The majority of the floor of the posterior fossa is composed of the occipital bone, whereas the posterior face of the petrous portion of the temporal bone defines the anterior lateral extent. Centrally, the foramen magnum allows passage of the spinal cord and the vertebral arteries. Immediately lateral to the foramen magnum, each hypoglossal canal allows passage of a hypoglossal nerve from the intracranial cavity. Lateral to this, the jugular foramen lies at the junction of the occipital bone (medial posterior margin) and the temporal bone (anterolateral margin). The jugular vein (laterally) and the ninth, tenth, and eleventh cranial nerves (medially) traverse this foramen.

Superior to the jugular foramen, the IAC serves as an entrance of the seventh and eighth cranial nerves into the temporal bone. In the cerebellopontine angle (CPA), the seventh nerve lies anteromedial to the eighth nerve. As the eighth nerve enters the IAC, it trifurcates into the auditory, superior vestibular, and inferior vestibular nerves. In the lateral end of the IAC (fundus), these three nerves, along with the seventh nerve, fill each of the quadrants of the IAC (Figure 25–2).

Infratemporal Fossa

The area below the temporal bone is designated the infratemporal fossa. The internal carotid artery and the internal jugular vein pass through here in a vertical direction.

Medial to the internal jugular vein, cranial nerves IX, X, and XI exit the jugular foramen and pass through the infratemporal fossa. The deep lobe of the parotid abuts the anterolateral margin of the infratemporal fossa.

EVALUATION

History and Physical Examination

Key aspects of history taking and physical examination as they relate to skull base disorders are highlighted. A past medical history should always be taken to include use of medications, allergies, alcohol and tobacco use, and any past history of malignancy or neurologic disorder, such as multiple sclerosis. It is very important to rule out the possibility of metastasic neoplasms or systemic illness.

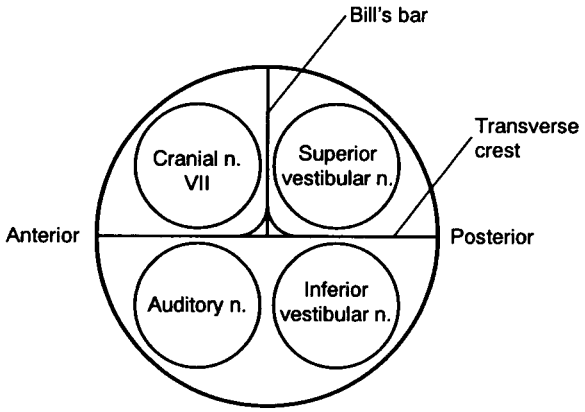

FIGURE 25–2. Schematic drawing of the position of the four nerves at the lateral aspect of the internal auditory canal. The transverse crest and Bill's bar are important identifying landmarks.

Although some skull base lesions may be an incidental finding (eg, on MRI), most patients will be symptomatic. Their complaints can range from nonspecific symptoms, such as headache, to very localized findings, such as unilateral hearing loss. In directing questions to the patient, one should remember that most symptoms are related to encroachment on nervous and vascular structures along the skull base.

Evaluation of a patient with a skull base disorder requires a thorough head and neck examination, otologic/neurotologic examination, and general neurologic examination with emphasis on the cranial nerves. Specific signs symptoms and findings will be discussed with each disorder.

Diagnostic Testing

Physiologic tests are also useful in diagnosis and treatment of skull base disorders.

Patients with audiovestibular complaints or suspected cerebellopontine disorders undergo basic audiologic evaluation including pure-tone averages, speech reception thresholds, word recognition scores, and tympanometry. These tests supply valuable information concerning the function of the

external auditory canal, tympanic membrane, middle ear and ossicles, cochlea, and auditory nerve. If a retrocochlear lesion is suspected, stapedial reflexes are obtained and rollover (decreasing discrimination with increasing intensity) is evaluated (Table 25–1). If there is suspicion of a retrocochlear lesion after initial evaluation, further testing (either ABR or MRI scan) is done (Figure 25–3).

Auditory brainstem response testing is a very useful, noninvasive screening test used most commonly when an acoustic neuroma is suspected. Although absolute latencies of the five obtained waves are helpful, the most commonly used measurement in evaluation of an acoustic neuroma is the interaural comparison of wave V latencies. A difference of greater than 0.2 ms is considered significant. The sensitivity of ABR, using a click stimulus, is reported between 93 and 100% [7]

False positives range from 8 to 25%.[8] Care must be used in evaluating a patient with pure-tone thresholds greater than 65 dB at 4 kHz as an abnormal response may be attributable simply to the inability to activate the auditory system adequately.

The ABR is also useful in the identification of other disorders. In seventh nerve vascular compressive syndromes, the wave I–III latencies tend to be prolonged. This is felt to be caused by the irritation/compression from the pulsation of the blood vessel against the nerve. Abnormalities can also be seen in other disorders, such as multiple sclerosis. Up to 93% of patients with multiple sclerosis have ABR abnormalities.[9] Various wave amplitude and latency abnormalities are possible, with wave V amplitude and wave II–V latencies being the most common.

The ENG is used to evaluate the vestibular labyrinth, the vestibular portion of the eighth nerve, and the central portions of the vestibular system.

TABLE 25–1. Audiologic Evidence of Retrocochlear Lesions

Asymmetric sensorineural hearing loss
Stapedial (acoustic) reflex abnormalities
Tone decay
Rollover in discrimination scores
Decreased discrimination out of proportion to hearing loss

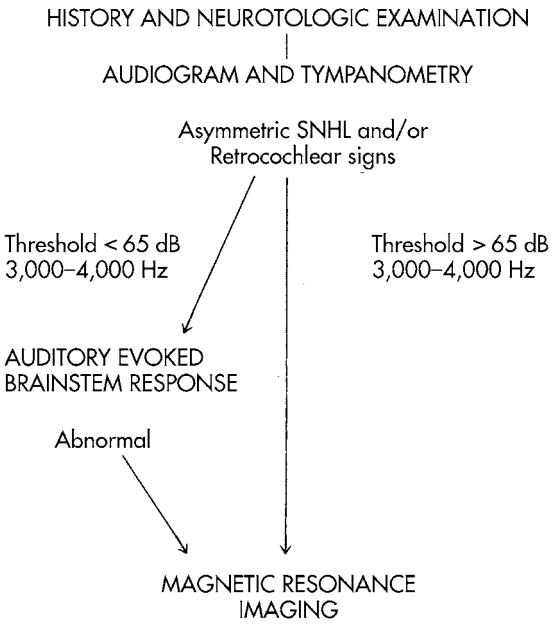

FIGURE 25–3. Flow diagram demonstrating our procedure for evaluation of patients suspected of having retrocochlear disease. SNHL = sensorineural hearing loss.

The caloric portion of the ENG allows each labyrinth to be evaluated individually. The information is very helpful when attempting to document objectively the side of vestibular abnormality when considering an ablative vestibular neurectomy.

Seventh cranial nerve status is frequently important in skull base disorder decision making. Most commonly, the level of clinical function is the important feature. At times, in the completely paralyzed face, it is important to evaluate the integrity of the nerve. This provides useful prognostic information and is also helpful in Bell's palsy or herpes zoster oticus (Ramsay Hunt syndrome) when surgical decompression of the seventh nerve is being considered. Several tests are available including electroneuronography (evoked electromyography), maximal stimulation test, nerve excitability test, and electromyonography. (The descriptions, indications, and details of each of these tests are discussed in Chapter 24.)

Diagnostic Imaging

Imaging is frequently the key diagnostic method in skull base abnormalities. In mass lesions, it is especially critical in treatment planning.

Magnetic resonance imaging came into regular use in the late 1980s. Soft tissue detail is significantly improved from previous techniques. Gadolinium diethylenetriamine pentaacetic acid (DTPA), a paramagnetic contrast agent, allows definition of many tissues and lesions. It is given intravenously, and, unlike iodine compounds, adverse reactions to it are extremely rare. In the CPA, MRI has allowed identification of smaller acoustic neuromas than in the past. Even very small acoustic neuromas that do not show significant tissue distortion readily enhance with gadolinium (Figure 25–4, A and B). One distinct advantage of MRI is that, in one "pass" through the scanner, complete information is entered into the computer and an image can be created in any plane, most commonly the axial, coronal, or sagittal planes. A drawback of MRI is the complete lack of visualization of bone, making it difficult to evaluate any bony abnormality or soft tissue– bony interfaces. Magnetic resonance imaging is contraindicated in patients with metal implants such as pacemakers and surgical clips. Claustrophobia and obesity can be relative contraindications, although newer "open" scanners frequently allow enough room for obese patients and help alleviate claustrophobic symptoms.

Computed tomography (CT) became the prevalent imaging tool in the 1970s, and although it allowed the best soft tissue detail at the time, it has subsequently been surpassed by MRI. High-resolution CT scanning of the temporal bone and skull base remains the best study of bony anatomy and of bone destruction by space-occupying lesions (Figure 25–5). Intravenous iodine-based contrast can be used to enhance soft tissue visualization.

Angiography can be useful as both a diagnostic and a treatment modality. Primary vascular abnormalities such as aneurysms, arteriovenous malformations, and arteriovenous fistulae are readily seen on angiography. Vascular tumors such as glomus jugulare (Figure 25–6) and glomus vagale can be clearly identified, with their blood supplies delineated. Angiography is also useful to establish the patency, location, and relationship of the blood vessels adjacent to the lesions.

In lesions that involve or are adjacent to the internal carotid artery, preoperative occlusion studies are of predictive value when considering resection of the artery. After catheterization of the internal carotid artery, the vessel is balloon occluded, and the patients are monitored. Patients tolerating occlusion are at lower risk for neurogenic sequelae postoperatively if the artery is resected or damaged during surgery.[10]

In vascular lesions such as glomus jugulare tumors, angiography with embolization has been used as an isolated treatment modality but more

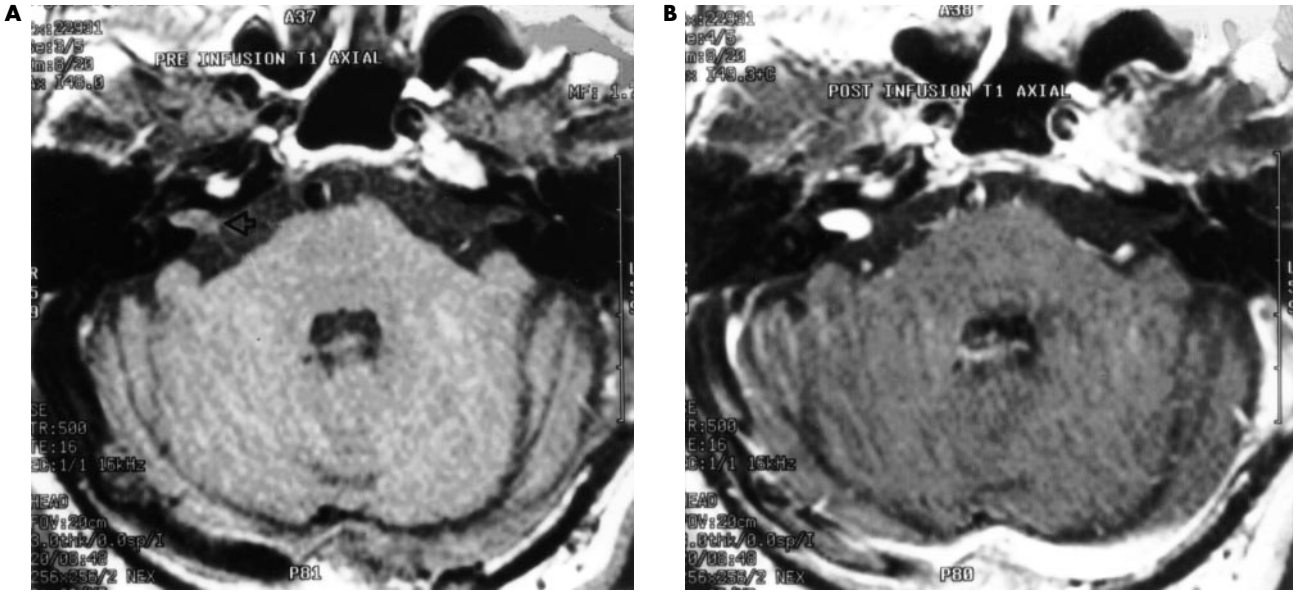

FIGURE 25–4. Magnetic resonance image of a patient with a small right intracanalicular acoustic neuroma. *A*, The T_1 image shows subtle contrast changes without significant internal auditory canal enlargement (*arrow*). *B*, Gadolinium enhancement of the T1 image clearly delineates the tumor.

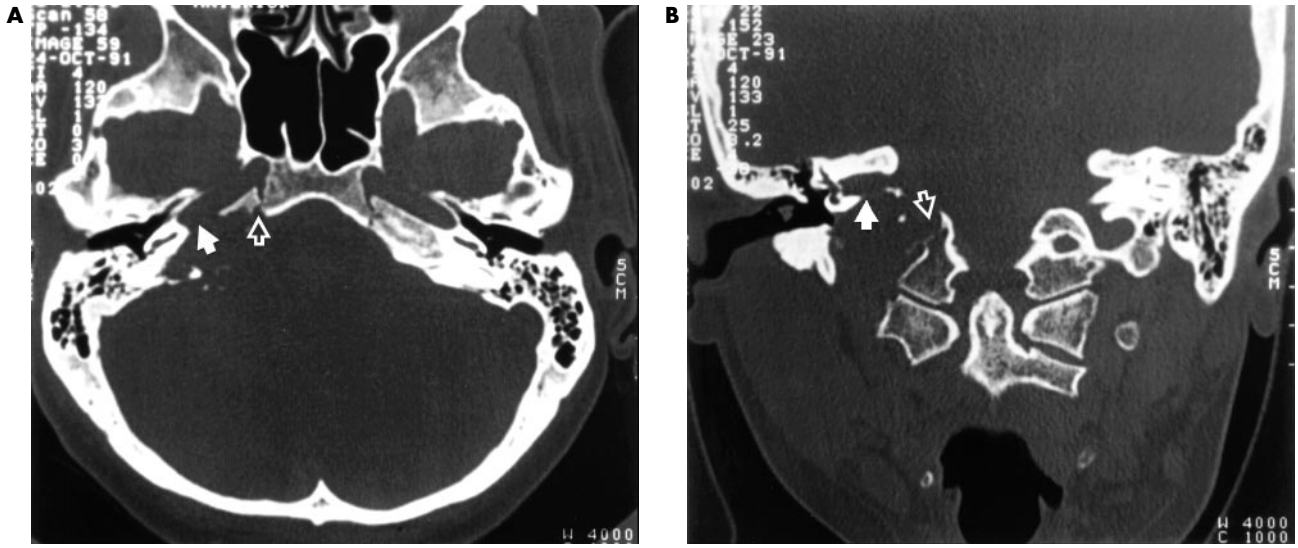

FIGURE 25–5. Computed tomographic scan of the temporal bone in which a chondrosarcoma arises from the right foramen lacerum. There is significant bone erosion of the petrous apex. *A*, Axial view demonstrates erosion of bone along the horizontal portion of the carotid canal (*black arrow*) and the clivus portion of the sphenoid bone (*open arrow*). *B*, Coronal view reveals bone erosion of the inferior aspect of the canal of the internal carotid artery (*black arrow*) and hypoglossal canal (*open arrow*).

commonly is used as a preoperative adjunct. Preoperative embolization has been shown to decrease significantly intraoperative blood loss in these patients.[11,12]

SKULL BASE DISORDERS

There are a large variety of skull base disorders (see Table 25–2 for differential diagnosis of skull base lesions). Although many of these are mass lesions, other entities, such as infectious diseases, inflammatory abnormalities, and vascular compression syndromes, must be considered. Although malignant lesions do occur, fortunately, most of the skull base entities are benign. When evaluating a patient with a malignant skull base lesion, it is important to rule out the possibility of a metastasis from a regional or distant site.

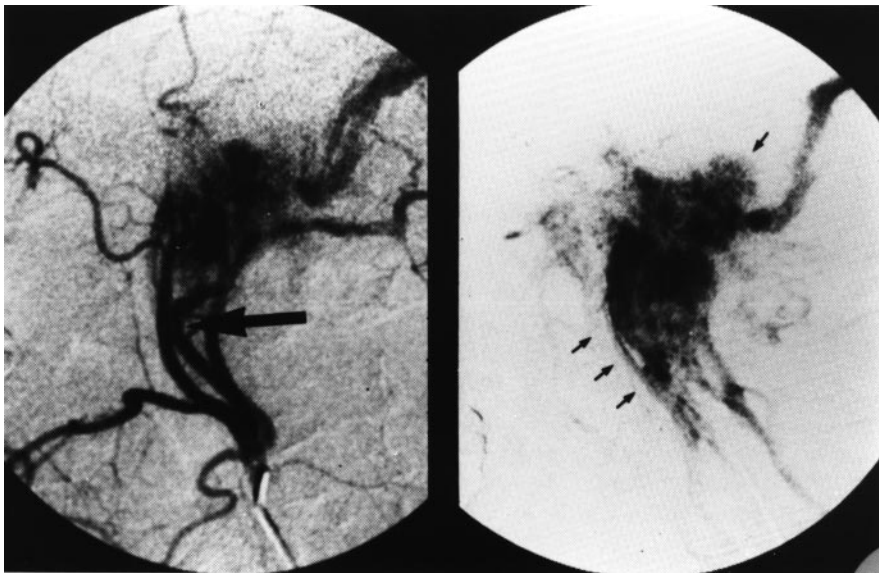

FIGURE 25–6. Angiogram showing a large glomus jugulare tumor. The ascending pharyngeal artery (*large arrow*) is the dominant feeding vessel. Tumor fills the jugular vein (*triple arrow*) and extends into the posterior fossa (*small single arrow*). Reproduced with permission from Young N et al.[11]

Primary cholesteatomas
Rare lesions
Rhabdomyosarcoma
Plasmacytoma
Melanoma
Giant cell tumor
Osteoblastoma
Lipoma
Chondrosarcoma
Leukemia
Eosinophilic granuloma
Dermoid/teratoma
Histiocytosis
Hemangiopericytoma
Ewing's sarcoma
Petrositis

Some mass lesions may be unique to specific areas of the skull base, whereas others can arise in more than one site. The following section will briefly review lesions by location. The more important entities will subsequently be discussed individually.

Lesions of the Anterior Part of the Skull Base

Mass lesions of the anterior part of the skull base include benign fibro-osseous lesions and osseous lesions as well as malignant entities such as sinonasal tumors and esthesioneuroblastoma.

Fibro-osseous lesions, fibrous dysplasia and ossifying fibroma, are common benign lesions of the anterior part of the skull base. Fibrous dysplasia may occur in monostotic (one site) or polyostotic (more than one site) forms. The monostotic form is the most common. Ossifying fibromas have a higher growth rate than fibrous dysplasia. They are differentiated on CT from fibrous dysplasia by the appearance of a bony capsule. Another common lesion is an osseous lesion, an osteoma. Osteomas frequently arise in the frontal and ethmoid sinuses and involve the anterior part of the skull base secondarily. Pathologic differentiation among these lesions is sometimes difficult. Treatment of these lesions is necessary only when functional problems arise or cosmetic deformity occurs.[13]

Two malignant lesions that can involve the anterior part of the skull base are paranasal sinus carcinoma and esthesioneuroblastoma. Ethmoid and, less commonly, frontal sinus tumors (most of which are squamous cell carcinomas) involve the anterior part of the skull base through direct extension. Wide surgical removal, usually in combination with radiation or chemotherapy, is necessary when treatment for cure is planned. Esthesioneuroblastomas are of neural crest origin and represent about 2% of all malignant nasal neoplasms. The cribriform plate is involved early as this lesion arises from the olfactory epithelium.[14] Total gross removal may require craniofacial resection as well as orbital exenteration in addition to sinus eradication.

Middle Fossa/Petrous Apex Lesions

Mass lesions of the middle cranial fossa and petrous apex include benign entities such as cholesterol granuloma, meningiomas, cholesteatomas, and schwannomas. The latter three lesions are discussed in more detail later in this chapter. Malignant lesions such as chordoma, chondrosarcoma, and nasopharyngeal carcinoma can also affect this area.

Cholesterol granulomas are fluid-filled cysts that may arise in any portion of the air cell system of the temporal bone, more commonly in the petrous apex. They occur in well-pneumatized temporal bones in air cells that are poorly ventilated. The negative pressure causes a hemorrhage in the air cell. Once the blood begins to break down, there is a for-

eign body reaction to one of the breakdown components, cholesterol.[15] Cholesterol granulomas have a propensity to affect cranial nerves. The patient usually presents with hearing loss, although vertigo, facial paresis, and diplopia may be present. Diagnosis is usually confirmed with CT and MRI (Figure 25–7). This lesion appears very bright on both T_1- and T_2-weighted images. Treatment consists of surgical drainage with maintenance of ventilation.[16]

Of the potentially malignant lesions, chordoma is relatively insidious. This neoplasm is thought to arise from the primitive notochord, and the majority involve the petroclival area. Symptoms are caused by progressive involvement of adjacent cranial nerves. The typical CT shows an irregular mass with bony destruction. Magnetic resonance imaging reveals a low-intensity mass on T_1 and T_2, with variable enhancement. Extensive surgery in combination with high-dose radiation therapy is the treatment of choice.[17]

Chondrosarcomas are rare, comprising less than 1% of skull base tumors.[18] They are thought to arise from trapped embryologic rests in and around the foramen lacerum. Hearing loss is the initial complaint of most patients, although complaints may include tinnitus, vertigo, unsteadiness, diplopia, and facial paresis. Computed tomography shows irregular bony destruction with the contrast enhancement (see Figure 25–5). The lesion also brightly enhances on MRI. Total removal of the tumor is the optimum treatment. Radiation therapy is controversial.

Nasopharyngeal cancer is discussed in Chapter 60. Larger lesions can invade the skull base and present with symptoms of a skull base lesion.

Posterior Fossa/Internal Auditory Canal Lesions

Most mass lesions of the posterior fossa are benign. Acoustic neuromas account for roughly 90% of the lesions, whereas meningiomas account for about 5%. These will be discussed later. Other mass lesions include epidermoids, lipomas, and arachnoid cysts. The majority of the malignant lesions that do occur in this area are metastatic. Epidermoids arise from trapped rests of keratinized squamous epithelium and comprise 1% of CPA tumors.[19] Careful removal of all squamous cell elements is necessary to prevent aseptic meningitis or recurrence.

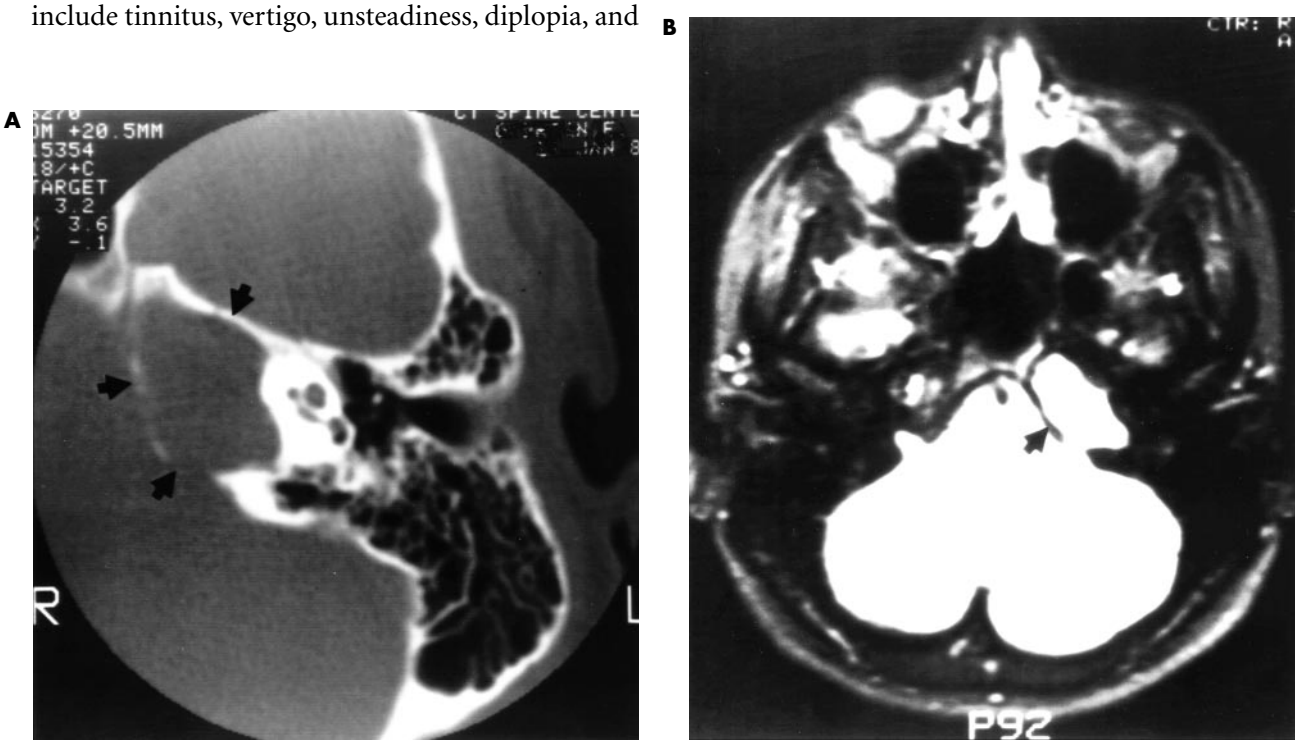

FIGURE 25–7. Patient with a large cholesterol granuloma of the left petrous apex. *A*, Bone window axial computed tomographic scan shows soft tissue density replacing the entire left petrous apex (*arrows*). *B*, T_1-weighted magnetic resonance image shows this bright lesion (*arrow*).

Lipomas can occur in the IAC and CPA. Internal auditory canal lipomas tend to present earlier because of neural compression, whereas CPA lipomas may not cause symptoms until they are much larger. Diagnosis is made with MRI.[20] Arachnoid cysts, which are collections of CSF trapped by arachnoid granulations, comprise about 1% of CPA lesions. They are very frequently asymptomatic and are incidental findings on MRI (Figure 25–8). If symptomatic, surgical treatment involves opening of the cyst wall.[21]

Metastatic lesions from any other location to the CPA is possible. Fortunately, this occurrence is rare. Tumors most likely to metastasize are breast tumors, adenocarcinomas, prostrate cancers, and clear cell tumors of the genital organs.[22]

SKULL BASE DISORDERS BY DIAGNOSIS

Neuroma/Schwannoma

Acoustic Neuroma Acoustic neuromas are the most common lesion of the CPA, representing 90% of all tumors in this area. Acoustic neuromas constitute about 6% of all intracranial tumors. In the United States, there is an incidence of approximately 1 in 100,000, resulting in roughly 2,500 new cases diagnosed each year. The name is a misnomer because they actually arise from the Schwann cells surrounding the vestibular portion of the eighth cranial nerve. Since Schwann cells are peripheral nerve entities, then, by definition, these must arise in the IAC.

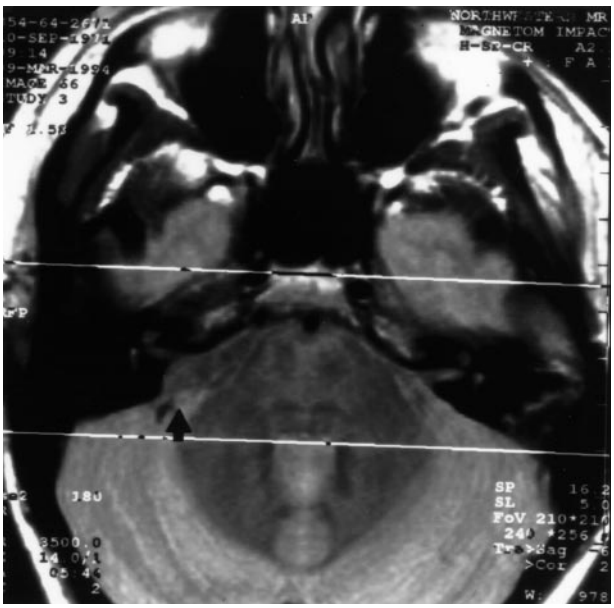

FIGURE 25–8. T_1-weighted magnetic resonance image shows an apparent soft tissue mass (*arrow*) in the cerebellopontine angle in a patient who presented with headaches and vertigo. At surgical resection, an arachnoid cyst was identified.

Acoustic neuromas occur in two forms: sporadic and those associated with neurofibromatosis 2. The sporadic form constitutes well over 90% of all acoustic neuromas. Neurofibromatosis 2 is a rare autosomal dominant genetic disorder whose gene is located on chromosome 22, resulting in bilateral acoustic neuromas and other central nervous system neoplasms.

Unilateral hearing loss is the most common presenting symptom. Other symptoms that may occur are tinnitus, dysequilibrium, vertigo, headache, and aural fullness. Later symptoms can include facial numbness, facial weakness, and diplopia. When the tumors are very large, neuropathies of cranial nerves III, IV, VI, IX, X, and XI, as well as cerebellar and brainstem compression, can occur.

Acoustic neuromas are relatively slow-growing tumors. Grossly, they appear yellow to gray and may have a cystic structure. Histopathologically, there are morphologic patterns: Antoni A and Antoni B. Antoni Type A is represented by small, densely packed spindle-shaped cells with dark staining nuclei. In Antoni A, the cells may have a whirled appearance referred to as Verocay bodies. They have no clinical significance. Antoni Type B refers to loosely packed vacuolated cells. Nuclei appear large and atypical and are densely staining. This is the predominant form in large tumors. There may also be a mixed pattern. The pattern does not correlate with the clinical presentation. Staining for S-100 immunoperoxidase is confirmatory for a Schwann cell.

The introduction of MRI in the 1980s has revolutionized the diagnosis of acoustic neuromas. Prior to MRI, CT was employed. Computed tomography was a valuable diagnostic tool if the tumor extended into the CPA or there was widening of the porus acusticus by the tumor. However, smaller intracanalicular tumors had to be diagnosed by air-contrast CT, requiring a lumbar puncture and injecting air in the subarachnoid space. Magnetic resonance imaging has made this procedure obsolete. Acoustic tumors readily enhance with the injection of gadolinium (see Figure 25–4). Tumors as small as 2 to 3 mm

are easily seen. This allows for the diagnosis of acoustic neuromas prior to the onset of severe clinical symptoms. Also, asymptomatic lesions that are contained in the IAC can be readily followed.

Surgical removal is the treatment of choice when the tumor is symptomatic or begins to extend beyond the IAC.[23] Total removal with the preservation of the facial nerve should be attempted. The choice of procedure, translabyrinthine, suboccipital, or middle fossa, depends on the size of the tumor and the status of the hearing. These approaches will be discussed later in this chapter. In very large tumors and in high-risk patients, there is a role for subtotal removal of the tumor to relieve symptoms.

Recently, stereotactic radiation or gamma knife has been advocated for treatment of acoustic neuromas. This involves a one-time dose of radiation focused on the center of the mass. The usual dose is 10 to 25 Gy. This causes shrinkage and necrosis of the mass. It has been employed in the elderly and other high-risk patients. The drawbacks are lack of elimination of the tumor and complications, including hydrocephalus and cranial nerve neuropathies. For further elaboration, see Chapter 20.

Facial Nerve Neuroma Facial nerve neuromas are one of the few primary lesions of the nerve. Initial symptoms may include facial paresis or facial muscular fasciculations. They are found primarily in the intratemporal portion of the nerve, with the geniculate ganglion area being the most common. Magnetic resonance imaging is helpful in the workup of patients with this lesion. These lesions are usually removed when facial weakness is present. Patients are usually reluctant to have them removed when they still have facial function, especially since the result will be a temporary total paralysis. These lesions are usually slow growing and can be watched for a period of time. Treatment is surgical removal with nerve grafting. For further elaboration, see Chapter 24.

Other Neuromas Schwannomas of the other cranial nerves are relatively unusual, but fifth and ninth, eleventh, and twelfthth nerve tumors must occasionally be treated. The petrous apex (especially with the fifth nerve) and the infratemporal fossa can be involved. Symptoms are generally related to the involved nerve but can be caused by compression of adjacent structures. Trigeminal and vagal schwannomas are more common, whereas ninth, eleventh, and twelfth cranial nerve schwannomas are rare. They are diagnosed with contrast MRI, whereas CT can reveal expansion of the bone. Surgical removal is the treatment of choice for symptomatic lesions.

Meningiomas

Meningiomas are the most common benign intracranial tumors and can be found in all areas of the skull base. In the CPA, they comprise 5% of all tumors. They are thought to arise from the arachnoid villi. Unlike acoustic neuromas, they do not originate in the IAC but arise broadly from the petrous face. At presentation, meningiomas are usually larger than acoustic neuromas, probably because they do not compress the contents of the IAC. Symptoms are related to the impingement on surrounding structures; however, compared with acoustic neuromas, they more commonly spare hearing. The gross appearance of a meningioma is a yellow to gray globular mass.

Microscopically, it is characterized by sheets of polygonal cells. The boundaries of the cell are obscure. Nuclei contain chromatin and are pale staining. Histologically, calcifications known as psammoma bodies can be seen. On MRI, meningiomas appear as well-circumscribed heterogeneous masses that enhance with gadolinium, as well as have the dural tail sign (Figure 25–9). On CT scan, the calcifications may be visible. Angiography may also be helpful as these lesions tend to be vascular. Surgical removal is necessary when symptoms appear.[24,25]

Cholesteatoma

Cholesteatomas of the petrous apex are thought to arise from epithelial rests trapped during development. The squamous cell debris begins to organize as a cyst, which starts a destructive process that may erode bone. Another danger is secondary infection, which can cause intratemporal as well as intracranial abscess formation. Presenting symptoms can include hearing loss, otorrhea, facial paresis, or diplopia. This diagnosis is also confirmed with a combination of CT and MRI. Computed tomography shows a smooth expansile lesion with bony destruction. On MRI, the T_1 intensity is low, whereas the T_2 intensity is usually increased. This lesion does

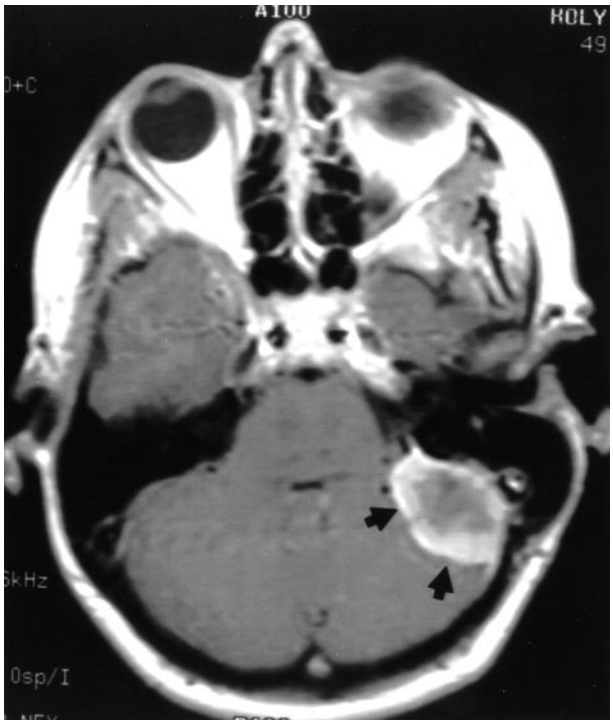

FIGURE 25–9. Gadolinium-enhanced T_1-weighted magnetic resonance image of a large meningioma (*arrows*) originating from the posterior face of the left petrous pyramid.

not enhance with gadolinium. Surgical extirpation is the treatment of choice.[26]

Glomus Tumors

Glomus tumors are slow-growing, vascular lesions, with the majority (97%) being benign. They are paragangliomas that arise from groups of chemoreceptor cells of neural crest origin, which are predominantly found along the course of Jacobson's nerve and within the adventitia of the jugular bulb. Tumors arising from Jacobson's nerve and limited to the promontory are classified as glomus tympanicum tumors, whereas those arising from the glomus bodies of the jugular bulb are classified as glomus jugulare tumors. The classification of these tumors can be found in Table 25–3. Glomus tumors have been reported to be multicentric in up to 10% of patients.[27] Glomus vagale tumors arise from the chemoreceptors along the vagus nerve. Glomus tumors may secrete vasoactive substances or be associated with other tumors, such as pheochromocytomas, which secrete these substances.

The diagnosis of glomus tumors is often difficult because the presenting signs and symptoms can be nonspecific, mimicking other otologic and neurologic conditions. By history, patients with glomus tumors typically present with pulsatile tinnitus, followed by the development of hearing loss. The hearing loss is usually conductive because the middle ear is filled with tumor, although a sensorineural hearing loss may develop if the cochlea is invaded.

Patients with glomus tympanicum tumors present with smaller tumors because the middle ear becomes involved earlier than with glomus vagale or jugulare tumors. On the other hand, patients with glomus jugulare tumors may present with dysfunction of jugular foramen contents (Vernet's syndrome, involving cranial nerves IX, X, and XI).

Careful otoscopic evaluation, preferably with an operating microscope, is essential. Classically, a red tumor mass beneath an intact tympanic membrane is seen. If limited to the promontory with all tumor margins visible, it probably represents a small glomus tympanicum tumor. If the tumor extends beyond the level of the annulus (especially inferiorly), its classification cannot be made visually.

A small mass seen in the floor of the middle ear may represent the "tip of the iceberg" of a large glomus jugulare tumor that may extensively involve the skull base. These tumors may blanch with positive pressure on pneumotoscopy (Brown's sign) or have cessation of tumor pulsation with ipsilateral carotid artery compression (Aquino's sign). The tumor also may extend through the tympanic membrane and present as an aural polyp. An audible bruit or evidence of vascular pulsations during tympanometry may also be present in these patients.

A glomus tumor filling the middle ear may also cause a diffusely discolored appearance of the tympanic membrane, which may be mistaken for serous fluid. Other entities that can be confused with glomus tumors include a dehiscent jugular bulb or, rarely, a dehiscent carotid artery. Cholesterol granuloma can easily be confused with large glomus tumors because they can make the tympanic membrane appear reddish-blue. Judicious use of the appropriate diagnostic imaging techniques readily differentiates these possibilities.

Any attempt at biopsy should be deferred until a complete workup is done. A systematic protocol allows one to make the diagnosis and to define the extent of the tumor (Figure 25–10).

TABLE 25–3. Classifications of Glomus Tumors

Fisch Classification of Glomus Tumors of the Temporal Region

Type A	Tumors limited to the middle ear cleft
Type B	Tumors limited to the tympanomastoid area with no infralabyrinthine compartment involvement
Type C	Tumors involving the infralabyrithine compartment of the temporal bone and extending to the petrous apex
Type D1	Tumors with an intracranial extension less than 2 cm in diameter
Type D2	Tumors with an intracranial extension greater than 2 cm in diameter

Glasscock-Jackson Classification of Glomus Tumors

Glomus Tympanicum

Type I	Small mass limited to the promontory
Type II	Tumor completely filling the middle ear
Type III	Tumor filling the middle ear and extending into the mastoid
Type IV	Tumor filling the middle ear, extending into the mastoid or through the tympanic membrane to fill the external auditory canal; may also extend anterior to the internal carotid artery

Glomus Jugulare

Type I	Small tumor involving the jugular bulb, middle ear, and mastoid
Type II	Tumor extending under the internal auditory canal; may have intracranial extension
Type III	Tumor extending into the petrous apex; may have intracranial extension
Type IV	Tumor extending beyond the petrous apex into the clivus or infratemporal fossa; may have intracranial extension

De La Cruz Glomus Tumor Classification with Associated Surgical Approach

Classification	Surgical Approach
Tympanic	Transcanal
Tympanomastoid	Mastoid—extended facial ridge
Jugular bulb	Mastoid-neck (possible limited facial nerve rerouting)
Carotid artery	Infratemporal fossa ± subtemporal
Transdural	Infratemporal fossa/intracranial
Craniocervical	Transcondylar
Vagal	Cervical

Fisch Classification of Glomus Tumors

A	Limited to the middle ear
B	Involves the middle ear and mastoid, without infralabyrinthine involvement
C	Extends into the infralabyrinthine area and to the petrous apex; originates in the jugular bulb and may erode overlying bone
C1	May erode carotid foramen but does not involve the artery
C2	Involves vertical part of the carotid canal
C3	Invades vertical and horizontal parts of the carotid canal but does not reach the foramen lacerum
C4	Involves the whole intrapetrous part of the carotid from the foramen lacerum to the cavernous sinus
D	Intracranial extension
De1	Extradural < 1 cm
De2	Extradural > 1 cm
Di	Intracranial, intradural
Di3	Intracranial, unresectable

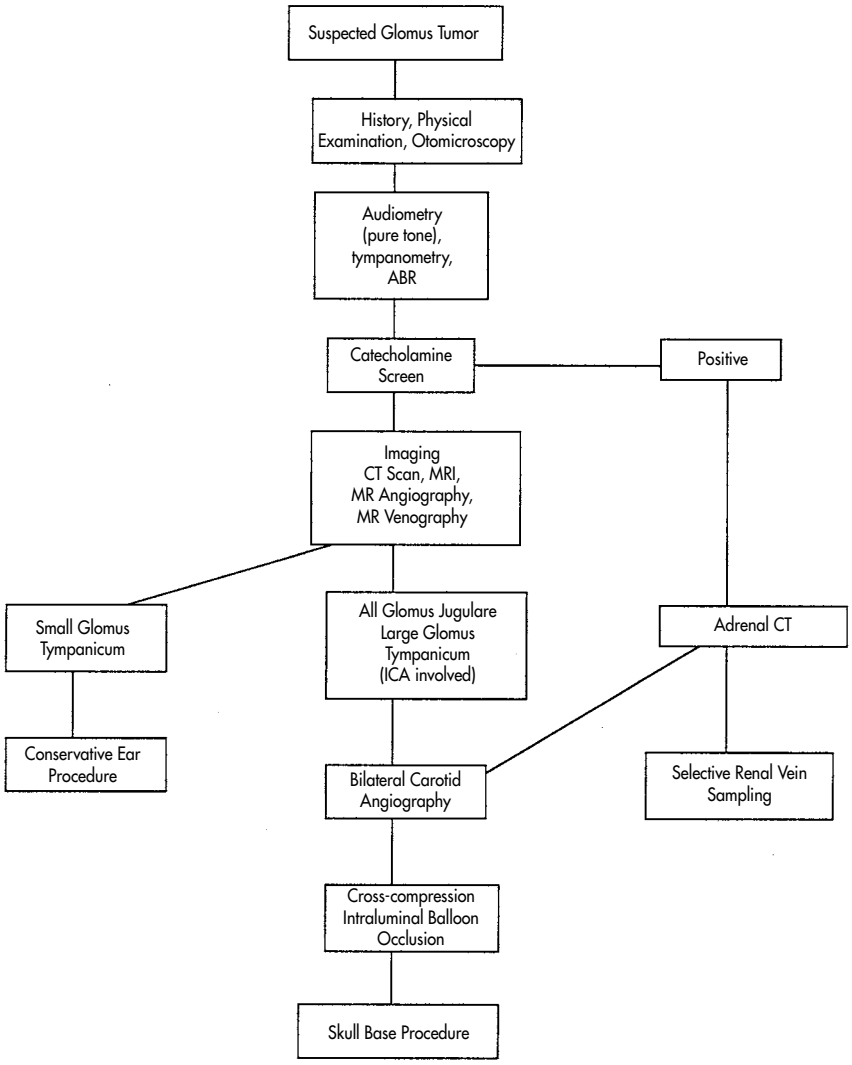

FIGURE 25–10. Glomus tumor diagnostic and treatment algorithm. ABR = auditory brainstem response; CT = computed tomography; MRI = magnetic resonance imaging; ICA = internal auditory canal.

These patients should undergo high-resolution CT with contrast injection. If the tumor is limited to the middle ear and there is no bony destruction, the tumor is classified as a glomus tympanicum tumor, and no further radiologic workup is needed.[28] If the CT shows any bony destruction or connection with the jugular bulb, an MRI is obtained, which helps to define any intracranial extension or jugular vein or carotid artery involvement and also screens for the presence of a second glomus tumor in the head and neck.[29,30] If workup reveals a glomus jugulare tumor and the patient is a surgical candidate, preoperative four-vessel angiography is indicated.

Glomus Tumor Algorithm The characteristic salt-and-pepper appearance on MRI corresponds to flow voids. Special subtraction MRI sequences may help distinguish a glomus tympanicum tumor from a glomus jugulare tumor.[31] Flow-sensitive weighting of the MRI can produce a magnetic resonance arteriography and magnetic resonance venography that are very useful in imaging glomus tympanicum lesions. The flow-sensitive modalities can indicate occlusion of the jugular bulb and vein, which can be particularly helpful for identifying involvement of the jugular bulb itself. It must be remembered, however, that an enhanced MRI involves T_1 imaging that produces a bright signal characteristic for fat, which is a major constituent of bone marrow. Thus, this characteristic may overestimate the degree of tumor involvement when there is paraganglioma adjacent to bone marrow–containing spaces such as the petrous apex.[32] A particular value of flow-weighted MRI is that it can be a useful screening test for synchronous paragangliomas.[33] This study can identify

glomus tumors in the temporal bone and along the carotids without the need for intra-arterial infusion.[34] After angiography, superselective embolization of the tumor-feeding vessels is performed at the same time. During cerebral angiography, the patency of the venous drainage system of the opposite side and the patency of the cerebral crossflow are evaluated. A combination of CT, MRI, and angiography clearly defines the extent of the disease and therefore limits unexpected findings at the time of operation.

Surgical removal is the treatment of choice. Preoperative embolization can decrease operative morbidity. Radiation therapy can be used alone; however, it is usually reserved for patients with concurrent medical problems or the elderly, who may be at higher risk for surgical complications.

Encephaloceles

Encephaloceles are defined as intracranial contents beyond the confines of the cranial vault. Various components may be extruding. In meningoceles, only the meninges and CSF have herniated. Encephalomeningoceles represent herniations of the brain along with meninges, whereas hydroencephalomeningoceles represent the herniation of ventricles along with the brain.

Encephaloceles can be divided into acquired and spontaneous lesions. An acquired lesion is one that occurs secondary to an event such as trauma, chronic infection, or surgery. Lesions are referred to as spontaneous if no preceding event is present. Spontaneous lesions can be further subdivided into congenital and idiopathic lesions. Congenital lesions occur in 1 in 3,000 to 10,000 live births. They are more common in the anterior and posterior fossa. Congenital temporal lobe herniations are rare but do occur. There are many theories to try to explain temporal lobe herniations. Most patients with a herniation are found to have multiple defects in the temporal bone. Arachnoid granulations greater than 3 mm are thought to cause bony erosion, leading to herniation.[35]

Presentation is similar in all types of lesions. They can present with CSF rhinorrhea or otorrhea, recurrent meningitis, serous otitis media, or a conductive hearing loss. Diagnosis is made with a combination of CT for bony detail and MRI for soft tissue detail. Surgical repair is necessary if they become symptomatic. For lesions greater than 1.5 cm, the recommended treatment involves a transmastoid exposure of the lesion from below combined with a middle fossa craniotomy to expose the superior aspect of the defect.

Infectious Lesions

Petrous apicitis is a coalescence of the cells in the apex usually associated with a chronic infectious process, mastoiditis, or cholesteatoma. Infectious agents include *Staphylococcus, Haemophilus*, or *Pseudomonas*. Symptoms include aural discharge, retro-orbital pain, and a sixth nerve palsy (Gradenigo's syndrome). Possible sequelae can include intracranial abscess formation, meningitis, and other cranial nerve palsies. Computed tomography will reveal bony destruction with irregular borders. On MRI, the T_1 image shows low signal intensity; however, the lesion is very bright on T_2. Gadolinium infusion shows a ring of enhancement around the lesion. Treatment includes intravenous antibiotics and a surgical procedure to establish adequate and sustained drainage and ventilation of the petrous apex.

Vascular Compression Syndromes

Vascular compression syndromes are abnormal excitation of the nerve owing to sustained contact with adjacent blood vessels. Prolonged contact of a blood vessel to a neural sheath causes chronic excitation and reorganization of the cranial nerve nucleus, resulting in hyperfunction.[36] Depending on the involved cranial nerve, this condition may result in hemifacial spasm, trigeminal neuralgia, or cochleovestibular compression syndrome.

Hemifacial spasm consists of involuntary facial muscle spasms. These usually begin with the orbicularis oculi and proceed to involve the lower parts of the face. Eventually, the patient can develop facial weakness thought to be caused by demyelination secondary to the compression. The unilaterality of this disorder helps to differentiate it from essential blepharospasm.

Trigeminal neuralgia is characterized by piercing facial pain. Tactile stimulation of the face, pain, cold, or dental work can cause hyperactivity in the nucleus, resulting in the pain. Cochleovestibular compression syndrome has been reported to result in continuous vertigo, hearing loss, nausea, tinnitus, and imbalance.

In these patients, all other potential causes must be ruled out. For those failing more conservative treatment (ie, medical therapy to relieve symptoms), surgical exploration of the nerve and decompressing the offending vascular structure are an option. In the CPA, this is usually the anterior inferior cerebellar artery or posterior inferior cerebellar artery, but veins may also be the culprits.

MANAGEMENT

It is beyond the scope of this chapter to review the treatment issues for each of the skull base disorders, but a general overview of available modalities and techniques is designed to give the reader some basis for understanding their roles.

Some of the lesions discussed are malignant by definition. The majority are benign but clinically "malignant" either because of the debility of symptoms or their proximity to neural and vascular structures. The histologic classification, severity of symptoms, and proximity to important structures play a role in treatment decision making. Treatment options generally include surgery, radiation, chemotherapy, or simple observation. Oncologic chemotherapy has a limited role in the management of skull base lesions aside from an occasional primary or metastatic cancer. This discussion centers around mass lesions that require intervention or pathophysiologic disorders that have failed medical therapy.

Radiation

External beam radiation has been used as an adjunct to surgery in certain lesions such as olfactory neuroblastoma. Primary radiation traditionally has been used in the more common benign lesions (such as acoustic neuroma) in the elderly or medically disabled, but treatment results vary. Primary risks include damage to the brain and nerves and the superficial structures such as skin as well as osteoradionecrosis of the bone.

More recently, stereotactically directed gamma radiation ("gamma knife") has been discussed as a treatment option.[37] Numerous cobalt sources (approximately 200) are positioned in a hemispheric pattern oriented toward a common point. In this technique, high doses of radiation are given to a more localized area in shorter periods of time than in traditional radiation therapy. Commonly, patients receive their total radiation dose in a single treatment. Thus, the risks should be less than traditional radiation, and the time involved is greatly reduced (1 day versus approximately 6 weeks). Its use is limited to somewhat smaller tumors (acoustic neuromas < 2 cm), and it appears to be an option for surgically unsuitable patients with appropriate-size tumors. The obvious benefit is avoidance of a large, usually intracranial surgical procedure. In the specific example of acoustic neuroma, the initial risks are markedly less than surgical intervention, but over time, the risks to adjacent structures such as the facial or cochlear nerves approach or exceed the surgical risks. Halting or limiting the growth of the tumor is the usual outcome, with regression less commonly noted. Leskell first used the gamma knife in 1969.[38] Local control rates on tumor growth were first reported to be 86% for unilateral tumors[39]; Flinkinger et al reported a local control rate of 89%.[40] Maire et al reported a 6-year actuarial rate of 82% local control (no growth) with external beam radiation.[41] Owing to the expense of gamma-knife radiation recently, development of linear accelerator–based stereotactic radiation has ensued. It is less expensive and used for conventional radiation. Mendenhall et al treated patients with a linear accelerator–based stereotactic radiation and reported a local control rate of 98% and actuarial control rate of 95%.[42]

Although surgery is the mainstay for the treatment of patients with acoustic neuromas, radiation therapy has improved and now is considered an alternative option for a certain subset of patients, especially patients who are not surgical candidates.[41] An occasional problem arises when tumors do not respond to radiation and require surgical treatment. The surgical risks are increased since the radiation-damaged tissue is generally more difficult to dissect.

Surgery

Considerations The skull base is an area dense with important neural, vascular, and structural entities. Preoperative discussions with patients must include a thorough review of the pathologic entity as well as the potential and planned morbidity of the treatment. Each procedure and skull base area have their own individual structures at risk.

In the majority of accessible tumors, surgical removal is the treatment of choice. Surgery also

allows access to particular structures such as the seventh cranial nerve for microvascular decompression and the eighth cranial nerve for vestibular neurectomy. Success depends on many factors. Two important aspects are accurate assessment of the clinical entity preoperatively and, of course, the skill of the surgeon. The choice of surgical approach depends on the pathologic process and the expertise of the surgeons(s).

Expected morbidity, such as loss of any residual hearing in a translabyrinthine approach for acoustic neuroma removal, should be discussed and weighed against the benefits of surgery in general and specifically of a particular procedure/approach. In the case of the translabyrinthine approach, decreased risk to facial nerve and less cerebellar retraction are the primary advantages.

Complications of Skull Base Surgery See Table 25–4 for complications of skull base surgery.

The more important complications result from alteration of function of intracranial structures. Infarction of intracranial structures, such as the cerebellum or brainstem, from excessive retraction or blood vessel damage can result in significant morbidity or death.

Intracranial hemorrhage may occur in the immediate or late postoperative period. Treatment usually includes immediate opening of the wound and return to the operating room for complete drainage of the blood with identification and control of the bleeding site. If identified and treated early, there may be no residual sequelae, but important functional defects are possible.

Complications may arise simply as a result of entrance into the CSF-containing space. Meningitis is a known risk and tends to occur between the third and seventh postoperative days. Because of the frequent postoperative malaise, head/neck discomfort, and fevers from meningeal irritation, meningitis can be difficult to identify in this situation. A low threshold of suspicion and early lumbar puncture will allow early identification and rapid resolution with the institution of appropriate intravenous antibiotics.[43]

Cerebrospinal fluid leaks can occur at any time after the operation, but the risk is greatest in the first 10 days. In high-risk procedures, CSF lumbar drains may be placed at the time of operation to keep intracranial pressures low and decrease tension on wound closures. Drainage may occur through the nose (CSF rhinorrhea), the ear (CSF otorrhea), or the incision. In the anterior approaches (craniofacial), the fluid will generally drain through the nose anteriorly, whereas in the posterior approaches, the CSF reaches the nose through the eustachian tube and may result in either anterior or posterior rhinorrhea. If a tympanic membrane perforation is present at the time of operation in the middle or posterior fossa or occurs in the postoperative period, CSF otorrhea may occur. Initial treatment of CSF leak consists of head elevation and either lumbar puncture or placement of an indwelling lumbar spinal drain. If these conservative measures are unsuccessful, then surgical exploration and reclosure of the wound are necessary.

Hydrocephalus
Seizures

Injury to any of the vascular structures (ie, carotid artery) or neural structures (ie, cranial nerves) is possible and must be dealt with intraoperatively if the structure has been interrupted and postoperatively if there are significant sequelae. In the lateral and posterior approaches, altered function of the seventh cranial nerve is a frequent postoperative problem. Transection of the nerve intraoperatively requires immediate primary repair or cable grafting, if possible. In this case, delayed and incomplete recovery would be expected. If the continuity is maintained, but injury occurs secondary to stretching or contusion, recovery generally occurs, but time and completeness are variable. Risk to the cornea, which results from incomplete eye closure, is the most important issue. For expected transient weaknesses, local eye care such as use of lubricants is all that is generally needed. For longer periods of altered function or permanent paralysis, procedures such as upper eyelid gold weight implantation, lower eyelid ectropion repair, or tarsorrhaphy are frequently indicated for adequate corneal protection. In cases of permanent paralysis, nerve grafting, twelfth to seventh end-to-side (jump graft) or end-to-end grafting, or muscle transposition (ie, temporalis) may be useful for rehabilitation of the entire face.

Intraoperative Monitoring Preservation of neural structures is a crucial part of skull base surgery. Although there is no substitute for surgical knowledge, neural monitoring is a useful adjunct. The motor nerve integrity can be followed by monitoring EMG activity in the appropriate muscles. Increased activity will be seen as the nerve is manipulated. The nerve of interest can also be electrically stimulated in the operative field to verify its identity. The seventh nerve is probably the most commonly and easily monitored motor nerve.

In the hearing preservation approaches in acoustic neuroma surgery, auditory function can be monitored in several ways. Most commonly, continuous ABR can be elicited. This has the advantage of being readily available and easy to set up but the disadvantage of requiring many averaged trials to detect an alteration. This can translate into a significant delay between the occurrence of a compromising action and the detection of the change in the ABR. The recording of an electrocochleogram during a procedure is frequently used. As in ABR, stimulation is with repeated auditory clicks through an external auditory canal insert. Since recordings are generally obtained with a needle electrode on the promontory, the responses are more robust, require fewer trials, and ideally require less time between the operative maneuver and the change in the observed waveform. Direct eighth nerve monitoring records nerve impulses traveling in the auditory nerve. The electrode is placed on the nerve proximal to the operative site so that any alteration in the physiologic status of the peripheral part of the auditory system will be immediately detected.[44]

Surgical Approaches Because of the complexity of the skull base and the diversity of the possible abnormalities, many surgical approaches have been developed. They are continually being modified, and new ones are being described.[45,46]

Craniofacial Approach. For lesions that involve the roof of the ethmoid sinuses or the superior nasal vault (cribriform area), visualization from above (cranially) and below (facially) can be obtained through a craniofacial approach. The most common lesions include olfactory neuroblastoma and ethmoid sinus cancer.

The approach from above is initiated with a bicoronal incision originating anterior and superior to the auricles bilaterally followed by flap elevation over the forehead (Figure 25–11). An anterior craniotomy exposes the frontal sinus, which is completely removed, and the frontal lobes that are gently elevated, necessitating transection of the olfactory nerves. This allows visualization of the floor of the anterior cranial fossa, including the roofs of the orbits and cribriform plate area. Visualization can be obtained back to the area over the anterior portion of a fully pneumatized sphenoid sinus. The cribriform plate and various amounts of bone can be resected. Ideally, the tumors are extradural, although dura (and even brain parenchyma) can be resected.

The approach from below is more variable but generally involves at least an ethmoidectomy. Most commonly, a lateral rhinotomy incision is used to allow a generous view of the nasal vault and associated paranasal sinuses. If necessary, the ethmoidectomy can be combined with maxillectomy or orbital exenteration. Reconstruction and closure vary, depending on the resection performed. At the com-

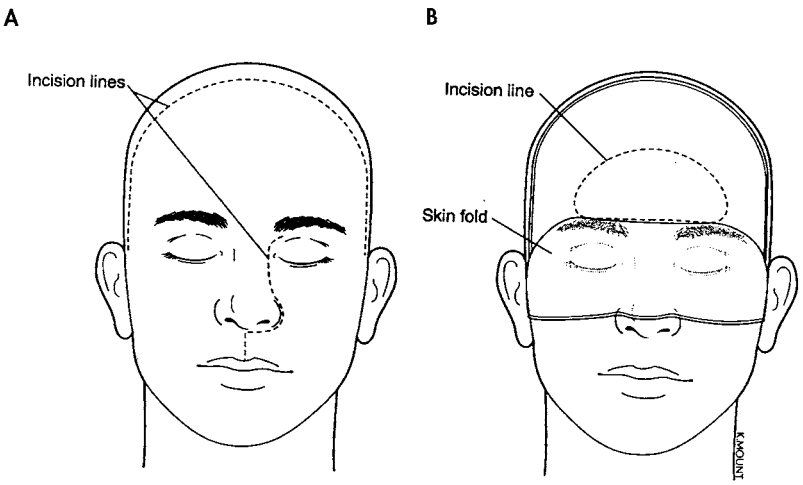

FIGURE 25–11. A, The skin incisions for a craniofacial resection are shown. *B*, After elevation of the forehead skin and retraction inferiorly, an approximate outline of the frontal craniotomy (*dotted line*) can be seen.

pletion of the procedure, dural repair can be accomplished with temporalis fascia, fascia lata, or a local pericranial flap. In the most limited resections, the anterior cranial bone flap is replaced, and the upper and lower incisions are closed primarily. For more extensive resections, local or distant flaps may be required to reconstruct the defect, and/or surgical prostheses may be necessary.

Infratemporal Fossa Approach. For access to the infratemporal fossa and the jugular foramen, the infratemporal fossa approach is available. Glomus jugulare and vagale tumors, vagal neuromas, and deep lobe parotid tumors may arise in this area.

A large curvilinear incision is made to allow access to the lateral skull and the upper cervical areas (Figure 25–12). The skin flap is elevated anteriorly. The sternocleidomastoid muscle must be detached from its mastoid insertion to allow the generous exposure that is usually necessary. The seventh nerve is identified exiting from the stylomastoid foramen. The ninth, tenth, and eleventh cranial nerves can be identified at the skull base exiting from the jugular foramen into the neck. The hypoglossal nerve is seen crossing lateral to the carotid at approximately the level of the carotid bifurcation.

The internal jugular vein and internal carotid artery are identified and isolated so they can be easily controlled.

Superiorly, the structures are located through a transmastoid approach. After the mastoidectomy, the sigmoid sinus, posterior and middle cranial fossae dura, and vertical portion of the facial nerve are identified (Figure 25–13). In the majority of these procedures, the external auditory canal is removed, and the lateral canal skin is closed on itself. The facial nerve is skeletonized in the mastoid and middle ear and then completely mobilized. It is retracted anteriorly to allow direct visualization of the more

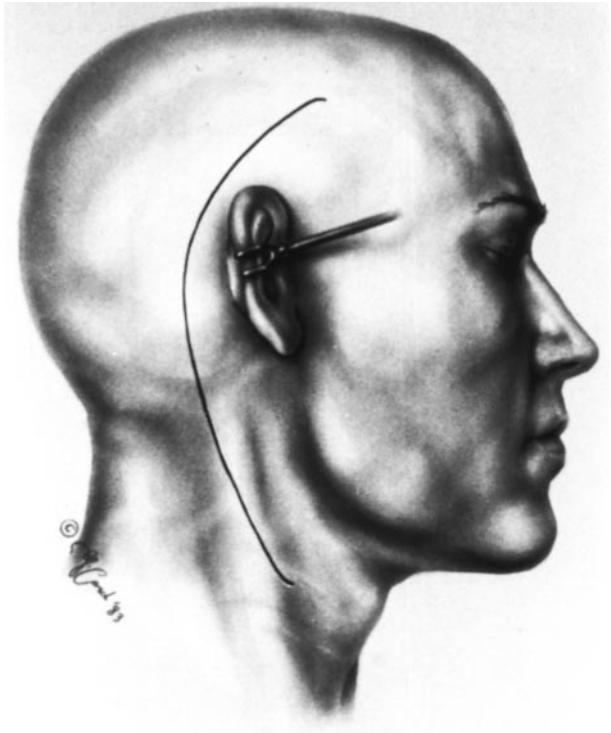

FIGURE 25–12. A large C-shaped incision extending from the parietal area across the mastoid and inferiorly into the cervical area is necessary for complete exposure in the infratemporal fossa approach. Reproduced with permission from Wiet RJ, Causse J, editors. Complications in otolaryngology: head and neck surgery. Vol 1. Philadelphia: BC Decker; 1986.

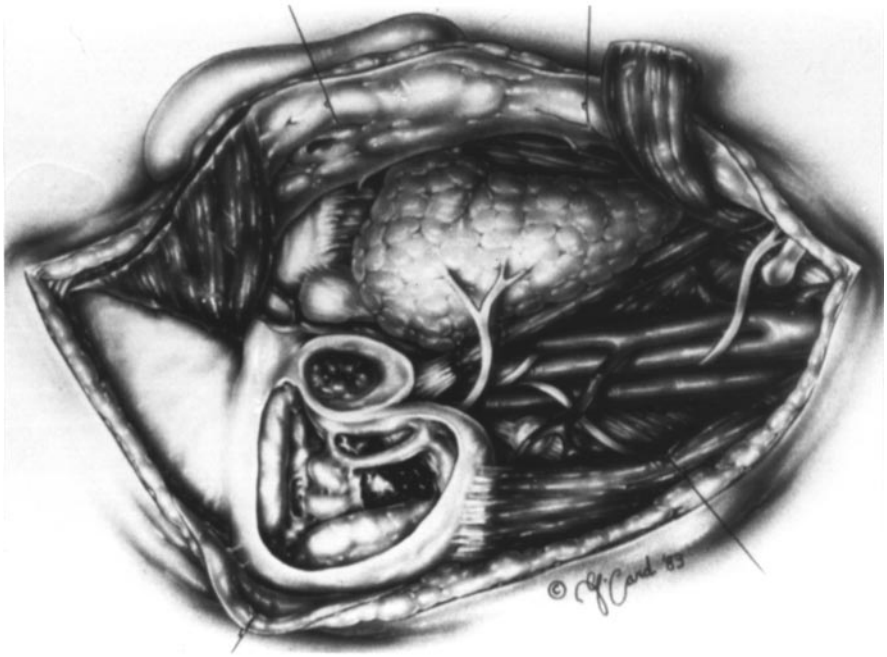

FIGURE 25–13. After cervical exposure and mastoidectomy, most of the important structures are visible. In this drawing, a glomus jugulare tumor can be seen medial to the facial nerve in the mastoid. Reproduced with permission from Wiet RJ, Causse J, editors. Complications in otolaryngology: head and neck surgery. Vol 1. Philadelphia: BC Decker; 1986.

medial structures (Figure 25–14). Having done this, the remaining infralabyrinthine bone is removed to allow access to the tumor, the entire sigmoid sinus/jugular bulb/internal jugular vein, and the internal carotid artery anteromedial to the jugular vein. Removal of the tumor is then generally possible. In glomus jugulare tumors, the sigmoid sinus, jugular bulb, and upper portion of the internal jugular vein are resected with the tumor. The operation may be continued intracranially in the same sitting or in a second stage for larger tumors. In glomus jugulare tumor operations, major blood loss is usually encountered, although it is usually markedly decreased with preoperative embolization.

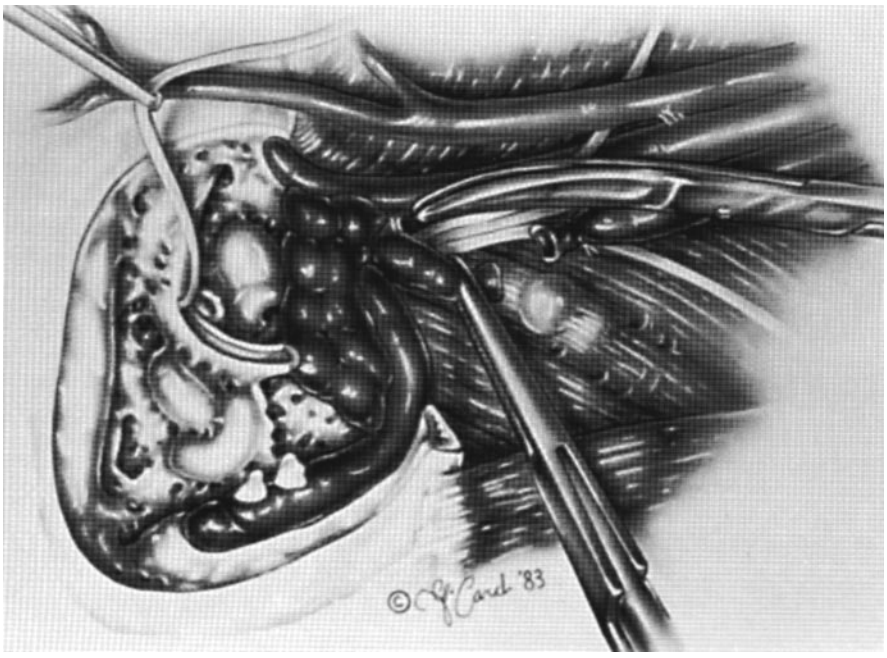

FIGURE 25–14. After mobilization of the facial nerve and removal of additional bone medially, excellent visualization of the glomus jugulare tumor is possible. Reproduced with permission from Wiet RJ, Causse J, editors. Complications in otolaryngology: head and neck surgery. Vol 1. Philadelphia: BC Decker; 1986.

In most situations, the wound can be closed primarily. In more extensive resections, abdominal fat grafting, local tissue flaps such as temporalis muscle, or free vascularized grafts may be necessary.

Internal Auditory Canal/Posterior Fossa Approaches. These surgical approaches overall are the most commonly used and are designed to allow exposure of the IAC, the CPA, and the petrous apex. The middle cranial fossa, translabyrinthine, and retrosigmoid approaches can all be used for resection of acoustic neuromas (Figure 25–15). The middle cranial fossa and retrosigmoid approaches are classified as hearing preserved, and in many instances, the cochlear division of the eighth nerve can be preserved, allowing at least the possibility of hearing postoperatively. In the translabyrinthine approach, the vestibular portion of the labyrinth is intentionally removed. Although this allows better visualization of the seventh nerve and the IAC, any residual hearing is predictably and completely lost. Each has its advantages and indications.

Middle Cranial Fossa Approach. The middle cranial fossa procedure approaches the IAC from above, and here the labyrinth can be preserved in an attempt to conserve hearing. This procedure is commonly used in the resection of acoustic neuromas and for vestibular neurectomy. In the IAC, the vestibular portions of the eighth nerve are distinct from the cochlear division, and, at least theoretically, the vestibular nerve can be sectioned more precisely. In acoustic neuroma surgery, the middle cranial fossa approach is used when two main criteria are fulfilled: the tumors are completely within the IAC (intracanalicular) and the patient has preoperative hearing that is good enough to justify a procedure that is somewhat more complex than the other approaches.

This procedure can also be used to access the area medial to the IAC (petrous apex) for lesions such as cholesterol granulomas. For larger temporal lobe encephaloceles, visualization through the middle cranial fossa approach is necessary to bring the brain back into the intracranial cavity and to cover

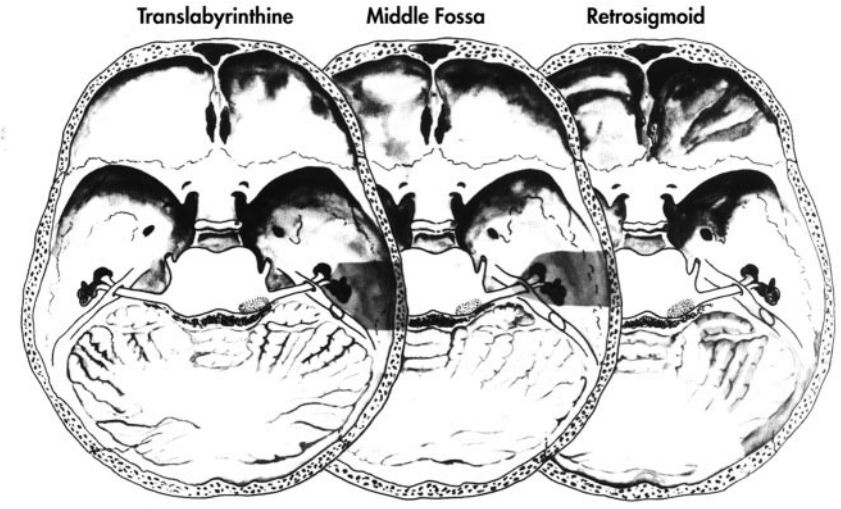

FIGURE 25–15. Diagram of the three main approaches to tumors of the cerebellopontine angel (CPA). The translabyrinthine approach gives the surgeon the best exposure but sacrifices hearing. The middle fossa offers the least exposure and thus is useful only for intracranial tumors in patients in whom hearing preservation will be attempted. The retrosigmoid approach gives good exposure of the CPA but offers the least number of landmarks for identification of the facial nerve. We reserve it for small tumors of the CPA in patients in whom hearing preservation is worthwhile. Reproduced with permission from Monsell EM, McElveen JT, Hitselberger WE, House WF. Surgical approaches to the human cochlear nuclear complex. Am J Otol 1987;8:450–5.

the bony defect adequately (generally with a bone flap). Additionally, this approach is used for exploration of the geniculate and labyrinthine portion of the seventh nerve in cases of temporal bone trauma and for bony decompression for Bell's palsy.

With the surgeon at the head of the table, the patient is placed in a supine position with the head turned so the involved side is up. Although different incisions have been used, the simplest is a vertical incision extending from a point in the preauricular area 1 cm anterior to the auricle directly superiorly for 6 to 8 cm. The incision is carried down to the bone.

A 3 × 3 cm bone flap is created in the underlying bone and is removed to expose the dura overlying the temporal lobe. The temporal lobe is elevated off the floor of the middle cranial fossa until the foramen spinosum and middle meningeal artery are seen anteriorly, the greater superior petrosal nerve is seen anteromedially, and the superior petrosal sinus is seen posteriorly (Figure 25–16). The pertinent surface of the temporal bone can now be visualized. The arcuate eminence (the bony elevation over the superior semicircular canal) and the greater superficial petrosal nerve are the most common overt landmarks. From these, the facial nerve and the IAC can be identified once drilling has begun. The superior semicircular canal (laterally) and the cochlea (medially), which lie on each side of the IAC, must not be violated or hearing will be lost.

In vestibular neurectomy, the superior and inferior vestibular nerves are identified in the IAC and transected. For seventh nerve decompression, exposure of the geniculate ganglion and labyrinthine portion of the seventh nerve with opening of the nerve sheath is completed. In acoustic neuroma resection, the tumor is carefully removed from the IAC, with care being taken to preserve the seventh nerve and the cochlear branch of the eighth cranial nerve.

Fascia and/or a muscle plug are used to close the dural defect, and the retracted temporal lobe is placed back in its anatomic position. The bone flap is replaced, and the incision is carefully closed.

Retrosigmoid Approach. In the retrosigmoid approach, the CPA is approached directly, and the IAC can be approached posteriorly. Because this approach allows a generous view of the CPA, it is useful in a variety of conditions and is used most frequently for CPA tumor resection, vestibular neurectomy, and microvascular cranial nerve decompression. Because this is a hearing preservation approach, it is used in situations in which serviceable hearing is present and the tumor is extracanalicular but is less than 2 cm. However, for

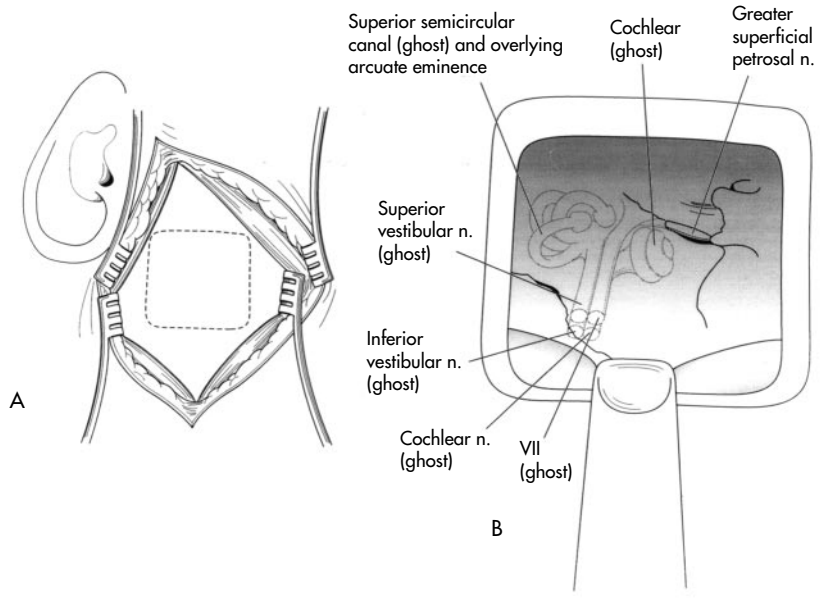

FIGURE 25–16. A, View of the left middle cranial fossa approach from the surgeon's position showing the area of planned craniotomy (*dotted line*) after a vertical incision has been opened. *B*, A view through the craniotomy allows exposure of the middle cranial fossa floor after retraction of the temporal lobe. The significant underlying structures are outlined.

intracanalicular tumors, the middle cranial fossa approach is more appropriate. In tumors greater than 2 cm, hearing preservation is unlikely, so the translabyrinthine approach is used.

First, a curvilinear incision is made 4 cm posterior to the auricle to create an anteriorly based flap (Figure 25–17). The bone of the mastoid and occipital area is exposed. A bone square is created with the sigmoid sinus defining the anterior limit and the transverse sinus defining the superior limit. Removal of the bone plug exposes the dura overlying the cerebellum. The dura is incised 5 to 10 mm posterior to the sigmoid sinus and inferior to the transverse sinus. The cerebellum is retracted posteriorly to expose the CPA. In acoustic neuroma resection, the posterior lip of the IAC must be drilled away to allow visualization of the intracanalicular portion of the tumor.

Since the fifth to eleventh nerves can be readily viewed, microvascular decompression of the fifth (for trigeminal neuralgia), seventh (for hemifacial spasm), or eighth (for tinnitus or disabling positional vertigo) nerves can be readily accomplished by gently placing a strip of Teflon felt between the offending blood vessel and the nerve to prevent the irritating contact. Vestibular neurectomy is performed by identifying the longitudinal septum between the vestibular and the cochlear portions of the eighth nerve and transecting the upper (vestibular) half. With vestibular neurectomy, control of vertigo in Meniere's disease is generally reported to be greater than 90% regardless of the approach used.[47,48] Cerebellopontine angle tumors such as acoustic neuromas and meningiomas can be resected through this approach.

On completion of the procedure, the dura is closed in a watertight fashion. If this is not possible, an abdominal fat graft is laid over the closure to seal the dural defect. Although some surgeons drill away the bone of the entire cranial defect, we prefer to preserve the bone square and replace it at the completion of the procedure. The skin is closed in the usual manner.

Translabyrinthine Approach. The translabyrinthine approach allows a generous view of the IAC, CPA, and petrous apex, if necessary. This approach is generally used in patients with poor hearing as any remaining hearing will be predictably and totally lost.

Less brain retraction is required than in the middle cranial fossa or the retrosigmoid approach, and unlike the retrosigmoid approach, the facial nerve can be identified prior to tumor identification/removal. This approach is used in essentially all acoustic neuromas that are larger than 2 cm or in any patient with poor hearing regardless of the tumor size. Tumors greater than 4 to 5 cm may require this approach combined with the retrosigmoid approach for complete resection (Figure 25–18).

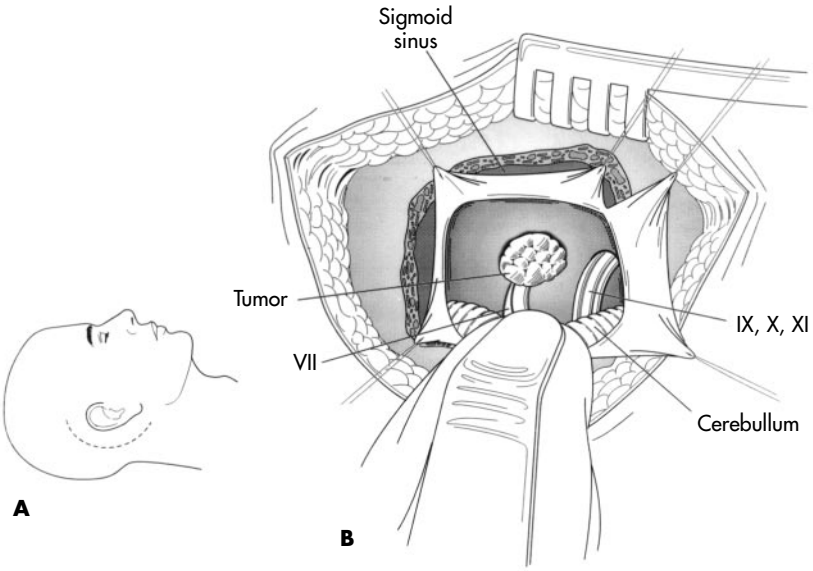

FIGURE 25–17. A, With the patient in the supine position, approximate incision line for the retrosigmoid approach is identified (*dotted line*). *B*, After craniotomy, dural incision, and retraction of the cerebellum, the cerebellopontine angle can be viewed. In this drawing, an acoustic neuroma is seen extending out of the internal auditory canal.

With the patient in the supine position and the head rotated away from the side of interest, a postauricular incision is made 2 to 3 cm behind the postauricular sulcus (Figure 25–19). The mastoid bone is completely exposed, and a drill is used to remove completely the bone of the mastoid. The sigmoid sinus, posterior fossa dura, and middle cranial fossa are completely decompressed. The vertical portion of the facial nerve is identified and left with a thin bony covering. The fossa incudus is clearly identified, and the incus is removed so that the middle ear space may be viewed and carefully packed at the end of the procedure. A labyrinthectomy is completed, and as drilling continues medially, the IAC is exposed. The dura of the posterior fossa and IAC is opened, and the IAC and CPA are viewed. In the fundus (lateral) portion of the IAC, a vertical crest of bone (Bill's bar) is present and is a useful landmark since the facial nerve is anterior and the superior vestibular nerve is posterior. After completion of the procedure, the middle ear space is carefully packed with small pieces of temporalis muscle, the aditus is covered with compressed bone pate and bone wax, and the remainder of the surgical defect is filled with fat obtained from the abdomen.[49] The incision is meticulously closed, and a mastoid dressing is placed.

In selected situations, the translabyrinthine approach can be "extended" to allow better access medially and anteriorly. In the *transcochlear* approach, drilling is continued after a complete mastoidectomy and labyrinthectomy.[50] The facial nerve is skeletonized and mobilized posteriorly from the stylomastoid foramen to the geniculate ganglion. The cochlea is then completely exenterated and the internal carotid artery skeletonized, allowing a generous view of the internal carotid artery, petrous apex, clivus, sixth and twelfth nerves, and the basilar and vertebral arteries, if necessary. A more extended view can be obtained through the *transotic* approach, with the tympanic membrane, malleus, incus, and posterior external auditory canal wall removed in addition to skeletonization and mobilization of the seventh nerve and exenteration of the cochlea.[51] In the *modified transotic* approach, the seventh nerve is left in the fallopian canal, decreasing the risk to it.[52]

Approaches to the Temporal Bone. A large amount of skull base pathology occurs within the temporal bone. Frequently, there are specific approaches available that are generally simpler than the intracranial procedures.

Tympanotomy is performed through the external auditory canal and allows exposure of the mesotympanum. Frequently, glomus tympanicum and congenital cholesteatoma are limited enough to be removed through this approach. Mastoidectomy

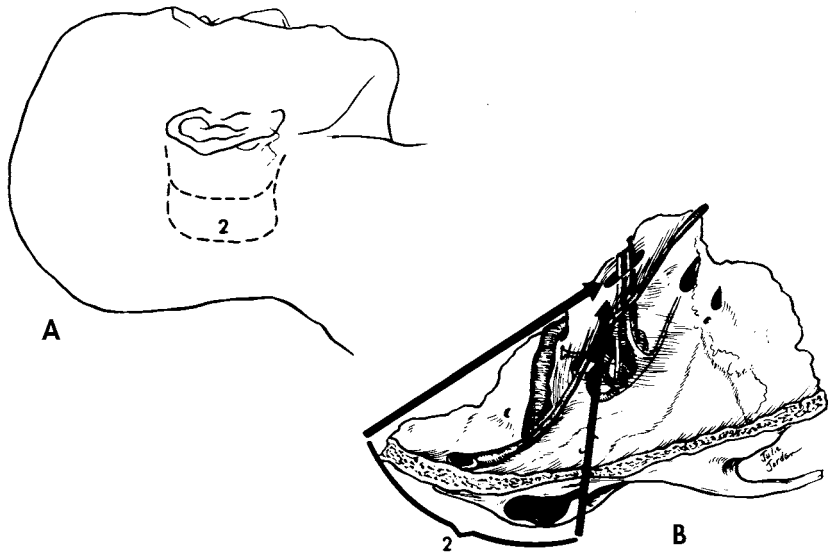

FIGURE 25–18. *A*, Postauricular incision for the translabyrinthine approach and its modification (2) for the combined approach. *B*, A combination of the translabyrinthine approach and retrosigmoid approach to the cerebellopontine angle may be used to excise larger tumors.

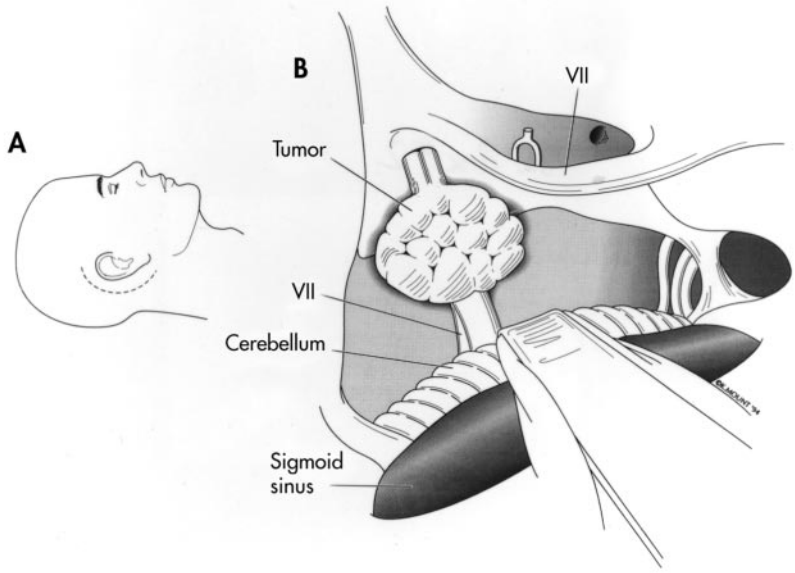

FIGURE 25–19. *A*, The approximate postauricular incision for the translabyrinthine approach is shown (*dotted line*). *B*, After the drilling is complete, generous visualization of the cerebellopontine angle is possible. An acoustic neuroma is seen arising from the eighth cranial nerve.

allows visualization of the mastoid air cell system and enables access to the antrum and epitympanum as well as the labyrinth and deeper structures of the temporal bone. Exploration and/or decompression of the second genu and vertical segment of the seventh nerve are possible.

Smaller tegmental encephaloceles can be repaired through this approach, although ones larger than 2 cm will also require a middle fossa approach. Access to the tympanum is possible from the mastoid between the facial nerve and the chorda tympani via the facial recess, opening the bone around the posterior and inferior parts of the external auditory canal. A good view of the posterior and inferior parts of the tympanum can then be obtained, especially for larger glomus tympanicum tumors.

In specific situations, limited access of the petrous apex is all that is necessary. In petrous apicitis and petrous cholesterol granuloma, drainage of the contents resolves the problem. If hearing is poor, a labyrinthectomy will allow a generous view medially. If useful hearing is present, the labyrinth must be avoided. The retrofacial approach is available after a complete mastoidectomy. Drilling is continued posterior to the facial nerve and inferior to the posterior semicircular canal. In the case of a cholesterol granuloma, the cyst is opened, and a stent is placed to maintain the drainage (Figure 25–20). Multiple other paths are available and are chosen based on the location of the lesion and the aeration of the temporal bone.

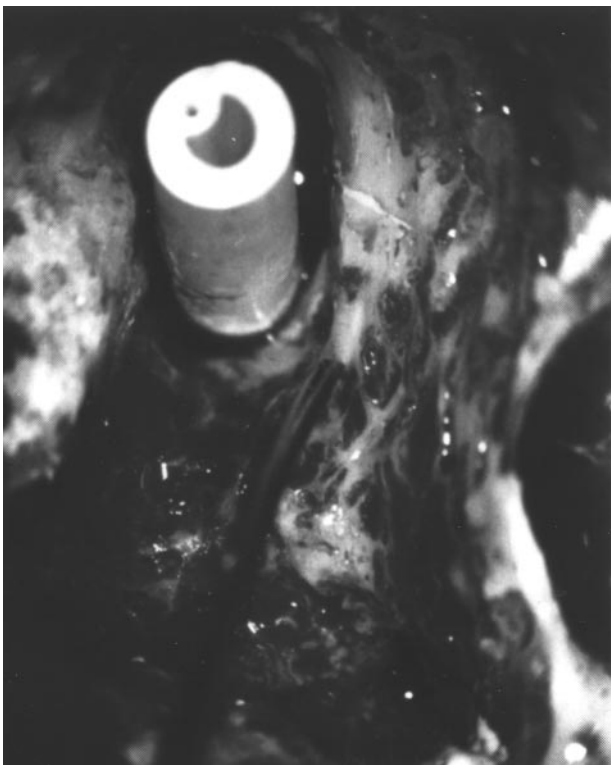

FIGURE 25–20. Infralabyrinthine approach and stent placement into a cholesterol granuloma of the left petrous apex. This patient presented with vertigo, which resolved postoperatively.

CHAPTER 26

Anatomy and Physiology of the Nose and Paranasal Sinuses

John Jacob Ballenger, MD

ANATOMY OF THE NOSE AND PARANASAL SINUSES

External Aspects of the Nose

From the tip or apex, the nose slopes upward and slightly posteriorly to reach the forehead at a junction marked by a slight depression termed the nasion (or radix nasi). Above each eye there are slightly projecting bony arches and between the arches a slightly flattened area known as the glabella. The rhinion is found at the lower end of the suture between the two nasal bones.

The membranous columella lies between the two nares and extends posteriorly from the nasal apex to the center of the upper lip. The philtrum, a gently rounded, convex, vertically oriented depression in the skin of the upper lip, extends upward from the center of the upper lip to the base of the membranous columella. On either side of the columella are the skin-lined nares, bounded by the lower lateral (alar) cartilages above, the floor of the nose below, and the columella medially. Just within the naris is a slight dilation, the nasal vestibule, lined by skin containing coarse hair or vibrissae and sebaceous and sweat glands.

The two nasal bones together with the two upper and lower lateral cartilages form the external framework of the nose (Figures 26–1 and 26–2). The caudal margins of the upper lateral cartilages usually overlie the upper margins of the lower lateral cartilages, and by elevating the tip of the nose,

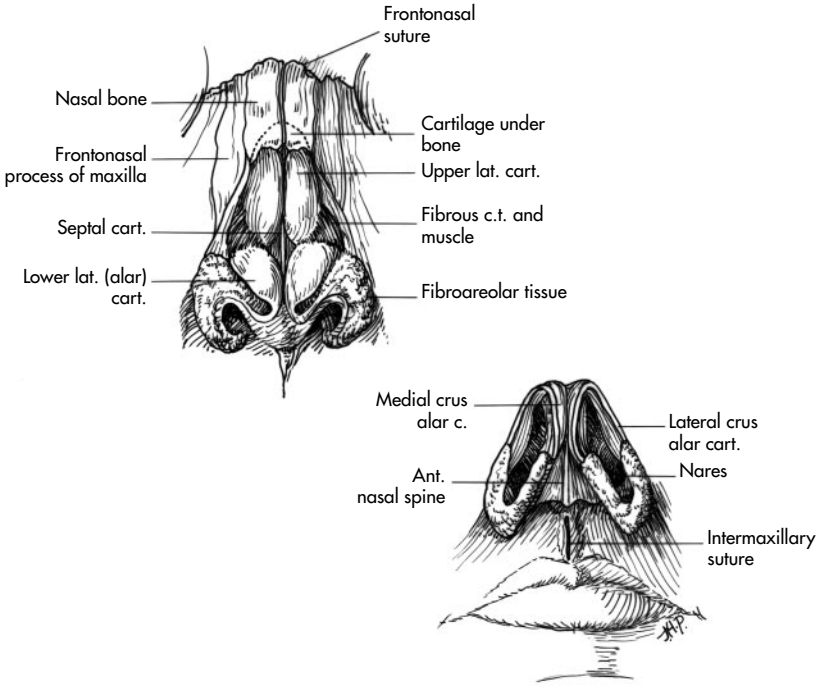

FIGURE 26–1. Dorsal and inferior surfaces of the nose.

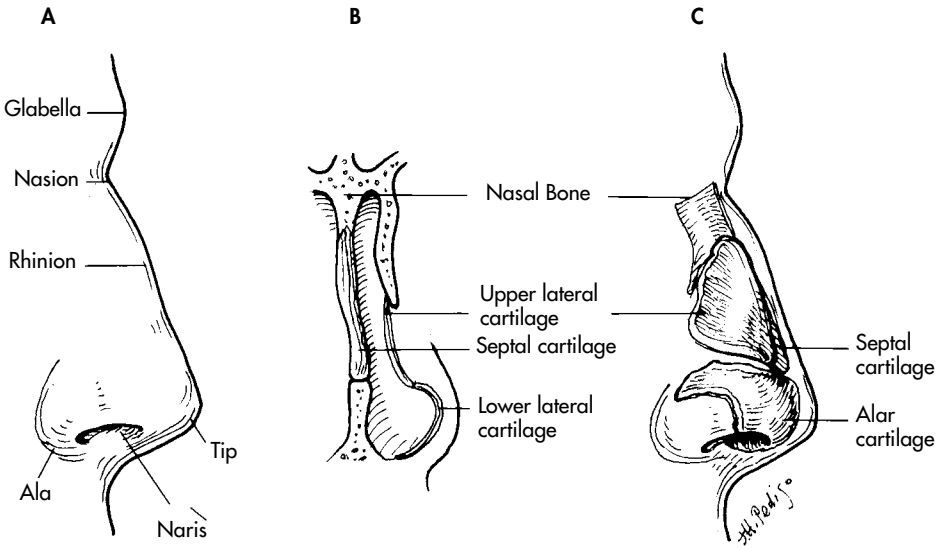

FIGURE 26–2. *A*, Lateral profile of the nose. *B*, Coronal section of the nose. *C*, Lateral view of nasal cartilages.

this margin can be demonstrated within the nose. The junction is called the limen nasi or nasal valve area; it is the narrowest part of the nasal airway and accounts for almost half of the total airflow resistance. At times, the medial margins of the lower lateral cartilages may lie close to but separate from the septum and thus provide less support for the nasal dorsum. Lying lateral to the two alar cartilages in the soft tissues of the nose are frequently found one or more unattached, small, functionless sesamoid cartilages.

The horseshoe-shaped lower lateral cartilage provides the framework of the naris. Its weak medial crus, together with its fellow from the other side, is incorporated into the substance of the columella.

In the bony skull, the pear-shaped opening to the nose is the pyriform aperature, and in the midline of the inferior border, a midline prominence, the anterior nasal spine, is located. The superior and lateral margins of the pyriform aperature are formed by the nasal bones and the frontal processes of the maxillae, and the base or floor by the alveolar processes of the maxillae.

There are two sets of alar muscles: the dilators (dilator naris, m. procerus, caput angulare) and constrictors (m. nasalis and depressor septi). They all receive innervation from cranial nerve VII.

Nasal Septum

The nasal septum is a midline structure derived from several bony and cartilaginous sources: superiorly and posteriorly by the perpendicular plate of the ethmoid bone and anteriorly by the septal (quadrilateral) cartilage, premaxilla, and membranous columella. Inferiorly, it is formed by the crests of the vomer, maxillary, and palatine bones and posteriorly by the sphenoidal crest (Figure 26–3).

Nasal Cavities: Nose

The palatal processes of the maxilla and horizontal processes of the palate bones form the floor of the nose. The roof of the nose is formed by alar cartilages, the nasal bones, the nasal processes of the frontal bones, and the bodies of the ethmoid and sphenoid bones. The cribriform plate (lamina cribrosa) forms the major portion of the roof of the nasal lumen. The inner surfaces of the maxillae, the lacrimal bones, the superior and middle turbinates, the inferior turbinate, and the medial pterygoid make up the lateral wall.

The three scroll-like, pitted turbinate bones, or the conchae, on each side of the nose divide the nasal lumen into meatus. The space between the inferior turbinate and floor of the nose is the inferior meatus, the space between the inferior and middle turbinates is the middle meatus, and the space above the middle turbinate is the superior meatus. Occasionally, there is a supreme turbinate. The middle and superior turbinates are extensions of the ethmoid bones, whereas the inferior turbinate is a separate bone attached by its superior border to the lateral nasal wall. At the anterior ends of the middle and inferior turbinates, a low cuboidal or squamous cell epithelium is found.

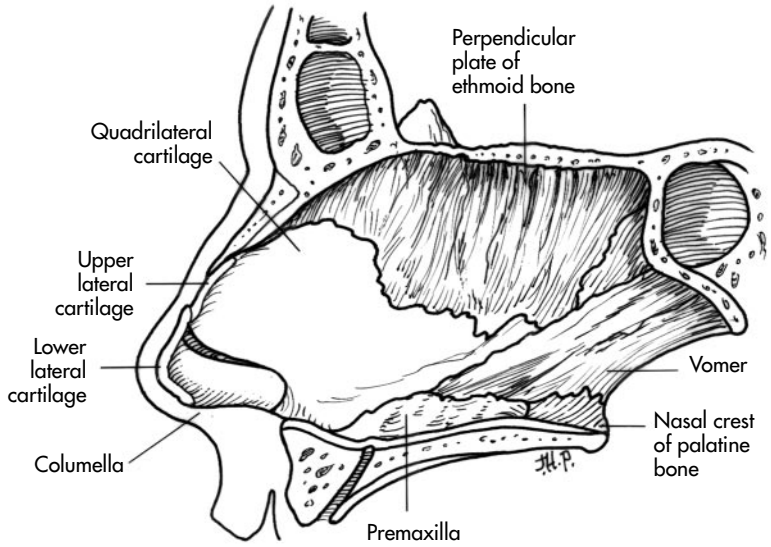

FIGURE 26–3. The nasal septum.

Posteriorly, the surfaces of both middle and inferior turbinates are covered with pseudostratified ciliated columnar (respiratory) epithelium. The epithelial stroma of the middle turbinate contains many glands. The large, tortuous, valveless, anastomosing veins, called sinusoids, are found mainly in the middle and inferior turbinates. By the degree of fluid contained in the sinusoids, they can influence the size of the nasal airway and, in effect, are capacitance structures. They respond to neural, mechanical, thermal, physiologic, and chemical stimuli.

Superior Meatus The superior meatus (also called the ethmoid fissure) is a slit-like space above the middle turbinate and is situated between the nasal septum and the ethmoid bone (Figure 26–4). The posterior ethmoid cells open into the central portion of this meatus. Above and posterior to the superior turbinate is the sphenoid recess, into which the sphenoid sinus opens.

Middle Meatus This meatus lies between the middle and inferior turbinates. It contains the orifices of the frontal and maxillary sinuses and also the anterior ethmoid cells. Hidden by the anterior half of the overhanging middle turbinate is a deep crescentic groove, the infundibulum. The crescent-shaped opening is called the hiatus semilunaris. The inferior medial wall of the infundibulum forms a shelf-like ledge known as the uncinate process and above the ledge a hemispheric prominence termed the ethmoid bulla.

The frontal, maxillary, and anterior ethmoid sinuses open into the infundibulum. Some ethmoid cells may open above the ethmoid bulla, and the frontonasal duct may have a separate opening. Additional details of endoscopic anatomy of the nose are given in Chapter 34.

Inferior Meatus The inferior meatus lies below the inferior turbinate. On its lateral surface, 3 to 5 cm beyond the naris, is found the orifice of the duct from the lacrimal gland. The floor of the meatus is congruent with the roof of the mouth.

Nares The anterior nares are formed medially, superiorly, and laterally by the lower lateral cartilages and the floor by the upper lip. Each naris measures about 1.5×1.0 cm, whereas the choanae are 2.5×1.5 cm. Just within the naris is a skin-lined enlargement, the nasal vestibule. The thin skin here contains coarse hair (the vibrissae) and sebaceous and sweat glands. The choanae are formed by the horizontal plate of the palatine bone inferiorly, the vomer medially, the vaginal process of the spenoid bone superiorly, and the medial pterygoid plate laterally.

Paranasal Sinuses

There are four paired paranasal sinuses: the maxillary, ethmoid, sphenoid, and frontal. In health, each is filled with air and communicates with the nasal lumen through an ostium. The bony ostium is slightly larger than the aperature in the mucous membrane. Each sinus is lined by a relatively thin, ciliated mucous membrane whose cilia beat the overlying blanket of mucus toward the sinus ostium

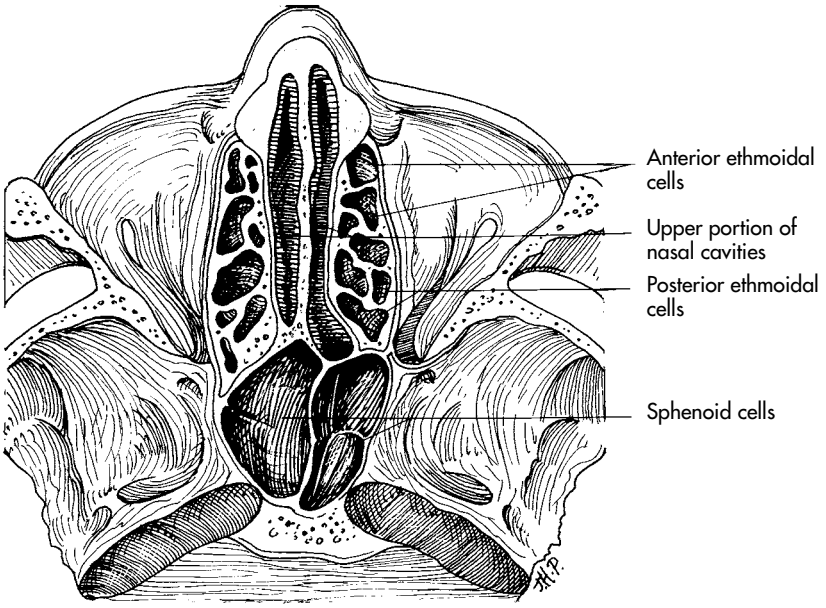

FIGURE 26–4. Horizontal section through the nose.

to join the mucous blanket in the nose. The cilia in the sinal mucous membrane become more numerous as the ostium is approached.

For clinical purposes, the sinuses are divided into two groups, anterior and posterior, depending on their location in reference to the line of attachment of the middle turbinate to the lateral wall of the nose. The anterior group consisting of the frontal, maxillary, and anterior ethmoid cells open into or near the infundibulum. The posterior group, made up of the posterior ethmoid cells and the sphenoid sinuses, opens above the middle turbinate.

Maxillary Sinus The growth of this sinus, the largest of the four, is biphasic (Table 26–1). The first period occurs during the first 3 years of life followed by a final period from ages 7 to 17 to 18 years. Much of the growth is an invasion into the alveolar process following eruption of permanent dentition.

The maxillary sinus (also called the antrum of Highmore) occupies the body of the maxilla. The sinus is generally pyramidal in shape, with its base formed by the lateral wall of the nasal cavity and its apex directed toward the zygomatic process. Its roof separates the sinus from the orbit. The floor is formed by the alveolar process of the maxilla and the hard palate. In children, the sinus floor lies at or above the level of the floor of the nasal interior, whereas in the adult, the sinus floor may lie 5 to 10 mm below. The anterior wall corresponds with the canine fossa and separates the sinus from the

TABLE 26–1. Maxillary Sinuses

Embryology	First of the paranasal sinuses to develop, beginning as a bud along the inferolateral surface of the ethmoidal portion of the nasal capsule about gestation day 65
Size	Birth: 7–8 × 4–6 mm
	Adult: 31–32 × 18–20 mm
	Volume (adult): 15 mL
Blood supply	Arterial branches of the internal maxillary including the infraorbital, lateral nasal branches of the sphenopalatine, descending palatine, and posterior and anterior superior alveolar arteries; most sinus walls drain into the maxillary vein, which shares communication with the pterygoid plexus
Innervation	Mucosal sensation from the lateroposterior nasal and superior alveolar branches of the infraorbital nerve, all derived from cranial nerve V_2

TABLE 26–2. Ethmoid Sinuses

Embryology	First appears during third and fourth fetal months as evaginations of the lateral nasal wall
Size	Adult: 20–24 × 20–24 × 10–12 mm (anterior group)
	20–21 × 20–22 × 10–12 mm (posterior group)
	10 to 12 cells each side
Blood supply	Nasal branches of the sphenopalatine artery and anterior and posterior ethmoid arteries, branches of the ophthalmic artery from the internal carotid system; maxillary vein, making connections with the cavernous sinus
Innervation	Posterior nasal branches of the maxillary nerve (cranial nerve V_2), the anterior and posterior ethmoidal branches of the ophthalmic nerve (cranial nerve V_1)

cheek. The posterior wall lies against the contents of the infratemporal space and pterygomaxillary fossa.

The antrum communicates with the infundibulum through an ostium located in the upper anterior part of the medial wall of the sinus. In 10 to 30%, an additional (accessory) ostium is present. The bony orifice is larger than the membranous one. The ostium serves as an entry conduit for most nerves and blood vessels.

The apices of the second upper bicuspid and first and second molar teeth are located in close relation to the floor of the sinus and may be separated only by mucous membrane, thus permitting easy spread of a dental infection into the sinus. The superior wall or roof is usually traversed in its central portion by the infraorbital nerve that may, at times, be protected only by a thin plate of bone.

Ethmoid Sinus At birth, usually three or four cells of the ethmoid sinus are present and, along with the maxillary sinus, are the only sinus cavities that are large enough to be of clinical importance (Table 26–2). The cells lie either in front of and below (anterior ethmoid cells) or posterior and above (posterior ethmoid cells) the attachment of the middle turbinate to the lateral nasal wall. They lie on either side of the superior halves of the nasal cavities and are separated from the orbits by the laminae papyraceae (Figures 26–5 and 26–6).

The anterior ethmoid cells open into the infundibulum of the middle meatus and the posterior cells into the superior meatus. The middle turbinate may be the site of an ethmoid cell, a concha bullosa, which can obstruct free sinus drainage but is usually asymptomatic. There are many variations of pneumatization of the ethmoid cells.

TABLE 26–3. Frontal Sinus

Embryology	Upward extension occurs at about 4 months gestation of the anterior portion of the nasal capsule in the region of the frontal recess
Size	Adult: 3 × 2.5 × 2 cm
	Adult volume: 6 to 7 mL
Blood supply	Supratrochlear and suborbital branches of the ophthalmic artery; venous drainage into the cavernous sinus
Innervation	Mucosal sensation derives from supratrochlear and supraorbital branches of the frontal nerve of cranial nerve V_1

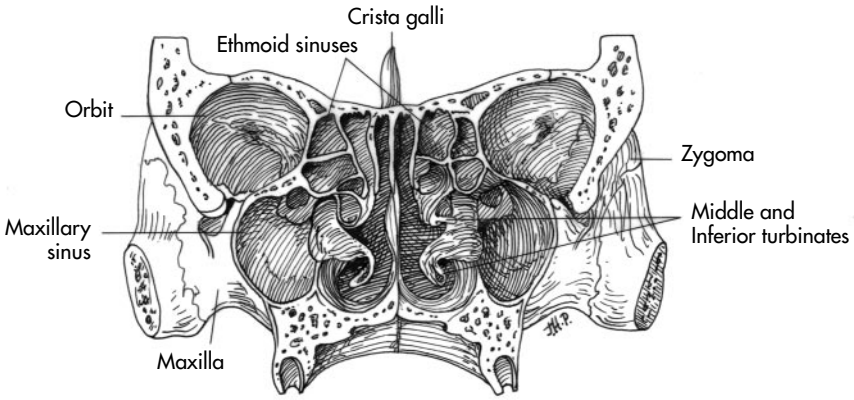

FIGURE 26–5. Coronal section through the nose.

Agar nasi cells are the most anterior of the anterior ethmoid cells and are located anterior to the anterosuperior attachment of the middle turbinate. They lie in close proximity to the frontal recess and can occasionally obstruct the nasofrontal duct. The anterior ethmoid cells frequently extend into the uncinate process and may invade the lumen of the frontal sinus as a frontal bulla or invade the body of sphenoid bone.

Haller cells are ethmoid cells that may obstruct maxillary ventilation in the region of the sinus ostium. They occur in about 10% of the population and may be without symptoms. Onodi cells are posterior ethmoid cells that can extend laterally or superiorly toward the nearby sphenoid sinus and lie near the optic nerve as well.

Frontal Sinus The frontal sinus can rarely be imaged before the second year of life (Table 26–3). At this time, it slowly invades the frontal bone and has much diversity of shape. The frontonasal duct enters the nose near the upper portion of the infundibulum. The anterior wall of the sinus is composed of diploic bone, and the posterior wall is composed of a compact, bony plate.

Sphenoid Sinus Pneumatization of the sphenoid bone occurs during middle childhood, proceeding rapidly after 7 years of age to its final form at 12 to 15 years (Table 26–4). Each sinus communicates with the sphenoethmoidal recess of the superior nasal meatus by means of a small aperature of 0.5 to 4 mm. The bony ostium is usually larger than the membranous and, for gravity drainage, is disadvantageously located 10 to 20 mm above the sinus floor.

Several vital structures lie closely adjacent to the sinus: the optic nerve and the hypophysis above, the pons posteriorly and external and lateral to the

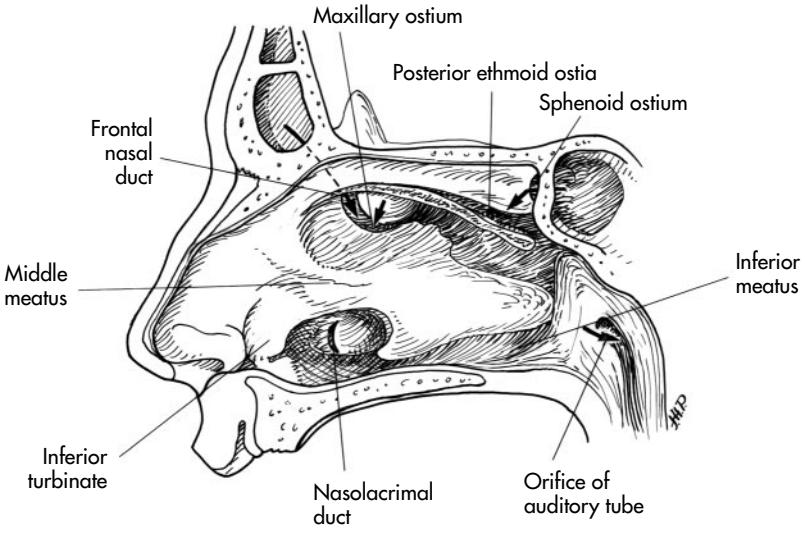

FIGURE 26–6. Schematic drawing of the right lateral nasal wall with the entire middle concha and the anterior third of the inferior part of the concha removed.

TABLE 26–4. Sphenoid Sinus

Embryology	Originates during third fetal month as an evagination of the mucosa in the sphenoethmoidal recess
Size	Adult: 20 × 22 × 16 mm; volume: 7.5 mL
Blood supply	Branches of the sphenopalatine and posterior ethmoid arteries
Innervation	Posterior ethmoid nerve from cranial nerve V_1, nasal and sphenopalatine branches of cranial nerve V_2

sinus, the cavernous sinus, the superior orbital fissure, the carotid artery, and several cranial nerves. The nerve of the pterygoid canal (vidian nerve) may encroach on the sinus floor.

Ostiomeatal Unit The ostiomeatal unit refers to the relationship between the middle meatus and anterior group of sinuses, particularly the anterior ethmoid cells (Figure 26–7). If there is an anatomic deformity (eg, concha bullosa) or a disease process that brings two mucosal surfaces into direct contact, local ciliary stasis occurs, and likely infection of one or more paranasal sinuses may be inaugurated. This pathogenesis is further described in Chapter 34.

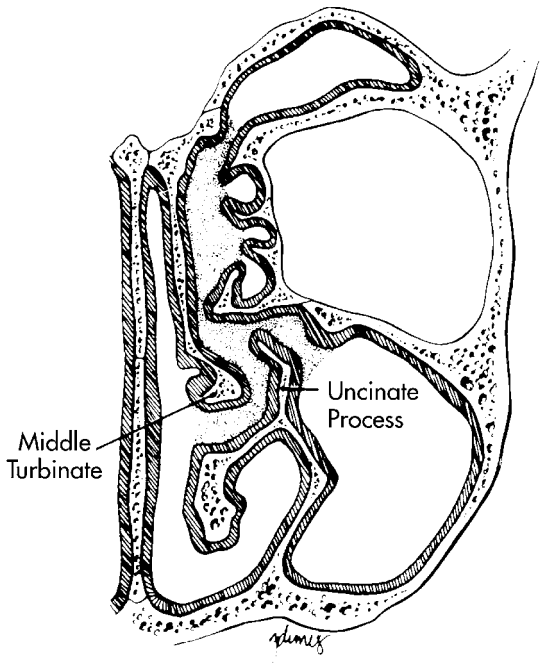

FIGURE 26–7. Concept of the ostiomeatal unit (*shaded*). (Courtesy of Dr. David W. Kennedy.)

Function of the Paranasal Sinuses

Prevailing theories of the function of the sinuses are numerous, but none are generally accepted. They include lightening the skull, a vocal resonating box, increased olfaction, humidification of the inspired air, and assistance in regulation of intranasal pressure.

It has been proposed that the sinuses provide a source of environmentally uncontaminated mucus that is delivered to the midportions of the middle and superior meatus and dilutes the contamination of the mucus more directly exposured to the incoming air.

Pterygopalatine Fossa

This space, an elongated triangular area with apex laterally, lies between the rounded posterior border of the maxillary sinus and the pterygoid process. It is bounded medially by the perpendicular plate of the palatal bone and superiorly by the undersurface of the sphenoid bone.

Just medial to the sphenopalatine foramen, an opening in the perpendicular plate of the palatal bone opposite the posterior end of the middle turbinate, is the sphenoethmoid recess. Through the foramen, vessels and nerves pass to the nasal cavity. The pterygopalatine (sphenopalatine) ganglion is located just lateral to the foramen.

Also communicating with the pterygopalatine space are the foramen rotundum and the pterygomaxillary and inferior orbital fissures. A wire passed up the greater or lesser palatine canals enters the fossa from below. Within the fossa are also found the second division of the fifth cranial nerve, the third division of the internal maxillary artery, and the vidian nerve. Infection into the pterygopalatine space may spread from the molar teeth. Entrance for drainage

can be made through the alveobuccal sulcus above the third molar tooth or through a Caldwell-Luc operation with removal of the posterior wall of the antrum and direct exposure into the pterygopalatine fossa.

Nasal Mucous Membrane

The skin within the nasal vestibule is a tough, keratinized, squamous cell epithelium containing coarse hairs (the vibrissae) and sebaceous and sweat glands. As the turbinates are approached, the epithelium blends first into a cuboidal cell type and then into the respiratory type. As the nasopharynx is reached, the respiratory type blends to a moist, nonkeratinized, squamous cell mucous membrane similar to that in the oral cavity. The nasal mucous membrane is further considered later in this chapter.

The mucosa of the paranasal sinuses contains pseudostratified ciliated columnar to cuboidal cell epithelium, is thin, and contains a few glands. The basement membrane is thin. Cilia, somewhat more abundant near the sinus ostia, propel the overlying blanket of mucus through the ostium, where it joins that in the nose.[1]

Nerve Supply of the Nose

The nerve supply of the nose (olfaction is considered in Chapter 27) consists mainly of ophthalmic and maxillary divisions of cranial nerve V. The former gives rise to the nasociliary nerve, dividing into the anterior and posterior ethmoid and infratrochlear branches. The anterior ethmoid nerve passes over the anterior end of the cribriform plate (Figures 26–8 and 26–9) and enters with the anterior ethmoid artery by way of the anterior ethmoid foramen, dividing into medial and lateral branches.

The medial branch passes forward and downward on the nasal septum and the lateral branch a similar part of the lateral wall. An external branch exits at the distal end of the nasal bone to reach the external surface of the nose. The posterior ethmoid crosses the cribriform plate to enter the nose with the artery through the posterior ethmoid foramen to the nasal septum as well as the olfactory region.

Branches from the maxillary division give rise to the posterior superior nasal nerves that enter the nose by way of the sphenopalatine foramen and pass over the anterior face of the sphenoid bone to reach the nasal septum as the nasopalatine nerve (n. of Cotunnius) and finally reach the incisive canal. Laterally, a branch, the posterior inferior, passes downward and forward to distribute on the middle and inferior conchae.

The autonomic innervation of the nose consists of parasympathetic and sympathetic fibers. The former originates in the superior salivary nucleus and travels via the nervus intermedius to the geniculate ganglion, where it joins with the greater superficial petrosal nerve. As this nerve leaves the temporal bone, it is joined by the deep petrosal nerve to form the nerve of the pterygoid

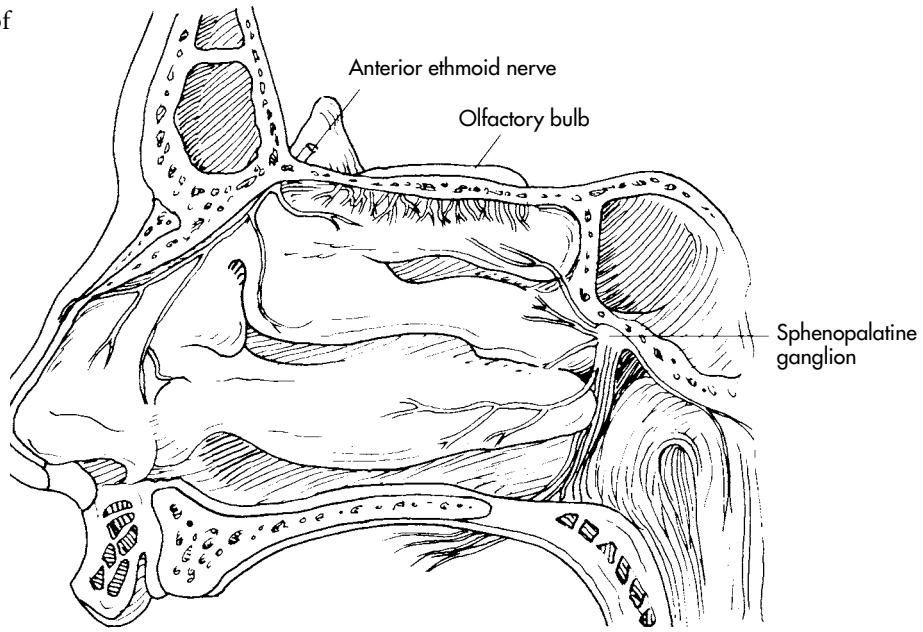

FIGURE 26–8. Nerve supply of the lateral wall of the nose.

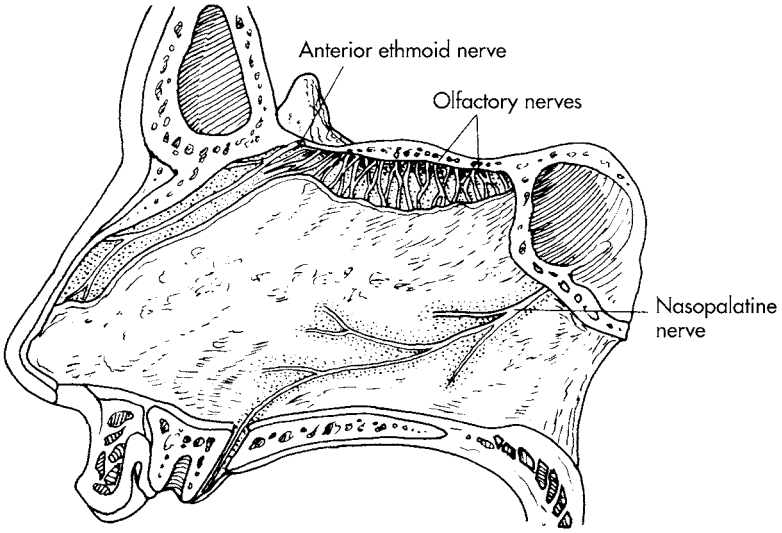

FIGURE 26–9. Nerve supply of the medial wall of the nose.

canal, or vidian nerve, to synapse in the sphenopalatine ganglion.

The postganglionic sympathetic fibers follow the internal carotid artery and form the deep petrosal nerve, which joins the greater superficial petrosal nerve to form the vidian nerve. Postganglionic sympathetic fibers pass through the sphenopalatine foramen without synapsing to innervate the nasal mucosa via the posterior nasal nerve.

Blood Supply of the Nose

The blood supply of the nasal interior comes from the anterior and posterior ethmoid branches (crossing the ethmoid plate) of the ophthalmic and sphenopalatine arteries. The latter is the terminal branch of the internal maxillary artery. The anterior and superior portions of the septum and the lateral wall of the nose receive blood via the anterior ethmoid arteries, the smaller posterior branch supplying only a small posterior region, including the olfactory area.

The internal maxillary artery, usually the penultimate branch of the external carotid artery, passes lateral to the pterygoid plate to enter the pterygoid fossa and continue as the sphenopalatine artery into the nasal cavity by way of the sphenopalatine foramen at the posterior end of the middle turbinate. Within the nose, the artery divides into posterior lateral nasal and posterior septal branches that accompany second and third divisions of the trigeminal nerve. There is an anastomosis between the lateral nasal arteries and the ethmoid; thus, bleeding can arise from either. Other branches of the sphenopalatine artery descend in the greater palatine canal to enter the oral cavity and spread over the undersurface of the palate.

Veins follow a course similar to that of the sphenopalatine artery and drain into the ophthalmic plexus and partly to the cavernous sinus. The nasal venous system is without valves and thus predisposes the spread of infection upward to the cavernous sinus.

Lymphatics

The lymphatics of the nasal vestibule drain forward toward the lip and external aspects of the nose. The lymphatics of the nasal fossa drain posteriorly, one collecting trunk in the olfactory region and a second below. They carry the lymph posteriorly to either the lateral retropharyngeal or subdigastric nodes.

PHYSIOLOGY OF THE NOSE

The nose is the entrance to the lower respiratory tract as well as to the olfactory epithelium (olfaction is discussed in Chapter 27). In its passage through the nose, the incoming air is prepared for reception by the alveolar sacs. In health, the nasal mucosa has the ability to cleanse itself and to condition the air.[2] The part played by the nose as a resonator is obvious to all who have suffered from the common cold.

Respiratory Mucosa

The pseudostratified respiratory mucosa consists of ciliated, intermediate, basal, and goblet cells. They rest on a well-defined basement membrane supported by a relatively deep, loose lamina propria

containing small blood vessels, venous plexuses, ducts of mucous and serous glands, sensory nerves, and blood cells (primarily lymphocytes). The blood capillaries and the venules are thin walled and possess a fenestrated endothelial lining and a porous basement membrane.

The tall (15 to 20 μm) columnar ciliated cell is the predominant cell and extends from the basement membrane to the luminal surface, where cilia admixed with microvilli are present. The microvilli are shorter than the cilia (3 μm × 0.1 μm versus 6 to 7 × 0.13), and some are branched. The microvilli contain bundles of microfilaments and display hair-like projections. The function of the microvilli is unknown, although it is clear that they greatly increase the cell surface area.

The ciliated cell cytoplasm forms complex interdigitations with adjacent cell membranes, presumably to permit intercellular exchange. Irregular intercellular spaces exist to accommodate edema fluid and inflammatory cells for implementation of the immune response.

Basal cells lie on the basement membrane and likely are progenitors of the columnar and goblet cells. Evidence suggests that the primary progenitor may be a nonciliated columnar cell that can form a ciliated cell. Goblet cells taper upward from the basement membrane to an expanded body at the lumen, where microvilli are found on their exposed surfaces. The nucleus is situated basally, and secretory granules that contain mucin are seen toward the lumen.

Columnar cells extend from a narrow base at the basement membrane to an expanded surface area covered by microvilli. These cells are related to adjacent cells by tight junctions apically and by interdigitations of the cell membrane. This cell may be the progenitor of the airway epithelium.

Airway

The nose provides a semirigid passageway for in- and outgoing air. On entering the nose, the air is directed upward by the nares (Figure 26–10). The air stream turns 80 to 90 degrees posteriorly as it reaches the nasal vault to traverse a mostly horizontal path until it impacts against the posterior wall of the nasopharynx. At this point, joined by the air stream from the other side, an 80- to 90-degree downward bend occurs. Each of these two bends, termed "impaction points," likely facilitates the removal of particulates contained in the incoming air. Impaction against the adenoid may enable the adenoid to respond immunologically by "sampling" the contaminants contained in the air. "Sniffing" draws the inspired air higher in the nasal cavities to reach the olfactory areas. The expiratory route is generally the reverse of the inspiratory and also may reach the olfactory area. In 1941, Proetz renewed interest in and advanced the study of nasal physiology.[3]

Air Stream

The anterior nasal valve, or ostium internum, is located at the limen nasi, some 1.5 to 2 cm posterior to the nares. At this point, the cross-section of the airway is 20 to 40 mm^2 on each side, is the narrowest part of the upper respiratory tract, and provides about 50% of the total airway resistance. Posterior to this in the horizontal section of the nasal airway, the cross-section widens while the air stream remains narrow and thus provides a large surface area in intimate contact with the air stream.

Evidence has accumulated that there is a 2½- to 4-hour cyclic alteration of nasal resistance from one side to the other.[4,5] A prolonged increase in nasal

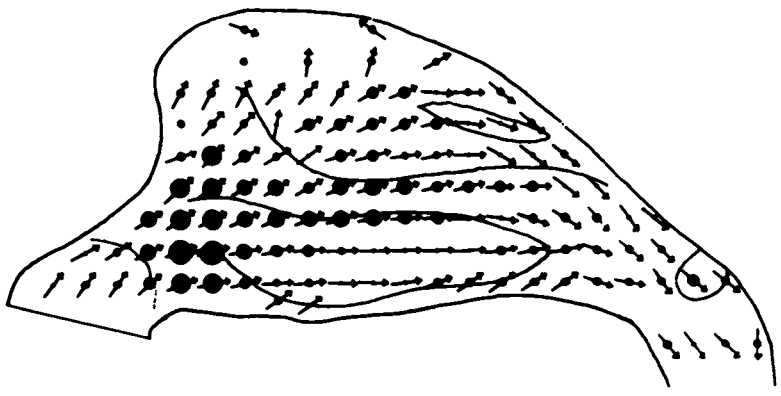

FIGURE 26–10. Diagram of the nasal airway and air speed, the size of the dot indicating the velocity. Reproduced with permission from Brau JD, Proctor DF, Reid LM, editors. Respiratory defense mechanisms. Part I. New York: Marcel Dekker; 1977.

resistance can lead to cor pulmonale, cardiomegaly, and pulmonary edema. The most common sequel to increased nasal resistance is mouth breathing, thus bypassing the air conditioning and cleansing functions of the nose.

Air Speed

The air speed is greatest at the anterior nasal valve, reaching 3.3 m/s at an inspiratory flow rate of 200 mL/s compared with 1 mm/sec in secondary bronchi (see Figure 26–10). Beyond the valve, the air speed slows down, thus enabling a longer contact between the incoming air and the nasal walls. At the choana, the stream again narrows.

Particle Removal

The aerodynamic equivalent diameter (AED) is the diameter of a unit density sphere with the same settling speed as the particle in question. Particles of approximately 5 μm AED or greater are 80 to 85% removed by the nose and nasopharynx. Smaller particles penetrate to varying degrees to the lower respiratory tract. Virus-containing droplets coalesce into diameters, frequently exceeding 5 to 6 μm, and thus are largely retained in the nose.

Air Conditioning

The air is heated (or cooled) by radiation from the mucosal blood vessels. Humidification occurs by evaporation from the mucous blanket. That this is an efficient mechanism is attested to by the fact that, in the nasopharynx, the inspired air is near normal body temperature and the relative humidity is near 100%. The mucosal blood vessels lie in two layers of more or less parallel rows. The more superficial layer sends capillaries into the epithelium, and the capillaries of the deeper layer near the basement membrane are fenestrated to facilitate fluid movement. The flow of blood is from posterior to anterior, opposite to the flow of inspired air and mucus. The mechanism of a "counter current" adds to the efficiency of the system.

The nasal mucous membrane is cooler by varying amounts than the expired air; thus, some condensation on and warming of the membrane occur —a so-called regenerative effect.

Respiratory Cilia

In humans, the respiratory cilia are found throughout the respiratory tract except for the nasal vestibule, the posterior oropharyngeal wall, portions of the larynx, and terminal ramifications of the bronchial tree. They are found in the eustachian tube, much of the middle ear, and the paranasal sinuses. Cilia in a modified form also occur in the maculae and cristae in the inner ear and in the eye as retinal rods.

Ciliary Ultrastructure Human cilia extend about 6 μm above the luminal surface of the cell and are about 0.3 μm in width. As many as 100 are found on each cell in the nose. Each cilium appears to be anchored to a basal body located just below the cell surface. The structure of the centriole of a dividing cell is similar to the basal body, the former giving rise to the latter and the latter to the cilium.

Each cilium is encased by an extension of the cell plasma membrane. Within the cilium is a sheaf of longitudinally arranged microtubules (or fibrils) termed an axoneme. The microtubules are, in fact, doublets or pairs with nine outer pairs arranged in a cartwheel pattern at the periphery of the axoneme. In addition, two single microtubules are located in

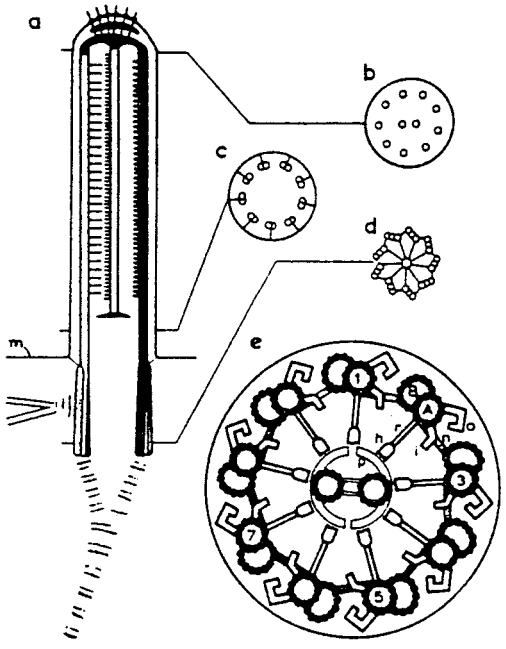

FIGURE 26–11. Diagram of the ultrastructural arrangement of ciliary tubules at various levels.

the center of the axoneme, creating the characteristic "9 plus 2" pattern (Figure 26–11).

At the tip of the cilium is a dense cap or crown from which three to seven "claws," 25 to 35 nm long, project. Below the cell membrane and the axoneme is a short, cylindrical basal body, and below this, the tubules (with a third added to form a triplet) seem to extend into the apical cytoplasm of the cell as a "rootlet." They converge into a cone-shaped form and acquire periodic striations. This structure, the basal foot, curves in the direction of the effective ciliary beat.

The basal foot has a cross-striated appearance resembling that of collagen fibers. In addition, other fine microtubules, which appear to be branched, attach to adjacent basal bodies, to each other, and ultimately to the junctional complex of the cell, constituting the terminal web.

Looking top-downward on the outer ring of doublets, each is composed of two juxtaposed microtubules—a slightly more centrally located subfiber, A, and a slightly more peripherally located subfiber, B (see Figure 26–11). Two regularly arranged arms extend from A toward B. They are composed of adenosine triphosphate and are called dynein arms. Also present are links attaching each subfiber A to B of the adjacent doublet. They are believed to be of an elastic material called nexin. Extending centrally from A to the central pair are radial spokes.

At the base of the cilium, the two central microtubules terminate, and each of the peripheral doublets continues downward to enter the basal body as a triplet with a subfiber, C, added.

Ciliary Beat The to-and-fro movement of the cilium is termed the ciliary beat (Figure 26–12). The forward beat is the more forceful, effective stroke in which the cilium is fully extended, and the claws at the tip penetrate the top layer of mucus bordering on the luminal surface and propel the mucus forward. The recovery stroke is less forceful and slower, and the shaft curls back on itself so that it does not reach the overlying flakes of mucus. Beating is metachronous and occurs 1,000 or more times per minute.

The motion of the cilium is caused by the sliding of one tubule against an adjacent one, thus creating a shearing force that induces the bending. The nature of the "nervous" connection between adjacent cilia is not clear; perhaps the "touch" of one cilium against the adjacent cilium is enough to initiate the coordinated, metachronous movement. Energy for this work is derived from the adenosine triphosphate found in the dynein arms. The "spokes" seem to detach and reattach several times during the bending process. The axis of motion of the cilium is defined by a line perpendicular to a plane connecting the central pair of tubules.

In health, particles resting on the mucous blanket are moved by active cilia at 3 to 255 mm per

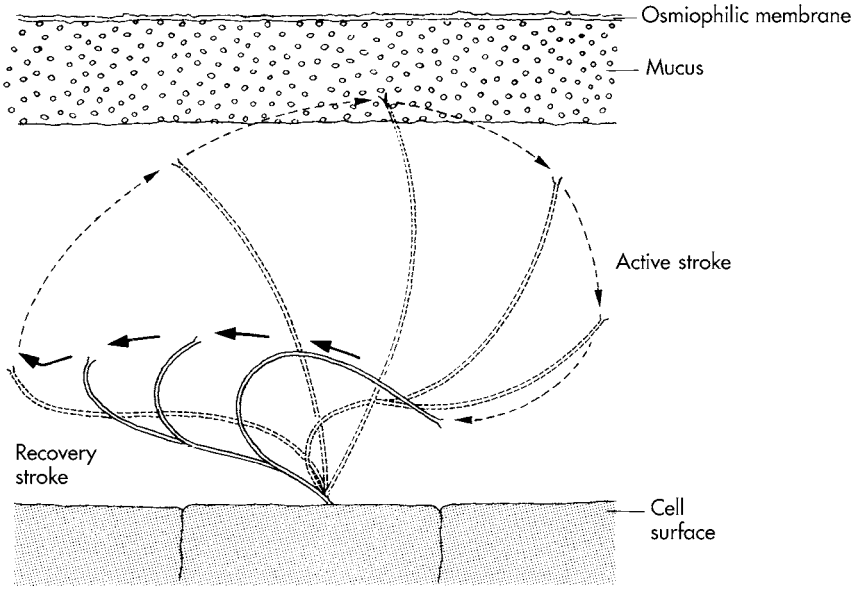

FIGURE 26–12. Diagram of the normal ciliary cycle.

minute, with an average of about 6 mm per minute. Apparent health exists, however, with speeds at some variance from this average. Dryness of the mucosa is quickly detrimental to ciliary activity. Other factors known to influence clearance speeds are the relative humidity and the pH of the fluids. β_2-Adrenergic agonists accelerate the wave frequency, whereas α_2-adrenergic activity retards the movement.

Numerous structural abnormalities of the axonemal tubules have been found (Figure 26–13).

Either a dye or saccharin can be used to measure the movement of material resting on the mucous blanket of the nose. Dye or saccharin is placed on the anterior aspect of the nasal mucosa and the time until the color of the dye is seen in the pharynx or the taste is reported by the subject is recorded. The use of tagged particles, developed by Quinlan et al, involves placing an anion exchange resin particle about 0.5 mm in diameter tagged with a technetium 99m ion on the anterior nasal ciliated mucosa, and its clearance can be followed accurately with a gamma camera or multicollimated detectors.[6]

Mucous Blanket

The bilayered mucous blanket, produced mostly by the serous and goblet glands, is a 12 to 15 μm thick, sticky, tenacious, adhesive sheet consisting of an upper, more tenacious mucus riding on the tips of the ciliary shafts and a deeper, thinner periciliary layer.[7] The blanket functions as a lubricant, protects against desiccation, and traps particulate matter and soluble gases. It amounts to 1 to 2 L per day.

In health, the pH is slightly acid. Its approximate composition is 2.5 to 3% glycoprotein, 1 to 2% salts, and 95% water. Immunoglobins comprise about 70% of the protein content. Mucus is found throughout the nose (except the vestibule), paranasal sinuses, middle ear, eustachian tube, and bronchial tree (and extending into the alveoli in the form of surfactant). The beating of the underlying cilia propels the blanket of mucus, along with trapped or dissolved material, in a more or less continuous movement toward the pharyngeal end of the esophagus.

Enveloping the shafts of the mucosal cilia is the thicker, less viscid, and deeper periciliary layer, and above this, interfacing with the luminal surface, is the more viscid layer of mucus riding on the periciliary fluid below. The mucus on the luminal surface may take the form of flakes. Soluble and insoluble matter caught in the mucus and on the mucous flakes are carried posteriorly by the movement of the mucous blanket to the upper end of the esophagus.

Mucociliary Transport

The mucociliary transport or clearance system is really two systems working in concert with one another. Its motive force is dependent on the actively beating cilia reaching the flakes of mucus at the luminal surface and propelling the flakes and surrounding mucus posteriorly to the esophagus. The mechanism by which the deeper periciliary, less viscid fluid, with its dissolved contaminants and likely viruses, also moves posteriorly is less well understood. More needs to be learned about the rheology and the effects of various viscoelastic properties, as well as the thickness of the mucous blanket under

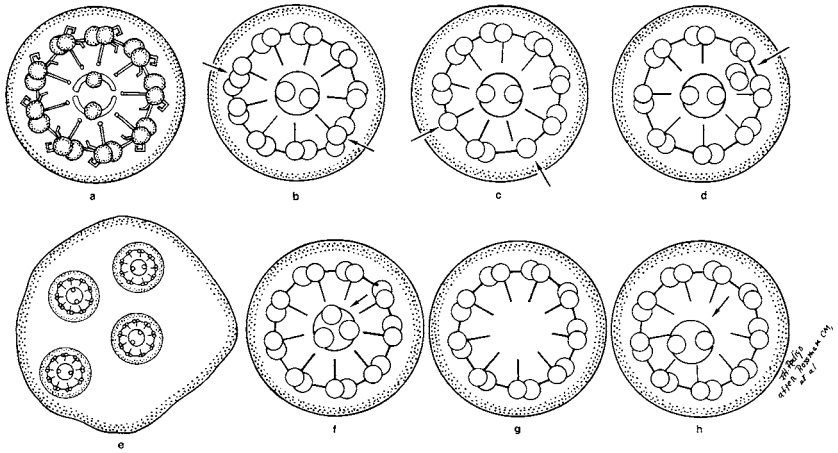

FIGURE 26–13. Some observed abnormal alterations of axonemal tubules.

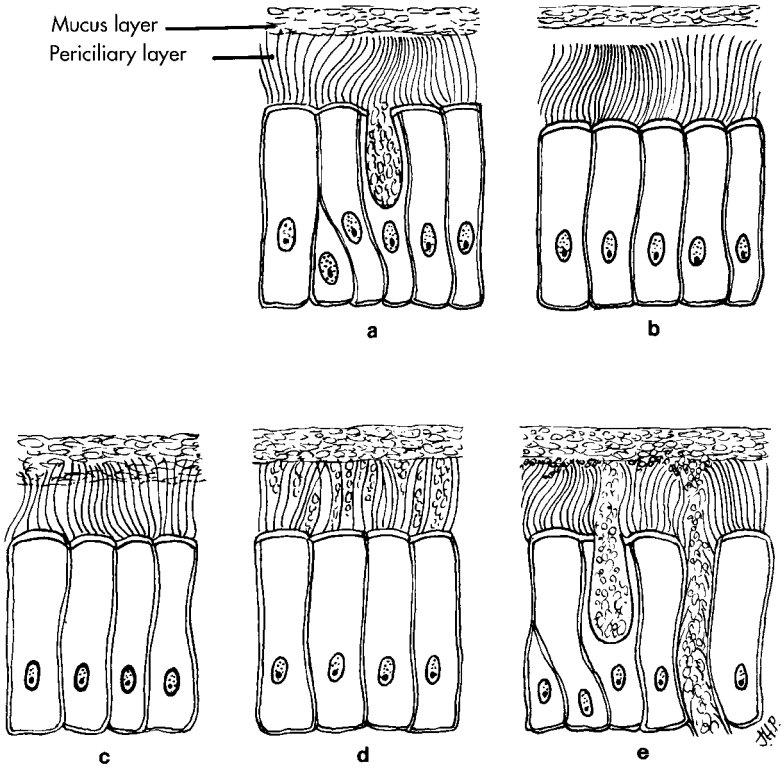

FIGURE 26–14. Various possible alterations of the mucous blanket.

varying conditions (Figure 26–14) and its relation to health and the cleansing function of the nose.

Although most bacteria seem to impede the metachronous ciliary cycle and efficient transport system little or not at all, *Bordetella pertussis*, *Mycoplasma pneumoniae*, and *Pseudomonas aeruginosa*, among others, do so. Some respiratory viruses and bacteria, notably influenza virus, rhinovirus, adenovirus, herpes simplex virus, and respiratory syncytial virus, seem to impede mucociliary transport by altering either the axonemal ultrastructure or the viscoelastic properties of the mucous blanket[8] (see Figure 26–13). The relationship of healthy mucociliary activity to disease is discussed further in Chapter 33.

CHAPTER 27

Olfaction and Gustation

Richard L. Doty, PhD, Steven M. Bromley, MD

The chemical senses are important to humans as they determine the flavor of foods and beverages and provide a sensitive and early means for detecting dangerous environmental situations, including the presence of fire, spoiled food, and leaking natural gas. Unfortunately, taste and smell are typically ignored by otolaryngologists, even though (1) the stewardship of these senses falls within the purview of their specialty; (2) some otolaryngologic operative procedures compromise the functioning of these senses; (3) alterations in chemosensory function can be an early sign of a number of diseases, including Alzheimer's disease (AD) and idiopathic Parkinson's disease (PD); and (4) losses or distortions of chemosensation are of considerable personal and practical significance to the patient. The latter should not be underestimated and is particularly acute for patients whose lifestyle, livelihood, or immediate safety depends on smelling and tasting (eg, cooks, firemen, homemakers, plumbers, professional food and beverage tasters, employees of natural gas works, chemists, and numerous industrial workers).

This chapter provides an overview of the anatomy and physiology of the smell and taste systems, describes basic chemosensory pathology, and discusses up-to-date means for quantitatively assessing, managing, and treating disorders of these generally neglected sensory systems.

THE OLFACTORY SYSTEM

Anatomy and Physiology

Olfactory Neuroepithelium The olfactory neuroepithelium contains the olfactory receptors of cranial nerve I (CN I)* and lines the cribriform plate and sectors of the superior turbinate, middle turbinate, and septum. Although it reportedly comprises ~ 2 cm^2 of the upper recesses of each nasal chamber, it is not a homogenous structure, at least in the adult, as metaplastic islands of respiratory-like epithelium accumulate within its borders beginning early in life, presumably as a result of insults from viruses, bacterial agents, and toxins.[1] On the basis of immunohistochemical and anatomic criteria,[2] at least six major classes of cells can be identified in this neuroepithelium: bipolar sensory receptor cells, supporting or sustentacular cells, microvillar cells, Bowman's gland and duct cells, globose basal cells, and horizontal basal cells. The ~ 6 million *receptor cells* are derived embryologically from the olfactory placode and thus are of central nervous system (CNS) origin. The cilia of these cells, which extend into the mucus of the nasal lumen, harbor the seven-domain transmembrane olfactory receptors. The axons of these cells ultimately unite into bundles of 50 or so "fila" ensheathed by glial cells that traverse the cribriform plate to form the outermost layer of the olfactory bulb. The *sustentacular cells* insulate the receptor cells from one another and extend microvilli, rather than cilia, into the mucus. These cells contribute to the mucus of the region and may be involved to some degree in deactivating odorants and xenobiotic agents. The function of the ~ 600,000 *microvillar cells* located at the epithelial surface is unknown. Although earlier workers reported that an axon-like process projects from these cells to the olfactory bulb,[3] more recent studies have been unable to confirm such a projection.[4] *Bowman's*

*It should be noted that humans possess elements of two other intranasal neural systems in addition to CN I: the nervus terminalis or terminal nerve (CN O) and the trigeminal nerve (CN V). CN O, known for its high gonadotropin-releasing hormone content, is apparently unresponsive to volatile chemicals. Chemically induced CN V sensations include coolness, sharpness, and warmth. Although a rudimentary vomeronasal organ is present on each side of the base of the nasal septum in most persons, this organ is nonfunctional. Despite reports of chemically induced local potentials within this structure, it has no neural connection with the central nervous system, and no accessory olfactory bulb exists in humans.

glands are a major source of the mucus in the olfactory region, whereas the *globose and horizontal basal cells* are the progenitor cells of the other cell types[2] (Figure 27–1).

Olfactory Bulb and Olfactory Cortex The first processing station in the olfactory system, the olfactory bulb, is located directly over the cribriform plate. Its neural components are arranged in six concentric layers: the olfactory nerve, glomerular, external plexiform, mitral cell, internal plexiform, and granule cell (Figure 27–2). The receptor cell axons of the olfactory nerve layer enter the glomeruli within the second layer of the bulb, where they synapse with the dendrites of the mitral and tufted cells within the spherical glomeruli. These second-order cells, in turn, send collaterals that synapse within the periglomerular and external plexiform layers, resulting in "reverberating" circuits in which negative and positive feedback occur. Indeed, mitral cells modulate their own output by activating granule cells (which are inhibitory to them). Whereas the olfactory bulbs of younger persons have thousands of glomeruli arranged in single or double layers within the glomerular layer, older persons typically have far fewer numbers of glomeruli, reflecting the decrease in olfactory receptor cell numbers within the epithelium. After the age of 80 years, such structures are nearly absent.[5,6]

The mitral and tufted cell axons project ipsilaterally to the primary olfactory cortex via the olfactory tract without an intervening thalamic synapse. The primary olfactory cortex is comprised of the anterior olfactory nucleus (AON), piriform cortex, olfactory tubercle, entorhinal area, periamygdaloid cortex, and corticomedial amygdala. Some projections occur, via the anterior commissure, from pyramidal cells of the AON to contralateral elements of the primary olfactory cortex. A number of projections from primary to secondary (ie, orbitofrontal) cortex are direct, whereas others relay within the thalamus. Recent functional imaging studies have found that odors reliably and significantly activate, in a concentration-dependent manner, posterolateral areas of the cerebellum, whereas sniffing alone tends to activate mainly anterior central cerebellar regions.[7] The cerebellar activity may reflect the circuits involved in modulating sniff size relative to the intensity of an odor or other movement-related behaviors.

Olfactory Transduction Humans can detect and discriminate among thousands of airborne odorants. Ten to 15% of the incoming air stream is shunted toward the olfactory cleft during inhalation (Figure 27–3). Some of the odorant molecules within this deflected air stream move from the air to the largely aqueous phase of the olfactory mucus, where they diffuse or are actively transported via "odorant binding proteins" to the olfactory receptors. Receptor activation then leads to transduction

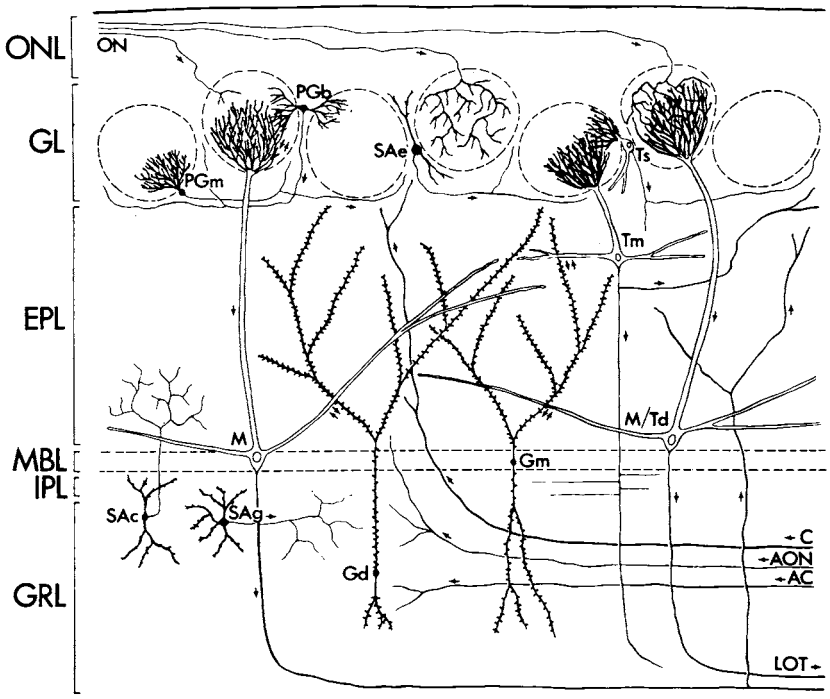

FIGURE 27–2. Diagram of major layers and types of olfactory bulb neurons in the mammalian olfactory bulb, as based on Golgi-stained material. Main layers are indicated on the left as follows: ONL = olfactory nerve layer; GL = glomerular layer; EPL = external plexiform layer; MBL = mitral cell body layer; IPL = internal plexiform layer; GRL = granule cell layer; ON = olfactory nerves; PGb = periglomerular cells with biglomerular dendrites; PGm = periglomerular cell with monoglomerular dendrites; SAe = short axon cell with extraglomerular dendrites; M = mitral cell; M/Td = displaced mitral or deep tufted cell; Tm = middle tufted cell; Ts = superficial tufted cell; Gm = granule cell with cell body in mitral cell body layer; Gd = granule cell with cell body in deep layers; SAc = short axon cell of Cajal; SAg = short axon cell of Golgi; C = centrifugal fibers; AON = fibers from anterior olfactory nucleus; AC = fibers from anterior commissure; LOT = lateral olfactory tract. cascades that produce action potentials within the olfactory receptor neurons.

Most olfactory receptors are representatives of a large (~ 1,000) multigene family of G protein–coupled seven-transmembrane receptors.[9] Each olfactory receptor neuron seems to express only one type of receptor, and neurons expressing the same gene appear randomly distributed within a few segregated strip-like "spatial zones" of the neuroepithelium, at least in the rodent. Each receptor binds a number of odorant molecules, although not all odorant molecules activate all receptors. Since the olfactory neurons that express a given receptor gene project to the same glomeruli of the olfactory bulb,[10] the glomeruli can be considered functional units. Data from a variety of sources suggest that it is the pattern across the activated receptors or glomeruli that serves as the proximal code for odorant quality.

The stimulatory guanine nucleotide-binding protein, G_{olf}, is activated by most olfactory receptor proteins.[11] In turn, G_{olf} induces production of the second messenger cyclic adenosine monophosphate by activating the enzyme adenyl cyclase. Cyclic adenosine monophosphate then diffuses through the cytoplasm, producing cellular depolarization by opening cyclic nucleotide–gated ionic channels and Ca^{2+}-dependent Cl^- or K^+ channels. Cyclic guanosine monophosphate is also activated by some odorants. It appears, among other things, to modulate the sensitivity of olfactory receptor neurons during adaptation.[12] G proteins other than G_{olf} (eg, G_{i2} and G_o) are present in olfactory receptor cells and aid in axonal

signal propagation, axon sorting, target innervation, and other such processes.[14]

Receptor Cell Regeneration The olfactory neuroepithelium has the ability to regenerate, although in cases in which significant damage to the basement membrane has occurred, regeneration is nonexistent or incomplete. Although, under normal circumstances, relatively continuous neurogenesis occurs within basal segments of the epithelium, many receptor cells are relatively long lived and appear to be replaced only after they are damaged.[15] Receptor cell death, as well as replenishment from progenitor cells, is determined by both endogenous and exogenous factors.[16] For example, differentiated neurons send regulatory signals that program the numbers of new neurons that need to be produced by the stem cells to maintain equilibrium in the cell population.[17] Apoptotic cell death occurs in cells representing all stages of regeneration, implying that biochemical regulation of neuronal numbers occurs at multiple stages of the neuronal lineage.[18]

Classification of Olfactory Disorders

Smell dysfunction can be reliably classified as follows: *anosmia*: inability to detect olfactory sensations (ie, absence of smell function); *partial anosmia*: ability to perceive some, but not all, such sensations; *hyposmia* or *microsmia*: decreased sensitivity to odors; *hyperosmia*: abnormally acute smell function; *dysosmia*: distorted or perverted smell perception to odor stimulation (sometimes termed cacosmia or parosmia, depending on the nature of the perversion); *phantosmia*: a dysosmic sensation perceived in the absence of an odor stimulus (ie, an olfactory hallucination); and *olfactory agnosia*: inability to recognize an odor sensation even though olfactory processing, language, and general intellectual functions are essentially intact, as in some stroke patients. Olfactory dysfunction can be either bilateral (binasal) or unilateral (uninasal), although, most commonly, such dysfunction is bilateral. Although presbyosmia is sometimes used to describe smell loss owing to aging, this term is less specific than those noted above (ie, it does not distinguish between anosmia and hyposmia) and is laden, by definition, with the notion that it is age per se that is causing the age-related deficit.

Clinical Evaluation of Olfactory Function

Three steps are involved in assessing a patient with chemosensory dysfunction: (1) obtaining a detailed clinical history, (2) testing olfactory function quantitatively, and (3) physically examining the head and neck.[19,20]

History Usually, precipitating antecedent events, such as head trauma, viral upper respiratory infections, allergies, toxic exposures, or iatrogenic (eg, operative) interventions, provide a basis for establishing causality, although in some patients a determination of the basis of the problem is complicated. When a clear-cut cause is not apparent, the clinician must explore a number of potential avenues to ascertain likely causal events or combinations of causal events. It is essential that potential underlying medical conditions known to have chemosensory consequences (eg, renal failure, liver disease, hypothyroidism, diabetes, or dementia) be identified

or ruled out. Questions regarding epistaxis, discharge (clear, purulent or bloody), nasal obstruction, allergies, and somatic symptoms, including headache or irritation, may have localizing value. A review of the history of tobacco, alcohol, or recreational drug use may also provide clues to etiology (eg, chronic alcoholism or Wernicke-Korsakoff syndrome). A detailed assessment of the medications being used prior to and during the onset of the dysfunction is important as many common medications (eg, antihypertensive and antilipid agents, antibiotics) can produce smell or taste disturbances. Importantly, medication-induced deficits may take some time to appear, so simply because a patient has been taking a drug for some time does not rule out its possible etiologic involvement. Likewise, some medication-induced alterations do not disappear immediately on drug cessation.

Specifics concerning the nature, timing of onset, and duration and pattern of fluctuations, if any, of the patient's chemosensory symptoms should be obtained. For example, *sudden olfactory loss* suggests the possibility of head trauma, infection, ischemia, or a psychogenic condition. *Gradual loss* can reflect the development of degenerative processes, progressive obstructive lesions or tumors within the olfactory receptor region or more central neural structures. *Intermittent loss* can be indicative of an intranasal inflammatory process.[20]

A family history of smell dysfunction may suggest a genetic basis. Delayed puberty in association with anosmia (with or without midline craniofacial abnormalities, deafness, and renal anomalies) suggests the possibility of Kallmann's syndrome or some variant thereof. Subtle signs of central tumors, dementia, parkinsonism, and seizure activity (eg, automatisms, occurrence of blackouts, auras, and déjà vu perceptions) should be sought in both the history and the physical examination.

Quantitative Olfactory Testing Many patients are inaccurate in describing their chemosensory function; some are unaware of a chemosensory deficit, whereas others overstate the nature of their problem. Hence, one should employ modern means for quantitatively assessing olfactory function in the office setting. Reliable quantitative testing is needed to (1) verify the validity of the patient's complaint, (2) characterize the exact nature and degree of the problem, (3) accurately monitor changes in function over time (including those resulting from therapeutic interventions), (4) detect malingering, and (5) obtain an objective basis for determining compensation for disability. In the past, many physicians have tested olfaction by simply asking the patient to identify several crude odorants, such as licorice, coffee grounds, or tobacco, placed under the nose. Unfortunately, such qualitative testing can lead to false positives (eg, patients have difficulty identifying odors without response alternatives), lacks reliability, has no normative reference, and is easily faked by malingerers.

During the last two decades, a number of standardized and practical psychophysical tests have been developed.[21] The most widely used test is the 40-item University of Pennsylvania Smell Identification Test (UPSIT; commercially known as the Smell Identification Test™; Figure 27–4).[22] This reliable (test–retest $r = .94$) test employs microencapsulated ("scratch and sniff") odorants and is available in English-, French-, German-, and Spanish-language versions. It can be self-administered in 10 to 15 minutes in the waiting room by most patients and scored in less than a minute by nonmedical personnel. In addition to providing a percentile rank of a patient's performance relative to age- and sex-matched controls, an absolute determination of normosmia, mild microsmia, moderate microsmia, severe microsmia, anosmia, or probable malingering can be made.

In some cases, unilateral testing is warranted, although usually olfactory problems are bilateral. To assess olfaction unilaterally, the naris contralateral to the tested side should be occluded without distorting the nasal valve region. This can be easily accomplished by sealing the contralateral naris using a piece of Microfoam™ tape (3M Corporation, Minneapolis, Minnesota) cut to fit the naris borders (Figure 27–5). The patient is instructed to sniff the stimulus normally and to exhale through the mouth. Such occlusion not only prevents air from entering the olfactory cleft from the contralateral naris (orthonasal stimulation), it also prevents active movement of odor-laden air into the occluded side from the nasopharynx on exhalation (retronasal stimulation).

The measurement of olfactory event-related potentials (OERPs) is available in only a few specialized centers. In essence, synchronized brain electroencephalographic (EEG) activity induced by repeated pulsatile presentations of an odorant is iso-

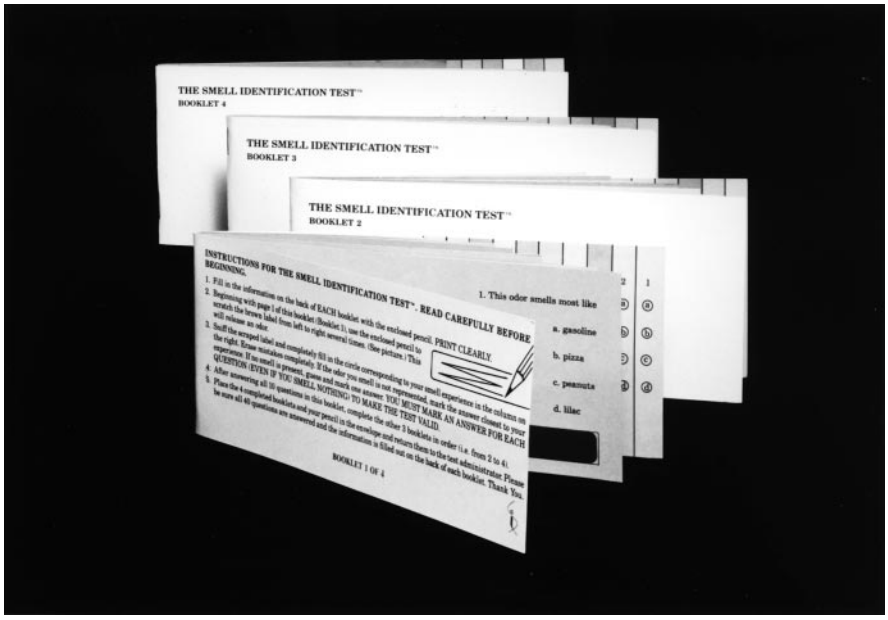

FIGURE 27–4. The four booklets of the 40-odorant University of Pennsylvania Smell Identification Test (UPSIT; commercially known as the Smell Identification Test™). Each page of each 10-page booklet contains a microencapsulated odorant that is released by means of a pencil tip and a multiple-choice question as to which of four possibilities smells most like the odorant. Forced-choice answers are recorded on columns on the last page of the test. Courtesy of Sensonics, Inc., Haddon Heights, New Jersey. Copyright © 2000, Sensonics, Inc.

lated from overall EEG activity. Averaging of responses from repetitive stimulation increases the signal-to-noise ratio. Although OERPs are relatively sensitive and useful in detecting malingering, they are presently unable to localize where in the olfactory pathway an anomaly exists, unlike their visual and auditory counterparts. Unfortunately, OERP testing requires specialized and expensive equipment capable of delivering odorant pulses with rapid rise times (~ 30 to 40 ms) to the olfactory neuroepithelium within a background of continuously flowing warmed and humidified air without inducing confounding somatosensory sensations.[23]

The electro-olfactogram (EOG) is another electrophysiologic measure of the olfactory system.[24] This surface potential, detected via an electrode placed on the surface of the olfactory neuroepithelium, reflects summated generator potentials mainly from olfactory receptor neurons. The recording of the EOG is, from a practical perspective, often more difficult than that of the OERP, and far fewer patients are amenable to such recording. The placement of the recording electrode is under endoscopic guidance, but since local anesthesia must be avoided, the placement of the electrode can be quite unpleasant, and sneezing and mucous discharge are common. Importantly, even after the electrode has been placed within the region of the olfactory epithelium, it cannot be recorded in many subjects. This may reflect the topographic distribution of specific olfactory receptors in combination with the relatively few odorants used or the presence of metaplasia of respiratory-like epithelium within the olfactory epithelium.

Physical Examination, Laboratory Tests, and Medical Imaging Careful otolaryngologic and neurologic assessment is warranted in patients complaining of olfactory dysfunction.[19,20] Visual field and acuity tests, as well as optic disk examinations, should be performed to determine whether intracranial mass lesions that produce increased intracranial pressure, papilledema, and optic atrophy are present (eg, Foster Kennedy syndrome, which consists of ipsilateral anosmia, ipsilateral optic atrophy, and contralateral papilledema owing to a meningioma of the ipsilateral optic nerve). With nasal endoscopy, employing both flexible and rigid endoscopes, specific attention should be paid to the olfactory meatal area. The nasal secretions should be carefully evaluated, as well as the color, swelling, surface texture, inflammation, erosion, ulceration, and atrophy of the nasal mucosa. Mucopus below the eustachian tube orifice suggests involvement of the osteomeatal complex, whereas mucopus above this orifice suggests posterior ethmoid and/or sphenoid sinus disease. Masses, polyps, and adhesions of the turbinates to the septum may all compromise airflow to the

olfactory receptor region. Unusual spaciousness, dryness, and crusting, as seen in atrophic rhinitis, suggest atrophy of the lamina propria. A pale mucous membrane can be indicative of allergy, usually resulting from edema within the lamina propria. Industrial or environmental pollutants, as well as excessive tobacco smoking, can produce metaplasia within the epithelium, in addition to swelling, inflammation, exudates, erosion, and ulceration.

Blood, serum, or other laboratory tests may help to identify or confirm underlying medical conditions that may relate to the dysfunction, including infection, nutritional deficiencies (eg, vitamins B_6 and B_{12}), allergy, diabetes mellitus, and thyroid, liver, and kidney disease. Although biopsies of the olfactory epithelium can be made, their interpretation is hindered by sampling issues and the fact that metaplasia of respiratory-like epithelium occurs throughout the olfactory epithelia even of persons with normal olfactory function.

Medical imaging can be invaluable in understanding the basis of a number of smell and taste disturbances. Magnetic resonance imaging (MRI) is the method of choice for evaluating soft tissue (eg, olfactory bulbs, tracts, and cortical parenchyma). Computed tomography (CT) is the most useful and cost-effective technique to assess sinonasal tract inflammatory disorders and is superior to MRI in the evaluation of bony structures adjacent to the olfactory pathways (eg, ethmoid, cribriform plate). Coronal CT scans are particularly useful in evaluating paranasal anatomy. Plain radiographs have substantial limitations and are rarely useful. Positron emission tomography, functional MRI (fMRI), and single-proton emission CT have limited usefulness at the present time outside of research institutions.

Detection of Malingering

Traditionally, it has been suggested that malingering can be detected reliably by having a patient inhale a strong CN V stimulant, such as ammonia, and asking the patient whether a smell is perceived. If denial occurs, the assumption is made that malingering is present. Unfortunately, this procedure is unreliable since usually CN V stimulants produce reflexive coughing, secretion from nasal mucous membrane, or other rejection reactions that the patient obviously cannot deny. Furthermore, CN V thresholds vary considerably, such that some patients experience little reaction to the ammonia and truthfully report perceiving no sensations.

A preferred method of the detection of malingering is to employ forced-choice psychophysical tests, such as the UPSIT. On such tests, malingering appears as the reporting of fewer correct responses than expected on the basis of chance (as would be expected in an anosmic). Since, in the case of the UPSIT, there are four response alternatives for each item and the patient must provide an answer even if no smell is perceived, 25% of the items, on average, should be correctly identified by chance alone (ie, 10 of 40). A sampling distribution exists around this expected probability, and empirical data are available on this point.[22,25] The theoretical probability of a true anosmic having an UPSIT score of 5 or less is less than 5 in 100. The theoretical probability of a true anosmic scoring 0 on the UPSIT is less than 1 in 100,000.[22] In general, if a patient scores within the probable malingering region of UPSIT scores, the UPSIT should be administered again to confirm the apparent avoidance of correct responses. Multiplication of the two probabilities is then used to establish

the statistical likelihood of malingering. Malingering is also suspected if the patient reports smell loss in the presence of a clear OERP, although olfactory agnosia in such cases cannot be ruled out.

It is noteworthy that malingering is sometimes discovered in head injury patients by their scores on forced-choice taste tests, rather than their scores on forced-choice smell tests, since bona fide smell loss is, in fact, present (negating the ability to avoid correct answers on the olfactory element of the examination). Such malingering implies relatively normal taste function and reflects the patient's naive attempt to embellish the "taste loss" that, in fact, results from lack of retronasal stimulation of the olfactory receptors.

Evidence for a general tendency to malinger can also be obtained using neuropsychological tests specifically designed for this purpose, for example, tests sensitive to head trauma patients trying to feign memory disturbances. Among those that are widely used is Rey's Memory Test (RMT), also known as Rey's 3 × 5 Test, and the Rey 15-item Memory Test.[26] The rationale behind this test is that malingerers typically fail at a memory task that all but the most developmentally disabled or severely brain-injured persons perform easily.

Causes of Olfactory Dysfunction

Olfactory dysfunction can result from three general causes: (a) *conductive* or *transport impairments* from nasal passage obstruction (eg, by chronic rhinosinusitis, polyposis, excessive mucus secretion, etc), (b) *sensorineural impairment* from injury to the olfactory neuroepithelium (eg, by viruses, airborne toxins, etc), and (c) *central olfactory neural impairment* from injury to CNS structures (eg, tumors, masses impinging on the olfactory tract, etc). These categories, however, are not mutually exclusive. For example, both blockage of airflow to the receptors and damage to the receptors and/or more central elements of the olfactory system can be simultaneously present or occur in stages. Thus, chronic rhinosinusitis can produce damage to the olfactory neuroepithelium in addition to blocking airflow, and altered neuroepithelium function can, over time, lead to degeneration within the olfactory bulb, a central structure.

There are numerous causes of olfactory disturbance (Table 27–1). Most cases of chronic anosmia or hyposmia are attributable to previous upper respiratory infections, head trauma, and nasal and paranasal sinus disease, reflecting long-lasting or permanent damage to the olfactory neuroepithelium.[27] Other causes include intranasal neoplasms (eg, inverting papillomas, hemangiomas, and esthesioneuroblastomas), intracranial tumors or lesions (eg, olfactory groove meningiomas, frontal lobe gliomas), neurologic diseases (eg, AD, idiopathic PD, multiple sclerosis [MS], schizophrenia), exposure to airborne toxins (including cigarette smoke), iatrogenic interventions (eg, septoplasty, rhinoplasty, turbinectomy, radiation therapy, medications), epilepsy, psychiatric disorders, and various endocrine and metabolic disorders.[†] The more common disorders or entities associated with smell loss are described in detail later in this section.

Most dysosmias reflect dynamic changes in the olfactory epithelium and remit over time.[27,28] Many anosmic patients report that prior to onset of their anosmia, they experienced a period of weeks or months when dysosmia was present. Usually, some smell function is present during the period of dysosmia. In rare instances, dysosmias present as aura-like hallucinations presumably associated with central (eg, temporal lobe) dysfunction. In many such cases, no seizure activity can be documented, and no evidence of CNS lesions or tumors is apparent. Nonetheless, low doses of anticonvulsant medication may be effective in mitigating the frequency and severity of some of these dysosmias. Dysosmias can also occur in a number of neurologic or psychiatric

[†]It has long been known that exogenous agents, including a number of neurotropic viruses, can enter the CNS from the nasal cavity via the olfactory nerve cells and that cauterization of the olfactory neuroepithelium can protect against infection from viruses instilled either intranasal or systemically.[29,30] In fact, otolaryngologists in the late 1930s prophylactically sprayed the noses of schoolchildren with zinc sulfate during poliomyelitis outbreaks.[31] The "olfactory vector hypothesis" has been proposed as an explanation for both the olfactory loss and the cause of several common neurologic diseases.[32–35]

TABLE 27–1. Agents, Diseases, Drugs, Interventions, and Other Etiologic Categories Associated in the Medical or Toxicologic Literature with Olfactory Dysfunction.*

- Air Pollutants and Industrial Dusts
  - Acetone
  - Acids (eg, sulfuric)
  - Ashes
  - Benzene
  - Benzol
  - Butyl acetate
  - Cadmium
  - Carbon disulfide
  - Cement
  - Chalk
  - Chlorine
  - Chromium
  - Coke/coal
  - Cotton
  - Cresol
  - Ethyl acetate
  - Ethyl and methyl acrylate
  - Flour
  - Formaldehyde
  - Grain
  - Hydrazine
  - Hydrogen selenide
  - Hydrogen sulfide
  - Iron carboxyl
  - Lead
  - Nickel
  - Nitrous gases
  - Paint solvents
  - Paper
  - Pepper
  - Peppermint oil
  - Phosphorus oxychloride
  - Potash
  - Silicone dioxide
  - Spices
  - Trichloroethylene
- Drugs
  - Adrenal steroids (chronic use)
  - Amino acids (excess)
    - Cysteine
    - Histidine
  - Analgesics
    - Antipyrine
  - Anesthetics, local
    - Cocaine HCl
    - Procaine HCl
    - Tetracaine HCl
  - Anticancer agents (eg, methotrexate)
  - Antihistamines (eg, chlorpheniramine malate)
  - Antimicrobials
    - Griseofulvin
    - Lincomycin
    - Macrolides
    - Neomycin
    - Pencillins
    - Streptomycin
    - Tetracyclines
    - Tyrothricin
  - Antirheumatics
    - Mercury/gold salts
    - D-Penicillamine
  - Antithyroids
    - Methimazole
    - Propylthiouracil
    - Thiouracil
  - Antivirals
  - Cardiovascular/antihypertensives
  - Gastric medications
    - Cimetidine
  - Hyperlipoproteinemia medications
    - Atorvastatin calcium (Lipitor)
    - Cholestyramine
    - Clofibrate
  - Intranasal saline solutions with
    - Acetylcholine
    - Acetyl-β-methacholine
    - Menthol
    - Strychnine
    - Zinc sulfate
  - Local vasoconstrictors
  - Opiates
    - Codeine
    - Hydromorphone HCl
    - Morphine
  - Sympathomimetics
    - Amphetamine sulfate
    - Fenbutrazate HCl
    - Phenmetrazine theoclate
- Endocrine/Metabolic
  - Addison's disease
  - Congenital adrenal hyperplasia

TABLE 27–1. *(continued)*

Endocrine/Metabolic *(continued)*
- Cushing's syndrome
- Diabetes mellitus
- Fröhlich's syndrome
- Gigantism
- Hypergonadotropic hypogonadism
- Hypothyroidism
- Kallmann's syndrome
- Pregnancy
- Panhypopituitarism
- Pseudohypoparathyroidism
- Sjögren's syndrome
- Turner's syndrome

Hallucinogenic Agents
- Lysergic acid diethylamide
- Psilocybin

Infections—Viral/Bacterial/Parasitic
- Acquired immune deficiency syndrome (AIDS)
- Acute viral rhinitis
- Bacterial rhinosinusitis
- Bronchiectasis
- Fungal
- Influenza
- Rickettsial
- Microfilarial

Lesions of the Nose/Airway Blockage
- Adenoid hypertrophy
- Allergic rhinitis
  - Perennial
  - Seasonal
- Atrophic rhinitis
- Chronic inflammatory rhinitis
- Hypertrophic rhinitis
- Nasal polyposis
- Rhinitis medicamentosa
- Structural abnormality
  - Deviated septum
  - Weakness of alae nasi
- Vasomotor rhinitis

Medical/Surgical Interventions
- Adrenalectomy
- Anesthesia
- Anterior craniotomy
- Arteriography
- Chemotherapy
- Frontal lobe resection
- Gastrectomy
- Hemodialysis
- Hypophysectomy
- Influenza vaccination
- Laryngectomy
- Oophorectomy
- Paranasal sinus exenteration
- Radiation therapy
- Rhinoplasty
- Temporal lobe resection
- Thyroidectomy

Neoplasms—Extranasal and Extracranial
- Breast
- Gastrointestinal tract
- Laryngeal
- Lung
- Ovary
- Testicular

Neoplasms—Intracranial
- Frontal lobe gliomas and other tumors
- Midline cranial tumors
  - Parasagittal meningiomas
  - Tumors of the corpus callosum
- Olfactory groove/cribriform plate meningiomas
- Osteomas
- Paraoptic chiasma tumors
  - Aneurysms
  - Craniopharyngioma
  - Pituitary tumors (especially adenomas)
  - Suprasellar cholesteatoma
  - Suprasellar meningioma
- Temporal lobe tumors

Neoplasms—Intranasal
- Neuro-olfactory tumors
  - Esthesioepithelioma
  - Esthesioneuroblastoma
  - Esthesioneurocytoma
  - Esthesioneuroepithelioma
- Other benign or malignant nasal tumors
  - Adenocarcinoma
  - Leukemic infiltration
  - Nasopharyngeal tumors with extension
  - Neurofibroma
  - Paranasal tumors with extension
  - Schwannoma

disturbances, which are usually diagnosed on other grounds (eg, psychosis, MS). Infrequently, dysosmia may be owing to the perception of foul odors produced by the body, such as those from purulent nasal secretions in sinusitis or from exhalations in halitosis or uremia. Other disorders that may present as dysosmia include trimethylaminuria (fish odor syndrome) and cat odor syndrome, a pediatric neurologic disorder associated with a ß-methylcrotonyl-CoA carboxylase deficiency. Such rare disorders usually exist in the presence of a normally functioning olfactory system.

