridor Stridor is a symptom, rather than a diagnosis, caused by turbulent airflow resulting from an abnormality of the larynx, trachea, or bronchi. Stridor can be high or low pitched; inspiratory, expiratory, or biphasic; wet or dry. Lesions of the extrathoracic portion of the airway tend to cause inspiratory noises, and lesions of the intrathoracic airways tend to cause expiratory sounds; severe lesions in any location can cause biphasic sounds. Some lesions involving the supraglottis or the vocal folds, such as vocal fold paralysis or laryngomalacia in infants, tend to cause high-pitched noises, whereas laryngomalacia in children after infancy and other glottic lesions can cause low-pitched noises. Lesions in the trachea tend to cause low-pitched noises, and abnormalities of the distal, small airways cause high-pitched sounds. Wheezing is a classic example of a high-pitched, expiratory noise coming from the distal airways. Wet sounds suggest anatomic or neuromuscular difficulties in clearing secretions.

Lesions affecting the trachea and bronchi may be within the lumen, intrinsic to the walls, or extrinsic. Intraluminal lesions include strictures, neoplasms, infectious masses, granulation tissue, or foreign bodies. Intrinsic lesions include stenotic complete tracheal rings. Extrinsic compression may result from lesions within the mediastinum or esophagus, such as substernal goiter, aortic aneurysm, benign or malignant mediastinal tumors,[2] vascular rings and slings or an anomalous innominate artery, and esophageal foreign bodies[5] (Figure 67–1). Tracheal obstruction resulting from aerophagia as a manifestation of tardive dyskinesia from neuroleptic medications has been reported.[6] In children, the anterior tracheal wall may be depressed from prolonged tracheostomy.[7] Dynamic causes of stridor, such as some manifestations of tracheomalacia in children, are generally examined with fiber-optic bronchoscopy; overdiagnosis of normal respiratory dynamics should be avoided.[8]

It may be difficult to determine the origin of the stridor prior to endoscopy, so evaluation of the larynx, discussed in other chapters, is often indicated prior to tracheobronchoscopy. The suspected lesion, patient characteristics, and the circumstances of the endoscopy are considered when determining whether to proceed with fiber-optic and/or rigid tracheobronchoscopy. Airway control may necessitate rigid endoscopy, intubation, or tracheostomy; reasonable preparations should be made prior to instrumenting the airway.

Chest Trauma Bronchoscopy is indicated when a tracheal tear or bronchopleural fistula is suspected following blunt or penetrating chest trauma. Symptoms of tracheal or bronchial disruption include dyspnea, hemoptysis, subcutaneous and mediastinal emphysema, inspiratory stridor, hoarseness, cough-

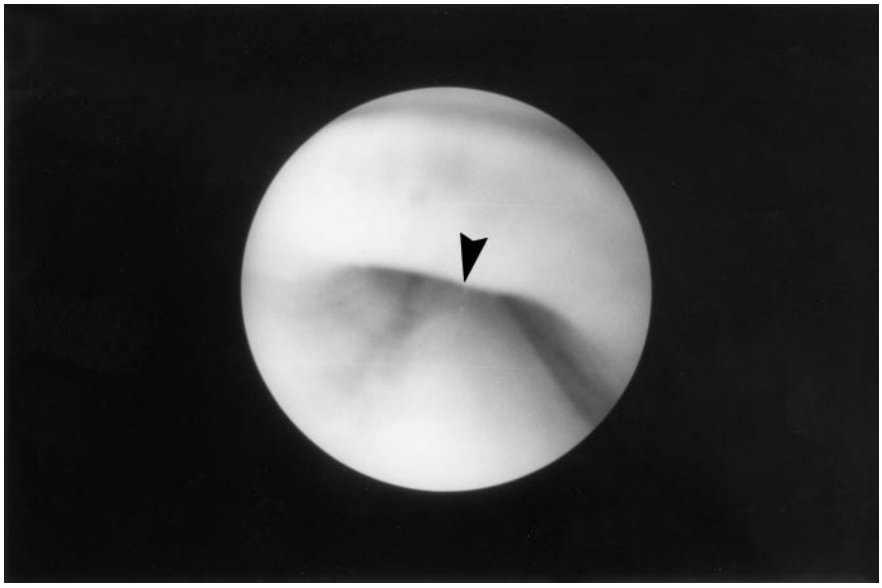

FIGURE 67–1. Endoscopic view: *arrow* shows anterior tracheal compression from an anomalous innominate artery.

ing, localized pain or tenderness, and, in severe cases, cyanosis; the most uniform early sign of tracheal disruption is subcutaneous emphysema.[9] Significant injury can occur with minimal evidence of trauma, such as from impact against a padded dashboard. Radiographic signs include pneumomediastinum, deep cervical emphysema, subcutaneous emphysema, pneumothorax, fractures limited to the upper rib cage, air surrounding a bronchus, and obstruction in the course of an air-filled bronchus.

Tracheobronchial trauma can occur at every level of the trachea and almost all of the major bronchi, but more than 80% of the injuries are within 2.5 cm of the carina.[9] The cervical trachea is protected by the mandible and sternum anteriorly and by the vertebrae posteriorly.[9] Tracheobronchial disruption has an estimated overall mortality of 30%[9]; 15% of patients sustaining cervical tracheal disruption die from hypoxia within 1 hour of injury.[9]

Bronchoscopy is the most reliable means of establishing the site, nature, and extent of bronchial disruption.[9] Thoracotomy and repair are indicated as soon as the patient's condition permits unless the bronchial tear involves less than one-third of the bronchial circumference and intercostal underwater drainage results in complete and persistent re-expansion of the lung with early cessation of air leakage.[9]

Inhalation Injury Thermal or chemical inhalation injury can produce significant edema and mucosal necrosis. Clinical findings may include facial, oropharyngeal, or nasal burns; carbonaceous sputum; wheezing; rales; rhonchi; and hoarseness. Arterial blood gas measurements may indicate hypoxemia, hypercapnia, and the presence of carboxyhemoglobin. Chest radiography is not usually helpful in the early stages of interstitial lung injury. Endoscopy is a valuable diagnostic tool and may reveal erythema, edema, ulceration, necrosis, or soot deposits; findings may be subtle in early airway injury.[10,11] If the patient's history suggests the possibility of thermal injury to the tracheobronchial tree, close observation is indicated and bronchoscopy should be considered, even in the absence of clinical findings.[10]

Respiratory Infections Bronchoscopy should be considered in adult patients who do not respond adequately to empiric antibiotics covering the most common respiratory pathogens, including *Streptococcus pneumoniae, Staphylococcus aureus, Haemophilus influenzae, Mycoplasma pneumoniae*, and *Legionella pneumophila*, as well as in critically ill or immunocompromised patients in whom atypical pathogens can cause fatal disease. Standard suction catheter aspiration may inappropriately sample microorganisms colonizing the upper airway, whereas bronchoscopy facilitates bronchial washings and broncheoalveolar lavage, allowing sterile, directed collection of specimens from distal bronchial segments. Lung abscesses can be drained endoscopically.[12] Transbronchial needle aspiration of interstitial infiltrates often provides the causative microorganism.

Abnormal Chest Radiograph Bronchoscopy performed for evaluation of patients with abnormal chest radiographs is more likely to be diagnostic when the radiograph demonstrates lobar collapse and hilar abnormalities and is less likely to be diagnostic in evaluation of nodular lesions and infiltrates.[13] Su et al found that persistent postobstructive consolidation was caused by an endobronchial mass in 65% of cases.[13]

Evaluation and Biopsy of Endobronchial Lesions Biopsy of endobronchial lesions can be accomplished using rigid or fiber-optic bronchoscopy; rigid bronchoscopy or transbronchial fine-needle aspiration may be more effective for tumors with necrotic centers. Several biopsy specimens should be obtained to improve the yield. Brushings and biopsies may be obtained for both visible and bronchoscopically invisible parenchymal lung lesions[14]; fluoroscopic guidance may be useful.[12] Endoscopy is also useful in evaluating potential complications of intubation, such as granulomas, webs, stenoses, or necrosis.[5]

Malignancy Staging and Follow-up In the United States, lung cancer is the most common malignancy causing death. Central lesions can be biopsied using a bronchoscope and forceps; bronchoalveolar lavage and cytologic brushings improve cytologic yield when performed after biopsy using forceps. The therapeutic response of endobronchial tumors can be monitored using bronchoscopic visualization and bronchoalveolar lavage in conjunction with high-resolution computed tomographic (CT) scans.

Transbronchial needle aspiration through a fiber-optic bronchoscope can be used to biopsy submucosal endobronchial lesions and peripheral nodules and masses,[14] as well as paratracheal, subcarinal, and perihilar areas for diagnosis and staging of thoracic malignancies, obviating the need for mediastinoscopy under general anesthesia. However, this technique is not widely used because of its low yield and technical difficulty.[15] Reported complications include pneumothorax and pneumomediastinum.[15]

Bronchoalveolar Lavage Bronchoalveolar lavage is used to evaluate pulmonary inflammation in diseases such as asthma, sarcoidosis, extraesophageal reflux disease, idiopathic pulmonary fibrosis, hypersensitivity pneumonitis, pulmonary alveolar proteinosis, hemosiderosis, histiocytosis X, and other interstitial lung diseases. Bronchoalveolar lavage is also used for identification of infectious lung diseases and confirmation of aspiration based on quantitative evaluation of lipid-laden macrophages.[14,16,17] Microbiologic, cytologic, or chemical studies may be performed on lavage fluids.[17]

The tip of the bronchoscope is wedged into a subsegment of the lung and multiple aliquots of 20 to 60 mL (in adults) of sterile saline solution are injected, aspirated, and collected separately.[18] In adults, a total volume of at least 100 mL is generally recommended to obtain adequate alveolar sampling.[19]

Bronchopleural Fistulae Bronchopleural fistulae are usually iatrogenic but may also result from tuberculosis, pneumonia, empyema, lung abscess, or trauma. If the site of the fistula is not readily visible, the specific location may be identified by serially inflating a balloon to occlude each bronchial segment until the source is identified or by injecting a small bolus of xenon 133 into the bronchial segments. Tracheobronchography is unique in its potential to localize fistulae.[20] Bronchoscopic application of sealants may be effective in closing small fistulae.[21]

Tracheoesophageal Fistulae Most tracheoesophageal fistulae are congenital, but acquired lesions, such as posterior erosion of the trachea, may result from intubation or tracheostomy, particularly if a foreign body, such as a nasogastric tube, resides simultaneously in the esophagus.[7]

Therapeutic Procedures

A variety of procedures can be performed endoscopically, avoiding the need for open surgical procedures. Endoscopically guided intubation is discussed in Chapter 65. Percutaneous tracheostomy is controversial because of concern over complications;[22] endoscopic guidance may reduce this risk.[23,24]

Stent Placement Endobronchial stents can be used to bypass areas of obstruction caused by lesions that may be malignant or benign and may be intrinsic or extrinsic to the lumen. In adults, stents are used as a temporizing measure to maintain airway patency while the patient is being treated for malignancy or to provide palliation for terminal disease. Expandable wire stents can be inserted with a fiber-optic bronchoscope and/or fluoroscopic guidance and are most commonly used for malignant lesions; extraction may be hazardous.[14,25] Rigid bronchoscopes are essential for the insertion, manipulation, and removal of silicone stents,[14] which can be used for benign conditions such as subglottic or tracheal stenosis, tracheobronchomalacia, and postanastomotic stenosis, as well as malignant lesions.[14] Complications of stents include migration of the stent, inspissation of mucus, ingrowth of granulation tissue into metallic stents,[14] erosion of the wall of the airway, and aortobronchial fistula, especially when inserted for treatment of airway obstruction secondary to compression by vascular structures.[26]

Laser Procedures Laser therapy can be used to resect or debulk both benign and malignant tumors that obstruct the airway or to prepare the airway for insertion of airway stents.[14] Carbon dioxide lasers allow precise destruction or excision of tissue, hemostasis of microcirculation, preservation of adjoining tissue, and minimal postoperative edema[27] but can only be applied using rigid instruments. Neodymium:yttrium-aluminum-garnet lasers[14] can be passed through fiber-optic bronchoscopes and applied using noncontact tips[28] but can cause submucosal damage, which progresses and does not become fully evident until after application is completed. Argon lasers are available with contact tips.[28]

Risks are related both to the anesthesia and the laser; anesthesia risks include hypoxemia, hypercarbia, and inadequate airway control. Risks of lasering include laser damage to unprotected areas of the operative field, patient, or operating room person-

nel; airway burns; severe hemorrhage; and perforation causing pneumothorax or pneumomediastinum.[14] Both oxygen and nitrous oxide support combustion, so the primary gas for anesthetic maintenance should consist of blended oxygen and air. The inspired oxygen content should be reduced to 30% or as close to this level as possible. Matte-finished instruments are used to minimize reflection.[27] The patient's eyes and face are protected with moistened towels, and operating room personnel must wear protective goggles appropriate for the type of laser being used.[27]

Airway burns can range from minor reflected injury of adjacent mucosa to transluminal destruction of the trachea. Ignition of the endotracheal tube can produce local thermal burns of the trachea and diffuse injuries to the lower respiratory tract from the inhalation of toxic materials, especially if polyvinyl chloride tubes are used.[27] Treatment includes immediate extubation, paralysis of the patient, and reintubation with a small endotracheal tube. Laryngoscopy and bronchoscopy are performed to evaluate the extent of damage and to remove charred debris and foreign material. Saline lavage, systemic corticosteroids and antibiotics, and careful monitoring of pulmonary function are indicated.[27] Perforation into the esophagus, mediastinum, pleural space, or major pulmonary vessels can cause severe hemorrhage, pneumothorax, or pneumomediastinum.[14,29]

Foreign-Body Removal Foreign-body aspiration is more common in young children than adults since they explore the world with their hands and mouths and have incomplete dentition, limited oromotor control, and immature judgment. The most common type of foreign body aspirated by children is food, particularly nuts.[5] Adults may aspirate when alcohol, sedatives, or head trauma alter their judgment or mental status, with cervicofacial trauma, or when neurogenic disease or physical conditions, such as dentures, impair sensation or control of the food bolus.

Patients who aspirate foreign bodies may present with gagging, coughing, and choking; however, over time, the symptoms may become quiescent. Children or impaired adults may not be able to recall or report the event, and the event may not have been witnessed. Endoscopy is indicated if there is a suggestive history despite a lack of radiographic findings, a suggestive radiograph despite a lack of supportive history, or pulmonary disease that follows an atypical course. Occasionally, a foreign body may be visible in radiographic images (Figure 67–2); sometimes only the sequelae are demonstrated. Jackson described a check-valve mechanism of airflow past a foreign body, resulting in obstructive emphysema, and a stop-valve mechanism, resulting in atelectasis (Figures 67–3 and 67–4).[30] Lack of deflation of a lung or bronchus may be demonstrated by comparing inspiratory and expiratory chest radiographs (Figure 67–5). For patients who are unable to cooperate or in whom the findings are subtle, lateral decubitus radiographs or airway fluoroscopy may be useful (Figure 67–6). In both children and adults, a high index of suspicion must be entertained to avoid missing an aspirated foreign body.[5] Delay in diagnosis can lead to hypoxemia, pneumothorax, asphyxiation, obstructive pneumonitis, lung abscess,

FIGURE 67–2. Radiograph of an adolescent with a chewed pen cap in his mid-trachea (*arrows*).

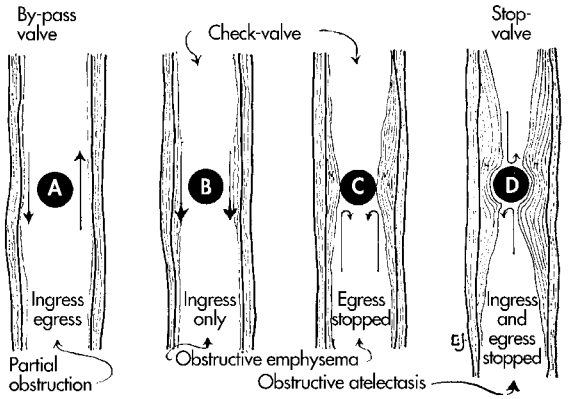

FIGURE 67–3. Three types of bronchial obstruction encountered clinically. Reproduced with permission from Jackson C. Bronchoscopy and esophagoscopy. A manual of peroral endoscopy and laryngeal surgery. 2nd ed. Philadelphia: WB Saunders; 1927.

bronchiectasis, pulmonary torsion, granuloma, and polyp formation.[31]

Although fiber-optic bronchoscopic retrieval of foreign bodies has been performed successfully,[31] rigid bronchoscopy is preferred in most cases, especially in the pediatric population. Rigid bronchoscopes with Hopkins rod telescopes offer a larger instrument internal diameter to allow easier retrieval of larger foreign bodies, superior optics, a wider variety of removal instruments, and the capability to control the airway.

To remove airway foreign bodies, optical or other forceps can be advanced just proximal to the foreign body, then the jaws are opened to distract adjacent mucosa, and the forceps are advanced beyond the widest portion of the foreign body or any portion that protrudes sufficiently to provide adequate purchase. Airway foreign bodies must be grasped in a secure manner and controlled during their removal. "Stripping off" a foreign body during its passage through the trachea or in the larynx may convert partial airway obstruction to total obstruction with an inability to ventilate the patient.[2] In children, this risk is increased in the subglottis because of its intrinsic relative narrowness. If control over a foreign body is lost within the trachea or subglottis, the foreign body can be pushed into a main bronchus, allowing ventilation of at least one lung. Visualization of a distal foreign body may be enhanced by having the anesthesiologist apply positive-pressure ventilation, similar to a Valsalva's maneuver. Attempts to remove a foreign body with a sharp end may cause additional trauma: "Advancing points perforate, trailing points do not" (Figure 67–7). Some foreign bodies can be rotated to decrease this risk; others can be sheathed by advancing the bronchoscope over them or be withdrawn into the lumen of the bronchoscope. For selected foreign bodies with a lumen, such as beads, a Fogarty catheter can be passed through the lumen of the object, the balloon inflated, and the catheter withdrawn so that the foreign body is controlled between

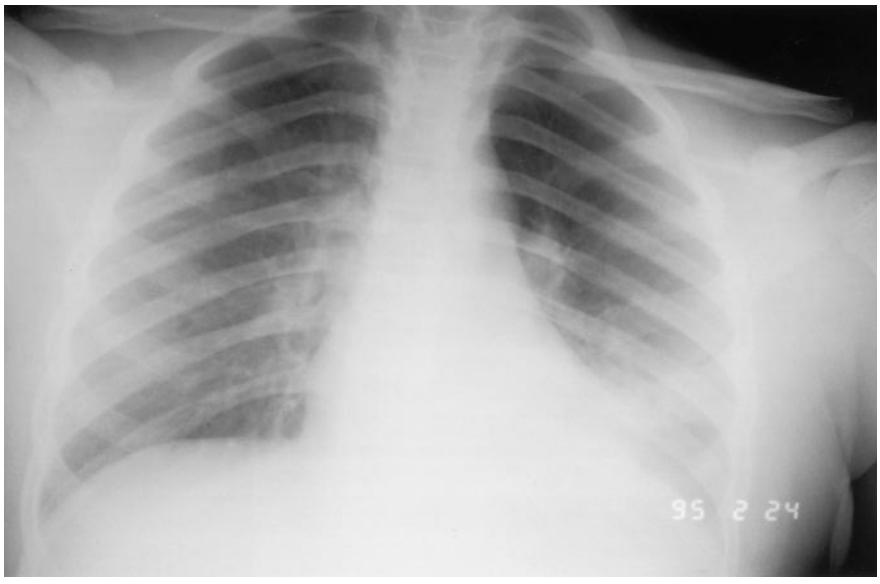

FIGURE 67–4. Chest radiograph demonstrating persistent left lower lobe atelectasis from an impacted sunflower seed.

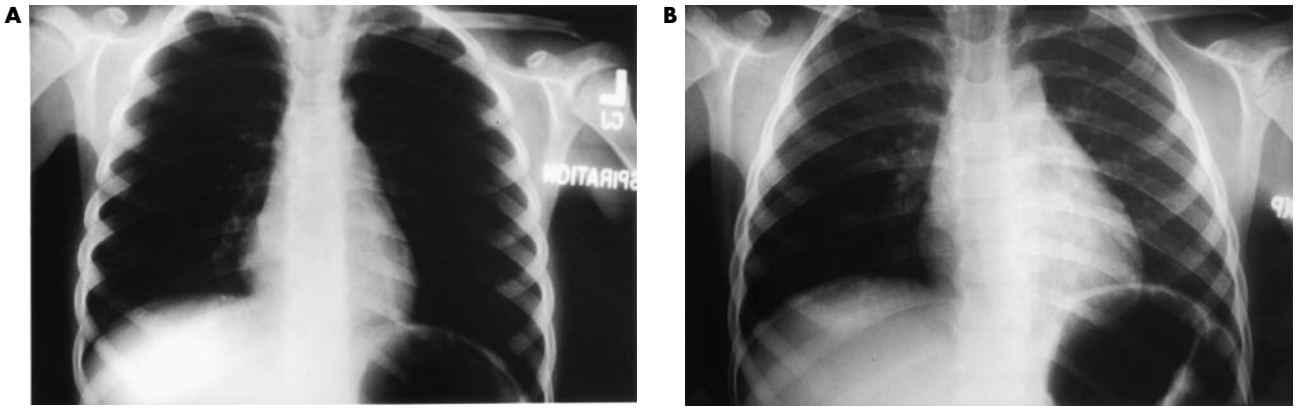

FIGURE 67–5. *A*, Inspiratory and *B*, expiratory radiographs demonstrating lack of deflation of the right lung in a child with a foreign body in the bronchus intermedius.

the balloon and the bronchoscope. Using a Fogarty catheter to dislodge a foreign body without controlling it is not recommended. Balloon breakage has been reported.[32] After removal of a foreign body, examination should be repeated in case there are additional foreign bodies; pulmonary toilet can be accomplished while the bronchoscope is still in situ.[5]

In unusual circumstances, tracheostomy may be necessary to control the airway,[33] and selected foreign bodies may be removed through a tracheostomy incision[33] or thoracotomy.