In contrast to cases of anosmia, hyposmia, and dysosmia, cases of hyperosmia are rare. Although untreated adrenal cortical insufficiency has been reported to produce hyperosmia in humans, this finding has yet to be confirmed, and no evidence for hypersensitivity following adrenalectomy has been found in animal studies.[37] There have been suggestions of hyperosmia in syndromes such as multiple chemical sensitivity, but the limited data available also fail to support this notion.[38] Hyperosmia reportedly occurs in some cases of epilepsy during the interictal period, although most patients with

long-term epilepsy and intractable seizure activity, such as candidates for temporal lobe resection, are hyposmic.[39]

Upper Respiratory Infections Upper respiratory system viruses (eg, influenza, colds) are the most common cause of *permanent* smell loss in adulthood.[27] Factors that predispose individuals to virus-induced smell dysfunction and the mechanisms underlying it remain unclear, although direct insult to an already compromised neuroepithelium is most likely, and, in rare cases, central structures may also become involved. If neural damage is present, topical or systemic corticosteroid treatment is ineffective. Reduced numbers of olfactory receptor cells and other epithelial abnormalities are commonly found in biopsies taken from the olfactory epithelia of patients with postviral anosmia or hyposmia.

Head Trauma Smell loss or distortion occurs in ~ 15% of patients with significant head trauma but can be present even in mild cases in which rapid acceleration/deceleration of the brain has occurred (coup contra coup injury) (Figure 27–6). In general, the severity of trauma is roughly correlated with the degree of loss. Occipital blows tend to produce more frequent and more severe olfactory deficits than frontal blows.[40] The physiologic mechanisms involved include shearing of the olfactory fila and contusions of the olfactory bulb and frontal and temporal poles.[41] Although the cribriform plate may become fractured in some cases, such fractures are not a prerequisite for smell loss.[40] In a recent study of 268 patients evaluated at the University of Pennsylvania Smell and Taste Center who had experienced head trauma, 66.8% had anosmia and 20.5% hyposmia. Of 66 patients retested 1 month to 13 years later, only 3, none of whom initially had anosmia, regained normal olfactory function. Dysosmia prevalence decreased from 41.1 to 15.4% over post-trauma periods averaging several years.[40]

Even though the loss of smell following head trauma is usually immediate, this is not always the case, and it may take the patient a while to recognize the presence of the loss. In some cases, delayed loss reflects delayed receptor cell death. Rodent research shows that intracranial hemorrhage and ischemia can lead to degeneration of the olfactory epithelium without transection of the olfactory nerves.[42]

Nasal and Sinus Disease It is now apparent that the olfactory loss associated with nasal or sinus disease is not solely caused by decreased conduction of airflow to the olfactory receptors. Although medical (eg, administration of topical or systemic corticosteroids) or surgical (e.g., excision of polyps) treatment can improve olfactory function in some cases, return to normal levels is not the norm.[43] In the case of rhinosinusitis, for example, factors other than, or in addition to, nasal airflow blockage are responsible for the loss. Chronic inflammation is, in fact, likely toxic to olfactory neurons. Hence, many cases of rhi-

nosinusitis have a significant sensorineural component. The severity of histopathology within the olfactory epithelium of chronic rhinosinusitis patients is correlated with the degree of smell loss, as measured by the UPSIT.[44] Olfactory biopsies from patients with nasal disease are less likely to yield olfactory epithelial tissue than biopsies from controls.[45] The same is true for anosmic versus nonanosmic rhinosinusitis patients.[46]

Central Nervous System Neoplasms Olfactory disturbances can arise from tumors impinging on the olfactory bulbs or tracts, such as frontal lobe gliomas, olfactory groove meningiomas, and suprasellar ridge meningiomas arising from the dura mater of the cribriform plate, as well as from tumors on the floor of the third ventricle, pituitary tumors extending above the sella turcica, and tumors in the temporal lobe or uncinate convolution.[19] Foster Kennedy syndrome can result from tumors impinging on the bulb or tract.[47] *Pseudo* Foster Kennedy syndrome has been found in patients with increased intracranial pressure who had previous unilateral optic atrophy.[48]

Aging Age-related smell loss is well documented and occurs in most older people, including those who are healthy and taking no medications (Figure 27–7).[49] Such loss clearly impacts on the quality of life of the elderly, influencing nutrition, appetite, and, possibly in some cases, even general immunity and defensive responses to illnesses.[50,51] About one half of the population between 65 and 80 years of age experiences significant decrements in the ability to smell. Over the age of 80, this figure rises to nearly 75%. This is in marked contrast to persons under the age of 65 years, of whom only 1 to 2% suffers from major difficulty smelling.[49]

Despite the association with age, smell loss in the later years should not be attributed simply to age, per se, as often an accumulation of damage over the years is the culprit, and a single event, such as a bad cold, can be the precipitating factor. In general, the age-related changes in smell function reflect decrements in both olfactory receptors and the number of olfactory bulb glomeruli.[6] Interestingly, recent data suggest that age-related closure of cribriform plate foramina by ossification is common in skulls from older persons.[52] Whether other age-related factors increase the susceptibility of the epithelium to damage from exogenous agents is not clear.

Neurodegenerative and Other Neurologic Diseases An exciting chapter in the study of olfaction has been the discovery that a number of neurologic disorders are commonly accompanied by olfactory deficits, including AD, idiopathic PD, Huntington's disease, alcoholic Korsakoff's syndrome, Pick's disease, the parkinsonism dementia complex of Guam,

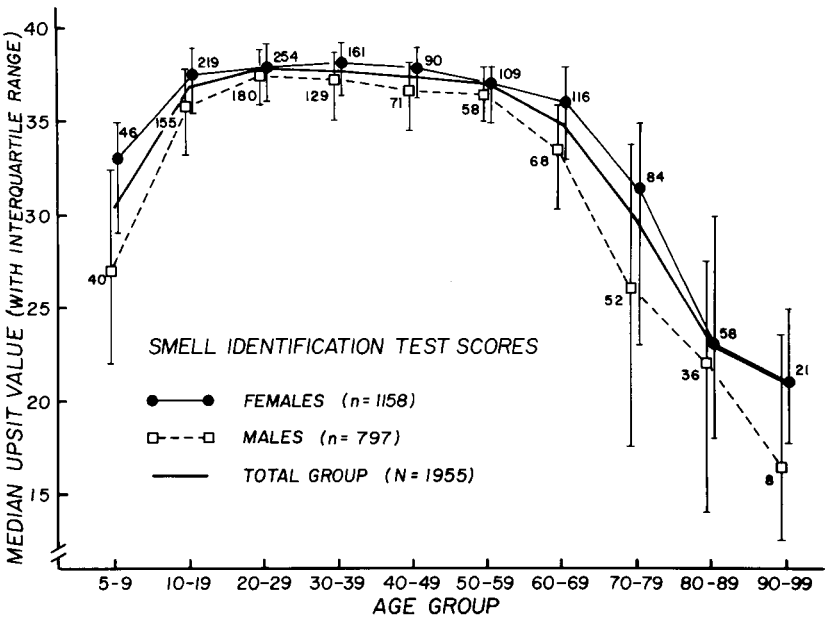

FIGURE 27–7. Scores on the University of Pennsylvania Smell Identification Test (UPSIT) as a function of age and gender in a large heterogeneous group of subjects. amyotrophic lateral sclerosis, schizophrenia, and MS.[32,53–55] Indeed, olfactory dysfunction appears to be the first clinical sign of AD and idiopathic PD.[56,57] Although usually considered a neurodevelopmental disorder, smell loss is present in patients with schizophrenia and appears to be correlated with disease duration, suggesting a possible degenerative component to this disorder in olfaction-related pathways.[55] It has recently been shown that patients with schizophrenia have much smaller olfactory bulbs and tracts than those of matched controls.[58]

Several studies provide data suggesting that smell testing is useful in identifying persons at risk for later significant cognitive decline or AD. Graves et al administered a 12-item abbreviated version of the UPSIT (termed the Brief-Smell Identification Test™ or B-SIT) and several cognitive tests to 1,985 Japanese American people around the age of 60 and then readministered these tests to 1,604 of these people 2 years later.[59] Sixty-nine percent of the follow-up participants were genotyped for apolipoprotein E (apoE). Low B-SIT scores in the presence of one or more APOE-epsilon 4 alleles were associated with a very high risk of subsequent cognitive decline, and the B-SIT identified persons who later came to exhibit cognitive decline better than a global cognitive test did.

More recently, the UPSIT was administered by Devanand et al to 90 outpatients with mild cognitive impairment and to matched healthy controls at 6-month intervals over a 5-year period.[60] Patients with mild cognitive impairment had lower UPSIT scores than did controls. Most importantly, patients with low UPSIT scores (< 34) were more likely to develop AD than the other patients. Low UPSIT scores, combined with lack of awareness of olfactory deficits on the part of the patients, predicted the time to development of AD. UPSIT scores from 30 to 35 showed moderate to strong sensitivity and specificity for diagnosis of AD at follow-up.

The underlying cause for the olfactory deficit of AD is not yet clear, even though AD is associated with loss of neurons in the anterior olfactory nucleus, olfactory bulb, and layer II of the entorhinal cortex.[32,61] Disproportionate numbers of neurofibrillary plaques and tangles are found within limbic brain regions that receive olfactory bulb projections. Central cholinergic deficits may also be involved since (1) individuals with no history of cognitive loss who are in the early histopathologic stages of AD exhibit a cholinergic deficit within the inferior temporal lobe and (2) drugs that alter cholinergic function alter the ability to smell. For example, the cholinesterase inhibitor physostigmine improves odor discrimination performance, at least in rats,[62] whereas scopolamine, a muscarinic cholinergic antagonist, reportedly decreases olfactory sensitivity in humans.[63]

In idiopathic PD, bilateral olfactory deficits occur early on in the disease, such as at the onset of hemiparkinsonism, and occur at a higher frequency than some cardinal signs of this disorder (eg, tremor).[57] The olfactory impairment is unrelated to use of antiparkinsonian medications, duration of illness, and severity of the symptoms and signs, such as tremor, rigidity, bradykinesia, or gait disturbance.[64] Since smell loss is absent or infrequent in a number of other neurologic disorders that exhibit similar motoric signs, smell testing can aid in differential diagnosis in some cases.[32] For example, patients with essential tremor, progressive supranuclear palsy, multiple system atrophy, and parkinsonism induced by the proneurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine exhibit little or no olfactory dysfunction.[33] It is of interest that familial PD is also associated with olfactory impairment that occurs independently of the parkinsonian phenotype.[65]

It has generally been assumed that olfactory function in MS is normal since the axons of the primary olfactory receptors are unmyelinated. However, myelin is present in other segments of the olfactory pathway, and we have recently shown that, at any one time, about a third of MS patients exhibit some degree of smell loss.[66] Furthermore, we have found that the degree of olfactory loss is directly related to the number of MRI-determined plaques in central brain regions associated with olfactory processing (eg, inferior middle temporal lobe and periorbital frontal cortex) (Figure 27–8).[54,66] Indeed, a seemingly one-to-one longitudinal association is present between UPSIT scores and changes in plaque load over time (Figure 27–9),[67] implying that olfactory function waxes and wanes as the plaque numbers increase and decrease. In effect, knowledge of a patient's UPSIT score accurately predicts the plaque load in the olfaction-related regions and vice versa.

Exposure to Neurotoxic Agents A number of environmental and industrial chemicals have been linked to olfactory dysfunction, including acrylates,

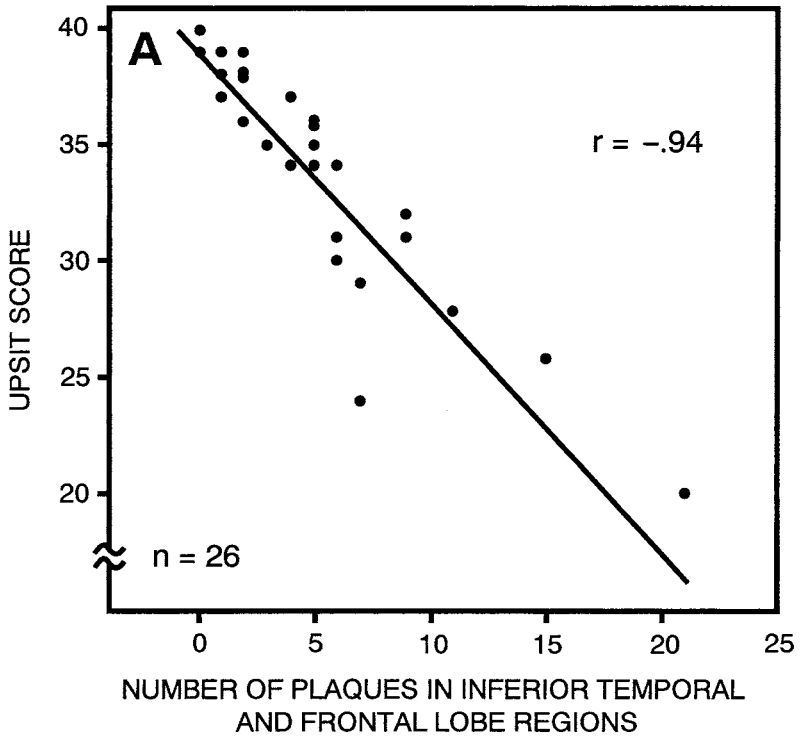

FIGURE 27–8. Relationship between the number of multiple sclerosis–related plaques in subtemporal and subfrontal lobes and scores on the University of Pennsylvania Smell Identification Test (UPSIT). No such relationship was present between UPSIT scores and plaques in brain regions outside of the primary olfactory cortical areas ($r = –.08$). Reproduced with permission from Doty RL, Li C, Mannon LJ, Yousem DM. Olfactory dysfunction in multiple sclerosis. N Engl J Med 1997;336:1918–9.

benzene, cadmium, cigarette smoke, formaldehyde, solvents, and nickel dust, among others, although few well-controlled studies exist in this area, and most reports are largely anecdotal.[68] In many cases, the decrements are specific to the exposed compounds and reflect long-term adaptation rather than damage to the olfactory receptors, being reversed after the worker is away from the workplace for a relatively short period of time. In the case of cigarette smoking, olfactory ability decreases as a function of cumulative smoking dose. Long-term cessation of smoking leads to a gradual improvement of olfactory function that is inversely related to the amount and duration of prior smoking activity.[69]

Other Causes As noted earlier in this chapter, medications commonly affect smell function and should be considered early in an evaluation, especially in the context of a new drug therapy (see Table 27–1). Olfactory hallucinations occur in mesial temporal lobe seizures and migraine, as well as in some other central brain lesion disorders. In epilepsy, the hallucinations are usually unpleasant and are rarely isolated events.[39]

Prognosis and Treatment of Olfactory Disorders

Prognosis seems to be better for patients with less severe deficits (ie, for patients with UPSIT scores > 25) than for those with severe microsmia or anosmia. This likely reflects, in cases having sensorineural damage, less extensive necrosis within the basal cell layer of the epithelia and possibly less fibrosis around the foramina of the cribriform plate that can prevent regeneration or appropriate migration of receptor axons to the bulb. It is important for many patients to know the true degree of olfactory loss, given that prognosis relates to the magnitude of the loss. Quantitative testing places the patient's problem into an overall perspective; thus, it can be very therapeutic for an older person to learn that although his or her smell function is not what it used to be, it still falls above the average of his or her peer group.

Treatments are available for some olfactory disorders owing to blockage of airflow to the olfactory neuroepithelium (ie, conductive disorders). Mechanical obstruction secondary to polyposis,

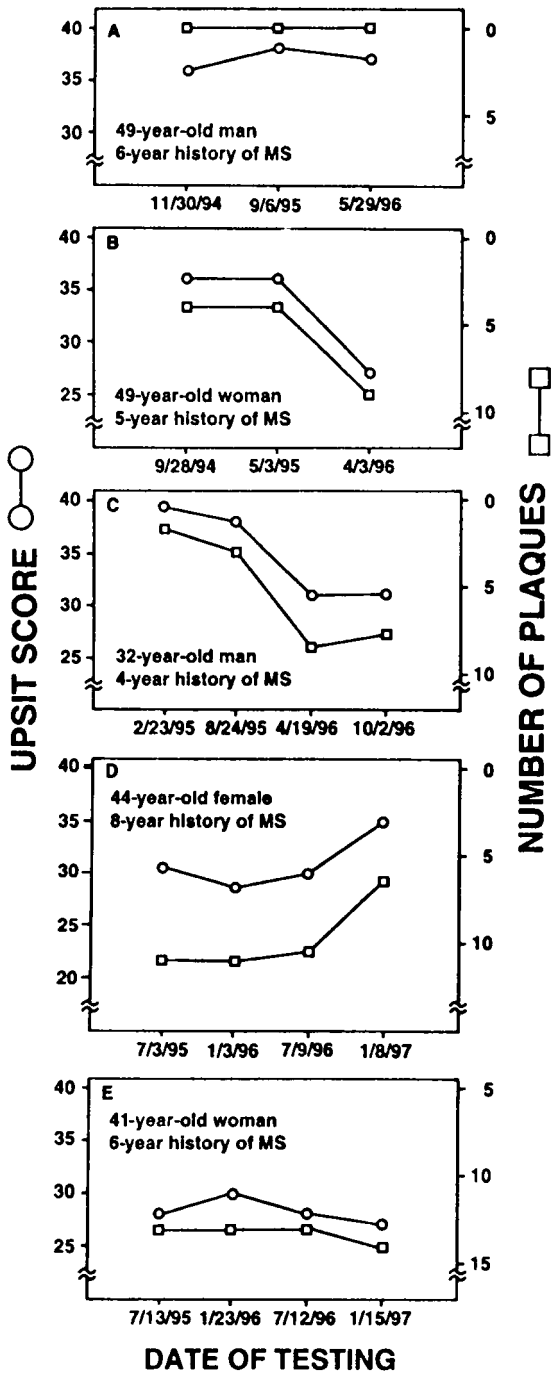

FIGURE 27–9. Longitudinal changes in University of Pennsylvania Smell Identification Test (UPSIT) scores and plaque numbers within the inferior frontal and inferior temporal lobe regions of five patients with multiple sclerosis (MS) (*A* to *E*). Note that the plaque number is inversely plotted. Also note the close association between the measures across time in all cases. intranasal tumors, and distorted intranasal architecture can often be corrected surgically, and inflammatory causes of nasal and sinus disease can often be addressed medically. However, quantitative olfactory testing is advised before and after the treatment to ensure an accurate assessment of the intervention and to assess relapse. Examples of treatments that have restored olfactory function in some patients include allergy management, topical and systemic corticosteroid therapies, antibiotic therapy, and various invasive interventions, including functional endoscopic sinus surgery. A brief course of systemic corticosteroid therapy can be useful in distinguishing between conductive and sensorineural olfactory loss as patients with the former will often respond positively to the treatment. Longer-term systemic corticosteroid therapy, however, is not advised. Topical nasal corticosteroids may be ineffectual in altering smell dysfunction because the corticosteroid fails to penetrate the higher recesses of the nose. Administering nasal drops or sprays in the head-down Moffett's position can sometimes increase efficacy.

Sensorineural causes of olfactory dysfunction are more difficult to manage. When spontaneous recovery occurs in head trauma patients whose loss reflects damage to the olfactory receptor cell axons, it typically does so within 3 or 4 months of the injury. Patients who quit smoking tobacco typically have dose-related improvement in olfactory function and flavor sensation over time,[69] although tobacco smoking by itself rarely causes complete loss of the sense of smell. Some *central olfactory neural impairments* (eg, tumors within the mesial temporal lobe or tumors that impinge on the olfactory bulbs or tracts) can, in some cases, be resected in a manner that allows for at least some restoration of olfactory function. Chitanondh reported successful treatment of seven patients with seizure disorder, olfactory hallucinations, and psychiatric problems by stereotactic amygdalotomy, concluding that "stereotactic amygdalotomy has a dramatic effect on olfactory seizures, auras, and hallucinations. It is a safe surgical procedure and can be done without neurological deficit."[70]

Some cases of extremely debilitating chronic dysosmia (usually of a number of years duration and often unilateral), in which weight loss is marked or daily functioning is markedly impaired, are amenable to surgical intervention (eg, ablation of regions of the olfactory epithelium or olfactory bulb

removal). Of the surgical approaches, intranasal ablation or stripping of tissue from the olfactory epithelium on the affected side is more conservative and less invasive than removal of the olfactory bulb and/or tract via a craniotomy.[71] Should the dysosmia reappear after intranasal intervention, additional or repeat ablations can be performed. In the majority of cases, demonstrable smell loss does not accompany the dysosmic condition, reiterating the requirement of at least some degree of olfactory system function for the dysosmic expression.

Discontinuance, dose changes, or substitution of other modes of therapy can be effective for some medications that induce distortions of olfaction. Although there are advocates for zinc and vitamin therapies, there is no compelling evidence that these therapies work, except in rare cases in which frank zinc or vitamin deficiencies are present.

THE GUSTATORY SYSTEM

Anatomy and Physiology

Such sensations as sweet, sour, bitter and salty, as well as possibly "metallic" (iron salts), "umami" (monosodium glutamate, disodium guanylate, disodium inosinate), and "chalky" (calcium salts), are mediated via the taste buds of the gustatory system. Unlike olfaction, taste sensations are carried by several cranial nerves (ie, CN VII, IX, X), as discussed in detail below. Because of this fact, complete loss of taste function is rare from peripheral insults or trauma (since all nerves would have to be involved) and is more likely owing to systemic or central causes. Intraoral CN V free nerve endings are also stimulated by some foods and beverages (eg, carbonated or spicy foods), contributing to the overall gestalt of flavor. Hence, a piece of milk chocolate in the mouth is not only sweet but has texture and temperature. The sensation of "chocolate," however, is dependent on retronasal stimulation of the olfactory receptors. Unfortunately, as noted earlier in this chapter, many patients and their physicians fail to distinguish between "taste" sensations mediated by the taste buds from CN I–mediated "taste" sensations (eg, strawberry, chocolate, meat sauce, etc).

Taste Buds The goblet-shaped taste buds are distributed over the dorsal surface of the tongue, margin of the tongue, base of the tongue, soft palate, pharynx, larynx, epiglottis, uvula, and first third of the esophagus.[72] The majority of taste buds are found on the lingual surface within the protruding papillae. Of the four types of papillae—fungiform, foliate, circumvallate, and filiform—only the first three harbor taste buds. Taste buds are continually bathed in secretions from the salivary glands and nearby lingual glands. Ebner's glands discharge into the troughs surrounding the vallate papillae, and lingual glands empty into the long fissures between the folds of the foliate papillae on the posterior aspect of the margin of the tongue. The saliva contains not only proteins such as amylase (which initiates starch breakdown of foodstuffs) but also growth factors important for wound healing and the maintenance of taste buds. Indeed, removal of the submandibular and sublingual salivary glands in rats leads to taste bud loss that can be prevented by supplying epidermal growth factor in the drinking water.[73]

The human tongue contains, on average, around 4,600 taste buds.[72] Each bud is comprised of 50 to 150 thin epithelial cells arranged much like the segments of an orange or grapefruit (Figure 27–10). The opening to the bud is termed the taste pore, and the excavation below the pore is termed the taste pit. Several types of cells are found within the taste bud, including cells that project microvilli into the taste pit and basal cells from which other cell types arise. On the basis of granule density in their apical regions, *light cells, dark cells*, and *intermediate cells* can be identified within each bud.[74] Like the cells of the olfactory neuroepithelium, taste bud cells have the propensity to replace themselves periodically, with the time course for at least some of this "turnover" being between 2 and 3 weeks.[75]

Gustatory Neural Transduction A tastant must be in solution to enter the taste pore. Hence, placing sugar or salt crystals on a dry lingual surface does not immediately lead to sweet or salty sensations, a common mistake made by some practitioners in attempting to assess taste function. After entering the taste pore, the tastant initiates the transduction process via one of two mechanisms: (1) activating receptors coupled to G proteins that, in turn, activate second-messenger systems (a process that probably occurs with sweet and bitter-tasting stimuli), and (2) directly gating apical ion channels on the microvillae within the taste bud pit (a process that probably occurs with sour and salty tasting stimuli). Gustducin, a specialized G protein specialized for taste

reception, has been identified in taste receptor cells of fungiform, foliate, and circumvallate papillae.[77]

Taste threshold sensitivity is directly related to the number of taste papillae and hence taste buds that are actively stimulated.[78] Furthermore, taste thresholds are inversely correlated with stimulus duration.[79] Interestingly, there are agents, when swished in the mouth, that selectively alter the quality of taste perceptions. For example, miraculin, a glycoprotein from the berry of the African shrub *Syncepalum dilcificum*, temporarily changes most sour-like sensations to sweet sensations. Gymnemic acid, an extract from the leaves of the Indian plant *Gymnema sylvestre*, can mitigate the perception of sweet sensation (and the corresponding electrophysiologic activity) without significantly changing the perception of the other taste qualities.[80]

Taste Afferent Nerves Different taste buds are innervated by different cranial nerves, depending on the region of the oral cavity in which they are located. Unlike CN I, such nerves are mixed motor and sensory nerves that transmit multiple forms of information. An understanding of this fact can be important when clinical syndromes that involve taste dysfunction are considered. The nerve fibers from each of the taste nerves enter the brainstem and synapse within the nucleus of the tractus solitarius (NTS), which extends from the rosterolateral medulla caudally along the ventral border of the vestibular nuclei (Figure 27–11).[81]

Taste sensations from the taste buds of the fungiform papillae on the anterior two-thirds of the tongue and the taste buds of the soft palate are conveyed by two respective branches of the facial nerve (CN VII): the chorda tympani nerve and the greater petrosal nerve via the lesser palatine nerve. Cranial nerve VII also supplies the salivary and lacrimal glands, the mucous membranes of the oral and nasal cavities, the muscles of facial expression, and the stapedius muscle. Cranial nerve VII taste fibers, whose cell bodies are located within the geniculate ganglion, share a common path with the lingual nerve (CN V_3) proximal to the tongue (see Figure 27–11).

All circumvallate and most, if not all, foliate taste buds within the posterior one-third of the tongue are innervated by the lingual-tonsillar branch of the glossopharyngeal nerve (CN IX). The taste buds in the region of the nasopharynx are supplied by the pharyngeal branch of this nerve. The nerve cell bodies of these gustatory afferent fibers are found within the petrous ganglion immediately outside the jugular foramen, where the fibers eventually pass to enter the cranium. Cranial nerve IX also innervates the stylopharyngeus muscle, the parotid gland, the baroreceptors of the carotid sinus, and the pharyngeal mucous membrane.

The taste buds on the epiglottis, aryepiglottal folds, and esophagus are innervated by the vagus nerve (CN X) via the internal portion of its superior laryngeal branch.[82] Nontaste sensory functions are mediated by this nerve from the external ear, external auditory canal, external surface of the tympanic membrane, and vocal cords. Cranial nerve X also mediates (1) visceral sensation from the larynx and the gut; (2) motor function to the smooth muscle of the pharynx, larynx, and viscera; and (3) motor

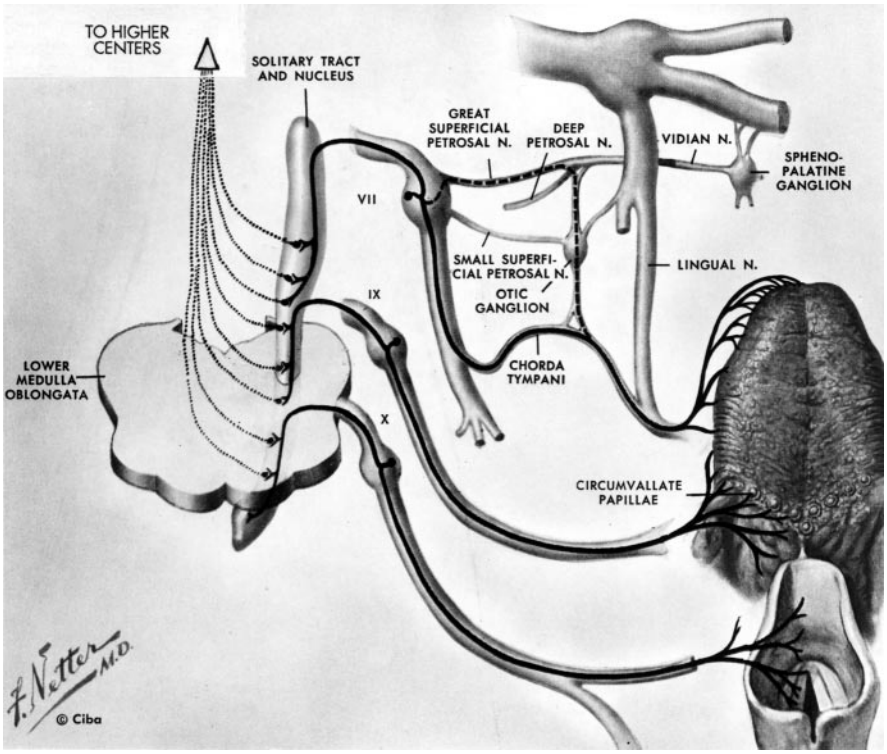

FIGURE 27–11. Distribution of cranial nerves to gustatory regions. Cranial nerve VII fibers from the geniculate ganglion innervate taste buds on the anterior portion of the tongue and on the soft palate. Cranial nerve IX fibers from cell bodies within the petrous ganglion innervate taste buds on foliate and vallate papillae of the tongue, as well as pharyngeal taste buds. Cranial nerve X fibers from cell bodies in the nodose ganglion innervate taste buds on the epiglottis, larynx, and esophagus. function to all striated muscles of the pharynx, larynx, and palate except the stylopharyngeus (CN IX) and tensor veli palatini (CN V_3). Afferent fibers from the superior laryngeal nerve project via their cell bodies in the inferior nodose ganglion.

Central Gustatory Regions: Functional Anatomy

The first central relay station of the taste system is the NTS.[82] The afferents from CN VII, IX, and X synapse, respectively, within the NTS in descending (and overlapping) order. Cells from the NTS also make reflexive connections, via the reticular formation, with cranial motor nuclei that control such taste-related behaviors as chewing, licking, salivation, swallowing, and preabsorptive insulin release, as well as the muscles of facial expression.[83] The major gustatory projections from the NST, however, are the tertiary ones that ultimately lead to activation of cortical gustatory structures. These occur via the thalamic taste nucleus (TTN) in primates, that is, the parvicellular division of the ventroposteromedial thalamic nucleus.[84] From the TTN, fibers project to the primary taste cortex deep in the parietal operculum and adjacent parainsular cortex.[85] Positron emission tomography and fMRI studies have found taste stimulus–induced activation largely within the insula and perisylvian regions, including the frontal operculum, superior temporal gyrus (opercular part), and inferior sectors of the pre- and postcentral gyrus.[87,88] A secondary cortical taste region is present within the caudomedial/caudolateral orbitofrontal cortex, several millimeters anterior to the primary taste cortex.[81]

The specific role of the gustatory cortical regions in the processing of taste information is not clear. These regions contain multimodal neurons responsive to touch and temperature, as well as taste.[89] Some structures within the right hemisphere seem to play a more important role in taste perception than their left-hemisphere counterparts. For example, citric acid presented to the whole mouth increases regional cerebral blood flow more in the right than in the left anteromedial temporal lobe and more in the right than in the left caudomedial orbitofrontal cortex, although bilateral activation is observed in the caudolateral orbitofrontal cortex.[90] Also, patients who have had right anterior temporal lobe resection for intractable seizure activity have higher citric acid recognition thresholds than both controls and left anterior temporal lobe resection patients. There is some evidence, however, that handedness may need to be controlled in such stud-

ies. Thus, whereas fMRI data suggest that the superior part of the insula is activated by tastants similarly in left- and right-handed subjects, this is not the case for the inferior parts of the insulae, where the left is relatively more activated in right-handed subjects and the right is relatively more activated in left-handed subjects.[87]

Classification of Gustatory Disorders

Gustatory disorders can be classified in a manner similar to olfactory disorders: *ageusia*: inability to detect qualitative gustatory sensations from all (total ageusia) or some (partial ageusia) tastants; *hypogeusia*: decreased sensitivity to tastants; *dysgeusia*: distortion in the perception of a normal taste (ie, an unpleasant taste induced by a stimulus that is normally associated with pleasant sensations) or the presence of a taste in the absence of a stimulus (sometimes termed phantogeusia); *gustatory agnosia*: inability to recognize a taste sensation, even though gustatory processing, language, and general intellectual functions are essentially intact. Some patients complain of oral sensations of burning or numbness, which may or may not have their genesis in gustatory afferents, for example, *burning mouth syndrome* in which the sensation of "burning" occurs within the mouth without obvious physical cause.

Total ageusia is rare and, when present, is usually produced by central (eg, ischemic) events since regeneration of taste buds can occur, and peripheral damage would have to involve multiple pathways to induce taste loss. Thus, whereas 433 of 585 patients (74%) studied at the University of Pennsylvania Smell and Taste Center who exhibited olfactory loss complained of both smell and taste disturbance, less than 4% had verifiable whole-mouth gustatory dysfunction, and even that was limited.[27] Regional deficits are much more common. For example, in one study, sensitivity to three concentrations of NaCl was measured on the tongue tip and 3 cm posterior to the tongue tip in 12 young (20 to 29 years of age) and 12 elderly (70 to 79 years of age) subjects. On average, the young subjects were more sensitive to NaCl on the tongue tip than on the more posterior stimulation site and exhibited, at both tongue loci, an increase in detection performance as the stimulus concentration increased. The elderly subjects, who would be expected to exhibit, at worse, moderate deficits on whole-mouth testing, performed at chance levels.[91]

Most patients are unaware of regional taste deficits. In fact, most patients can sustain loss of taste sensation on one half of the anterior part of the tongue following unilateral sectioning of the chorda tympani in middle ear surgery without noticing the problem. Such lack of awareness stems, in part, from the redundancy of the multiple taste nerves, as well as compensatory mechanisms.

Clinical Evaluation of Gustatory Function

History A history similar to that described earlier for patients complaining of olfactory disturbance should be obtained from patients complaining of gustatory disturbance. Specific consideration as to the type of stimuli that can or cannot be detected by the patient is essential to distinguish between retronasal CN I flavor loss and true taste bud–mediated gustatory loss. One should specifically inquire as to whether the patient can detect the saltiness of potato chips, pretzels, or salted nuts; the sourness of vinegar, pickles, or lemons; the sweetness of sugar, soda, cookies, or ice cream; and the bitterness of coffee, beer, or tonic water. If the patient indicates that there is a problem in such detection, the possibility of a true taste bud–mediated dysfunction exists.

Previous or current problems with salivation, chewing, swallowing, oral pain or burning, dryness of the mouth, periodontal disease, speech articulation, bruxism, or foul breath odor should be ascertained. Inquiry as to diet, oral habits, stomach problems, and possible problems with acid reflux is relevant, given that acid reflux into the oral cavity can irritate or damage taste buds. Recent dental work or exposure to radiation should be noted. Documentation of hearing or balance problems should be made since past or current ear infections or surgery can result in altered chorda tympani function and produce taste loss or distortions. A careful assessment of medication use is critical. As described in detail later in this chapter, many drugs, including lipid-reducing agents, antibiotics, and antihypertensives, can produce significant distortions or other alterations in taste function.

Physical Examination A thorough head and neck examination is essential for ascertaining the potential cause of a gustatory disorder.[20] Nongustatory deficits in CN VII, IX, and X can shed light on

whether gustatory dysfunction may be present (eg, abnormal facial motion, swallowing, salivation, gag reflex, voice production). Changes in epithelial color or signs of scarring, inflammation, or atrophy of lingual papillae should be noted. Neoplastic lesions deep in the tongue's musculature should be ruled out by palpation. Specific attention to the condition of the teeth and gums is important since exudates produced by gingivitis may produce or contribute to dysgeusic symptoms. An inspection of the nature and integrity of the fillings, bridges, and other dental work should also be made (eg, dissimilar metals can induce small electrical currents that, in turn, produce abnormal oral sensations). In cases for which an explanation of the taste problem is not clear, neuroimaging to rule out CNS tumors or lesions should be performed.

In some instances, it may be useful to evaluate biopsies of circumvallate or fungiform papillae to determine the presence of pathology. The tongue can also be stained with a dark food dye and can be photographed under high illumination and low-power magnification to allow for counting or better visualizing selected classes of papillae. In general, there is a high correlation between the number of fungiform papillae and the number of taste buds.[78]

Quantitative Gustatory Testing Quantitative taste testing is rarely performed in the clinic, largely because of issues of practicality (eg, time and expense of presenting and preparing limited shelf-life taste stimuli). Although a number of whole-mouth taste tests have been described in the literature,[92] regional taste testing is needed to establish the function of each of the nerves innervating multiple taste bud fields. As noted above, whole-mouth tests are insensitive to even complete dysfunction of one or several of the nerves that innervate the tongue.

Regional taste testing can be made using either chemical or electrical stimuli. The former requires applying known concentrations of liquid stimuli (eg, sucrose, citric acid, caffeine, and sodium chloride as prototypical representatives of sweet, sour, bitter, and salty taste qualities) to the tongue or oral cavity (in some cases in comparison with blank trials), rinsing the stimuli off between trials, and expectorating after each presentation. Such testing can be quite time consuming. For example, if responsiveness to each of the four basic taste qualities is to be made on left and right anterior (CN VII) and posterior (CN IX) tongue regions, 16 trials (4 tastants × 4 tongue regions) would be needed to present a single stimulus for each quality. Since multiple stimuli are required to produce reliable responses, the number of trials increases considerably.

In a regional chemical test used at our center, a single suprathreshold concentration of each of four stimuli (sucrose, citric acid, sodium chloride, and caffeine) is employed. The stimuli have been equated for perceived intensity (using a magnitude matching procedure) and are presented at the same volume (15 μL from an Eppendorff pipette; Brinkman Instruments, Westbury, New York) and kinematic viscosity (1.53 mm^2/s^2 using tasteless cellulose gum). Equating viscosity eliminates context effects and tactile cues and increases control of solution spread when placed on the tongue in microliter quantities. The stimuli are presented six times to each tongue region, resulting in a test consisting of 96 stimulus trials and 96 rinses. Testing time is between 1 and 1½ hours. The task of the subject is to report the presence of a sweet, sour, bitter, or salty sensation using a forced-choice procedure with these four alternatives available and to rate the perceived intensity of the stimulus on a standardized rating scale with logarithmic visual properties.

A more practical approach to taste testing is to employ an electrogustometer, a device that presents brief μA currents to small regions of the tongue for known durations (Figure 27–12).[93] No stimulus preparation or rinsing is required. Electrogustometric thresholds can be obtained easily, although their relationship to chemical thresholds is still not clear, and extreme care must be taken to apply the stimulator to the same region of the tongue on each trial as considerable regional variation in sensitivity is present. At low current ranges, electrogustometry has been demonstrated to activate only taste afferents, not trigeminal (CN V) afferents. Unfortunately, sound normative data based on forced-choice testing paradigms are still generally lacking for such devices.

Imaging Studies Imaging studies of the gustatory pathways can be useful in explaining the gustatory symptoms of some patients. In addition to detecting large central lesions and tumors, modern MRI techniques can detect discrete lesions (eg, infarcts) within brain structures that correlate both with

FIGURE 27–12. The Rion TR-06 electrogustometer, a practical device for quantitatively assessing regional taste function. patient complaints and with the results of sensory testing. As noted in detail in the next section, MRI-determined infarcts in the pons have been repeatedly associated with ageusia and dysgeusia.[94,95]

Causes of Gustatory Dysfunction

Although central or systemic factors are the most likely causes of ageusia, local factors can significantly alter taste perception. Proximal mechanisms include (1) the release of foul-tasting materials from oral medical conditions (eg, gingivitis, sialadenitis); (2) problems in movement of tastants to the taste buds (eg, damage to taste pores from a burn); (3) damage to the taste buds proper, as from caustic or allergic reactions to toxins or oral products; (4) damage to taste nerves (eg, postviral Bell's palsy, dental or surgical procedures); and (5) CNS damage (eg, from tumors, epilepsy, infarcts). One cause of dysgeusia can be the use of different metals in the mouth that set up subtle electrical currents within the oral cavity. The more common causes of taste disorders are discussed below.

Aging Although whole-mouth taste acuity declines with age, the perceptual decrease is not as marked as that seen for olfaction.[96] Compared with younger persons, the elderly tend to perceive tastes as being less intense. In conjunction with the loss seen with the sense of smell, decrements in taste function can be harmful to some of the elderly, leading to anorexia, weight loss, malnutrition, impaired immunity, and worsening of a medical illness.[50,97] As noted earlier, whole-mouth testing reveals moderate degrees of age-related taste loss, whereas regional taste testing reveals marked age-related decrements.[91]

Bell's Palsy Bell's palsy is the most frequent cause of facial nerve damage. Usually of viral origin (eg, herpes simplex), this disease affects both sexes of all ages. This disorder typically begins with pain in or behind the ipsilateral ear, followed by symptoms of unilateral facial weakness over the course of a few days (maximum paralysis within 48 to 72 hours). Hyperacusis occurs in many cases owing to a weakening of the stapedius muscle. Although commonly accompanied by ipsilateral taste loss over the anterior two-thirds of the tongue, patients are often unaware of the taste problem without formal testing. There is a suggestion that return of taste function by 2 weeks after onset is a positive prognostic indicator for complete and relatively rapid recovery from facial paresis, whereas longer-lasting taste impairment is associated with poor prognosis. The taste-salivary reflex arc, which extends from the taste

nerves via the NST to the parasympathetic fibers innervating the salivary glands, can also be compromised in this disorder.

Herpes zoster oticus, termed Ramsay Hunt syndrome, results from active infection of the geniculate ganglion and involves pain and vesicles in the external auditory canal or soft palate. Bartoshuk and Miller described a patient with Ramsay Hunt syndrome that involved both CN V and CN IX on the left side.[98] Intensity ratings were obtained for each of the four taste qualities at regular intervals across a nearly 600-day period for the front, back, and palate regions. About 3 months after the herpes attack, the entire left side of the patient was devoid of taste function. After 400 days, all taste qualities were perceived on the left rear and palate regions, but only sweetness could be perceived on the left front. Full taste recovery of the anterior part of the tongue was not present even by the end of the nearly 600-day-long testing period.

Burning Mouth Syndrome In some cases, burning mouth syndrome, also called glossodynia or glossalgia, is associated with salty or bitter dysgeusias. This poorly understood syndrome is characterized by idiopathic intense "burning" pain within the mouth without obvious physical cause. To what extent this disorder is mediated via gustatory or CN V afferents is not known. The burning sensation typically begins by late morning and continues throughout the day.[99] Suggested causes include (1) diabetes mellitus (possibly predisposing to oral candidiasis); (2) nutritional or hormone deficiencies (eg, iron, folic acid, B vitamins, estrogen, zinc); (3) denture allergy (including reactions to amalgam fillings); (4) mechanical irritation from dentures or oral devices; (5) parafunctional habits of the mouth (eg, tongue thrusting, teeth grinding, jaw clenching); (6) tongue ischemia as a result of temporal arteritis; (7) oral candidiasis; (8) periodontal disease; (9) reflux esophagitis; and (10) geographic tongue.[100] Anxiety and depression are common in the population with burning mouth syndrome.

Central Lesions and Tumors Taste dysfunction has been attributed to a variety of tumors and other lesions, including acoustic neuromas, tumors of the hypophysis with marked extrasellar growth, facial nerve schwannomas extending into the middle cranial fossa, and cerebellopontine angle lesions. Contralateral dysgeusia has been observed in patients with lateralized infarcts of the thalamus and in patients with infarcts in the corona radiata (reflecting the crossed taste pathways at this level of the nervous system).[101] Unilateral lesions above the brainstem do not usually cause complete loss of function because of the multiple areas involved in processing taste information.

Gustatory problems can arise from damage to the brainstem structures related to taste, often in conjunction with impairment of other cranial nerves or long tracts. Regions susceptible to damage include the NTS and the pontine tegmentum, which involves both gustatory lemnisci. Hemiageusia from an ipsilateral MS plaque at the midpontine tegmentum has been reported.[94] Similarly, ageusia to all taste qualities on the right side of the tongue was noted in a patient who had a small hemorrhage in the right tegmentum of the middle pons.[102] Recently, three cases of ipsilateral hemiageusia owing to focal ischemic lesions in the brainstem have been described.[103]

An example of unilateral hypogeusia resulting from a brainstem infarct is shown in Figure 27–13. In this case, ischemic activity is evident in a region of the upper medulla near the right NTS (note that, in this image, the patient's right side is on the left of the picture, and the left side is on the right of the picture). This individual complained of dysgeusia on the right side of the tongue and evidenced on testing a decrement in the ability to discern sweet, sour, bitter, and salty sensations that was greater on the right than on the left. Both CN VII and CN IX seemed to be involved.

Head and Neck Trauma Trauma-related taste loss is much less common than trauma-related smell loss, with fewer than 1% of persons with major head injury exhibiting ageusia to sweet, sour, salty, or bitter taste qualities.[27,104] Nonetheless, taste loss, as well as dysgeusia, can occur in some types of head trauma. For example, basilar temporal bone fractures and other injuries that impinge on the middle ear have the potential for impairing chorda tympani nerve–mediated taste function unilaterally, as well as for altering salivary secretion. Traumatic injury to the lingual nerve in and around the mouth and tongue can also occur in some trauma cases. This nerve, a branch of the mandibular division of CN V_3, is the most proximal pathway to the tongue for

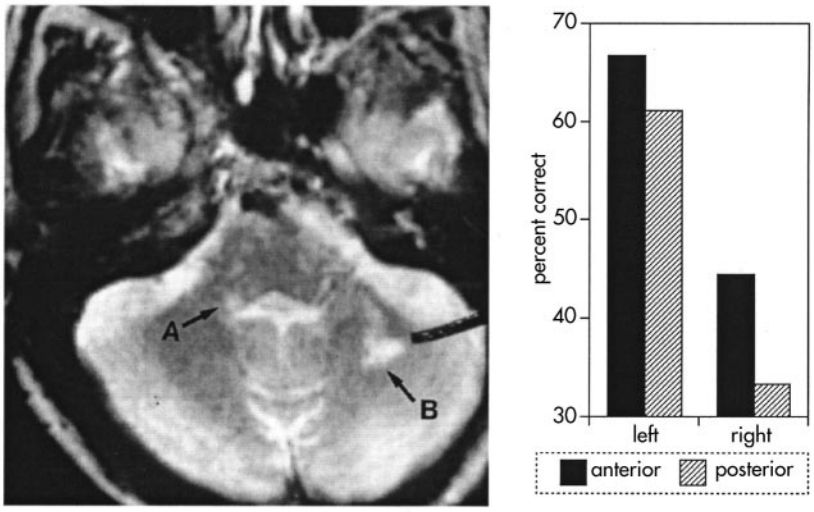

FIGURE 27–13. Left, Axial T_2-weighted (2500/90) magnetic resonance scan through the upper brainstem reveals a hyperintensive infarct (4 × 3 mm) in the right side of the medulla (*arrow A*). Note also the large infarct (15 × 8 mm) inside the white matter of the left side of the cerebellum (*arrow B*). *Right*, Taste identification scores showing relative decrement on the right side of the tongue. From a 65-year-old-woman with a history of ministrokes who developed a persistent salty/metallic dysgeusia and soreness on the right side of the tongue following a severe 2-day bout of emesis accompanied by marked dehydration and increased blood pressure but unaccompanied by fever. general somatic sensation (touch) and special visceral sensation of taste (owing to concurrent chorda tympani fibers).

Trauma-induced damage to the auriculotemporal nerve can produce a rare clinical syndrome of post-traumatic gustatory neuralgia, characterized by paroxysmal, lancinating facial pain in the cutaneous distribution of the auriculotemporal nerve following gustatory stimulation.[105,106] This condition, which can also be caused by viruses and by iatrogenic trauma (eg, that induced by parotid gland surgery, temporomandibular joint surgery, carotid endarterectomy, orthognathic surgery, and oncologic surgery), produces episodic, transient, electric shock-like pain in the preauricular region of the affected side.[105] Taste-mediated post-traumatic sweating and flushing in this same region are known as Frey's syndrome. Although usually provoked by taste stimuli, there is suggestion that such responses can be provoked, in some cases, by the smell of food or even emotional excitement.[105]

Iatrogenic Surgical Damage Numerous surgical interventions can induce taste dysfunction. The glossopharyngeal nerve is susceptible to damage during tonsillectomy, bronchoscopy, or laryngoscopy,[107–109] reflecting the close proximity of the lingual branch of this nerve to the muscle layer of the palatine tonsillar fossa.[110] Surgical treatment for snoring (eg, uvulopalatoplasty),[111] as well as surgery-related procedures such as endotracheal intubation (causing injury to the lingual nerve)[112] and the employment of a laryngeal mask,[113] has been associated with taste loss or alteration.

The chorda tympani nerve is at particular risk from surgical procedures that involve the middle ear, given its course between the malleus and the incus. The nerve is often stretched or sectioned during tympanoplasty, mastoidectomy, and stapedectomy, in some cases producing long-lasting symptoms. Bull, for example, found that 78% of patients with bilateral section and 32% of patients with unilateral section of the chorda tympani had persistent adverse gustatory symptoms.[114]

A recent study evaluated gustatory function in 17 patients before third molar surgery and at 1 and 7 months after surgery.[115] On average, an ~15% reduction of perceived intensity was observed 1 month after surgery for NaCl, citric acid, and quinine hydrochloride. The taste quality of NaCl was identified correctly less often after than before third molar extraction. Citric acid intensity perception

had not recovered at 6 months after the surgery. These data suggest that not only do gustatory deficits commonly occur after third molar extraction, they also can persist for at least 6 months after surgery and seem to be associated with the depth of impaction.

Medications Medications produce taste disturbances more frequently than olfactory disturbances. Such side effects can be very debilitating and, in rare instances, have contributed to extreme weight loss and even suicide. Among offending agents are antiproliferative drugs, lipid-reducing drugs, antihypertensive agents, diuretics, antifungal agents, antirheumatic drugs, antibiotics, and drugs with sulfhydryl groups, such as penicillamine and captopril.[36,116] Onset of taste dysfunction following the use of some agents can take weeks or even months. For example, in a well-controlled study of 87 patients experiencing taste loss as a result of the antifungal agent terbinafine, the average time period from the first intake of the drug and the experience of taste loss was 35 days. In most cases, recovery after drug cessation took several months.[117]

Taste function is reportedly altered by repetitive use of some oral topical agents, including hydrogen peroxide or corticosteroids. Some medications (eg, anticholinergics, antidepressants, antihistamines) reduce glandular secretion, causing hyperviscous saliva, a condition that, in time, can result in lessened taste acuity. It is noteworthy that approximately one-fourth of all cardiac medicines (including antilipemic agents, adrenergic blockers, angiotensin-converting enzyme inhibitors, angiotensin II antagonists, calcium channel blockers, vasodilators, anticoagulants, antiarrhymics, and various diuretics) are listed in the *Physicians' Desk Reference* as having potential side effects of "altered taste," "bad taste," "bitter taste," or "metallic taste."

Radiation Therapy Radiotherapy for head and neck cancer can induce taste loss and dysgeusia, salivary dysfunction, and conditioned taste aversions. Such problems can significantly alter quality of life and, on occasion, appetite to the degree that nutrition is compromised. Symptoms usually begin early in the course of treatment, and post-treatment recovery can take months and, in rare instances, years.[118] The cause of such disturbances can be quite varied, including direct radiation-induced damage to taste cells and buds, salivary glands, and taste nerve fibers (which normally provide trophic factors that maintain the integrity of the taste bud). The xerostomia secondary to salivary gland damage can influence food transport, protection from bacterial invasion, and salivary proteins potentially involved in taste transduction[119] and can aid in the promotion of opportunistic oral infections (eg, oral candidiasis).[120] Although typically idiosyncratic and transient, some taste aversions can be long lasting and can produce generalized anorexia and cachexia. A means for mitigating such aversions is to have the patient consume a novel food immediately before the first course of chemo- or radiotherapy. This simple maneuver somehow focuses the aversion primarily on the novel food and interferes with the formation of conditioned aversions to preferred dietary items.[121]

Other Causes Among other reported causes of taste dysfunction are hypothyroidism, renal disease, liver disease, myasthenia gravis, Guillain-Barré syndrome, numerous neoplasms, and familial dysautonomia (a genetic disorder with lack of taste buds and papillae). Idiopathic dysgeusia has been associated with blood transfusions.[122] Complaints of taste loss or distortion are reported in many carcinomas and mass lesions. For instance, whereas squamous cell carcinoma of the mucous membranes of the upper aerodigestive tract can interfere with taste by direct destruction of receptors, mass lesions along the course of CN VII, IX, and X may cause impairment through neural compression. Carcinoma-related malnutrition may also lead to ageusia.

A persistent and unpleasant sweet dysgeusia was recently described in three patients with small cell carcinoma of the lung.[123] The dysgeusia was the presenting symptom in all three cases, and hyponatremia secondary to the syndrome of inappropriate secretion of antidiuretic hormone was present in each case. Resolution of the dysgeusia paralleled an increase in serum sodium concentration after water restriction alone. The close association between the dysgeusia and the low serum sodium concentration suggests that hyponatremia is the causative factor, rather than the carcinoma, antiduretic hormone, medications, or chemotherapy.

Gustatory symptoms have been reported in association with epileptic seizures. Examples of taste sensations that have been reported in such cases include "peculiar," "rotten," "sweet," "like a cigarette," "like rotten apples," and "like vomitus."[39] Some of

these "tastes," however, likely represent smell sensations that are miscategorized as tastes by both the patients and their physicians.

Selective taste nerve damage or alterations may produce some forms of *hyper*geusia and dysgeusia. For example, one study found that anesthetizing a single chorda tympani nerve reportedly increases the perceived intensity of bitter substances, such as quinine, applied to taste fields innervated by the contralateral glossopharyngeal nerve.[124] In contrast, perceived intensity of NaCl applied to an area innervated by the ipsilateral glossopharyngeal nerve appeared decreased. When both chorda tympani nerves were anesthetized, the taste of quinine is intensified, and the taste of NaCl was diminished in areas innervated by the glossopharyngeal nerve on both sides of the tongue. In about 40% of the subjects, a phantom taste, usually localized to the posterior part of the tongue contralateral to the anesthesized area, appeared in the absence of stimulation. This phantom taste was eliminated when the region of origin was anesthetized. These authors suggest that such phantoms arise because of release of inhibition normally present between the central projection areas of the different taste nerves.

Treatment of Taste Dysfunction

As with other sensory systems, prognosis in cases of taste dysfunction is likely inversely related to the degree of neural or structural damage, although clinically such damage can rarely be assessed. Fortunately, the taste nerves and buds appear to be relatively resilient, as many cases of taste loss or distortion spontaneously resolve over time.[28] In some dysgeusic cases, antifungal and antibiotic treatments have been reported to be useful, although double-blind studies of the efficacy of such treatments are lacking, and some of these agents themselves can produce taste disturbance. Chlorhexidine employed in a mouthwash has been suggested as having possible efficacy for some salty or bitter dysgeusias, possibly as a result of its strong positive charge.[125] In the case of neural damage from viruses or other agents, presumably the damaged taste afferents regenerate. Thyroxine replacement therapy reportedly brings back taste sensitivity to normal levels in cases of taste loss secondary to hypothyroidism.[126] Taste disorders caused by medications can, in some instances, be reversed by discontinuing the offending drug, by employing alternative medications, or by changing drug dosage. It should be kept in mind, however, that a number of pharmacologic agents appear to induce long-term alterations in taste that may take months to disappear after drug discontinuance.

Since most patients with burning mouth syndrome are postmenopausal, dysgeusias associated with this disorder may, in some cases, respond to estrogen replacement therapy. Topical capsaicin may also be helpful in some cases. Given that burning mouth syndrome is often associated with anxiety and depression, tricyclic antidepressants (eg, amitriptyline, desipramine, nortriptyline) and benzodiazepines appear, in selected instances, to have some therapeutic efficacy.[127]

CONCLUSIONS

Disorders of the chemical senses of taste and smell are relatively common, particularly in the elderly, and can result from a broad array of causes. Such causes range from simple irritation of the receptive elements to serious neurologic disorders, including AD and idiopathic PD. In this chapter, a succinct overview of the anatomy and physiology of the chemical senses, as well as of the primary causes of chemosensory dysfunction, has been provided. Approaches to therapy have been discussed, with an emphasis on the need for quantitative psychophysical evaluation of patients before initiating surgical or medical interventions. Clearly, a number of disorders of the chemical senses can be approached with optimism as long as the physician establishes the exact nature of the problem and is aware of the available avenues of treatment and objective assessments of efficacy.

CHAPTER 28

Cellular Biology of the Immune System

Joel M. Bernstein, MD, PhD

Immunology, the study of the immune system, grew out of the common observation that human beings who recover from certain infectious diseases are thereafter immune to the disease, that is, they rarely develop the same disease again. Immunity is highly specific: an individual who recovers from measles is protected against the measles virus but not against other common viruses, such as mumps or chickenpox. Such specificity is a fundamental characteristic of immune responses. In other vertebrate systems, cells such as macrophages and neutrophils also play an important role in defending vertebrates against infection, but they are only one part of a much more complex and sophisticated defense strategy. This chapter is devoted to the specific immune response.

Many of the responses of the human immune system initiate the destruction and elimination of invading microorganisms and any toxic molecules produced by them. Because these immune reactions are destructive, it is essential that they be made only in response to molecules that are foreign to the host and not to those of the host itself, resulting in autoimmunity. This ability to distinguish foreign molecules from self-molecules, in general, is another fundamental feature of the human immune system. Occasionally, it fails to make this distinction and reacts destructively against the host's own molecules; such autoimmune diseases can be fatal.

Although the immune system evolved to protect vertebrates from infection by microorganisms and larger parasites, most of what we know about immunity has come from the studies of the responses of laboratory animals to injections of noninfectious substances, such as foreign proteins and polysaccharides. Almost any macromolecule, as long as it is foreign to the recipient, can induce an immune response; any substance capable of eliciting an immune response is referred to as an *antigen* (*anti*body *gen*erator). Remarkably, the immune system can distinguish between antigens that are very similar, such as between two proteins that differ in only a single amino acid or between two optical isomers of the same molecule.[1]

This chapter specifically addresses two broad classes of immune responses: antibody response and cell-mediated immune responses. *Antibody responses* involve the production of antibodies, which are proteins called *immunoglobulins* (Igs). The antibodies circulate in the bloodstream and permeate the other body fluids, where they bind specifically to the foreign antigen that induced them. Binding by antibody inactivates viruses and bacteria and bacterial toxins by blocking their ability to bind to receptors on host cells. Antibody binding also marks invading microorganisms for destruction, either by making it easier for a phagocytic cell to ingest them or by activating a system of blood proteins, collectively called *complement*, which kills the invaders. The complement system is addressed in this chapter as well.

Cell-mediated immune responses, the second class of immune responses, involve the production of specialized cells, which react with foreign antigens on the surface of other host cells. The reacting cell, for example, can kill a virus-infected host cell that has viral antigens on its surface, thereby eliminating the infected cell before the virus has replicated. In other cases, the reacting cell secretes chemical signals that activate macrophages to destroy the invading microorganisms. The main challenge in immunology has been to understand how the immune system specifically recognizes and reacts aggressively to a virtually unlimited number of different foreign macromolecules but avoids reacting against the tens of thousands of different self-macromolecules made by host cells. Thus, initially in this chapter, the functional and structural features of antibodies that enable them to recognize and destroy extracellular antigens are considered. After discussing how this antibody diversity is generated,

this chapter then considers the special features of cell-mediated immune responses that are crucial in the defense against intracellular microorganisms. Wherever possible, the fundamental principles of immunobiology are applied to diseases of the middle ear and sinuses and particular reference is made to immunobiology of the tonsils and adenoids. Finally, an overview of three classes of soluble mediators of inflammation is discussed using the nasal polyp as a model of chronic inflammation.

CELLULAR BASIS OF IMMUNITY

The Human Immune Response Is Composed of Trillions of Lymphocytes

The cells responsible for immune specificity belong to a class of white blood cells known as lymphocytes.[2] They are found in large numbers in the blood and the lymph and in specialized lymphoid organs such as the thymus, bone marrow, lymph nodes, spleen, appendix, tonsils, and adenoids (Figure 28–1).

There are approximately 2×10^{12} lymphocytes in the human body, which make the immune system comparable in cell mass to the liver or brain.

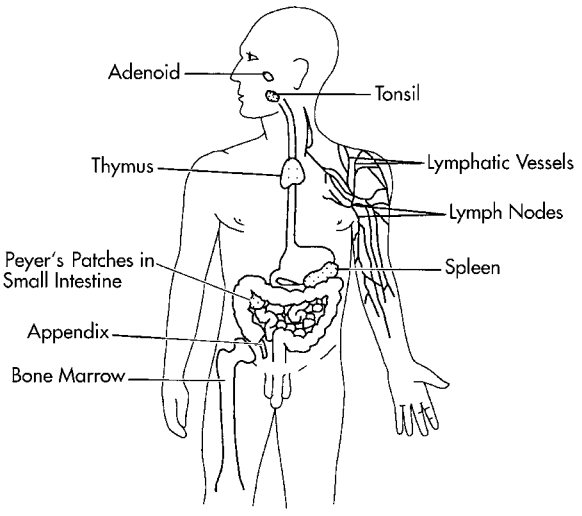

FIGURE 28–1. Human lymphoid organs. Lymphocytes develop in the thymus and bone marrow, which are therefore referred to as *primary* (or *central*) *lymphoid organs*. The newly formed lymphocytes migrate from these primary regions to *secondary* (or *peripheral*) *lymphoid organs*, where they can react with antigen. Only some of the secondary lymphoid organs are shown; many lymphocytes, for example, are found in the skin and lungs.

About 40 years ago, it was discovered that the two major classes of immune responses are mediated by different classes of lymphocytes: *T cells*, which develop in the thymus and are responsible for cell-mediated immunity, and *B cells*, which in mammals develop in the adult bone marrow or the fetal liver and produce antibodies.[3] This dichotomy of the lymphoid system was initially demonstrated in animals with experimentally induced immune deficiencies. These studies on immune-deficient animals demonstrated that individuals deficient in T cells were unable to make cell-mediated immune responses and had somewhat impaired antibody responses. We now know that there are two main classes of T cells; helper T cells and cytotoxic T cells.[4] Helper T cells enhance the response of other white blood cells, and some of these T cells help B cells to make antibody responses. Cytotoxic T cells, by contrast, kill infected cells; because they are involved directly in defense against infection, unlike helper cells, they, together with B cells, are sometimes referred to as *effector cells*.

Lymphocytes Develop in Primary Lymphoid Organs and React with Foreign Antigens in Secondary Lymphoid Organs

It is now known that lymphocytes develop from *pluripotent* hemopoietic *stem cells*, which give rise to all of the blood cells, including red blood cells, white blood cells, and platelets.[5] These stem cells are located primarily in the liver in fetuses and in the bone marrow of adults. T cells develop in the thymus from precursor cells that migrate in from the hemopoietic tissues via the blood in mammals (Figure 28–2). B cells develop from stem cells in the hemopoietic tissues themselves. Because they are sites in which lymphocytes develop from precursor cells, the thymus and the bone marrow are referred to as primary lymphoid organs. Other lymphocytes, however, mature and migrate via the blood to the secondary peripheral lymphoid organs such as the lymph nodes, spleen, and epithelium-associated lymphoid tissue found in the gastrointestinal tract, respiratory tract, skin, tonsils, and adenoids. It is chiefly in the secondary lymphoid organs that T and B cells react with incoming foreign antigens. The bone marrow in mammals continues to generate large numbers of new B cells, approximately 5×10^7/day in the mouse throughout life.[6]

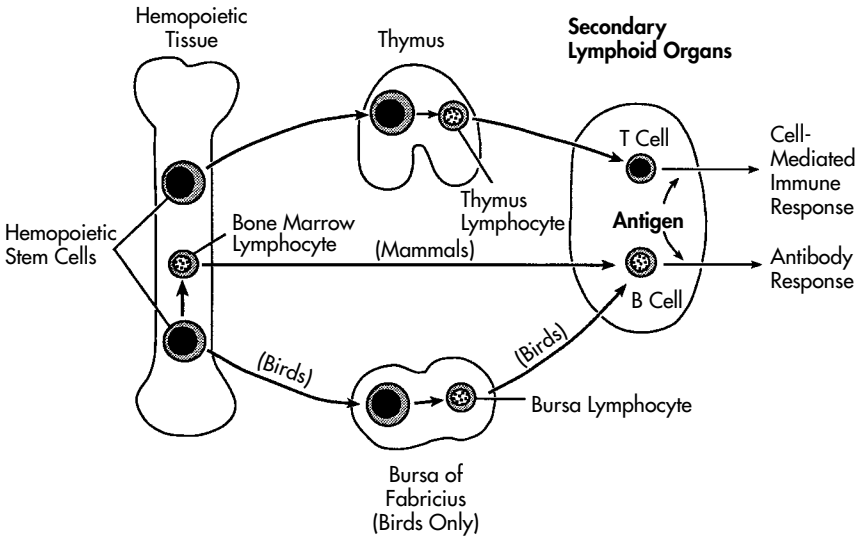

FIGURE 28–2. The development of T and B cells. The primary lymphoid organs are where lymphocytes develop from precursor cells. The bursa of Fabricius (birds only) is the lymphoid organ for B-cell development, whereas in mammals, the bone marrow is the predominant precursor of B cells. T cells in secondary lymphoid organs are primarily involved in cell-mediated immune response, whereas B cells are primarily involved in antibody responses.

Cell-surface markers make it possible to distinguish and separate T and B cells. T and B cells become morphologically distinguishable only after they have been stimulated by antigen. Both are activated by antigens to proliferate and mature further. Activated B cells develop into antibody-secreting cells, the most mature of which are *plasma cells* that are filled with an extensive rough endoplasmic reticulum. In contrast, activated T cells contain very little endoplasmic reticulum and do not secrete antibodies, although they do secrete a variety of mediators called *lymphokines*, *interleukins* (ILs), or *cytokines*. Since both T and B cells occur in all secondary lymphoid organs, it has been necessary to find ways to distinguish and separate the two cell types and their various subtypes to study their individual properties. Fortunately, there are many differences in the plasma membrane proteins of the different types of lymphocytes that can serve as distinguishing markers. Antibodies that react with the *Thy-1 protein*, for example, which is found on T cells but not on B cells in mice, are widely used to remove or purify T cells from a mixed population of mouse lymphocytes.[7] Similarly, antibodies against *CD4* and *CD8 proteins*, which are discussed later, are widely used to distinguish and separate helper T cells and cytotoxic T cells, respectively, in both mice and humans.[8]

The Immune System Works by Clonal Selection

The most remarkable feature of the immune system is that it can respond to millions of different foreign antigens in a highly specific way, for example, by making antibodies that react specifically with the antigen and induce their production. How this immune system produces such diversity of specific antibodies led to the emergence of the theory in the 1950s that came to be known as the *clonal selection theory*.[9] According to this theory, each animal first randomly generates a vast diversity of lymphocytes, and then those cells that react against the foreign antigens that the animal actually encounters are specifically selected for action. The theory is based on the proposition that during development, each lymphocyte becomes committed to react with a particular antigen before ever being exposed to it. Each cell expresses this commitment in the form of cell-surface receptor proteins that specifically fit the antigen. The binding of antigen to the receptors activates the cell, causing it to proliferate and mature. Therefore, a foreign antigen selectively stimulates those cells that express complementary antigen-specific receptors and are thus already committed to respond to it. This is what makes the immune response antigen specific.

The term "clonal" in clonal selection arises from the postulate that the immune system is composed of millions of different families, or *clones* of cells, each consisting of T or B cells descended from a common ancestor. Each ancestral cell is already committed to make one particular antigen-specific receptor protein, and all cells in a clone have the same antigen specificity. It is now known that the antigen-specific receptors on both T and B cells are encoded by genes that are assembled from a series of

gene segments by a unique form of genetic recombination that occurs early in the cell's development, beginning before it has encountered antigen.

Most antigens stimulate many different lymphocyte clones. Those parts of an antigen that combine with the antigen-binding site on the antibody molecule or on a lymphocyte receptor are called *antigenic determinants* or *epitopes*.[10] Most antigens have a variety of antigenic determinants that stimulate the production of antibodies or T-cell responses. Some determinants are more antigenic than others, so the reaction to them may dominate the overall response. Such determinants are said to be *immunodominant.* Even an antigen that activates many clones will stimulate only a tiny fraction of the total lymphocyte population. To ensure that these few lymphocytes are exposed to the antigen, antigens are generally collected by specialized *antigen-presenting cells* in secondary lymphoid organs, through which T and B cells continuously circulate. Antigens that enter through the gut are trapped by gut-associated lymphoid tissue, those that enter through the skin or respiratory tract are retained locally and/or are transported via the lymph to local lymph nodes, and those that enter the blood are filtered out in the spleen. The antigen-presenting cells of the tonsil, also called M cells, are in the crypts and present antigen to T lymphocytes and subsequently to B lymphocytes in the crypts.[11] However, in the germinal centers of the tonsil or adenoids, B cells may present antigen to helper T cells.[12] This will be discussed in a further section of this chapter.

The majority of T and B lymphocytes continuously recirculate between the blood and the secondary lymphoid tissue. In a lymph node, for example, lymphocytes leave the bloodstream, squeezing out between specialized endothelial cells, so-called high endothelial venules; after percolating through the node, they accumulate in small lymphatic vessels that leave the node and connect with other lymphatic vessels that pass through other lymph nodes downstream and finally pass into a large vessel called the thoracic duct, which carries them back to the blood. Lymphocyte recirculation depends on specific interactions between the lymphocyte cell surface and the surface of specialized endothelial cells lining small veins of the secondary lymphoid organs; because their endothelial cells are unusually tall, they are called postcapillary high endothelial venules (Figure 28–3). These migrations are guided by various *homing receptors* on lymphocytes and by the ligands for these receptors (often called *counter-receptors*) on endothelial cells.[13] Both receptors and counter-receptors have been identified by monoclonal antibodies that bind to the surface of either lymphocytes or the specialized high endothe-

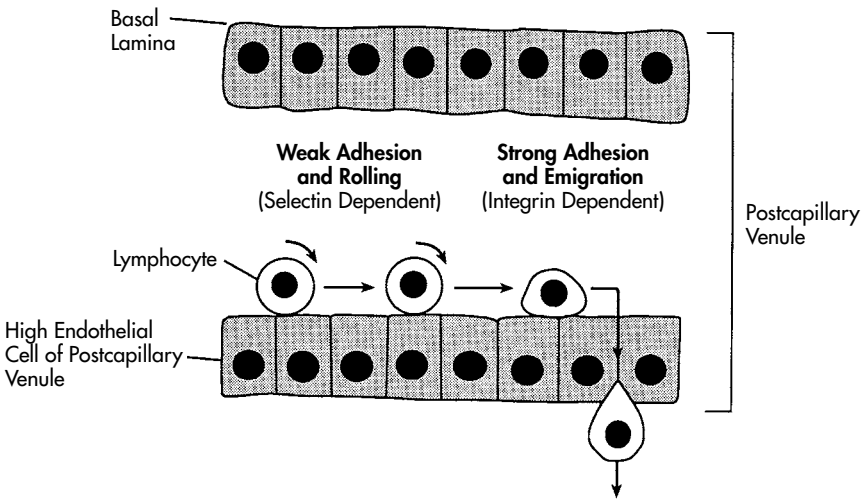

FIGURE 28–3. Migration of a lymphocyte out of the bloodstream into a lymph node. A circulating lymphocyte adheres weakly to the surface of the specialized high endothelial cells in a postcapillary venule in a lymph node. This initial adhesion, mediated by E-selectin on the lymphocyte surface, is sufficiently weak that it enables the lymphocyte to roll along the surface of the endothelial cells. The lymphocyte rapidly activates a stronger adhesion system mediated by an integrin, which enables the cell to stop rolling and migrate out of the venule between the endothelial cells.

lial cells and inhibit the ability of the lymphocytes both to bind the endothelial cells and tissue sections of secondary lymphoid organs and allows them to recirculate in vivo. Lymphocyte migration into lymph nodes, for example, depends on the cell adhesion protein called *E-selectin*, which belongs to the selectin family of cell-surface selectins, which are glycoproteins.[14] This homing receptor, which is present on most lymphocytes, binds to a specific sugar group on a highly glycosylated, mucin-like counter-receptor that is expressed exclusively on the surface of high endothelial cells lining postcapillary venules and lymph nodes. E-selectin binding causes the lymphocytes to adhere weakly to the endothelial cells and to roll slowly along their surface. The rolling continues until another, much stronger adhesion system is activated. This strong adhesion, which is mediated by a member of the *integrin* family of cell adhesion molecules on the lymphocyte surface, allows the lymphocytes to stop rolling and crawl out of the blood vessel into the lymph node.[15]

Other homing receptors on lymphocytes are found to be responsible for the subsequent segregation of T and B cells into distinct areas of the lymph node. For example, B cells are primarily restricted to the follicle and mantle zone of the tonsil and adenoids, and T cells are primarily located between the secondary follicles and in the reticular epithelium of these organs.[16] Once they are activated by antigen, most lymphocytes lose many of their homing receptors and acquire new ones: instead of migrating though lymphoid organs, they migrate through the nonlymphoid tissues to sites of inflammation. The migration of activated lymphocytes and other white blood cells into sites of inflammation is largely mediated by other combinations of selectins and integrins. For example, in nasal polyps, there is an up-regulation of eosinophils because of the integrin VLA-4 (very late activation antigen 4), which is increased on the surface of eosinophils, and a counter-receptor on the small blood vessels of venules in the nasal polyp called VCAM-1 (vascular cell adhesion molecule). Very late activation antigen 4 and VCAM-1 are receptor and counter-receptor and account for the significant increase of eosinophils in nasal polyps.[17]

The immune system, like the nervous system, can remember. This is why we develop lifelong immunity to many common viral diseases after our initial exposure to the virus, and this is why immunization works. If an animal is injected once with antigen A, its immune response, either antibody or cell mediated, will appear after a lag period of several days, rise rapidly and exponentially, and then more gradually fall again. This is characteristic of a *primary immune response* occurring on an animal's first exposure to an antigen. If some weeks, months, or even years are allowed to pass and the animal is reinjected with another antigen A, it would usually produce a *secondary immune response*, which is very different from the primary immune response. The lag period is shorter, and the response is greater. These differences indicate that the animal has "remembered" its first exposure to antigen A. Therefore, the secondary response reflects antigen-specific immunologic memory for antigen A (Figure 28–4).

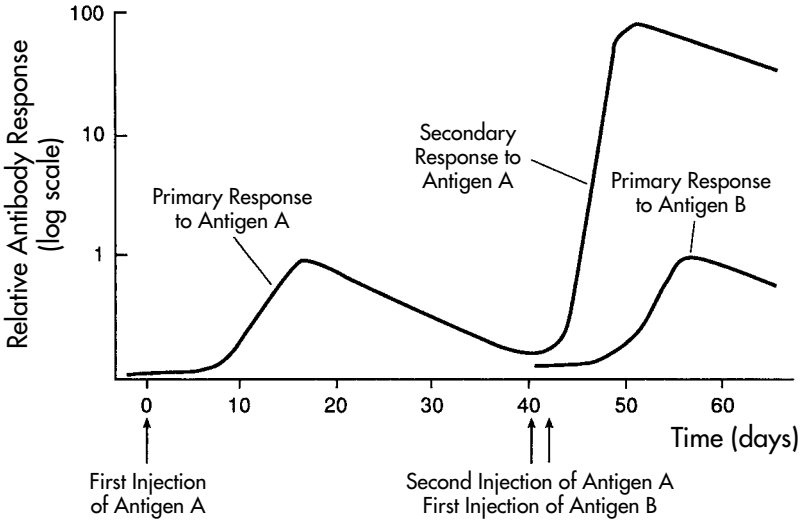

FIGURE 28–4. Primary and secondary antibody responses. The secondary response induced by a secondary exposure to antigen A is faster and greater than the primary response and is specific for A, indicating that the immune system has specifically remembered encountering antigen A before. Evidence for the same type of immunologic memory is obtained if T-cell-mediated responses rather than B-cell antibody responses are elicited.

The clonal selection theory provides a useful conceptual framework for understanding the cellular basis for immunologic memory. In an adult animal, the T and B cells in the secondary lymphoid organs are a mixture of cells in at least three stages of maturation, which can be designated *virgin* (or naive) cells, *memory* cells, and *activated* cells. When *virgin* cells encounter antigen for the first time, some of them are stimulated to multiply and become *activated cells*, which we define as cells that are actively engaged in making a response (activated T cells carry out cell-mediated responses, whereas activated B cells secrete antibodies). Other virgin cells are stimulated to multiply and mature instead into *memory cells*, which are not themselves making a response but are readily induced to become activated cells by a later encounter by the same antigen (Figure 28–5). One reason for the increased responsiveness of memory cells is that their receptors have a higher affinity for antigen. Memory T cells seem to respond to antigen more readily than virgin T cells, not only because they have higher-affinity receptors for antigen but also because they adhere more strongly to other cells and transduce extracellular signals more efficiently. Thus, immunologic memory is generated during the primary response in part because the proliferation of antigen-triggered virgin cells creates many memory cells, a process known as *clonal expansion* (see Figure 28–5).

The failure to respond to self-antigens is attributable to acquired immunologic tolerance.[18] How is the immune system able to distinguish foreign molecules from self-molecules? One possibility might be that an animal inherits genes that encode receptors for foreign antigens but not self-antigens, so its immune system is genetically constituted to respond only to foreign antigens. Alternatively, the immune system could be inherently capable of responding to both foreign and self-antigens but could "learn" during development not to respond to self-antigens. The latter explanation has been shown to be correct. The mechanisms of this acquired immunologic tolerance are critically important so that humans, in general, do not develop immunologic disease directed against the self, which results in autoimmunity, which could lead to death. The resulting state of antigen-specific immunologic unresponsiveness is known as *acquired immunologic tolerance*.

The learning process that leads to self-tolerance can involve either killing the self-reactive lym-

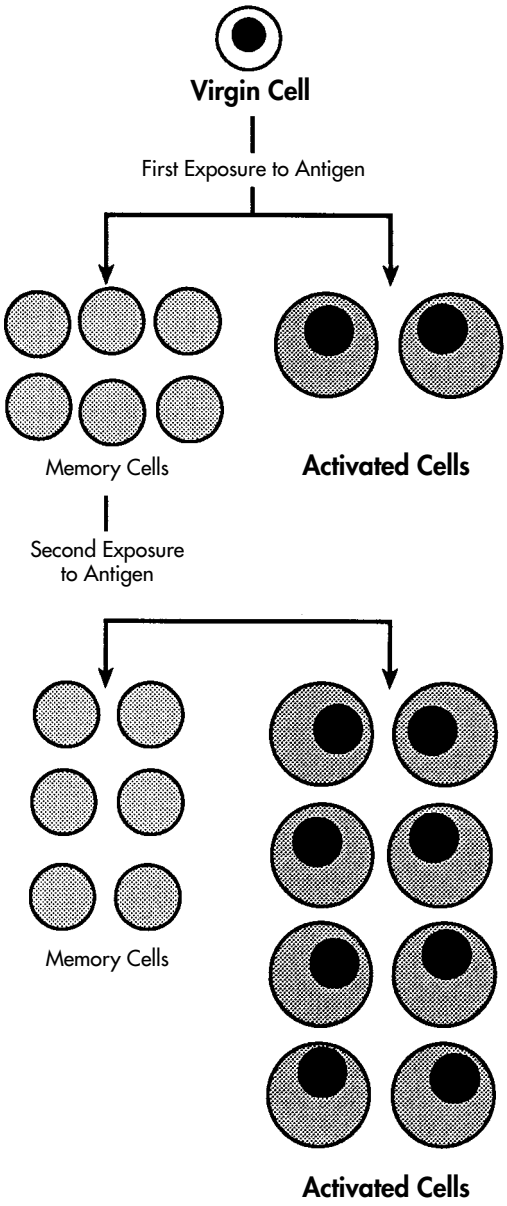

FIGURE 28–5. A model for the cellular basis of immunologic memory. When virgin T or B cells are stimulated by their specific antigens, they proliferate and mature; some become activated to make a response, whereas others become memory cells. During a subsequent exposure to the same antigen, the memory cells responded more readily than did the virgin cells: they proliferate and give rise to activated cells and to more memory cells. In the model shown, an individual virgin cell can give rise to either a memory cell or an activated cell, depending on the conditions. In an alternative model (not shown), the virgin cells that mature into memory cells are different from those that mature into activated cells. It is not known which of these models is correct.

phocyte (*clonal deletion*) or functionally inactivating cells and leaving them alive (*clonal anergy*). Tolerance to self-antigens sometimes breaks down, causing T or B cells or both to react against their own tissue antigens. Myasthenia gravis is an example of such an *autoimmune disease*.[19] Affected individuals make antibodies against the acetylcholine receptors on their own skeletal muscle cells; the antibodies interfere with the normal functioning of the receptors so that such patients become weak and can die because they cannot breathe.

In summary, the immune system evolved to defend vertebrates against infection. It is composed of millions of lymphocyte clones. The lymphocyte in each clone shares a unique cell-surface receptor that enables it to bind to a particular antigenic determinant consisting of a specific arrangement of atoms on a part of a molecule. There are two classes of lymphocytes: B cells, which are produced in the bone marrow and make antibodies, and T cells, which are produced in the thymus and make cell-mediated immune responses. Beginning early in lymphocyte development, many lymphocytes that would react against antigenic determinants on self-macromolecules are eliminated or inactivated; as a result, the immune system normally reacts only to foreign antigens. The binding of a foreign antigen to a lymphocyte initiates a process by the cell that helps to eliminate the antigen. As part of the response, some lymphocytes proliferate and mature into memory cells that are able to respond more readily to antigen than do virgin cells. Thus, the next time the same antigen is encountered, the immune response to it is much faster and stronger. The remainder of this chapter discusses the structure and property of antibodies that are the result of B-cell maturation and the development of T-cell immunity.

FUNCTIONAL PROPERTIES OF ANTIBODIES

Synthesized exclusively by B cells, antibodies are produced in millions of forms, each with a different amino acid sequence and a different binding site for antigen.[20] Collectively, these antibodies are called *Igs*. They are among the most abundant protein components in the blood, constituting about 20% of the total plasma protein by weight.[21] All antibody molecules made by an individual B cell have the same antigen-binding site. The antibodies made by a newly formed B cell are not secreted. Instead, they are inserted into the plasma membrane, where they serve as a receptor for antigen. Each B cell has approximately 10^5 such antibody molecules in its plasma membrane.[22] Each of these antibody molecules is noncovalently associated with an invariant set of transmembrane polypeptide chains that are involved in passing signals to the cell interior when the extracellular binding site of the antigen is occupied by antigen. Each B cell produces a single species of antibody with a unique antigen-binding site. When a virgin or memory B cell is activated by antigen, it proliferates and matures to become an antibody-secreting cell (plasma cell). The activated cells make and secrete large amounts of soluble rather than membrane-bound antibody, which has the same unique antigen-binding site as the cell-surface antibody that served earlier as the antigen receptor.[23] Plasma cells seem to have committed so much of their protein synthesizing machinery to making antibody that they are incapable of further growth and division, and most die after several days.

ANTIBODIES HAVE TWO IDENTICAL ANTIGEN-BINDING SITES

The simplest antibodies are Y-shaped molecules with two identical *antigen-binding sites*, one at the tip of each arm of the Y (Figure 28–6). Because of

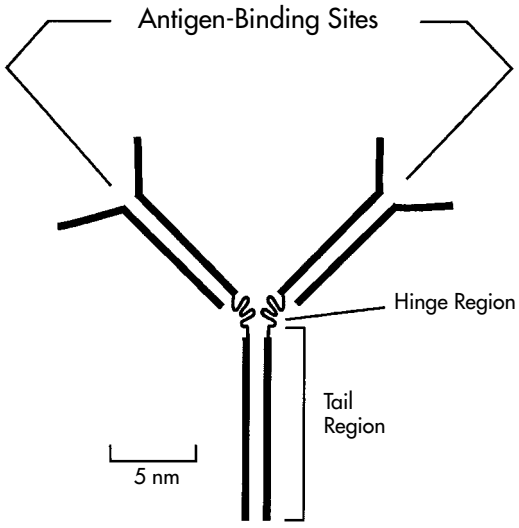

FIGURE 28–6. A simple representation of an antibody molecule. Note that its two antigen-binding sites are identical.

their two antigen-binding sites, they are said to be *bivalent*. As long as an antigen has three or more antigenic determinants, bivalent antibody molecules can cross-link it into a large lattice, which can be rapidly phagocytosed and degraded by macrophages (Figure 28–7).[24] The efficiency of antigen binding and cross-linking is greatly increased by a *flexible hinge region* in antibodies, which allows the distance between the two antigen-binding sites to vary.

The protective effect of antibodies is not due simply to their ability to bind antigen. They engage in a variety of activities that are mediated by the tail of the Y-shaped molecule. This part of the molecule determines what will happen to the antigen once it is bound to the antibody. One of several different tailed regions can confer on the antibody different functional properties such as the ability to activate complement or to bind to phagocytic cells. The basic structural unit of an antibody molecule consists of four polypeptide chains; two identical *light* (*L*) *chains*, each containing about 220 amino acids, and two identical *heavy* (*H*) *chains*, each usually containing about 440 amino acids.[25] The four chains are held together by a combination of noncovalent and covalent disulfide bonds. The molecules are composed of two identical halves, each with the same antigen-binding site, and both light and heavy chains usually cooperate to form the antigen-binding surface (Figure 28–8, A). There are five classes of heavy chains, each with different biologic properties. In higher vertebrates, there are five classes of antibodies, IgA, IgD, IgE, IgG, and IgM, each with its own class of heavy chain, α, δ, ε, γ, and μ, respectively.[26] Immunoglobulin A molecules have α chains, IgG molecules have γ chains, and so on. In addition, there are a number of subclasses of IgG and IgA; for example, there are four human IgG subclasses (IgG1, IgG2, IgG3, and IgG4), having $\gamma 1$, $\gamma 2$, $\gamma 3$, and $\gamma 4$ heavy chains, respectively.[27] The various heavy chains impart a distinctive confirmation to the hinge and tail regions of the body and give each class (and subclass) characteristic properties.

Immunoglobulin M, which has a μ heavy chain, is always the first class of antibody produced by developing B cells, although many of these cells eventually switch to making other classes of antibody, which are discussed below. The immediate precursor of the B cell, called a *pre-B cell*, initially makes μ chains, which associate with non–light-chain polypeptides, often referred to as surrogate light chains, which insert into the plasma membrane. As the synthesis of bona fide light chains increases,

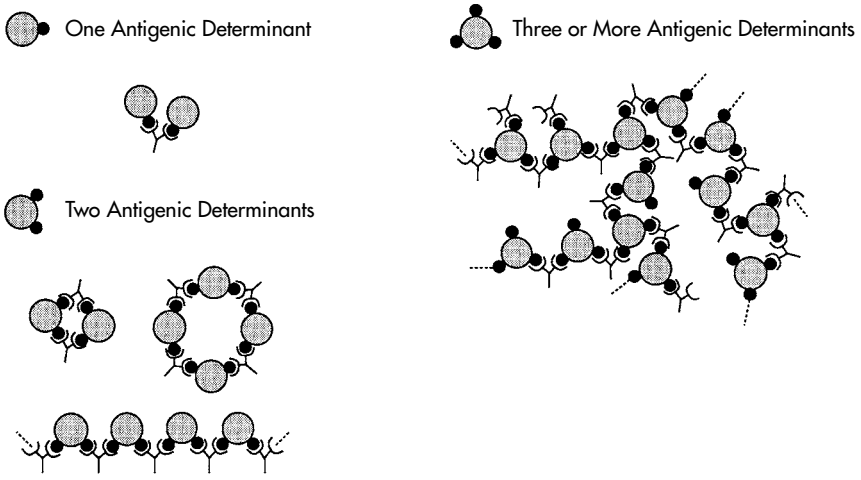

FIGURE 28–7. Antibody–antigen interactions. Because antibodies have two identical antigen-binding sites, they can cross-link antigens. The types of antibody-antigen complexes that form depend on the number of antigenic determinants on the antigen. Here a single species of antibody (a monoclonal antibody) is shown binding to antigens containing one, two, or three copies of a single type of antigenic determinant. Antigens with two antigenic determinants can form small cyclic complexes or linear chains with antibody, whereas antigens with three or more antigenic determinants can form large three-dimensional lattices that readily precipitate out of solution. Most antigens have many different antigenic determinants, and the different antibodies that recognize these different determinants can cooperate in cross-linking the antigen.

these combine with the μ chains, displacing the surrogate light chains, to form a four-chain IgM molecule (with two μ chains and two light chains), which inserts into the plasma membrane. The cell now has cell-surface receptors with which it can bind antigen, and, at this point, it is called a *virgin B cell*. Many virgin B cells soon start to produce cell-surface IgD molecules as well, with the same antigen-binding site as the IgM molecules. Finally, it is to be noted that IgM, IgD surface-positive B cells are found in the mantle zone in the palatine tonsil and nasopharyngeal tonsil.[28]

Immunoglobulin M is not only the first class of antibody to appear on the surface of the developing B cell, it is also the major class secreted into the blood in the early stages of a *primary* antibody response. In its secreted form, IgM is a pentamer composed of five four-chain units and thus has a total of 10 antigen-binding sites. Each pentamer contains one copy of another polypeptide chain called a *J chain* (joining chain).[29] The J chain is produced by IgM-secreting cells and is covalently inserted between two adjacent tails (Fc regions) (Figure 28–8, B). The binding of antigen to the Fab regions of the secreted pentameric IgM molecule induces the Fc regions to bind to and thereby activate the first component of the *complement system*.[30] When the antigen is on the surface of an invading microorganism, the resulting activation of complement unleashes a biochemical attack that kills the microorganism. Unlike IgM, IgD molecules are rarely secreted by an activated B cell, and their functions (other than receptors for antigen) are unknown.

The major class of Ig in the blood is *IgG*, which is produced in large quantities during *secondary* immune responses.[31] Besides activating the complement system, the Fc region of an IgG molecule binds to specific receptors on macrophages and neutrophils. Largely by means of such *Fc receptors*, these phagocytic cells bind, ingest, and destroy infecting microorganisms that have become coated with the IgG antibodies produced in response to the infection (Figure 28–9).

Immunoglobulin G molecules are the only antibodies that can pass from mother to fetus via the placenta. Immunoglobulin G is also secreted into the

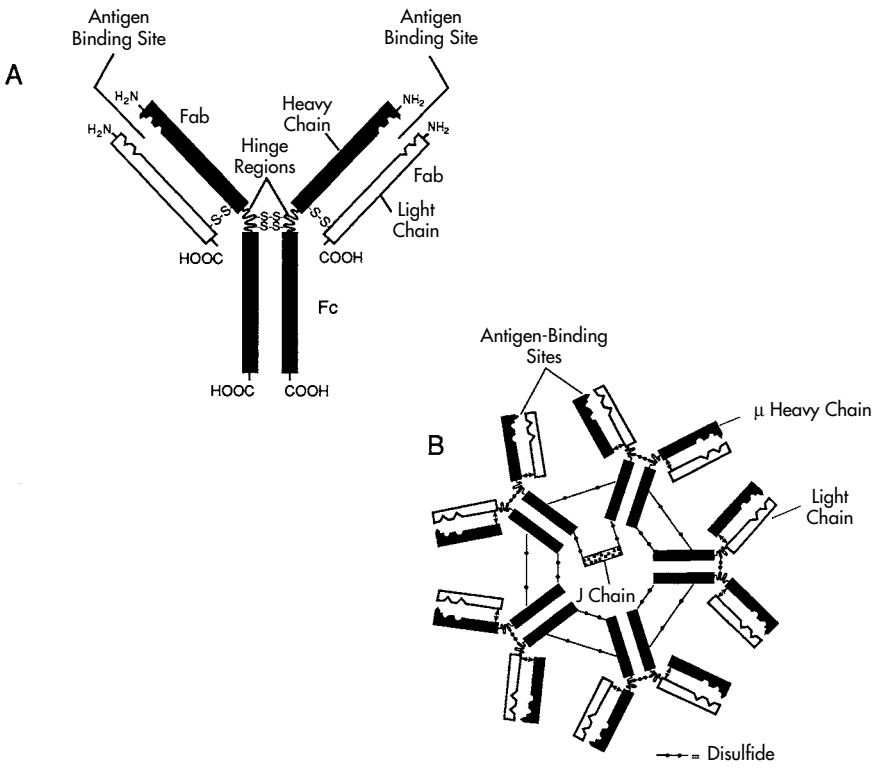

FIGURE 28–8. A, Schematic drawing of a typical antibody molecule. It is composed of two identical heavy chains and two identical light chains. Note that the antigen-binding sites are formed by a complex of the amino-terminal regions of both light and heavy chains, and the tail and hinge regions are formed by the heavy chains alone. *B*, A pentameric immunoglobulin (Ig) M molecule. The five subunits are held together by disulfide bonds. A single J chain, which has a structure similar to that of a single Ig domain, is disulfide bonded between two μ heavy chains. The J chain is required for the polymerization process. The addition of each successive four-chain IgM subunit requires a J chain, which is then discarded, except for the last one, which is retained.

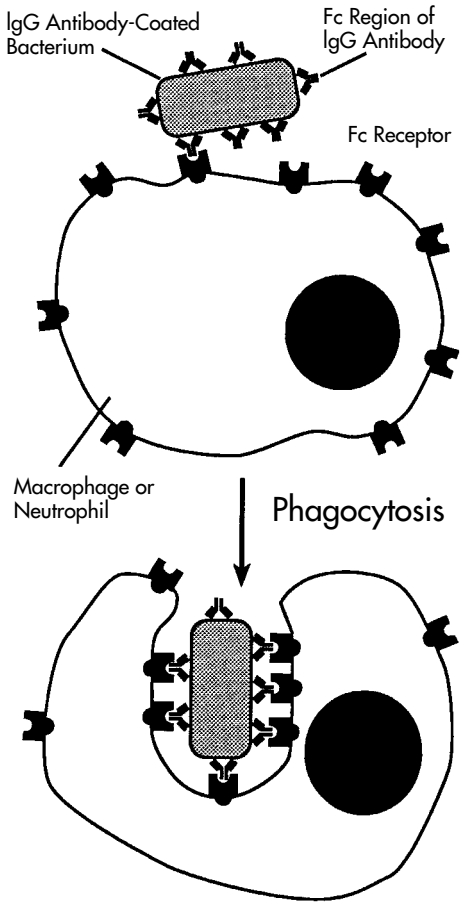

FIGURE 28–9. Antibody-activated phagocytosis. An immunoglobulin (Ig)G-antibody-coated bacterium is efficiently phagocytosed by a macrophage or neutrophil, which has cell-surface receptors able to bind the Fc region of IgG molecules. The binding of the antibody-covered bacterium to these Fc receptors activates the phagocytic process.

mother's milk and is taken up from the gut of the neonate into the blood.

Immunoglobulin A is the principal class of antibody in secretions (saliva, tears, milk, and respiratory and intestinal secretions).[32] Immunoglobulin A is transported through secretory epithelial cells from the extracellular fluid into the secreted fluid by another type of Fc receptor that is unique to secretory epithelia. A highly schematized diagram of dimeric IgA with J chain is shown in Figure 28–10, and the mechanism of transport of a dimeric IgA molecule across an epithelial surface such as, for example, the nasal mucosa is shown in Figure 28–11. The mechanism of transport of dimeric IgA into secretions of the mucosa-associated immune system is shown in Figure 28–11.

The Fc region of *IgE* molecules binds with unusually high affinity to yet another class of Fc receptors. These receptors are located on the surface of *mast cells* in tissues and on *basophils* in the blood, and the IgE molecules bound to them in turn serve as receptors for antigen.[33] Antigen binding triggers the cells to secrete a variety of biologically active amines, especially histamine. These amines cause dilation and increased permeability of blood vessels and are largely responsible for the clinical manifes-

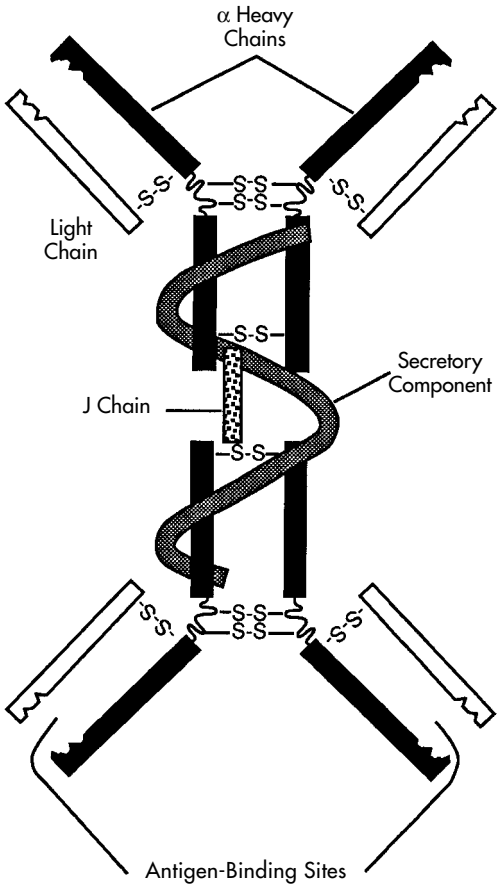

FIGURE 28–10. A highly schematized diagram of a dimeric immunoglobulin (Ig)A molecule found in secretions. In addition to the two IgA monomers, there is a single J chain and an additional polypeptide chain called the *secretory component*, which is thought to protect the IgA molecules from being digested by proteolytic enzymes in the secretions. The secretory component molecule is found on the basolateral surface of the epithelial cells and appears to be the receptor for the J chain.

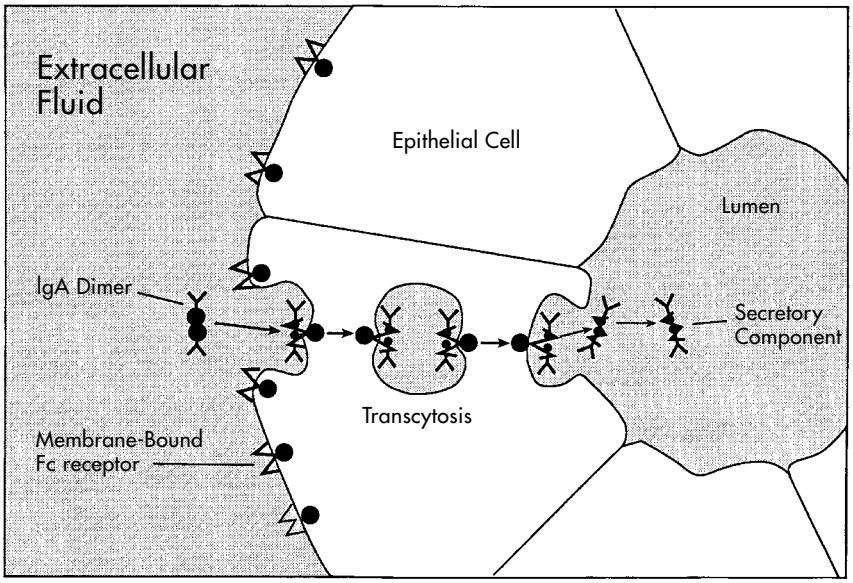

FIGURE 28–11. The mechanism of transport of a dimeric immunoglobulin (Ig)A molecule across an epithelial cell. The IgA molecule, as a J chain–containing dimer, binds to a specialized transmembrane Fc receptor protein on the nonluminal surface of the secretory epithelial cell. The surface of the receptor-IgA complexes are ingested by receptor-mediated endocytosis, transferred across the epithelial cell cytoplasm in vesicles, and then secreted into the lumen of the opposite side of the cell by exocytosis. When exposed to the lumen, the part of the Fc receptor protein that is bound to the IgA dimer (*the secretory component*) is cleaved from its transmembrane tail, thereby releasing the antibody in the form shown in Figure 28–10.

tations of such allergic reactions as hay fever, asthma, and hives. Mast cells also secrete factors that attract and activate a special class of white blood cells called eosinophils, which can kill various types of parasites, especially if the parasites are coated with IgE or IgA antibodies. The properties of the various classes of antibodies in humans are summarized in Table 28–1.

Antibodies Can Have Either κ or λ Light Chains But Not Both

In addition to the five classes of heavy chains, higher vertebrates have two types of light chains, κ and λ, either of which may be associated with any of the heavy chains.[34] An individual-antibody molecule always consists of identical light chains and identical heavy chains; therefore, its two antigen-binding sites are always identical. This symmetry is crucial for the cross-linking function of secreted antibodies. Consequently, an Ig molecule may have either κ or λ light chains but not both. No difference in the biologic function of these two types of light chains has yet been identified.

Antibodies Recruit Complement to Help Fight Bacterial Infections

Complement, so called because it *complements* and amplifies the action of antibody, is one of the principal means by which antibodies defend vertebrates against most bacterial infections. Individuals with a deficiency in one of the central complement components (called C3) are subject to repeated bacterial infections, just as are individuals deficient in antibodies themselves. The complement system consists of at least 20 interacting soluble proteins that are made mainly by the liver and circulate in the blood and extracellular fluid.[35] Most are inactive until they are triggered by an immune response or, more directly, by an invading microorganism itself. The ultimate consequence of complement activation is the assembly of the so-called late *complement components* into large protein complexes, called *membrane attack complexes*, that form holes in the membrane of a microorganism and thereby destroy the microorganism.[36]

Because one of its main functions is to attack the membrane of microbial cells, the activation of

TABLE 28–1. Properties of the Major Classes of Antibody in Human

	Class of Antibody				
Properties	*IgM*	*IgD*	*IgG*	*IgA*	*IgE*
Heavy chains	μ	δ	γ	α	ε
Light chains	κ or λ	κ or λ	κ or λ	κ or λ	κ

Percent of total Ig in blood	10	< 1	75	15	< 1
Activates complement	++++	–	++	–	–
Crosses placenta	–	–	+	–	–
Binds to macrophages and neutrophils	–	–	+	–	–
Binds to mast cells and basophils		–	–	–	+

Ig = immunoglobulin.

complement is focused on the microbial cell membrane, where it is triggered either by antibody bound to the microorganism or by microbial envelope polysaccharides, both of which activate the early *complement components*. There are two sets of early components belonging to two distinct pathways of complement activation: *the classic pathway* and the *alternative pathway*. The early components of both pathways act locally to activate *C3*, which is the pivotal component of complement, whose cleavage leads not only to the assembly of membrane attack complexes but also to the recruitment of various white blood cells, particularly neutrophils (Figure 28–12).

The early components and C3 are proenzymes that are activated sequentially by a limited proteolytic cleavage: the cleavage of each proenzyme in the sequence activates the component to generate a serine protease, which cleaves the next proenzyme in the sequence, and so on. Since each activated enzyme cleaves many molecules of the next proenzyme in the chain, the activation of the early components consists of an amplifying *proteolytic cascade*. Thus, each molecule activated at the beginning of the sequence leads to the production of many activated components, including many membrane attack complexes.

Many of these cleavages liberate a small peptide fragment and thereby expose a membrane-binding site on the large fragment, which binds tightly to the target cell membrane and helps to carry out the next reaction in the sequence, eventually leading to the formation of membrane attack complexes. In this way, complement activation is confined largely to the particular cell surface where

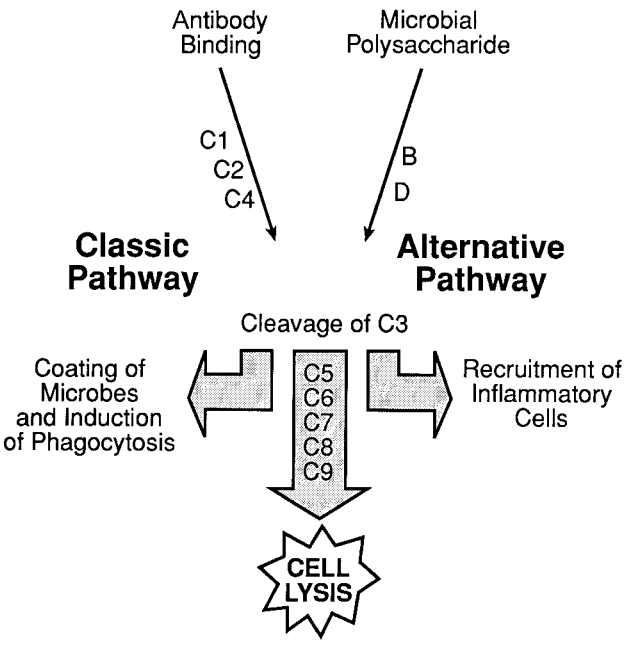

FIGURE 28–12. The principal stages in complement activation by the classic and alternative pathways. In both pathways, the reactions of complement activation usually take place on the surface of an invading microbe, such as a bacterium. C1–C9 and factors B and D are the reacting components of the complement system; various other components regulate the system. The early components are shown with *thin arrows*, whereas the late components are shown with *broad arrows*.

it began. The larger fragment of C3 is called C3b. It binds covalently to the surface of a target cell. There it not only acts as a protease to catalyze the subsequent steps in the complement cascade but also is recognized by specific receptor proteins on macrophages and neutrophils that enhance the ability of these cells to phagocytose the target cell. The smaller fragment of C3, C3a, acts independently as a diffusable signal that promotes an inflammatory response by encouraging white blood cells to migrate into the site of the infection.

The classic pathway is usually activated by clusters of IgG or IgM antibodies bound to antigens on the surface of a microorganism. The alternative pathway, in contrast, is activated by polysaccharides in the cell envelopes of the microorganisms even in the absence of antibodies. The alternative pathway therefore provides a first line of defense against infection before an immune response can be mounted and also amplifies the effects of the classic pathway once an immune response has begun.

The self-amplifying destructive properties of the complement cascade make it essential that key activated components be rapidly inactivated after they are generated to ensure that the attack does not spread to nearby normal host cells. Deactivation is achieved in at least two ways. First, specific inhibitor proteins in the blood terminate the cascade by either binding or cleaving certain components once they have been activated by proteolytic cleavage.[37] Second, many of the activated components in the cascade are unstable; unless they bind immediately to an appropriate component in the chain or nearby membrane, they rapidly become inactive. The assembly of the late complement components to form a membrane attack complex is illustrated in Figure 28–13.

In summary, a typical antibody molecule is a Y-shaped protein with two individual antigen-binding sites at the tips of the Y (the Fab regions), and binding sites for complement components and/or various cell-surface receptors are on the tail of the Y (the Fc region). Antibodies defend humans against infection by inactivating viruses and bacterial toxins and by recruiting the complement system in various cells to kill and ingest invading microorganisms. Multiple studies performed in our laboratory have shown that IgG is the principal Ig involved in defense against acute bacterial infections of the middle ear and sinuses.[38] On the other hand, IgA is the principal Ig covering the nasopharyngeal mucus and in preventing adherence of potentially pathogenic microorganisms.[39]

Each B-cell clone makes antibody molecules with a unique antigen-binding site. Initially, the molecules are inserted into the plasma membrane,

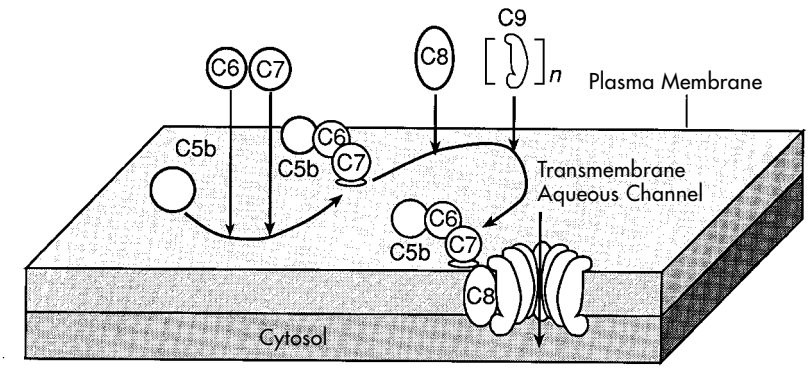

FIGURE 28–13. Assembly of the late complement components to form a membrane attack complex. When C3b is produced by either the classic or alternative pathway, it is mobilized on the membrane, where it causes the cleavage of a complement protein called C5 to produce C5a and C5b. C5b remains loosely bound to C3b (not shown) and rapidly assembles with C6 and C7 to form C5,6,7, which then binds firmly via C7 to the membrane, as illustrated. This complex adds one molecule of C8 to form C5,6,7,8. The binding of a molecule of C9 to C5,6,7,8 induces a confirmational change in the C9 that exposes a hydrophobic region and causes the C9 to insert into the lipid bilayer of the target cell next to C8. This starts a chain reaction in which the altered C9 binds a second molecule of C9, which undergoes a confirmational change and inserts into the bilayer, where it combines with another molecule of C9, and so on. In this way, a large transmembrane channel or pore is formed by a chain of C9 molecules.

where they serve as receptors for antigen. Antigen binding to these receptors activates the B cells (usually with the aid of helper T cells) to multiply and mature into either memory cells or antibody-secreting cells, which secrete antibodies with the same unique antigen-binding site as the membrane-bound antibodies. These B-cell clones are found in the tonsils and adenoids, and these two lymphoepithelial structures represent primarily B-cell tissues that are primarily responsible for a first line of defense against invading viruses and other microorganisms, possibly as well as food antigens.[40]

Each antibody molecule is composed of two identical heavy chains and two identical light chains. Typically, parts of both the heavy and light chains form the antigen-binding sites.[41] There are five classes of antibodies (IgA, IgD, IgE, IgG, and IgM), each with a distinctive heavy chain (α, δ, ε, γ, and μ, respectively). The heavy chains also form the Fc region of the antibody, which determines what other proteins will bind to the antibody and therefore what biologic properties the antibody class has. Either type of light chain (κ or λ) can be associated with any class of heavy chain, but the type of light chain does not seem to influence the properties of the antibody.

The complement system cooperates with antibodies to defend vertebrates against infection.[42] The early components are proenzymes that circulate in the blood and are sequentially activated in an amplifying series of limited proteolytic reactions. The most important complement component is the C3 protein, which is activated by proteolytic cleavage and binds to the membrane of the microbial cell, where it helps to initiate the local assembly of the late complement components and to induce the phagocytosis of the microbial cell. The late components form large membrane attack complexes in the microbial cell membrane and thereby kill the invading microorganism. Two final subjects on antibodies need to be discussed; the fine structure of antibodies and antibody diversity.

Light and Heavy Chains Each Contain Three Hypervariable Regions That Together Form the Antigen-Binding Site

Scrutiny of the amino acid sequences of a variety of Ig chains shows that the variability in the variable regions of both the light and heavy chains is, for the most part, restricted to three small hypervariable regions in each chain.[43] The remaining part of the variable region, known as the *framework regions*, is relatively constant. These findings led to the prediction that only 5 to 10 amino acids in each hypervariable region form an antigen-binding site. This prediction has since been confirmed by x-ray diffraction studies of antibody molecules. In agreement with the size of the antigen-binding site of an antibody molecule, the antigenic determinant that is specifically recognized by an antibody is generally comparatively small; it can consist of fewer than 25 amino acid residues on the surface of the globular protein and can be as small as a dinitrophenol group.[44]

Both light and heavy chains are made up of repeating segments, each about 110 amino acids and each containing one intrachain disulfide bind, that fold independently to form compact functional units or *domains*. As shown in Figure 28–14, a light

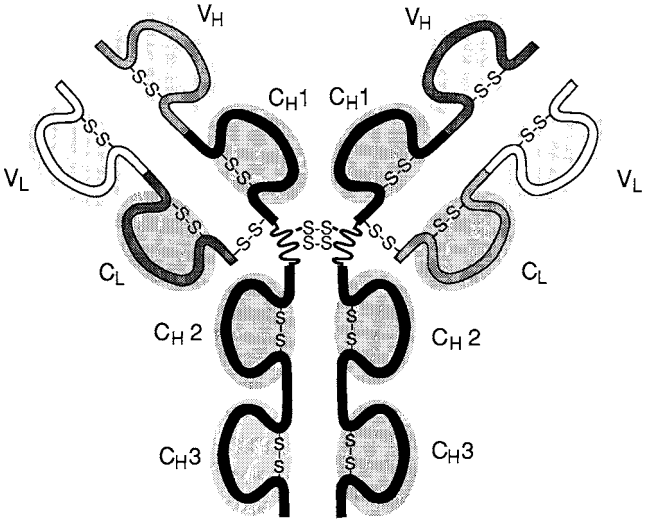

FIGURE 28–14. Immunoglobulin (Ig) domains. The light and heavy chains in an Ig molecule are each folded into repeating domains that are similar to one another. The variable domains of the light and heavy chains (V_L and V_H) make up the antigen-binding sites, whereas the constant domains of the heavy chains (mainly C_H2 and C_H3) determine the other biologic properties of the molecule. The heavy chains of IgM and IgE antibodies have an extra constant domain (C_H4). Hydrophobic interactions between domains on adjacent Ig chains play an important part in holding the chains together in the Ig molecule: C_L binds to C_H1, for example, and the C_H3 domains bind to each other.

chain consists of one variable (V_L) and one constant (C_L) domain, whereas most heavy chains consist of a variable domain (V_H) and three constant domains (C_H1, C_H2, C_H3).[45] The μ and ε chains each have one variable and four constant domains. The variable domains are responsible for antigen binding, whereas the constant domains of the heavy chains excluding C_H1 form the Fc region that determines the other biologic properties of the antibody. The similarity between their domains suggests that Ig chains arose during evolution by a series of gene duplications, beginning with the primordial gene cloning for a similar 110 amino acid domain of unknown function. This hypothesis is supported by the finding that each domain of the constant region of the heavy chain is encoded by a separate coding sequence (exon).[46] The amino acid sequence variation in the variable regions of both light and heavy chains is for the most part confined to several small hypervariable regions; they form protruding surface loops that come together to form the antigen-binding site.

Generation of Antibody Diversity

Finally, a brief comment of antibody diversity is necessary to complete our discussion of the B-cell repertoire and antibody function as part of the humoral immune system. It is estimated that even in the absence of antigen stimulation, a human makes at least 10^{15} different antibody molecules, its *preimmune antibody repertoire*.[47] Antibodies are proteins, and proteins are encoded by genes. Antibody diversity, therefore, poses a special genetic problem: how can an animal make more antibodies than there are genes in its genome? (The human genome, for example, is thought to contain fewer than 10^5 genes.) This problem is not quite as formidable as it might first appear. Because the variable regions of both the light and heavy chains contribute to an antigen-binding site, an animal with 1,000 genes encoding light chains and 1,000 genes encoding heavy chains could combine their products in 1,000 × 1,000 ways to make 10^6 different antigen-binding sites, assuming that any light chain can combine with any heavy chain to make an antigen-binding site. Nonetheless, the mammalian immune system has evolved unique genetic mechanisms that enable it to generate an almost unlimited number of different light and heavy chains in a remarkably economical way by joining separate *gene segments* together before they are transcribed.

Antibodies are produced from three pools of gene segments, encoding κ light chains, λ light chains, and heavy chains, respectively.[48] In each pool, separate gene segments that code for different parts of the variable regions of light and heavy chains are brought together by site-specific recombination during B-cell differentiation. The light chain pools contain one or more constant (C) gene segments and sets of variable (V) and joining (J) segments. The heavy chain pool contains a set of C gene segments and sets of V, diversity (D), and J gene segments. To make an antibody molecule, a V_L gene segment is recombined with a J_L gene segment to produce a DNA sequence coding for the V region of the light chain, and a V_H gene segment is combined with a D and a J_H gene segment to produce a DNA sequence coding for the V region for the heavy chain. Each of the assembled gene segments is then cotranscribed with the appropriate C-region sequence to produce a messenger ribonucleic acid molecule that codes for the complete polypeptide chain. By variously combining gene segments that code for V_L and V_H regions, mammals can make thousands of different light chains and thousands of different heavy chains. Since the antigen-binding site is formed where V_L and V_H come together in the final antibody, the heavy and light chains can pair to form antibodies with millions of different antigen-binding sites. This number is enormously increased by the loss and gain of nucleotides at the site of gene-segment joining, as well as by somatic mutations that occur with very high frequency in the assembled V-region coding sequences following antigen stimulation.

All B cells initially make IgM antibodies. Later, some make antibodies of other classes but with the same antigen-binding site as the original IgM antibodies. Such class switching allows the same antigen-binding sites to be distributed among antibodies with varied biologic properties. In regard to the tonsils and adenoids, such B class switching has been well documented. The mantle zone of the secondary follicles possesses primarily IgD and IgM. The follicular areas of the tonsils and adenoids possess IgM, IgA, and IgG. The reticular epithelium possesses mainly IgG followed by IgA, IgM, and IgD. Finally, only approximately 2% of the tonsillar lymphocytes are mature plasma cells that secrete Igs.[49]

T-CELL RECEPTORS AND SUBCLASSES

The diverse responses of T cells are collectively called *cell-mediated immune reactions.*[50] Like antibody responses, they are exquisitely antigen specific and are at least as important in defending vertebrates against infection. T cells differ from B cells, however, in several important ways.[51] First, they act only at short range, interacting directly with another cell in the body, which they either kill or signal in some way. These latter cells may be considered target cells such as cells infected with a virus or even tumor cells; B cells, by contrast, secrete antibodies that can act far away. Second, T cells are specialized to recognize foreign antigen only when it is displayed on the surface of a target cell. For this reason, the form of antigen recognized by T cells is different from that recognized by B cells: whereas B cells recognize intact antigens, T cells recognize peptide fragments of protein antigens that have been partially degraded inside the target cell and then carried to the cell surface and displayed there. In this way, T cells are able to detect the presence of microorganisms that proliferate inside cells, as well as foreign extracellular antigens that cells have ingested. There are two main classes of T cells: cytotoxic T cells and helper T cells.[52] *Cytotoxic T cells* directly kill cells that are infected with a virus or some other intracellular microorganism. *Helper T cells*, in contrast, help stimulate the response of other cells: they help activate macrophages and B cells, for example.

T-Cell Receptors Are Antibody-Like Heterodimers

Because T-cell responses depend on direct contact with the target cell, the antigen receptors made by T cells, unlike antibodies made by B cells, exist only in membrane-bound form and are not secreted. On both cytotoxic and helper T cells, receptors are composed of two disulfide-linked polypeptide chains called α and β, each of which contains two Ig-like domains and shares with antibodies the distinctive property of a variable amino-terminal region and a constant carboxyl-terminal region (Figure 28–15).[53]

The gene pools that encode the α and β chains are located on different chromosomes and contain, like antibody gene pools, separate V, D, J, and C gene segments, which are brought together by site-specific recombination during T-cell development in the thymus.

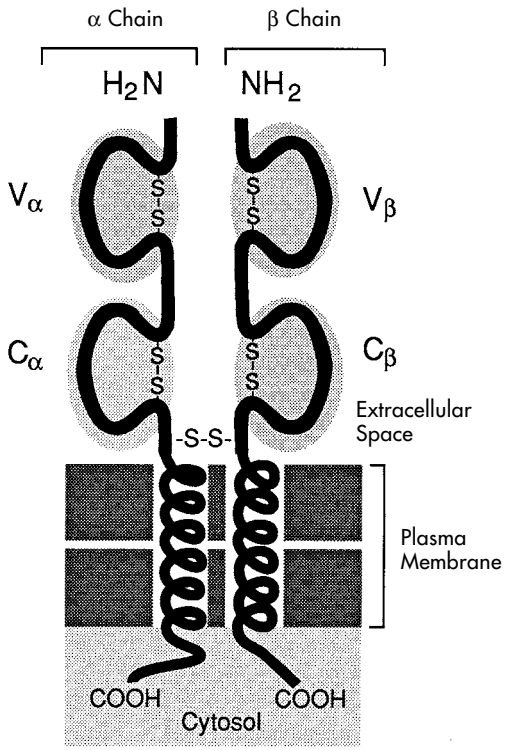

FIGURE 28–15. A T-cell receptor heterodimer. The receptor is composed of an α and a β polypeptide chain. Each chain is about 280 amino acids long and has a large extracellular part that is folded into two immunoglobulin-like domains, one variable (V) and one constant (C). It is thought that an antigen-binding site formed by a V_α and a V_β domain is similar in its overall dimensions in geometry to the antigen-binding site of an antibody molecule. Unlike antibodies, however, which have two binding sites for antigen, T cell receptors have only one. The α/β heterodimer shown is noncovalently associated with the large set of invariant proteins that help activate the T cell when the T-cell receptors bind to antigen. A typical T cell has about 20,000 such receptor complexes on its surface.

A small minority of T cells, instead of making α and β chains, make a different type of receptor heterodimer, composed of γ and δ chains.[54] These cells arise early in development and are found mainly in epithelia (eg, in the skin and gut) and also in the nasal mucosa. As is the case for antigen receptors on B cells, the T-cell receptors are tightly associated in the plasma membrane with a number of invariant proteins that are involved in passing a signal from an antigen-activated receptor to the cell interior.

Different T-Cell Responses Are Mediated by Distinct Classes of T Cells

The two major classes of T cells have very different functions. *Cytotoxic T cells* kill cells harboring harmful microbes, whereas *helper T cells* help activate the responses of other white blood cells, mainly by secreting a variety of local mediators collectively called lymphokines, ILs, or cytokines. These proteins are discussed later in this chapter. Thus, cytotoxic T cells provide protection against pathogenic microorganisms, such as viruses and some intracellular bacteria, which multiply in the host cytoplasm, where they are sheltered from attack by antibodies. The most efficient way of preventing such microorganisms from spreading to other cells is to kill the infected cell before the microorganism can proliferate. Helper T cells, in contrast, are crucial for stimulating responses to extracellular microorganisms and their toxic products. There are at least two types of helper T cells: *T_H1 cells*, which activate macrophages to destroy microorganisms that they have ingested, and *T_H2 cells*, which stimulate B cells to proliferate and secrete antibodies, particularly of the IgE and IgG classes.[55]

Both cytotoxic T cells and helper T cells recognize antigen in the form of peptide fragments that are generated by degradation of foreign protein antigens inside the target cell; therefore, both depend on the presence in the target cell of special proteins that bind these fragments, carry them to the cell surface, and present them there to the T cells. These special proteins are called *MHC molecules* because they are encoded by a complex of genes called the major histocompatibility complex (MHC).[56] There are two structurally and functionally distinct classes of MHC molecules: *class I MHC molecules*, which present foreign peptides to cytotoxic cells, and *class II MHC molecules*, which present foreign peptides to helper cells.[57] A close look at the MHC molecules themselves must now be undertaken to understand T-cell immunity.

Major Histocompatibility Complex Molecules and Antigen Presentation to T Cells

Major histocompatibility complex molecules were recognized long before their normal function was understood. They were initially defined as the main target antigens in *transplantation reactions*. When organ grafts are exchanged between adult individuals, either of the same species (allografts) or of different species (xenografts), they are usually rejected. This graft rejection is an immune response to antigens on the surface of the graft itself. It has been shown that these reactions are mediated mainly by T cells and that they are directed against "genetically foreign" versions of cell-surface proteins called *histocompatibility molecules*. The MHC family of proteins encoded by the cluster genes of the MHC is by far the most important of these. Major histocompatibility complex molecules are expressed on the cells of all higher vertebrates. They were first demonstrated in mice and were called *H-2 antigens*. In humans, they are called HLA antigens (human leukocyte–associated antigens) because they were first demonstrated on leukocytes (white blood cells). Three remarkable properties of MHC molecules baffled immunologists for a long time. First, MHC molecules are overwhelmingly the preferred target antigens for T-cell-mediated transplantation reactions. Second, an unusually large fraction of T cells is able to recognize foreign antigen MHC molecules: whereas fewer than 0.001% of an individual's T cells respond to a typical viral antigen, more than 0.1% of them respond to a single foreign MHC antigen. Third, many of the loci that code for MHC molecules are the most *polymorphic* known in higher vertebrates, that is, within a species, there is an extraordinarily large number of alleles (alternate forms of the same genes)[58] at each locus (in some cases as many as 100), each allele being present at a relatively high frequency in the population. For this reason, and because each individual has five or more loci encoding MHC molecules, it is very rare for two individuals to have an identical set of MHC proteins, making it very difficult to match donor and recipient for organ transplantation in humans (except in the case of genetically identical twins). Why is there this apparent obsession of one's own T cells to recognize foreign MHC molecules when a vertebrate does not usually need to be protected against invasion by foreign vertebrate cells? This puzzle has been solved since it has been discovered that the MHC molecules serve to focus T cells on those host cells that have foreign antigen on their surface and that the T cells respond to foreign MHC molecules in the same way as to self-MHC molecules that have foreign antigen bound to them.[59]

Thus, in summary, foreign protein molecules are presented to the T-cell receptor only in the context of their association with self-MHC molecules. In a sense, this is a form of physiologic autoimmunity in that a foreign molecule can be recognized by a T cell only when it is combined with a self-MHC molecule.

There Are Two Principal Classes of MHC Molecules

Class I and class II MHC proteins have very similar overall structures, as shown in Figure 28–16. They are both transmembrane heterodimers whose extracellular amino-terminal domains bind antigen for presentation to T cells. Each *class I MHC gene* encodes a single transmembrane polypeptide chain (called α), most of which is folded into three extracellular globular domains (α_1, α_2, α_3). Each α chain is noncovalently associated with a small extracellular protein called β_2-*microglobulin,* which does not span the membrane and is encoded by a gene that does not lie in the MHC cluster.[60] β_2-Microglobulin and the α_3 domain, which are closest to the membrane, are both homologous to an Ig domain. The two amino-terminal domains of the α chain, which are farthest from the membrane, bind antigen and contain the polymorphic (variable) amino acids that are recognized by T cells in transplantation reactions. Like class I MHC molecules, class II MHC molecules are heterodimers with two conserved Ig-like domains close to the membrane and two antigen-binding polymorphic (variable) amino-terminal domains farthest from the membrane. In these molecules, however, both chains (α and β) are encoded within the MHC, and both span the membrane. The presence of Ig-like domains in class I and class II proteins suggests that MHC molecules and antibodies have a common evolutionary history. The locations of the genes that encode class I and class II MHC proteins in mice and humans are shown in Figure 28–17.[61]

Class I and Class II MHC Molecules Have Different Functions

Class I MHC molecules are expressed on virtually all nucleated cells, presumably because cytotoxic T cells must be able to focus on any cell in the body that happens to become infected with an intracellular

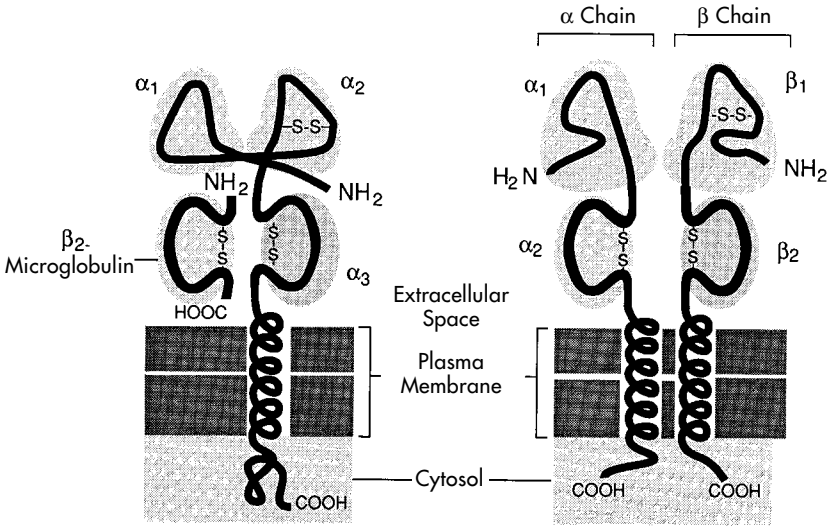

FIGURE 28–16. Class I and class II major histocompatibility complex (MHC) proteins. On the left, the α chain of the class I molecule has three extracellular domains, α_1, α_2, and α_3, encoded by separate exons. It is noncovalently associated with a smaller polypeptide chain, β_2-microglobulin, which is not encoded within the MHC. The α_3 domain and β_2-microglobulin are immunoglobulin (Ig)-like. Whereas β_2-microglobulin is invariant, the α chain is extremely polymorphic, mainly in the α_1 and α_2 domains. On the right in class II MHC molecules, both chains are polymorphic (β more than α), mainly in the α_1 and β_1 domains; the α_2 and β_2 domains are Ig-like. Thus, there are striking similarities between class I and class II MHC proteins. In both, the two outermost domains interact to form a groove that binds foreign antigen and presents it to T cells. All of the chains are glycosylated except for β_2-microglobulin.

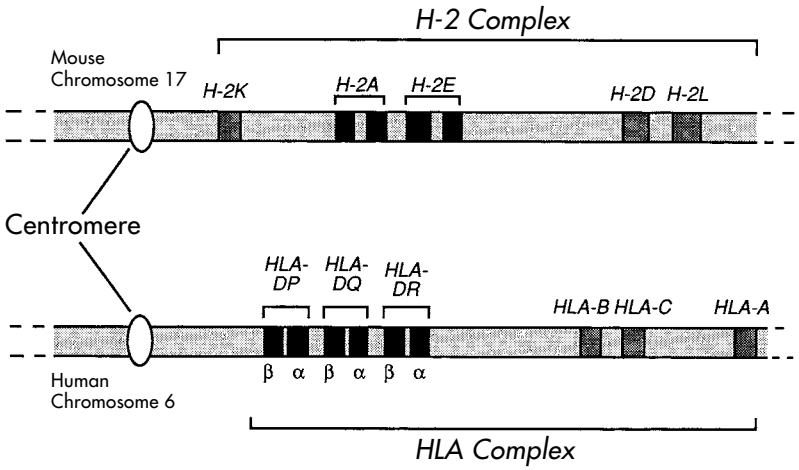

FIGURE 28–17. The H-2 and human leukocyte antigen (HLA) gene complexes. This simplified schematic drawing shows the location of the genetic loci that encode the transmembrane subunits of *class I* and *class II* major histocompatibility complex (MHC) proteins. There are three types of class I proteins (H-2K, H-2D, and H-2L in the mouse, and HLA-A, HLA-B, and HLA-C in the human). There are two class II MHC loci in the mouse, H-2A and H-2E, and more than three in humans, of which only three are shown, HLA-DP, HLA-DQ, and HLA-DR. Each class II locus encodes at least one α chain and at least one β chain, but some encode more than one α or β chain.

microbe such as a virus. Class II molecules, in contrast, are normally confined to specialized cells, such as B cells, macrophages, and other antigen-presenting cells that take up foreign antigens from the extracellular fluid and interact with helper T cells (Figure 28–18). The principal features of the two classes of MHC proteins are summarized in Table 28–2.

It is important that cytotoxic T cells focus their attack on cells that *make* foreign antigens, whereas helper T cells focus their help on cells that take up foreign antigens from the extracellular fluid. The former type of target cell is a menace, but the latter type is essential for the body's immune defenses. The immune system must be able to dispose of extracellular foreign antigens as many bacteria multiply outside cells, and some secrete protein toxins, such as tetanus toxin and botulinum toxin, that can be lethal. Helper T cells help eliminate such pathogens, both by helping B cells make antibodies against microbes and their toxins and by activating macrophages to destroy ingested microbes.

To ensure that there is no misdirection of cytotoxic and helper functions, each of the two major classes of T cells, in addition to the antigen receptor that recognizes a peptide-MHC complex, also expresses a *coreceptor* that recognizes a nonpolymorphic part of the appropriate class of MHC molecule. *CD4 and CD8 proteins act as MHC-binding coreceptors on helper and cytotoxic T cells, respectively.*[62] The affinity of T-cell receptors for peptide-MHC complexes on the target cell is usually too low to mediate a functional interaction between the two cells. *Accessory receptors* are normally required to help stabilize the interaction by increasing the overall strength of the cell-to-cell adhesion; when they also have a direct role in activating the T cell by generating their own intercellular signals, they are called *coreceptors*. Unlike T-cell receptors or MHC molecules, the accessory receptors do not bind antigen and are invariant and nonpolymorphic. The most important and best understood of the coreceptors on T cells are the CD4 and CD8 proteins, both of which are single-pass transmembrane proteins with extracellular Ig-like domains. Like T-cell receptors, they recognize MHC proteins, but unlike T-cell receptors, they bind to nonvariable parts of the protein, far away from the peptide-binding groove. *CD4* is expressed on helper T cells and binds to class II MHC molecules, whereas CD8 is expressed on cytotoxic T cells and binds to class I MHC molecules (Figure 28–19). The CD4 and CD8 proteins are not only required to increase the strength of cell-to-cell

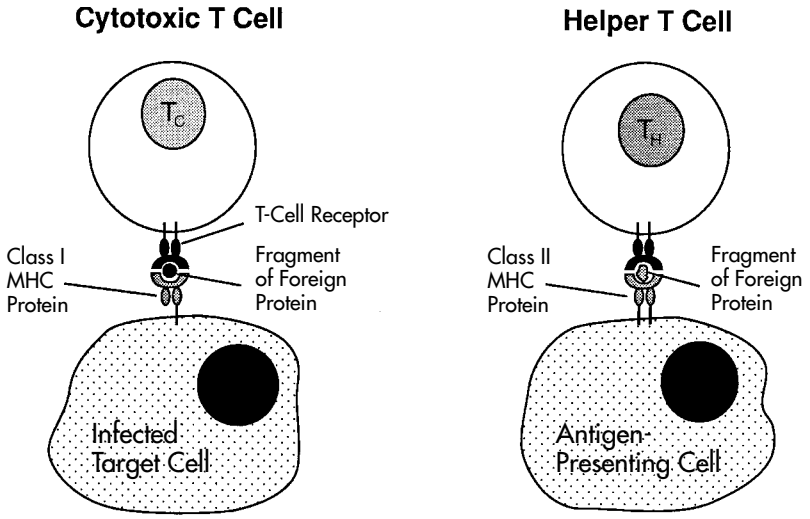

FIGURE 28–18. Cytotoxic and helper T cells recognize different major histocompatibility complex (MHC) molecules. Cytotoxic T cells recognize foreign antigens in association with class I MHC proteins on the surface of any infected host cell, whereas helper T cells recognize foreign antigens in association with class II MHC proteins on the surface of an antigen-presenting cell, such as a macrophage or a B cell. The foreign antigen bound to a class I MHC molecule is synthesized within the target cell, whereas the foreign antigen bound to a class II MHC molecule has been taken up by the cell by endocytosis and processed before it is presented on the cell surface. In transplantation reactions as well, helper T cells react against foreign class II MHC proteins, whereas cytotoxic T cells react against foreign class I MHC proteins.

adhesion and to help activate the T cell, they are also needed for T-cell development; if the genes that encode CD4 and CD8 are inactivated by targeted genetic recombination, then either helper T cells or cytotoxic T cells, respectively, do not develop. Ironically, CD4 also functions as a receptor for the acquired immune deficiency syndrome (AIDS) human immunodeficiency virus, allowing the virus to infect helper T cells.

CYTOTOXIC T CELLS

Cytotoxic T cells recognize fragments of viral proteins on the surface of virus-infected cells. As men-

TABLE 28–2. Properties of Class I and Class II MHC Molecules

	Class I	*Class II*
Genetic loci	H-2K, H-2D, H-2L in mice; HLA-A, HLA-B, HLA-C in humans	H-2A and H-2E clusters in mice; DP, DQ, DR, and several others in humans
Chain structure	α chain +β_2-microglobulin	α chain + β chain
Cell distribution	Most nucleated cells	Antigen-presenting cells (including B cells), thymus epithelial cells, some others
Involved in presenting antigen	Cytotoxic T cells	Helper T cells
Source of peptide fragments	Proteins made in cytosol	Endocytosed plasma membrane and extracellular proteins
Polymorphic domains	$\alpha_1 + \alpha_2$	$\alpha_1 + \beta_1$

MHC = major histocompatibility complex; HLA = human leukocyte antigen.

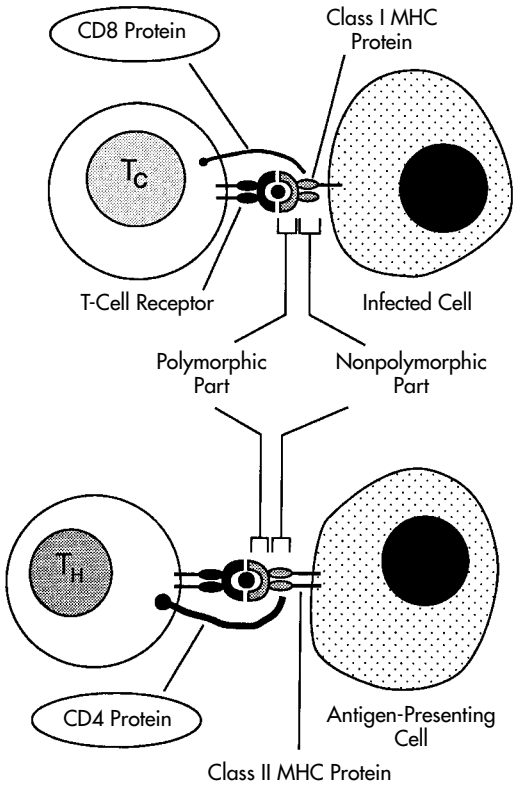

FIGURE 28–19. CD4 and CD8 coreceptors on the surface of T cells. Note that these proteins bind to the nonvariable part of the same major histocompability complex (MHC) molecule that the T-cell receptor has engaged, so that they are bought together with T-cell receptors during the cell activation process. Antibodies against CD4 and CD8 are widely used to distinguish helper and cytotoxic T cells, respectively.

tioned above, T cells of any individual that recognize a specific antigen will do so only when that antigen is associated with the allelic forms of MHC molecules expressed by that individual, a phenomenon known as *MHC restriction*. It has been shown that cytotoxic T cells, when activated by, for example, influenza virus, specifically recognize internal proteins of that virus that would not be accessible in the intact virus particle. Subsequent evidence has suggested that the T cells have recognized degraded fragments of the internal viral proteins. Because a T cell can recognize tiny amounts of antigen (only a few hundred molecules), only a small fraction of the fragments generated from viral proteins has to get to the cell surface to attract an attack by a cytotoxic T cell.[63] Proteins destined for the cell surface usually begin their journey by crossing from the cytosol into the lumen of the endoplasmic reticulum (ER). Once inside ER, the peptides bind to MHC molecules that they encounter there and are then carried to the cell surface with them. When T cells are activated by antigen, they secrete various signaling protein molecules, including *interferon-gamma (IFN-γ)*, which greatly enhances antiviral responses.[64] The IFN-γ induces the expression of many genes within the MHC chromosomal region, including those in class I and class II MHC proteins, the two specialized proteasome subunits, and the two subunits of the peptide pump located in the ER. Thus, all of the machinery required for presenting viral antigens to cytotoxic T cells is coordinately called into action by IFN-γ, creating a positive feedback that amplifies the immune response and culminates in the death of the infected cell.

Once a cytotoxic T cell recognizes a viral peptide bound to a class I MHC molecule on the surface of a target cell, its job is to destroy the cell before the virus that gave rise to the peptide can produce new viral particles that can escape from the infected cell. The mechanism by which cytotoxic T cells kill their targets is not known. They seem to employ at least two strategies, both of which are thought to operate by inducing the target cell to undergo *programmed cell death* (also called *apoptosis*).[65] In one strategy, binding to a target cell stimulates the cytotoxic T cells to release a pore-forming protein called *perforin*, which is homologous to the complement component C9 and polymerizes in the target cell plasma membrane to form transmembrane channels.[66] Perforin is stored in secretory vesicles and is released by local exocytosis at the point of contact with the target cell. The secretory vesicle also contains serine proteases and other proteins, which are also thought to play a part in killing the target cell, perhaps by entering the target cell through the perforin channels and inducing programmed cell death. The second strategy, by contrast, involves the cytotoxic T cell activating a receptor on the surface of the target cell, thereby signaling the target cell to undergo programmed cell death.[67]

HELPER T CELLS AND T-CELL ACTIVATION

Unlike cytotoxic T cells, *helper T cells* do not act directly to kill infected cells or to eliminate microorganisms. Instead, they stimulate macrophages to be more effective in destroying pathogens, and, most importantly, they help other types of lymphocytes to

respond to antigen. Helper T cells recognize fragments of endocytosed foreign protein antigens in association with class II MHC proteins.

Like the viral antigens presented to cytotoxic T cells, the antigen presented to helper T cells on antigen-presenting cells is degraded fragments of foreign protein that are bound to class II MHC molecules in much the same way that virus-derived peptides are bound to class I MHC molecules. But both the source of the peptide fragments presented and the route they take to find the MHC molecules are different from those of peptide fragments presented by the class I MHC molecules to cytotoxic T cells. Rather than being derived from foreign proteins synthesized inside the target cell, the peptides presented to helper T cells are derived from extracellular microbes or their products, which have been ingested by antigen-presenting cells and degraded in the acidic environment of endosomes.[68] These peptides do not have to be pumped across the membrane because they do not originate in the cytosol; they are generated in the compartment that is topographically equivalent to the extracellular space. They never enter the lumen of the ER, where the class II MHC molecules are synthesized and assembled, but instead bind to preassembled class II heterodimers in a late endosomal compartment. Once the peptide binds, the class II MHC molecule alters its confirmation, trapping the peptide in the binding groove for presentation at the cell surface to helper T cells.

Most of the class I and class II MHC molecules on the surface of the target cell have peptides derived from self-proteins in their binding groove: for class I molecules, fragments of degraded cytosolic and nuclear proteins; for class II molecules, fragments of degraded membrane and serum proteins that pass through the endosome-lysosome system. Only a small fraction of the class II MHC molecules on the surface of an antigen-presenting cell will have foreign peptides bound to them. This, however, suffices to initiate an immune response because only a few hundred such molecules are required to activate a helper T cell, just as only a few hundred peptide–class I MHC complexes on a target cell are required to activate a cytotoxic T cell.

Just as a B cell must be activated to proliferate and differentiate into an antibody-secreting cell before it can function, so, too, must a T cell be activated to proliferate and differentiate before it can kill an infected target cell or help a macrophage or B cell. The initial activation of a T cell usually occurs when it recognizes foreign peptide bound to an MHC molecule on the surface of an antigen target cell. For a helper T cell, the appropriate target is an *antigen-presenting cell*.

Antigen-presenting cells are derived from the bone marrow and comprise a heterogeneous set of cells, including *interdigitating dendritic cells* in lymphoid organs and *Langerhans' cells in skin*, as well as the B cells and macrophages that will subsequently be the target of T-cell help. Together with thymus epithelial cells, which have a special role in T-cell development and activate T cells in some mammals, these specialized antigen-presenting cells are the only cell types that normally express class II MHC molecules. In addition to class II MHC molecules, antigen-presenting cells also express a second cell-surface molecule, called B7, that plays a crucial part in activating T cells.

Two Simultaneous Signals Are Required for Helper T-Cell Activation

To activate a helper T cell, an antigen-presenting cell must provide at least two signals. *Signal 1* has already been discussed; it is provided by a foreign peptide bound to a class II MHC molecule on the surface of the presenting cell that activates the T-cell receptor complex. Depending on the type of helper T cell, a *signal 2* is provided by either a secreted chemical signal such as IL-1, or by the plasma membrane–bound signaling molecule *B7* on the surface of the antigen-presenting cell. B7 is recognized by a coreceptor protein called CD28, which is present on the surface of the helper T cell and is a member of the Ig superfamily.[69] If helper T cells receive both signals, they are activated to proliferate and secrete a variety of cytokines. In contrast, if they receive signal 1 without signal 2, they are altered so that they can no longer be activated even when they receive both signals. This has been suggested to be one mechanism whereby T cells become *tolerant*. Some accessory proteins present on the surface of T cells are summarized in Table 28–3.

Helper T Cells, Once Activated, Stimulate Themselves and Other T Cells to Proliferate by Secreting Interleukin-2

The combined action of signal 1 and signal 2 provokes helper T-cell proliferation by a curiously indi-

TABLE 28–3. Some Accessory Proteins on the Surface of T Cells

Protein	*Approximate Molecular Weight*	*Super-family*	*Expressed on*	*Ligand on Target Cell*	*Functions*
CD3	γ chain = 25,000 δ chain = 20,000 ε chain = 20,000 ζ chain = 16,000	Ig Ig Ig —	All T cells	—	Helps transduce signal when antigen-MHC complex binds to T-cell receptors
CD4	55,000	Ig	Helper T cells	Class II MHC	Promotes adhesion to antigen-presenting cells and to B cells; signals T cell
CD8	70,000 (homodimer or heterodimer)	Ig	Many helper and cytotoxic T cells	Class I MHC	Promotes adhesion to infected target cells; signals T cell
CD28	80,000 (homodimer)	Ig	Cytotoxic T cells	B7	Provides signal 2 to some T cells

Ig = immunoglobulin; MHC = major histocompatibility complex; ICAM = intercellular adhesion molecule.

rect mechanism. It causes the T cells to stimulate their own proliferation by simultaneously secreting a growth factor called *IL-2* and the synthesized cell-surface receptors that bind it. The binding of IL-2 to these IL-2 receptors then directly stimulates the T cells to proliferate.[70] By this *autocrine mechanism*, helper T cells can continue to proliferate after they have left the surface of the antigen-presenting cell (Figure 28–20). The helper T cell can also stimulate the proliferation of any other nearby T cells, including cytotoxic T cells, which have first been induced by antigen to express IL-2 receptors. Because the expression of IL-2 receptors is strictly dependent on antigen stimulation, however, IL-2 causes the proliferation of only T cells that have encountered that specific antigen.

Helper T Cells Are Required for Most B Cells to Respond to Antigen

Although there are some antigens, including microbial polysaccharides, that can stimulate B cells to proliferate and differentiate into antibody-secreting cells without T-cell help, the activation of B cells by helper T cells is mediated by both membrane-bound and secreted signals. Once activated, the helper T cell can help activate a B cell that specifically displays the same complex of foreign antigen and class II MHC protein on its surface. The display of antigen on the B-cell surface reflects the selectivity with which it takes up foreign molecules from the extracellular fluid. The specific membrane-bound antibodies on the surface of the B cell are ingested and then degraded and recycled to the cell surface in the form of peptides bound to class II MHC proteins. Thus, the helper cell activates those B cells that make membrane-bound antibodies that specifically recognize the antigen that initially activated the T cell. In secondary antibody responses, memory B cells themselves may act as antigen-presenting cells and activate helper T cells, as well as be the subsequent targets of the helper T cells. The mutually reinforcing actions of T and B cells lead to an immune response that is both intense and highly selective. The membrane-bound signaling molecule is a transmembrane protein called *CD40 ligand*, which is expressed on the surface of activated, but not resting, helper T cells. It is recognized by the *CD40* transmembrane protein on the B cell.[71] The interaction between CD40 ligand and CD40 is required for helper T cells to activate B cells

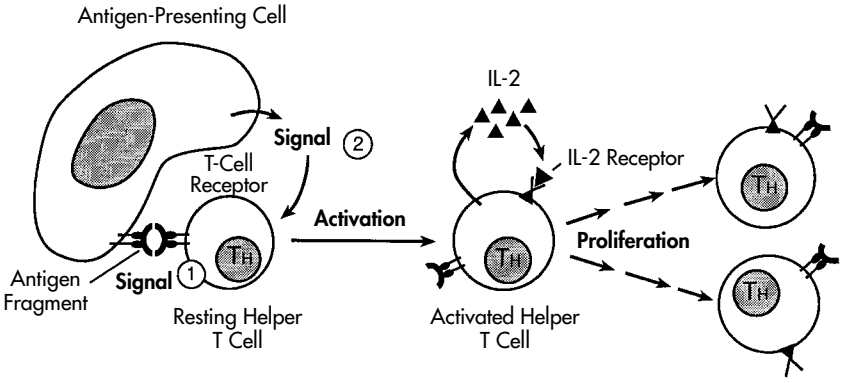

FIGURE 28–20. The stimulation of T-cell proliferation by interleukin (IL)-2. Signals 1 and 2 activate the helper T cells to make IL-2 receptors and to secrete IL-2. The binding of IL-2 to its receptors stimulates the cell to grow and divide. When the antigen is eliminated, the T cells eventually stop producing IL-2 and IL-2 receptors, so cell proliferation stops. Some helper T cells do not make IL-2; their proliferation, like that of cytotoxic cells, is stimulated by IL-2 made by neighboring helper T cells (signals 1 and 2 are discussed in the text).

to proliferate and mature into memory and antibody-secreting cells. This interaction is critical for T-cell help: individuals whose T cells lack the CD40 ligand because of the mutation in the gene encoding the protein can make only IgM antibodies and are severely immune deficient, being susceptible to the same infections that affect AIDS patients, whose helper T cells have been destroyed.

Secreted signals from the T cells provide additional help by activating B cells to proliferate, mature, and, in some cases, switch the class antibody they produce. *Interleukin-4* is one such signal.[72] It stimulates B-cell proliferation and maturation and promotes the switching to IgE and IgG1 antibody production: if the IL-4 gene is inactivated by targeted recombination in a mouse, the mouse is unable to make IgE and makes very little IgG1.

Thus, most B cells, like T cells, require multiple signals for activation, one provided by antigen binding to the membrane-bound Ig molecules and the others provided by the helper T cells; as in the case of T cells, if a B cell receives the first signal only, it may be functionally inactivated. The comparison of the signals required to activate helper T cell and a B cell are outlined schematically in Figure 28–21.

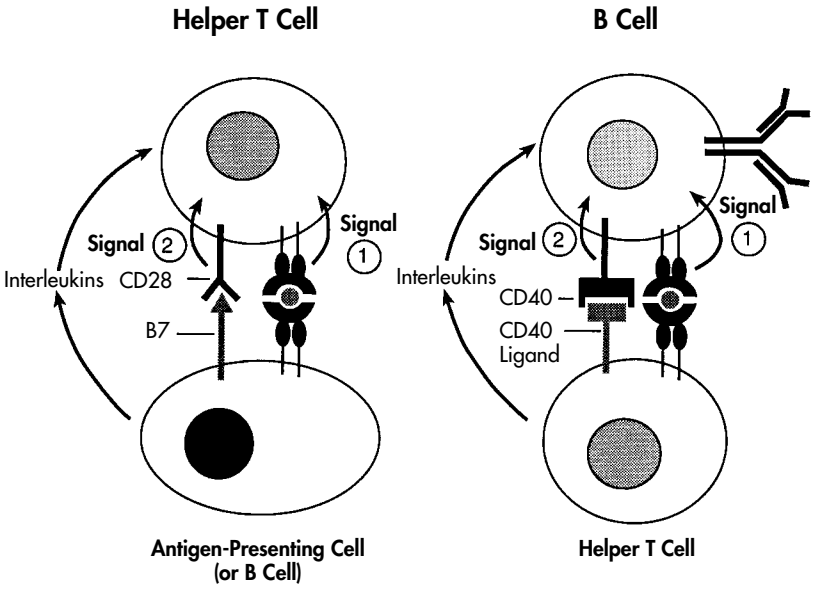

FIGURE 28–21. Comparison of the signals required to activate a helper T cell and B cell. Note that signal 2 can be provided either by a secreted signaling molecule (an interleukin) or by a cell-to-cell contact interaction.

Some Helper T Cells Help Activate Cytotoxic T Cells and Macrophages by Secreting Interleukins

There are at least two functionally distinct subclasses of helper T cells that can be distinguished by the cytokines that they secrete. T_H1 cells secrete IL-2 and IFN-γ and are concerned mainly with helping cytotoxic T cells and macrophages.[73] T_H2 cells secrete IL-4 and IL-5 and are concerned mainly with helping B cells and eosinophils.[74] The properties of some ILs are outlined in Table 28–4. The antigen-triggered secretion of ILs underlies the familiar tuberculin skin test. If tuberculin is injected into the skin of an individual who had been immunized against tuberculosis, a characteristic immune response occurs in the skin. It is initiated at the site of injection by the secretion of ILs by memory helper T cells that react to the tuberculin. The ILs attract macrophages and lymphocytes into the site, thereby causing the characteristic swelling of a positive reaction to tuberculin.

Another important effect of IFN-γ is to induce the expression of class II MHC proteins on the surface of some cells such as endothelial cells that do not normally express them, thereby enabling these cells to present antigen to helper T cells.[75]

In summary, helper T cells help activate B cells and macrophages. They are themselves initially activated when they recognize peptide fragments derived from foreign extracellular proteins that are endocytosed by specialized antigen-presenting cells. The ingested proteins are degraded in endosomes, and some of the resulting peptide fragments bind to class II MHC molecules, forming complexes that are carried to the cell surface, where the helper T cells recognize them. The activation of the helper T cell requires at least two signals: signal 1 is provided by the MHC-peptide complex, whereas signal 2 is provided by either the B7 protein on the surface of an antigen-presenting cell or a signal secreted by this cell. Once activated, helper T cells stimulate their own proliferation by secreting IL-2 and activate their target cells by a combination of membrane-bound and secreting signaling molecules. Developing T cells that recognize peptides in association with self-MHC molecules are positively selected in the thymus, whereas developing T cells that react strongly with self-peptides bound to self-MHC molecules are eliminated in the thymus. Thus, those immature T cells that will be capable of recognizing foreign peptides presented by self-MHC molecules are selected to survive, whereas the remainder, which would be

TABLE 28–4. Properties of Some Interleukins

Cytokines (IL)	*Approximate Molecular Weight*	*Source*	*Target*	*Action*
IL-1	15,000	Antigen-presenting cells	Helper T cells	Helps activate
IL-2	15,000	Some helper T cells	All activated T cells and B cells	Stimulates proliferation
IL-3	25,000	Some helper T cells	Various hemopoietic cells	Stimulates proliferation
IL-4	20,000	Some helper T cells	B cells	Stimulates proliferation, maturation, and class switching to IgE and IgG1
IL-5	20,000	Some helper T cells that make IL-4	B cells, eosinophils	Promotes proliferation and maturation
IL-6	25,000	Some helper T cells and macrophages	Activated B cells, T cells	Promotes B-cell maturation to Ig-secreting cells; helps activate T cells
γ-Interferon	25,000 (dimer)	Some helper T cells that make IL-2	B cells, macrophages, endothelial cells	Activates various MHC genes and macrophages

Ig = immunoglobulin; MHC = major histocompatibility complex.

of no use to the animal, die. Thus, MHC restriction is a required property of the immune system that emerges as T cells develop in the thymus. Positive selection still leaves a large problem to be solved. If developing T cells with receptors that recognize self-peptides associated with self-MHC molecules were to mature in the thymus and migrate to peripheral lymphoid tissues, they would wreak havoc. A second, *negative selection* process in the thymus is required to avoid this disaster. A fundamental feature of the immune system is that it can distinguish self from nonself and normally does not react against self-molecules. This state of *immunologic self-tolerance* is acquired mainly during T-cell development. It is not enough, therefore, for the thymus to select *for* T cells that recognize self-MHC molecules; it must also select *against* T cells that recognize self-MHC molecules complex with self-peptides. In other words, it must pick out for survival just those T cells that would be capable of recognizing self-MHC molecules complexed with foreign peptides, even though these peptides are not present in the developing thymus. Thus, the required goal can be achieved by (1) ensuring the death of T cells that bind strongly to the peptide-MHC complexes in the thymus while (2) promoting the survival of those that bind weakly and (3) permitting the death of those that do not bind at all. Process 2 is the positive selection that has been discussed above. Process 1 is called *negative selection*.

In summary, the T-cell repertoire is shaped mainly by a combination of positive and negative selection processes that operate during T-cell development in the thymus. These processes ensure that only T cells with potentially useful receptors survive and mature, whereas the others undergo programmed cell death: T cells that will be able to recognize foreign peptide complex with self-MHC molecules are positively selected, whereas T cells that react strongly with self-peptide complex with self-MHC molecules are eliminated.

THE IMMUNE SYSTEM AND THE INFLAMMATORY RESPONSE

The final part of this chapter briefly reviews certain surface molecules that are up-regulated in inflammatory tissues with specific emphasis on nasal polyposis as a model of chronic inflammation. A knowledge of these inflammatory cytokines as well as integrins that are heterodimeric proteins that promote cell to cell-surface interaction and counter-receptors on the surface of endothelial cells of blood vessels is emphasized because the cell-to-cell interaction is responsible for the migration of inflammatory cells into the tissue following an immune response.[76] A great deal of molecular biologic information has accumulated on the pathogenesis of nasal polyposis. It appears that eosinophils and lymphocytes are the predominant inflammatory cell in nasal polyp tissue. The events leading up to the extravasation of eosinophils into the lamina propria of nasal polyps are regulated by the proinflammatory cytokines, tumor necrosis factor alpha (TNF-α) and IL-1β.[77] These cytokines up-regulate VLA-4 on the surface of eosinophils and VCAM-1 on the surface of the endothelial cells of blood vessels.[78] Chemokines such as RANTES (regulated upon activation, normal T cell expressed and secreted) and eotaxin are responsible for the movement of eosinophils into the lamina propria of the nasal polyp.[79] The release of major basic protein from eosinophils has an effect on alteration of the epithelial architecture and on the sodium and chloride flux into and out of the apical epithelial cell of the tissue.[80] Therefore, it is incumbent on the student of chronic inflammation to understand how the immune process, which has been thoroughly discussed in this chapter, can effect the inflammatory response. Therefore, to conclude this chapter on the immune response and its effect on inflammation, a brief review of cytokines, integrins, and endothelial cell receptors is undertaken.

CYTOKINES

Cytokines are a group of signaling molecules involved in communication between cells, including those of the immune system.[81] Cytokine-mediated events occur during the initiation and effector stages of immune responses and the development of hematopoietic cells. Within the last decade, there has been an explosion of knowledge of cytokine and cytokine receptor structures and genes along with a clarification of the roles of individual cytokines. This section focuses on two proinflammatory cytokines, namely TNF-α and IL-1β. However, there are over 20 cytokines that have been identified, as well as their receptors.[82] A schematic overview of the role of various cytokines on T_H1- and T_H2-dependent

immune reactions is summarized in Figure 28–22. Tumor necrosis factor α can be derived from macrophages, T cells, thymocytes, B cells, and natural killer cells. The target of TNF-α may be tumor cells, transformed cell lines, fibroblasts, macrophages, osteoclasts, neutrophils, adipocytes, eosinophils, endothelial cells, chondrocytes, and hepatocytes. Tumor necrosis factor α is known to be made by activated macrophage and other cells and to have wide-ranging proinflammatory effects. It is purified from natural sources and has a molecular weight of 17 kDa. It has a vast array of biologic activities that include promoting bone resorption by osteoclasts, stimulation of T-cell production, enhancement of B-cell proliferation and Ig secretion, the activation of vascular endothelial cells, increasing eosinophilic toxicity for parasites, and the stimulation and proliferation of fibroblasts, among other activities. It is apparent that many of the biologic activities of TNF-α are important in both immunity and inflammation. They act in a very wide range of cellular targets and cause enormous

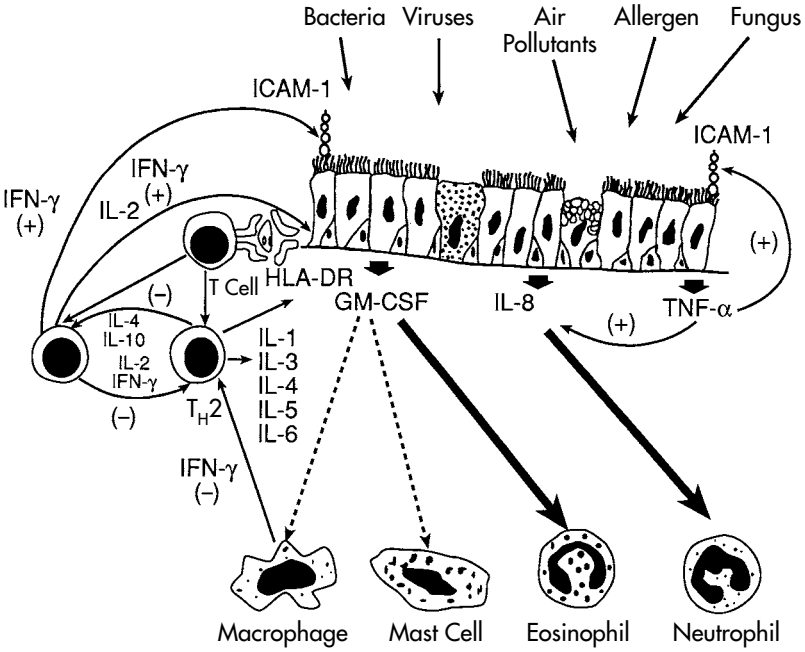

FIGURE 28–22. Diagram of the effect of multiple irritants on the epithelial cell in the lateral wall of the nose. Bacteria, virus, air pollution, allergy, or fungus can have an effect of up-regulating various cytokines such as granulocyte-macrophage colony stimulating factor (GM-CSF), interleukin (IL)-8, or tumor necrosis factor (TNF)-α directly by changing the genetic potential of the respiratory epithelial cell. These cytokines can mobilize from the microvasculature of the nasal polyp various inflammatory cells including neutrophils, macrophages, mast cells, and, particularly, eosinophils. Tumor necrosis factor-α and IL-1β that may be released by the stimulated epithelial cells can up-regulate very late activation antigen-4 and vascular cell adhesion molecule (VCAM)-1 that are receptors on eosinophils and counter-receptors on endothelial cells, respectively, and, in this way, specifically direct eosinophils into the tissue of the nasal polyp. Finally, interferon (IFN)-γ may be released by the epithelial cell and produce intercellular adhesion molecule (ICAM)-1 on the epithelial cell, which is a receptor for the rhinovirus as well as for neutrophils. The five stimulators of the epithelial cell as seen at the top of the figure can also induce human leukocyte antigen (HLA)-DR on the basolateral surface of the cell. This class II antigen can, in turn, up-regulate the immune response for both T_H1 and T_H2 lymphocytes, with the final outcome of the production of the typical cytokines for the T_H1 lymphocytes (IFN-γ and IL-2) and for the T_H2 lymphocyte (IL-4 and IL-5), which, in turn, can up-regulate the eosinophilia in the nasal polyp. It is thus suggested that the lateral wall of the nose, either by mucosal contacts or more likely by specific aerodynamic airflow, can allow various stimulants to activate the epithelial or constitutive cells of the lateral wall of the nose to produce a heightened inflammatory response in a genetically predisposed individual for the development of nasal polyposis.

numbers of cellular changes. For the purposes of this discussion, TNF-α, along with IL-1β, which is discussed briefly below, has the effect of increasing the surface receptors on eosinophils, particularly VLA-4, and of up-regulating VCAM-1 on the endothelial cells of blood vessels of nasal polyps.

Interleukin-1β is produced by macrophages, endothelial cells, T and B cells, fibroblasts, epithelial cells, and osteoblasts. The cellular target for IL-1β includes thymocytes, neutrophils, hepatocytes, chondrocytes, muscle cells, endothelial cells, epidermal cells, osteocytes, macrophages, T and B cells, and fibroblasts. The biologic activities of IL-1β parallel those of TNF-α. In regard to chronic inflammation, IL-1β also has a powerful effect on the up-regulation of VLA-4 on eosinophils and VCAM-1 on nasal polyp vascular endothelial cells. It is emphasized that both of these cytokines (TNF-α and IL-1β) can be synthesized by constitutive cells of the nasal mucosa, including the epithelial cells and the endothelial cells. Thus, any kind of irritation caused by inflammatory mediators or external environmental irritants can stimulate the constitutive cells of the nasal mucosa to produce proinflammatory cytokines, which, in turn, cause a whole array of inflammatory effects in the lateral wall of the nose in the development of nasal polyposis. It is to be emphasized that the cellular immunology as described in this chapter following stimulation of helper T cells, cytotoxic cells, and B cells will give rise to the synthesis of cytokines that produce chronic inflammation.

Integrins

The integrins are the major family of cell-surface receptors that mediate adhesion to the extracellular matrix and sometimes cell-to-cell adhesive interactions.[83] These integrin-mediated adhesive interactions are involved in the regulation of many cellular functions, including embryonic development, tumor cell growth and metastasis, prolonged cell death, homeostasis, inflammation, immune reaction, and bone resorption, among other phenomena. Integrins are composed of α and β transmembrane subunits selected from 16 alpha and 8 beta subunits that heterodimerize to produce more than 20 different receptors that bind specific ligands. Integrins link to intracellular cytoskeletal complexes and bundles of actin filaments. There are many intracellular signaling pathways activated by integrin-ligand interactions. In continuing our explanation of the role of the eosinophil in nasal polyps, the VLA family of integrins is of most importance. Very late activation antigen 4 is also the α4, β1 heterodimer on the surface of eosinophils. Beta-1 integrins are essentially involved in cell–extracellular matrix interactions and β2 subfamily in leukocyte–leukocyte and leukocyte–endothelial cell communications. The soluble α4, β1 fusion protein exhibits divalent cation-dependent binding to VCAM-1. Furthermore, anti-VLA-4 monoclonal antibodies can inhibit eosinophil infiltration in the allergic conjunctivitis model of the guinea pig, suggesting that specific monoclonal antibodies directed against specific integrins or adhesion cell molecules might be the future for the treatment of nasal polyposis. Because VLA-4 is up-regulated on the surface of eosinophils in chronic inflammation, it would be interesting to consider the role of antagonists to VLA-4, also known as integrin α4, β1. The most advanced in this endeavor is a humanized anti-α4 antibody, which is in phase 2 clinical trials for multiple sclerosis. The first reported small-molecule VLA-4 antagonist to advance to clinical trials is currently in phase 1 as an aerosol for treating asthma. Thus, the future of the treatment of many chronic inflammatory diseases, as mentioned above, may be the purification and clinical use of antagonists of various integrins that are up-regulated on the surface of inflammatory cells.

Vascular cell adhesion molecule 1 Lymphocytes migrate from the blood across endothelial cells to reach foreign substances sequestered in peripheral lymphoid organs and inflammatory sites. This migration is inhibited by anti-VCAM-1 or anti-α4 integrin, suggesting that VCAM-1 adhesion is required for migration. Studies suggest that endothelial cells not only are a scaffold for lymphocyte adhesion but also play an active role in promoting lymphocyte migration. In addition to lymphocyte migration, there is abundant evidence to suggest that TNF-α is a cytokine implicated in the pathogenesis of numerous chronic and acute inflammatory conditions. Furthermore, TNF-α is an effective inducer of eosinophil accumulation in vivo, and this response appears to be dependent on an interaction between α4 integrins and VCAM-1. Thus, it appears that the proinflammatory cytokines are capable of up-regulating integrins on the surface of eosinophils, particularly VLA-4, and that this integrin has a specific

predilection to adhere to VCAM-1 on the surface of vascular endothelial cells. The final phase of eosinophilic migration into the nasal polyp stroma is ultimately dependent on the chemokines.

Chemokines The relatively recent appreciation of a new class of cytokines, the chemokines, has done much to enhance our understanding of the extracellular signals involved in the movement of various populations of white blood cells.[84] Investigation of the molecular underpinnings of chemokine function and their involvement in inflammatory processes of all kinds is beginning to yield information about the mechanisms of pathogenesis of a number of conditions, as well as provide hope for new therapeutic insights. Chemokines share structural similarities, including four conserved cystine residues that form disulfide bonds in the tertiary structures. Traditionally, the chemokines superfamily has been divided into two subgroups: C-X-C (where X is any amino acid) and C-C according to whether an intervening residue spaces the first two cysteines in the motif. This structural distinction has been shown to delineate a general, although not absolute, distinction in the biologic properties of these molecules: most C-X-C cytokines are chemoattractants for neutrophils but not monocytes, whereas C-C chemokines appear to attract monocytes but not neutrophils. There are probably more structural distinctions that can be made that may illuminate chemokine function. However, for our purposes, there are two major chemokines of the C-C family known as RANTES and eotaxin.

Eosinophils are the predominant cell type recruited in inflammatory reactions in response not only to allergen challenge but also to the up-regulation of specific cytokines that are related to T_H2 lymphocytes. The data from many studies suggest that RANTES and eotaxin induce eosinophil transepithelial migration with great potency and efficacy. It is interesting to note that activation of the endothelial cells by either TNF-α or IL-1β promotes migration of eosinophils from the vasculature in conjunction with RANTES and eotaxin.

SUMMARY

The immune response through both T cells and B cells can release a cascade of cytokines that are responsible for the specific migration of inflammatory cells into sites of the upper respiratory tract. For the otolaryngologist, knowledge of these cytokines, integrins, and chemokines will be necessary in the future. Although the antibiotic era is still with us, eradicating chronic inflammatory disease such as nasal polyposis, chronic sinusitis, and chronic otitis media with antibiotics probably cannot be accomplished. Our knowledge of the molecular biology of the inflammatory response will require knowledge of the biology of the immune system and the inflammatory mediators that are released by immune cells such as T cells, B cells, macrophages, fibroblasts, and other cells. It may very well be that the future of clinical medicine will be an understanding of the molecular nature of these proteins and glycoproteins released by the immune cells as well as inflammatory cells and to counteract their activity with specific monoclonal antibodies directed against either the cytokine itself or the receptor for the cytokine on tissue cells. Ultimately, this will be the future of otolaryngology as well as medicine in general.