Removal of Mucus Plug and Pulmonary Toilet

Critically ill patients may not have the respiratory

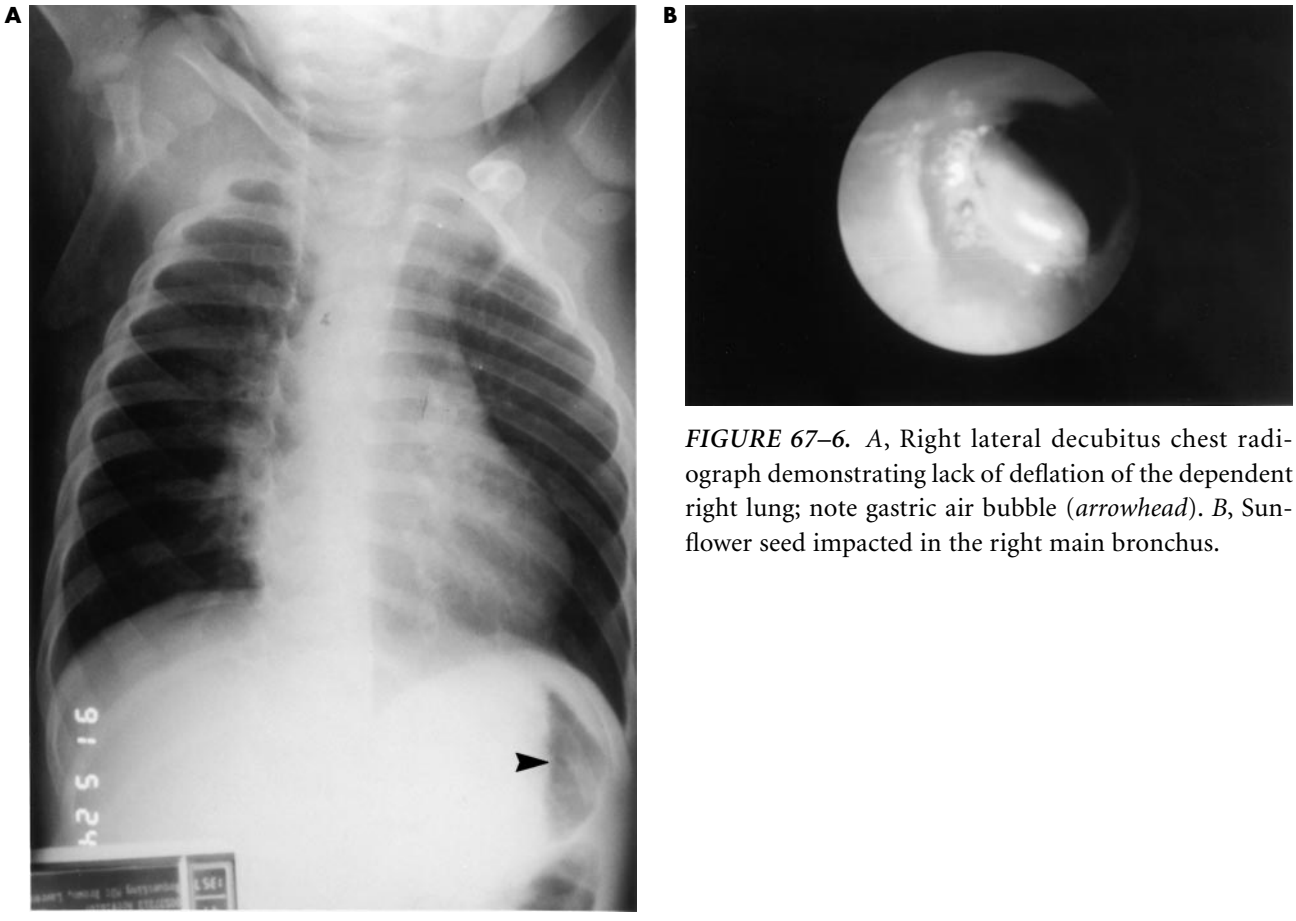

FIGURE 67–6. *A*, Right lateral decubitus chest radiograph demonstrating lack of deflation of the dependent right lung; note gastric air bubble (*arrowhead*). *B*, Sunflower seed impacted in the right main bronchus.

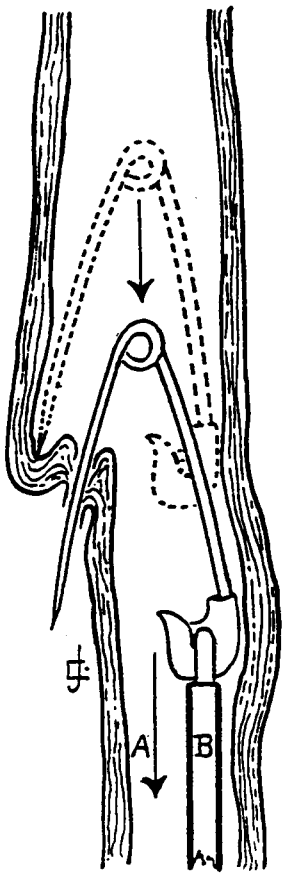

FIGURE 67–7. Schematic drawing of what will happen from ignoring the dictum "Advancing points perforate, trailing points do not." Reproduced with permission from Jackson C. Bronchoscopy and esophagoscopy. A manual of peroral endoscopy and laryngeal surgery. 2nd ed. Philadelphia: WB Saunders; 1927.

support and muscular strength to mobilize mucus plugs or other tenacious secretions interfering with ventilation. If aggressive respiratory therapy is inadequate or is contraindicated in patients with neuromuscular disease or head or spinal trauma,[31] bronchoscopy can be used to visualize, irrigate, and suction problematic secretions, improving pulmonary toilet. Furthermore, fiber-optic bronchoscopes can be used with fluoroscopic guidance to drain lung abscesses.[12]

Delivery of Medication, Radioactive Agents, or Other Therapies Surfactant and chemotherapeutic, antifungal, and antituberculous drugs have been administered directly into the lung on an investigational basis using bronchoscopic visualization.[31,34] Small bronchopleural fistulae can be closed by application of sealants using bronchoscopic guidance.[21]

Bronchoscopes can be used to guide the placement of brachytherapy catheters bearing radioactive source material into an obstructed airway.[14,35] Potential complications include hemorrhage and the formation of fistulae between the airway and other thoracic structures.[14]

Uncommon indications for bronchoscopy include application of hematoporphyrin derivatives or cryotherapy in the management of airway malignancies and bronchoscopic electrocautery to coagulate and vaporize endobronchial lesions.[14]

Tracheobronchial Conditions

Acute bronchiolitis is a viral disease of the lower respiratory tract that generally manifests in children under 2 years of age since inflammatory airway obstruction has a greater impact on young children with narrower airways. Respiratory syncytial virus (RSV) is responsible for more than 50% of cases. Following a viral prodrome, patients develop respiratory distress characterized by paroxysmal wheezy cough, dyspnea, and irritability with tachypnea, air hunger, and cyanosis. Treatment is generally supportive, including oxygen supplementation.[36]

Bacterial tracheitis is an acute infection of the upper airway that does not involve the epiglottis but can cause life-threatening sudden airway obstruction, particularly in children. Patients, generally less than 3 years of age, develop a brassy cough, high fever, and "toxicity" with gradually worsening inspiratory stridor. Thick, copious secretions complicate mucosal swelling at the level of the cricoid cartilage. Bacterial tracheitis may occur as a complication following a viral respiratory tract infection. The usual treatments for croup, a viral laryngotracheobronchitis, are ineffective, and intubation is often necessary; appropriate antimicrobial therapy is also indicated. *Staphylococcus aureus* is the most commonly isolated pathogen; *Moraxella catarrhalis* and *H. influenzae* can also cause bacterial tracheitis.[36]

Pneumonias can be divided into three groups: community acquired, nosocomial, and ventilator associated. Initial management includes appropriate empiric antibiotic therapy directed toward common pathogens based on the type of pneumonia and the patient's immune status. Cultures, obtained when patients have inadequate response despite standard

therapy, are often obtained from expectorated material, which may be contaminated by oropharyngeal flora. Bronchoscopy allows directed aspiration of secretions directly from the tracheobronchial tree and has proven to be of benefit in immunocompromised patients.[37] Proper disassembly and cleaning of equipment between patients and proper specimen collection techniques must be used to prevent contamination. Bronchoalveolar lavage and bronchoscopic protected specimen brushing can retrieve specimens adequate for quantitative analysis. Bronchoscopy is indicated for lung abscesses unresponsive to postural drainage and chest physiotherapy to rule out an underlying carcinoma or foreign body and to obtain secretions for culture.

Bronchiectasis, irreversible dilatation of the bronchial tree, most commonly presents with chronic purulent sputum production and hemoptysis. Bronchiectasis may be postinflammatory, obstructive, or congenital. Stasis of secretions leads to infections that damage the bronchial walls, resulting in further dilatation and distortion. Infectious causes include RSV, pertussis, rubella, and tuberculosis. Obstructive lesions include tumors, foreign bodies, extrinsic compression, and impacted mucus. Congenital causes include bronchial webs and atresia, immotile cilia syndrome, cystic fibrosis, and syndromes associated with abnormal cartilage formation such as Williams-Campbell syndrome (absence of annular bronchial cartilage distal to the first division of the bronchi) and Mounier-Kuhn's syndrome (congenital tracheobronchomegaly).[38] High-resolution CT or tracheobronchography are useful imaging modalities in suspected bronchiectasis.[20,38]

Mycetomas are formed by the conglomeration of fungal elements, most commonly *Aspergillus* species, within a pulmonary cavity. The diagnosis is made clinically, based primarily on chest radiographs demonstrating a solid, round, sometimes mobile, mass within a spherical or ovoid cavity; when the mass is peripheral, pleural thickening is often present. Serum precipitin to *Aspergillus* species has > 95% sensitivity for aspergilloma. Bronchoscopy is indicated for directed culture sampling if serum precipitin is negative or for evaluation of hemoptysis or progressive disease. Hemoptysis is the most common and potentially catastophic complication of mycetomas, causing 26% mortality in patients with aspergilloma. Bronchial artery embolization is only temporarily effective in managing acute hemoptysis. Surgical resection provides definitive treatment but is associated with high mortality and morbidity. Other treatment modalities, such as endobronchial instillation of antifungal agents, are under investigation.[39,40]

The incidence of *Mycobacterium tuberculosis*, a bacillus transmitted by airborne inhalation of infected droplets, has declined in recent years; an increasing proportion of new cases occurs among immigrants. Presenting pulmonary symptoms include productive or nonproductive cough, chest pain, and hemoptysis. Constitutional symptoms include chills, fever, night sweats, and loss of appetite and weight.[41] Diagnosis can be difficult but is supported by a reactive purified protein derivative skin test, chest radiograph with various abnormal findings, and identification of acid-fast bacillus by culture or histology. The sensitivity for three consecutive early morning sputums is disappointing at 50 to 80%. Bronchoscopy, with broncheoalveolar lavage and/or biopsy, has a high yield and should be considered in high-risk patients who have negative sputum cultures or patients who are unable to expectorate adequately.[41] Newer, more sensitive methods, such as polymerase chain reaction, are being investigated to detect mycobacterium in lavage fluid and sputum.[41,42]

Multidrug-resistant tuberculosis was a serious problem from 1993 to 1996, with the highest rates of resistance occurring in foreign-born, human immunodeficiency virus–positive patients and previously treated patients.[43] By instituting initial antituberculosis therapy with four first-line antibiotics, such as isoniazid (INH), rifampin (RMP), pyrazinamide (PZA), and ethambutol (EMB) or streptomycin, the incidence of new cases of multidrug resistance has declined significantly.[41,42]

Tuberculosis in children is usually contracted from adults and adolescents in the household rather than from other children in day care or school; congenital infection is rare. The presentation of primary pediatric tuberculosis may be subtle, including erythema nodosum and nonspecific constitutional symptoms. As tuberculin skin testing may be negative in 40% of these children, chest radiography demonstrating hilar and paratracheal lymphadenopathy is important in the diagnostic process. If young children cannot provide sputum specimens, three morning gastric aspirate specimens may be obtained. Children, especially those younger

than 6 years of age, have a more rapid progression of disease from inoculation to dissemination; they are treated immediately from the time of exposure until the incubation period has passed and repeat diagnostic tests are negative. The principal drugs used to treat pediatric tuberculosis include EMB, INH, PZA, and RMP; pyridoxine is given to infants to prevent neurologic complications of INH therapy. *Mycobacterium tuberculosis* in children is rarely contagious.[42]

Nontuberculous mycobacterial diseases encompass all *Mycobacterium* species other than *M. tuberculosis. Mycobacterium avium-intracellulare* complex is the most common nontuberculous mycobacterial disease and is treated principally with clarithromycin, azithromycin, RMP, and EMP.[43] *Mycobacterium kansasii* is the most virulent of the nontuberculous mycobacterial pathogens[43] and is treated with INH, RMP, and EMB. Rarely, atypical mycobacteria may present as an endobronchial mass (Figure 67–8).

Cystic fibrosis, a multisystem disorder of children and adults characterized by maldigestion and chronic obstruction and infection of the airways, is the most common life-threatening genetic trait in Caucasians. Otolaryngologists are most often involved for management of nasal polyposis resulting from chronic sinusitis. Exocrine gland dysfunction manifests as a paucity of water in mucous secretions and difficulty clearing mucous secretions, contributing to respiratory tract infection, particularly with *S. aureus* and *Pseudomonas aeruginosa*. Diagnosis is confirmed with high levels of chloride in sweat. Tracheobronchial suctioning or lavage may be temporarily helpful in treating atelectasis or mucoid impaction.[44] Biopsy samples for evaluation of cystic fibrosis or other ciliary dysmotility disorders can be obtained from the carina with a cup forceps or by brushing; specimens are placed in glutaraldehyde for electron microscopy.

Interstitial lung disease encompasses a wide variety of pulmonary diseases characterized by diffuse parenchymal opacities. Although more than 160 causes have been reported, pneumoconiosis, drug-induced disease, and hypersensitivity pneumonitis account for over 80% of cases (Table 67–1). A thorough history can elucidate patient exposure to a large variety of injurious inorganic dusts such as coal, carbon black, asbestos, or talc; chemicals such as polyvinyl chloride, sulfur dioxide, or ammonium; pharmacologic agents such as cyclophosphamide, methotrexate, certain anticonvulsants, and beta-blocking agents, etc; and radiation therapy. Open or thoracoscopic lung biopsy, considered the gold standard for diagnosis, is not always a viable option in the elderly or patients whose respiratory status is significantly compromised; less invasive bronchoscopy with bronchoalveolar lavage may provide useful information.[34,45,46]

Sarcoidosis is a non-necrotizing granulomatous disease of unknown etiology, more common in African Americans. Patients most commonly present with nonproductive cough and dyspnea; head

and neck manifestations include cervical adenopathy, uveitis or episcleritis, parotid swelling, nasal obstruction, neuropathies such as facial palsy and sudden sensorineural hearing loss, epiglottic swelling, and nasal mucosal edema. Ninety to 95% of patients with sarcoidosis have an abnormal finding on chest radiography, most commonly hilar adenopathy. Occasionally, endobronchial granulomas or stenoses occur.[47] Elevated serum angiotensin-converting enzyme levels appear to correlate with the activity of the disease but should not be used in isolation. Laboratory studies may also reveal elevated liver enzymes, particularly aspartate aminotransferase and alkaline phosphatase, elevated erythrocyte sedimentation rate, eosinophilia, hypercalcemia, and hypergammaglobulinemia. Fiberoptic bronchoscopy with transbronchial biopsy is the invasive procedure of choice for diagnosis; bronchoalveolar lavage is investigational. Corticosteroids are the mainstay of therapy.[48] Pediatric sarcoidosis is rare and presents with fatigue and lethargy.[49]

Idiopathic pulmonary fibrosis is a chronic fibrosing interstitial pneumonia of unknown etiology associated with the histologic appearance of "usual" interstitial pneumonia. This diffuse parenchymal disease occurs almost exclusively in adults, usually over 50 years of age, who present with slowly progressive dyspnea and nonproductive cough. Rales, particularly at the lung bases, are noted on auscultation in 80% of patients; fever is rare, and the disease is limited to the lungs. Characteristic abnormal findings on chest radiograph include asymmetric, bilateral, peripheral areas of reticular opacification. High-resolution CT is not diagnostic but can help determine prognosis; a fibrotic appearance portends a worse prognosis than a predominantly ground-glass appearance. Diagnosis is usually presumptive, based on clinical criteria; bronchoscopy and laboratory evaluation may be indicated to exclude other pulmonary diseases. Open or thoracoscopic lung biopsy is generally obtained to establish a histologic diagnosis; bronchoalveolar lavage is investigational. Although corticosteroids are standard therapy, no clear evidence exists proving that corticosteroids or any other available treatment is efficacious.[50,51]

Relapsing polychondritis (discussed in Chapter 66) manifests with acute, recurrent, progressive inflammation and degeneration of cartilage and connective tissue, including that within the tracheobronchial tree, affecting men and women in equal numbers. Serious airway manifestations occur in about half of patients with relapsing polychondritis; bronchoscopy is useful to identify and quantify inflammation, stenosis, or dynamic collapse of the tracheobronchial tree. Bronchoscopic stent placement may be required to maintain airway patency.

Wegener's granulomatosis (discussed in Chapter 66) is a necrotizing granulomatous vasculitis,

affecting both the upper and lower respiratory tracts and the kidneys. The introduction of fiber-optic bronchoscopes has revealed tracheobronchial involvement in more than half of patients with Wegener's granulomatosis.[52,53]

Benign Neoplasms and Tumorlike Masses Although some neoplasms occurring within the trachea and bronchi are histologically benign, they may still cause airway obstruction. Recurrent respiratory papilloma has a predilection for the larynx, but the trachea and bronchi may be involved by disseminated disease (Figure 67–9). Traumatic granulomas may occur at sites of repeated mucosal trauma, such as the carina or main bronchi in patients with endotracheal or tracheostomy tubes undergoing repeated mechanical suctioning. Granulation tissue can also develop within the tracheal lumen at the superior margin of a tracheostoma; initially, the tissue is soft and friable; over time, it may become fibrotic.

In patients with *tracheopathia osteochondroplastica*, multiple submucosal nodules, consisting of cartilage and lamellar bone, can be seen projecting into the lumen of the tracheobronchial tree. Right middle lobe collapse is a common finding. The differential diagnosis of multiple nodular lesions of the tracheobronchial tree include papillomatosis, amyloidosis, and sarcoidosis.[54] If the lesions cause airway obstruction, they can be excised bronchoscopically.

Other reported benign lesions of the trachea or bronchi include inflammatory pseudotumors, plasma cell granulomas, fibrous histiocytomas, fibrolipomas, histiocytosis X, hamartomas, intratracheal ectopic thyroid tissue, pleomorphic adenomas, fibromas, fibrous histiocytomas, hemangiomas, hemangiopericytomas, paragangliomas, peripheral nerve sheath tumors, granular cell tumors, and leiomyomas.[1,14]

Malignant Neoplasms *Bronchogenic carcinoma*, often referred to as "lung cancer," is the most common malignancy in the United States. Long-term tobacco use is the single greatest risk factor for developing lung cancer; approximately 87% of all cases of lung cancer are attributable to tobacco use. Additional environmental factors, particularly exposure to asbestos and radon, increase the risk of lung cancers in smokers. The risk of a nonsmoker developing lung cancer is 1% or less of that of a smoker.[55] The symptoms of lung cancer are nonspecific; the most common symptom is cough; other pulmonary symptoms include dyspnea, hemoptysis, chest pain, and manifestations of paraneoplastic syndromes. Chest radiograph may demonstrate lung consolidation, atelectasis, infiltrate, or a solid nodule; CT of the chest with contrast often provides better definition of the lesion and is useful for assessing disease recurrence, persistence, or response to treatment. Bronchoscopy has emerged as an integral tool for the diagnosis and staging of lung cancer and may obviate the need for open biopsy. Bronchoscopy provides direct visualization of central lesions and can be combined with bronchoalveolar lavage, brushings, or biopsy to increase the diagnostic yield. Transbronchial needle aspiration of mediastinal lymph nodes can be performed to stage disease.

Bronchogenic carcinomas are divided histologically into non–small cell cancers, including squa-

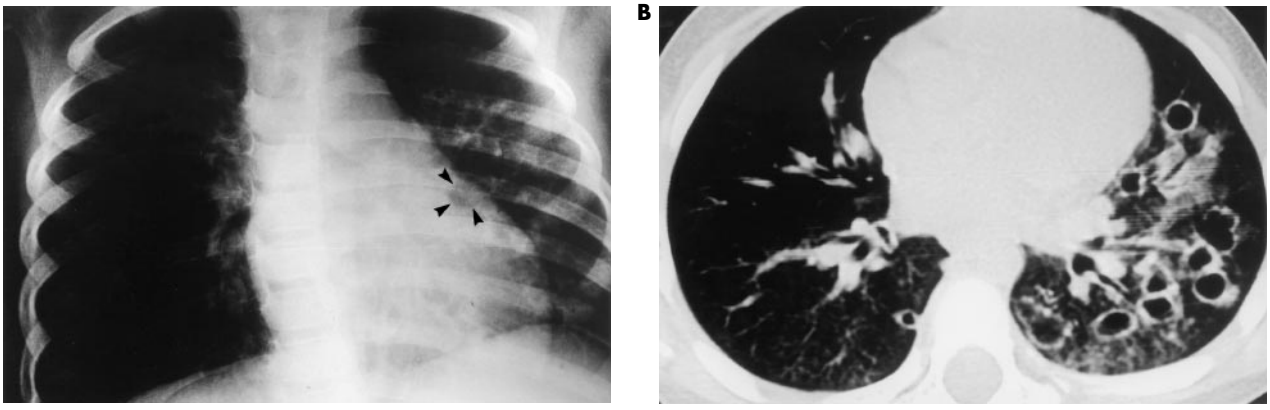

FIGURE 67–9. A, Chest radiograph and *B*, computed tomogram showing multiple cavitary pulmonary papillomas in a child with recurrent respiratory papillomatosis.

mous cell carcinoma, adenocarcinoma, and large cell carcinoma, and small cell cancers. Surgery is the primary treatment modality for non–small cell cancer; radiation therapy and chemotherapy are reserved for advanced cases and cancers not amenable to surgical resection. Small cell cancer is noted for rapid growth and early development of widespread metastases; although it is extremely sensitive to radiation and chemotherapy, 5-year survival is only 3 to 8%, and recurrence is common.[55]

Only approximately 4% of primary lung tumors are not bronchogenic carcinomas. Bronchial *carcinoid* is a neuroendocrine neoplasm comprising approximately 2% of primary lung tumors. This reddish, polypoid, endobronchial mass often presents with obstructive symptoms. As the tumors arise from Kulchitsky's cells, part of the amine precursor uptake, and decarboxylation (APUD) system, they may secrete hormones such as adrenocorticotrophic hormone, antidiuretic hormone, gastrin, somatostatin, calcitonin, and growth hormone. Carcinoid tumors are categorized as typical, which is relatively benign and is treated with conservative resection, or atypical, also referred to as neuroendocrine carcinoma, which is more aggressive and often has metastasized widely by the time of diagnosis. Aggressive local resection with lymph node dissection is recommended for locoregional disease; chemotherapy is indicated when distant metastases are present. Five-year survival is about 60% and is dependent on the histologic subtype.[56]

Other malignant neoplasms of the trachea or bronchi include spindle cell, oat cell, and adenoid cystic carcinomas; adenocarcinomas; mucoepidermoid carcinomas; malignant melanomas; sarcomas; lymphoreticular neoplasms; and malignancies invading the trachea or bronchi from adjacent structures (Figure 67–10).[1]