CHAPTER 29

Acquired Immune Deficiency Syndrome

Frank E. Lucente, MD, Samir Shah, MD, Jeffrey Vierra, MD

Acquired immune deficiency syndrome (AIDS) has emerged as one of the most extraordinary diseases in human history. We have seen the unfolding of a medical mystery in which an apparently new disease has appeared, first reported in the United States in 1981, and has since become a major worldwide epidemic. Acquired immune deficiency syndrome is caused by human immunodeficiency virus (HIV). Human immunodeficiency virus infection of macrophages, monocytes, and CD4 (helper) T lymphocytes leads to a cell-mediated immune deficiency that predisposes to a constellation of opportunistic infections and malignancies.[1,2]

More than 1,200,000 cases of AIDS have been reported in the United States since 1981, and as many as 900,000 Americans are estimated to be living with HIV infection. The epidemic is growing most rapidly among minority populations and is a leading killer of African American males. According to the US Centers for Disease Control and Prevention (CDC), the prevalence of AIDS is six times higher in African Americans and three times higher in Hispanics than among whites.[3]

Acquired immune deficiency syndrome has had a significant impact on the practice of otolaryngology. The fact that many patients originally presented with physical findings in the head and neck region, especially during the 1980s, required a high level of vigilance for detecting these findings as manifestations of HIV infection. Implementation of measures for handling instruments in the office and operating room emerged as part of the universal precautions that were promulgated as a way of controlling spread of the infection.

EPIDEMIOLOGY

To date, an estimated 36 million persons are living worldwide with HIV/AIDS. Of these, most reside in sub-Saharan Africa and Southern and Southeast Asia. Less than 3% of the HIV infected worldwide reside in North America. Since the start of the epidemic, more than 12 million persons have died of AIDS-related complications worldwide. Of the 16,000 new cases of HIV infection that are estimated to occur each day worldwide, more than 40% are among women, more than 50% are among 15 to 24 year olds, and 10% are among children less than 14 years old.[4]

Human immunodeficiency virus transmission occurs by unprotected heterosexual or homosexual sexual contact, use of HIV-infected contaminated needles, infusion of contaminated blood and blood products, or from mother to child in utero, perinatally or through breast-feeding. The patterns of transmission vary from country to country.[1,5] In sub-Saharan Africa and Southern and Southeast Asia, heterosexual transmission is the predominant mode of transmission, although intravenous drug use is a major factor in India and parts of Southeast Asia. In Northern Europe, homosexual transmission is most common, whereas intravenous drug use is the major risk factor in Southern Europe, particularly Spain and Italy. In the United States, homosexuals were the major risk group at the outset of the epidemic, but over the past several years, the rate of increase in new cases has been greatest among women, heterosexuals, and minorities.

There are significant racial and socioeconomic differences in the distribution of HIV/AIDS cases among the various risk groups. Whites predominate among homosexuals with HIV, whereas African Americans and Hispanics are disproportionately represented among HIV positives, with injection-drug use as a risk factor. Poverty has been shown to be independently associated with higher rates of HIV/AIDS, and racial minorities are disproportionately represented among those living below the poverty line.

TRANSMISSION

The known routes of transfer of the HIV virus are blood, blood products, unsafe sexual activity, and transmission from mother to child perinatally. Although researchers have detected HIV in the saliva of infected individuals, no evidence exists that the virus is spread by contact with saliva. Laboratory studies reveal that saliva has natural compounds that inhibit the infectivity of HIV.[6]

Perinatal transmission is responsible for almost all new cases of HIV in children.[7] The rate of perinatal transmission has declined more than 50% since 1993 with the introduction of voluntary testing and counseling of pregnant women and the widespread implementation of the 1994 US Public Health Service recommendations for zidovudine (AZT) therapy of pregnant women.[6] Current recommendations call for instituting antiretroviral therapy in pregnant women using complete antiretroviral regimens as one would use were the patient not pregnant.[8]

Currently, the blood supply in developed countries is safe from HIV contamination by virtue of donor deferral and routine screening for HIV antibodies. In the United States, the risk of acquiring HIV from screened blood is estimated as 1 in 225,000 units; the rare infection would be caused by blood from an infected individual who had not seroconverted at the time of donation.

Human immunodeficiency virus transmission from patient to health care worker and vice versa via accidental exposure to contaminated secretions or blood is rare. Universal precautions or standard precautions have been recommended by the CDC as a means to prevent transmission of bloodborne pathogens. The precautions applied to all patients regardless of specific diagnosis include the use of gloves when contact with blood and potentially infected secretions is possible, protective eyewear when splattering of blood or secretions is possible, and gowns when clothing is likely to be soiled. An important element of prevention of nosocomial spread of disease is needle-stick prevention. Concerns about needle-stick injury and HIV transmission has spurred the development of safer needle devices, which have been designed to retract or cover the needle after use, and "needleless" connectors for intravenous devices. The impact of these devices and other innovations on preventing nosocomial transmission of HIV and other pathogens has yet to be demonstrated.

In instances of significant occupational exposure to HIV, postexposure prophylaxis is recommended. The degree of risk is a function of many factors, including the type of exposure (deep versus superficial punctures, whether there was actual injection of blood, mucosal or cutaneous exposures on intact versus abraded or open surfaces), the volume of infected blood or secretion (exposure with a hollow, blood-filled needle versus a scalpel blade or suture needle), postinjury treatment of the wound, time between injury and evaluation for postexposure prophylaxis, and the ex vivo time of the blood or secretions prior to exposure. Factors of critical importance, but frequently unknown at the time of exposure, are the patient's prior viral therapy history, the resistance pattern of the patient's HIV strain, and the viral burden or "load." When an injury is assessed as posing a significant risk of transmission of HIV from a known or suspect source, postexposure prophylaxis should be instituted as soon as possible after the injury and certainly no longer than 24 hours after exposure. Highly active antiretroviral regimens are instituted, the selection of agents being chosen based on known prior treatment and viral resistance profile of the source when available, and are continued for 4 to 6 weeks. The exposed health care worker should be encouraged to have pretreatment HIV testing with follow-up testing at 6 weeks, 3 months, and 6 months. Postexposure counseling should include a discussion of the degree of risk from the specific exposure and a review of universal precautions and methods to prevent injuries in the future. The health care worker should practice safer sex using barrier protection to minimize potential transmission of incubating HIV infection. Counselors should be available to the health care worker and to his/her family members to provide information and support following exposure and through the follow-up period until infection has been ruled out with the 6-month HIV test.

THE HIV-VIRUS AND ITS LIFE CYCLE

Human immunodeficiency virus is a member of the *Lentivirinae* subfamily of retroviruses. The HIV virion has a lipid bilayer perforated by 72 external spikes consisting of the two major viral envelope proteins, glycoprotein 120 and 41 (Figure 29–1). The

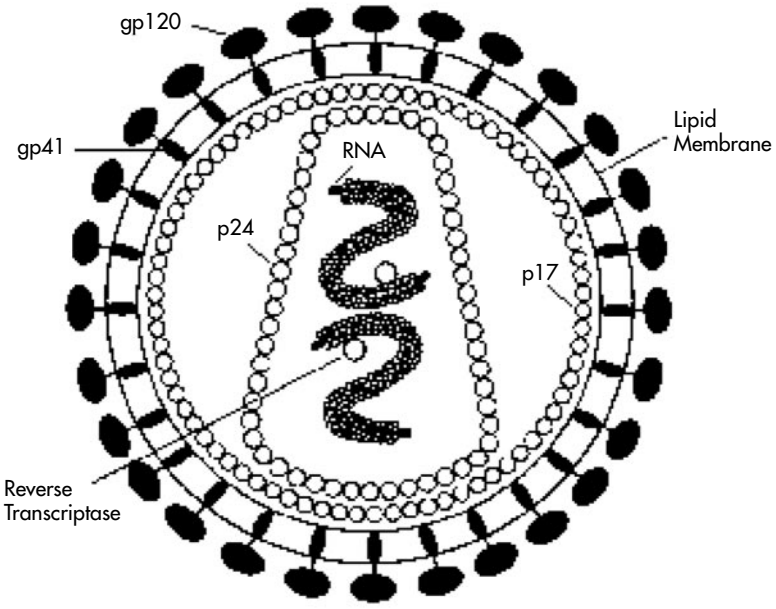

FIGURE 29–1. Human immunodeficiency virus structure. gp = glycoprotein; RNA = ribonucleic acid.

viral core contains four proteins: the p24 capsid protein, the p17 matrix protein, and the p6 and p7 nucleocapsid proteins. The core also contains two copies of single-stranded ribonucleic acid (RNA) and three viral enzymes: reverse transcriptase, integrase, and protease.

Human immunodeficiency virus infects cells by binding to a combination of cell-surface receptors. The CD4 receptor is a high-affinity target for binding by glycoprotein 120, which is necessary but not sufficient for binding of the virion to the cell. CD4 receptors are expressed on T lymphocytes, macrophages, and, to a lesser extent, a variety of somatic cells. Some strains of HIV preferentially infect CD4 (helper) T lymphocytes, whereas others preferentially infect macrophages. This preference or tropism is mediated by the differential expression of chemokine receptors on T cells and macrophages. Human immunodeficiency virus strains trophic for activated T lymphocytes bind by the CD4 receptor and CXCR4 chemokine coreceptor. Macrophage tropic strains bind by the CD4 receptor and the CCR5 chemokine receptor.

After binding to the cell receptors, the HIV envelope fuses to the cell membrane, and the virus is internalized (Figure 29–2). Viral replication begins with the viral enzyme reverse transcriptase mediating the synthesis of deoxyribonucleic acid (DNA) complementary to the viral RNA genome. This DNA-RNA heteroduplex then dissociates, and then a second DNA strand, complementary to the first, is synthesized. Viral encoded integrase enzyme then mediates the incorporation of the double-stranded DNA into the host genome. Transcription of RNA from this proviral DNA provides the coding for viral polyproteins, which are cleaved by viral proteins to produce the structural proteins and enzymes, which are eventually incorporated into progeny virus, which bud off the infected cell.

CLINICAL COURSE

The median time from infection with HIV to the development of AIDS-related symptoms among untreated patients is approximately 10 years, with a wide variation in time to progression. Approximately 10% of HIV-infected persons progress to AIDS within the first 2 to 3 years following infection. In contrast, 5 to 10% of patients are so-called nonprogressors, having stable CD4 cell counts after 15 or more years of follow-up. Factors that determine the rate of progression of untreated disease include patient age (more rapid progression over age 40 years), genetic differences, the virulence of the infecting strain, the viral load that is directly proportional to the rate of decline of the CD4 lymphocyte count, and co-infection with other microbes (eg, hepatitis C). The onset of clinical disease is related to the decline in immune competence as CD4 lymphocytes are depleted.[1–3] The most signifi-

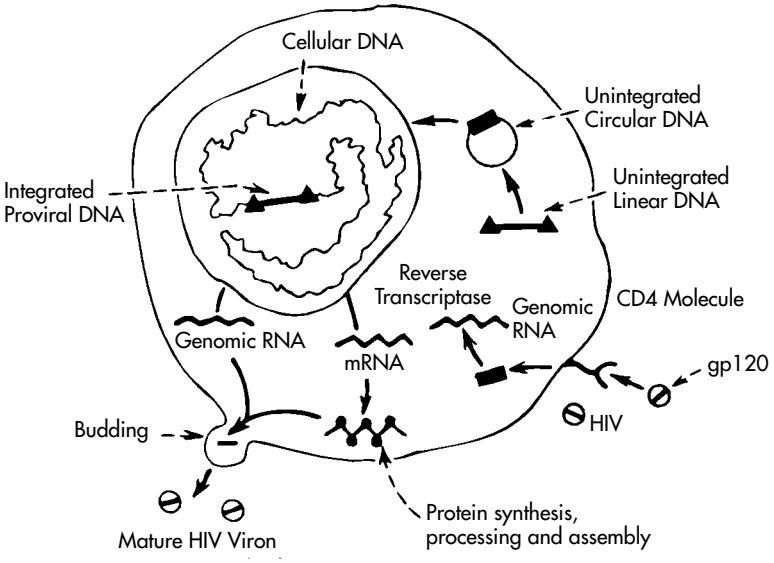

FIGURE 29–2. Human immunodeficiency virus (HIV) life cycle: on the *right side* of the diagram, the glycoprotein (gp) 120 has tropism for the CD4 molecule. The HIV genomic ribonucleic acid (RNA) is uncoated and enters the cell. The genomic RNA is transcribed by the reverse transcription enzyme to double-stranded deoxyribonucleic acid (DNA). The DNA translocates to the nucleus, where it becomes integrated into the cellular DNA by the enzyme integrase as a provirus. It can remain dormant for years or be activated to transcribe messenger and genomic RNA of the virus. The virus is assembled at the periphery and buds off as a mature HIV variant. mRNA = messenger ribonucleic acid. Adapted from Fauci AS. The human immunodeficiency virus: infectivity and pathogenesis. Science 1988;239:617.

cant complications, that is, opportunistic infections and malignancies, occur after reduction of CD4 cell below 200/mm^3.

OPPORTUNISTIC INFECTIONS

Opportunistic infections have remained the proximate cause of death for nearly all AIDS patients. Advances in prophylaxis have decreased the incidence of *Pneumocystis, Toxoplasma, Mycobacterium avium-intracellulare* complex (MAC), *Cryptococcus*, and other opportunistic infections and consequently their contribution to morbidity and mortality.[1]

Patterns of specific opportunistic infections vary geographically, among risk groups, and as a result of medical interventions. In the United States and Europe, over 90% of AIDS patients with Kaposi's sarcoma are homosexual or bisexual men, probably because they are co-infected with human herpesvirus 8, a newly identified viral cofactor (with HIV) for Kaposi's sarcoma. Toxoplasmosis and tuberculosis (TB) are more common in tropical areas, where the prevalence of latent infections with *Toxoplasma gondii* and *Mycobacterium tuberculosis* in the general population is high. Even in developed countries, where background levels of TB are low, HIV has caused increased rates and atypical presentations of TB. Widespread use of effective prophylaxis against such agents as *Pneumocystis carinii* and MAC has reduced the risk of these infections in developed countries.

ANTIRETROVIRAL THERAPY

Recommendations regarding the use of antiviral drugs in HIV are in flux. When and what to initiate, when to change regimens, and how to minimize the development of resistance and cross-resistance are continually being re-evaluated. Clearly, monotherapy results in resistance and loss of efficacy as a result of the huge viral burden, short viral half-life, and propensity to mutate.

Viral loads are critical in determining the efficacy of regimens; the goal is to make all viral loads undetectable because high loads drive CD4 loss and ultimate immune suppression. The current recommendation is to initiate a three-drug regimen in patients with a detectable viral load of over 5,000 to

10,000 HIV RNA copies per milliliter, regardless of CD4 count. This regimen offers sustained viral suppression compared with double- and single-drug regimens.

Triple combinations containing a protease inhibitor are considered the most potent of all regimens. The difficulty with multidrug therapy is that the patient may not fully comply because of the number of pills and adverse effects. Even minimal noncompliance causes drug resistance and loss of efficacy. When changing a failing regimen, two new drugs (preferably three new drugs) should be started. All regimens must be individualized, and, occasionally, when patients are unable to comply with the rigors of three drugs, double therapy is preferable to no therapy. The classes of anti-HIV drugs include reverse transcriptase inhibitors (nucleoside and non-nucleoside) and protease inhibitors (Table 29–1).[9]

Nucleoside reverse transcriptase inhibitors are phosphorylated to active metabolites that compete for incorporation into viral DNA. They inhibit the HIV reverse transcriptase enzyme competitively and act as a chain terminator of DNA synthesis. Non-nucleoside reverse transcriptase inhibitors directly bind to the reverse transcriptase enzyme at sites separate from the nucleoside-binding site. In general, viral resistance to these drugs occurs quickly, and they should not be used as monotherapy except in specific cases.

Protease inhibitors are the most potent class of antiviral drugs; they target the viral proteinase enzyme. Inhibition of viral protease prevents cleavage of an important structural polyprotein that results in noninfectious viral particles. Primary and accessory mutations of the gene encoding the viral proteinase lead to cross-resistance between this class of drugs. The only well-studied dual-protease regimen is ritonavir and saquinavir, which has demonstrated significant, sustained viral load reduction and CD4 gain. Some in vitro data suggest that saquinavir and indinavir are antagonists. Other combinations of multiple protease inhibitors are under study. The protease inhibitors are metab-

TABLE 29–1. Drugs for Human Immunodeficiency Virus Iinfection

Drug	*Usual Oral Adult Dosage*	*Cost**
Protease Inhibitors		
Amprenavir (Agenerase, Glaxo Wellcome)	1,200 mg bid	604.80
Indinavir (Crixivan, Merck)	800 mg q8h	463.50
Nelfinavir (Viracept, Agouron)	750 mg tid or 1,250 mg bid	583.20
Ritonavir (Norvir, Abbott)	600 mg bid	667.82
Saquinavir (Invirase, Roche	600 mg tid	586.36
(Fortovase, Roche)	1,200 mg tid or 1,800 mg bid	587.85
Nucleoside Reverse Transcriptase Inhibitors		
Abacavir (ABC; Ziagen, Glaxo Wellcome)	300 mg bid	349.20
Didanosine (ddI; Videx, Bristol-Myers Squibb)	200 mg bid	217.60
Lamivudine (3TC; Epivir, Glaxo Wellcome)	150 mg bid	259.86
Stavudine (d4T; Zerit, Bristol-Myers Squibb)	40 mg bid	273.70
Zalcitabine (ddC; Hivid, Roche)	0.75 mg tid	212.10
Zidovudine (ZDV; Retrovir, Glaxo Wellcome)	200 mg tid or 300 mg bid	303.60
Zidovudine plus lamivudine (Combivir, Glaxo Wellcome)	1 tablet bid	563.46
Non-nucleoside Reverse Transcriptase Inhibitors		
Delavirdine (Rescriptor, Pharmacia & Upjohn)	400 mg tid	239.77
Efavirenz (EFV; Sustiva, Dupont)	600 mg qd	394.20
Nevirapine (Viramune, Roxane)	200 mg bid	278.64

*Cost to the pharmacist for 30 days' treatment, based on wholesale price (AWP) listings, June 1999 in US dollars.

olized through cytochrome P-450, and all concomitant drugs should be reviewed for potential interactions.

OTORHINOLARYNGOLOGIC MANIFESTATIONS

Patients who are HIV positive can acquire otorhinolaryngologic diseases similar to those experienced by patients without HIV infection. However, the patient may experience unusual presentations and recurrent or refractory disease. The evaluation and treatment of patients with HIV-related head and neck disease frequently require an interdisciplinary approach, including the input of the infectious diseases specialist, oncologist, ophthalmologist, dermatologist, dentist, and oral surgeon.

Ear

Acute bacterial or serous otitis media is frequently encountered among HIV-infected individuals.[10] Patients present with aural fullness, hearing loss, and, occasionally, otorrhea. The clinical response to appropriate therapy with antibiotics and decongestants is in part dependent on the patient's underlying immune status. Patients with well-preserved cell-mediated immune function as measured by the CD4 cell count are more likely to respond normally, whereas those with impaired immunity more frequently experience refractory or recurrent disease requiring tympanostomy tube placement.

Otitis externa is caused by the same bacterial pathogens as in the non–HIV-positive population.[11] Unusual conditions, which may involve the auricle, pinna, and external auditory canal, are Kaposi's sarcoma, molluscum contagiosum, herpes simplex virus (HSV), varicella-zoster virus, and seborrheic dermatitis. Diagnosis of these conditions is usually clinical, and treatment is specific to the etiology.

Sensorineural hearing loss can occur in up to 69% of AIDS patients; cytomegalovirus (CMV) is often implicated because CMV inclusion-bearing cells can sometimes be found in cranial nerve VIII in the internal auditory canal, in the cochlea, or in vestibular endolymphatic epithelium. Other causes of the hearing loss may include primary cochlear effects of the HIV virus, ototoxic drugs, or demyelination in the auditory tract.[12] Facial paralysis is common in HIV patients and is probably a reflection of the higher incidence of viral infections.

Skin

Dermatologic involvement in the head and neck also occurs quite commonly.[12] Seborrheic dermatitis presents with erythema and scaling of the skin of the forehead and the malar area, although it may be more generalized. Treatment is with topical corticosteroids and topical antifungal agents. Eosinophilic folliculitis or "itchy bump disease" presents as an intensely pruritic papular rash, which can occur on the head and neck but more commonly involves the upper back, upper chest, and proximal limbs. The treatment of this condition of unknown cause is difficult. Topical or systemic corticosteroids, phototherapy, and high-dose itraconazole have all been demonstrated to provide relief for some patients.

Skin diseases owing to virus include dermatomal varicella-zoster (shingles), herpes simplex, and molluscum contagiosum. Herpes zoster is frequently an early indication of underlying HIV infection. In patients with well-preserved immune function, the natural history of the infection is similar to that of non–HIV-positive persons. The painful vesicular/pustular lesions usually remain localized to a single dermatome. The time course from initial presentation as a papule to crusting and healing is 2 to 3 weeks. In patients with significant immune deficiency, the risk of dissemination is increased, and the duration of acute illness may be prolonged. Complications of herpes zoster include Ramsay Hunt syndrome (facial palsy owing to facial nerve involvement); ophthalmic involvement including keratitis, iritis, uveitis or retinitis caused by involvement of the ophthalmic division of the trigeminal nerve; and postherpetic neuralgia, which may cause prolonged or permanent dysesthesias. The diagnosis of shingles is made clinically in most cases. Definitive diagnosis by Tzanck preparation of vesicular fluid demonstrating multinucleated giant cells or culture of the fluid is rarely necessary. Treatment is indicated for all patients with immune deficiency to hasten crusting and healing, reduce infectivity, and prevent dissemination. Early treatment, that is, within 24 to 48 hours after the onset of rash, with systemic antiviral agents has been shown to decrease the risk of postherpetic neuralgia. Recur-

rences of shingles are uncommon, and thus routine use of chronic suppressive therapy, is not indicated.

Herpes simplex presents with characteristic pruritic or painful papules of the vermilion border of the lip. Over a period of 7 to 10 days, the lesions progress through vesicular, pustular, crusting, and ulcerative stages before spontaneously healing. In patients with advanced cell-mediated immune deficiency, the ulcerative lesions may persist and extend widely unless treated with systemic antiviral agents. Recurrences of orolabial herpes are common, but chronic suppression should be limited to those patients who have demonstrated a pattern of frequent recurrences.

Nose

Externally, herpex simplex can often be seen involving the nasal vestibule.[12] The infection presents as a chronic nonhealing inflammatory process that extends onto the septum, the nasal alae, and, ultimately, the upper lip and face. Again, early culture for diagnosis and treatment with appropriate antiviral agents will show substantial improvement.

Chronic rhinitis with nasal crusting and dryness is particularly common among patients with HIV infection. Although no specific treatment has been routinely successful, administration of guaifenesin (1,200 mg twice daily) and humidification are useful.

Sinusitis occurs with increasing frequency as the CD4 cell count decreases. The bacteriology of acute sinusitis in patients with a CD4 cell count above 200/mm^3 is similar to that in non-HIV patients. Treatment for these patients is directed against *Streptococcus pneumoniae* and *Haemophilus influenzae*. In patients with more severe immune deficiency, microorganisms such as *Pseudomonas aeruginosa*, *Staphylococcus aureus*, fungal pathogens, and other opportunists become more important. Empiric broad-spectrum antibiotic therapy is indicated in those patients with more advanced immune deficiency.[13] Paranasal sinus puncture may be necessary for accurate microbiologic diagnosis in a patient who fails empiric therapy.

Allergic rhinitis has been shown to occur secondary to eosinophilia and an increase in immunoglobulin E levels from HIV.[12] Treatment with topical nasal corticosteroids and second-generation antihistamines alleviates symptoms. Allergy testing may be useful to identify allergens that can be avoided. Desensitization shots are generally avoided, however, owing to the perceived risks of CD4 cell activation that may lead to increased HIV replication.

Oral Cavity and Oropharynx

Oral candidiasis is one of the most common head and neck problems encountered in HIV-infected patients. It may present with tender, erythematous mucosa of the tongue, palate, and other mucosal surfaces or with white plaques or pseudomembranes, which can be readily scraped to reveal an erythematous base. Diagnosis is usually made clinically. A microbiologic diagnosis can be made with KOH smear and/or culture of the exudate. Treatment with topical agents such as nystatin swish or clotrimazole troches is usually effective for oral disease. With more extensive disease or esophageal involvement associated with odynophagia and dysphagia, systemic therapy with an absorbable agent such as ketoconazole, fluconazole, or itraconazole is indicated.

Angular cheilitis presents as erythema and fissures at the corner of the mouth and may be caused by *Candida* species, herpes simplex, or vitamin deficiency. Angular cheilitis responds to specific therapy.

There are multiple causes for oral ulcerations including HSV, CMV, and aphthous ulcers. The small, painful, clustered ulcers caused by herpes simplex can occur on any mucosal surface and are usually self-limited. Treatment with systemic acyclovir, valacyclovir, or famciclovir is indicated for nonresolving ulcers, extensive ulceration, and chronic suppression of frequent recurrences.

Cytomegalovirus ulcers are generally fewer in number and larger in diameter than herpes simplex or aphthous ulcers. They are usually associated with systemic CMV infection in patients with profound cell-mediated immune deficiency (CD4 < 50 cells/mm^3). Diagnosis is by biopsy and culture of the ulcer. Treatment is with systemic antiviral therapy, and ganciclovir, foscarnet, or cidofovir is always indicated. Because of the high rate of recurrence, long-term suppressive therapy is required unless immune function improves with use of highly antiretroviral therapy. Antiviral therapy for CMV can be safely withdrawn when patients have stable

(> 6 months) immune reconstitution with CD4 counts above 100 cells/mm^3.

Recurrent aphthous ulcers are common in persons with HIV infection at all stages of disease. The lesions range in size from 1 to 2 mm shallow ulcerations on mucosal surfaces to giant oral ulcers as large as 2 to 3 cm. Diagnosis is usually clinical, but biopsy and cultures may be indicated in some patients to exclude HSV, CMV, or lymphoma. Treatment with topical corticosteroids or in more extensive, posterior pharyngeal, or esophageal disease with systemic corticosteroids is usually effective in decreasing pain and promoting healing. Cautery with silver nitrate can provide immediate pain relief and speed healing. Thalidomide has recently been approved for use in treating aphthous ulcers.

Good oral hygiene and regular dental care are important in patients with HIV. Gingivitis and periodontal disease are more prevalent in HIV patients, particularly with advanced disease. Linear gingival erythema occurs with or without significant plaque accumulation. Periodontal disease occurs in up to 50% of patients with advanced HIV disease. The periodontal disease may be severe with resultant halitosis, regression of the gingivae, and loosening and loss of the teeth. Therapy must be aggressive and includes débridement, topical antiseptics, and systemic antibiotics.

The Epstein-Barr virus is the etiologic agent of a unique oral finding in patients with HIV, hairy leukoplakia. This condition consists of white patches usually involving the lateral borders of the tongue. It often manifests early in the course of HIV disease and may be the initial clue to underlying HIV infection. The diagnosis is clinical. Unlike candidiasis, the white plaques cannot be scraped from the mucosa. Treatment is not indicated except for cosmetic reasons. Oral and topical acyclovir have been shown to cause regression of leukoplakia, although recurrence is invariable.

Warts on mucosal surfaces caused by human papillomavirus can present as plaque-like or verrucous lesions. The diagnosis is usually clinical with biopsy confirmation. Treatment is local excision/ablation.

Larynx

The larynx is an often difficult area to evaluate and accurately diagnose. Viral (HSV, CMV) and fungal infections (histoplasmosis, coccidiomycosis, aspergillosis, and candidiasis) have been described in the larynx of HIV-infected patients.[14] Diagnosis is often made after laryngoscopy with biopsies and cultures.

Esophagus

The esophagus is a common target in patients with HIV disease, with odynophagia and/or dysphagia being the most frequent presenting complaints. *Candida* is the most common cause of these symptoms. Esophageal candidiasis is usually but not invariably associated with oral candidiasis. Other causes include HSV, CMV, and aphthous ulcerations. The diagnosis of *Candida* esophagitis can be reliably inferred by the presence of oral thrush and odynophagia/dysphagia. An empiric trial of therapy with systemic antifungal agents is indicated. If the symptoms fail to improve within several days, endoscopic evaluation is indicated to exclude viral or aphthous esophagitis or other less common conditions, including severe reflux esophagitis, Kaposi's sarcoma, lymphoma, and tubercular and MAC esophagitis. Endoscopic biopsy and cultures provide definitive diagnosis. Therapy is directed at the specific cause.

Neck

Lymphadenopathy of the head and neck is most commonly reactive secondary to HIV itself. Generalized lymphadenopathy is a finding in acute retroviral infection and is associated with fever and other systemic symptoms. Patients in the chronic phase of HIV infection may be asymptomatic, with the exception of progressive generalized lymphadenopathy. This reactive lymphadenopathy is generally symmetric and does not require biopsy for confirmation of its benign nature. Other conditions that may present with lymphadenopathy of the head and neck include malignancies such as lymphoma, Kaposi's sarcoma, squamous cell carcinoma, and a variety of infections, including those owing to *Mycobacterium tuberculosis*, MAC, *S. aureus*, cat-scratch disease, and *Treponema pallidum*. In these instances, lymphadenopathy is commonly asymmetric and associated with other findings such as fever, weight loss, cutaneous findings (Kaposi's sarcoma, impetigo), or oropharyngeal disease (lymphoma, squamous cell carcinoma).

Salivary glands, especially the parotid glands, develop cysts that are often bilateral and are called benign lymphoepithelial cysts. These lesions typically arise from the intraparotid lymph nodes rather than the parotid salivary gland tissue. Computed tomography shows multiple cystic lesions, and the diagnosis can be confirmed with fine-needle aspiration. No treatment is required if the patient is asymptomatic. Aspiration of these cysts may be warranted for cosmetic reasons. However, the fluid is likely to recur, and it is important for the patient to understand the limitation of such treatment. Surgical excision of the cysts is not recommended owing to the possibility of facial nerve damage.

Neoplasms

Kaposi's sarcoma has a predisposition for the mucous membranes as well as for the skin of the face.[15] The primary treatment for Kaposi's sarcoma has been radiation therapy. This is done at low dosage levels ranging from 1.5 to 2.5 Gy. For localized disease, other treatment options may include laser therapy, cryotherapy, and intralesional injection with chemotherapeutic agents.

Non-Hodgkin's lymphoma is the second most common malignancy seen in HIV patients. It presents in extranodal locations, usually of B-cell origin, and can be fairly aggressive with rapid onset and progression. This malignancy is treated with a combination of chemotherapy and radiation therapy.

Squamous cell carcinoma of the head and neck in the HIV-infected patient presents at a more advanced stage, has an aggressive tumor growth rate, and tends to occur in younger patients. Treatment plans should take into account the adverse response HIV patients can have to radiation therapy. Surgical management should be considered based on the underlying health and immune status of the patient.

CONCLUSION

Over 50% of patients with HIV and AIDS present with a symptom or physical finding in the head and neck region. The most common findings include otitis media, seborrheic dermatitis, chronic rhinitis, oral candidiasis, and lymphoid hyperplasia. Treatment should be individualized and requires a team approach for management.

CHAPTER 30

Etiology of Infectious Diseases of the Upper Respiratory Tract

John L. Boone, MD

Upper respiratory infection (URI) is one of the most common ailments for which patients seek medical care. The importance of understanding the causes of these infections is evident. This chapter is divided into five sections. The first reviews pathogens of URIs according to anatomic sites. The following sections cover those viral, bacterial, fungal, and miscellaneous infections that are of special interest or importance.

CAUSES BY ANATOMIC SITE

The pathogens principally responsible for URIs are listed by anatomic site in Table 30–1. This listing is not intended to be exhaustive but is limited to causes that are predominant for each site.

Common Cold

The common cold is an acute, self-limited viral disease characterized by rhinorrhea and nasal congestion, sometimes accompanied by throat irritation, fever, and malaise. Symptoms generally begin 1 to 2 days after the onset of viral infection and peak at 2 to 4 days. Cough is associated with approximately 30% of colds and typically does not become the most bothersome symptom until the fourth or fifth day of illness, when nasal symptoms decrease. The average incidence of the common cold in preschool children is five to seven per year. The incidence decreases with age and averages two to three per year by adulthood.[1] Infection is spread by direct contact with virus-contaminated respiratory secretions. Inoculation occurs at the nasal mucosa and, perhaps, the conjunctiva.

More than 200 viruses have been associated with the common cold. The most important come from the six viral families listed in Table 30–1. Most common colds are caused by rhinoviruses of the family *Picornaviridae*, of which there are more than 100 serotypes. Makela and coworkers, using viral culture and polymerase chain reaction (PCR) techniques, detected rhinoviruses in approximately half of 200 young adults with common colds over a 10-month period.[2] Rhinovirus infections occur year round, with peaks in the early spring and fall months in the temperate zones and during the rainy periods in the tropics. Coronaviruses account for about 10% of infections. At least two serotypes cause URIs, and re-infections are common. Parainfluenza viruses and the respiratory syncytial virus are members of the *Paramyxoviridae* family. They are primarily known as causes of lower respiratory tract infections but also account for a proportion of common colds. Re-infections occur throughout life. Influenza viruses usually produce a primary influenza-like illness. However, subsequent infections with the same or a similar serotype may result in common cold symptoms. Adenoviruses are an important cause of upper and lower respiratory tract infections, including the common cold. Specific serotypes are associated with pharyngoconjunctival fever and epidemic keratoconjunctivitis. Adenoviruses are also important causes of pharyngitis and pneumonia, especially in military recruits.

Most of the information regarding the pathogenesis of the common cold is derived from studies of experimentally induced rhinovirus infections. The rhinovirus is a nonenveloped 30 nm ribonucleic acid (RNA) virus characterized by a single positive stranded genome not only acting as a template for RNA synthesis but also encoding for a single polypeptide necessary for viral replication. After inoculation, the virus invades the host by binding to the intracellular adhesion receptor molecule 1 (ICAM-1) receptors of the basal epithelial cells,

TABLE 30–1. Anatomic Sites of Infection

Infection by Site	*Causative Agents*
Common cold (upper respiratory tract)	Viral
	Rhinoviruses
	Coronaviruses
	Parainfluenza viruses
	Respiratory syncytial virus
	Influenza viruses
	Adenoviruses
Pharyngitis	Viral
	Rhinoviruses
	Coronaviruses
	Adenoviruses
	Influenza viruses
	Parainfluenza viruses
	Respiratory syncytial virus
	Coxsackieviruses
	Bacterial
	Group A β-hemolytic streptococci
	Anaerobic bacteria
	Neisseria gonorrhoeae
Acute supraglottitis (epiglottitis)	Bacterial
	Haemophilus influenzae type b
	Group A streptococci
Acute laryngotracheobronchitis	Viral
	Parainfluenza viruses
	Influenza viruses
Acute sinusitis	Bacterial
	Streptococcus pneumoniae
	Haemophilus influenzae
	Moraxella catarrhalis
Chronic sinusitis	Bacterial (mixed infections common)
	Streptococcus pneumoniae
	Haemophilus influenzae
	Moraxella catarrhalis
	Anaerobes
	Staphylococcus aureus
	α-Hemolytic streptococci
Acute otitis media	Bacterial
	Streptococcus pneumoniae
	Haemophilus influenzae

Chronic otitis media	Bacterial (mixed infections common)
	Streptococcus pneumoniae
	Haemophilus influenzae
	Moraxella catarrhalis
	Anaerobes
	Staphylococcus aureus
	Pseudomonas aeruginosa

mainly located in the ICAM-1-rich area of the adenoid.[3] After attachment, the entire virus is translocated across the epithelial cell membrane and uncoated to release viral RNA into the cytoplasm for replication. Translation of the entire genome leads to a large polyprotein that, when cleaved, results in newly formed viral proteins. These newly formed proteins (RNA) can aggregate and eventually be released when the host cell disintegrates. After intracellular invasion and replication, the rhinovirus infection spreads intranasally and to the pharynx. Typical for rhinovirus infections are the isolated scattered foci of infected epithelium between large areas of normal epithelium. In contrast to other common cold viruses such as influenza and adenoviruses, the epithelium does not show any striking damage or cytopathic alterations during a rhinovirus infection.[3]

The mechanism(s) by which rhinovirus infection of epithelial cells in the upper airway causes the symptoms of the common cold is incompletely understood. The original concept that symptoms resulted from destruction of nasal epithelium has not been supported by biopsies, which have shown no striking damage or cytopathic alteration other than an increased number of polymorphonuclear neutrophils in the submucosa and epithelium. It appears that the viral infection per se does not produce symptoms; rather, it is the host response to the viral infection that is responsible for the symptoms.

A rhinovirus infection of the epithelium evokes the synthesis and release of mediators and cytokines, which result in a cascade of the inflammatory reactions held responsible for common cold symptoms. Vasodilatation, increased vascular permeability, cellular infiltration, and the release of various mediators characterize this response. One cytokine, interleukin-8 (IL-8), is a strong chemoattractant for neutrophils. Interleukin-8 is also capable of activating the recruited neutrophils, resulting in the release of their cytotoxic granule content. Another cytokine, IL-6, stimulates B-lymphocyte differentiation into plasma cells, with resultant production of immunoglobulins. Interleukin-6 also induces acute-phase proteins, such as C-reactive protein, and mediates T-cell activation, growth, and differentiation. Interferon-gamma (IFN-γ), another cytokine, stimulates macrophage accumulation, activation, and cytokine production. In addition, it stimulates natural killer (NK) cell function and antigen-specific B-cell proliferation. Tumor necrosis factor alpha (TNF-α) stimulates T and B lymphocytes and activates endothelial cells to express viral adhesion molecules and to release further cytokines.[3] Bradykinin, a known potent inflammatory mediator, causes vasodilatation, increases vascular permeability, and stimulates pain and glandular secretions via neuronal reflexes.

The similarity between the clinical manifestations of allergic rhinitis and the common cold has prompted attempts to establish the role of histamine in the common cold. Several studies have reported no increase in histamine in nasal secretions during rhinovirus infection. Prostaglandin D_2, another mediator derived from mast cells, cannot be detected in the nasal secretions of subjects infected with rhinovirus. Nasal biopsy studies show no change in mast cell numbers or mast cell degranulation. These studies suggest that it is unlikely that histamine or other mast cell mediators make an important contribution to the pathogenesis of rhinovirus colds.

The current concepts of the pathogenesis of symptoms in rhinovirus infection may one day allow the development of methods to block or dampen the host response. It may be that such an approach would allow the host to become immune to the infecting virus without the accompanying symptomatic illness.[4]

Pharyngitis

In most cases of acute pharyngitis, particularly mild cases, it is not possible to determine a specific microbiologic cause on clinical grounds alone. In a study of pharyngitis in adults, clinical findings such as fever, lymphadenopathy, and exudate correlated imperfectly with microbiologic findings.[5]

About 70% of acute sore throats are caused by viruses. Most of these occur as part of common cold or influenza syndromes. The most common viral agents are rhinovirus, coronavirus, adenovirus, and influenza and parainfluenza viruses.[6] Other associated viruses include respiratory syncytial virus, herpes simplex virus (types 1 and 2), coxsackievirus, Epstein-Barr virus, cytomegalovirus (CMV), and human immunodeficiency virus (HIV).

Adenoviruses are common agents of acute pharyngitis and cause a major share of pharyngitis in military recruits. Sore throat is severe and may be accompanied by cough, hoarseness, and substernal

pain. Fever, chills, malaise, myalgias, and headache are generally present. Adenoviruses are also the cause of pharyngoconjunctival fever, a syndrome characterized by fever, pharyngitis, and follicular conjunctivitis. Community epidemics of this infection most often center around contaminated public swimming pools.

Herpangina is a vesicular and ulcerative pharyngitis caused by coxsackieviruses or, less frequently, echoviruses. It is seen primarily in children 3 to 10 years old or, less commonly, in adolescents and young adults. Outbreaks are most common in the summer and fall. Onset is heralded by fever, which is followed by the development of small (1 to 2 mm) mucosal vesicles and ulcers. Over 2 to 3 days, these enlarge to 3 to 4 mm and are surrounded by erythematous rings. Lesions are most commonly noted on the anterior tonsillar pillars, as well as the soft palate, tonsils, pharyngeal walls, and posterior aspects of the buccal mucosa. Uninvolved areas of the pharynx appear normal or are only slightly erythematous. Fever and sore throat are sometimes accompanied by constitutional symptoms, including anorexia and abdominal pain, which can mimic appendicitis. Most cases of herpangina are mild and resolve without complications in 3 to 6 days.

Herpes simplex viruses (types 1 and 2) can cause acute pharyngitis indistinguishable from that caused by other respiratory viruses. More typically, vesicles and shallow ulcers accompany an infection. Herpes simplex virus is to be suspected when palatal or pharyngeal ulcers are accompanied by gingivostomatitis. Chronic herpetic lesions can occur in immunocompromised patients and are characterized by progressively large, shallow, painful ulcers.

Infectious mononucleosis most often presents with fever, pharyngotonsillitis, fatigue, and cervical lymphadenopathy. The illness is caused predominantly by the Epstein-Barr virus (EBV). Cytomegalovirus is an occasional cause of infectious mononucleosis-like disease. In such cases, pharyngitis and cervical lymphadenopathy may be mild or absent. These two viruses are addressed in more detail later in this chapter.

Primary infection with HIV may cause an acute febrile pharyngitis.[7] Fever, sore throat, and varying constitutional symptoms precede onset of lymphadenopathy by about a week.

Group A β-hemolytic streptococcus (GABHS), also known as *Streptococcus pyogenes*, is the most common bacterial cause of acute pharyngitis. Incidence is age related. In one study of school-aged children, GABHS accounted for 40% of cases of pharyngitist.[6] A prospective study of symptomatic adults patients found 10% with culture-proven GABHS pharyngitis.[8] Although GABHS pharyngitis was previously thought rare in infants, a more recent study found a 25% incidence of GABHS in children less than 3 years old.[9] As mentioned, attempts to correlate clinical findings with the presence of GABHS in acute pharyngitis have shown imperfect results. Features suggestive of GABHS, however, include pharyngeal exudate, dysphagia, headache, painful cervical lymphadenitis, fever, and the absence of cough, coryza, and hoarseness. Diagnosis may be confirmed by rapid antigen tests and/or throat culture. Timely diagnosis is important to prevent suppurative or nonsuppurative complications of GABHS infection. These complications are discussed later in this chapter.

The role of groups B, C, and G streptococci in the pathogenesis of symptomatic pharyngitis is uncertain. These non–group A streptococci may be responsible for a small portion of pharyngitis but are not associated with the nonsuppurative complications seen in GABHS.

Vincent's angina is an acute oropharyngeal ulcerative condition caused by a combination of anaerobic gram-negative and fusobacterial microorganisms. *Fusobacterium necrophorum, Treponema vincentii, Peptococcus, Bacteroides,* and other anaerobic microorganisms have been identified. Poor oral hygiene, fatigue, stress, malnutrition, and endocrine or metabolic disturbances are predisposing factors. Infection typically manifests as unilateral pseudomembranous tonsillar ulceration with pain, fetid breath, and cervical lymphadenopathy. Acute necrotizing ulcerative gingivitis (ANUG), or "trench mouth," is a similar ulcerative process of the gingiva. Penicillin and metronidazole are effective in the treatment of Vincent's angina and ANUG.

Neisseria gonorrhoeae should be considered as a cause of pharyngitis in sexually active patients, especially those with known orogenital contact. In a study of adults with gonorrhea, gonococcal pharyngitis was found in 20% of homosexual men, 10% of women, and 3% of heterosexual men. About 50% of infected individuals were asymptomatic, although odynophagia, low-grade fever, and erythema may occur. Gonococcal pharyngitis may occur without

associated urethritis and may serve as a source of disseminated disease.[10]

Acute Supraglottitis (Epiglottitis)

Acute supraglottitis is cellulitis of supraglottic structures including the epiglottis and aryepiglottic folds. Edema progresses rapidly and may result in airway obstruction.

Formerly, *Haemophilus influenzae* type b (Hib) was the etiologic agent in almost all cases of supraglottitis in children. However, with the advent of the Hib vaccine, the rates of disease caused by this microorganism have dramatically decreased.[11] Although *H. influenzae* is still identified in areas where the vaccine is available, group A streptococcus has been more frequently recovered in more recent studies.[11,12] When caused by group A streptococcus, supraglottitis was seen in an older age at onset (mean 6.2 years) and associated with slower recovery, greater involvement of the aryepiglottic folds, and negative blood cultures. This differs from the presentation of Hib supraglottitis, which includes younger age, involvement of the epiglottis, faster recovery, and positive blood cultures.[11] Other causes of acute supraglottitis in children are uncommon and include *Staphylococcus aureus*, other streptococci, *H. influenzae* non-type b, and *H. parainfluenzae*. Immunocompromised patients are more likely to have these and other, more unusual pathogens.

Acute supraglottitis is increasingly recognized in adults. In most cases, no causative microorganism is found, either by blood or throat culture. Using serology, PCR, and blood culture to investigate their series of adult epiglottitis patients, Trollfors and coworkers found Hib in about 25% and *Streptococcus pneumoniae* in 20% of patients.[13] No pathogen was identified in 43% of patients. Other pathogenic bacteria have been cultured from adult patients with supraglottitis, including *H. parainfluenzae, S. aureus,* and group A streptococci.

Acute Laryngotracheobronchitis (Croup)

Acute laryngotracheobronchitis, or croup, produces inflammation of the subglottic areas that result in stridor and respiratory distress. Most patients are children between the ages of 3 months and 3 years. The viral infection begins in the nasopharynx and, after a prodromal period of coryza and low-grade fever lasting for 12 to 72 hours, spreads to the respiratory epithelium of the larynx, trachea, and bronchi.

Parainfluenza viruses (types 1, 2, and 3) are the most frequent etiologic agents, accounting for almost 75% of isolated viral agents.[14] Influenza A virus, respiratory syncytial virus, adenoviruses, enteroviruses, and rhinoviruses are less commonly isolated. Rarely, *Mycoplasma pneumoniae* has been isolated from children with croup. Bacterial agents such as *S. pneumoniae, S. aureus*, and *Moraxella catarrhalis* have been associated with croup. They likely represent superinfection of a preceding viral disease.

Sinusitis

The microbiology of sinusitis varies according to the chronicity of the infection, as well as the age and underlying condition of the patient. Accurate culture requires aspiration or irrigation because of the presence of resident microflora in the nasal cavity and nasopharynx.

Acute community-acquired sinusitis in adults is most frequently associated with *S. pneumoniae* and nontypable *H. influenzae*. In children, to these pathogens may be added *M. catarrhalis.*[15] Anaerobic bacteria are recovered in about 5 to 10% of cases of acute sinusitis in adults, usually in the presence of dental disease. Anaerobes are rarely recovered from cases of acute sinusitis in children, presumably because of the relative absence of odontogenic infections in the young. *Staphylococcus aureus* is an uncommon cause of acute sinusitis, found in only about 3% of cases. In contrast, *S. aureus*, α-hemolytic streptococci, and *S. pneumoniae* were reported as the predominant pathogens of isolated sphenoid sinusitis. Although this may reflect increased contamination by resident nasal flora, antimicrobial coverage for *S. aureus* is prudent in patients with acute sphenoid sinusitis. Viral URIs undoubtedly play an important role in predisposing a patient to acute sinusitis; however, viruses, including rhinoviruses, adenoviruses, and influenzae and parainfluenzae viruses, are isolated in only 15 to 20% of antral aspirates taken from patients with acute sinusitis.

In studies of chronic sinusitis, the most common microorganisms identified were those seen in

acute sinusitis plus *S. aureus*, coagulase-negative *Staphylococcus*, and anaerobic bacteria. Infection is often polymicrobial, and anaerobic bacteria play a far greater role in both adults and children than in acute sinusitis.[16] Such anaerobes include *Bacteroides, Peptostreptococcus*, and *Fusobacterium*. Staphylococcal species, including *S. aureus*, are also far more frequently encountered in chronic sinusitis, as are α-hemolytic streptococci.

Nosocomial sinusitis, such as that seen following prolonged nasotracheal intubation, is commonly polymicrobial and has a high incidence of *S. aureus*, anaerobes, and gram-negative bacteria such as *Pseudomonas aeruginosa, Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis,* and *Enterobacter* species.[17]

In cystic fibrosis patients with acute sinusitis, *P. aeruginosa* and *H. influenzae* were the most frequently isolated pathogens.[18]

Otitis Media

Otitis media is the most common illness diagnosed by pediatricians. Acute otitis media (AOM) is a suppurative infection of the middle ear with a relatively rapid onset. Recurrent otitis media refers to episodes of repeated AOM separated by a month or more. Chronic otitis media includes the diagnoses of otitis media with effusion, as well as chronic suppurative otitis media with and without cholesteatoma.

In children with AOM, *S. pneumoniae, H. influenzae*, and *M. catarrhalis* are the microorganisms most frequently isolated after tympanocentesis and culture of middle ear fluid (MEF). Several studies have demonstrated that *S. pneumoniae* causes about 35% of AOM episodes, nontypable *H. influenzae* 25%, and *M. catarrhalis* 15%.[19,20] Most AOM associated with *H. influenzae* is caused by nontypable strains. In about 10% of *H. influenzae* infections, the otitis is caused by type b. Such type b infections may have a higher incidence of concomitant bacteremia or meningitis and should be preventable by immunization. *Staphylococcus aureus*, other streptococci, and *P. aeruginosa* were found in less than 3% of AOM. *Chlamydia pneumoniae*, which is susceptible only to macrolides and tetracyclines, was isolated in 8% in one study of young children.[21] The most notable recent trends in the bacteriology of AOM have been the rise in the proportion of patients infected with drug-resistant *S. pneumoniae* and an overall increase in β-lactamase-producing *H. influenzae* and *M. catarrhalis*. Bluestone and colleagues also studied the bacteriology of 34 adults with AOM. *Streptococcus pneumoniae* (21%) and *H. influenzae* (26%) were again the most frequently isolated microorganisms. This study confirmed the importance of *H. influenzae* beyond the age of preschool children.[19]

Streptococcus pneumoniae is more likely than *H. influenzae* or *M. catarrhalis* to cause a more severe and persistent AOM. In the absence of therapy, *S. pneumoniae* tends to persist longer than these other microorganisms. Also, there is an increased likelihood of finding *S. pneumoniae* in AOM less responsive to antibiotic therapy. Acute otitis media caused by *S. pneumoniae* is less likely to require a preceding viral infection and more likely to induce a greater inflammatory response.[22]

Viruses play a significant role in the pathogenesis of AOM. Clinical experience shows that AOM usually occurs concurrently with, or immediately after, a viral URI. Also, the seasonal rates of AOM parallel that of viral URI. Several studies have demonstrated the effect of viral URIs in inducing eustachian tube dysfunction. The pathogenesis by which viral URIs turn into AOM or facilitate bacterial AOM is not yet clear. Heikkinen noted that in vitro studies have shown an increase in levels of inflammatory mediators (bradykinin, IL-1, IL-6, IL-8, leukotriene C4, and TNF) in nasopharyngeal secretions in response to a viral infection. Intranasal challenge of these mediators has been shown to provoke eustachian tube dysfunction in adult volunteers. Respiratory viruses have also been shown to have a suppressive effect on polymorphonuclear and cell-mediated immune function, presumably increasing the host's susceptibilty to bacterial infections.[23] Fainstein et al have shown that experimentally induced influenza virus infection increases the adherence of *S. pneumoniae* and *H. influenzae* to pharyngeal epithelial cell.[24]

Viral culture and antigen detection techniques have allowed demonstration of viruses or viral antigens in the MEF of about 20% of children with AOM. Respiratory syncytial virus, influenza viruses, parainfluenza viruses, rhinovirus, and adenovirus are most commonly identified. In about two-thirds of the cases, bacteria were also identified, indicating a mixed infection. Virus as the only pathogen in MEF has been detected in 6% of AOM cases.[24]

Recently, studies using the more sensitive PCR technique have detected RNA genomic sequences in about 50% of MEF in AOM. Heikkinen et al noted that respiratory syncytial virus is especially capable of causing inflammation in the middle ear, as well as facilitating subsequent bacterial infection.[25] Vaccination against influenza A has been shown to reduce the incidence of bacterial AOM in children during an expected influenza epidemic. It is to be expected that effective vaccines against the major viral pathogens predisposing to AOM, especially RSV, will reduce the incidence of AOM in children.[23]

Neonatal otitis media is most frequently associated with microorganisms similar to those seen in infants; however, gram-negative enteric microorganisms and *S. aureus* are more frequently identified than in older children.[26]

The bacteriology of recurrent otitis media in children with episodes separated by a month or more is essentially that of AOM.

In their 10-year review, Bluestone and associates studied the bacteriology of otitis media with effusion in children.[19] *Haemophilus influenzae* (15%), *M. catarrhalis* (10%), and *S. pneumoniae* (7%) were most frequently isolated. Other streptococci, *S. aureus*, and *P. aeruginosa* were isolated in less than 3% of cases. No growth was found in 30%. This and other reports refute previous assumptions that MEF in otitis media with effusion is sterile.

Chronic suppurative otitis media is defined by the presence of chronic infection in the middle ear and discharge through a tympanic membrane perforation or patent pressure equalization tube. Mastoiditis is invariably present. Bacteria isolated are seldom those seen in an initial AOM. Polymicrobial infections are common. *Pseudomonas aeruginosa* is most commonly isolated, and *S. aureus* is seen more frequently than in AOM.[27] Anaerobes, including anaerobic gram-positive cocci, *Bacteroides* species, and *Fusobacterium*, are present in 50% of cases.[28] In chronic suppurative otitis media with cholesteatoma, *P. aeruginosa, S. aureus*, and anaerobes again predominate.[29]

SPECIFIC VIRUSES

Epstein-Barr Virus

Epstein-Barr virus, a member of the herpesvirus family, is a double-stranded deoxyribonucleic acid (DNA) virus. Two strains have been identified in humans. Epstein-Barr is ubiquitous, infecting more than 90% of the world's population. In less industrialized societies, nearly all inhabitants are infected during childhood, when symptoms of infection are mild. In the United States, western Europe, and other industrialized countries, infection may be delayed until adolescence or young adulthood and may manifest as infectious mononucleosis because of the reaction of a more mature immune system.

Infection by EBV is largely limited to epithelial cells of the pharynx and to B lymphocytes. The surface receptor for the virus on these cells is the CD21 molecule, which is also the receptor for the CD3 component of complement. Primary infection is initiated in the oropharyngeal epithelium, where replication, host cell lysis, and release of virions take place. Adjacent B lymphocytes are infected and disseminate the virus to local and distant lymphoid tissues and to other epithelial cells, including the nasopharynx and salivary glands. Within B lymphocytes, the virus establishes a latent infection. The DNA genome circularizes to form an episome, or extrachromosomal element, in the nucleus of the cell. Transformation of the infected B lymphocyte causes them to become "immortalized," which is to say that they acquire the ability to proliferate indefinitely. Such resting memory B cells are thought to be the site of persistence, or latent infection, of EBV within the body.[30] The host's immune system responds to infection first with NK cells, then with human leukocyte antigen (HLA) class I restricted cytotoxic and suppressor T lymphocytes and by antibody-producing anti-EBV B lymphocytes. The NK and T lymphocytes appear in the peripheral blood as "atypical lymphocytes." Cytokines released from these cells are largely responsible for the clinical manifestations of primary EBV infection. In infants and small children, these immune responses are weak, and symptoms of infection are mild. The immune systems of adolescents and young adults respond more vigorously and cause the symptoms of infectious mononucleosis.

Epstein-Barr virus is the predominant cause of infectious mononucleosis, which is characterized by fever, fatigue, pharyngitis, and lymphadenopathy. Splenomegaly, mild hepatitis, and cerebritis may also occur. Uncommon manifestations include jaundice, pneumonitis, blood dyscrasias, and central nervous

system syndromes. The diagnosis is suggested by the clinical features. Abnormal laboratory findings include the presence of atypical lymphocytes in the peripheral blood, elevation of hepatic enzymes, and the presence of positive heterophil antibodies (the "Monospot" or Paul-Bunnell test). Heterophil antibodies are immunoglobulin (Ig)M antibodies that bind to red blood cells from nonhuman species such as sheep or horses. Many rapid test kits for their detection are commercially available. The percentage of patients with acute EBV infection who have heterophil antibodies in their serum increases relative to the time since onset of symptoms. The percentage is also higher in patients over 4 years of age. In one study of young adults, 69% tested positive for heterophil antibodies by 1 week and 80% by 3 weeks after the onset of symptoms. A pediatric study found fewer than 50% of children under age 4 to have any detectable heterophil antibodies at any time.[31]

Epstein-Barr virus is closely linked to nonkeratinizing nasopharyngeal carcinoma and to Burkitt's lymphoma, a tumor of B lymphocytes limited largely to children in tropical Africa and New Guinea. Epstein-Barr virus genomes are also found in about one-third of the non-Hodgkin's B-cell lymphoma found in patients with acquired immune deficiency syndrome (AIDS).

Oral hairy leukoplakia is common in patients with HIV and represents infection by EBV of epithelial cells. It consists of white lesions with a hairy or corrugated appearance located on the lateral surface of the tongue. Epstein-Barr virus replication is evident only in the upper layers of the epithelium.

Cytomegalovirus

Cytomegalovirus, the largest member of the herpesvirus family, consists of a core of double-stranded DNA genome surrounded by a protein coat. The virus is ubiquitous, and serologic evidence suggests that up to 80% of adults have been infected. Most primary infections in immunocompetent persons are asymptomatic. An upsurge in interest in CMV has resulted from an appreciation of its role as an opportunistic pathogen in immunocompromised patients, including those with HIV infection.

The details of pathogenesis in CMV infection are less well understood than for EBV. Infection may be acquired by contact with the saliva, sputum, urine, or genital fluid of infected persons; through blood transfusion or solid organ transplantation; or by transplacental transfer to a fetus. Ductal epithelial cells of the major salivary glands and proximal renal tubules are especially involved by primary infection. Once acquired, the virus infects nucleated blood cells and spreads systemically. After primary infection, CMV generally remains in an asymptomatic latent state, but immunosuppression may result in reactivation and disease.

In infants and children, CMV infection generally causes few symptoms. In young adults, however, CMV can produce a mononucleosis syndrome with fever, fatigue, pharyngitis, lymphadenopathy, and relative lymphocytosis. It is estimated that 20% of infectious mononucleosis is caused by acute CMV infection. Pharyngitis, lymphadenopathy, and splenomegaly are less common and severe than in cases caused by EBV. Patients with CMV mononucleosis will show a relative lymphocytosis but will have a negative heterophil antibody (Paul-Bunnell) test.

Primary or reactivated CMV infections commonly cause disease in immunosuppressed hosts, such as persons with HIV infection or those who have undergone bone marrow or solid organ transplantation. Cytomegalovirus itself may adversely affect the immune system, causing suppression of NK-cell and T-lymphocyte function. Clinical features in immunosuppressed patients include encephalitis, chorioretinitis, hepatitis, pneumonitis, colitis, and esophagitis. Cytomegalovirus has also been identified as a cause of oral ulcers in immunosuppressed patients. Diagnosis in these cases in based on tissue biopsy, which demonstrates the characteristic histologic findings of intranuclear CMV inclusions surrounded by clear halos ("owl eyes"), as well as clusters of intracytoplasmic inclusions seen with periodic acid–Schiff or Gomori's methenamine silver techniques.

Cytomegalovirus is among the most common viral pathogens causing congenital abnormalities. Fetal involvement follows a primary CMV infection of a woman lacking antibody to the virus during pregnancy. Clinical features include mental retardation, hearing loss, jaundice, chorioretinitis, microcephaly, and pneumonitis, among others.

Human Immunodeficiency Virus

Human immunodeficiency virus is a retrovirus. It is able to convert its own single-stranded RNA to dou-

ble-stranded DNA for incorporation into a host cell genome. The principal targets are T helper (CD4) cells, which are central to the function of cell-mediated immunity. Impairment of these cells renders a patient susceptible to a variety of opportunistic infections and unusual malignant diseases.

Human immunodeficiency virus attaches to CD4 receptors and enters T-helper cell lymphocytes. The single-stranded RNA is converted by the enzyme reverse transcriptase into double-stranded DNA. The viral DNA is incorporated into the host cell genome. A latent phase follows that corresponds to clinically quiescent infection. Activation and viral replication lead to cell death and the destruction of large numbers of CD4 cells. It is possible that activation is speeded by the presence of DNA viruses such as herpes simplex virus and CMV. The presence or absence of opportunistic infections corresponds with the patient's CD4 count. A normal count is 700 to 1,200 cells/mm^3. CD4 counts below 200 cells/mm3 are associated with increased susceptibility to opportunistic infections. Such patients benefit from antibiotic prophylaxis.

Humoral immunity is adversely affected by HIV as well. Immunoglobulin G2 and IgG4 subclass deficiencies predispose patients to recurrent sinopulmonary infections. Patients with HIV may also develop elevated IgE levels, which may be responsible for an increased incidence of allergic rhinitis.

The reported prevalence of sinusitis in HIV patients varies widely, although clinicians generally agree that the incidence is higher than in immunocompetent patients. Retrospective studies have estimated the prevalence of disease at 10 to 20%. Two prospective studies placed the incidence at 30 to 68%.[32] Several reports suggest that the incidence of sinus disease increases with progressive immunodefiency, as measured by declining CD4 counts.[33,34] In addition, IgE levels increase in many HIV-infected patients with disease progression. Such immune dysfunction, with the resultant increase in allergic disease, may predispose HIV-infected patients to recurrent rhinosinusitis. The prevalence of specific pathogens in sinusitis of those HIV-infected patients with a CD4 count of greater than 200 cells/mm^3 is similar to that of non–HIV-infected patients. In acute sinusitis, *S. pneumoniae* and *H. influenzae* are most frequently recovered. In chronic sinusitis, *S. aureus*, anaerobic bacteria, and *P. aeruginosa* are also described.[35] Patients with HIV with CD4 counts less than 200 cells/mm^3 are more susceptible to unusual pathogens. Infections with *P. aeruginosa* are more frequent. Other pathogens reported include CMV, *Pneumocystis carinii, Acanthamoeba castellanii*, and *Legionella pneumophila.* Patients with AIDS are at increased risk for invasive fungal sinusitis. *Aspergillus fumigatus* has been most frequently reported. Other fungal pathogens have included *Pseudallescheria boydii, Candida albicans, Cryptococcus neoformans, Rhizopus arrhizus*, and mucormycosis, among others.[36]

Studies have suggested that children with HIV infection have an increased incidence of otitis media. Moreover, those HIV-infected children with a deteriorating immune system, as indicated by a decline in the CD4 count, are at greater risk for recurrent or chronic disease than those who retain an intact immune system.[37] Causative microorganisms do not seem to differ from those found in immunocompetent hosts. *Streptococcus pneumoniae, H. influenzae*, and *M. catarrhalis* predominate. Unusual pathogens, however, should be suspected when a patient has a severely depressed immune system or responds poorly to standard antibiotic therapy.

Adult HIV-infected patients appear to have an increased incidence of serous otitis media. This may be partly attributable to poor eustachian tube function. The eustachian tube may be affected by adenoidal hypertrophy, nasopharyngeal tumors such as Kaposi's sarcoma and non-Hodgkin's lymphoma, or allergic rhinitis prompted by increased IgE levels. *Pneumocystis carinii* is a common cause of pneumonia in AIDS patients. Although extrapulmonary infections are rare, several reports have described otitic involvement. Patients present with aural discharge and the presence of a polyp in the middle ear or external auditory canal. Several patients have had no history of prior *P. carinii* pneumonia. Diagnosis is made by biopsy of the polyp and demonstration of pneumocystis on Gomori's methenamine silver stain. These aural infections have responded well to trimethoprim-sulfamethoxazole. Other unusual pathogens have caused otitis media or mastoiditis, including *A. fumigatus, Candida albicans*, and *Mycobacterium tuberculosis*. Chronic otitis media, cholesteatoma, and intracranial complications of otitis media do not appear to occur more often in the HIV-infected population than in other patients.[38]

Oral candidiasis is a common feature of HIV infection and is often the first finding of the disease. Candidal infections are considered in more detail later in this chapter. As noted earlier, oral hairy leukoplakia is thought to be caused by EBV. The lesion is most frequently located on the lateral surface of the tongue and has a white corrugated or filiform appearance. Epstein-Barr virus replication is evident only in the upper layer of the epithelium. Herpes simplex viral infections are more common in HIV-infected patients. Lesions are generally more severe, numerous, and persistent than in immunocompetent patients. Herpes labialis is frequent and may extend onto the face to form a giant herpetic lesion.

Opportunistic infections of the larynx must be considered in HIV-infected patients with hoarseness or stridor. Candidiasis is the most common cause. Laryngeal candidiasis is most often part of a more widespread infection involving the oral cavity or esophagus. Absence of candidiasis in these sites, however, does not exclude laryngeal infection. The vocal folds are most frequently involved. Candidal infection of the epiglottis is much less common but is capable of causing stridor and airway compromise, especially in children.[39,40] Laryngeal infections caused by CMV and *Cryptococcus neoformans*, among others, have been described in HIV-infected patients. A series of five HIV-infected patients with supraglottitis was reported by Rothstein and associates.[41] A pale, floppy epiglottis with supraglottic edema, cervical lymphadenopathy, normal to low white blood cell count without a shift to the left, and rapidly progressive airway obstruction comprised the typical presentation. No unusual pathogens were recovered from epiglottic cultures in these patients. The most common pathogens were *S. pneumoniae* and *S. aureus*. Conservative medical management was not successful. Patients required airway intervention with appropriate antibiotic therapy.

SPECIFIC BACTERIA

Group A β-Hemolytic Streptococcus (Streptococcus pyogenes)

Group A β-hemolytic streptococcus, or *S. pyogenes*, is a chain-forming, gram-positive coccus. More than 80 serotypes have been recognized based on a series of distinct surface proteins, the M proteins. The M protein strains of GABHS that cause pharyngitis are generally distinct from those causing impetigo or pyoderma. M proteins inhibit phagocytosis of GABHS by host leukocytes in the absence of type-specific antibodies and therefore play an important role in the virulence of these microorganisms.[42]

Group A β-hemolytic streptococcus secretes certain toxins and enzymes that have clinical effects or cause antibodies to be produced that may be used for serologic identification. Streptolysins O and S induce lysis of host cell membanes, including red blood cells. Streptolysin O is antigenic and is the basis of the antistreptolysin O (ASO) antibody assay, the most widely used of the many streptococcal antibody tests. Pyogenic (also called erythrogenic) exotoxins are produced by some serotypes of GABHS. Three exotoxins have been identified: streptococcal pyogenic exotoxin A (SPE A), SPE B, and SPE C. These exotoxins are thought to be in part responsible for the clinical manifestations of scarlet fever and of streptococcal toxic shock-like syndrome (TSLS).

The leading role of GABHS as a cause of pharyngitis is discussed earlier in this chapter. The greater significance of these microorganisms lies in their capacity to cause complications. These complications may be broadly separated into three categories: suppurative, toxin mediated, and nonsuppurative.

Suppurative complications of GABHS include peritonsillar abscess, retropharyngeal abscess, suppurative cervical lymphadenitis, sinusitis, otitis media, and mastoiditis. Group A β-hemolytic streptococcus is a prominent cause of peritonsillar and retropharyngeal abscesses. Similarly, GABHS and *S. aureus* are the most important causes of suppurative cervical lymphadenitis. In contrast, GABHS plays a minor role in the pathogenesis of sinusitis, otitis media, and mastoiditis.

Toxin-mediated complications of GABHS pharyngitis include scarlet fever and streptococcal TSLS. Both are thought to be associated with the release of streptococcal pyogenic exotoxins by certain M protein serotypes. In the 1980s, an increase in the incidence and severity of scarlet fever, as well as the emergence of TSLS, suggested an increase in the number of virulent GABHS strains capable of producing pyogenic exotoxins. Serotypes M-1 and M-3, in particular, were found to be associated with TSLS.[43] Investigators have postulated that manifestations of scarlet fever, including the characteristic

rash, are attributable to host hypersensitivity to these pyogenic exotoxins.

Initial manifestations of scarlet fever include sore throat, fever, and constitutional symptoms such as vomiting, headache, and malaise. The characteristic rash follows 12 to 48 hours later, beginning on the trunk before quickly becoming generalized. The rash appears diffusely erythematous with fine red papules. It blanches on pressure, may become petechial, and fades in 2 to 5 days, leaving a fine desquamation. Skin folds, such as the groin and axilla, are most intensely involved. The face is flushed, with circumoral pallor. Enlargement and erythema of the papillae of the dorsal tongue produce a characteristic "strawberry tongue."

In the late 1980s, reports emerged of GABHS infections associated with hypotension, progressive multisystem organ failure, and other features suggestive of a toxin-mediated disorder. Because of a partial resemblance to staphylococcal toxic shock syndrome, the new disorder was named streptococcal TSLS. The syndrome occurs most often in healthy adults. Most patients have a severe soft tissue focus of infection, such as necrotizing fasciitis and/or myositis; however, 10 to 20% of cases have been associated with pharyngitis.[43] The syndrome most typically consists of hypotension, fever, rash, desquamation, and multisystem organ failure, which is out of proportion to the extent of local signs and symptoms. Bacteremia is present in about half of the cases. In a reported series of 50 patients, the mortality rate was 24%. Group A β-hemolytic streptococcus isolated from patients with TSLS appears to come from a limited group of M protein serotypes. M-1 and M-3 strains, in particular, have been associated with TSLS. Streptococcal pyogenic exotoxin A stimulates production of TNF by peripheral monocytes in vitro. A cytokine, IL-1β, is thought to contribute to the pathophysiology of shock and tissue injury. Treatment of streptococcal TSLS involves support of failing organ systems, appropriate antibiotics, and, if present, aggressive surgical débridement of necrotizing fasciitis or myositis.

Nonsuppurative complications of GABHS pharyngitis include poststreptococcal glomerulonephritis and acute rheumatic fever (ARF). The pathogenesis of these conditions is unclear, but each is suspected to be immune mediated.

Poststreptococcal acute glomerulonephritis (AGN) is a delayed, nonsuppurative complication resulting in inflammation of the renal glomeruli. Acute glomerulonephritis may follow either pharyngitis or cutaneous infections caused by GABHS. A limited number of strains are "nephritogenic." M-12 is the M protein serotype most frequently related to pharyngitis-associated nephritis.[42] The pathogenesis of AGN is unclear. Antibodies to antigens of nephritogenic streptococci may cross-react with structurally similar renal antigens, producing injury. Alternatively, inflammation may result from deposition of streptococcal antigen-antibody complexes within the kidney. Acute glomerulonephritis associated with GABHS pharyngitis occurs most frequently in school-aged children. The latent period following pharyngitis averages 10 days. Clinical features include fever, moderate edema, hypertension, and azotemia. Mild cases may have few symptoms. The urine is smoky or brown in color with a high specific gravity, proteinuria, and hemoglobinuria. Microscopic examination reveals red blood cells, white blood cells, and hyaline, granular, or red blood cell casts. Other laboratory findings include a mild normocytic normochromic anemia, prolonged erythrocyte sedimentation rate (ESR), decreases in C3 complement, and elevations of the blood urea nitrogen and serum creatinine. Unlike in ARF, recurrences are rare. The long-term prognosis in children is excellent, with few cases leading to residual renal disease. Prognosis in adults is more guarded.

Acute rheumatic fever is a nonsuppurative complication of GABHS characterized by inflammatory lesions of the heart, joints, subcutaneous tissues, and central nervous system. Pyodermic infections are not associated with ARF. The disease has become uncommon in more prosperous areas of the world, although local outbreaks thought to be caused by highly rheumatogenic strains of GABHS are periodically reported. In poorer regions, ARF remains prevalent and accounts for a large proportion of cardiac disease in children and young adults.[44] The pathogenesis of ARF is poorly understood. Current evidence supports an immune mechanism. Humor- and cell-mediated immune re- sponses to rheumatogenic antigens of GABHS are thought to cross-react mistakenly with structurally similar antigens in host tissues. Pathologic findings of ARF include inflammatory lesions of connective tissues in the heart, joints, blood vessels, and subcutaneous tissues. A unique feature, seen mainly in the heart, is the Aschoff's nodule, a granuloma that results from

injury to collagen. Cardiac findings also include pericarditis, myocarditis, and/or endocarditis. Valvular involvement begins as edema and inflammation of the leaflets and chorda tendinae. With healing, the valves may become thickened and deformed, the chordae shortened, and the valve commissures fused. These changes result in valvular stenosis or insufficiency. The mitral valve is affected in 75 to 80% of cases, the aortic valve in 30%, and the tricuspid and pulmonary valves in under 5%. Acute rheumatic fever occurs most often in children 5 to 15 years of age; it is rare before age 4 or after age 40. Symptoms and signs usually commence 1 to 3 weeks after the streptococcal pharyngitis. No single symptom, sign, or laboratory test is diagnostic of the disease. The Jones criteria, most recently updated in 1992, remain useful in making the diagnosis.[45] If supported by evidence of preceding group A streptococcal infection, the presence of two major manifestations, or one major and two minor manifestations, a high probability of ARF is indicated. Supporting evidence includes a positive throat culture, positive rapid streptococcal antigen test, or an elevated or rising streptococcal antibody titer. Major manifestations include carditis, polyarthritis, chorea, erythema marginatum, and subcutaneous nodules. Minor manifestations include clinical findings such as arthralgia or fever, laboratory findings such as an elevated ESR or C-reactive protein, and a prolonged PR interval on an electrocardiogram. Treatment of ARF includes the use of salicylates and corticosteroids to quiet inflammation. Neither agent prevents the development of rheumatic heart disease, the only long-term sequelae of ARF. Rheumatic patients are at extremely high risk of developing recurrent ARF after streptococcal infections and require antibiotic prophylaxis.

Corynebacterium diphtheriae

The corynebacteria are nonmotile, pleomorphic, unencapsulated, gram-positive bacilli. Diphtheria is caused by toxin-producing strains of *Corynebacterium diphtheriae* or, occasionally, the related microorganism *Corynbacterium ulcerans*. The infection is now rare in countries with immunization programs but remains widespread elsewhere. In 1990, an epidemic centered in the former Soviet Union demonstrated the potential for resurgence of this disease should efforts to maintain high levels of immunity in a population lapse.

Humans are the only known reservoir for *C. diphtheriae*. Transmission occurs via contact with respiratory secretions or exudate from infected skin lesions. The virulence of *C. diphtheriae* results from the action of a potent exotoxin capable of inhibiting intracellular protein synthesis. After host cell uptake, the exotoxin catalyzes inactivation of the transfer RNA translocase elongation factor 2. Loss of this enzyme prevents the interaction of messenger RNA and transfer RNA, stopping further addition of amino acids to developing polypeptide chains. Local action of the exotoxin in the upper respiratory tract induces a characteristic pseudomembrane comprised of fibrin, leukocytes, erythrocytes, dead respiratory cells, and microorganisms. Systemically, the exotoxin has a predilection for the heart (myocarditis), nerves (demyelination), and kidneys (tubular necrosis). Some strains of *C. diphtheriae* do not produce exotoxin. Such strains will not produce severe systemic symptoms or the characteristic pseudomembrane.

The posterior structures of the mouth and the proximal parts of the pharynx are the most common sites for respiratory tract diphtheria. Onset is abrupt and involves sore throat, malaise, and low-grade fever. Initial erythema usually progresses to development of an adherent pseudomembrane typically on one or both tonsils with extension to the soft palate, oropharynx, and nasopharynx. Its color may vary from creamy to grayish green. The pseudomembrane is surrounded by a deep red border, and attempts at removal result in bleeding. Cervical lymph nodes are usually enlarged, and severely ill patients may have a bull-neck appearance. Non–exotoxin-producing strains of *C. diphtheriae* will not produce a pseudomembrane. Infections produced by such strains may closely resemble streptococcal pharyngitis.

Laryngeal and tracheobronchial involvement usually results from direct spread from the pharynx, although the disease may occasionally begin there. Symptoms include hoarseness, respiratory distress, and a brassy cough. If the presence of a laryngeal or tracheal membrane is found on laryngoscopy, consideration must be given to early endotracheal intubation or tracheostomy to forestall airway obstruction, especially in children.

Nasal diphtheria initially causes purulent or serosanguinous nasal discharge. Patients with chronic nasal diphtheria may act as carriers of the disease.

Diphtheria exotoxin has its most striking effects on the heart and nervous system. Clinically significant myocarditis occurs in 7 to 20% of respiratory tract diphtheria cases. Neuropathy can involve cranial nerves IX and X, causing palatal or pharyngeal paralysis with resultant regurgitation of swallowed fluids through the nose.

Diphtheria must be suspected in any unimmunized patient with a severe, rapidly spreading pharyngeal exudate. Diagnosis is confirmed by culture on Loeffler's or Tindale's medium. Because routine methods of throat culture do not promote the isolation and identification of *C. diphtheriae*, the laboratory must be alerted to use selective media when the disease is suspected. Toxin production is demonstrated by immunodiffusion on solid culture media (Elek test), by monoclonal enzyme immunoassay for toxin (EIA), or by PCR testing of the isolate's DNA, using primers for the *tox* gene.

Treatment of diphtheria involves the use of antitoxin and antibiotics and protection of a compromised airway. Diphtheria antitoxin only neutralizes the exotoxin before its entry into cells, so it is critical that it be administered as soon as a presumptive diagnosis has been made, without awaiting diagnostic confirmation. Penicillin and erythromycin are the antibiotics of choice. By eradicating the pathogen, they end local disease, further production of exotoxin, and transmission of disease.

Klebsiella rhinoscleromatis (Rhinoscleroma, Scleroma)

Klebsiella rhinoscleromatis (*K. pneumoniae*, subspecies *rhinoscleromatis*) is a capsulated gram-negative coccobacillus that causes a chronic granulomatous disease of the upper respiratory tract. It is endemic to tropical and subtropical areas of Africa, Central and South America, and Asia. Most European cases are reported from Eastern Europe. In temperate zones, cases are generally imported from endemic areas. Poor hygiene, crowded living, and malnutrition are predisposing factors. Females are more frequently affected than males. The disease tends to present in the second and third decades of life. The nose is almost always involved. Less commonly, the paranasal sinuses, lacrimal sacs, pharynx, larynx, and trachea are affected. Nasal lesions often begin at the mucocutaneous junction of the vestibule. The disease usually progresses through three stages. The catarrhal stage is manifested by prolonged purulent rhinorrhea, crusting, and nasal obstruction. Diagnosis in this stage is difficult because of the nonspecific findings. In the granulomatous stage, multiple nodules form and coalesce to form bluish-red or pale, rubbery granulomas.[46] Most cases are diagnosed in this stage. Severe cases can progress to local destruction and cosmetic deformity. Broadening of the nasal dorsum produces the characteristic Hebra nose. The final fibrotic stage causes cicatrix formation. Nasal or nasopharyngeal stenosis is common. Stenosis of the larynx or trachea can cause life-threatening airway obstruction. Diagnosis of rhinoscleroma is made by clinical findings and biopsy. Histologic findings include granulomatous inflammation and the presence of Mikulicz's cells and Russell's bodies. These findings are most characteristic of the granulomatous stage, in which *K. rhinoscleromatis* is most easily isolated. Mikulicz's cells are "foamy histiocytes" caused by gram-negative bacteria in the cytoplasm of macrophages. Russell's bodies are eosinophilic structures within the cytoplasm of plasma cells. In advanced cases, fibrosis may obscure characteristic findings. Treatment of rhinoscleroma is with prolonged antibiotics. The most commonly used antibiotics are tetracycline (2 g/day), ciprofloxacin (1 g/day), and streptomycin (1 g/day). The criteria for cessation of therapy are clinical improvement and repeated negative tissue culture. Surgical débridement may be indicated to alleviate airway obstruction. Laryngeal dilatation, endoscopic resection, or tracheostomy may be required for laryngeal stenosis.

Mycobacterium tuberculosis

Mycobacterium tuberculosis, an acid-fast bacillus, is a cause of infection throughout the upper respiratory tract. Its incidence has again increased with the advent of AIDS. Two sites of special interest are the larynx and middle ear.

Tuberculosis is the most common cause of granulomatous disease of the larynx. It is usually, but not invariably, associated with active pulmonary disease. Spread from the lung to larynx is largely ascribed to direct inoculation by bacilli-laden sputum, but hematogenous and lymphatic spread from pulmonary foci is recognized as well. Symptoms of laryngeal tuberculosis may include hoarseness, odynophagia, dysphagia, and referred otalgia. Exam-

ination may show edema, submucosal nodules, and shallow ulcerations. Lesions may progress to deeper ulceration, perichondritis, and arytenoid fixation. The posterior part of the larynx is most commonly involved, although any portion of the larynx may be involved.[47] Laryngeal tuberculosis may mimic carcinoma or chronic laryngitis. Syphilis, mycotic infections, sarcoidosis, and Wegener's granulomatosis must also be considered. A chest radiograph is helpful in suggesting the diagnosis if active pulmonary disease is present. A sputum smear may show acid-fast bacilli. The diagnosis may be confirmed by biopsy. Laryngeal tuberculosis responds well to antitubercular chemotherapy. Fibrotic changes from advance disease may require surgical reconstruction.

Tuberculous otitis media may result from either hematogenous spread from pulmonary foci or from direct inoculation by bacilli-laden sputum refluxed through the eustachian tube. Otorrhea may be scant or profuse. Although the disorder is often painless, many patients experience otalgia. Granulation tissue and occasionally polyps are seen in the middle ear. Conductive hearing loss may result from effusion, mucosal thickening, tympanic membrane perforation, or ossicular destruction. Classically, tympanic membrane perforations have been described as initial small multiple perforations that coalesce to a near-total perforation. More recent studies show that simple perforations are more common, however. Denudation and destruction of the ossicular chain are common. Facial nerve paralysis is more common in aural tuberculosis than in otitis media caused by other bacteria. Tuberculous otitis media can also cause mastoiditis, which, in turn, may progress to subperiosteal abscess and a draining fistula. Other complications may include labyrinthitis, meningitis, and osteomyelitis of the petrous pyramid. The diagnosis of aural tuberculosis is best made by biopsy of granulation tissue or polyps. Histologic presence of caseating granulomata and acid-fast bacilli confirms the diagnosis. Smear and culture of aural discharge are unreliable because the bacilli can be demonstrated in only a minority of patients. Chest radiograph abnormalities suggestive of pulmonary disease are present in only 50% of patients with aural tuberculosis.

Treatment of aural tuberculosis consists of long-standing antitubercular chemotherapy. Surgical intervention may be indicated in the presence of facial nerve paralysis, subperiosteal abscess, persistent postauricular fistula, labyrinthitis, or extension of the infection into the central nervous system. Cortical mastoidectomy may disclose thick granulation tissue and possible bony necrosis. Tympanoplasty or ossicular reconstruction should be delayed until the infection has been controlled.

Mycobacterium leprae

Mycobacterium leprae is a gram-positive, acid-fast bacillus. It prefers an ambient temperature of less than 37°C and, as a result, has a predilection for skin, peripheral nerves, and the upper aerodigestive tract. Leprosy presents in three general forms. In the lepromatous form, the patient is unable to generate an effective immune response to *M. leprae* because of a selective unresponsiveness of T lymphocytes. This form of leprosy tends to be the most widespread and destructive. Most upper aerodigestive tract leprosy is of the lepromatous form. In the tuberculoid form, the host has a normal T-cell response. Tuberculoid form lesions are generally less widespread. They consist of plaques and macules with sharp, raised borders. An intermediate third form of leprosy is the borderline form, which reflects a partial reduction in immune response.

The nose is by far the most frequently involved site in the upper aerodigestive tract. Approximately 95% of patients with lepromatous leprosy have nasal involvement. Lesions begin as a pale, nodular, plaque-like thickening of the nasal mucosa. Untreated lesions can progress to ulceration, septal perforation, and saddle-nose deformity. Symptoms include rhinitis, obstruction, crusting, and bleeding. The anterior end of the inferior turbinate is the site most likely to give a positive biopsy.

The larynx is less commonly involved. Involvement nearly always begins at the tip of the epiglottis. Mucosal thickening is followed by granuloma formation and ulceration. Symptoms may include hoarseness and pain. Laryngeal leprosy can closely mimic carcinoma. Untreated lesions may progress to fibrosis and airway obstruction, requiring tracheostomy.

Mycobacterium leprae has never been cultured in vitro. Diagnosis is most reliably made by tissue smear or biopsy, which may show granulomatous changes and the presence of bacilli. Rifampin, dapsone, and clofazimine are the most widely used

antileprosy drugs. Treatment is generally with the standard World Health Organization regimen.[48]

Actinomyces

Actinomycosis is caused by anaerobic gram-positive bacterium of the family *Actinomycetaceae*. The filamentous, branching appearance of these oral saprophytes on microscopy caused their initial misidentification as fungi. *Actinomyces israelii* is the microorganism most frequently incriminated in human disease. These inhabitants of the normal oral flora take advantage of infection, trauma, or surgical injury to penetrate mucosa and invade adjacent tissue. Cervicofacial infections commonly follow dental infections or manipulations. Such infections most commonly affect otherwise healthy individuals.

The clinical manifestations of cervicofacial actinomycosis may vary from an indolent infection to a more rapidly progressive, tender, fluctuant swelling resembling a typical pyogenic infection.[49] Most cases, however, present as a chronic infection with few systemic symptoms. A typical presentation shows a slowly progressive, mildly tender induration of the neck, buccal, and mandibular regions. Infection spreads without regard to tissue planes. Progression leads to formation of a hard, board-like lesion ("lumpy jaw"), suppuration, draining fistulae, and the presence of "sulfur granules" (white-yellow granules of bacterial filaments, 1 to 5 mm in diameter) in exudates or tissues. Overlying skin can be dark red to purple, and associated cutaneous sinus tracts remain chronic, with little tendency to heal. Osseous involvement of the mandible occurs in 15% of cases.

A diagnosis of actinomycosis is based on the clinical presentation, positive culturing of the microorganism, and observation of sulfur granules or acid-fast–negative pleomorphic filaments in exudate or tissue sections.[50] Anaerobic culturing must be meticulous to obtain growth. Even with proper precautions, actinomycosis is identified from culture in fewer than 50% of cases. Fine-needle aspiration has been shown to be useful in obtaining specimens for histologic examination and culture.

Treatment of cervicofacial actinomycosis consists of prolonged antibiotics and surgical débridement. Although sensitive to penicillin, nearly all cases require surgical drainage, curettage, or lesion resection.[49] The duration of penicillin therapy will vary from 2 to 18 months. Concomitant hyperbaric oxygen treatment in severe cases should be considered as well.

SPECIFIC FUNGAL INFECTIONS

Candidiasis

Candida albicans is the most frequent of several species that cause candidiasis. It is a dimorphic fungus with both yeast and hyphal forms. *Candida albicans* is a commensal of the oral cavity and pharynx. Infection usually only follows changes in the local bacterial flora, mucosal integrity, or host immunity. Local factors that may predispose patients to candidiasis include xerostomia and dentures. Systemic factors are numerous and include prolonged antibiotic use, diabetes mellitus, immunocompromised states (eg, HIV, cytotoxic therapy), pernicious anemia, and hematologic malignant diseases.

Oral candidiasis ("thrush") can vary greatly in appearance. Zegarelli has described several variants.[51] The pseudomembranous variant resembles white milk curds overlying an erythematous base. The erythematous variant appears flat, irregular, and dusky red. When candidiasis occurs beneath dentures, it is flat and red and extends up to but not beyond the denture border. A hyperplastic variant resembling lichen planus manifests as a true leukoplakia without pseudomembrane or erythematous base. Oral candidiasis is often asymptomatic but may also cause a "burning" pain. Candidiasis may also be responsible for median rhomboid glossitis, as well as some cases of angular cheilitis.

Candidiasis less commonly infects the larynx and pharynx. When involved, the larynx is covered by a thick, white exudate. Hoarseness is the most common symptom, followed by pharyngeal pain. Severe cases may proceed to airway obstruction and laryngeal scarring. Diagnosis is best made by direct laryngoscopy and biopsy.

Aspergillosis

The *Aspergillus* species are ubiquitous saprophytic fungi found in soil and decaying organic material. *Aspergillus fumigatus* and *Aspergillus flavus* are the most common of many species to cause disease. Hyphae show regular septa with frequent acute

branching. *Aspergillus* infections are distributed worldwide, although chronic disease is especially prevalent in the Sudan and Saudi Arabia. Infection is acquired by the inhalation of spores. The lungs, nose, and paranasal sinuses are the most commonly affected sites.

Aspergillus is the most common cause of fungal sinusitis. The maxillary and ethmoid sinuses are most frequently involved. Conditions that obstruct sinus drainage such as allergic rhinitis, nasal polyps, and chronic bacterial sinusitis may predispose patients to fungal sinusitis. Infections take one of four forms. Acute invasive fungal sinusitis occurs primarily in immunocompromised patients. Vascular invasion by hyphae with resultant thrombosis and necrosis may cause a fulminant course resembling craniofacial mucormycosis. Erosion into the orbits, cranium, palate, and skin is common. Chronic invasive fungal sinusitis occurs more frequently in immunocompetent patients. Progression of the infection is generally slow, with mild early signs and symptoms. Extension into the orbit or cranium may produce proptosis, ophthalmoplegia, and headache. The third form of fungal sinusitis is the "fungus ball." This is a tangle of fungal hyphae within a sinus cavity but without invasion of sinus mucosa. The maxillary sinus is most commonly involved. A fourth form of fungal sinusitis is allergic fungal sinusitis (AFS). Most patients with AFS are immunocompetent and present with features of refractory sinusitis and nasal polyposis. Many also have a history of atopy or asthma. The pathogenesis of AFS is incompletely understood, but evidence supports a Gell and Coombs type I (IgE-mediated) immune response to fungal antigens. Type III and IV immune responses may also be involved. The pathologic hallmark of AFS is "allergic mucin," consisting of eosinophils, Charcot-Leyden crystals, and scattered fungal hyphae. Although AFS is not thought to be invasive, bony erosion is seen on computed tomographic (CT) scans in 20% of reported cases. Laboratory abnormalities include eosinophilia, elevated total serum IgE, and elevated IgE radioallergosorbent test (RAST) titers to specific fungi. The diagnosis of AFS is confirmed by demonstration of allergic mucin and culture of the fungus.

The presence of *Aspergillus* or other fungi must be suspected in cases of sinusitis that do not respond to the usual medical treatment. Computed tomographic scans may show a characteristic pattern of alternating high- and low-density signals and may also be useful in determining the extent of the disease. Often the proper diagnosis is suggested only at surgery, with discovery of mucus-covered, inspissated, cheesy material typical of fungal sinusitis. Diagnosis is confirmed by histology and culture. Treatment of acute invasive and chronic invasive forms requires surgical drainage, débridement, and the use of systemic antifungal agents. Treatment for a fungus ball requires only surgical removal and aeration of the involved sinus. Systemic antifungal agents are not required. Allergic fungal sinusitis is treated by surgical débridement and aeration of the involved sinus followed by the use of systemic and topical intranasal corticosteroids. Recurrence is common and may be heralded by rising serum total IgE levels. Specific immunotherapy with multiple relevant fungal and nonfungal antigens has reduced the necessity for corticosteroid therapy, while preventing recurrence of the disease and the need for repeat surgery.[52]

Phaeohyphomycoses (Dematiaceous Fungi)

Dematiaceous fungi are defined by the presence of melanin in the walls of their hyphae or spores. These fungi are increasingly recognized as causes of fungal sinusitis previously ascribed to *Aspergillus* species. The list of dematiaceous fungi causing sinusitis is rapidly expanding and currently includes *Drechslera, Bipolaris, Exserohilum, Curvularia, Alternaria,* and *Cladosporium* species. Signs and symptoms are essentially indistinguishable from those of chronic indolent *Aspergillus* sinusitis. These fungi are also common causes of AFS. Diagnosis and treatment are similar to that of aspergillosis.

Mucormycosis

Mucormycosis (zygomycosis) is an infection caused by fungi of the *Mucoraceae* family, which includes *Rhizopus, Mucor*, and *Absidia* species. Nearly all cases occur in patients with diabetes mellitus or who are otherwise immunocompromised. These fungi are found in soil and decaying organic matter. When examined microscopically, their hyphae are broad (7 to 20 μm), with few septa and irregular 90-degree branching.

Craniofacial (rhino-orbital-cerebral) mucormycosis usually originates in the nose or sinuses.

Vascular invasion by hyphae leads to thrombosis with resultant ischemic infarction and necrosis. This accounts for the potentially rapid erosion and spread of this infection into the orbit, cranium, palate, or face. Patients with nasal involvement present with purulent or serosanguinous drainage, ulceration, or necrosis. The lateral nasal wall and turbinates are the most frequent site of initial involvement. Edema and erythema are followed by cyanosis and black necrosis. Orbital extension may cause periorbital swelling, proptosis, and ophthalmoplegia. Cranial involvement may cause cranial neuropathies, focal neurologic deficits, and coma. Anesthesia of an involved area may provide an early clue to the presence of mucormycosis.[53]

Prompt diagnosis requires a high index of suspicion and is confirmed by biopsy. Frozen sections may speed diagnosis. A CT scan delineates the extent of the infection. Treatment requires a prolonged course of amphotericin B, as well as aggressive surgical débridement of all nonviable tissue. Antifungal azoles are ineffective. The underlying condition must be corrected if possible.

Histoplasmosis

Histoplasma capsulatum is a dimorphic fungus that exists in a mycelial form in the soil and a budding yeast form at body temperature. It is found throughout the world and in the United States is especially prevalent in the Mississippi and Ohio River valleys. The disease is acquired by inhalation of airborne conidia, often during contact with soil contaminated by avian or bat feces. An increased incidence has been seen in patients with AIDS.

Disseminated histoplasmosis occurs most frequently in patients with impaired cell-mediated immunity. In such patients, lesions of the upper aerodigestive tract are most often seen. The larynx is most commonly involved, with preference for the anterior part of the larynx and epiglottis. Symptoms include sore throat, hoarseness, and dysphagia. Other sites of involvement include the tongue, palate, buccal mucosa, and pharynx. Lesions may appear nodular or ulcerative and may mimic carcinoma, syphilis, tuberculosis, or any other granulomatous lesion. Biopsy is a reliable method of diagnosis. It shows a granulomatous response with budding yeast cells. Amphotericin B is the drug of choice for severe, refractory, or relapsing infections. An oral azole, particularly itraconazole, may be used for milder infections or suppressive therapy.

Blastomycosis

Blastomyces dermatitidis is a dimorphic fungus that grows in a mycelial form at room temperature and as a budding yeast at body temperature. Blastomycosis is most prevalent in the eastern portion of North America and over a wide area of Africa. Infection is thought to be acquired by the inhalation of spores. Dissemination occurs by hematogenous seeding from primary pulmonary foci and, when present, is most frequent in the skin, bone, and genitourinary tract. Skin lesions are most commonly located on the face, extremities, scalp, and neck. The appearance of these lesions may vary. Most begin as papules that, over a course of weeks or months, progress to relatively painless ulcerative or verrucous lesions. Long-standing lesions may show central healing with extensive fibrosis. Subcutaneous abscesses and draining sinuses may also be present.

Involvement of the nose, sinuses, larynx, or mouth may cause well-circumscribed, indurated lesions of the mucosa. As in skin involvement, these lesions are relatively painless, may be ulcerative or verrucous, and may closely mimic squamous cell carcinoma in appearance. Biopsy shows pseudoepitheliomatous hyperplasia of the mucosa with microabscesses, granulomas, and the presence of fungi. Treatment involves the use of systemic antifungal agents. Many patients with indolent head and neck manifestations of blastomycosis can be treated with a prolonged course of oral itraconazole.[54] Intravenous amphotericin B is used in more severe infections.

Cryptococcosis

Cryptococcus neoformans, a yeast with a thick polysaccharide capsule, is saprophytic and distributed worldwide. A common natural source is avian droppings. Many patients with cryptococcosis are immunosuppressed. Acquired immune deficiency syndrome is now the most important predisposing factor. Cryptococcosis occurs in about 8% of AIDS patients and is a commonly recognized cause of life-threatening infection. The fungus is acquired by inhalation, with primary pulmonary infection followed by hematogenous spread. The next most com-

mon site of involvement is the central nervous system. Other frequently involved sites include the bones and skin. The upper respiratory tract is rarely involved. Laryngeal lesions have been described as edematous, exudative, or verrucous. Diagnosis is made by biopsy, which shows pseudoepitheliomatous hyperplasia, granulomatous changes, and the presence of encapsulated fungi. The antifungal azoles and amphotericin B are used for treatment.

Coccidioidomycosis

Coccidioides immitis is a dimorphic fungus, growing in mycelial form in the soil and as thick-walled endospore-forming spherules at body temperature. Coccidioidomycosis is endemic to desert and semiarid portions of the southwestern United States and northern Mexico, as well as scattered areas of Central and South America.

Infection is acquired by the inhalation of spores. Most symptomatic patients develop only a mild to moderate flu-like illness that resolves spontaneously. A few patients develop a severe pulmonary illness that may include hematogenous dissemination. Immunocompromised hosts are especially at risk. The most frequent sites of spread are to the skin, bones, and meninges. In the upper respiratory tract, the larynx is most frequently involved.[55] Lesions may involve any area of the larynx and may appear nodular or ulcerative. Biopsy shows granulomatous changes. Fungal staining shows the characteristic spherules filled with endospores. Antifungal azoles may be effective in indolent disseminated disease, but amphotericin B is required for severe infections.

Paracoccidioidomycosis

Paracoccidioides brasiliensis is a dimorphic fungus found in mycelial form at cooler temperatures and in yeast form at body temperature. Paracoccidiodomycosis is endemic to those areas of Latin America with hot, humid summers and dry, temperate winters. The greatest number of cases are from Brazil, although the disease has been reported from Mexico to Argentina. The fungus is a saprophyte found in soil and decaying organic matter. Infection is acquired through the respiratory tract. Hematogenous spread may then occur to other areas of the body. The mucous membranes of the oral cavity, nose, pharynx, and larynx are involved in approximately half of all cases. In a smaller number of cases, the fungus may be directly inoculated into the mucosa by chewing or cleaning of the teeth with plant fragments. Pulmonary infection is found in the majority of symptomatic patients. Dyspnea, hemoptysis, and chest pain may occur. Lymphadenitis and hepatosplenomegaly are also common.

Lesions of the mucosa of the oral cavity, nose, pharynx, and larynx are painful and manifest as well-defined areas of hyperemic granulation tissue and ulceration. Enlargement of lymph nodes draining these lesions may be present. Clinical manifestations include hoarseness, odynophagia, sore throat, and dyspnea. Destruction of underlying cartilages may lead to nasal collapse. Cutaneous involvement may be present, with areas of the face around the mouth and nose most frequently involved.

Diagnosis is made by the results of smear, culture, and biopsy. Serologic tests may be helpful. Biopsy demonstrates pseudoepitheliomatous hyperplasia with intraepithelial abscesses, granulomatous changes, and the presence of fungi. Treatment is with antifungal azoles, amphotericin B, and sulfonamides.[56]

Conidiobolomycosis

Conidiobolus coronatus is present in soil and decaying organic matter and is endemic to tropical regions of Africa and America. This chronic granulomatous infection begins in the nasal submucosa before extending to the contiguous facial skin. Nasal symptoms may include obstruction, rhinorrhea, and epistaxis. Infection may slowly spread bilaterally to the skin of the nose, upper lip, and cheeks or to the paranasal sinuses, orbits, and pharynx. The skin remains intact but turns shiny and erythematous. Diagnosis is suggested by the clinical picture and is confirmed by potassium hydroxide smear, culture, and biopsy. Treatment is with antifungal agents, although long-term results have been disappointing.

MISCELLANEOUS INFECTIONS

Leishmaniases

The leishmaniases are caused by species of the protozoan genus *Leishmania*. These parasites are transmitted from animal hosts to humans by sandflies.

The disease is endemic to Central and South America, South Asia, the Middle East, Africa, and the shores of the Mediterranean. *Leishmania* are obligate intracellular parasites that primarily inhabit macrophages. Expression of the disease can vary and depends on the species of parasite and on the immune status of the human host. Three major clinical forms of the disease are recognized: visceral, cutaneous, and mucosal.

Visceral leishmaniasis, also known as kala-azar, reflects parasitic infection of the spleen, liver, bone marrow, and lymph nodes. Fever and weight loss are followed by hepatomegaly and massive splenomegaly. Uncommonly, the mucosa of the upper respiratory tract is involved. Untreated patients with kala-azar may die of hepatic failure.

Cutaneous leishmaniasis typically progresses from small papules and nodules to ulcerative lesions, with a central depression and raised, indurated border. Healing may be accompanied by considerable scarring. The external nose is frequently involved. Cutaneous lesions of the nose may extend to the skin of the vestibule but do not ordinarily involve nasal mucosa.

Mucosal (mucocutaneous) leishmaniasis is the least common form of the disease. It occurs as a sequela of the cutaneous form of the disease and appears when the initial skin lesions have healed. The nasal mucosa is most frequently involved. Septal perforation is common, and nasal deformity may result. Advanced lesions may extend onto the external nose, lip, and palate. Mucosal lesions of the oral cavity and larynx have also been described.

The diagnosis of leishmaniasis can be made directly by identification of the intracellular amastigote in stained histologic sections of tissue or by culture of the promastigote from biopsy. Indirect diagnosis can be made by serologic tests (enzyme-linked immunosorbent assay, direct agglutination, others), PCR testing, or monoclonal antibody staining of tissue smears.[57]

Pentavalent antimony in the form of sodium stibogluconate is the most widespread treatment for leishmaniasis. Amphotericin B, pentamidine, and paromomycin are alternate therapies.

Rhinosporidiosis

The etiologic agent of rhinosporidiosis, *Rhinosporidium seeberi*, has been difficult to classify. Because its mature stage consisted of large, thick-walled, spherical structures containing smaller daughter cells (endospores), it was thought to be a fungus. Recent studies, however, by amplifying and sequencing a portion of the *R. seeberi* 18S ribosomal DNA subunit, have demonstrated it to be phylogenetically related to a group of fish parasites referred to as the *Dermocystidium,* rosette agent, *Ichthyophonus*, and *Psorospermium* (DRIPs) clade. These novel aquatic Protistan parasites are near the animal-fungal divergence.[58]

Rhinosporidiosis is endemic to South Asia and is occasionally seen in tropical Africa and America. It is most frequently contracted by immersion in contaminated water. Rhinosporidiosis is a chronic inflammatory disease that most frequently involves the nasal mucosa. The conjunctiva, oral cavity, and larynx are less commonly involved. In the nose, the disease typically manifests as a friable, painless, polypoid growth. Nasal obstruction and bleeding are the most common symptoms. Histologic findings include chronic inflammatory changes and the presence of sporangia. Surgical excision is the preferred treatment. No effective medical treatment as yet exists.

CHAPTER 31

Imaging of the Nasal Cavities, Paranasal Sinuses, Nasopharynx, Orbits, Infratemporal Fossa, Pterygomaxillary Fissure, Parapharyngeal Space, and Base of the Skull

Mahmood F. Mafee, MD

The development of computed tomography (CT) and magnetic resonance imaging (MRI) has been regarded as the most important contribution to diagnostic medical imaging techniques since Roentgen discovered the x-ray in 1895. Computers were first used in nuclear medicine in the 1960s, but it was the introduction of CT in 1971, an invention of Godfrey N. Hounsfield, who won the Nobel Prize for his pioneering research, that accelerated interest in the application of computers to the broader aspects of radiology. Like CT, MRI has proven to be a major breakthrough in diagnostic medical imaging. Based on the pioneering work of Paul Lauterbur in the early 1970s,[1] MRI, with its continued refinement, is considered to be the most important medical imaging advance of the century.

COMPUTED TOMOGRAPHY

The technique of CT employs a narrow highly collimated rotating (scanning) x-ray beam that is used to irradiate the patient from numerous projections. Detectors with high detection efficiency, located on the other side, opposite to the source of the beam, register the amount of radiation that has passed through the part of the body.[2] The data collected are processed by a computer, which, by solving thousands of equations instantaneously, produces a true tomographic section.[2,3] The reconstruction of the subject cross-section resides in the computer as a series of digital numbers, usually referred to as "CT numbers."[2] These numbers are related to the linear x-ray attenuation of the material in the volume element (voxel) at the location of interest.[2]

Zero is arbitrarily chosen to represent water. The numbering system –500 to +500 used on the original scanners is referred to as old Hounsfield units.[2] The numbering system, –1,000 or less to +1000 or more, is referred to now as Hounsfield units (HU). In this system, air is black (dense air, –1,000 HU) and bone is white (dense bone, +1,000 HU). Fat absorbs the x-ray less than water and more than air; therefore, its CT numbers will be negative, usually between –50 and –140 HU. The CT number of circulating blood is +40 to +50; congealed blood, +50 to +80; calcium, +80 to +500; muscle, +30 to +40; cerebrospinal fluid (CSF), +5 to +12; bone, +100 to +1000; and air, –100 to –1000.

The viewing devices (console) provided with CT scanners usually have a set number of gray scales (eg, 50, 100, 150, 300, 1,000, or more). The range of CT numbers covered by these gray scales (the contrast) is adjustable (eg, window-width control) (Figure 31–1).[2] The location of the center of the gray scale also is adjustable (window-level control) (see Figure 31–1). This manipulation of window width (image contrast) and window level (mean level; see Figure 31–1) by the CT radiologist at the console gives the most effective diagnostic information, ensuring that the diagnostic sensitivity is limited by the recorded image and not the observer's eye. A window width of 80 units with the level of 35 examines values ranging from +75 to –5 (see Figure 31–1). With the window level = L = +35 and window width = W = +80 setting, values higher than +75 will be white, those lower than –5 will be black, and those between +75 and –5 will be shades of gray (see Figure 31–1).

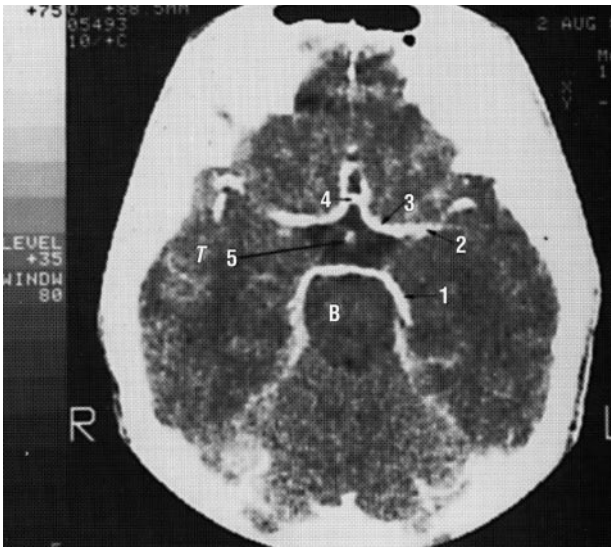

FIGURE 31–1. Normal circle of Willis. Postcontrast axial computed tomographic (CT) scan of the lower part of the head at the level of the suprasellar cistern demonstrates the enlarged pituitary stalk (5) in the center of the low-density star-shaped suprasellar cistern. The posterior cerebral (1), middle cerebral (2), anterior cerebral (3), and anterior communicating (4) arteries are clearly seen as high-density images because of their higher iodine-contrast content. This image was obtained with a window width of +80 (+75, –5) and a window level of +35. With this setting, values higher than +75 will be white (bones), and those lower than –5 will be black (air in the frontal sinus). Note the differential enhancement of the white and gray matter in the brainstem (B) and temporal lobe (T). The gray matter, by virtue of its richer vascularity, shows more enhancement than the white matter. The cerebrospinal fluid (suprasellar cistern, cerebral aqueduct) appears as a low-density image in CT.

Spiral or Helical Computed Tomography

Since the introduction of CT, significant improvements in CT technology have been made. The introduction of spiral or helical CT has a great impact in cross-sectional imaging. Spiral CT has introduced the concept of volumetric (three-dimensional) imaging with x-ray. In spiral CT technology, continuous patient motion through the gantry combined with uninterrupted beam rotation leads to the spiral pattern of volumetric data acquisition. Spiral CT affords us with new opportunities. The speed with which studies can be carried out allows much faster patient throughput. The new-generation multislice volumetric spiral CT provides unprecedented power and speed, allowing scanning of the whole body in a few seconds. This has opened the door to new applications, such as CT angiography, cardiac imaging, and rapid dynamic CT. With spiral CT, the quality of reformatted or postprocessed images has significantly improved. For children and agitated patients in whom speed is of the utmost importance, spiral CT is extremely useful to provide acceptable diagnostic information in a matter of a few seconds.

MAGNETIC RESONANCE IMAGING

Nuclear Magnetic Resonance Phenomenon and Magnetic Resonance Imaging

Magnetic resonance imaging is a fascinating field and has introduced an entirely new and important parameter in the evaluation of abnormalities of the head and neck and neurologic disorders.[4–6] The technique of MRI scanning is considerably more complex than CT, and its full diagnostic potential is often not realized because clinicians have an inadequate understanding of the basic principles of MRI and the various technological modifications available for study of specific lesions. Advances in MRI technology are occurring on an ongoing basis; therefore, MRI protocols can vary from institution to institution.

Historical Background

In 1936, C. J. Gorter, using calorimetric techniques, described his unsuccessful attempt to observe the lithium (Li) nuclear magnetic resonance (NMR) in lithium chloride (LiCl).[7] In 1938, I. Rabi and coworkers described the first successful molecular beam NMR.[8] Subsequent to the successful molecular beam nuclear magnetic experiments, Gorter and Broer, in 1942, again attempted to observe NMR in powders of LiCl and potassium fluoride, but no resonance was observed.[9] Despite Gorter's failure, two independent groups, Felix Bloch and coworkers and Edward Purcell and coworkers in 1946, were successful in demonstrating NMR in condensed matter, work for which they shared the Nobel Prize in physics in 1952.[10,11]

Historically, the impetus of the development of MRI is attributable to Lauterbur, who, in 1973, by

using the interaction of magnetic fields, generated the first two-dimensional MRI.[1] This depicted the proton density and the spin-lattice relaxation time (T_1) distribution (see section of MR phenomenon) in two 1 mm tubes of water.[1] Subsequently, numerous NMR techniques have been developed generating data from a point, line, plane, or multiple planes within a volume and from the entire volume.[12]

MAGNETIC RESONANCE PHENOMENON

Elementary Physics

In discussing x-rays and their effects on atoms, we are concerned with their extranuclear structure, that is, the arrangement of planetary (orbital) electrons, outside the nucleus. In MR phenomenon, we are concerned with nuclear structures of atoms, that is, the nucleons ("nucleon" is the generic term for a proton or neutron). The existence of nuclear spin and nuclear angular momentum, the entity essential to the MR phenomenon, was first suggested by the Austrian physicist Wolfgang Pauli in 1924 when he observed the behavior of light in a magnetic field.[4] Since then, it has been verified that atomic nuclei have an angular momentum arising from their inherent property of rotation or spin. Pairs of protons or neutrons, however, align in such a way that their spins cancel out, and a net spin (net rotation) will therefore exist for a nucleus only when it contains an odd (unpaired) proton, an odd neutron, or both.[13] Since protons carry a positive charge, the nuclei have an associated electric charge distribution; therefore, the spin generates a current flowing about the spin axis, which, in turn, generates a small magnetic field. Each nucleon of nonzero spin has an inherent magnetic field (magnetic dipoles) and a magnetic moment (a magnetic moment is a vector quality represented by an arrow, which describes the magnetic field's strength and direction), or dipole, associated with it that can be thought of as behaving like a tiny spinning bar magnet with north and south poles (Figure 31–2). Therefore, these tiny spinning magnets can interact with the electromagnetic field.[12–14] In a sample of materials, the nuclear magnets (magnetic moments or dipoles) will be pointing in random directions,[12–14] and the result of many nuclei in a random arrangement is that there is no net magnetization (one cancels the other) in any direction (see Figure 31–2). However, if the nuclei are placed in an external static magnetic field, the randomly oriented magnetic dipoles respond to the force of the field by trying to line up in the direction of the field (see Figure 31–2). In the magnetic field, therefore, there is a net (sum) magnetization produced parallel to and in the same direction as the applied field (see Figure 31–2). The magnetic behavior of the entire population of nuclei can be defined as a macroscopic or bulk magnetization vector or moment (M) (see Figure 31–2), which represents the net effect of all of the magnetic moments of the nuclei of a given nuclear species in the sample.

In the absence of an external magnetic field, the net magnetization is, of course, zero owing to random orientation of nuclei. When the external magnetic field B_o (see Figure 31–2) is imposed on the sample, however, the nuclear dipoles become orientated parallel to the applied field, and the net magnetization (spin vector, M) (see Figure 31–2) yields a finite equilibrium that will point in a direction parallel to the external magnetic field B_o (see Figure 31–2). This direction conventionally defines the longitudinal (Z) axis (see Figure 31–2). By convention, the spin system is presented in a cartesian coordinate system (X, Y, Z), with the Z-axis parallel with the direction of the external magnetic field B_o. (see Figure 31–2).

Precession Motion

Let us focus particular attention on the nuclei of the hydrogen atoms, protons, which, from the standpoint of the MR phenomenon, are particularly favorable nuclei. The hydrogen atom is now referred to as a proton. Each proton can be regarded as a small, freely suspended bar magnet spinning rapidly about its magnetic axis. If a group of protons are placed in a static magnetic field of particular strength (B_o), the magnetic moment of each proton experiences a couple (from the north and south pole), a force or torque tending to turn its magnetic moment (M) parallel to the static magnetic field (see Figure 31–2). Because it spins, the proton responds to this couple by rotation about the line of force (like a gyroscope precessing about the gravitational force); therefore, its axis is tilted and begins to precess (rotate) about the direction of the magnetic field in a movement known as "precessing" (see Figure 31–2). The precessional motion traces a cone in a manner analogous to the wobbling of a toy top as it spins and tries to orient itself in the earth's gravitational field. The frequency of the precessional motion given by the famous theorem of Larmor and the Larmor equation, ω (omega)

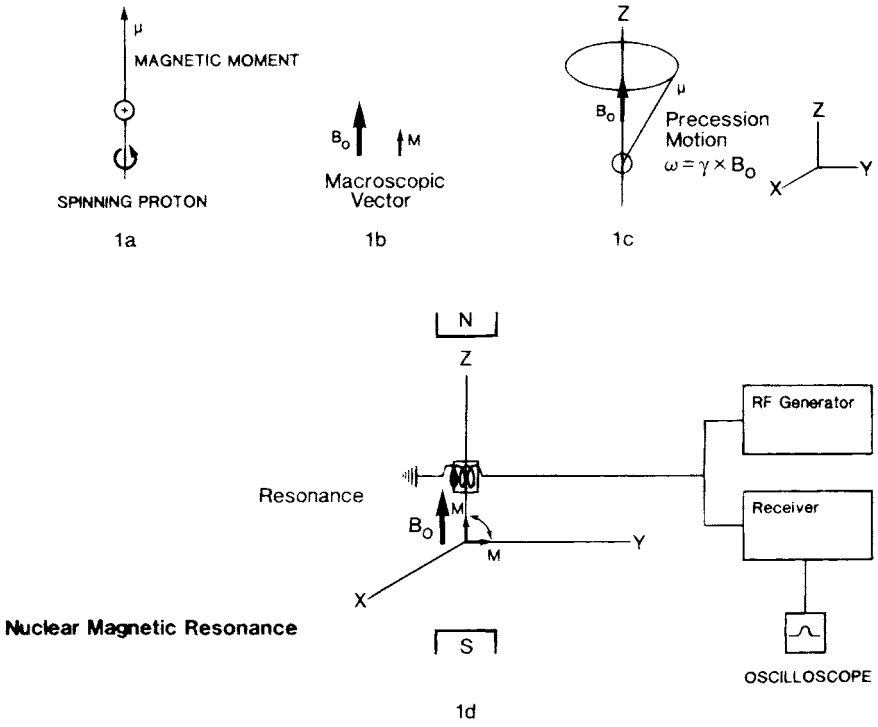

FIGURE 31–2. Nuclei of odd number of neutrons, protons, or both, such as hydrogen (proton), have a net spin or "nuclear angular momentum." Each spinning nucleus generates a magnetic field and hence a magnetic moment that is a vectoral quantity with both direction and magnitude (1a). Nuclear magnets of the nuclei with spin will be pointing in random directions. Therefore, there is no net magnetization in any direction. If the nuclei are placed in an external static magnetic field B_o (1b), the randomly oriented magnetic moments line up in the direction of field at a state of equilibrium. The magnetic behavior of the entire population of nuclei is defined as a macroscopic or bulk magnetization vector M (1b). When a proton is placed in a magnetic field B_o (1c), it experiences a couple (from the north and south poles), tending to turn its magnetic moment parallel to the field. Because it spins, the proton responds to this force like a gyroscope, and its axis of the magnetic moment vector M wobbles or precesses about the direction of the magnetic field B_o (1c). The frequency (ω) of this precessional motion is unique for each nuclear magnetic sensitive element and is given by the famous theorem of Larmor ($\omega = \gamma \times B_o$). By convention, the spin system is presented in a cartesian coordinate system (X, Y, Z) with the Z-axis parallel with the external magnet field B_o. When the spin system (M) is placed in an external magnetic field (B_o), besides the creation of precession, another phenomenon, a resonance condition, is produced in which the nuclei can absorb energy at sharply defined frequency (Larmor frequency) from an electromagnetic pulse (wave) and re-emit the energy as electromagnetic radiation of the same frequency after the incident beam has been turned off. Let us wind a coil around a nuclear magnetic sensitive specimen and place it inside a magnet (with north, N, and south, S, poles), as shown in 1d, and supply it with radiofrequency (RF) current at Larmor frequency. A short pulse of each resonant RF current can be arranged to tip the net magnetization vector (M) through 90 degrees in the X-Y plane (1d) that is perpendicular to B_o. This is called 90-degree pulse. The magnetization M now continues to rotate in the X-Y plane at the same frequency and induces a voltage (current) in a receiver coil (antenna) in the X-Y plane. If the pulse is then turned off, the excited spin system (the nuclei) returns to its state of equilibrium and loses the excess energy. The vector (M) continues to rotate freely in the X-Y plane, causing the induced current (signal) in the antenna to fade. This decaying signal is called the "free induction decay" (FID), which can be amplified, detected, and displayed on an oscilloscope or fed into a computer to provide pictorial information. The return of the excited spin system to the state of equilibrium, the so-called relaxation, is characterized by two sample-related time constants. T_1 (spin-lattice relaxation time) is the time constant required for the net magnetization (M) to return from the X-Y plane to its equilibrium along the Z-axis. T_2 (spin-spin relaxation time or transverse relaxation time) is the time constant of the decay of FID.

$= \gamma$ (gamma) $\times B_0$, states that the frequency of the precessional motion (ω) is proportional to the couple and therefore to the strength of the applied static external magnetic field (B_0) and the constant of proportionality gamma, the so-called gyromagnetic property (or ratio) of the specific nucleus.[4] The equation shows that as the magnetic field changes, so does the nuclear precessional rate of motion (angular frequency ω or Larmor frequency). This is an important point in MRI because it enables us to locate the origin of the MR signal and to pinpoint spatially the source of each frequency (ω).

Nuclear Magnetic Resonance

Resonance is a physical phenomenon that permits the transfer of energy from an object, particle, or system vibrating mechanically or electronically to another similar object, particle, or system, causing the latter to vibrate at the same frequency. When a substance containing nuclei of nonzero spin is placed in a magnetic field, a resonance condition is produced, which means that there will be a strong interaction or resonant effect.[4,15] The nuclei can then absorb energy at a sharply defined frequency from electromagnetic radiation and re-emit the energy as electromagnetic radiation of the same frequency after the incident beam has been turned off.[4,13–15] Either the absorption or the re-emission can be measured. To secure this resonant effect, the applied electromagnetic radiation (pulse) from the radiofrequency (RF) generator (see Figure 31–2) must have the same frequency as the Larmor precession frequency (natural resonant frequency) of the sample (ie, it has to be resonant). Hence, the name "nuclear magnetic resonance" has been designated for the phenomenon. In short, the precession is a resonance effect, and if a system has a natural resonance (frequency resonance, frequency of oscillation), energy needs can most efficiently be imparted at the resonance frequency. For example, at the field strength of 1.5 tesla (1 tesla = 10,000 gauss), a pulse at 63.87 megahertz (MHz) will excite hydrogen (protons), whereas a pulse at 25.86 MHz will excite phosphorus nuclei.[4]

Relaxation Phenomenon and Times

As mentioned earlier, in the presence of a static magnetic field, B_o, nuclei with nonzero spin orient themselves with the magnetic field lines that point in the "Z" direction at a state of equilibrium "rest" (see Figure 31–2). At equilibrium, the nuclei possess their lower energy level. When an electromagnetic radiation (RF) or RF pulse (wave) is used at a sharply designated frequency (Larmor frequency) because of resonant condition, some of the nuclei can absorb energy from the RF pulse, become excited (attain higher energy level), and change the direction of their magnetic moments. When the RF pulse is turned off, the excited nuclei relax and return to their original orientation (equilibrium, lower energy level), losing the excess energy by emitting electromagnetic radiation (the source of the MR signal) of the same frequency as the applied RF pulse by transferring energy to surrounding (lattice) molecules. This process is called "relaxation" and is characterized by two sample-related relaxation time constants: the longitudinal (spin-lattice) relaxation time (T_1) and the transverse (spin-spin) relaxation time (T_2). When the RF pulse of specific frequency (Larmor frequency) is applied, it affects the NMR-sensitive nuclei in two ways: (1) the RF pulse excites the nuclei and makes them move into a higher energy level, and (2) the net magnetization vector (M) (see Figure 31–2) will precess along the direction of the main field (Z axis) with an ever-increasing angle depending on the intensity and duration of the RF pulses (Figure 31–3). The magnetization vector (M) will consequently spiral down toward the X-Y plane (90-degree pulse) and then continue to rotate in the X-Y plane (see Figure 31–3). The magnetization vector M can be considered as having a component, M_z (longitudinal magnetization), along the z-axis (see Figures 31–2 and 31–3) and a component, M_{xy} (transverse magnetization), in the x-y plane perpendicular to the field axis (Z) (see Figure 31–3). At equilibrium, the "longitudinal magnetization" M_z is equal to the net magnetization M, and the "transverse magnetization" M_{xy} is zero (see Figure 31–3). After RF excitation, the precessional angle (see Figures 31–2 and 31–3) continues to increase as long as the RF pulse is applied (see Figure 31–3). The precessional or Larmor frequency (cycles per second), however, remains constant, being fixed by the inherent properties of the nuclei and the strength of the static magnetic field, B_o. After the excitation of the RF pulse, M_z decreases and M_{xy} increases (see Figures 31–2 and 31–3). The RF needed to tip the vector (M) through an angle of 15 degrees is described as a 15-degree pulse. Pulses of 90 and 180 degrees cause corresponding increases in the

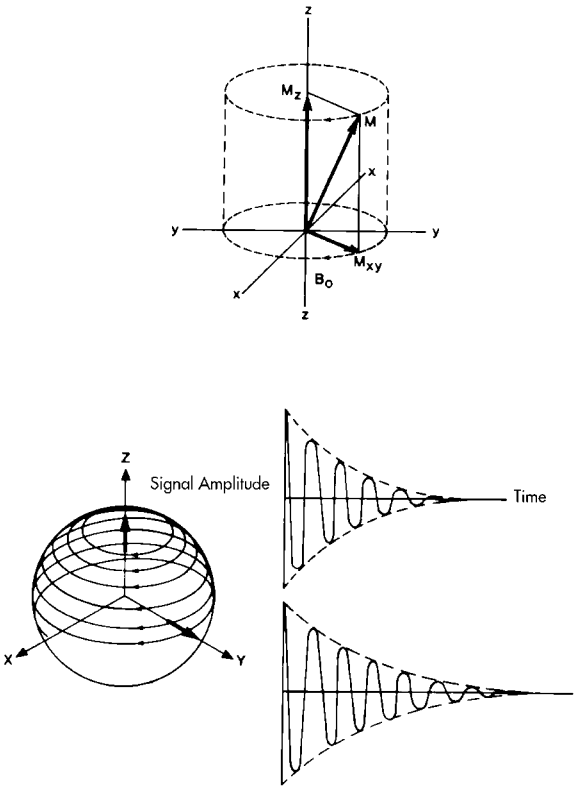

FIGURE 31–3. The precessing net magnetization vector (M) can be considered as having a component, M_z, along the axis of the main field (B_o) and a component, M_{xy}, in a plane perpendicular to the field axis such as the x-y plane (*top image*). At equilibrium, the net magnetization is aligned with the main field so that M_z has its maximum (M_z = M) and M_{xy} has its minimum (zero) magnitude. After a 90-degree pulse, the M_{xy} has its maximum and M_z its minimum (zero) magnitude. Following application of a radiofrequency (RF) pulse, the net magnetization vector M, will precess at an ever-increasing angle to the main field direction (bottom image), with the precession occurring at the inherent or natural Larmor frequency. If the RF pulse is long enough or strong enough, the net magnetization vector (M) spirals down toward the X-Y plane (*bottom image*). When the RF pulse is turned off, the spin system will relax, and the excess energy is released as decaying signal (free induction decay) with a time constant T_2. The T_2 relaxation time for most tumors is longer than that for normal tissue. In other words, the nuclear magnetic resonance signal of the tumor (lower decaying pulse) decays longer than the normal tissue (upper decaying pulse).

precessional angle.[13] After a 90-degree pulse, the vector (M) will be in the x-y plane, and when the nuclei are flipped through 180 degrees, the net magnetization vector (M) will be in the opposite direction of the main field, B_o. The "transverse magnetization" M_{xy} is time dependent and has a rotational or "precessional property" in the x-y plane. Such rotating magnetic current acts as a radiator of RF energy and therefore, according to Faraday's law of induction, can induce a current (voltage) in a receiver coil (inductance antenna) in the x-y plane (see Figure 31–2). Immediately after the application of a specific pulse through the transmitting coil (see Figure 31–2), the transverse magnetization M_{xy} continues to rotate freely in the x-y plane, generating an induced current (signal) that can be detected either by the same coil (acting as transmitting and receiving coil) that transmitted the pulse or by a specific receiver coil (antenna). The emitted signal is called the free induction signal or the free induction decay (FID). The magnitude and length of the FID (NMR signal) are determined by the relaxation times.[15]

T_1 Relaxation Time

The T_1 relaxation time represents the time constant required for the net magnetization vector (M) to return to its equilibrium after it has been perturbed by the RF pulse. In other words, T_1 is the time that characterizes the recovery of the net magnetization (M), after it is perturbed, to its equilibrium state in the field direction (see Figures 31–2 and 31–3). The alignment of nuclei is not instantaneous but rather grows exponentially, increasing to approximately 63% of its final value within a period equal to the time constant (T_1). It will reach 95% of the final value at a time equal to three times the constant. Therefore, in reality, T_1 is the time that characterizes the recovery (return of excited spin to equilibrium) of 63% of nuclear magnetization. T_1 is called "spin-lattice relaxation" because the thermal equilibrium state, hot state (excited spin) to cold state (spin at rest or equilibrium), is reached through an exchange of energy with its molecular environment or lattice. The alternative term, "longitudinal relaxation time," is used to reflect the fact that T_1 characterizes the behavior of the M_z component of the magnetic vector (M) (see Figure 31–3) when magnetization reverts to its equilibrium orientation in the direction of the applied field (Z) (see Figure 31–3). Basically, T_1 is a measure of how fast energy can be transferred from the spinning nuclei to their surrounding environment or lattice by random collision between

molecules or the rate at which thermal equilibrium is restored after being disturbed.

T_2 Relaxation Time

As mentioned, the NMR signal picked up after an RF pulse is known as FID. The signal is proportional to the magnetization in the sample and would be produced continuously if the individual nuclear spins were able to maintain their coherence (synchronization) with no shifting of their relative phases.[14] The FID signal, however, decays because of spin-spin ("dipole-dipole") interaction (magnetic interaction of neighboring nuclei) and the inhomogeneity of the static magnetic field B_o, both causing fluctuation in local magnetization with resultant fluctuation (any error) in precessional frequency (around Larmor frequency) of the individual proton. This causes the resonance of protons within the sample to lose synchronization and their vectors to develop a phase difference. The signal decays exponentially in time, with a time constant characterized by the T_2 (see Figure 31–3). Basically, T_2 is the time taken for the transverse magnetization, M_{xy}, to decrease by 63% of its original value. In a period three times as long as this, the transverse magnetization will almost have disappeared. In short, T_2 relaxation time is the time taken for the decay of FID or MR signal to decrease by 63% of its original intensity value.

For water, T_1 and T_2 are several seconds, the precise value depending on the purity of the water. For cellular water, T_1 and T_2 are shorter. T_1 is shorter in liquids (seconds) than in solids (minutes). In solids and/or in a sample of materials at low temperatures, where the atoms and molecules move about very little, transfer of thermal energy is slow; therefore, T_1 can last for hours.[13] T_1 is short in liquids because of the mobility of the atoms and molecules and the consequent rapid transfer of thermal energy.

For protons in pure water, T_1 and T_2 are approximately equal.[13] T_2 is short in solids (microseconds) and long in fluids. In pure fluids, because of rapid motion of the atoms and molecules (random process), the magnetic field contribution from neighboring nuclei averages zero, and only the main magnetic field determines the resonant frequency. In this case, T_2 is very long. If the nuclei find themselves in impure liquids where molecules attach to proteins and have low translational and rotational speeds, this averaging random process of the magnetic field contribution from neighboring nuclei is more effective, and the resonant frequency is therefore different (rapid phase difference and loss of coherence) for each nucleus; this makes T_2 short. Solids, on the other hand, have fixed atoms and molecules that maintain local field variation (spin–spin or dipole–dipole interaction), which result in a rapid loss of coherence and a very short T_2. Relaxation times are affected by viscosity, temperature, and the presence of dissolved ions and molecules.[14]

Nuclear Magnetic Resonance Spectroscopy and Chemical Shift

Nuclear magnetic resonance spectroscopy is a plot of signal intensity versus resonance frequency. The appearance of NMR spectra depends on the density and molecular environment surrounding a nucleus. The presence of neighboring atoms and the "shielding currents" that are associated with the distribution of electrons around adjacent atoms slightly modifies the strength of local magnetic fields at particular nuclei and hence modifies the resonance frequency[12–14,16] so that the details of molecular structure change the NMR frequency of a nucleus in that molecule. The extent of this field change depends on the electronic environment of the observed nucleus; consequently, identical nuclides have slightly different resonance frequencies (lines) if they are residing in different chemical structures (environments). For example, the resonant frequency of a hydrogen proton within a water molecule differs slightly from that of a hydrogen proton within a fat molecule, and the resonant frequency of a 31P nucleus bound in an adenosine triphosphate (ATP) molecule varies slightly from that of a 31P nucleus within a phosphocreatine molecule. These small but specific displacements or shifts in frequency produce separate absorption peaks in a spectrum (chemical shift), which are "fingerprints" of the molecular conformations and directly aid in the determination of chemical structures.[13–18] The chemical shift is measured and listed in parts per million with respect to the signal from a reference such as a signal of tetramethylsilane. The chemical shift is of paramount importance in analytic chemistry since it allows the assignment of different signals (lines) in an NMR spectrum to corresponding substances or molecular groups. For example, the proton spectrum of acetic acid CH_3-COOH provides two lines. One line represents the three protons (hydrogen) of the

methyl group and another line the carboxyl proton. The three protons of the methyl group have an identical electronic environment, so their signal appears as a single resonance line. In 31P spectra of muscle tissue, the signal of phosphocreatine is used as a reference signal. The 31P spectrum of a muscle typically shows five signals that are related to inorganic phosphate, phosphocreatine, and the three phosphorus atoms of ATP (alpha, beta, and gamma).

Currently, NMR spectroscopy is one of the most powerful tools used in chemical analysis.[13] The combined MRI, in vivo spectroscopy, has become a routine procedure to provide morphologic as well as noninvasive biochemical "noninvasive biopsy" information of internal structures of human tissues.[16–18]

Clinical Use of T_1-Weighted, Proton-Weighted, and T_2-Weighted Magnetic Resonance Imaging

Magnetic resonance scanners produce images that represent one or more of NMR parameters. These are (1) hydrogen (proton) density (also called spin density), (2) the state of motion of hydrogen, (3) the tissue relaxation times T_1 and T_2, and (4) chemical shift. All forms of unprocessed MR signals depend on nuclear spin density.

The ability to rotate net magnetization (M) (see Figures 31–2 and 31–3) from the direction of the static magnetic field (B_o) into some other orientation by applying an RF pulse is fundamental to MR spectroscopy and imaging techniques because it provides a flexible method for investigating relaxation processes and other phenomena.[14] By choosing an appropriate pulse sequence, the intensity of an MR image can be made to reflect one or more of several NMR parameters inherent to the tissue being examined.[13,14] Although the proton density, chemical makeup, T_1 and T_2, and motion represent intrinsic tissue properties, the transition of these parameters onto the MR image is also dependent on the particulars of the imaging technique used to form that image. This subject has been described by many authors in several articles.[19,20]

The 90- and 180-degree pulses are used for NMR techniques.[14] In forming an MR image, the RF pulse must be applied repeatedly. After each 90-degree pulse, the magnetization of the sample is reduced to zero as this rotates the longitudinal magnetization vector (M) into the transverse (x-y) plane to become transverse magnetization M_{xy} (see Figures 31–2 and 31–3). Therefore, the longitudinal component of magnetization M_z is zero. The longitudinal component of magnetization will recover exponentially with a time constant of T_1. Rapid repetition of pulses (irradiation of sample) would not allow much recovery of magnetization, and little signal would be detected after each successive 90-degree exciting pulse. Thus, a certain time (repetition time = TR) is introduced between successive RF pulses. As the TR increases, the signal and imaging time increase. After RF pulse, as discussed earlier, the FID signal decays exponentially in time with a time constant T_2. The interval between application of the RF pulse and reception of a signal or spin echo is called echo time or time of echo (TE). As TE increases, signal decreases (see Figure 31–3), and contrast between tissues of different values of T_2 changes. If the signal is obtained immediately after RF excitation, it will not undergo any T_2 decay; therefore, although it is a strong signal, it has no T_2 dependence. If, instead, the signal is obtained sometime after RF excitation, the available signal, although weaker, has an exponential dependence on T_2. Strong signals (proton-weighted [PW] and T_1-weighted [T_1W] images) yield better signal-to-noise levels or ratios and, therefore, better spatial resolution. With better optical resolution, anatomy is better appreciated. However, in the image, the differences owing to T_2 relaxation time (T_2-weighted [T_2W] image) contribute to contrast resolution with better pathologic details to the extent that T_2 often contributes to tissue characterization.

Spin-Echo Pulse Sequence

The spin-echo (SE) pulse sequence is the most commonly used technique to acquire MR images. T_1-weighted MR images can be obtained using the SE pulse sequence with a short TR of 400 to 1,000 ms and a short TE of 20 to 25 ms. The SE pulse sequence of long TR (1,000 to 3,000 or more ms) and short TE (20 to 40 ms) provides proton density (PW) MR images. Long TR (1,000 to 3,000 or more ms) and long TE (40 to 120 or more ms) provide the T_2W MR images.

Inversion Recovery Pulse Sequence

Various pulse patterns that emphasize different aspects of the evoked NMR signal can be exploited to

alter the contrast of MR images.[13] In an "inversion recovery" (IR) pulse sequence, a 180-degree (inverting) pulse, followed by a 90-degree (read) pulse, must be applied repetitively for signal averaging purposes.[12,17] Because of application of a 180-degree pulse and the fact that magnetization must be allowed to recover after the 180-degree inverting pulse, the IR sequence is slower than SE in data collection.

Fluid-Attenuated Inversion Recovery

Fluid-attenuated inversion recovery (FLAIR) is used to suppress the high CSF signal in T_2W MR images so that pathology adjacent to CSF is seen more clearly. This is a powerful pulse sequence to detect demyelinating disease, subarachnoid hemorrhage, leptomeningeal pathology, and most of intracranial pathology.

Use of Gadolinium Contrast Material

Gadolinium, a rare earth element, is used in conjunction with T_1W pulse sequences. With a standard dose of 1 mmol/kg, it has little effect on T_2W MR images. The use of gadolinium-diethylenetriamine pentaacetic acid contrast material improves lesion delineation. It is often used with fat suppression T_1W MR technique in the head and neck or where the lesion may be obscured within high-intensity fat.

The gadolinium T_1W pulse sequence is the best to evaluate intracranial extension of head and neck lesions. Gadolinium also enhances normal structures, including mucosa, lymphoid tissue, extraocular muscles, and slow-flowing blood in veins.

The viewing devices (console) provided with MR scanners, like CT scanners, have a set number of gray scales that can be used to adjust the contrast. The MR parameters (TR, TE) and pulse sequences (SE, IR), the strength of the magnet (eg, 1.5 tesla), and the time and number of images in each series of pulse sequences are recorded on the screen and reflected on each frame of hard-copy MR films. Therefore, a simple method for beginners is to look for TR and TE to recognize the T_1W, PW, and T_2W images. A short TR (less than 1,000 ms) and a short TE (20 to 25 ms) is a T_1W image (Figure 31–4). A long TR (more than 1,000 ms) and a short TE (20 to 40 ms) is a PW image, and a long TR (1,000 ms or more) and long TE (more than 40 ms) is a T_2W image (Figure 31–5). T_1-weighted and PW images provide better anatomic details, and T_2W images are best for pathologic details.

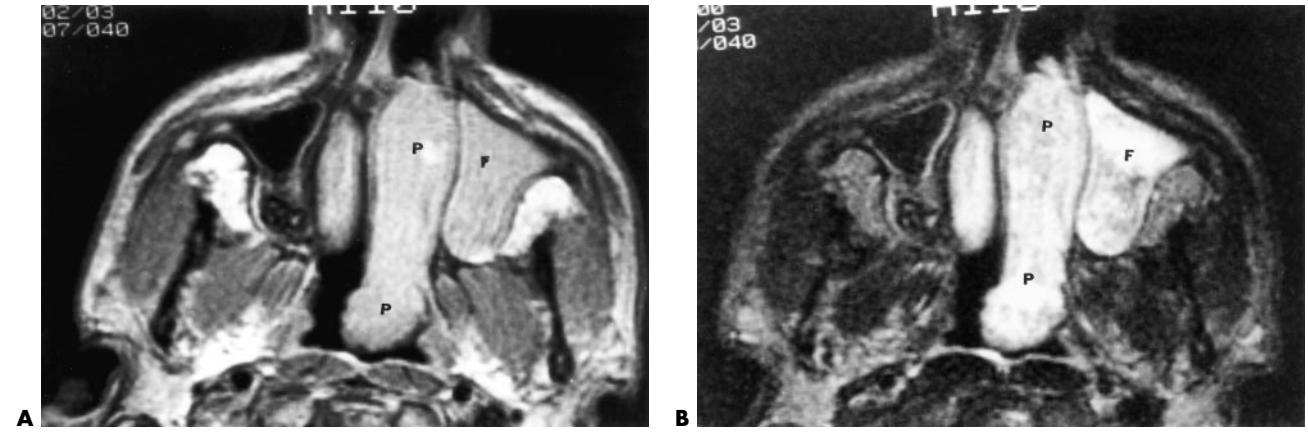

FIGURE 31–5. Inverted papilloma. Proton-weighted (PW) (2000/02, TR/TE) (*A*) and T_2-weighted (T_2W) (2000/80, TR/TE) (*B*) magnetic resonance (MR) images showing a large inverted papilloma (P). Notice the hyperintensity of the tumor on the T_2W MR image. Extension of the tumor in the left maxillary sinus is better demonstrated on T_2W scan. Fluid (F) in the sinus has an intermediate signal on PW and a hyperintense signal on T_2W MR scans.

Magnetic Resonance Angiography and Venography

Magnetic resonance angiography (MRA) and venography (MRV) are noninvasive techniques used to depict blood vessels in a projective format similar to conventional invasive angiography, without the use of ionizing radiation or iodinated contrast materials (Figure 31–6, A and B). On standard SE pulse sequences, rapidly moving blood will usually yield a signal void (dark) regardless of the orientation of the plane of the image. Therefore, MRA must employ

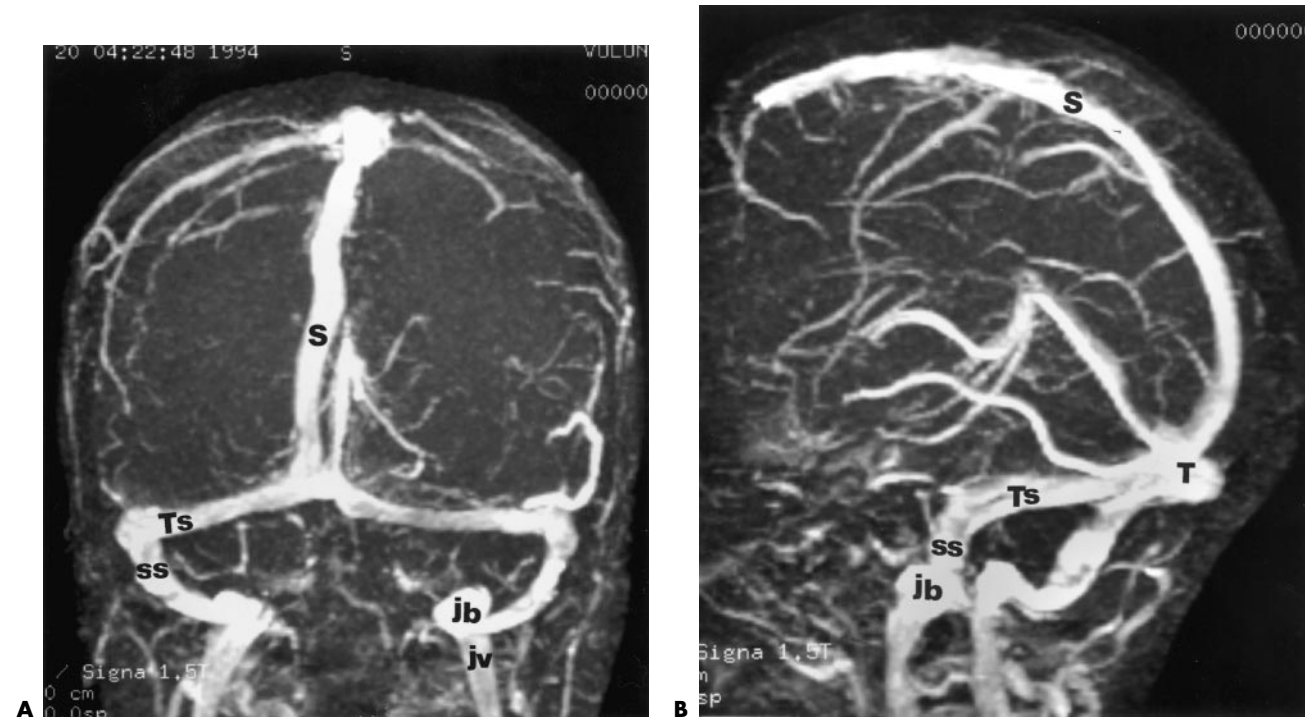

FIGURE 31–6. A, Magentic resonance venogram: two-dimensional time-of-flight coronal venography shows normal venous structures. S = superior sagittal sinus; Ts = transverse sinus; ss = sigmoid sinus; jb = jugular bulb; jv = internal jugular vein. *B*, Sagittal magnetic resonance venogram shows normal venous structures. certain RF pulse sequences to produce signal from flowing blood. In MRA, the appearance of flowing blood depends on two main flow-related effects: time-of-flight (TOF) and phase contrast (PC).

Technical advances, such as the development of the two-dimensional and three-dimensional gradient-echo (GRE) pulse sequences (Figure 31–7), led to more widespread use of MRA and MRV. These noninvasive techniques of studying blood flow not only permit the evaluation of the vascular anatomy of the head and neck but also provide information on flow direction, velocity, and blood vessel patency. Both TOF and PC MRA can be obtained as a series of two-dimensional images or as a three-dimensional data set. This leads to the logical terminology of two-dimensional TOF, three-dimensional TOF, two-dimensional PC, and three-dimensional PC for the two fundamental approaches to vascular MRI techniques.

Clinical application best suited for two-dimensional TOF MRA includes mapping dural venous sinuses, evaluating the vascular structures of the neck for evidence of thrombosis or invasion by tumor, evaluating for carotid or vertebral dissection, and assessing the draining veins of arterial venous malformations. Two-dimensional TOF MRV can be used to evaluate suspected intracranial venous thrombosis; however, thrombus may appear bright (as a result of the short T_1 of methemoglobin) and can be confused for a patent venous sinus, resulting in a false-negative examination.[21]

A GRASS (gradient-recalled acquisition in the steady state) image shows the hyperintense internal carotid artery (i), internal jugular vein (j), vertebral artery (*arrow*), and hyperintense mass (M) within the right jugular vein.

Standard Film Radiography versus Computed Tomography and Magnetic Resonance Imaging

The modern diagnostic radiology department is equipped with a variety of medical imaging systems. Each has advantages and limitations. Plain film radiography is simple, fast, and inexpensive and produces sharp images of high-contrast structures (air, fluid, bone) (Figures 31–8 to 31–15); however, high-contrast objects can obscure low-contrast objects, and the presence of overlying objects can sometimes be misleading.

Tomography

The conventional radiographic films and screens are inherently nonuniform (less sensitive than the computer) and would limit subject-contrast discrimination (resolution) to possibly 3 to 5%, which is greater than the range for some soft tissue. Because of these limitations, standard tomography such as polytomography is no longer used if a CT unit is available.

Computed tomography and MRI allow the reconstruction of tissue contrast in true cross-sections (ie, without being influenced by nearby or distant tissues in the section), with excellent tissue-contrast discrimination (resolution).[2] Both modalities, and in particular MRI, provide the best anatomic cross-sectional imaging technology available to date. The new-generation high-resolution scanner, with a smaller pixel (picture element), the combination of thin section (1 to 1.5 mm) and extended bone range possibility (expansion of the HU scale up to 4,000 units, ie, +3,000 to –1,000), provides clear definition and differentiation of soft tissue structures while also providing superior bone detail to complex motion tomography (Figures 31–16 to 31–18). Dynamic CT provides excellent definition of vascular structures and can differentiate vascular tumors such as chemodectomas from

less vascular lesions such as neurogenic tumors (Figure 31–19).[22–24]

Magnetic Resonance Imaging

One of the advantages of MRI is the ability to obtain transverse (axial) and direct coronal, sagittal, and oblique images without needing to change the position of the patient. The contrast relationships of different tissues on MRI are much different than on CT scanning (see Figure 31–17). The technical factors of various pulse sequences to obtain an MR image, in addition to physical and biochemical composition of the sample, play a significant role in tissue contrast in MR images. Water, such as in vitreous cavity (see Figure 31–17, B), has long T_1 and T_2 relaxation times and would appear as hypointense (dark) in T_1W and PW (proton-density) (see Figure 31–17, B) images and as hyperintense (bright) in T_2W MR scans. The lens has an

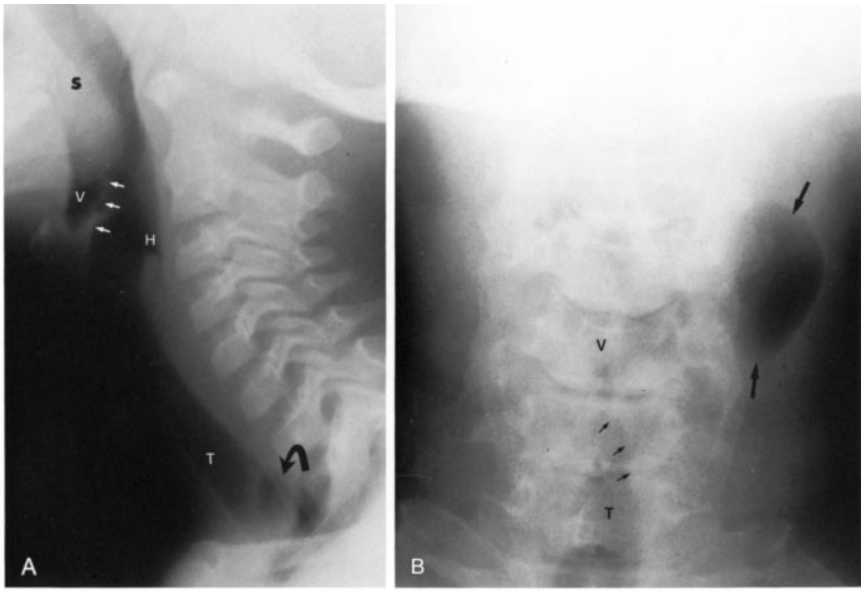

FIGURE 31–12. Fish bone and edema of the retropharyngeal space. Lateral neck, showing marked increased thickness of the prevertebral space (compare with normal Figure 31–11, A). Note the fish bone (*arrow*). Anterior to the fish bone are partially calcified cricoid and thyroid cartilages.

intermediate signal intensity (gray) in T_1W and PW scans (see Figure 31–17, B) and appears as a hypointense image in T_2W scans.

Fat has short T_1 and intermediate T_2 relaxation times and would therefore appear as a hyperintense image in T_1W and PW (see Figure 31–17, B) scans and as a hypointense image in T_2W scans. In the SE fat suppression technique, T_1W MR images can be obtained so that fat appears hypointense. This pulse sequence is commonly used in head and neck regions to suppress the signal of fat in T_1W MR images, allowing better delineation of pathologic tissues adjacent to normal fat. Tissues of intermediate structure (muscles) have an intermediate signal on T_1W and PW scans and a low signal on T_2W MR scans (see Figure 31–17, B). Solid structures such as cortical bone, enamel, dentin, and fibrous tissues (sclera, tendons, fasciae) are hypointense (dark) on T_1W, PW, and T_2W scans because of their sparsity of mobile hydrogen atoms. The cortical bone will appear black, whereas the medullary cavity will be bright because of signals from fat content. Air in paranasal sinuses, because of the lack of hydrogen atoms, appears dark in all MR scans. In SE pulse sequences, vascular structures such as carotid arteries and internal jugular veins are identified readily as low–signal intensity (dark) structures. With normal rapid blood flow, excited spins are carried away from the selected imaging section before a signal (echo) is formed (signal void phenomenon), creating a dark image with signal intensity similar to that of air, cortical bone, enamel, and dentin. In fast spin-echo (FSE) T_2W MR images, the fat, unlike conventional SE T_2W MR images, will be hypertense. However, FSE pulse sequences can be obtained with a fat suppression technique in which the fat appears hypointense, similar to conventional SE T_2W MR images.

Dynamic Magnetic Resonance Imaging

Fast-scan or narrow flip angle MRI (dynamic MRI) is performed using the GRE pulse sequence such as "GRASS" technique. The GRASS, which stands for gradient-recalled acquisition in the steady state, is a new imaging technique. Its prime characteristic is the ability to provide T_1, T_2, and PW images in a short time. A striking feature of GRASS images is the high-intensity appearance of vascular structures, "MRA," especially when vessels transect the image slice (see Figure 31–7). The GRASS images are obtained with very short TR (25 to 100 ms), short TE (8 to 15 ms), and a variable flip angle (10 to 60 degrees).

Tissue Characterization of T_1- and T_2-Weighted Images

Damadian and coworkers showed that malignant tissues, except melanotic tumors, have a long T_1 and T_2 relaxation time.[25] Nonmelanotic tumors, therefore, are hypointense on T_1W scans and would appear as hyperintense images on T_2W scans. Most melanotic lesions on T_1W and PW MR scans would appear relatively hyperintense and become hypointense on T_2W MR scans.[26,27] Acute hemorrhage appears isointense to slightly hypointense on T_1W scans and would appear very hypointense on

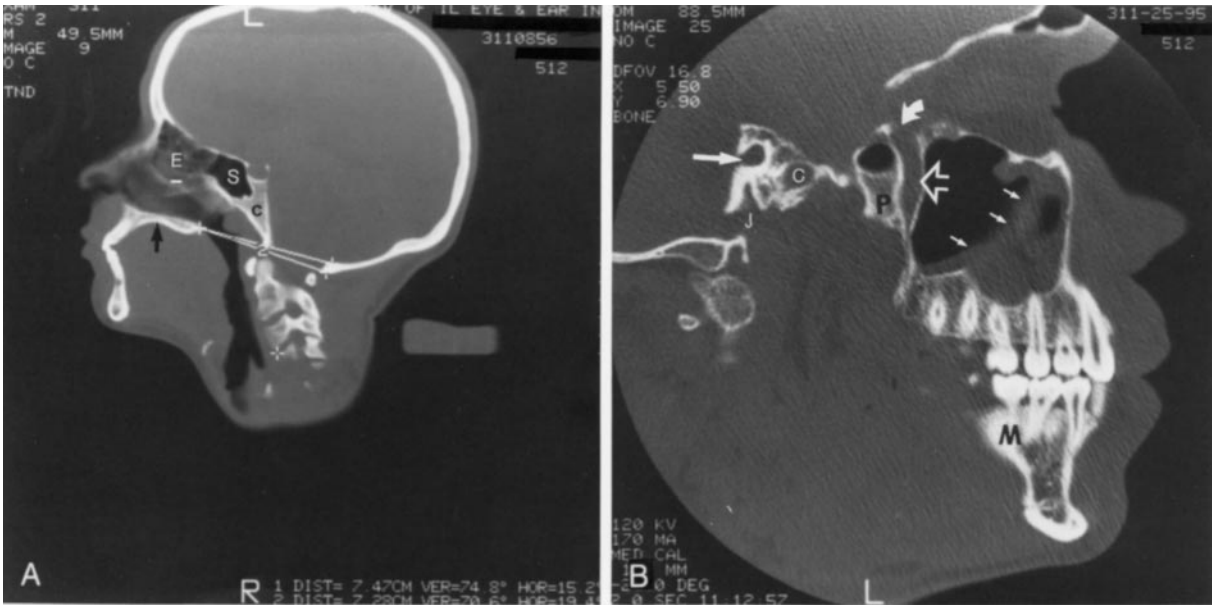

FIGURE 31–16. *A*, Direct sagittal computed tomographic (CT) scan of the midline head, showing the hard palate (*arrow*), sphenoid sinus (S), clivus (C), ethmoid air cells (E), and craniocervical junction. *B*, Sagittal CT scan showing mucosal thickening of the maxillary sinus (*short arrows*), pterygomaxillary fissure (*hollow arrow*), pterygoid plate (P), pterygopalatine fossa and inferior orbital fissure (*curved arrow*), carotid canal (C), jugular fossa (J), internal auditory canal (*long arrow*), and mandible (M).

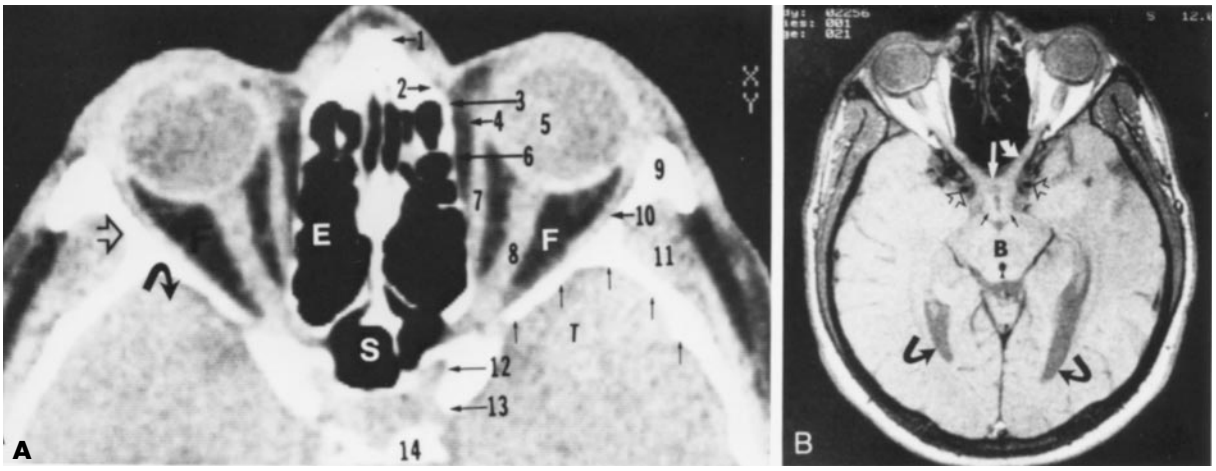

FIGURE 31–17. *A*, Normal ethmoid: axial computed tomographic (CT) scan through the plane of optic nerves, showing the nasal bone (1), nasal process of the maxilla (2), lacrimal bone (3), periorbital fat (4), globe (5), lamina papyracea (6), medial rectus muscle (7), optic nerve (8), zygomatic process of the frontal bone (9), lateral rectus muscle (10), temporal fossa (11), temporal line (*curved arrow*), cranial opening of the optic canal (12), anterior clinoid process (13), and posterior clinoid process (14). Note ethmoid (E) and sphenoid (S) sinuses and retroglobar fat (F). Two of the "triple lines" seen in the submentovertical projection (see Figure 31–10), the orbital line (posterior wall of the orbit) (*open arrow*) and middle cranial fossa line (*arrows*), are seen. *B*, Proton-weighted axial magnetic resonance scan showing optic nerves, optic chiasm (*long white arrow*), hypothalamus (*short black arrows*), brainstem (B), and cerebral aqueduct (*arrowhead*). Note visualization of the intracanalicular segment of the optic nerve (*curved white arrow*) that is hardly seen in the CT scan. Notice that in this proton-weighted image, the water in the vitreous cavity and cerebrospinal fluid in the lateral ventricles (*curved black arrows*) are hypointense and fat in the retrobulbar space and is hyperintense in the subcutaneous space. The blood vessels are hypointense (*hollow arrows*).

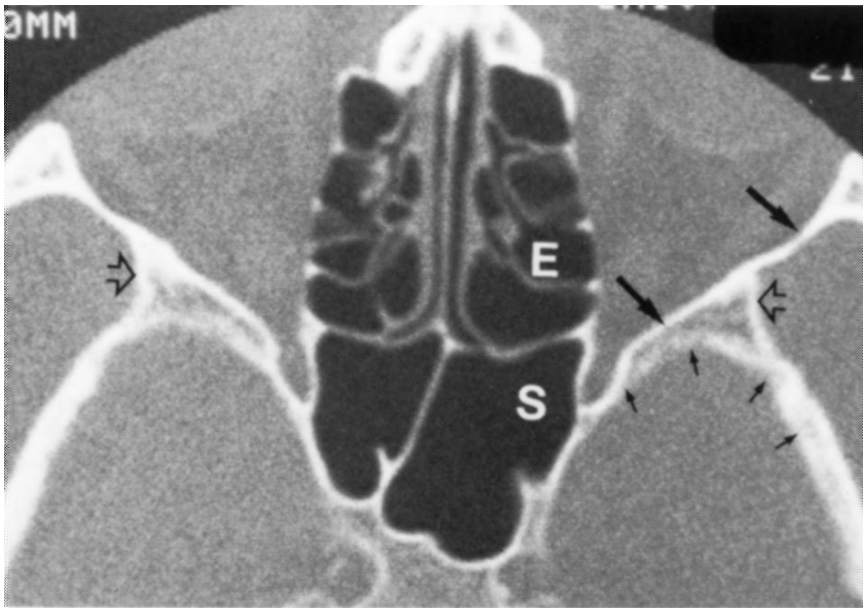

FIGURE 31–18. Normal ethmoid and sphenoid sinuses. High-resolution axial computed tomographic (CT) scan at the level of the middle of the orbit, using the extended bone CT range technique showing the ethmoid labyrinth (E) with their intact and sharply delineated septa and sphenoid sinuses (S). Note the sphenoethmoidal plate, intersphenoid septum, and sharply delineated orbital (*long arrows*) and anterior middle cranial fossa (*short arrows*) lines. Part of the innominate lines are also well visualized (*hollow arrows*). The innominate line (see Figure 31–10) is related to the outer cortex of the greater wing of the sphenoid bone.

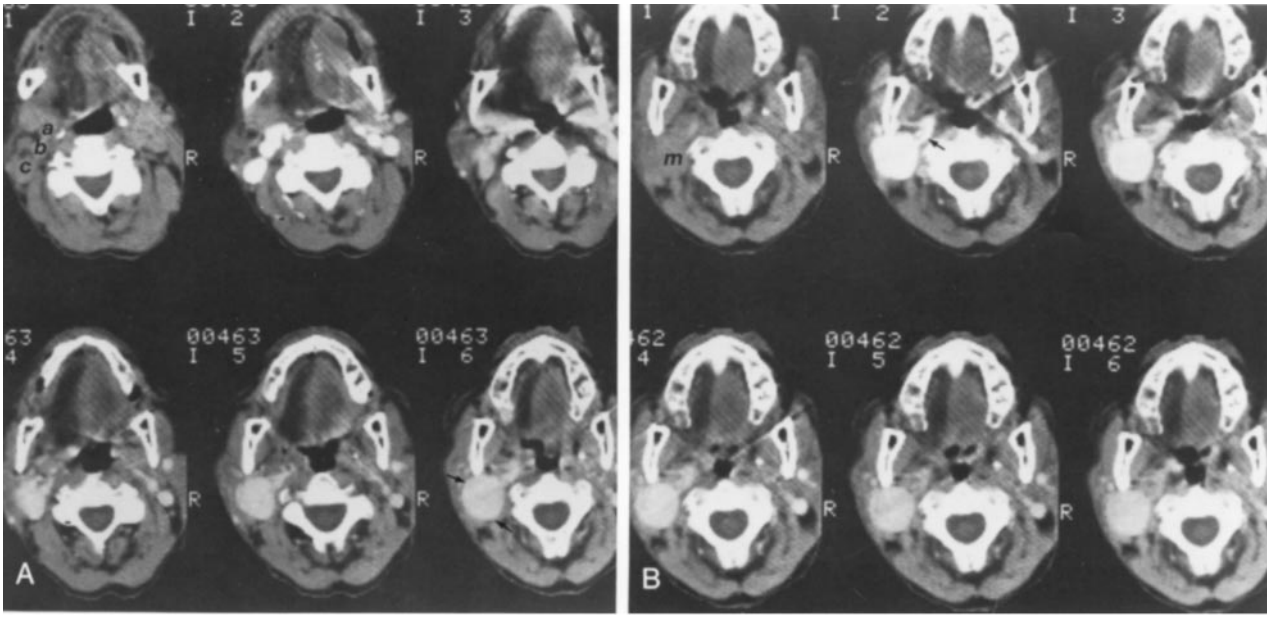

FIGURE 31–19. *A*, Glomus vagale tumor. Incremental dynamic computed tomographic (CT) scan with the first section obtained at the level of the tongue and extending superiorly (with automatic table incrementation) to the level of the superior alveolar ridge in this patient with a large right neck mass. Notice sequential enhancement of the external (a) and internal (b) carotid arteries and the internal jugular vein (c). A rounded enhancing mass is recognized on sections 5 and 6 (*arrows*), which show a prominent feeding vessel (see *B*). *B*, Glomus vagale tumor. Dynamic CT scan performed at the level of the right neck mass in the same patient in *A*. Note intense enhancement of a paravertebral mass (m) in the second section and rapid washout of contrast in the remainder of the sections. The glomus tumors often behave like an arteriovenous malformation in CT dynamic study. Note the large artery (most likely the ascending pharyngeal artery) (*arrow*) feeding this tumor. Note also the marked atrophy of the right side of the tongue in this patient with twelfth nerve palsy caused by superior extension of the tumor into the posterior cranial fossa and with associated destruction of the hypoglossal canal. Reproduced with permission from Mafee MF et al.[24]

T_2W MR scans. Chronic blood would appear hyperintense on T_1W, PW, and T_2W MR scans. Dense calcifications would appear hypointense on T_1W, PW, and T_2W MR scans, and proteinaceous fluid such as a thick mucosal secretion and exudate would appear hyperintense on T_1W, PW, and T_2W MR scans. Highly proteinaceous fluid may appear hypointense on T_2W MR images. Inspissated mucus may appear very hypointense on T_2W MR scans.

Positron Emission Tomography

Positron emission tomography (PET) using 2-^{18}F-fluoro-2-deoxy-D-glucose (FDG) has come to play a definite role in head and neck oncology.[28] Positron emission tomography depends on the altered metabolic activity of the tumoral tissue, of which increased glycolysis is a hallmark. 2-^{18}F-fluoro-2-deoxy-D-glucose, a glucose analog, is trapped preferentially within tumor cells with increased glycolysis, allowing for their detection. As a metabolic imaging modality, FDG-PET has been shown to have a significant impact in the diagnosis and management of head and neck malignancies. It is a powerful tool in the assessment of recurrence of malignancies and seems to be more effective and reliable than anatomic imaging techniques for the evaluation of head and neck tumors.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING OF ANATOMIC SITES

Normal Computed Tomography and Magnetic Resonance Imaging Anatomy of the Face and Neck

A complete description of the anatomy of the face and neck is discussed in this volume. Emphasis here is placed on the structures that are most pertinent to understanding CT and MRI scans in the broad field of otorhinolaryngology.

Nasal Cavities, Paranasal Sinuses, Orbits, and Nasopharynx

Nasal Cavities The paranasal sinuses and nasal cavities are closely related in their development. They are present at birth; however, the sphenoid sinuses are too small to be seen, and the frontal sinuses develop later from the anterior ethmoid air cells. Ethmoid and maxillary sinuses are the only sinuses that are large enough at birth to be seen on imaging studies (CT, MRI) and to be clinically significant in rhinosinusitis. The framework of the external nose is composed of bones and hyaline cartilages. Its bony framework consists of the nasal bones, the frontal processes of the maxillae, and the nasal part of the frontal bone. The posterior nasal apertures or choanae are two oval openings, each measuring about 2.5 cm in the vertical and 1.25 cm in the transverse direction. The choanae are best evaluated on axial CT and MRI scans (Figure 31–20). The roof, floor, and medial (septal) and lateral walls of each half of the nasal cavity can be best evaluated on coronal CT and MR scans (Figure 31–21). The roof of the nasal cavity is narrow from side to side. The lateral wall of the nasal cavity is very irregular owing to the presence of nasal conchae. The nasal conchae are best evaluated on coronal CT scans, projecting downward and slightly medially, each forming the roof of a passage or meatus (inferior, middle, and superior), which communicates freely with the nasal cavity (see Figure 31–21). The inferior concha is an independent thin bone that articulates with the nasal surface of the maxilla and the perpendicular plate of the palatine bone. The

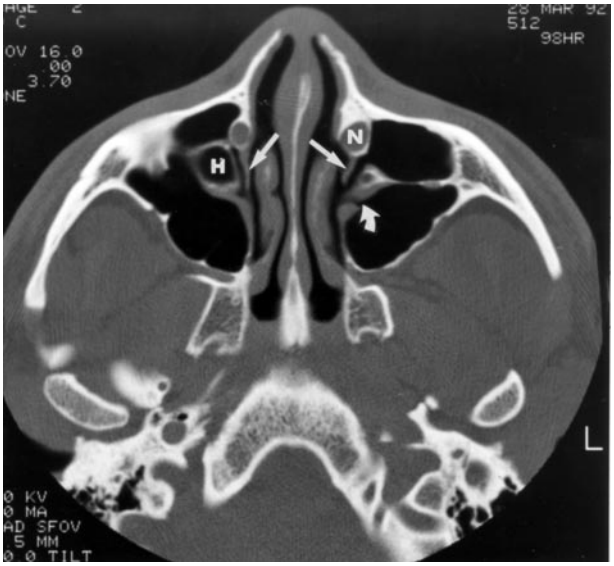

FIGURE 31–20. Axial computed tomographic scan shows the nasolacrimal canal (N), ostium of the maxillary sinus (*curved arrow*), Haller cells (H), and uncinate processes (*straight arrows*).

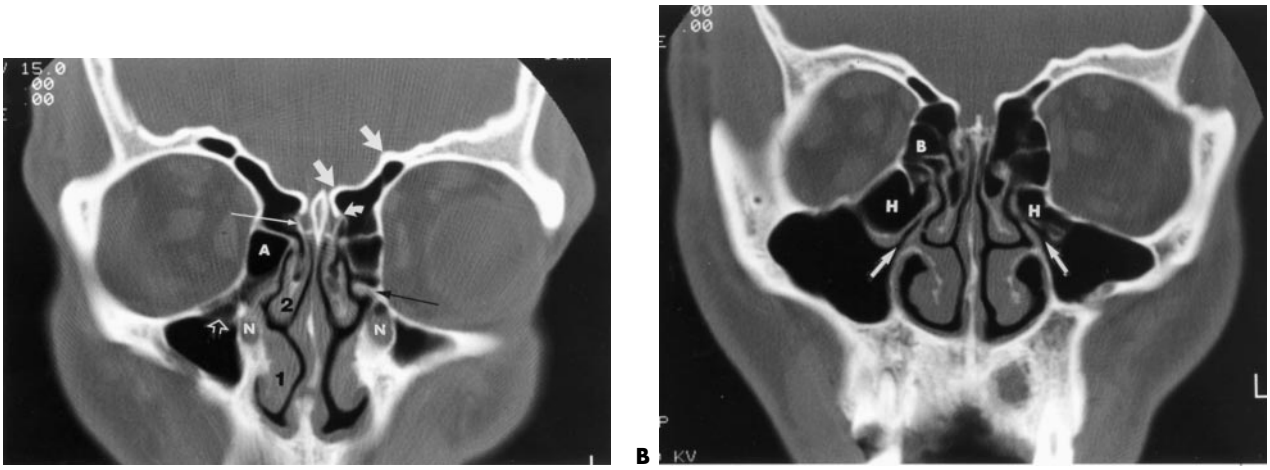

FIGURE 31–21. *A*, Coronal computed tomographic (CT) scan, same patient as in Figure 31–20, shows the inferior turbinate (1), middle turbinate (2), nasolacrimal ducts (N), uncinate process (*long black arrow*), Haller cell (*hollow arrow*), agger nasi cell (A), lateral lamella (*long white arrow*), fovea ethmoidalis (*double white arrows*), and canal for the ethmoidal artery (*curved arrow*). *B*, Coronal CT scan, same patient as in *A*, shows the bulla (B), Haller cells (H), and maxillary ostia (*arrows*), opening into the infundibulum.

inferior meatus receives the orifice of the nasolacrimal canal (see Figure 31–21, A). The middle and superior conchae are bony projections from the medial surface of the ethmoidal labyrinth (see Figure 31-21, A). The middle concha extends backward to articulate with the perpendicular plate of the palatine bone. The middle meatus receives the opening of the anterior and middle ethmoid air cells, frontal sinuses, and maxillary sinuses (Figure 31–21, A). The superior concha is a small curved lamina that lies above and behind the middle concha. The superior meatus receives the opening of the posterior ethmoidal air cells (Figure 31–22). A narrow interval, the sphenoethmoidal recess (see Figure 31–22), separates the superior concha from the anterior surface of the body of the sphenoid, through which the sphenoidal sinus opens into the nasal cavity (see Figure 31–22). A fourth concha (concha suprema) is

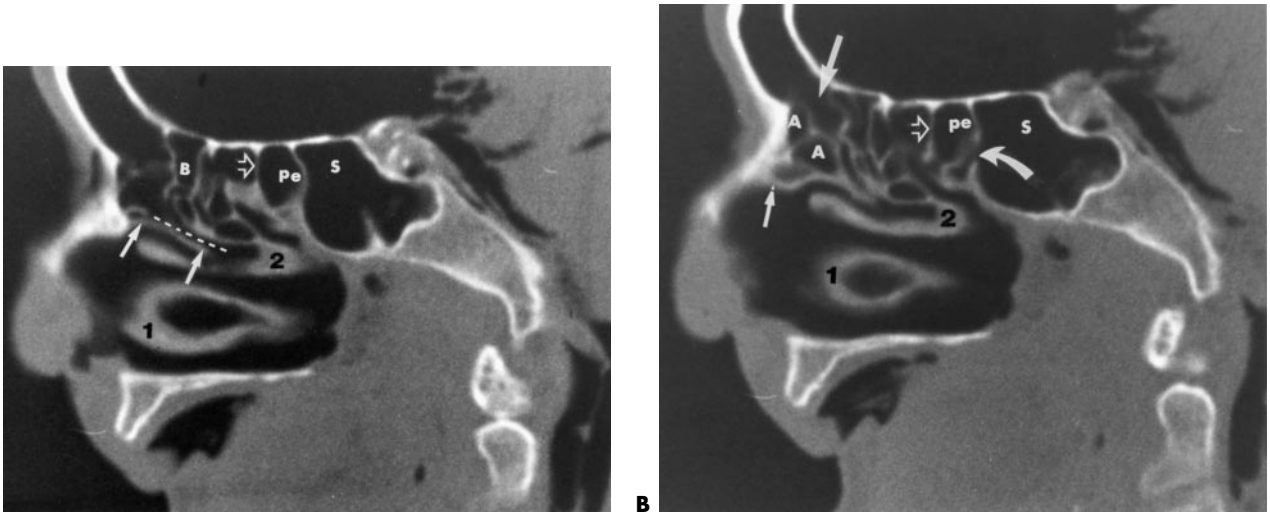

FIGURE 31–22. *A*, Sagittal computed tomographic (CT) scan shows the uncinate process of the ethmoid (*arrows*), infundibulum (*broken line*), bulla (B), basal lamella (*hollow arrow*), posterior ethmoid sinus (Pe), sphenoid sinus (S), and middle (2) and inferior (1) turbinates. *B*, Sagittal CT scan shows the inferior turbinate (1), middle turbinate (2), uncinate process (*small straight arrow*), agger nasi cell (A), frontal recess (*large straight arrow*), basal lamella (*hollow arrow*), posterior ethmoid sinus (pe), sphenoid sinus (S), and sphenoid sinus ostium (*curved arrow*).

often present on the medial surface of the ethmoidal labyrinth above and behind the posterior end of the superior concha. Immediately behind the superior meatus, the sphenopalatine foramen, which opens into the pterygopalatine fossa, pierces the lateral wall of the nasal cavity. It transmits the sphenopalatine artery, nasopalatine artery, and the nasopalatine and superior nasal nerves from the pterygopalatine fossa.