Other Tracheobronchial Disorders Congenital *tracheal stenoses* may result from complete tracheal rings or other cartilage deformities (Figure 67–11). Acquired stenoses may result from inhalation thermal or chemical burns or from intubation.[57] Pressure necrosis from an endotracheal or tracheostomy tube, or their attached cuffs, may result in healing by cicatrization, resulting in a spectrum of lesions.[7] Management of acute stenosis is controversial; some authorities advocate cautious dilatation,[7] and the application of mitomycin-C is under investigation.[58] The use of a laser to enlarge the airway lumen may ultimately cause more scarring and stricture formation,[7] although it may be indicated for highly selected lesions. A tracheostomy or T tube may be used for temporary or long-term management; definitive treatment involves surgical resection, expansion, and/or reconstruction.[7] Flow volume curves are of little practical use in the management of severe tracheal stenoses.[7]

Radiologic Evaluation

Specialized radiographic examinations, such as barium swallow, CT, and magnetic resonance imaging or magnetic resonance angiography, may be useful

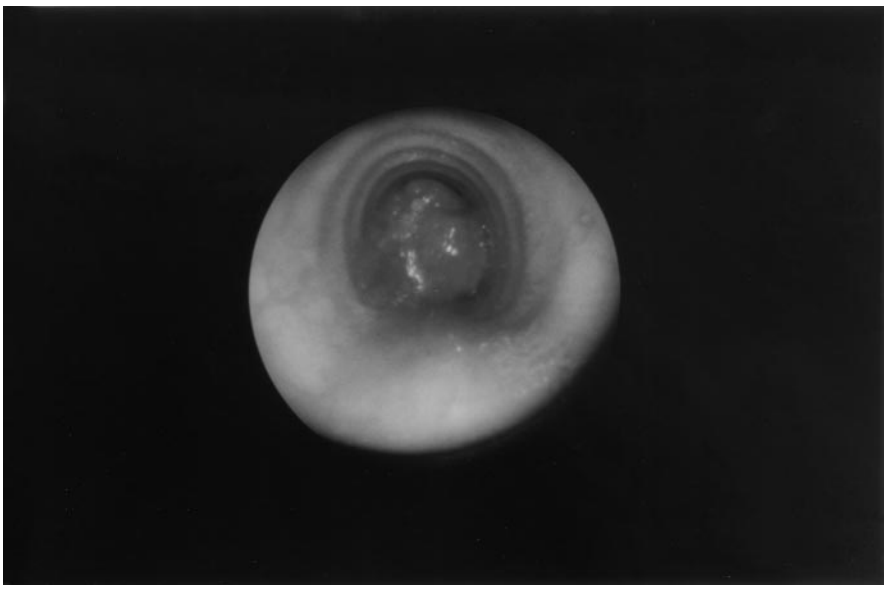

FIGURE 67–10. Endoscopic view of tracheal mucoepidermoid carcinoma in a 14-year-old child.

to define airflow dynamics, distal anatomy, or the relationship between the airway and adjacent structures or masses. Tracheobronchography is an elegant and well-tolerated procedure allowing superimposition of three-dimensional anatomy, providing a unified view of the airway rather than a planar slice image (Figure 67–12).[20] Radiographic tracheobronchial three-dimensional reconstruction and "virtual" endoscopy are investigational. Radiographic procedures can provide information about dynamic processes that is difficult to obtain by other methods but cannot provide tactile information or tissue samples.[14]

ESOPHAGOLOGY

Within the last few decades, improvements in lenses and illumination, as well as increased availability, have allowed esophagoscopes to evolve into primary diagnostic and therapeutic tools for managing many esophageal disorders. Open-tube esophagoscopes are used to examine and treat esophageal disease; flexible fiber-optic upper gastrointestinal endoscopes also allow examination of the stomach and duodenum.

Anatomy

The esophagus is a vertical muscular tube that extends from the hypopharynx to the stomach, measuring 23 to 25 cm in length in the adult. Beginning at the lower border of the cricoid cartilage, it passes through the neck, superior mediastinum, and posterior mediastinum anterior to the cervical and thoracic vertebrae, terminating at the cardiac orifice of the stomach.

The esophagus starts in the midline but then curves slightly to the left. It returns to the midline in the mediastinum and then deviates to the left as it passes anteriorly into the esophageal hiatus of the diaphragm. Importantly, the curvatures in the anteroposterior plane follow the convexity of the bodies of the thoracic vertebrae. The abdominal portion of the esophagus, which is only 1.25 cm long, is in the esophageal groove on the posterior surface of the left lobe of the liver.

In the superior mediastinum, the esophagus is posterior to the trachea and in contact with the common carotid arteries. The recurrent laryngeal nerves lie in the angle between the esophagus and the trachea, and the thoracic duct lies on its left side. Both lobes of the thyroid gland come in contact with the esophagus. The esophagus passes posterior and to the right of the aortic arch and then proceeds along the right side of the descending aorta until the inferior portion of the mediastinum is reached, where it passes anterior and slightly to the left of the aorta. Inferior to the arch of the aorta, the left bronchus crosses and indents the esophagus anteriorly. The thoracic duct is posterior to the lower portion of the esophagus, and the azygos vein is to the right side of the esophagus in the thorax. The right vagus nerve descends posterior to

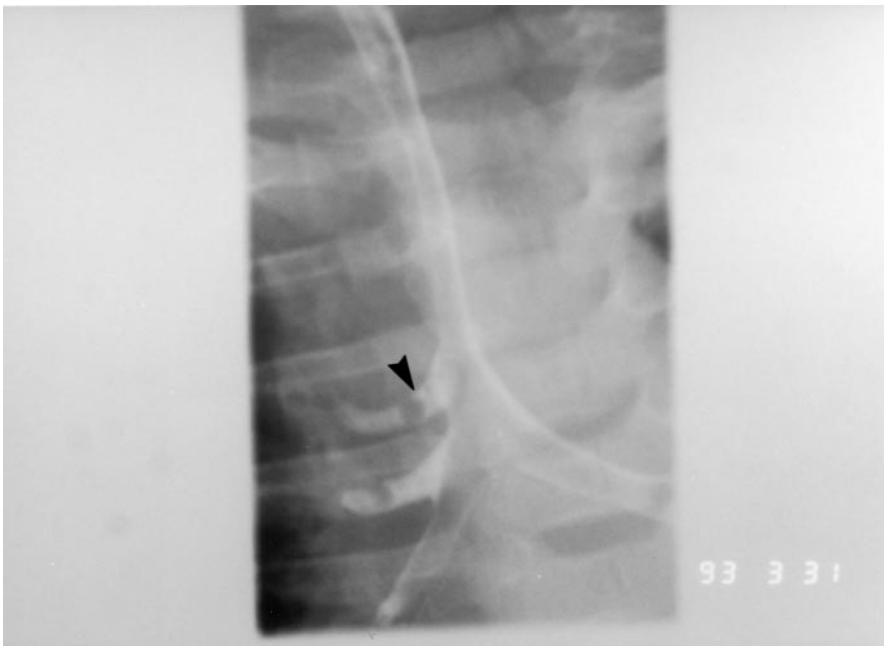

FIGURE 67–12. Tracheobronchogram demonstrating narrow tracheal caliber and duplicate right upper lobe bronchus (*arrowhead*) in a child with complete tracheal rings.

the esophagus, and the left vagus descends anterior to the esophagus.

The esophagus is lined by nonkeratinizing stratified squamous epithelium covering a thin lamina propria. The muscularis mucosae are composed of smooth muscle fibers arranged longitudinally, becoming thicker in the lower third of the esophagus. The submucosa consists primarily of thick collagenous and coarse elastic fibers and contains mucous glands and Meissner's plexus.

The muscle of the esophagus is composed of an inner circular layer, which is continuous with the inferior constrictor of the pharynx, and an outer longitudinal layer. The longitudinal fibers are arranged proximally into fascicles, which attach to the cricoid cartilage. Distally, the fascicles blend to form a uniform layer surrounding the esophagus. Auerbach's myenteric plexus lies between the two muscle layers. The muscle is striated in the upper third, mixed in the middle third, and nearly all smooth in the lower third. The outer coat, or fibrosa, consists of loose fibroelastic tissue rather than a strong serosa like that found in the gastrointestinal tract distal to the esophagus. The circular layer of muscle is slightly thicker at the level of the cricoid cartilage and blends with the cricopharyngeal muscle, which is attached to the cricoid cartilage. This upper esophageal sphincter is a high-pressure zone in esophageal manometry and corresponds with the cricopharyngeal muscle.[59] The lower esophageal sphincter is approximately 3 cm long and may descend 1 to 3 cm with normal respiration. A single distinct muscle responsible for the lower sphincter action has not been identified.

Radiologic Evaluation

Radiologic studies are generally obtained prior to endoscopy to evaluate esophageal structure and function, as well as diseases of adjacent organ systems that may affect the esophagus. Radiopaque esophageal foreign bodies can be demonstrated on posteroanterior or lateral chest and/or neck radiographs; nonradiopaque objects may be deduced from intraluminal air in the cervical esophagus. Lateral neck radiographs are taken with the patient's neck slightly flexed on the thorax, the head extended on the neck, and the shoulders positioned caudally and dorsally. Noncontrast radiographs may demonstrate swelling, air from a perforation, displacement of air-filled structures by neoplasm, cervical spine osteophytes that may cause dysphagia, or other abnormalities affecting the tissues between the cervical vertebrae and the larynx and trachea.

Radiographic contrast materials, such as barium sulfate suspensions of various consistencies, are used to outline the contours of the esophagus. Water-miscible solutions may be indicated if a fistula, per-

foration, or aspiration is suspected. Contrast studies may demonstrate congenital or acquired atresia, stenosis, and aerodigestive fistulae; extrinsic compression by aberrant vessels or cervical or mediastinal masses or foreign bodies[5]; and intraluminal abnormalities such as foreign bodies, varices, esophagitis, tumors, or ulceration. Three typical patterns are demonstrated in patients with congenital vascular anomalies. A large posterior esophageal indentation in the presence of anterior tracheal compression suggests a vascular ring consisting of a double aortic arch or the complex of a right aortic arch, left ductus arteriosus, and aberrant left subclavian artery (Figure 67–13). An oblique small retroesophageal indentation with a normal trachea is usually the result of an aberrant right subclavian artery with a left aortic arch, which is generally asymptomatic or, rarely, an aberrant left subclavian artery with a right aortic arch. The only vascular anomaly that passes between the trachea and the esophagus, causing an anterior esophageal indentation with a posterior tracheal indentation, is a "pulmonary sling," comprising an anomalous left pulmonary artery arising from the right pulmonary artery.[60]

Cinefluoroscopy is particularly valuable in demonstrating deglutition problems in the pharynx and motility and mucosal disturbances in the esophagus. A permanent record of the details, progress, and treatment response can be obtained in patients with achalasia, gastroesophageal reflux, esophageal dysmotility, esophageal spasm, Schatzki's rings, hernias, diverticula, and scleroderma.

Computed tomography and *magnetic resonance imaging* of the neck and chest have become a vital part of esophageal cancer staging, allowing distinction between intramural processes and extrinsic compression and demonstrating tumor extent and regional lymph adenopathy.