Maxillary Sinuses Maxillary sinuses begin to develop around the sixty-fifth day of gestation. The size of the sinus at birth is about 6 to 8 cm^3. Air can be seen on CT scans within the maxillary sinuses at or a few days after birth. Rapid expansion occurs from 7 to 18 years, related to eruption of the permanent teeth. They are the largest accessory air sinuses of the nose, and when fully developed, they occupy the body of the maxilla, and each is approximately 15 mL in volume (see Figures 31–20 and 31–21). The natural opening of the sinus is high above the floor and poorly placed for natural drainage. The middle meatus is of such a shape that pus running down from the frontal sinus or the anterior ethmoidal sinuses is directed by the hiatus semilunaris into the opening of the maxillary sinus, which may, in some cases, act as a secondary reservoir for pus discharged from these sinuses. Accessory ostia are present in 15 to 40% of cases, usually in the membranous medial sinus wall.

Ethmoid Sinuses Ethmoid cells begin to develop around the third to fourth month of fetal life, and there may be a few cells (four to five cells) present at birth. At birth, the size of the anterior ethmoid cells is approximately 5 mm high, 2 mm long, and 2 mm wide. The size of the posterior cells is 5 mm high, 4 mm long, and 2 mm wide. By the age of 12 years, the ethmoid air cells have almost reached their adult size (see Figure 31–22).

Because fat, fluid, and bone are natural contrast material, the orbit is the ideal structure for a highly detailed CT and MRI scan. A scan taken through the orbits shows the relationship of the ethmoid sinuses, sphenoid sinuses, pituitary fossa, cavernous sinuses, and temporal lobes with the orbit (see Figure 31–17). The cortical bones, which appear hyperdense on CT images (see Figure 31–17, A), are seen on MR as hypointense images because of little MR signal from them (see Figure 31–17, B). The bone marrow appears on T_1W MRI as a hyperintense image owing to the presence of fat. The air is seen as a dark image on both CT (low electron density) and MR (low proton density) images (see Figure 31–17).

The ethmoid sinuses are positioned between the orbits and comprise approximately 10 to 12 cells within the labyrinth of the ethmoid bone. The fine bone septa of the ethmoid labyrinth, the lamina papyracea, olfactory groove, cribriform plate and its lateral lamella, fovea ethmoidalis, canals for ethmoidal arteries, and maxillofacial bony structures will be best imaged by extended-bone window high-resolution CT (Figures 31–18, 31–22, and 31–23).[29,30] The anatomic landmarks of the ethmoid bone and ostiomeatal unit, such as the uncinate process, infundibulum, middle meatus-ethmoid complex, ethmoid bullae, middle turbinate, and cribriform plate (as well as the ostium of the maxillary sinuses), are best evaluated on coronal as well as axial and reformatted sagittal CT images (see Figures 31–20 and 31–21).[31–34] Just anterior to the superior attachment of the middle turbinate and anterior to the frontal recess (frontonasal duct) are the agger (ridge) nasi (a rudimentary turbinate) and agger nasi cells (see Figure 31–22). The agger nasi cells can invade the lacrimal bone or the ascending process of the maxilla. Just posterior and inferior to the agger nasi cells lies the ethmoidal uncinate process, a thin curved bar of bone from the lateral side of the ethmoidal labyrinth that forms a portion of the lateral nasal wall. It projects downward and backward and is subject to considerable variation in size. It ranges in height from 1 to 4 mm and is 14 to 22 mm long.[31] Anteriorly, it articulates with the lacrimal bone and ethmoidal process of the inferior nasal concha (see Figure 31–21). The superior edge of this process is free and forms the medial boundary of the hiatus semilunaris (see Figure 31–23). The ethmoidal infundibulum is a trough-shaped cavity (cleft) that is below the bulla ethmoidalis and above and lateral to the uncinate process. The infundibulum is best visualized on coronal CT scans (see Figure 31–21). In more than 50%, the infundibulum continues superiorly as the frontonasal duct into the frontal sinus.[32] The basal (ground) lamella, which separates the anterior and posterior air cells, can best be evaluated on axial as well as coronal CT scans. An air space (cleft) is usually found between the basal lamella and the bulla, which may extend superiorly to the bulla. This is called the sinus lateralis. This sinus lateralis, unlike the other anterior ethmoidal air cells that open into

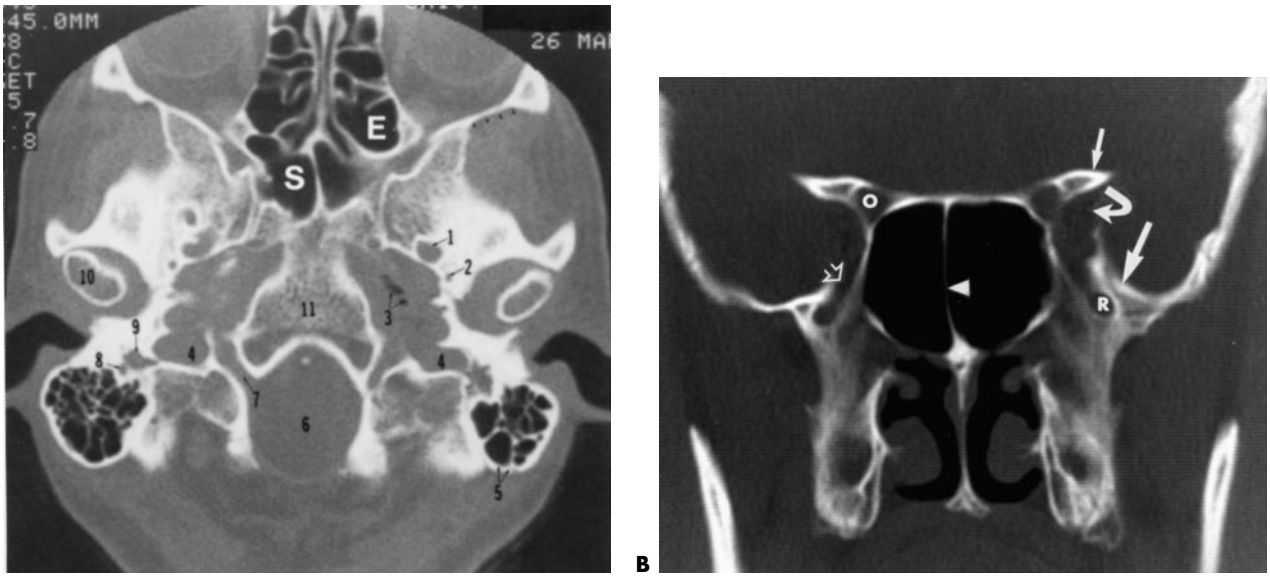

FIGURE 31–23. Normal base of the skull. *A*, High-resolution axial computed tomographic (CT) scan at the level of the clivus (11), using the extended-bone CT range technique showing the ethmoidal labyrinth (E), sphenoid sinus (S), posterior wall of the orbit (*arrowheads*), foramen ovale (1), foramen spinosum (2), air in the eustachian tube (3), jugular fossae (4), mastoid air cells (5), foramen magnum (6), hypoglossal canal (7), vertical portion of the facial nerve canal (8), lateral extension of the right jugular fossa (9), and mandibular condyle (10). *B*, Coronal CT scan shows the anterior clinoid (*small straight arrow*), superior orbital fissure (*curved arrow*), greater wing of the sphenoid (*large arrow*), foramen rotundum (R), intersphenoid septum (*arrowhead*), inferior orbital fissure (*hollow arrow*), and optic canal (O).

the infundibulum, may communicate with the frontal recess or open directly and independently into the middle meatus. Certainly, individual structural differences in ethmoidal and ostiomeatal complexes and other paranasal sinuses are to be expected, and the reader ought not be discouraged should certain illustrations in the literature fail to be identical with the images he or she will review for any individual patient. Certain anatomic variations are observed more commonly, and these are as follows: (1) concha bullosa, a pneumatized middle turbinate; (2) low position of the fovea ethmoidalis and dehiscence of the lateral lamella of the cribriform plate; (3) bulging of the optic canal into the posterior ethmoidal complex; and (4) deviation of the uncinate process. The superior edge of the uncinate process may elevate medially to obstruct the middle meatus and, more importantly, may deviate laterally to obstruct the infundibulum. Marked lateral deviation (commonly seen in patients with a hypoplastic maxillary sinus) or even fusion of the uncinate process to the medial orbital wall may endanger the orbit. (5) Haller cells are ethmoidal air cells extending along the medial floor of the orbit (infraorbital ethmoid air cells) (see Figure 31–21, B). (6) Onodi cells are posterior ethmoidal air cells, encroaching into the sphenoid sinus. (7) An asymmetric intersphenoid septum or septae are important because the posterior extension of this partition usually marks the location of the internal carotid artery groove (sulcus), which at times may be dehiscent, resulting in bulging of the internal carotid artery into the sphenoid sinus. Other anatomic variations include deviation of the nasal septum, paradoxical middle turbinate, uncinate process pneumatization (bulla), pneumatized superior turbinate, pneumatized cristal galli, congenital dehiscence or post-traumatic deformity of the medial wall or floor of the orbit, and exposed inferior orbital nerve within the maxillary sinus.

Frontal Sinuses Developmentally, the frontal sinus begins during the fourth month of fetal life in the region of the frontal recess. At birth, it is indistinguishable from the anterior ethmoid cells. Postnatal growth is slow. It is visible after the first or second year of life and is well developed by 7 to 8 years. Its size increases until the late teens. Each frontal sinus drains into the middle meatus of the nasal cavity via the frontonasal duct, best visualized on sagittal CT scans (see Figure 31–22). This communication between the

frontal sinus and nasal cavity is not strictly a duct but an internal channel positioned between the sinus and the anterior part of the middle meatus, referred to as the frontal recess. The natural ostium of the frontal sinus can be found at the superior-anterior end of the infundibulum. When the frontal recess air cells and agger nasi cells in this area are carefully removed, the ostium will come into view.

Sphenoid Sinuses Developmentally, the sphenoid sinuses begin during the third fetal month as evaginations of mucosa of the nasal cavity. At birth, the sinuses remain small and are little more than evaginations of the sphenoethmoid recess. After the fifth year, invasion of the sphenoid bone is more rapid, and by the age of 7, the sinus extends posteriorly to the level of the sella turcica. Further enlargement occurs after puberty. The pneumatization of sphenoid bone may be extensive. The sinuses may extend posteriorly to the clivus, anteriorly to the tuberculum sella and planum sphenoidale, and out into the anterior clinoids (see Figures 31–22 and 31–23). Lateral extension results in pneumatization of the base of the pterygoid processes as well as part of the greater wing of the sphenoid. Each sinus drains into the nasal cavity. The sphenoidal ostium drains into the superior meatus in the sphenoethmoidal recess, above the superior concha, well above the floor of the sinus. On average, the ostium measures 2 × 3 mm and lies 10 mm above the floor of the sinus.

Use of Computed Tomographic Scan for Computer-Aided Endoscopic Surgery Functional endoscopic sinus surgery has become a frequently performed operation in patients with chronic rhinosinusitis.[35,36] A preoperative CT scan is obtained in all patients according to the protocol of the specific system used. The CT protocol requires contiguous, 1 to 3 mm-thick, nonoverlapping, axial sections. Images are transferred to the computer-aided surgery system by means of an optical disk or storage tape. The CT scan is performed using fiducials; therefore, correlation of the patient's anatomy with corresponding points on the CT images is accomplished by the registration process.

Pathology of Paranasal Sinuses and Nasal Cavity

The inherently superior contrast resolution of CT and the three-dimensional effect of the combined axial and coronal sections have established CT as the method of choice in the staging of maxillofacial neoplasms and the evaluation of chronic and complicated inflammatory processes of the paranasal sinuses and face.[32–34] Magnetic resonance imaging has been used to evaluate maxillofacial anatomy as well as pathology. Familiarity with CT dictates that the MR evaluation complements and does not substitute for the CT evaluation. Magnetic resonance imaging is superior to CT for evaluation of the extent of soft tissue involvement and intracranial invasion by sinonasal tumors. A detailed discussion of the various pathologic entities of the paranasal sinuses and nasal cavity is limited by the scope of this chapter, although certain conditions will be described to illustrate the role of CT and MRI in the evaluation of patients with paranasal sinus and nasal diseases.

Conventional plain films still can be used to provide the screening studies in various pathologic conditions of the sinuses and in particular in maxillofacial trauma and give orientation and direction to further examinations using CT.[33,34] Developmental anomalies, such as a palatomaxillary cleft, are more clearly seen using CT (Figure 31–24). The appearance of lesions of the paranasal sinuses and face on CT scans usually does not provide sufficient evidence for a specific histologic diagnosis; however, cystic (Figure 31–25), cartilaginous, and osseous tumors are an exception (Figure 31–26). Fibrous dysplasia (FD) also frequently shows characteristic

FIGURE 31–24. Coronal computed tomographic scan, showing a right palatomaxillary cleft (*arrows*). Note the crista galli (1), cribriform plate, roof of the ethmoid sinuses (fovea ethmoidalis and olfactory plates), lamina papyracea, and middle and inferior turbinates.

FIGURE 31–25. *A*, A computed tomographic (CT) scan showing a smoothly marginated soft tissue image with cursor measurement of water density (mean = 5) in the left maxillary sinus. This is characteristic of a retention cyst. Notice the nasolacrimal canals (*arrows*). *B*, Coronal CT scan showing a mucous cyst with cursor measurement of 47.9 HU on the floor of the left maxillary sinus. The mucous cysts usually show a high CT number compared with retention cysts. Note excellent bone details and visualization of the nasal turbinates, maxilloethmoid plate, and superior and inferior orbital fissures (*upper and lower arrows*).

islands of bone formation within a dense, rather uniform, stroma on a CT scan (Figure 31–27). Periosteal reaction and cortical break are not seen in FD.

Infection Conventional radiography is adequate for the diagnosis of acute sinusitis. Even though antibiotics have cut down on the incidence of complicated sinusitis with orbital involvement, it still occurs and may even be the first sign of sinus infection in children.[37] Infection can spread from the sinuses to the orbit by direct extension. It can also spread by way of numerous valveless communicating veins between the sinuses and the orbit.[37] In complicated sinusitis, CT is the best method to demonstrate the nature and the source of the problem. The orbital extension of sinusitis includes orbital periostitis, subperiosteal induration (phlegmon) (Figure 31–28), subperiosteal abscess (Figure 31–29), orbital cellulitis, orbital

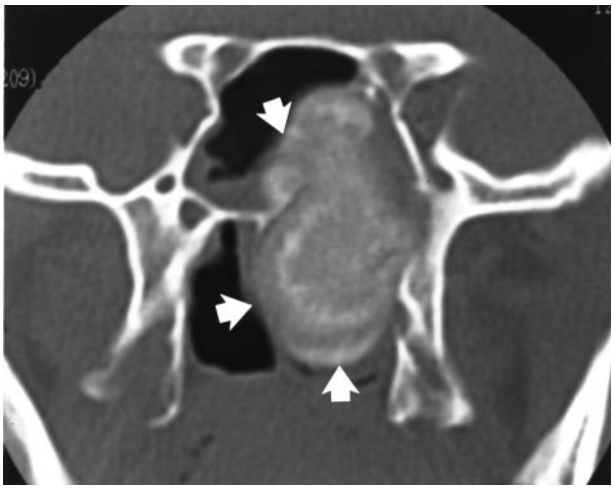

FIGURE 31–26. Ossifying fibroma. A coronal computed tomographic scan showing a large ossifying fibroma (*arrows*).

FIGURE 31–27. Fibrous dysplasia. Axial computed tomographic scan showing fibrous dysplasia involving ethmoid and sphenoid bones.

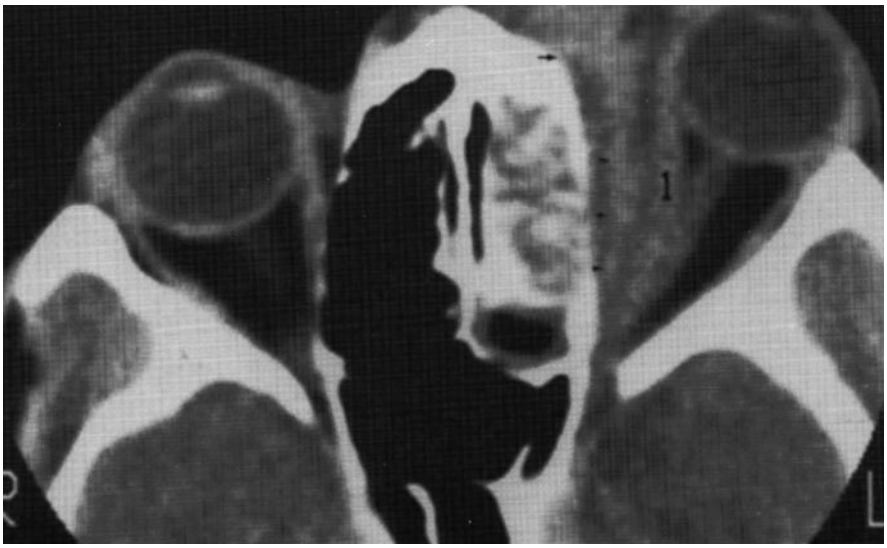

FIGURE 31–28. Ethmoid periostitis and subperiosteal phlegmon. Note soft tissue replacement of air in the left ethmoid labyrinth with thickening of the trabeculae. The left lamina papyracea is thickened and in some areas dehiscent. These findings are indicative of periostitis. Note soft tissue swelling (not yet leading to necrosis and abscess formation) in the left periorbita (*arrowheads*), resulting in displacement of the left medial rectus muscle (1). Notice proptosis of the left eye and marked periorbital edema and inflammation anterior to the orbital septum (*arrow*).

abscess, and ophthalmic vein thrombophlebitis (Figure 31–30).[37–41] Should the infection spread from the sinuses into the cranial cavity, one or more of the following complications may ensue: cavernous sinus thrombosis, meningitis, epidural (see Figure 31–30), subdural, or brain abscesses.[37–41] Intracranial complications are better evaluated by MRI than CT scanning (Figure 31–31).

Periostitis and osteomyelitis of the frontal bone can complicate frontal sinusitis.[37] An infection of the frontal sinus severe enough to involve the orbit may also extend through the posterior plate of the frontal sinus to involve the anterior cranial fossa (see Figure 31–30).[37] Orbital complications that result from sphenoid sinusitis can best be evaluated with CT and MRI scans (see Figure 31–31).

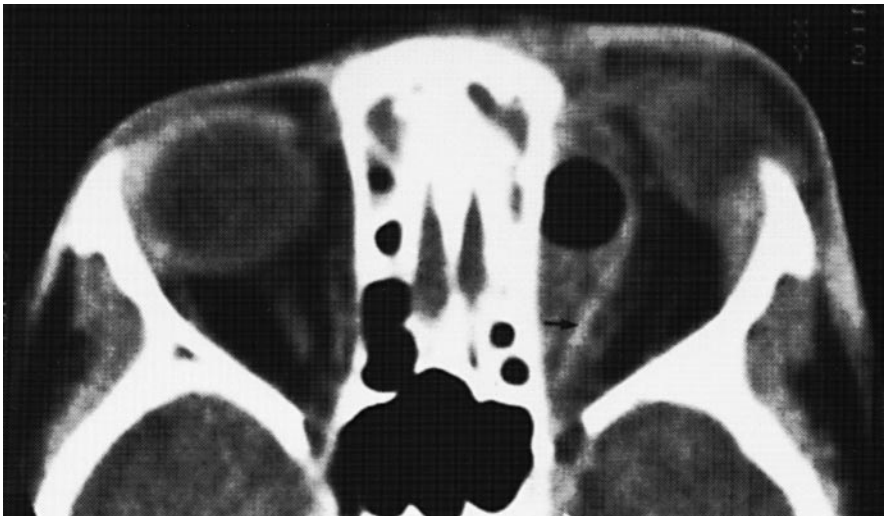

FIGURE 31–29. A computed tomographic scan showing proptosis of the left eye and a subperiosteal abscess. A large gas pocket is seen (*dark round area*) within the abscess. Note the displaced left medial rectus muscle (*arrow*).

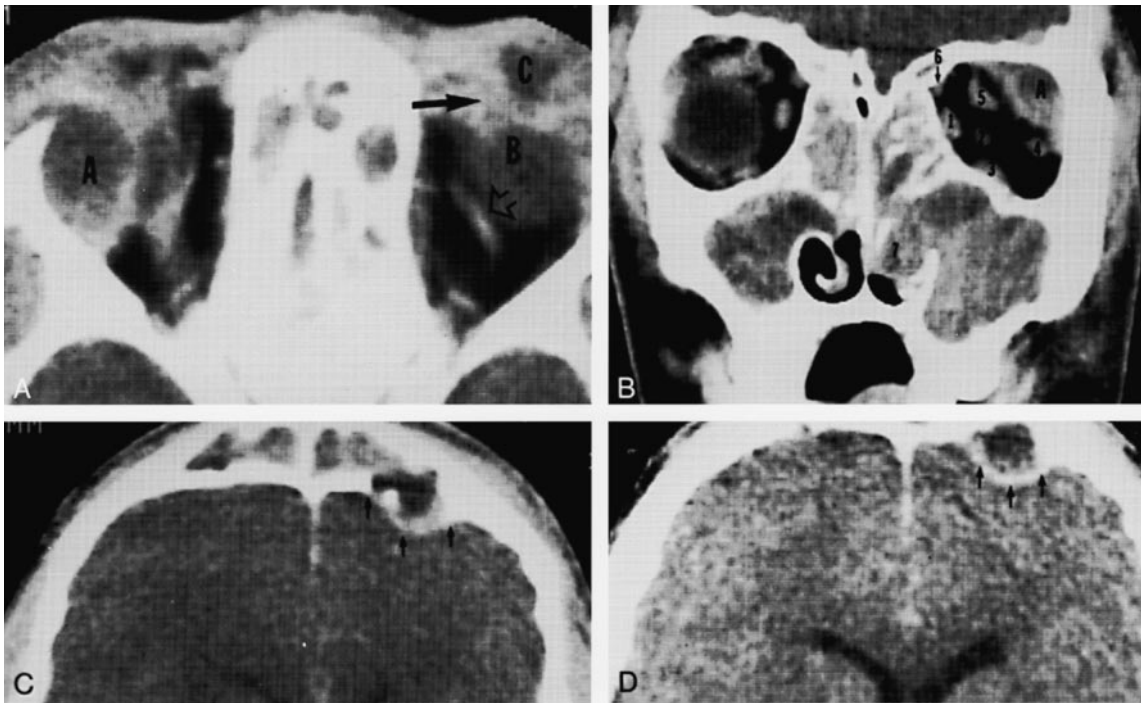

FIGURE 31–30. *A*, A computed tomographic (CT) scan showing increased density of the ethmoid labyrinth and bilateral retro-orbital soft tissue inflammation (cellulitis) (A and B). Note also a low-density image involving the left upper eyelid (C). The eyelid lesion (C) was drained, and 3 mL of pus were removed. *Hollow arrowhead* points to the superior ophthalmic vein, and the *arrow* points to the retroseptal granulation tissue. *B*, Postcontrast semicoronal CT scan of the same patient in *A* showing enhancing soft tissue densities (polyps and hyperplastic mucosa) involving the maxillary and ethmoid sinuses. Notice the polyp in the right nasal cavity (7) and periorbital cellulitis involving the right orbit (A). 1 = medial rectus muscle; 2 = optic nerve; 3 = inferior rectus muscle; 4 = lateral rectus muscle; 5 = superior rectus muscle; 6 = superior oblique muscle. *C*, A CT scan of the same patient in *A* and *B* showing increased density of the frontal sinuses with erosion of the posterior table of the left frontal sinus (*arrows*). *D*, Postcontrast CT scan obtained 5 mm superior to *C*, showing enhancement along the exposed and displaced dura (*arrows*).

Chronic inflammatory disease is often associated with sclerosis of the walls of the sinuses and ethmoidal trabeculae[41] (Figures 31–32 and 31–33). Fungi, particularly *Aspergillus*, may be considered possible causative agents. Fungal sinusitis can be divided into several categories: fungus ball formation, allergic fungal sinusitis, and acute and chronic sinusitis. "Fungal ball" refers to a saprophytic colonization of a cavity by fungus hyphae without invasion of adjacent tissue. It usually occurs in the lung (typically in a parenchymal cavity or an ectatic bronchus), the paranasal sinuses, nasal and auricular cavities, or the urinary tract.[42] *Aspergillus* is most commonly involved in the formation of fungus balls, although they may occasionally be caused by *Candida, Sporothrix*, or *Penicillium* or by bacteria, namely *Nocardia*.[42] Fungus balls are generally asymptomatic unless they are associated with bleeding. Fungus ball is seen as an area of increased density and calcification within the center of an involved sinus. Allergic fungal sinusitis can slowly expand and erode into surrounding structures. Atopy, asthma, and chronic illness requiring multiple courses of antibiotics are characteristic of this infection.[43] Neither fungus ball formation nor allergic fungal sinusitis has been associated with diabetes.[43]

Polyposis of the paranasal sinuses and nasal cavity (Figure 31–34) and mucocele of the maxillary (Figure 31–35), frontoethmoid (Figure 31–36), and sphenoid sinuses (Figure 31–37) are best evaluated by CT and MRI scans.[29,33,44,45] Mucoceles and benign tumors tend to expand the area of origin by virtue of their slow growth.[29,44] The gradual pressure, atrophy, and erosion of the bone by the enlarging soft tissue

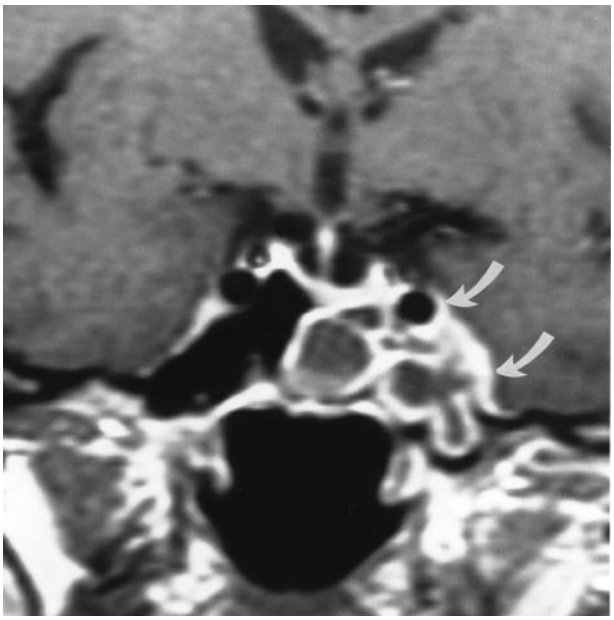

FIGURE 31–31. Aggressive aspergillosis, postcontrast T_1-weighted magnetic resonance scan showing left sphenoid sinusitis, extending into the left cavernous sinus (*arrows*).

mass of the mucocele and the expansile low-density appearance on CT (see Figures 31–36 and 31–37), with no enhancement after contrast infusion (except

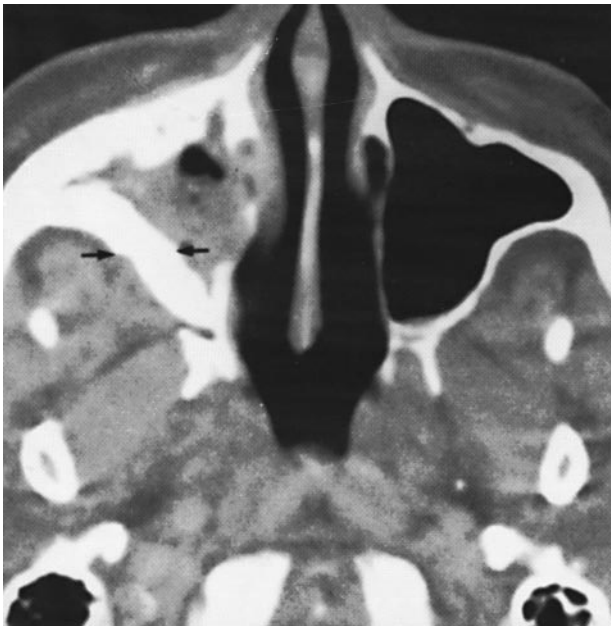

FIGURE 31–32. A computed tomographic scan showing marked hyperplastic mucosa with periosteal thickening (*arrows*) (osteoblastic sinusitis).

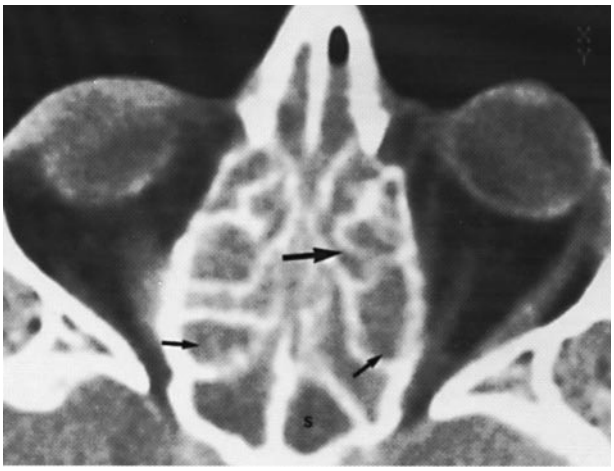

FIGURE 31–33. Chronic hyperplastic polypoid sinusitis. Postcontrast axial computed tomographic scan showing enhanced soft tissues in the ethmoid labyrinth (*arrows*), sphenoid sinuses (s), and nasal cavity in this patient with nasal and paranasal sinus polyposis.

around the inflamed capsule and peripheral calcifications), make the CT diagnosis of mucocele almost certain. Mucoceles may extend into the orbit or intracranially from the frontal, ethmoid, and sphenoid sinuses (see Figure 31–37). Computed tomography is the diagnostic method of choice for the diagnosis and management of the mucocele. Mag-

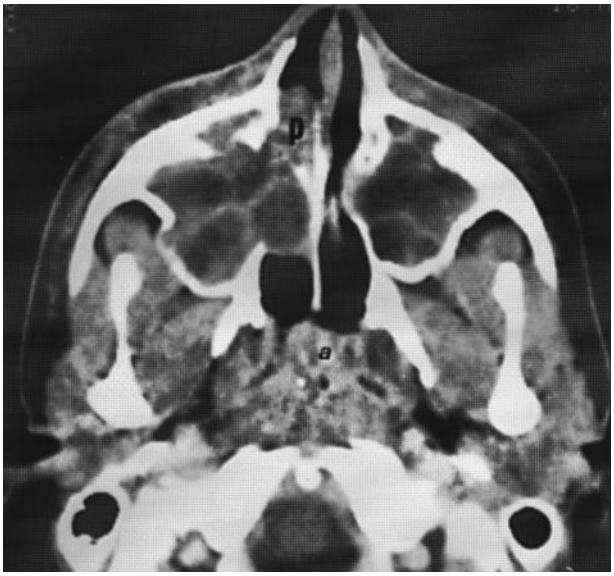

FIGURE 31–34. Nasal and paranasal sinus polyps. Postcontrast axial computed tomographic scan, showing polyp in the right nasal cavity (p) and enhancing soft tissue in the maxillary sinuses. Note the large adenoid (a).

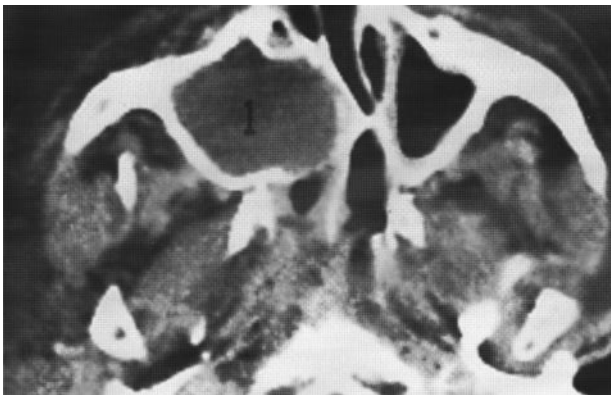

FIGURE 31–35. A computed tomographic scan showing expansion and replacement of the right maxillary sinus (1) by a soft tissue of low density, which is characteristic of a mucocele.

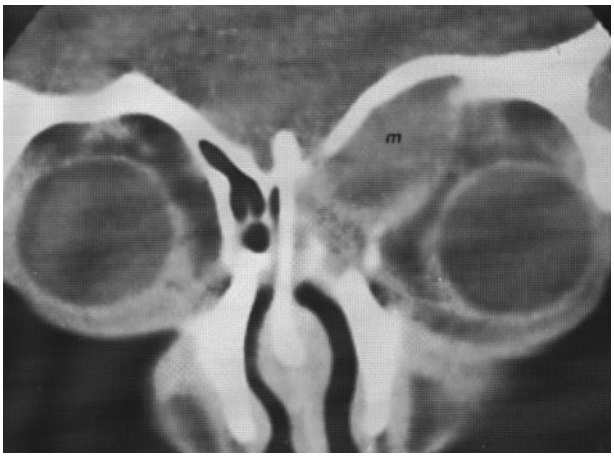

FIGURE 31–36. Mucocele of the ethmoid sinus. Post-contrast coronal computed tomographic scan showing expansion and replacement of the supraorbital recess of the left ethmoid sinus by a soft tissue of relatively low density (m). There is erosion and lateral displacement of the lamina papyracea and the superiomedial rim of the left orbit.

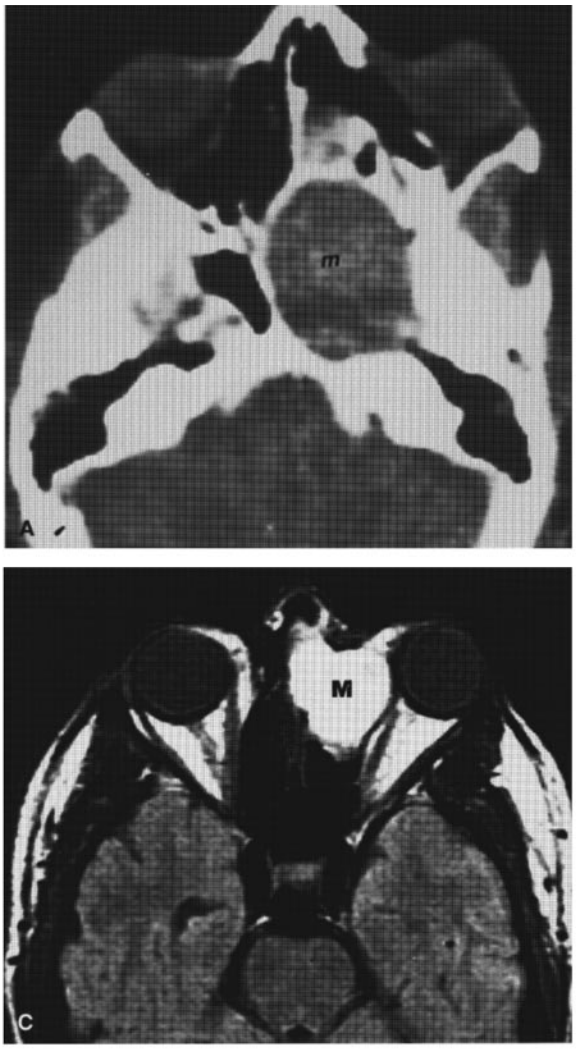
netic resonance imaging can provide valuable information regarding intracranial extension of a mucocele. The signal characteristics of mucoceles are variable according to the protein concentration of the secretions. Mucoceles are most often hyperintense on both T_1W and T_2W MR images (see Figure 31–37). Some mucoceles may appear hypointense on T_2W MR images, owing to high proteinaceous content. Calcifications and inspissated mucus can easily be missed by MRI. At times, a sinus filled with inspissated mucus can appear on MRI as a perfectly aerated and normal sinus. Magnetic resonance imaging should be used as a complementary study to evaluate mucoceles. At present, MRI is the best imaging method for postoperative investigation of the obliterated frontal sinus.[46]

Tumors of the Paranasal Sinuses Computed tomography and MRI have made significant contributions to the imaging evaluation of tumors of the paranasal sinuses and other head and neck tumors.[44–49] Computed tomography and MRI have also been valuable in the management of malignant tumors, particularly in the planning of portals for radiation therapy.[50]

Conventional radiography is adequate for the diagnosis of paranasal osteoma. Computed tomography, however, is indicated when there is orbital extension or other complications (Figure 31–38). Fibro-osseous lesions of the head and neck are best evaluated using CT scan. With MRI, serious mistakes may be made in the evaluation of the fibro-osseous lesions, particularly by a less experienced radiologist. Malignant tumors of the nasal cavity and paranasal sinuses account for only 0.2 to 0.8% of all malignant neoplasms and only 3% of all tumors occurring in the head and neck.[45,47–49] Approximately 50 to 65% of malignant sinonasal tumors arise within the maxillary sinuses, 10 to 25% in the ethmoid sinuses, 0.1 to 4% in the frontal and sphenoid sinuses, and 15 to 30% in the nasal cavity.[45] Malignant tumors of the nasal cavity and paranasal sinuses destroy bone and invade the adjacent soft tissue structures (Figures 31–39 and 31–40). Extension into the orbit, pterygopalatine fossa (Figure 31–41, A), and cranial cavity can best be demonstrated by contrast-enhanced CT or MRI (Figure 31–41). On CT scans, osteogenic or chondrogenic sarcomas of the sinonasal cavities demonstrate irregular islands of tumor bone formation, irregular periosteal reaction, and marked bone destruction[45] (Figure 31–42, A). On the other hand, osteoclastoma or giant cell tumor produces bone destruction as well as bone expansion (Figure 31–42, B). Early subperiosteal extension of a neoplastic condition is best evaluated by CT or MRI scans. Computed tomography remains the study of choice for osseous and chondrogenic lesions such as osteoma, osteoid osteoma, osteoblastoma, ossifying fibroma, chondroblastoma, osteogenic and



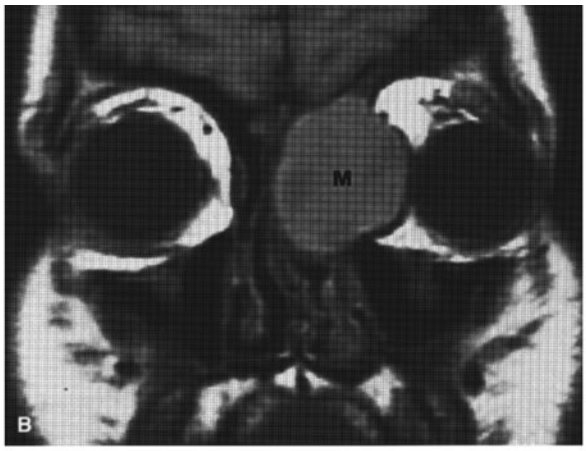


FIGURE 31–37. *A*, A computed tomographic scan showing expansion and replacement of the left sphenoid sinus by a soft tissue of low density, which is characteristic of a mucocele (m). *B*, Mucocele of the left ethmoid sinus. T_1-weighted magnetic resonance coronal (MR) scan shows an expansile rather hyperintense mass (M) involving the left ethmoid sinus. *C*, Proton-weighted axial MR scan, the same patient as in *B*, showing that the mass (M) is markedly hyperintense.

chondrogenic sarcomas, and developmental conditions such as FD.[33,45] Although CT is more specific in the diagnosis of osteogenic and chondrogenic sarcomas, MRI is more sensitive for the determination of the extent of their soft tissue components as well as the presence of subtle or obvious intracranial spread.[33] Magnetic resonance imaging is superior to CT in differentiating inflammatory conditions from neoplastic processes.[45,47] Most inflammatory lesions are hyperintense on T_2W MR images as opposed to most malignant tumors and lymphoreticular proliferative, myeloproliferative, and chronic granulomatous disorders.[45, 47] Most tumors of the sinonasal cavities are not as hyperintense as the surrounding inflammation and retained secretions; therefore, MRI plays an important role in the mapping and staging of these tumors. The intraorbital and intracranial complications of sinus surgery for

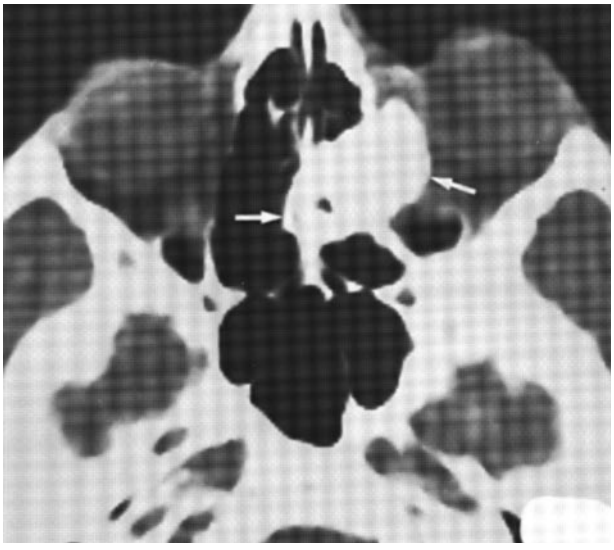

FIGURE 31–38. A computed tomographic scan showing a left ethmoid sinus osteoma extending into the left orbit (*arrows*).

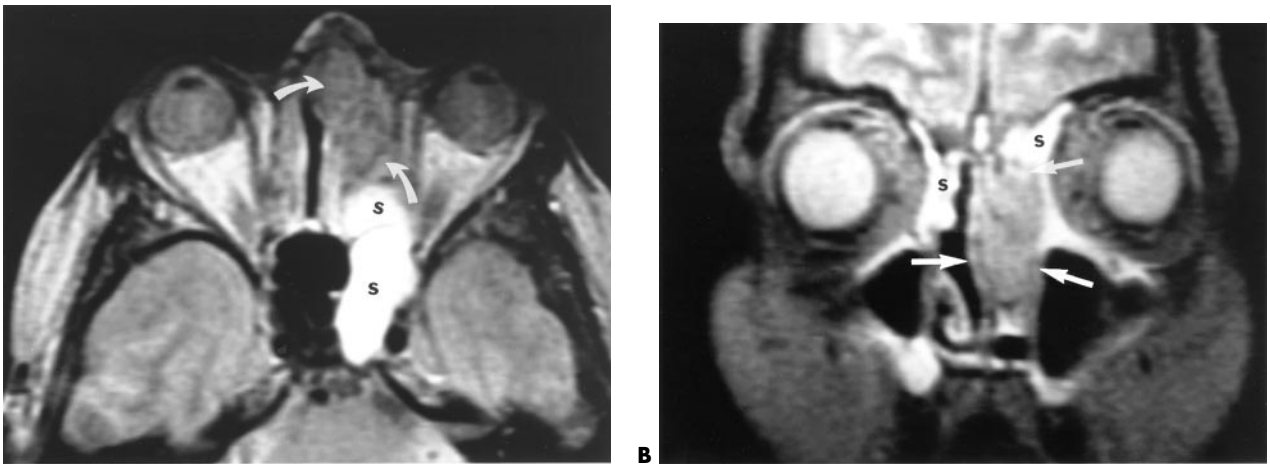

FIGURE 31–39. Squamous cell carcinoma of the sinonasal cavities. *A*, Axial proton-weighted magnetic resonance (MR) scan showing a large mass (*arrows*) involving the left nasal cavity and ethmoid complex. Note mucosal secretion (S) in the left posterior ethmoid sinus and left sphenoid sinus. *B*, Coronal T_1-weighted MR scan, showing a large mass (*arrows*). Note mucosal secretion (S) in the ethmoid air cells.

tumors or inflammatory conditions are best demonstrated by MRI.

Trauma Conventional plain film examination can be used for radiologic diagnosis of the isolated maxillofacial fracture.[51] In complex maxillofacial trauma, CT provides the most cost-effective imaging modality.[51] Current-generation spiral CT scanners provide excellent bone detail. The orbit is superbly suited to CT scanning. Orbital findings in trauma are well documented.[51] The fracture fragments and foreign bodies projecting into the orbit and fat and muscle herniation projecting into the ethmoid or maxillary sinuses are readily identified together with any hematoma and/or pneumo-orbit (Figure 31–43). Computed tomography is the procedure of choice for evaluation of the position of the Silastic implant for the repair of orbital floor fracture. The fracture of the lamina papyracea, which is difficult to image conventionally, can be imaged using axial and coronal sections.

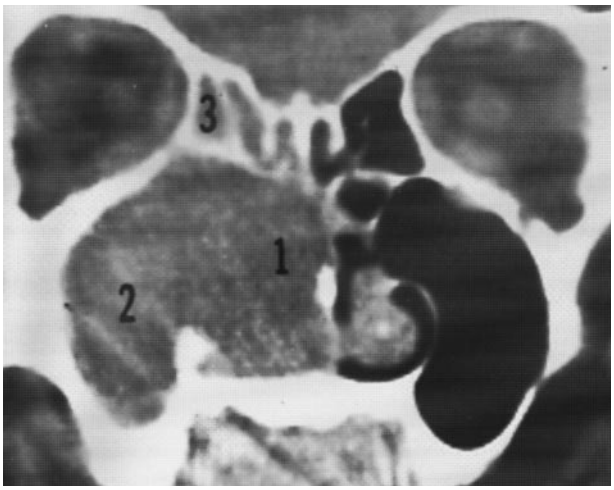

FIGURE 31–40. Carcinoma of the nasal cavity. Postcontrast coronal computed tomographic scan showing a large tumor in the left nasal cavity (1) extending into the left maxillary sinus (2) and left ethmoid sinus (3). Note destruction of the medial wall of the left maxillary sinus and partial destruction of the maxilloethmoidal plate.

The intracranial and intraorbital extension of complex maxillofacial fractures, shattering craniofacial fractures, and medial and lateral orbital wall and orbital apex fractures can be imaged using CT scanning in a manner not previously possible.[51] The axial dimension of posterior maxillary, alveolar, and pterygoid plate fractures and the posterior extensions of the Le Fort group of fractures are particularly suited to axial CT imaging (Figure 31–44).[30] Displacement and rotation of the malar bone and bone fragments in tripod fractures can best be demonstrated with axial CT (Figure 31–45). Sphenoid sinus fractures can be evaluated using axial and particularly direct coronal section and sagittal reformatted images. The coronal CT sections should be taken only in the injured patient who is physically stable and is without cervical spine injury. In a sphenoid sinus fracture, opacification of the sinus

FIGURE 31–41. *A*, Carcinoma of the right maxillary sinus. Postcontrast axial computed tomographic (CT) scan showing a large mass involving the right maxillary sinus (1) and extending into the right nasal cavity. There is erosion of the anterior wall of the maxillary antrum (*arrows*). Note destruction of the posterior wall of the right maxillary sinus and extension of the tumor into the right infratemporal fossa (2). Note the tumor in the right pterygopalatine fossa with partial erosion in the pterygoid portion of the right sphenoid bone (*arrow*). *B*, Rhabdomyosarcoma; axial CT scan shows a large mass in the right ethmoid sinus (*black arrows*) with extension into the right orbit (*white arrows*). Note extension of the tumor in the superior portion of the right maxillary sinus (*hollow arrow*) with tumor seen in the pterygopalatine fossa (*curved arrow*). *C*, Esthesioneuroblastoma; axial CT scan shows a mass in the left ethmoid sinus (*arrows*) with opacity of the sphenoid sinuses. *D*, Coronal CT scan of the same patient as in *C* showing markedly enhanced mass (*arrows*) in the anterior cranial fossa caused by extension of the tumor along the cribriform plate into the cranium.

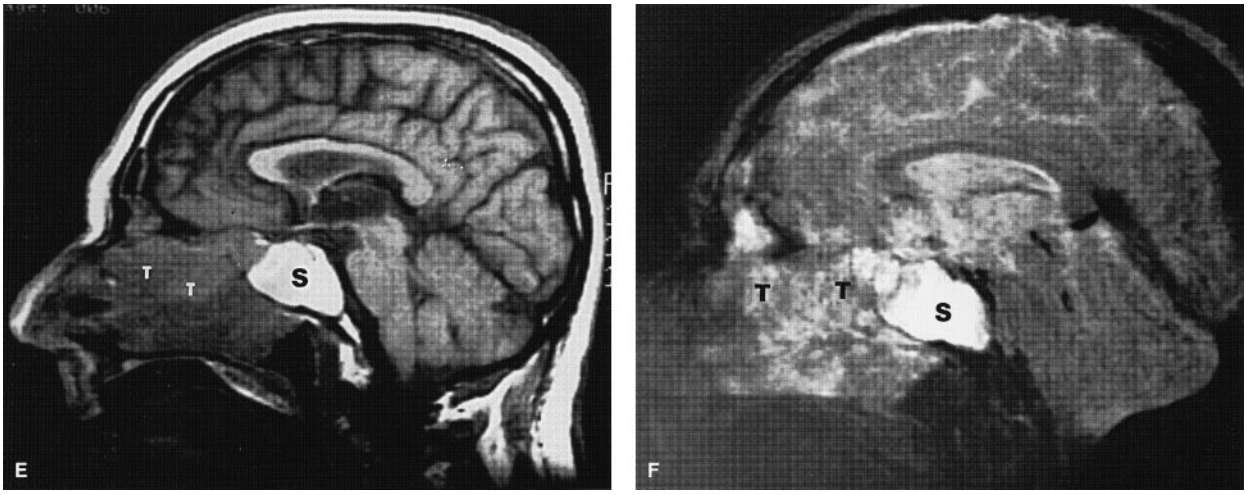

FIGURE 31–41 continued. *E*, Adenocarcinoma of the nasal cavity and ethmoid sinus. T_1-weighted sagittal magnetic resonance (MR) scan shows a large tumor (T) within the nasal cavity and ethmoid cells. Note the hyperintensity of the retained secretion in the sphenoid sinus (S). *F*, T_2-weighted sagittal MR scan of the same patient as in *E*. The tumor (T) appears hyperintense. The retained fluid remains hyperintense within the sphenoid sinus (S).

with blood or CSF can be readily recognized with a CT scan.

Three-dimensional reconstruction of CT images is a well-established imaging modality that has been investigated in various clinical settings. Perhaps one of its most useful applications is in trauma. Rotational abnormalities are better appreciated on three-dimensional images (see Figure 31–45).

Cerebrospinal Fluid Leak and Pneumocephalus

In trauma patients, the recognition of free air within the cranial cavity and cisternal and ventricular system is the result of a dural and subarachnoid tear. This can occur at any number of sites: the posterior wall of the frontal sinus, the roof of the ethmoid labyrinth, the cribriform plate, the walls of the sphenoid sinus, the middle and posterior cranial fossae, and beyond. Localization of the fracture site and

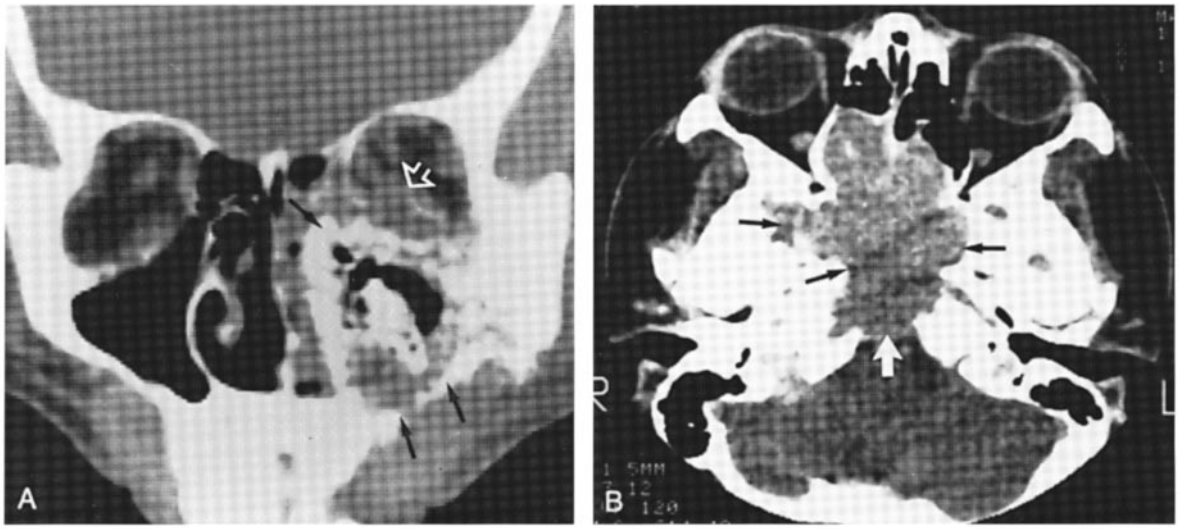

FIGURE 31–42. *A*, Osteogenic sarcoma computed tomographic (CT) scan showing a large maxillary tumor with irregular islands of bone formation (*arrows*) and with marked bone destruction. Notice invasion of the floor of the orbit (*hollow arrow*). *B*, Giant cell tumor of the sphenoid bone; axial CT scan shows a destructive tumor of the sphenoid bone (*black arrows*) with extension into the posterior ethmoid cells. Notice destruction of the clivus (*white arrow*) and exposed dura.

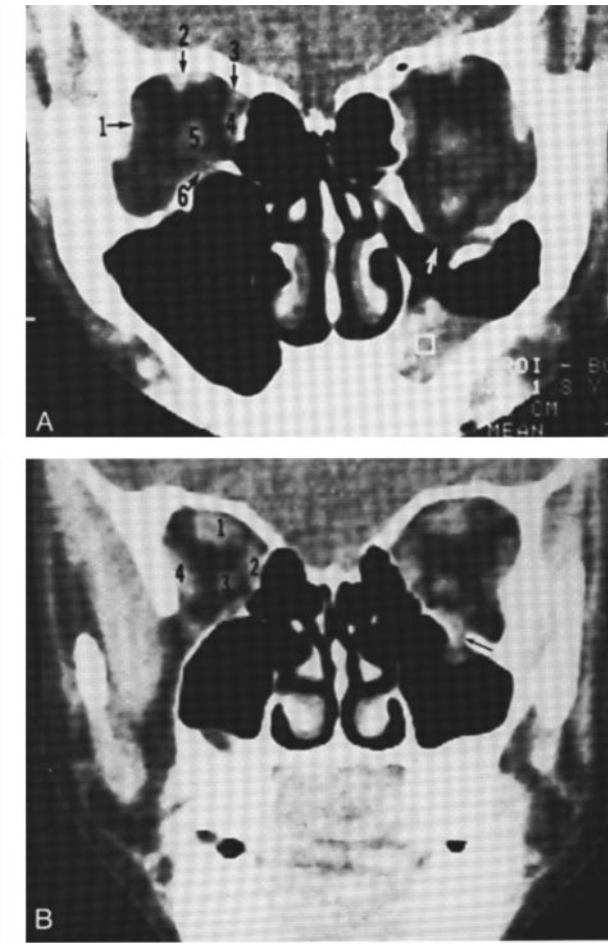

FIGURE 31–43. *A*, Coronal computed tomographic (CT) scan showing a "blowout fracture" of the right orbital floor with displacement of the periorbital fat and fractured fragments into the right maxillary sinus (*arrow*). Notice fluid in the right maxillary sinus with a cursor measurement of 36, which is indicative of hemorrhage. 1 = lateral rectus muscle; 2 = superior rectus muscle; 3 = superior oblique muscle; 4 = medial rectus muscle; 5= optic nerve; 6 = inferior rectus muscle. *B*, Coronal CT scan showing a fracture of the floor of the right orbit (*arrow*) with the inferior rectus muscle partially hooked over the fracture site. 1 = superior rectus muscle; 2 = medial rectus muscle; 3 = optic nerve; 4 = lateral rectus muscle. *C*, Coronal CT scan showing a fracture of the right medial orbital wall with entrapment of the medial rectus muscle (*arrow*).

bone fragments in axial and, if possible, direct coronal display, using thin sections (1.5 to 3 mm) in critical areas is mandatory. Contrast examination with intrathecal, water-soluble, iodinated contrast material is not indicated at this stage since most acute CSF leaks will close spontaneously or with operative fracture reduction alone.[30] In persistent CSF leaks, all such fistulae should undergo CT cisternography (Figure 31–46).[52,53] The examination must be carried out during a period of active CSF rhinorrhea or otorrhea for effective imaging results.[52,53] Other examinations, such as a radionuclide CSF scan, may not be needed.[30] When the leak is large, MRI may be sufficient to make the correct diagnosis. Aggressive arachnoid granulations, causing CSF leak, may be detected by MR following IV administration of gadolinium contrast material. There will be local enhancement at the site of arachnoid granulation.

Nasopharynx The nasopharynx is a cuboidal structure whose anterior limits are the choanae. The roof is attached to the base of the skull at the clivus and slopes downward to become the posterior pharyngeal wall, which overlies the atlas and its related ligaments and muscles. The inner surface of the pharyngeal musculature (pharyngeal constrictor muscle) is lined by the pharyngobasilar fascia. The pharyngobasilar fascia, or pharyngeal aponeurosis, encircles the space between the upper border of the superior constrictor muscle and the skull base. The eustachian tube opens into the nasopharynx by piercing the pharyngobasilar fascia. The most prominent anatomic landmark on the lateral wall of nasopharynx on each side is the cartilaginous medial end of the eustachian tube (torus tubarius) (Figures 31–47 and 31–48). Between the torus and the posterior wall is the fossa of Rosenmüller, a cleft-like space whose apex reaches the anterior margin of the carotid canal (see Figures 31–47 and 31–48).[54,55]

Computed tomography and MR examinations of the nasopharynx delineate the air-containing cavity of the nasopharynx, the mucosal surfaces, and the deep

FIGURE 31–44. A complex maxillofacial fracture. Axial computed tomographic (CT) scan showing fractures of the anterior and medial walls of both maxillary sinuses. Note marked soft tissue swelling of the face, air in the subcutaneous tissue (*arrow*), and opacification of the maxillary sinuses caused by hematoma. Fracture of the left zygoma (1), fracture of the left pterygoid plates (*posterior arrow*), and normal mandible (2). *B*, Axial CT scan obtained 1 cm superior to *A*. Note bilateral fractures of the inferior orbital rims (*anterior arrows*) extending along the zygomaticomaxillary suture on the left and involving the posterior wall of the left maxillary sinus (*open arrow*). Note fractures of the left zygomatic arch (*arrow*), the floor of the right orbit, and the posterior wall of the right maxillary sinus. *C*, Coronal CT scan of the same patient in *A* and *B*. Note separation of the left frontozygomatic suture (*arrows*) and lateral displacement of the left fractured malar bone. Note fractures of the anterior wall of both maxillary antra and shattered fractures of the ethmoid sinuses and floors of both orbits.

fascial planes (Figures 31–47 and 31–48). The anatomic landmarks of the nasopharynx and the muscles affecting eustachian (pharyngotympanic) tube function, the tensor and levator palatini and the stylopharyngeus, are better depicted on MR images (see Figure 31–47, A). The cartilaginous end of the eustachian tube bulges into the airway, producing the mucosal prominence known as the torus tubarius (see Figure 31–48, A).

The pharyngeal recesses or fossae of Rosenmüller extend posteriorly and superiorly to the tori (see Figure 31–48). The pharyngeal openings of the eustachian tubes are located on the anterior and inferior surfaces of the tori (see Figure 31–48). Scans taken using a modified Valsalva's maneuver show distention of both the eustachian tubes and lateral recesses. On axial and coronal CT and MR images obtained during respiration, air is rarely seen more than 3 to 5 mm within the pharyngeal end of the eustachian tube. The tympanic end of the eustachian tube can easily be seen in thin (1 to 1.5 mm) axial CT scans. The intrapharyngeal muscles (levator and tensor veli palati and salpingopharyngeus) lie between the pharyngobasilar fascia and the mucosa. The pharyngobasilar fascia is not seen as a separate discrete structure on CT images. The levator veli palatini is the major contributor to intrapharyngeal muscle density seen on CT.[54,55] The muscle belly produces a characteristic oval image just deep to the mucosa posterior to the torus (see Figure 31–47, B). The tensor veli palatini opens the eustachian tube and can be imaged on MR as a distinct muscle bundle (see Figure 31–47, B).

The prevertebral musculature (mainly the longus capitis muscles) is identifiable readily on CT and MRI scans (see Figures 31–47 and 31–48). The parapharyngeal space (PPS), filled with loose fibrofatty tissues, lies between the pharyngeal muscles and the lateral and medial pterygoid muscles (see Figure 31–48, B). This space is subdivided by a consistent layer of fascia into prestyloid and poststyloid

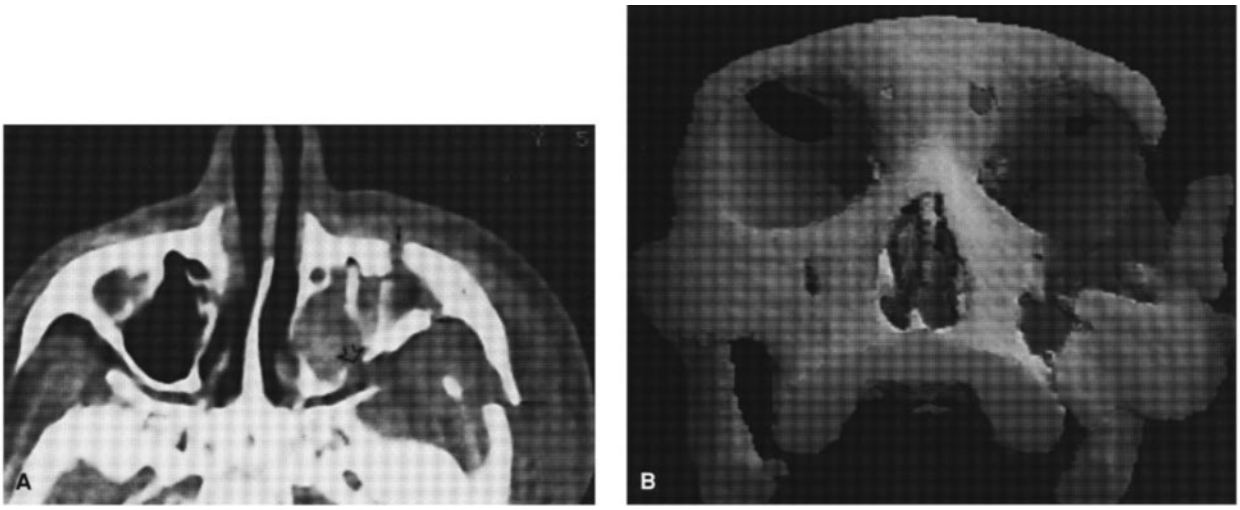

FIGURE 31–45. *A*, Malar fracture. Axial computed tomographic (CT) scan showing fractures involving the inferior orbital rim and the left malar bone, which extend along the left zygomaticomaxillary suture (*small arrow*). Notice fracture of the left zygomatic arch, fracture of the posterior wall of the left maxillary sinus (*open arrowhead*), and bone fragments within the left maxillary antrum with associated left antral submucosal hematoma. *B*, Malar fracture. Three-dimensional image reformation from regular CT scans showing the fractures and displacement of the malar bone.

compartments. The relationship between the medial pterygoid fascia, representing the medial wall of the masticator space, and the fascia of the tensor veli palatini, representing the medial wall of the prestyloid PPS, allows better preoperative differentiation and perhaps more accurate diagnosis. Specifically, tumors that arise in the prestyloid PPS are most often of salivary gland origin.[56] We have seen neurogenic tumors and hemangiopericytoma in the prestyloid PPS. Tumors that arise in the masticator space are unlikely to be of salivary gland origin. Tumors that arise in the poststyloid PPS are most often of neurogenic or chemoreceptor (paraganglion) origin. The fat content of the PPS allows one to identify it as hypodense (dark) on CT scan (see Figure 31–47, A) and hyperintense (bright) on T_1W and PW MR images (see Figure 31–47, B).

FIGURE 31–46. Cerebrospinal fluid rhinorrhea. Coronal computed tomographic scan after intrathecal injection of metrizamide showing contrast-enhanced subarachnoid space of the anterior cranial fossa (*upper arrow*) just above the crista galli. Note the fracture of the left cribriform plate (*lower arrow*) and the presence of metrizamide (high density) within the ethmoid labyrinth and the air metrizamide fluid level in the left maxillary sinus.

Squamous cell carcinomas account for 80% of nasopharyngeal cancers. The remaining nasopharyngeal tumors will prove to be lymphomas (including plasmacytoma and Burkitt's lymphoma), chloroma, chordoma, and a variety of rare conditions, including adenocarcinomas, melanoma, rhabdomyosarcoma, schwannoma, lipoma, liposarcoma, Kaposi's sarcoma, and metastasis. Magnetic resonance imaging and CT scans of the nasopharynx are indispensable in patients with clinically diagnosed nasopharyngeal disease in whom information concerning the extent of disease is necessary (Figures 31–49 through 31–53) and in those patients in whom a search is being made for an unknown primary tumor of the head and neck (see Figure 31–51). Hypertrophied and normal lymphoid tissue is seen commonly within the nasopharynx.[54] Ade-

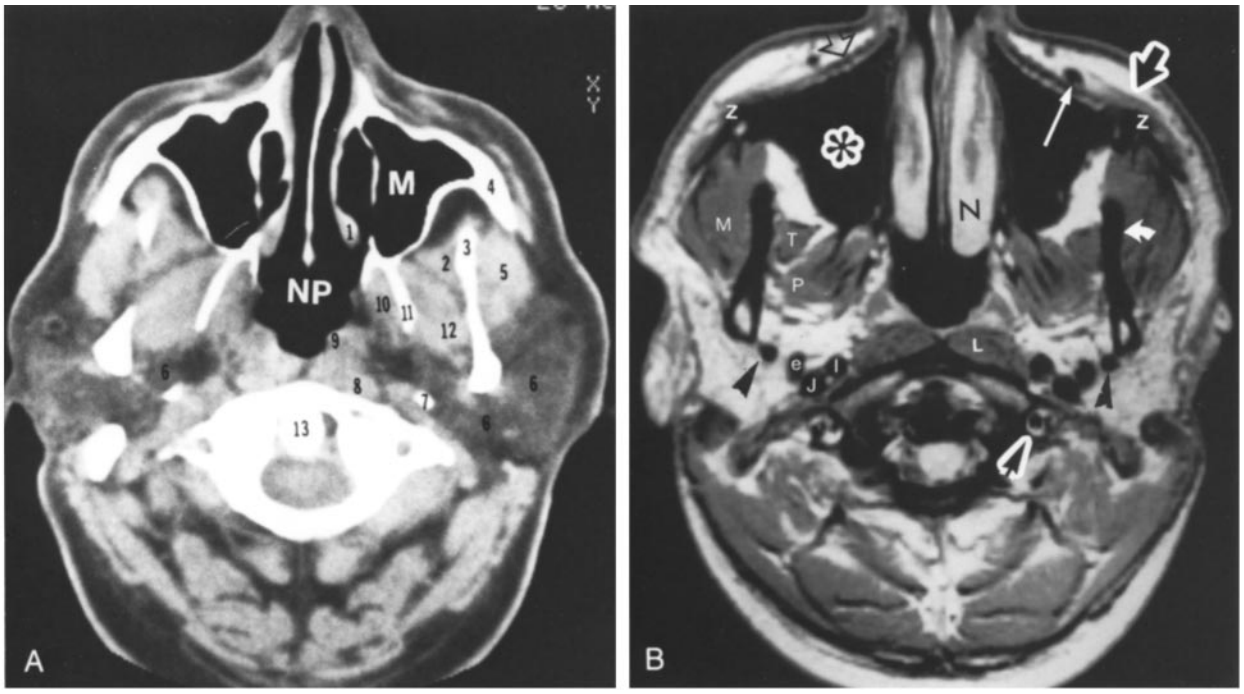

FIGURE 31–47. Normal nasopharynx, maxillary sinus, and infratemporal fossa. *A*, Axial computed tomographic scan through the midportion of the maxillary sinuses (M) and upper part of the odontoid process (13) showing the nasal septum, inferior turbinate (1), nasopharynx (NP), temporalis muscle (2), coronoid process (3), zygoma (4), masseter muscle (5), parotid gland (6), styloid process (7), longus capitis muscle (8), torus tubarius (9), tensor veli palatini muscle (10), lateral pterygoid plate (11), and lateral pterygoid muscle (12). The density seen behind the torus is mainly caused by the levator veli palatini muscle. The tensor veli palatini is rarely seen as a distinct muscle bundle. Part of the density seen medial to the lateral pterygoid plate is caused by the tensor veli palatini muscle (10). Medial to the deep lobes of the parotid glands (6), the symmetric low-density parapharyngeal spaces are seen. Posterior to the styloid process are seen the densities of the petrostyloid neurovascular structures. *B*, Axial proton-weighted magnetic resonance scan showing the quadratus labii superioris muscle (*open arrow*), obicularis oculi and zygomaticus muscles (*white and black arrows*), angular vein (*white arrow*), zygomatic bone (Z), maxillary antrum (*), nasal turbinate (N), masseter muscle (M), pterygoid muscles (P), mandible (*curved arrow*), retromandibular vein (*arrowhead*), vertebral artery (*white and black arrows*), longus colli muscle (L), external (e) and internal (I) carotid arteries, internal jugular vein (J), and temporalis muscle (T).

noidal tissue is usually symmetric and has a lobulated pattern. Benign lymphoid tumor of the nasopharynx is limited to the mucosa and is smooth in outline. Any extension into the deeper plane with obliteration of the facial planes should be considered evidence of a more aggressive lesion[54,55] (Figures 31–49, 31–50, 31–54, and 31–55). Extension of the nasopharyngeal carcinoma into the nasal cavity (see Figure 31–49), infratemporal fossa, orbit, and cranial cavity is best demonstrated by contrast-enhanced CT examination or MRI.[55] Nasopharyngeal carcinomas and, in particular, lymphoepitheliomas are infiltrative. Lymphomas, which are the second most common malignant nasopharyngeal tumors, are bulky and often respect the fascial planes. In children, rhabdomyosarcoma of the nasopharynx as well as lymphoepithelioma (see Figure 31–52) and lymphoma should always be included in differential diagnosis of a nasopharyngeal mass. Lymphoepitheliomas or the so-called Schmincke tumors refer to undifferentiated nonkeratinizing tumors that have numerous lymphocytes. These tumors can be seen in young adults and children (see Figure 31–52). We have seen them in children as young as 5 to 12 years of age. A dynamic CT or a dynamic MR study should be used to differentiate lesions such as juvenile angiofibroma (see Figure 31–54) and for any nasopharyngeal hypervascular lesion such as extension of the glomus tumor along the eustachian tube into the nasopharynx (see Figure

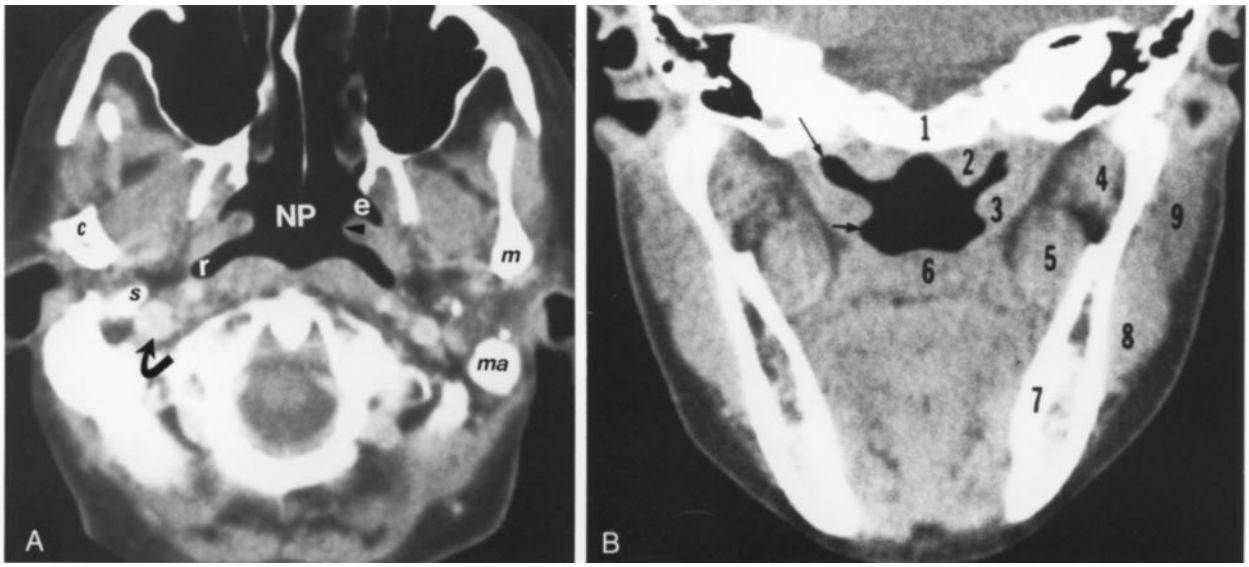

FIGURE 31–48. *A*, Normal nasopharynx. Axial computed tomographic (CT) scan through the midnasopharynx (NP) with the patient instructed to blow against a closed mouth. Note the torus tubarius (*arrowhead*) and extension of air into the eustachian tube (e) (anterior to tori) and Rosenmüller's fossae (r) (posterior to tori). Note enhancement of the retrostyloid vascular structures (internal jugular vein) (*curved arrow*) after intravenous iodine-contrast infusion. The upper part of the parotid gland is seen posterior to the mandible (m) and anterior to the mastoid process (ma). s = styloid process; c = mandibular condyle. *B*, Semicoronal CT section of the nasopharynx showing the clivus (1), longus capitis muscle (2), torus tubarius (3), lateral (4) and medial (5) pterygoid muscles, soft palate (6), mandible (7), masseter muscle (8), and parotid gland (9). Note the eustachian tube opening (*lower arrow*) just inferior to the tori (3) and superior extension of Rosenmüller fossa (*upper arrow*).

31–55) and hypervascular metastases such as metastatic hypernephroma and thyroid carcinoma.

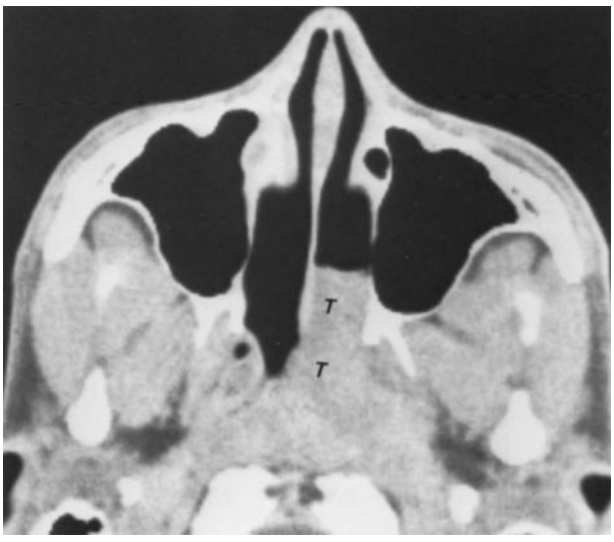

FIGURE 31–49. Nasopharyngeal carcinoma. Axial computed tomographic scan of the nasopharynx showing a large soft tissue tumor (T) occupying the left side of the nasopharyx and extending into the left nasal cavity.

Benign lesions of the nasopharynx such as inflammatory processes (Figure 31–56), Tornwaldt's cyst, parapharyngeal cyst, polyps, papillomas, juvenile angiofibromas, neuromas, fibromas, and lipomas are all well suited for MRI and CT.[54,55]

Orbits

Because fat, fluid, and bone are natural contrast material, the orbits are the ideal structures for highly detailed CT and MRI scans. Scans taken through the orbits show the relationship of the ethmoid sinuses, sphenoid sinuses, pituitary fossa, cavernous sinuses, and temporal lobes with the orbits (see Figure 31–17). The cortical bones, which appear hyperdense on CT images (see Figure 31–17), are seen on MR as hypointense images (see Figure 31–17). The bone marrow appears on T_1W scans as hyperintense owing to the presence of fat. The air is seen as a dark image on both CT and MRI scans. The optic nerves within the orbits can be visualized with both CT and MRI. The intracanalicular portion of the optic nerve is best seen on MRI (see Figure 31–17). The lateral orbital wall separates the orbit from the middle cra-

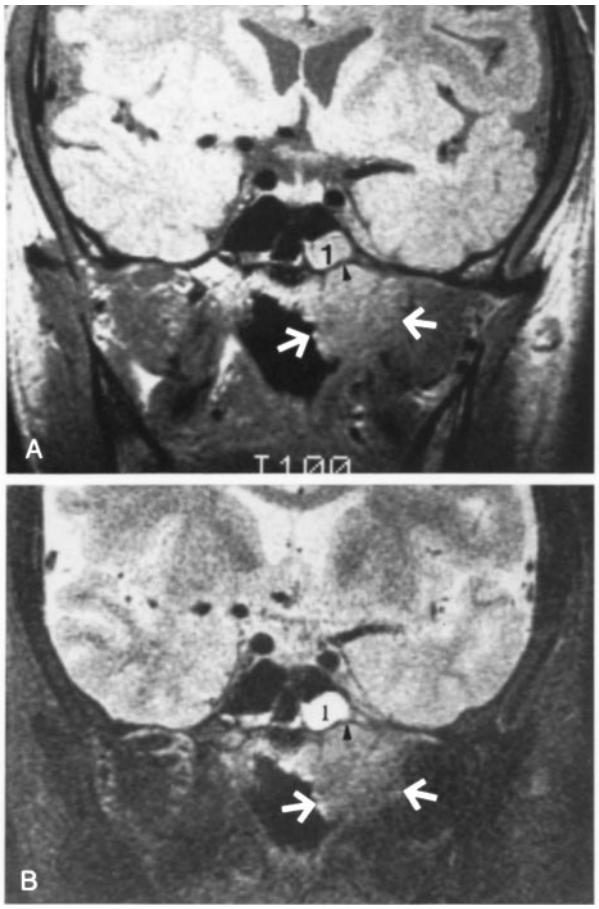

FIGURE 31–50. Squamous cell carcinoma of the nasopharynx. Proton-weighted (*A*) and T_2-weighted (*B*) magnetic resonance (MR) scans show the tumor (*arrows*) and a retention cyst (1) in the left sphenoid sinus. Note the difference between the signal of the tumor and the cyst in the T_2-weighted MR scan. The bone of the base of the skull adjacent to the tumor is not involved (*arrowhead*).

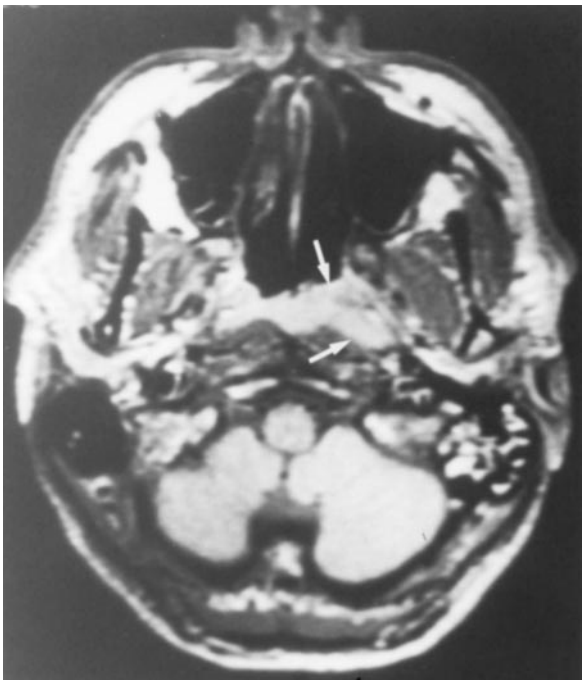

FIGURE 31–51. Nasopharyngeal carcinoma. Proton-weighted magnetic resonance scan showing an infiltrative process involving the left Rosenmüller's fossa (*arrows*).

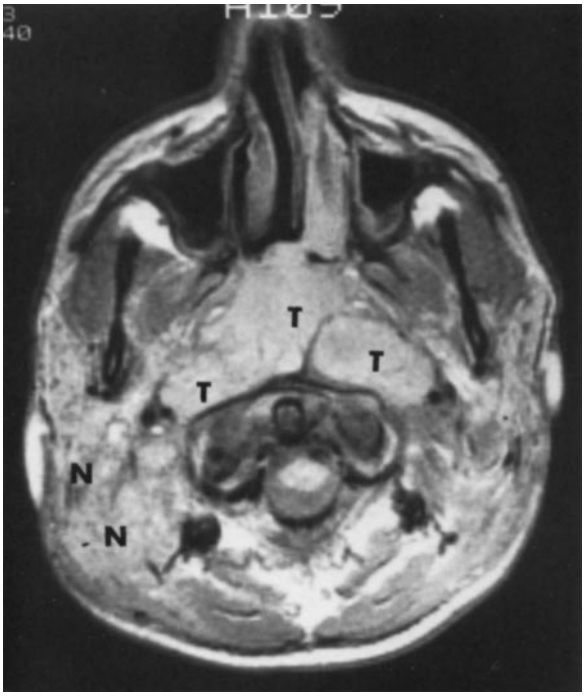

FIGURE 31–52. Poorly differentiated carcinoma with lymphoid stroma in a 16-year-old boy with a 4-month history of nasal stuffiness, fever, and neck masses. Proton-weighted magnetic resonance scan shows massive nasopharyngeal tumor (T) with large cervical lymph nodes (N).

nial and temporal fossae. Computed tomography and MRI are most valuable to evaluate orbital extension of sinonasal pathology (see Figures 31–38, 31–40, and 31–41). Orbital extension of nasopharyngeal tumors, pterygopalatine lesions, and infratemporal fossa pathology can be best evaluated by MRI, particularly on postgadolinium fat-suppressed T_1W MR scans.

Infratemporal Fossa

The boundaries and content of the infratemporal fossa or zygomatic fossa were once difficult to image using radiographic techniques before the advent of

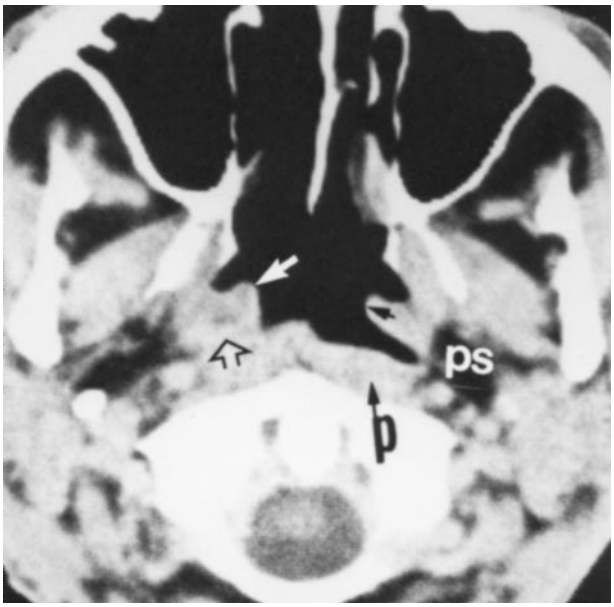

FIGURE 31–53. Clinically unrecognized nasopharyngeal tumor. Notice the normal torus tubarius on the left (*arrowhead*) and anterior to that the normal eustachian tube opening and posterior to that the normal Rosenmüller's fossa and parapharyngeal space (ps). Notice enlargement of the right torus tubarius (*white arrow*) and early infiltration in the adjacent portion of the parapharyngeal space by a soft tissue mass (*hollow arrow*). Biopsy of this lesion revealed carcinoma. p = left paravertebral muscle, longus capitis.

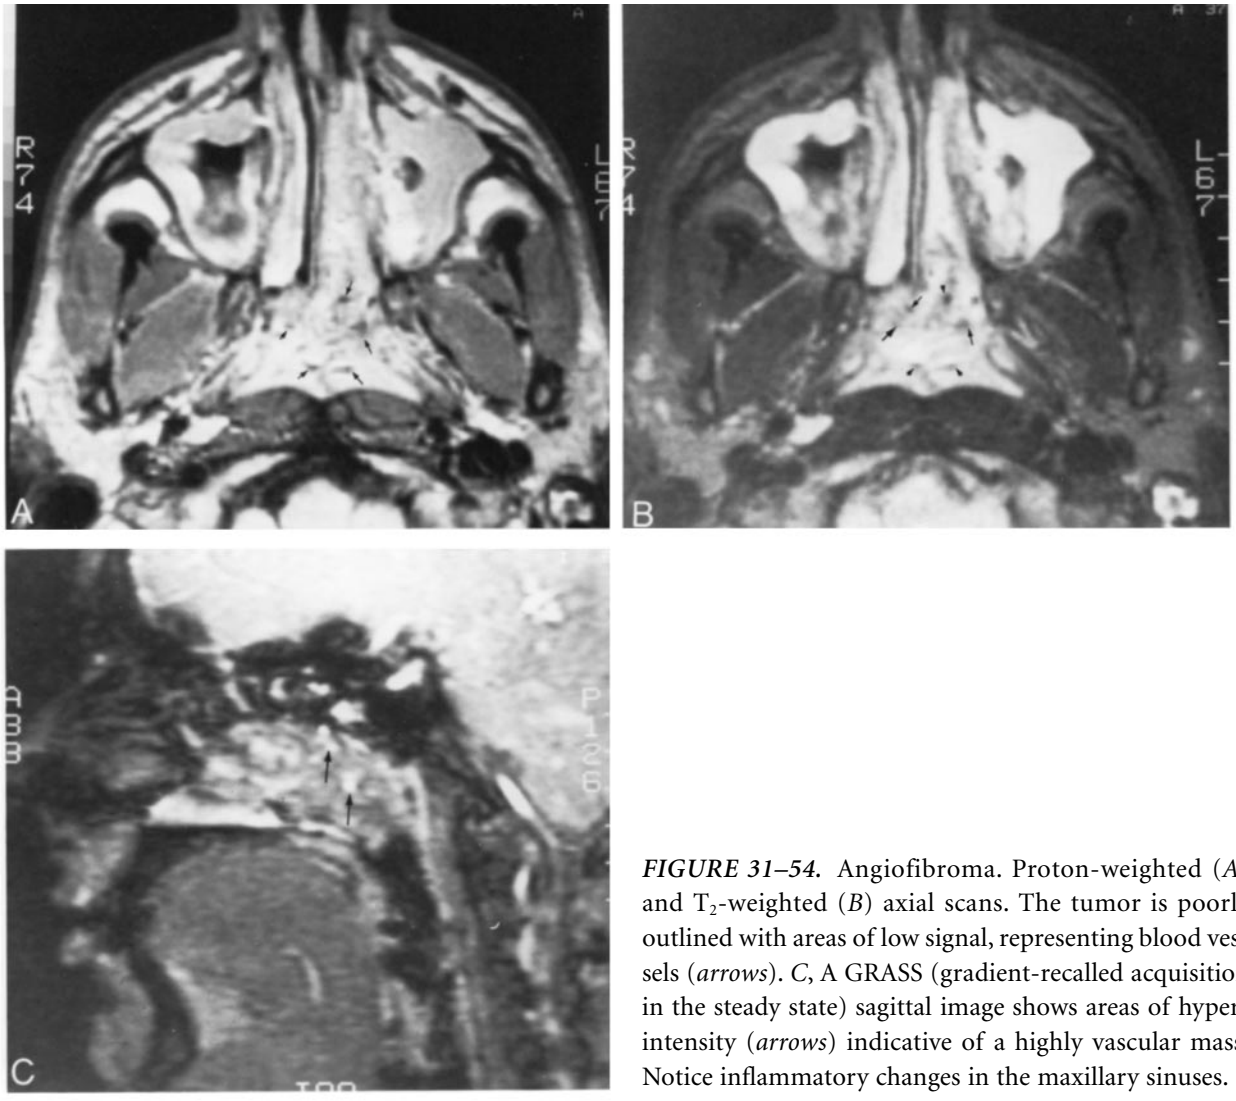

FIGURE 31–54. Angiofibroma. Proton-weighted (*A*) and T_2-weighted (*B*) axial scans. The tumor is poorly outlined with areas of low signal, representing blood vessels (*arrows*). *C*, A GRASS (gradient-recalled acquisition in the steady state) sagittal image shows areas of hyperintensity (*arrows*) indicative of a highly vascular mass. Notice inflammatory changes in the maxillary sinuses.

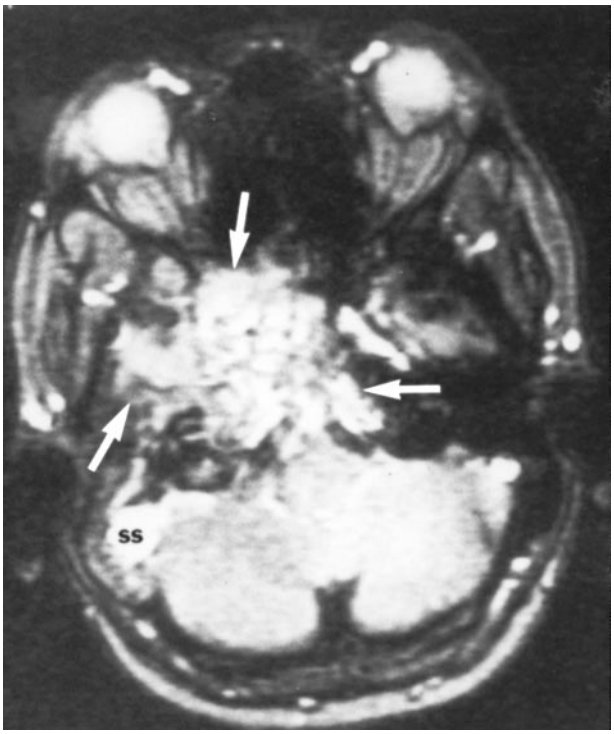

FIGURE 31–55. Diffuse glomus tumor extension in the nasopharynx. Dynamic magnetic resonance (MR) image shows an extensive mass (*arrows*) in the base of the skull with extension into the nasopharynx. With this MR dynamic GRASS (gradient-recalled acquisition in the steady state) technique, vascular tumors appear bright. Notice the hyperintensity of the vasculatures. ss = sigmoid sinus.

CT scanning. They can be evaluated in detail by CT and MRI in axial, coronal, and direct or reformatted sagittal sections (see Figure 31–16, B). The infratemporal fossa is an irregularly shaped cavity that lies below the infratemporal crest of the greater wing of the sphenoid, which is at a level with the upper border of the zygomatic arch. It is medial and deep to the zygomatic arch and is bound anteriorly by the infratemporal surface (posterior wall) of the maxilla and ridge from its zygomatic process (Figures 31–47 and 31–48). It lies lateral to the PPS[54–56] and is bound medially by a line from the styloid process to the lateral pterygoid plate[55] and laterally by the zygomatic arch and the articular tubercle of the temporal bone. Above the level of the zygomatic arch, the infratemporal fossa is continuous with the temporal fossa. Inferiorly, the infratemporal fossa has no floor but is continuous with the space external to the buccinator muscle and buccal space (Figure 31–57).[55] This space contains most of the mandible; pterygoid, masseter, part of the temporalis muscles; deep lobe of the parotid gland; internal maxillary vessels; mandibular and maxillary nerves; and pterygoid plexus of veins.[55–56] The foramen ovale, foramen spinosum, and alveolar canal open into it.[56]

Pterygomaxillary Fissure

Along the superior and medial parts of the infratemporal fossa are two fissures that meet at right angles.

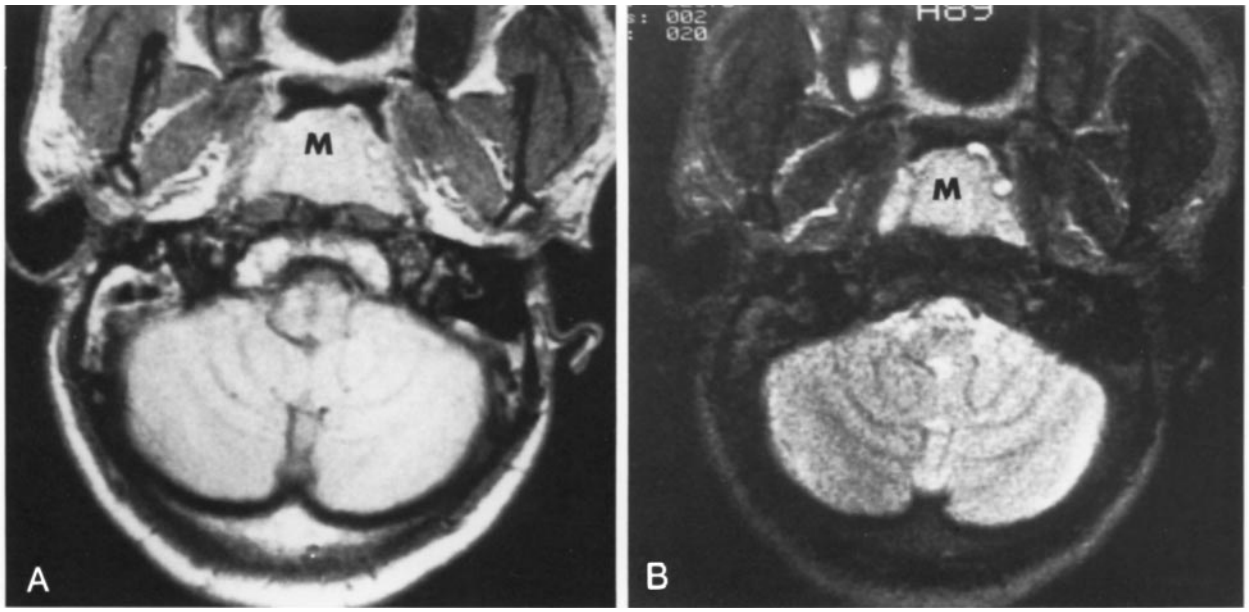

FIGURE 31–56. Scleroma of the nasopharynx. Proton-weighted (*A*) and T_2-weighted (*B*) axial magnetic resonance scans show a mass (M) in the nasopharynx.

The horizontal limb is the inferior orbital fissure, which is shown best in coronal and axial CT sections (see Figure 31–23), and the vertical limb is the pterygomaxillary fissure, which is formed by the divergence of the maxilla from the pterygoid process of the sphenoid and is shown best in sagittal (see Figure 31–16, B) and horizontal (axial) CT and MRI images. The pterygomaxillary fissure connects the infratemporal fossa with the pterygopalatine fossa (see Figure 31–16, B) and transmits the terminal part of the internal maxillary artery and veins.[55,56] The pterygopalatine (sphenomaxillary or sphenopalatine) fossa is a small, pyramidal space at the angle of the junction of the inferior orbital fissure and pterygomaxillary fissure at the apex of the orbit (see Figure 31–16, B). It is bound by the infratemporal (posterior) surface of the maxilla, the vertical plate of the palatine bone, and the base of the pterygoid process (see Figure 31–16, B). It communicates with the nasal cavity by the sphenopalatine foramen, with the infratemporal fossa by the pterygomaxillary fissure, and with the orbit by the inferior orbital fissure. The sphenopalatine foramen transmits the sphenopalatine vessels and the superior nasal

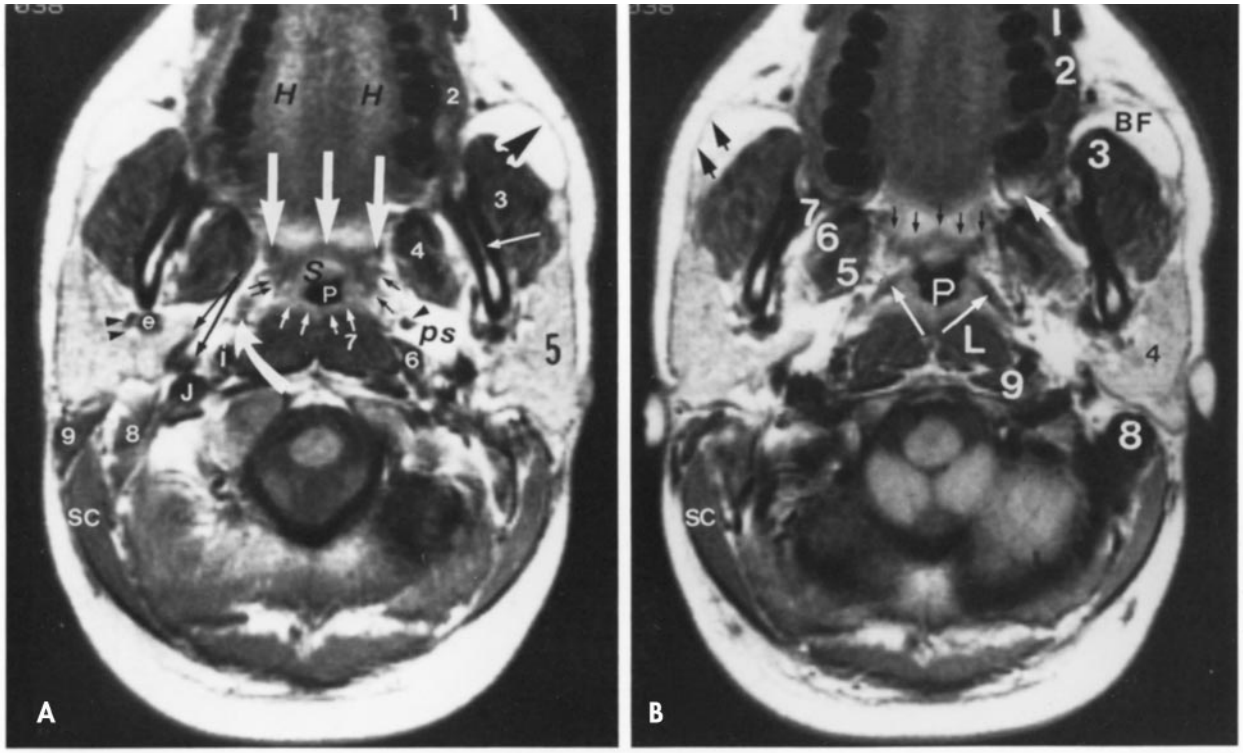

FIGURE 31–57. All magnetic resonance images (*A* to *E*) are proton density 2000/20 of the same normal subject. *A*, This section passes through the lower part of the alveolar process of the maxilla and upper part of the ramus of the mandible (*white arrow*) and shows the following structures: quadratus labii superioris (1), buccinator (2), masseter (3), and internal pterygoid (4) muscles; parotid gland (5); rectus capitis anterior (6), longus capitis (7), rectus capitis lateralis (8), digastric (9), splenius capitis (sc), and superior constrictor (*small white and black arrows*) muscles; pharynx (P); soft palate (S); parapharyngeal space (ps); pharyngeal vein (*black arrowhead*); retromandibular vein (*black arrowheads*); external (e) and internal (I) carotid arteries; internal jugular vein (J); pharyngopalatinus muscle (*large white arrows*); hard palate (H); and platysma muscle (*white and black arrowheads*). Note part of the levator veli palatini muscle (*curved white arrow*). *B*, This section is 3 mm superior to *A* and passes through the midportion of the alveolar process of the maxilla, upper end of the coronoid process of the mandible, and mastoid portion of the temporal bone (8). The following structures are seen: quadratus labii superioris (1), buccinator (2), and masseter (3) muscles; parotid gland (4); medial (5) and lateral (6) pterygoid and temporalis (7) muscles; mastoid process (8); rectus capitis anterior (9), longus capitis (L), splenius capitis (sc), levator veli palatini (*white arrows*), and pharyngopalatinus (*small black arrows*) muscles; nasopharynx (P); buccopharyngeal space (*white arrow*); buccal fat (BF); and platysma muscle (*black arrows*).

Continued on next page

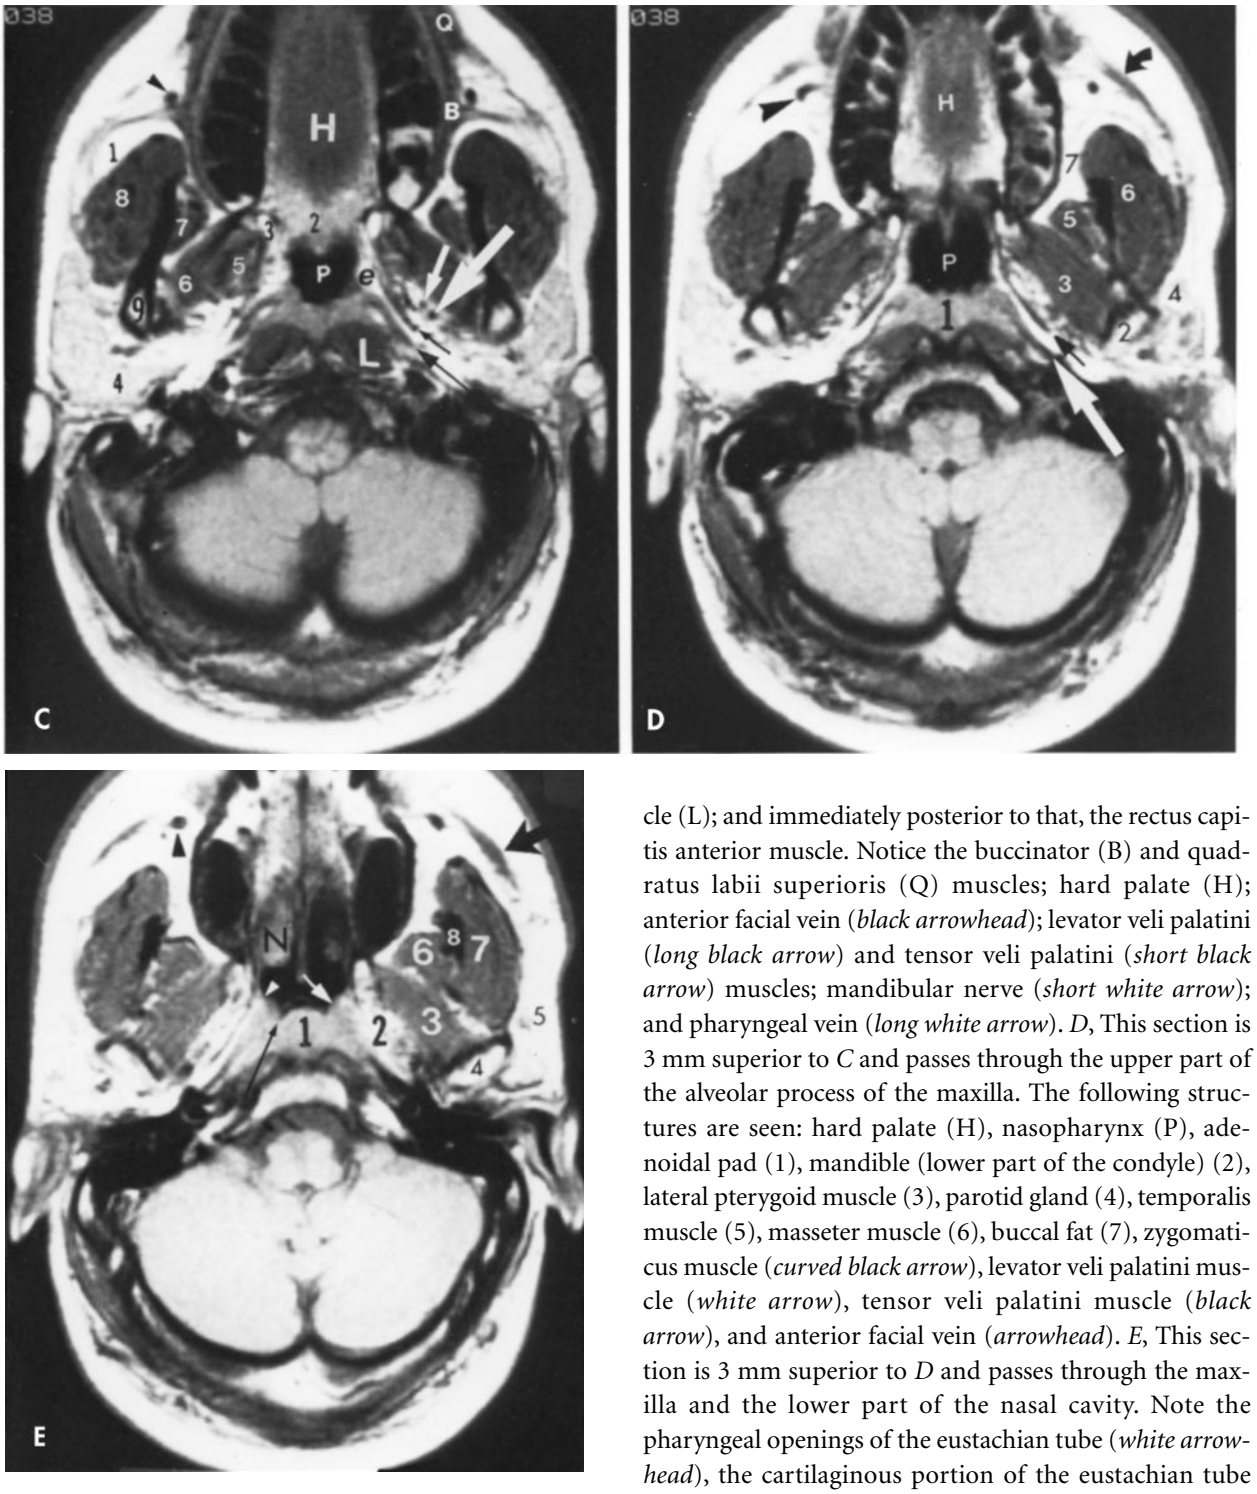

FIGURE 31–57 continued. *C*, This section is 3 mm superior to *B* and passes through the upper part of the alveolar process of the maxilla and upper part of the mandibular ramus. The following structures are seen: buccal fat (1); soft palate (2); parapharyngeal fat (3); parotid gland (4); medial (5) and lateral (6) pterygoid, temporalis (7), and masseter (8) muscles; mandible (9); eustachian tube (e); nasopharynx (P); longus capitis muscle (L); and immediately posterior to that, the rectus capitis anterior muscle. Notice the buccinator (B) and quadratus labii superioris (Q) muscles; hard palate (H); anterior facial vein (*black arrowhead*); levator veli palatini (*long black arrow*) and tensor veli palatini (*short black arrow*) muscles; mandibular nerve (*short white arrow*); and pharyngeal vein (*long white arrow*). *D*, This section is 3 mm superior to *C* and passes through the upper part of the alveolar process of the maxilla. The following structures are seen: hard palate (H), nasopharynx (P), adenoidal pad (1), mandible (lower part of the condyle) (2), lateral pterygoid muscle (3), parotid gland (4), temporalis muscle (5), masseter muscle (6), buccal fat (7), zygomaticus muscle (*curved black arrow*), levator veli palatini muscle (*white arrow*), tensor veli palatini muscle (*black arrow*), and anterior facial vein (*arrowhead*). *E*, This section is 3 mm superior to *D* and passes through the maxilla and the lower part of the nasal cavity. Note the pharyngeal openings of the eustachian tube (*white arrowhead*), the cartilaginous portion of the eustachian tube (torus tubarius) (*white arrow*), the pharyngeal recess or Rosenmüller's fossa (*long black arrow*), adenoidal pad (1), parapharyngeal space (2), lateral pterygoid muscle (3), mandible (condyle) (4), parotid gland (5), temporalis muscle (6), masseter muscle (7), coronoid process (8), zygomaticus muscle (*short black arrow*), anterior facial vein (*black arrowhead*), and nasal turbinate (N). Reproduced with permission from Mafee MF et al.[5]

and nasopalatine nerves. Five foramina open into the pterygopalatine fossa, including the foramen rotundum, pterygoid (vidian) canal, and sphenopalatine foramen, which, in turn, lead to the pterygopalatine canal (see Figures 31–16, B, and 31–23). The fourth foramen, the pharyngeal canal, which transmits the pharyngeal nerve and artery, is a potential communication between the nasopharynx and the fossa. The fifth foramen, the pterygopalatine canal, is placed inferiorly at the junction of the anterior and posterior walls and leads into the greater palatine canal. The pterygopalatine canal transmits the palatine vessels and nerves, serving as a potential communication with the oral cavity. The fossa contains the maxillary nerve, pterygopalatine ganglion, and terminal part of the internal maxillary artery.[55,56] Many of the superficial and deep muscles of the face are imaged on CT and MRI scans at the level of the infratemporal fossa and nasopharynx (see Figures 31–47 and 31–48). The lateral pterygoid muscle is a short, thick muscle, somewhat conical in shape, which extends almost horizontally between the infratemporal fossa and the condyle of the mandible (see Figure 31–47). It has its origins in the lateral surface of the lateral pterygoid plate and lateral surface of the greater wing of the sphenoid bone and inserts into the articular disk of the temporomandibular joint and the condyle of the mandible (see Figures 31–47 and 31–48).[55,56] The main mass of the medial pterygoid muscle lies deep and inferior to the lateral pterygoid muscle (see Figures 31–47 and 31–48) and arises from the medial surface of the lateral pterygoid plate, palatine bone, and maxilla and inserts into the angle and ramus of the mandible (see Figure 31–48).[55,56] In axial CT and MRI sections taken at the level of the low nasopharynx and soft palate, the medial pterygoid muscle occupies a position on the inside of the ramus of the mandible, similar to that of the masseter on the outside (see Figure 31–57). Both pterygoid muscles can be visualized in a coronal section taken at the level of the infratemporal fossa (see Figure 31–48, B). The masseter is a thick, somewhat quadrilateral muscle that arises from the zygomatic process of the maxilla and the zygomatic arch and inserts into the angle and lateral surface of the ramus and the lateral surface of the coronoid process of the mandible.[55,56] In axial and coronal sections, the masseter is seen as a thick, somewhat quadrilateral muscle, anterior and inferior to the parotid gland, occupying a position on the outside of the ramus of the mandible (see Figures 31–47, 31–48, and 31–57). The temporalis is a broad, radiating muscle, arising from the whole of the temporal fossa.[55,56] It passes inferiorly deep to the zygomatic arch and inserts into the medial surface, apex and anterior border of the coronoid process, and anterior aspect of the ramus of the mandible (see Figures 31–48 and 31–57).[55,56] The temporalis muscle is seen anterolateral to the lateral pterygoid muscle and pterygoid process as it inserts on the coronoid process. Symmetric, low-density, fascial-fatty planes are seen on CT scans between the lateral pterygoid and infratemporal muscles. They are continuous with the symmetric fat pad just anterior to the infratemporal muscles and posterior to the posterior wall of the maxillary sinus. Obliteration of these fascial-fatty planes is usually indicative of extension of a neoplastic or inflammatory process into them (Figure 31–58).

Parapharyngeal Space

The PPS is an irregular, predominantly fat-filled space within the suprahyoid neck (see Figures 31–47, 31–48, and 31–57). Various synonyms for PPS have been used, including lateral PPS, pharyngomasticatory space, pterygopharyngeal space, and pharyngomaxillary space. The PPS is subdivided into the prestyloid and retrostyloid compartments. Fascia that extends from the styloid process to the tensor veli palatini muscle crosses posteriorly in the PPS fat and separates the PPS into those two spaces. The carotid sheath is considered anatomically to be the posterior compartment of the PPS. Infection and both benign and malignant tumors of the infratemporal fossa (Figure 31–58) and PPS are manifested by obliteration or distortion of the normal soft tissue planes and/or by a mass effect.[56,57] Tumors and inflammatory processes in these areas are difficult to assess clinically (Figures 31–59, 31–60, and 31–61). However, they are identified readily by MRI and CT. Tumors of the PPS are rare, accounting for only 0.5% of head and neck neoplasms.[55] Neuromas of the vagus, trigeminal, sympathetic chain (Figures 31–62 and 31–63, A) and hypoglossal nerves and neurofibromas that arise within the PPS present as rounded masses bulging into the nasopharynx.[55,56] The benign nature of the tumor is often predicted by an evaluation of CT and MRI scans, which show mass effect but not obliteration or invasion of the fascial planes (see Figure 31–59). Eighty percent of PPS tumors are benign, and 20% are malignant. The most common

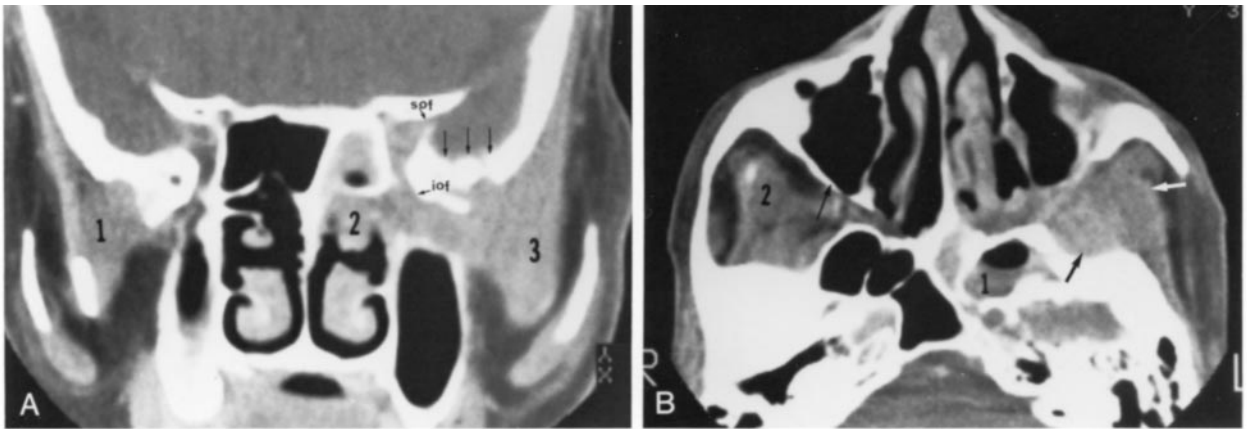

FIGURE 31–58. *A*, Mucormycosis. Semicoronal computed tomographic (CT) scan showing a soft tissue density in the left nasal cavity (2) and left sphenoid sinus, with bone destruction along the superior aspect of the lateral wall of the left nasal cavity and soft tissue infiltration along the inferior orbital fissure (iof) and into the apex of the left orbit along the superior orbital fissure (sof) (compare with the density of the right inferior and superior orbital fissures). There is also involvement of the left infratemporal fossa (3) with an irregularity of the bone of the left middle cranial fossa (*arrows*) caused by osteomyelitis. *B*, Mucormycosis. Postcontrast axial CT scan of the same patient in *A* showing soft tissue density in the left sphenoid sinus (1) and left nasal cavity, with extension into the left infratemporal fossa causing obliteration of the deep fascial plane (*white and black arrows*). Compare with the normal right infratemporal fossa (2). Note also involvement of the posterior portion of the left maxillary sinus as compared with the right side (*arrow*).

primary tumors are salivary gland neoplasms that originate from the deep lobe of the parotid gland or from ectopic minor salivary gland tissue. These tumors are located in the prestyloid PPS. On CT and MRI, these tumors displace the internal carotid artery posteriorly (Figures 31–59, 31–60, and 31–61). Neurogenic tumors and paragangliomas are the most common tumors of poststyloid PPS. Unlike prestyloid PPS masses, these retrostyloid PPS masses result in displacement of the internal carotid artery anteriorly (Figures 31–62, 31–63, and 31–64). Tumors of the mandible are usually confined to the bone; however, extension deep into the adjacent infratemporal fossa may occur. Extension of the nasal, maxillary,

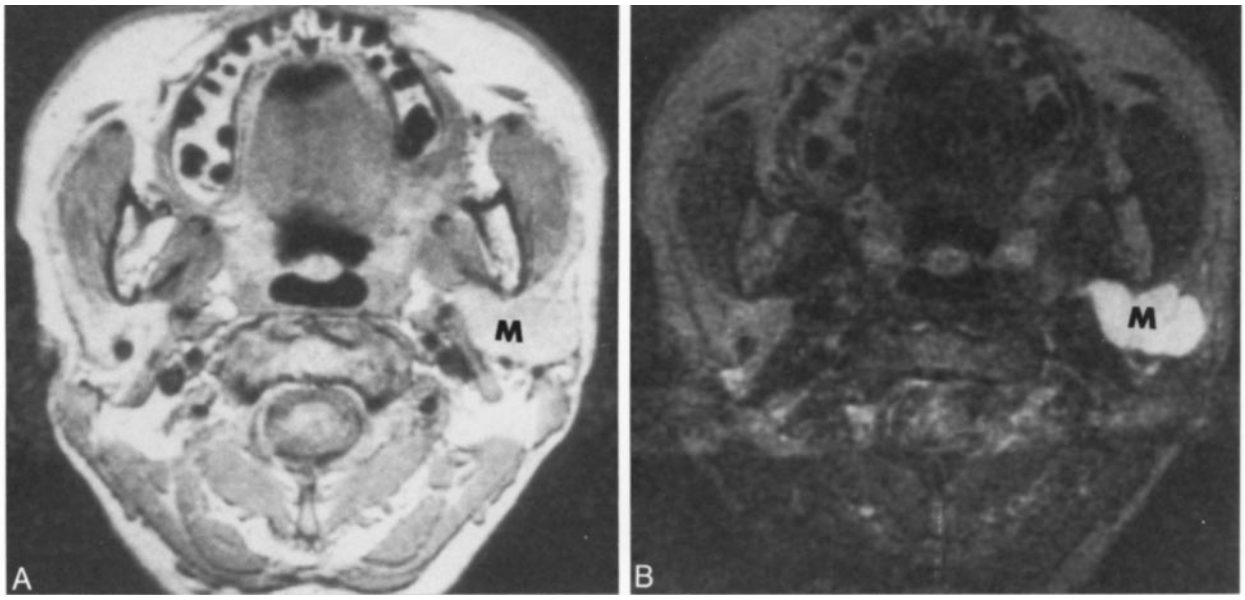

FIGURE 31–59. Pleomorphic adenoma. Proton-weighted (*A*) and T_2-weighted (*B*) axial magnetic resonance scans show a well-defined mass (M) involving the left parotid gland.

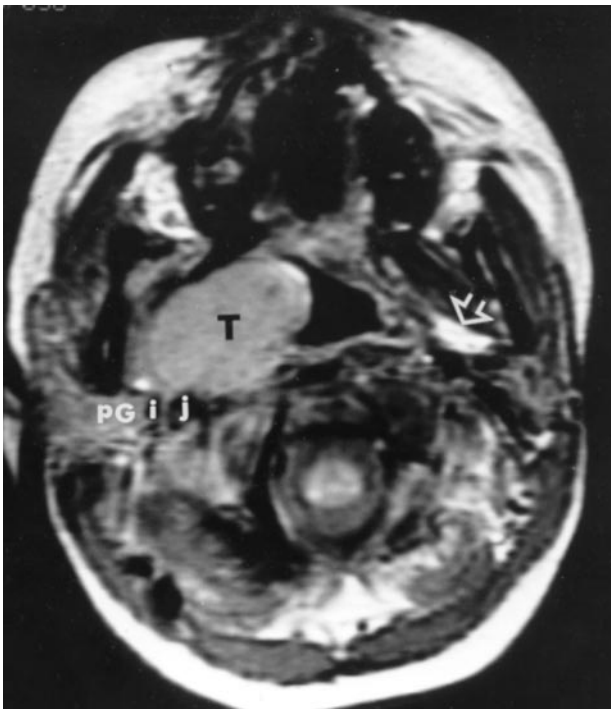

FIGURE 31–60. Parapharyngeal adenocarcinoma. Proton-weighted axial magnetic resonance scan shows a large tumor (T) involving the right parapharyngeal space. Notice the normal left parapharyngeal space (*arrow*). i = internal carotid artery; j = internal jugular vein; PG = parotid gland.

ethmoid, and sphenoidal lesions into the infratemporal fossa and the pterygopalatine fossa can be delineated clearly by MRI and CT scans.

Carotid Sheath The carotid sheath, forming a tubular investment for the carotid artery, internal jugular vein, and vagus nerve, is within the retrostyloid PPS,[55,56] abutting but separated from the infratemporal fossa by the "styloid diaphragm," an aponeurotic sheet of the pharyngobasilar fascia passing from the pharyngeal wall to the styloid process and its muscles.[55] Intravenous iodine-contrast material is given to define the internal carotid artery and internal jugular vein from the density of cranial nerves IX to XII, the sympathetic trunk, normal lymph nodes, and the density of three muscles arising on the styloid process (ie, stylohyoideus, stylopharyngeus, and styloglossus) (see Figure 31–48, A).

Tumors of the carotid space are often neurogenic or paraganglionic in nature (see Figure 31–61). Invasion of the carotid artery by metastatic nodal disease can be demonstrated by CT and MRI. Both techniques may not be reliable for carotid artery invasion, particularly if the artery is not completely surrounded by invading tumor.

Base of the Skull

The base of the skull is an anatomic region that can be best evaluated using CT. The combination of CT and MRI provides maximum information concerning hard tissue and soft tissue structures. Part of the anatomy of the base of the skull has been reviewed in the sections on the nasal and paranasal cavities. Many of the important structures of the skull base are illustrated in Figures 31–16 and 31–21 to 31–23. The unique ability of CT to image both bone and soft tissue structures with excellent tissue-contrast discrimination (resolution) makes it ideal to study the base of the skull and temporal bones. Both CT and MRI provide an accurate assessment of the total extent of disease and precise identification of intraorbital or intracranial extension of the tumor or inflammatory process. Computed tomography is superior to MRI for a detailed bony process (see Figures 31–16 and 31–23), and MRI is superior to CT for a detailed soft tissue process. In many instances, they are complementary to each other. Use of the

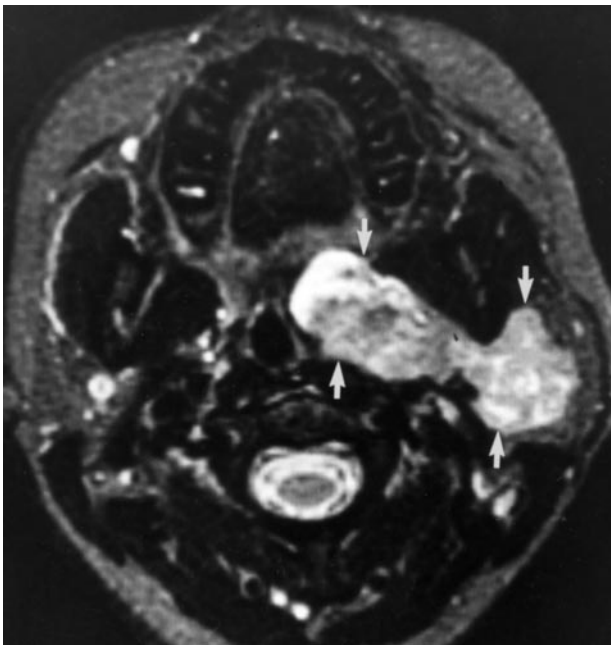

FIGURE 31–61. Malignant tumor of the parotid gland. T_2-weighted axial magnetic resonance scan shows a large mass involving the deep lobe of the left parotid gland, extending into the parapharyngeal space (*arrows*). This was reported as being compatible with liposarcoma.

extended-bone CT range (scale) high-resolution scan is a major imaging advantage and provides the best diagnostic bone detail available to date (see Figures 31–16 and 31–21 to 31–23).

Applications of Magnetic Resonance Imaging and Computed Tomography in Pathologic Conditions of the Skull Base

With MRI and CT, the diagnosis and management of patients with disease involving the skull base, nasopharynx, and head and neck lesions have been advanced significantly.[55–60] Primary and secondary tumors of the base of the skull cause expansion, destruction, or sclerotic reaction of the bones of the skull base. The base of the skull is an anatomic region where a variety of congenital, inflammatory, neoplastic, and traumatic lesions may develop. Computed tomography and MRI are the most sensitive methods of detecting various lesions of the skull base (Figure 31–65). In general, skull base lesions can be divided into three categories: (1) intracranial lesions that involve the skull base; (2) primary or secondary osseous lesions, as well as fractures; and (3) extracranial lesions that involve the skull base. The intracranial lesions that affect the skull base may result from congenital anomalies (see Figure 31–4, A); developmental inclusion cysts (epidermal, dermoid) (Figure 31–66); craniopharyngiomas; neuronteric cysts, neoplasms such as meningiomas, chordomas, aggressive pituitary adenomas, and neuromas (Figure 31–67); and vascular lesions such as aneurysms. Intra-axial lesions of the

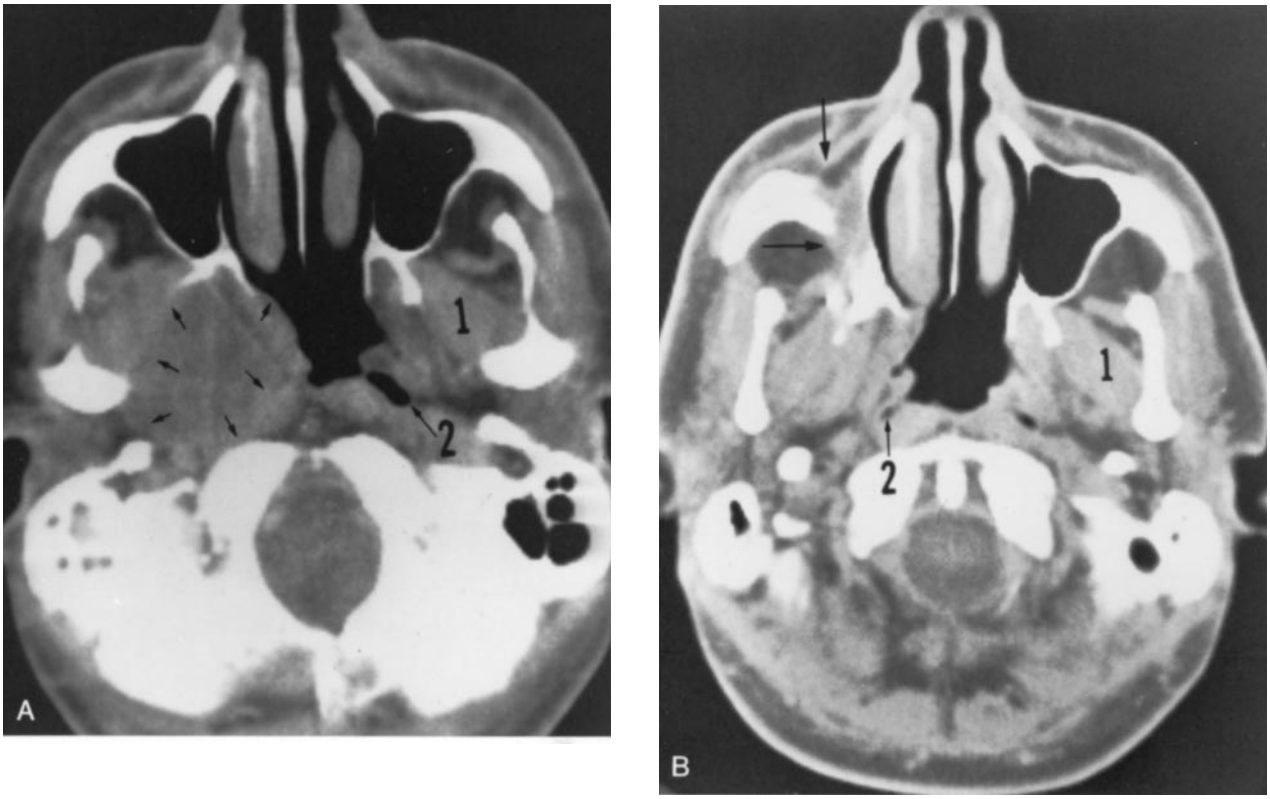

FIGURE 31–62. *A*, Paranasopharyngeal neurofibroma. Axial computed tomographic (CT) scan in a patient with a 12-year history of recurrent right serous otitis media showing a large, smoothly marginated mass (*arrows*) in the right parapharyngeal region that is protruding into the nasopharynx. Note the normal Rosenmüller's fossa on the left (2) and its obliteration on the right. Note also expansion of the pterygoid fossa without bone destruction as well as distortion of the right pterygoid muscle, all of which indicate the benign and slow-growing nature of the lesion. 1 = left lateral pterygoid muscle. *B*, Parapharyngeal neurofibroma. Axial CT scan of the same patient in *A* following extended transantral removal of the right parapharyngeal tumor. The superficial landmarks of the right side of the nasopharynx (effaced in *A*) are symmetric with those on the left and appear normal in this CT scan. Notice extension of air in the right Rosenmüller's fossa (2) and right eustachian tube and the symmetric appearance of lateral pterygoid muscles (1) and parapharyngeal spaces. Note postsurgical changes of the maxillary sinus (*arrow*).

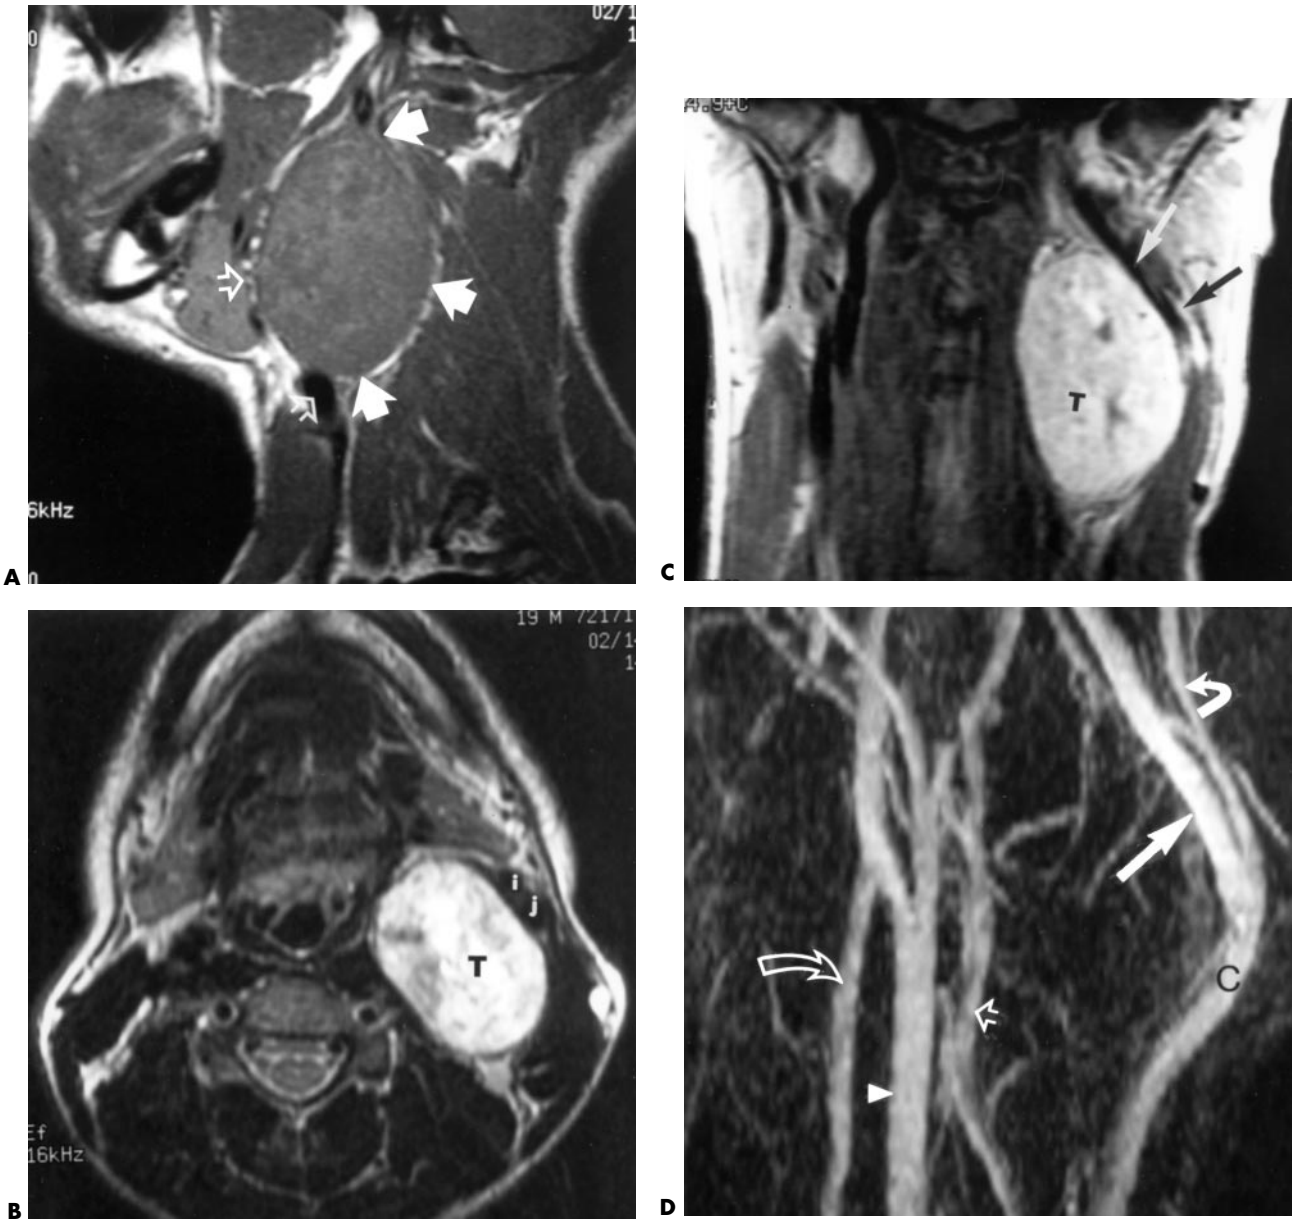

FIGURE 31–63. *A*, Parapharyngeal schwannoma. T_1-weighted sagittal magnetic resonance scan shows a large mass (*large arrows*), resulting in anterior displacement of the internal carotid artery (*hollow arrows*). *B*, T_2-weighted axial magnetic resonance (MR) scan of the same patient in *A* shows marked hyperintensity of the tumor (T). i = internal carotid artery; j = internal jugular vein. *C*, Coronal MR scan of the same patient in *A* and *B* shows the tumor (T) and laterally displaced carotid artery (*arrows*). *D*, Two-dimensional time-of-flight magnetic resonance angiogram showing laterally displaced common (C), internal (*straight arrow*), and external (*curved arrow*) carotid arteries. Note the left vertebral artery (*hollow arrow*), right common carotid artery (*arrowhead*), and right vertebral artery (*curved hollow arrow*).

brain do not affect the skull base. Primary osseous lesions of the skull base include congenital cholesteatoma (epidermoid) (see Figure 31–66), cholesterol granuloma (hematic cyst) (Figure 31–68), osteoma, osteoid osteoma, osteoblastoma, osteoclastoma (giant cell tumor), intraosseous hemangioma, fibrous dysplasia, chordoma, chondroma, chondromyxoid tumor chondrosarcoma, osteogenic sarcoma, lymphoma including plasmacytoma, Langerhans' histiocytosis, hemangiopericytoma, aggressive fibromatosis, and metastasis. Metastatic lesions are most commonly from primary tumors of the lung, breast, prostate, thyroid, and kidney; leukemia; and neuroblastoma (children).

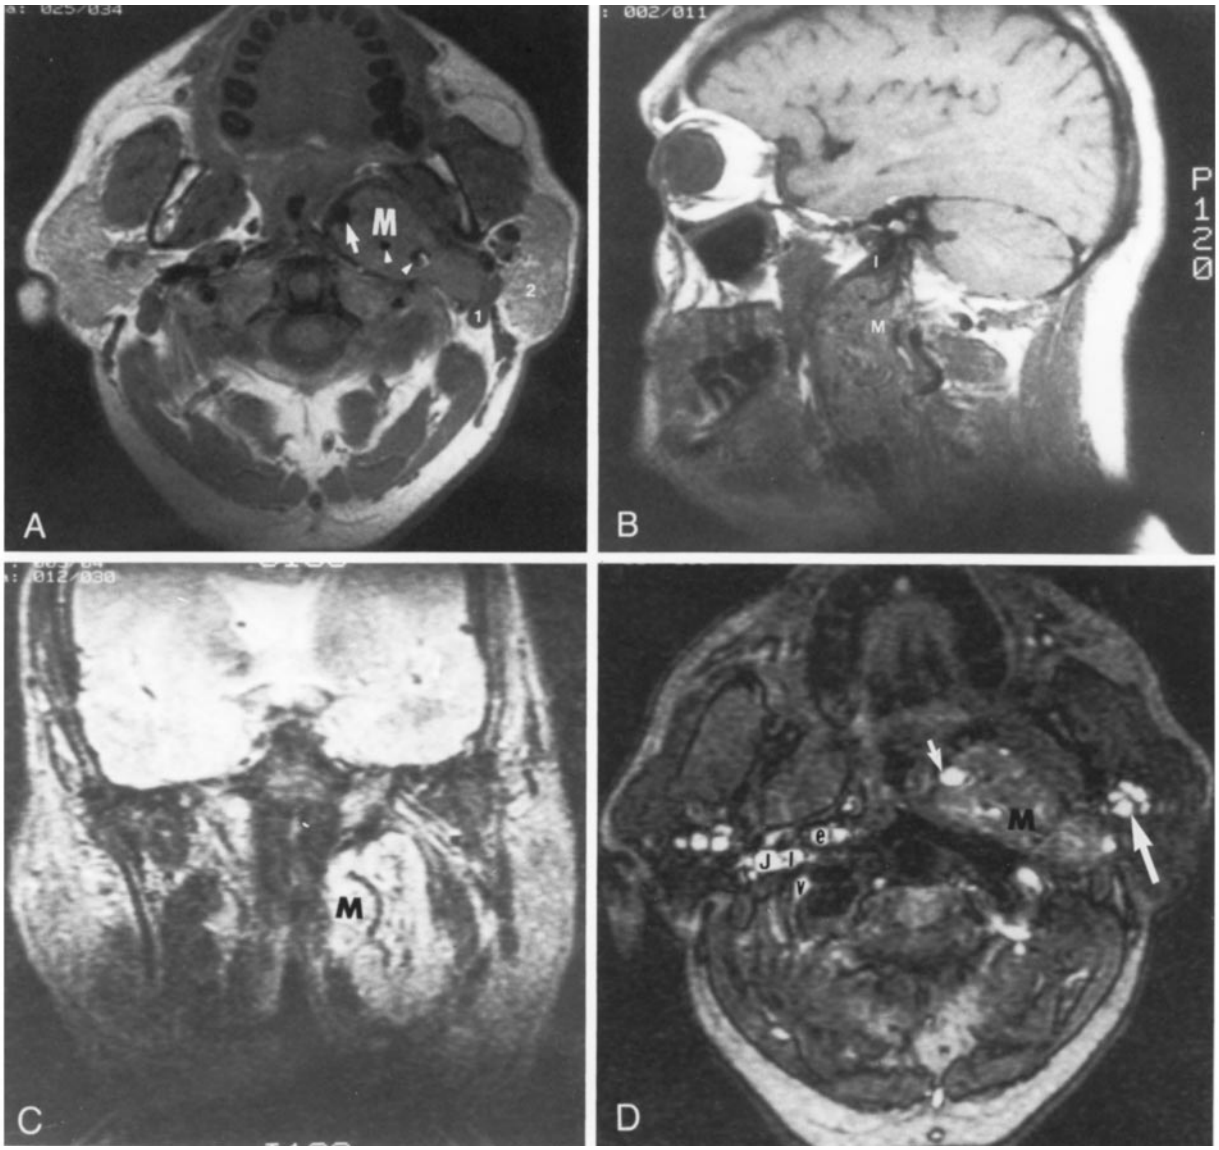

FIGURE 31–64. Carotid body tumor. *A*, Proton-weighted axial magnetic resonance (MR) scan shows a large mass (M) displacing the internal carotid artery (*arrow*) toward the parapharyngeal space. Note prominent vessels within the mass (*arrowheads*). 1 = posterior belly of the digastric muscle; 2 = parotid gland. *B*, Sagittal T_1-weighted MR scan showing the carotid body tumor mass (M). Note marked anterior displacement of the internal carotid artery (I) and serpiginous low-density vascular structures within the mass. *C*, T_2-weighted coronal MR scan showing a hyperintense mass (M) with several tortuous low-density images representing prominent vessels within the mass. The location of the mass as seen in sagittal and coronal MR scans is high, raising the possibility of a glomus vagale rather than a carotid body tumor. *D*, A dynamic GRASS (gradient-recalled acquisition in the steady state) axial MR image showing the tumor (M). Note the hyperintensity of the arteries and veins in this section. e = external carotid artery; I = internal carotid artery; J = internal jugular vein; v = vertebral artery. Note the retromandibular veins (*large arrow*) and displaced left internal carotid artery (*small arrow*). Reproduced with permission from Mafee MF et al.[5]

The extracranial lesions commonly affecting the skull base include carcinoma of the nasopharynx; tumors and infections of the sinonasal cavities (see Figure 31–40); necrotizing otitis externa, glomus complex tumors, and carcinoma of the temporal bone (Figure 31–69); hemangiopericytoma; juvenile angiofibroma; neurogenic tumors; and metastatic retropharyngeal and skull base nodal deposits.

Tumors and inflammatory lesions of the paranasal sinuses, orbits, or nasal cavities, which

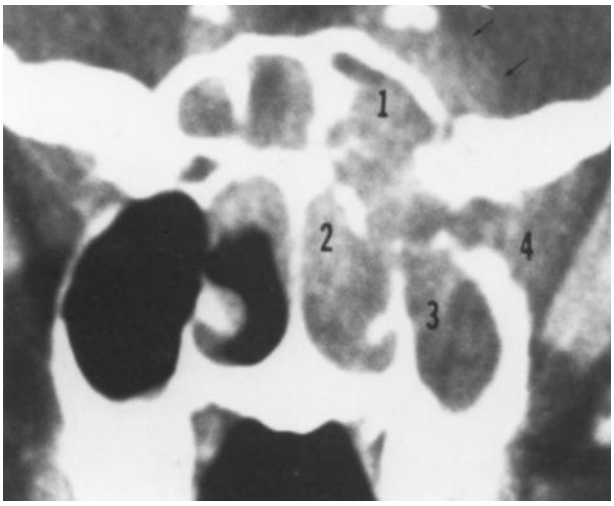

FIGURE 31–65. Nasopharyngeal carcinoma. Postcontrast semicoronal computed tomographic scan of the nasopharynx showing a large nasopharyngeal tumor (2) with extension into the sphenoid sinus (1), maxillary sinus (3), and infratemporal fossa (4). There is also tumor extension into the apex of the orbit and along the cavernous sinus. Note extensive irregular bone destruction of the floor of the sphenoid sinus.

may involve the skull base, include mucoceles (see Figure 31–37), carcinoma (see Figure 31–41), esthesioneuroblastoma (see Figure 31–41), lacrimal gland tumors (adenoid cystic carcinoma), rhabdomyosarcoma (see Figure 31–41), lymphoma, Wegener's granulomatosis, and Langerhans' histiocytosis. In adults, the most common lesion of the sinuses that invades the skull base is squamous cell carcinoma. In younger age groups, lymphoma is more common. In patients with diabetes and those who are immunocompromised, opportunistic fungus infections, such as mucormycosis and aspergillosis, involve the sinonasal cavities and rapidly invade the skull base (see Figure 31–58). Rhinocerebral mucormycosis is a well-recognized disorder in patients with diabetic ketoacidosis, but about half of the patients with diabetes who have this infection do not have ketoacidosis. The infection can be acute, subacute, or chronic. *Aspergillus* species are the most common cause of chronic fungal sinusitis. Involvement of the sphenoid sinus may extend to adjacent structures such as the orbit, cavernous sinuses, and temporal lobe, either directly or by retrograde phlebitis, with relative sparing of bone.

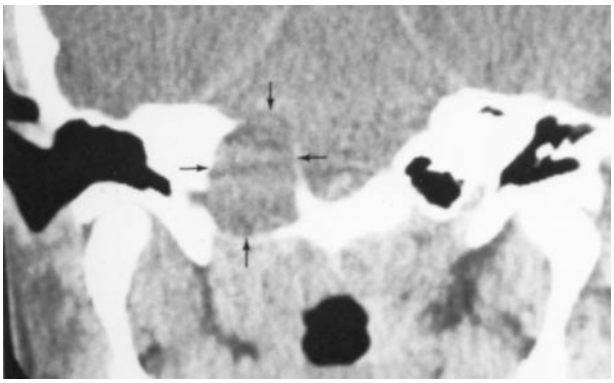

FIGURE 31–66. Primary cholesteatoma (epidermoid cyst). Contrast-enhanced coronal computed tomographic scan showing a nonenhanced low-density image in the region of the right petrous apex (*arrows*). Note moderate enhancement only in the peripheral portion (capsule) of the lesion. Lack of enhancement, relatively low density, its expansile nature, and smooth border of destroyed bone are almost characteristic of an epidermoid cyst. Reproduced with permission from Mafee MF et al.[58]

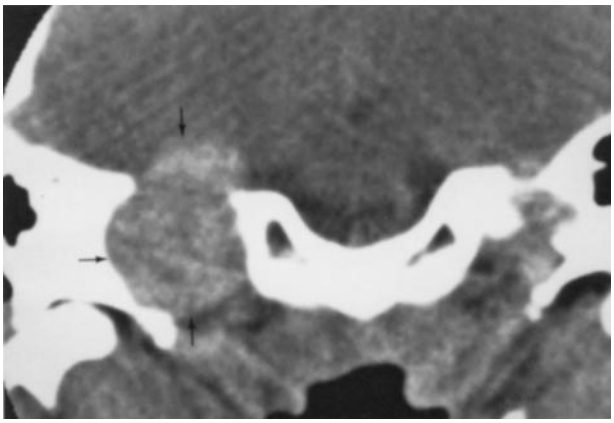

FIGURE 31–67. Schwannoma of the jugular fossa. Contrast-enhanced coronal computed tomographic scan showing a moderately enhanced soft tissue mass in the region of the right enlarged and eroded jugular fossa (*arrows*). The extra- and intracranial components of the tumor are clearly visualized. Note the smooth border of the destroyed bone similar to that in Figure 31–66, which is indicative of the slow-growing nature of the lesion as opposed to irregular bone destruction seen with the malignant process in Figure 31–70. Reproduced with permission from Mafee MF et al.[58]

Benign lesions such as primary cholesteatoma (see Figure 31–66) and cholesterol granuloma (see Figure 31–68) involving the base of the skull demonstrate characteristic bone expansion, with CT showing a low-density image (because of desquamated debris and cholesterol content) and no enhancement after intravenous injection of iodinated contrast

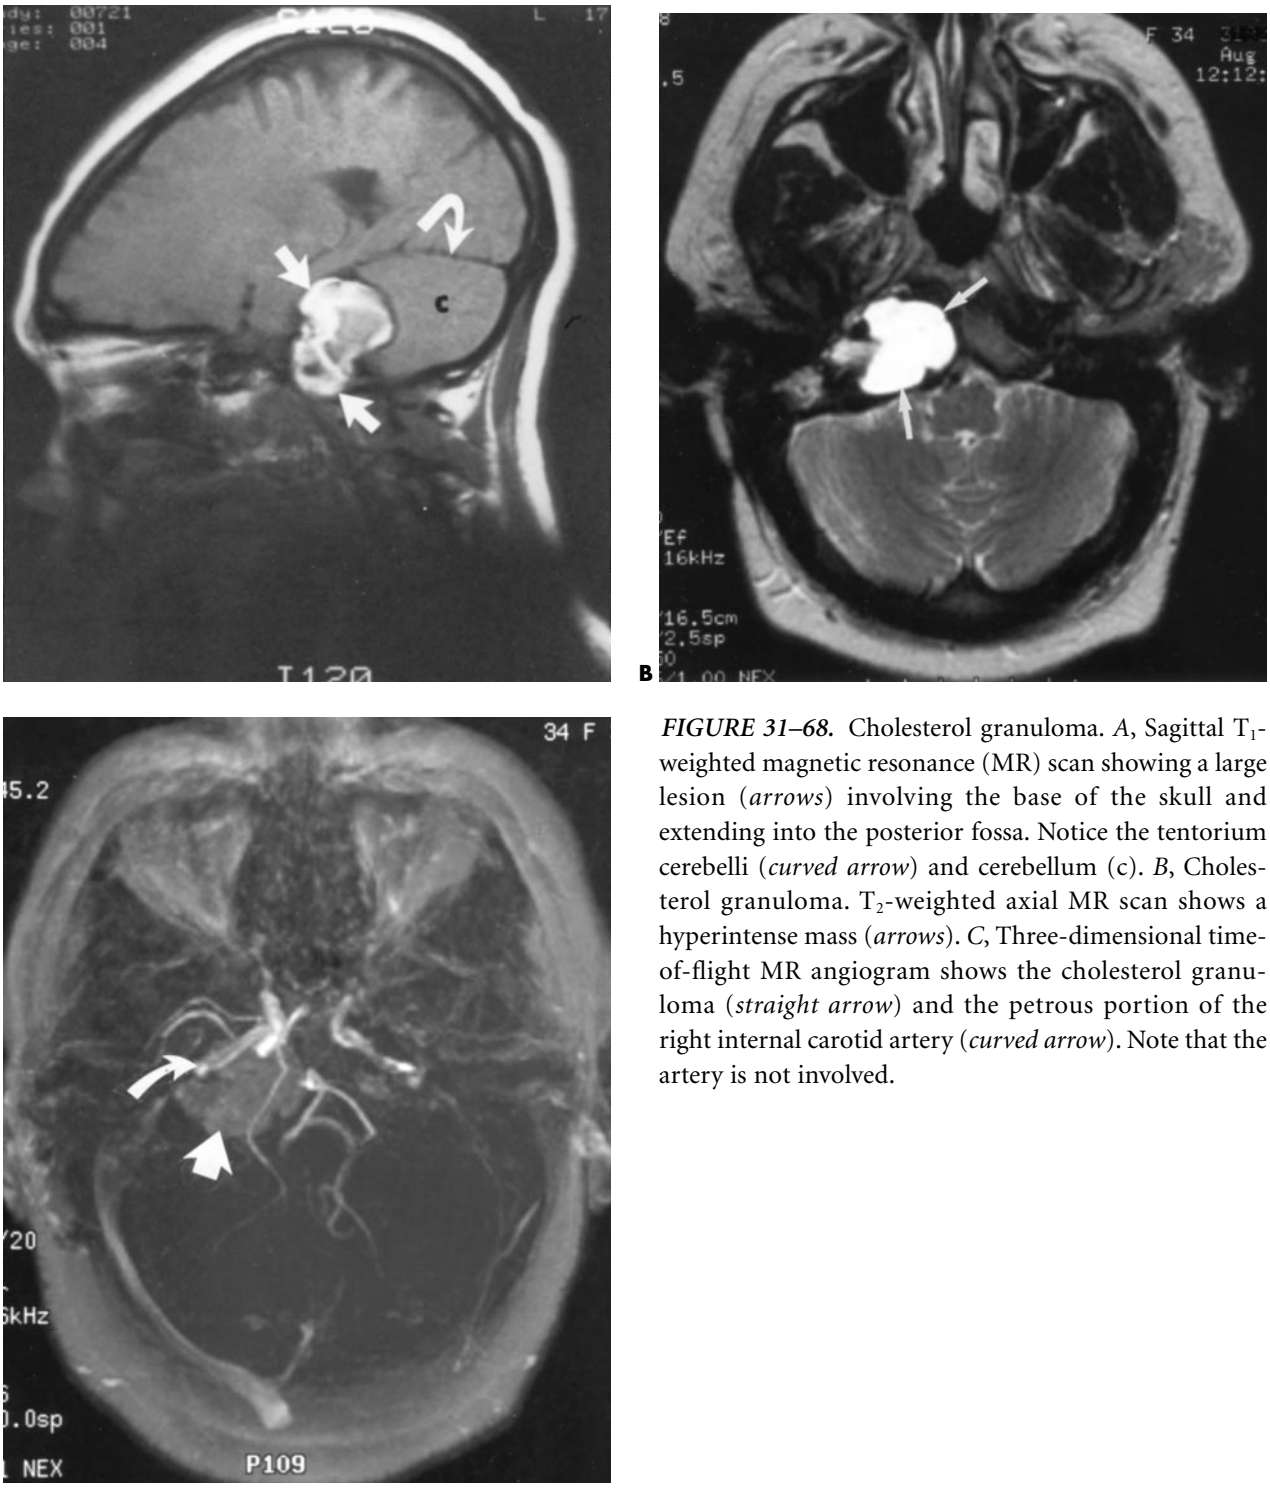

FIGURE 31–68. Cholesterol granuloma. *A*, Sagittal T_1-weighted magnetic resonance (MR) scan showing a large lesion (*arrows*) involving the base of the skull and extending into the posterior fossa. Notice the tentorium cerebelli (*curved arrow*) and cerebellum (c). *B*, Cholesterol granuloma. T_2-weighted axial MR scan shows a hyperintense mass (*arrows*). *C*, Three-dimensional time-of-flight MR angiogram shows the cholesterol granuloma (*straight arrow*) and the petrous portion of the right internal carotid artery (*curved arrow*). Note that the artery is not involved.

medium (see Figure 31–66).[58–60] Although cholesteatomas may not be differentiated from cholesterol granulomas on CT scans, they often can be easily differentiated by MRI. On T_1W images, epidermoid cysts (cholesteatomas) are seen as a hypointense or isointense image relative to brain and appear hyperintense to brain on T_2W MR images. Cholesterol granulomas, however, appear as a hyperintense image on both T_1W and T_2W MR scans (see Figure 31–68, B). Cholesterol granulomas may be homogeneous or heterogeneous. The heterogeneity of signal is usually owing to hemosiderin debris.[60] Primary

FIGURE 31–69 continued. *E*, Postembolization angiogram of the same patient in *D* shows decreased vascularity of the tumor bed.

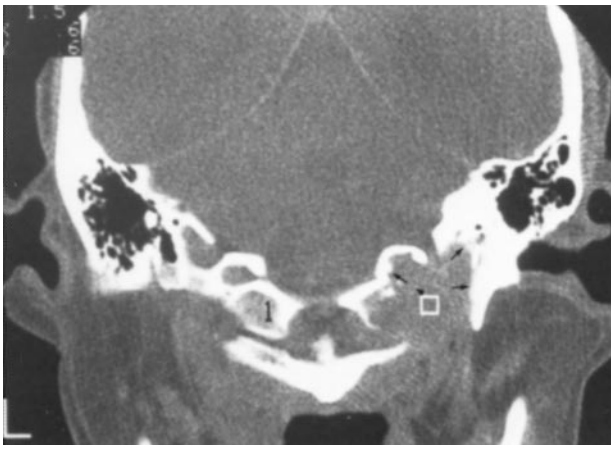

FIGURE 31–70. Liposarcoma of the base of the skull. Contrast-enhanced coronal computed tomographic scan showing extensive bone destruction of the right jugular fossa and occipital condyle (*arrows*). Note erosion of the right occipital condyle as compared with the left one (1).

cholesteatoma (epidermoid) can be differentiated from arachnoid cysts using FLAIR or diffusion-weighted (DW) MR pulse sequence. Cholesteatomas appear hypertense on FLAIR and DW MR images, whereas arachnoid cysts appear hypointense. Unlike cholesteatomas and cholesterol granulomas, lesions such as jugular fossa schwannoma and glomus jugulare tumors, beside causing bone destruction, will demonstrate moderate to marked enhancement after intravenous infusion of contrast medium (see Figure 31–69). On T_1W MR scans, schwannomas are seen as a hypointense image to brain and become hyperintense on T_2W MR scans. Glomus tumors also have a similar MR appearance; however, they usually show signal void (dark) areas because of their increased vascularity. The intracranial extension of a base of the skull lesion is best demonstrated on postcontrast-enhanced MRI. Destruction of the jugular fossa and hypoglossal canal is demonstrated in Figure 31–70 in a patient with liposarcoma of the base of the skull who presented with twelfth nerve palsy. The same appearance may be present on CT of a patient with metastatic carcinoma or lymphoma, including multiple myeloma. As far as the glomus complex tumors are concerned, CT reveals the bone destruction and total extent of the disease and gives accurate assessment of middle ear, intracranial, extracranial, and nasopharyngeal extension.[23,55] Dynamic CT has been valuable in the diagnosis and differentiation of glomus complex tumors from other pathologic entities such as meningioma and metastatic and recurrent neck tumors.[22,55] The MRI features of glomus jugulare tumors and their pre- and postembolization angiographic characteristics are illustrated in Figure 31–71.

Trauma Computed tomography is the modality of choice for fracture of the skull base. The site of the leak in CSF rhinorrhea or otorrhea can be detected most accurately using CT water-soluble contrast cisternography (see Figure 31–46).

FIGURE 31–71. *A*, Coronal computed tomographic scan showing a soft-tissue mass (m) in the region of the right enlarged and eroded jugular fossa. Note extension of the tumor along the carotid sheath down to the level of the soft palate (*curved arrows*). *B*, Coronal T_1-weighted magnetic resonance (MR) scan shows a large mass in the left jugular fossa (*arrows*). *C*, Coronal post–gadolinium-diethylenetriamine pentaacetic acid T_1-weighted MR scan shows marked enhancement of the lesion (*arrows*). *D*, Standard angiogram shows marked vascularity of the tumor (*arrows*). *E*, Postembolization angiogram shows a marked decrease in tumor vascularity. At surgery, the tumor was completely resected, and the patient recovered with no neurologic deficit. (Courtesy of Arvind Kumar, MD, University of Illinois at Chicago Medical Center.)

CHAPTER 32

Allergic Rhinitis

Jayant M. Pinto, MD, Robert M. Naclerio, MD

Allergic rhinitis, the most common of all atopic diseases, is an important public health problem. It affects up to 20% of the adult population in the United States.[1] It is the sixth most prevalent chronic condition in the United States, and its prevalence is increasing.[2] In an otolaryngologist's practice, the prevalence of allergic rhinitis in patients coming to the office exceeds that of the general population and is in the range of 50%. Although it is a benign chronic disease of the upper airway, quality-of-life studies demonstrate that allergic rhinitis causes significant impairment of function, exceeding that of heart disease and asthma.[3,4] In the United States, the public health impact is significant, with approximately $1.5 billion spent annually on office visits and medications. Diminished functional capacity owing to allergic rhinitis alone causes the loss of 3.5 million work days and 2 million school days each year.[5] These numbers are augmented when one considers related disorders such as asthma and sinusitis, which are thought to be affected by allergic rhinitis.

Evidence supporting an increase in the incidence of allergic rhinitis comes from studies of Swedish military conscripts, with skin testing used to document the existence of atopy.[6] The prevalence of allergic rhinitis was 4.4% in this 18-year-old Swedish population in 1971 and increased to 8.1% by 1981. Similar trends have been observed in studies performed in the 1990s.[7,8] The cause of the increasing prevalence of allergic rhinitis is not clear. Because the increase has occurred within a decade, it does not represent a genetic shift in the population. Pollution may play a role by increasing nasal responsiveness to environmental allergens. Common outdoor pollutants include sulfur dioxide (SO_2), nitrogen dioxide (NO_2), and ozone, whereas indoor pollutants include sidestream cigarette smoke. Exposure to high levels of SO_2, NO_2, and ozone leads to bronchial hyperresponsiveness and potentiates the pulmonary response to allergen, perhaps converting asymptomatic to symptomatic asthmatic patients.[9,10] Similarly, skin test–positive subjects who lack clinical symptoms of allergic rhinitis may be converted into symptomatic patients by exposure to environmental pollutants. Another purported role for pollution is that of an adjuvant in the development of immunoglobulin (Ig)E antibodies, which are central to the allergic reactions.[11] Studies in both animals and humans suggest that diesel exhaust particles enhance IgE production by a variety of mechanisms.[12] Evidence against the role of outdoor pollutants comes from a German study comparing the prevalence of rhinitis and asthma in genetically similar populations in a West and an East German city.[13] Despite higher levels of SO_2 and particulate matter in the air in the East German city, the incidence of rhinitis and asthma was considerably lower than in the comparison city in West Germany.

Another potential explanation for the apparent increased prevalence of allergic rhinitis involves the role of indoor allergens. Evaluation of specific IgE antibodies suggests that increased rates of sensitization occur more frequently to common indoor allergens such as dust mites and household pets than to outdoor allergens such as grass pollens. This study suggested that "Western"-style housing with better weatherproofing and decreased ventilation may be increasing the indoor allergen burden, leading to an increased rate of sensitization.[14] In support of this notion is a study of allergen avoidance in children of atopic parents.[15] Compared with a control group, reduction of allergen load in the first 2 years of life led to a lower than expected incidence of allergic rhinitis at the age of 2 years. Indeed, the prevalence in the former East Germany increased sharply during the years after reunification with the former West Germany, suggesting that factors associated with a Western affluent lifestyle may play a role in the development of allergic disease.[8] Although untested, proposed risk factors included

exposure to automobile exhaust, indoor heating and ventilation systems, indoor allergens, smaller family size, and a relatively higher socioeconomic status. Several other determinants have been identified, including breast-feeding, month of birth, and age of entry to day nursery.

Another hypothesis is that a decrease in infections in early childhood may affect the development of atopic diseases. This hypothesis is based on observations that show a higher prevalence of allergic diseases in individuals brought up in smaller and more affluent families, particularly in children and young adults in developed nations. The increase of allergic diseases is associated with certain socioeconomic conditions found in these countries. One common effect of these conditions is the decreasing prevalence of childhood infections that are assumed to have a protective effect for the development of allergy. This decreasing prevalence of early childhood infections can be explained by a lowered risk of exposure to infectious agents early in life as a result of increased immunization, improved sanitary conditions, and smaller family size.[16–25]

A skew in the balance between T-cell subpopulations from (normal) T helper 1 (TH1)-cell responses toward (atopic) TH2-cell responses, including increased production of IgE, may be caused by decreasing exposure to infectious agents. In support of the hygiene theory are studies demonstrating an inverse relationship between the frequency of allergic disorders and childhood infection.[16–18,25] Additional evidence comes from studies in which children attending day care have been shown to develop more infections than those who do not. A study of 1,035 children in Tucson, Arizona, showed that exposure to other children at day care was protective against the development of asthma and frequent wheezing in childhood.[25] Children with more exposure to other children were less likely to have wheezing after age 6 through age 13 years, although they wheezed more in the first 2 years of life. The mechanism of these phenomena is not known. However, signals to the developing immune system provided by infections may cause alterations in the functional responses of lymphocytes.[26] For example, the absence of a driving signal toward a TH1 response may allow the development of TH2 responses, resulting in a more atopic phenotype later in life (Figure 32–1).[26]

Symptoms of allergic rhinitis can begin at any age but are most frequently first reported in adolescence or young adulthood.[27] Rates of prevalence are similar for males and females, and no racial or ethnic variations are reported.[28] The incidence of developing an allergic diathesis is higher in children whose parents suffer from allergic rhinitis. If one parent has allergies, the chances of the child's having rhinitis are 29% and increase to 47% when both parents have the disease.[29] The rate of loss of allergic rhinitis symptoms has been estimated to be about 10%, which occurs in patients with the mildest form of the disease.[30]

A genetic component to allergic diseases, including asthma, allergic rhinitis, and others, has long been suggested. Several investigators have conducted genome-wide screens in a variety of populations in the search for susceptibility genes involved in allergic diseases, primarily asthma.[31–35] These atopic diseases may be linked by common mechanisms.[36] A number of chromosomal regions show evidence for linkage in multiple populations for asthma- and atopy-related phenotypes.[37] Positional cloning efforts are under way in these regions. Heterogeneity of phenotype, gene environment interaction, complexity of molecular mechanisms, an unknown mode of inheritance, and the possibility of small effects of a number of genes have complicated these approaches. To date, no loci have been conclusively identified for association with allergic rhinitis. However, positive associations of certain HLA (human leukocyte–associated antigens, also known as major histocompatibility complex [MHC]; for more information, see Chapter 28) alleles with dust and mite allergens have been reported.[38] This remains an area of intense interest and will likely accelerate with the recent completion of the first draft sequence of the human genome.

Part of the clinical importance of allergic rhinitis lies in its association with complications related to chronic nasal obstruction. Total nasal obstruction, regardless of cause, can result in sleep disturbances. Whether interference with sleep or the effects of systemically released mediators contribute to the fatigue associated with the disease is unknown. Evidence for a systemic role has been outlined.[39] Allergic rhinitis is the third most common cause of hyposmia.[40] Sinusitis often occurs in conjunction with allergic rhinitis. For example, the prevalence of abnormal sinus radiograph studies is greater in

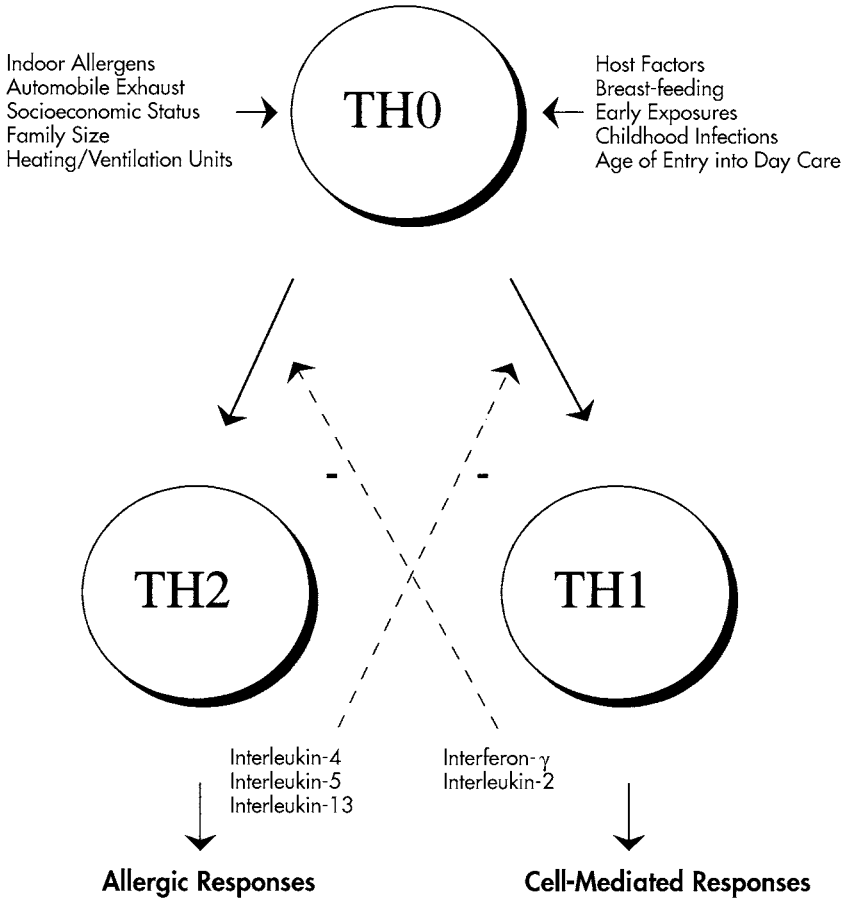

FIGURE 32–1. Current theory on the development of allergy disease. A variety of lines of evidence suggest that fewer respiratory illnesses during early childhood may predispose to later allergic disease. This may be attributable to signals to the developing immune system, driving it toward allergic responses via the TH2 pathway. Other environmental stimuli have been suggested to affect the development of allergic disease; these may similarly alter immune responses with resultant allergic disease, although they remain unproved. Cytokines produced in TH1 and TH2 responses inhibit the expression of the counterpart response. The TH1 pathway is primarily responsible for cell-mediated immunity, whereas the TH2 pathway is important in the production of allergic responses, including the production of immunoglobulin E.

patients with perennial allergic rhinitis compared with those with seasonal disease and approaches 50%.[41] Whether nasal polyps result from allergic rhinitis remains an open question. Settipane and Chafee, in an allergy practice setting, found that 2.1% of patients with allergic rhinitis had nasal polyps.[42] Although this is higher than the 0.3% incidence of nasal polyposis reported for the general population in the 1980 American Health Survey, it is less than the 12.5% incidence noted by Settipane and Chafee in nonallergic asthmatic patients.[42]

The contribution of allergic rhinitis to middle ear disease is debated. Studies by Friedman and colleagues suggest that an induced allergic reaction can cause eustachian tube dysfunction.[43] Moreover, allergic mediators have been found in the middle ear fluid of patients with otitis media with effusion.[44] Expression of TH2 cytokines and inflammatory cells has been documented in the middle ear mucosa of allergic patients.[45] Other data provide less support for a significant role of allergic rhinitis in the pathophysiology of otitis media.[46] Allergic rhinitis occurs in 80% of asthmatic subjects, and 40% of allergic rhinitic patients have asthma, suggesting a close link between the two diseases.

PATHOPHYSIOLOGY

IMMUNOGLOBULIN E

The distinguishing characteristic of allergic rhinitis is the involvement of IgE. In an individual with a susceptibility for developing allergic disease, an initial contact with allergen leads to the production of specific IgE molecules, a process termed sensitization. This begins when macrophages and other antigen-presenting cells process the allergen before presenting it to T-helper cells, which then interact with B lymphocytes, leading to their differentiation into IgE-producing plasma cells, a process involving interleukin (IL)-4 and IL-13 and accessory molecules such as CD40. These newly formed IgE molecules bind to high-affinity receptors principally located on mast cells and basophils and to low-affin-

ity receptors located on eosinophils, monocytes, and platelets. The high-affinity IgE receptors on mast cells mediate the initial allergic response. In the nasal mucosa of allergic subjects, mast cells are usually found within the mucosal connective tissue stroma, in the vicinity of blood vessels and glandular structures.[47] Seasonal exposure increases the number of mast cells located close to the surface in the nasal epithelium without affecting their overall number, suggesting that these cells migrate from the deeper to the more superficial layers of the nasal mucosa during the pollen season.[47] Recent studies demonstrating epsilon germline gene transcripts in biopsy specimens obtained from asymptomatic patients with seasonal allergic rhinitis and exposed to allergen ex vivo suggest that production of IgE may occur, at least in part, locally within the nasal mucosa.[48] This elevates the importance of local targeting of therapeutic interventions.[49]

Early Response

In a sensitized individual, another encounter with the same allergen provokes an immediate (early) allergic reaction. Within seconds of entering the nasal cavity, antigens interact with specific IgE molecules on the surface of mast cells. Cross-linking of two adjacent IgE molecules by antigen initiates a sequence of intracellular events resulting in mast cell degranulation and the subsequent release of preformed and newly generated mediators into the nasal milieu. The preformed mediators are stored within granules in the cytoplasm and include histamine, tryptase, heparin, and chondroitin sulfate. The newly generated mediators are synthesized from the phospholipids of the cell membrane subsequent to mast cell activation. These mediators include platelet activating factor (PAF), prostaglandins (PGs), and leukotrienes. Evidence suggests that mast cells produce ILs by IgE mechanisms, and these, unlike the lipid and granule mediators, require hours to be synthesized and released.[50,51] Released mediators can also initiate extracellular events that generate additional mediators; for example, the generation of kinins depends, in part, on the transudation of precursor proteins, kininogens, from the plasma that increase as a result of the action of histamine on vascular H_1 receptors. Other non–mast cell mediators are also associated with this early response to antigen.

For ascertaining the importance of any mediator in the pathophysiology of allergic rhinitis, three criteria should be satisfied: (1) the mediator should be present during the allergic reaction, (2) instilling the mediator in the nasal cavity should mimic part of the pathophysiology and symptoms of the disease, and (3) a mediator antagonist must partially or totally attenuate disease expression. To establish the importance of different mediators in allergic rhinitis, several investigators have attempted to satisfy one or more of these criteria.

Multiple mediators have been recovered at increased levels in nasal secretions after allergen challenge, and these include histamine,[52] kinins,[53] plasma and glandular kallikrein,[54,55] mast cell tryptase,[56] PGD_2,[53] leukotriene C_4 (LTC_4),[57] leukotriene B_4 (LTB_4),[58] and major basic protein (MBP)[59] (Figure 32–2). Furthermore, several of these mediators have been used to challenge the nasal mucosa and observe resultant responses. Histamine provocation, for example, produces rhinorrhea, congestion, pruritus, and sneezing by stimulating receptors on sensory nerves and blood vessels.[60] Instillation of serotonin produces sneezing,[61] whereas PGD_2[62] and kinins[63] all produce nasal congestion.[64] The other approach to establishing the importance of a mediator involves the use of antagonists; the best example is H_1 antihistamines: the clinical utility of H_1 receptor antagonists serves to demonstrate the importance of this inflammatory mediator.

Whereas mast cell degranulation and the released inflammatory mediators mimic most of the symptoms of allergic disease, the short duration of these events, as opposed to the prolonged symptoms of clinical disease, suggests that additional inflammatory processes are probably important in clinical disease. Furthermore, increased responsiveness and mucosal cellular changes that accompany chronic allergen exposure cannot be explained by this mechanism alone. Many of these phenomena relate to the cellular infiltration that is a hallmark of the inflammatory response.[65]

Late Response

Various techniques of experimental nasal allergen provocation, in addition to being useful for an understanding of the early response, assist investigators in understanding subsequent inflammatory events. Following challenge, there is an increase in

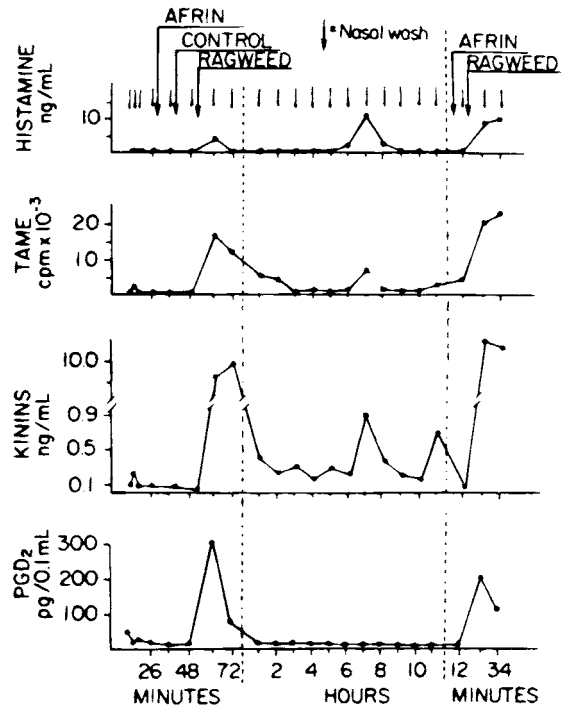

FIGURE 32–2. The nasal response to allergen provocation in allergic subjects challenged with ragweed extract. The abscissa depicts the time after allergen provocation: minutes = time points of the early response, hours = time points of the late response, and minutes (to the right) = time points of the rechallenge response. *Short arrows* at the top of the graph represent nasal lavages, and *long arrows* represent times of administration of different substances into the nasal cavities. There was a rise in all measured mediators during the early reaction. After a quiescent phase, there was a recurrence in elevations in the levels of histamine, tosyl-L-arginine methyl ester (TAME)-esterase, and kinins, but not prostaglandin D_2 (PGD_2) in nasal lavages. During rechallenge, there was an exaggeration of the nasal response to challenge with a dose identical to that used during the early reaction for histamine, TAME-esterase, and kinins. This is an illustration of the priming response, whereby subjects respond more vigorously to a dose of allergen after previous stimulation. Reproduced with permission from Naclerio RM et al.[67]

symptoms and mediator levels characteristic of the early allergic reaction, which soon returns toward baseline. If one continues to monitor the response for several hours, symptoms recur, associated with an elevation of levels of inflammatory mediators in approximately 50% of the patients, the late-phase response (Figure 32–3).[66,67] During the late-phase response, subjects have a recurrence of sneezing, rhinorrhea, and congestion, with congestion predominating.[68] The late reaction is also accompanied by increases of some, but not all, of the inflammatory mediators associated with the early reaction and the presence of mediators not seen in the early response.[66]

As in clinical disease, a striking characteristic of the late-phase response is cellular inflammation. One sees an increase in basophils, eosinophils, neutrophils, and mononuclear inflammatory cells in nasal secretions, as recovered by nasal lavage.[69] Nasal mucosal biopsies, performed 24 hours after topical allergen provocation, also show increases in the number of inflammatory cells, but, in contrast to the nasal secretions, in which eosinophils and neutrophils account for the majority of recovered cells, mononuclear cells predominate.[70] These are mostly of the T-helper category, as evidenced by positive staining with antibodies against CD4, and a portion of them are activated, as documented by IL-2 receptor expression (CD25+).[71,72] These T lymphocytes have been shown to express messenger ribonucleic acid (mRNA) for TH2-type cytokines.

The cellular changes observed after allergen provocation are similar to observations of nasal cytology during seasonal disease. In separately conducted studies, Bryan and Bryan and Okuda and Otsuka observed basophilic cells in nasal secretions during seasonal pollen exposure of allergic individuals.[73–76] In contrast to nasal secretions, which represent the most superficial compartment of the nasal mucosa, examination of nasal mucosal scrapings,[77,78] or biopsies[47,77,78] that sample deeper layers, showed that the majority of metachromatic cells in these compartments were mast cells. Enerbäck and colleagues, using biopsies and cytologic imprints to examine the cellular content of the nasal mucosa during the birch pollen season in Sweden, showed a seasonal increase in mast cell number on the surface of the nasal epithelium after 4 or 5 days of pollen exposure.[47] Mast cells are found in high concentrations beneath epithelial surfaces, whereas their counterparts, basophils, circulate in the bloodstream. The consensus in most studies is that basophils predominate in nasal secretions, whereas mast cells are more abundant in the epithelium and lamina propria of allergic subjects exposed to antigen either experimentally or naturally. Bentley and colleagues also

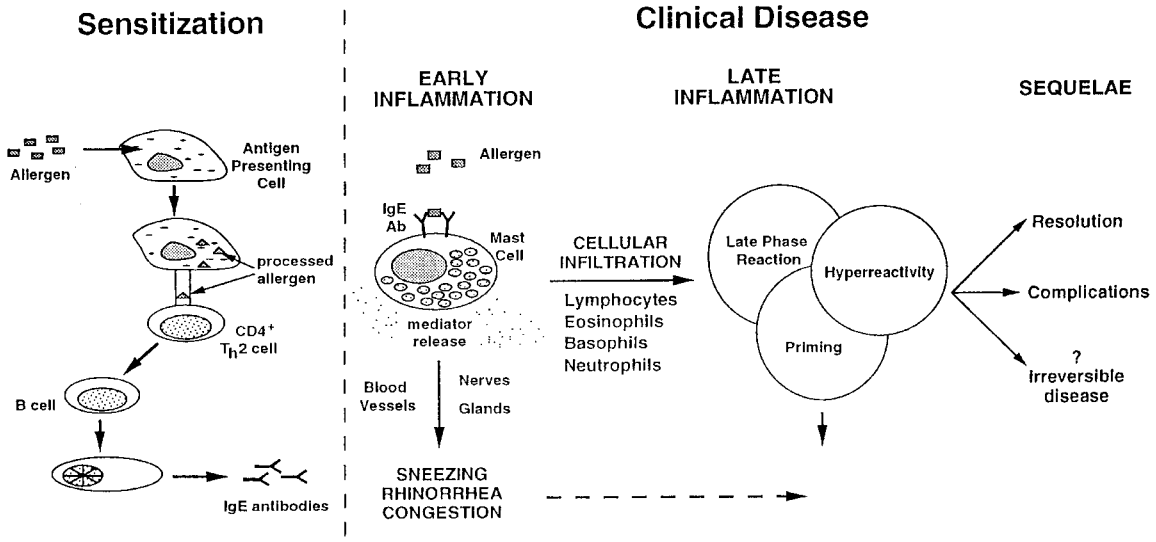

FIGURE 32–3. Pathophysiology of allergic rhinitis. On the left side of the schematic, sensitization to allergen is depicted and involves the production of specific immunoglobulin (Ig) E antibodies to certain allergens. On subsequent exposure to the allergen, depicted on the right, there is cross-linking of specific IgE receptors with resultant degranulation of mast cells and the release of inflammatory mediators. Subsequent to the early reaction, inflammatory cells infiltrate the nasal mucosa, and the late-phase response develops. This is accompanied by a state of increased reactivity that renders the nasal mucosa more responsive to subsequent exposure to allergen (priming) or other stimuli (hyperreactivity). Finally, natural allergic disease might resolve or lead to complications such as sinus infections or otitis media. Reproduced with permission from Naclerio RM. Allergic rhinitis. N Engl J Med 1991;325:860–9.

reported a significant seasonal increase in total MBP^+ and activated eosinophils in the submucosa of allergic patients when compared with preseasonal biopsies or biopsies from nonallergic control subjects.[79]

Adhesion Molecules

Studies have also demonstrated increases in endothelial adhesion molecules, namely, vascular cell adhesion molecule 1 (VCAM-1) in nasal biopsies obtained from allergic subjects 24 hours after nasal allergen challenge.[80] This molecule is expressed on the surface of vascular endothelial cells and interacts with a counterligand, very late activation antigen 4 (VLA-4), which is present on the surface of several leukocytes including lymphocytes, monocytes, eosinophils, and basophils but not neutrophils.[81,82] The VLA-4/VCAM-1 adhesion pathway has been suggested as a mechanism for specific eosinophil, as opposed to neutrophil, migration from the circulation into allergic inflammatory sites.[81,83,84] Other adhesion molecules thought to be important in the recruitment of inflammatory cells from the intravascular compartment into tissue sites of allergic inflammation are intercellular adhesion molecule 1 (ICAM-1), which is constitutively expressed in the nasal mucosa, and E-selectin, which is modestly up-regulated 24 hours after allergen provocation.[80] Intercellular adhesion molecule 1, a ligand for the $ß_2$ integrin molecules leukocyte function-associated antigen-1 and membrane attach complex-1, which are present on the surface of leukocytes, mediates the attachment of all classes of leukocytes to endothelial cells,[82] and E-selectin binds to sialyl Lewis X expressed on the surface of leukocytes.[85] The expression of adhesion molecules has also been studied by Montefort and colleagues, who compared the expression of endothelial cell adhesion molecules in nasal biopsies from subjects with perennial allergic rhinitis and normal control subjects. These investigators found enhanced expression of ICAM-1 and VCAM-1, but not E-selectin, in the mucosa of allergic subjects.[86] Intercellular adhesion molecule expression has been shown to be suppressed by H_1 antihistamines.

Cytokines and Chemokines

In addition to the role of inflammatory mediators in allergic disease, cytokines are increasingly being recognized as important mediators of allergic inflammation and have been shown to have proinflammatory effects in vitro. Such effects include increasing the production of cells in the bone marrow, aiding in the survival of cells in the nasal mucosa, synergizing with other cellular activators, and acting as chemoattractants. Although initially thought to originate exclusively from lymphocytes, other inflammatory cells such as mast cells, basophils, and eosinophils can also produce cytokines.[87,88] Inflammatory cell recruitment enhances the interactions among cells and leads to additional cytokine production, thereby amplifying the reaction, causing further cellular recruitment, and increasing the survival of already recruited inflammatory cells.[89] Some of these inflammatory cells elaborate substances that can cause local damage and mucosal modifications characteristic of chronic rhinitis. The presence of cytokines in nasal secretions and tissues after allergen provocation and natural allergen exposure is beginning to be recognized. Durham and colleagues have demonstrated an increase in the number of cells bearing mRNA for IL-3, IL-4, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF) in nasal mucosal biopsy specimens after allergen challenge.[90] Furthermore, increased levels of IL-1ß and GM-CSF have been measured in nasal secretions during the late-phase reaction, and these elevations peaked at the fifth hour after allergen provocation.[91]

The chemokines are chemoattractant cytokines that play an important role in the function and expression of leukocyte and endothelial adhesion molecules. One such mediator, IL-8, is released by epithelial cells and appears to be necessary for transendothelial migration of neutrophils. Another chemokine, RANTES (*r*egulated on *a*ctivation, *n*ormal *T e*xpressed and *s*ecreted), a member of the CC chemokine subfamily, selectively promotes chemotaxis of memory T lymphocytes, monocytes, and eosinophils. Monocyte chemotactic proteins (MCPs), also members of the CC chemokine subfamily, include MCP-1, MCP-2, MCP-3, and MCP-4. These exert chemotactic activity on monocytes, basophils, lymphocytes, and eosinophils.[92] Another CC chemokine, eotaxin, appears to contribute to the specific recruitment of eosinophils through the eotaxin receptor CCR-3, which is expressed on eosinophils and other leukocytes.[93] Corroborating the importance of these chemokines in allergic reactions are studies demonstrating RANTES, macrophage inflammatory protein 1-α, and IL-8 in nasal lavages after allergen provocation.[94] Interleukin-8 protein has also been localized to the nasal mucosa of both patients with perennial allergic rhinitis and normal controls.[95] Additional studies have shown increased numbers of RANTES, eotaxin, and MCP-3 and MCP-4 mRNA-positive cells in nasal mucosal biopsy specimens 24 hours after allergen challenge.[92] In another study, Kuna and colleagues showed that challenging the nasal cavity with RANTES resulted in the influx of eosinophils, basophils, and lymphocytes into nasal secretions, which were increased significantly compared with those after diluent challenge and more marked in the allergen-challenged nose.[96] Hanazawa and colleagues administered eotaxin intranasally and showed a significant eosinophil influx into nasal secretions, coupled with an increase in nasal nitric oxide 8 hours after challenge.[93] Thus, in vitro, in vivo, and challenge studies all support the importance of chemokines in the pathophysiology of allergic rhinitis, specifically in enhancing cellular recruitment.

Nasal Reactivity

Besides the development of recurrent symptoms hours after a nasal challenge, the inflammatory cellular influx is accompanied by increased nasal reactivity. This has been demonstrated by responsiveness to specific stimuli, such as the antigen that initiated the reaction, and to nonspecific stimuli, such as the secretagogues histamine and methacholine. In the 1960s, John T. Connell[97] coined the term "priming" to refer to increased specific responsiveness. Priming may explain why patients become more symptomatic to the same amounts of pollen in the environment later during the allergy season. Nonspecific reactivity implies increased responsiveness to nonantigenic substances and has been studied by provoking of individuals with methacholine; histamine; cold, dry air; and bradykinin. Like priming, nonspecific reactivity is not obligatorily linked to the appearance of a late reaction. Walden and colleagues found increased sensitivity to histamine 24 hours after antigen challenge.[98] The response to histamine challenge returned to baseline 10 days later, suggesting that increased respon-

siveness to histamine was reversible. Other studies showed a positive correlation between the number of eosinophils 24 hours after antigen challenge and the magnitude of the responsiveness to histamine, and this hyperresponsiveness was inhibited by pretreatment with topical corticosteriods.[99,100]

Majchel and colleagues examined the effect of seasonal exposure on nasal responsiveness to histamine by challenging allergic subjects with histamine before, at the peak of, near the end of, and 2 weeks after the ragweed pollen season.[101] These investigators observed a significant increase in symptoms at the peak of the pollen season that returned to baseline with the disappearance of pollen. The increase above baseline at the peak of the season was not significant for any of the parameters measured. However, they suggested that increased reactivity to histamine with seasonal exposure appears to represent a change in baseline rather than an increased sensitivity to histamine itself. This change in baseline reactivity was inhibited in subjects who were receiving immunotherapy.

Similar studies demonstrate nasal hyperresponsiveness to the cholinomimetic agonist methacholine.[102] Klementsson and colleagues measured the volume of nasal secretions after intranasal administration of 6 mg of methacholine before and after antigen challenge of allergic subjects out of allergy season and observed significant increases in methacholine-induced secretions at 2, 4, 6, 8, 10, and 24 hours after antigen challenge, compared with baseline.[103] Although eosinophils in nasal secretions increased significantly after antigen challenge, no correlation was seen between their numbers and the increase in nonspecific hyperresponsiveness to methacholine. These workers also showed that premedication with two different H_1 antihistamines (terfenadine and cetirizine) resulted in inhibition of both the acute allergic response and the allergen-induced increase in responsiveness to methacholine without affecting eosinophil influx after antigen.[104] This observation was confirmed by Baroody et al for the H_1 antihistamine terfenadine and extended to the antihistamine loratidine.[105] In contrast, corticosteroids, given topically or orally, have dramatic inhibitory effects on cellular infiltration and both specific and nonspecific hyperresponsiveness.[99,100,106] An important consequence of nonspecific hyperactivity is the increased symptoms on exposure to irritants, such as gasoline odors, reported by patients during their allergy season.

Neural Reflexes

Neural reflexes are thought to be involved in the pathophysiology of allergic rhinitis. Sneezing and itching seen during the early response to allergen provocation involve the nervous system. Konno and Togawa and others demonstrated the importance of neural reflexes in patients with allergic rhinitis by showing that stimulating one nasal cavity with histamine led to bilateral nasal secretions.[107] Unilateral intranasal challenge with antigen in subjects with allergic rhinitis led to an increase in sneezes, rhinorrhea, nasal secretions, histamine, nasal airway resistance,[108] and PGD_2[109,110] on the side of challenge. Contralateral to the challenge, rhinorrhea and secretion weights increased significantly, as did PGD_2.[110] The contralateral secretory response was rich in the glandular markers lactoferrin and lysozyme[109] and was inhibited by atropine, an anticholinergic agent, suggesting that the efferent limb was cholinergically mediated.[108] The muscarinic receptors that mediate the actions of acetylcholine in the human nasal mucosa are of both the M_1 and M_3 receptor subtypes and coexist at high densities in submucosal glands.[111]

Immunohistochemical studies have established the presence of several neuropeptides in addition to sympathetic and parasympathetic nerves and their transmitters in the nasal mucosa. These neuropeptides are secreted by unmyelinated nociceptive C fibers (tachykinins, calcitonin gene-related protein [CGRP], neurokinin A [NKA], and gastrin-releasing peptide), parasympathetic nerve endings (vasoactive intestinal protein [VIP], peptide histidine methionine), and sympathetic nerve endings (neuropeptide Y). Substance P (SP), a member of the tachykinin family, is often found as a cotransmitter with NKA and CGRP and has been found in high density in arterial vessels and, to some extent, in veins, gland acini, and the epithelium of the nasal mucosa.[112] In addition to the identification of these neuropeptides in the nasal mucosa, Okamoto et al showed that incubation of nasal biopsy specimens of perennial rhinitics and nonallergic rhinitics with SP or mite allergen resulted in significant increases in mRNA for IL-1β, IL-2, IL-3, IL-4, IL-5, IL-6, tumor necrosis factor-α, and interferon-γ in specimens from allergic subjects but not nonallergic con-

trols.[113] In nasal challenge studies in allergic subjects, Mosimann and colleagues showed that levels of SP, CGRP, and VIP all increased significantly immediately after antigen challenge, with significant but modest increases in SP during the late response.[114] These experiments suggest that neuropeptides are released in vivo in man after allergen challenge and might be partly responsible for symptoms of the allergic reaction. Repetitive application of capsaicin, the essence of chili peppers, depletes sensory nerves of their content of SP and CGRP and initiates both central and axonal reflexes. Unlike its effects in rodents, the capsaicin-induced nasal secretory response in humans is primarily glandular and not attributable to increased vascular permeability.[115] In support of its proinflammatory effects, capsaicin nasal challenge caused significant increases in neutrophils, eosinophils, and mononuclear cells from the prechallenge baseline, with no difference between rhinitic and normal subjects.[116] Furthermore, capsaicin desensitization reduced nasal symptoms recorded for 24 hours after allergen challenge, and this reduction persisted for up to 2 months.[117]

Therefore, several experimental findings highlight the importance of neurogenic control of the allergic response. These include the presence of nasonasal reflexes after nasal antigen provocation, the presence of neuropeptides in nasal tissues and their recovery in nasal secretions after antigen challenge, the ability of these peptides to produce symptoms and inflammatory responses similar to those obtained after exposure to antigen, and the clinical efficacy of capsaicin, which depletes the stores of these substances.

Relationships with Related Organs

Multiple lines of evidence support the observation that allergic rhinitis and sinusitis are closely associated disease entities, although controlled studies of the incidence of rhinosinusitis in patients with allergic rhinitis have not been conducted. Benninger, in a study of outpatients in an otolaryngology practice, found that 54% of those with chronic sinusitis also had allergic rhinitis.[118] Grove and Farrior described a 50% incidence of positive skin tests in patients undergoing sinus surgery, whereas Friedman reported an incidence of atopy in 94% of patients undergoing sphenoethmoidectomies.[119,120] Van Dishoeck and Franssen described allergy as an underlying factor in 40 to 67% of patients with chronic sinusitis.[121] Complementing the above data that allergic rhinitis occurs frequently in patients with chronic sinusitis are data showing a high prevalence of sinus disease in patients with allergic rhinitis. Sinus radiographs are abnormal in more than 50% of adults and children with perennial allergic rhinitis.[122,123] In contrast, Enberg reported a low incidence of sinus abnormalities in patients with perennial nonallergic rhinitis.[124] Magnetic resonance imaging scans demonstrate increased evidence of sinus mucosal abnormalities during major pollinating seasons.[125] A study of subjects with ragweed rhinitis during the pollen season showed that 60% of the subjects had sinus mucosal abnormalities on computed tomography (CT).[126] Multiple mechanisms are postulated to explain these relationships. In one recent study of subjects with seasonal allergic rhinitis outside their season, the nose was challenged with allergen, and nasal and ipsilateral maxillary sinus responses were monitored by use of lavage. There was a late increase in total cell count (the percentage of eosinophils and total eosinophils within the sinus cavity in the allergen-challenged subjects) but not in the control experiments. There were significantly more total cells after allergen challenge compared with the control group as well as a higher number of total eosinophils.[127] This study highlights the fact that important relationships exist between the nose and sinus in the response to allergen, possibly through regional or central neural reflexes.

There are important relationships between the nose and other organs in the pathophysiology of allergic rhinitis. A relationship between pulmonary disease such as asthma and allergic rhinitis has long been observed. Allergic rhinitis and asthma often coexist. Allergic rhinitis can lessen the severity of asthma,[128] and treatment of allergic rhinitis by intranasal corticosteroids can improve the symptoms of asthma and reduce bronchial hyperresponsiveness.[129] Treatment with orally inhaled corticosteroids not only prevented development of increased bronchial hyperresponsiveness to methacholine but also reduced nasal symptoms, eosinophils from nasal brushings, markers of eosinophil activation in nasal lavage fluid, and peripheral blood eosinophilia.[130]

A recent study by Braunstahl and colleagues demonstrated that segmental provocation with allergen in the lungs produced allergic inflammation in the nose in atopic patients.[131] Another study

examined the ability of the nose to condition cold, dry air. Assanasen et al demonstrated that asthmatics have a reduced ability to warm and humidify cold, dry air as compared with normal subjects; subjects with seasonal allergic rhinitis also had a reduced ability to condition air, with possibly adverse implications for the lower airways.[132] Pathophysiologic connections between the nose and lungs are still not entirely understood and remain an active topic of investigation. The above data, however, support the presence of important physiologic and pathophysiologic connections between contiguous areas of the respiratory tract.

Nasal inflammation with an allergic or infectious cause may be a factor involved in the development of otitis media. Studies of the pathogenesis of otitis media have identified interactions among infection, allergic reactions, and eustachian tube dysfunction.[133] In the presence of allergic rhinitis, treatment may improve symptom resolution and therapeutic response. The inflammation found in allergic rhinitis is thought to promote eustachian tube dysfunction and support the development of otitis through mediators and cytokines. This remains an area of ongoing investigation.

Summary of Pathophysiology

The pathophysiology of allergic rhinitis can be summarized as follows: After sensitization of the nasal mucosa to a certain allergen, subsequent exposure leads to cross-linking of specific IgE receptors on mast cells and their resultant degranulation, with the release of a host of inflammatory mediators that are responsible for allergic nasal symptoms (see Figure 32–3). Proinflammatory substances produced by other inflammatory cells are also generated after antigen exposure, most prominent among which are eosinophil products and cytokines. Cytokines are thought to be generated, in part, by lymphocytes, which are found in abundance in both resting and stimulated nasal mucosa. Recent evidence also points to an important role for mast cells in the storage and probable production and secretion of cytokines. Cytokines can up-regulate adhesion molecules on the vascular endothelium and possibly marginating leukocytes, leading to the migration of these cells into tissues. Other cytokines also promote chemotaxis and survival of recruited inflammatory cells. Another important player is the nervous system, which amplifies the allergic reaction by both central and peripheral reflexes that result in changes at sites distant from those of antigen deposition. All of these changes lower the threshold of mucosal responsiveness and amplify it to a variety of specific and nonspecific stimuli, making allergic individuals more responsive than nonallergic individuals to stimuli to which they are exposed in daily life (see Figure 32–3).

ALLERGENS

Allergens are foreign substances capable of provoking an IgE-mediated response. Most allergens are between 5 and 20 μm in diameter, a size that permits their complete removal by the nose. They are proteins with molecular weights between 10 and 40 kD. No distinguishing surface characteristics appear to differentiate allergens from nonantigenic substances.

Allergens are often categorized into indoor and outdoor types. In general, outdoor allergens are responsible for seasonal allergic rhinitis, whereas indoor allergens usually cause perennial rhinitis. Pollens causing allergy in temperate climates are released into the air from plants, trees, weeds, and grasses and are carried over great distances. Thus, cutting down trees around a suburban home in an effort to reduce the amount of pollen has little effect. About 75% of patients with seasonal allergens have symptoms caused by ragweed, 40% by grasses, and 5% by trees alone. Approximately 25% have allergies to both grass and ragweed, and 5% have allergies to all three pollens.[27] Trees clearly have geographic variations; for example, Western red cedar is limited to the Northwest. Grasses are diverse and include timothy grass, often used for feeding horses; Kentucky bluegrass, widely used in lawn grass mixtures; orchard grass; rye grass; and English plantain. Common short ragweed is found throughout North America, with the exception of Newfoundland, and is conspicuously absent from the European continent.

Pollination, and hence the allergy season, occurs in a predictable annual pattern for different regions of the country.[134] The pattern, however, varies throughout the country. In the Northeast, trees pollinate in mid-March to late April, grasses follow in May and June, and ragweed flowers from mid-August until the first frost. In the South, tree blooming begins in early February. In contrast to the sharply demarcated grass season that occurs in the North, in the South, grasses may pollinate from

March through September, and in some areas, pollination may be a year-round process. The pattern in the central United States resembles the patterns seen on the east coast. In the California lowlands, grass pollen is present from early March through November, and trees and short ragweed are present as in other regions. In the Northwest coastal region, trees and grass pollen are present, but the region is ragweed free. In the traditionally arid Southwest, previously a haven for allergy sufferers, increased urbanization and irrigation have contributed to increasing the pollen load. Humans tend to bring their allergens with them.

The most frequent perennial allergens are animal danders, dust mites, cockroaches, and molds. Dust mites are microscopic, eight-legged organisms of the genus *Dermatophagoides*, including *D. pteronyssinus*, *D. farinae,* and *Euroglyphus maynei*. They are the major allergens in "house dust." Dust mites are found throughout the world, with the exception of extremely dry climates such as northern Sweden, central Canada, and areas at elevations above 10,000 feet. These mites feed on human epithelial scales and thrive in warm, humid environments (60 to 70% relative humidity, temperature 65 to 80°F). Bedding provides an ideal environment for proliferation of dust mites. Other sites for mite accumulation are upholstered furniture, carpets, and stuffed toys. Dust mite feces, the source of the allergen, are relatively large particles that remain airborne for short periods, unlike outdoor pollen. When an individual sits on a bed, the particles become airborne and are inhaled. Because these particles are large, they settle from the air rapidly, and air filtration systems cannot effectively remove them. Lowering the indoor relative humidity to less than 50% during the summer months has a profound effect on the mite population and the antigen load throughout the year,[135] suggesting a role for dehumidifiers even in homes with central air conditioning.

Animal danders are an important source of indoor allergens. Cat and dog danders are the most frequent, but mice, guinea pigs, and horses can all be responsible for allergic symptoms. Laboratory workers can become allergic to animals at work. In most cases, the allergen is found in secretions. In cats, *Fel d I* is the principal allergen secreted in cat saliva. It dries on fur and is spread to furniture, bedding, and carpets. When these reservoirs are disturbed, the allergen becomes airborne and can provoke symptoms. Cat dander is "sticky," and children with cats can carry enough to school to cause symptoms in cat-allergic children who have no cats in their homes.[136]

The cockroach is an important source of allergen in inner-city populations. Both the American (*Periplaneta americana*) and German cockroach (*Blattella germanica*) have been identified as important allergens in asthma. Allergenicity occurs to body parts and to feces. Molds, although less well studied, are sources of allergens, particularly in warm, humid environments. They tend to be found inside older homes in areas of decreased ventilation or increased dampness. Although a phenomenal variety of molds exists, *Alternaria* and *Cladosporium* are principally responsible for symptoms owing to outdoor exposure, and *Aspergillus* and *Penicillium* are most prevalent indoors.

The patient's work environment may also be a source of allergens. Symptoms occurring only at work and subsiding on weekends may reflect an occupational disorder. At risk are flour handlers, workers in paint and plastic industries, woodworkers, fish and shellfish processors, and animal handlers. Unfortunately, few specific tests exist for the diagnosis of these disorders.

Allergic reactions to natural rubber latex have increased, especially in health care workers who have high exposure by direct skin contact and inhalation of latex particles from powdered gloves. This problem is being addressed by studies on improving diagnostic methods for latex allergy and evaluating strategies for prevention.

CLINICAL PRESENTATION

History

Antigen exposure causes itching within seconds, which is soon followed by sneezing. Rhinorrhea ensues, and within about 15 minutes, nasal congestion peaks. Besides nasal symptoms, patients often complain about ocular pruritus, tearing, pharyngeal itching, throat clearing, cough, and ear popping. Other commonly reported symptoms include postnasal drip, increased lacrimation, dry cough, red eyes, headaches (pressure) over the paranasal sinus areas, and loss of smell or taste. These symptoms are nonspecific and have significant clinical overlap with other disorders. Itching of mucous membranes and repetitive sneezing, however, are the symptoms most suggestive of

allergic disease. The relative importance of each symptom may vary among individuals, but nasal congestion tends to be the most bothersome, although each symptom is usually present, at least to some degree.

When obtaining the history, the physician should attempt to link exposure to allergens temporally with the occurrence of symptoms. This temporal correlation is the hallmark of allergic rhinitis. Patients with seasonal allergies complain of recurrent symptoms only at specific times of each year that coincide with pollination periods. In contrast, a history of year-round symptoms may indicate sensitivity to a perennial allergen or multiple seasonal allergens. Symptoms immediately following exposure to a potential source of allergen, such as a cat, strongly suggest an allergy to that source. Exposures to perennial allergens tend to be accentuated in winter in colder climates, when ventilation is reduced. Symptoms occurring only at work or during the workweek and subsiding on weekends may reflect an occupationally related disorder. The presence of domestic pets (including birds) and whether these sleep in the patient's room must be determined.

Additional considerations in history taking include the response to prior therapy and evidence of complications. Related effects of the pathophysiology must be addressed. For example, nasal obstruction may lead to mouth breathing. In children, this may be manifested as adenoid facies, with a high palatal arch and abnormal dental development. In adults, nasal obstruction may contribute to snoring and sleep-disordered breathing. Obstruction of sinus ostia may predispose to sinusitis. Eustachian tube dysfunction may occur,[137] but this has not been shown to lead to an increased incidence of otitis media with effusion.[138,139]

A general medical history remains important. The medical history may document systemic disorders that affect the nose, such as hypothyroidism. Pregnancy can produce nasal congestion and may require modification of treatment strategies. The presence of pulmonary disease such as asthma should be sought. Indeed, a significant percentage of patients with allergic rhinitis have asthma. Between 5 and 10% of asthmatic subjects may have intolerance to aspirin and nonsteroidal anti-inflammatory drugs. A family history of allergic rhinitis increases the chances of the patient's having an allergic disorder. Nasal symptoms might also be caused by intake of medications such as beta blockers, which may contribute to nasal congestion through interference with the adrenergic mechanism. Tricyclic antidepressants may produce dryness of the nasal mucosa by virtue of their anticholinergic effects. Angiotensin-converting enzyme inhibitors can produce a chronic cough. Birth control pills can cause nasal congestion, and topical eyedrops can also induce nasal symptoms.

Examination

Attentive history taking and physical examination, combined with appropriate diagnostic tests, are required for establishing the correct diagnosis because allergic rhinitis shares features of other nasal disease entities. The classic description of allergic facies includes mouth breathing, allergic "shiners" (resulting from periorbital venous stasis from chronic nasal obstruction), and a transverse supratip nasal crease from long-term rubbing of the nose upward to relieve itching. These classic presentations occur especially often in children, but absence of these signs does not exclude the disease.

Physical examination must be complete. Ocular examination may demonstrate injection of the conjunctiva or swelling of the eyelids. Examination of the nose begins with observing the external appearance for gross deformities such as a deviation suggesting previous trauma or expansion of the nasal bridge suggestive of nasal polyps. A nasal speculum permits evaluation of the anterior third of the internal nasal architecture and the character of the nasal mucosa. Structural anomalies providing an anatomic basis for obstruction or recurrent infections such as septal deviations or spurs should be sought. The character and consistency of nasal secretions should be noted. These can vary from thin and clear to thick and whitish. The nasal mucosa may be swollen and pale-bluish, although these signs are not pathognomonic of the disease, as previously thought. The examination of allergic individuals often appears normal, and the primary importance of the physical examination is to rule out other causes of or contributors to the symptoms.

Decongestion of swollen nasal mucosa with a topical decongestant improves visualization and allows the differentiation of reversible from irreversible changes. Combining the vasoconstrictor with a topical anesthetic allows complete examination with an endoscope. The choanae and the nasopharynx can be visualized in this manner. The

region of the middle meatus should also be examined carefully because secretions there might be suggestive of acute or chronic sinusitis. Nasal polyps that were not visualized by anterior rhinoscopy may be seen during a careful endoscopic examination. Nasal polyps are infrequent in allergic rhinitis (< 2%) but are found in up to 20% of patients with cystic fibrosis.[42] The presence of nasal polyps in children suggests the diagnosis of cystic fibrosis because polyps are rarely found in this age group. These children should undergo sweat or genetic testing.

DIAGNOSIS

The identification of allergen(s) responsible for the patient's symptoms is important both for establishing the diagnosis and for the institution of avoidance measures. Symptoms occurring in temporal relation to allergen exposure suggest sensitization but are not diagnostic. Sensitization implies the presence of elevated levels of IgE directed against a specific allergen and can be demonstrated by a wheal and flare response to skin testing with allergen extracts or by measuring the level of antigen-specific IgE antibodies in the serum. However, individuals can show evidence of sensitization by a positive skin test or elevated specific antibody levels in the serum without having evidence of clinical disease. This emphasizes the importance of obtaining a good history in the evaluation of patients with suspected allergic disorders. In patients with a positive history, the magnitude of skin responses often corresponds to the severity of symptoms.

Skin Testing

Skin testing furnishes an excellent in vivo method to demonstrate sensitivity to a given allergen. This test evaluates the presence of specific IgE antibodies on skin mast cells, the reactivity of these cells, and the reaction of the end-organ to released mediators. Its advantages include greater sensitivity, the rapidity with which results can be obtained, and low cost. Like all diagnostic tests, skin testing also has disadvantages, which include the inability to perform the test in patients with dermatologic problems such as dermatographism and extensive eczema, poor tolerance of many children for multiple needle pricks, the inhibitory effect of certain ingested drugs such as antihistamines on skin test reactivity,[140,141] the need to maintain the potency of the allergen extracts, and the possibility of systemic reactions.

Skin testing often begins with puncture testing, which provides low-dose allergen exposure. A small drop of concentrated allergen is placed on the skin (usually on the volar surface of the forearm or the back), and a minute quantity is introduced into the dermis with a sharp object. Positive responses occur within 10 to 15 minutes and produce a characteristic raised central area of induration (wheal), with a surrounding zone of erythema (flare). The response is graded in comparison with a positive histamine or codeine response, and a negative control with the diluent for the allergen extracts is also included to control for nonspecific reactivity to the vehicle. The positive control ensures that the patient can mount a cutaneous reaction to histamine, and the absence of a reaction can unmask interference by medications, decreased skin reactivity, or technical problems with the procedure. Skin testing is valid in infants and young children, but the criteria for a positive reaction need to be adjusted because the reactions are smaller.[142] Measurement of serum-specific IgE levels is also valid in this younger age group.[143] It is important, however, to test with only relevant antigens. Infants are more likely to be allergic to foods, and children are more likely to be allergic to perennial rather than seasonal allergens.

Negative puncture tests are usually confirmed by intradermal tests, which are more sensitive. In an intradermal test, a small (0.01 to 0.05 mL) quantity of dilute allergen is injected into the superficial dermis, and the same wheal and flare responses are observed and graded in comparison with a positive histamine or codeine control. Because antihistamines can interfere with the results of skin testing, most H_1 receptor antagonists are withheld for 2 days before skin testing. Tricyclic antidepressants suppress responses for several weeks, as can tranquilizers and antiemetics of the phenothiazine class through intrinsic anti-H_1 activity. Short-term oral corticosteroid treatment has no effect on skin test reactivity but may have an inhibitory effect if the agent is taken for long periods. Testing with extracts that are standardized (ragweed, grass pollens) is more reliable than for nonstandardized antigens such as foods and chemicals.

In Vitro Immunoglobulin E Measurements

Drawing blood for the measurement of specific IgE can circumvent some of the disadvantages of skin

testing. False-positive results may occur if patients have elevated IgE levels in their sera because of nonspecific binding. Therefore, although IgE levels alone are of limited usefulness in the diagnosis of allergic rhinitis, and because elevated levels can also exist in patients with nonallergic conditions, these levels must be obtained in conjunction with a determination of specific IgE levels. False-negative results may also occur from inhibition by IgG antibodies with similar affinities as in patients receiving immunotherapy. Data from clinical studies comparing the results of skin testing and in vitro tests for specific IgE determination (the radioallergosorbent assay or RAST) in allergic subjects suggest a good correlation between the two,[144] with a higher sensitivity for skin testing.[145] Therefore, both determinations of specific IgE levels and skin testing are useful in the diagnosis of allergic disorders, but their results should always be interpreted in the context of clinical symptoms. The disadvantages of this form of allergy testing include cost, slightly lower sensitivity, and the time delay between drawing the blood and obtaining the results.

Other Diagnostic Tests

Peripheral eosinophilia, although nonspecific, may indicate the presence of other atopic diseases. Nasal cytologic examination allows the identification of eosinophils and other inflammatory cells in nasal secretions and may be helpful in differentiating an infectious from an allergic cause during a clinical exacerbation of symptoms. In normal individuals, smears show the presence of epithelial cells, including some ciliated and goblet cells, with few eosinophils, neutrophils, basophils, or bacteria. In subjects with an infection, neutrophils increase in nasal secretions, and in symptomatic allergic subjects, the percentage of eosinophils increases. A value greater than 10% is suggestive of allergic disease.[146–150] Eosinophils, however, may also be present in the absence of IgE-mediated disease. Approximately 25% of patients with chronic rhinitis and negative skin tests demonstrate eosinophilia on nasal cytologic study, and this entity is known as the nonallergic rhinitis with eosinophilia syndrome (NARES). Regardless of the cause, the presence of eosinophilia usually implies a favorable clinical response to corticosteroid therapy.[151]

Soft tissue radiography of the neck can evaluate adenoid size, a major consideration in the differential diagnosis of rhinitis in children, especially when the predominant symptom is nasal obstruction. Sinus disease often complicates perennial allergic rhinitis and may be a consideration in the differential diagnosis. In the past, sinus plain films were used, but CT is now standard for evaluation of the presence and extent of sinus abnormalities. The common association of upper and lower airway disease makes tests of pulmonary functions useful adjuvants. This statement applies to such diverse disorders as cystic fibrosis, asthma, and bronchopulmonary aspergillosis.

THERAPY

Environmental Modifications

The most potent treatments cannot eliminate symptoms in the face of an overwhelming allergen load. Complete avoidance of the allergen(s) to which the patient is sensitive eliminates symptoms of the disease. Thus, measures aimed at reducing the allergen load from the patient's environment are effective in reducing symptoms. Although many methods of environmental control (removal of a pet, restriction of activities, home renovations) are difficult to execute, particularly with children, simple measures can be very effective. In seasonal allergic rhinitis, patients can reduce exposure by keeping windows closed on days when pollen counts are high and limiting physical activity outdoors in the early morning and evening when pollen counts peak. Air conditioning can help, and the addition of special filters can prevent pollen grains and mold spores from entering the home. Pollen counts are often given during daily weather reports, and the previous day's pollen counts are the best predictor of the next day's counts. Rain, however, profoundly reduces the levels of outdoor pollens.

Measures to reduce exposure to dust mites concentrate on bedding.[152] These include replacing feather pillows and bedspreads with synthetic ones that can be washed in hot water (hotter than 130°F) and covering mattresses with commercially available plastic covers ($< 10\ \mu m$). Removing carpets and frequent vacuuming also help. Where carpets cannot be removed, acaricidal products can directly kill mites. Stuffed toys can be placed in the freezer for 2 days to reduce the number of dust mites.

In subjects with allergies to animal dander, removal of a domestic pet is the best step. Reduction in the allergen load after pet removal may take up to

6 months, however; thus, symptoms may persist. Furthermore, complete removal of a pet may be difficult, but eliminating the animal from the bedroom, where we spend an average of 8 hours per day, is a helpful alternative. In the case of cats, regular washing of the animal may help decrease the allergen load.[153]

Humidifiers must be cleaned regularly to avoid becoming a source of mold allergens, which thrive in moist environments. The humidity should not exceed 40 to 45% because higher levels encourage the growth of dust mites and molds. The use of high-efficiency particulate air (HEPA) filters and of electrostatic filters effectively removes particulates larger than 1 μm in diameter. Particles, however, must be airborne for removal, such as pollens, whereas heavy particles that settle from the air rapidly, such as dust mites, are not eliminated by these measures.[154] High-efficiency particulate air filters are preferred to electrostatic ones as they filter out particulate matter without generating ozone, an irritant.

General household changes may also be helpful. Repair of any plumbing or drainage problem areas in the house must be undertaken to eliminate mold. Decontamination of surfaces contaminated with mold by use of diluted bleach and elimination of soiled organic materials is useful. Appropriate packaging of garbage and pesticide application are necessary to eliminate cockroaches. Use of well-fitting, semirigid masks when vacuuming offers useful protection from airborne allergens such as dust mites.[155]

PHARMACOLOGIC THERAPY

Antihistamines

Three receptors exist for histamine. H_1 receptors are found on blood vessels, on sensory nerves, on smooth muscles of the respiratory and digestive tracts, and in the central nervous system. Stimulation leads to vasodilatation, increased vascular permeability, sneezing, pruritus, glandular secretion, and increased intestinal motility. H_2 receptors have a distribution similar to that of H_1 receptors but are principally involved in the regulation of gastric acid secretion. H_3 receptors are located principally in the brain and seem to be involved in the regulation of histamine synthesis and release. The contribution of histamine to the early allergic response, largely mediated by the H_1 receptor, has long been recognized and is the rationale for the large number of H_1 antagonists in clinical use.

H_1 antihistamines have been classified as first-generation, or sedating, and second-generation, or nonsedating, antihistamines. The first generation of antihistamines is effective, but they have some undesirable side effects because of their lack of selectivity and subsequent nonspecific stimulation of other receptors. Among these side effects are sedation, anticholinergic effects, functional and performance impairment, and gastrointestinal distress. When applied topically, some act as local anesthetics. The most important of the side effects is sedation, which is reported in approximately 20% of patients.[156] Objective studies of performance have documented the problem. The correlation with the subjective reporting of sedation was weak, however, and the problem appeared more significant than previously believed; that is, a larger number of subjects developed impaired performance compared with the number reporting sedation. Furthermore, impaired performance can persist after the subjective feeling of somnolence dissipates—hence, the importance of warning patients who are taking these medications not to perform some tasks such as operating heavy machinery or driving. Although some side effects may be useful, such as the use of diphenhydramine for treating insomnia, they are usually a nuisance and limit compliance. In one study, diphenhydramine caused worse impairment to driving than consuming alcohol to the level of being legally drunk.[157] In this study, performance after a second-generation agent was similar to that after a placebo.

Second-generation antihistamines are less lipophilic than first-generation H_1 antihistamines and do not penetrate the blood-brain barrier. Therefore, they produce no more somnolence than does placebo. Their greater receptor selectivity also reduces the incidence of anticholinergic side effects. In addition to antagonizing histamine at the H_1 receptor, some antihistamines, such as azatadine, of the piperidine class, and terfenadine, a nonsedating antihistamine, inhibit histamine release after intranasal antigen challenge.[158,159] Treatment with some antihistamines also reduces the production of leukotrienes and kinins, which are mediators with proinflammatory effects,[159,160] as well as the allergen-induced increased responsiveness to methacholine.[104] Another anti-inflammatory property of antihistamines is a reduction of soluble ICAM-1 lev-

els in nasal secretions, a property demonstrated by both loratidine and cetirizine.[161]

Oral antihistamines are readily absorbed. Their onset of action is rapid, usually within 60 minutes, and maximum benefit occurs within hours.[160] Metabolism of most antihistamines occurs primarily through the hepatic cytochrome P-450 system. Drugs that interfere with this system, such as antifungal agents, can lead to the accumulation of antihistamines to toxic levels. One exception is cetirizine, which is primarily excreted in the urine and does not depend on the cytochrome P-450 system. The clinical effectiveness of antihistamines exceeds the duration of measurable serum levels. This phenomenon may be attributable to the presence of active metabolites. Another explanation for the prolonged efficacy of H_1 receptor antagonists beyond their measurable serum levels relates to extended tissue levels.

In the United States, four common second-generation antihistamines are in clinical use: azelastine, cetirizine, fexofenadine, and loratidine.[162] Azelastine, a phthalazinone derivative, is an intranasal preparation with efficacy comparable to that of other antihistamines. Although it does not cause somnolence, azelastine may cause a sensation of altered taste immediately after use.[163] Cardiac arrhythmias, fatal ventricular tachycardia, or prolongation of the QT interval associated with concomitant administration of agents that interfere with the cytochrome P-450 system have been reported with two older second-generation antihistamines, terfenadine and astemizole. These agents are no longer available in the United States. Fexofenadine, a metabolite of terfenadine, does not possess these cardiac risks. Second-generation agents have been shown to be effective. Both cetirizine and fexofenadine have been demonstrated to improve quality of life, as measured by generic and disease-specific tools.[164,165] They cause little or no somnolence, do not affect performance, and have no anticholinergic effects.[166] Azelastine and fexofenadine are approved for children older than 12 years, loratidine may be used in children age 6 or older, and cetirizine may be used in children as young as 2 years.[167]

All antihistamines are effective in the treatment of allergic rhinitis and differ principally in their side effects, duration of action, and cost. In equipotent doses, they are equally effective in suppressing histamine-induced skin wheals.[168] H_1 receptor antagonists are most effective in treating sneezing, nasal and ocular pruritus, and rhinorrhea associated with allergic rhinitis but have little or no effect on nasal congestion. Thus, they are often combined with an oral decongestant. Generic first-generation H_1 blockers are considerably less expensive than their nonsedating counterparts. Some clinicians have tried to circumvent the sedation caused by first-generation antihistamines by directing that they be taken before bedtime, when somnolence is not a problem. The next day, prolonged tissue levels provide continued efficacy without the undesirable side effect of drowsiness.[169] Some studies, however, suggest that performance is impaired despite the lack of drowsiness. It is therefore important to warn patients receiving these drugs about their effect on daily activities, such as driving or operating heavy machinery. Patients who lack medical insurance or formulary coverage often use first-generation agents despite their significant side effects. This poses considerable public health concerns, given recent studies demonstrating the marked performance impairment associated with their use. Unfortunately, the nonsedating antihistamines are more expensive than the traditional antihistamines.

Decongestants

Decongestants exert their effect through stimulation of α_1- or α_2-adrenergic receptors. These receptors are present on resistance vessels, where they control blood flow, and on capacitance vessels, where they control blood volume. In capacitance vessels, α_2 receptors outnumber α_1 receptors.[170] In resting conditions, sympathetic nervous activity regulates nasal patency by maintaining the sinusoids contracted to approximately half maximal capacity. The resting state is affected by the nasal cycle, a periodic, reciprocal alteration of nasal cavity congestion and decongestion that affects about 80% of normal individuals. Increased sympathetic stimulation, such as occurs during exercise, reduces nasal congestion.

Oral decongestants exert their effects directly and by stimulating norepinephrine release. The two major decongestants are pseudoephedrine and phenylpropanolamine, which can be prescribed separately or in combination with antihistamines. Use of phenylpropanolamine in diet medication has been associated with rare hemorrhagic stroke and has been withdrawn from the US market. Because oral decongestants also stimulate adrenergic recep-

tors other than those in the nasal vasculature, overdosage has been associated with hypertensive crisis. When given in prescribed doses, however, they do not induce hypertension in normotensive patients, nor do they alter the pharmacologic control of stable hypertensive patients. Current recommendations suggest that decongestants should not be used in patients with uncontrolled hypertension, in those with severe coronary artery disease, or in patients receiving monoamine oxidase inhibitors. Decongestants should be prescribed with caution in patients with diabetes, hyperthyroidism, closed-angle glaucoma, coronary artery disease, cardiac insufficiency, prostatic hypertrophy, or urinary retention.[171] Their major side effect is insomnia, which occurs in approximately 25% of patients.

Topical decongestants are effective in reducing nasal congestion, regardless of the cause, and these include catecholamines (such as phenylephrine) and imidazoline derivatives (such as xylometazoline or oxymetazoline). Prolonged use can bring about rhinitis medicamentosa, which is characterized by reduced duration of action and rebound nasal congestion after cessation of therapy. Because this phenomenon can appear even after a short period, use of these agents should be limited to a few days. These agents are best reserved for patients in whom nasal congestion is so severe that it precludes the use of other topical preparations such as intranasal corticosteroids or more restful sleep is required during acute exacerbations of disease. Seizures have occurred in children given these medications intranasally.

Topical Intranasal Corticosteroids

Topical intranasal glucocorticosteroids are potent medications for the treatment of allergic rhinitis. These agents profoundly reduce multiple aspects of the inflammatory response to allergen. Corticosteroids penetrate the interior of the cell, where they are bound by a glucocorticoid receptor in the cytoplasm. The glucocorticoid-receptor complex then penetrates the nucleus, where it inhibits the synthesis of the proinflammatory cytokines IL-1, -2, -3, -5, and -6; interferon-γ; tumor necrosis factor-α; and GM-CSF[172] and induces the synthesis of other anti-inflammatory substances such as vasocortin and lipocortin. These agents reduce eosinophil survival and function induced by IL-1, -3, and -5.[173,174] Treatment with intranasal flunisolide resulted in significant inhibition of mediator release during both early- and late-phase reactions after antigen challenge, along with a significant inhibition of the influx of basophils, eosinophils, neutrophils, and mononuclear cells in nasal secretions.[174,175] Treatment with intranasal corticosteroids also reduced the antigen-induced hyperresponsiveness of the nasal mucosa to subsequent antigen[174] and histamine provocation.[100] Intranasal corticosteroid administration also leads to a reduction in inflammatory cells and TH2-type cytokines within the nasal mucosa.[92] For example, treatment with fluticasone inhibits the allergen-induced increase in IL-4, IL-13, eotaxin, and MCP-4 mRNA. In addition, intranasal corticosteroids increase the level of TH1-type cytokines such as interferon-γ and IL-12, which can suppress the transcription of IL-4.[92] These beneficial anti-inflammatory effects of intranasal corticosteroids support the findings in several placebo-controlled clinical trials of a variety of these agents that demonstrated their efficacy in the reduction of nasal symptoms in both seasonal[176] and perennial[177] allergic rhinitis. Corticosteroid-induced cellular modifications require several hours to appear, and this might explain why their onset of action was gauged in days, although more recent studies show that fluticasone affects symptoms within 12 hours.

Topical corticosteroids effectively suppress the response to allergen provocation. In contrast to systemic corticosteroids, pretreatment with topical corticosteroids reduces the acute nasal response to allergen challenge, as shown by a reduction in symptoms and in levels of recovered inflammatory mediators in nasal secretions (Figure 32–4).[174] Treatment with topical corticosteroids also reduces symptoms, the levels of mediators, and cellular infiltration during the late-phase reaction to allergen challenge and the priming response to antigen (see Figure 32–4).[70,174] These agents also inhibit hyperresponsiveness to nonantigenic stimuli such as histamine.[99] Topical corticosteroids also prevent the increase in mast cells and inflammatory cells seen during seasonal exposure to allergen.[147] Furthermore, they also resulted in suppression of the seasonal increase in specific IgE antibodies during the ragweed season.[178] A direct vasoconstrictor effect of topical glucocorticosteroids, found in the skin, does not occur on the nasal mucosa.[179]

Currently, topical forms of corticosteroids include flunisolide, beclomethasone dipropionate, triamcinolone, budesonide, mometasone, and fluti-

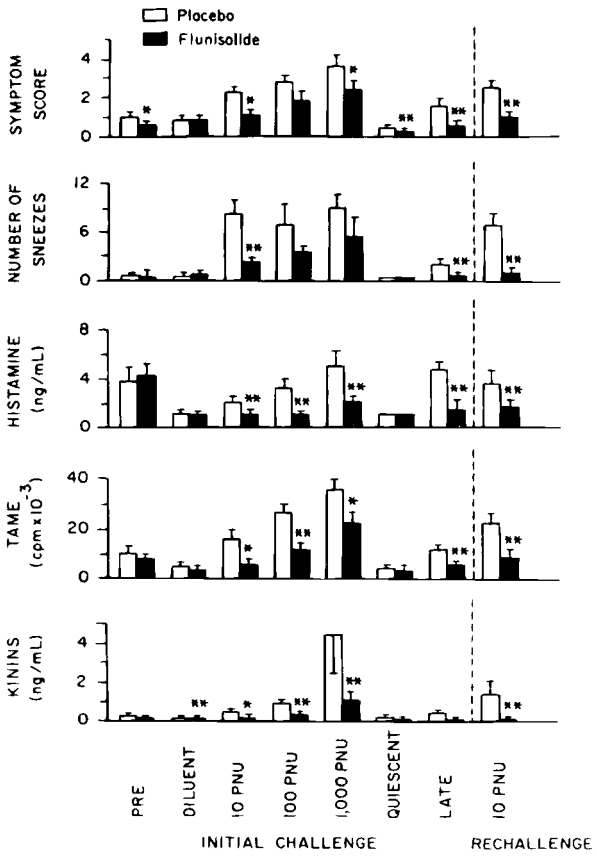

FIGURE 32–4. Effect of intranasal corticosteroids (flunisolide) on the nasal response to allergen. The protocol of challenge is seen on the abscissa: Pre = prewash at the initiation of the allergen challenge protocol; Diluent = challenge with the diluent for the allergen extract to control for nonspecific reactivity; 10, 100, and 1,000 protein nitrogen units (PNU) = increasing doses of allergen used for challenge; Quiescent = the initial hours after allergen provocation; Late = the late-phase response; 10 PNU = rechallenge with the lowest dose of allergen 10 hours after the initial challenge. As can be seen from the response with subjects on placebo (*open bars*), there was a significant increase over diluent in all of the parameters measured during both the early and late responses. There was also an increase in responsiveness to the lowest dose of allergen (10 PNU) as assessed by levels of histamine, tosyl-L-arginine methyl ester (TAME)-esterase, and kinins in nasal lavages, indicative of the priming response. Pretreatment with flunisolide (*closed bars*) resulted in inhibition of the early, late, and rechallenge responses to allergen. Adapted from Pipkorn U et al.[174]

casone. Although differences in the potency and strength of receptor binding among these molecules can be demonstrated in vitro and in certain in vivo models, none of these variations has been shown to translate into major clinical differences. These drugs are principally distinguished by the form of administration (pressurized aerosol, metered-dose inhaler, powder), by the frequency of administration (either once or twice daily), and by the potential to cause systemic toxicity. Their onset of action has been reported to be as short as 1 day, with most preparations having a noticeable clinical effect by 3 days and a peak effect by 2 weeks. Previous studies suggested that these medications work best with continued use as opposed to intermittent, as needed use.[180] However, there is evidence that they may be effective when used intermittently.[181] A study compared the efficacy of intranasal fluticasone and placebo nasal sprays used as needed in patients with seasonal allergic rhinitis and showed that as needed use of the intranasal corticosteroid led to significant improvement in symptoms and quality-of-life scores compared to placebo.[182] Additionally, data indicate that the as needed use of intranasal corticosteroids is more effective for perennial allergic rhinitis than is a second-generation antihistamine.[183]

Side effects are relatively rare.[184] The most frequent is nasal irritation, which occurs in approximately 10% of patients. This is manifested as a nasal burning sensation or sneezing. Two percent of patients have blood-tinged secretions either because of the medication or because of the delivery system.[183] Although septal perforations have been reported, they are extremely rare.[185] Nasal biopsies after prolonged use of these agents have not shown thinning of the nasal epithelium or abnormalities in the nasal mucosa.[186–188] Mucosal superinfection with *Candida albicans*, occasionally found with the use of topical, orally inhaled corticosteroids in the treatment of asthma, has not been a significant problem in the nose.[189]

Systemic side effects have long been a matter of concern. Dexamethasone, the first available topical corticosteroid in the United States, had measurable systemic absorption, leading to adrenal suppression after prolonged use.[190] The newer preparations now available on the market have lower systemic absorption, and at the standard doses used for the treatment of allergic rhinitis, no detectable effects on the hypothalamic-pituitary-adrenal axis have been found. One report of the development of retrocapsular cataract during beclomethasone therapy appeared,

but some of these patients had also received systemic corticosteroids.[191] An Australian study suggested a significant increase in cataract formation associated with prolonged use of these medications, but the effect was small and not much greater than not wearing sunglasses.[192] In a more recent study in the United Kingdom, the use of intranasal corticosteroids was not associated with an increased risk of cataracts.[193] A reduction in bone growth in children has concerned pediatricians.[194] This problem has been studied best in asthmatic children, and the majority of studies suggest no effect and are confounded by the effect of asthma itself on growth in these patients.[195] Therefore, for long-term use, a topical corticosteroid with low bioavailability, administered in the lowest dose necessary to provide relief of symptoms, seems advisable and safe. A recent placebo-controlled clinical study has shown that treatment of children with perennial allergic rhinitis with beclomethasone dipropionate caused a reduction in growth velocity compared with the effect of placebo.[196] This effect was observed in the absence of laboratory evidence of hypothalamic-pituitary-adrenal axis suppression, suggesting that growth velocity may be a more sensitive indicator of systemic corticosteroid exposure than assessment of the hypothalmic-pituitary axis in pediatric patients. On the other hand, treatment of children with perennial allergic rhinitis with mometasone furoate for a year did not result in any growth retardation or hypothalamic-pituitary-adrenal axis suppression compared to placebo.[197] The long-term effects of the reduction in growth velocity, including the final impact on adult height and the ability to catch up in growth after discontinuation of treatment, have not been adequately studied. Recent recommendations state that the growth of pediatric patients receiving intranasal corticosteroids should be monitored regularly (every 3 to 6 months) with an accurate instrument (stadiometer) by trained staff in a consistent way. Furthermore, it seems wise to use the newer agents with the lower systemic bioavailability such as mometasone and fluticasone for the treatment of children. These agents have been approved by the US Food and Drug Administration (FDA) starting at the ages of 3 (mometasone) and 4 years (fluticasone), with the recommended dose being half that used for adults. Mometasone and fluticasone are poorly absorbed from the gastrointestinal tract, with the remaining fraction of absorbed drug rapidly metabolized by the liver.[198,199]

In comparative trials, topical corticosteroids were more potent in relieving nasal symptoms than cromolyn[200] or antihistamines.[201,202] Previously, the addition of antihistamines to intranasal corticosteroids was thought to benefit ocular symptoms and add more rapid onset of effectiveness at the initiation of treatment, although a meta-analysis showed antihistamines and topical corticosteroids to have equivalent effects on ocular symptoms.[203] In a study comparing intranasal corticosteroids with immunotherapy, budesonide was found to be superior to Pollinex-R (Bencard Allergy Service, Weston, Ontario, Canada). Pollinex-R is not a standard, accepted form of immunotherapy, however, and further investigation is warranted in that regard.[204]

Systemic Corticosteroids

Clinical practice confirms the impression that oral corticosteroids reduce symptoms during seasonal allergies, but this has not been documented in placebo-controlled trials.[205] These agents are usually administered to patients during severe exacerbations of allergic symptoms when total nasal obstruction prevents the introduction of a topical intranasal corticosteroid. Furthermore, these agents are used successfully in combination with antibiotics for treatment of sinus infections complicating allergic exacerbations. Depot injections of corticosteroids have efficacy comparable with short-term oral prednisone therapy and enjoy some popularity in Europe, including Scandinavia.[206] Corticosteroid injections into the turbinates are also perceived as clinically effective but have rarely been used in North America since the advent of intranasal corticosteroids and because of a small associated risk of blindness.[207] Although this complication can be minimized by use of a corticosteroid with small particle size, the need to take this infrequent risk in lieu of alternative successful therapies has led to a decline in the popularity of this form of treatment.

Cromolyn Sodium

Cromolyn is available over the counter as a 4% solution for intranasal use and has been shown to be clinically effective in the treatment of allergic rhinitis. It exerts a protective effect on the allergic response when given four to six times daily beginning before the development of symptoms.[208] Although it was

initially thought to prevent mast cell degranulation, the exact mechanism of action of this agent is unknown. Its effectiveness approximates that of antihistamines,[209] but the need for frequent dosing limits compliance. Like antihistamines, cromolyn is more helpful for sneezing, rhinorrhea, and nasal itching than for nasal congestion.[210] Its safety profile, however, makes it an attractive treatment, especially in children and pregnant women. When effective, the potency of this agent parallels that of antihistamines but is less than that of intranasal corticosteroids.

Anticholinergic Agents

Ipratropium bromide is the only anticholinergic agent available for topical use in the United States. Anticholinergic agents inhibit parasympathetic stimulation of glandular secretion by competing for muscarinic receptors on glands. They are highly effective in reducing rhinorrhea but have no effect on the other symptoms of allergic rhinitis.[211,212] The clinical benefit of anticholinergic agents is primarily limited to the treatment of patients with rhinitis in whom rhinorrhea is the predominant complaint. This could occur in a variety of nasal conditions such as allergic and nonallergic rhinitis, as well as the rhinorrhea precipitated by exposure to cold, windy environments, often referred to as "skiers' nose."[213] The dosage should be titrated to avoid excessive drying of the nasal mucosa and epistaxis, which are the most frequent side effects. This agent serves as a useful adjuvant therapy with topical corticosteroids and antihistamines for control of rhinorrhea.

Leukotriene Modifiers

Among the numerous mediators released into the nose on antigen challenge, leukotrienes have been shown to contribute to nasal congestion in allergic rhinitis.[57,58] Symptoms of allergic rhinitis have been shown to be reduced by two clinically available leukotriene modifiers, zafirlukast and montelukast.[214,215] These drugs, although not currently indicated in the primary treatment of allergic rhinitis, may be useful in the treatment of patients with allergic rhinitis and concomitant asthma. The combination of a leukotriene modifier with an antihistamine increases the efficacy of both medications.[216] This combination can be considered as an alternative in patients who do not tolerate intranasal corticosteroids.

Ophthalmic Preparations

Treatment of ocular symptoms of allergy employs a regimen of medications similar to those used for nasal manifestations. After avoidance, pharmacotherapy includes the use of topical decongestants, antihistamines, mast cell–stabilizing agents, and anti-inflammatory preparations.[217] Topical decongestants such as phenylephrine and tetrahydrozoline decrease vascular congestion and eyelid edema through α-adrenergic receptors. Several over-the-counter topical antihistamines are available, some in combination with a decongestant. Recently, second-generation topical antihistamines have become available. Levocabastine is a long-lasting topical antihistamine with a rapid onset of action that has been shown to be effective.[218] Azelastine has recently been approved for the treatment of allergic conjunctivitis.[219] Emedastine and olopatadine are also new topical agents that have also been shown to be effective.[220,221] Ophthalmic formulations of ketotifen fumarate, pemirolast potassium, and nedocromil sodium, agents with mast cell–stabilizing agents and other properties, have recently been approved by the FDA for use in adults and children with itching of the eyes owing to allergic conjunctivitis. Ketorolac, a nonsteroidal anti-inflammatory agent, diminishes ocular itching and hyperemia and is the only agent in this class approved by the FDA for treatment of allergic conjunctivitis.[222] Mild topical corticosteroids can be used in patients who continue to have symptoms despite treatment with the aforementioned agents, but these can cause local complications. Rapidly inactivated topical corticosteroids are under investigation for use in this disease. Although a number of new drugs are now in use, there are few randomized, placebo-controlled trials comparing the efficacy of these agents.

Immunotherapy

The exact mode by which immunotherapy achieves efficacy remains to be fully elucidated.[223] Studies show that this treatment induces a state of specific T-cell tolerance with a subsequent reduction in mediator release and tissue inflammation.[224] Immunotherapy produces several immune modifications in the peripheral blood and nasal mucosa that probably

contribute to its efficacy.[225,226] Treatment causes a rise in serum-specific IgG antibodies, a suppression in the usual seasonal rise in specific IgE antibodies with a decline over years, and an increase in IgA and IgG antibodies in nasal secretions.[227,228] It reduces in vitro lymphocyte responsiveness to antigen[229] and decreases IL-2 release by inflammatory cells.[230] In experimental models of nasal provocation, immunotherapy reduces both early and late responses to ragweed antigen challenge, cellular influx into nasal secretions, and priming.[231] During the allergy season, immunotherapy leads to an inhibition of eosinophil migration into nasal secretions[232] and a reduction in nonspecific hyperreactivity to histamine.[233] A randomized, double-blind, placebo-controlled trial of the discontinuation of immunotherapy for grass-pollen allergy showed a sustained reduction in the late skin response and associated CD3+ T-cell infiltration and IL-4 mRNA expression.[234] These results suggest that long-term changes occur in immune function as a result of immunotherapy, possibly owing to a switch from TH2 to TH1 responses.

Indications for immunotherapy have not been established by experimental studies but rather have evolved over years of clinical experience.[233] The primary indication is symptoms not adequately controlled by avoidance measures and pharmacotherapy. Patients with perennial symptoms may prefer immunotherapy to yearlong daily medication. In making their selection, patients must be advised that immunotherapy offers control of symptoms but is slow in onset and, unlike pharmacotherapy, is effective only for the allergens for which the patient is treated. Whether years of successful therapy cure the disease after discontinuation of immunotherapy is an important but unanswered question. However, one study suggested that improvement in rhinitis symptoms persists for several years after the end of treatment.[234]

Immunotherapy begins with low-dose injections of allergen extracts and builds to a maintenance dose. Injections usually begin at weekly intervals and are then reduced in frequency when maintenance doses are reached. The choice of allergens for treatment must be made after a careful diagnostic workup so that the probability of treatment being started with extracts from all of the allergens responsible for symptoms is increased. Treatment should not be given if skin or serum testing cannot confirm evidence of an IgE-mediated mechanism. Whereas excellent relief can be expected with pollen allergens, dust mites, and some animal danders, treatment with molds is less reliable. Immunotherapy with too many allergens is impractical, and usually treatment with no more than 6 to 10 allergens is attempted. Enzymes from some allergens can destroy other extracts, reducing the expected potency of the treatment.[233] Furthermore, combining allergens of different clinical sensitivities may interfere with reaching adequate maintenance doses for all allergens. Patients who are taking beta blockers should not receive immunotherapy because, if anaphylaxis occurs, they cannot be resuscitated. Immunotherapy of symptomatic asthmatic patients should be administered with extreme caution because these patients have the greatest morbidity. Immunotherapy should not be started in pregnant women because of the risk of anaphylaxis and the resultant effect of hypotension on the fetus.

Improvement of symptoms may begin as soon as 12 weeks, but an optimal effect usually takes 1 year to attain.[233] Effectiveness of immunotherapy requires administration of sufficient amounts of allergen. For ragweed, this has been shown to be between 6 and 12 μg of Amb a 1 (the major antigen in ragweed) per injection. The effect is antigen specific; thus, selection of relevant antigens for treatment is paramount. Patients who do not achieve symptomatic improvement after 1 year of immunotherapy should have it discontinued. No information is available on the length of time over which effective immunotherapy should be pursued, but most physicians treat for 2 to 5 years.

Allergen injections should be administered under the supervision of a qualified medical practitioner, and patients should be observed for at least 30 minutes after every injection. Local reactions at the site of injection are frequent with effective dosages and require no therapy. Repeated strong reactions (ie, greater than 4 cm in diameter) persisting for 24 hours should lead to consideration of dose reduction. Proper resuscitative equipment should be present because anaphylactic reactions can occur at any time during treatment, even in patients receiving maintenance dosages. Factors that seem to contribute to increased complications, including fatalities, seem to be labile, corticosteroid-dependent asthma that has required prior hospitalizations, high sensitivity to allergen (as demonstrated by serum-specific IgE tests or skin test), and a history of prior systemic reactions.[235] Therefore, although death from immunotherapy is uncommon (the risk is estimated at one

fatality for every 2 million injections), special precautions need to be taken with asthma, and a waiting period of at least 20 minutes after administration of the injection is recommended for all patients, with longer intervals (30 minutes) appropriate for high-risk patients.[236] Concern over mortality has led to decreased use in the United Kingdom.

Future Therapies

As the molecular dissection of the complex immunologic pathophysiology of allergic rhinitis has developed, new targets are surfacing for pharmacologic development. Perhaps the most obvious target is IgE, given its central role in allergic rhinitis. An antihuman IgE antibody (rhuMAb-E25) showed promise in early trials[237,238]; a phase 3 trial suggested that this therapy may have potential.[239] A third generation of antihistamines is in phase 2 and phase 3 clinical trials (desloratadine and norastemizole). Development of drugs combining antihistamines and antileukotriene agents is under way. Perhaps most exciting are advances in cytokine biology. Drugs targeting several cytokines known to play a role in the inflammatory process are being developed and tested. These include monoclonal antibodies to IL-4, IL-13, and IL-5; monoclonal antibodies to the receptors of IL-4 and IL-13; and soluble IL-4 and IL-13 receptors.[240] Classes of investigational agents that target other molecules thought to be important in the inflammatory processes of allergic rhinitis include tryptase inhibitors, phosphodiesterase-4 inhibitors, chemokine inhibitors, and adhesion receptor antagonists.[240]

A perhaps more elegant therapeutic strategy would be to effect long-lasting changes in immune responses away from an allergic phenotype. Such a strategy might alter the natural course of disease and allow discontinuation of medication. This type of immunotherapy may involve immunization with allergen, modified allergen, peptides of allergen, or complementary deoxyribonucleic acid (cDNA) of allergen, with adjuvants, including immunostimulatory DNA sequences, cytokines, and bacterial products.[241] These therapies will require further study but ultimately may prove useful in expanding the armamentarium against allergic rhinitis.

Special Considerations

Several patient populations require careful attention in the treatment of allergic rhinitis. In the case of elite athletes, preventive therapy must be initiated so that effects on peak performance can be avoided.[242] The Olympic Committee bans pseudoephedrine-containing agents. Similarly, care must be taken in the treatment of elderly patients with respect to side effects, clearance, and drug interactions. Treatment of rhinitis during pregnancy poses special problems. Rhinitis and nasal congestion frequently occur during pregnancy (30%) and are related to hormonal changes.[243,244] Pregnant patients require careful consideration in the choice of therapy. Ideally, no medication should be used, particularly during the first trimester. Avoidance measures should be implemented first. If symptoms of rhinitis interfere with maternal well-being, pharmacologic management is considered.[245] The patient must be advised that no drug can be considered absolutely safe because most drugs cross the placenta and can be measured in fetal blood.

The American College of Obstetricians and Gynecologists (ACOG) and the American College of Allergy, Asthma and Immunology (ACAAI) make the following recommendations. Pseudoephedrine has been recommended as the decongestant to be used in pregnancy, even though studies show an association with a rare birth defect, gastroschisis.[246] Therefore, the recommendation remains to avoid oral decongestants during the first trimester.[247] Chlorpheniramine and tripelennamine have been recommended as the antihistamines of choice for use in pregnancy, based on animal and human studies. Animal studies have been reassuring for cetirizine and loratidine but not for azelastine or fexofenadine. In patients who do not tolerate chlorpheniramine and tripelennamine and who fail other therapies, use of cetirizine and loratidine could be considered.[247] Sodium cromoglycate is a safe drug during pregnancy and should be considered in the treatment of allergic rhinitis before corticosteroids. No data exist on the teratogenicity of intranasal corticosteroids in humans,[170] although they are thought to be safe and effective.[248] They are widely used during gestation, given their effectiveness in allergic disease and the lack of systemic effects. Studies on inhaled corticosteroids and pregnancy would suggest that beclomethasone and budesonide would be the agents to be initiated. Because the available intranasal corticosteroids do not vary in efficacy or safety and lack systemic side effects, one may consider continuing treatment with these agents in a patient who has well-controlled disease prior to pregnancy and who continues to require

treatment.[247] Newer forms of intranasal corticosteroids with lower bioavailability may be a more prudent choice. Leukotriene modifiers show adverse effects in animals and cannot be recommended in pregnancy. Maintenance immunotherapy may be safely continued during pregnancy in patients who are not prone to systemic reactions. Because of the increased risk of systemic reactions, immunotherapy should not be initiated during pregnancy.

TOWARD A RATIONAL CHOICE OF THERAPY

Prevention remains the mainstay of treatment of allergic rhinitis (Figure 32–5). If allergen exposure can be reduced, this should be part of long-term management. Short-term avoidance does not result in an instant resolution of symptoms and is rarely completely achievable.

Pharmacotherapy provides the fastest relief. Antihistamines begin to take effect within 1 hour and traditionally constitute the first line of intervention. They are excellent for the treatment of sneezing and watery rhinorrhea. When cost is not an issue, nonsedating antihistamines should always be prescribed. To minimize cost, one can administer a long-acting, sedating antihistamine around bedtime and allow its efficacy to persist into the next day without its sedative side effect, although adverse central nervous system effects may still occur. Decongestants can be added to antihistamines in fixed combinations or as separate agents for relief of nasal congestion. Cromolyn sodium is an alternative to antihistamines as an initial treatment, but the need for frequent dosing, with the resultant reduction in compliance, should be kept in mind. Leukotriene modifiers may be used for effects against congestion in asthmatic or refractory cases and may be used in combination with antihistamines in patients who do not tolerate other therapies.

When antihistamines and/or decongestants are insufficient in relieving symptoms, topical corticosteroids should be recommended. These have been shown to be equally effective as antihistamines even when used on an as needed basis. They are highly effective in reducing all of the nasal symptoms of allergic rhinitis, including congestion. They are nonsedating, have few side effects, and are well tolerated by patients. The daily cost of treatment with nasal corticosteroids is less than that of the daily use of nonsedating antihistamines. Topical corticosteroids are initially given at the dose recommended in the *Physicians' Desk Reference*. Patients should be seen 2 weeks after initiation of therapy for monitoring for the development of local side effects. Superficial septal erosions can occur secondary to trauma from the nozzle, and the application technique should be carefully reviewed with these patients. The dosage is adjusted depending on the response: if a patient is doing better but continues to have breakthrough symptoms, the frequency of administration is increased; if excellent control is achieved, the frequency or the dose should be reduced.

Furthermore, periods of exacerbations can be predicted, based on a patient's pattern of allergies; therefore, the medication dosage can be varied accordingly. Ocular symptoms may be minimally controlled by intranasal corticosteroids; thus, adding an ophthalmic preparation or an oral antihistamine may be necessary.

In children, the long-term use of certain topical corticosteroids is approved in patients as young as age 3 years or older. For most topical corticosteroids, it is recommended to reduce the dose by half in young children. Because of the slight possibility that intranasal corticosteroids could interfere with growth, these medications should always be given in the lowest effective dose. Growth should be carefully and regularly monitored. Treatment with topical corticosteroids requires patient education. The physician must often reassure patients as to the safety of intranasal corticosteroids compared with oral preparations.

Initiation of immunotherapy depends on patient preference and the response to pharmacotherapy. Immunotherapy has not been shown to be more effective than intranasal corticosteroids.

Surgical management of nasal obstruction is presented in Chapter 33. Major septal deviations should be corrected because they may interfere with the delivery of intranasal medications. Less severe obstructions should be corrected only if symptoms persist after adequate control of the allergic symptoms. Similarly, turbinate reduction by means of submucous resection, vaporization with the laser, electrocautery, or radiofrequency ablation may be adjuvant procedures in patients with allergic rhinitis but more often find use in the management of nonallergic rhinitis (see Chapter 33). Functional endoscopic sinus surgery, presented in Chapter 34, can be used for the treatment of chronic rhinosinusitis, which frequently complicates perennial rhinitis.[249]

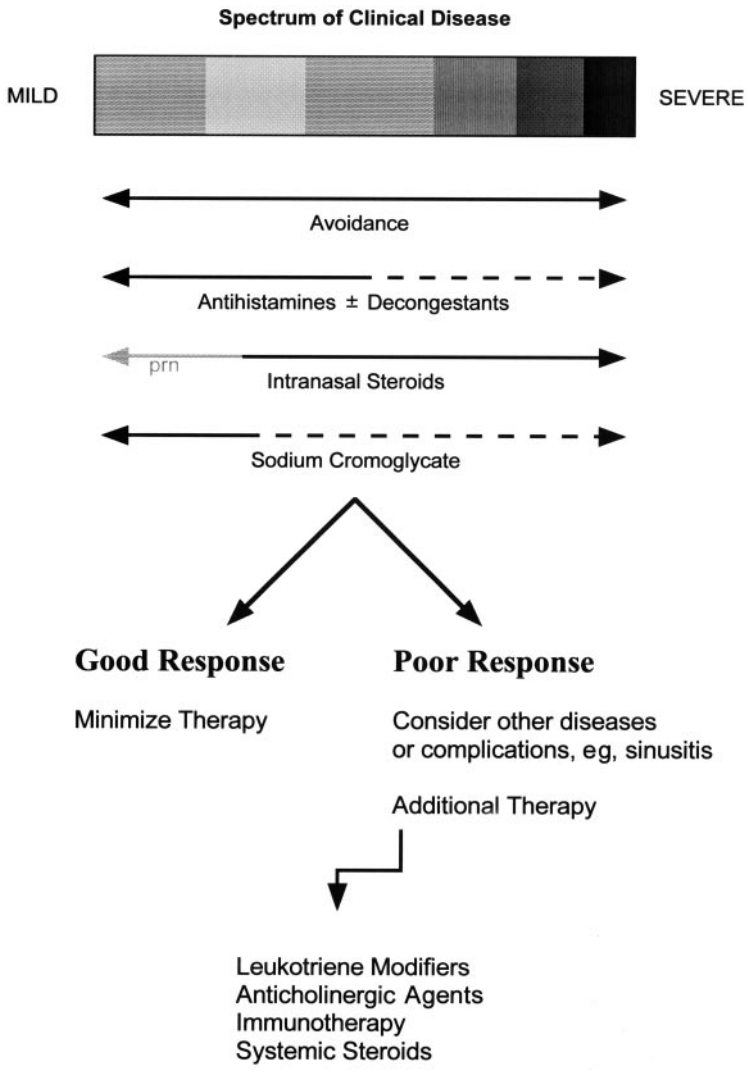

FIGURE 32–5. Approach to the treatment of allergic rhinitis. This schematic depicts the different treatments available for allergic rhinitis and establishes some guidelines for the use of these therapies in different stages of severity of the disease. Avoidance should be used in all stages. Antihistamines and/or decongestants as well as sodium cromoglycate are commonly used for allergic rhinitis of mild to moderate severity. Topical intranasal corticosteroids are also effective against a range of symptoms, including on an as needed basis. Severe disease usually warrants more aggressive treatment. This may require combination or adjuvant therapy. Anticholinergic agents play a limited role in the control of rhinorrhea. Leukotriene modifiers are useful in the treatment of congestion, especially in asthmatic patients. Systemic corticosteroids are reserved for severe allergic rhinitis leading to complete nasal obstruction. Immunotherapy can be offered to patients who fail medical therapy. Clearly, these guidelines need to be varied in the context of different clinical settings as some patients with mild disease might benefit from intranasal corticosteroids, whereas some other patients with more severe disease might respond well to antihistamine/decongestant combinations. prn = as needed.

CHAPTER 33

Acute and Chronic Nasal Disorders

Valerie J. Lund, MS, FRCS, FRCS(Ed)

A wide range of acute and chronic conditions may affect the nose, either arising locally or occurring as part of systemic disease. These may be broadly divided into allergic and nonallergic, with the latter divided into infectious and noninfectious (Table 33–1). This chapter considers some of the infectious conditions, the nonallergic, noninfectious diseases, and a number of other conditions that enter into the differential diagnosis of patients presenting with nasal symptoms. From an anatomic and physiologic perspective, the nose is rarely affected in isolation, and the majority of conditions impact on the adjacent paranasal sinuses to a greater or lesser extent. Thus, there has been agreement on the term "rhinosinusitis" in a number of international consensus documents[1,2] as primarily relating to infection although, in reality, probably applicable to most disease processes in this region. Similarly, the upper and lower respiratory tract should be considered as one organ, with many conditions manifesting themselves in both areas, sometimes in subtly different ways (eg, asthma and nasal polyps).

INVESTIGATION

A considerable number of tests and procedures are now available for the investigation of sinonasal disease (Table 33–2). However, not all are routinely available or indeed applicable to each individual patient, and their selection will depend on clinical indicators and local factors.

HISTORY AND EXAMINATION

In practical terms, the nose has a limited repertoire of responses in any given condition, that is, nasal congestion, discharge, sneezing, itching, and epistaxis with associated symptoms of headache and/or facial pain. However, a careful history will usually suggest the diagnosis. A thorough general medical history should be followed by questions specific to rhinologic symptoms including information on environmental and occupational factors and family history. The frequency, duration, and severity of symptoms should also be discussed, and a visual analog score can be used to semiquantify severity by simply asking the patients to mark on a 10 cm line where they feel they lie for a particular symptom during the last week.[3] This method can be repeated on each subsequent visit, with the patients acting as

their own controls. Consistent obstruction on the same side suggests a polyp, structural problem, or, more rarely, a tumor or even a congenital unilateral choanal atresia. Hyposmia and anosmia are most often associated with nasal polyps or more severe disease such as Wegener's granulomatosis or sarcoidosis. Secondary symptoms related to blockage of the airways include frequent sore throats, dryness of the mouth and oropharynx, a nasal quality to the voice, and snoring. A full drug history may also give a clue to the source of the problem. Symptoms specific to particular conditions are discussed in the relevant sections.

Examination of the nose should be performed in all cases of rhinologic complaint and should include anterior rhinoscopy using a nasal speculum and head light and rigid endoscopy combined with flexible nasoendoscopy in selected cases to ensure a full evaluation of the nasal cavity and nasopharynx.

The quantity and quality of secretion should be noted, both the viscosity and color, and specimens may be taken for a nasal smear. Similarly, under endoscopic control, a swab may be taken from the middle meatus, which provides a reasonable correlation with the bacteriology of the dependent sinuses.[4]

The appearance of the mucosa is rarely altered in a way that is pathognomonic for a particular disease. However, it is usually reddened in acute infections and overuse of topical medications, whereas a typical allergic mucosa appears pale and swollen. In granulomatous conditions such as Wegener's and sarcoidosis, the mucosa is generally reddened, friable, and associated with crusting and evidence of previous epistaxis. A careful examination of the nasal cavity should reveal polyps, tumor, foreign bodies, or septal deflections, although it is important that the unwary examine beyond the deflection wherever possible as secondary pathology may be present and go unnoticed. The presence of a septal perforation should raise the possibility of cocaine abuse, previous surgery, or one of the systemic granulomatous diseases, although most often it is "idiopathic," resulting from minor or repeated trauma.

Physical examination should not be confined to the nose alone and should be accompanied by a full otolaryngoloic examination including posterior rhinoscopy, indirect laryngoscopy, and palpation of the neck in selected cases. It should also be remembered that many conditions affecting the nose and sinuses also affect the lower respiratory tract, and this may be revealed by appropriate examination.

(For allergy testing, see Chapter 32, and for imaging, see Chapter 31.)

MUCOCILIARY FUNCTION

Nasomucociliary Clearance

A simple test of mucociliary function can be performed by placing a 0.5 mm piece of saccharin on the anterior end of the inferior turbinate approximately 1 cm from the end to avoid areas of squamous metaplasia. The time taken to taste something sweet in the mouth is measured,[5] which normally takes 30 minutes or less. If longer than an hour has elapsed, it is worth repeating the test in case the particle has fallen out and checking that the patient is capable of tasting saccharin.

Ciliary Beat Frequency

When the saccharin test is prolonged or if specific ciliary abnormalities are suspected, it is possible to examine the cilia directly by taking a sample with a small disposable, cupped spatula (Rhinoprobe) and observing cilia activity under a phase-contrast microscope with a photometric cell.[6] The frequency can be measured with a real-time analyzer and expressed in hertz, the normal range from the inferior turbinate being 12 to 15 Hz. However, this technique is not available in every center.

Electron Microscopy

If the nasomucociliary clearance time and ciliary beat frequency are abnormal, samples may be obtained with the spatula or via direct biopsy for electron microscopy studies to diagnose conditions such as primary ciliary dyskinesia (PCD).

Nitric Oxide Measurement

The level in parts per million of nitric oxide present in the expired nasal and pulmonary air can be helpful in establishing normal mucociliary function.[7] In PCD, the nitric oxide level that is an indirect marker of ciliary metabolism is much reduced to double figures or less in the nose and single figures from the chest. However, as nitric oxide is predominantly produced in the sinuses, conditions such as nasal polyposis that obstruct gas exchange from these areas can also result in a very low reading from the nasal gases. The level is commensurately elevated in the presence of inflammation.

NASAL AIRWAY ASSESSMENT

Nasal Expiratory or Inspiratory Peak Flow

Nasal expiratory or inspiratory peak flow, which uses a peak-flow meter, has the advantage of being inexpensive, quick, and easy to perform. It is useful for repeated examinations and compares well with active anterior rhinomanometry.[8] Of the two methods, forced inspiration is preferred, although it can produce significant vestibular collapse in some individuals. Forced expiration inflates the eustachian tube, which may be uncomfortable and may also produce an unpleasant quantity of mucus in the mask.

Rhinomanometry

Rhinomanometry attempts to measure nasal airway resistance by making quantitative measurement of nasal flow and pressure.[9] It employs the principle that air will flow through a tube only when there is a pressure differential passing from areas of high to low pressure. When the nasal mucosa is decongested, the reproducibility of rhinomanometry is good, but it requires some expertise to produce consistent results and has therefore remained primarily a research tool. Active anterior rhinomanometry is more commonly used as the posterior technique cannot be used in 20 to 25% of individuals owing to an inability to relax the soft palate.

Acoustic Rhinometry

In acoustic rhinometry, an audible sound pulse is electronically generated and is passed into the nose, where it is altered by variations in the cross-sectional area. The reflected signal is picked up by a microphone and analyzed, allowing determination of area within the nasal cavity as a function of distance. From this, volumes may be derived, thus providing topographic information rather than a measure of airflow.[10] It appears to be more reproducible and to have greater applicability than rhinomanometry but is still being evaluated as a clinical tool.

OLFACTION

Olfactory Thresholds

Estimation of olfactory thresholds may be established by presentation of serial dilutions of pure odorants such as carbinol.[11] The patient is presented with two bottles, one containing only the diluent solution as the control and the other the odorant in progressively increasing or decreasing concentrations. Each is sniffed in turn until a point is reached when the patient cannot distinguish between the control and test bottle. This indicates the minimum detectable odor.

Scratch and Sniff Tests

The University of Pennsylvania Smell Identification Test (UPSIT) uses patches impregnated with microencapsulated odorants.[12] The patient is forced to choose among a number of options after scratching the patch to release the odor. The results are well validated for age and sex and take into account answers guessed correctly as well as give an indication of malingering.

Alternative identification tests include the Zurich Smell Test, in which eight odorants must be correctly identified. The test choices are offered pictorially and in English.[13] The Sniffin' Sticks combine both a qualitative and a quantitative assessment of olfaction.[14]

Blood Tests

A wide range of hematologic investigations may be appropriate given the suspected differential diagnosis (eg, thyroid dysfunction, Wegener's granulomatosis, sarcoidosis, and immune deficiency).

INFECTIOUS RHINITIS

The separation of infections in the nose from those in the paranasal sinuses is now recognized as incorrect, and it is generally accepted that the term "rhinosinusitis" better encompasses infections in this region, although one area may be affected to a greater or lesser extent. This has been supported by the work of Gwaltney et al,[15] who have demonstrated with computed tomographic scanning that during a simple uncomplicated viral cold, the majority of subjects have some involvement of the paranasal sinuses. A long list of causative agents can produce infection in this region (Table 33–3).

Etiologic Factors

A number of congenital conditions may predispose patients to infection of the respiratory tract.

Primary Ciliary Dyskinesia Some individuals are born with a congenital abnormality of the cilia that affects their motility. Electron microscopic examination reveals disorganized microtubules and the absence of dynein arms. In addition to nasal problems, patients usually exhibit lower respiratory tract infection, serous otitis media, and infertility problems. In full-blown Kartagener's syndrome, patients have bronchiectasis, sinus infection, and situs inversus in approximately 50% of cases.

Cystic Fibrosis Cystic fibrosis is an autosomal recessive disease, the most common inherited fatal disease of white children, caused by a defective mucosal chloride transport gene. In its most severe form, it presents with malabsorption and progressive obstructive pulmonary disease, but approximately one-third of children and one half of adults suffer from multiple bilateral nasal polyps, and the majority of patients have a chronic pansinusitis (Figure 33–1). The polyps have been attributed to an abnormality of sodium and water transport across membranes, and the histology of the polyps differs significantly from that in other conditions in that they have less eosinophils and more lymphocytes and plasma cells. *Pseudomonas aeruginosa* is commonly found in association with the sinus disease and may be targeted specifically with appropriate antibiotics such as the quinolones. The majority of patients are managed by a combination of medical therapies with intranasal corticosteroids and surgery. The results of surgery are compromised by the condition although are still regarded as worthwhile by patients. Other medical therapies have included intranasal furosemide, amiloride, and messenger ribonuclease.

Viral Infections

The most obvious and frequently occurring example of infection is the common cold. A number of viruses are associated with upper respiratory tract infections of varying degrees of severity including over 100 different types of rhinoviruses. This, combined with the

ability of viruses for mutation, has so far confounded attempts at prophylactic immunization. Most young adults suffer from two to three colds each year, and it is estimated that 0.5 to 2% of these become bacterially infected. Predisposing factors such as climatic and environmental changes, fatigue, and stress have all been implicated, but the huge variety of viruses makes it unlikely that there is preexisting immunity, and, as a consequence, most individuals are susceptible most of the time. The virus is normally transported into the nose by direct contact with the fingers rather than by airborne contamination, and once the virus gains access to the respiratory epithelium, it will produce ciliary stasis and damage to the cilia. The

FIGURE 33–1. Coronal computed tomographic scan showing massive nasal polyposis with expansion of the nasal cavity and ethmoid complexes in a patient with cystic fibrosis.

condition is characterized by edema, increased secretion, and desquamation of respiratory epithelium. Clinically, after 1 to 3 days incubation, a prodromal or "dry" phase follows. The subject feels unwell and shivery with a headache, muscle aches, and loss of appetite, while the nose feels irritated and sneezing occurs. The catarrhal phase follows after a few hours accompanied by profuse watery secretion, nasal obstruction, a reduced sense of smell, and an increase in constitutional symptoms. The infection then enters a mucous phase in which symptoms improve or may continue after 5 days owing to secondary bacterial infection with a progressively mucopurulent discharge. Other areas of the upper respiratory tract may be affected including the pharynx, middle ear, and tonsils.

From a practical point of view, little can be done other than symptomatic relief with decongestants and antipyretics, although recent studies have suggested that a combination of oral chlorpheniramine and intranasal ipratropium bromide may be effective in reducing symptoms if taken early in the prodromal phase. Antibiotics should be reserved for secondary bacterial infection.

Influenza, in its many forms, constitutes a more specific and potentially serious viral upper respiratory tract infection, resulting in pandemics with significant morbidity and mortality in susceptible populations. Damage to the ciliated epithelium is more profound, facilitating secondary bacterial colonization, and the olfactory epithelium may be permanently damaged, leading to anosmia. Vaccines have been developed and are increasingly used as prophylaxis in vulnerable populations, but their usefulness is again limited by the potential for viral mutation.

Bacterial Infections

Folliculitis and Vestibulitis Specific bacterial infections can occur in the nasal vestibule when *Staphylococcus aureus* invades a pilosebaceous follicle to produce an extremely painful, indurated area. This will spontaneously burst and discharge its purulent contents after 4 to 5 days. The condition is extemely painful as the vestibular skin is tightly bound to the underlying cartilages, providing little room for swelling. Local cleaning and systemic antibiotics, which should include floxacillin, should be given, taking into account problems of local bacterial resistance. If the abscess is localized and fluctuant, it may be incised, but the condition should always be treated seriously as it is associated with the potential complication of cavernous sinus thrombosis by retrograde spread of infection along the angular and superior ophthalmic veins.

The cavernous sinus lies on either side of the sphenoid bone. It is broken up by trabeculae into many venous cavernous spaces through which the third, fourth, and first two divisions of the fifth cranial nerve, sixth cranial nerve, and internal carotid artery pass. It is connected by an extensive valveless venous system to the nose, adjacent face, nasopharynx, pharynx, orbit, and paranasal sinuses, allowing retrograde spread of infection from any of these areas. The condition carries a serious morbidity, often with bilateral blindness and mortality. It is a complication predominantly of the young, with two-thirds being under 20 years.[16] The patient will complain of headache and painful paresthesia in the distribution of the trigeminal nerve, following which other cranial nerves related to the cavernous sinus become involved, affecting extraocular movement and resulting in ophthalmoplegia. The sudden development of bilateral orbital signs should alert the clinician to this complication. Prior to antibiotics, cavernous sinus thrombosis carried a 50% mortality, which nevertheless still stands at a significant 10 to 27%.[17] Computed tomography and

magnetic resonance imaging confirm the diagnosis, and high-dose broad-spectrum systemic antibiotic therapy should be given, together with anticoagulation in selected cases.

The increase of asymptomatic carriage of methicillin-resistant *S. aureus* (MRSA) in the nasal vestibule is a source of considerable concern as it is implicated in nosocomial infection, with serious consequences for debilitated patients. Despite vigorous eradication programs, the incidence of MRSA appears to be increasing worldwide.

A mild form of nonspecific infective vestibulitis is often encountered, producing mild irritation, small fissures, or pustules. The application of white petroleum jelly or antibiotic ointments such as chlortetracycline hydrochloride 3% may be used.

Erysipelas and Other Specific Infections Erysipelas is an acute beta-hemolytic streptococcus infection of the skin and soft tissue of the head and neck following a cut or surgical incision. The onset is usually abrupt, with fever, redness, tenderness, and induration of the involved skin. On the face, the infection frequently displays a butterfly pattern across the nose, adjacent cheeks, and upper lip. The infection generally responds well to penicillin or erythromycin and should be distinguished from cellulitis, which is a more generalized deep infection of the skin and subcutaneous tissues also caused by *Staphylococcus* or *Streptococcus*.

A variety of other specific infections may occur in this region including diphtheria, rhinosceleroma, leprosy, tuberculosis, and syphilis.

In diphtheria, caused by *Corynebacterium diphtheriae,* the nose may be affected primarily or secondarily to infections of the oropharynx. The false membrane associated with the condition is made of fibrin, neutrophils, necrotic epithelium, and the bacillae. Removal of the membrane leaves a bleeding surface. Treatment is with parenteral penicillin, with the antitoxin reserved for acute cases. A carrier state can occur after contact, and the individual may need to be isolated until nose swabs are negative.

In rhinoscleroma, a chronic inflammatory condition is characterized by large, deforming masses distending the nasal cavity. The condition, ascribed to *Klebsiella rhinoscleromatis*, was once found in Central and Eastern Europe but now occurs in Central and South America, Africa, the Middle East, and India, where it is associated with a poor standard of health and living conditions. The disease classically has three phases: rhinitic, infiltrative, and nodular, finally resulting in adhesions, stenosis, and atresia. The large red tumor-like masses of the nodular phase are characterized histologically by the presence of Mikulicz's cells, large cells with clear cytoplasm containing the bacilli, and by Russell's bodies, which are plasma cells with eosinophilic staining cytoplasm and prominent nuclei. Large doses of streptomycin and tetracycline over 4 to 6 weeks are needed until two consecutive biopsies are negative. Topical acriflavine solution has also been used.

In leprosy caused by the acid-fast *Mycobacterium leprae*, two forms in the nose are recognized: tuberculoid and lepromatous. The microorganism may enter via the nose, transferred by a fingernail; incubation can take up to 10 years. In tuberculoid leprosy, solitary lesions occur as small anesthetic patches, whereas in lepromatous leprosy, a diffuse infiltration of the skin, mucous membranes, and nerves is found, producing nodular thickening particularly in the region of the anterior inferior turbinate. The septum is progressively involved, leading to perforation of the cartilage and a typical nasal deformity of collapse and stenosis. Dapsone is still the treatment most generally used worldwide, although increasing resistance has led to newer agents and combinations with rifampin and clofazimine.

In tuberculosis, the nose may be involved secondary to pulmonary involvement, with nodular or ulcerative lesions usually found on the anterior part of the cartilaginous septum, on the inferior turbinate, or in the choanae. The lesions show the usual appearances of caseating epithelioid granulomas together with the presence of acid-alcohol-fast bacilli. The condition responds to standard systemic antituberculosis therapy together with topical saline douching. Lupus vulgaris is a chronic indolent form of tuberculosis, producing the classic "apple jelly" nodules at the mucocutaneous junction of the vestibule.

In syphilis caused by *Treponema pallidum*, the nose may be affected in the primary, secondary, or tertiary phases as well as in its congenital form. A primary chancre can occur on the external nose or vestibule around 3 to 4 weeks after contact and then disappears spontaneously within 6 to 10 weeks. Smears taken at this time may reveal the *Treponema*, although the serology can be negative in the early stages. Secondary syphilis appears around 6 to 10

weeks after infection and may produce no more than simple catarrhal rhinitis, although a serologic diagnosis can be made during this phase. Tertiary syphilis is associated with a gumma that appears as a firm, reddened nodule invading the mucous membrane, periosteum, and bone and often producing tenderness over the bridge of the nose, posterior septal perforations, and nasal collapse. Serology is positive in 90% of these patients. Congenital syphilis may manifest itself with "snuffles" a few weeks after birth or as a latent form occurring at puberty, with the characteristic nasal saddling, dental abnormalities, and sensorineural hearing loss. The condition must be distinguished from other granulomatous diseases and should be treated with standard antibiotics such as penicillin. For more information on infections, see Chapter 30.

NONALLERGIC, NONINFECTIOUS RHINITIS

Idiopathic (Vasomotor) Rhinitis

The term "idiopathic rhinitis" relates to any inflammation of the nose the cause of which is unknown. It is the diagnosis of exclusion as underlying causative or contributory factors can often be found if carefully sought. Patients are generally manifesting an upper respiratory hyperresponsiveness or reactivity, which is simply an exaggeration of normal defense mechanisms to nonspecific environmental triggers such as changes in temperature and humidity or exposure to irritants (eg, cigarette smoke or strong odors). An extreme example of a normal physiologic response can be seen in "skier's nose" in reaction to cold, dry air.[18] The commonly used term "vasomotor rhinitis" is less satisfactory as it suggests a known pathophysiologic mechanism for the condition that is far from proven.[1]

Cigarette smoke is known to affect mucociliary clearance[19] and has been shown to cause an eosinophilic inflammation in the nasal mucosa of nonatopic children.[20] Challenge of smoke-sensitive individuals produces rhinorrhea and obstruction, and in smokers, eye irritation and hyposmia are more common than in nonsmokers. It has also been shown that the more people smoke, the more they experience the symptoms of chronic rhinitis.[21]

In nonallergic, noninfectious rhinitis, symptoms vary in intensity but consist of nasal blockage, anterior rhinorrhea, and postnasal discharge, sometimes with sneezing. There is no characteristic seasonal variation, and ocular symptoms are almost always missing. Skin prick tests are negative or do not correlate with the symptoms (ie, may be positive to grass pollen).

Therapy may encompass avoidance of obvious triggers, but most patients require medication, the mainstays of which are topical corticosteroids that are safe for long-term use. If watery rhinorrhea is the most significant or only symptom, a topical anticholinergic agent such as ipratropium bromide may be helpful. Topical decongestants are best avoided because of their side effects in the long term (sic), and although oral decongestants are popular, their effect is variable and not without cardiovascular and central nervous system effects. Topical capsaicin has been investigated for intractable nonallergic rhinitis[22] as it produces a short-term neuronal defunctionalization, but the effects are short-lived and are accompanied by an unpleasant burning sensation, so its role remains undetermined.

Surgery has a limited role to play. Vidian neurectomy has had a vogue but has largely been abandoned as the effects are unpredictable and at best short-lived. Correction of septal deformity and/or turbinate hypertrophy is occasionally indicated if medication fails.

Occupational/Environmental Rhinitis

Airborne agents present in the workplace may affect the upper respiratory tract, producing either an allergic reaction or a nonallergic hyperresponsiveness. Chemicals such as acid anhydrides, platinum salts, glues, and solvents, as well as dusts from grain and wood, may act as irritants.[23] Considerable controversy now surrounds the adverse effects of environmental pollutants such as ozone, sulfur dioxide, nitric dioxide, particulate matter, volatile organic compounds, and formaldehyde. Some contradictory evidence needs to be clarified by carefully constructed epidemiologic studies that may ultimately support present concerns.

A careful history will usually indicate the cause, confirmed by improvement once the patient is removed from the suspected irritant. However, there may be a reluctance to complain if a worker's job is jeopardized, and chronic exposure may produce

chronic symptoms, which do not abate for a week or more after exposure ceases.

The nasal symptoms of blockage and watery discharge may be accompanied by occupational asthma, conjunctivitis, and dermatitis. Clinical findings are usually nonspecific, and confirmation may require direct nasal challenge evaluated with symptom scores and assessment of nasal patency. Carefully graded exposure to increasing doses of the suspected agent in special ventilated environmental chambers may be necessary, especially if there are medicolegal consequences of the diagnosis.

Separation of patient and irritant, either by change of job, improved ventilation, or use of masks, may suffice complemented by conventional pharmacotherapy (eg, topical corticosteroids).

Hormonal Rhinitis

A range of physiologic and pathologic endocrine conditions can affect the nose. Changes are known to occur in the nose during puberty, the menstrual cycle, and pregnancy,[24] with some women experiencing significant blockage, watery discharge, and, sometimes, severe epistaxis. The symptoms are worst during the last trimester of pregnancy, relating to the blood estrogen level, and resolve with delivery. In women with preexisting perennial rhinitis, the nasal symptoms may improve or deteriorate during pregnancy. Hormonal change may also be responsible for the mucosal atrophy that occurs after the menopause.

In specific endocrine disorders such as hypothyroidism[25] and acromegaly, nasal stuffiness and discharge may occur.

From a therapeutic perspective, if the symptoms during pregnancy are sufficiently debilitating, medication must be considered, always taking the risk/benefit ratio into consideration. In the first instance, saline douche may be of benefit, but, if ineffective, topical nasal corticosteroids have been used for many years without any evidence of a teratogenic or other adverse effects. Certainly, extensive studies in asthmatics using inhaled corticosteroids have failed to show any abnormalities.[26] Oral decongestants theoretically could cause vascular disturbance in the placenta and fetus, but oral pseudoephedrine given within the recommended dosage is approved for use in pregnancy and has been widely prescribed in the United States.

Drug-Induced Rhinitis

A number of medications are known to produce nasal symptoms. These include

- aspirin and other nonsteroidal anti-inflammatory agents (NSAIDs). Aspirin intolerance typically increases nasal congestion and secretion and is associated with nasal polyposis and nonallergic asthma. Avoidance of aspirin and NSAIDs is clearly important, although there is some controversy as to whether avoidance of salicylate-like substances in the diet is beneficial or not. Some have argued that complete avoidance may render individuals more susceptible to inadvertent challenge, whereas others believe a completely salicylate-free diet to be worse than the disease. Other strategies have included salicylate desensitization, which must be performed with great care in a hospital to manage any severe respiratory reactions.
- cardiovascular preparations such as reserpine,[27] guanethidine,[28] phentolamine, methyldopa, angiotensin-converting enzyme (ACE) inhibitors,[29] and α-adrenoceptor antagonists, which are all known to affect the nose, typically producing nasal stuffiness.
- topical ophthalmic beta blockers.
- chlorpromazine.
- oral contraceptives, again by hormonal modulation.
- cocaine, which is more often used recreationally than medically and is a significant irritant, producing frequent rhinorrhea and resultant sniffing, hyposmia, and septal perforation.[30,31] In extreme cases, a midline destruction of the nose may result, which has proved difficult to distinguish from T-cell lymphoma or Wegener's granulomatosis.

Rhinitis medicamentosa is a well-described condition classically resulting from long-term abuse of topical decongestants.[32,33] The patient initially suffers a rebound congestion, which leads to further use of the decongestant, and ultimately develops significant mucosal atrophy. Consequently, these preparations are not recommended for longer than 7 to 10 days. Once the condition is established, it can prove difficult to wean a patient off the medication. The reason for originally starting the drug should be considered, and in mild cases, it may be possible to substitute a topical nasal corticosteroid.

However, if there are no contraindications, an initial short course of oral prednisolone (30 mg/day for 5 days) may be necessary.[1]

Food-Induced Rhinitis

Food can produce nasal symptoms in a variety of ways. Although allergy to food is a rare cause of isolated rhinitis, hypersensitivity may result in reaction to the foods themselves or to colorants and preservatives.[34] Alcoholic beverages can produce physiologic vasodilatation with associated nasal blockage as well as allergic and nonallergic reactions to their many components.

Gustatory rhinorrhea may result from spicy hot foods, probably owing to the capsaicin content of red pepper. This substance is known to stimulate sensory nerves, inducing release of neuropeptides such as tachykinins.[22]

Emotion

Sexual arousal and stress are known to have an effect on the nose—hence "honeymoon rhinitis," probably owing to autonomic stimulation, although therapeutic intervention is rarely sought.

Atrophic Rhinitis

Primary atrophic rhinitis has been attributed to infection, most notably to *Klebsiella ozaenae*[35] (from the word "ozaena" meaning "stench"), but may also relate to environmental factors and general health. The condition is characterized by progressive atrophy of the mucosa with loss of the turbinate bone and resulting in a capacious cavity full of foul-smelling crust. This should be distinguished from secondary atrophy following excessive surgery, trauma, radiotherapy, and chronic granulomatous conditions.

Primary atrophic rhinitis has become less common in countries where social conditions and health have generally improved. It affects both sides of the nose, occurs after puberty, and is more common in women. Because of this, an endocrine imbalance has been postulated as a cause, whereas others believe it has an autoimmune basis, possibly initiated by a virus or owing to vitamin or iron deficiencies.

The most unpleasant symptom is the foul smell, of which the patient is often unaware. The copious crusts often bleed when they detach and may extend into the nasopharynx, producing an unpleasant choking sensation and snorting. The nose paradoxically feels blocked, owing to the drying effect in the abnormally patent airway.

Having eliminated other possible underlying conditions by appropriate hematology and imaging, local treatment with saline or alkaline douching, emollients and lubricants such as 25% glucose and glycerine drops, and regular decrusting may suffice. Antibiotics directed at *Klebsiella* are rarely successful in the long term, although the fluoroquinolones and metronidazole have been used. A wide range of surgical procedures have been suggested, largely aimed at reduction of the size of the cavity, all with limited success. Closure of the nostrils with small skin flaps, as advocated by Young,[36] can be helpful, but relapse often occurs on reopening. It was suggested that reduction of airflow inhibited growth of the microorganisms, but this is unproven.

Nonallergic Rhinitis with Eosinophilia/ Eosinophilic Rhinitis Syndrome

Nonallergic rhinitis with eosinophilia syndrome (NARES) was described 20 years ago, although its existence as a separate entity is disputed. It should probably be regarded as a subgroup of idiopathic rhinitis characterized by nasal eosinophilia and perennial symptoms of sneezing, itching, rhinorrhea, blockage, and sometimes hyposmia in the absence of demonstrable allergy. It is possible that it represents an early stage of aspirin sensitivity and may be associated with asthma and nasal polyposis. Intranasal corticosteroids are the mainstay of medical treatment combined with surgery for the polyps.[37]

Gastroesophageal Reflux

Reflux is increasingly thought to play a role in nonallergic rhinitis, particularly in children.[38]

MECHANICAL NASAL OBSTRUCTION

A common nasal complaint is one of nasal blockage, congestion, or obstruction. This may arise for a variety of reasons, be it a genuine mechanical obstruction to airflow, a response to autonomic or sensory changes in the nose, inflammation within the osteomeatal complex, allergic changes, or even a per-

ception paradoxically in the presence of a patent or overpatent airway. It is important to investigate this complaint carefully to elucidate the cause since in the past there has been a tendency to offer surgery for the septum and/or turbinates without consideration or treatment of other contributory factors, inevitably compromising a successful symptomatic outcome.

Septal Deviation

Causes Septal deformity can be congenital or acquired, although it should be recognized that a completely straight septum is the exception rather than the rule. This may be attributable to prenatal or perinatal factors, in utero or during delivery. A true dislocation of the septum is rare; more often, a horizontal fracture above the maxillary crest occurs, which can be relocated immediately. Small microfractures may go unnoticed, presenting in later life, or be exacerbated by falls during the "toddler" stage that may go unnoticed. In adolescents and young adults, sports injuries, assault, and traffic accidents may all have their impact.

Effects Any part of the nasal internal and external structure may be damaged, leading to deflections and deformities of the cartilages and bones. The effects may not be immediately obvious to the individual until infection or allergy intervenes. With age, loss of tensile strength in collagen may lead to collapse of the nasal valve region, uncovering preexisting nasal asymmetry. The sensation of nasal obstruction may alternate with the nasal cycle or be apparent when lying on that side. Disordered airflow may result in crusting and epistaxis on the deflected area. "As goes the septum, so goes the nose" correctly indicates that septal deviation can be associated with cosmetic deformity of the bridge and columella. (For nasal reconstruction, see Chapter 38.)

Assessment of the external and internal nose, including anterior rhinoscopy and rigid endoscopy, is important to assess the septal position, spurs, and turbinates and exclude other pathology, particularly in the middle meatus and nasopharynx. Instillation of a topical decongestant may help determine the degree of mucosal swelling, particularly of the anterior part of the nasal septum and inferior turbinates. Where available, objective measures of airway can be helpful.

Treatment Septal manipulation is only of value in neonates when trauma has occurred during delivery. Septoplasty or submucous resection have been described to correct septal deviation. The distinction between these two techniques relates primarily to the approach, and in practice, most surgeons perform a combination of the two. The anterior approach used for septoplasty via a transfixion incision gives excellent access to the whole septum, whereas the lateral approach used for submucous resection denies access to the caudal septum. Theoretically, there is also a difference in the amount of cartilage resected, but in practice, this will vary from individual to individual.

Complications

Septal Hematoma The septal cartilage relies on the perichondrium and overlying mucosa for its blood supply. A hematoma may form between the cartilage and the perichondrium or between the perichondrium and the septal mucosa (Figure 33–2). In the former case, the blood supply to the cartilage will be damaged, and unless the hematoma is drained, cartilage death may ensue. This situation is further exacerbated by secondary infection leading

to absorption of the cartilage and saddling of the nose. Consequently, the hematoma should be drained and the nose packed, together with giving broad-spectrum antibiotics.

Septal Perforation There are many causes of septal perforation, the most common of which is some form of trauma, be it iatrogenic or self-inflicted (Table 33–4) (Figure 33–3). The most common site following septal surgery is in the region of the chondrovomerine suture. Consequently, if a mucoperichondrial tear occurs during the surgery, it is advisable to insert a piece of free cartilage at this point, ideally sutured in position.

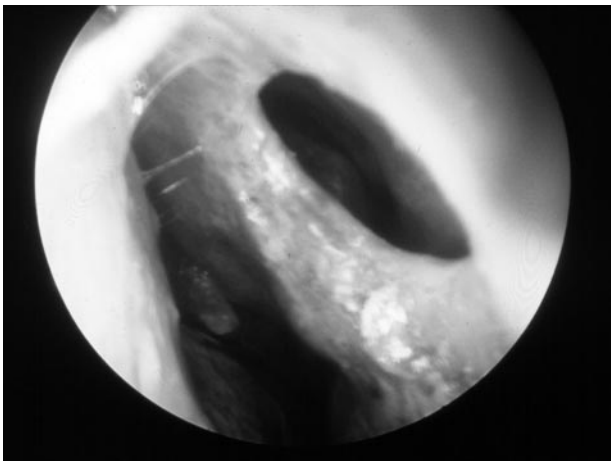

FIGURE 33–3. An endoscopic view of an anterior septal perforation.

Fortunately, many septal perforations are asymptomatic, but those of small diameter may make a whistling sound, and the larger ones may be associated with crusting, spotting of blood, and the sensation of nasal obstruction owing to turbulence of airflow. The more anterior the perforation is, the more likely it is to cause symptoms. Although they will never heal spontaneously, only a minority of perforations require active treatment. In the first instance, a trial of nasal douching with or without a topical corticosteroid may be given.

Many operations have been described to effect closure of septal perforations, the number being inversely proportional to the overall success of such interventions. These have included rotation and advancement of local tissue flaps, in particular "drop down" techniques, free grafts including fascia, split skin, and composites of, for example, pinna cartilage and skin. Bilateral labial flaps from the gingivolabial sulcus tunnelled through into the nose have also been used, but even if successful, all of these procedures suffer from the disadvantages of not providing a ciliated columnar epithelium and being rather bulky.

Alternatively, the perforation may be quickly and easily filled with a commercially available button, which can be customized to the individual perforation and left in place long term.

Infection/Toxic Shock Syndrome Infection after nasal surgery is uncommon but, when it occurs, is very painful and may cause a significant elevation of

body temperature. Cases of toxic shock syndrome have been described as a result of nasal packing. The condition is caused by the toxin produced by a *Staphylococcus* that, when absorbed, produces headache, myalgia, nausea, and vomiting secondary to the pyrexia. Tachycardia, hypertension, hypotension, and erythema of the skin are followed sometime later by desquamation of the skin of the hands. Toxic shock must be dealt with promptly and definitively. Cultures for *S. aureus* must be taken, a β-lactamase-resistant antistaphylococcal antibiotic given systemically, and all packs and stitches removed.

Turbinate Enlargement

Causes The inferior turbinates and, to a lesser extent, the adjacent septum and middle turbinates have a complex submucosal structure, composed of vascular sinusoids under autonomic control. Under normal physiologic conditions, the inferior turbinates change in size with the nasal cycle throughout the day. This may be overridden by a number of factors, such as exercise, posture, emotion, environmental temperature, and humidity. Generally, one is unaware of these changes unless one side of the nose is narrower. A compensatory hypertrophy of the inferior turbinate is often seen on the wider side. A wide range of pathologic processes including allergy, inflammation, and infection can produce symptomatic swelling of the turbinates.

Effects Resistance to airflow primarily occurs in the valve region at the anterior end of the inferior turbinates. To a lesser extent, the middle turbinate changes, obstructing the middle meatus and abutting the septum.

Treatment *Medical* Although topical decongestant sprays can significantly shrink the mucosa, long-term use will lead to rebound congestion and rhinitis medicamentosa. Topical nasal corticosteroids, by contrast, can be used over long periods of time for most forms of perennial rhin(osinus)itis.

Surgical Surgery should be considered only after careful evaluation of the cause of the patient's symptoms and after failure of adequate medication. Most of the techniques can be performed under local or general anesthesia and using head-light, microscope, or endoscopic visualization.[39] As no randomized controlled prospective trial has been performed to determine which of the many techniques is superior in the short or long term, choice devolves to personal preference, and all may be accompanied by hemorrhage and crusting:

- *Lateral outfracture.* Single or multiple fractures of the inferior turbinate bone can be done with or without a submucous incision. The turbinate is pushed closer to the medial wall of the maxilla and may even be pressed into the maxilla (antroconchopexy), but the long-term results are debatable as the turbinate may resume its original position and the procedure does not deal with any soft tissue swelling or its cause.
- *Submucous diathermy.* This has been popular since the early 1900s. A pointed electrode, insulated except for the terminal 3 to 5 mm, is introduced into the anterior end of the inferior turbinate and passed along the whole length. The probe is then withdrawn slowly, over 20 seconds, and the procedure is repeated at two or three points. Hemorrhage and adhesions can occur, and the patient should be warned that there will be blockage owing to reactionary swelling for some weeks after the surgery.
- *Linear electrocautery*. This is done with a red-hot wire electrode to produce a thermal burn or a high-frequency coagulating current using a ball-tip electrode. The technique enjoyed some popularity in the past but has largely been replaced by more precise laser therapy.
- *Turbinectomy.* Partial or subtotal removal of the turbinate offers a permanent solution to hypertrophy. The attachment of the inferior turbinate precludes genuine total turbinectomy unless a portion of the lateral nasal wall is removed. Apart from the occasional mulberry enlargement of the posterior end of the inferior turbinate, it should be remembered that the anterior end of the turbinate offers the greatest resistance to airflow. As with all inferior turbinate surgery, patients must be warned about postoperative hemorrhage, which can be profuse. A secondary hemorrhage rate of 8% is quoted in the literature, which will be severe in 1%.
- *Submucous resection*. Dissection of the mucoperiosteum of the turbinate is described in the original literature, although is difficult to perform in practice owing to the irregularities of the bone. It is best achieved by taking off an anterior sliver and

then nibbling back the exposed bone so that the mucosal edges fall together.

- *Laser turbinectomy.* A variety of cutting and coagulating lasers have been used to "cauterize" and reduce the inferior turbinate, including carbon dioxide, argon, KTP and neodymium:YAG lasers. A cross-hatching of the mucosa is thought to optimize shrinkage while preserving mucosa.
- *Cryosurgery with liquid nitrogen*. This was popular in the past but has largely been superseded by other techniques.
- *Intraturbinal corticosteroid injection.* Enthusiasm for intraturbinal corticosteroid injection diminished after reports of temporary and permanent blindness appeared. These may have occurred owing to retrograde flow of particulate matter into the ophthalmic circulation, possibly associated with inadequate vasoconstriction.

Foreign Bodies

Types and Effects A wide range of objects including metal, plastic, organic materials, and live insects find their way into the nose, either accidentally or deliberately, with size being the only limiting factor. The result is a unilateral chronic purulent nasal discharge, which in a young child should be attributed to a foreign body until proved otherwise. If the foreign material has been present for some time, it may form the nidus for deposition of calcium and magnesium salts, producing a rhinolith that is usually radiopaque.

Treatment The history may be misleading and examination difficult, especially if the patient is uncooperative and the nasal mucous membrane is swollen. Imaging may be helpful but is not exclusive if negative. Therefore, it is often necessary to examine the nose under a short general anesthetic, which should include a throat pack to avoid aspiration of the object.

GRANULOMATOUS CONDITIONS

A range of systemic conditions, including granulomas, vasculitides, connective tissue disorders such as systemic lupus erythematosus, relapsing polychondritis, eosinophilic angiocentric fibrosis, and skin conditions such as pemphigus, pemphigoid, and scleroderma can all manifest in the nose. Consequently, one should have a low threshold of suspicion as one may have the first opportunity to make the diagnosis.

Sarcoidosis

Cause and Effects Sarcoidosis is a systemic condition of unknown cause characterized by noncaseating epithelioid granulomas. It rarely occurs in isolation in the upper respiratory tract, usually being found in association with lower respiratory involvement. The condition has a predilection for certain geographic areas such as the rural southeast United States and Scandinavia and certain ethnic groups such as West Indians and is more common in women.

Nasal symptoms include obstruction, mucopurulent blood-stained discharge, and crusting.[40] There may be associated sinus infection, septal perforation with saddling of the nasal bridge, and violaceous lesions of lupus pernio on the nasal skin. The mucosa is inflamed with crust and old blood, and a "strawberry skin" effect may be seen of the yellowish granulomas against the reddened lining.

Diagnosis includes erythrocyte sedimentation rate, serum calcium, and angiotensin-converting enzyme, although there is no one absolute test for this condition. The Kveim test, which was hitherto the most accurate, has been withdrawn in the United Kingdom owing to concerns over slow viruses. Radiology of the chest is mandatory, and plain radiographs may show punched-out erosion of the nasal bones similar to that seen in dactylitis (Figure 33–4). Nasal biopsy can be useful when mucosal change is

FIGURE 33–4. Coronal computed tomographic scan showing osteitis of the nasal bones in a patient with sarcoidosis.

present but is positive in only 7% when the nose appears normal.[40] The condition must be distinguished from other granulomatous diseases such as tuberculosis, leprosy, berylliosis, Wegener's granulomatosis, and acquired immune deficiency syndrome (AIDS).

Treatment Local treatment with saline douche and topical corticosteroids is helpful, and the nose may improve with systemic treatment that usually includes oral corticosteroids and a variety of cytotoxic agents. Surgery, except for sinus infection, should be avoided as this can exacerbate collapse of the nose.

Wegener's Granulomatosis

Cause and Effects This systemic condition characterized by granulomas and vasculitis is also of unknown cause. An autoimmune basis or infection has been suggested but remains unproven.[41] It was originally described affecting the upper and lower respiratory tracts, together with a focal glomerulonephritis, which rapidly led to renal failure and death. It is now known to affect any part of the body ab initio and to have a variable natural history, progressing inexorably in some individuals over a few weeks or months or to a more insidious limited form in others that may continue for some years before affecting other organs. Whether all of the latter ultimately progress to the full-blown disease is unknown.

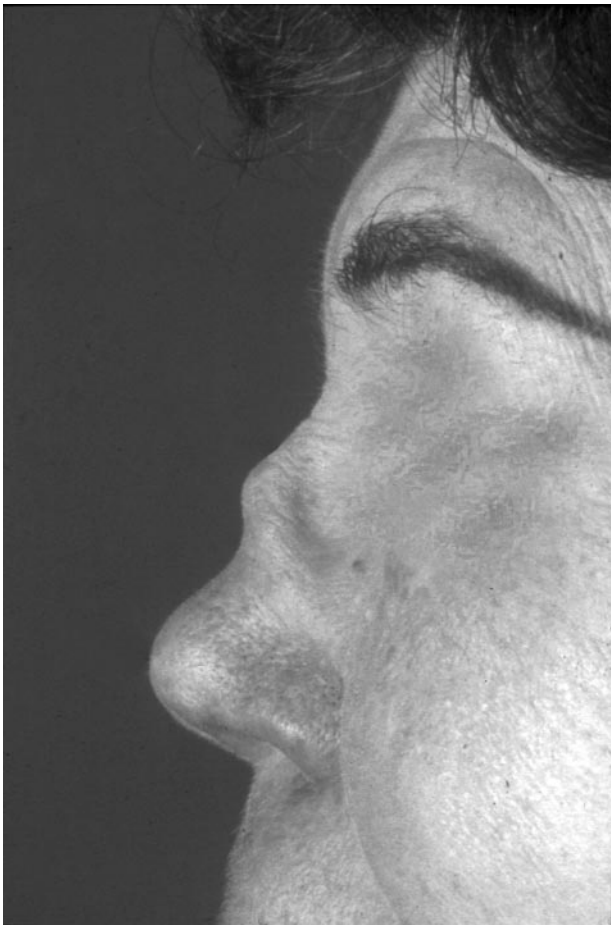

FIGURE 33–5. Photograph showing typical collapse of the nasal bridge in a patient with Wegener's granulomatosis.

Patients often present with a short history of progressive malaise, pyrexia, weight loss, and a disproportionate feeling of "unwellnesss" in comparison with what are often fairly nonspecific findings. In the nose, the swollen, inflamed mucosa produces blockage and blood-stained crusting. There may be destruction of the septum with a characteristic implosion of the nasal bridge (Figure 33–5). The nasopharynx, ears, mouth, larynx, trachea, cranial nerves, and orbit may all be involved.

Diagnosis of the condition relied in the past on clinical acumen supported by a high erythrocyte sedimentation rate, C-reactive protein, and evidence of pulmonary and renal damage. The advent of the C-ANCA (antineutrophil cytoplasmic antigen) greatly assisted diagnosis, being highly specific and sensitive for the condition. However, a negative C-ANCA does not absolutely exclude the condition, particularly in the limited form and/or when oral corticosteroids have been given. Computed tomography of the nose and paranasal sinuses may show some midline destruction and often shows opacification of the sinuses (Figure 33–6). This may be attributable to active granulomatous infiltration, burnt-out disease with fibrotic change, or secondary infection. Unfortunately, biopsy is not diagnostic, at best being described as "consistent with" Wegener's granulomatosis, but is helpful to exclude other pathology such as T-cell lymphoma.

Treatment Medical therapy includes systemic corticosteroids, a range of cytotoxic drugs (eg, cyclophosphamide and azathioprine), immunoglobulin infusions, cotrimoxazole, and plasma exchange. Earlier diagnosis and careful monitoring have significantly improved the outcome for these patients, but the condition remains life threatening in its more severe forms. The nose is again managed with douching and topical corticosteroids. Surgery

FIGURE 33–6. Coronal computed tomographic scan in a patient with Wegener's granulomatosis showing midline destruction of the septum and loss of the inferior turbinates.

may be required for secondary infection, but attempts to reconstruct the nose should be resisted until the disease has been quiescent for some years.

AMYLOIDOSIS

Apart from amyloid deposits in the skin of the vestibule in generalized amyloidosis, involvement of the nose and sinuses is extremely rare. In contrast to the upper respiratory tract as a whole, only a handful of isolated amyloid deposits have been reported, whereas in generalized plasmacytic malignant lymphoma, 20% of patients may have sinonasal amyloid deposits. The diagnosis may be confirmed histologically by the presence of Congo red reactivity and green birefringence in polarized light. Colchicine has been used in the treatment of the condition.

EPISTAXIS

The nose has an extremely good blood supply from both the external and internal carotid arteries, with crossover between the right and left sides. Many conditions can produce nose bleeds, both local and general (Table 33–5). The majority of local causes are some form of self-inflicted, accidental, or iatrogenic trauma. A range of general causes does not include hypertension per se but rather the underlying problem of atherosclerosis in which changes in the tunica media lead to loss of elasticity and the ability of vessels to constrict.

TABLE 33–5. Causes of Epistaxis

- Local
  - Idiopathic
  - Trauma
    - Self-inflicted
    - Maxillofacial fractures
    - Iatrogenic surgery
    - Drying, septal deviation
    - Foreign bodies
    - Septal perforation
  - Inflammation, allergy
    - Atrophic rhinitis
  - Infective
  - Tumors
    - Benign, eg, angiofibroma
    - Malignant

  - Atherosclerosis
  - Bleeding dyscrasias
    - Coagulation disorders
      - Congenital
        - Hemophilia
        - Christmas disease
        - von Willebrand's disease
      - Acquired
        - Deficiency of clotting factors, eg, liver and renal failure
        - Massive transfusion
        - Vitamin deficiency
        - Anticoagulants
        - Myelosuppressive drugs, eg, chemotherapeutic agents, anti-inflammatories, antibiotics
    - Hemopoietic
      - Leukemia
      - Aplastic anemia
      - Dysproteinemia
      - Lymphoma
      - Widespread metastases
  - Hereditary hemorrhagic telangiectasia
  - Endocrine
    - Vicarious menstruation
    - Pregnancy

Hereditary hemorrhagic telangiectasia is an autosomal dominant, non–sex-linked transmitted condition characterized by telangiectasias that are deficient in muscle and/or elastic tissue (Figure 33–7). The majority of patients experience epistaxis of varying severity, although the lesions can be found anywhere in the body. Although a wide range of treatment options have been described, a treatment algorithm shows how this may be tailored for the individual patient.[42]

Management In most cases, the clinical history and examination, including endoscopy, will provide the diagnosis, although in appropriate cases, hematologic screening and imaging, including arteriography, may be required.

The treatment will be determined by the severity of the bleed and ranges from first aid measures and cauterization to various forms of packing, arterial ligation, or embolization together with correction of any underlying medical problem.

First Aid Measures. Cauterization. Small prominent vessels on the septum have been traditionally cauterized with silver nitrate sticks or electrocautery as an outpatient procedure. However, this is not usually appropriate for significant active bleeding. Cauterization under endoscopic control for posterior epistaxis is being used with some success and may avoid packing and inpatient stay.

Packing A range of packing materials is available from resorbable hemostatic materials to ribbon gauzes soaked in various substances (eg, Vaseline, bismuth), and commercially manufactured balloons and packs. Any packing must be used as atraumatically as possible to avoid damage to the columella and mucosa and subsequent adhesions and perforation of the nasal septum. Patients with packing in place generally require admission to hospital to ensure that the packing does not become dislodged or impact adversely on their respiratory function. While packing is in place, patients require antibiotics to prevent the development of infection and the possibility of toxic shock.

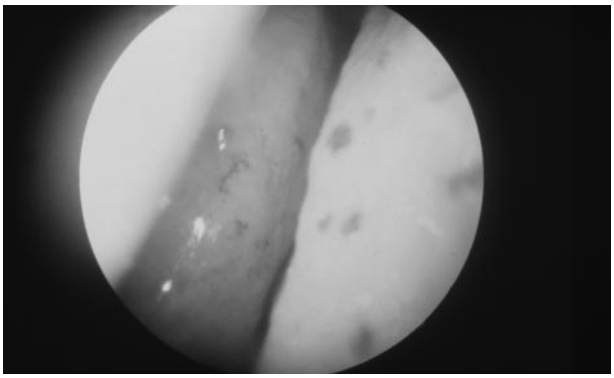

FIGURE 33–7. An endoscopic view of nasal lesions in hereditary hemorrhagic telangiectasia.

Surgery It is often better to intervene earlier rather than later in patients with persistent bleeding from the nose. Endoscopic examination may reveal the precise bleeding spot, which can then be cauterized or lasered. In more severe cases, arterial ligation may be required. This may be directed at the anterior and posterior ethmoidal, maxillary, or sphenopalatine arteries or, in severe cases, the external carotid artery. The ethmoidal vessels may be accessed via a small external incision and represent the internal carotid component of the nasal blood supply. The internal maxillary artery can be reached via the posterior wall of the maxillary sinus through an anterior antrostomy, but finding its many branches can be a time-consuming affair, and many surgeons now prefer the direct approach to the sphenopalatine artery, which can be approached endoscopically as it passes from the sphenopalatine canal into the mucosa of the lateral wall of the nose just beneath the horizontal attachment of the middle turbinate. The external carotid artery can be ligated in the neck on one or both sides.

Embolization In some centers, interventional radiology is the preferred option for reducing the blood supply to the nose by embolization techniques.

RHINOPHYMA

In rhinophyma, a disfiguring enlargement of the nose develops owing to an overgrowth of sebaceous tissue. Tissue overgrowth begins at the tip of the nose and progresses to involve the ala nasi and the columella and is associated with a florid discoloration. The affected tissue may be pared down using a knife, electrodissection, or laser therapy, producing good cosmetic results.

MALIGNANT TUMORS OF THE SKIN OF THE NOSE

Basal Cell Carcinoma

The skin of the nose is the most common site for basal cell carcinoma in the head and neck. It is considerably more common than squamous cell carcinoma, with a peak incidence in the sixth to eighth decades. The most common areas are the side, dorsum, and tip of the nose, and the lesion may be a small nodular growth or form a chronic ulcer with a rolled edge. Although many behave in an indolent fashion, unless treated appropriately, they have a tendency to recur, which may lead to considerable destruction of the face. The side of the nose adjacent to the medial canthal area can prove particularly problematic.

Basal cell tumors are usually very sensitive to radiotherapy but may require surgical excision, particularly for recurrence. A variety of local rotation flaps or full-thickness skin grafts are available.

Squamous cell carcinoma, though less common, may also affect the skin of the nose, again in the sixth to eighth decades. The lesion is generally nodular, resembling a keratoacanthoma, but can ulcerate. When ulcerated, differentiation from a basal cell carcinoma may be difficult (Figure 33–8). Treatment again relies on radiotherapy and/or surgery. Squamous cell carcinoma has a higher propensity for metastatic spread than basal cell carcinoma, and lesions in the midline, particularly on the columella, may disseminate bilaterally, producing a potentially poor prognosis as in continuity, lymphatic resection is not possible.

CHAPTER 34

Sinusitis and Polyposis

Andrew P. Lane, MD, David W. Kennedy, MD

EPIDEMIOLOGY

Rhinosinusitis is an extremely prevalent disorder that has a significant impact on the quality of life of affected individuals and places a large economic burden on the United States as a whole. It is estimated that approximately 33 million Americans per year get sinusitis, with 26.7 million office visits attributed to sinus and related airway disorders.[1,2] The cost of these visits is nearly 6 billion dollars, on top of which people spend an additional 2 billion dollars annually for over-the-counter sinusitis medications.[2,3] There is a loss in worker productivity related to rhinosinusitis, with 12.5 million workdays lost and 58.7 million days of restricted activity owing to the disease.[4]

In 1995, sinusitis was the fifth leading diagnosis for which antibiotics were prescribed nationwide.[5] When sinusitis recurs, it has been shown that subsequent episodes cost successively more for diagnostic tests and therapy.[6] Rhinosinusitis affects men and women equally, and it is thought to be more common in childhood than in adults. However, the health care expenditures are approximately split 30% for children and 70% for adults.[2] In demographic terms, rhinosinusitis is more common in the Midwest and South than in the northeast and western United States. The incidence is higher in spring, winter, and fall than it is during the summer months.

PATHOPHYSIOLOGY DEFINITION AND CLASSIFICATION OF RHINOSINUSITIS

Acute Rhinosinusitis

Etiology and Pathophysiology The underlying causes of acute rhinosinusitis are multiple and include a variety of host and environmental factors (Table 34–1). Ultimately, however, the common pathway of acute sinusitis is thought to be the presence of bacteria in a sinus cavity with an obstructed ostium. This requires not only blockage of the normal anatomic outflow of the sinus but also a failure of the mucociliary clearance function of the mucosa that would ordinarily remove the bacteria. In addition, abnormalities of the quantity or consistency of the sinonasal secretions can affect mucociliary clearance and promote bacterial growth. Finally, immunodeficiencies, such as selective immunoglobulin (Ig) A or IgG deficiency or human immunodeficiency virus (HIV) infection, lead to an increased incidence of acute sinusitis owing to an inability to clear pathogenic bacteria.

There are multiple factors that can lead to anatomic obstruction of the sinus ostia. In most

cases, it is edema secondary to inflammation that constricts the small sinus openings in a reversible fashion. This may result from a viral upper respiratory infection, allergy, environmental irritants, or barotrauma. Irreversible blockage caused by fixed anatomy may contribute to the problem or be the sole etiologic agent. Examples of anatomic obstruction would include septal deviations, polyps, nasal tumors, foreign bodies, or postsurgical synechiae. Additionally, sinus disease is often related to a host of anatomic variants such as Haller's cells, agger nasi cells, concha bullosa, and paradoxical middle turbinate, although this relation has not been definitively supported by randomized, controlled studies. Whatever the cause, once the ostium becomes occluded, a local hypoxia develops in the sinus cavity, and sinus secretions accumulate. This combination of low-oxygen tension and a rich culture medium of secretions allows exponential bacterial growth to occur within the sinus.

A normal sinus is generally considered to be a sterile environment. Bacteria that find their way into the sinus are rapidly eliminated by the action of ciliated columnar epithelial cells moving a layer of viscous secretions created by epithelial goblet cells and submucosal glands. Abnormalities of the cilia themselves, or of the double-layered mucus blanket within which the cilia beat, may hinder bacterial removal. Ciliary function may be defective secondary to underlying disease states such as primary ciliary dyskinesia or Kartagener's syndrome or to injury by environmental irritants or surgical trauma. In animal models of sinusitis, bacterial products and endogenous mediators of inflammation disrupt epithelial cilary activity.[7] The quality of the mucus in the sinuses is of critical importance in the effectiveness of ciliary clearance. In cystic fibrosis and severe dehydration, for example, the viscosity and elasticity of the mucus are increased by alterations in water and electrolyte transport. Additionally, increased production of mucus, which can occur in response to airborne irritants, allergens, cold air exposure, or viral upper respiratory infections, also may exceed the rate of mucociliary clearance. Any of these situations will lead to the accumulation of mucus in the sinuses, with poor removal of bacteria and the creation of a favorable environment for bacterial growth.

Any systemic disease leading to an immunocompromised state will potentially predispose a patient to acute sinusitis. Chronic illness, such as diabetes, or malnutrition, metabolic derangement, chemotherapy, or long-term corticosteroid therapy will similarly increase the tendency to develop acute sinusitis. The intensive care unit setting is particularly conducive to the development of a nosocomial sinusitis owing to the presence of critical illness in conjunction with nasotracheal and/or nasogastric tubes, which cause mechanical obstruction of sinus drainage. Although fluid and mucosal thickening in the sinuses is common, acute sinusitis is rarely the sole or main cause of fever or sepsis in this patient population.[8] Antral puncture is only indicated in the presence of an endoscopic examination that reveals purulence.[9] Immunocompromised patients with HIV infection or other severe immune deficiencies are prone to sinus infection with unusual pathogens such as fungi and atypical mycobacteria. Bone marrow transplant patients are another group with a high incidence of acute sinusitis and a propensity toward developing life-threatening invasive fungal sinusitis.

Classification Sinusitis is a clinical diagnosis, based largely on history and physical examination findings. In 1997, the Rhinosinusitis Task Force of the American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS) attempted to create a uniform diagnostic paradigm for sinusitis by organizing common sinonasal symptoms and signs into major and minor factors.[10] The presence of two or more major factors, or one major and two minor factors, is considered suggestive of sinusitis. These signs and symptoms of sinusitis are discussed in the diagnosis section of this chapter. The Task Force defined five categories of adult rhinosinusitis in their report. These categories are based on duration, history, and physical examination. They do not take into account radiologic findings. Table 34–2 shows a list of major and minor factors associated with the diagnosis of rhinosinusitis that are used in this classification scheme. The first category is "acute," which is defined, in part, as having a duration of less than or equal to 4 weeks. The patient's history must include either two or more major factors or one major and one minor factor. If the patient has nasal purulence on endoscopy, the presence of a strong history is not necessary. Acute rhinosinusitis should be considered if patient symptoms worsen after 5 days or if symptoms persist for more than 10 days.

TABLE 34–2. Major and Minor Factors Associated with the Diagnosis of Rhinosinusitis

Major factors
Facial pain/pressure*
Facial congestion/fullness
Nasal obstruction/blockage
Nasal discharge/purulence/discolored postnasal discharge
Hyposmia/anosmia
Purulence in nasal cavity on examination
Fever (acute rhinosinusitis only)†
Minor factors
Headache
Fever (in nonacute cases)
Halitosis
Fatigue
Dental pain
Cough
Ear pain/pressure/fullness

*Facial pain/pressure alone does not constitute a suggestive history for rhinosinusitis in the absence of another major symptom or sign.

†Fever in acute sinusitis alone does not constitute a strongly suggestive history for acute sinusitis in the absence of another major symptom or sign.

The next category is "subacute," which is defined by a duration of 4 to 12 weeks. "Recurrent acute" is defined as four or more episodes of rhinosinusitis per year with complete resolution between episodes.

Chronic Rhinosinusitis

Rhinosinusitis lasting longer than 12 weeks is classified as chronic. If the symptoms worsen periodically and then return to baseline with treatment, the AAO-HNS Task Force separately categorizes this as acute exacerbations of chronic rhinosinusitis. The pathophysiology of chronic sinusitis shares many similar features with acute sinusitis, but with some important differences. The predisposing conditions for chronic disease parallel those for acute infections in terms of environmental, systemic, and local host factors. However, in addition, multiple episodes of acute sinusitis themselves may cause scarring and mucosal dysfunction that lead to chronic sinus infections. Symptoms in chronic sinusitis are usually more insidious than in an acute situation and therefore may be more difficult to diagnose. Another important distinction is that the underlying process in chronic sinusitis is not necessarily infectious and is often a self-perpetuating inflammatory process. The exact nature of the mucosal dysregulation is unknown but in some cases can be recalcitrant to all medical and surgical therapies currently available. Many times, the only effective treatment is systemic corticosteroids, which provide short-term control of symptoms at the risk of serious complications related to their use.

Whereas acute sinusitis is histologically an exudative process characterized by neutrophilic infiltration and necrosis, chronic sinusitis is a proliferative process remarkable for thickening of the mucosa and lamina propria. The predominant infiltrative cell in chronic sinusitis is the eosinophil, both in the allergic and the nonallergic patient. There is evidence that potent eosinophil-attracting chemokines are produced in the sinus mucosa, elaborated by a variety of cell types under the stimulation of cytokines produced largely by T cells.[11] An increase in the levels of interleukin-4 and -5 in the sinonasal tract promotes the continued proliferation and prolonged life span of eosinophils.[12] A number of other proinflammatory cytokines are up-regulated and participate in the process of directing lymphocyte and granulocyte traffic, while causing further production of cytokines in an autocrine fashion. Degranulation of eosinophils releases a number of destructive enzymes that damage the epithelium. This disrupts the normal barrier function and the mucociliary activity of the mucosa, allowing bacteria and fungi to colonize the sinus cavities. The damage to the epithelium irritates sensory nerve endings, causing pain and stimulating changes in mucus secretion and endothelial permeability via reflex pathways. Corticosteroids disrupt this vicious cycle by interfering with the transcription of many cytokines at the nuclear level. Without these mediators in the sinus mucosa, the inflammatory process is halted, and there is a return to more normal function. However, for reasons that remain poorly understood, the reversal of inflammation is often temporary and recurs once the corticosteroids are withdrawn.

Fungal Rhinosinusitis

Some forms of sinusitis are caused by fungal microorganisms within the sinonasal tract. The fungal infection can be either invasive or noninvasive.

One noninvasive form is a fungal ball growing within a sinus cavity. The invasive forms can present in either an indolent, chronic form or a fulminant, acute form. The latter frequently occurs in immunosuppressed patients, such as diabetics in ketoacidosis, transplant recipients, HIV-infected individuals, and patients undergoing chemotherapy. Without control of the underlying immunosuppression, the process is rapidly progressive and may extend into the orbits and intracranial space despite aggressive surgical and medical management. The disease is uniformly fatal if the immune failure cannot be corrected. Even if the underlying condition is controlled, significant morbidity and mortality may result based on the ultimate extent of the disease. In contrast, chronic invasive sinusitis tends to occur in immunocompetent hosts and generally advances very slowly. Vascular invasion in the chronic form is minimal or nonexistent. The microorganisms involved in fulminant fungal sinusitis are varied, but the *Mucoraceae* family (most often *Rhizopus oryzae*) and *Aspergillus* species are most frequent (Figure 34–1, A and B). A number of fungal microorganisms have been reported as pathogens in chronic invasive disease, with *Aspergillus* being the most typical. *Mucor*, *Alternaria*, *Curvularia*, *Bipolaris*, *Candida*, *Drechslera*, *Sporothrix schenckii*, and *Pseudallescheria boydii* (which is unresponsive to amphotericin B) have specifically been cultured.[13] A further classification of chronic invasive fungal sinusitis was proposed by deShazo et al based on histopathology.[14] The form of the disease that lacks a granulomatous response has been associated with a high rate of persistence, recurrence, and a poor prognosis. However, the presence or absence of a granulomatous histology is not apparent in the clinical presentation and does not currently alter treatment.

In addition to fungal balls, the other noninvasive form of fungal sinusitis is an entity known as allergic fungal rhinosinusitis (AFRS). It is the most common form of fungal sinus disease, although the pathogenesis remains poorly understood. The diagnosis of AFRS depends on five criteria: (1) type I hypersensivity, (2) nasal polyposis, (3) characteristic computed tomographic (CT) scan appearance (hyperdense material in the sinus cavity), (4) positive fungal stain or culture, and (5) no evidence of tissue invasion.[15] The disease is also characterized by increased total IgE, antigen-specific IgE, and peripheral eosinophil count. Allergic fungal rhinosinusitis is often unilateral and can cause bony erosion with orbital or intracranial extension (Figure 34–2). At surgery, there is typically thick, brown-green mucus that has been called "peanut butter"-like. Histologically, this mucus contains eosinophils in sheets, Charcot-Leyden crystals, and fungal hyphae. The critical element that separates AFRS from chronic eosinophilic rhinosinusitis is the presence of allergy to fungus.[16] Allergic fungal rhinosinusitis is not caused by the abnormal presence of fungus in the nose but rather an abnormal response to nonpathogenic fungi that exist in the environment. It has been shown by Ponikau et al that fungi are ubiquitous and can be isolated out of every nose, given sufficiently sensitive culture techniques.[17] A wide range of fungal species have been implicated in allergic fungal

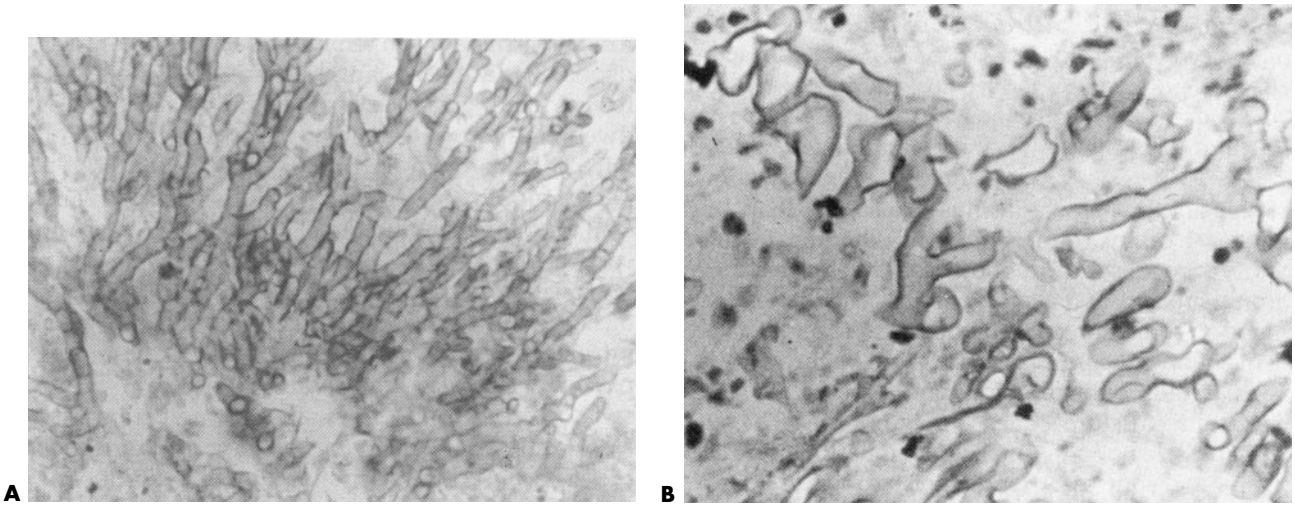

FIGURE 34–1. *A*, Hematoxylin and eosin stain of *Aspergillus*. *B*, Hematoxylin and eosin stain of *Mucor*.

FIGURE 34–2. Coronal computed tomographic scan showing typical appearance of allergic fungal sinusitis on the patient's left side. Incidental note is made of fluid in the right maxillary sinus.

sinusitis, and it is important to identify the specific species if desensitization is to be attempted. The mainstays of therapy are surgical débridement and systemic corticosteroids. Allergy desensitization and the use of antifungal medications are controversial but may be of benefit in some patients.

POLYPOSIS

Etiology

Nasal polyposis is a prevalent condition that is said to affect between 1 and 4% of the general US population.[18] Based on autopsy studies, the true incidence of polyps may be much greater, although most polyps are small and presumably asymptomatic. The etiology of nasal polyps is largely unknown and has long been a topic of debate. Although historically many have believed polyps to be a manifestation of allergy, in part because of the histologic prominence of eosinophils, epidemiologic evidence for this is lacking. The incidence of allergy is not higher in patients with nasal polyps than in the population as a whole, nor do polyp patients have elevated rates of positive allergy skin tests.[19] Nasal polyps are associated with a number of systemic diseases including aspirin intolerance, intrinsic asthma, primary ciliary dyskinesia, and cystic fibrosis. They are frequently observed in chronic rhinosinusitis, including allergic rhinosinusitis, and other chronic sinonasal inflammatory states. Overall, the mechanisms behind polyp formation are believed to be multifactorial. Recent evidence suggests an important role for proinflammatory cytokines, chemokines, and chemotactic factors in the pathogenesis of inflammatory polyps, along with a variety of environmental, genetic, and biochemical factors that have previously been proposed.[20]

Gross Appearance and Histology

When significant intranasal polyposis is present, polyps can easily be seen by anterior rhinoscopy. Grossly, they are translucent to pale gray, pear shaped, smooth, soft, and freely mobile. Polyps arise from the lateral nasal wall and in many cases are limited to the middle meatus, where they can only be visualized endoscopically (Figure 34–3). Inflammatory polyps are usually seen bilaterally. Histologically, polyps are composed of a fibromyxomatous stroma covered by typical respiratory epithelium that may display benign squamous cell metaplasia. The epithelium displays very few nerve endings and submucosal glands, and the basement membrane is thickened. As compared to adjacent lateral nasal wall mucosa, there is a marked abundance of eosinophils and mast cells in inflammatory polyps.

Diagnosis

The typical complaints associated with polyposis are nasal congestion, rhinorrhea, and olfactory dysfunction. A thorough nasal endoscopic examination is

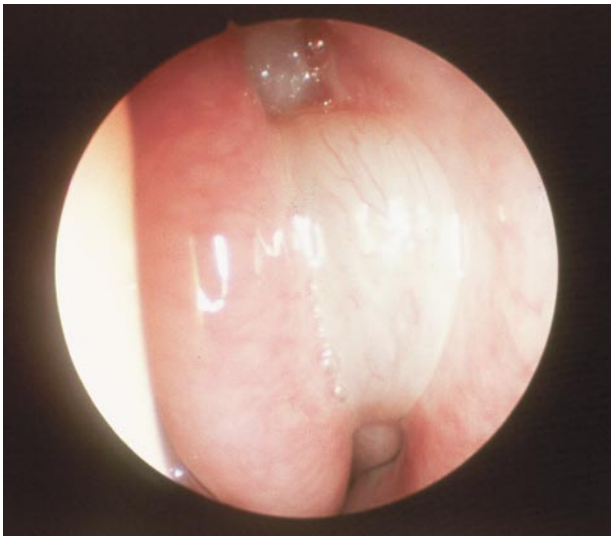

FIGURE 34–3. Polyp in the left middle meatus.

necessary for all patients with polyp disease to assess the gross appearance and sites of origin. When evaluating a patient with nasal polyps, the differential diagnosis of nasal masses should be entertained, including the possibility of systemic disease. For example, the finding of nasal polyps in children should elicit consideration of cystic fibrosis or ciliary dyskinesia. Unilateral polyps should raise concern for allergic fungal sinusitis or inverted papilloma. Sinonasal neoplasms may display a similar endoscopic appearance to polyps; thus, consideration should be given to the possibility of carcinoma, sarcoma, angiofibroma, meningioma, or esthesioneuroblastoma in certain patients. A single, unilateral polyp originating high in the nasal cavity or with a stalk that is not clearly visible may represent an encephalocele or meningocele. Visible pulsations on endoscopy and enlargement of the mass with ipsilateral internal jugular vein compression (Furstenberg's sign) help to confirm the diagnosis. As a rule, if the intranasal mass does not have the characteristic appearance of a polyp, is unilateral, bleeds easily, or has a stalk that is not clearly identified, imaging studies are indicated before proceeding with management (Figure 34–4). High-resolution CT may reveal bony dehiscences or erosion. Magnetic resonance imaging (MRI) is confirmatory of meningoencephalocele and is advisable when evaluating an area of skull base erosion adjacent to an opacified sinus. Magnetic resonance imaging is also useful for identifying the extent of nasal tumors and differentiating tumor from secondary mucosal disease and retained secretions. These radiologic studies should be obtained prior to performing a biopsy of any unusual nasal mass.

FIGURE 34–4. Coronal computed tomographic scan showing a meningocele in the right ethmoid. The appearance of encephaloceles and meningoceles may mimic that of nasal polyps in some patients.

Management

The most important element in the treatment of nasal polyposis is medical therapy with corticosteroids. Both oral corticosteroids and topical nasal corticosteroids are effective in shrinking polyps and controlling their recurrence. Topical corticosteroids are first-line therapy that should be employed prior to considering surgical intervention. Unless there is a contraindication, a trial of a tapering course of oral corticosteroids is also frequently used prior to surgical resection. Should surgery eventually become necessary, topical corticosteroids and occasionally oral corticosteroids may be needed for long-term maintenance. A variety of topical nasal corticosteroid preparations are available today with similar efficacy in reducing polyps. They differ primarily in the propellant and additives rather than in the active ingredients. However, these factors may make one brand more acceptable than another to a given patient. Head positioning is important during intranasal corticosteroid use to direct the medication in contact with the polypoid mucosa. Since most recurrent polyps after surgery occur in the frontal recess, the head-inverted position is necessary to obtain the maximal benefit in the localized area of disease.

The use of oral corticosteroids in polyposis and sinusitis is somewhat controversial because of the myriad side effects and complications associated with them. However, the effectiveness of oral corticosteroids is remarkable, sometimes with even a short taper. In some patients, recurrence of nasal polyps can be prevented with very low doses given for prolonged periods of time. The dose of corticosteroids prescribed is dependent on the extent of disease. Typically, for moderate to severe polyposis, the upper end of the taper is 30 to 40 mg of prednisone per day for 3 to 4 days. A similar dose is used preoperatively to maximize shrinkage of the polyps and to reduce the mucosal reactivity and vascularity. Also, since asthma is a comorbid condition in many patients with polyps, the corticosteroids help to stabilize bronchial hyperreactivity preoperatively. Antibiotics are often used along with corticosteroids in treatment for polyps occurring secondary to an infectious chronic

sinusitis. Most patients with nasal polyps have some concurrent sinusitis at the time of presentation, and this is likely to be an exacerbating factor. Aggressive treatment of the underlying sinusitis will lead to more rapid resolution of inflammatory polyps.

Surgery for polyps is indicated when medical management fails to give symptomatic improvement or if complications develop. Also, in those polyp patients with asthma, surgical intervention may be considered when repeated sinus infections are causing a worsening of the lower airway disease. The operative technique of polyp removal is the same as other endoscopic sinus surgery and is described in detail later in this chapter. Powered instrumentation using a microdébrider is particularly useful in polyp surgery because it is rapid and spares the mucosa, while the continuous suction allows excellent visualization to be maintained in the face of bleeding. The postoperative monitoring of the sinus cavities is absolutely critical for the success of sinus surgery. Recurring disease should be addressed early in an office setting by débriding small polyps under topical anesthesia. Although complete resolution of mucosal abnormalities is rare, continued medical management and vigilance in follow-up make revision surgery unnecessary in the vast majority of patients. Successful treatment ultimately depends on a commitment by both the patient and the physician to an intensive postoperative course, which may be quite prolonged and involve multiple débridements.

COMPLICATIONS OF RHINOSINUSITIS

The complications of sinusitis can be divided broadly into those involving the orbits and those that involve the intracranial space. In the antibiotic era, such complications have become less commonplace, but they still have the potential for serious morbidity or even mortality. Awareness and early recognition of complications are necessary to minimize adverse sequelae. Fortunately, improved diagnostic modalities and advances in medical and surgical techniques have significantly reduced the risk of blindness or life-threatening intracranial infections.

Orbital complications of sinusitis occur because the orbit is bounded by the sinuses inferiorly, superiorly, and medially. This close proximity leads to early extension of infections that are not treated adequately or in the setting of impaired host immunity. Most orbital complications occur in young children, but those in older children and adults are typically more severe and necessitate surgery. Ethmoiditis most commonly leads to orbital involvement, followed by infections of the maxillary, frontal, and sphenoid sinuses. Infections of the ethmoid can directly erode the thin lamina papyracea or extend through suture lines or foramina into the orbit. The other mechanism of spread is hematogenously via retrograde thrombophlebitis of valveless veins. Chandler et al described a classification scheme for orbital complications of sinusitis in 1970.[21] The first stage, preseptal periorbital cellulitis, consists of eyelid swelling anterior to the orbital septum without involvement of the orbital contents (Figure 34–5, A and B). When the orbital soft tissue becomes involved, the result is orbital cellulitis, a diffuse process of inflammation without abscess formation. Patients with this complication are generally proptotic, with some degree of ophthalmoplegia and chemosis. When pus accumulates between the bone and the orbital periosteum, the result is a subperiosteal abscess (Figure 34–5, C and D). This will displace the orbit inferolaterally and may cause some proptosis. Unrecognized or untreated, the process can expand to cause extraocular muscle impairment, chemosis, and loss of visual acuity. Pus within the orbital tissue is an orbital abscess and can be intraconal or extraconal. In either case, marked proptosis, limitation of extraocular movement, and visual loss are commonly observed when an orbital abscess is present. Finally, the most serious complication is cavernous sinus thrombosis. This may result from extension of ethmoid or sphenoid sinusitis directly or via thrombophlebitis of the ophthalmic vein. Here, proptosis, chemosis, ophthalmoplegia, and decreasing visual acuity are the rule. In the early stages, fever, headache, periorbital edema, or photophobia may herald the onset of cavernous sinus thrombosis. Once it occurs, the process can extend to the opposite side, and bilateral findings are considered a diagnostic hallmark. Cranial neuropathies of nerves II to VI are seen, and pituitary insufficiency may occur. From the cavernous sinuses, the infection can spread rapidly through the dural sinuses, causing a range of intracranial complications.

Intravenous antibiotics are the mainstay of medical therapy and may be combined with topical

decongestants to promote sinus drainage. Corticosteroids are generally not recommended in the face of active infection. When orbital complications are suspected, a complete neuro-ophthalmologic examination is essential. However, even without funduscopic abnormalities, blindness can still result. Optic nerve injuries stem most often from pressure effects within the orbit. The damage may be caused by ischemia or be secondary to direct compression of the optic nerve. Also, permanent visual loss can result from irritation of the optic nerve by the adjacent infection. It is also important to obtain a radiologic study when evaluating a patient with orbital complications of sinusitis. Computed tomographic scans are helpful in identifying the involved sinuses and in defining the location of an abscess. Magnetic

resonance imaging is an excellent complementary study when intracranial extension needs to be evaluated. Serial CT scans may be used to monitor the progress of medical management and to help determine if surgery is needed.

The decision to proceed to surgery is made based on a number of factors and is individualized to the particular patient. Certainly, progressive visual loss demands aggressive management and drainage of the source of infection. Medical therapy is typically not effective once an abscess develops, and so surgical incision and drainage are required at that point. Often the extent of the infection is unclear, even with radiologic imaging, and the decision should be based on the clinical picture. Surgical intervention should be considered when there is disease progression after 24 hours of antibiotics or no improvement after 2 to 3 days of therapy. Ideally, surgery involves approaching both the orbital complication and underlying sinusitis simultaneously. Endoscopic approaches will generally be used to approach the sinuses and can even be employed in experienced hands to drain ethmoid subperiosteal abscesses. The classic technique for managing orbital complications is the external ethmoidectomy approach. Frontal sinus trephination may also be employed for acute frontal sinusitis. These techniques are described in detail later in this chapter.

Intracranial complications of sinusitis occur less frequently than orbital complications but are potentially life threatening if not recognized and treated. Most intracranial infections arise from the frontal sinus, although extension from the other sinuses is possible. The most frequent route of spread is retrograde thrombophlebitis via the diploic veins of Breschet in the posterior table of the frontal sinus. These valveless veins communicate directly with dural veins and empty into the sagittal sinus. The types of complications that may develop include osteomyelitis of the frontal bone, meningitis, epidural abscess, subdural empyema, and intracerebral abscess. Pott's puffy tumor is a well-circumscribed swelling of the forehead caused by anterior extension of frontal sinusitis. The edema of the skin and soft tissue overlies a collection of pus under the periosteum of the anterior table of the frontal sinus.

Abscesses in the epidural space often do not give localizing findings and do not give abnormal lumbar puncture results other than a high opening pressure. Headache and low-grade fever are common findings, and only when the abscess becomes enlarged do effects of increased intracranial pressure become evident. Epidural abscesses can extend by rupturing into the subdural space to create an empyema. Because of the barrier function of the arachnoid, subdural infections do not necessarily progress to meningitis. However, as the empyema spreads from anterior to posterior, inflammation of the leptomeninges will occur, resulting in significant edema. This edema can lead to increased intracranial pressure and eventually cortical ischemia. Early signs include headache, fever, and leukocytosis, whereas later findings may be much more severe such as hemiparesis, hemiplegia, or seizures. When the intracranial pressure becomes high enough, bradycardia, hypotension, and decreased mental status will ensue. Unless treated, transtentorial herniation can follow, causing death. Brain abscesses in the frontal lobe can also begin insidiously and then progress rapidly to fatal herniation. Abscesses in this location are frequently neurologically silent except for subtle mood or personality changes. If the abscess becomes large enough, or if the surrounding edema is extensive, symptoms of increased intracranial pressure may become evident. Rupture of the abscess into the ventricles will quickly lead to death.

When intracranial complications are suspected, the study of choice is a CT scan of the brain and sinuses with and without contrast. Magnetic resonance imaging is a more sensitive tool in the early stages of intracranial infection and can demonstrate enhancement of the dura in meningitis. Magnetic resonance imaging is also excellent for showing dural sinus thrombosis. Lumbar puncture may be helpful in making the diagnosis but needs to be performed with caution in the setting of a potentially increased intracranial pressure. Lumbar puncture is generally nondiagnostic in abscesses and subdural empyema but will clearly indicate meningitis if it is present.

The mainstay of therapy for suspected intracranial complications is intravenous antibiotics capable of crossing the blood-brain barrier. If cultures can be obtained from the affected sinuses, this will guide specific antibiotic choice. A neurosurgical consultation is sought when a procedure may be necessary to drain an intracranial collection. Since these complications often cause seizures, input from a neurologist

may be helpful in determining appropriate anticonvulsant medications. Corticosteroids are usually not used during an active infectious process; however, they are sometimes employed to reduce severe brain edema. Surgery should be directed at the involved sinuses as well as the intracranial process unless the patient's condition limits operative time, in which case, the neurosurgical procedure takes precedence. Epidural abscesses are drained via bur holes without violating the dura. Subdural empyema can be approached with either bur holes or a craniotomy. The morbidity from subdural empyema is high with either technique, and the mortality is between 12 and 18%.[22] Brain abscesses actually have a lower mortality, although the morbidity remains high. These collections can be either serially aspirated or excised, based largely on the accessibility of the lesion and the stability of the patient.

DIAGNOSIS OF RHINOSINUSITIS

History

The diagnosis of rhinosinusitis is made difficult by the similarity in symptomatology with allergic rhinitis and acute viral rhinitis. In rhinosinusitis, the most common complaints are nasal obstruction and nasal congestion. These sensations likely result from the thickening of the sinus and nasal mucosa, along with reactive swelling of the inferior and middle turbinates. Postnasal discharge is also a common symptom reported by sinusitis patients. These symptoms, which largely reflect inflammation of the nasal cavities, are present in allergies and colds as well as sinusitis. One factor that may help in the differentiation is the duration and timing of symptoms. Allergic rhinitis often has a seasonal component and is associated temporally with exposure to known allergens. Upper respiratory tract infections usually last less than 10 days or are at least on their way toward resolution by then. Both allergic rhinitis and colds can trigger rhinosinusitis and may therefore be present in the history prior to onset of sinus symptoms. It is estimated that 0.5 to 2% of upper respiratory tract viral infections go on to cause sinusitis.[23] A history of a "cold" that lasts longer than 10 days, especially with green nasal discharge, is suspicious for sinusitis.

Facial pain, pressure, or fullness can be a more localizing symptom of sinus disease that may help in its identification. Particularly in acute sinusitis, pain over the maxillary or frontal regions can be a prominent feature in the patient's history. Maxillary sinus pain may also be referred to the upper teeth and palate. Ethmoid sinusitis classically causes pain between or behind the eyes. Sphenoid sinus inflammation or infection tends to cause more insidious pain that may be referred to the occipital, vertex, or bitemporal regions of the skull. Of course, there are many other causes of headache and dental pain other than sinusitis; thus, facial or head pain is not a specific finding. Also, pain is a less common finding once sinusitis becomes chronic, except when there is an acute exacerbation. Similarly, acute sinusitis is sometimes associated with systemic symptoms such as malaise, fever, and lethargy, whereas chronic sinusitis typically is not. A common symptom seen in chronic disease more often than in the acute situation is olfactory loss. Sore throat and cough may be present in either case. As discussed earlier, the Rhinosinusitis Task Force of the AAO-HNS has identified major and minor symptoms associated with rhinosinusitis that can be helpful in making the diagnosis (see Table 34–2).

It is important in the history to elicit any symptoms related to orbital or intracranial extension of the infection. Mild periorbital swelling is not uncommon in frontal, ethmoid, or maxillary sinusitis. This swelling is often worse in the morning and improves over the course of the day. However, massive periorbital edema, orbital pain, diplopia, or change in vision may signal the presence of an orbital complication. Change in mental status or meningeal signs can herald an intracranial process related to ethmoid, frontal, or sphenoid sinusitis.

Physical Examination

The external findings in sinusitis may be limited and nonspecific. Periorbital, forehead, or cheek swelling is sometimes apparent, and there may also be associated tenderness to palpation or percussion in these regions. The oral cavity and oropharynx should be examined for dental pathology and for the presence of postnasal discharge. Anterior rhinoscopy can reveal mucosal hyperemia and edema of the septum and inferior turbinate. It may be possible to discern mucopurulent discharge in this manner, although the site of origin is not likely to be visualized. Transillumination of the maxillary and frontal sinuses is

sometimes described and can be of supportive help in diagnosis but has largely been supplanted by more specific techniques of examination.

In recent years, there has been tremendous advance in the use of nasal endoscopes for the diagnosis of nasal and sinus disease. Such endoscopes may be either rigid or of a flexible fiber-optic design. Pretreatment of the nasal cavities with decongestant and topical lidocaine allows a very thorough inspection in the office setting with minimal discomfort to the patient. Septal deformities, polyps, and other anatomic abnormalities impacting sinus drainage can be readily observed endoscopically. The middle meatus can be seen directly, and any purulent discharge may be traced either to the middle meatus or sphenoethmoidal recess. A swab can then be used to obtain this material under endoscopic control, yielding highly accurate cultures that may direct specific antibiotic therapy (Figure 34–6). The characteristics of the sinonasal discharge can give clues as to the nature of the underlying pathology. For example, clear, thin secretions are more typical of viral or allergic inflammation. Thick, opaque, rubbery secretions are often referred to as "allergic mucin" because of the histologic presence of numerous eosinophils and their granular contents. This type of secretion is often seen in chronic sinusitis and may be suggestive of AFRS in certain clinical settings.

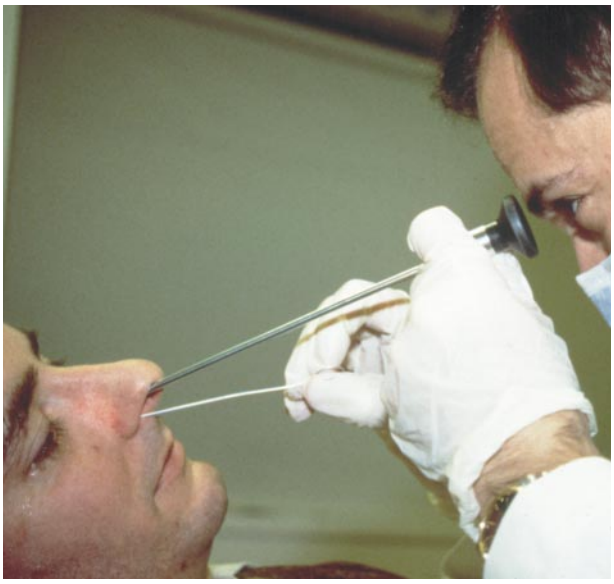

FIGURE 34–6. Technique of sinonasal endoscopy with direct culture of purulent discharge.