Endoscopic ultrasonography, a new, minimally invasive, innovative tool, using fiber-optic endoscopic visualization for cancer staging, provides information about intrinsic lesions, including mucosal and intramural involvement, and extrinsic masses. Ultrasonography can delineate the depth of invasion, identify possible metastatic lymph nodes, and guide fine-needle aspiration biopsies.[61,62]

Supplemental Evaluation

Twenty-four-hour multichannel pH probe studies are performed to evaluate gastric reflux. The distal pH sensor is placed 5 cm above the lower esophageal sphincter. The location of the proximal sensor has not been standardized, but some authorities advo-

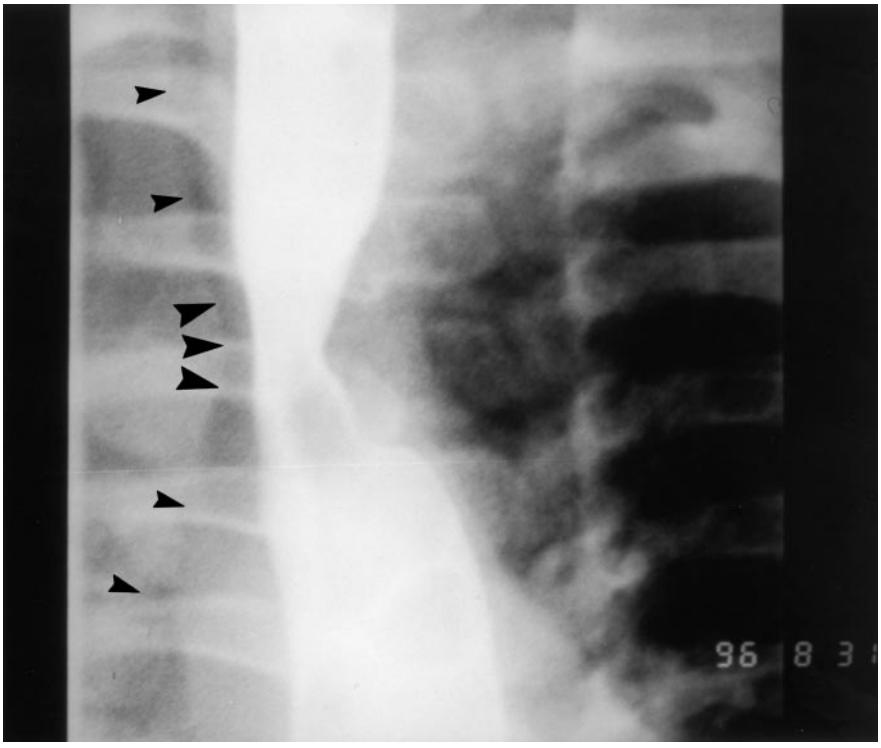

FIGURE 67–13. Barium esophagram demonstrating a double aortic arch, evidenced by a posterior filling defect in the esophagus, adjacent to a portion of the trachea that seems "tethered" to the esophagus (*larger arrowheads*). Note that the trachea widens and diverges from the esophagus both proximal and distal to the area constricted by the vascular ring.

cate placement 1 to 2 cm above the upper esophageal sphincter. Esophageal manometry of upper and lower esophageal sphincters assesses competence, spasm, or incomplete relaxation.

Indications for Esophagoscopy

Indications for esophagoscopy include complaints of dysphagia, odynophagia, regurgitation, and pyrosis; blunt trauma to the neck with associated subcutaneous air; penetrating neck trauma; radiographic evidence of esophageal masses or strictures; caustic or foreign-body ingestion; congenital anomalies; vocal fold palsies; suspicion of aerodigestive malignancies (primary, synchronous, or secondary); secondary esophageal involvement by autoimmune and idiopathic diseases; mechanical obstruction; and neuromuscular disorders. Additional interval evaluations may be indicated to monitor disease progression and treatment effects.

Esophageal *strictures* may result from caustic ingestion and as a manifestation of diseases such as Plummer-Vinson syndrome, Behçet's syndrome, gastroesophageal reflux, and Crohn's disease. Strictures may occur as a result of tracheoesophageal fistulae or malignancies or their management (Figure 67–14). Rigid or fiber-optic esophagoscopes can be used to visualize the esophageal lumen for direct dilatation or to pass a guidewire. If the esophagoscope cannot be passed through the stricture, the guidewire tip can be cautiously advanced and the stricture can be serially dilated over the guidewire; fluoroscopic guidance may be helpful. Jackson illustrated the potential for inadvertently perforating an acquired diverticulum proximal to a stricture (Figure 67–15).[30]

Stent placement using a guidewire and fiber-optic visualization may provide palliation for patients with nonoperable, obstructing esophageal cancer. Self-expanding metal stents are passed through the narrowed area of the tumor over a guidewire; once expanded, they cannot be removed.[63] To position a nonexpandable stent, the stenosis is first dilated with bougies or balloon dilators.

Therapeutic Esophagoscopy

Foreign Bodies Many foreign bodies pass uneventfully through the digestive system, but some become lodged in the esophagus and require surgical removal. In Western literature, meat is the most common esophageal foreign body found in adults and coins are the most common in children[64]; the ingestion is often witnessed.[65] Patients may be asymptomatic, or they may have dysphagia or emesis or develop stridor, fever, or a cough aggravated by eating.[5,65] Most children with esophageal foreign bodies are under 3 years of age, and most of the foreign bodies are coins[65] (Figures 67–16 and 67–17). Hawkins reported that 50% of children with ingested coins had them lodged for longer than 3 days, and every patient with coins lodged for longer than 7 days had respiratory symptoms, and some were febrile or had respiratory infections.[65] Lodgment occurred most commonly just below the cricopharyngeal muscle, as well as in the thoracic esophagus at the level of compression by the aortic arch or left main

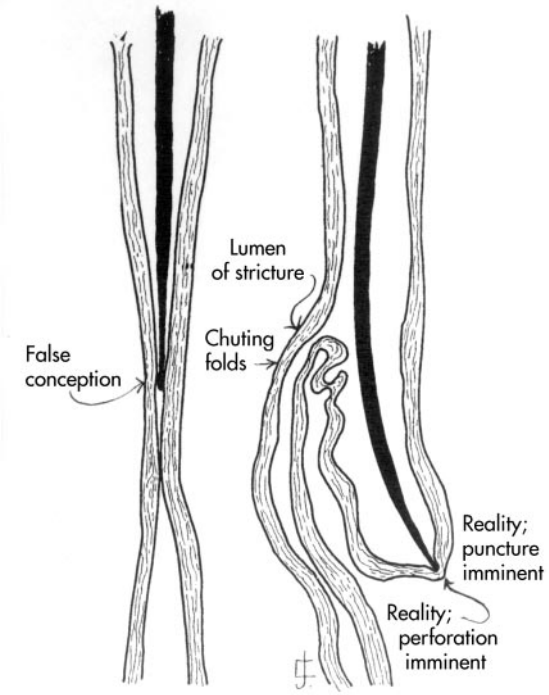

FIGURE 67–15. Mechanism of perforation by blind bougienage. On encountering resilient resistance, the operator, having a false conception, pushes on the bougie. Perforation results because, in reality, the bougie is in a pocket of a suprastrictural eccentric dilatation. Reproduced with permission from Jackson C. Bronchoscopy and esophagoscopy. A manual of peroral endoscopy and laryngeal surgery. 2nd ed. Philadelphia: WB Saunders; 1927.

bronchus or at a stricture.[65] Children and adults with atypical impactions may have predisposing conditions such as esophageal strictures or neuromuscular disturbances.[66]

Two-view neck and chest radiographs are often useful in identifying both the location and shape of a foreign body or its sequela, such as an esophageal air-fluid level. Barium is sometimes indicated to define a foreign body or to elucidate an underlying anatomic condition predisposing to foreign-body lodgment. Radiologic signs suggestive of perforation include retropharyngeal air, widening of the retropharyngeal soft tissue, leakage of contrast, or an extraluminal foreign body.[64]

Pharmacologic agents such as nifedipine have been used with varying degrees of success to facilitate the passage of an impacted foreign body by manipulating esophageal muscular tone;[67] glucagon does not appear to be effective in the dislodgment of esophageal coins in children.[68] Enzymatic digestion of a meat bolus with papain (Adolph's Meat Tenderizer) has largely been abandoned because of an unacceptable complication rate.[67] Emetic agents are ineffective and unsafe.[69]

In asymptomatic patients, a 24-hour observation period is safe; coins that reach the stomach are likely to pass through without complication and may be followed radiographically.[70] Button batteries, sharp objects, and objects causing bleeding, acute or severe airway compromise, pain, or dysphagia should be removed promptly.

Sharp objects have a perforation rate of 15 to 35%.[71] Even coins can cause stridor, esophageal erosion, aortoesophageal or tracheoesophageal fistula, mediastinitis, or paraesophageal abscess.[65,72] Other complications of esophageal foreign bodies include esophageal edema, laceration or erosion, hematoma,

FIGURE 67–16. Lateral neck radiograph demonstrating two coins, back to back, in the esophagus.

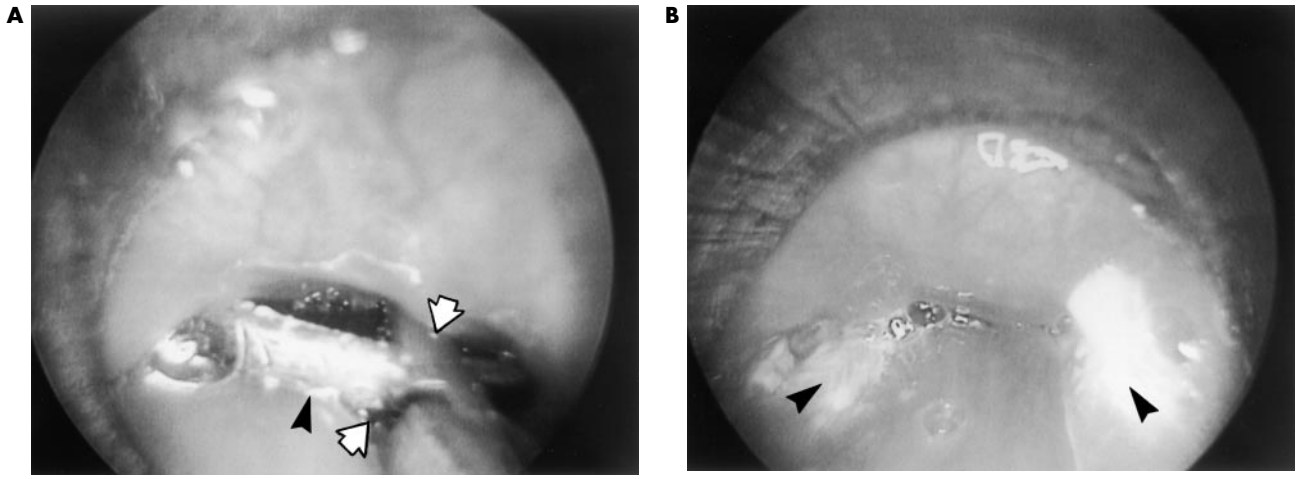

FIGURE 67–17. *A*, Coin (*black arrowhead*) grasped by side-channel alligator forceps (*white arrows*) for extraction. *B*, Minor eschar visible bilaterally after coin is removed. Note normal mucosa anteriorly, with fine vessels visible.

granulation tissue, retropharyngeal abscess, mediastinitis, migration of the foreign body into the fascial spaces of the neck, arterial-esophageal fistula with massive hemorrhage, respiratory problems, strictures, and proximal esophageal dilation; fatalities have been reported.[64,65,72]

Button batteries, commonly used in hearing aids, watches, electronic devices, toys, and even novelty clothing items, can cause significant injury to the esophagus as a result of direct current flow through tissue, local hydrolysis, and local hydroxide accumulation. The discharge state of the battery does not relate to patient outcome.[69] Patients who have ingested button cell batteries should undergo radiography to determine the location of the battery. Batteries lodged in the esophagus should be removed emergently as burns may occur as early as 4 hours after ingestion and perforation as soon as 6 hours after ingestion; fatalities have been reported.[69,73] Removal should be done endoscopically to allow direct visualization. Batteries that have passed beyond the esophagus need not be retrieved unless they remain lodged in the stomach for more than 48 hours or the patient manifests signs or symptoms of injury to the gastrointestinal tract,[69,74] The battery should be identified by size and imprint code or by evaluation of a duplicate, measurement of the battery compartment, or examination of the product, packaging, or instructions. If the chemical system cannot be identified from packaging or product instructions, it can be determined from the imprint code by calling the National Button Battery Ingestion Hotline at 202-625-3333. When mercuric oxide cells are ingested, blood and urine mercury levels are necessary only if the cell is observed to split in the gastrointestinal tract or radiopaque droplets are evident in the gut.[69]

Endoscopic removal of foreign bodies allows evaluation of any esophageal injury and visualization of multiple or radiolucent foreign bodies.[65,67] Although some foreign bodies can be safely removed using a fiber-optic esophagoscope, rigid esophagoscopes with Hopkins rod telescopes remain the gold standard for evaluation and removal of esophageal foreign bodies.