Radiology

Since rhinosinusitis is primarily a clinical diagnosis, and considering the improvements in diagnostics brought about by endoscopy, there is a limited role for radiologic studies in the initial assessment of suspected sinusitis. In earlier times, plain x-ray films were considered screening studies for acute disease and are fairly specific for maxillary sinusitis when air-fluid levels are seen. However, for chronic mucosal disease and for imaging of every other sinus, plain films are not useful and therefore are rarely obtained. Certainly, there are situations in which imaging studies are needed for evaluation of the sinuses: for example, clinical sinusitis that fails to resolve with medical therapy or persistent sinus symptoms without endoscopic evidence of disease. The imaging study of choice today is CT with fine coronal sections at the level of the ostiomeatal complex. This technique is excellent in assessing bony detail and thus provides an accurate road map for endoscopic sinus surgery. It is also sensitive in demonstrating mucosal thickening and revealing trapped secretions within the sinus cavities. Unfortunately, the mucosal changes seen by CT are not specific for sinusitis and thus should be interpreted cautiously. Viral respiratory tract infections and allergy will both cause mucosal thickening in the absence of infectious or chronic sinusitis. The mucosal changes associated with viral rhinitis can last for up to 2 weeks after the resolution of symptoms, and changes resulting from an acute bacterial sinusitis can last over a month. Indeed, about 40% of normal people without sinonasal complaints will have abnormalities of the sinus mucosa on CT scan that may be transient and not indicative of true disease.[24]

Radiologic imaging of the sinuses plays an important role when complications are suspected and in differentiating inflammatory from neoplastic disease. Computed tomography is useful in demonstrating bony dehiscences that may predispose a patient to intraoperative complications. When such defects are present in the skull base, they may be important in the intracranial spread of infections or be sites of origin for nasal encephaloceles that may be confused for polyps. Magnetic resonance imaging is a complementary study that is more sensitive than CT in showing soft tissue detail (Figure 34–7). It can

clearly demonstrate dural inflammation that would not be appreciable by CT and shows the communication of encephaloceles with the intracranial space. In invasive fungal sinusitis, MRI can reveal vascular abnormalities that represent fungal infiltration of neurovascular structures, sometimes allowing the process to be detected early when it is more treatable. In the setting of orbital complications of sinusitis or sinus surgery, CT is generally the better study, unless intracranial complications are suspected as well. Another use of MRI is to evaluate symptoms referable to the frontal sinus after it has been surgically obliterated and cannot be monitored endoscopically. Whereas CT merely shows opacification of the sinus, MRI can differentiate fat used in the obliteration from retained mucosa, secretions, and infection. The disadvantage of MRI is mainly that bony anatomy is not seen with this technique, making it useless as a surgical map. Also, to a greater extent than even CT, mucosal disease on MRI is difficult to interpret because of the high sensitivity and the presence of abnormalities in many asymptomatic people.

Staging Systems for Rhinosinusitis

In addition to the establishment of diagnostic criteria for rhinosinusitis, there have been several efforts in the last decade to formulate a standardized staging system to be applied across individuals and used

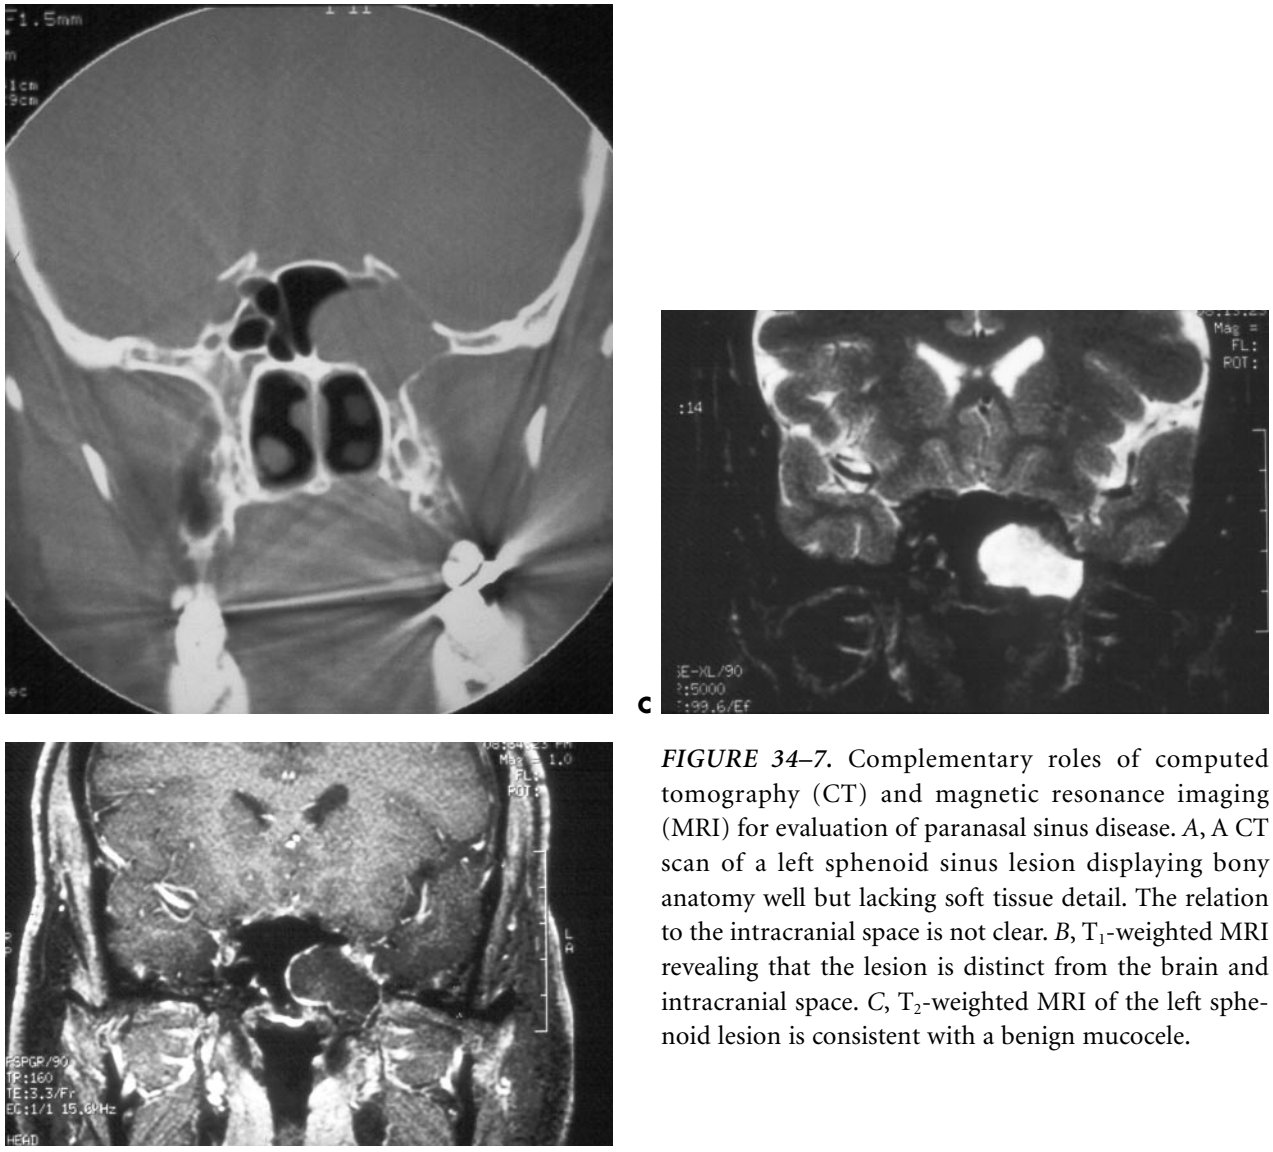

FIGURE 34–7. Complementary roles of computed tomography (CT) and magnetic resonance imaging (MRI) for evaluation of paranasal sinus disease. *A*, A CT scan of a left sphenoid sinus lesion displaying bony anatomy well but lacking soft tissue detail. The relation to the intracranial space is not clear. *B*, T_1-weighted MRI revealing that the lesion is distinct from the brain and intracranial space. *C*, T_2-weighted MRI of the left sphenoid lesion is consistent with a benign mucocele.

to follow the course of the disease. These staging systems have attempted to identify parameters of the history, physical examination, and sinus CT scan with prognostic significance. Most rely heavily on CT findings such as mucosal thickness, anatomic abnormalities, and the location of involved sinuses because these are relatively objective criteria that are readily quantifiable. Unfortunately, the radiographic appearance can be misleading when viewed as an isolated snapshot in time and generally cannot identify the underlying pathophysiology. Better staging information can be obtained by incorporating nasal endoscopy and intraoperative findings into the paradigm. The modified Lund-Mackay System is the staging system for rhinosinusitis currently recommended by the AAO-HNS.[25] This system includes patient symptoms as well as scores derived from radiographic, demographic, endoscopic, and operative findings. Since it is comprehensive and relatively simple to use, the modified Lund-Mackay System may help to unify the various staging techniques that have been described in the literature. Future modifications may involve the inclusion of any biochemical or molecular markers that are demonstrated to have prognostic significance in rhinosinusitis.

PEDIATRIC RHINOSINUSITIS

Pediatric sinus disease is gaining increasing recognition in terms of its prevalence and economic impact. As in adults, the diagnosis of rhinosinusitis in children is made largely on clinical grounds and is similarly difficult to distinguish from viral upper respiratory tract infections. The principal complaints in pediatric sinus disease are nasal congestion, cough, and purulent rhinorrhea. Unfortunately, a good history and physical examination may be unobtainable, especially in very young children. Usually, an otoscope is the most effective instrument to examine the nose of a young child. To the extent possible, attention should be directed toward viewing the region of the middle meatus to look for purulence. Radiologic studies such as CT may be helpful where the physical examination is limited, although the same problems of interpretation exist as do in adults. The pathophysiology of sinus disease in children mirrors that of the adult population, with anatomic, local, and host factors playing important parts. In a child with nasal polyps and recurrent sinusitis, the diagnosis of cystic fibrosis must be strongly entertained. Unique issues in children that may play a causative role in the pathogenesis of sinusitis include adenoid hypertrophy and gastroesophageal reflux disease. There is good evidence that removal of large, obstructive adenoids is beneficial for chronic pediatric sinusitis. However, removal of nonhypertrophied adenoids is controversial for this indication. Antireflux therapy for sinusitis is also somewhat controversial in the absence of other overt manifestations. The mainstay of the medical treatment of pediatric rhinosinusitis is antibiotic therapy directed against the typical sinus pathogens. This is discussed further in the next section as it pertains also to the adult disease.

TREATMENT

Medical Therapy

Acute Rhinosinusitis Once the diagnosis of acute sinusitis is ensured, the goal of therapy is to prevent disease progression and the possibility of serious sequelae. Without treatment, acute sinusitis is often self-limiting, with approximately 40% resolving spontaneously.[26] However, prompt treatment is believed to hasten the resolution of tissue edema and bacterial contamination, restoring ostial patency and sinus ventilation before permanent mucosal damage occurs. There is no debate that antibiotics should be instituted for all cases of acute sinusitis. In three of four randomized trials reviewed by Hueston et al, the use of antibiotics was supported by a more rapid resolution of symptoms.[27] Historically, there has been a dramatic reduction in the incidence of complications secondary to sinusitis since the introduction of antibiotics.

The selection of first-line antibiotics for acute sinusitis is directed by the knowledge of the most common pathogens. Typically, patients will be seen initially by their primary care physician and treated with inexpensive agents such as amoxicillin or trimethoprim-sulfamethoxazole (TMP-SMX). The effectiveness of these agents is hampered by emerging patterns of resistance in many geographic areas, however. Resistance to TMP, by *Streptococcus pneumoniae* in particular, has increased in recent years and has been reported to be greater than to penicillin. For amoxicillin, recent in vitro evidence suggests that current doses may be inadequate, although clinical trials at higher doses have not been completed.[28] In

general, these first-line agents should not be used when resistant microorganisms are suspected.

The choice of a second-line antibiotic is dependent on a number of variables including patient allergies, dosing schedule, proven efficacy, physician experience, and the patient's previous response history, as well as resistance patterns in the community. β-Lactam cephalosporins have long been the most common second-line agents, although macrolides and fluoroquinolones have recently been increasing in popularity. The use of penicillin, erythromycin, cephalexin, cefixime, and tetracycline is condemned for their limited spectrum of activity. In addition, first-generation cephalosporins have poor *Haemophilus influenzae* coverage and should be used cautiously. The most relevant pharmacokinetic parameter of β-lactam antibiotics is the time above minimal inhibitory concentration, which has been shown to correlate with efficacy. In this regard, cefprozil, cefuroxime, and cefpodoxime are the most consistently reliable agents of this class against penicillin-sensitive and intermediately penicillin-resistant strains. These antibiotics are effective in twice-daily dosing and have an adequate spectrum of activity. For β-lactamase-producing strains of *H. influenzae* or *Moraxella catarrhalis*, the use of amoxicillin-clavulanate may be indicated. In this case, a separate prescription for amoxicillin alone must be written to give a double dose of that drug without increasing the clavulanate dose. It should be noted that clavanulate has no effect on resistant *S. pneumoniae* microorganisms because their mechanism of resistance is different. The newer macrolides such as azithromycin and clarithromicin may be acceptable second-line agents, especially in penicillin-allergic patients, although pneumococcal resistance to these agents is on the rise. Any microorganism that is resistant to erythromycin will also be resistant to these newer agents. Finally, the newer fluoroquinolones such as levofloxacin, moxifloxacin, and gatifloxacin are good second-line agents for patients with activity against *S. pneumoniae*. However, as has been observed with other classes of antibiotics, resistance will develop if these drugs are used inappropriately; thus, they are recommended only for moderate-to-severe infections or treatment failures.

Once antibiotics have been instituted, the duration of therapy is controversial. Symptoms should begin to improve within 48 to 72 hours, and it is important to maintain appropriate follow-up to ensure that the complete course of antibiotics is taken. A good guideline is a 10- to 14-day course of therapy, which can be lengthened for persistent symptoms.

Ancillary Therapy. A variety of therapeutic measures can augment the effectiveness of antibiotics in the treatment of acute sinusitis. The goal of these interventions is to restore proper nasal function through improvement in ciliary function and reduction of mucosal edema. Many simple, inexpensive supportive measures are effective because they help to clear crusts and thick mucus. Examples include nasal saline sprays, humidifiers (warm or cool), steam, hot soup, or tea. Mucolytic agents such as guaifenesin also are useful because they lead to thinning of the mucus, which promotes clearance and prevents stasis.[29] Systemic and topical decongestants act on α-adrenergic receptors to cause vasoconstriction and reduction of edema and are therefore appropriate to relieve nasal obstruction, re-establish ostial patency, and ventilate the sinuses. Topical decongestants have minimal systemic side effects and are rapid in onset. However, use of these agents for longer than 3 consecutive days can result in rebound congestion and rhinitis medicamentosa. Systemic decongestants can be used for longer periods of time but may be associated with insomnia, hyperactivity, cardiac stimulation, worsening of hypertension, and negative interactions with concurrent medications. For these reasons, systemic decongestants should be prescribed with caution in some patient groups. The use of decongestants in conjunction with antibiotics has been shown to be more effective than antibiotics alone.

Antihistamines have been used empirically in patients with sinusitis and allergy, although no studies show a clearly beneficial role for these medications. In the setting of acute infectious sinusitis, first-generation antihistamines may actually be counterproductive because of their anticholinergic side effects of mucosal dryness, crusting, and increased mucus viscosity. The newer second-generation antihistamines cause less of these undesirable changes and therefore may be suitable in cases of sinusitis in which allergy plays an important role. Topical nasal corticosteroids are also excellent for the management of allergic rhinosinusistis but have no proven value in the treatment of acute infectious sinusitis. Systemic corticosteroids are

potent anti-inflammatory agents that are effective in the treatment of allergic disease as well as other inflammatory conditions of the nose. Because corticosteroids reduce tissue edema and inhibit inflammatory mediator production, they almost certainly are beneficial in the treatment of acute sinusitis. However, a number of potential complications are associated with corticosteroid use, including hypothalamic-pituitary-adrenal axis suppression, gastric ulcers, psychiatric changes, sleep disturbances, and exacerbation of diabetes, as well as long-term sequelae such as osteoporosis, weight gain, ocular problems, and hypertension. For these reasons, the use of corticosteroids is not widely accepted for acute sinusitis. In general, the risk of adverse side effects when corticosteroids are used conservatively over short, tapered doses is minimal; therefore, these drugs are reasonable adjunctive therapy for acute sinusitis treated primarily with antibiotics.

Chronic Rhinosinusitis In chronic sinusitis, the microorganisms primarily involved are coagulase-positive and coagulase-negative species of *Staphylococcus* and *Streptococcus*. Antibiotic therapy should therefore be directed at these pathogens, although resistance is a constant problem. The use of antibiotics with activity against anaerobes is controversial since some studies show these microorganisms to be of minor importance; however, these agents can be used alone or in combination with other antibiotics when anaerobes are identified in sinus fluid. The duration of antibiotic therapy in chronic sinusitis is not clearly defined but is typically on the order of 4 to 8 weeks. The goals of ancillary therapy for chronic sinus disease are similar to those in the acute situation; however, there are some important differences. When an underlying condition such as allergy, polyposis, fungal infection, or systemic disease is present, the treatment must first be directed toward controlling these processes. In the case of allergic rhinosinusitis, management with antihistamines, topical nasal corticosteroids, and immunotherapy will be of more value than it would in an acute infection. Likewise, systemic corticosteroids are indispensable for the treatment of polyps and sinus inflammation caused by systemic granulomatous or autoimmune diseases. In patients with chronic sinusitis who have undergone previous sinus surgery, there is access for direct irrigation of the sinus cavities with topical antibiotic solutions. This can also be performed with greater difficulty in unoperated patients using indwelling catheters into the maxillary sinuses. There is some evidence to suggest a role for this strategy in chronic sinus disease failing systemic antibiotic therapy. As compared to acute sinusitis, the mechanisms of chronic rhinosinusitis are more obscure and seem to involve many factors other than infection. In fact, much of the infectious component of chronic disease may be secondary to the compromise of the normal mucosal barrier mechanisms by long-term inflammation. In the future, new therapies may target elements of the ongoing inflammatory response in an attempt to allow healing to occur and restore normal mucosal function.

Surgical Therapy

Endoscopic sinus surgery More than 100 years have passed since the first nasal endoscopy was performed by Hirschmann, who used a modified cystoscope. Since then, major advances in optics, biomechanics, and radiographic imaging have allowed evaluation and treatment of paranasal sinus disorders with greater precision.

Naumann recognized the relationship between the middle meatal-anterior ethmoid complex, termed the ostiomeatal unit (Figure 34–8), and the

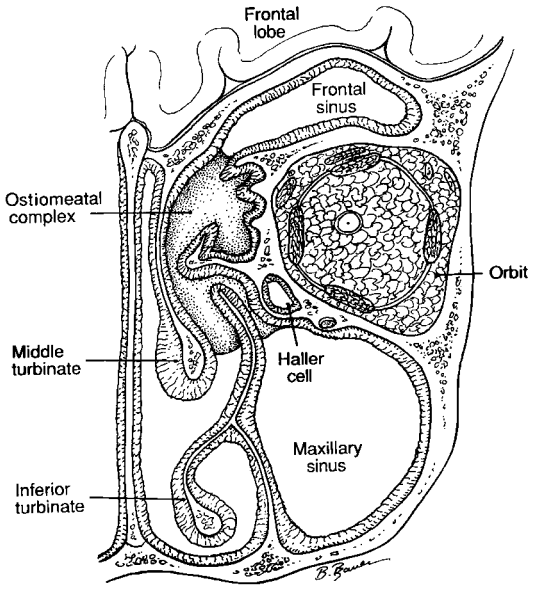

FIGURE 34–8. The ostiomeatal unit (*shaded*). Obstruction of this area leads to disease within the maxillary and frontal sinuses.

pathogenesis of maxillary and frontal sinus disease.[30] After decades of painstaking work, Messerklinger demonstrated that relieving the ostiomeatal unit of obstruction and inflammation could reverse mucosal disease within the frontal and maxillary sinuses, thus rejecting the "irreversibility" theory.[31] Functional endoscopic sinus surgery (FESS) is the natural extension of his labors. Through the work of Kennedy and associates, Stammberger and others advanced endoscopic techniques that are now used to treat an extended list of medical problems in addition to inflammatory processes of the paranasal sinuses (Table 34–3).[32–34]

Even though visualization and instrumentation have improved, endoscopic sinus surgery carries the same risks as traditional sinus surgery. The use of endoscopes has not decreased the complication rate. Surgeons performing endoscopic sinus surgery must understand the anatomy, physiology, technique, and complications related to this surgical procedure.

Technique. The instruments necessary for a safe and complete operation are pictured in Figure 34–9. The majority of the dissection is carried out using the 0-degree endoscope because the angulation of the other telescopes can be disorienting. The 30-degree endoscope is usually required for examination and manipulation of the maxillary sinus ostium and frontal recess. The 70-degree endoscope is excellent for viewing the antrum and for identification of an anterior frontal sinus. Attaching a commercially available endoscope washer facilitates surgery by defogging and clearing secretions from the tip of the telescope.

Choanal atresia repair
Epistaxis control

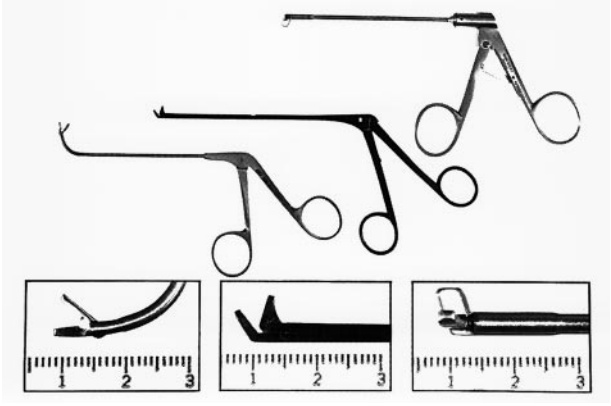

FIGURE 34–9. Micro-through-cutting instruments with varying angles allow mucosa-sparing dissection throughout all regions of the paranasal sinuses. The Stammberger down-biting punch is excellent for enlarging the maxillary ostium.

An important principle in endoscopic sinus surgery is the preservation of mucosa wherever technically feasible. To this end, there have been many improvements in the design of forceps to promote precise removal of tissue without stripping of sinus mucosa. Use of such "through-cutting" instruments greatly facilitates rapid healing and reduces postoperative care needs. Another important innovation has been the introduction of powered instrumentation to endoscopic sinus surgery. In 1994, Setliff first described the application of microarthroscopy-type microdébriders for removal of diseased nasal and sinus tissue. These instruments use an oscillating blade, accompanied by suction and irrigation, to shave away targeted soft tissue while sparing adjacent mucosa (Figure 34–10).[35] The chief advantages of this technique are the continuous suction and a largely bloodless operative field. Powered instrumentation has become widely accepted for the removal of polyps and soft tissue masses. The utility of this technology has been limited by an inability to remove effectively the bony partitions that contribute to the pathogenesis of sinusitis. For this rea-

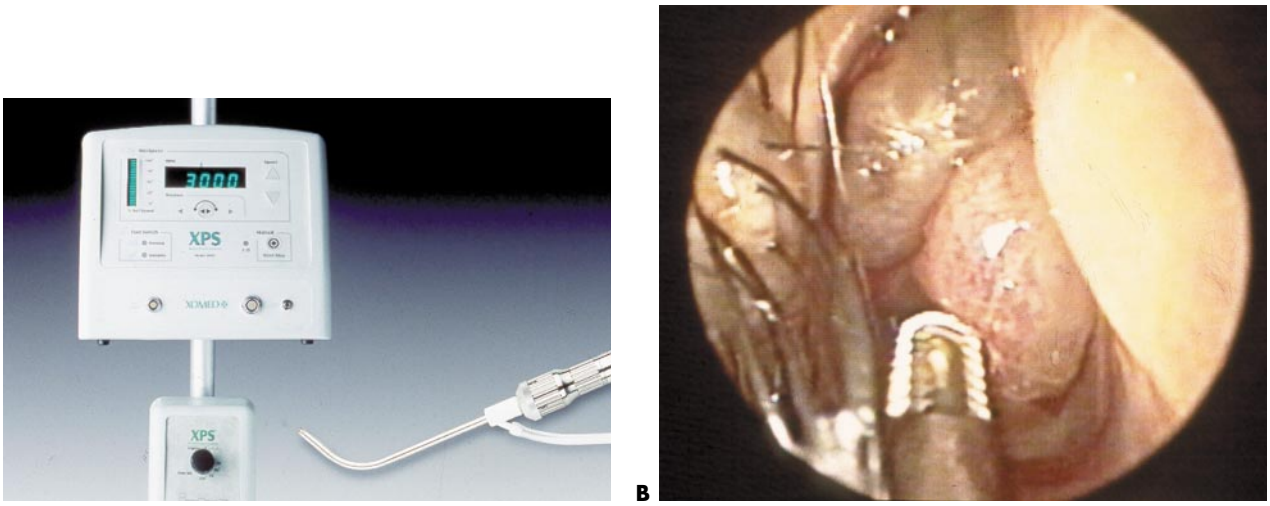

FIGURE 34–10. *A*, Microdébrider used for powered dissection in endoscopic sinus surgery. *B*, Intraoperative endoscopic view of a microdébrider being used to remove nasal polyps.

son, microdébriders and manually operated forceps serve complementary roles and are generally used concurrently in FESS procedures.

Another significant advance in endoscopic sinus surgery has been the development of computer-assisted image-guided technology. Accurate three-dimensional CT reconstruction with real-time intraoperative computer guidance has become widely available in recent years. There are several devices available today that use either electromagnetic or infrared tracking and are relatively user friendly. With some systems, the patient must undergo a preoperative CT wearing a specially fitted headpiece that is worn again in the operating room. The computer uses the headpiece to determine head position and correlate this with the preoperative CT. In other systems, anatomic landmarks are selected from the CT scan and identified on the patient in the operating room, instead of making use of a headpiece. Probes and instruments are then tracked with an infrared or electromagnetic system to determine their position continuously. The surgeon views the sinus CT in multiple planes on the monitor, with the instrument tip position displayed in real time (Figure 34–11). The accuracy of the system is on the order of 2 mm currently, although the technology is constantly undergoing refinement and improvement. Overall, image-guided surgery is helpful in all sinus cases but especially valuable for difficult revision cases with few landmarks or where unusual or distorted anatomy is present.

Anesthesia The operation can be performed under local or general anesthesia. Local anesthesia with intravenous sedation may be preferable because sensory information remains intact along the periorbita and skull base. Allowing the patient to listen to favorite music during surgery reduces the amount of anxiolytics necessary during the procedure. On the other hand, general anesthesia is preferable for patients who are very anxious about being awake and for those who become disinhibited under sedation. There has been a general tendency toward performing more endoscopic sinus surgery under general anesthesia in recent years. One reason for this is that the meticulous nature of mucosa-preserving sinus surgery has increased the length of the procedure to the point that it may be difficult for patients to remain still comfortably. Also, the advent of image-guided surgery has made it necessary for the patient to wear a tight-fitting headpiece, which is not tolerable for long periods of time. It is reasonable to present the advantages and disadvantages of both anesthetic approaches to patients and let them decide which they prefer preoperatively. Patients electing local anesthesia must be informed that they will be put to sleep if they cannot tolerate being awake for the duration of the procedure or if they become disinhibited with sedation.

Before the patient enters the operating suite, oxymetazoline hydrochloride nasal spray is used for initial mucosal shrinking. The nasal mucosa is then further decongested and anesthetized, one side at a

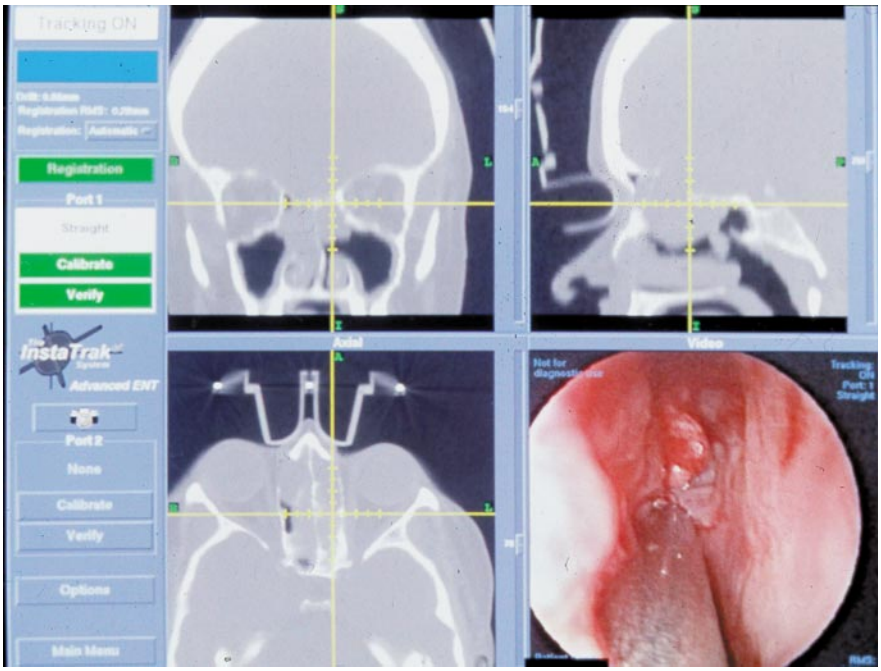

FIGURE 34–11. Use of computer-assisted surgical navigation in endoscopic sinus surgery. In this case, an area suspicious for preexisting dural exposure is identified intraoperatively. The location of the probe is shown at the crosshairs on the triplanar computed tomographic scan images in real time. A skull base defect is verified radiographically and correlated with the endoscopic appearance.

time, with 150 mg of topical cocaine followed by injections of 1% lidocaine with 1:100,000 epinephrine at the sphenopalatine neurovascular bundle (Figure 34–12). Septal abrasions should be avoided; otherwise, visualization becomes difficult from repeated soiling of the telescope. In addition, the sphenopalatine ganglion is anesthetized through the nose or through the greater palatine foramen. Allowing at least 10 minutes for maximal vasoconstriction decreases bleeding. The second side of the nose is anesthetized when surgery on the first side is near completion.

PROCEDURE The surgeon should be comfortable and relaxed during the dissection. The preoperative CT scan should be readily available in the operating room for repeated viewing. The surgeon must perform a meticulous dissection with adequate visualization if complications are to be avoided.

To begin, an infundibulotomy is made using a sickle knife along the anterior and inferior edges of the uncinate process. The uncinate is grasped with Blakesley forceps and removed, taking care not to strip mucosa from the lateral nasal wall. Gentle medial displacement of the uncinate during the

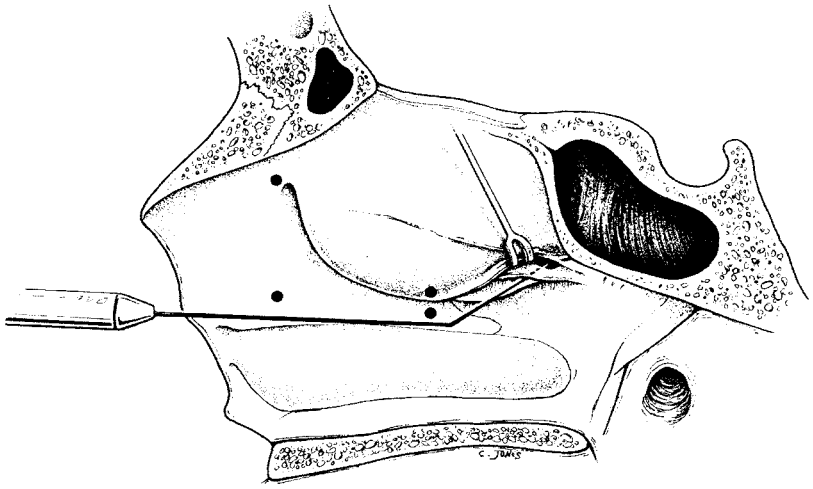

FIGURE 34–12. Recommended injection sites for endoscopic sinus surgery. An angled tonsil needle is used for intranasal injection of the sphenopalatine neurovascular bundle.

infundibulotomy helps define the line of the incision. If possible, the location of the maxillary sinus ostium is noted along with any accessory ostia. Extent of surgery is based on the preoperative assessment; however, for purposes of instruction, a description of a sphenoethmoidectomy with frontal sinusotomy and antrostomy follows.

The bulla ethmoidalis is entered and removed. The medial orbital wall should be identified as early as possible during the dissection. Every attempt at preserving the mucosa along the medial orbital wall is made to improve and hasten postoperative healing. The posterior ethmoid is entered through the inferior and medial area of the basal lamella. The skull base is most easily identified within the posterior ethmoidectomy and serves as the superior boundary for the dissection. The safest way to remove bony partitions within the ethmoid is to feel behind the partitions with up-biting forceps prior to removal (Figure 34–13). This technique assists in avoiding orbital or intracranial penetration.

The sphenoid ostium is located and, if necessary, widened beginning inferiorly and medially. The ostium is usually a few millimeters from the posteroinferior edge of the superior turbinate. The free edge of the superior turbinate may be difficult to appreciate when working in the ethmoid sinus but can be palpated medially. Alternatively, placing an endoscope medial to the middle turbinate usually brings the free edge of the superior turbinate in view. The sphenoid sinus can also be entered by amputating the inferior aspect of the superior turbinate. Care must be taken not to remove this turbinate completely because olfactory neuroepithelium could be injured. Absolutely no blind tissue removal is performed within the sphenoid because this may lead to optic nerve or carotid artery injury.

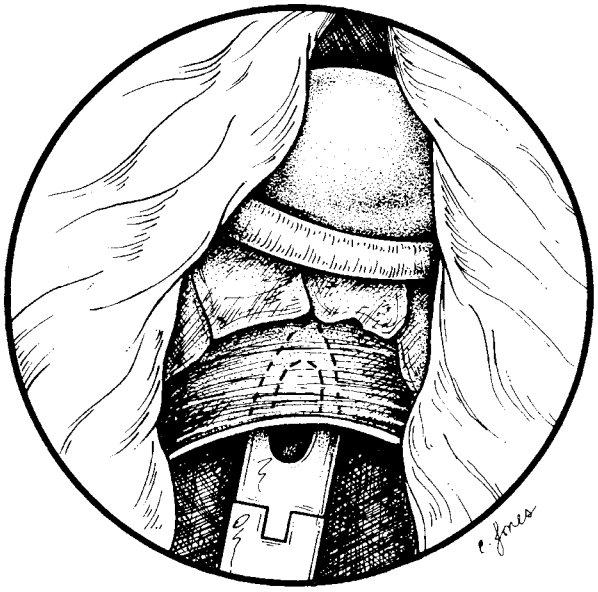

FIGURE 34–13. Blakesley forceps are used to palpate behind bony partitions before removal.

At this point, the dissection is continued anteriorly along the skull base, with care not to injure the anterior and posterior ethmoid arteries. The mucosa along the skull base is also preserved. The frontal recess is dissected only if required because manipulation of this region can lead to stenosis of the frontal ostium. In addition, frontal recess surgery increases the requirement for postoperative care.

Operating within the frontal recess is the most challenging segment of the operation. Changing to the 30- or 45-degree endoscope is helpful for dissecting this area. The dome of the ethmoid should be identified and followed anteriorly as the skull base ascends. The skull base represents the posterior limit of dissection in this area. All motions should be made away from the skull base in an anterior direction. Anteromedial ethmoid cells and agger cells can be removed with a frontal recess curette. Eicken curved suction is helpful in this area. The size of the frontal ostium should be recorded for postoperative reference.

Finally, attention is turned toward the maxillary sinus ostium. The 30-degree telescope is usually required to identify the natural ostium of the maxillary sinus. If necessary, the ostium is enlarged posteriorly and inferiorly. Beginning from within the ostium, the mucosa of the posterior fontanelle is split and then removed with the aid of a back-biting instrument. The remaining uncinate is removed at this time to prevent postoperative scarring in this area.

At the conclusion of the operation, an expandable sponge covered with a water-soluble antibacterial ointment is placed lateral to the middle turbinate. Additional packing is rarely required. Most patients are released the day of surgery and return to the clinic on the first postoperative day for removal of the sponge.

Postoperative Care The overall success of FESS is in large part attributable to appropriate postopera-

tive care. The goal during this period is to promote mucosal generation within the sinus cavities. To facilitate this generation, sinus cavities are examined and cleaned of blood, fibrin clots, and crusts at regular intervals following surgery. Endoscopes should be used, as opposed to blind manipulation, to prevent injury to healthy mucosa and for directed débridement. This is especially true for the frontal recess.

Systemic antibiotics are used in the postoperative period, and their use may be prolonged when severe, chronic inflammation is present. Agents covering the typical sinus flora, such as amoxicillin/clavulanate, cephalosporins, or quinolones, are the most common antibiotics chosen in uncomplicated cases. When there is known exposed osteitic bone, broader coverage with clindamycin and TMP-SMX may be indicated. If postoperative endoscopy reveals purulence, this material should be cultured and antibiotic therapy tailored appropriately. Patients may be instructed to irrigate the nose with saline solution twice daily. For the majority of patients with chronic sinusitis, surgery alone does not result in a permanent disease resolution. Long-term, culture-directed, systemic antibiotics and prolonged use of topical nasal corticosteroids are frequently required. Occasionally, antibiotics are added to the nasal irrigation solution for patients with recalcitrant chronic sinusitis. In some circumstances, such as in aspirin-sensitivity triad disease failing multiple previous sinus surgeries, long-term oral corticosteroid therapy using a low-dose, alternating-day regimen may be required to prevent recurrence.

It is critical to the ultimate success of endoscopic sinus surgery that meticulous, sometimes aggressive, débridement be performed in the weeks following the procedure. At each postoperative visit, the nasal cavities are sprayed with tetracaine and a nasal decongestant, and cocaine may be applied with nasal applicators as needed. Since the mucosa is particularly sensitive in the early postoperative period, the patient is instructed to take an oral narcotic/analgesic before arriving. The goal of these postoperative débridements is to clear crusts, osteitic bone fragments, and forming scar tissue before these factors create persistent inflammation and disease recurrence. In some instances, diseased sinus cells that were missed in the operation will be recognized and need to be opened. As in the operating room, mucosal preservation is paramount in postoperative débridement and sinus cavity revision. Local anesthetic injection may be necessary to allow the patient to tolerate the intranasal manipulation comfortably. Endoscopic surveillance and proactive treatment of residual disease eliminate the need for most revision surgery and lead to long-term success.

Open Sinus Procedures Although FESS can be used effectively for most medically recalcitrant sinus disease, there are still occasional circumstances under which open sinus procedures may be indicated.

Maxillary Sinus. Caldwell-Luc Operation. In cases of symptomatic maxillary sinus mucoceles, antrochoanal polyps, mycetoma, or foreign bodies not accessible via an intranasal endoscopic approach, the traditional open procedure has long been the Caldwell-Luc procedure. This procedure may be performed under general anesthesia or locoregional anesthesia via blocks of the infraorbital, sphenopalatine, and posterosuperior alveolar nerve. Topical 4% cocaine can be placed intranasally in the region of the anterior ethmoid nerve and the medial wall of the maxillary sinus.

Technique. The procedure begins with a gingivobuccal incision, made from the second molar to the ipsilateral canine tooth (Figure 34–14). The incision should be made just above the apex of the buccogingival sulcus to preserve an inferior flap of soft tissue that will facilitate closure. Dissection proceeds sharply through the submucosal tissue and the maxillary periostium down to bone. A periostial elevator is used to raise the periosteum and overlying soft tissue superiorly to the level of the infraorbital foramen, being careful not to injure the neurovascular bundle. Medially, the periosteum is elevated to the pyriform aperture. Once adequate exposure is achieved, the maxillary sinus in entered through its anterior wall using an osteotome or cutting bur. The antrum is entered superior to the roots of the canine and premolar teeth. A sphenoid punch and a Kerrison rongeur are used to remove additional bone and enhance exposure. Bone can be removed superiorly, medial and lateral to the infraorbital nerve, preserving the infraorbital foramen itself.

The approach gives good visualization of all portions of the maxillary sinus and allows complete removal of infectious material and masses that

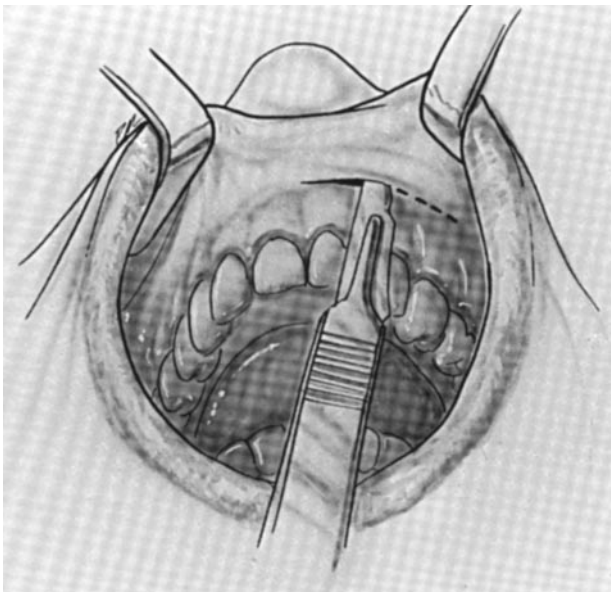

FIGURE 34–14. Mucosal incision for a Caldwell-Luc procedure.

would not be easily reached through a middle meatus antrostomy. Stripping of the mucosa with forceps or curettes is to be condemned and will result in permanent sinus dysfunction. Furthermore, creation of an inferior meatus antrostomy, which is typically performed in conjunction with the Caldwell-Luc procedure, is nonphysiologic in terms of mucociliary clearance patterns and may result in recirculation of purulent material. At the conclusion of the maxillary sinus procedure, the gingivobuccal incision is closed with either interrupted or running absorbable suture.

Complications The most common complication of the Caldwell-Luc approach is paresthesia or anesthesia of the cheek, teeth, and gingiva secondary to traction on the infraorbital nerve. Fortunately, this is self-limited in the majority of cases and resolves in less than 6 months. However, as many as 30% of patients will report some degree of persistent dysesthesia in the infraorbital nerve distribution.[36] Other complications include hematoma formation, maxillary tooth root injury, and superior alveolar nerve damage. There have also been rare reports of oroantral fistula and epiphora from nasolacrimal duct trauma after the Caldwell-Luc operation. It should be noted that the Caldwell-Luc procedure generally results in fibrosis and new bone formation in the maxillary sinus, leading to antral contracture. This can affect interpretation of postoperative films and make revision surgery more difficult.

Ethmoid Sinuses. External Ethmoidectomy. The external ethmoidectomy has largely been supplanted by the endoscopic approach; however, there remain some situations in which this approach may prove useful. For example, excellent exposure may be provided externally for biopsies of certain orbital lesions or lesions of the ethmoid or frontal sinuses. Also, this approach may be employed for rapid and safe access for orbital complications of acute ethmoid or frontal sinusitis. Repair of cerebrospinal fluid leaks originating from the cribriform plate or ethmoid roof may be addressed via an external approach, depending on the preference of the surgeon.

Technique The external ethmoidectomy incision generally begins at the inferior margin of the medial aspect of the eyebrow, curving gently downward midway between the medial canthus and the anterior aspect of the nasal bones (Figure 34–15). The incision is carried successively through the skin, subcutaneous tissues, and periosteum. Bipolar cautery is used to control bleeding from the angular vessels, and care is taken to preserve the supraorbital bundle. The periosteum is elevated both medially and laterally to facilitate eventual closure. Attention is given to protecting the trochlea and the attachment of the medial canthal ligament during periosteal elevation. The lacrimal sac is elevated atraumatically from the lacrimal fossa.

Dissection proceeds in the subperiosteal plane beyond the posterior lacrimal crest, exposing the medial wall of the orbit. The anterior ethmoid neurovascular bundle is encountered approximately 24 mm posterior to the anterior lacrimal crest. The anterior ethmoid artery, found in the frontoethmoid suture line, is clipped or electrocoagulated and divided. A malleable retractor is placed laterally for exposure and to protect the periorbita. Inadvertent entry into the periorbita will result in herniation of orbital fat into the field. Although it is not routinely necessary to dissect further posteriorly, the posterior ethmoid artery is located approximately 12 mm posterior to the anterior ethmoid artery and approximately 6 mm anterior to the optic foramen. The surgeon must be extremely careful in ligating the posterior ethmoid artery as the exact distance to the optic nerve is variable.

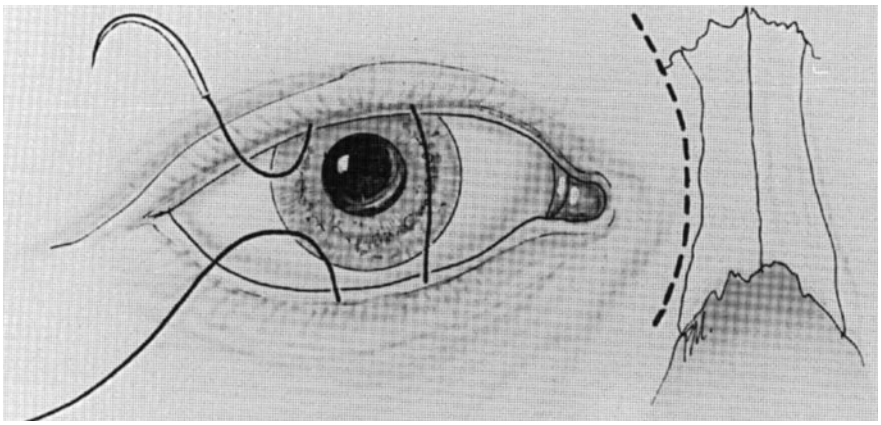

FIGURE 34–15. Incision for external ethmoidectomy.

Once the lacrimal bone, frontal process of the maxilla, lamina papyracea, and orbital process of frontal bone have been widely exposed, the ethmoid is entered through the lacrimal fossa with a mallet and gouge or drill. The opening is circumferentially enlarged with the Kerrison rongeur. When the frontoethmoid suture is reached, no further bone should be removed superiorly as this represents the level of the anterior cranial fossa. The lamina papyracea is taken down to allow complete exenteration of the ethmoid cells. Working intranasally, an uncinectomy and anterior ethmoidectomy will link the ethmoid cavity to the middle meatus. The middle turbinate should not be removed.

In some cases, the frontal sinus may be disrupted during the external ethmoidectomy procedure. To promote drainage of the frontal sinus, Silastic stents have sometimes been placed extending from the frontal sinus to the anterior aspect of the inferior turbinate and secured with a permanent suture. A period of at least 6 weeks is needed to produce a mucosally lined tract between the frontal sinus and the middle meatus. Even with stenting, stenosis tends to occur, and the orbital contents have a tendency to medialize into the frontal recess and interfere with sinus outflow.

At the end of the procedure, the nose is packed with 1 cm gauze or preformed surgical sponges impregnated with antibiotic ointment. The periosteum and subcutaneous tissues are closed with 3-0 absorbable sutures, and skin closure is accomplished with 6-0 nylon or mild chromic sutures.

Complications. A poorly designed incision can result in cosmetic problems such as a hypertrophic scar, medial canthal blunting, or medial canthal webbing. Webbing can be addressed with a Z-plasty at a later time or may be prevented by performing one at the time of the initial surgery. Injury to the lacrimal system can also occur, with epiphora as a consequence. If dissection proceeds into the orbit, serious complications such as cranial nerve injury or visual loss are possible. Retrobulbar hematoma and cerebrospinal fluid leak are other less common but potentially catastrophic complications of the external ethmoidectomy.

Frontal Sinus. Open approaches to the frontal sinus are indicated for chronic, complicated frontal sinusitis that has not responded to trephination or conventional endoscopic sinus surgery. Other indications include intracranial or orbital extension of disease, mucocele or mucopyocele, and osteomyelitis of the frontal bone.

Trephination. This approach to the frontal sinus is useful in the face of acute infection when mucosal bleeding may hamper an intranasal endoscopic approach. It is safe and rapidly performed and can decompress a pus-filled frontal sinus prior to a more definitive procedure. The procedure is also useful in conjunction with FESS to help locate the natural drainage pathway of the frontal sinus and to visualize the ostium from above and below.

Technique. An incision is made beneath the medial portion of the eyebrow, taking care to bevel the incision parallel to the hair follicles. The incision is carried through skin, subcutaneous tissue, and the periosteum over the frontal sinus floor. Once the

incision is completed, the wound can be retracted superiorly and medially over the anterior table of the frontal sinus. A drill is used to make a hole into the sinus in a controlled fashion (Figure 34–16). If the hole is made with a diameter greater than 4 mm, an endoscope can be inserted to visualize the interior of the sinus. Purulence is removed for culture, and the sinus is irrigated. The wound is closed with deep absorbable sutures and nylon or prolene on the skin. A catheter may be left in the trephination and brought out through the wound to allow for irrigation in the postoperative period.

Frontal Sinus Obliteration with Osteoplastic Flap. Frontal sinus obliteration is an old procedure that has been revived and refined for use in recalcitrant cases of frontal sinusitis. After endoscopic surgery, the frontal sinus ostium is sometimes very difficult to keep open from within the nose when osteoneogenesis is present. More extensive intranasal drill-out procedures may be successful in establishing long-term patency of a frontal sinus drainage pathway, but many times it is not possible to maintain an opening into the sinus with any endoscopic or open surgical technique. In these patients, frontal sinus obliteration may be the only viable option. The technique has the advantage of unparalleled visualization of the entire frontal sinus and elimination of the need to reconstruct the nasofrontal drainage outflow. The negatives of the technique include the external scar, potential for forehead hypesthesia, and the loss of a connection between the nose and sinus through which endoscopic surveillance can be performed.

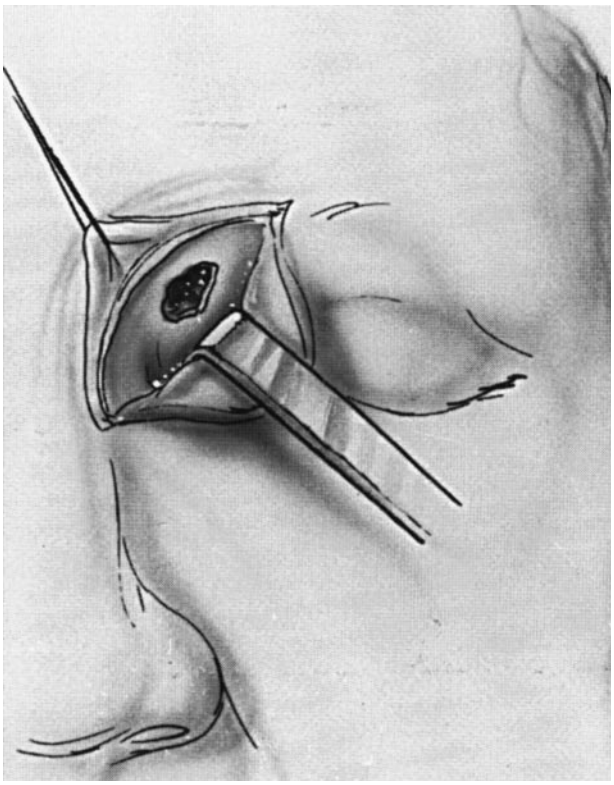

FIGURE 34–16. Frontal sinus trephination.

Technique The osteoplastic flap frontal sinus obliteration can be performed through either a gull-wing suprabrow incision or a bicoronal approach with the incision behind the hairline. Typically, the type of incision is determined by the patient's hairline and the presence of suitable forehead creases in which to place the scar. A 6-foot Caldwell radiograph of the sinuses is obtained preoperatively, and a template of the frontal sinus is fashioned and sterilized. The patient's face and hair are prepared for a bicoronal approach, and the abdomen is prepared for harvest of abdominal fat.

The bicoronal incision is made approximately 2 cm behind the hairline and curved laterally toward the ears on both sides (Figure 34–17). Since the scalp is very vascular, hemostasis must be maintained with Raney clips and careful cautery (avoiding hair follicles) to prevent excessive blood loss. The flap is elevated above the level of the pericranium down to the

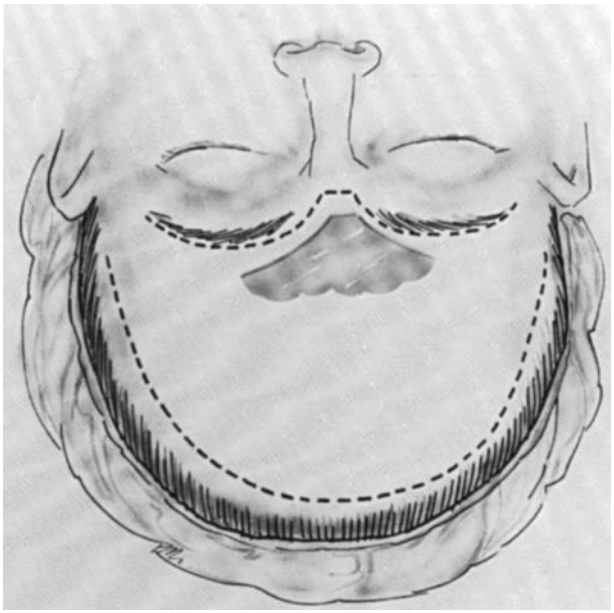

FIGURE 34–17. Incisions used for the osteoplastic approach to the frontal sinus.

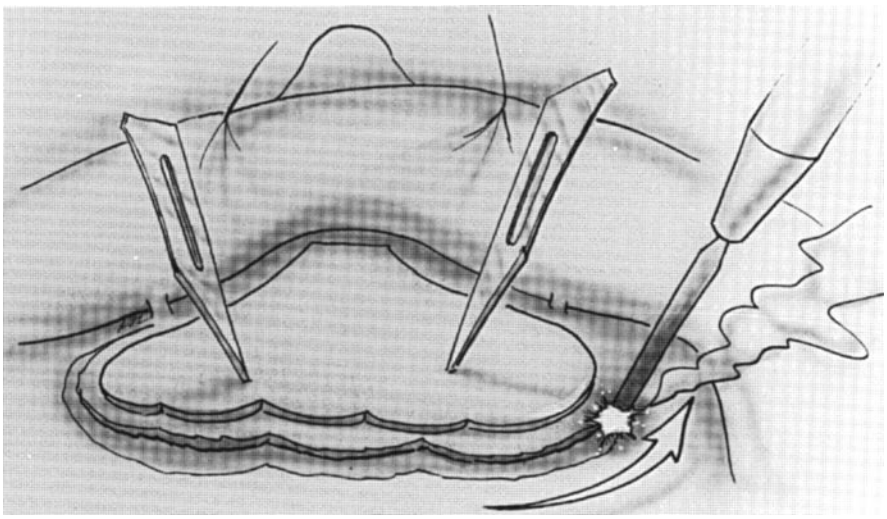

FIGURE 34–18. Periosteal incison being made around margins of the template. The *arrow* indicates the direction of the periosteal incision made with the cautery handpiece.

root of the nose and superior orbital rims. Near the orbits, the supraorbital neurovascular bundle should be identified and protected. With the flap elevated, the template is placed to show the borders of the frontal sinus, which are marked with a pen. Other techniques used to define the sinus boundaries are transillumination of the sinus through a trephination or the use of surgical navigation. Once the borders are marked, the periosteum is incised along the marked edges and elevated 1 to 2 mm (Figure 34–18). The periosteal flap remains attached inferiorly at the orbital rims to preserve a blood supply.

An oscillating saw is used to make the bone cuts through the anterior table of the frontal sinus. The cuts are beveled at about a 45-degree angle directed toward the sinus, both to prevent inadvertent penetration outside the sinus and to assist in repositioning the flap at the end of the procedure. Even with this degree of beveling, care must be taken to avoid cutting the posterior table of a very shallow sinus. With the bony cuts completed, the intersinus septum is cut and the flap is elevated with an osteotome. The bone flap, with the periosteum attached superficially, is reflected inferiorly to expose the sinus (Figure 34–19). To perform an obliteration successfully, it is absolutely critical to remove all of the mucosa from within the sinus. The gross mucosa is relatively easily stripped from the sinus and its recesses. However, rests of mucosa exist within the small foramina of Breschet in the bone of the anterior and posterior tables. Therefore, all of the bony surfaces of the frontal sinus must be meticulously burred down under microscopic visualization before placing the fat graft. The frontal ostium is occluded with pericranium or temporalis muscle to obliterate the connection to the nasal cavity. Abdominal fat is usually harvested through a periumbilical incision and cut to fit snugly within the confines of the sinus. When the graft is in place, the bone flap is replaced and fixed with small titanium plates to recreate the normal frontal contour. Drains are placed in the incision, and the wound is closed in layers.

Complications The most significant disadvantage of a frontal sinus obliteration procedure is the loss of the ability to image the sinus following the procedure. This can make assessment of postop-

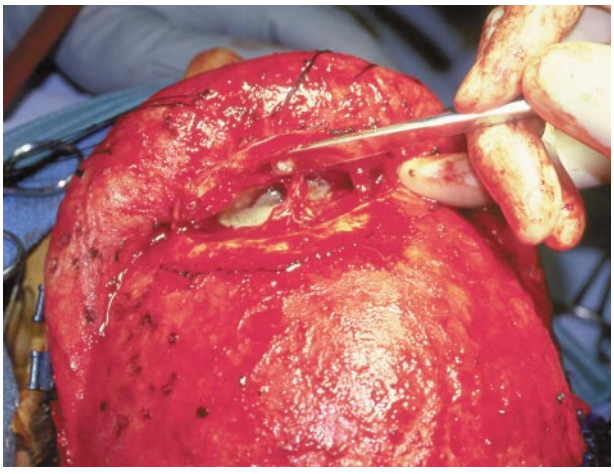

FIGURE 34–19. The osteoplastic flap approach to frontal sinus obliteration. Here the osteoplastic flap has been elevated, and the frontal sinus can be seen.

erative frontal sinus complaints difficult and delay detection of some late complications. Perioperative complications of the osteoplastic frontal sinus obliteration procedure include hematoma, infection or abscess of the bicoronal or abdominal wound, and dural injury from bone cuts outside the sinus. The major long-term complications of obliteration are pain or altered sensation, visible bony defects, and mucocele formation. Pain and sensory abnormalities often result from trauma or sectioning of the supraorbital nerve. Bone defects can occur from depression or protrusion of the osteoplastic flap or the development of hyperostosis. Mucoceles take many years to develop but can ultimately lead to extensive operations to secondarily remove the entrapped mucosa. The frontal recess is the most likely place for mucosa to have been incompletely removed, but there are always crevasses around the periphery of the frontal sinus that can harbor rests of mucosa. Incomplete separation of the nasal cavity from the obliterated sinus can eventually result in an infected graft and fat necrosis.

Sphenoid Sinus. Although the sphenoid sinus is readily accessible endoscopically through the nose, external approaches are frequently used to achieve wider exposure for resection of masses or for pituitary surgery. Some techniques, such as the external ethmoidectomy and transantral approaches, are seldom used today because of the oblique angle toward the sphenoid. Most commonly, the open procedures involve operating through the nasal septum to the face of the sphenoid. This can be accomplished via a transnasal septoplasty approach, an open rhinoplasty-type incision, or a sublabial incision. The transnasal approach has become more popular with the increased use of the endoscope; however, the technique requires a relatively large nose unless an alar incision is used. The external rhinoplasty incision gives unparalleled access and visualization but has the potential to leave a noticeable columellar scar. The sublabial approach is the one most often employed because it is easy, leaves no nasal scars, does not depend on nasal size, and allows the speculum to be placed in the midline. The drawbacks involve oral contamination of the wound and difficulties with oral incisions in denture wearers.

Sublabial, Transseptal Technique. After induction of general anesthesia, the upper gingivobuccal sulcus, nasal septum, and floor of the nose are injected with 1% lidocaine with 1:100,000 epinephrine. A scalpel is used to make an incision in the upper labial sulcus, leaving a cuff of mucosa attached to the gingiva to facilitate closure. The incision is carried down to the maxillary bone, and the periosteum is elevated to the inferior margin of the pyriform aperture until the anterior nasal spine is exposed. The right septal periosteum is incised at the caudal margin, and mucoperichondrial flaps are elevated along the right side of the septum and along both floors of the nasal cavities. The septum is divided at the bony-cartilaginous junction, and mucoperiosteal flaps are elevated bilaterally from the bony septum. The pockets along the nasal floors are then connected with the septal pockets, and the cartilaginous septum is dislocated from the maxillary crest toward the left. The perpendicular plate of the ethmoid is then removed with forceps, taking care not to place any torque on the superior attachment of the bone to the ethmoid roof. Once the rostrum of the sphenoid is reached, fluoroscopy or surgical navigation may be used to verify proper positioning. The anterior face of the sphenoid can then be entered directly in the midline or by first locating the natural ostia and using these as the superior and lateral landmarks. For pituitary surgery, the speculum is then inserted, and the procedure is generally turned over to neurosurgery. After pituitary tumor resection, the sphenoid mucosa is often stripped away, and the sinus is obliterated with fat or bone grafts. The septal flaps are carefully reapproximated, and the septum is returned to the midline in the maxillary crest. The sublabial incision is closed with absorbable suture, and the nose is packed.

External Rhinoplasty Technique. The sublabial approach was first described by Cushing and was then reintroduced and popularized by Hardy in 1968.[37] Although it has become the standard, drawbacks to this approach include limited exposure secondary to the overhanging upper lip, loss of nasal tip projection from resection of the anterior nasal spine, postoperative dental hypesthesia, and difficulty with denture fitting in older patients. The external rhinoplasty approach was designed to avoid these limitations of the traditional sublabial technique.[38] In this procedure, the nasal columella, dome, septum, and nasal floors are injected with 1% lidocaine with 1:100,000 epinephrine. A columellar

flap is created with an external rhinoplasty incision and elevated onto the dome of the nose. The medial crural ligaments are divided to expose the caudal edge of the septal cartilage. A mucoperichondrial flap is then raised on the left side of the septum beyond the bony-cartilaginous junction and onto the maxillary crest and floor of the nose. At this point, the cartilage is separated posteriorly and inferiorly so that posterior and inferior tunnels can be elevated on the right side and connected. Once the speculum is inserted, the perpendicular plate of the ethmoid is resected and the vomer followed to the anterior face of the sphenoid sinus. The sphenoid is entered, removing the mucosa, intersinus septum, and posterior wall to reach the pituitary. After the hypophysectomy is performed by neurosurgery, the sphenoid is obliterated, and the septal flaps are replaced. The medial crura is repaired with 4-0 chromic suture. The columellar incision is closed with 5-0 mild chromic, and the nose is packed.

Complications The nasal complications are typically related to the septoplasty portion of the procedure. These include septal perforation, saddle deformity, and tip deformity. Epistaxis and wound infection are also possible nasal problems postoperatively. Potentially serious neurologic and vascular complications may occur in sphenoid surgery since the carotid artery and optic nerves travel in the lateral wall of the sinus. Even if the optic nerve is not injured directly during surgery, overpacking of the sinus with fat can cause optic chiasmal compression and visual loss. Another possible complication is cerebrospinal fluid leak, which should be treated when it is recognized intraoperatively. During the postoperative period, patients must be closely monitored for evidence of change in mental status or signs of active bleeding. The cause of these findings will generally be discovered through radiologic evaluation, and the proper intervention can be planned and undertaken by the operative team.

FUTURE DIRECTIONS

There have been many recent advances in the medical and surgical approaches to sinus disease. Computerized guidance systems continue to improve and have the potential to assist the surgeon greatly in operating safely at the skull base for difficult sinus disease. An improved understanding of the necessity for mucosal preservation in endoscopic sinus surgery has reduced the incidence of postoperative scarring and sinus dysfunction requiring revision surgery. With the current armamentarium available for early diagnosis and aggressive treatment, most sinus disease can be controlled and serious complications averted.

However, considering the prevalence of rhinosinusitis, its economic cost, and quality of life impact on those who suffer with it, there is much about the pathophysiology of the disease that has yet to be learned. In particular, chronic rhinosinusitis that is recalcitrant to current methods of medical and surgical management awaits a new therapeutic approach. As with many areas in medicine, the future of diagnosis and treatment in sinus disease will likely use the rapidly expanding tools of molecular biology and the unfolding knowledge of the human genome. Already there has been the discovery that some patients with recurrent sinusitis have alterations in the membrane ion channel gene that is responsible for cystic fibrosis.[39] Perhaps there are other subtle, undiscovered differences at the genomic level that predispose patients to chronic sinonasal inflammation. As the underlying mechanisms of chronic sinus disease are uncovered, more directed pharmacologic therapy may be devised that spares the patient the side effects and complications of systemic corticosteroids. Ultimately, specific genetic markers associated with an increased risk of sinusitis may be identified. With this information, early genetic screening will allow preventive treatment or even gene therapy to be instituted prior to the onset of symptoms. This has already begun with other types of diseases, and it is only a matter of time before the methodology is applied to rhinosinusitis.

CHAPTER 35

Headache and Facial Pain

James M. Hartman, MD, Richard A. Chole, MD, PhD

The craniofacial region is the most common location in which pain drives patients to seek medical attention.[1] The wide diversity of causes and the extreme overlap of historical features coupled with nonspecific physical findings serve to challenge the physician's ability to diagnose and ultimately relieve or control patients' craniofacial pain. However, an understanding of the different types of craniofacial pain provides a powerful tool to meet the challenge.

INNERVATION FOR PAIN

Nociceptors serve as the sense organs in which noxious stimuli create a response that excites afferent nerve fibers that provide the brain with information about location, intensity, quality, and duration of the response.[2] Neurochemicals responsible for this excitation include serotonin and substance P as well as other neurotransmitters. These afferent fibers are carried to the central nervous system in cranial nerves V, IX, X, and XI and the first three cervical nerves.

Pain-sensitive innervation of facial structures is extensive, whereas intracranial pain sensation is limited to specific structures. The extracranial tissues innervated for pain sensation include the muscles of the head and neck, the scalp and facial skin, sinonasal mucosa and perichondrium, temporomandibular joint (TMJ) synovium and capsule, tooth pulp, the external and middle ear, orbital contents, salivary glands, cervical spine, and craniofacial periosteum. Intracranial structures with nociceptive neurons include major arteries, specifically the internal carotids, vertebral basilars, middle meningeals, ophthalmics, and the circle of Willis, and the major venous sinuses. Nonvascular structures with pain nerve fibers are represented by cranial nerves V, VI, VII, IX, and X and the upper three cervical nerves themselves, as well as the pituitary fossa and the base of skull dura mater. The remaining intracranial structures are asensate to pain, including the brain, most of the dura, the ventricles, and the cranium. The afferents converge on nuclei in the brainstem where multiple synaptic connections occur including transmission to the ipsi- and contralateral thalamus and the somatosensory cerebral cortex. The thalamic nuclei appear to play a role in the affective response to pain, whereas the cortical centers' role is in localization and intensity recognition of noxious stimuli.[2] The extensive convergence of afferent neurons in brainstem nuclei, however, limits the brain's ability to distinguish between sources. The result is referral of pain to tissues with a past experience recognized as pain.[3] Specific patterns of referral of pain are common; for example, from the TMJ and muscles of mastication, radiation is to the ear, cheek, and temple[4]; from the tonsillar fossa and supraglottic larynx to the middle ear; and from the maxillary sinus to the maxillary teeth, whereas pain from the sphenoid sinus is more often referred to the vertex or occiput, and, of course, angina is sometimes referred to the jaw.

PATHOPHYSIOLOGY

Multiple mechanisms resulting in excitation of nociceptive neurons (ie, generating the perception of pain) are partially understood. One common mechanism is sustained muscle contraction resulting in tension headache. The exact source of excitation is unclear but may be the result of ischemic changes or the production of nitric oxide.[5] Another common scenario is vasodilation of intracranial arteries stimulating trigeminal sensory pathways, which release vasoactive peptides that increase the pain response.[6] The vasodilation seems linked to subtypes of serotonin 5-hydroxytryptamine (5-HT) receptors in vessel walls. Other subtypes of 5-HT receptors, such as 5-HT_{1B}, yield vasoconstriction and inhibit the pain response.[7] It is this basis on

which triptan antimigraine agents have their effect by selectively binding to 5-HT_{1B} receptors. An inflammatory mechanism is thought to be responsible when neuropeptides such as substance P are released with mucosal inflammation. These result in neural excitation, resulting in the perception of pain.[8] Neural inflammation following injury or tumor invasion has an excitatory effect. Direct nerve pressure may induce nociceptor activity, as seen in foraminal stenosis. Many agents that result in vasodilation can trigger headache including hypoxia, carbon monoxide, caffeine withdrawal, acute alcohol withdrawal, oral contraceptives, hypoglycemia, and antihypertensive and other vasodilators such as nitroglycerin and monosodium glutamate found in Chinese food.[9] Finally, cerebral mechanisms are also thought to play a role. For example, some migraineurs have been found to have defective release of endogenous opiates,[10] and lowered cortical pain thresholds occur in chronic tension headaches.[11]

CLASSIFICATION

Understanding headache and facial pain is essential to facilitate diagnosis and treatment. To this end, definitions and features of clinical syndromes were organized by the International Headache Society (IHS).[12] This classification, with inclusion of diagnostic criteria for headaches, cranial neuralgias, and facial pain, was created in 1988 and has facilitated the diagnostic approach and management of craniofacial pain across many medical fields. Table 35–1 lists the classification of most headaches, neuralgias,

TABLE 35–1. International Headache Society Classification of Headache and Facial Pain

- Migraine type
  - Without aura (common migraine)
  - With aura (classic migraine)
  - With prolonged aura (complicated migraine)
  - Ophthalmoplegic
  - Retinal
- Tension type
  - Episodic (muscle contraction headache)
  - Chronic (chronic daily headache)
  - Oromandibular dysfunction (myofascial pain dysfunction syndrome) (temporomandibular joint pain dysfunction syndrome)
- Cluster (Horton's cephalalgia)
- Post-traumatic headache
- Vascular intracranial disorder
  - Transient ischemic attack–associated headache
  - Intracranial hematoma
  - Subarachnoid hemorrhage
  - Unruptured aneurysm
  - Giant cell arteritis (temporal arteritis)
  - Carotid or vertebral artery pain
    - Dissection
    - Carotidynia
  - Cerebral venous thrombosis
  - Acute arterial hypertension
    - Pheochromocytoma
    - Malignant hypertension (accelerated)
    - Preeclampsia and eclampsia
- Nonvascular intracranial disorder
  - Benign intracranial hypertension (pseudotumor cerebri)
  - Post–lumbar puncture headache
  - Cerebrospinal fluid fistula headache
  - Intracranial infection
    - Meningitis
    - Encephalitis
    - Brain abscess
    - Subdural empyema
  - Intracranial neoplasm
- Headache from substance exposure or withdrawal
  - Acute exposure
    - Nitrate- or nitrite-induced headache (hotdog headache)
    - Monosodium glutamate–induced headache (Chinese restaurant syndrome)
    - Carbon monoxide–induced headache
    - Alcohol-induced headache
  - Chronic exposure
    - Ergotamine-induced headache
    - Analgesics abuse headache
    - Oral contraceptives use
  - Acute withdrawal
    - Alcohol (hangover)

- Chronic withdrawal
  - Analgesics
  - Ergotamine
  - Caffeine
  - Narcotics
- Headache with extracranial infection
  - Viral
  - Bacterial
- Headache from metabolic disorder
  - Hypoxia
    - High-altitude headache
    - Sleep apnea headache
  - Hypoglycemia
- Headache or facial pain associated with craniofacial disorder
  - Cranial disorder
    - Osteomyelitis
    - Multiple myeloma
    - Paget's disease
  - Cervical spine disorder (cervicogenic headache)
  - Eye disorder
    - Acute glaucoma
    - Refractive errors
  - Sinonasal disorder
    - Acute sinus headache
    - Rhinogenic headache
  - Odontomandibular disorder
    - Periodontitis
    - Pulpitis
  - Glossitis (burning mouth syndrome)
  - Temporomandibular joint disease
- Cranial neuralgia
  - Compression of cranial nerve or cervical root 1, 2, or 3
  - Inflammation of cranial nerves
    - Acute herpes zoster
    - Chronic postherpetic neuralgia
    - Tolosa-Hunt syndrome
    - Gradenigo's syndrome
    - Raeder's paratrigeminal neuralgia
  - Trigeminal neuralgia (tic douloureux)
    - Idiopathic
    - Compression of trigeminal ganglion
      - Vascular
      - Tumor
      - Cholesteatoma
      - Aneurysm
      - Multiple sclerosis
  - Glossopharyngeal neuralgia
  - Occipital neuralgia
  - Anesthesia dolorosa
    - Postsurgical after trigeminal rhizotomy
- Unclassifiable facial pain (atypical facial pain)

Formerly used nomenclature is in parenthesis.

and facial pains. Greater detail can be found in the IHS classification publication.

PATIENT EVALUATION

History is the essential tool to establish a diagnosis for headache or facial pain. It must be comprehensive to ensure accuracy of diagnosis. Once the features of the cephalalgia are discovered, one can refer to the IHS classification to determine which specific diagnostic criteria are fulfilled (Table 35–2).[13–15]

Serious or even life-threatening conditions associated with headache usually will present with distinct characteristics of the headache and nervous system or systemic complaints (see Table 35–3 for specific serious conditions in which headache is a presenting symptom[16]). Warning features of the headache include sudden onset and highest severity, steady crescendo of intensity, awakening with headache, and exacerbation by coughing or straining. Dangerous associated systemic symptoms include fever, sudden vomiting, declining mental status, syncope, or seizures. Specific physical ailments such as stiff neck, tender or enlarged temporal artery, unilateral rhinorrhea, skull percussion tenderness, or focal neurologic defects such as visual field loss, diplopia, hemiparesis, and facial nerve palsy should be alarming. Finally, a history of preex-

isting malignancy or immunosuppression may herald a serious condition.[17]

The physical examination is guided by history and clinical suspicions. Routine measures should include a check of blood pressure and temperature; assessment of mental status and cranial nerve function; and a visual examination inclusive of pupil size, extraocular movement, visual fields, and funduscopy. Range of motion testing of the jaw and neck should be performed along with palpation of the TMJ and muscles of mastication and paraspinal musculature searching for trigger points for neuritic or muscular pain. Abnormalities may be observed in the external or middle ear, the sinonasal passages, the mouth, and dentition, or herpetic lesions may be seen in dermatomes. Palpation of the temporal arteries should also be performed. Asymmetric skull percussion tenderness may suggest a subdural process. Laboratory testing, including cerebrospinal fluid (CSF), should be limited and guided by clinical impression. Radiologic imaging with computed tomography (CT), magnetic resonance imaging (MRI), or magnetic resonance angiography (MRA) may be indicated when organic pathology is suspected or to reassure the patient.

SPECIFIC CLINICAL SYNDROMES

The characteristic features of many craniofacial pain diagnoses are presented along with specific treatment recommendations (see Table 35–1 for specific conditions in the classification system).

Migraine-Type Headaches

Migraines comprise the second most common form of headache, with a prevalence of 18% in women and 6% in men and costing billions of dollars for treatment and lost productivity.[18] Its peak age of onset is in the second or third decade, but children and even infants may also be affected.[19] Migraine headaches usually occur as recurrent episodes of severe, throbbing, unilateral head pain of sudden onset lasting 4 to 72 hours. However, 40% of migraineurs have bilateral pain. The headache often strikes after awakening in the morning. In children, migraine headaches usually end between 2 and 48 hours. Routine activities of daily living exacerbate the symptoms. Coexisting symptoms with the headache are common including nausea, vomiting, photophobia, and phonophobia. Stress is the usual precipitating factor. A family history of migraine is often present.

Migraine is divided into several types: those without aura (formerly *common migraine*) and those with aura (formerly *classic migraine*) are the two most common by far. Migraine without aura is the most common type. It lacks any preheadache warning symptoms. Migraine with aura is also common, comprising 20% of migraine sufferers. The typical

aura lasts less than 1 hour and immediately precedes the onset of cephalalgia. It may be precipitated by menses, pregnancy, oral contraceptives, certain foods, or bright lights. *Migraine with prolonged aura* has symptoms of the aura that last through and beyond the headache up to 7 days. Features of aura include focal neurologic symptoms including visual changes such as scotomata or sensory and motor disturbances such as paresthesia, hemiparesis, or asphasia. Brainstem dysfunction may also occur, resulting in ataxia, lethargy, diplopia, tinnitus, vertigo, or dysarthria. *Ophthalmologic and retinal migraine* are rare but result in paresis of ipsi- or contralateral oculomotor nerves or monocular blindness secondary to retinal ischemia, respectively.[20]

Prodromes and postdromes are also common features, occurring in approximately 60% of migraine patients.[13] They experience premonition phenomena hours to days before the onset of head pain. Specific feelings include mood changes, fatigue, anorexia, or autonomic symptoms such as diarrhea or frequent urination. The postdrome essentially consists of general fatigue, irritability, and food cravings or anorexia. The IHS classification requires that the following criteria be met to diagnose migraine: For migraine without aura, at least five attacks lasting 4 to 72 hours, with at least two of the following features present: unilaterally, pulsatile quality, moderate to severe intensity, and exacerbation by physical activity. The headache must be associated with nausea, vomiting, photophobia, or phonophobia. For migraine with aura, at least two attacks with at least three of the following must occur: one or more reversible aural symptoms occurs, the symptom has a gradual onset over more than 4 minutes, the aura resolves in less than 1 hour, and the time between aura and headache is less than 1 hour.[12] Some migraine sufferers will complain of aural symptoms and not experience headache.

Treatment of migraine disorders includes initiation of supportive and educational measures such as a headache diary to decrease the frequency of attacks. Medical therapy falls into two major categories: symptomatic and preventive treatment. The former attempts to abort attacks at their onset or control pain during the headache. Specific measures prove useful including the application of ice, isolation in a dark quiet room, using biofeedback or acupuncture, and inducing sleep, as well as avoiding known triggers (Table 35–4).[13,21]

Symptomatic treatment must be individualized to provide adequate relief with minimal risk and side effects. Stratified care for which a variety of treatment choices are available to the patient has proven successful.[22] Relief should not be limited to headache but also constitutional symptoms such as nausea and vomiting or insomnia. Factors influencing choice of drugs should include the frequency that medications will be required, contraindications, route of administration, prior medication successes and failures, or the need for breakthrough headache therapy.[13] The earlier therapy is initiated, the more likely a good or complete response will occur. Nonspecific migraine therapy includes analgesics and judicious use of opiates for only severe attacks. Specific therapy uses compounds that are known agonists of the 5-HT_1 receptor and include ergot derivatives and synthetic triptan compounds. Often antiemetics or metoclopramide should be given first

TABLE 35–5. Symptomatic Pharmacologic Treatment Options for Migraine[13,21,23–27]

Mild headaches
Acetaminophen, oral or rectal
NSAIDs: naproxen or ibuprofen, oral butalbital and acetaminophen with or without caffeine, oral
Acetaminophen and isometheptene and dichloralphenazone (Midrin), oral
Moderate headache
Indomethacin, oral or rectal
Ergotamine tartrate, oral, sublingual, or rectal
Dihydroergotamine mesylate (Migranol), intranasal spray or subcutaneous
Sumatriptan (Imitrex or Imigran), subcutaneous autoinjector, oral, or intranasal spray
Naratriptan (Amerge), oral
Rizatriptan (Maxalt), oral
Zolmitriptan (Zomig), oral
Lidocaine, intranasal spray
Butorphanol, intranasal spray
Butalbital and acetaminophen and codeine with or without caffeine, oral
Severe headache
Dihydroergotamine mesylate, as for moderate, also intramuscular or intravenous
Ketorolac, intramuscular
Diphenhydramine, intravenous
Prochlorperazine, intravenous
Chlorpromazine, intravenous
Haloperidol, intravenous
Opiates: morphine sulfate, intramuscular or intravenous

NSAID = nonsteroidal anti-inflammatory drug. Adapted from Saper JR,[13] Wilkinson M,[21] Silberstein SD and Young WB,[23] Young WB,[24] Logemann CD and Rankin LM,[25] Maizels M,[26] and Finkel AG et al.[27]

to avoid worsening or triggering nausea. To avoid chronic ergotamine-induced headache, it should not be taken more than 2 days a week.[23] In addition to nausea, angina may be induced by these compounds; thus, their use in patients with risk of coronary artery disease is contraindicated (see Table 35–5 for agents available for abortive therapy[13,21,23–27]).

The recurrence rate for headache in a 24-hour period is reported for some drugs: intranasal dihydroergotamine mesylate has a 14% relapse, whereas triptans relapse between 22 and 45%,[25] and intranasal lidocaine relapses 40% of the time.[26] It is important to realize that severe attacks can be so disabling that occasional referral to the emergency department or admission for pain management is necessary. Finally, in difficult to treat cases, referral to a headache center or neurologist is appropriate. For children, Annequin and associates reviewed the use of various agents and found good effectiveness for both acetaminophen and ibuprofen. Oral dihydroergotamine mesylate and sumatriptan in any form were also effective.[19] Opiates should be avoided. Again, abortive therapy should be initiated early in the attack.

Prophylactic therapy is indicated when the frequency of episodes is greater than two per week.

Dosages should be titrated within recommended levels, and therapeutic trials of any agent should last at least 3 weeks. Specific prophylactic agents are listed in Table 35–6.[7,19,27–29] Preventive medical therapy in children has had some success, although fewer reports exist. Among specific agents used for children, propranolol is most frequently used. Other regimens make use of metoprolol, valproate, flunarizine, cyproheptadine, and pizotifen, a serotonin receptor antagonist.[19]

Tension-Type Headache

Tension-type headaches include a variety of previously described craniofacial pain conditions such as tension headache, stress headache, muscle contraction headache, fibromyalgia, chronic daily headache, myofascial pain syndrome, and TMJ dysfunction syndrome. This category of headaches is by far the most common, afflicting approximately 80% of the adult population, but these headaches usually do not result in a physician evaluation. The IHS delineated both episodic and chronic varieties of tension-type headaches and noted whether there is an associated pericranial muscle disorder, more specifically, muscular tenderness or increased electromyographic activity. It is more likely to occur in women, and usually a family history of headaches is present. The headaches are characteristically bilateral, with a tightening or band-like sensation in the frontotemporal region around the head and spreading to the occipital region or trapezius muscles. The onset is gradual, whereas the quality is dull, nonthrobbing, and constant, sometimes lasting for weeks. These headaches typically do not have associated autonomic symptoms as migraine headaches do, although it is possible when the headaches are severe. The cephalalgia is triggered or exacerbated by stress or anxiety in most patients. Some evidence has discounted the idea that persistent muscle contraction is the cause of the pain. Instead, new theories suggest an abnormality in central pain control.[30] The subdivision of *episodic tension-type headaches*, previously referred to as muscle contraction headaches, requires certain diagnostic criteria, specifically at least 10 prior episodes of headaches less than 15 days a month, lasting 1 half hour to 1 week and having at least two of the following characteristics: a tightening quality, mild-to-moderate intensity, bilaterality, and no exacerbation by routine exertion.[30]

The other category of tension-type headache is chronic and was previously labeled chronic daily headache. Some debate still exists as to whether all chronic daily headaches are tension type. The IHS criteria for *chronic tension-type headaches* are the same as the episodic variety, with the exception that headache frequency is greater than or equal to 15 days per month for at least 6 months. The IHS also recognizes that migraine headaches can transform into a chronic daily headache with features more similar to tension-type headaches. This may represent an evolution of the headache process or often is related to overuse of treating drugs. According to Silberstein and Lipton, chronic daily headache must be divided into both tension type and migrainous type, as well as other entities.[31] They note that the chronic tension type constitutes about 25% of all daily headache patients.

Treatment of tension-type headaches uses nonpharmacologic and medical therapy. First, chronic medication overuse must be eliminated, a step that will improve many cephalalgia sufferers. Depression should be treated if present. Nonmedical remedies include reassurance, muscle relaxation, simple muscle exercises, stress management, biofeedback, and physical therapy with thermal modulation, ultrasonography, or electrical stimulation. Pharmacotherapy varies between episodic and chronic varieties. Most patients who suffer episodic tension-type headache will respond to analgesics, such as aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs). Antidepressants, especially amitriptyline, have also

TABLE 35–6. Prophylactic Medications for Migraine[7,19,27–29]

Antidepressants: amitriptyline, nortriptyline, doxepin, or trazodone
Ergotamine in a sustained-release form (Bellergal)
Beta blockers: metoprolol, atenolol, or propranolol
Nonsteroidal anti-inflammatory drugs (NSAIDs): naproxen, ibuprofen, or aspirin
Calcium channel blockers: verapamil, nifedipine, nimodipine, or flunarizine
Anticonvulsants: divalproex, valproic acid, gabapentin, or topiramate
Others: methysergide, fluoxetine, cyproheptadine, pizotifen, riboflavin, or lithium

proven effective. Agents capable of fostering dependence are best avoided. These include caffeine, opiates, and benzodiazepines.

The use of medications in the management of chronic tension-type headaches is more diverse. Injection of local anesthetics into trigger points may provide sustained relief.[32] Amitriptyline has been used most often, with proven success.[31] Sodium valproate, topiramate, L-5-hydroxytryptophan, and L-arginine have also been used with reported success. Injection of botulinum toxin (Botox) into pericranial muscles has recently been shown to be safe and effective, although the mechanism of relieving pain is poorly understood.[31]

Cluster Headaches

Cluster headaches, previously known as Horton's cephalalgia, are less common than tension-type or migraine-type headaches; however, the severity of the headaches is much greater. They affect men more often than women. They are unilateral, excruciating, and located around the eyes or in the maxilla and usually occur in middle age. The episodes typically last minutes to 3 hours. They tend to occur several times per day for several weeks, and then long headache-free periods occur; hence, they occur in clusters. Ten percent of patients will have chronic episodes. No aura or nausea occurs, but the cephalalgia is associated with unilateral lacrimation, rhinorrhea, and injected conjunctiva. Ptosis and miosis may also occur. The headaches often wake a patient at the same time each night. Typically, the patient "searches for relief" by pacing or rocking back and forth. Alcohol and histamine injections are capable of precipitating attacks, and attacks are more common in the spring or fall.[33] The IHS classification of cluster headaches requires meeting the following diagnostic criteria: at least five episodes of classic cluster headache (characteristics as outlined above) occurring with a frequency of every other day up to eight times per day.[12]

Intracranial lesions, associated with the cavernous sinus or in other locations, as well as viral meningitis and skull base invasion by nasopharyngeal carcinoma, may produce cluster-like headaches that are more apt to be chronic. Therefore, a patient with atypical features of cluster headache should raise suspicions of an organic lesion, especially when periodicity of headaches is lacking or an incomplete response to known efficacious medications is noted.[33] The etiology is unclear, but several mechanisms are suspected. Circadian hormonal fluctuation suggests a hypothalamic dysfunction, whereas excitation of a nerve plexus in the carotid sheath and adventitia may increase trigeminal discharge rates, resulting in facial pain.[34] A subset of patients demonstrate an autosomal dominant transmission in their families.

Variants of cluster headache also occur. *Sluder's "lower half" neuralgia* refers to cluster headaches limited to the maxillary area with autonomic symptoms.[34] It is more common in women in their thirties and forties. *Chronic paroxysmal hemicrania* (*Sjaastad's syndrome*) is a variant with shorter, more frequent attacks, occurs more often in women, and is absolutely responsive to indomethacin.[12] *SUNCT syndrome* (an acronym for short-lasting unilateral neuralgiform headache attacks with conjunctival injection, tearing, sweating, and rhinorrhea) is a cluster-like headache, mostly in men, in which attacks last 10 to 60 seconds. It may be precipitated by touch to the nose or periorbital area, chewing, or ingestion of citrus fruits.[35]

Treatment of cluster headaches has abortive measures and prophylactic therapy. Along with providing reassurance for the patient, episodes can be ended with inhalation of 100% oxygen for 10 minutes. Administration of ergotamine sublingually or rectally works within 1 hour. Dihydroergotamine intramuscularly or intravenously provides relief in 30 minutes or 10 minutes, respectively. Sumatriptan works best when given subcutaneously, taking about 10 minutes to take effect. These four agents all work by inducing a central vasocontriction.[33] Intranasal 4% lidocaine may also be effective. At least three episodes of cephalalgia should be treated with any one agent before declaring it a failure and moving to another agent. Analgesics are too slow to be effective, and corticosteroids have not been proven to be beneficial.

Prophylactic medications are the mainstay of treatment. In general, they should be used during the months when the cluster headaches are occurring and gradually discontinued after at least a 2-week headache-free period.[34] Effective prophylaxis has been achieved with a variety of agents and is most often achieved using calcium channel blockers such as nifedipine or verapamil, low-dose ergotamine in sustained-release form, lithium carbonate, and methysergide for no greater than 4 months to avoid the rare complication of retroperitoneal fibro-

sis. Multidrug therapy may be necessary. Corticosteroids over 3 to 4 weeks may be helpful. Newer approaches have studied valproate, intranasal capsaicin, pizotifen, and phototherapy with bright light, with all finding significant success. Histamine desensitization may offer relief to patients with chronic cluster headaches refractory to treatment.[33] Invasive approaches for refractory cases include trigeminal nerve blockade and blockade of the sphenopalatine ganglion. The most effective procedure for typical cluster headache is radiofrequency ablation of the trigeminal ganglion.[34] When sphenopalatine ganglion (Sluder's) neuralgia is the diagnosis, removal of a precipitating septal spur or coagulation of the ganglion may be beneficial.

Post-traumatic Headache

Head trauma has been associated with the onset of acute or chronic headaches. These may be associated with postconcussive vertigo, decreased concentration, memory loss, and depression as part of the post-traumatic syndrome.[36] The pain is frontal, occipital, and constant, yet percussion of the skull is not painful, as is sometimes seen in subdural hematomas.[27] The IHS classification requires the onset of headache in less than 14 days after injury or regaining consciousness. The acute subclass lasts less than 8 weeks and the chronic greater than 8 weeks. Treatment is composed of reassurance, physical therapy and simple exercises, short courses of NSAIDs or over-the-counter analgesics, tricyclic antidepressants to modulate pain, injection of local anesthetic into trigger zones, carbamazepine for neuropathic pain, and avoiding recurrent head trauma.[36]

Headache Associated with Vascular Disorders

The IHS classifies eight vascular disorders that are associated with headache. The diagnosis hinges on historical, physical, and radiographic data, as well as evaluation of the CSF when indicated. Also, the headache must occur in close temporal relation to the onset of the underlying disorder. Two of the eight disorders, acute ischemic cerebrovascular disease or venous thrombosis, will not be reviewed here.

Intracranial Hematoma *Intracranial hematomas* (intracerebral, subdural, or epidural) often have headache as a presenting symptom. It is moderate to severe and on the side of the hematoma. Ipsilateral skull tenderness to percussion is common. Hemotympanum or mastoid bruising may occur. Associated symptoms include altered level of consciousness and sometimes nausea and vomiting, as well as focal central nervous system changes. There is usually an antecedent history of head trauma, although the trauma may be temporally remote. Anticoagulated patients may relay only minor head bumps. Diagnosis is confirmed by CT of the head. Treatment typically involves a craniotomy for drainage, but spontaneous resolution may occur over time. Once the hematoma is resolved, the headache ceases to occur.

Subarachnoid Hemorrhage *Subarachnoid hemorrhage* accounts for 1 to 4% of all headaches evaluated in the emergency department.[16] It typically presents as the worst headache of the patient's life. Besides the severe intensity, the cephalalgia is sudden and may gradually worsen; it is bilateral and associated with neck stiffness, fever, transient loss of consciousness, diplopia, or seizures. A prodromal or warning headache that is severe occurs in as many as 50% of patients several days or weeks before the major hemorrhage. Physical examination may reveal a changed mental status, restlessness, nuchal rigidity, retinal hemorrhages, papilledema, and focal or general neurologic signs such as cranial nerve III or VI palsy, aphasia, hemiparesis, or ataxia. If aneurysmal bleeding is the source, onset is in minutes; with arteriovenous malformation leaking, the onset is often more insidious, occurring in less than 12 hours. Rupture of a moyamoya lesion may also produce subarachnoid hemorrhage. The neurologic sequelae include devastating brain injury or death, but sometimes only minimal change occurs.

Diagnosis may be difficult as blood seen on CT may be mistakenly attributed to trauma if a fall occurred during any loss of consciousness rather than being suspected to be from a ruptured aneurysm. Hypertension may occur with the hemorrhage and can be confused with hypertensive crisis. Even electrocardiogram findings are common after subarachnoid hemorrhage and may incorrectly suggest cardiac disorders.[16] The evaluation should, however, begin with a noncontrast head CT with 3 mm cuts to find collections of blood. A lumbar puncture and evaluation of CSF should be per-

formed next if the CT was negative for blood or mass effect. Abnormal findings include elevated CSF pressure and red blood cells in the CSF. As traumatic taps may lead to the presence of red blood cells, their presence should be correlated with the CSF pressure. Xanthochromia is a much more specific finding for subarachnoid hemorrhage. If any test indicates that a subarachnoid hemorrhage has occurred, angiography and neurosurgical consultation are warranted urgently for treatment of the aneurysm or arteriovenous malformation. Radiographically detected unruptured aneurysms and vascular malformations should also receive neurosurgical evaluation to prevent catastrophic hemorrhage.[37]

Giant Cell Arteritis *Giant cell arteritis*, often called temporal arteritis, is associated with polymyalgia rheumatica. Essentially, they are different manifestations of the same condition. The cause is unknown, but speculation relates immune responses, infectious triggers, and genetic susceptibility.[38] The condition mostly affects women over 50 years of age. It presents as a new-onset, daily, intermittent or continuous, temporal localized headache that is moderate to severe, burning sharp or throbbing, unilateral or bilateral and lasts months to years.[17]

Patients with giant cell arteritis complain of aching of the jaw during chewing, weight loss, generalized fatigue, and low-grade fever and often have extremity pain attributable to coexistent polymyalgia rheumatica. Visual symptoms include blurring, scotomata, and even sudden blindness. Physical findings consist of palpably thickened or tender scalp arteries that may have a diminished or absent pulse. Palpation of muscle does not reveal trigger points, and muscle strength is typically normal. An erythrocyte sedimentation rate (ESR) is almost always elevated over 50 mm per hour in patients with giant cell arteritis. If the diagnosis is suspected, a temporal artery biopsy is essential to confirm the diagnosis. Inflammation in the artery is often segmental; therefore, a 5 cm long segment of artery should be excised; even then, false negatives may occur.[38] Histologic examination of involved vessels reveals necrosis in the vessel's media with infiltration of macrophages and giant cell formation. Color duplex ultrasonography is being investigated as a diagnostic tool to potentially replace biopsy. Treatment should begin immediately to avoid sudden blindness, a complication found in up to 30% of untreated patients. This is secondary to involvement of the ophthalmic artery. Prednisone is the drug of choice and should be administered in high daily doses of 60 mg. Pain reduces dramatically within days. Once headache has gone into remission and the ESR corrects, prednisone can be tapered over a period of weeks to a daily maintenance dose of 5 to 10 mg while continuing to check for a rise in the ESR.[38] Often treatment must be continued for several years to avoid the complication of blindness.[15] Sometimes the segmental excision of the temporal artery relieves the patient of localized tenderness. However, this does not preclude the need for treatment with corticosteroids.

Carotid Artery Pain *Carotid artery pain* may occur secondary to *dissection or idiopathic carotidynia* or after endarterectomy. Carotid artery dissection is characterized by head and neck pain on the side of the condition following trivial trauma in a young or middle-aged patient. It may cause referred otalgia,[39] Horner's syndrome, lower cranial nerve palsies, and pulsatile tinnitus. Hours later, signs of cerebral or retinal ischemia develop.[40] Dissection can be demonstrated by ultrasonography, MRI with MRA, intra-arterial angiography, or surgical findings. For treatment, early anticoagulation is essential to avoid the 15% risk of mortality. This is followed by warfarin for 6 months. If ischemic signs persist after acute heparinization, surgical intervention may be warranted.[40] Carotidynia is a self-limited inflammation of the carotid fascia or adventitia. It may be induced by viral infection. Physical findings include carotid tenderness, swelling, or intense pulsations. Structural evaluation of the artery is normal. Treatment with NSAIDs may alleviate the pain until spontaneous resolution occurs.

Arterial Hypertension *Arterial hypertension* can be acute or chronic. Chronic hypertension is not typically associated with headache. On the other hand, acute hypertension certainly may cause cephalalgia. The acute rise in blood pressure can be secondary to administration of pressors, vasoactive glomus tumors including pheochromocytoma, malignant hypertension (including hypertensive encephalopathy), or preeclampsia and eclampsia. Typically, headache begins with diastolic pressures greater than 115 mm Hg. It is throbbing, associated with nausea, and does not respond to analgesics.[27]

Treatment involves controlling and correcting the source of the hypertension. Once this is achieved, the headache resolves within 7 days.[12]

Headache Associated with Nonvascular Intracranial Disorders

The IHS classifies six intracranial conditions as nonvascular causes of headache. The symptoms, signs, and diagnostic investigations of four of these are presented below.

High CSF pressure associated headache may be caused by benign intracranial hypertension, formerly known as pseudotumor cerebri or otitic hydrocephalus, and high-pressure hydrocephalus that sometimes follows head trauma. *Benign intracranial hypertension* is defined by the findings of papilledema: an otherwise normal neurologic examination (with a rare exception being abducens palsy); no intracranial mass, venous sinus thrombosis, or ventricular enlargement on head CT or MRI; a normal protein, white cell count, and culture in the CSF; and, most importantly, an increased intracranial pressure of greater than 200 mm of water on lumbar puncture or intraventricular pressure monitor.[12] The associated headache is intermittent, retro-orbital, with gradual worsening, and is exacerbated by coughing or Valsalva's maneuver. Associated symptoms include unilateral or bilateral pulsatile tinnitus,[41] visual dimming occurring for a minute or two at a time, eventual constriction of visual fields, and possible blindness. It may be triggered by otitis media or mastoiditis, irregular menses, recent rapid weight gain, corticosteroid withdrawal, or ingestion of vitamin A, tetracycline, or nalidixic acid. Treatment consists of weight reduction, a low-sodium diet, and diuretics, specifically acetazolamide or furosemide. Lumbar puncture can be used and repeated to reduce CSF pressure acutely to relieve headache. Cerebrospinal fluid diversion by a ventriculoperitoneal shunt may be necessary for refractory cases or when visual fields fail to improve.[27] Transnasal, transethmoidal optic nerve decompression with release of the optic nerve sheath and annulus of Zinn may also be necessary to correct chronic visual field disturbances. *High-pressure hydrocephalus* differs from benign intracranial hypertension by the identification of enlarged ventricles on head CT or MRI.

Low CSF pressure also commonly precipitates a headache. This may be in response to a lumbar puncture or CSF fistula. The headache appears or worsens when the head is upright and resolves after lying down. The pain is constant when the head is upright and is located in the occipital region or vertex. Nausea is common, and vomiting relieves the headache during the regurgitation. Oculomotor or abducens palsies have been reported. Resolution is rapid (usually within several days) following lumbar puncture unless a persistent fistula occurs at the tap site. If this is suspected, a blood patch of the epidural space at the site of puncture is curative. This condition may occur without lumbar puncture and should raise suspicions of post-traumatic, iatrogenic, or spontaneous CSF fistula. If this occurs, site identification by intrathecal metrizamide CT or myelography should be performed and a surgical repair initiated.

Intracranial infection includes meningitis, encephalitis, brain abscess, or subdural empyema, which may present with a generalized, bilateral, severe, constant headache often with nuchal rigidity, positive Kernig's and Brudzinski's signs, and fever. The onset is rapid, usually over several hours.[17] Ambiguous presentations may occur in immunosuppressed patients, atypical infections such as tuberculosis, fungal meningitis, neurosyphilis, or epidural abscess. If a head CT has ruled out an intracranial mass, culture and antigenic studies of CSF from lumbar puncture are diagnostic.[27] Treatment requires appropriate intravenous antibiotic therapy and surgical drainage of abscesses.

Primary or metastatic *intracranial neoplasms* present with discrete or generalized, intermittent or continuous, mild to moderate, unilateral, dull headache that worsens over time in 30% of patients. Early morning headache is a warning symptom, as is exacerbation by Valsalva's maneuver or cough. Sudden vomiting, cranial nerve dysfunction, and seizures may occur.[17,27] Control of pain may be initially achieved with non-narcotic analgesics, but, eventually, narcotics or neuralgia medications become necessary. Removal of the neoplasm, when feasible, is usually curative of the headache.

Headache Associated with Substances or Their Withdrawal

Headaches are often caused by ingestion or withdrawal of specific substances. The onset of a headache during carbon monoxide poisoning and

the hangover after drinking alcohol serve as prime examples. Several particular conditions warrant greater description. Headache induced by chronic intake or withdrawal after chronic use of some medicines is a common phenomenon. Patients typically have a history of a different type of headache, usually migraine, in the past that did not occur daily. Escalating regular use of acute headache remedies to greater than 2 days per week may "transform" migraine into a chronic daily headache.[42] The cephalalgia occurs daily (often early in the morning) and is generalized, bilateral, dull, and of moderate severity. It may be associated with nausea and be brought on with mild exertion. Tolerance to the offending analgesic seems to allow less and less relief to the patient, resulting in the use of increased dosages. Finally, headache-free intervals cease to exist. Both ergotamine and dihydroergotamine have been implicated, as have non-narcotic and narcotic analgesics. Common examples include aspirin, acetaminophen, NSAIDs, barbiturates, codeine, hydrocodone, oxycodone, and propoxyphene. The IHS noted that use of ergot derivatives for 3 months puts the patient at risk, as does taking more than 50 g of aspirin or more than 100 tablets of an analgesic per month. Resolution within a month after discontinuing the substance is typical.

Treatment requires understanding on the part of the patient along with complete elimination of the problem medication for at least 2 months. No substitution to another analgesic should occur. Avoidance of tyramine and caffeine in the diet is recommended, whereas use of antidepressants is recommended and helpful. Nonpharmacologic modalities should be employed, more specifically, biofeedback, transcutaneous electrical nerve stimulation (TENS), and physical therapy. Inpatient withdrawal may be necessary. Prophylactic therapy for the primary headache should also be instituted to decrease the need for ongoing abortive medications.

Headache from withdrawal of a chronically used substance may also occur. It typically follows a period of abstinence from the agent of less than 12 to 48 hours and is relieved by ingestion of the substance. Persistent elimination of the substance allows resolution of the headache within 14 days. Frequent examples consist of caffeine, ergot derivatives, and narcotics.[12] The headache is diffuse, dull, and mild to moderate in severity. It may be associated with nervousness, restlessness, nausea and vomiting, insomnia, and tremor. Persistent abstinence is the mainstay of treatment but may require hospitalization to prevent the patient from consuming more of the offending medication.

Headaches Associated with a Metabolic Disorder

Hypoxia, as seen in high-altitude headache, is a known source of cephalalgia. Descent and oxygen therapy are the treatment. A more common cause of chronic hypoxia is found in sleep apnea syndrome, in which morning headache is common. It is diffuse, dull, and mild and may be associated with short-term memory loss and inability to concentrate. The diagnosis is suggested by more significant symptoms of the syndrome, specifically fatigue, daytime somnolence, and apneas witnessed by a bed partner. Resolution of the headache occurs quickly following correction of the hypoxia by continuous positive airway pressure or surgical intervention.

Headache or Facial Pain Associated with Craniofacial or Cervical Disorders

When pathology afflicts any extracranial organ of the head or the skull itself, pain may ensue. Facial or head pain is localized to the affected structure but may radiate or be referred. If the pathology is corrected, headache resolves in less than 1 month. Examples affecting the cranial bones include osteomyelitis, multiple myeloma, and Paget's disease.

Cervicogenic headache is a relatively common condition created by a disorder afflicting the cervical spine, often following neck trauma. Women are more frequently affected than men. It is characterized by fluctuating or constant headache that is unilateral, unchanging, dull, and nonpulsatile. It tends to start at the occiput and radiate to the frontal region, where the pain is most intense. If it is bilateral, one side is usually of worse intensity. Pain may also radiate into the shoulder or arm. Attacks are precipitated by awkward positions or neck movement or palpation of trigger points such as the greater occipital nerve or over the C2 vertebral body.[43] Associated symptoms of nausea and photophobia or phonophobia are present in 50% of patients. Neck examination reveals a reduced range of motion of the spine and possibly muscle tenderness, spasm, hypertrophy, or atrophy. Criteria for its

diagnosis have been proposed by Sjaastad and Fredriksen.[44] These criteria essentially define all of the features of the syndrome as represented above.

Cervical radiographic data reveal either abnormalities on flexion and extension films, abnormal posture, or evidence of bone or joint pathology. Ipsilateral injection of local anesthetics for blockade of the greater occipital nerve or the C2 root will relieve pain not only in the innervation zones but also in the frontotemporal region.[44] Treatment centers around physical therapy and stretching exercises, use of NSAIDs, and chronic nerve blockade for refractory cases.

Sinonasal disorders are a frequent source of headaches but are probably overcredited by the population as a whole. However, frontal headache and facial pain are two of the three major symptoms suggesting the presence of sinusitis, the other being purulent nasal drainage. Acute sinusitis is a leading cause of facial pain, second only to dental disorders. The IHS classified headache from sinus origin as when it is associated with purulent drainage and they begin together; when plain radiography, CT, MRI, or transillumination reveal opacification or air-fluid levels in one or more sinuses; and when the sinusitis is treated, the headache resolves.[12] The cephalalgia is pressure-like or dull, of moderate intensity, unilateral or bilateral, periorbital, worsened by bending or with Valsalsa's maneuver, worse in the morning, and associated with purulent nasal drainage, nasal obstruction, altered sense of smell, exacerbating asthma, cough, malaise, and dizziness. Nausea and visual change are infrequent associated symptoms.[8,39,45]

Pain with the inflammatory process lasts days or weeks with fluctuating severity. The location and extent of the sinusitis do not correlate well with the severity or site of pain.[45] However, a few tendencies are common. The area overlying an infected sinus is often tender. Pain for sinusitis referred to upper maxillary teeth is typically originating in the maxillary sinus. Occipital or vertex pain from sinusitis is most likely to represent sphenoid sinus disease. Any infected sinus can refer pain to the frontal, retroorbital, and temporal regions. Physical examination finds tenderness to percussion over involved sinuses. Transillumination is infrequently useful to delineate the presence of sinusitis. Other physical findings center around inflammatory changes in the nose. Radiographic imaging is helpful to confirm an uncertain diagnosis of sinusitis or to evaluate response to treatment. As plain films have poor sensitivity, a screening coronal sinus CT has become the imaging study of choice. Treatment requires medical therapy to reverse the inflammatory cause of the headache and includes antibiotics, decongestants, and possibly corticosteroids, with analgesics used in the interim for symptomatic relief until the sinusitis is reversed.

Rhinologic headaches other than those caused by sinusitis also occur, albeit much more rarely. Nasal anatomic abnormalities occasionally associated with facial pain include impacted septal deviations or spurs, hypertrophic turbinates, and even an occasional large maxillary retention cyst.[3] However, most sinonasal neoplasms do not cause pain. The cause of rhinogenic pain may be related to direct sensory stimulation from two mucosal surfaces contacting each other. The pain is usually dull and aching and unilateral. An anatomic abnormality can be seen on examination after decongesting the nose. Topical lidocaine can be used as a diagnostic test as the pain should diminish or disappear after application if the cause is mucosal contact. Medication may effectively control turbinate hypertrophy, but surgical approaches are effective in managing the anatomic defects.[39]

Elongated styloid process, better known as *Eagle's syndrome*, consists of recurrent throat and neck pain exacerbated by swallowing. Otalgia, dysphagia, and foreign-body sensation are often present and are secondary to an elongated styloid process impinging on the carotid plexus or branches of cranial nerve IX. It may develop subsequent to tonsillectomy because of inflammatory changes. Palpation of the styloid process in the tonsil fossa exacerbates the dull pain, whereas injection of a local anesthetic in a diagnostic maneuver provides relief. A lateral plain film of the head reveals a styloid process greater than 2.5 cm long.[46] Reassurance and medical therapy with NSAIDs or corticosteroid injection around the stylohyoid ligament may be successful. Otherwise, treatment involves surgical shortening of the calcified stylohyoid ligament (elongated styloid process) through the tonsillar fossa.[39]

A burning sensation in the oral mucosa is an uncommon but not rare complaint. The condition is known as *glossodynia, burning mouth syndrome*, or oral dysesthesia. It most often occurs in women and is chronic, with a prevalence of about 5%.[47] Local,

systemic, and psychogenic factors play a role in causation. Local factors include mucosal lesions, oral candidiasis, local chemical irritation, and xerostomia. Systemic factors consist of iron, zinc, or vitamin B_{12} deficiency and the use of female replacement hormones, sedatives, antihypertensives, or antidepressants. Anxiety and depression are associated with glossodynia. Physical examination is usually normal without a mucosal lesion. Treatment includes reassurance; discontinuing smoking and alcohol-containing mouthwashes; drinking cooler coffee; therapeutic trials of nystatin oral rinse or dexamethasone solution to rinse and expectorate; iron, zinc, or vitamin B_{12} replacement therapy; oral lubrication or use of salivary stimulants; and using antidepressants.

Temporomandibular joint disorders are frequent causes of facial pain and headache. These disorders are divided into two major groups: those with demonstrable organic disease (uncommon) and those of myofascial origin from masticatory muscles (very common). The IHS established the following diagnostic criteria for TMJ disease, at least two of which must be met: pain with jaw motion, noise with jaw movement, decreased range of motion, and a tender joint. These are associated with abnormal TMJ radiographs and pain that is mild to moderate and centered over the TMJ.[12] Women are far more likely to suffer from TMJ pain. The pain is located preauricularly and in the temporal region of the head; is intermittent, lasting hours to days; is mild to moderate in intensity; can be unilateral or bilateral; and is exacerbated by jaw movement. Associated features include otalgia, bruxism, trismus, TMJ crepitus, and jaw locking. Usually, no muscular trigger point exists, and there are no nausea or visual changes. Etiology of the discomfort includes diseased joints that can occur on the basis of arthritis (the most common cause), traumatic causes such as fractures or dislocations, internal derangements of the intra-articular disk, or developmental defects.

Physical findings include audible joint clicking on one side or both and decreased range of motion. Normal vertical opening between central incisors ranges from 42 to 55 mm.[17] Palpation should cover the head and neck musculature and TMJs including intraoral pterygoid palpation, noting any asymmetry, tenderness, spasm, hypertrophy, atrophy, triggering of referred pain, or crepitus when opening or closing. If pathology is suspected, a TMJ radiographic series may reveal a joint abnormality. The usual indications for imaging include suspected fractures, degenerative joint disease, ankylosis, or tumors.

Management of TMJ disease includes reassurance, education, NSAIDs, restriction of jaw opening, a soft diet, and physical therapy. Occasionally, biofeedback or corticosteroid injection may be helpful. If pain is chronic, tricyclic antidepressants may be beneficial. Because of the potential for dependency in chronic conditions, narcotics are best avoided. Acute disk or condylar displacements may require manual reduction to relieve pain and restore range of motion or relieve a joint locked open or closed. Often sedation or general anesthesia is necessary to relax the muscles to facilitate the manual reduction. The use of a bite appliance may alleviate chronic headache or muscle pain secondary to bruxism or joint pain secondary to anterior disk displacement.[48] Arthrocentesis, sclerotic therapy, and arthroscopic surgery are reserved for chronic dislocations, disk derangements, or condylar anomalies.

Oromandibular dysfunction involves pain in the TMJ without organic disease. Other terms describing this condition include myofascial pain dysfunction syndrome and TMJ pain dysfunction syndrome. The etiology of pain seems to have its origin in myofascial tissues or central processes disinhibiting sensory pain pathways. The IHS system classified this as a tension-type headache that does not purely meet the criteria of episodic or chronic tension-type headaches. A diagnosis requires at least three of the following: the creation of noise with jaw movement, limited range of motion, pain during jaw use, locking of the jaw, or a history of clenching or grinding of the teeth.[12] The pain is typically a continuous, dull, aching, poorly localized, usually unilateral discomfort of mild-to-moderate degree involving the ear, angle of the jaw, and temple. The pain rarely wakes the patient, and the location of pain may shift. The patterns of referred pain often do not make neurologic sense. It may be associated with swelling, numbness, stiffness, or erythema. The hallmarks of this myalgia are the presence of trigger points that, when palpated, reproduce the referred pain.[49] Examination will reproduce the pain when masticatory and neck muscles are palpated. Full range of jaw motion may be lost with this disorder. A trigger point injection of an anesthetic (like 1% procaine) can confirm that point's significance by relieving the pain.[49]

Therapy consists of reassurance, modification to a soft diet, physical therapy, trigger point local

anesthetic injection, and medications. Amitriptyline for at least 2 months is an effective choice, whereas NSAIDs may or may not be. Occlusal splints relieving bruxism may help, as might attention to abnormal occlusal factors that can precipitate the disorder.[32] Because of the self-limited nature of the condition, invasive approaches should be avoided.

Cranial Neuralgias

Cranial neuralgias are conditions affecting nerves with sensory functions in the head and neck, resulting in severe stabbing or throbbing pain in the distribution of the involved nerve. They can involve any cranial nerve with sensory fibers or cervical roots one, two, or three. The conditions are subdivided into persistent painful disorders and paroxysms of pain (tic-like) disorders.

Traumatic injury to a nerve or inflammatory changes can result in chronic neuralgia. Trauma or surgery to the cranium or face may result in entrapment neuritis or formation of a neuroma, typically 2 to 6 months later. The occurrence is greatest in the third branch of the trigeminal nerve because of the frequency of injury related to mandible fracture or tooth extraction. Symptoms include hypersensitivity and pain to light touch, pain in an area of skin that has lost its sensory innervation, and aggravation by cold or emotional duress. The pain is sharp and lancinating. A central cause of a neuritic pain can occur as *anesthesia dolorosa* following surgical ablation of the trigeminal ganglion. The condition is characterized by sharp pain and numbness in the distribution of any or all branches of the trigeminal nerve after trigeminal rhizotomy or trauma. Treatment uses anticonvulsant medications, in particular, carbamazepine, or sometimes baclofen or clonazepam. Amitriptyline has also been employed with success.[36] Injection of local anesthetics into trigger points or surgical resection or repair of neuromas is necessary for refractory cases.

Inflammatory conditions are also well known to cause neuralgia. A prime example is *acute herpes zoster* of a branch of the trigeminal nerve, the seventh cranial nerve, or cervical roots. The ophthalmic branch of cranial nerve V is the most commonly involved nerve. An intense burning or stabbing pain is in the distribution of the involved nerve and is followed within 1 week by a herpetic eruption in the skin distribution of the same nerve. Motor divisions of involved nerves may be paretic. The pain subsides within 6 months of the onset, but the motor palsies have a poor prognosis for complete recovery. Treatment of the acute phase consists of a 10-day course of prednisone and acyclovir. Nonsteroidal anti-inflammatory drugs or opiates may be necessary to control pain. Acute herpes zoster is common in lymphoma patients, so a new outbreak should raise suspicions about that possible comorbidity.

Chronic postherpetic neuralgia exists when herpes zoster pain persists for more than 6 months. It remains in the distribution of the originally afflicted nerve. It is more likely to occur in patients who are over 60 years old when the acute infection starts, and in this group, it is less likely to spontaneously resolve.[12] Nonsteroidal anti-inflammatory drugs and opiates fail to relieve the neuralgia. Instead, anticonvulsants are more effective and may be paired with tricyclic antidepressants or baclofen to enhance their efficacy.

Other inflammatory neuralgia syndromes include the following: (1) *Tolosa-Hunt syndrome*: episodic unilateral orbital pain with palsies in one or more of cranial nerves III, IV, and VI. Episodes last about 8 weeks untreated but generally resolve within 3 days after starting corticosteroids. It has been related to granulation tissue at the cavernous sinus or superior orbital fissure or in the orbit.[12] (2) *Gradenigo's syndrome*: progressive, intense, unilateral, retro-orbital pain with abducens palsy and otorrhea secondary to petrous apicitis of the temporal bone. (3) *Raeder's paratrigeminal neuralgia*: retro-orbital pain with intact trigeminal sensation and an incomplete Horner's syndrome, resulting in an ipsilateral dilated pupil. The paratrigeminal space housing the gasserian ganglion of cranial nerve V, cranial nerves III and IV, and the carotid artery may be encroached on by abnormal vascular structures and produce the syndrome.[9]

Trigeminal neuralgia (TGN), previously called tic douloureux, is the most common cranial neuralgia and most often affects adults over 50 years old and women more than men. Typically, recurrent episodes of unilateral, excruciating, stabbing pain occur most often in the distribution of the maxillary and mandibular branches of the trigeminal nerve. During an episode, ipsilateral twitching may occur—hence the name "painful tic." They occur without warning, while patients are awake, and recur several to many times a day, with each episode lasting seconds to minutes. Numbness does not occur.

Light touching of the face may precipitate an attack, as can movement of the trigger zone by talking, chewing, or shaving. Physical findings include an intact neurologic examination and the presence of a trigger zone most often located in the nasolabial fold, lips, or gums. Diagnostic evaluation should include an MRI of the head and a lumbar puncture if the MRI is normal. The former is to rule out central causes including vascular anomalies or aneurysm, tumor, cholesteatoma, or multiple sclerosis (MS). Patients with MS are predisposed to TGN, and 2% of patients with TGN have multiple sclerosis.[17] The latter is to rule out MS, neurosyphilis, and cryptococcal or tuberculous meningitis. Treatment of idiopathic TGN includes patient education and reassurance with pharmacologic control. Carbamazepine will provide symptomatic relief acutely in the majority of patients.[17] Other agents shown to be effective include gabapentin, phenytoin, baclofen, sodium valproate, and chlorphenesin. Any drug should be employed for at least 2 weeks, and medications may be used in combination. Tricyclic antidepressants and NSAIDs may also be beneficial. Surgical radiofrequency ablation, specifically trigeminal rhizotomy, is recommended for patients refractory to medical therapy, whereas temporary blockade may be indicated for patients experiencing intense activation of the disease. See Chapter 20 for vascular compression syndromes and their management.

Glossopharyngeal neuralgia is a disorder similar to TGN but affecting cranial nerve IX instead. Men in their forties or fifties are more likely to have this disorder. The pain characteristics include repetitive, brief attacks of lancinating pain located in the soft palate, base of the tongue, pharynx, and ear. The trigger point is located in the tonsil fossa and can be provoked by swallowing or yawning. Associated symptoms may include hiccoughing, nausea, vertigo, tinnitus, aural fullness, hearing loss, dysgeusia, bradycardia, and syncope. Evaluation and management are identical to those for TGN.[39]

Superior laryngeal neuralgia is characterized by unilateral lancinating attacks of pain at the side of the larynx over the thyrohyoid membrane. Pain radiates to the ear and submandibular region and is precipitated by swallowing, straining the voice, playing a musical instrument, or turning the head. The pain paroxysms last minutes to hours for days or weeks at a time. Dysphonia may be present secondary to involvement of the external branch of the superior laryngeal nerve affecting the cricothyroid muscle. Injection of local anesthetic as a nerve blockade confirms the diagnosis when pain is relieved.[39] The condition is managed with anticonvulsants as in TGN or with surgical sectioning of the superior laryngeal nerve.

Occipital neuralgia is a paroxysmal stabbing aching pain over the occiput in the distribution of the greater or lesser occipital nerve combined with reduced sensation in the same area. Associated symptoms include visual disturbances, dizziness, nausea, tinnitus, and scalp paresthesias. The physical findings include a positive Tinel's sign or palpable tenderness of the involved occipital nerve.[50] Confirmation of the diagnosis is made by obtaining relief from pain after an injection of local anesthetic is performed to block the nerve. Management consists of heat, physical therapy, rest, TENS units, NSAIDs, baclofen, or carbamazepine. Cervical collars are of questionable benefit. Invasive measures for refractory cases include local blockade with bupivacaine in combination with an injectable corticosteroid, alcohol blockade, or even nerve section.[50]

Unclassifiable Facial Pain (Atypical Facial Pain)

Atypical facial pain fails to fit the profile of any specific craniofacial condition. The prosopalgia (facial pain) is unilateral or bilateral, is located in the face and upper neck, and is a constant ache or burning with excruciating exacerbations. It does not localize to anatomic regions or have relation to specific structures as TMJ arthralgia or myofascial pain does. It lasts for years, is exacerbated by stress, and is associated with paresthesias of the face or mouth.[17] Comorbidities include chronic fatigue, depression, personality disorders, irritable bowel syndrome, and other idiopathic pain disorders. The cause is unknown, but theories propose central causes for which neuroregulation of pain input is disinhibited, systemic causes for which tyramine metabolism is deficient,[51] and psychogenic causes for which personality disorders are linked to the development of chronic pain conditions.

Treatment involves a multidisciplinary approach. Each patient should be reassured, receive only essential dentistry, and sparingly use analgesics. Tricyclic antidepressants are the mainstay of therapy; they should be taken at night and titrated up to a desired response. Other options include serotonin

reuptake inhibitors, monoamine oxidase inhibitors, benzodiazepines, and phenothiazine. Once a good response has occurred, therapy should be maintained until the patient has been pain free for several months before it is discontinued.[51] Psychiatric evaluation may be beneficial. Refractory cases might respond to one of the several neurosurgical procedures.

CHAPTER 36

Neoplasms of the Nose and Paranasal Sinuses

Ara A. Chalian, MD, David Litman, MD

The poor prognosis for patients with nasal and paranasal sinus malignancy has led many investigators to focus their attention on it. Unfortunately, no true consensus has been reached regarding many aspects of treatment for these disease entities. This stems from the wide variety of tumors found in the area, the relatively short clinical course of patients afflicted with these neoplasms, and the rarity with which the tumors occur. However, with recent developments in fiber optics, radiographic imaging, and a growing consensus on staging and nomenclature, a vast amount of clinical information is now becoming available.

PATHOLOGY

Despite the rarity of nasal and paranasal sinus neoplasms, many histologically diverse types are described in the literature (Table 36–1). The following discussion focuses on the most common pathology seen in this area.

Whereas most sinus neoplasms are malignant, in the nasal cavity, there is a fairly even distribution between benign and malignant disease.[1] The majority of these benign lesions are papillomas that may be subdivided into three categories: fungiform (50%), inverted (45%), and cylindrical cell (5%).[2]

TABLE 36–1. Neoplasms of the Nose and Paranasal Sinuses

Benign	*Malignant*
Epithelial tumors	Epithelial tumors
Papillomas	Squamous cell carcinomas
Adenomas	Adenocarcinomas
	Adenoid cystic carcinomas
Nonepithelial tumors	Mucoepidermoid carcinomas
Osteomas	Melanomas
Fibromas	Esthesioneuroblastomas
Chondromas	Teratomas
Hemangiomas	Teratocarcinomas
Nerve sheath tumors	
	Nonepithelial tumors
	Rhabdomyosarcomas
	Neurogenic sarcomas
	Leiomyosarcomas
	Fibrosarcomas
	Angiosarcomas
	Hemangiopericytomas
	Osteogenic sarcomas
	Chondrosarcomas
	Lymphomas
	Extramedullary plasmacytomas
	Giant cell tumors

Fungiform papillomas present as exophytic septal lesions. Histologically, they have a nonkeratinizing squamous epithelium covering a fibrovascular stroma. In contrast to the other varieties of papilloma, they are not associated with malignant degeneration.[2]

Inverted papillomas (IPs) are characterized by a squamous or transitional cell epithelium surrounding a fibrovascular stroma with endophytic growth. They are most often found on the lateral nasal wall and have been reported to be associated with squamous cell carcinoma in 5 to 15% of patients.[3]

Cylindrical cell papillomas, also known as oncocytic schneiderian papillomas, share with IPs both their localization to the lateral nasal wall and their association with malignant disease. Pathologically, the epithelial lining contains multiple layers of eosinophilic cells, goblet cells, and microcysts full of mucin.[2]

Additional benign tumors of epithelial origin include adenomas, cholesteatomas, and dermoids. Adenomas of the sinonasal tract are histologically identical to those arising in other areas of the body. They occur most commonly in the fourth to seventh decade and usually involve the nasal septum. Excision is curative in over 90% of all cases. Similarly, cholesteatomas and dermoids pathologically resemble those seen in other areas of the body and are relatively rare in the sinonasal region. Cholesteatomas are composed of desquamated epithelium, whereas dermoid tumors contain specialized dermal appendages.[4] When they do occur in the sinuses, they are typically in the frontal or ethmoid sinuses.[4]

Fibrous dysplasia has been described as occasionally arising within the maxilla. It occurs in both polyostotic and monostotic forms, with monostotic being more common. Growth is slow, and treatment consists of local excision for lesions that are physically obstructive or cosmetically deforming.[4] The surgery typically is conservative and involves a sculpting excision of the lesion to restore the tumor site to its natural contour.

Malignant epithelial neoplasms constitute the majority of sinonasal tumors, representing 45 to 80% of all sinus neoplasia.[5,6] Of these, squamous cell carcinoma is the most common. Sixty percent of these neoplasms arise in the maxillary sinus, 20 to 30% in the nasal cavity, 10 to 15% in the ethmoid sinuses, and 1% in the frontal and sphenoid sinuses.[2] As in other areas of the head and neck, the tumor may present with varying degrees of differentiation.

Glandular carcinomas are the next most common tumors, comprising 4 to 15% of all sinus neoplasms.[6] Of these, adenocarcinomas are the most common, representing 5 to 19% of nasal and paranasal sinus tumors.[7–9] There is a lack of consistency in the literature regarding the classification of these tumors. In general, these tumors are classified as low grade on the basis of uniform glandular architecture and uniform cytologic characteristics. High-grade adenocarcinomas have a predominantly solid growth pattern and moderate to prominent nuclear pleomorphism.[5] The prognostic significance of the two types is debatable, but it is felt that the low-grade adenocarcinomas have a propensity toward local recurrence and rarely metastasize, whereas high-grade adenocarcinomas more frequently display regional and distant metastases.[5]

Adenoid cystic carcinomas are somewhat less common than adenocarcinomas but still comprise a sizable portion of sinonasal tumors in most studies. The tumor consists of groups of small cells arranged in one of several patterns described as tubular, cribriform, and solid.[5,10] Low-grade adenoid cystic carcinomas are defined as those with less than 30% solid component.[5] Conversely, high-grade carcinomas consist of tumors with a greater than 30% solid component (Figure 36–1). High-grade carcinomas are characterized by a shorter survival period and more frequent incidence of distant metastases.[5] Both subtypes have a predilection for perineural invasion.[5,11]

Mucoepidermoid carcinoma (Figure 36–2) is an extremely rare form of glandular carcinoma. It is composed of a combination of squamous cells and glandular, mucus-producing, basal cells.[2] They are notable for their propensity toward distant metastases.[10]

Although rare, two tumors of neuroectodermal origin are occasionally encountered. These are sinonasal melanoma and olfactory neuroblastoma (esthesioneurocytoma, esthesioneuroblastoma). Melanoma of the sinuses represents less than 7% of all sinonasal malignancies. It does not differ significantly from that in other parts of the body, although 30% have been noted to be amelanotic.[5,12,13] Melanoma may have plasmacytoid, spindle cell, or epithelioid cytologic features.[12] Additionally, archi-

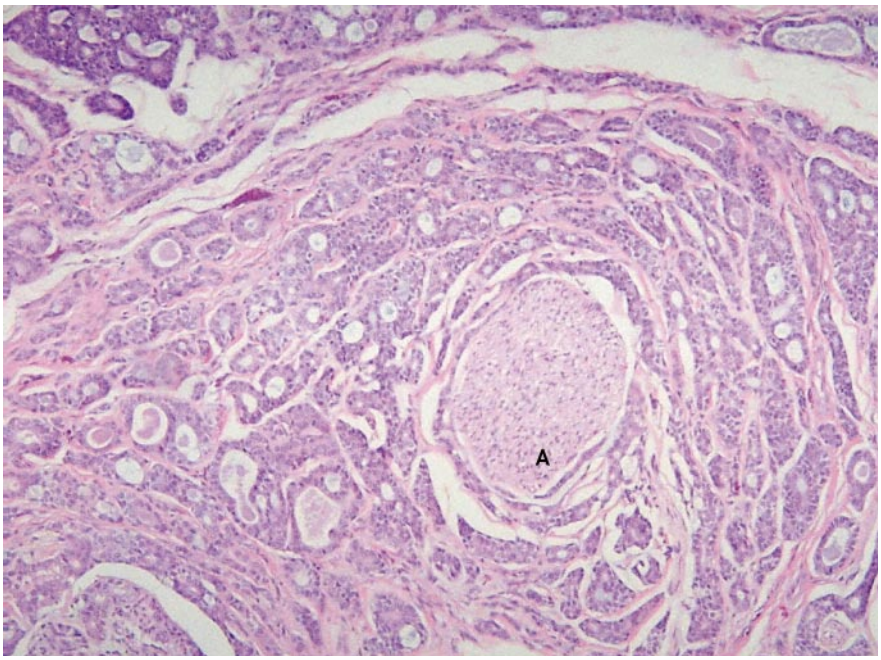

FIGURE 36–1. Photomicrograph of adenoid cystic carcinoma showing low-grade histology and cribriform and tubular architecture with nerve (A), demonstrating perineural invasion. (Hematoxylin-eosin stain, ×20 original magnification.) Courtesy of Michael D. Feldman, MD.

tectural patterns vary and may be sarcoma-like, epithelioid, or pleomorphic.[12] Immunohistochemical staining is helpful and should include anti-S100, HMB-45, and antivimentin.[2,12]

Olfactory neuroblastoma (Figure 36–3) is the second tumor of neuroectodermal origin that may arise in the paranasal region. This neoplasm presents with one of two cell patterns. It may have either a nesting pattern of small cells surrounded by stroma or diffuse sheets of tumor cells with a lack of stroma.[2] Immunohistochemical staining is helpful as esthesioneuroblastoma displays a sustentacular cell pattern of S-100 staining as well as positive staining for neurofilament protein, neuron-specific enolase, and synaptophysin.[2,12,14] Electron microscopy aids in the diagnosis of this tumor by allowing one to identify cells containing microtubules and neurofilaments that are specific to this neoplasm.[2]

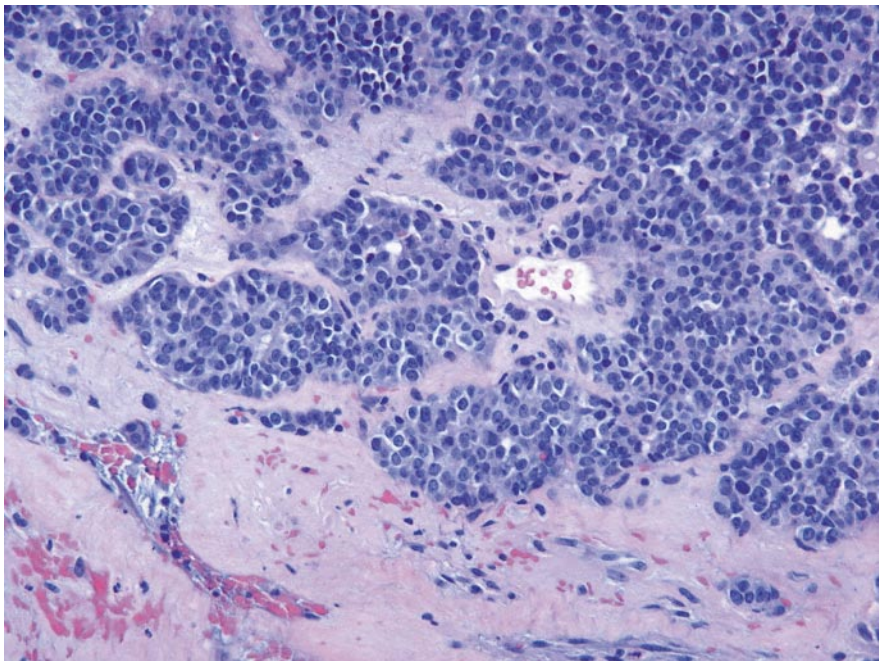

FIGURE 36–3. Photomicrograph of olfactory neuroblastoma showing small round tumor cells with fine nuclear chromatin growing in sheets. (Hematoxylin-eosin stain, ×20 original magnification.) Courtesy of Michael D. Feldman, MD.

Lymphoma makes up approximately 18% of all nonsquamous malignancies of the paranasal sinuses.[13] Most commonly, this consists of diffuse large B-cell lymphoma; however, natural killer/T-cell lymphoma is quite common.[15]

A myriad of neoplasms, both benign and malignant, may be found in the nose and paranasal sinuses. Even benign processes can have devastating consequences owing to local invasion or destruction in the presence of the numerous vital structures located in the area. Malignant tumors have a worse prognosis, but whether one histologic subtype is worse than another is subject to debate.

EPIDEMIOLOGY

The greatest obstacle in understanding nasal and paranasal sinus tumors is the rarity with which they occur. This rarity frustrates clinical studies exploring treatment options. Similarly, the low incidence, combined with their nonspecific symptoms, often leads to a critical delay in diagnosis. Commonly cited data indicate that these neoplasms account for 0.2 to 0.8% of all carcinomas and for 3% of those occurring in the upper aerodigestive tract.[1] Demographically, these tumors occur predominantly in the age range from 50 to 90 years. Their frequency in the young is low, being 0.1 to 0.3 per 100,000 in the first decade of life.[1] However, by the eighth decade, the frequency has risen to 7 per 100,000.[1] These tumors occur in all races, and there is no gender predilection.

The histologic differential diagnosis of paranasal sinus tumors is enormous. However, squamous cell carcinoma is by far the most frequently encountered malignancy, accounting for up to 80% of all neoplasms according to some studies.[1] This is followed by the salivary gland tumors (4 to 15%) and sarcomas (4 to 6%).[1] Other pathologic entities such as lymphomas, esthesioneuroblastomas, and melanomas are usually represented in most case series but rarely make up a substantial percentage in any one study.

Of the different sites, the maxillary sinus is commonly identified as the primary site, representing 55 to 80%.[16] It is followed by the nasal cavity (27 to 33%), the ethmoid sinuses (9 to 10%), and the frontal and sphenoid sinuses (1 to 2%).[6,17,18]

Environmental factors play a large role in the development of paranasal sinus malignancy. Up to 44% of these tumors are attributed to occupational exposures. The most well known is the association between wood dust and adenocarcinoma. Exposure to wood dust increases the relative risk of adenocarcinoma by 540 times.[10] However, it should be noted that squamous cell carcinoma also shares this relationship to wood dust, with prolonged exposure resulting in a 21 times increase in relative risk. Smoking has also been suggested to play a role in

nasal and paranasal sinus cancers. Additionally, numerous other industrial substances have been shown to be associated with the development of paranasal sinus malignancy (Table 36–2). [6,19]

Interestingly, there is also evidence that environmental pollution may be associated with an increasing incidence of paranasal sinus malignancy.[19] In a recent retrospective study, Calderon-Garciduenas et al found substantial increases in the rates of paranasal malignancy when comparing the years 1976 to 1986 and 1987 to 1998.[19] They postulated that this might be related to increasing exposure to complex chemical pollutants in their patient population during these time periods.

Rhinorrhea	Cranial nerve dysfunction
	Proptosis
	Facial pain
	Facial swelling
	Trismus

PATIENT EVALUATION

In contrast to many other areas in the head and neck, paranasal sinus tumors are not characterized by an early presentation. The typical delay in diagnosis is commonly cited as 8 months or more.[6,10] This is secondary to the fact that the early symptoms of paranasal sinus tumors are among the most common symptoms seen by primary care physicians. Complaints such as nasal obstruction, rhinorrhea, and epistaxis rarely receive thorough evaluations outside of offices of otorhinolaryngologists until they have become excessively prolonged or other symptoms develop. Late symptoms include epistaxis, ocular dysfunction secondary to extraocular muscle invasion or cranial nerve involvement, proptosis, facial pain, facial swelling, facial numbness, loosening of teeth, epiphoria, visual loss, anosmia, trismus, and even facial weakness (Table 36–3). The presence of any early symptom lasting over 4 weeks or any late symptom should prompt one to obtain further diagnostic studies.

Once the patient is suspected of having a paranasal sinus neoplasm, it is essential that a complete and organized evaluation be undertaken. This includes a thorough head and neck examination, radiologic evaluation, biopsy, and treatment planning.

PHYSICAL EXAMINATION

Although every patient warrants a complete and thorough examination, important areas the practitioner should focus on when examining a patient with a suspected paranasal sinus tumor include the orbital, oral, and neurologic examinations.

Proptosis, chemosis, or evidence of extraocular muscle impairment signifies orbital invasion and provides the practitioner with a readily available means of determining tumor extent. Evaluation by an ophthalmologist may be helpful for patients with subtle physical findings.

Similarly, the oral examination may help to delineate tumor spread. Key findings include mass effect in the palate and gingivobuccal sulcus. Trismus indicates invasion of the pterygoid muscles. The extent of tumor invasion is the primary focus, but other practical considerations for the surgeon include planning for operative intubation in the patient who cannot open his or her mouth.

The clinician must be sure to palpate the parotid glands and neck thoroughly in search of clinically positive lymph nodes. Such findings are prognostically significant, and their presence may significantly alter patient management.

A thorough neurologic examination must also be performed. Cranial nerve I dysfunction may be

related to either nasal obstruction or nerve involvement. A gross assessment of visual acuity and oculomotor function should be undertaken. If an abnormality is noted, a more thorough examination by an ophthalmologist is warranted for reasons of treatment planning. Finally, facial/palatal anesthesia should be noted to assess involvement of the trigeminal nerves.

Fiber-optic assessment of the nasal cavity may be performed with either a flexible or a rigid endoscope. This portion of the examination provides information on the origin of the tumor, where it extends, and its size. Occasionally, owing to the late presentation and advanced stage of disease, this portion of the examination is limited because of the difficulty in passing the endoscope posterior to the tumor. This is especially true of nasal cavity and ethmoid sinus tumors that tend to obstruct the nasal cavity. Decongestants and topical anesthesia are helpful in this endeavor.

Imaging

Various imaging options are available to the practitioner evaluating the patient with paranasal sinus cancer. However, the two most commonly employed today are computed tomography (CT) and magnetic resonance imaging (MRI). Both provide information useful in treatment planning. In practice, the majority of patients undergo both types of imaging prior to receiving treatment.

On CT, malignant tumors of the paranasal sinuses and nasal cavity appear as dense, homogeneous, destructive masses. The primary benefit of CT scans is the detailed demonstration of bony structure.[20] Finely cut coronal scans provide information regarding the integrity of both the orbital walls and skull base (Figure 36–4). Posterior extension of the tumor toward the pterygopalatine fossa, pterygomaxillary fissure, and infratemporal fossa may also be appreciated.[20] Although not diagnostic, CT scans may also provide evidence of advanced perineural invasion through the demonstration of enlarged neural foramina. The primary disadvantage of CT is the inability to distinguish between soft tissue and retained secretions. Another disadvantage is that although CT can give one an idea of the integrity of the orbital wall and skull base, this often does not correlate with orbital or dural invasion.

Magnetic resonance imaging is more sensitive in determining the true extent of tumor expansion. On T_1-weighted images, most tumors exhibit a low signal intensity that enhances after the administration of gadolinium. On T_2-weighted images, these tumors show a higher signal intensity than muscle but are not as bright as secretions[20] (Figure 36–5). The primary advantage of MRI is the ability to distinguish nasal secretions from tumor mass. Additionally, MRI allows accurate prediction of both dural involvement and venous sinus invasion. Specifically, the presence of pial enhancement, focal dural nodules, or dural thickening of more than 5

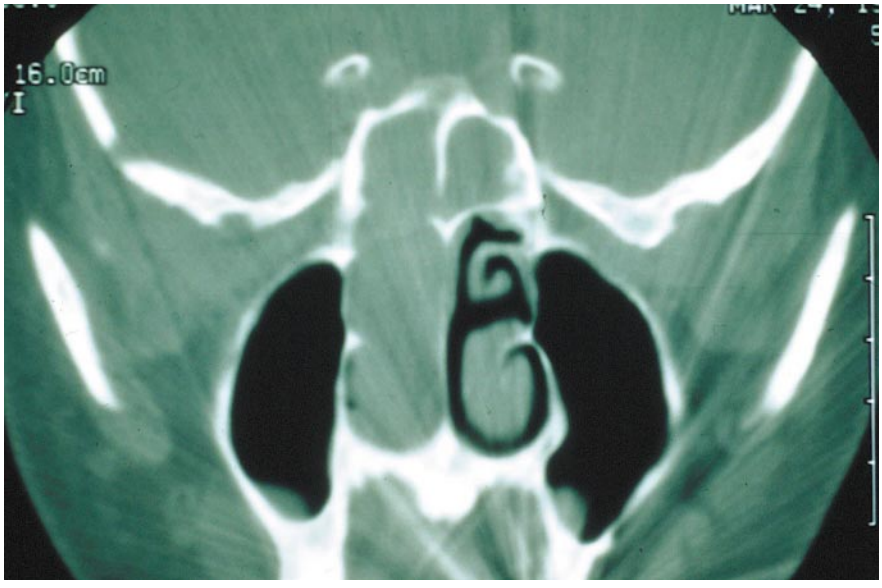

FIGURE 36–4. Coronal computed tomographic scan of the posterior part of the nasal cavity and the skull base showing tumor eroding the face of the right sphenoid sinus. One cannot differentiate retained mucus from tumor.

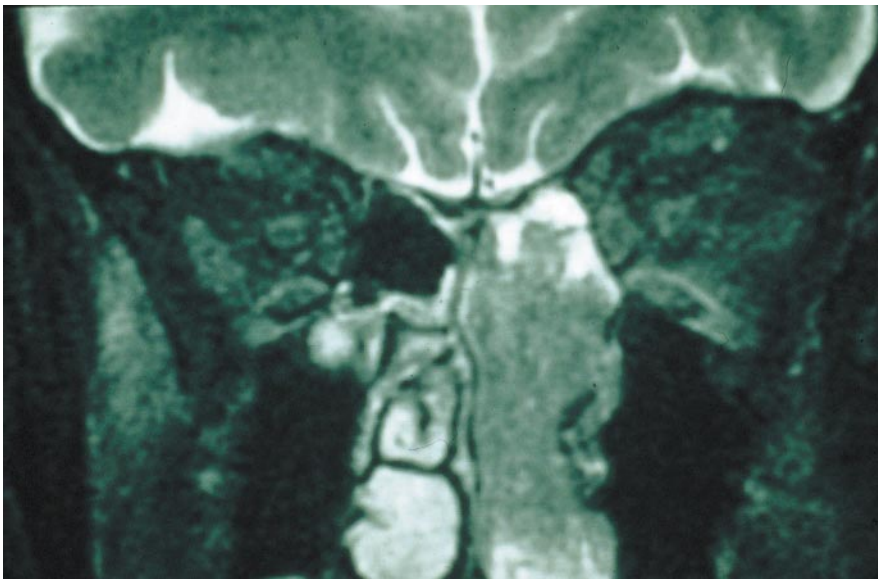

FIGURE 36–5. T_2-weighted coronal MRI showing a tumor in the left nasal cavity and ethmoid sinus with retained mucus (high signal intensity) above the tumor.

mm is highly sensitive and accurate in predicting the presence of dural invasion.[18] Disadvantages of MRI are its inability to provide information regarding the invasion of compact bone.[20] Additionally, like CT, MRI is not accurate in predicting perineural or orbital involvement.[18]

Angiography should be reserved specifically for patients in whom there is suspected internal carotid artery involvement. When carotid artery involvement is suspected, magnetic resonance angiography will often suffice to confirm or refute it.[21,22] Indications for conventional angiography are (1) preparation for embolization of a vascular lesion preoperatively, (2) to define intracranial arterial anatomy in a patient who is to undergo arterial bypass, and (3) balloon occlusion testing in a patient who will likely have the carotid artery sacrificed.

Most patients benefit from multiple imaging modalities during the workup of their paranasal neoplasm. Key issues, such as orbital involvement, skull base invasion, and vascular involvement, play significant roles in determining the proper treatment modality for the individual patient.

Staging

In an analysis of the various staging systems employed for maxillary cancer, Willatt et al listed four goals that an adequate staging system should meet.[23] They include (1) a balanced distribution of staging, (2) the ability to stage the majority of patients, (3) a correlation between T stage and treatment, and (4) a correlation between T stage and survival. Unfortunately, such a system has not been developed for paranasal sinus tumors. The lack of uniformity in staging is a major impediment to comparing treatment modalities from various studies. Since paranasal sinus tumors are so rare and no one clinic can hope to have a large number of patients to study, such comparisons are mandatory to form conclusions concerning the proper treatment of patients with paranasal sinus malignancy.

In the United States, the favored staging system is that proposed by the American Joint Committee on Cancer (Table 36–4). It is largely based on Ohngren's line.[23] This classification divides the facial

TABLE 36–4. American Joint Committee on Cancer Staging System for Malignant Neoplasms of the Maxillary Sinus

T1	Limited to antral mucosa without bony erosion
T2	Bony erosion of the infrastructure (hard palate, middle nasal meatus, or inferior nasal meatus)
T3	Invasion of cheek skin, posterior wall of sinus, or anterior ethmoid cells
T4	Invasion of orbital contents, cribriform plate, posterior ethmoid cells, sphenoid sinus, nasopharynx, soft palate, pterygopalatine fossa, infratemporal fossa, or skull base

skeleton into two parts by a theoretical plane drawn from the medial canthus of the eye to the angle of the mandible. Tumors of the maxillary sinus posterior to this plane have a poorer prognosis. However, this staging system fails to classify tumors that do not originate in the maxillary sinus. Obviously, this is a major limitation in discussing the wide variety of tumors that may occur in the nasal cavity and ethmoid sinuses.

One method to overcome this difficulty is to describe individually the site of involvement for each patient. This is cumbersome and presents difficulty in outcome analysis. As an alternative, many authors now use the staging system proposed by the International Union Against Cancer (UICC) (Table 36–5). Although the UICC staging system accounts for the most common sites of paranasal sinus malignancy, its variation from the AJCC staging of maxillary cancer makes analysis of studies using the different staging systems difficult. However, for the present time, the UICC staging system is the most complete system currently in use.

TABLE 36–5. International Union Against Cancer (UICC) Staging System for Malignant Neoplasms

Maxillary sinus	
T1	Tumor is limited to the antral mucosa with no erosion or destruction of bone
T2	Tumor causes bone erosion or destruction, except for the posterior antral wall, including extension into the hard palate and/or the middle nasal meatus
T3	Tumor invades any of the following: bone of the posterior wall of maxillary sinus, subcutaneous tissues, skin of cheek, floor or medial wall of orbit, infratemporal fossa, pterygoid plates, ethmoid sinuses
T4	Tumor invades orbital contents beyond the floor or medial wall including any of the following: the orbital apex, cribriform plate, base of skull, nasopharynx, sphenoid, frontal sinuses
Ethmoid sinus	
T1	Tumor is confined to the ethmoid with or without bone erosion
T2	Tumor extends into the nasal cavity
T3	Tumor extends to the anterior orbit and/or maxillary sinus
T4	Tumor with intracranial extension, orbital extension including apex, involving sphenoid and/or frontal sinus and/or skin of external nose

PROGNOSIS

Because of the previously discussed difficulty in comparing various clinical studies, it is difficult to state the extent that various clinical factors play in prognosis. Clearly, an advanced stage is associated with a worse prognosis. In fact, it has been asserted that the most accurate predictor of poor prognosis is the T category.[10,13,24] For example, although the overall total 5-year survival for patients with paranasal sinus malignancy may range from 40 to 50%, patients categorized as T1 and T2 may have a 5-year survival as high as 70%.[7–10,13,16] Conversely, patients with a tumor category of T3 or T4 commonly have 5-year survivals as low as 30%.[10] Specifically, tumors with anterior skull base involvement are known to have the worst prognosis.[10,18] Because of this, many authors have argued that a shorter delay in diagnosis would result in lower T categories at the time of presentation and improvement in overall survival.[25]

Lymph node involvement at the time of diagnosis is known to be associated with a uniformly dismal prognosis.[8,10,26] This manifestation of disease is rare in patients with paranasal sinus tumors and approximates 10% in most series.[7,8,16,25] It is because of the poor prognosis associated with lymph node disease that some clinicians now recommend for patients with advanced stages of paranasal sinus malignancy elective treatment of the N0 neck.

Interestingly, many studies have shown that histologic subtype does not play a role in the overall prognosis.[7,9,10,13,27] However, this is contradicted by other reports demonstrating improved survival in tumors such as adenoid cystic carcinoma and lymphoma and poor survival rates in undifferentiated carcinoma as well as melanoma.[8,9] Additionally, some investigators feel that tumor differentiation plays a role in prognosis, with well to moderately differentiated tumors having significantly better prognosis than poorly differentiated tumors.[8] The true extent that histology and differentiation play in patient prognosis remains to be clarified.

TREATMENT

A variety of treatment options are available to the clinician dealing with paranasal sinus tumors. As with tumors in other areas of the head and neck, these include surgery, radiation, and chemotherapy. Additionally, within each modality, a variety of combinations and techniques may be used. Regardless of the order of treatment, multimodality therapy is widely advocated.[16,24,26,27]

Surgery

There has been a long history of treating patients with nasal and paranasal sinus tumors with surgical resection. These attempts predate the modern era of computer imaging, fiber-optic endoscopy, and advanced surgical techniques. Advancement in technology has paved the way for advances in surgical care. Developments in imaging and the ability to perform an endoscopic examination allow one to assess preoperatively tumor size, location, and the integrity of surrounding structures.

As technological advances expand our ability to resect more advanced lesions, the surgeon is forced to address the question of what is resectable in the context of what is curable. Unfortunately, the answers to these two questions may not coincide. Proposed criteria for unresectable lesions include (1) transdural extension, (2) invasion of the prevertebral fascia, (3) bilateral optic nerve involvement, and (4) gross cavernous sinus invasion.

Operative technique in paranasal sinus surgery includes both the resection and the approach through which the resection takes place. The choice of resection is based on the location of tumor and may consist of a variety of procedures ranging from endoscopic removal of gross tumor to a total maxillectomy with orbital exenteration. The focus is to achieve total resection of the tumor since local recurrence is by far the most common cause of failure. En bloc resection is ideal, although this is rarely possible. A number of approaches are available depending on the size and location of the tumor and the excision to be performed. They include the endoscopic approach, midfacial degloving, lateral rhinotomy, lateral facial (Fisch-Mattox) approach, craniotomy, and combined craniofacial approaches.

Endoscopic Sinus Surgery The endoscopic approach to paranasal sinus malignancy is an option for treatment for low-grade or benign tumors involving the lateral nasal wall, ethmoid sinuses, or the sphenoid sinus. The primary advantage of this approach is the lack of need for facial incisions. Other advantages include the magnification that modern endoscopy provides.[17]

There has been a great deal of controversy surrounding the use of the endoscopic approach versus the more traditional transfacial approaches, even in treatment for benign lesions such as IP. Those advocating an endoscopic approach include Waitz and Wigand, who reported a recurrence rate of 17% using endoscopic medial maxillectomy for the resection of IP.[28] Their technique involved piecemeal removal of all gross tumor followed by histologically guided resection of tumor margins. Underlying bone was drilled to ensure total tumor removal. The authors noted that not only was their recurrence rate comparable to what they experienced for extranasal procedures, but the surgery was effective even in large lesions involving the posterior ethmoidal cells, nasofrontal duct, and sphenoid sinus. They concluded that many "mutilating" transfacial procedures could be avoided through the judicious use of nasal endoscopy. Sukenik and Casiano reported a 94% cure rate using only endoscopic resection of IP.[3] The efficacy of this treatment modality has been confirmed by Stankiewicz and Girgis, who demonstrated that the endoscopic approach could be effectively used in patients with recurrent disease as long as the papilloma was in an area that could be visualized with endoscopic equipment.[29]

Proponents of the transfacial approach cite the importance of en bloc resection in preventing tumor recurrence. The average rate of recurrence of IP using en bloc resection has been noted to be 8%, which is less than the 17 to 20% recurrence noted when using the intranasal approach.[30] Additionally, when IP recurs, there is the potential for multicentricity and malignancy. However, many investigators have noted that recurrent tumors are generally detected early in routine follow-up and can also be managed through an endoscopic approach.[31]

Tumor types other than IP have also been treated through the endoscopic approach. Good results have been obtained using this approach for hemangioma, esthesioneuroblastoma, adenoid cystic carcinoma, adenocarcinoma, and even squamous

cell carcinoma.[32] In fact, the most important factor in deciding on an endoscopic approach is not the type of tumor but rather the extent. Early tumors limited to the lateral nasal wall are good candidates for endoscopic resection (Figure 36–6). This may range from endoscopic medial maxillectomy to total ethmoidectomy with mucosal stripping and the drilling of potentially involved bone.[31] A contraindication to an endoscopic approach is invasion of inaccessible areas, including the lateral part of the maxillary sinus, periorbita, lacrimal sac, supraorbital ethmoid cells, frontal sinus, and skull base.[31] Certainly, the current standard dictates that the vast majority of patients with malignant lesions should be treated with an open en bloc resection. Additionally, even when one is dealing with a low-grade tumor, many authors caution that patients should be prepared preoperatively for the possibility of conversion to an open procedure.[29,32]

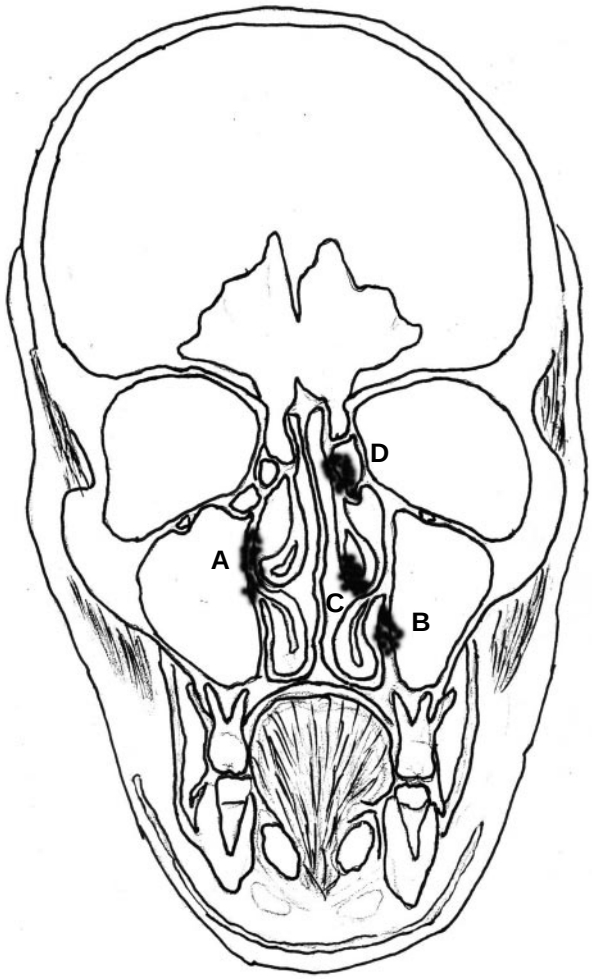

FIGURE 36–6. Diagram of intranasal tumor sites that can be considered for endoscopic intranasal resection: A, middle meatus; B, inferior meatus; C, middle turbinate; D, anterior ethmoid cells.

Most surgeons would agree that in the hands of a skilled endoscopist, endoscopic resection of early nasal and paranasal sinus tumors is appropriate. However, care must be taken to ensure that negative surgical margins are obtained as this has been shown to improve significantly patient prognosis.[31] Additionally, because of the risk of recurrence, frequent follow-up with serial endoscopic examination is strongly encouraged. Regardless of treatment approach, the role of serial endoscopy is established for follow-up of the patient's nasal or surgical cavity. Complications include cerebrospinal fluid (CSF) leaks, visual/orbital injury, synechia, and changes in the sense of smell.

Midfacial Degloving Approach Midfacial degloving represents one of many open approaches that one may use to approach an endonasal tumor. This approach consists of (1) bilateral intercartilaginous incisions, (2) a septocolumellar complete transfixion incision, (3) bilateral sublabial incisions, and (4) bilateral piriform aperture incisions.[33] This is a versatile approach that can provide access to a wide variety of areas, including the nasal cavity, nasopharynx, maxillary antrum, orbital floor, and zygoma (Figure 36–7). It may be combined with a craniotomy for tumors involving the anterior part of the skull base.[33] Various types of excisions can be performed through this approach such as medial maxillectomy, total maxillectomy with or without orbital exeneration, ethmoidectomy, sphenoidectomy, and resections of tumors invading the anterior part of the skull base when done in association with a craniotomy.

The primary advantages of the procedure are its lack of extensive facial incisions and good access provided for inferiorly based tumors. Additionally, there is a fairly low complication rate associated with the procedure.[33] Disadvantages include difficulty with access to superiorly based tumors. Other transfacial procedures are preferred for superiorly based tumors unless otherwise contraindicated.[6] Complications specific to midfacial degloving include lip numbness, vestibular stenosis, and oroantral fistula.[33]

Lateral Rhinotomy Lateral rhinotomy serves as the basis for the majority of transfacial procedures.

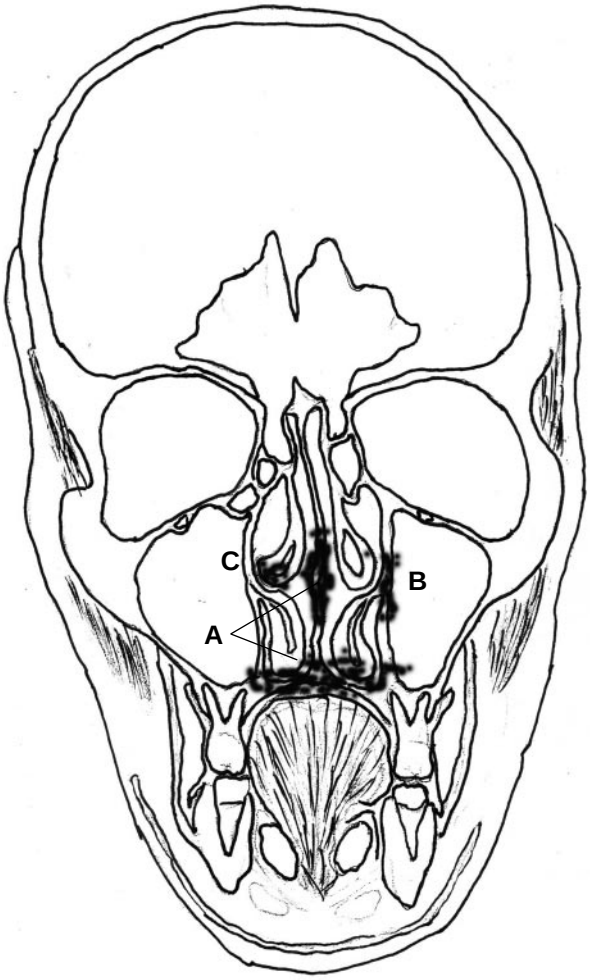

FIGURE 36–7. Diagram of tumor sites accessible through midfacial degloving: A, septum/nasal floor; B, lateral nasal wall, inferior meatus, middle meatus; C, middle turbinate; and nasopharynx (with or without Le Fort I osteotomy).

It consists of a curvilinear incision beginning at the inferomedial aspect of the brow and extending inferiorly midway between the nasal dorsum and medial canthus[34] (Figure 38–8). The distal portion of the incision should advance nasally from the nasofacial groove to allow for the optimal esthetic result. The incision can be extended through a variety of techniques, making it a versatile approach. Such extensions include a lip-splitting incision for retraction of the cheek (Figure 36–9), incision beneath the ipsilateral eyelid for further retraction (Weber-Ferguson incision), incision above the ipsilateral eyelid for orbital exenteration, or a superior nasal incision for access to the contralateral frontoethmoidal region.[35] The approach provides fairly wide access to tumors involving the supraorbital ethmoidal area, frontal duct, lacrimal fossa, orbit, or cribriform plate.[6] Through this approach, one may perform a variety of excisions including medial maxillectomy, total maxillectomy, radical maxillectomy, bilateral ethmoidectomy, and resection of most superiorly based tumors that are not directly invading the cribriform plate or fovea ethmoidalis[35] (Figure 36–10). It may be used in conjunction with a craniotomy for tumors that have invaded the skull base (craniofacial resection).

The primary advantage of the procedure is the wide access it provides combined with the relative ease in which the incisions may be modified to achieve better access. Disadvantages of the procedure include orbital complications including blepharitis, epiphora, and intermittent dacryocystitis related to transection of the nasolacrimal duct.[35] Proper attention must be paid to providing adequate reconstruction to this system at the time of surgery. This includes precise reconstruction of the medial canthal tendon in conjunction with dacryocystorhinostomy. In this setting, canaliculi stenting is not required. Another disadvantage of this approach is the presence of facial incisions. The cosmetic result is usually acceptable, but the degree of scarring, as well as the patient's feelings about it, can be difficult to predict.

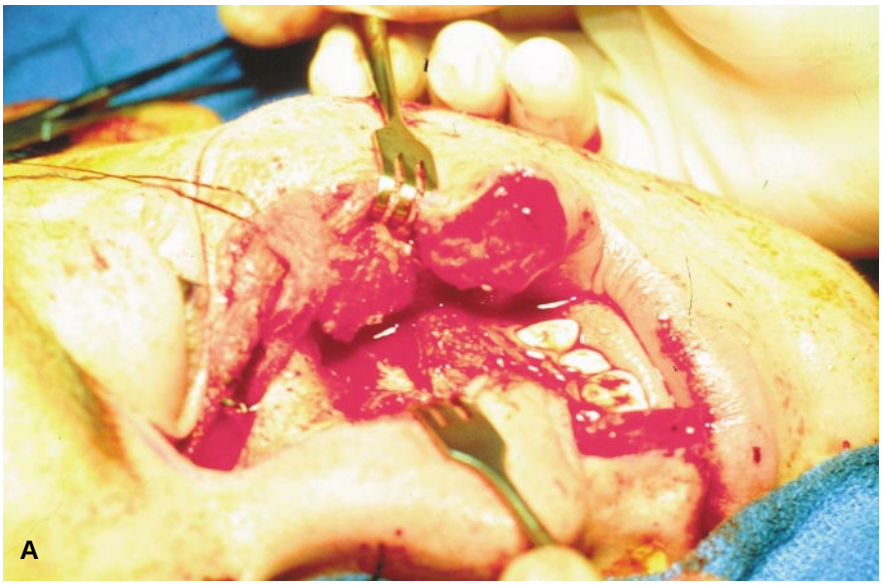
Approach to the Frontal Sinus Primary involvement of the frontal sinus is rare, but the advanced nature of paranasal sinus tumors at presentation results in frequent invasion by tumors of nasal or ethmoid sinus origin. In these cases, the frontal sinus may be approached through a "gullwing" extension of the lateral rhinotomy inferior to the eyebrow in the upper eyelid sulcus. This is especially useful if the skin has been breached by tumor, in which case, one should include a wide margin of surrounding skin.[6] If the anterior table is not involved by tumor, one may use a bifrontal craniotomy through a coronal incision.[6,34] This may be used by itself for isolated frontal lesions or in combination with a lateral rhinotomy for lesions extending superiorly from the ethmoid sinuses or nasal cavity.[34]

The frontal sinus defect may be "cranialized," obliterated, or reconstructed. A specific complication associated with the management of frontal sinus tumors is the formation of a mucocele. This is

FIGURE 36–8. *A*, Lateral rhinotomy incision; intraoperative view of incision extending from the inferomedial eyebrow to the midpoint between the medial canthus and the nasal dorsum and to the junction of the alar base with the upper lip. *B*, Lateral rhinotomy incision appearance; early postoperative view. Note that the incision should ascend beyond the nasofacial groove in the middle third of the nose to the junction with the thinner nasal skin.

best avoided through careful removal of all frontal sinus and frontal recess mucosa followed by obliteration of the frontal recess with fascia and bone chips[34] in patients undergoing "cranialization" or obliteration. Reconstructed or preserved frontal sinuses will require radiographic follow-up. Additional complications include the poor cosmetic outcomes that may result when the anterior table must be resected. This defect is best reconstructed with a split calvarial bone graft.[34]

Anterior Lateral Skull Base Approach Although standard transfacial approaches offer good access to the sinonasal region, tumors that extend to the pterygopalatine fossa, sphenoid sinus, or nasopharynx are best approached through the lateral face/skull base[6] (Figure 36–11). The most well-described approach is the lateral facial split or the infratemporal fossa type C procedure of Fisch and Mattox.[6] The approach consists of a preauricular or modified Blair incision. The temporalis muscle is elevated and swung over the zygoma. Additionally, the zygoma may be removed, the pes anserinus of the facial nerve divided, retracted, or skeletonized, and the mandible disarticulated and advanced anteriorly. This provides exposure of the internal



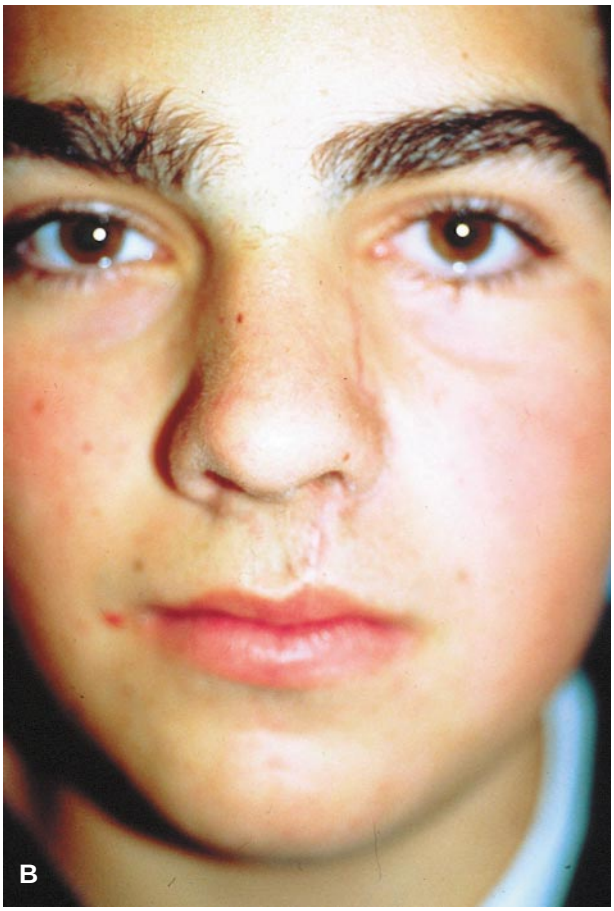


FIGURE 36–9. Intraoperative (*A*) and postoperative (*B*) views of lip-splitting extension of lateral rhinotomy incision. The extension of the incision to the lip can be along the philtral margin (preferred) or in the midline.

carotid artery from the bifurcation to the cavernous sinus.

The benefit of this approach is the access it provides to the central part of the skull base. Wide exposure of the internal carotid artery not only allows the opportunity to assess potential involvement with the tumor but also provides the option of bypass. In extreme cases, this exposure may necessitate division of the facial nerve or result in facial nerve weakness from traction on the nerve. In patients requiring facial nerve division, reconstructive neurorrhaphy is recommended.

Craniotomy/Craniofacial Approach An alternative approach to paranasal sinus tumors is the transcranial resection. The transfacial approaches described above are difficult and most often inappropriate to use in tumors adherent to the anterior part of the skull base. There is the added risk of CSF leak when attempting extracranial excisions in this area. Transcranial access is the approach of choice in tumors involving the cribriform plate or fovea ethmoidalis, especially when the tumor is of meningeal or cranial origin. Patients in whom there is known skull base involvement or intracranial invasion from the sinonasal cavity and possible adherence to or invasion of the dura require a combined craniofacial approach[36] (Figure 36–12). Most of these exposures will be with a transfacial (lateral rhinotomy) or midfacial degloving approach to guide the nasal and paranasal sinus components of

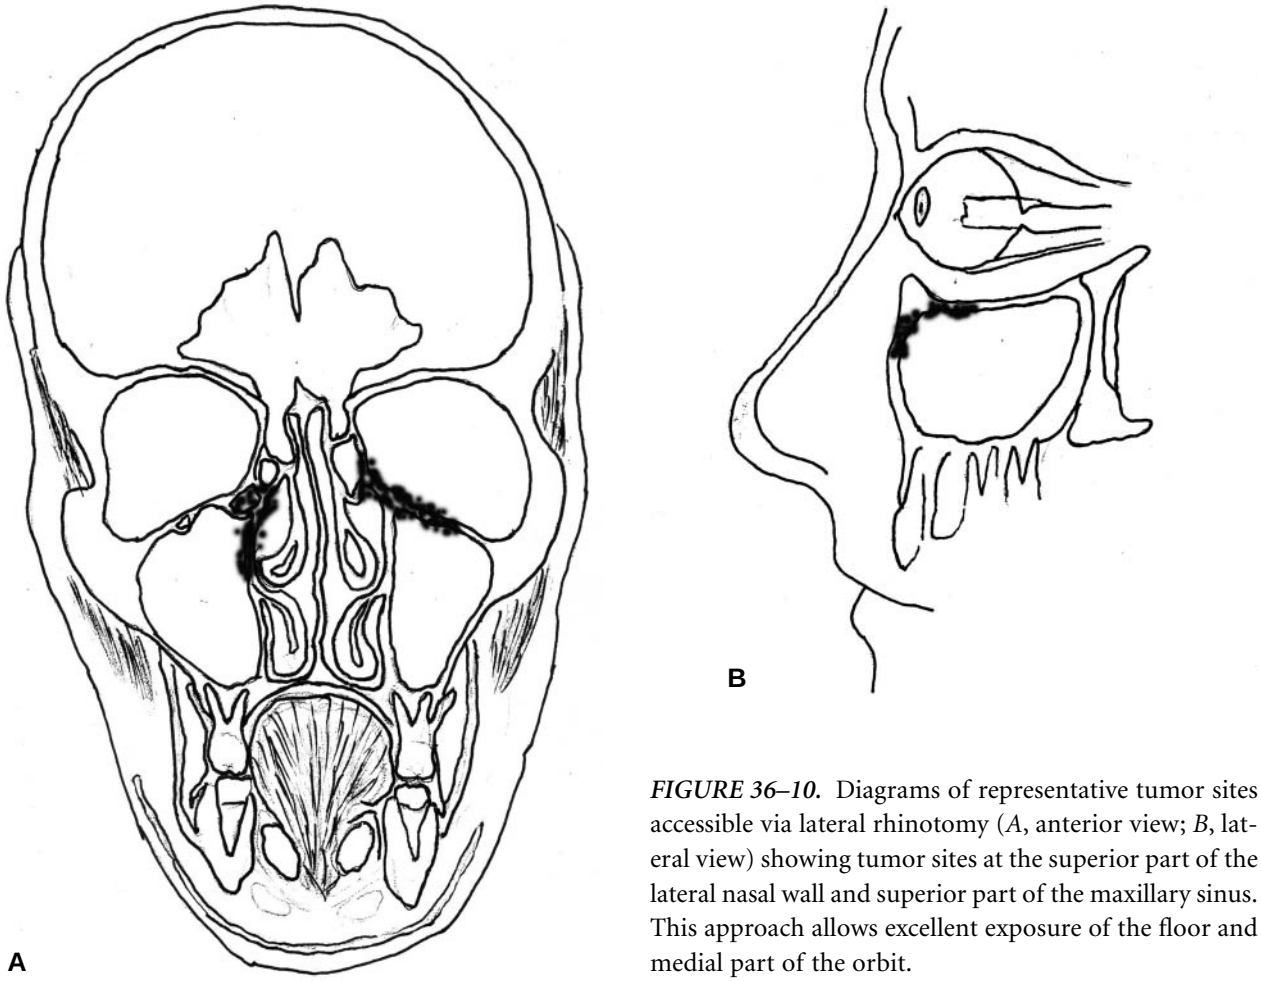

FIGURE 36–10. Diagrams of representative tumor sites accessible via lateral rhinotomy (*A*, anterior view; *B*, lateral view) showing tumor sites at the superior part of the lateral nasal wall and superior part of the maxillary sinus. This approach allows excellent exposure of the floor and medial part of the orbit.

the resection. Endoscopic guidance has added a minimally invasive component to guide the intranasal cuts for small tumors of the anterior part of the skull base. In the more uncommon scenario, the approach has the additional advantage of having no facial incisions. The intracranial exposure is recommended as the first step to ensure that the tumor is not unresectable owing to transdural or brain invasion.

The procedure involves a bicoronal incision with bifrontal craniotomy. An anteriorly based pericranial flap is created to provide an anatomic division between the dura and sinuses at the end of the procedure. An anterior osteotomy is placed above the supraorbital rims. The frontal lobes are gently retracted to provide access to the anterior cranial floor. The dura is then elevated except where it is directly involved in tumor and in the cribriform plate region. Small dural defects may be closed primarily, but larger defects that prohibit primary closure are grafted with cadaveric dura. At the end of the procedure, the pericranial flap is sutured to the dura, bone flaps are replaced, and the skin is closed. A lumbar drain, CSF-penetrating antibiotics, and high-dose corticosteroids are recommended in the perioperative period.[6]

In addition to the inherent morbidity of a craniotomy, a significant disadvantage of the approach is the limited access to the inferior and medial parts of the orbit as well as the maxillary sinus. For this reason, the procedure should be combined with a transfacial approach when there is involvement of the floor of the maxilla, the base of the nasal septum, or the soft tissues of the face or when one suspects that the excision will include orbital exenteration (Figure 36–13). The com-

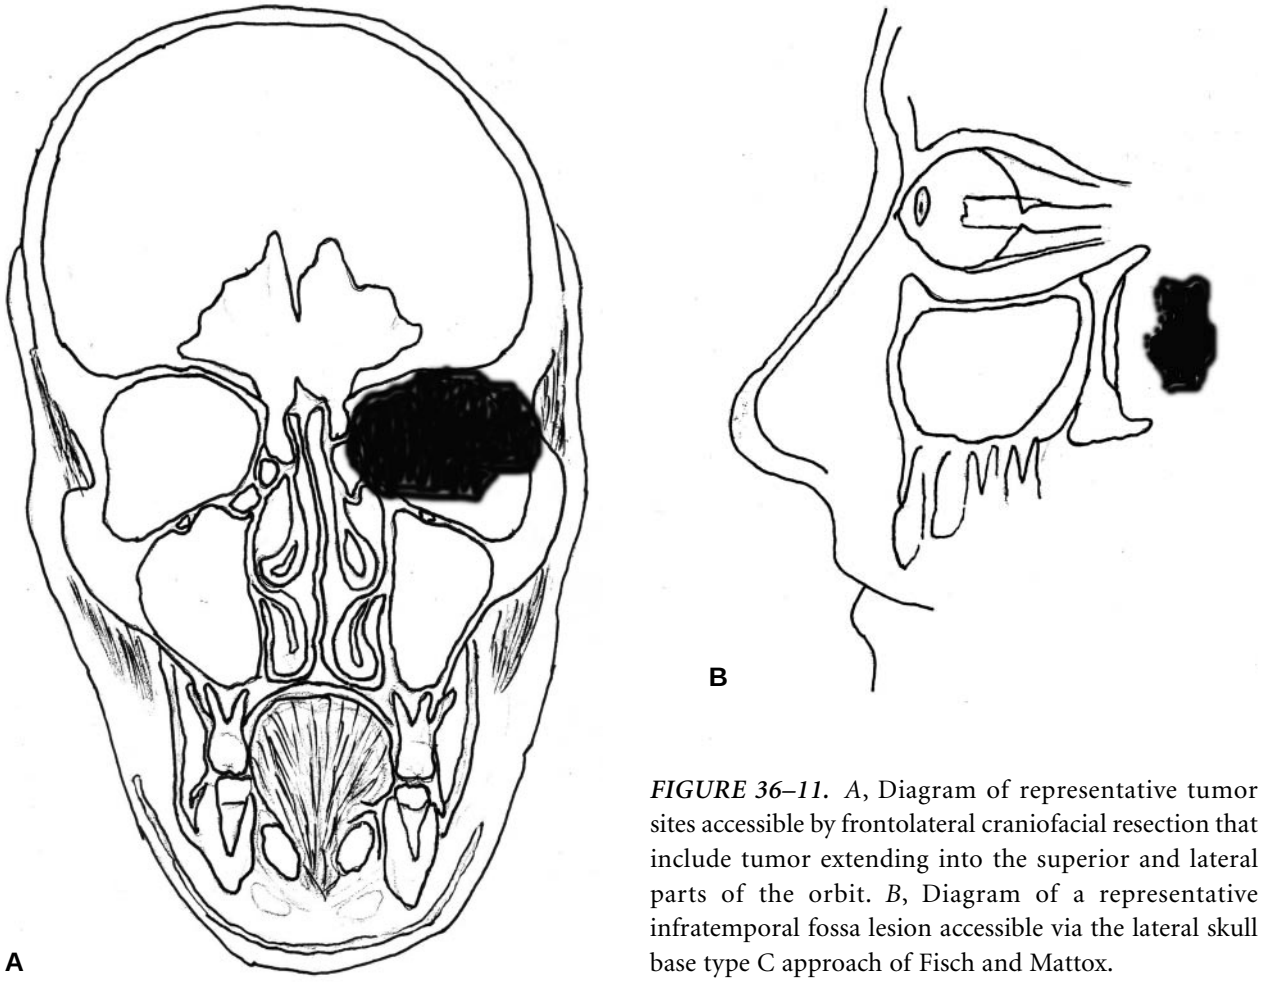

FIGURE 36–11. A, Diagram of representative tumor sites accessible by frontolateral craniofacial resection that include tumor extending into the superior and lateral parts of the orbit. *B*, Diagram of a representative infratemporal fossa lesion accessible via the lateral skull base type C approach of Fisch and Mattox.

bined craniofacial resection has allowed better access to the inferior and lateral nasal walls. This reduces operative morbidity by decreasing the amount of retraction needed on the frontal lobes and providing greater ease in obtaining adequate hemostasis.[36]

Specific complications related to the cranial or craniofacial approach include CSF leak, meningitis, and pneumocephalus. Our practice has been to use a tracheostomy to decrease the incidence of pneumocephalus. However, should it occur, it may be easily treated with aspiration. The other complications are rare when a pericranial flap has been used in conjunction with adequate perioperative antibiotics and a lumbar drain.[36]

The subfrontal craniofacial approach has been used for anterior skull base resections and offers the advantage of minimal brain retraction.[37] This technique may allow resection of one side of the cribriform plate with preservation of contralateral olfactory fibers. The craniofacial approach allows definite confirmation of tumor resectability from the dura/brain. If tumor is grossly through dura or into brain, these patients are at higher risk for carcinomatous meningitis. For our team, this has been a contraindication for craniofacial resection on patients with high-grade tumors. The lesions in these patients are typically not resected, and the patients are referred for multimodality therapy.

Radiation Therapy

Radiation therapy plays a large role in the treatment of patients with paranasal sinus tumors. Because of the late stage in which most of the patients present,

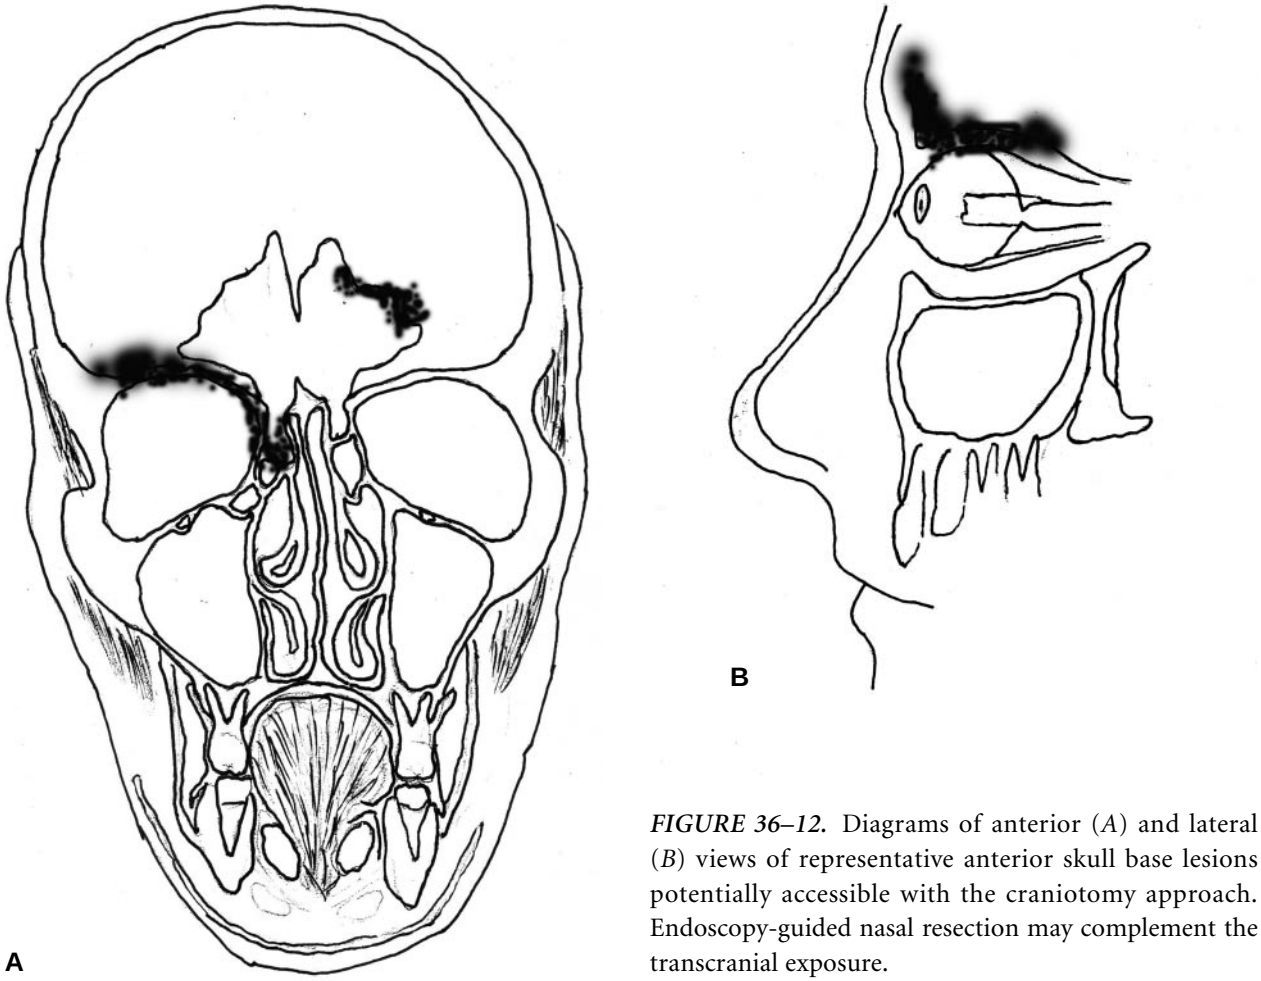

FIGURE 36–12. Diagrams of anterior (*A*) and lateral (*B*) views of representative anterior skull base lesions potentially accessible with the craniotomy approach. Endoscopy-guided nasal resection may complement the transcranial exposure.

multimodality therapy is nearly universal.[6,26,38] Additionally, in rare patients with early-stage cancers, radiation therapy alone has been shown to be as effective as surgical excision.[20,38,39] Some neoplasms such as lymphomas, plasmacytomas, and esthesioneuroblastomas appear to be especially radiosensitive.[6,10,38]

There is no clear evidence supporting preoperative radiation versus postoperative radiation.[6,27] Each has its distinct advantages and disadvantages. Postoperative radiation currently appears to be the most popular choice for several reasons. The dose of radiation that may be given is lower when using radiation to control microscopic residual disease, resulting in less morbidity.[38] Postoperative doses may range between 60 and 70 Gy. Patients who are not operative candidates may receive doses as high as 74 to 79 Gy.[40] Another reason for postoperative irradiation is the difficulty in determining the true borders of the radiated tumor and the potential for increased surgical morbidity in the irradiated field.[6] The pathologic results from the surgical specimen may be used to guide the radiation treatment. This is extremely important when dealing with areas such as the orbit, where intraoperative examination and subsequent pathology may be the only way to determine definitively the presence of tumor and help define required doses yet minimize morbidity.[38]

Notwithstanding, there are persuasive arguments for the use of preoperative radiation therapy as well. In common situations in which there is involvement of vital structures (orbit, dura, etc), preoperative irradiation can be used to "sterilize" these areas. This strategy is frequently used to preserve the eye when radiographic evaluation demonstrates that the structure is at risk. Debate continues as to whether this serves to preserve

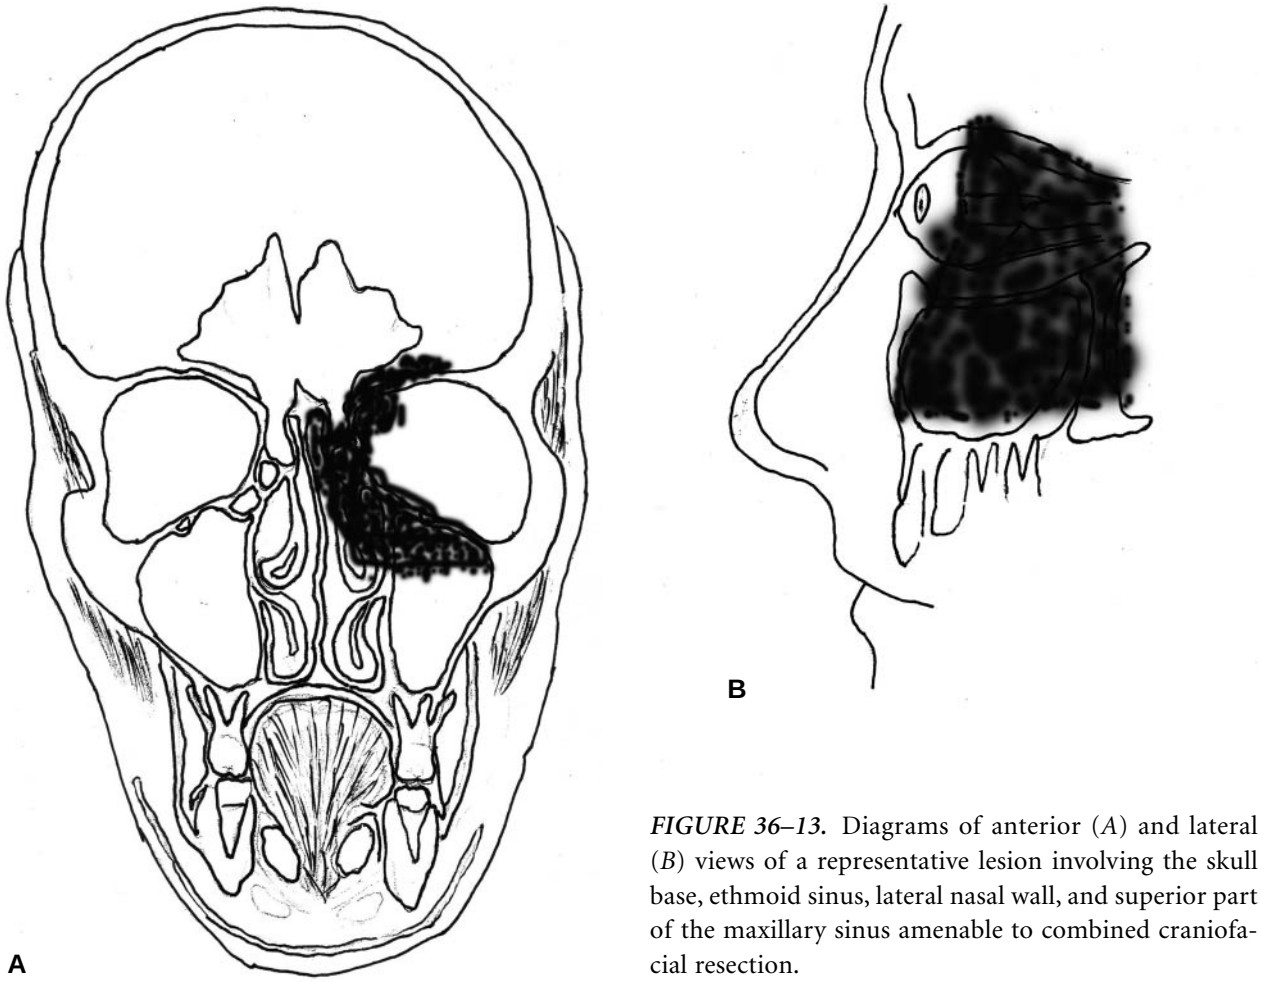

FIGURE 36–13. Diagrams of anterior (*A*) and lateral (*B*) views of a representative lesion involving the skull base, ethmoid sinus, lateral nasal wall, and superior part of the maxillary sinus amenable to combined craniofacial resection.

anatomic structures and improve survival. Some argue that preradiation surgery devascularizes the tumor bed, making the residual tumor less radiosensitive secondary to hypoxia. When there are grossly positive margins after surgery, higher doses of radiation are required to eradicate the disease.[38] It has been shown by Polin et al that presurgical response to radiation therapy is predictive of patient prognosis.[14] In their study of patients with esthesioneuroblastomas, patients with a favorable response to radiation demonstrated a significantly higher rate of disease-free survival.

As with surgery, there are numerous risks to radiation treatment. The majority relate to damage to the orbits and brain. Reported complications include blindness, central nervous system sequelae, otitis media, nasolacrimal duct obstruction, sinusitis, nasal bone destruction, chronic orbital pain, osteoradionecrosis, retinopathy, and medial canthus fistula.[16,40,41] The rates of these complications increase as higher doses of radiation are used. For instance, the retina and optic nerve exhibit a tolerance of approximately 50 Gy. Parsons et al found the rate of unilateral blindness in these patients to be as high as 33%.[39] Bilateral blindness occurred in 10% of the patients. Structures surrounding the orbit are also important to consider. The risk of injury to the lacrimal gland with resulting corneal ulceration, opacification, or vascularization increases substantially with doses greater than 30 Gy.[39] Neurologic sequelae are less common (10%). The rates of these complications have diminished markedly with the use of CT for treatment planning.[42] Computed tomographic scans allow for precise localization of both the tumor and surrounding critical structures. This localization provides for

treatment planning that minimizes radiation given to surrounding structures.

Chemotherapy

Several trials have evaluated the effects of chemotherapy in treating patients with paranasal sinus tumors. Although results have been promising, there is no definitive evidence that chemotherapy improves survival. However, several studies have shown evidence of tumor regression with the addition of chemotherapy.[38,43] For instance, Brasnu and colleagues have used cisplatin as a neoadjuvant chemotherapy prior to surgical resection in the treatment of adenocarcinoma reaching the skull base.[41] In this setting, the investigators achieved a 22.7% complete clinical response and a 13.6% complete histologic response. As with radiation therapy, a response to chemotherapy was found to be predictive of a better prognosis.[14,41] The morbidity of this treatment was minimal and was not increased by the addition of postoperative radiation therapy. Platinum-based chemotherapy has also been shown to be effective against esthesioneuroblastomas and other paranasal sinus tumors as well.[14,38,43] Alternatively, Sakai et al noted 5-fluorouracil (5-FU) in combination with radiation and surgical curettage to be relatively effective with minimal morbidity, although Tsujii and Tsuji found no difference in patients whether they were treated with 5-FU or not.[42,44] Although chemotherapy has not shown an improvement in overall survival, it must be remembered that it is difficult to prove an improvement in survival with *any* therapy for this disease. Further research is required and should be encouraged.

CONTROVERSIAL TOPICS IN PARANASAL SINUS TUMORS

Obviously, there is still much to be learned concerning the optimal management of paranasal sinus malignancy. However, two topics in particular warrant consideration.

Orbital Preservation

In the past, radical excision with orbital exenteration was performed if the tumor approached the orbit.[45] With the emphasis on multimodality therapy, there is a trend toward using preoperative radiotherapy and/or chemotherapy with the goal of preserving structures such as the orbit. Proponents of orbital preservation argue that the orbit is surrounded by a layer of periosteum that is resistant to tumor invasion.[46,47] This argument has been furthered by clinicoanatomic studies demonstrating the presence of a distinct fascial layer separating orbital fat from periorbita as well as an infrequent incidence of tumor invasion of orbital contents.[45,48,49] Proponents argue that for this reason, there is rarely a reason to remove the orbit at the time of surgical resection.

Surgeons favoring radical excision of the orbit point out that there is no reliable radiographic means to determine the extent of orbital involvement. Additionally, with the use of neoadjuvant radiation treatment, it can be difficult to determine the extent of orbital involvement at the time of surgical excision. The function of the eye must also be considered when making the decision to pursue preservation. Stern et al have shown that ocular function tends to be poor when the orbital floor is removed during excision.[50] There is also the morbidity of radiation therapy to consider. Postradiation complications involving the orbit include keratitis, cataracts, retinopathy, glaucoma, and chronic pain. As has been previously discussed, the rates of these complications can be quite high.

At the present time, the decision to preserve the eye is made on an individual basis. Clinical studies demonstrate that as long as the periorbita is not involved, it is oncologically sound to leave the orbit intact. However, attention must be paid to the chances of obtaining useful function from the preserved organ. This analysis should be based on both the amount of resected orbital floor as well as the final amount of radiation the orbit will receive. As Stern et al pointed out, "Strong consideration should be given to orbital exenteration at the time of surgery when the orbital floor is resected—especially if postoperative radiation fields will include the eye."[50]

Elective Treatment of the Neck

Traditionally, elective treatment of the N0 neck has not been advocated secondary to the low rate of occult lymph nodal disease.[6,40] Additionally, many argue that the primary lymphatic watershed of the sinonasal region is the retropharynx. Therefore, the

areas most likely to contain regional cancer reside in this region and not in the neck. This dogma has recently been challenged based on the following reasoning: the rate of lymph nodal recurrence ranges from 12 to 28%.[27] Patients with neck relapse are known to have inferior long-term survival and a higher risk of distant metastases compared with those who did not have locoregional failure. This work has been corroborated by Paulino et al, who also found that patients with T3 and T4 tumors have a higher rate of nodal recurrence and those patients with nodal recurrence had poorer survival rates.[51] In addition to this, Le et al demonstrated that elective neck irradiation effectively prevented nodal recurrence in the 25 patients in whom it was used.[52] For this reason, it is now considered reasonable to irradiate the N0 neck in the presence of a primary tumor of advanced stage (T3 and T4).

CONCLUSION

What we know concerning nasal and paranasal sinus tumors stands in stark contrast to the questions that need to be answered. Small cohorts and isolated case presentations contribute relatively little toward global understanding. As consensus is reached regarding staging, cross-study comparisons will be facilitated. This will undoubtedly lead to a greater understanding of these tumors in terms of pathogenesis, prognosis, and optimal treatment options.

CHAPTER 37

Reconstruction of the Outstanding Ear

Daniel G. Becker, MD, Stephen Y. Lai, MD, PhD

The normal auricle has a well-recognized configuration of depressions and projections. Although there are many variations, significant deviations from "normal" are immediately evident. In particular, prominent ears are readily apparent and are a relatively frequent cause of patient concern.

Correction of the outstanding ear requires a careful understanding of the discrete elements that comprise the normal ear. Careful anatomic analysis to determine the precise cause allows appropriate preoperative planning for the correction of a protruding ear. In selecting appropriate techniques from the many that are described in the literature, the surgeon must place greatest emphasis on reliably achieving a natural-looking improvement. In general, techniques that reposition rather than resect cartilage may be safer and are therefore preferred.

EMBRYOLOGY

Development of the auricle or pinna is initially visible in the 39-day-old embryo.[1] The auricle is formed from six mesenchymal proliferations (hillocks of His) at the dorsal ends of the first and second branchial arches surrounding the first branchial groove. These elements begin in the lower neck and ascend to the level of the eyes at the side of the head during gestation. Cartilage formation is visible in the seventh week, and hillock fusion occurs in the twelfth week of gestation. The recognizable shape of the auricle is visible by the twentieth week of gestation. Although each of the six hillocks was previously correlated to a specific element of the auricle, current studies suggest that the first branchial arch elements contribute to the tragus and the second branchial arch elements form the remaining structures.[2–4]

Despite much speculation, the functional role of the auricle in humans remains unclear. Unlike the pinnae of other species, the auricles of humans and primates have poorly developed external musculature and mobility. As an immobile structure, the auricle appears to facilitate localization of high-frequency sounds.[1] In other species, the auricle can be manipulated to determine the direction of sound and to protect the internal auditory structures. Voluntary apposition of the tragus and antitragus protects the ear from water and insect entry.

ANATOMY

Surface Features

The vertical axis of the ear along its longest dimension is rotated approximately 20 degrees from the vertical axis of the skull. The width should be approximately 55% of the length. "Idealized" dimensions are 63.5 mm by 35.3 mm for males and 59.0 mm by 32.5 mm for females.[3] The auricle is 85% of adult size by 3 years of age and is 90 to 95% of full size by 5 to 6 years of age, although it may elongate an additional 1 to 1.5 cm during life.[5] The helical rim along its lateral edge is approximately 1 to 2 cm from the mastoid skin. The angle of protrusion of the auricle or the auriculomastoid angle is usually between 15 and 30 degrees.

Among important surface features is the helix, the prominent rim of the auricle (Figure 37–1). Parallel and anterior to the helix is another prominence known as the antihelix or antihelical fold. Superiorly, the antihelix divides into a superior and an inferior crus, which surround the fossa triangularis. The depression between the helix and antihelix is known as the scapha or scaphoid fossa. The antihelical fold surrounds the concha, a deep cavity posterior to the external auditory meatus. The crus helicis, which represents the beginning of the helix, divides the concha into a superior portion, the cymba conchae, and an inferior portion, the cavum conchae. The cavity

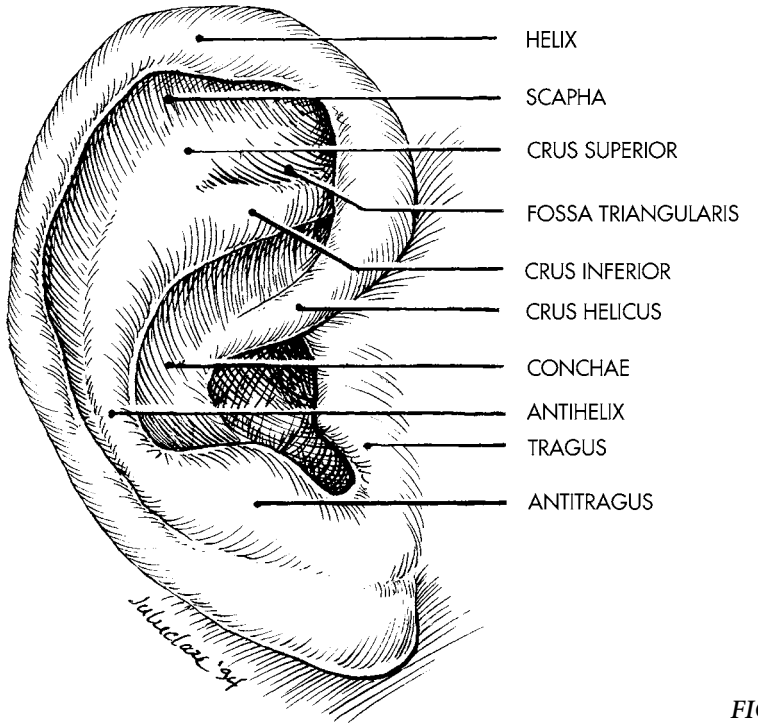

FIGURE 37–1. Auricular landmarks.

formed by the concha on the anterior (lateral) surface of the ear corresponds to a bulge or convexity on the posterior (medial) surface of the ear that is known as the eminence of the concha.

Anterior to the concha and partially covering the external auditory meatus is the tragus. The antitragus is posteroinferior to the tragus and is separated from it by the intertragic notch. Below the antitragus is the lobule that is composed of areolar tissue and fat. Anatomic variations such as preauricular tags or Darwin's tubercle, a small projection along the helix, may be present on the ear and should be recognized and documented in the preoperative assessment.[6]

Structural Features

Except for the lobule, the auricle is supported by thin, flexible elastic fibrocartilage. This cartilaginous framework is 0.5 to 1.0 mm thick and covered by a minimum of subcutaneous tissue.[4] The skin is loosely adherent to the posterior surface and helix of the auricular cartilage. The close approximation of the skin to the anterior surface of the cartilage provides the auricle with its unique topographic features (Figure 37–2).

The auricle has two groups of ligaments and musculature. The extrinsic ligaments connect the auricle with the side of the head and the intrinsic ligaments connect various parts of the cartilage to itself and to the external auditory meatus. The intrinsic group of muscles is rudimentary and serves no recognizable functional purpose. These include the major helix, minor helix, tragus, antitragus, transverse, and oblique muscles. The extrinsic muscles include the anterior auricularis, superior auricularis, and posterior auricularis. Certain individuals may have limited control of these muscles to "wiggle" the auricle.

The arterial supply of the auricle is derived from the anterior auricular branch of the superficial temporal artery, the posterior auricular branch of the external carotid artery, and a branch of the occipital artery. Venous drainage is from the posterior auricular vein and the superficial temporal, external jugular, and retromandibular veins. Lymphatic drainage from the ear moves anteriorly to the parotid lymph nodes and posteriorly to the cervical lymphatics.

Innervation to the extrinsic muscles is supplied by the facial nerve (cranial nerve [CN] VII). The posterior auricularis is innervated by the posterior auricular branch of the facial nerve proximal to the pes anserinus.[1] The temporal branch of the facial nerve innervates both the anterior and superior auricularis. Many nerve branches contribute to the sensory innervation of the auricle. The greater auricular nerve (C3) and the mastoid branch of the lesser

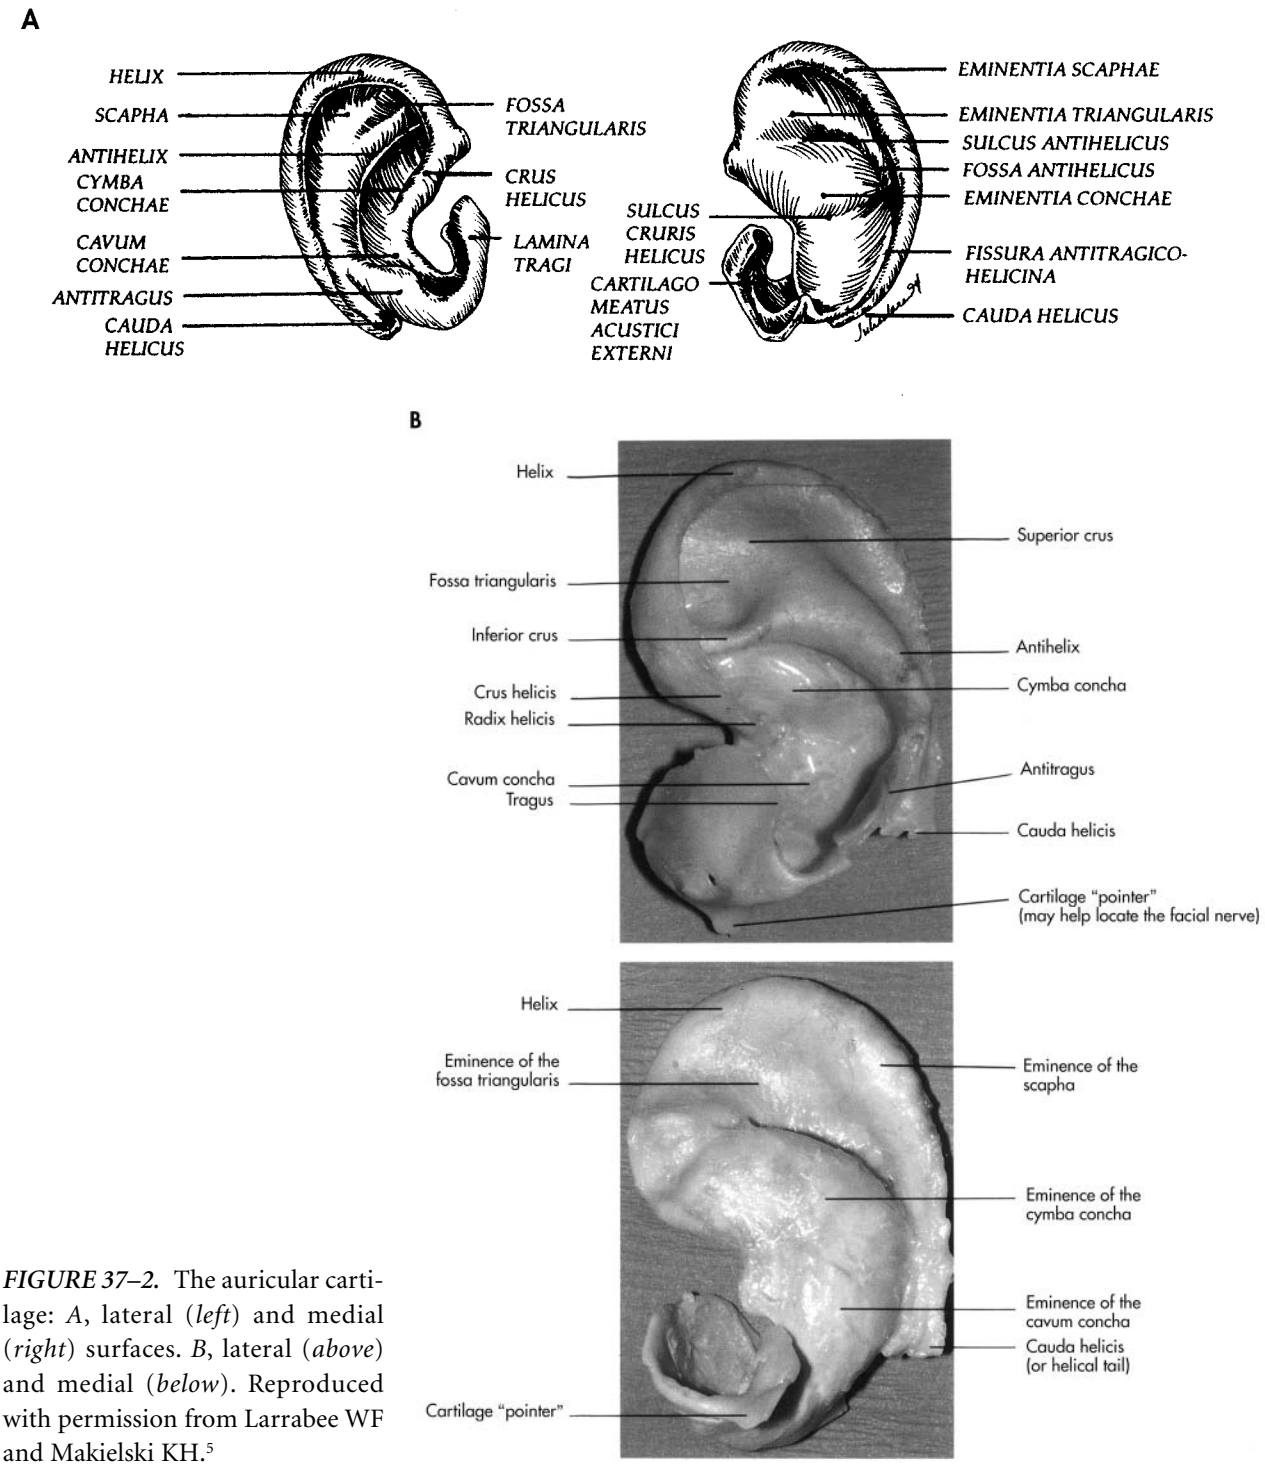

FIGURE 37–2. The auricular cartilage: *A*, lateral (*left*) and medial (*right*) surfaces. *B*, lateral (*above*) and medial (*below*). Reproduced with permission from Larrabee WF and Makielski KH.[5]

occipital nerve (C2, C3) carry sensation from the posterior surface of the auricle. The auriculotemporal nerve (CN V_3) provides sensory innervation to the anterosuperior portion of the auricle. Branches from the facial nerve (CN VII) and Arnold's nerve (CN X) innervate the concha.[4–6]

PATHOGENESIS OF THE OUTSTANDING EAR

Malformations of the auricle are not unusual and range from complete absence to macrotia. The incidence of abnormally protruding ears is approxi-

mately 5% in Caucasians.[7] As the auricle assumes a recognizable form by the end of the twelfth gestational week, the greatest number of malformations occur. Although they may be a dominant or recessive trait, most ear deformations are inherited as an autosomal dominant trait with incomplete penetrance.[8] Understanding the pathogenesis of these deformities aids the plastic surgeon in developing an operative plan.

Davis and Kittowski pointed out that during development, the ear protrudes from the head because the crura of the antihelix are not formed.[9] The margins of the auricle curl in the sixth fetal month to form the helix, followed by the folding of the antihelix and the development of the superior and inferior crura. The formation of the antihelix and its crura brings the auricle closer to the head.

The most common cause of outstanding ears is the lack of development of the antihelical fold (Figure 37–3). This malformation of the antihelix is present in approximately two-thirds of all cases of protruding ears. However, other pathologic features may also contribute to the outstanding ear. A wide, protruding conchal wall is present in approximately one-third of all cases. Additionally, the prominent concha is often accompanied by a thickened antitragus.[10]

The outstanding ear is a single entity within a wide spectrum of auricular malformation. Depending on the degree of severity, the protruding ear may also have structural abnormalities seen in the classically described "lop ear" and/or "cup ear." The term "lop ear" is used to describe a deformity of the helix characterized by a thin, flat ear that is acutely folded downward at the superior pole. In the "cup ear"

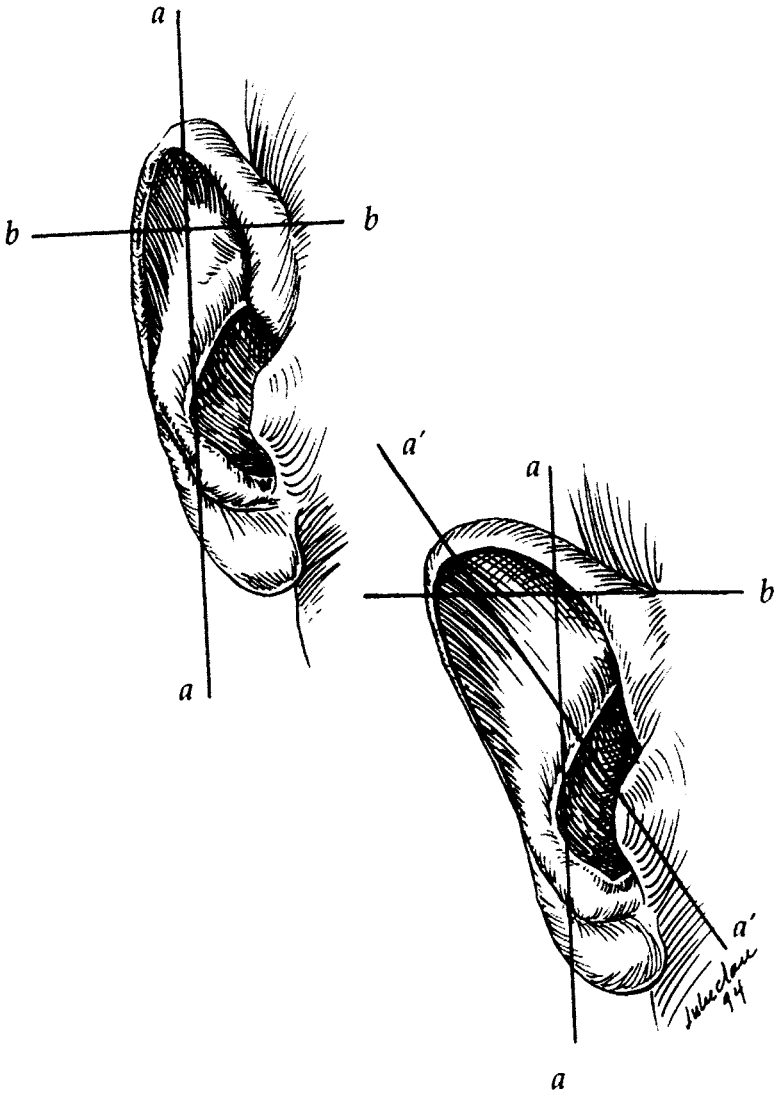

FIGURE 37–3. The most common pathology of the outstanding ear is underdevelopment of the antihelical fold. In the *upper figure*, the customary relationship of the ear to the head is seen. The plane of the scapha (represented by *a-a*) makes a right angle with the plane of the concha (represented by *b-b*). In the *lower figure*, *a′-a′* makes a much broader angle with *b-b*.

deformity, weak cartilage with resulting limpness of the auricle results in cupping or deepening of the conchal bowl. The "cup ear" is often smaller than normal and folded on itself. Poor development of the superior portion of the ear results in a short, thickened helix and a deformed antihelix (Figure 37–4). The surgical techniques used to correct the outstanding ear may be applied to the "lop ear" and to the "cup ear," but the correction of these malformations extends beyond the scope of this chapter.[7–10]

Preoperative Evaluation

Patients with outstanding ears typically present early in childhood, although some present in adulthood. The optimal age for surgical correction is between 4 and 6 years of age. At this age, the auricle is near or at full adult size, and the child is capable of participating in the postoperative care of the ear. Also, the child is typically about to enter school, and, unfortunately, children with protruding ears are commonly subjected to severe ridicule by their young peers.[11–13]

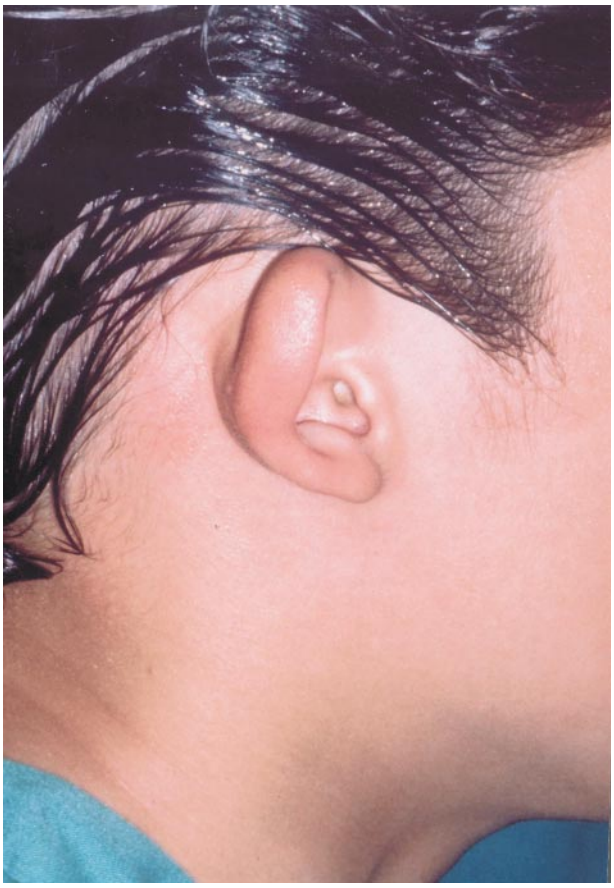

FIGURE 37–4. "Cup ear" deformity.

A comprehensive and quantitative approach for complete evaluation of the patient's ears is essential.[12] The auricles are compared with each other, both in overall symmetry and projection from the head. The proportion of the auricles to facial features and the head must be appreciated. The appearance of the auricles is judged by the symmetry from the front along the lateral helical rim. The superior aspect of the auricles should be level with the eyebrows. Additionally, development of the surface landmarks should be noted, along with additional features such as preauricular tags. The individual features within the auricle should be assessed in relation to other surface landmarks. For example, there should be a balance between the size and prominence of the helix and antihelix or between the tragus and antitragus. Finally, the redundancy of the postauricular skin should be noted, and the thickness and stiffness of the cartilage should be assessed and compared between the ears.

Precise measurements can be made to document the height, width, and axis of the auricle. Additionally, the angular relationships of the auricle and concha to the mastoid can be documented. Symmetry between the two ears can also be compared by a standard set of measurements, which can provide standards for assessment preoperatively and intraoperatively.[13]

Although the classic description of the outstanding ear attributes this deformity to the absence of the antihelical fold, two other attributes must be carefully assessed. Overprojection of the concha and/or the lobule will also contribute to the appearance of the protruding ear. Consideration and correction of these elements will contribute to the ultimate goal of a normal-appearing auricle.

As with any cosmetic procedure, preoperative and postoperative photographs are absolutely critical for careful planning of the surgical procedure and to document changes to the auricle. Uniform lighting and views of the auricle should be used before and after the surgery. The photographs should include a full-face anterior and full-head posterior view, an oblique/lateral view of both sides of the head, and close-up views of the ears. For patients with long hair, a hair clip or headband can be useful to prevent the hair from obstructing accurate photodocumentation.

GOALS OF SURGERY FOR THE OUTSTANDING EAR

The primary goal of otoplasty is to re-establish a "natural" appearance to the auricle and the relationship of the auricle with the head. Careful assessment of the outstanding ear, as described above, will reveal those individual elements of the auricle that contribute to its abnormal appearance. McDowell provided guidelines that should be considered when undertaking correction of the protruding ear[14]:

1. Symmetry of shape and protrusion of the ears should vary no more than 3 mm. Correction will often require bilateral alterations.
2. Maintain the normal appearance and curvature of the auricular components. The helix should arch backward naturally from its crus. It should be furled at its superior aspect and lead smoothly to the lobule. The antihelix should similarly curve forward into the superior crus.
3. The distance of the helical rim from the mastoid skin should be 10 to 12 mm at the superior pole, 16 to 18 mm at the middle one-third, and 20 to 22 mm at the level of the cauda helix. The proper auriculomastoid angle is 15 to 25 degrees. Achieving these distances may require reduction of an overly large conchal bowl.
4. The helical rim should not be seen beyond the antihelix from the frontal view, at least down to the mid-ear.
5. The postauricular sulcus should be preserved.
6. Protrusion of the upper one-third of the ear must be corrected. Protrusion of the lower ear may be tolerable, but only if the superior portion of the auricle has been corrected.
7. All visible surfaces should be smooth, without buckles, puckering, scars, and ridges that would reveal operative manipulation.

Although the physical dimensions and structural features are essential in the evaluation of the outstanding ear, the subjective assessment of the patient and his/her parents is also important. The surgeon should understand precisely what a patient dislikes about his/her ears and what he/she hopes the operation will achieve. This will help the surgeon determine if surgery can achieve the patient's desires and whether the patient's goals are realistic. Thus, the surgeon can explain the specific goals and limitations of otoplasty to the patient and his/her parents. Also, at times, unrealistic expectations for the surgery may exist. If this is the case, surgery should be deferred, and referral for counseling may be appropriate.

Coexisting anomalies, bleeding disorders, and any history or tendency toward hypertrophic scarring or keloid formation should be noted and addressed preoperatively.

SURGICAL TECHNIQUES: A HISTORICAL PERSPECTIVE

In 1845, Dieffenbach described correction of the outstanding ear through removal of skin from the back of the ear and suturing of the auricular cartilage to the periosteum of the mastoid bone.[15] In 1881, Ely and others described similar procedures with the additional excision of the posterior portion of the auricular cartilage.[16] More complicated procedures were later described that involved complex cartilage manipulations and even the use of fascia lata. However, these procedures are now primarily of historical interest because they resulted in ears that were abnormally flattened against the head and that often had sharp visible edges, excess skin wrinkling, and other problems.

In 1910, Luckett identified the absence or underdevelopment of the antihelical fold as the cause of the classic protruding ear.[17] His technique for the correction of this deformity involved the excision of a crescent-shaped segment of posterior skin and cartilage from the intended site of the antihelical fold and re-creation of the antihelix by everting and suturing together the cartilage edges. Unfortunately, this approach resulted in less than optimal results and fell out of favor. Nevertheless, Luckett's identification of the primary cause of protruding ears led to the development of currently employed techniques.

Otoplasty techniques have evolved toward the goal of a natural-appearing ear that is not too close to the head and does not have sharp ridges along the anterior surface of the auricle. Davis and Kittowski described a technique in which the new antihelix fold was placed in line with the inferior crus. In their approach, skin was removed from the posterior auricular surfaces of the concha and mastoid.[9] Cartilage was then removed from the region of the new antihelix, and the remaining edges were everted and sutured together.

Young would later modify this approach by creating the new antihelix along the superior crus.[18] Becker advocated multiple incisions along natural

lines of the cartilage to shape a new antihelix and to conceal surgical ridges along normal folds of the auricle.[19] However, this method still required excision of cartilage. Although the results from this approach were gratifying, like other cartilage-splitting procedures, the excision of cartilage from the antihelix occasionally left a sharpened ridge. This ridge was reported to be acceptable to most patients at the time but was disconcerting to the surgeon seeking a natural-looking result.[6]

In the late 1950s, Gibson and Davis demonstrated techniques to modify the shape of cartilage.[20] Disruption of perichondrium from one side of the cartilage led to bowing of the cartilage toward the surface with the intact perichondrium. Nachlas and associates and Stenstrom and Heftner described procedures based on this cartilage-sculpting principle.[11,21] Access to the anterior surface of the auricular cartilage involves a posterior auricular incision and either dissection over the helical rim or an incision through the auricular cartilage. Various instruments such as a wire brush, rasp, or diamond bur are used to disrupt the anterior perichondrium to permit bowing of the cartilage to form a new antihelix. These techniques are technically complex, requiring a great deal of surgical experience.

Mattress Suture Otoplasty

In the mid-1960s, Mustarde described a corrective otoplasty technique that gained quick and ready acceptance and wide popularity as it was seen as a marked improvement over existing techniques.[22] Horizontal mattress sutures placed in the auricular cartilage along the scapha re-create the natural curve of the antihelix, blending gently into the scaphoid fossa. Dimensions of the horizontal mattress sutures have been described with outer cartilage bites of 1 cm separated by 2 mm. The distance between the outer and inner cartilage bites is 16 mm (Figure 37–5).[13]

Advantages of this approach included that no through-and-through cartilage incisions are necessary, so the potential sharp edges of other techniques are avoided. Also, transperichondrial sutures may be positioned, test-tied, and then maintained or replaced as necessary to develop a natural antihelix. This was in contrast to the cartilage-splitting approach, in which the cartilage incision was irreversible and uncorrectable. Furthermore, the procedure has satisfactory long-term results and requires less dissection of the ear and less surgical trauma than other approaches. Surgeons also found this approach relatively easy to learn and to teach.

Whereas Mustarde's technique addressed the most common deformity of the protruding ear, the absent antihelix, Furnas described a suture fixation method to address the deep conchal bowl.[23] Furnas described the placement of a permanent suture to adjust the apposition of the conchal bowl to the mastoid periosteum, decreasing the angle between the concha and the mastoid. Additionally, a suture from the fossa triangularis to the temporalis fascia may further correct conchal height or contour. Care must be taken when placing the suture to avoid rotation of the auricle anteriorly with resultant external auditory canal narrowing.

Combination Techniques

Subsequent to the description of mattress suture techniques, cartilage-cutting approaches have remained useful in combination with suture tech-

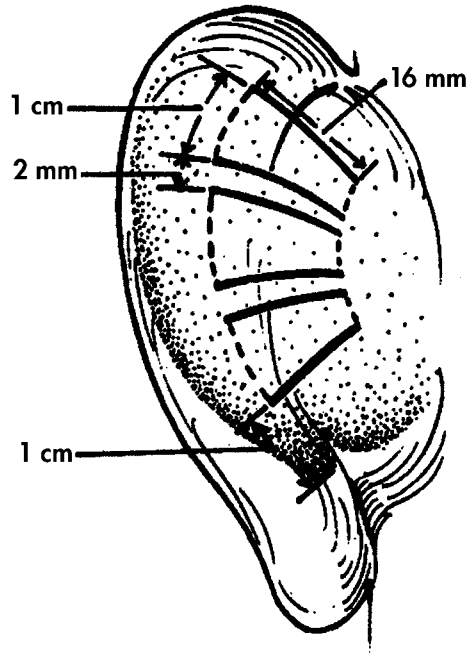

FIGURE 37–5. Posterior view demonstrating placement of sutures in a Mustarde suture otoplasty technique. The sutures must be placed through cartilage and anterior perichondrium but not through anterior skin. They should be placed close enough together so that the ear does not buckle when the sutures are secured. Reproduced with permission from Nachlas NE et al.[13]

niques. Pitanguy and Flemming devised a method to create an island flap of cartilage that was secured anteriorly to the rest of the conchal cartilage by placement of permanent horizontal mattress sutures.[24] Converse and Wood-Smith described a technique of thinning portions of the cartilage between incisions that followed natural lines of the cartilage. This technique facilitated the creation of an island of cartilage that sets anteriorly to the rest of the conchal cartilage to refashion the antihelix.[25] The technique of Farrior requires the removal of multiple longitudinal wedges from the level of the superior crus and the location of the new antihelical fold.[26] The auricular cartilage is then incised to permit shaping by the placement of horizontal mattress sutures.

All of these techniques have been employed by experienced surgeons to create a gently curved appearance to the antihelix and a pleasing appearance to the postoperative ear. The cartilage-cutting techniques may be especially useful when large anatomic deformities must be corrected or when the auricular cartilage is especially inflexible or thick. However, the caveat must be repeated that these are technically difficult procedures that require substantial surgical experience.

Mattress Suture Otoplasty: Method of Tardy

Mattress suture techniques with modifications are widely used today. One approach will be reviewed in detail here (Figure 37–6).[6] Suture fixation techniques are relatively easy to perform and do not require incisions or excisions of the cartilage that permanently alter cartilage characteristics or leave permanent postoperative stigmata.

Although the horizontal mattress suture is the primary mode of repair in this technique, it is important to emphasize the importance of addressing thick and inflexible cartilage. The mattress suture procedure is frequently augmented by thinning, weakening, and occasionally limited incision of the cartilage to achieve natural and symmetric results. Thinning the cartilage by shave excision or with a bur and incisions through the cartilage to facilitate folding will reduce the tension on the horizontal

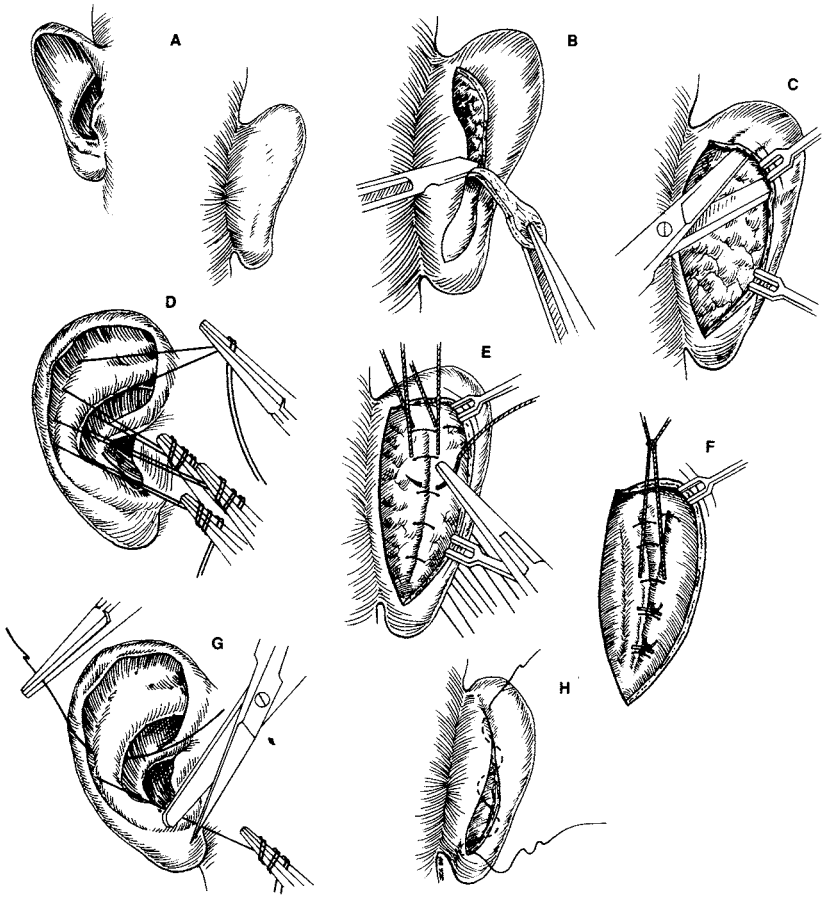

FIGURE 37–6. Modified mattress suture otoplasty technique (method of Tardy). *A*, Anterior and posterior outstanding ear deformity. *B*, Conservative excision of postauricular skin for surgical access. *C*, Conservative undermining of the skin. *D*, Temporary silk sutures placed as guides to accurate placement of permanent buried transperichondrial mattress sutures. *E*, Temporary sutures indicate sites for mattress suture placement. *F*, Transperichondrial mattress sutures positioned and test-tightened to determine the precise effect in creating a new antihelical fold. *G*, Temporary guide sutures removed. *H*, Postauricular incision closure shown here with a running intradermal absorbable suture. Alternative methods of incision closure are acceptable.

mattress sutures. Thus, every surgeon performing otoplasty must be comfortable addressing the protruding ear with more than one technique. Knowledge of one technique only is inadequate.

In the operating room, the ears are reassessed with regard to the causes of protrusion. Special attention is directed to the depth of the conchal bowl, the position of the lobule, and the strength and flexibility of the auricular cartilage. The periauricular areas are prepared with a sterile cleansing solution (hexachlorophene or povidone-iodine) and draped with sterile towels. The postauricular skin and subcutaneous tissue are infiltrated with local anesthetic (eg, 1% lidocaine with 1/100,000 epinephrine) for analgesia and hemostasis. The head is draped in a manner that permits comparison of both ears intraoperatively.

A fusiform or "elliptical dumbbell"-shaped incision is made posteriorly, exposing the portion of auricular cartilage in the area of the soon-to-be-formed antihelix. Care is taken to avoid removal of skin in the postauricular sulcus, which would cause flattening of the ear against the head. The skin is excised, leaving the posterior deep soft tissue and perichondrium that facilitates later scar formation, which is the strength of the repair. The remaining skin is undermined to the postauricular sulcus and to the helical rim. Meticulous hemostasis should be maintained at this juncture and throughout the procedure.

A deep conchal bowl, when it exists, may be addressed initially. Undermining along the posterior aspect of the cartilage reveals the posterior eminence of auricular cartilage underlying the conchal bowl. Excess cartilage in the posterior eminence frequently causes this area to impinge on the mastoid process, preventing the ear from resting closer to the head. Using a scalpel, small disks of cartilage can be shaved from this region to allow retropositioning of the auricle. This cartilage sculpturing is often sufficient to retroposition the ear and makes conchal setback sutures unnecessary. Excision of cartilage in this area will weaken the cartilage, reducing overall tension on the mattress sutures that will be placed in the antihelix region. *Great care is taken to achieve partial-thickness excision of cartilage, and through-and-through excision is avoided*. Nevertheless, on occasion, the auricle with a very deep cavum conchae may require conchal setback sutures or, rarely, the excision of a semilunar segment of cartilage within the cavum conchae to reconstruct the neoantihelix properly.

The new antihelix is created by manipulating the auricular cartilage and blending this fold into the inferior crus. Temporary 4-0 silk marking sutures may be placed from anterior to posterior to mark the location of the horizontal mattress sutures and thereby precisely guide their placement. This method avoids the use of ink or sharp needles to guide placement of the permanent sutures.

Once the new antihelix has been marked, 4-0 braided nylon (Tevdek) horizontal mattress sutures are placed sequentially, from caudal to cephalad along the neoantihelical fold. These horizontal mattress sutures are placed through the posterior perichondrium, auricular cartilage, and anterior perichondrium. Careful palpation with the free hand along the anterior surface of the auricle ensures that the needle does not pass through the anterior skin. Incorporation of the anterior perichondrium in the horizontal mattress suture is necessary to prevent the suture from tearing through the cartilage when it is tied down. Additionally, the sutures are not placed near the incision site to prevent future suture extrusion.

The horizontal mattress sutures are placed from caudal to cephalad and test-tied. Sutures are removed and replaced as necessary to achieve the desired fold on the auricular cartilage and then held with a hemostat. The sutures are tied securely once the antihelix has been completely formed. Typically, four or more mattress sutures are necessary to distribute the tension evenly and to hold the repair until sufficient scar tissue forms, usually in 2 to 3 months. If the sutures are adequately placed, it is unnecessary to overcorrect the repositioning of the auricle since the sutures will maintain their position without slippage. The postauricular skin is closed with a fast-absorbing 5-0 chromic gut suture in a continuous fashion.

Following creation of a neoantihelical fold, the position of the lobule is assessed. Ideally, the helix and antihelix should be in the same plane as the lobule. Commonly, simple skin excision and reattachment are sufficient to position the lobule in the appropriate plane, although more extensive intervention may be required at times.

The procedure is completed on the opposite ear. Frequent comparison between both ears ensures as symmetric a repair as possible. Given the nature of auricular deformities, complete symmetry between both ears is nearly impossible (Figure 37–7).

At the conclusion of the surgery, a conforming dressing is applied followed by a bulky head dress-

D

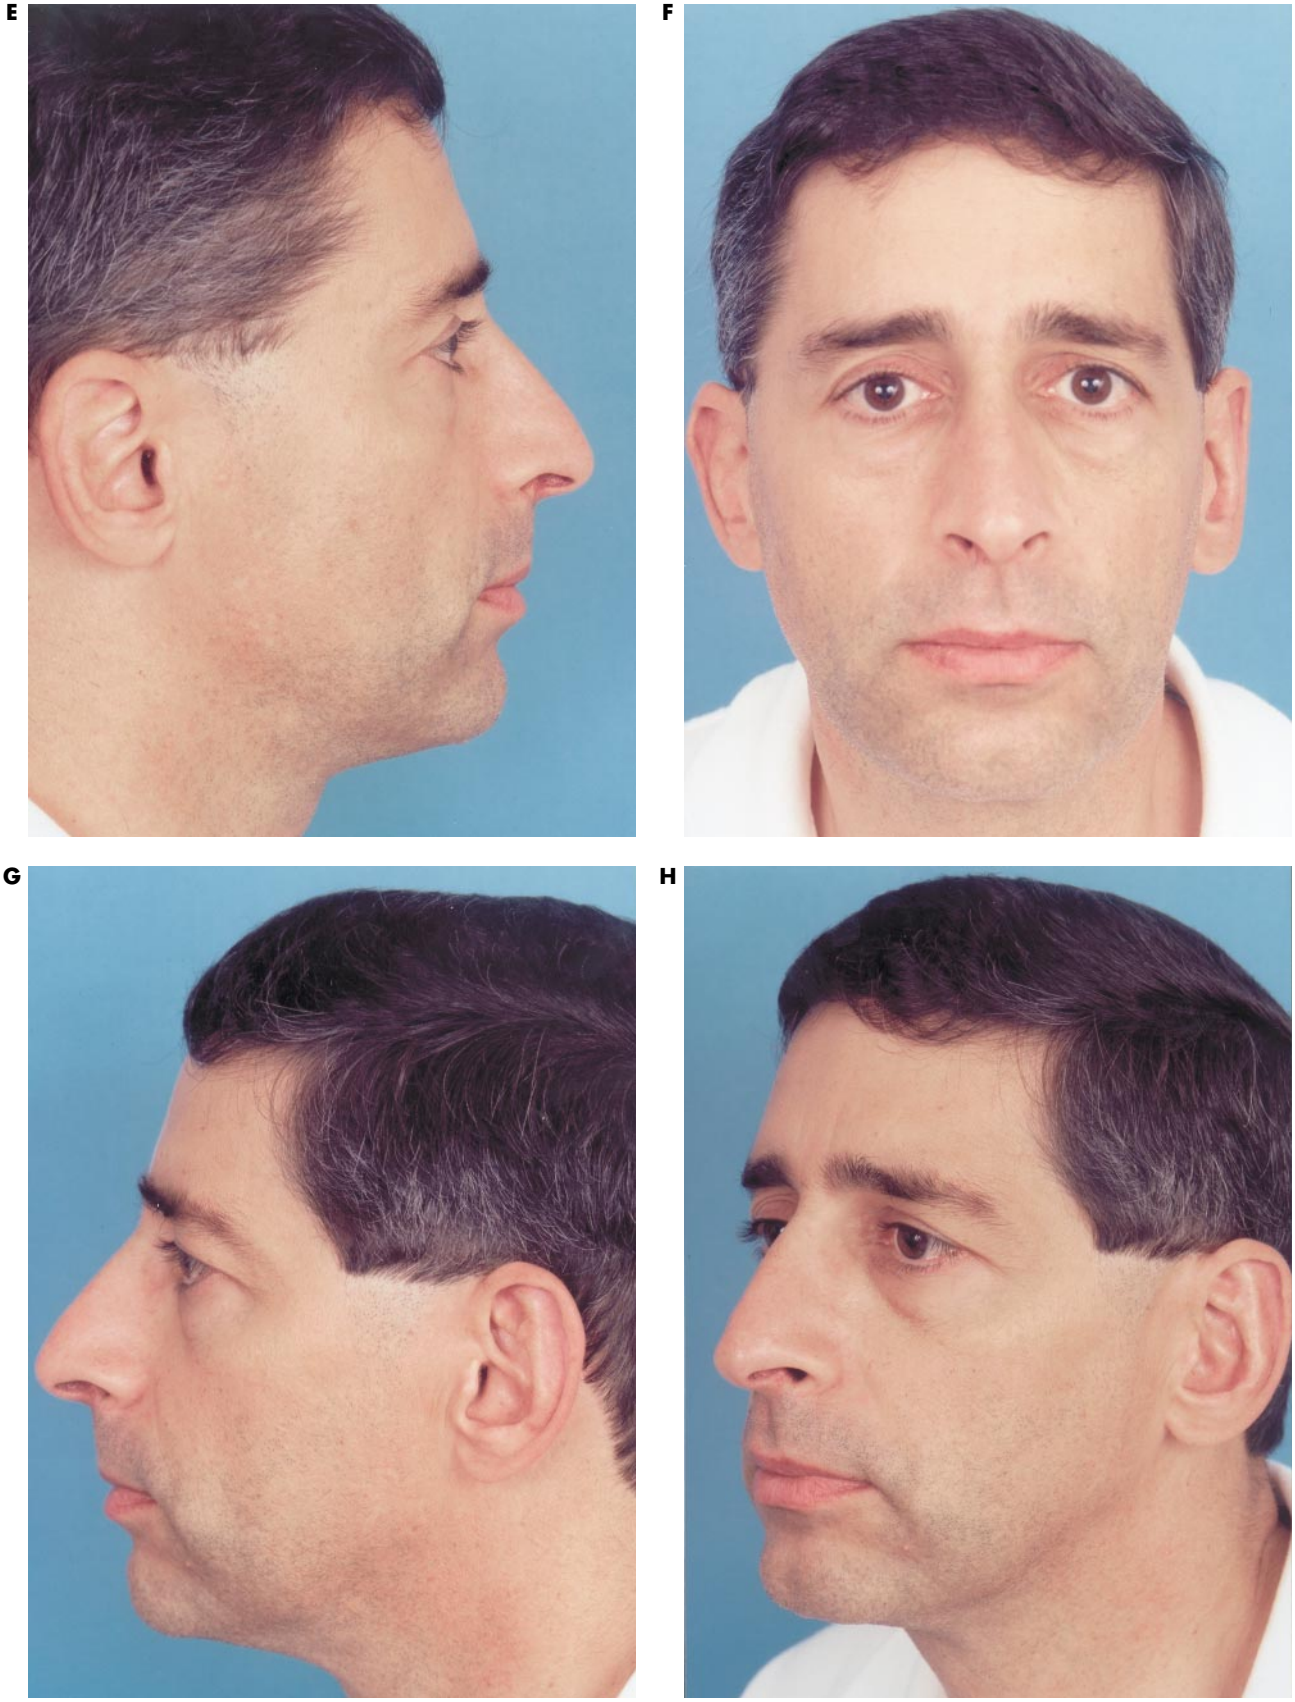

FIGURE 37–7. Preoperative (*A* to *E*) and postoperative (*F* to *H*) photographs of a patient who underwent left otoplasty with the technique described here. This patient had a relatively minor deformity of the right ear and was not disturbed by it, so only a left otoplasty was performed.

ing, which is removed and replaced with a smaller dressing that the patient wears for an additional 36 to 72 hours.

Outcomes and Complications

Surveys have demonstrated high rates of patient satisfaction (82 to 95%) following otoplasty.[21,27,28] Unsatisfactory cosmetic results were reported in 4.8 to 13.6% of cases; the rate was often higher for cartilage-cutting techniques.[29] Rates of relapse of auricular protrusion range from 2 to 13%.[27,30,31] Interestingly, more than almost half of the patients in this group reported an injury in the postoperative period.[30]

Regardless of the surgical techniques employed, complications (Table 37–1) are reported to occur at rates ranging from 7.1 to 11.4%.[13,27,28,30] In the early postoperative period, patient concerns regarding postoperative pain or periauricular "tightness" should be taken seriously as they may herald the presence of a hematoma. Physical examination might reveal fluctuance under a tense, dusky area of skin. The incidence of hematoma formation is about 3% and occurs slightly more often in cartilage-cutting techniques.[28]

TABLE 37–1. Otoplasty Complications

Early complications
Hematoma
Infection
Perichondritis/chondritis and permanent auricular deformity
Late complications
Paresthesia/hypersensitivity
Suture extrusion
Suture granuloma formation
Skin necrosis
Hypertrophic scarring
Keloid fomation
Anatomic/esthetic complications
Inadequate correction
Antihelix overcorrection and hidden helix
Telephone ear
Prominent concha
Malposition of the lobule
Sharp cartilage edges
Distortion of the external auditory canal (stenosis)

The cartilaginous framework is avascular, and incisions of the cartilage and manipulation of the thin skin–subcutaneous envelope may compromise the structural integrity of the auricle. Meticulous hemostasis during otoplasty and a postoperative pressure dressing are valuable measures for preventing postoperative complications. Immediate and late complications, if unrecognized, may lead to undesirable anatomic sequelae. Chondritis and necrosis of the auricle are among the most feared and potentially devastating complications. Early manifestations of these situations must be quickly identified and managed to protect the integrity and appearance of the auricle. Intraoperatively, great care must be taken during dissection, and hemostasis must be diligently maintained. In the event that a hematoma forms, the wound must be opened and the hematoma evacuated rapidly. Otherwise, infection leading to perichondritis, chondritis, and permanent cosmetic deformity may ensue.

Infection may occur secondary to an unevacuated hematoma but may also result from lapses in sterile technique or the presence of contaminated suture. Evolution to perichondritis occurs in approximately 1% of all cases.[28] Treatment must be aggressively implemented to prevent chondritis and resulting cartilage necrosis and auricular deformity. Antibiotic treatment must empirically cover *Pseudomonas aeruginosa*. Persistent infection may also necessitate the removal of permanent sutures and débridement locally. Preoperatively, a single dose of a broad-spectrum antibiotic can minimize the risk of infection.

In the late postoperative period, patients may complain of paresthesias and hypersensitivity, especially to cold temperatures in the weeks to months following otoplasty. These symptoms may indicate that injury may have occurred that is related to aggressive traction on the sutures intraoperatively or as a result of nerve transection. The complaints usually resolve or become tolerable over the next 4 to 6 months without active intervention.

Over the long term, permanent sutures may induce granuloma formation or be extruded. Suture extrusion may occur in as many as 10% of patients, but, typically, the area heals without adverse sequelae. In placing sutures, care must be taken in distributing cartilage tension over an adequate number of permanent cartilage-shaping sutures. Additionally, techniques to weaken the cartilage may decrease the

overall tension applied to the sutures and decrease the risk of suture extrusion.

As the wound heals, there is some risk of hypertrophic scarring and keloid formation, especially on the posterior surface. This is more common in younger patients, patients with a history of scarring, and in African American and Asian American patients. Conservative treatment includes triamcinolone acetonide injection weekly. Scar excision and closure without tension are also a consideration.

Esthetic complications arise from either incomplete or overly aggressive treatment of the original deformity. Although not considered a deformity in the nonoperated ear, a helical rim that is retropositioned relative to the antihelix is undesirable and is usually secondary to overcorrection of the neoantihelix. This deformity can be seen if Mustarde sutures are drawn too tightly or if overaggressive skin excision is undertaken.

In undertaking conchal repositioning, care must be taken in suture placement. Sutures placed too far posteriorly on the concha or too far anteriorly on the mastoid can result in stenosis of the external auditory canal.

Overcorrection of the middle portion of the ear leads to a "telephone ear" deformity owing to the relative prominence of the superior and inferior poles. One commonly described cause of the telephone ear deformity is over-reduction of the hypertrophic concha. Alternatively, overcorrection of the upper and lower poles may result in the "reverse telephone ear" deformity.

As discussed in this chapter, otoplasty methods that incise rather than reposition cartilage run the risk of visible sharp edges or prominent creases.

With significant attention focused on the antihelical fold and addressing the cavum concha, the position of the lobule may be overlooked. The lobule and helix should lie in approximately the same plane. Although amputation of the cauda helices or cauda repositioning is sometimes necessary, most commonly, excision of a soft tissue triangular segment from the posterior lobular surface is effective.

CHAPTER 38

Nasal Reconstruction and Rhinoplasty

M. Eugene Tardy Jr, MD

Incisions and Excisions

External nasal incisions should be sited in inconspicuous areas, leading to minimal distortion of nasal features and symmetry.[1] *Junctions of facial landmarks* hide surgical scars well; therefore, incisions along the nasomaxillary groove, the alar-facial junction, and the columellar-labial (or nasolabial) junction heal inconspicuously. Lesion excision in these areas should be preplanned so that the ultimate suture line(s) will symmetrically re-create these natural landmark borders. Strict attention to maintaining or re-creating symmetry leads to superior esthetic results. Local pedicle flaps transposed into these areas should be similarly designed.

Natural folds created by the synergistic interaction of muscle groups at the root of the nose provide ideal sites for incision and excision camouflage. Horizontal, oblique, and vertical wrinkles apparent in this area, blending into the glabellar region, provide wide latitude in scar camouflage in the aging patient (Figure 38–1). Redundant nasal and glabellar skin allows considerable excisional license without sacrificing normal landmarks. It is usually possible and always preferable to reconstitute these natural folds during the course of repair.

Alternate, but less ideal, incision sites exist. Midcolumellar incisions generally heal with minimal scar evidence,[2] although the lateral columellar incision lends similar surgical access and creates less potential scar. Staggered or W-shaped incisions in the caudal midcolumellar area are acceptable for tumor excision and as an approach to external rhinoplasty procedures.

Congenital nasal tumors (dermoid cysts, lymphangiomas) in children require incisional approaches through the nasal dorsum, with wide exposure required for total excision. A precise midline dorsal incision or semilunar transverse incision creates a visible but symmetric scar that, if meticulously repaired, fades acceptably with time. Open rhinoplasty incision approaches may be preferable.

Mature nasal scars on exposed nasal epithelium (ie, not camouflaged in landmark junctions or natural folds) may be rendered less conspicuous with superficial mechanical dermabrasion. Minimal

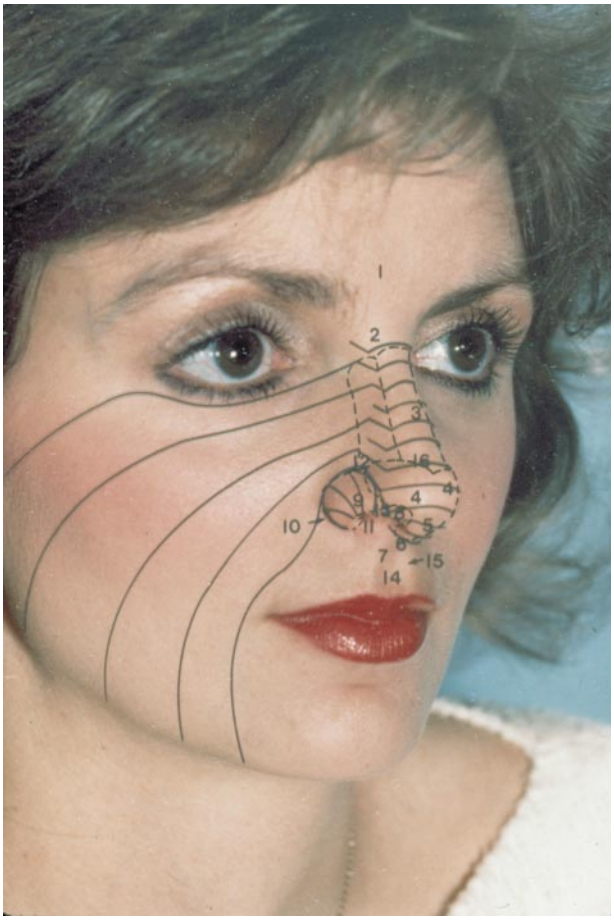

FIGURE 38–1. Favorable lines for incision and excision in the nasal and paranasal region.

scars resulting from laceration repair or pedicle flap reconstruction of the lower half of the nose respond particularly well to dermabrasion techniques (widened, depressed scars caused by inexact dermal healing require re-excision and meticulous repair; dermabrasion is ineffective in such cases).

A useful technique for diminishing the extent of a large nasal excisional defect, a cardinal principle in defect repair, is to remove a portion of an existing nasal hump (bone and cartilage), creating a relative excess of skin for repair, proportionally diminishing the defect, and favorably improving the patient's profile and nasal length.

Several areas of nasal anatomy should be considered inviolate because scars there almost always heal with unacceptable results. Incisions or lacerations cutting across the delicate alar rim remain conspicuous (notching is a common sequela), as may incisions cutting across the columella in transverse fashion. Because most incisions bridging a concavity contract and heal as a tight, tethered "bowstring" contracture, transverse incisions crossing the concave upper lateral nasal skin toward the inner canthus must be avoided or repaired with multiple Z-plasty techniques.

Finally, the nasal defect created by traumatic laceration or lesion excision provides the surgeon with an unparalleled opportunity to study exposed nasal anatomy and framework, aiding considerably in an understanding of the delicate, precise structural rearrangement necessarily less apparent during septorhinoplasty.

Epithelial Reconstruction

Epithelial nasal defects commonly result from minor to major excision of nasal lesions, benign or malignant. Occasionally, epithelial reconstitution is necessary for replacement of irradiated nasal skin of poor quality. Traumatic avulsion defects demand immediate repair if esthetics are to be properly served and unacceptable scarring and contracture avoided. Because it occupies the conspicuous central portion of the face, the nose draws immediate attention to itself, and nasal defects, however minor, accentuate that attention. Therefore, camouflage repair of nasal defects deserves high esthetic and functional priority, with strict attention to achieving reconstructive symmetry by repair that respects topographic subunit principles (Figure 38–2).

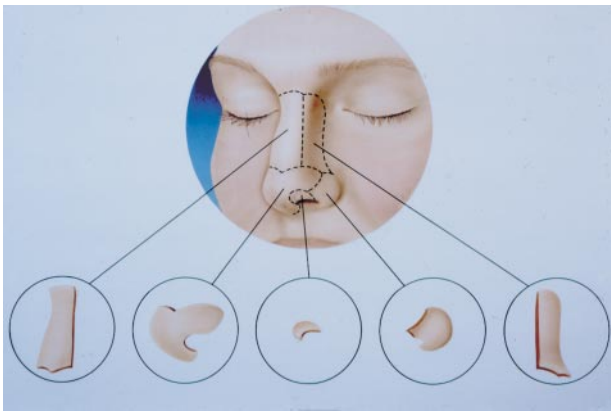

FIGURE 38–2. Topographic subunits of the nose (after Burget and Menich[1]).

Until recent decades, the split-thickness or full-thickness skin graft served the surgeon well as an effective tissue for immediate epithelial replacement. Skin is readily available around the head and neck, its rate of successful "take" is high, and one-stage repairs conserve the patient's time and the surgeon's time and skills.

Gradually, however, the multiple advantages of adjacent or regional pedicle flaps become apparent to head and neck surgeons interested and skilled in a higher degree of esthetic camouflage, effective one-stage (or, on occasion, two-stage) repair, and superior defect effacement and color match. Properly designed and executed flaps should replace missing tissue with like tissue, a fundamental concept in plastic surgery. Furthermore, flaps possess the following distinct advantages over skin grafts:

1. They provide their own blood supply.
2. They contract less than grafts.
3. Cosmetically and chromatically, they are superior to grafts.
4. They provide bulk and lining.
5. They create superior protection for bone and cartilage.
6. They resist infection.
7. They undergo minimal pigment change.
8. They may incorporate cartilage, bone, or skin in composite fashion.

In their simplest form, adjacent flaps may be classified as *advancement, rotation*, *transposition*, and *interposition* flaps, all designed and derived from tissue adjacent to the nasal defect. Regional flaps are best

used when more abundant tissue is required for repair or adjacent skin is inadequate or unsatisfactory. They use unipedicled flaps of similar texture, thickness, and color from adjacent regions (glabella, forehead, scalp, cheek, neck). A second stage of repair is required to transect the bridge of the flap, reconstructing both the defect and donor site to render them inconspicuous. Regional flaps are invariably designed and transposed from areas of relative epithelial excess and redundancy in the head and neck.

Advancement Flaps

Advancement flaps are created when tissue is undermined and advanced generally in a straight line, along the same axis as the defect.

Mobile cheek skin may be undermined and advanced to repair heminasal defects of varying proportions (Figure 38–3, A and B). Design is such that ultimate closure falls in the nasolabial fold and infraciliary area and at the junction of the nose to the face (Figure 38–4, A to C). Where possible, the nasolabial fold should be preserved or reconstituted to achieve bilateral facial symmetry, with incisions falling in the nasolabial crease. The inherent elasticity and redundancy of skin allow a variety of geometric designs in creating advancement flaps with ultimate suture lines lying in favorable areas for camouflage.

Advancement flaps along the dorsum of the nose may be created after transverse fusiform excision of lesions, diminishing the defect when possible by shortening the nose and accomplishing hump removal.

Rotation Flaps

A local flap in which the axis is created in a plane different from that of the defect is termed a rotation flap. Rotation flaps are extremely useful in nasal repair, particularly when designed so that the donor site may be closed in an inconspicuous straight line, natural fold, or landmark junction. Typical ideal donor sites are the nasolabial fold (Figure 38–5, A and B) and glabellar regions (Figure 38–6, A and B).

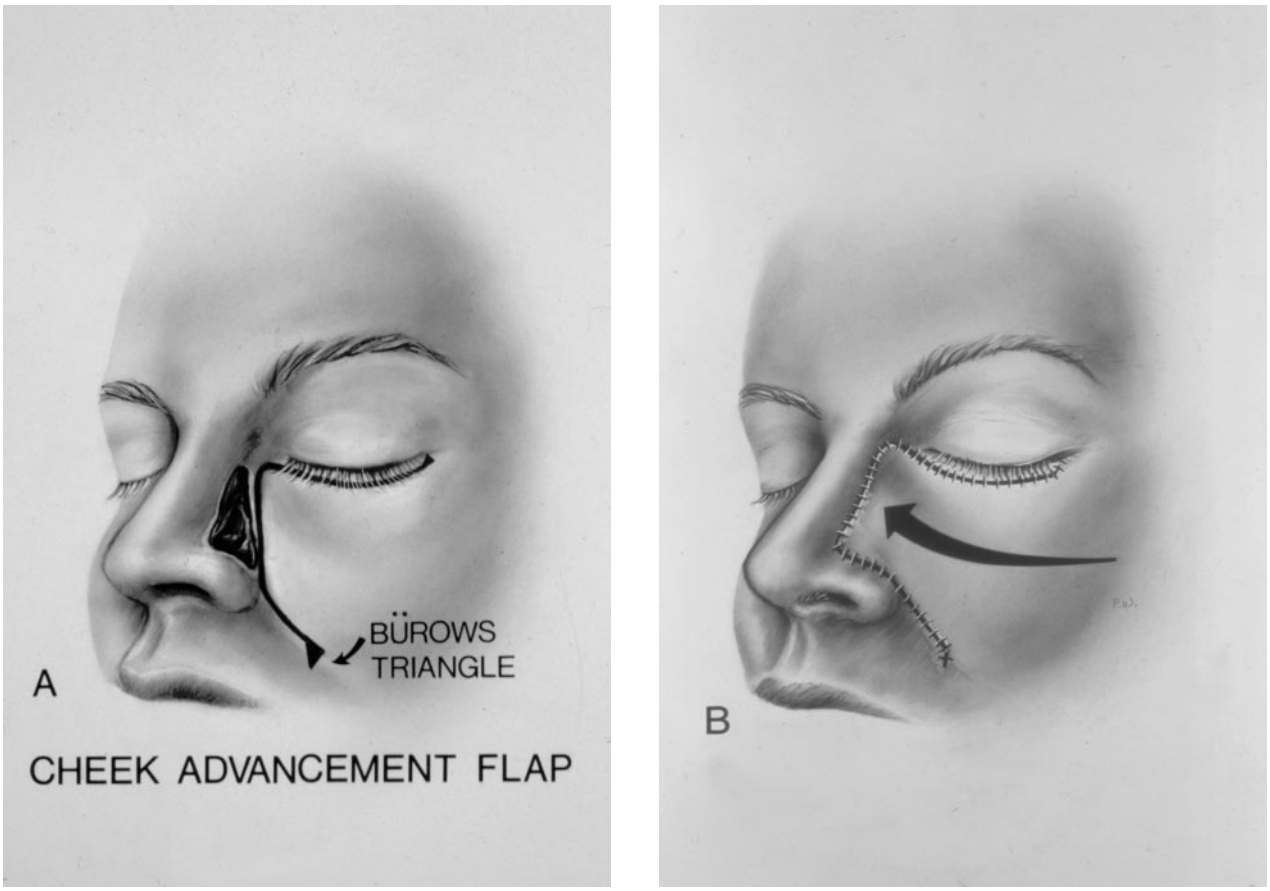

FIGURE 38–3. *A* and *B*, Cheek advancement flap for lateral nasal reconstruction.

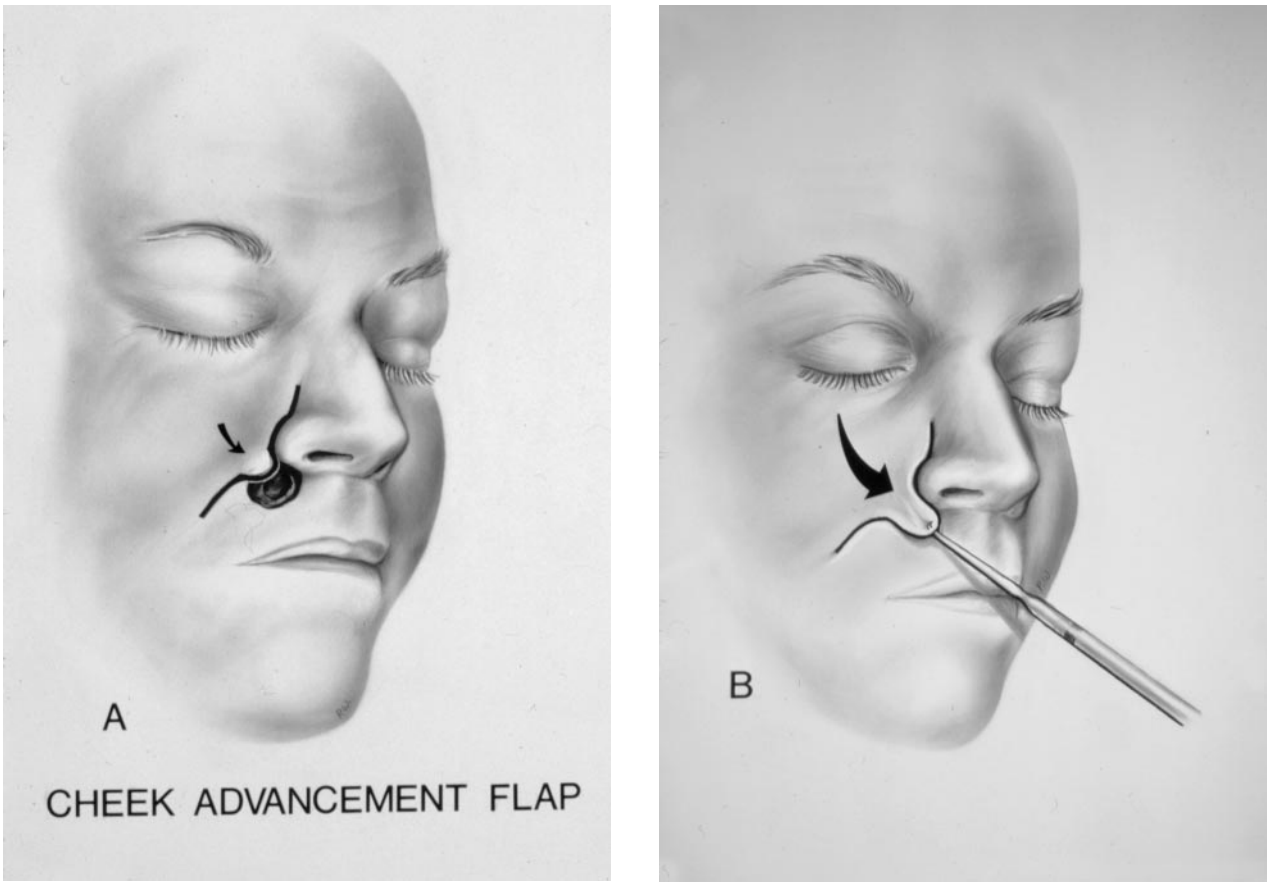

FIGURE 38–4. *A* to *C*, Modified cheek advancement flap to reconstruct the alar-facial junction and tissue void of the lateral upper lip.

The surgeon should approach any potential nasal defect with several alternative repair techniques in mind, ultimately choosing the flap or technique that possesses the most advantages and fewest risks for defect closure. The extent of almost all excisional defects may be diminished by circumferential undermining. The important concept of *reverse planning* is used, measuring the final defect size and planning the flap accordingly before creating final incisions. Small local flaps undergo minimal shrinkage during healing (less than 10%); therefore, almost exact flaps may be tailored to reconstitute the nasal defect precisely. Flap thickness should approximate the depth of the defect for full and complete effacement. Suture technique should include key interrupted, buried, absorbable sutures in the dermis and subcutaneous tissue to match the flap precisely to the defect, with nonabsorbable fine sutures used for 3 to 5 days to approximate epithelium. Tension-

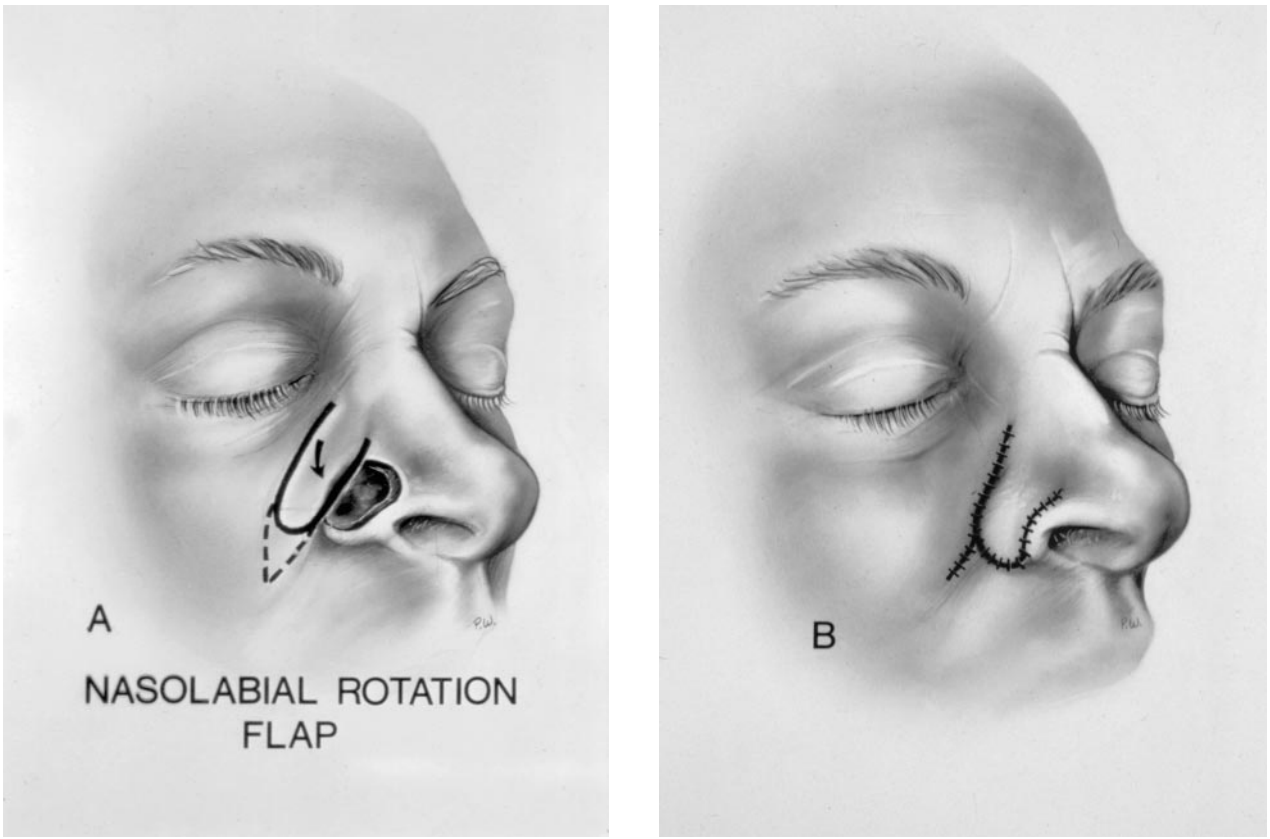

FIGURE 38–5. A and *B*, Nasolabial rotation flap for reconstruction of a nasal alar defect. The alar-facial junction is reconstituted.

reducing taping (Steri-strips) or tissue glues (Histoacryl blue, Dermabond) enhance wound approximation and allow earlier removal of sutures. Light compression bandages are used for 24 to 48 hours and then removed and replaced by Neodecadron ophthalmic ointment to keep the suture lines free of debris and clot, maximizing early healing.

Properly designed and executed, rotation flaps of adjacent nasal tissue may be expected to provide superior three-dimensional reconstruction of surgical and traumatic nasal defects within several weeks of repair. Defatting and "touch-up" procedures are rarely necessary. Light dermabrasion of the resulting fine nasal scars, 3 to 4 months later, can favorably enhance the blending effect.

Transposition Flaps

By far the most versatile of adjacent flaps is the transposition flap. Transposition flap designs available for nasal repair are varied and reliable. The variety of designs possible with transposed flaps provides the surgeon with many near-equal possibilities for nasal defect repair. Transposition flaps ordinarily allow primary closure of defects larger than those repaired with the simpler advancement and rotation flaps. When the flaps are properly designed, little tension is created on suture lines, and "dog ears" or "standing cones" are minimized.

In addition to the classic transposition flap design, *bilobed* transposition flaps, *rhomboid* transposition flaps, and the standard ubiquitous Z-plasty are superior methods of epithelial nasal reconstruction with adjacent tissue.

The classic transposition flap design is useful in the glabellar area, transposing redundant, lax tissue to upper lateral nasal defects. Proper design allows the ultimate incision lines to fall in or near natural folds, creating effective camouflage (Figure 38–7). Similar designs can take advantage of redundant nasolabial fold cheek tissue, sliding tissue medially to provide ample cover for lateral nasal tissue deficits; an undesirable side effect of this maneuver is the partial obliteration of the nasolabial groove, which is a highly desirable landmark.

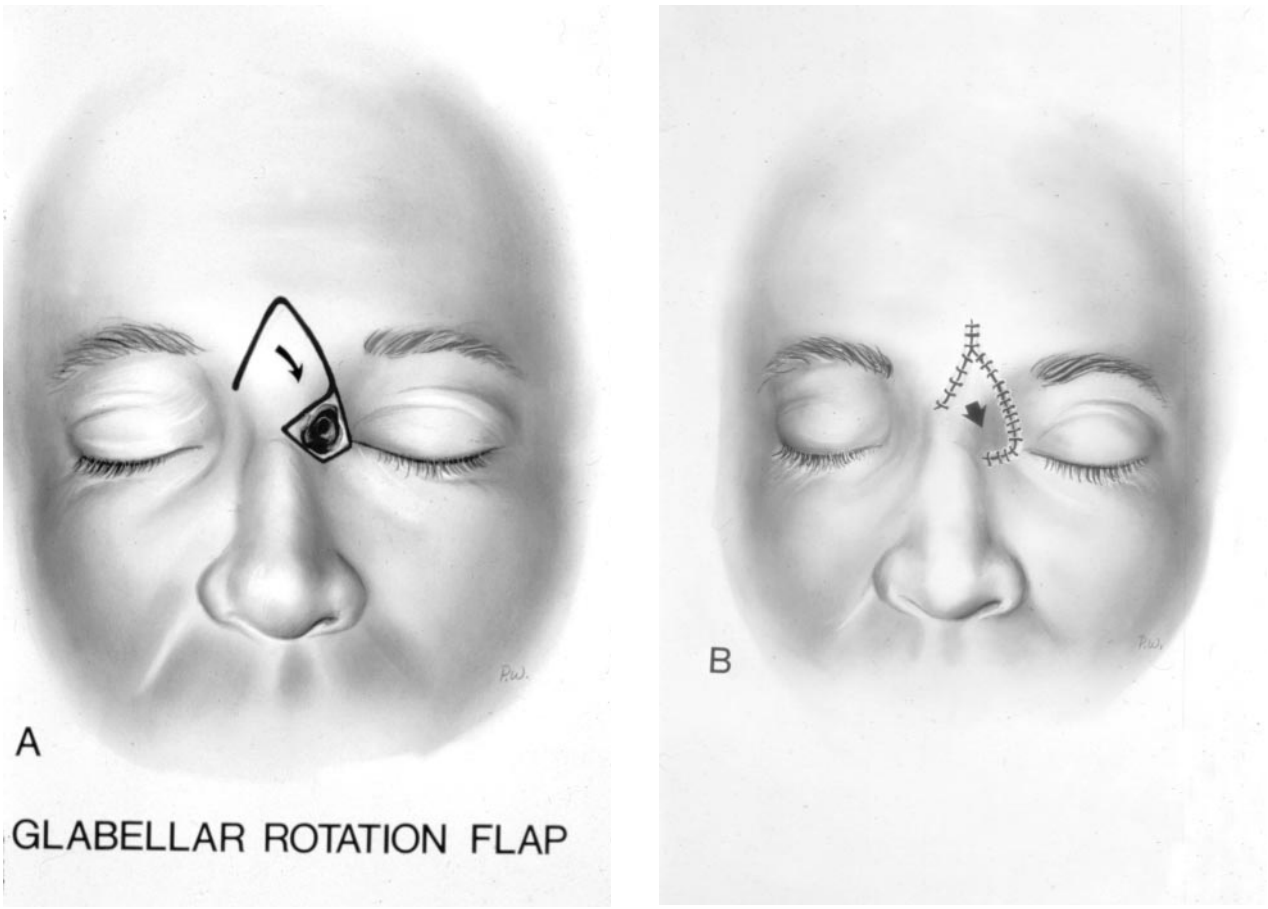

FIGURE 38–6. *A* and *B*, Glabellar rotation flap.

A tissue-abundant and versatile example of transposition flaps is the *bilobed flap* (Figure 38–8, A to C), consisting of two lobes separated by more or less of an angle and based on a common pedicle. This variety of flap design has several general applications in facial repair and two specific applications in nasal repair. Ideally, the dual flaps used should be similar (although not necessarily exact) in size and designed to rotate no more than 90 degrees for repair. In practice, this angle can vary from 45 to almost 120 degrees, depending on the location of the defect. In the upper half of the nose, in which the primary donor site of the bilobed flap may be easily reduced in size by undermining and advancement of its edges, the required size of the secondary donor flap may be reduced accordingly. The major advantage of the bilobed flap is derived from its use of the laxity (elasticity) and redundancy of tissue along two axes at approximately right angles to each other, compounding these tissues into one flap.

Abundant glabellar skin with vertical wrinkles, common in the aging face, combines favorably with the lax skin of the inner canthus area to supply tissue for the glabellar bilobed flap. The primary lobe of the flap is of ideal thickness and color match for dorsal nasal repair. The glabellar skin, which constitutes the secondary flap, is often thicker than inner canthal skin and must be carefully thinned after undermining to match evenly at the suture line. Heavy, thick eyebrows extending into the glabellar midline may impair the cosmetic effectiveness of this transposition flap.

Similar principles are involved in deriving donor skin for nasal resurfacing from redundant nasolabial fold skin (Figure 38–9, A and B). The secondary donor site is closed primarily in the fold, effectively camouflaging its presence. For large nasal defects especially, the cosmetic appearance of the healed flap is preferable in most situations to free skin or composite grafts. Tissue defects of the nonmobile

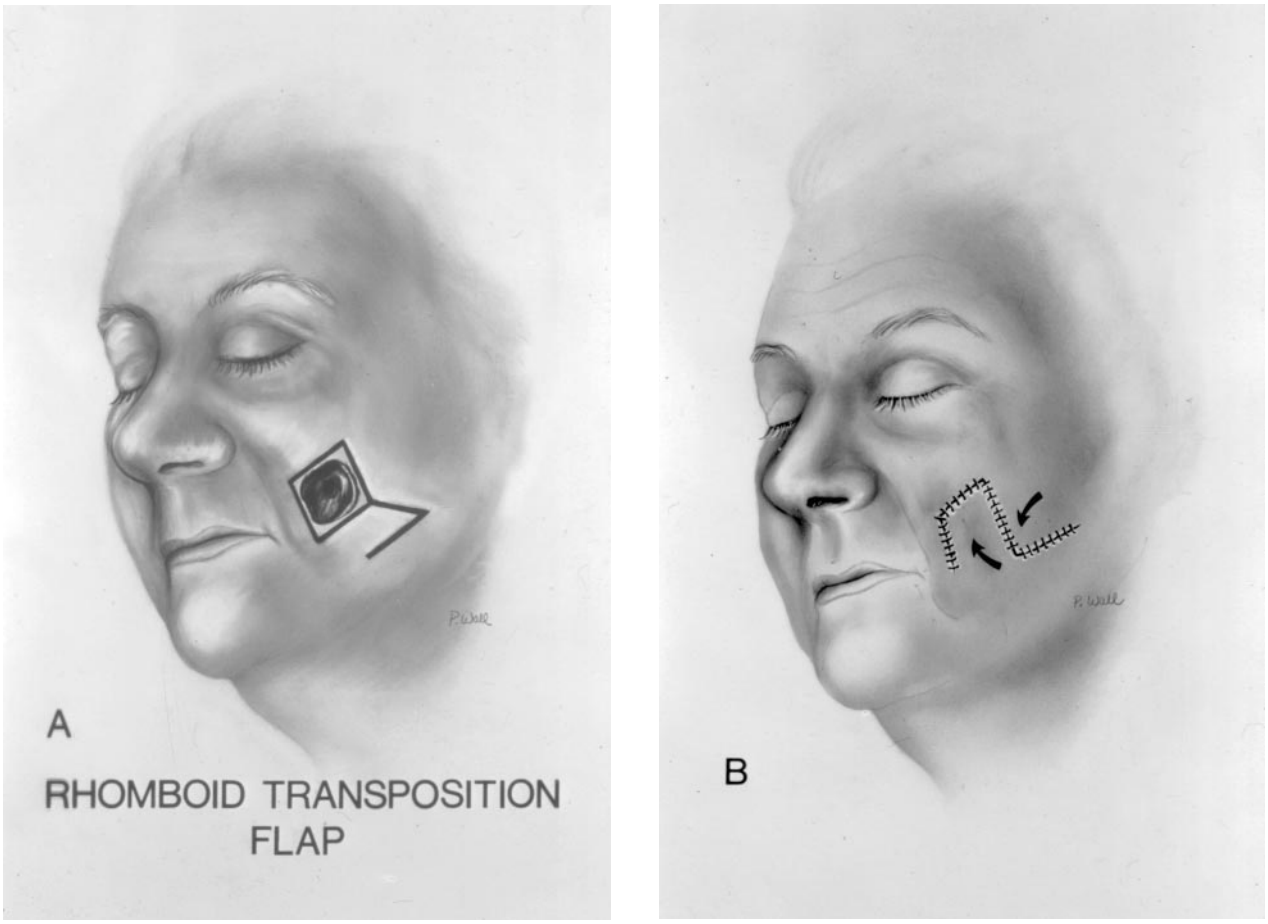

FIGURE 38–7. A and *B*, Rhomboid transposition flap.

skin of the nasal tip and infratip lobule are better repaired with full-thickness skin grafts harvested from the nasolabial fold or preauricular skin, however.

The principles involved in bilobed flap design can be used in a variety of reconstructive situations around the head and neck.

Regional Flaps

Pedicle skin flaps designed and transposed from head and neck regions other than those immediately adjacent to the nose are termed *regional flaps.* They are judiciously used when tissue in more abundance than that provided by adjacent flaps is required or when flap transport of buried skin, bone, or cartilage is required for framework reconstitution. In the latter incidence, the flap becomes a *composite* or *compound flap* and always requires delay and staging of 14 to 21 days before total elevation and transposition of the pedicle to the recipient site. Regional flaps are mainly designed around vigorous named vessels in the head and neck to allow nondelayed primary elevation and transposition. As circulatory efficiency in the flaps approaches its optimum level (14 to 21 days), the bridge of the flap is transected, final repair of the recipient site is effected, and all or a portion of the unused pedicle either is replaced in its previous anatomic bed or is discarded if donor site repair is unnecessary. Regional flaps from the midline forehead, scalp, and temple provide excellent tissue of appropriate bulk and near-ideal color match for nasal reconstitution. Furthermore, the ultimate donor sites in these areas are easily and effectively camouflaged, making them the site of choice for regional flap nasal repair. Tissue derived from cervical and more distant unexposed regions (shoulder, arm) lacks this ideal color match potential.

Midline Forehead Flap

Of all of the subtotal forehead flaps described for nasal reconstitution, the precise midline (or para-

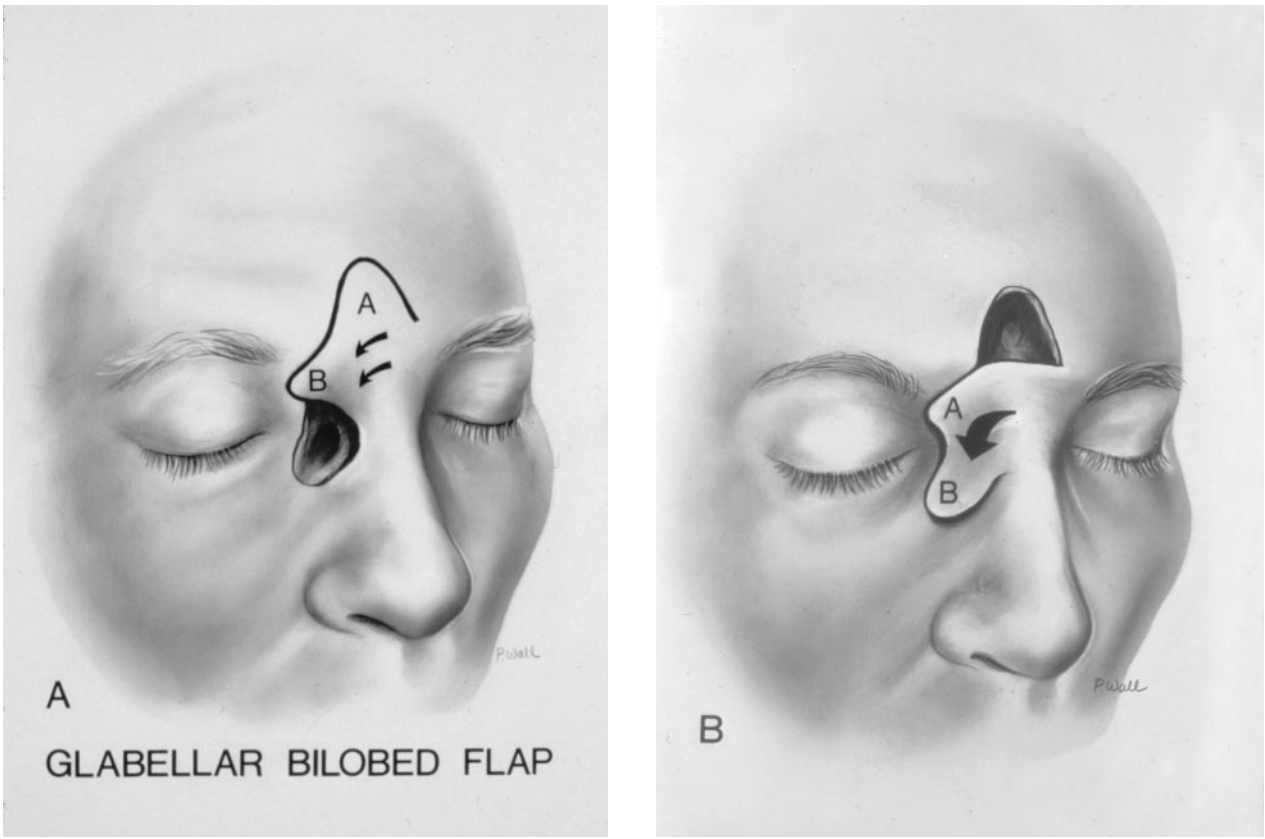

FIGURE 38–8. *A* to *C*, Bilobed transposition flap derived from redundant skin of the glabellar region.

median) vertical forehead flap is preferred for immediate transposition (Figure 38–10, A to C).[1] The color match is nearly perfect, the midline donor site defect may be closed immediately by advancing the lateral edges of the defect, and the resultant forehead scar is negligible if closure is meticulous and free of tension. Indeed, a midline vertical wrinkle already exists in many older patients, inviting scar camouflage. A flap width of 2.5 to 4 cm is available, and length is limited only by the extent of the hairline widow's peak. Abundantly nourished by the supratrochlear and dorsal nasal vessels, the midline forehead flap is suitable for primary restoration of defects of the lateral nasal epithelium, alar margin, and columella. A dressing of Adaptic gauze and antibiotic ointment substitutes for lining on the undersurface of the flap.

If desirable and appropriate, forehead tissue may be carried as a subcutaneous island pedicle flap beneath the tunnel of skin at the root of the nose; although this design provides one-stage repair, it

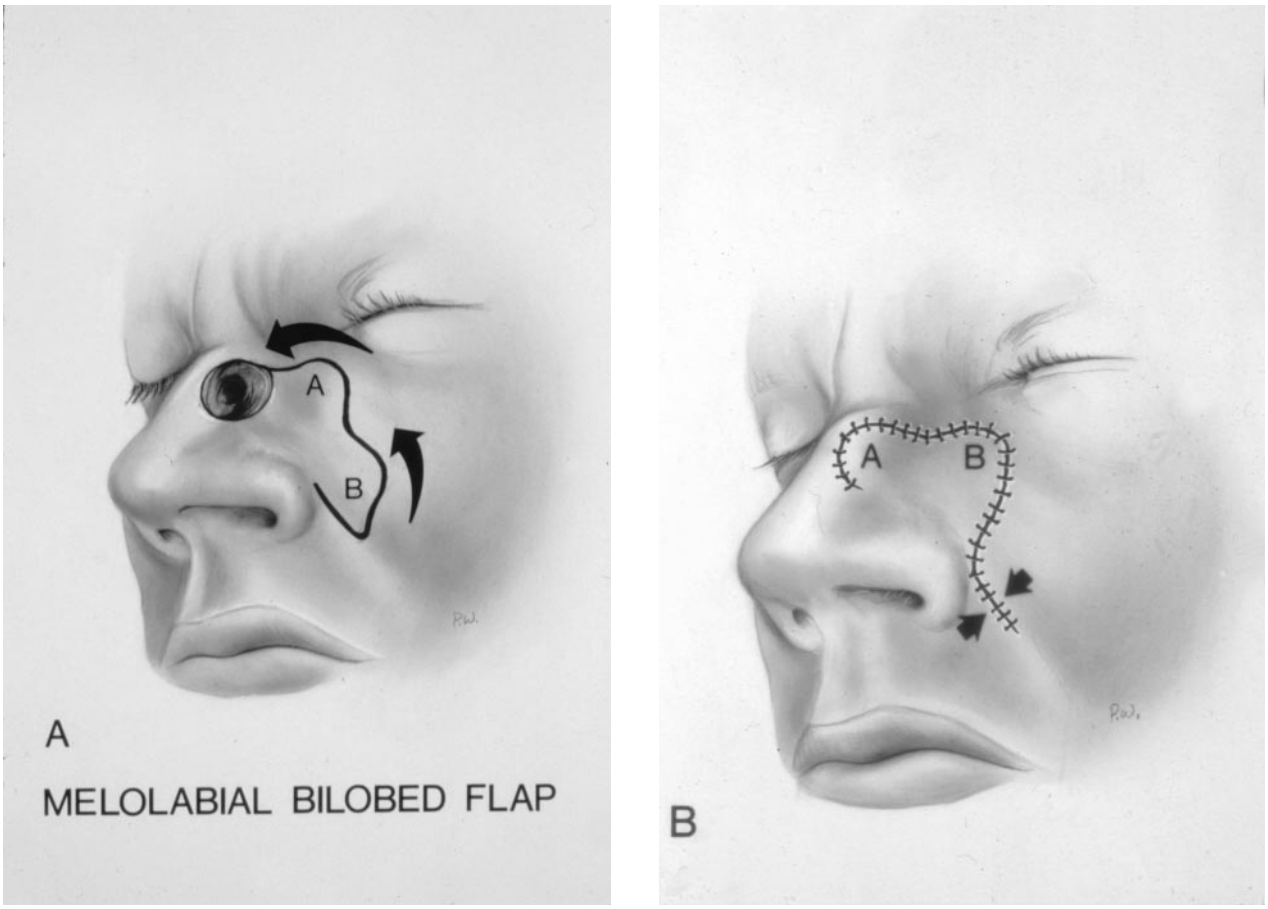

FIGURE 38–9. *A* and *B*, Paranasal bilobed transposition flap for reconstruction of lateral nasal defect.

adds unnecessary vascular hazard to the repair and often unsightly fullness in the tunnel region.

Fourteen to 18 days after primary flap elevation and transfer, the vascular viability of the transposed tissue is challenged by circumferential tourniquet compression; generally, division of the flap bridge is safely accomplished at this time. Most of the flap is discarded, restoring only sufficient tissue to reconstitute the oblique wrinkle lines at the root of the nose. Camouflage is excellent.

The esthetic advantage of the midline flap is apparent to all surgeons who use it regularly. Oblique, transverse, and "off-center" forehead flaps impose a higher penalty in ultimate scar legacy and therefore are less ideal esthetic choices. Midline flaps, carefully designed, preserve forehead symmetry and expression.

In near-total nasal reconstruction, midline forehead flaps can serve as the internal epithelial lining for the new nose, underlying a scalp flap designed to reconstitute nasal form. Redundant forehead skin created by tissue expansion is invariably stiff, less flexible and pliable; it is not considered ideal for nasal reconstruction.

Scalping flaps

Broad exposure of scalp and forehead tissue may be primarily elevated and transposed without fear of vascular embarrassment for near-total nasal reconstitution (Figure 38–11). In older men with balding tendencies, the donor site portion of the flap is best designed to lie on the scalp, ideally at the vertex of the skull. In younger patients and in women, the laterally placed skin superficial to the frontalis muscle is the donor tissue; a postauricular full-thickness skin graft covers the forehead defect over the intact frontalis muscle. Careful flap design with a reverse planning pattern technique provides ample tissue for alar simulation by enfolding skin edges for both

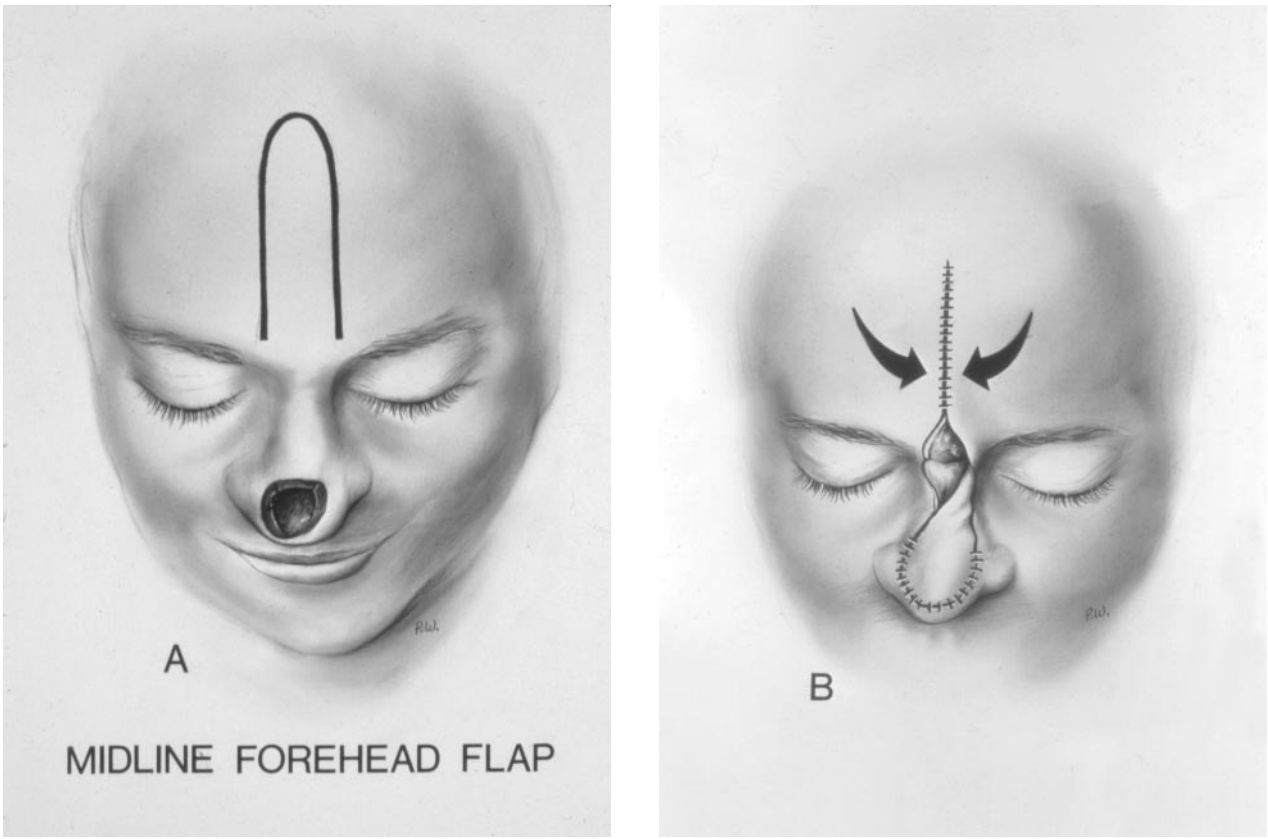

FIGURE 38–10. A to *C*, Midline forehead flap interposed into a large nasal defect. Flaps designed as paramedian, based on a single supratrochlear artery and vein, are preferable in certain reconstructive situations.

inner and outer nasal lining. Sufficient length must be incorporated into the design for adequate columellar length; failure to provide ample length disallows adequate tip projection. Small local turnover flaps should be developed when possible at the lateral edges of the nasal defect to provide an enhanced vascular bed for side-to-side rather than edge-to-edge suture repair.

Skin Grafts

Although infrequently used, skin grafts of split and full thickness are useful in nasal repair. The alternatives of primary closure or adjacent flap repair are generally preferable because of the inherent advantages previously detailed.

Skin grafts possess several distinct assets when employed for one-stage repair when no sacrifice of surrounding tissue is required: no further incisions

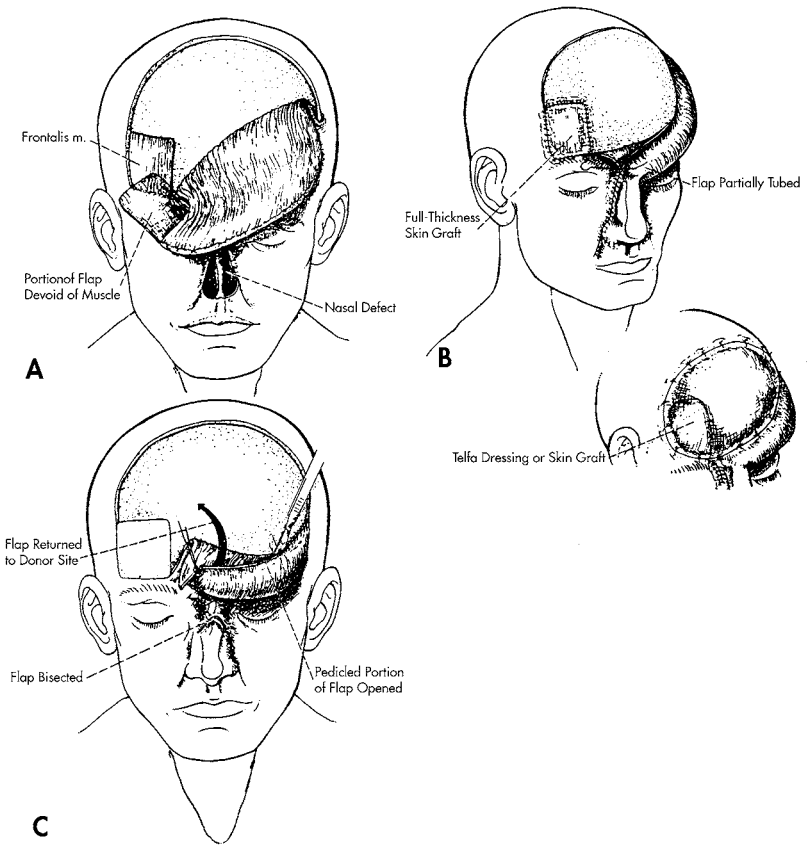

FIGURE 38–11. *A* to *C*, Scalping flap of Converse employs thin skin of the forehead for near-total nasal reconstruction.

are required adjacent to the defect, and planning is certainly less complex and sophisticated. Normal landmarks are generally undisturbed, and, should the graft fail for any reason, secondary grafting can proceed almost immediately after wound débridement, freshening, and infection control.

Superficial nasal epithelial defects of the lower half of the nose (trauma, burns, surgical excisions) are readily repaired with skin grafts derived from nasolabial, preauricular, or postauricular skin. The postauricular site has been shown by experience to be a less ideal color match than skin derived from the first two sites. An ideal but neglected donor site in older patients is *redundant skin of the nasolabial fold.* Full-thickness skin donated from this site is abundant and of excellent color match and allows camouflage of the donor defect in the nasolabial crease. Full-thickness defects of the nasal lobule and columella heal beautifully with nasolabial fold full-thickness skin grafts. Similarly, the preauricular and glabellar areas may harbor redundant skin with similar advantages. Seldom does the need arise to graft with skin derived from the more classic distant skin graft sites (inner arm, abdomen, thigh, buttocks).

Deep shave excision repair of the nose afflicted with rhinophyma may dictate the need for near-total skin graft repair of the nose. Shave excision and dermabrasion with preservation of epithelial islands, however, uniformly lead to re-epithelialization of remarkable esthetic appearance, thereby obviating grafting.

Grafts applied to the nose require delicate handling and special attention to detail in the operative and postoperative periods. Human noses are by no means inanimate; consequently, immobilization of skin grafts by means of stents or sutured-bolus dressings is necessary for the critical early period of 4 to 5 days. Tie-over bolus dressings compressing the graft dressed with Adaptic or Telfa gauze provide light but reliable immobilization and protection of the graft. In contradistinction, adjacent flaps require no compression dressing and thus provide convenience to the patient and early return to normal activities.

Split-thickness skin grafts seldom satisfy the need for three-dimensional augmentation or effacement of nasal defects; they may become depressed and thinner with time, seldom provide appropriate covering for implants of bone and cartilage, and

carry none of their own blood supply. For these reasons and those previously outlined, adjacent flaps remain the tissue of choice for immediate nasal repair in all areas except the nasal tip and infratip lobule. Specifically, grafts are generally inappropriate in areas of dense scarring and/or irradiation with consequently poor recipient site blood supply.

ESTHETIC SEPTORHINOPLASTY

Patients today seek functional and esthetic improvements in nasal appearance more than ever before. Rhinoplasty refinements currently allow subtle as well as major modifications with little discomfort, early healing, and predictable results. Perhaps no other surgical procedure blends artistic and technical skills to the degree required in esthetic rhinoplasty. Although it is one of the more common operations performed, only a few surgeons ever master its subtleties and nuances.

An artistic ability to visualize in advance the ultimate result is a critical skill necessary to surgical excellence. Successful rhinoplasty is initially preceded by careful analytic assessment of the nasal configuration, the deformity, and its relationship to the surrounding facial features. A realistic estimate of surgical correction, based on the possibilities and limitations imposed by the characteristics of the nasal tissues, is formulated—the preoperative "game plan." The goal of the surgery is to fashion a natural nose that is in harmony with its surrounding facial features and does not draw attention to itself.

The master surgeon is separated from the novice by the ability to *predict* the favorable and *compensate for* the unfavorable healing factors that influence ultimate nasal appearance evolving over many years. Only with continued experience and study, coupled with a continued impartial analysis of one's own long-term results, can the latter capability be developed and refined.

The truly capable surgeon must have wide knowledge of predictable procedures to be implemented in the unlimited variety of nasal configurations encountered. Strict adherence to basic principles does not necessarily always produce the ideal result. It is essential that an understanding of dynamic nasal structure transcend the components of static bone and cartilage; the relationship of shape and form to muscle tension and skin texture, the relationship of bone and cartilage to surrounding structures, the degree of postoperative thickening and/or relaxation of tissues, and the role of interrelated structures in the production of the deformity must be realized and evaluated.

Variations in rhinoplasty are manifold, ranging from minor corrections to complete reconstruction of the nose. Esthetic rhinoplasty aims at the creation of a nose that can be considered ideally proportioned, but proper physiologic function is essential. In post-traumatic deformities and many developmental and congenital deformities, the correction of respiratory derangements is paramount, and esthetics, although significant, is secondary. Some congenital deformities, such as the cleft lip or bifid nose, encompass both functional and cosmetic requirements of a special nature.

ESTHETIC RHINOPLASTY

The objective of esthetic nasal plastic surgery is the creation of a nose that is in harmony with the other features of the face. This simple statement represents a complex problem. The explanation of what is "beautiful" or "ideal" has been an age-old question, and the answer involves a multiplicity of emotional reactions and prejudices. In addition, values and assessments of beauty vary within different age groups and social structures. To evaluate what is beautiful entails a study of physical and cultural anthropology, ethnology, psychology, and esthetics, the ramifications of which may be endless.

Anthropometric Factors The anthropometrist uses basic measurements to divide and subdivide the face (Figures 38–12 and 38–13).[3] Designated points in the midline of the face are labeled as follows: the *trichion,* located in the center of the forehead at the hairline; the *nasion,* at the frontonasal suture line; the *subnasale,* a point at the root of the nasal spine; and the *gnathion,* the most anterior point of the symphysis of the mandible. If horizontal lines are drawn through these points, the face is normally divided into three equal parts. If, in profile view, another line is projected from the upper rim of the external auditory canal (the auricular point) to the lower rim of the orbit or infraorbital point, a line known as the *Frankfort horizontal* is formed. This line divides the face into two equal parts from the trichion to the gnathion (see Figure 38–12).

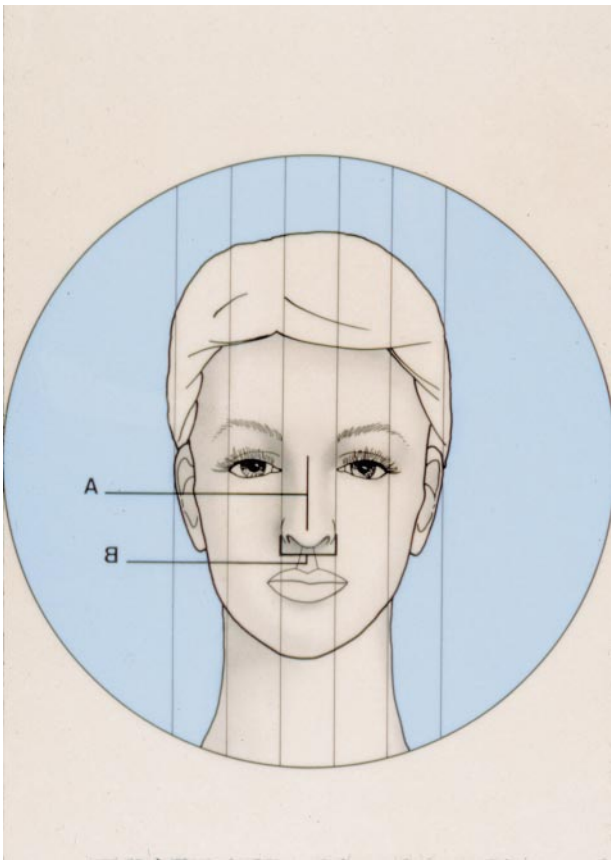

FIGURE 38–12. Anthropometric measurements of the "normal" face. The ideal face is equally divided into fifths.

Many of the basic observations on the divisions of the face were originally described in the fifteenth century by Leonardo da Vinci in the section of his notebooks entitled "Of the Parts of the Face." We use his accepted statement, "The space from the chin to the beginning of the bottom of the nose is the third part of the face, and equal to the nose and to the forehead," and have set up our blocks accordingly. After dividing these three groups into equal spaces, we are immediately led to certain observations. Although this spacing is equal, it is not monotonous for the forms lying next to each other occupy different numbers of spaces. Nevertheless, the proportions are equal, indicating a certain regularity in size, shape, and position of forms.[4] For example, the forehead occupies one entire group or one-third of the height of the face. The eye from the brow to lower lid fills one-third of the height of the nose, or, again, one can observe that the upper lip is to the lower lip and the chin as the height of the nostril is to the remainder of the nose. In this manner, one can divide and subdivide and compare indefinitely. It is interesting to notice that the eye tends to group a large area with a small one and to compare this grouping with other similar groupings of large and small areas.

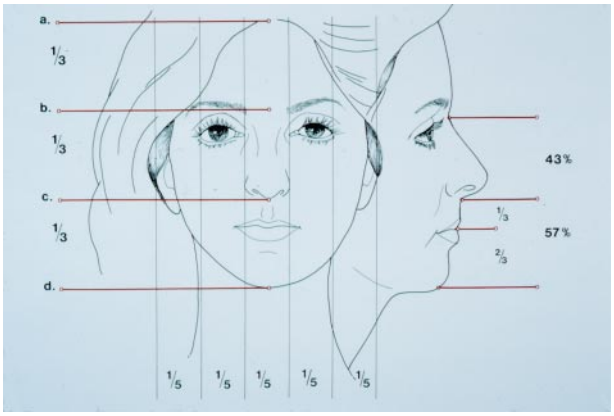

FIGURE 38–13. Relatively ideal facial dimensions.

The midline is the most obvious division of the front view. In the midline of the face, the measurement used is the width of one eye for "the space between the eyes is equal to the size of one eye" (da Vinci). Furthermore, by the size of the eye, the face is divided into five equal vertical sections. These may again be equally divided, and mathematical comparisons may be made, as before, to prove pleasing points of interest. An example is that the alae nasi occupy the space between the two inner canthi or one eye's breadth.

Psychological Factors The importance of beauty and the concept of our own body image, that is, the attitude regarding our physiognomy and body structure, are potent factors in the emotional and intellectual development of the individual.[4]

The nose, being a conspicuous organ, has definite secondary sexual characteristics and is frequently referred to as masculine or feminine. The patient with a poor body image, especially one who has an unconscious sexual or libidinous misidentification, may suffer a severe conflict because of a masculine or feminine appearance or the erroneous belief of such an appearance. Some of the most remarkable psychological changes in patients are in these individuals, often out of proportion to the surgical result. Regardless of the physical change from a masculine to a feminine nose, if the patient believes that the change has wrought a new identification

with his or her sex, the psychic change is spectacular. This psychic change is usually based on unconscious factors, the patient never being aware of the reasons for the dramatic change in attitude.

The psychological factors basic to an evaluation of one's appearance are instinctive and conditioned; therefore, much of the individual's reaction depends on his or her concept of the *body image.* To a great extent, this is influenced or conditioned in early life, usually by the attitude of the parents. The individual with a distorted and unrealistic self-image is usually an emotionally disturbed person. A *realistic* appraisal of one's own image, within reasonable limits, is usually indicative of a mature individual.[5]

Patients seeking rhinoplastic surgery for a gross deformity usually have a realistic view of themselves and a valid reason for correction of the deformity. The individual with a minor defect may harbor a poor self-image and sometimes exaggerates the deformity. The surgeon's ability to understand the motives and needs of patients seeking esthetic surgery is summarized by certain exhibited clues and characteristics. Diagnostic clues tending to identify the patient with a good prognosis include (1) obvious disfigurement, (2) occupational reason for seeking surgery to improve appearance, (3) a realistic wish to appear younger, and (4) a statement that the patient has "wanted to do this for a long time." A less ideal (or guarded) prognosis might be expected, according to Schulman, in patients who (1) state an unrealistic motive ("so I can look more masculine"), (2) request surgery on a sudden whim, (3) expect surgery to be the solution to all of their problems (eg, "to save my marriage"), (4) exhibit a history of hospitalization or treatment of recurrent psychiatric illness, (5) relentlessly go "surgeon shopping," (6) have undergone repeated surgery with consistent dissatisfaction, (7) are unable or unwilling to follow important instructions provided by surgeon or staff, (8) exhibit obsessive-compulsive tendencies, and (9) interact poorly with office personnel.

In summary, we can state that the motivations for and the psychological effects of rhinoplastic surgery are a complex subject. A few factors are reviewed, and an evaluation and a definition of beauty from perceptual and conceptual views are attempted.

Beauty of the human face is neither abstract nor absolute; it varies among different ethnic groups and is subject to the projection of the individual. This attitude is based on a multiplicity of factors varying according to the body image and cultural values of individual conditioning, particularly during the formative years, when it often becomes part of the unconscious mind.

In any ethnic group, beauty is the approximation of the so-called norm; for Western civilization, we have depicted this norm by mathematical proportions. It is therefore a form of esthetic ethnocentrism influenced by extraneous factors of culture. A great latitude in the variety and balance of features exists, so there are no absolute rules by which beauty may be determined.

Anatomic Description The nose on frontal view is in the shape of a pyramid, of which approximately the upper two-fifths comprise the bony vault and the lower three-fifths the cartilaginous vault (Figure 38–14). The upper narrow end joins the forehead at the glabella and is called the *radix nasi* or root of the nose, and its free angle at the lower point is termed the tip or *apex nasi.* The two elliptical orifices, the *nares,* are separated from each other by a skin cartilage septum known as the *columella.* The lateral surfaces of the nose form the dorsum by their union in the midline. The lateral surface ends below in a rounded eminence, the *ala nasi.*

The bony vault is composed of the two nasal bones, which are set on the nasal process of the frontal bone above, the frontal process of the maxilla laterally, and the perpendicular plate of the ethmoid and the septal cartilage below.

The upper portion of the cartilaginous vault consists of the two *upper lateral cartilages,* which are

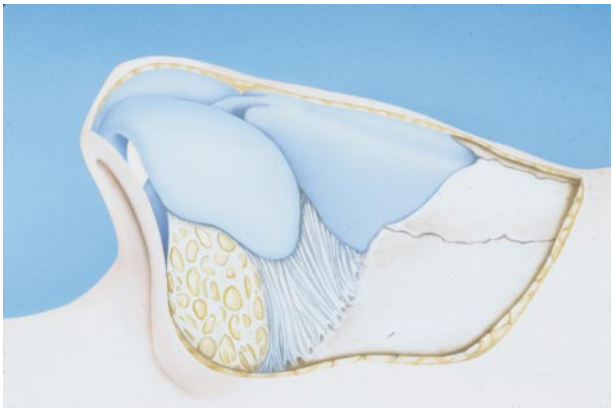

FIGURE 38–14. Normal anatomy of the lateral wall of the nose.

triangular and fuse with the septum in the midline. The upper margins underride the nasal bones and the frontal process of the maxillae and are attached to them by connective tissue. The lower cartilaginous vault is composed of two *lower lateral cartilages* (alar cartilages), which are of variable shape and more or less frame the nares and help in forming the alae. The two medial crura are attached to each other by fibrous tissue and to the lower end of the septum by skin, making up the columella and the membranous septum. Fairly near the midline, the lateral crura may slightly overlap the upper lateral cartilage and are attached to the lower rim of the upper lateral cartilage and the septum by connective tissue. They are also intimately attached to the overlying skin. The medial crura are loosely attached to the nasal septum and to each other by connective tissue. A few small loose cartilages (minor alar cartilages) are occasionally found laterally or just above the lateral crura.

The septum consists of both cartilage and bone. The septal cartilage is a single quadrilateral plate of cartilage that forms the anteroinferior portion of the septum. It unites with the bony portion of the septum behind with the perpendicular plate of the ethmoid, resting below on the groove of the vomer, the maxillary crest, and the maxillary spine (Figure 38–15). A tail-like posterior projection of the cartilage between the perpendicular plate and vomer is known as the sphenoid process. A small strip of cartilage, which is often absent, lies over the nasal spine and maxillary crests and is known as the vomeronasal cartilage of Jacobson.

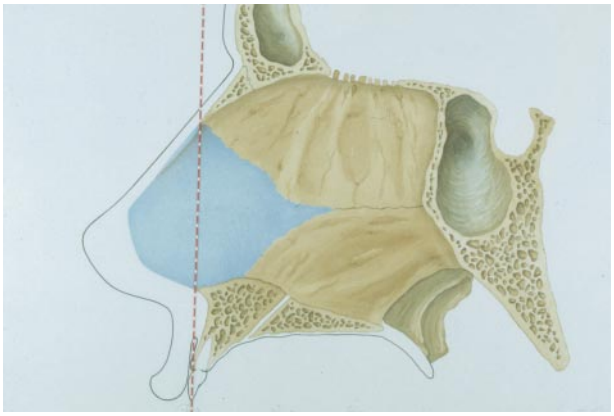

FIGURE 38–15. Normal anatomy of the nasal septum, lateral view.

The skin covering the external nose is thin and contains an areolar type of subcutaneous tissue. It is loosely attached in its upper half, but in its lower portions it is intimately bound to the lower lateral cartilages and may sometimes be thick and fatty and contain many sebaceous glands (Figure 38–16). The skin continues into the nares to supply lining to the nasal vestibule.

The muscles of the nose lie directly subjacent to the skin, and, occasionally, muscle bundles are attached to the cutis itself. The muscles comprise the procerus, nasalis, depressor septi, dilator naris posterior, dilator naris anterior, and angular head of the quadratus labii superioris (Figure 38–17).

The blood supply of the external nose is principally through the angular and lateral nasal branches of the external maxillary artery and the infraorbital branch of the internal maxillary artery. The internal nose is supplied by the sphenopalatine branches of the internal maxillary artery and the ethmoids from the ophthalmic artery. The veins terminate in the anterior facial and ophthalmic veins.

The motor nerve supply to the nose is by the facial nerve. The sensory supply includes the infratrochlear and nasal branches from the ophthalmic division of the trigeminal nerve and the infraorbital nerves from the maxillary division of the trigeminal nerve. The nasal septum is innervated by the ethmoid and nasopalatine nerves from the first and second divisions of the trigeminal nerve, respec-

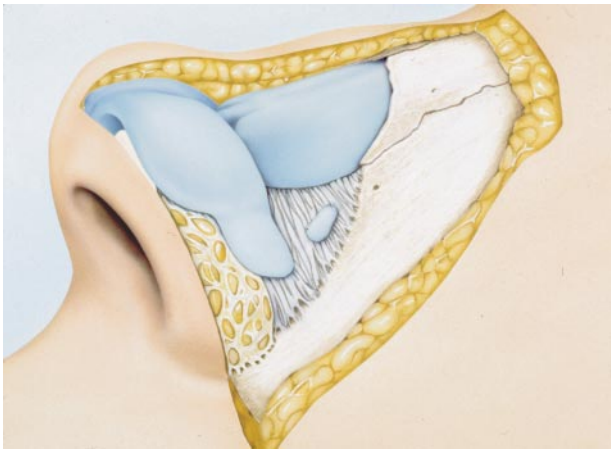

FIGURE 38–16. Rendering of a cadaver dissection displaying thick subcutaneous tissue cushioning the nasal skeleton, especially abundant at the nasal tip and supratip region.

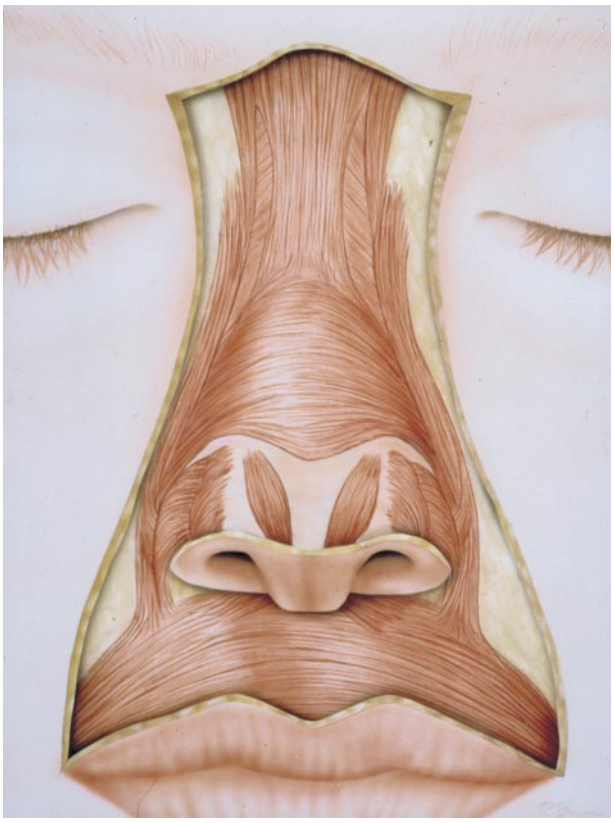

FIGURE 38–17. Mimetic musculature of the nose, interconnected in form and function in a superficial muscular aponeurotic system. Dissection in rhinoplasty should be beneath this layer, which contains the arterial and venous blood supply of the nose as well as lymphatic structures.

tively. The lateral wall of the internal nose receives fibers from the nasal branches of the palatine nerve, the ethmoid nerves, and a small branch from the anterior superior alveolar nerve.

Artistic Anatomy An artistic anatomic concept must be developed by the rhinoplastic surgeon when approaching the study of nasal anatomy.[6] The surgeon visualizes the nasal structure not only as static bone and cartilage but also as muscle tension, skin texture, relationship to surrounding structures, and the effect of related and interrelated structures on the shape of the nose. Furthermore, this concept divides the nose into an upper or immobile portion and a lower or mobile portion.

The immobile or upper portion of the nose is composed of the nasal bones and the upper lateral cartilages. The upper lateral cartilages are firmly attached to the undersurface of the nasal bones and maxillae by dense connective tissue and are fused with the septum in the midline, except for a small area at its lowermost end. The nasal bones are supported by the adjacent maxillae, the nasal process and spine of the frontal bone, and the septum below. Covering these structures are periosteum and perichondrium and the procerus and transverse nasalis muscles. The overlying superficial fascia or panniculus adiposus is thin, with scanty fat and fibrous tissue, allowing great mobility of the skin over this area.

The lower or mobile portion of the nose is composed of the two alar (lower lateral) cartilages and, occasionally, a few sesamoid cartilages superiorly and laterally. These cartilages are curved, thereby shaping the nares (Figure 38–18). The alar cartilages are more or less free-floating, being suspended and maintained in position by fibrous and muscular attachments to the two upper lateral cartilages, the septum, each other, and the overlying and surrounding skin.

The shape of the nasal tip is basically formed by the alar cartilages. Depending on the thickness of the skin, the amount of subcutaneous fat and areolar tissue, and the activity of the sebaceous glands, however, the configuration of the tip may vary considerably from the basic structure of the alar cartilages. Furthermore, the form of the nasal tip depends on its relative position to the immobile or fixed structures, which suspend and hold the tip in

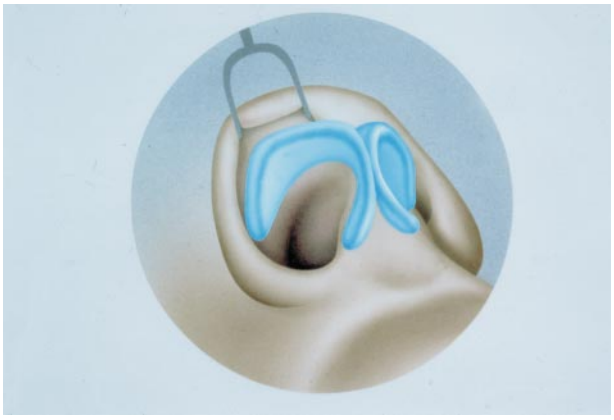

FIGURE 38–18. The paired alar (lower lateral) cartilages are essentially free-floating, mobile, and encased in soft tissues. They are loosely connected to the upper lateral cartilages, the ascending process of the maxilla, and the caudal septum.

position by firm fibrous attachments. A long, short, elevated, or depressed septum, long or short upper lateral cartilages, the shape of the nasal bones and maxillary processes, the spine of the maxilla, and the direction and tension of the surrounding muscles and fibrous connective tissue are determining factors in the position and shape of the nasal tip.

We are frequently surprised to note what remarkable changes in shape and position are accomplished by simply dissecting the tip free from the surrounding tissues. A further change is also noted when the last remaining suspensory attachment of the tip is freed by dissection of the alar cartilage from the enveloping skin. The skin at the nasal tip is immobile because of its firm adherence to the cartilage by dense fibrous connective tissue. This firm union aids in suspending and positioning the tip; thus, to mobilize it properly, the alar cartilage is detached from the overlying and surrounding skin. Occasionally, this may be all that is required to change the shape and direction of the tip. This is usually accomplished at the onset of the rhinoplastic operation. With mobilizing of the alar cartilages, the muscle fibers are also detached. The muscles involved are the nasalis (transverse and alar), dilator nares, depressor septi, and, occasionally, a few slips of the caput angularis of the quadratus labii superioris.

The muscles that surround and envelop the nose are part of the mimetic muscles of the face, which have no real fascial covering such as covers the skeletal muscles of the body. Instead, they are found below and in the panniculus adiposus or superficial fascia, and the fibers are inserted directly into the dermis and cutis of the skin. This arrangement of muscle fibers is a direct outgrowth of the highly complex development of speech, whereby small muscle fibers were needed superficially to allow multiple variations of facial movements.

Planning the Correction In planning the correction of the nasal deformity, the component features of the face and the general body build of the patient must be considered. Frequently, failure to consider the relationship of the nose with the chin, maxilla, and forehead mars an otherwise perfect rhinoplasty and results in a nose that appears unnatural for the particular individual.[7]

Procedures that have been advocated for analysis of deformity include marking angles on photographs, mechanical measuring instruments used directly on the face, and the use of computer imaging. All may be of value. It is, however, difficult to measure so subjective an abstraction as beauty in angles or degrees because of the many variables in physiognomy. Rather, one should strive to attain a harmonious relationship of all of the features. A simple but valuable method of studying the relationship of facial features is by the use of sketches made on the reverse side of the photograph. The photograph is held up to a light or placed on a roentgen film shadow box, and by pencil sketching and shading, the ultimate desired result may be depicted.

Whether or not sketches are made on them, pre- and postoperative photographs are an integral part of the surgical routine (Figure 38–19). In all plastic surgical undertakings, photographs are absolutely essential and should form a part of the patient's record. A series of standardized and uniform photographs is more informative than the most carefully detailed notes, both as a planning and self-instructional device and as a necessary medicolegal record.[8] Series of 5×7 inch black and white prints combined with color 2×2 inch color slides make ideal records in rhinoplasty photography and serve as an ideal immediate reference when projected full size in the operating room during surgery.[8] Preoperative photographs are followed by postoperative views taken at 1 week and then at 1, 3, 6, 12, 18, and 24 months. This carefully standardized photographic composite provides a clear uniform panorama of the dynamics of healing affecting the ultimate result and is a superior teaching record as well. The Frankfort horizontal line is used in proper positioning of the patient, providing uniformity and standardization from sitting to sitting. The following views are preferred (Figure 38–19): (1) frontal, (2) basal, (3) right lateral, (4) left lateral, and (5) right lateral, smiling.

Using single-lens reflex cameras, photographing with properly positioned dual electronic flash units and a pastel background complementary to skin tone (blue or green) is rapid and relatively simple. A fast, sharp lens of approximately 105 mm focal length avoids parallax distortion and provides precise uniformity. Commercial photographers are frequently used, but it is to the surgeon's advantage personally to master the details of precise photography. The advent of digital photography will provide significant recording and storage capabilities for nasal images.

FIGURE 38–19. Typical preferred pre- and postoperative rhinoplasty photographic views (smiling view optional).

Classic Steps of Rhinoplasty Rhinoplasty remains the most challenging of all esthetic operations because no two procedures are ever identical. Each patient's nasal configuration and structure require individual and unique operative planning and surgical reconstruction. Therefore, no single technique, even though mastered, will prepare the surgeon for the varied anatomic patterns encountered. It is essential to regard rhinoplasty as one operation planned *to reconstitute and shape* the anatomic features of the nose into a new, more pleasing relationship with one another and the surrounding facial features. Rhinoplasty should be approached as an anatomic dissection of the nasal structures requiring alteration, conservatively shaping and repositioning these anatomic elements. Many more problems and complications arise from *overcorrection* of nasal abnormalities than from *conservative* correction. Inappropriate technique applied persistently without regard for existing anatomy creates frequent complications. One truism, that it is not what is removed in rhinoplasty that is important but what is left behind, remains valid. Furthermore, one must comprehend clearly the dynamic aspects of operative rhinoplasty because all surgical steps are interrelated and interdependent: *most maneuvers lead to a temporary deformity to be corrected by the steps that follow.*

Most corrections of the long nose associated with a hump or dorsal prominence follow the basic principles formulated by Jacques Joseph in the first half of the twentieth century. His monumental treatise, *Nasenplastic und Sonstige Gesichtplastik,* published in 1931, has proved its fundamental soundness for over half a century.

The procedure varies in each patient by the amount of tissue excised and/or the relative repositioning, reorientation, and/or grafting of anatomic structures. Classically, then, rhinoplasty consists of the following interrelated steps (Figure 38–20):

1. Septoplasty
2. Tip remodeling, projection, and cephalic rotation
3. Hump removal (establishing the profile line)
4. Narrowing of the nose with osteotomies
5. Final correction of subtle deformities

Preoperative Preparations Thorough, compulsive preparation by the surgeon before surgery ensures a streamlined operative procedure, designed to achieve esthetic satisfaction and avoid complications. The optimum time for operation in respect to the physiologic and psychological condition of the patient (and the surgeon) should be chosen. Patients are counseled that the procedure will be a meaningful and exciting event in their lives with long-range implications rather than a necessarily unpleasant experience.

A complete physical examination is indicated, including routine laboratory tests such as blood count, urinalysis, and chemical and coagulation profiles. Untoward bleeding histories should be comprehensively resolved before proceeding. Recent upper respiratory infections, skin pustules, or allergic exacerbations may be sufficient reasons to postpone surgery. Conditions such as anemia, metabolic disorders, or nutritional deficiency states contraindicate any elective procedure. A patient who is a poor anatomic surgical risk usually heals poorly and unpredictably. An exacting history is essential to determine if any medication currently taken by the patient could create bleeding or untoward drug interaction.

General planning of the operative sequence should be carried out before surgery, with a well-devised "game plan." Intraoperative improvisation may be necessary but only if complementary to a careful preoperative game plan. Photographic evaluation with the patient, clearly defining exact patient expectations and demonstrating realistic expectations as well as anatomic limitations, is mandatory before embarking on surgical repair. The patient must clearly comprehend the details, ramifications, limitations, and potential complications of the procedure. This informed consent discussion is purely a physician-patient encounter; no individual or list of written "helpful hints" supplants this critical part of the preoperative conditioning.

Preoperative Medication The cardinal rules in preoperative medication of patients are to use as few different categories of drugs as possible and preferably to employ drugs whose actions may be reversed or antagonized. Too often, patients scheduled for rhinoplasty are given a wide array of different drugs, which confuse the pharmacologic picture considerably—certainly, a therapeutic error. Reliance on predictable narcotic and phenothiazine and neuroleptic drugs only has been found safe and effective, particularly with a combination of local infiltration and intravenous analgesia and anesthesia, carefully

titrated, controlled, and monitored by a medical anesthesiologist. Individual drug titration in each patient, with the drug slowly infused in minimal intravenous increments, provides a safe and comfortable combination of euphoria, analgesia, and obtundency. General anesthesia may be used with equal facility.

One or two small gauze pads (neurosurgical cottonoids) moistened with 5% cocaine solution are placed in each nasal passage. Superb surface anesthesia with intense nasoconstriction and turbinate shrinkage results.

Minimal intranasal subcutaneous infiltration of standard 1% lidocaine (Xylocaine) with 1:100,000 epinephrine (freshly mixed) is conservatively accomplished. Infiltration occurs only as the No. 27 gauge needle is being *withdrawn* to avoid the possibility of direct vessel injection. The intent is to diffuse a thin plane of anesthesia and vasoconstrictive influence *in the favorable tissue plane just above the cartilage structure of the nose,* where most dissection will be performed. Small amounts of infiltration anesthesia are added at the alar margins, piriform aperture, columella, and nasal septum. No attempt is made to create a specific block anesthesia of specific sensory nerves. This method effectively anesthetizes the operative field, creates excellent vasoconstriction, and avoids distortion of the nasal structures (a common error). Seldom is more than 4 to 5 mL of anesthetic solution required. Overaggressive injection leads to tissue ballooning, feature distortion, and consequent impaired surgical judgment.

It is essential that 10 to 15 minutes be allowed to elapse between the completion of injection and the initiation of surgical steps, thereby ensuring *intense vasoconstriction,* minimal bleeding, unre-

stricted vision, and, consequently, improved surgical technique. The surgeon must use a strong head light to maximize visualization.

The patient cleanses his face and nose gently with hexachlorophene the morning of surgery, rinsing thoroughly. No disinfectant is applied to the nose or face at surgery. Vibrissae are trimmed only if excessively long.

Surgery of the Nasal Tip *Philosophy of Tip Sculpture* Sculpture of the nasal tip is regarded, and properly so, as the most exacting aspect of nasal plastic surgery. The surgeon is challenged by the essentially bilateral, animate, and mobile nasal anatomic components. Because no single surgical technique may be used successfully in correction of the endless anatomic tip variations encountered, the surgeon must analyze each anatomic situation and make a reasoned judgment about which approaches and tip modification techniques will result in a predictably natural appearance. Factored into this judgment decision must be consideration of, among other things, the strength, thickness, and attitude of the alar cartilages, the degree of tip projection, the tip skin and subcutaneous thickness, the columellar length, the length of the nose, the width of the tip, and the tip-lip angulation and relationship.

One fundamental principle of tip surgery is that normal or ideal anatomic features of the tip should be preserved and, if possible, remain undisturbed by surgical dissection, and abnormal features must be analyzed, exposed, reanalyzed, and corrected by reduction, augmentation, or shape modification.[3]

Surgeons have gradually come to understand that radical excision and extensive sacrifice of alar cartilage and other tip support mechanisms all too frequently result in eventual unnatural or "surgical" tips. What appears pleasant and natural in the early postoperative period may heal poorly because of overaggressive attempts to modify the anatomy more extensively than the tissues allow. Cross-cutting or morselization of the lateral crura may provide an excellent early appearance but commonly results in distortion or loss of tip support as the soft tissues "shrink-wrap" the weakened cartilages over time. Rhinoplasty is, after all, a compromise operation in which tissue sacrifices are made to achieve a more favorable appearance. It therefore becomes judicious to develop a reasoned, planned approach to the nasal tip based entirely on the anatomy encountered coupled with the final result intended. A philosophy of a *systematic incremental anatomic approach* to tip surgery is highly useful to achieve consistently natural results. Conservative reduction of the volume of the cephalic margin of the lateral crus, preserving a substantially complete, undisturbed strip of residual alar cartilage, is a preferred operation in individuals in whom nasal tip changes are intended to be modest. As the tip deformity or asymmetry encountered becomes more profound, more aggressive techniques are required, from weakened and complete strip techniques to significant interruption of the residual complete strip with profound alteration in the alar cartilage size, attitude, and anatomy. Cartilage structural grafts to influence the size, shape, projection, and support of the tip are often invaluable.

Tip sculpture cannot be successfully undertaken, let alone mastered, until the *major and minor tip support mechanisms* are appreciated, respected, and preserved or, when indicated, reconstructed (Table 38–1). Loss of tip support and projection in the postoperative healing period is one of the most common surgical errors in rhinoplasty. This tip

TABLE 38–1. Tip Support Mechanisms

Major
Size, shape, and resilience of the medial and lateral crura
Medial crural footplate attachment to the caudal border of the quadrangular cartilage
Attachment of the upper lateral cartilages (caudal border) to the alar cartilages (cephalic border)
Minor*
Ligamentous sling spanning the paired domes of the alar cartilages
Cartilaginous septal dorsum
Sesamoid complex extending the support of the lateral crura to the piriform aperture
Attachment of the alar cartilages to the overlying skin and musculature
Nasal spine
Membranous septum

*On occasion, because of extreme anatomic variability, a "minor" tip support may assume the importance of one of the more major supports.

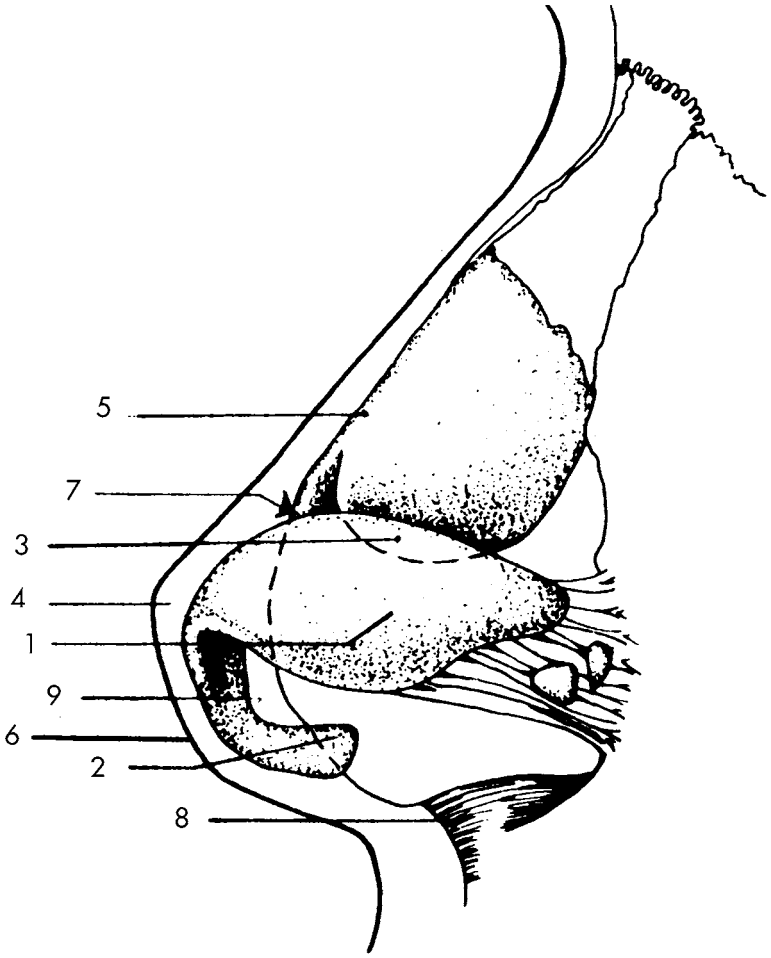

FIGURE 38–21. The *major* tip support mechanism of the nose consists of (1) the size, shape, and resiliency of the medial and lateral crura; (2) the wrap-around attachment of the medial crural footplates to the caudal end of the quadrilateral cartilage; and (3) the soft tissue attachments of the caudal margin of the upper lateral cartilage to the cephalic margin of the alar cartilage. The *minor* tip support mechanisms, which may in certain anatomic configurations assume major support importance, include (5) the dorsal cartilaginous septum, (4) the interdomal ligament, (9) the membranous septum, (8) the nasal spine, (6) the surrounding skin and soft tissues, and (7) the anterior septal angle.

"ptosis" is usually the inevitable result of the sacrifice of nasal tip support mechanisms.

In the majority of patients, the major tip support mechanisms (Figure 38–21) consist of (1) the size, shape, and resiliency of the medial and lateral crura; (2) the wrap-around attachment of the medial crural footplates to the caudal end of the quadrilateral cartilage; and (3) the soft tissue attachment of the caudal margin of the upper lateral cartilage to the cephalic margin of the alar cartilage. Compensatory re-establishment of major tip support should be considered if, during the operation, any or all of these major tip support mechanisms are compromised in any fashion.

The minor tip support mechanisms that, in certain anatomic configurations, may assume major support importance include (1) the dorsal cartilaginous septum, (2) the interdomal ligament, (3) the membranous septum, (4) the nasal spine, (5) the surrounding skin and soft tissues, and (6) the alar sidewalls.

Tip projection in every rhinoplasty operation is inevitably enhanced, reduced, or preserved in its original state. Anatomic situations in which each of these outcomes is desirable and intended are regularly encountered in a diverse rhinoplasty practice. The desirable surgical goal in every operation is preservation of the projection already existent if, as is true in the majority of rhinoplasty patients, preoperative projection of the tip is satisfactory. Other patients require an increase in the projection of the tip relative to the intended new profile line. A predictable variety of reliable operative methods exists for creating or augmenting tip projection; they are discussed later in this chapter. Finally, in a limited but clearly definable group of patients with overprojecting tips, a calculated intentional reduction of excessive tip projection is desirable to effect intentional retroprojection.

Successfully achieving these diverse surgical results requires an understanding of and a healthy respect for the major and minor tip support mechanisms, seasoned by the recognition of the intraopera-

tive surgical tip dynamic principles that interact in every tip operation. It clearly follows that the *appropriate tip incisions and approaches should be planned to preserve as many tip supports as possible.* Alar cartilage sculpturing should similarly respect this principle by conserving the volume and integrity of the lateral crus and avoiding, in all but the most extreme anatomic situation, radical excision and sacrifice of tip cartilage.

The surgeon should differentiate clearly among *incisions, approaches*, and *techniques*. Incisions are simply methods of gaining access to the underlying supportive structures of the nose and by themselves have little importance. Approaches to the nasal tip provide important exposure to the skeletal structures and consist of procedures to deliver the tip cartilages or to avoid complete delivery, or to operate on the alar cartilages without removing them from their anatomic beds. Sculpturing techniques are defined as surgical modifications: excision, reconstruction, or orientation of the alar cartilages calculated to cause significant changes in the definition, size, orientation, and projection of the nasal tip. Because of the amazing complexity of anatomic configurations encountered in nasal tip surgery, further modifications are frequently used to ensure stable refinements.

It is important to assess several factors before selecting the appropriate tip procedure. In planning tip remodeling, the surgeon must determine whether the tip requires (1) a reduction in the *volume* of the alar cartilages, (2) a change in the *attitude* and *orientation* of the alar cartilages, (3) a change in the *projection* of the tip, (4) a cephalic *rotation* with a subsequent increase in the columellar inclination (nasolabial angle), (5) a bilateral narrowing of the angle of the domes, and (6) reduction of the interdomal distance.

Ideally, conservative reduction of the volume of the cephalic margin of the lateral crus, preserving the majority of the crus while maintaining a complete (uninterrupted) strip of alar cartilage, is preferred. This procedure is satisfactory and appropriately safe when minimal conservational tip refinement and rotation are required. As the tip deformity increases in size and complexity, more aggressive techniques are required. A philosophy of a graduated incremental anatomic approach to nasal tip surgery has proved useful. This implies that no routine tip procedure is ever used; instead, the *appropriate incisions, approaches, and tip sculpturing techniques are selected based entirely on an analysis of the varying anatomy encountered.* Whenever possible, a complete strip operation is used, reserving more risky interrupted strip techniques for anatomic situations in which more profound refinement changes and significant rotation are desirable.

Surgical Approaches to the Tip. Nondelivery Approaches. In anatomic situations in which the nasal tip anatomy is favorable, only conservative refinements are necessary, and nondelivery approaches possess great value. Less dissection and less disturbance of the tip anatomy are necessary, and this reduces the chance for asymmetry, error, and unfavorable healing. Properly executed (when indicated), nondelivery approaches therefore allow the surgeon to control the healing process more accurately than when more radical approaches and techniques are chosen.

The transcartilaginous approach is preferred because of its simplicity and ease of use (Figure 38–22). The same tip refinements, however, may be accomplished through the retrograde approach. These approaches are chosen in patients whose tip anatomy is fundamentally satisfactory, requiring only volume reduction to accomplish a thinning sculpture of the cephalic or medial margin of the lateral crus. When tip projection is to be enhanced by the use of cartilage tip grafts, nondelivery approaches are preferred because precise recipient pockets may be more accurately created in the infratip lobule undisturbed by the minimal dissection inherent in nondelivery approaches. If sutured-in-place tip grafts are planned, a delivery or open approach is preferred.

Delivery Approaches. Delivering the alar cartilages as individual bipedicle chondrocutaneous flaps through intercartilaginous and marginal incisions is the preferred approach when the nasal tip anatomy is more abnormal (broad, asymmetric, etc) or when more dramatic tip refinements are necessary. Significant modifications in the alar cartilage shape, attitude, and orientation are more predictably attained when the cartilages are delivered (Figure 38–23). The basal photograph is usually helpful in determining which patients may best be approached in this manner. If the triangularity of the tip from below is satisfactory and only modest volume reduction of the lateral crus appears necessary, the nondelivery approach serves well. If, however, on basal and frontal views, the alar cartilages flare unpleasantly (Figure 38–24), tip triangularity

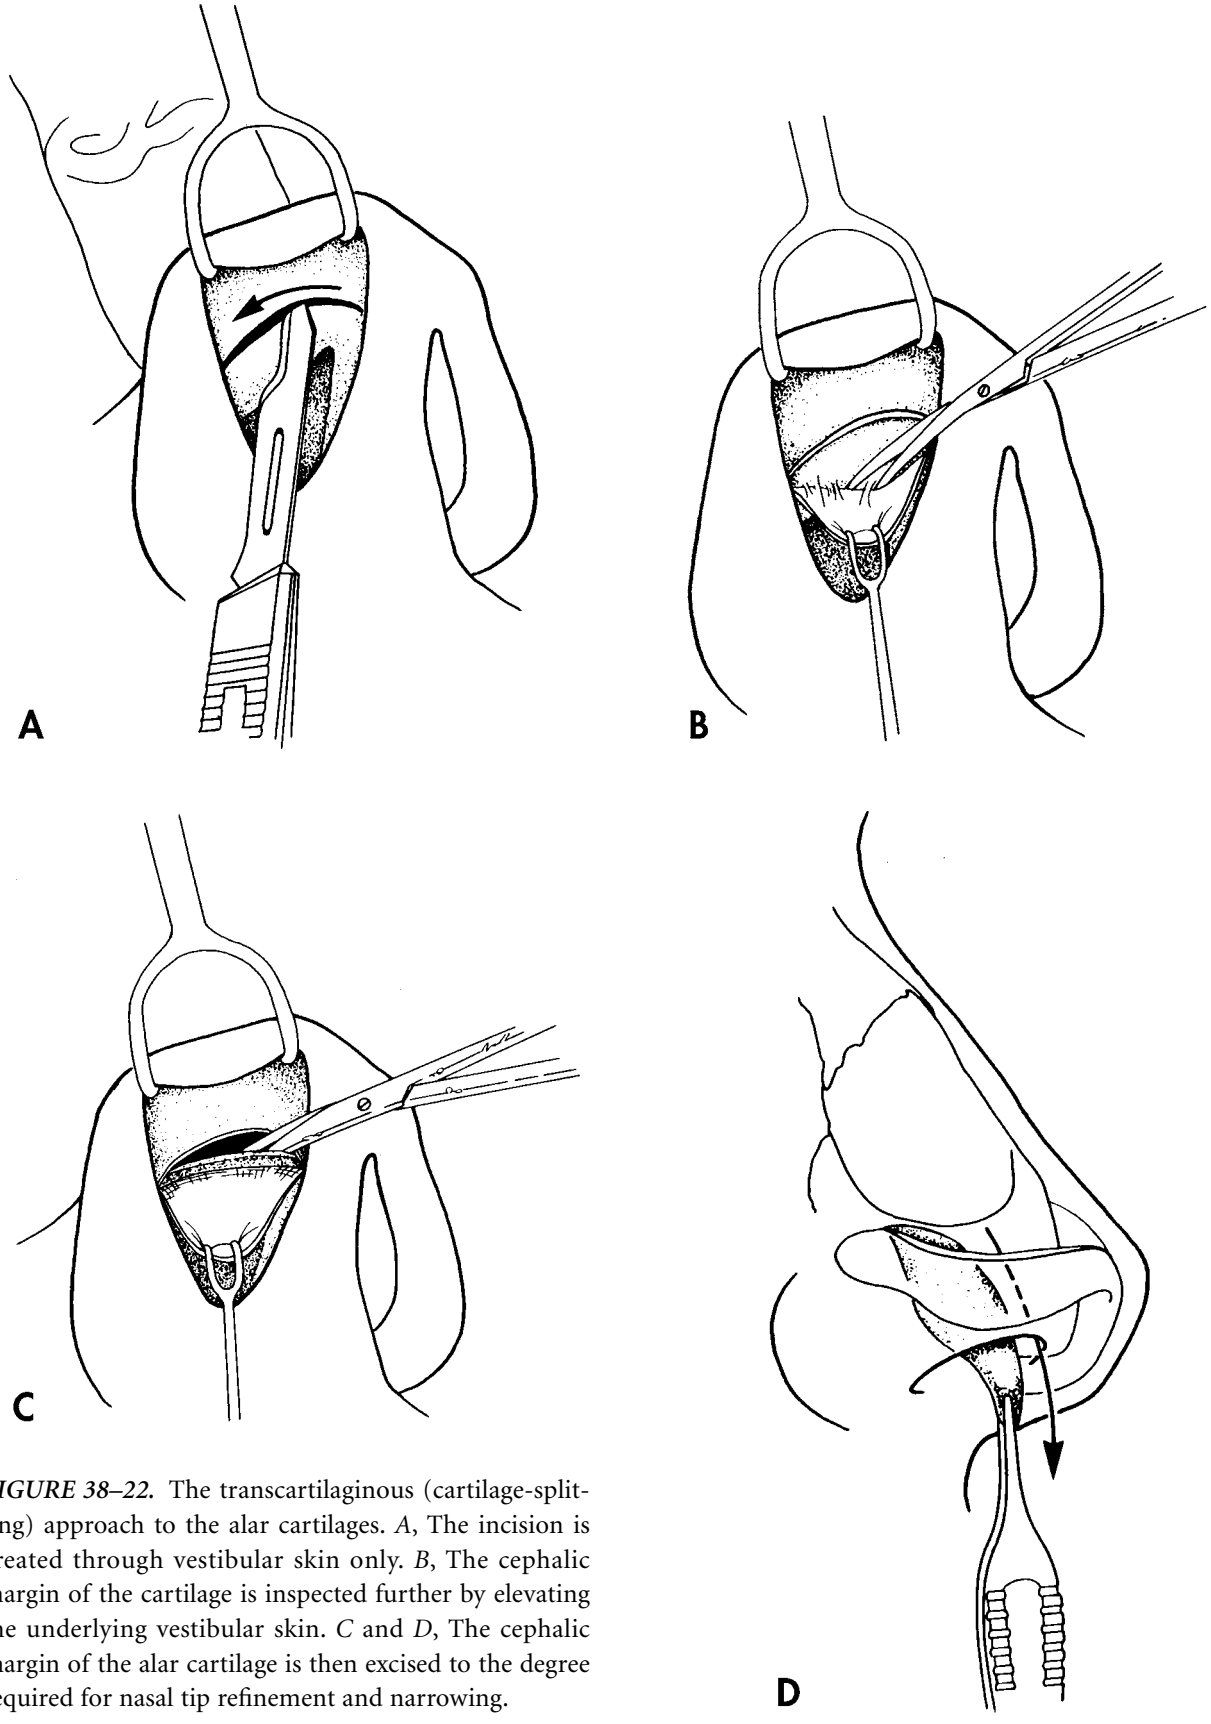

FIGURE 38–22. The transcartilaginous (cartilage-splitting) approach to the alar cartilages. *A*, The incision is created through vestibular skin only. *B*, The cephalic margin of the cartilage is inspected further by elevating the underlying vestibular skin. *C* and *D*, The cephalic margin of the alar cartilage is then excised to the degree required for nasal tip refinement and narrowing.