To grasp a foreign body during rigid esophagoscopy, the jaws of the forceps are opened after they have been inserted beyond the tip of the esophagoscope and may be used to push surrounding mucosa away from the foreign body. If the foreign body is too large to be withdrawn through the lumen of the esophagoscope, the esophagoscope is advanced to shield the foreign body. Sharp objects should be sheathed or rotated so that the point trails (see Figure 67–7). A blunt foreign body may be held tightly against the opening of the esophagoscope and the esophagoscope and foreign body withdrawn simultaneously in the plane of least resistance. Once proximal to the cricopharyngeus, the esophagoscope is tilted approximately 90 degrees to continue in an anterior direction through the pharynx and oral cavity. During the last phase of the maneuver, it may be more comfortable for the endoscopist to resume standing. Pediatric esophagoscopes offer the advan-

tageous capability of using side-channel instruments within the esophagoscope with the telescope simultaneously providing illumination and magnification.

Foreign bodies may escape endoscopic detection when the esophagoscope is advanced over a foreign body that is surrounded and obscured by granulation tissue; the foreign body may be seen while slowly withdrawing the esophagoscope. After foreign-body removal, it is reasonable to repeat the endoscopy to evaluate the possibility of mucosal erosions, additional foreign bodies, and underlying stricture or other lesion, especially if the foreign body was atypical.[65]

Alternative methods of removal, such as dislodging with a Foley catheter, are contraindicated if the foreign body has an unfavorable shape or if the patient has symptoms of airway involvement or any other complication.[65,75] Reported complications of Foley catheter removal include fatal airway obstruction, transient apnea, coin displacement to a main bronchus, esophageal perforation, esophageal tear, pneumomediastinum, bleeding, missed second coin, foreign body lost in the nasopharynx, aspiration pneumonia, and an inability to remove the coin.[65,75] Blind bougienage with Maloney dilators and insertion of nasogastric tubes to push the object into the stomach are occasionally used, but current opinion favors abandoning these methods as lacking safety and efficacy.[67] Other techniques include using suction or a protector hood secured to the tip of a fiber-optic esophagoscope or retrograde esophagoscopy from a gastrostomy.[71,72,76] Rarely, foreign bodies are so large or sharp that lateral pharyngotomy is necessary[77]; foreign bodies that have migrated into the soft tissues of the neck require open neck exploration.[64]

In comparing results, one must consider comparable foreign bodies, as well as whether complications result from the foreign body itself, from anesthesia or sedation, or from instrumentation. Berggreen et al compared rigid esophagoscopy to fiber-optic esophagoscopy with conscious sedation, Foley catheter technique under fluoroscopy (usually without sedation), blind bougienage with Maloney dilators, passage of a nasogastric tube to force the object into the stomach, and administration of intravenous glucagon or nifedipine. They reported that rigid esophagoscopy with the use of general anesthesia was more likely to be successful than all other techniques combined in both adults and children and that differences in complication rates were not statistically significant.[67]

Caustic Ingestion Patients who ingest caustic substances are at risk of serious esophageal injury, even in the absence of oropharyngeal burns.[74,78,79] Most ingestions occur in young children and are accidental; ingestions in adolescents and adults are often suicide gestures or attempts.[78,80,81] Initial treatment involves the immediate administration of water or milk to wash the corrosive material off the esophagus.[79] Attempts to remove the ingested material by emesis or lavage, adsorb it with activated charcoal, or neutralize it are contraindicated.[79]

Alkaline products account for the majority of ingestions and for the greatest number of serious injuries.[82] Liquid or solid drain cleaners and lye (sodium or potassium hydroxide); wall, oven, and toilet bowl cleaners (sodium hydroxide); laundry and automatic dishwasher detergents (sodium tripolyphosphate, silicates, and carbonates); Clinitest tablets (sodium hydroxide); and button batteries (potassium hydroxide) are common sources of corrosive injury. Acid ingestion is the second most common cause of severe burns. Hydrochloric acid, sulfuric acid, and swimming pool chemical ingestions can be dangerous; ammonia, chlorine bleach, and detergent ingestions, although common, are rarely responsible for significant esophageal morbidity.[82,83] Alkalis produce injury through liquefaction necrosis with penetration, whereas acids produce coagulation necrosis with a lesser degree of penetration. Liquids tend to cause wider and more severe injuries than tablets.[79]

Most authors advocate esophagoscopy to evaluate the extent and severity of injury for virtually all patients with caustic ingestions, finding that the presence or absence of symptoms is an unreliable predictor of esophageal injury.[79,80,84] Esophagoscopy is more accurate than any other means of evaluating esophageal involvement and is carried out under general endotracheal anesthesia within 24 to 48 hours of ingestion, to the upper limit of any full-thickness burn encountered.[74] First-degree (superficial) burns have mucosal hyperemia and edema or superficial mucosal desquamation; second-degree (transmucosal) burn injuries have mucosal sloughing with hemorrhages, exudates, and ulceration to and through the submucosa; and third-degree (transmural)

injuries have tissue sloughing with deep ulcerations or necrosis, including extension into the periesophageal tissues.[84] Esophagoscopy is contraindicated in the presence of a severe burn with evidence of laryngeal edema and in patients who have been on high doses of corticosteroids.[74]

In contrast, Crain et al found emesis, drooling, and stridor predictive of esophageal injury.[78] In 79 consecutive patients younger than 20 years of age, 50% (7/14) of patients with two or more of these three specific symptoms and signs had serious esophageal injury compared to normal endoscopic examination in all patients with fewer than two of these findings.[78]

Management remains controversial and may include hospitalization, antibiotics, corticosteroids, analgesics, sedation, and antireflux therapy. Corticosteroids are thought to be beneficial for moderately severe lye burns but are not indicated for severe lye and acid injury. The use of corticosteroids for third-degree burns is controversial as it may increase the likelihood of perforation or mask a perforation should one occur.[74] A prospective, randomized study of 60 children treated with and without corticosteroids following caustic ingestion with serious esophageal injury demonstrated that stricture formation was related only to the severity of the corrosive injury.[80] However, the finding of no benefit from corticosteroids may be related to the relatively low dosage of corticosteroids chosen.[74] Additional investigation and management options include interval barium esophagograms, the use of esophageal stents or the prolonged placement of a nasogastric tube, gastrostomy, anterograde or retrograde dilation of strictures, and esophageal replacement.[74,80] The long-term risk of cancer is increased in patients who require years of dilations.[74]

Selective esophagoscopy is reasonable for patients who ingest bleach or hair relaxers. Bleach ingestion does not usually result in stricture formation.[74] Hair relaxers, including "no-lye" preparations, have an alkaline pH; however, serious esophageal burns are uncommon, perhaps because of the solid nature of these products.[84] Emergency department or inpatient observation may be selectively used, with endoscopy reserved for those who do not tolerate oral intake, those with symptoms of complications, and those whose ingestion was intentional.[82,84,85]

Esophageal Diseases

Achalasia is a motor disorder of insidious onset and unknown etiology characterized by loss of peristalsis of esophageal smooth muscle and dysfunction of the lower esophageal sphincter, causing incomplete relaxation. In the early stages of achalasia, barium swallow may demonstrate spasm without dilation. The esophagus eventually becomes dilated and retains food; at this point, barium contrast may demonstrate esophageal dilatation, with a smooth tapered bird-beak appearance of the lower esophageal sphincter because of incomplete relaxation. Inhalation of amyl nitrite, a smooth muscle relaxant, results in sudden relaxation of the lower esophageal sphincter leading to rapid passage of the contrast through the sphincter.[86,87] Dysphagia is the most common symptom followed by regurgitation of food; other symptoms include aspiration, foul eructation, pyrosis, substernal pain, weight loss, and hemorrhage.[86,87] Histologically, the ganglion cells in Auerbach's plexus are significantly reduced in quantity or absent.

Endoscopy should be performed to assess the severity of retention esophagitis and to exclude malignancy. Achalasia is considered a premalignant condition; esophageal cancer eventually develops in 2 to 8% of patients.[63] Management options include dilating the lower esophageal sphincter or surgical myotomy; complications for both procedures include perforation and gastroesophageal reflux. Injection of botulinum toxin into the lower esophageal sphincter has shown promising results.[88]

Patients with *amyloidosis* often have neural or muscular involvement, resulting in abnormal or absent peristalsis. Lower esophageal sphincter pressures may be high, low, or normal, but relaxation is impaired. Symptoms can mimic achalasia.[89]

Pharyngoesophageal dysphagia, caused by cricopharyngeal spasm, a cricopharyngeal bar, cervical osteophytes, or cervical diverticula, may result in discomfort, weight loss, or aspiration. Diagnosis can be made with videoradiography and intraluminal manometry. Treatment options include dilatation, cricopharyngeal myotomy, and botulinum toxin injections.

Esophageal *diverticula* are categorized by their location and mode of development. Pharyngoesophageal ("Zenker's") and lower esophageal diverticula are thought to be related to disordered

motility of the cricopharyngeus and esophagus and to congenital or acquired weakness of the muscular walls; they do not contain a muscular layer and are classified as pulsion diverticula.[90] Traction diverticula, usually in the middle third of the esophagus, contain muscle and are thought to result from inflammatory processes adjacent to the esophagus, causing contracture and deformity of the entire wall. Traction diverticula are frequently asymptomatic incidental radiographic findings.

The cause of Zenker's diverticula remains controversial; however, cricopharyngeal muscle spasm is thought to contribute. Esophageal mucosa and minimal submucosal tissue herniate posteriorly through a weak area known as Killian's dehiscence or triangle, bound by the oblique layer of the inferior pharyngeal constrictor muscle, the transverse layer of the cricopharyngeus muscle, and the midline raphe. Patients report dysphagia, regurgitation of undigested food, aspiration pneumonia, and weight loss. Diagnosis is made radiographically by coating the diverticular sac with barium; treatment is surgical. Open cervical approaches consist of diverticulectomy or diverticulopexy with cricopharyngeal myotomy. Myotomy alone may be performed for small diverticula; diverticulopexy may be advantageous for debilitated patients because the sac is never violated so the patient may resume feeding quickly.[91] Feeley et al reported a 38% complication rate for diverticulectomy and myotomy, including wound infection, salivary fistula, and mediastinitis.[92] The "Dohlman procedure," endoscopic division of the esophagodiverticular wall incorporating division of the cricopharyngeus, was popularized by Dohlman and Mattsson in 1960 and was initially performed with electrocautery and then with a carbon dioxide laser.[90,93,94] Recently, endoscopic stapling has been advocated as a safer method, allowing division of the common septum while simultaneously sealing the transected edges. This minimally invasive, quick procedure facilitates a short hospital stay and early alimentation and is advantageous for elderly or debilitated patients.[95]

Inflammation, Esophagitis, and Gastroesophageal Reflux Disease An incompetent lower esophageal sphincter, increased intra-abdominal pressure, gastric outlet obstruction, dietary habits, or tobacco use may contribute to *gastroesophageal reflux*; the resultant contact between gastric acid and esophageal mucosa can cause chronic inflammation, strictures, webs, and dysmotility. The most common symptom is "heartburn"; other symptoms include chest pain, "backwash," or foul taste in the hypopharynx. Management may include dietary changes, weight loss, medications such as proton pump inhibitors and histamine H_2-receptor antagonists, or surgical procedures such as fundoplication.

Barrett's metaplasia comprises replacement of the normal esophageal stratified squamous epithelium with gastric-type columnar mucosa. This premalignant condition develops as a consequence of prolonged chronic gastroesophageal reflux. The diagnosis can be difficult to determine endoscopically because of the normal transition into gastric mucosa at the gastroesophageal junction. The presence of columnar epithelium 3 cm above the most proximal margin of the gastric folds is diagnostic and should be confirmed histologically. The incidence of adenocarcinoma in American patients with Barrett's esophagus is approximately 800 cases per 100,000 patients per year. Regular endoscopic surveillance for dysplasia and early carcinoma is indicated because of this 40-fold increase in risk.[96]

Infectious esophagitis, most commonly caused by herpes simplex, *Candida*, or cytomegalovirus, usually occurs in immunocompromised patients and diabetics. The primary symptoms are dysphagia and odynophagia. Endoscopy with biopsies, brushings, and culture may be necessary to establish the diagnosis. In bone marrow transplant patients with chronic *graft-versus-host disease*, an epithelial reaction of the esophageal mucosa can cause dysphagia and odynophagia.[97]

Connective Tissue Disorders The primary esophageal manifestations of connective tissue disorders are motility dysfunctions.

Scleroderma. Progressive systemic sclerosis, or scleroderma, is a progressive vasculitis and fibrosis involving multiple organs. Esophageal involvement, present in at least 70 to 80% of patients,[98] manifests with pyrosis, regurgitation, dysphagia, and odynophagia. The motor disorder manifestations include low-amplitude esophageal contractions that initially involve the smooth muscles of the lower two-thirds of the esophagus, with eventual progression to the striated muscle of the upper one-third of the esophagus. The weakened lower esophageal

sphincter, increased acid secretion, and delayed gastric emptying predispose these patients to esophageal reflux.[99]

Dermatomyositis. Polymyositis and *dermatomyositis* are inflammatory processes primarily affecting striated muscles. The proximal third of the esophagus, containing striated muscle, is the most commonly involved region of the gastrointestinal tract. Smooth muscle can also be affected, resulting in decreased pharyngeal and upper esophageal sphincter contraction pressures. Patients often present with nasal regurgitation and aspiration[98]; other common symptoms include dysphagia and esophageal regurgitation. Some authors believe that patients with these diseases are at increased risk of gastrointestinal malignancies.[98,99]

Other Connective Tissue Disorders. Sjögren's syndrome is characterized by the presence of two of the three following criteria: keratoconjunctivitis sicca, xerostomia, and chronic inflammatory connective tissue disease. Histologic evaluation demonstrates atrophy of the acinar structures, extensive lymphoplasmocytic infiltration, and sclerosis. Dysphagia is most commonly caused by xerostomia; however, rarely, esophageal dysmotility may occur.

Both *systemic lupus erythematosus* and *rheumatoid arthritis* may include esophageal dysmotility. *Mixed connective tissue disease* is a distinct clinical entity with features of systemic lupus erythematosus, progressive systemic sclerosis, myositis, and rheumatoid arthritis. Serologic studies may demonstrate an increase of antiribonucleoprotein antibodies. Seventy-five percent of patients have motor dysfunction of the esophagus; some also have pharyngeal involvement.[98]

Dermatologic Vesicobullous Diseases *Epidermolysis bullosa* comprises a group of hereditary disorders characterized by blister formation at sites of minor trauma. Bullae form on the skin or mucous membranes and result in ulcers that are slow to heal and ultimately form scars. Autosomal recessive dystrophic epidermolysis bullosa is most frequently associated with oral and esophageal involvement.[100] Oral blisters and dysphagia are the most common extracutaneous complaints.[101] Esophageal involvement often occurs in the cervical esophagus, probably from mechanical trauma, with dysphagia developing insidiously over the first decade of life.[101] Subsequent scarring and stricture formation are difficult to manage as conservative attempts to dilate the stricture may lead to additional trauma and bullae formation. Endoscopy is generally not recommended because of the possibility of causing mechanical trauma; evaluation by barium esophagram is preferred. A soft diet helps to decrease the incidence of mucosal trauma.[102]

Pemphigus vulgaris is a rare intraepidermal bullous disease marked histologically by suprabasal acantholysis. Oral lesions occur in 70% of patients; the oral cavity is the only site affected in more than 50%.[103] Esophageal involvement may cause dysphagia. Nikolsky's sign, separation of the epidermal layer from underlying tissue after applying lateral pressure to the skin, may be observed. Esophagoscopy is the diagnostic method of choice, and treatment is primarily corticosteroids.[103]

Benign mucous membrane (cicatricial) pemphigoid is a chronic, bullous disease of the elderly, causing webs and strictures most commonly involving the oral cavity and conjunctiva. Esophageal involvement is less common and may be evaluated with a barium esophagram and careful endoscopy; induction of bullous lesions owing to endoscopy has been reported.[104] Corticosteroids are the primary mode of therapy. Strictures may be treated with careful dilatation; however, the risk of perforation exists. Colon interposition has been successfully performed for severe strictures.[105]

Stevens-Johnson syndrome is a severe systemic hypersensitivity erythema multiforme reaction that presents with iris-like, target lesions and vesicobullous lesions of skin and mucous membranes. Although over 50% of cases of erythema multiforme are idiopathic, the most common causative agents in adults are medications such as sulfonamides, phenytoin, barbiturates, phenylbutazone, digitalis, and penicillin and, in children, infections with microorganisms such as *Streptococcus*, herpes simplex, and *Mycoplasma*. Extensive cutaneous and mucosal lesions are associated with conjunctivitis, fever, leukopenia, and bullous stomatitis; mucosal involvement can be painful enough to cause poor oral intake, and dehydration is a serious concern[106,107] (Figure 67–18). Treatment consists of removal of the underlying cause and supportive care. Corticosteroid therapy is often used in severe disease, but its efficacy is unproven.[106,107]

FIGURE 67–18. Oral cavity of a child with Stevens-Johnson syndrome, demonstrating skin, lip, tongue, and mucosal involvement.

Benign Tumors Benign esophageal tumors, less common than malignant esophageal tumors, are divided into epithelial and nonepithelial tumors. *Squamous papillomas* are the only benign epithelial tumor. Endoscopically, they appear as a warty tumor that usually remains small and asymptomatic. Benign nonepithelial tumors include leiomyomas, lipomas, fibromas, neurofibromas, gliomas, granular cell tumors, and osteochondromas.[97,108,109]

More than half of benign esophageal tumors are *leiomyomas*, presenting as intramural, encapsulated tumors arising from the muscularis mucosa. As they are usually of smooth muscle origin, they are most often found in the middle or lower third of the esophagus. No clinically characteristic features of leiomyoma exist; over half of patients are asymptomatic.[110] When symptoms are present, the most common complaints are dysphagia, pain, heartburn, and weight loss.[111] A chest radiograph may show a posterior mediastinal tumor or diffuse widening of the lower mediastinum. A barium esophagram will usually show a smooth filling defect; large tumors may cause irregular, lobulated filling defects. Computed tomography with contrast will show an intramural, eccentric, mediastinal mass with homogeneous enhancement. Endoscopic examination will reveal a submucosal mass. Histologically, a leiomyoma may resemble a malignant leiomyosarcoma.

Hemangiomas account for 2 to 3% of benign esophageal neoplasms. They appear pale blue and empty when compressed.[108] *Adenomatous polyps* are rare and are associated with Barrett's metaplasia.[97]

Esophageal cysts are also uncommon and may present with respiratory symptoms in infants and dysphagia and pain in adults. Cysts in infants are often lined with gastric mucosa; ulceration into the airway can cause hemoptysis. Appearance on a barium swallow study is similar to that of a leiomyoma except that the edges of an esophageal cyst have a more tapered appearance.[110]

Malignant Tumors *Squamous cell carcinoma* is the most common malignant esophageal tumor. Screening endoscopy should be performed in patients with known risk factors such as alcohol and tobacco abuse, achalasia, Plummer-Vinson syndrome, tylosis (palmar and plantar keratoderma), chronic stricture from ingestion of lye or corrosive substances, and celiac disease.[108,112] Often advanced disease presents at the time of diagnosis. The most common symptom is dysphagia; other symptoms include

aspiration pneumonia, hoarseness, unilateral neck mass, cough, fever, or a choking sensation. Endoscopically, lesions are usually found in the middle and lower third of the esophagus; they may be polypoid, ulcerative, or infiltrating. The most common complications of the carcinoma and its treatment are strictures, fistulae, and hemorrhage.[108]

Adenocarcinoma is the second most common esophageal epithelial malignancy, usually occurring in the distal esophagus in association with Barrett's metaplasia. Symptoms are similar to those of squamous cell carcinoma.

Other malignant epithelial tumors are rare and include variants of squamous cell carcinoma, such as spindle cell carcinoma, verrucous carcinoma or pseudosarcoma, adenoid cystic carcinoma, mucoepidermoid carcinoma, argyrophil cell carcinoma, and melanoma.[108]

Nonepithelial malignant esophageal tumors include leiomyosarcoma, rhabdomyosarcoma, and fibrosarcoma.[97,108] Direct esophageal infiltration or compression may be caused by thyroid, lung, or lymph node malignancies.[97,108]

Hematemesis

Esophageal varices, usually limited to the distal half of the esophagus, develop as a result of portal hypertension. Approximately 50% of cirrhotics with esophageal varices will bleed in their lifetime.[113] Mortality is highest in the first few days to weeks following the hemorrhage; early intervention is crucial for survival.[113–116] Endoscopic treatment options include sclerotherapy, ligation, or electro- or laser coagulation of bleeding points; ligation is considered the superior method.[77,114–116]

Mallory-Weiss tears develop in the gastric cardia and gastroesophageal junction after an episode of retching, vomiting, and coughing and are usually limited to the mucosa. Spontaneous cessation of bleeding occurs in 90% of patients.[117] This previously fatal condition now has a good prognosis with treatment; options include endoscopic bipolar cautery, sclerotherapy, and laser photocoagulation.

Boerhaave's syndrome describes the spontaneous, full-thickness esophageal tear that results most commonly from a prolonged bout of violent emesis. The patient may present with excruciating lower chest pain, shock, dyspnea, and extreme thirst. Survival is dependent on rapid diagnosis and treatment. Chest radiography may reveal pneumomediastinum or mediastinal widening; a swallowing study with radiopaque contrast will demonstrate the site of rupture. Esophagoscopy should not be performed as it will not add any additional information and may cause further damage.[118]

Other rare diseases that can present with esophagitis or stenosis include Wegener's granulomatosis, Crohn's disease, tuberculosis, syphilis, and Behçet's syndrome.[119–123]