FIGURE 38–23. *A*, The delivery approach to the nasal tip (*B* and *C*). Intercartilaginous (*B*) and marginal (*C*) incisions are used on either side to free and deliver the alar cartilage for evaluation and refinement. *D*, Delivery of the lower lateral cartilage for analysis, inspection, and reconstruction.

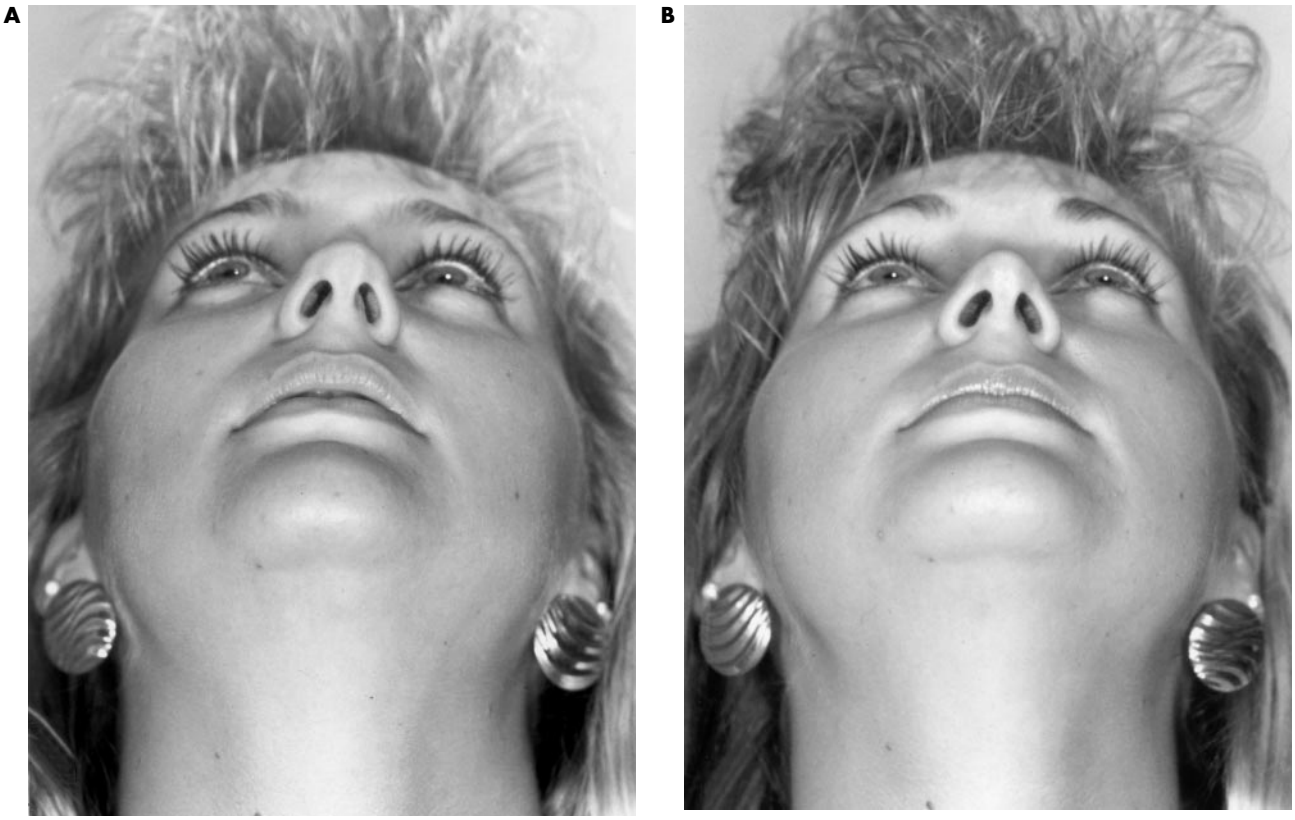

FIGURE 38–24. *A*, Basal view of a patient demonstrating a square- or trapezoid-shaped amorphous nasal tip, in which the delivery approach is preferred to refine cartilages and suture them together with a transdomal suture to achieve favorable triangularity. *B*, Improved basal view appearance 1 year after surgery.

is unsatisfactory or the tip appears too amorphous and bulbous, the domal angles are too wide, and the interdomal distance is excessive, a delivery approach is chosen to correct these esthetic deficiencies more thoroughly. Transdomal suture narrowing of broad domes (Figure 38–25), an effective and preferred technique, is effected by means of the delivery approach. In similar fashion, interrupted strip techniques (rarely employed) for more radical tip refinement and cephalic rotation are more efficiently accomplished when the cartilages are delivered. The increased surgical exposure provides the surgeon with an improved binocular view of the tip anatomy and affords the added ease of bimanual surgical modifications.

Open (External) Approach. The external or open approach to the nasal tip is in reality a more aggressive form of the delivery approach and is chosen with discretion in specific nasal tip deformities (Figure 38–26). When the nasal tip is highly asymmetric, markedly overprojected, severely underprojected, or anatomically confusing in its form (as in certain secondary revision cases), the open approach is considered. The transcolumellar scar is of negligible importance in this decision because it routinely

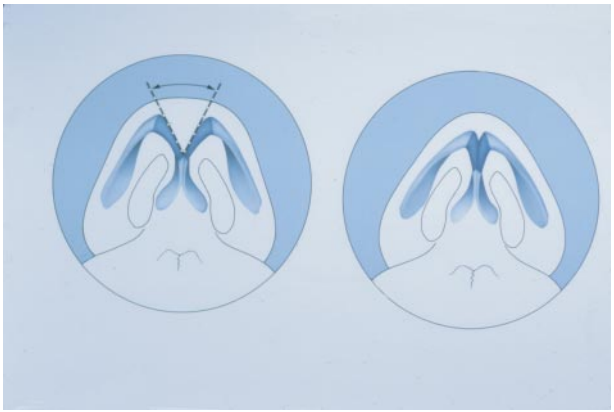

FIGURE 38–25. The triangular effect achieved by transdomal suturing of the alar cartilage domes, narrowing both the interdomal space and the bilateral domal angle.

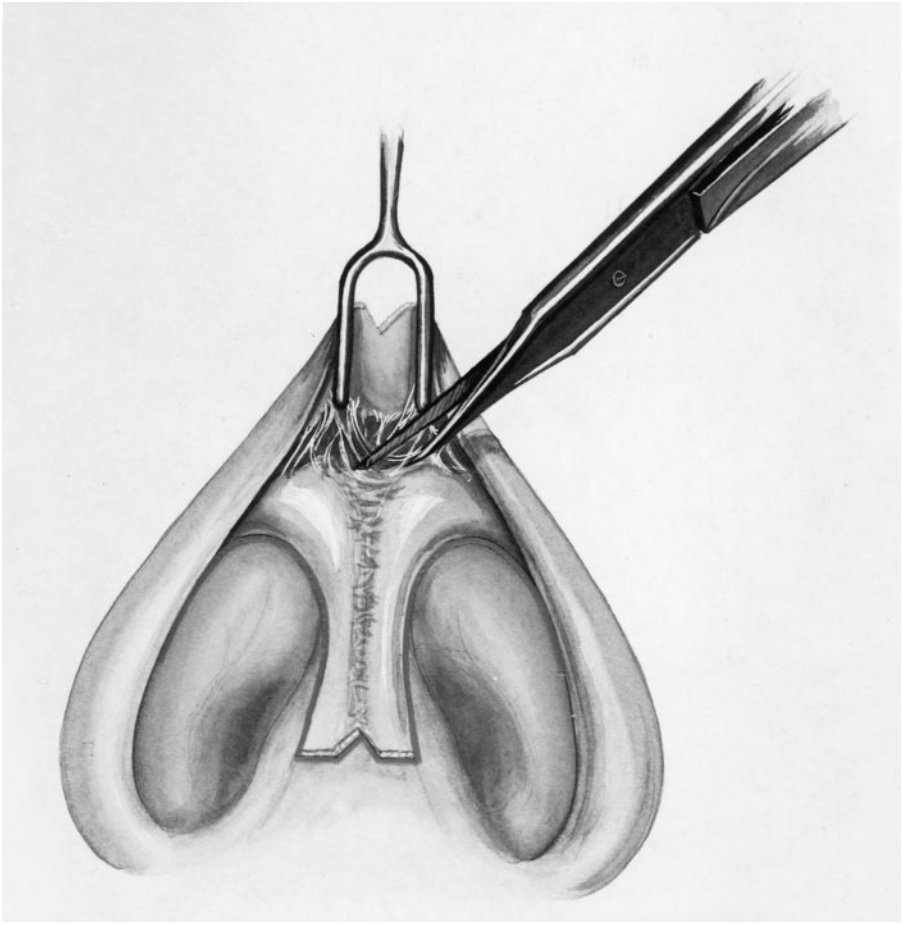

FIGURE 38–26. The open approach to the nasal tip, employing an irregularized incision across the columellar.

heals inconspicuously when meticulously repaired. The anatomic view is unparalleled through this approach, affording the surgeon diagnostic information unavailable through traditional closed approaches. These technical virtues must be balanced with the potential disadvantages of an enlarged scar bed, slightly delayed healing with some prolongation of tip edema, and an increased operating time. Clearly, when subtle and conservative tip surgery is indicated by the patient's existent anatomy, the open approach is unnecessary.

Alar Cartilage Sculpturing Techniques. The choice of the technique used to modify the alar cartilages and the relationship of the nasal tip with the remaining nasal structures should be *based entirely on the anatomy encountered* and the predicted result desired, as defined from the known dynamics of long-term healing. The astounding diversity of tip anatomic situations encountered demands a broad diversification of surgical planning and execution by the experienced surgeon.

Three broad categories of nasal tip sculpturing procedures may be identified. Although additional subtle technical variations exist, the three primary categories are (1) volume reduction with residual complete strip, (2) volume reduction with suture reorientation of the residual complete strip, and (3) volume reduction with interrupted strip.

Preserving intact the major portion of the *residual complete strip* of the alar cartilage is always preferred when the anatomy of the alar cartilages and their surrounding soft tissue investments allows. This preservative approach retains the supportive advantage of the intact cartilage strip (thus "mimicking" nature), discourages cephalic rotation when it is undesirable, eliminates many of the potential hazards of more radical techniques, and tends to produce a more natural final result (Figures 38–27 and 38–28).

Techniques involving a weakened (or suture-reoriented) residual complete strip have all the foregoing positive virtues and allow the surgeon to effect reorientation of the breadth of the domal angle, projection modification, and narrowing refinement, so

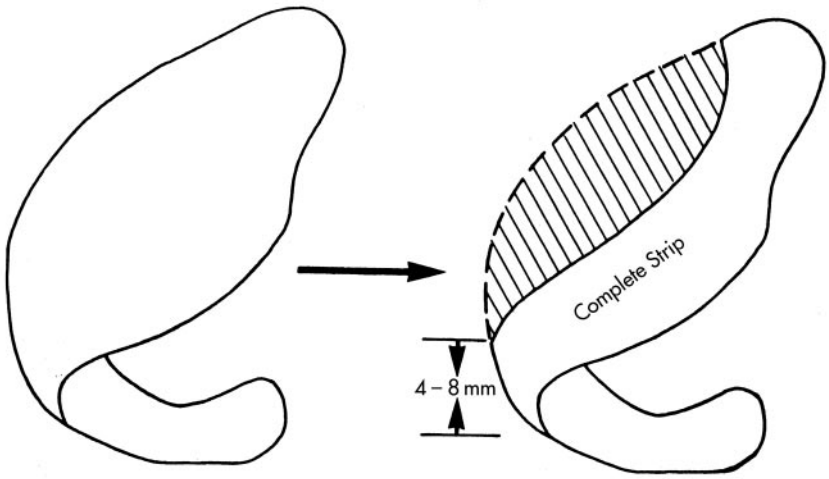

FIGURE 38–27. The minimum amount of complete strip that should remain after volume reduction of the alar cartilage.

desirable in the ideal postoperative appearance (Figures 38–29 and 38–30). The control of favorable healing is enhanced with these techniques, with the risk of complication diminished considerably.

Despite a laudable desire to preserve the integrity of the residual complete strip whenever possible, anatomic situations are occasionally encountered in which the shape, breadth, and orientation of the alar cartilages must be changed more radically by interrupting the complete strip in a vertical fashion somewhere along its extent to refine severe anatomic deficits[9] (Figures 38–31 and 38–32). When significant cephalic rotation is indicated, interrupted strip techniques are considered. The risks of asymmetric healing are higher when the alar cartilages are divided, however, and initial loss of tip support occurs immediately. The latter problem must be recognized and countermeasures taken during surgery to ensure that sufficient tip support is reconstituted. Shoring struts in the columella,

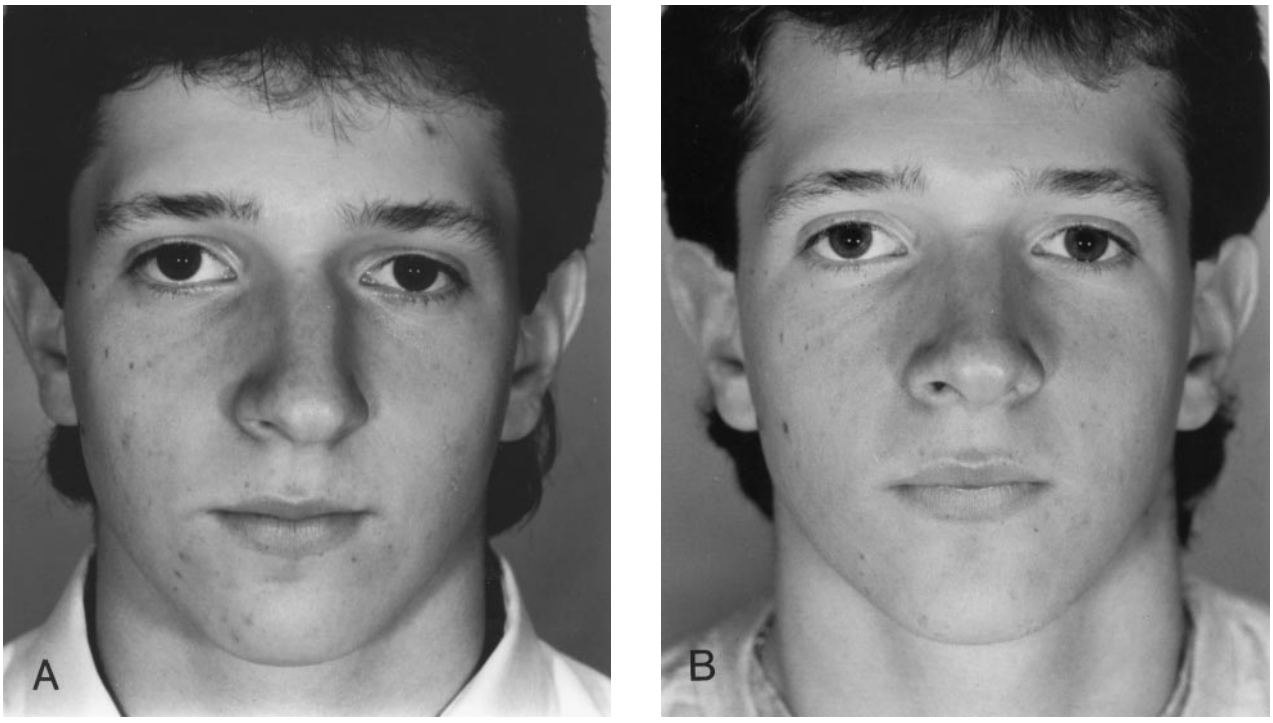

FIGURE 38–28. Patient before (*A*) and 1 year after (*B*) rhinoplasty using the transcartilaginous approach, preserving a generous complete strip of alar cartilage.

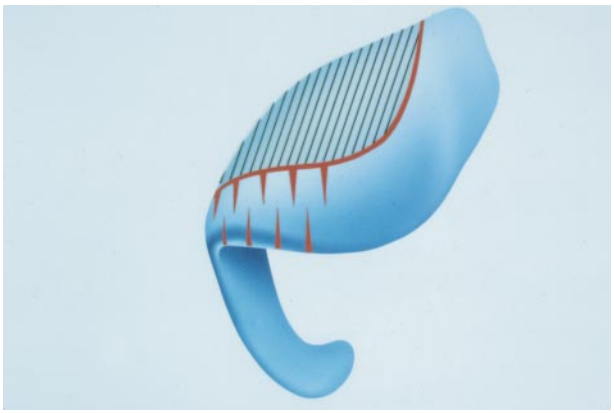

FIGURE 38–29. Weakening of residual complete strip by incomplete, noncoalescent incisions through the lateral crus. Although this technique helps to narrow bulky tips, less control over long-term favorable healing is realized.

infratip lobule cartilage grafts, and transdomal suturing are the most commonly used tip support adjuncts. Almost without exception, interrupted strips should be avoided in patients displaying thin skin with sparse subcutaneous tissue.

Tip Projection and Cartilage Tip Grafts. In addition to the creation of narrowing refinement and symmetry of the nasal tip, most evident in the frontal view, *appropriate projection* must be preserved or newly created to result in the most natural appearance possible. Clearly, the most attractive and elegant noses are those in which anterior projection is sufficient to set the tip subtly but distinctly apart from the nasal supratip areas. Ptotic or poorly projected tips produce a snubbed and indistinct appearance.[10]

Ideally on profile view, the nasal tip should be slightly elevated above the cartilaginous dorsum by 1 to 2 mm, blending gently rather than abruptly into the supratip (Figure 38–33). If the preoperative projection of the tip is normal and adequate, lowering the cartilaginous dorsum into proper alignment will achieve a satisfactory esthetic appearance provided that no loss of tip support occurs during the operative or postoperative periods. Preserving the major and minor tip support structures increases this likelihood, whereas their sacrifice without compensatory re-establishment of support inevitably leads to eventual tip ptosis. If preoperative tip projection is

FIGURE 38–30. Patient before (*A*) and 1 year after (*B*) surgery. The nasal tip has been refined using a weakened complete strip technique with a transdomal suture repair created through a delivery approach.

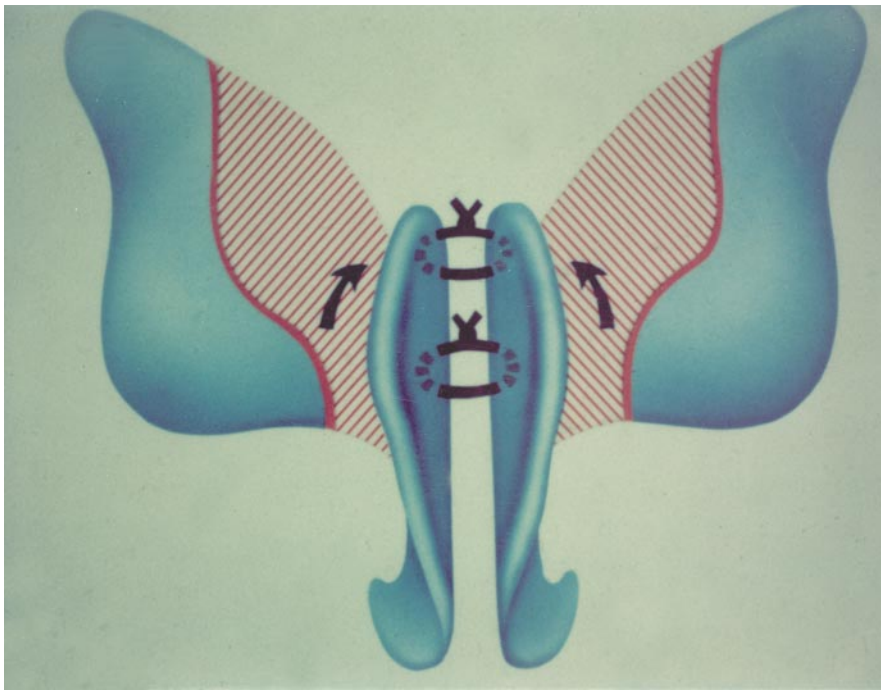

FIGURE 38–31. Interruption of the lower lateral cartilage at the domal angles, creating an interrupted complete strip.

FIGURE 38–32. Patient before (*A*) and 1 year after (*B*) rhinoplasty using a delivery approach and interrupted-strip technique for refinement of the nasal tip. Heavy bulbous cartilages accompanied by thick skin and subcutaneous tissues dictated the need for this more radical technique.

FIGURE 38–33. An ideal nasal profile in a patient in whom the nasal tip leads the supratip cartilaginous dorsum by 1 to 2 mm.

inadequate, attempts to over-reduce the supratip cartilaginous dorsum to produce pseudoprojection of the tip are inadvisable and lead to apparent flattening or widening of the middle third of the nose.

If tip projection is inadequate, several reliable methods may be used singly or in tandem to establish permanent improvement. All involve reorientation of the alar cartilages or addition of autogenous cartilage grafts to strengthen or sculpt the projection and/or attitude of the tip and infratip lobule.

Because the long-term viability and stability of sutured-in-place cartilage tip grafts are well established, they are regularly used with success if the surgical modification of existing alar cartilage configuration is not adequate to produce the desired degree of projection.[2,3] In revision rhinoplasty in particular, cartilage tip grafts are irreplaceable in skeletal reconstruction beneath scarred skin and asymmetric topography.

Two distinct varieties of tip grafts are preferred: those that directly overlie the dome profile of the alar cartilage and those that redefine and contour the skeletal anatomy of the infratip lobule (Figure 38–34). Because these grafts (single or laminated) lie in intimate subcutaneous pockets, exacting sculpture of their size and shape is mandatory. Harvested from septal or auricular cartilage, they are ideally inserted with or without suture fixation into small pockets dissected to accommodate exactly the dimensions of the graft(s). Bilateral marginal incisions beneath the anatomic dome area facilitate the careful pocket creation and render final positioning and stabilization of the graft easier than if only one unilateral incision is used. Suture fixation to the alar cartilages may be necessary if the tip region has been widely developed in a primary delivery or open approach method, disallowing the creation of a stable, limited, defined pocket. The edges of the grafts must be beveled or softened to avoid visible contour irregularities or to offset deformities. Carved in triangular, trapezoid, or shield-like shapes, tip grafts may accentuate favorable tip-defining points and highlights while imparting a more natural appearance to tips with congenital or postsurgical inadequacies (Figure 38–35).

If additional projection is required, it may be achieved in a variety of ways. Autogenous *cartilage struts* positioned below and/or between medial crura are effective in establishing permanent tip stability

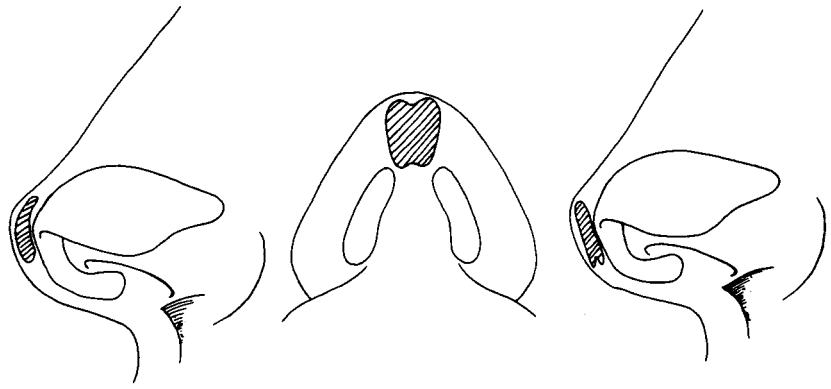

FIGURE 38–34. Cartilage grafts positioned in the nasal tip or infratip lobule serve well to contour and create ideal projection.

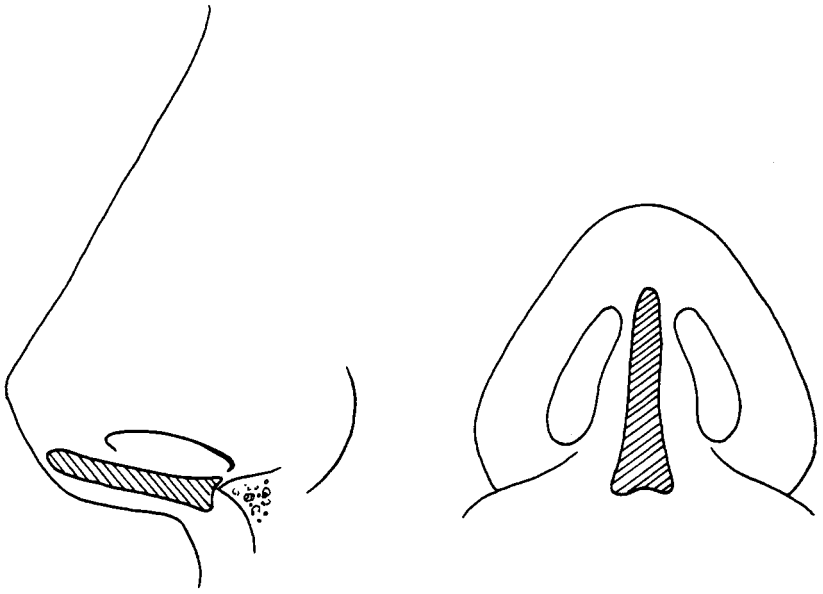
FIGURE 38–35. Sculptured tip graft and columellar strut (from nasal septal cartilage) designed to support and project the nasal tip.

and slight additional projection (Figure 38–36). *Plumping grafts* of cartilage fragments, introduced into the base of the columella through a low lateral columellar incision, provide an additional platform for the tip projection resulting from the strut. Cartilage struts should be shaped with a gentle curve to match the anatomy of the curved columella, at times aiding in the creation of a distinct "double break," but should never extend to the apex of the tip skin lest a tent-pole appearance develops. If the medial crural footplates diverge in a widely splayed fashion, further tip projection may be gained by resecting excessive intercrural soft tissue and suturing the medial crura together.

FIGURE 38–36. Autogenous cartilage struts may be positioned in precise pockets or sutured into position between the medial crura.



Tip Rotation. In many patients undergoing rhinoplasty, *cephalic rotation* of the nasal tip complex (alar cartilages, columella, and nasal base) assumes major importance in the surgical event, whereas in other individuals, the *prevention* of upward rotation is vital. Certain well-defined and reliable principles may be invoked by the nasal surgeon essentially to calibrate the degree of tip rotation (or prevention thereof). The dynamics of healing play a critical role in tip rotation principles; the control of these postoperative healing changes distinguishes rhinoplasty from less elegant procedures. In the past, over-rotation of the nasal tip created an unhealthy stigma for the rhinoplasty procedure. Most individuals recognize and prefer the esthetic advantages of the stronger nose possessed of sufficient length to impart character and suitable proportions to the face.

The planned degree of tip rotation depends on a variety of factors, which often include (1) the length of the nose, (2) the length of the face, (3) the length of the upper lip, (4) facial balance and proportions, (5) the patient's esthetic desires, and (6) the surgeon's esthetic judgment.

An important distinction must be drawn between *tip rotation* and *tip projection*. Although certain tip rotation techniques may result in desirable increases in tip projection, the converse is not true. Tip rotation and projection, in fact, complement each other, and their proper achievement in individual patients is constantly interrelated. A classic example of this interdependent relationship is illustrated by the almost inevitable loss of tip projection when interrupted strip techniques are chosen to enhance cephalic rotation; steps must be planned to restore adequate long-term tip projection by one of the several methods recommended.

Finally, a distinction must be drawn between true tip rotation and the *illusion* of tip rotation achieved by contouring cartilage grafts placed in the infratip lobule, columella, and nasolabial angle. Favorable modifications in the tip-lip complex profile areas with autogenous implants may obviate the need for any actual tip rotation, thus preserving a long, and at times more desirable, nasal appearance. Reduction of the nasal profile, particularly the supratip cartilaginous pyramid, may also impart the illusion of rotation and a shortened nose, although occasionally at the expense of a strong and narrow dorsum.

Nasal tip rotation results fundamentally from planned surgical modifications of the alar cartilages, but increments of rotation may also be realized from additional adjunctive procedures on nasal structures adjacent to the alar cartilages, which exert a favorable influence on calibrated tip rotation methods. *Shortening of the caudal edge of the septum, excision of the caudal margins of overlong upper lateral cartilages, and septal shortening with a high transfixion incision* are regularly used to enhance the effects of a planned degree of tip rotation.[11]

Because tip rotation is only one of the many objectives of rhinoplasty, decisions regarding rotation must be interrelated with planning for tip volume reduction, alar cartilage thinning reduction, and modifications in the attitude and angulation of the alar cartilages.

The techniques and healing dynamics described are not absolute but are reasonably predictable. Most tip rotation techniques may be incorporated in an organizational scheme that incorporates three procedures preserving a complete, intact strip of alar cartilage (Figure 38–37) and three additional procedures involving interrupted strip techniques (Figure 38–38). Unique anatomic situations are regularly encountered that require modifications of this scheme to achieve a more refined result, but the fundamental principles elaborated remain constant. In addition, the thickness and strength of the alar cartilages, along with the character of their enveloping soft tissue and skin, dictate, to a degree, which techniques may safely and predictably be used in each anatomic situation.

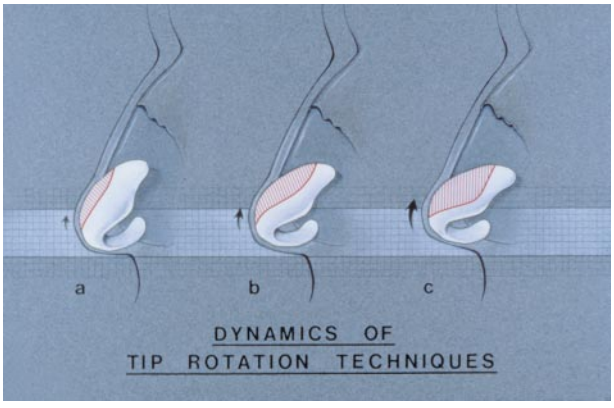


FIGURE 38–37. A to *C*, Preserving an intact strip of lower lateral cartilage tends to resist upward rotation. The greater the tissue void created, the greater is the tendency of scar tissue contracture to result in slight upward rotation as the tissue void is closed.

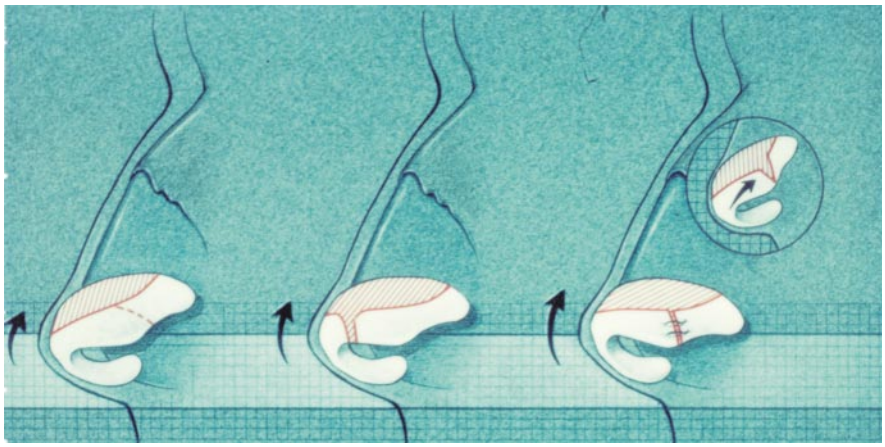

FIGURE 38–38. Interrupted strip techniques tend to foster cephalic rotation by weakening the strength of the residual cartilage strip, allowing scar contracture to pull the tip cephalically.

Complete strip techniques are always preferable tip procedures when the nasal anatomy permits, and the goals of the surgical procedure may be met without resorting to the less predictable interrupted strip procedures. Preserving a complete, uninterrupted segment of alar cartilage remnant contributes to a more stable and better supported nasal tip that tends to *resist* cephalic rotation during healing.

Interrupted strip techniques, combined with volume reduction of excessive alar cartilage, tend to result in a more substantial degree of cephalic rotation of the tip complex. Once the complete strip of residual alar cartilage is divided (interrupted), the result is a relative instability of the nasal tip, on which the forces of upward scar contraction create a variable degree of cephalic rotation, underscoring the principle that during scar contracture, tissues are generally moved from areas of instability (in this case, the unstable nasal tip cartilages) toward areas of stability (the bony-cartilaginous nasal pyramid).

Tip Rotation with Complete Strip Techniques. Volume reduction of the alar cartilage causes a tissue deficit of minimal, moderate, or maximal proportions, depending on the degree of cartilage removal indicated or desirable. Essentially, no cephalic tip rotation results from minimal volume reduction alone, whereas the greater tissue void resulting from moderate to maximal volume reduction tends to create progressively greater degrees of minimal tip rotation. Indeed, preservation of the complete strip is regularly indicated and preferred to *resist* the forces of upward rotation when the preoperative nasal length is to be maintained.

Substantial planned tip rotation when complete strip techniques are used depends therefore on the addition of adjunctive procedures to achieve cephalic elevation of the tip such as septal shortening with a high septal transfixion or on designing illusions of tip rotation with a high septal transfixion or the use of cartilage battens, struts, or plumping implants.

Tip Rotation with Interrupted Strip Techniques. When the integrity and spring of the alar cartilage are broken, cephalic rotation is fostered by virtue of upward scar contracture forces acting inexorably on alar cartilage segments, which are now more flail and less supported. These techniques are particularly useful when the attitude of the alar cartilages is one of a profound downward inclination, imparting a depressed or snarl-like appearance to the nose. Caution must be exercised constantly in the use of interrupted strips in patients with thin skin and/or more delicate cartilages because the absence of good tip-supporting structures sets the stage for loss of projection, alar collapse, notching, pinching, and asymmetry.

Lateral Interruption Techniques. In anatomic situations in which cephalic rotation is desirable and the anatomy of the bridge between the medial and lateral crus (the "dome") is esthetically pleasing, lateral interruption of the residual complete strip has merit[9] (see Figure 38–38). Avoiding interruption of the strip medially fosters symmetric healing and reduces the likelihood that uneven tip-defining points will become evident months after the operation. The lateral interruption allows the reduced alar cartilage to be pulled moderately upward by scar tissue during healing, but because the dividing cut is sited more laterally and therefore more deeply in the soft tissues of the tip, notching, pinching, and other asymmetries

are essentially prevented. If modification of the dome is necessary, transdomal suture techniques to narrow, refine, and even slightly project the tip may be favorably combined with lateral interruption.

MEDIAL INTERRUPTION TECHNIQUES. Many different methods of interruption of the residual complete strip at or near the dome have been described; each predictably leads to some degree of cephalic rotation, and the complete strip is converted to two or more segments of flail cartilage (see Figure 38–38). Planned rotation with this approach is reserved for patients with thicker skin and supporting structures to minimize undesirable consequences of asymmetric healing and even over-rotation. Elevation of the medial aspect of the nostril margin, an onerous stigma of nasal surgery, is more common with medial strip interruption.

Medial interruption techniques almost always result in a moderate to major loss of tip projection, and adjunctive procedures are required to restore or augment tip projection to avoid tip ptosis.

LATERAL INTERRUPTION TECHNIQUES WITH SUTURE ROTATION. An ideal method for significant tip rotation would combine lateral strip interruption to preserve the integrity of the strip medially with a calibrated triangular excision of cartilage laterally and stabilization of the cut cartilage edges with suture fixation[3] (Figure 38–39). The degree of rotation realized here is controllable by the surgeon, essentially eliminates most of the undesirable sequelae of interrupted strip techniques, and changes in a predictable and permanent way the attitude of the alar cartilages. The suture fixation helps to diminish loss of tip support inherent in most interrupted strip techniques. In individuals with thin or moderately thin skin with more delicate cartilages, this method is highly predictable and desirable.

As with the rotation concepts discussed in connection with complete strip techniques, the same adjunctive techniques for enhancing tip rotation may be useful to combine with interrupted strip techniques. Included among these adjunctive techniques to cephalic rotation are (1) shortening of the caudal edge of the septum, (2) shortening of the caudal margins of the upper lateral cartilages, (3) high septal incision for wedge excision of septum, and (4) reduction of overly convex medial crura (caudal margin) (Figure 38–40, A to D).

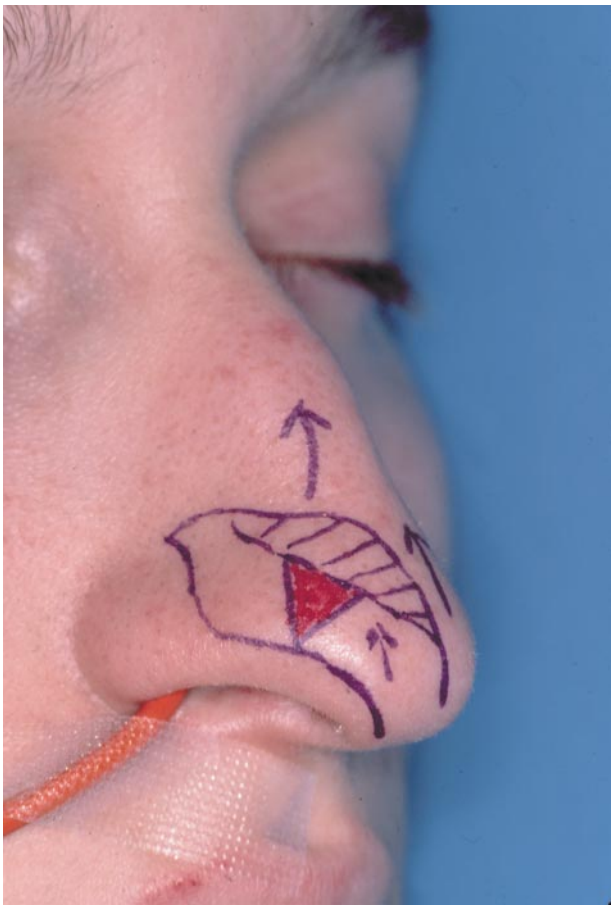

FIGURE 38–39. Lateral interruption of the residual lateral crus, with calibrated excision of a base-up triangle, allows a *controlled* cephalic rotation dependent on the geometry of the excised triangle.

Over-rotation, however, must be assiduously avoided because the correction of this undesirable postoperative situation is often difficult or impossible.

CORRECTION OF THE OVERPROJECTING TIP. Profound facial and nasal disharmony may result from the anatomic facial feature variant termed "the overprojecting nose." Because the entire nose, and especially the normal nasal tip, is composed of distinct, interrelated anatomic components, any one or a combination of several of these components may be responsible for the tip that projects too far forward of the anterior plane of the face. The guidelines for determining appropriate and inappropriate tip projection are now well accepted (Figure 38–41). When numerous patients with overprojecting tips are analyzed, it becomes apparent that no single anatomic component of the nose is constantly responsible for

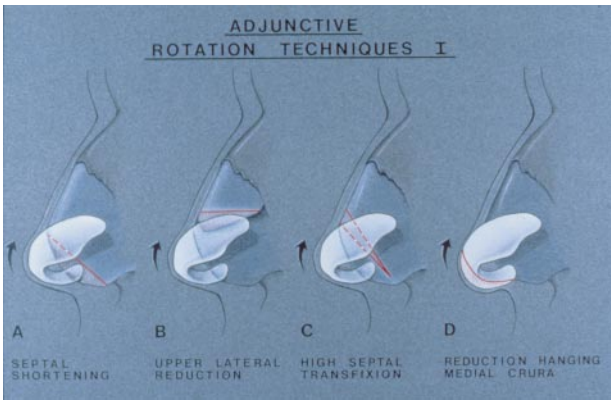

FIGURE 38–40. *A* to *D*, Adjunctive techniques tend to foster cephalic rotation of the nasal tip.

overprojection; therefore, no single surgical technique is uniformly useful in correcting all of the problems responsible for the various overprojection deformities.[3,4]

Accurate anatomic diagnosis allows preoperative development of a logical individualized strategy for correction and tip retropositioning. In almost every instance, *weakening or reducing of normal tip support mechanisms is required* to achieve normality, supplemented by reduction of the overdeveloped components. The following anatomic variants are commonly responsible individually or collectively for overprojection of the nasal tip.

Overdevelopment of the alar cartilages, commonly associated with thin skin and large nostrils, is frequently encountered in the overprojecting nose. The junction between the medial and lateral crura may form an overlarge dome of significant convexity, or the anatomic dome area may be sharply angulated, twisted, or even buckled, frequently demonstrating significant asymmetry of the entire tip and its tip-defining points. The hypertrophied cartilages must be delivered, their abnormalities visually diagnosed, and overall volume reduction of both the lateral and medial crura accomplished. Portions of the medial crus may require resection to retroposition the nasal tip satisfactorily.

Overprojection and obliteration of a definitive nasolabial angle may be the result of *overdevelopment of the caudal part of the quadrilateral cartilage* (Figure 38–42). The nasal spine may, in fact, be of normal size, but if it is even slightly overlarge, it compounds the problem of overprojection. In effecting repair, the caudal septal margin abutting the nasal spine should always be inspected and shave-reduced to normal proportion before sacrificing any of the nasal spine.

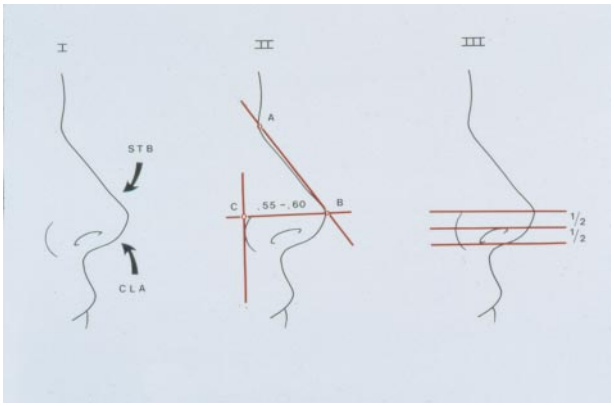

FIGURE 38–41. Goode has characterized the guidelines for nasal tip projection. If the tip projects from the alar-facial junction to the nasal tip–defining point more than 0.55 to 0.6 of a line connecting the tip-defining point and nasal frontal angle, the nose may be considered overprojected.

FIGURE 38–42. Overprojection of the nose as a result of overdevelopment of the caudal part of the quadrilateral cartilage.

A *high anterior septal angle* caused by an overdeveloped quadrilateral cartilage component may spuriously elevate the tip to an abnormally forward projecting position (Figure 38–43), even when associated with otherwise perfectly normal tip anatomy.[12] This condition tends to "tent" the tip away from the face and "tether" the upper lip, producing an indefinite nasolabial angle and, on occasion, creating abnormal exposure of the maxillary gingiva, particularly on smiling. Correction demands a departure from the normal operative sequence of correcting the tip first. The initial surgical steps are planned to lower the cartilaginous profile first, releasing the tip from an abnormal overprojected influence. Further tip refinement measures can then be carried out as desired and indicated by the alar cartilage anatomy.

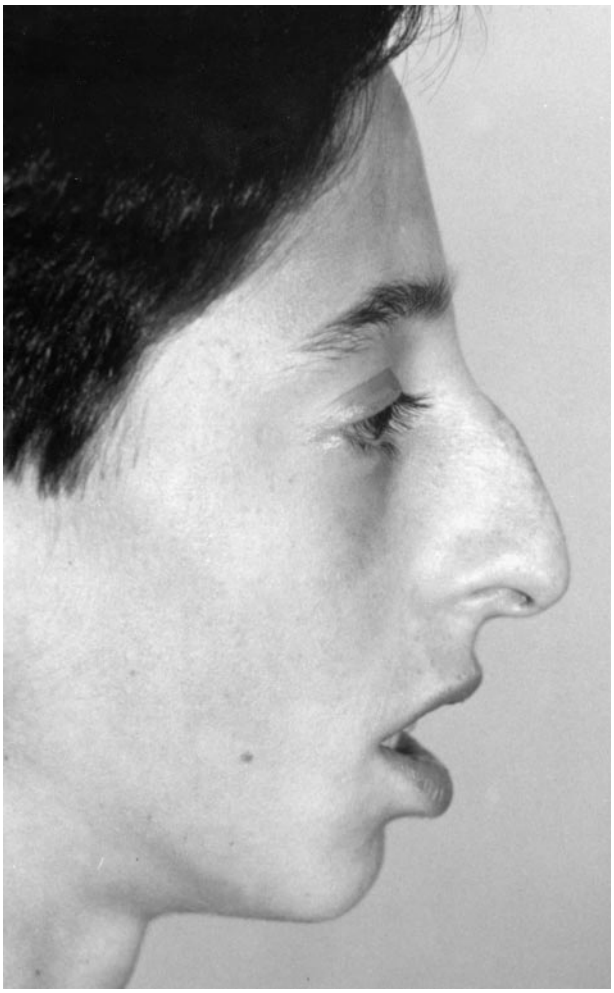

FIGURE 38–43. Overprojection of the nose secondary to an overdeveloped dorsal part of the quadrilateral cartilage component.

A less common cause of excess nasal tip projection is an *overlarge nasal bony spine*, which seemingly imparts an upward thrust of the tip components (which may otherwise be of normal dimensions). Compounding this abnormal appearance is often a coexistent blunting of the nasolabial angle, which may appear full, webbed, and excessively obtuse, with no obvious demarcation between the tip and columella. The upper lip may appear short, tethered, and tense, often exposing excessive gingiva in facial repose as well as in animation. Rongeur or osteotome reduction of the overlarge spine and associated caudal quadrilateral cartilage and soft tissue is a surgical prerequisite to tip retrodisplacement.

Tip overprojection may occur as a result of an *overly long columella* associated with excessively long medial crura. In this deformity, the infratip lobule is commonly insufficient, creating the effect of extremely large and disproportionate nostrils.[13] This deformity suggests the use of an external approach to the nasal tip to shorten the columellar length as well as that of the medial crura.

Various *combinations* of the foregoing hypertrophic anatomic problems may contribute to the overprojecting tip problem. In preoperative analysis, each nasal component must be compulsively identified and analyzed; only then can a definitive plan for natural correction be conceived. Generally, a combination of weakening of the major tip support mechanisms associated with reduction of the components responsible for the tip overprojection is carried out incrementally and as conservatively as possible to achieve the desired normal final result in a progressive fashion. The various components capable of creating or contributing to overprojection of the nose are shown in Table 38–2.

Iatrogenic overprojection may occur when surgeons intent on profoundly increasing tip projection produce an unnaturally sharp and projected tip con-

figuration (often associated with over-rotation of the tip).[4] These misadventures commonly result from overaggressive tip surgery in which portions of the lateral crus are borrowed and rotated medially to increase medial crus projection.

ALAR BASE REDUCTION. Appropriate retroprojection of the projecting nose typically requires diminishing the various major and minor tip support mechanisms to retroposition the tip closer to the face. A concomitant reduction of the alar component length and lateral flare (occasioned by tip retropositioning) is usually required to improve nasal balance and harmony. Alar wedge excisions of various geometric designs and dimensions are necessary to balance alar length and position (Figure 38–44). The exact geometry of these excisions is determined by the present and intended shape of the nostril aperture, the degree and attitude of the lateral alar flare, the width and shape of the nostril sill, and the thickness of the alae. It is axiomatic that the surgeon creating alar reduction by excision of alar or nostril floor tissue should always err on the side of conservatism and strive for symmetric repair because overaggressive and asymmetric tissue resection leads to an almost irreversible situation of disharmony and even nostril stenosis.

Profile Alignment Three anatomic nasal components are responsible for the preoperative profile appearance: the *nasal bones, the cartilaginous septum*, and *the alar cartilages*. Generally, all three must undergo modification to create a pleasing and natural profile alignment. If the nose is overlarge with a convex profile, reduction of the three segments is required. Less commonly (except in revision rhinoplasty), profile *augmentation* with autograft materials must be accomplished.

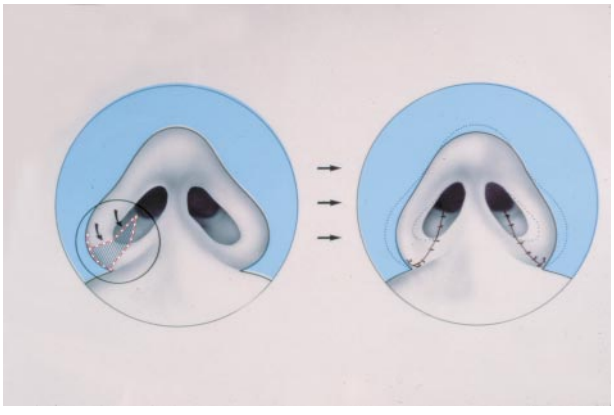

FIGURE 38–44. Alar wedge excisions of various geometric designs and dimensions are necessary to improve the alar flaring found in certain patients. The exact design of each tissue removal depends on the dimensions of the alar sidewalls and the nostril itself.

The surgeon visualizes the ultimate intended profile, extending from the nasofrontal angle to the tip-defining point, and then on around the infratip lobule and columella to the nasolabial angle. The extent of reduction of bone, cartilage, and soft tissue always depends on and should be guided by stable tip projection; *therefore, positioning the projection of the tip at the outset of the operative procedure is beneficial.*[13] Because the thickness of the investing soft tissues and skin varies at different areas of the profile and from patient to patient, dissimilar portions of cartilage and bone must be removed to create a straight or slightly concave profile ultimately.[14] Strong, high profiles generally suit the patient best in the long term, contributing to a more elegant nose on profile and oblique views and also a more narrow nasal appearance on frontal view (Figure 38–45). Over-reduced profiles result in a washed-out, indefinite, and widened appearance from the front, separating the eyes inadequately and reflecting light poorly.

In planning profile alignment, the two stable reference points are the existing (or planned) *nasofrontal angle* and the *tip-defining point*. Esthetics are generally best served when profile reduction results in a high, straight-line profile in men and the leading edge of the tip just slightly higher in women. A gentle slope of no more than 2 to 3 mm should exist between the caudal part of the cartilaginous dorsum and the most anteriorly projecting aspect of the nasal tip. Reversal of the usual preoperative tip-supratip relationship is required to achieve this esthetic ideal.

The degree and angulation of the "hump removal" depend on various factors, the most important of which are the size of the various involved anatomic components and the surgeon's confidence in the stability of postoperative tip projection.[14] These must be balanced with the personal preference for profile appearance combined with the surgeon's value judgment of facial esthetics.

Surgical access to the nasal dorsum is gained through the transcartilaginous, intercartilaginous, or transcolumellar incision, depending on which approach was used during tip refinement. In endonasal approaches, a complete transfixion inci-

FIGURE 38–45. Patient before (*A*) and 1 year after (*B*) rhinoplasty. A strong, high profile has been maintained.

sion for exposure is unnecessary and may compromise tip support by sacrificing the attachment of the medial crural footplates to the caudal septum.

The plane of tissue elevation over the nasal dorsum is important for several reasons. A relatively avascular potential plane exists intimate (superficial) to the perichondrium of the cartilaginous vault and just below the periosteum of the bony vault.[3,6] Elevating the soft tissue flap in this important plane (Figure 38–46) preserves the thickest possible ultimate epithelial soft tissue covering to cushion the newly formed bony and cartilaginous profile. Generally, only sufficient skin is elevated to gain access to the bony and cartilaginous profile; therefore, wide undermining is unnecessary in the typical rhinoplasty. In older patients with redundant and less elastic skin, or when access is needed for major autograft augmentation, wider undermining is carried out.[15] Even in the latter instance, the periosteal soft tissue layer over the intended site of the low lateral osteotomies is preserved intact to help stabilize the mobile bony pyramid after infracture osteotomy maneuvers.

The soft tissues over the cartilaginous dorsum are elevated by means of scalpel dissection with a No. 15c blade (Figure 38–47), and the periosteum over the bony pyramid is lifted from its stable bony attach-

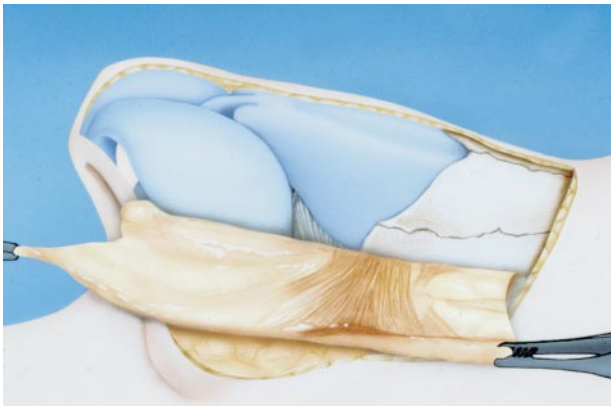

FIGURE 38–46. Favorable tissue dissection plane of the nose, located intimate to the cartilaginous structure of the nose, beneath the overlying superficial musculoaponeurotic system fascial network.

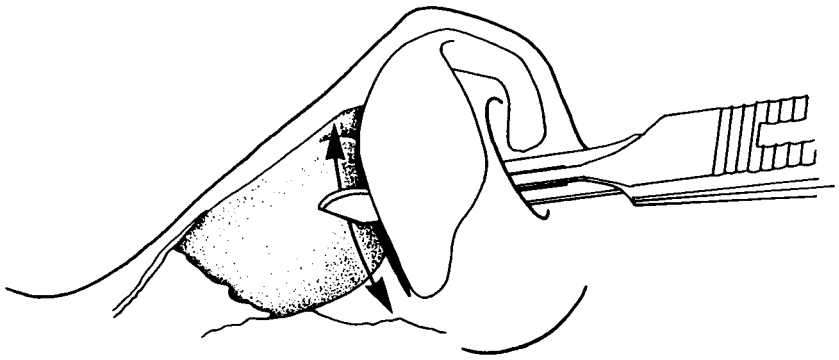

FIGURE 38–47. Elevation of the nasal skin and subcutaneous tissue layers by knife dissection, staying intimate to the perichondrium overlying the cartilaginous pyramid.

ment with the knife and sharp Joseph elevator (Figure 38–48). Because the periosteum inserts into the internasal suture line in the midline, the periosteum is lifted on either side of this suture and the space is brought into continuity with the sharp scissors. Little or no bleeding should ensue during uncovering of the nasal skeleton in these important planes, allowing direct visual assessment of the anatomy encountered.

Either of two methods of profile alignment is preferred: *incremental* or *en bloc.*[14] In the first method, the cartilaginous dorsum is reduced by incrementally shaving away the cartilaginous dorsum until an ideal tip-supratip relationship is established (Figure 38–49), followed by sharp osteotome removal of the residual bony hump.

If only minimal hump removal is contemplated, the knife is positioned at the osseocartilaginous junction, plunged through this area, and then advanced caudally to and around the anterior septal angle of the caudal portion of the septum. In

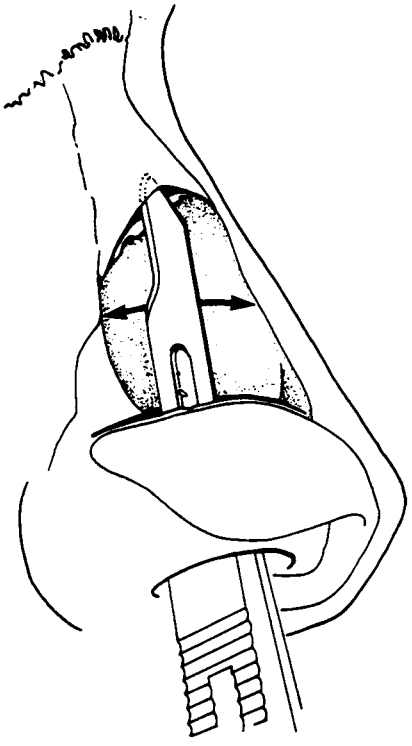

FIGURE 38–48. Elevation of the periosteum overlying the bony pyramid.

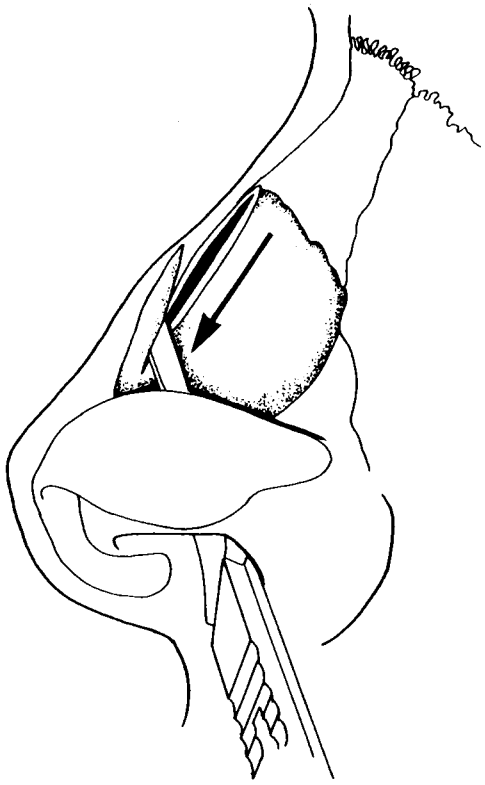

FIGURE 38–49. Incremental reduction of the cartilaginous pyramid.

large cartilaginous reductions, a portion of the upper lateral cartilage attachment to the quadrilateral cartilage must be removed with the dorsal septum, but leaving these two cartilaginous components attached by the intact underlying mucoperichondrial bridge.

A Rubin osteotome, honed to razor sharpness for each procedure and seated in the opening made by the knife at the osseocartilaginous junction, is advanced cephalically to remove the desired degree of bony hump in continuity with the cartilaginous hump (Figure 38–50).

Any remaining irregularities are corrected under direct vision with a knife and sharp tungsten carbide rasp. Palpating the skin of the dorsum with the examining finger moistened with hydrogen peroxide often provides clues to unseen irregularities, as does intranasal palpation of the profile with the noncutting edge of the No. 15 blade.

Except in large or severely twisted noses, it is unnecessary and potentially harmful to separate the upper lateral cartilages from the septum by cutting through the mucoperichondrial bridge of tissue connecting them at the nasal valve.[16]

Redundant soft tissue around the anterior septal angle may be trimmed away to improve tip-supratip definition. The caudal edge of the septum, assessed by stretching the partial transfixion incision posteriorly, lies exposed for geometric shortening or repositioning.

In patients in whom the nasofrontal angle is poorly defined or in need of retropositioning, weakening of the bone in the desired area is accomplished before bony hump removal. At the exact site in the midline where the nasofrontal angle is desired, a 2 mm osteotome is plunged transcutaneously into the midline of the nasal bones[3] (Figure 38–51). By angulating this small osteotome laterally on either side, the exact cephalic extent of bony hump removal may be controlled by *scoring the bone* in a horizontal line at the nasofrontal angle. During the bony hump removal phase of profile alignment, the nasal bones fracture cephalically where this weakening maneuver has established a bony dehiscence, allowing the surgeon some additional control over the ultimate site of the nasofrontal angle. Creating a more caudally placed angle provides the illusion of a shorter nose without actually shortening it, whereas establishing a more cephalically placed angle creates the appearance of a longer nose.

In patients in whom the nasofrontal angle is overly deep, augmentation with residual septal cartilage or remnants of the excised alar cartilages provides a beneficial esthetic refinement (Figure 38–52).

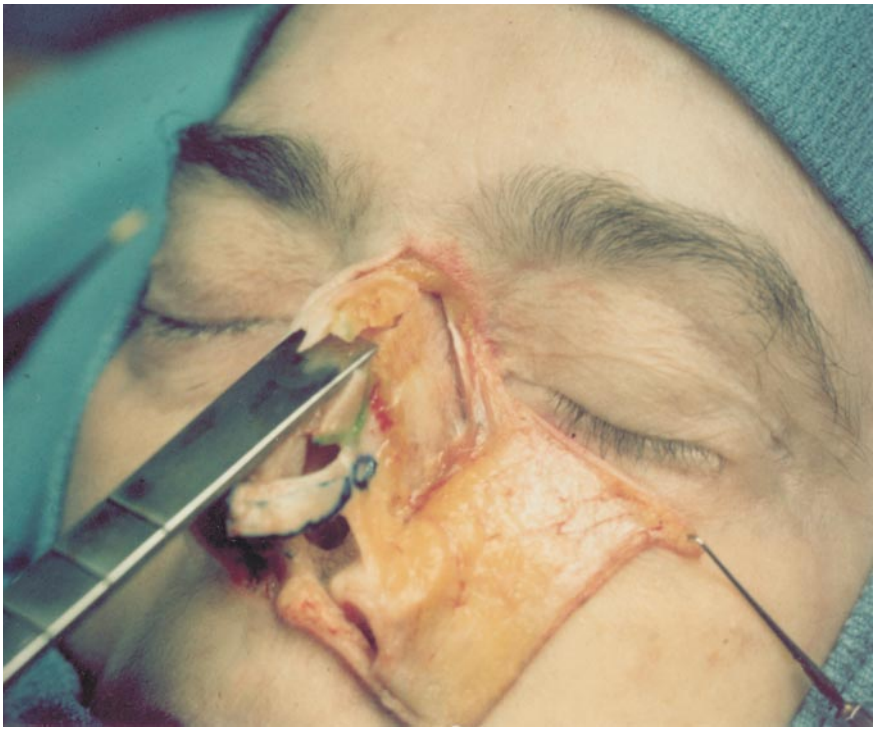

FIGURE 38–50. Sharp osteotome excision of the nasal bony hump.

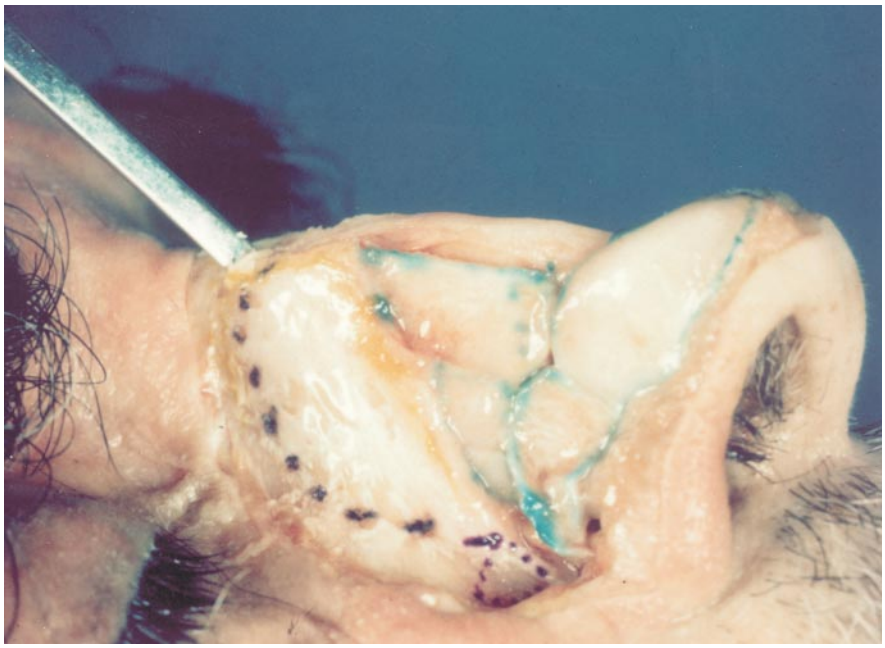

FIGURE 38–51. Weakening of the bone at the proposed nasofrontal angle by means of a percutaneous osteotomy using a 2 mm osteotome. The bone is scored and weakened to facilitate ultimate fracture at the intended site of the nasofrontal angle.

Further profile enhancements may be favorably developed with contouring cartilage grafts positioned along the dorsum, supratip area, infratip lobule, columella, and nasolabial angle. In the last site, so-called "plumping" grafts are commonly used to open an otherwise acute or unsatisfactory nasolabial angle and thereby contribute to improved profile appearance.[17] The illusion of tip rotation and nasal shortening results from this maneuver (Figure 38–53), reducing the degree of actual shortening required and preserving a longer and often more elegant nose.

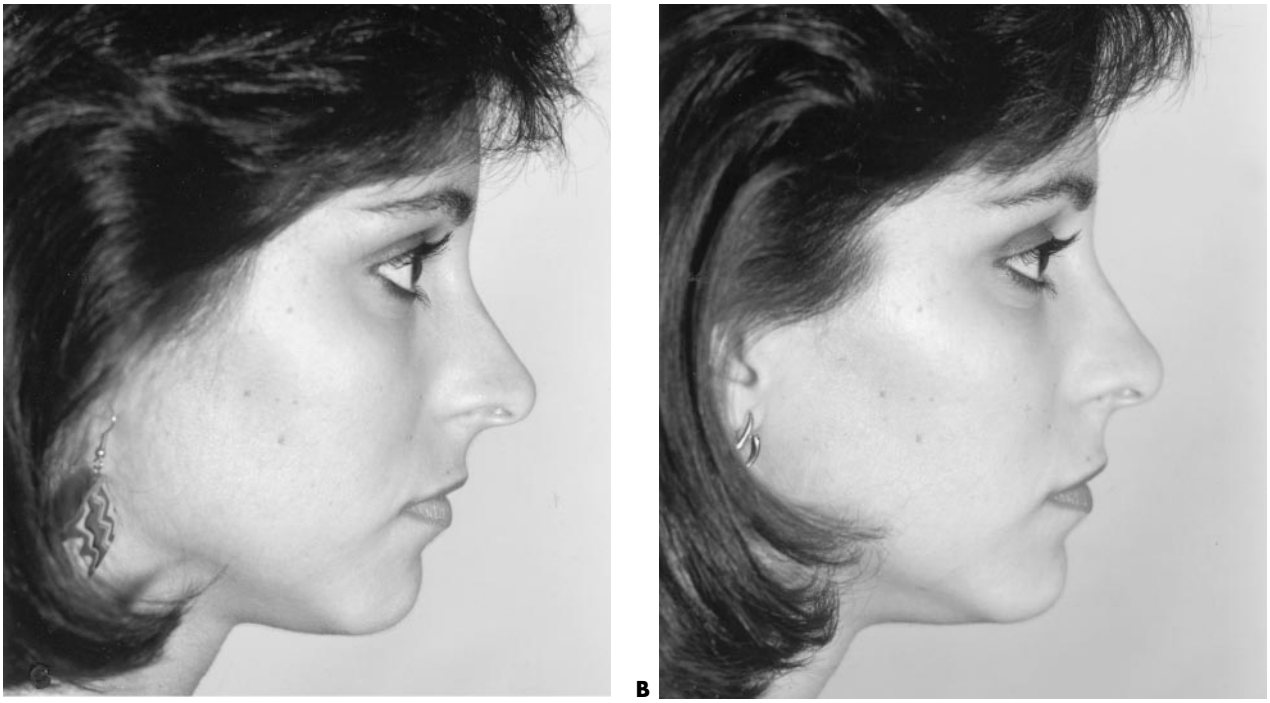

FIGURE 38–52. Patient before (*A*) and 1 year after (*B*) rhinoplasty whose profile has been improved by cartilaginous grafts positioned at the nasolabial angle and supratip dorsum.

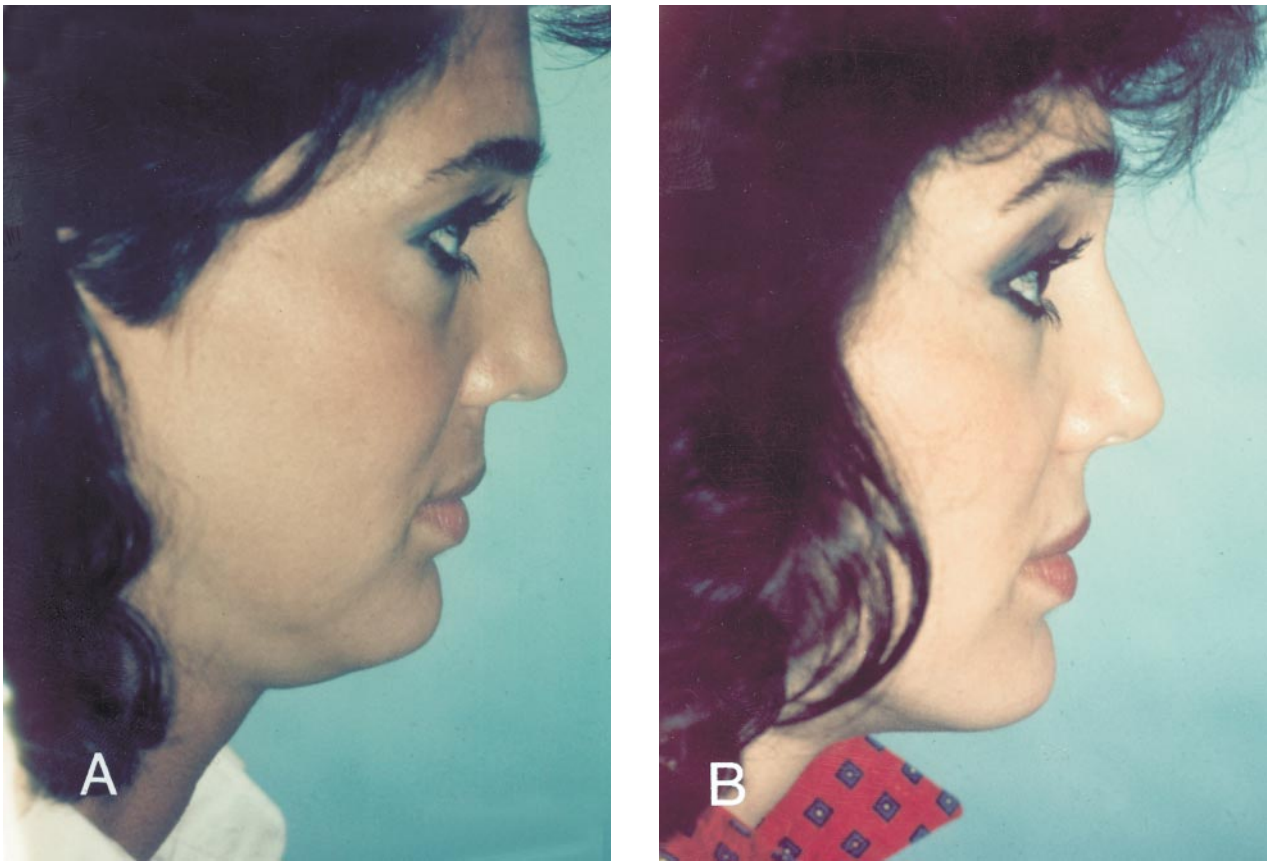

FIGURE 38–53. Patient before (*A*) and 1 year after (*B*) rhinoplasty, illustrating the benefits of augmentation of the retracted nasolabial angle and supratip dorsum.

Bony Pyramid Narrowing and Alignment Significant advances have been made over the past two decades in the reduction of osteotomy trauma in rhinoplasty surgery. Osteotomies, the most traumatic of all nasal surgical maneuvers, are best delayed until the final step in the planned surgical sequence, when vasoconstriction exerts its maximal influence and the nasal splint may be promptly positioned.[3,18,19]

Profile alignment in the typical reduction rhinoplasty inevitably results in an excessive plateau-like width of the nasal dorsum, requiring narrowing of the bony and cartilaginous pyramid to restore a natural and more narrow frontal appearance to the nose. The lateral bony sidewalls (consisting of the nasal bones and maxillary ascending processes) must be completely mobilized by nongreenstick fractures and moved medially (exceptions may exist in older patients with more fragile bones in whom greenstick fractures may be acceptable or even preferable). The upper lateral cartilages are also moved medially because of their stable attachment cephalically to the undersurface of the nasal bones.

To facilitate atraumatic low lateral osteotomy execution, medial oblique osteotomies angled laterally 15 to 20 degrees from the vertical midline are preferred (Figure 38–54). By creating an osteotomy dehiscence at the intended cephalic apex of the lateral osteotomy, the surgeon exerts added control of the exact site of backfracture in the lateral bony sidewall. A 2 or 3 mm sharp micro-osteotome is positioned intranasally at the cephalic extent of the removal of the bony hump (if no hump removal has been necessary, the site of positioning is at the caudal extent of the nasal bones in the midline). The osteotome is advanced cephalo-obliquely to its intended apex at an angle of 10 to 15 degrees, depending on the shape of the nasal bony sidewall. Little trauma results from medial oblique osteotomies, which prevent the ever-present possi-

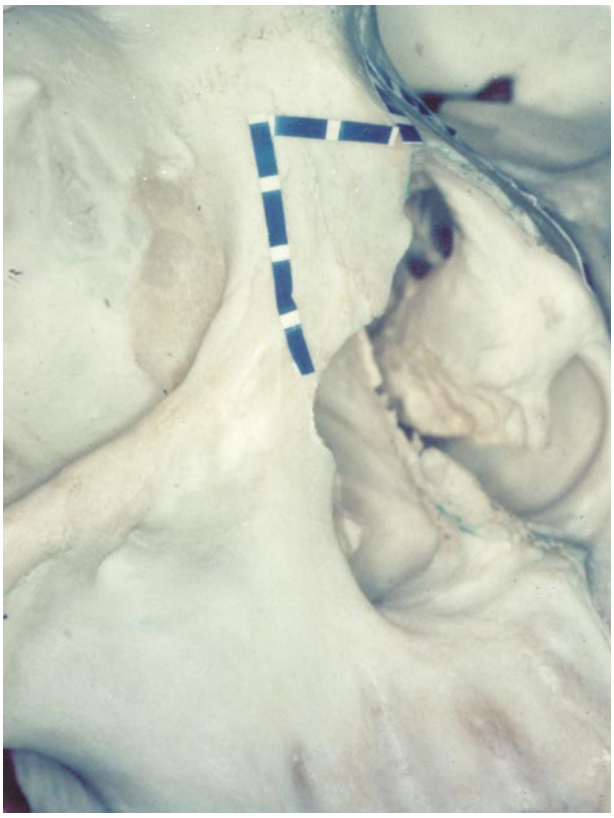

FIGURE 38–54. Medial oblique osteotomies course laterally, approximately 15 to 20 degrees from the vertical midline.

bility of eccentric or asymmetric surgical fractures from developing when lateral osteotomies alone are performed. In addition, bony narrowing to accomplish desired infracture as a consequence of lateral osteotomies combined with medial oblique osteotomies occurs without strong manual pressure exerted on the nasal bones, a traditional but unnecessary traumatic maneuver.

Trauma may be significantly reduced in lateral osteotomies if 2 or 3 mm micro-osteotomies are used to accomplish a controlled fracture of the bony sidewalls.[3] No need exists for elevation of the periosteum along the pathway of the lateral fractures because the small osteotomies require little space for their cephalic progression. Appropriately, the intact periosteum stabilizes and internally splints the complete fractures, facilitating stable and precise healing. The low curved lateral osteotomy is initiated by pressing the sharp osteotome through the vestibular skin to encounter the margin of the piriform aperture at or just above the inferior turbinate. This preserves the bony sidewall along the floor of the nose, where narrowing would achieve no favorable esthetic improvement but might compromise the inferior nasal airway without purpose. The pathway of the osteotome then progresses toward the base of the maxilla, curving next up along the nasal maxillary junction to encounter the previously created small medial oblique osteotomy (Figure 38–55). A complete, controlled, and atraumatic fracture of the bony sidewall is thus created, allowing infracture without excessive traumatic pressure. Immediate finger pressure is applied bilaterally over the lateral osteotome sites to forestall further extravasation of blood into the soft tissues. *In reality, little or no bleeding occurs during micro-osteotomies because the soft tissues embracing the bony sidewalls remain essentially undamaged.*

In most rhinoplasty procedures, controlled nasal fractures as a result of osteotomy should cause slight but definite mobility of the bony sidewalls stabilized by the internal and external periosteum,[19] which bridges the nasal fragments on either side of

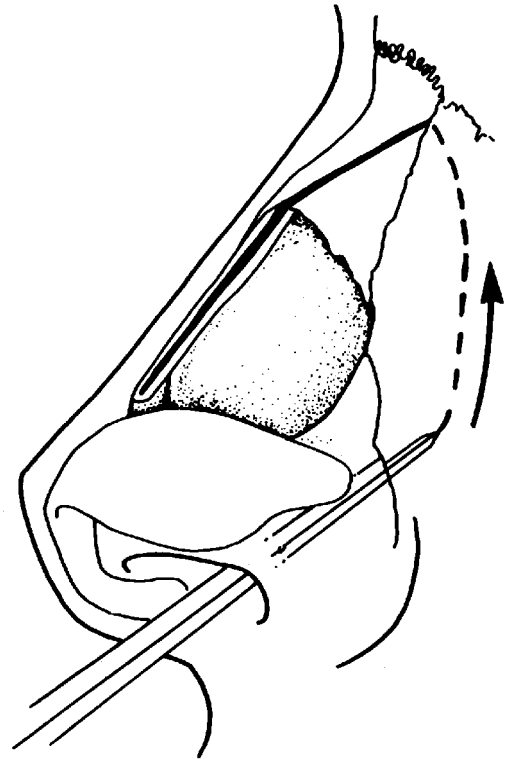

FIGURE 38–55. Curved low lateral osteotomies, created with a 2 or 3 mm osteotome, cause minimal trauma to the surrounding tissues.

the osteotome pathway. Large guarded osteotomies destroy this vital periosteal sling, potentially rendering the bony fragments unstable and susceptible to eccentric or asymmetric healing. In addition, trauma from large osteotomes may produce increased bleeding, edema, and unnecessary ecchymosis.

In deviated noses characterized by essentially convex or concave bony asymmetries, excessively wide or extremely thick bones (including revision rhinoplasty), *double* lateral osteotomies or *percutaneous* osteotomies may be considered for improved mobilization and regularization.[18] This decision is best determined preoperatively to allow the higher osteotomy to be accomplished before the low lateral osteotomy. Reversing this order necessitates attempting the higher osteotomy on an already mobilized lateral bony sidewall, a more difficult task.

On completion of satisfactory osteotomies and suitable esthetic nasal narrowing, the profile line is finally inspected and palpated for irregularities or inadequate alignment. Because the upper lateral cartilages move medially with the bony sidewalls following osteotomies, their dorsal margins should be trimmed to sit flush with or slightly lower than the cartilaginous profile line. Excess soft tissue, if present, is excised and the new nasal dorsum is inspected for and cleaned of any debris. Any profile grafts to be placed to improve the ultimate intended profile line are now scalpel-sculptured to size and placed accordingly. If limited undermining of the overlying dorsal epithelium has occurred, grafts may be placed with no requirement for suture fixation. If a large subcutaneous pocket exists, however, transcutaneous pull-out 5-0 mild chromic catgut sutures are used to fix the grafts into the intended site. The sutures, cut flush with the skin at 5 to 7 days, retract into the subcutaneous space and are absorbed.

Final subtle nasal refinements are now completed and may include caudal septal reduction, resection of excessive vestibular skin and mucous membrane, trimming of the caudal margins of the upper lateral cartilages (only if overlong or projecting into the vestibule), columellar narrowing, and bilateral alar base reduction. These final maneuvers are carried out with the assistant maintaining constant finger pressure over the lateral osteotomy sites to prevent even minimal oozing and intraoperative swelling. All incisions are closed completely with 5-0 chromic catgut suture. No permanent sutures are used.

Nasal dressings are now applied. No intranasal dressing or packing is necessary in routine rhinoplasty. If septoplasty has been an integral part of the operation, a folded strip of Telfa is placed into each nostril along the floor of the nose to absorb drainage. The previously placed transseptal quilting mattress suture (Figure 38–56) acts as a sole internal nasal splint for the septum,[3] completely obliterating the submucoperichondrial dead spaces and fixing the septal elements in place during healing. The external splint consists of a layer of compressed Gelfoam placed along the dorsum and stabilized in place with flesh-colored Micropore tape, extending over and laterally beyond the lateral osteotomy sites. A small aluminum and Velcro splint applied firmly over the nasal dorsum completes the operation (Figure 38–57).

Postsurgical Considerations The care of the postrhinoplasty patient is directed toward patient comfort, reduction of swelling and edema, patency of the nasal airway, and compression/stabilization of the nose.

Whether the patient is discharged on the afternoon of or the morning after surgery, all intranasal dressings are removed from the nose before the patient leaves. A detailed list of instructions is supplied for the patient or accompanying family member (Table 38–3); the important aspects of these "do's" and "don'ts" are emphasized. Prevention of trauma to the nose is clearly the most important consideration. Oral decongestant therapy is helpful,

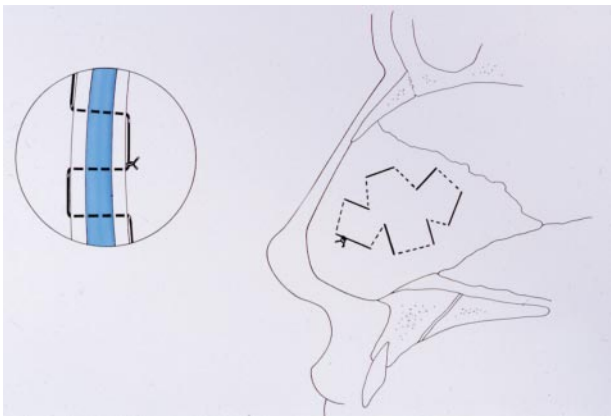

FIGURE 38–56. Quilting mattress transseptal suture woven back and forth through the dissected septum to close dead space, coapt the mucoperichondrial flap(s), and internally support the reconstructed septal components. *Inset:* Sagittal view.

FIGURE 38–57. Nasal splint applied to a reconstructed nose and maintained for 5 to 7 days to support, splint, and protect the nose. A strip of Gelfoam is initially laid over the dorsum to protect and compress the skin.

but the value of corticosteroids and antibiotics in routine rhinoplasty is conjectural.

The external splint is removed 5 to 7 days after surgery. An important consideration should be gentle removal of the tape and splint by bluntly dissecting the nasal skin from the overlying splint with a dull instrument without disturbing or tenting up the healing skin. Failure to follow this policy may lead to disturbance of the newly forming subcutaneous fibroblastic layer over the nasal dorsum, with additional unwanted scarring and even abrupt hematoma.

Septum in Rhinoplasty

The role of the septum in rhinoplasty has always been subject to debate. The difficulty arises because of a lack of definition, namely, between the septal operation performed as an entity and its being performed as a combined operation with rhinoplasty. Septal resection without rhinoplasty found many advocates for radical removal of the septum at the turn of the century. In 1937, Peer expressed the opinion that radical removal might be necessary for certain types of deflection but emphasized the need for a section of cartilage in the anterior position to replace the septum for nasal support.[20] Fomon and associates in 1946, 1948, and 1951 described a similar method but incorporated the rhinoplastic approach of Joseph.[21] The adherents to this method did not clearly define the limitations of this procedure with regard to rhinoplasty, although this was foreshadowed. These techniques apply primarily to the correction of the deviated/dislocated septum alone and are rarely indicated when combined with rhinoplasty, except in the badly traumatized nose.

A more complex problem arises with combined correction of both an external and a septal deformity. Radical removal of the septum performed

TABLE 38–3. Patient Instructions Following Nasal Plastic Surgery

A. INTRODUCTION

Please read and familiarize yourself with these instructions both BEFORE and AFTER surgery. By following them carefully, you will assist in obtaining the best possible result from your surgery. If questions arise, do not hesitate to communicate with me and discuss your questions at any time. Take this list to the hospital with you and begin observing these directions on the day of surgery.

B. INSTRUCTIONS

1. Do not blow nose until instructed. Wipe or dab nose gently with Kleenex, if necessary.
2. Change dressing under nose (if present) as needed.
3. The nasal cast will remain in place for approximately 1 week and will be removed in the office. Do NOT disturb it; keep it dry.
4. Avoid foods that require prolonged chewing. Otherwise, your diet has no restrictions.
5. Avoid extreme physical activity. Obtain more rest than you usually get and avoid exertion, including athletic activities and intercourse.
6. Brush teeth gently with a soft toothbrush only. Avoid manipulation of upper lip to keep nose at rest.
7. Avoid excess or prolonged telephone conversations and social activities for at least 10–14 days.
8. You may wash your face—carefully avoid the dressing. Take tub baths until the dressings are removed.
9. Avoid smiling, grinning, and excess facial movement for 1 week.
10. Do not wash hair for 1 week unless you have someone do it for you. DO NOT GET NASAL DRESSINGS WET.
11. Wear clothing that fastens in front or back for 1 week. Avoid slipover sweaters, T-shirts, and turtlenecks.
12. Absolutely avoid sun or sun lamps for 6 weeks after surgery. Heat may cause the nose to swell.
13. Don't swim for 1 month since injuries are common during swimming.
14. Don't be concerned if, following removal of dressing, the nose, eyes, and upper lip show some swelling and discoloration; this usually clears in 2–3 weeks. In certain patients, it may require 6 months for all swelling to completely subside.
15. Take only medications prescribed by your doctor(s).
16. Do not wear regular glasses or sunglasses that rest on the bridge of the nose for at least 4 weeks. We will instruct you in the method of taping the glasses to your forehead to avoid pressure on the nose.
17. Contact lenses may be worn within 2–3 days after surgery.
18. After the doctor removes your nasal cast, the skin of the nose may be cleansed gently with a mild soap or Vaseline Intensive Care Lotion. BE GENTLE. Makeup may be used as soon as bandages are removed. To cover discoloration, you may use "ERACE" by Max Factor, "COVER AWAY" by Adrien Arpel, or "ON YOUR MARK" by Kenneth.
19. DON'T TAKE CHANCES! If you are concerned about anything you consider significant, call me immediately.

with extensive rhinoplasty can result in a depressed nose because of a lack of septal support. The exception is the severely traumatized nose. In these cases, the dorsum is depressed, and it is impossible to shift the septum without sacrifice of large sections of cartilage. Radical removal of the septum may then be required, but a dorsal implant of a bone or cartilage graft is necessary to correct the depression.

To correct a deviated-dislocated septum associated with a rhinoplastic correction in the developmental type of deformity safely, techniques advocating the shifting and reconstruction of the septal cartilage with minimal removal of septum are currently considered preferable to radical septal resection.[22,23]

Deviated or Scoliotic Nose

Deviation of the entire nose involves both the bony and cartilaginous vaults; deviations of the lower half of the nose are caused mainly by septal derangements accompanied by secondary effects of the cartilaginous vault (Figure 38–58).

Associated asymmetries and deformities of the upper lateral cartilage commonly accompany severe septal scoliosis. The septal and external deformities are corrected together whenever feasible. Because the procedures are interdependent, a better evaluation of the problem is possible when they are carried out simultaneously, and the patient is saved considerable time and discomfort (Figure 38–59).

Correction of the cartilaginous component precedes the management of the bony deformity to allow adequate space for readjustment and infracturing of the bony vault. Furthermore, seldom can an externally twisted nose be adequately straightened without concomitant septal realignment. The admonition "as goes the septum, so goes the nose" holds much truth.

For a better understanding of the pathologic changes and mechanics involved in correcting this type of nasal deformity, a review of etiologic and anatomic factors is presented.

Etiologic and Anatomic Factors

At birth, the septum is almost completely cartilaginous, with the exception of the vomer and the two premaxillae and their processes.[24] The vomer develops bilaterally on each side of the cartilaginous nasal septum from a pair of ossification centers, which are present at the beginning of the third month of fetal life. The bilateral plates of the vomer unite from behind and grow forward at the expense of the

FIGURE 38–58. Deviation of the external nose caused by nasal septal deflection, before (*A*) and after (*B*) correction.

FIGURE 38–59. Patient before (*A*) and 1 year after (*B*) septorhinoplasty using preservative reconstruction of the nasal septum.

imprisoned cartilage. Their development is completed at age 15 years. Indication of the bilateral origin of the vomer is evidenced in the infant by a deep groove between the two plates. The groove is somewhat flattened in adults.

The premaxilla parallels the development of the vomer, but after the child is 6 years old, it develops rapidly. The ethmoid bone begins to ossify during the first year of postfetal life, and ossification is not completed until the end of the seventeenth year.

At birth, neither the palate bones nor the superior maxillae rise into a crest for the support of the lower edge of the septum, but in the adult, these bones have marked crests. The upward growth of the crests, along with the development of the premaxilla and vomer, combined with the downward growth of the septum from the ethmoid ossification centers and the downward expansion of the cranial cavity, may account for many deviations and dislocations of the septum. This disproportion of growth with pressure on the cartilaginous septum has been emphasized as a causative factor in septal deformities.

The vomer and premaxilla are enveloped by a periosteal covering that separates the bony portion of the septum from the cartilaginous septum, which, in turn, is enveloped in perichondrium. Microscopic studies of sections removed from the junction of bone and cartilage in the vomeroseptal maxillary crest region revealed the perichondrial envelopment of the septal cartilage and its fusion with the periosteum of the bone below. The two opposing membranes form a smooth surface between bone and cartilage, especially at the junction of the vomer, maxillary crest, and maxillary spine, where the groove of the vomer is usually shallow or flat. This region is therefore a weak point and a frequent site of traumatic dislocations. Furthermore, the bones themselves form a smooth surface. The lower end of the vomer is smooth and rests on the smooth concave surface of the maxillary crest, which, in turn, rests on the smooth concave surface of the nasal spine.

From observations made at the operating table, in the majority of patients, a dislocation is

usually accompanied by a deviation of the vomer and maxillary crest and spine along with the septal cartilage. These findings are either developmental in origin or traumatic at age 6 or 7. Trauma in early childhood is an important factor because the maxillary crests and vomer are not completely ossified, and a slight shifting of these tissues may cause the crest and vomer, as they develop, to grow to the side. This situation results in a flattening of the vomerian groove and the loss of its lip on the side of deviation. Some of these deviations may have their origin in birth trauma. Cases in which the septal cartilage is displaced from the vomer and maxillary crest are usually traumatic in origin, the injury occurring, in most instances, some time after the child reaches the age of 6 or 7. Complicated septal dislocation, accompanied by buckling, twisting, and reduplication of cartilage and marked internal deformity of depression and deviation, invariably results from trauma.[24]

Some developmental factors in the etiology of the dislocated septum may be gathered from the embryonal description of the nasopalatal relationship and the influence of palatal development on the floor of the septum. Formation of the premaxilla, eruption of the permanent incisor teeth, asymmetric development of the maxillary sinuses, thumb sucking and tongue pressure habits with resultant shifting of the alveolar ridge, mouth breathing, and congenital deformities such as cleft lip and palate are some causative factors that may account for developmental disturbances. The eruption of the permanent incisor teeth and its effect on the septum were well described by Mosher, who believed that deformities of the septum are infrequent and rarely marked in children before the second dentition. The disproportion in growth among the premaxilla, vomer, and ethmoid, with downward encroachment of the cranial cavity, is probably the dominant factor, however.

Nasal Septal Reconstruction *Introduction and Philosophy* The functions of the nasal septum have been described as follows: (1) support of the external nose, (2) regulation of air flow, and (3) support of nasal mucosa.

Since the turn of the last century, procedures designed to improve the nasal airway while preserving these functions have been developed (and occasionally discarded). The classic submucous resection with sacrifice of considerable portions of bone and cartilage has fortunately given way to more conservative procedures involving structural preservation and reconstruction. Aside from historical significance, there remains little purpose in retaining the term submucous resection, with its more radical implications. The term reconstruction of the nasal septum or septoplasty conveys the meaning of contemporary septal operations more clearly.

Preservative septal surgery is further justified by *normal* anatomy. Few "normal" septa are perfectly straight, existing without imperfection. Minor septal irregularities after appropriate reconstruction are inconsequential provided that they create no obstruction and contribute to no external nasal deformity. Radical septal resections in pursuit of a "straight" septum are therefore generally without virtue.

Septal reconstruction is usually carried out with (and usually as an integral part of) rhinoplasty. Reduction rhinoplasties invariably diminish breathing space. Reconstructive septoplasty can rescue an airway otherwise potentially compromised by a purely esthetic procedure. Invariably, the deformed septum contributes to the anatomic deficit inherent in the twisted nose and is best corrected at the outset of septorhinoplasty. lt is frequently remarkable at the operating table how initial septoplasty transforms the crooked nose into near-perfect cartilaginous alignment. As in all surgery for which perfection is the goal, a secondary procedure of lesser magnitude may be occasionally required (less than 5% of all procedures), and all patients deserve to know that fact before undergoing a reconstructive procedure ("the crooked nose has a memory").

Finally, preservative conservation septal surgery should totally negate the most severe sequelae of more radical septal resections: columellar retraction, saddle nose, airway collapse, loss of tip support, and septal perforation. The latter conditions present complex difficult reconstructive exercises and are better avoided than risked.

Principles of Septal Reconstruction. If the preceding philosophy is accepted, certain precepts emerge as cardinal to all septal surgery. These precepts have as their basis an increasingly detailed, atraumatic dissection and mobilization of the septal components, an assessment of the obstructive problem, and, finally, a reconstruction and realignment after

minimal tissue sacrifice. These major steps involve the following surgical phases, not always carried out in this sequence:

1. Whenever possible, elevate the mucoperichondrial flap only on one side.
2. Atraumatically disarticulate the attachment of the quadrilateral cartilage to the perpendicular plate of the ethmoid and to the vomer. If a vertical angulation exists just caudal to this articulation, a common site of deviation, the disarticulation can be positioned at this angulation.
3. Mobilize the quadrilateral cartilage along the floor of the nose at the maxillary crest. A narrow horizontal strip of cartilage may be removed to facilitate this mobilization without compromising septal support.
4. Isolate the *bony* septum between its bilaterally elevated mucoperiosteal flaps and medially reposition or resect the portion creating obstruction (bone grafts are commonly taken at this juncture).
5. Realign the cartilaginous septum with the conservative manipulations to be described subsequently.
6. Stabilize all realigned septal segments with quilting mattress transseptal absorbable sutures during the healing phase.

Certain vital fundamental technical concepts are required to accomplish these goals of septal reconstruction:

1. Perform all septal surgery under direct vision. Intense fiber-optic head lighting, long nasal specula, complete septal mobilization, and effective vasoconstriction make this an easily realized surgical prerequisite.
2. Preserve the contralateral mucoperichondrial flap for support, septal cartilage nutrition, and stability. Exceptions to this principle exist but are infrequent.
3. Preserve the caudal septal relationship with the membranous columella and feet of the medial crura. Severe caudal subluxation may negate this principle.
4. Dissect and mobilize the septal components fully before final deformity diagnosis. Only now should the extent of a conservative resection be planned.
5. Resist the temptation to resect more radically in pursuit of a "perfectly straight" septum.
6. In septorhinoplasty of the twisted nose, generally, the septal realignment is best created before tip and profile reconstruction. Septoplasty in combined procedures frequently requires more technical ingenuity than rhinoplasty.
7. Assiduously avoid removal of septal cartilage contributing important strength to the structure of the external nose.
8. Dissect from the "known to the unknown" to best avoid development of tears and flap perforation. If perforations are created, repair with fine suture technique.
9. Unless it contributes to deformity, preserve the upper lateral cartilage attachment to the septum.
10. Control and stabilize final septal alignment with judiciously placed transseptal sutures, thereby preventing cartilage segment overrides, hematoma, and unfavorable fibrosis. The need for long-term septal splints is thereby lessened or negated.
11. Avoid long-term intranasal packing and tamponade, a more traditional than useful exercise.
12. Constantly reassess and diagnose the obstructive problem during the course of septal surgery with inspection *combined with intranasal palpation*. As in rhinoplasty, the anatomic metamorphosis in septoplasty is dynamic and interdependent, each surgical step often dramatically influencing the next. Remain flexible in ideas and approach, ready to incorporate surgical options as required.
13. Understand that airway improvement, particularly in the twisted nose (or as the sequela of old comminuted fractures), may require nasal osteotomies to achieve optimum breathing space.

Progressive Integrated Technique of Septal Reconstruction. The surgical steps described subsequently have been evaluated over a period of 30 years and found to be effective in 90% of all septal deformities.[3,25] They are based on the principles of structural preservation and septal realignment rather than resection, with final suture stabilization of the realigned septal components. Deviation from these principles is not usually required, except in the rarer anatomic circumstances to be described.

Anesthesia and analgesia. With few exceptions, septoplasty and septorhinoplasty are performed under a combination of monitored intravenous analgesia, local infiltration, and topical anesthesia. The

patient's comfort is ensured, little bleeding develops, and the patient's condition is constantly monitored by the anesthesiologist. Intravenous sedation is administered in titrated fashion until patient comfort and tranquilization are achieved.

Neurosurgical cottonoids containing 5% cocaine solution (color coded for easy identification) are positioned under direct vision in each nasal cavity. One or two on either side ensure adequate topical anesthesia, vasoconstriction, and nasal tamponade. The mucoperichondrial flap on the intended side of dissection (ordinarily the concave side) is generously infiltrated with a standard solution of 1% lidocaine with epinephrine. Accurately piercing the submucoperichondrial plane with a No. 27 gauge needle provides a "hydraulic dissection," facilitating a rapid and bloodless flap elevation. Additional infiltration anesthesia is used according to the planned extent of septal dissection.

Twelve to 15 minutes of delay should now ensue while vasoconstriction becomes intense. During this period, final inspection and palpation of the cocainized internal nose often reveal irregularities high in the nasal vaults not previously seen. Radiograph evaluation at this juncture may aid in surgical planning. The value of *palpation* of the deformed septum and of the structural strength of the nasal tip supportive elements cannot be overemphasized.

MOBILIZATION OF QUADRILATERAL CARTILAGE. Elevation of the mucoperichondrial septal flap is usually initiated through a vertical incision placed 2 to 3 mm cephalic to the caudal end of the septal cartilage on the concave side of the septum (Figure 38–60). Actually, it makes little difference on which side this incision is placed. Preserving the normal attachment of the mucoperichondrial flap on the convex side of the septal deformity, however, seems technically easier. If severe caudal septal dislocation exists, a hemitransfixion or complete transfixion incision is generally used.

The submucoperichondrial plane is located and developed with a semisharp Dunning elevator under direct vision (Figure 38–61). If fracture adhesions, cartilage overlaps, or severe scarring interferes, the dissection is carried out by bypassing these vexing areas and dissecting above or below as required initially to circumvent areas of difficult dissection. Proper hydraulic lidocaine infiltration, as described, facilitates this elevation technique.

This dissection plane is continued onto the ethmoid perpendicular plate and vomer, elevating the continuous ipsilateral mucoperichondrial mucoperiosteal space. Moderate pressure with the tip of the elevator at the junction (articulation) of the cartilaginous and bony septal components disarticulates these elements and initiates the dissection

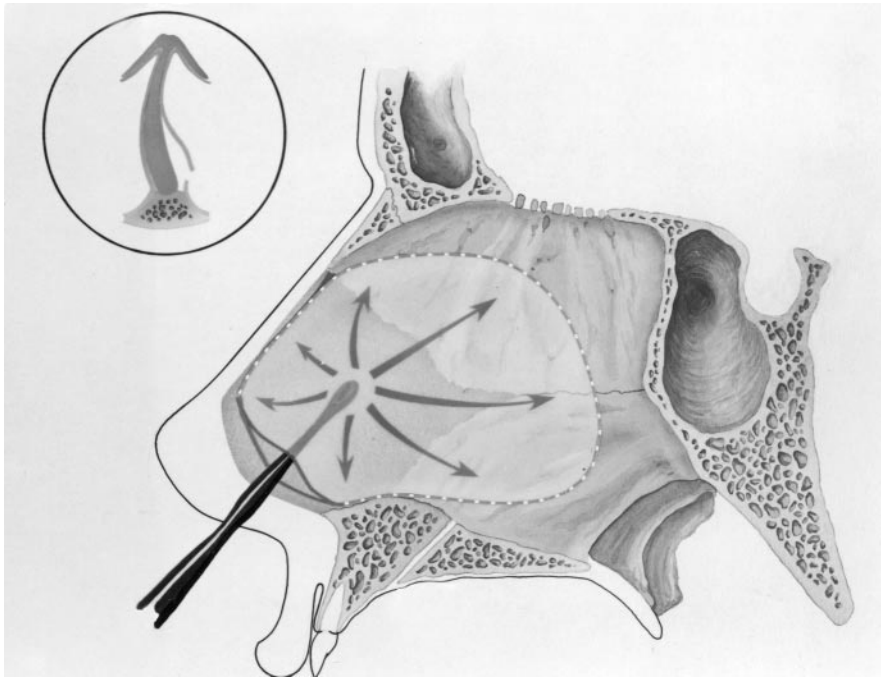

FIGURE 38–60. Septal incision is created just cephalic to the mucocutaneous junction. *Inset:* sagittal view.

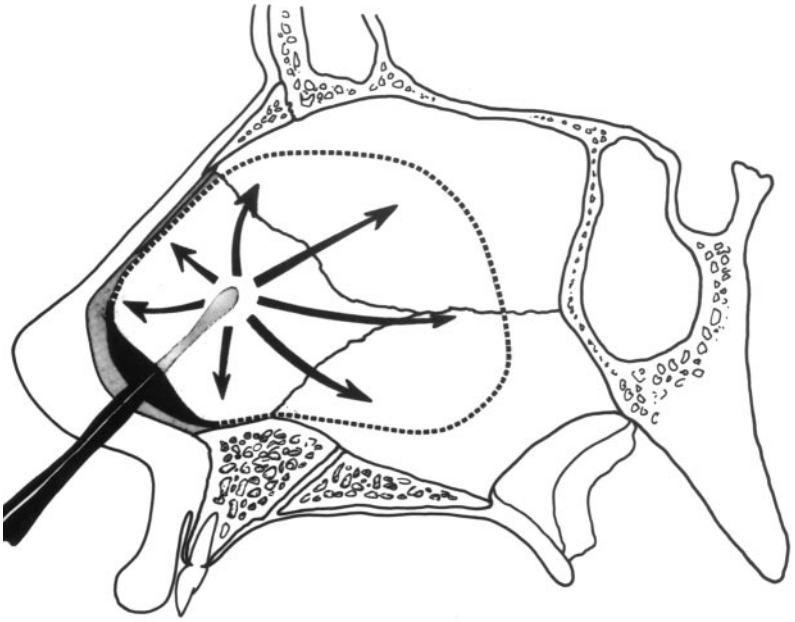

FIGURE 38–61. The submucoperichondrial plane up to and in continuity with the subperiosteal plane overlying the perpendicular plate of the ethmoid and vomer is created with a semisharp elevator.

of the contralateral mucoperiosteal flap (Figure 38–62). Because this area is a common site of septal fractures and angulation, the disarticulation can also be accomplished in a previous fracture line.

A reassessment of the septal anatomy (and deformity) is now in order. This initial dissection frequently has allowed the quadrilateral cartilage to return to the midline without further surgery, being freed from a deviated ethmoid or vomer. The cartilage may be held by a subluxation along the maxillary crest, which is overcome by resecting a horizontal strip of cartilage (and frequently bone) from along the floor of the nose. Any fibrous tissue bands further contributing to a displaced position of the cartilage are divided with sharp knife dissection. These steps will now have completely freed and mobilized the quadrilateral cartilage and usually allow its return to the midline without further surgical manipulation.

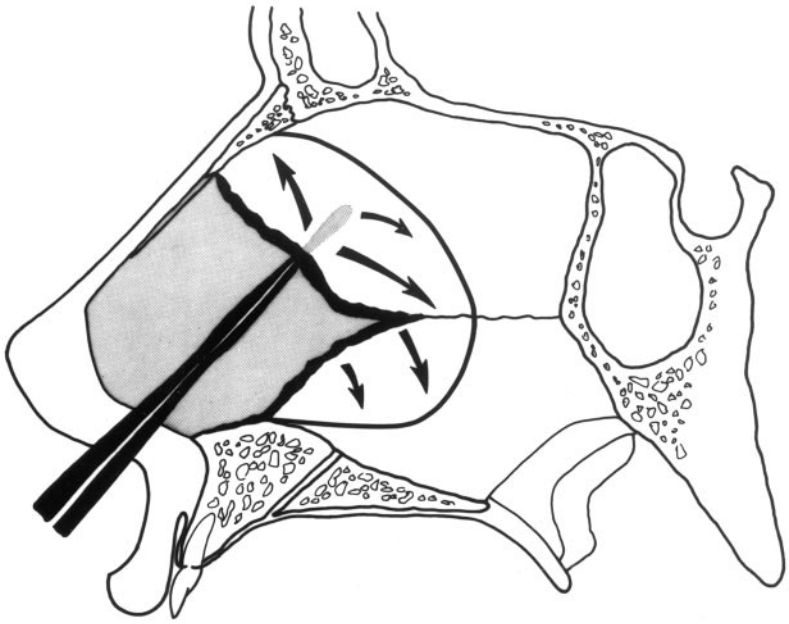

FIGURE 38–62. Disarticulation of the bony and cartilaginous septum.

CORRECTION OF BONY OBSTRUCTION. Deformities of the bony septum, particularly those high in the nasal vault, are now exposed between the blades of a long nasal speculum; selective resection of obstructing bone is gently carried out with small biting (Takahashi) forceps until the airway is clear (Figure 38–63). Larger pieces of bone required for graft or implants may be resected with fine osteotomes, heavy scissors, or bone-biting forceps. Great care should be taken in older patients (particularly osteoporotic women) to remove only small portions of the perpendicular plate of the ethmoid. The vomer provides an excellent source of bone-grafting material; flaps should be completely and bilaterally elevated to avoid creating flap tears or avulsions during vomerine resection.

These steps in surgical dissection of the septum are relatively routinely carried out in most patients and frequently are all that is required to establish a greatly improved airway. At this point in the septal reconstruction, a *reassessment* is in order before further surgery. Visually and palpably, the septal alignment is evaluated. If alignment is satisfactory and the airway adequate, flap suture closure is carried out, as described later. If the airway remains unsatisfactory, what creates the problem and how is it most easily and conservatively corrected? Once these questions are answered, a variety of the following corrections are variously carried out, depending on the existent deformity, its location, and its extent.

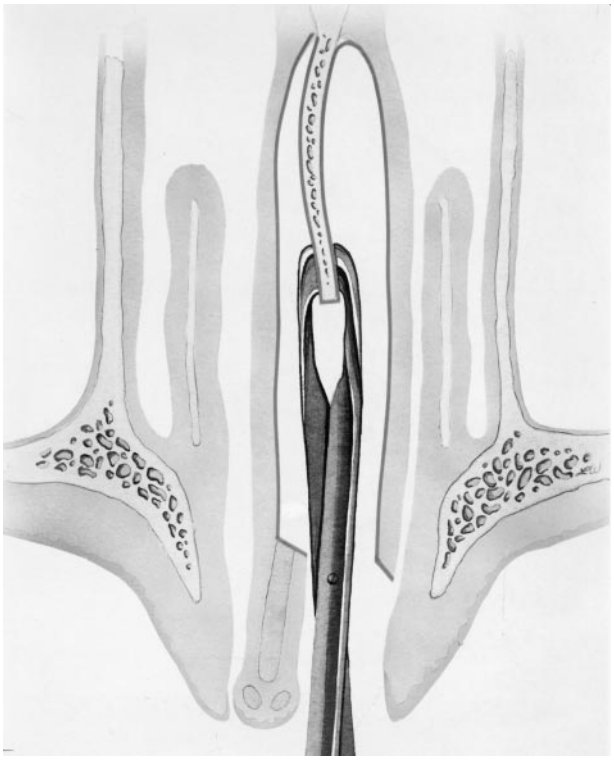

FIGURE 38–63. Removal of obstructing portions of the bony septum with a small biting forceps.

ANCILLARY CORRECTIVE PROCEDURES. Significant obstructing deformities along the floor of the nose (cartilaginous or bony spurs and ridges, which often contribute to drying, ulceration, and bleeding) may require an approach created by elevating a second compartment of periosteum along the floor of the nose (Figure 38–64). The periosteum overlying the premaxilla and maxillary crest is incised, and a submucoperiosteal pocket is created with the elevator. The two compartments (subperiosteal and subperichondrial) are then connected, exposing the maxillary crest deformity for osteotome and/or rongeur removal.

A vertical angulation of the septum, if contributing to deformity and obstruction (often the site of an old fracture), may be removed with a conservative vertical cartilage strip resection or wedge resections, with realignment carried out by absorbable suture technique (Figure 38–65).

Similarly, horizontal septal angulations or spurs are resected by means of conservative horizontal strips or wedges, again leaving all remaining cartilage segments securely attached to the contralateral undissected mucoperichondrium. Thinning the quadrilateral cartilage with *shave excision*

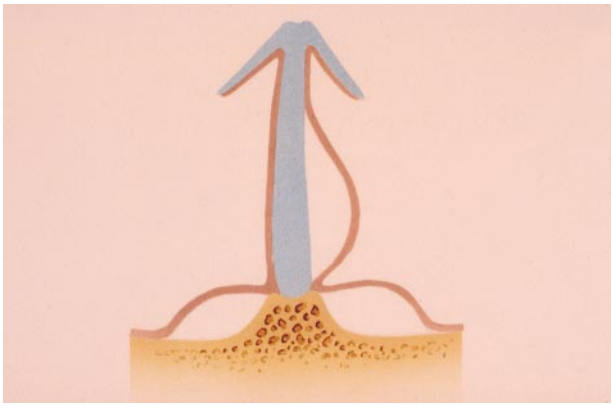

FIGURE 38–64. Elevation of an inferior compartment of periosteum along the floor of the nose to gain better access to deviated bony septal components.

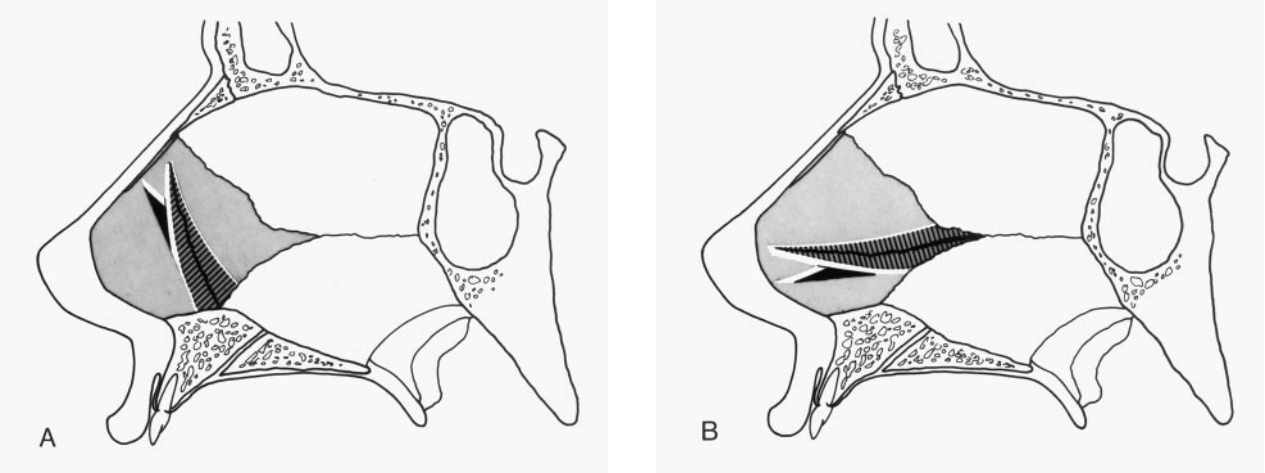

FIGURE 38–65. Vertical (*A*) or horizontal (*B*) angulations of the nasal septum may be removed with wedge resections.

techniques in a horizontal or vertical plane may contribute to airway improvement without significantly altering the supportive strength of the cartilage (Figure 38–66).

Significant dislocation of the caudal septum from the midline, whether developmental or traumatic, requires ingenuity in reconstructive techniques to resist the temptation to resect significant caudal segments, thereby risking columellar retraction and loss of tip support.

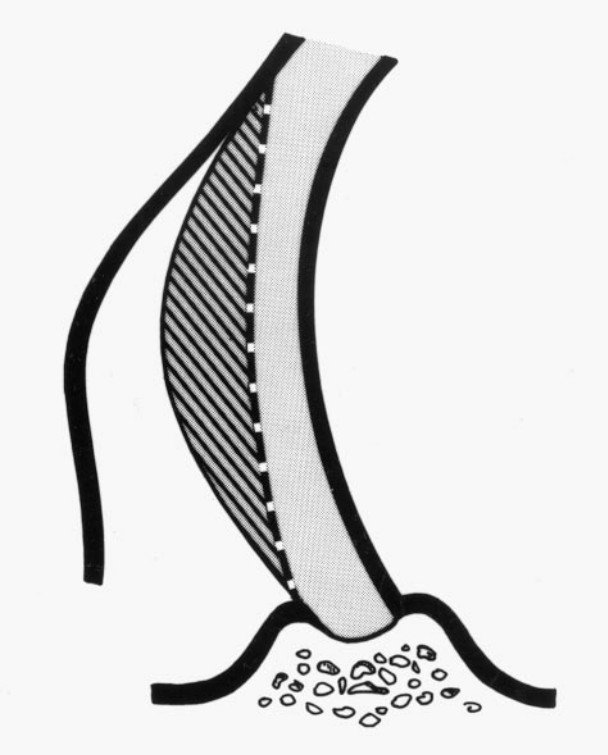

FIGURE 38–66. Shave excision techniques in overly thick quadrilateral cartilages may substantially improve the nasal airway.

A vertical incision (or narrow cartilage excision) cephalic to the point of angulation, combined with freeing the caudal segment from the nasal floor, generally creates a caudal "swinging door" segment that is sutured to the midline columella and occasionally to the midline mucoperiosteum. Further weakening of a deformed caudal segment without total structural sacrifice may be created by generous "cross-hatching," shave excision and even conservative morselization. Limited contralateral mucoperichondrial flap elevation at the caudal segment facilitates its realignment.

An overlong caudal septum, malaligned or not, may require thinning or shortening to facilitate repositioning, particularly during septorhinoplasty procedures.

Occasionally, a previously fractured nasal spine, positioned off the midline, will require refracturing and fixation to the midline to reposition the caudal septum adequately. Unless it deforms the nasolabial angle, the spine is seldom sacrificed, to avoid potential loss of tip support and columellar retraction.

Deformed upper lateral cartilages, the product of maldevelopment or trauma, are occasionally responsible for misalignment of the cartilaginous septum. Inspection and palpation confirm this suspicion. Submucosal dissection and freeing of the upper lateral cartilages from the septum allow further septal mobilization and realignment. This situation, however, is rarely encountered. Preserving the upper lateral septal attachment is preferred.

Final correction of some varieties of badly twisted noses may require realignment of the bony nasal pyramid to mobilize and straighten the septum (and therefore the nose) completely. Such instances are ordinarily the consequence of old trauma.

Persistent airway blockade after careful septal reconstruction is occasionally caused by enlargement of the inferior turbinate to fill partially the concavity created by septal deviation. Return of the septum to midline further diminishes the airway. Partial sacrifice of the inferior turbinate (resection, cautery, freezing, crushing, etc) has never seemed appropriate or physiologic. The author prefers a submucosal elevation of the turbinate tissue with resection of the bulky bone of the inferior concha (Figure 38–67). The turbinate is reattached with absorbable sutures and now occupies considerably less space than originally.

Infrequently, in the most severe quadrilateral cartilage deformities, extensive cross-hatching, crushing, or morselization of the cartilage is used to "break the spring" totally.[26] These procedures are generally reserved for the more caudal portions of the quadrilateral cartilage and are used only in the severest deformities. Bilateral mucoperichondrial flap elevation is usually required, and precise healing is often less predictable than when more conservative measures are employed.

Implantation of autogenous cartilaginous supports in the columella is frequently used, lending support to the tip, correcting retracted columellar deformities, and enhancing the nasolabial angle anatomy.[27] Thin cartilage wafers positioned along the cartilaginous profile line are useful in effacing a slight depression and can be particularly helpful in camouflaging a slightly deviated dorsum without risking breaking the dorsal support with surgical manipulations.

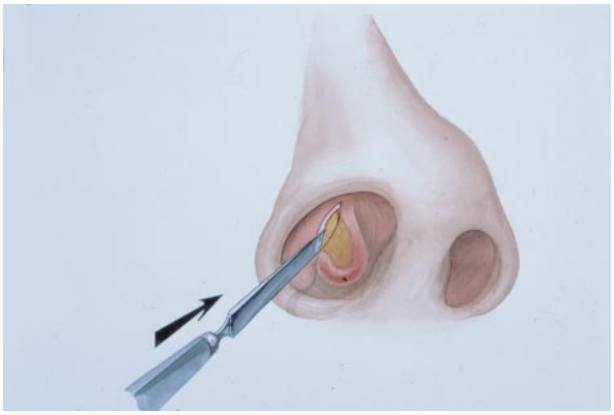

FIGURE 38–67. Reduction of an enlarged turbinate mass is effected by submucosal resection of the enlarged bony concha, preserving the majority of turbinate tissue.

Finally, the complete nasal surgeon should be aware of the septal reconstructive advantages offered by the technique of *external rhinoplasty.*[2] Advantages include a superb direct vision approach, direct anterior appraisal of the deformed elements, and superior suture realignment of reconstructed septal elements.

PRESERVATION OF REALIGNMENT. With progressive use of the foregoing integrated techniques, most deviated septa may be appropriately reconstructed rather than resected, and septal functions may be preserved without embarrassing septal support. Controlling the healing process totally is not possible, but it can be favorably influenced by the suture techniques to be described.

All incisions, including any small flap perforations that occasionally occur, are closed with 5-0 absorbable suture.

A series of similar transseptal transperichondrial through-and-through sutures are now positioned to coapt the septal flap(s), thereby closing all dead space (see Figure 38–56). Hemostasis is promoted, and hematoma is avoided. Further fixation sutures to preserve the realignment of cartilage segments are positioned after the manner of Wright to prevent slippage and overriding. The presence of one intact undissected mucoperichondrial flap provides a great advantage in stabilizing the septal reconstruction.

Septal splints are required only rarely when these methods are used. Telfa gauze rolls are placed in each nasal vault to absorb drainage and splint lightly the dissected flaps and are removed in 12 to 24 hours.

If osteotomies have been performed, or after the occasional external septorhinoplasty, an external cast is applied for 7 days.

CHAPTER 39

Facial Fractures

Paul J. Donald, MD, Jonathan Sykes, MD

With high-speed auto travel, the increasing participation in sports by people of all ages and both genders, and especially the high incidence of violent crime, facial fractures continue to be important injuries in our society. Management of facial fractures, contrary to the pattern of care in other countries of the world, is, in the United States, spread across the disciplines of oral surgery, plastic surgery, and otolaryngology. Because of the comprehensive training in head and neck anatomy and physiology, the otolaryngologist is uniquely prepared to best deal with these injuries. However, it is vitally important for the specialist to have a working knowledge of dental occlusion and facial esthetics and an understanding of the healing of membrane bone.

The first encounter with the patient with a facial fracture is usually in the emergency department. The patient is often the victim of an accident that involves many body systems, and, almost always, attention to these injuries takes precedence. The exception to this is the initial attention to the airway. Extensive soft tissue contusion, bilateral mandibular body fractures, and Le Fort fractures of the maxilla can all result in airway obstruction. In mandibular fractures, a nasotracheal intubation is appropriate; however, in maxillary fractures, there is always a risk of fracture to the cribriform plate or the fovea ethmoidalis. Intubation by the nasal route presents the danger of intracranial passage of the tube so that oral intubation, cricothyroidotomy, or tracheostomy should be used to secure the airway. Rarely will fractures of the facial skeleton present with life-threatening hemorrhage. The only time in the author's experience in which a problem of serious hemorrhage occurred was in an instance of a Le Fort III fracture in which both of the internal maxillary arteries were severed. Rarely, associated fractures of the temporal bone may rupture the petrous portion of an internal carotid artery, or a fracture through the basisphenoid bone may tear the cavernous portion of the internal carotid artery.

After the patient's condition has been stabilized, careful physical and radiographic examination of the cervical spine must be performed to rule out cervical spinal injury. At this point, a careful evaluation of the other important systems is performed.

Treatment of the patient with facial trauma should include a thorough history and physical examination to determine the location and extent of all injuries.[1] The goal of treatment of patients with craniomaxillofacial injuries should be reconstitution of all injured regions.[2] Both soft tissue and bony injuries should be assessed, and a treatment plan should be established. The goals of treatment should be the restoration of function and appearance. The premorbid form and function of dental, skeletal, and soft tissues should be re-established as much as possible. Recent photographs and dental records, if available, are most helpful to establish the pretraumatic appearance.

If the initial injury involves skin or mucosal lacerations, attempts should be made to use these lacerations when possible for the approach to fracture repair. If no epithelial injury is present, approaches to fractures should attempt to maximize exposure while minimizing scarring and risk to adjacent neurovascular structures.

As thorough a history as possible is taken. Often, however, these patients have suffered multiple injuries and may be either unconscious or intubated. Information may be gleaned from any friends or relatives at the scene or the police or ambulance attendants. Physical examination includes a careful inspection of dental occlusion, examination of the facial contour, and palpation of the facial bones. A computed tomographic (CT)

scan of the facial skeleton is crucial in securing the correct diagnosis.

After fracture diagnosis is completed, a systematic treatment plan is established. Surgical treatment of facial fractures involves adequate exposure, meticulous reduction, and stable fracture fixation. Surgical approaches should use transmucosal incisions or incisions that are camouflaged in relaxed skin tension lines or at the junctions of facial esthetic units.[3] Of course, the incision and approach chosen must not compromise the basic principle of providing adequate exposure for diagnosis and treatment of any fracture. After exposing the facial fracture, meticulous reduction must be performed and maintained until adequate fixation of the fracture can be done. Precise reduction is imperative when rigid fixation is used. Fixation techniques should allow for complete bone healing with reconstitution in three dimensions: height (superior-inferior), width (lateral-medial), and depth or projection (anterior-posterior).

Repair of soft tissue injuries is often as important as fracture treatment in the complete restoration of the patient with craniomaxillofacial injuries. This is especially true in the periorbital region, where injuries such as telecanthus, enophthalmos, and dysopia often accompany the skeletal injury. Complete treatment of facial injuries requires attention to these soft tissue injuries and accurate reattachment of soft tissue fascial layers after fracture repair.

The basic principles of diagnosis and initial treatment of patients with facial fractures are listed in Table 39–1. The principles of fracture repair are listed in Table 39–2. Adherence to these principles will maximize function and appearance.

DENTAL OCCLUSION

The key to proper fracture reduction is the restoration of the patient's premorbid occlusion. The understanding of dental occlusion is an essential element in the management of facial fractures. Dental occlusion, simply stated, is the relationship of the maxillary to the mandibular teeth. The most important functional relationship is that of their cutting and grinding surfaces. This relationship largely depends on the relative position of the teeth and their angulation to one another. In 1899, Angle described three basic types of occlusion.[4] Certain subtypes of this system, as well as other classifications of occlusion, have been devised, sometimes adding to the confusion rather than clarifying the problem. In the Angle system, the reference point is the relationship of the first maxillary molar tooth with the mandibular molar tooth below it. Each molar commonly has four grinding surfaces called cusps. The cusps adjacent to the tongue are called lingual and those adjacent to the cheek buccal. Those cusps situated toward the oropharynx in the posterior aspect of the oral cavity are described as distal, and those located more anteriorly are mesial (Figure 39–1).

Class I occlusion is the ideal form (Figure 39–2). In this type, the mesial buccal cusp of the first maxillary molar fits in the groove on the lateral or buccal surface of the first mandibular molar tooth. The buccal cusps of the maxillary teeth overlap the buccal surfaces of the mandibular molars.

In Class II occlusion, the mesial buccal cusp of the first maxillary molar is mesial, or in front of the buccal groove of the first mandibular molar (Figure 39–3). It may be over the first mandibular molar's mesial cusp or even between it and the second premolar (bicuspid). In Class III occlusion, the reverse of class II is seen. The mesial buccal cusp of the first maxillary molar now sits over the corresponding mandibular molar's distal cusp or between it and the second molar (Figure 39–4).

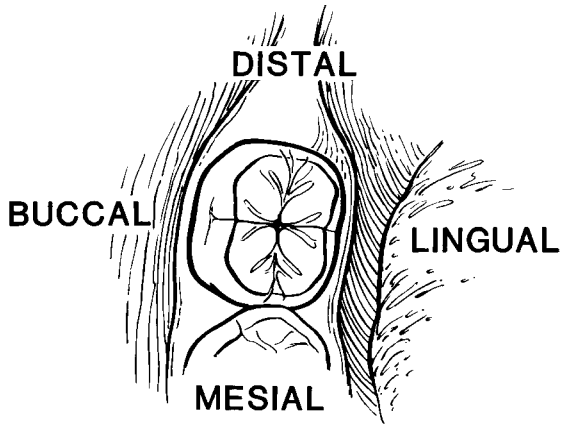

FIGURE 39–1. Orientation of molar cusps. Reproduced with permission from Donald PJ. The surgical management of structural facial dysharmony: a self-instructional package. No. 85100. Washington (DC): American Academy of Otolaryngology-Head and Neck Surgery; 1985.

Usually, these relationships are maintained in the remaining teeth as progression toward the anterior aspect of the dental arches occurs. In Class II and III occlusions, this results in aberrations in the relationship of the incisor teeth that are reflected in characteristic facial deformities.

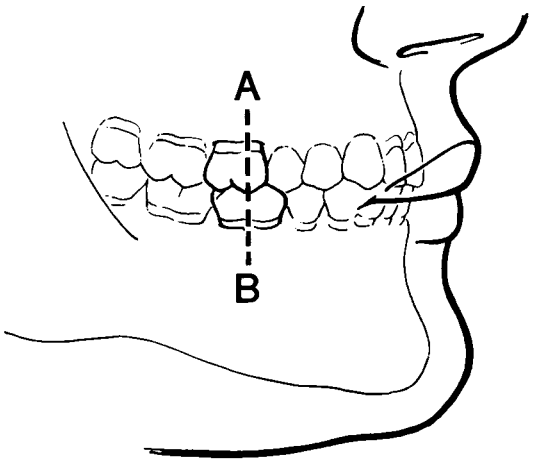

FIGURE 39–2. Class I occlusion. *A*, Mesial buccal cusp of a first molar. *B*, Buccal intercuspal groove of a mandibular first molar. Reproduced with permission from Donald PJ. The surgical management of structural facial dysharmony: a self-instructional package. No. 85100. Washington (DC): American Academy of Otolaryngology-Head and Neck Surgery; 1985.

In Class II, the mesial or anterior relationship of the maxillary teeth may result in a protrusion of the upper incisors beyond the lower. Not only does one see a jutting forward of these upper central teeth, a condition called overjet, but often the lower incisors bite more deeply toward the palate, a condition called overbite (Figure 39–5). The profile this condition produces is described as "bucktooth" or "weak-chin" look. This look is caricatured in cartoons by such characters as "Andy Gump" and "Sad Sack." If this condition comes about through the lack of mandibular development with a backward positioning of the lower jaw, it is called retrognathism. The setback chin often prevents the upper lip from completely covering the upper incisor teeth. Lack of lip protection of the upper incisors, caused by lip procumbency, renders them more vulnerable to injury; fractured incisors are not an uncommon finding in this group.

In Class III occlusion, the abnormal distal relationship of the maxillary molars, most commonly brought about by an abnormally protrusive mandible, translates into a position of the maxillary

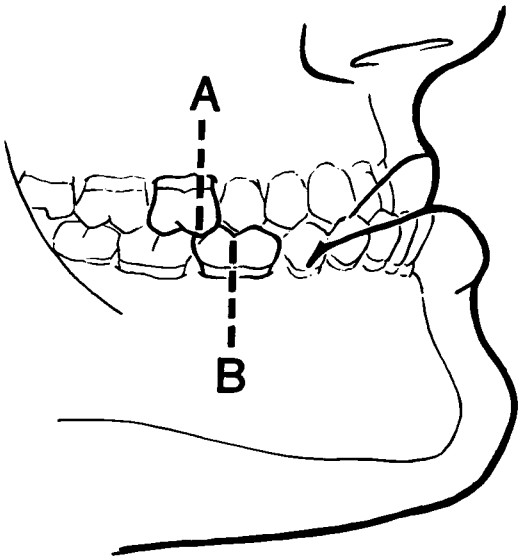

FIGURE 39–4. Class III occlusion. *A*, Mesial buccal cusp of a first molar. *B*, Buccal intercuspal groove of a mandibular first molar. Reproduced with permission from Donald PJ. incisors behind or distal to the mandibular incisors. This produces a so-called "bulldog" or "Dick Tracy" profile. The overbite results in the biting of the upper incisors into the gingival lingual sulcus below. The malocclusion is often so severe that the patient has an extremely difficult time chewing solid food. Often the occlusion of two or three cuspal pairs is all that is possible. In edentulous patients, it is often exceedingly difficult to fit them with a denture.

The opposite of the closed bite of overbite deformities may be seen in both class II and III types of malocclusion. This so-called open-bite deformity produces a marked functional disturbance and is extremely unsightly. Even though the molar teeth are in some form of apposition, the anterior teeth never meet.

Both Class II and III malocclusions may come about from discrepancies in development of either the mandible or the maxilla. Class II may arise from an underdeveloped mandible or from an abnormally protuberant maxilla. Similarly, a class III bite may come about as the result of a large, overdeveloped mandible or a retruded or retroplaced maxilla. Retrognathism is classically used to describe a class II type of occlusion and prognathism the class III type.

In addition to aberrations in the anteroposterior relationship of the dentition are deformities involving malposition in the medial and lateral direction, as well as abnormalities involving a lateral tilt of the occlusal plane. The maxillary molar teeth, instead of having their buccal cusps positioned lateral to the buccal face of the opposing mandibular molars, may be biting end to end or even over the lingual cusps of these latter teeth (Figure 39–6). This is called a lingual crossbite deformity. If both arches are symmetric, the maxillary molars of the opposing side will be put into a more buccal relationship with the opposing mandibular teeth, thereby creating a buccal crossbite on this particular side. Because an abnormality in the arch configuration of either or both of the dental arches is often present, it is not uncommon to have a crossbite on one side with a fairly normal occlusal relationship on the other. For instance, a

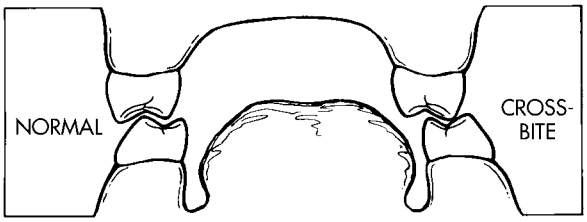

FIGURE 39–6. Coronal view of oral cavity showing normal relationship (*left*) with a maxillary buccal cusp related to the buccal surface of an underlying molar. An example of a lingual crossbite is shown (*right*). Reproduced with permission from Donald PJ. The surgical management of structural facial dysharmony: a self-instructional package. No. 85100. Washington (DC): American Academy of Otolaryngology-Head and Neck Surgery; 1985.

narrow maxillary arch coupled with a fairly normal mandibular arch, such as that seen in hemimandibular hypoplasia, often produces a buccal crossbite on one side and normal occlusion on the other. In patients with hypoplasia, the plane of the bite is commonly abnormal as well. These patients commonly have a diagonal bite, so when they bite down on a tongue blade placed laterally across the teeth, the blade tilts at an angle that is oblique to the horizontal plane (Figure 39–7). Of course, it is not uncommon to see a combination of many of these occlusal abnormalities in any given patient.

FRACTURES OF THE MANDIBLE

Anatomy

The mandible, a horseshoe-shaped bone, is the largest bone of the face. It is divided into regions well described by Dingman and Natvig.[5] The condyle is the portion extending from the mandibular notch to the condylar head, which articulates in the glenoid fossa. The coronoid process is the anterior superior extension of the mandibular ramus projecting above the mandibular notch into the infratemporal fossa. Below the mandibular notch is the ramus, which is composed of thin cortical bone. The angle is a non–tooth-bearing portion of the mandible between the ramus and the body. The parasymphyseal region is composed of the anterior arch of the mandible and is bounded by the two mental foramina. The bodies and the parasymphyseal areas are where the teeth are found. The alveolar ridge or process is composed of thin cortical bone (lamina dura) that encompasses the teeth and atrophies when the teeth are gone.[5] In the edentulous mandible, the tooth-bearing bone resorbs, decreasing mandibular height.

The inferior alveolar nerve enters on the medial (lingual) aspect of the mandibular ramus and passes through its own canal to the mental foramen. While traversing this canal, it gives off sensory innervation to the dentition and gingiva, as well as provides sensation to the ipsilateral lower lip and chin. After a fracture of the angle and body, this canal is often affected. Unless there is a complete

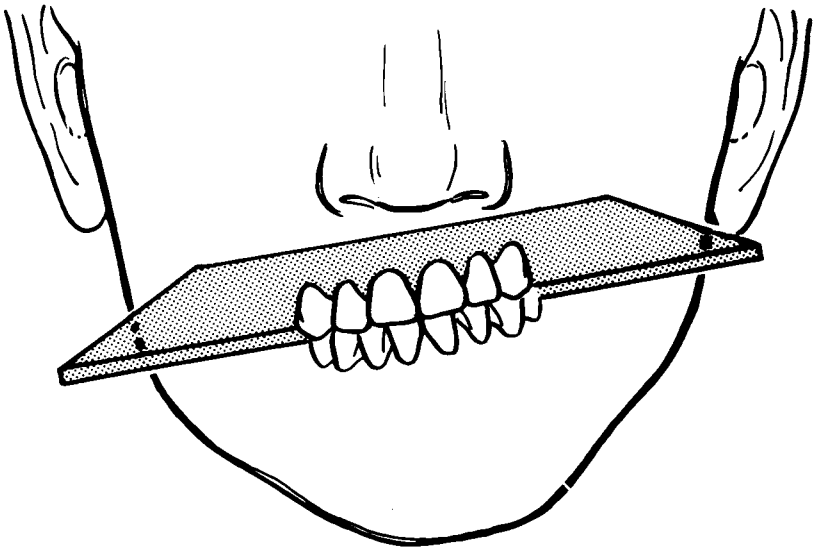

FIGURE 39–7. Obliquely oriented bite. Reproduced with permission from Donald PJ. The surgical management of structural facial dysharmony: a self-instructional package. No. 85100. Washington (DC): American Academy of Otolaryngology-Head and Neck Surgery; 1985.

transection or avulsion of the nerve, full sensation often returns within 9 months to a year.

The muscles of mastication inserting on the mandible include the temporalis, internal pterygoid, external pterygoid, and masseter. All of these muscles contribute to the movement of the temporomandibular joint, a synovial joint with both hinge and gliding action. This joint contains a capsule with a fibrocartilaginous disk. The capsule is densely innervated with proprioceptive and sensory fibers, which are extremely sensitive to subtle changes in movement of one or both joints. A slight alteration in occlusion from muscle spasm or a displaced fracture may alter the central perception of joint position. Feedback loops in the central nervous system force the contralateral muscles of mastication to compensate. This series of events may lead to chronic temporomandibular joint syndrome in an unrepaired or poorly repaired mandibular fracture.

Understanding the various attachments of the aforementioned muscles of mastication, as well as the mylohyoid, geniohyoid, genioglossus, and digastric muscles, is important in understanding the forces of displacement in a mandibular fracture. The floor of the mouth and extrinsic tongue muscles tend to displace fractures posteriorly and inferiorly. The medial pterygoid and masseter muscles act as a sling in the posterior body and angle area and tend to elevate a displaced fragment of the angle or posterior body. Condylar fractures are displaced by the pull of the lateral pterygoid muscle, which rotates and dislocates the fracture medially.[6]

Classification

Fractures of the mandible may be classified according to specific characteristics and anatomic location. A fracture is considered simple when both the external skin and oral mucosa are intact or compound (open) when a laceration in the skin or intraoral mucosa is present. If the patient is dentulous and the fracture line passes into the tooth root, the fracture is theoretically compounded because the periodontal pocket of that tooth often extends to the fracture site. If the fracture is incomplete and involves only one cortex, it is termed "greenstick." The comminuted mandible fracture is one with several fragments of bone. Mandibular fractures are most commonly characterized by anatomic location (Figure 39–8). The most frequent location of fractures of the mandible is the condylar-subcondylar region. Other common sites include the body and mandibular angle. The coronoid process is rarely fractured. An alveolar ridge fracture involves the occlusal surface of a part of the mandible but does not extend into the inferior cortical surface (Figure 39–9).

Mandibular fractures can also be classified as dentulous, edentulous, or pediatric. The latter category is important because of the vulnerability of unerupted dentition and the conical shape of the unerupted teeth, which do not hold a wire ligature well. The accuracy in approximation of the edentulous mandible is not as critical as is the exacting task of establishing the preinjury occlusion of the dentulous mandible. A denture can compensate for minor irregularities in the edentulous jaw.

The final classification may be made according to the stability of the fracture. Vertical instability results from the pull of the temporalis, masseter, and pterygoid muscles. The angle of pull of these muscles will tend to impact a jaw fracture that is obliquely inclined from distal to mesial (posterior to anterior), rendering it stable. On the other hand, if the inclination is the opposite direction, then the forces of these

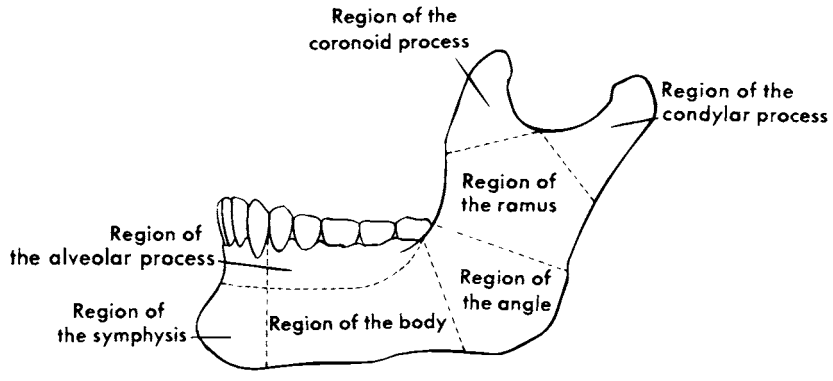

FIGURE 39–8. Schematic diagram of the regions of the mandible. The canine line can be seen to distinguish the parasymphyseal region from the body of the mandible. Reproduced with permission from Dingman RO and Natvig P.[5]

muscles will distract the distal segment in a superior and medial direction. An interesting scenario presents itself regarding an unfavorably inclined fracture in the distal part of the body, near the angle, just anterior to the third molar tooth. While the tooth is present, the fracture will not dislocate, but if the tooth is extracted, the fracture becomes unstable (Figure 39–10). A fracture becomes horizontally unstable by virtue of its obliquity in the occlusal plane. A fracture with an angulation running from the buccal to the lingual surface in a posterior to anterior direction is favorably aligned, whereas that in the opposing obliquity is unstable by virtue of the pull of the mylohoid muscle (Figure 39–11).

Diagnosis

A good history and physical examination, along with plain radiographic films, fully delineate the large majority of fractures to the mandible. When obtaining the history, one must determine the nature of the injury, including the weapon used (if any) and the force with which it was applied. Previous orthodontic work should be noted. Any history of previous mandibular or maxillary fractures should also be elicited. Questions regarding the neurologic status of the patient and questions pertinent to the status of the cervical spine should be answered. Not infrequently, a patient presenting with a mandible fracture has other associated facial fractures. Questions regarding pain, hearing, vision, and facial disharmony involving areas other than the mandible are pertinent.

A mandible fracture may cause the patient to complain of malocclusion (eg, "My teeth don't come together right."). Displacement of the maxillary or mandibular teeth of even less than 1 mm can cause severe patient complaints because of the sensitivity of the proprioceptive fibers in the periodontal membranes of the dentition as well as in the temporomandibular joint. The patient often complains of pain in the region of the fracture, most often from the disrupted periosteum surrounding the bone. Muscle spasm also plays a key role in contributing to the pain of mandible fractures, and difficult and painful opening of the jaw, or trismus, is a common complaint. Painful swallowing and sneezing may also occur. Numbness of the lower lip, from an avulsed or badly contused inferior alveolar nerve in any part of its course from the ramus to the parasymphyseal area, is commonly encountered.

Physical examination confirms the patient's complaint of malocclusion. If the fracture is in a tooth-bearing area, loose or missing teeth may be noted. Ecchymosis of the gingiva also indicates the presence of a fracture. Gross displacement of the fragments may be obvious (Figure 39–12). There may be a foul odor in the patient's breath from a combination of stagnant food, blood, and, frequently, alcohol. Bony crepitus and tenderness are also elicited on palpation. A thorough dental examination should be undertaken, including assessment of the presence or absence of teeth and the fractures of dental crowns. Dentures, even if broken, are preserved. The maxillomandibular occlusal relationships are documented. Soft tissue swelling over the point of contact is often found. If there is a missing tooth that is unaccounted for, aspiration is a possibility. In the unconscious patient, evidence of a recently lost unrecovered tooth necessitates a chest radiograph.

Radiographic evaluation can be used to confirm the physical findings and assess the severity of the fracture, including whether it is comminuted and whether there are actually fractured teeth

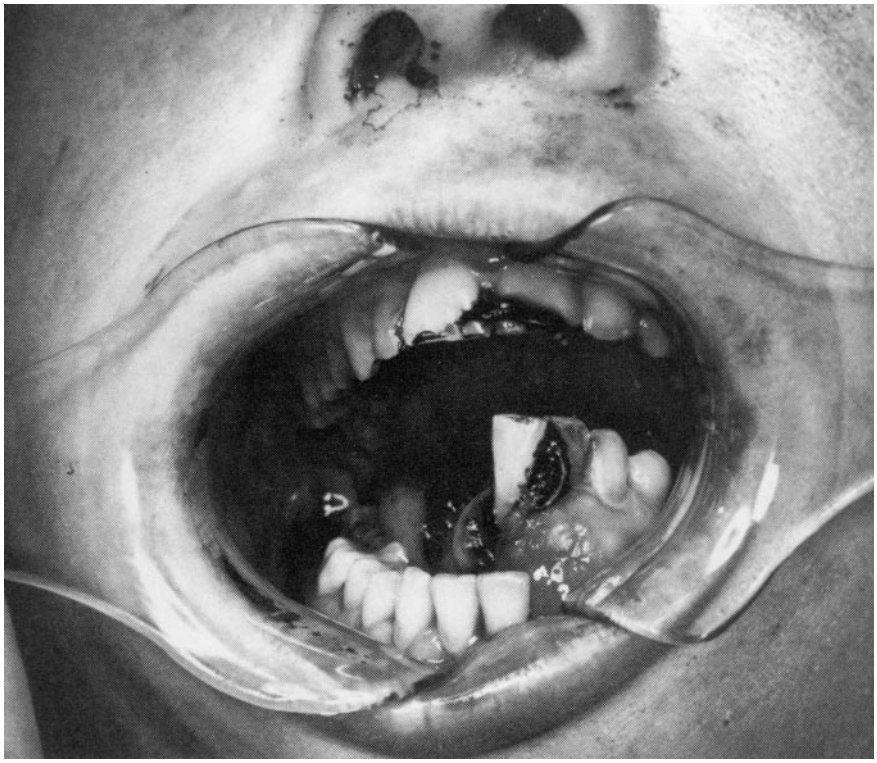

FIGURE 39–12. Patient with a grossly displaced fracture of the parasymphysis of the mandible.

involved. When there is one fracture in the mandibular arch, one must always be aware that there may be an occult fracture in the contralateral ramus or condyle. The panoramic radiograph, the so-called Panorex film, is excellent for viewing fractures of the ramus, angle, and body[7] (Figure 39–13). This type of radiograph is limited, however, in visualizing the symphyseal area as well as telescoping fractures of the condylar area. A modified Towne's view usually visualizes significant fractures of the condyles (Figure 39–14). If a strong suspicion of subcondylar fracture exists, a CT scan will delineate the degree of fragment overlap or displacement into the infratemporal fossa (Figure 39–15). If a parasymphyseal or symphyseal fracture is suggested clinically, but not visualized on plain radiographs, the CT scan will demonstrate it. Dental fractures are best diagnosed with dental occlusal films. If the patient sustains massive trauma, as in a motor vehicle accident or other collision, CT scans of other pertinent anatomic areas should be taken, including full facial and cervical spine films.[8] The scan is usually extended superiorly to rule out any intracranial injury.

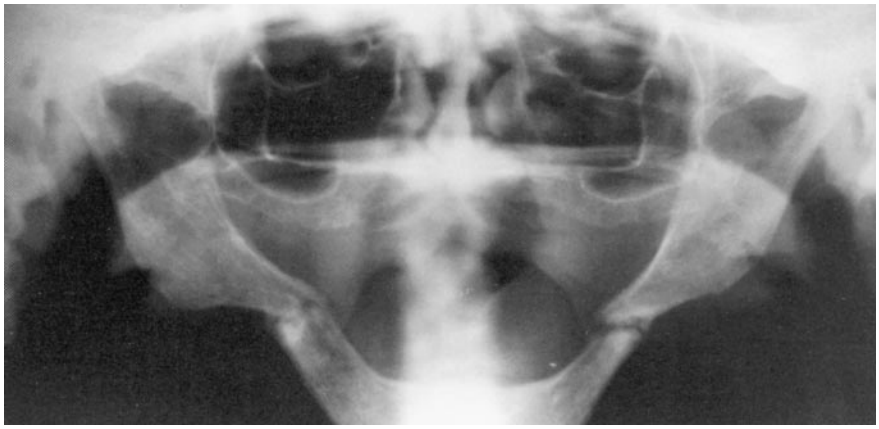

FIGURE 39–13. Panorex film showing a bilateral body fracture.

FIGURE 39–14. Modified Towne's view showing bilaterally displaced subcondylar fractures.

Treatment

After an adequate history and physical examination have been obtained and a radiographic assessment has confirmed the physical findings and ruled out any "occult" fracture, treatment is contingent on the following factors: (1) presence or absence of other serious trauma, either intracranial, intrathoracic, or intra-abdominal; clearance of the cervical spine by a qualified neurosurgeon or orthopedist; (2) adequate surgical consent from the patient; (3) a thorough dental evaluation, including preoperative documentation of occlusion; and (4) availability of bridgework or dentures that accompany the patient to the operating room.

Although many authorities recommended surgical intervention as early as possible to prevent infection, there is no conclusive evidence for this.[5,8–10] To decrease the incidence of infection, it is best to administer preoperative antibiotics. Surgery should be done as soon as possible with the previously mentioned factors taken into consideration. It must be emphasized that repairing a mandibular fracture is not, in the true sense of the word, an emergency but rather should be done as soon as possible when safe. Some fractures of the mandible do not require surgical intervention. Most commonly, nondisplaced ramus fractures, as well as some subcondylar fractures, when there is no complaint of malocclusion, should be treated with a soft diet. The

FIGURE 39–15. Linear tomogram demonstrating dislocation of the mandibular condyle into the infratemporal fossa.

remainder of mandible fractures,[5] especially when there is malocclusion, should be treated either by closed or open reduction or, in some cases, both.

The cornerstone of facial fracture repair is still intermaxillary fixation. This method of repair entails the ligation of the teeth of each arch to those that oppose it. According to Dingman and Natvig, ligation of teeth to each other dates back to the time of Hippocrates.[1] The ancients advised fixing the teeth to one another with gold wire or linen thread. The Greek physician Soranos of Ephesus first described the concept of support of the fractured jaw by a barrel-type bandage in the second century AD.[11] These first methods appeared to rely on healing resulting from the wiring of adjacent teeth in the same arch. William of Saliceto, who practiced in Bologna and Verona, first suggested interarch fixation for mandibular fractures in the thirteenth century. He used waxed, twisted silk threads and bound "the injured to the uninjured jaw." It remained for Gilmer, in 1887, to be the first to propose actual rigid interdental and intermaxillary fixation, which he accomplished with iron wire.[12]

Intermaxillary fixation began by separately wiring each tooth of the maxillary and mandibular arches and then connecting these wires one by one as the teeth were brought into occlusion. From this method, certain modifications were made and evolved into the method we know today. The most significant contribution was the development of the arch bar. Grunell Hammond, in 1871, may have described the first arch bar, a firm wire that went around the lingual and buccal surfaces of the teeth. Sauer, in 1882, used a circumferential gold wire with a spring attachment. These evolved into the Erich and Jelenko arch bars we recognize today. The Erich bar, the one most commonly used, is a malleable metal bar that easily adapts to the buccal surfaces of the teeth and has hooks to which intermaxillary wires or rubber bands can be attached. The Jelanko bar is rigid and difficult to accommodate to the dental arches. Only the application of eyelet wires and the Erich arch bar will be described.

Eyelet Wires The eyelet wire is best used for subcondylar fractures, greenstick fractures, and favorably aligned noncomminuted mandibular fractures in patients who are cooperative and compliant. The eyelet wire may also be used as temporary fixation until definitive fixation is done. The wire is constructed by taking a half-length of No. 26 gauge wire, bending it in half, and twisting in a small loop.

The idea of the eyelet wire is to capture two independent teeth on each side of a mandibular fracture and then fix these to two adjacent pairs of maxillary teeth (Figure 39–16). The ends of the wire are directed from the buccal side through the interdental space below the contact point and close to the gum between the pair of mandibular teeth distal to the fracture. In Figure 39–16, A, each wire is brought around the neck of each tooth, and the end of one is passed through the loop and twisted to its mate at a comfortable distance from the loop. The wire ligature now captures the two teeth (Figure 39–16, B). Care is taken to be sure that the wire is pushed below the embrasure of each tooth and cinched around the tooth neck. The pair of teeth mesial to the fracture line is now ligated in the same way. Similar wires are placed in the same fashion around the maxillary teeth that occlude with the opposing wired mandibular teeth. Pairs of mandibular and maxillary teeth are captured with eyelet wires on the opposite side of the arch for additional stabilization (Figure 39–16, C). The patient is placed in premorbid occlusion, and each loop on the mandibular side is individually wired to the loop above. The fracture is now fixed, and the wires are checked on a weekly basis. Occasionally, the interloop wires may loosen or break and may need tightening or replacement. The wire eyelet itself may also come loose and require tightening. Wires are removed at 3 weeks for subcondylar fractures and 6 weeks for others.

Arch Bars Erich arch bars generally come in a roll. The correct length of bar for each arch is measured by placing one end of the bar on the most distal tooth in the arch on which it is to be fixed. The bar is bent around to the space between the central incisors. This length is now doubled, and the bar is cut from the roll. Adjustments are made for missing molar teeth. If significant gaps of two or more teeth are present, the gap can be filled in with a pad of cold cure acrylic pressed into the bar.

Once trimmed to length, the bar is carefully contoured to the teeth by hand. Great care is taken to shape the distal ends to fit around the last teeth in the arch so that the bar will not dig into the cheek. Each bar is placed over the buccal surfaces of the teeth and wired into position with the hooks facing away from the occlusal surface.

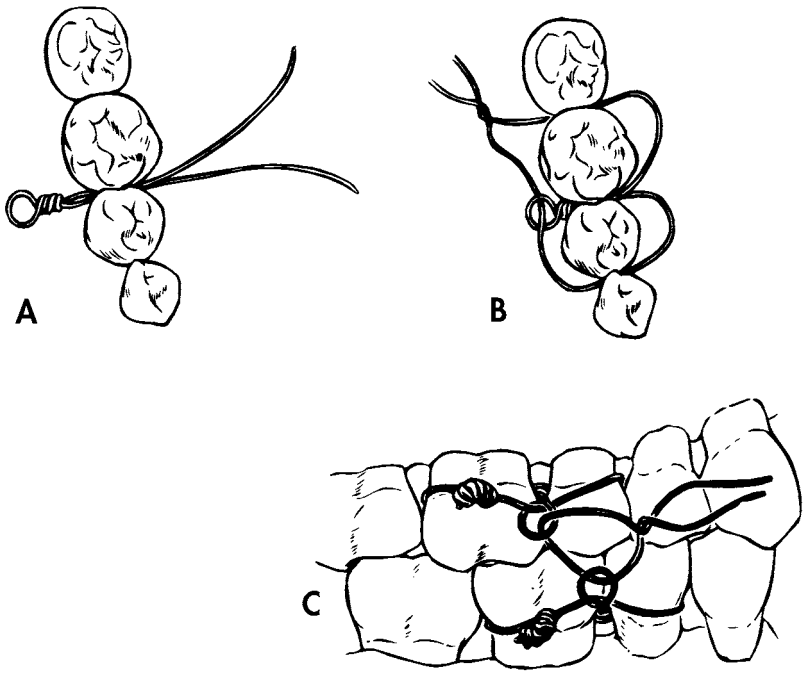

FIGURE 39–16. Technique of placing eyelet wires for intermaxillary fixation. Reproduced with permission from Bernstein L. Fractures of the mandible. Otolaryngol Clin North Am 1969;373–95.

The best teeth for securing the bar are the molars and premolars. The canine has the longest root but has a shape that is not conducive to retention of a wire. The incisor teeth, because of their peglike configuration, hold the wire even more poorly. If enough teeth are present in the arch, the four incisor teeth of each arch are left unligated. For the purposes of orientation, the application of the arch bar to the maxillary teeth will be described first. A 6-inch piece of prestretched 26-gauge wire is passed through the interdental space below the bar (Figure 39–17). Care is taken to prevent injury to the interdental papilla; however, in patients with periodontal disease, this may be unavoidable. The wire is placed around the tooth adjacent to the interdental space. The two ends are twisted together with forceps while a periosteal elevator holds the wire at the level of the neck of the tooth (Figure 39–18). The wire is twisted until tight. The resulting knot is turned into a tight loop and placed away from the lug on the arch bar. Its end is twisted away from the cheek. The molar and premolar teeth are all ligated to the arch bar using the ante-

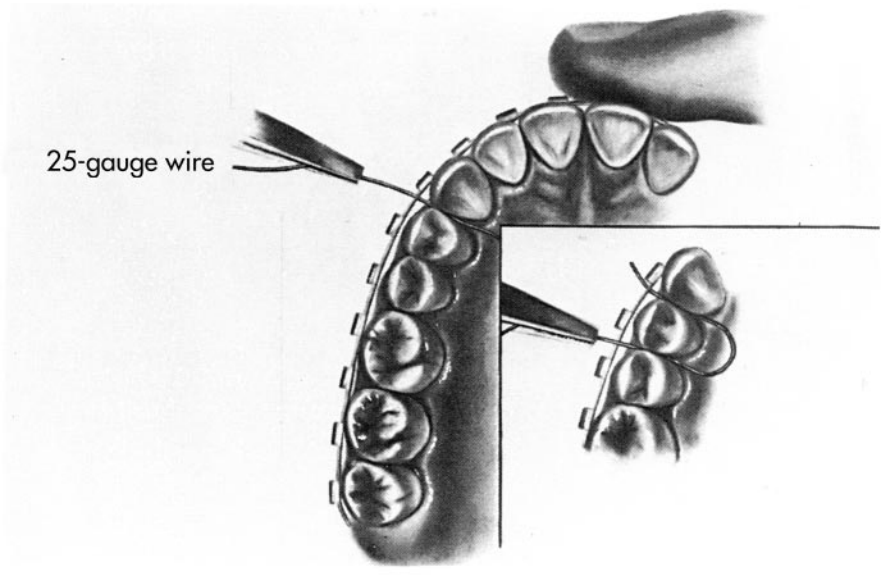

FIGURE 39–17. The wiring of an arch bar to the teeth (see text). Reproduced with permission from Chayra GA et al.[7]

rior wire above the bar and the posterior below formulation. All of the wires are twisted in a clockwise direction (see Figure 39–18). This convention helps in tightening loose wires during follow-up.

Special attention is spent in securing the canine tooth. Its long root embedded in thick bone makes it the key anchor for the bar. Because of its unfavorable shape, adaptation of the wire ligature enhances its holding ability. The wire is placed above the bar, both anteriorly and posteriorly to the tooth, and then looped around the anterior aspect of the bar (Figure 39–19).

Once bars have been placed on both upper and lower teeth, they are secured to one another either with wire or elastics (Figure 39–20). Dental wax may be placed on a protrusive edge that irritates the soft tissues. The patient is also given a stick of wax and instructed how to apply it to irritating wire or lugs. All patients are followed on a weekly basis to check for bar stability and tightness of the interarch wires. Loose wires are tightened and broken wires replaced. Additionally, careful attention is paid to dental hygiene and nutrition. Already carious dentition, a condition not uncommon in patients with facial fractures, is usually the reflection of past neglect. Careful and insistent instructions in proper brushing technique and use of a "water pick" type of device are essential features in the follow-up regimen. Dental caries can lead to the formation of dental abscess during the healing phase, which, in turn, results in osteomyelitis of the jaw.

Nutritional advice is important. The average weight loss in our patient population following intermaxillary fixation is 15 lb. A booklet on dental hygiene and nutrition is supplied to each patient, with instruction on brushing technique and diets that can be employed while in fixation. Of course, only food with a consistency that can be sucked in the free space around the back of the teeth can be used. Balanced high-calorie supplements such as Ensure-Plus® and Sustacal® can be used to augment caloric intake. These products come in both liquid and pudding forms and are quite palatable. When the patient is fixed into occlusion by either Erich arch bars or eyelet wires, it is important to supply the patient with wire cutters so that if he or she vomits, the interocclusal connection can be cut to prevent aspiration.

Gunning Splints In the edentulous patient, the patient's reduced mandible can be maintained by the use of Gunning splints. In 1861, T. P. Gunning of New York was, according to Dingman and Natvig,[5] the first to describe the use of intermaxillary splints, which he fabricated from vulcanite. To make the

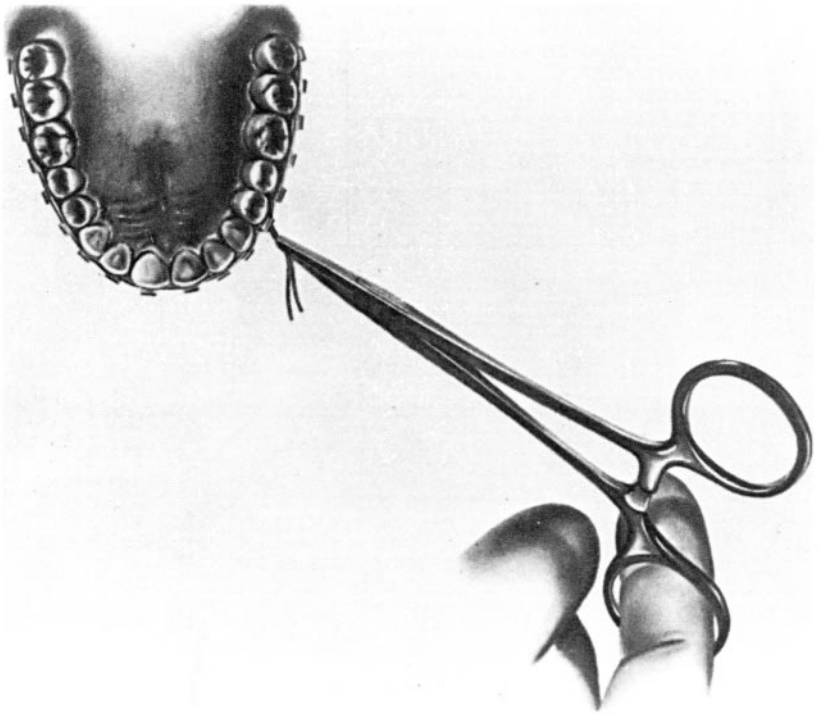

FIGURE 39–18. Wire twisting to lock the arch bar into position. Reproduced with permission from Chayra GA et al.[7]

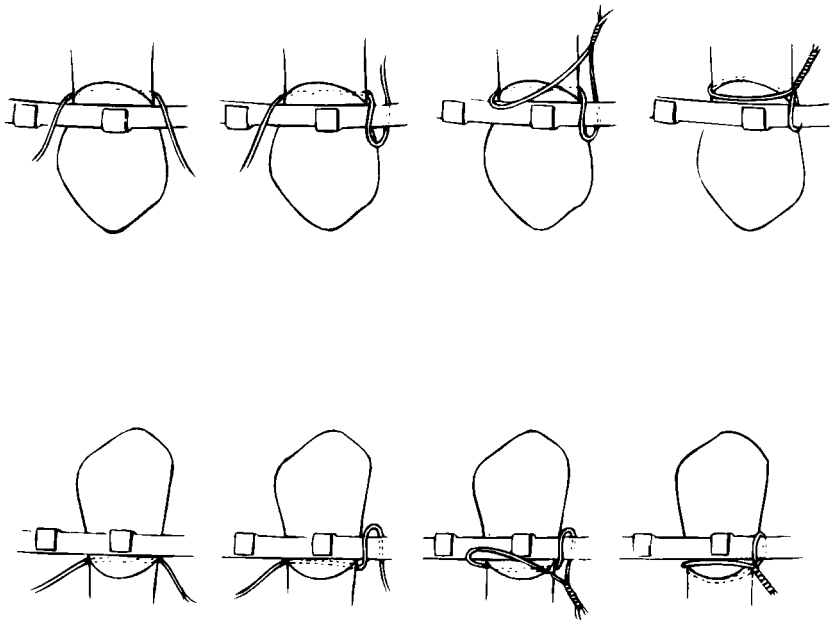

FIGURE 39–19. The special adaption for wiring a canine tooth. Reproduced with permission from Chayra GA et al.[7]

splint, a dental impression of the jaws is taken with an impression compound such as alginate and poured up in stone. The stone model of the mandible is cut at the fracture line and realigned in the normal anatomic position and fixed with sticky wax. An impression of the realigned model is taken, and a hot-cured acrylic stent is made. A stent is also made of the maxilla. A flange and corresponding groove are constructed so that the maxillary splint can fit into the mandibular splint in a lock and key type of articulation. Care is taken so that the normal preocclusal relationship is established between the mandible and the maxilla. An arch bar is imbedded into the splint prior to hardening so that the splints can be ligated together.

At the time of surgery, the mandibular fracture is reduced and the splint fixed to the jaw by at least four circum-mandibular wires. A pair of drop wires

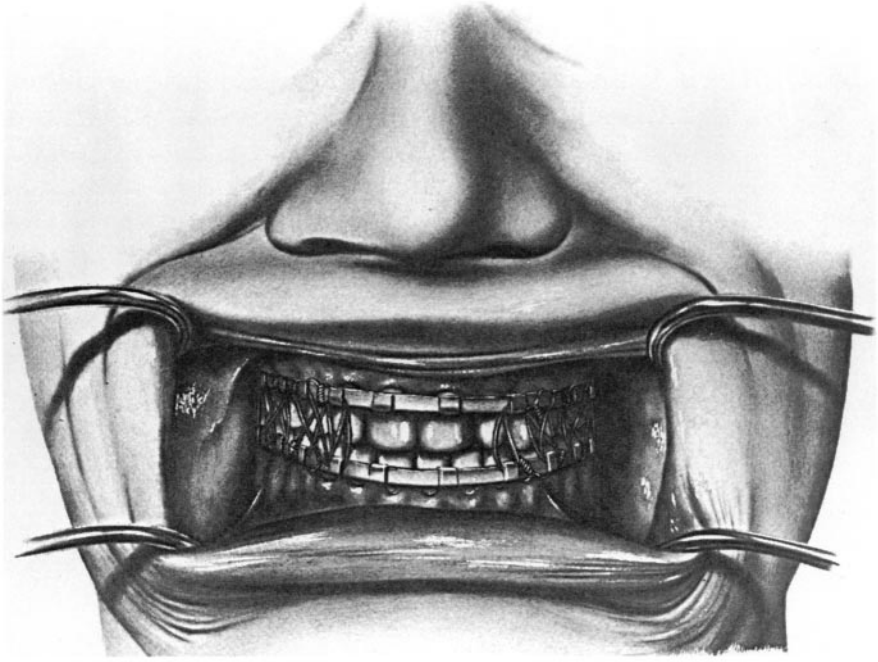

FIGURE 39–20. Maxillary and mandibular arch bars applied and intermaxillary wires in place. Reproduced with permission from Chayra GA et al.[7]

suspends the upper splint from the bone of the piriform apertures and from the zygomata by wires that encircle the arches. Once the flanges on each side of one splint are fitted into the slots of the corresponding splint, then the lugs of the maxillary and mandibular arch bars are wired together. Alternatively, the splint may be fixed with screws that pass through the splint and the unfractured alveolar ridge.

A cruder type of splint can be made in the operating room at the time of fracture reduction in the edentulous patient using cold cure acrylic. A lock and key arrangement is constructed, and arch bars are pressed into the lateral surfaces of the acrylic before it cures. This is a less precise splint and less comfortable for the patient. Any denture, even one that is broken, will serve well as a Gunning splint. Even a loose fitting denture will provide adequate stabilization of the fracture.

Fractures of the Parasymphyseal Area These fractures tend to occur in an oblique line, sometimes even approaching the midline from the mental foramen (Figure 39–21). The mental foramen is the most commonly involved site of a parasymphyseal fracture. A "pure" symphyseal fracture, that is, a fracture through the middle incisors, is rare. Either an ipsilateral or contralateral fracture of the angle, ramus, or condyle often accompanies unilateral parasymphyseal fractures. Parasymphyseal fractures may present with a crossbite on the involved side from the posterior pull of the mylohyoid. This is especially true when there is a concomitant ipsilateral fracture of the ascending portion of the mandible. Loose anterior dentition, ecchymotic mucosa, and grossly mobile fractured segments are the hallmarks of these fractures.

The presence of posteriorly displaced bilateral parasymphyseal fractures constitutes an airway emergency. An adequate airway should be established promptly by placing the fractured anterior mandibular segment in one's forefinger and thumb and projecting it anteriorly. Often an emergency tracheostomy or cricothyrotomy is indicated.

Treatment of a parasymphyseal fracture with only intermaxillary fixation in these cases is not usually adequate. It is often necessary to stabilize these fractures with interosseous wires, plate, or a lingual splint to prevent a permanent crossbite.[5,13–15] The approach to open reduction of these fractures can be either intraoral or external but is usually internal. Care must be taken to avoid avulsing the mental nerve by way of either approach.

Fractures of the Body and Angle of the Mandible Fractures of the mandibular body in patients with good dentition have the advantage of strong articulating mandibular and maxillary teeth. Intermaxillary fixation stabilizes many of these fractures sufficiently, alleviating the need for open reduction. The forces generated by the pterygomasseteric sling may distract these fractures, requiring open reduction. Once closed reduction is accomplished by means of Erich arch bars, a decision can be made whether the repair is stable. If not, an open reduction can be approached by means of a gingivobuccal incision intraorally.[16] Rarely, an extraoral approach will be necessary, and a modified Risdon incision is made with care taken to preserve the marginal mandibular branch of the facial nerve. Angle fractures may be treated the same way as body fractures. If the oblique line of fracture is in a favorable direction, closed reduction is adequate.

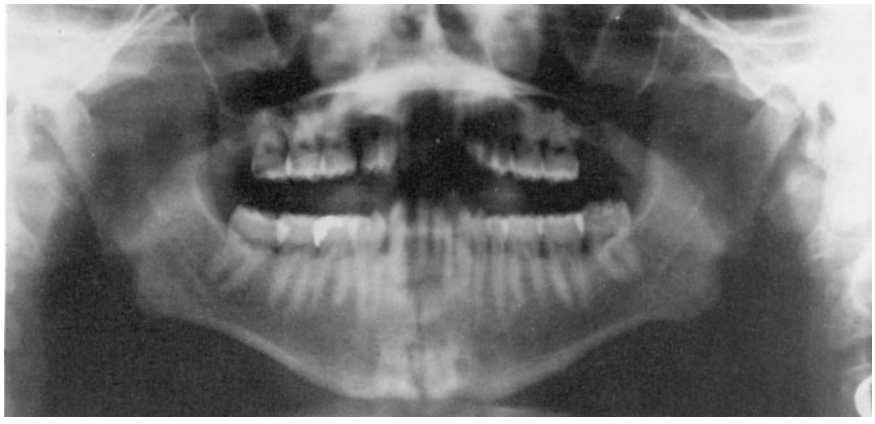

FIGURE 39–21. Parasymphyseal fracture.

When there is an "unfavorable" fracture, open reduction is often necessary.

Fractures of the Condylar Process and Ramus Subcondylar fractures are usually handled by closed reduction. Fractures of the mandibular ramus can be treated in a similar fashion to condylar fractures; that is, if there is displacement of the fractures and malocclusion results, closed reduction may be all that is needed. If there is a massive comminution, severe telescoping, or just displacement that is not adequately reduced by closed reduction, open reduction should be undertaken to avoid occlusal discrepancies. Severe condylar fractures are defined as (1) telescoping greater than 1.5 cm, (2) a condylar head displaced out of the condylar fossa, or (3) bilateral subcondylar fractures associated with a Le Fort or maxillary fracture.

The open approach is facilitated by an incision in the preauricular area extending into the temporal hairline, going deep to the temporalis fascia.[5,17] A flap of superficial temporalis fascia should be raised and the root of the zygoma followed down to the fracture site. The trunk of the facial nerve is avoided by staying on the zygomatic process of the temporal bone, tracking down to the glenoid fossa. With a gentle retraction of the superior parotid tissues, the fossa can be exposed and the fracture reduced by means of either a wire or a miniplate. Alternatives to repair of a condylar fracture include a Kirschner wire placed by way of the angle of the mandible projected superiorly toward the glenoid fossa.[18,19] External pin fixation with a Morris biphase and plating techniques have also been described.[20,21]

Open Reduction Before performing open reduction of a mandible fracture, it is always advisable, if possible, to place the patient in closed reduction to establish the occlusal relationship of the teeth. It is folly to attempt an open reduction of any sort when the maxillomandibular dental relationships have not yet been established.

Surgical Approaches Intraoral approaches have the advantages of scar camouflage and a more direct approach to fracture reduction and fixation. These approaches require more elaborate instrumentation to allow precise fracture fixation. Intraoral incisions allow less direct visualization of fractures; adequate exposure and accurate reduction through this approach require an experienced surgeon. Extraoral approaches have the advantage of increased exposure and increased visualization in the region of the posterior part of the body, angle, and ramus. External exposure requires a cervical incision; however, this involves potential risk to the marginal mandibular branch of the facial nerve.

The incision and approach chosen for a given fracture of the mandible depend on several factors. These include the location and type of the fracture, the available instrumentation and technology, and, most important, the surgeon's comfort with the given approach. The choice for fractures of the symphyseal and parasymphyseal region is intraoral. Linear posterior fractures may be approached intraorally, whereas more comminuted fractures or fractures with significant bone loss usually require an extraoral approach. The approach chosen should allow adequate exposure to diagnose, reduce, and immobilize the given fracture.

The symphyseal and parasymphyseal regions of the mandible are easily approached through either an intraoral or an extraoral route. The intraoral incision is made from canine tooth to canine tooth, leaving an adequate mucosal cuff for closure of the incision (Figure 39–22). Subperiosteal dissection is made, identifying and preserving the mental nerves. The symphyseal and parasymphyseal regions are also easily approached through an external submental incision oriented in relaxed skin tension lines. Reapproximation of the mentalis muscle must be carefully performed to prevent postoperative ptosis of the soft tissues of the chin.

The approach to the mandibular fracture posterior to the mental foramina depends on the surgeon's experience and the degree of the fracture.[12] Intraoral approaches to the body and angle are best performed by making a gingivobuccal incision immediately adjacent to the fracture. Repair of posterior mandibular fractures requires surgical experience and advanced technology to achieve fracture reduction fixation. Fracture fixation is achieved by a transbuccal system placed through transcutaneous facial stab incisions (Figure 39–23). The extraoral approach to fractures of the mandibular body, angle, or ramus is made through a transcervical incision two fingerbreadths below the angle of the mandible. Care is taken to elevate the marginal mandibular branch of the facial nerve to prevent injury. This approach is preferred when the patient has signifi-

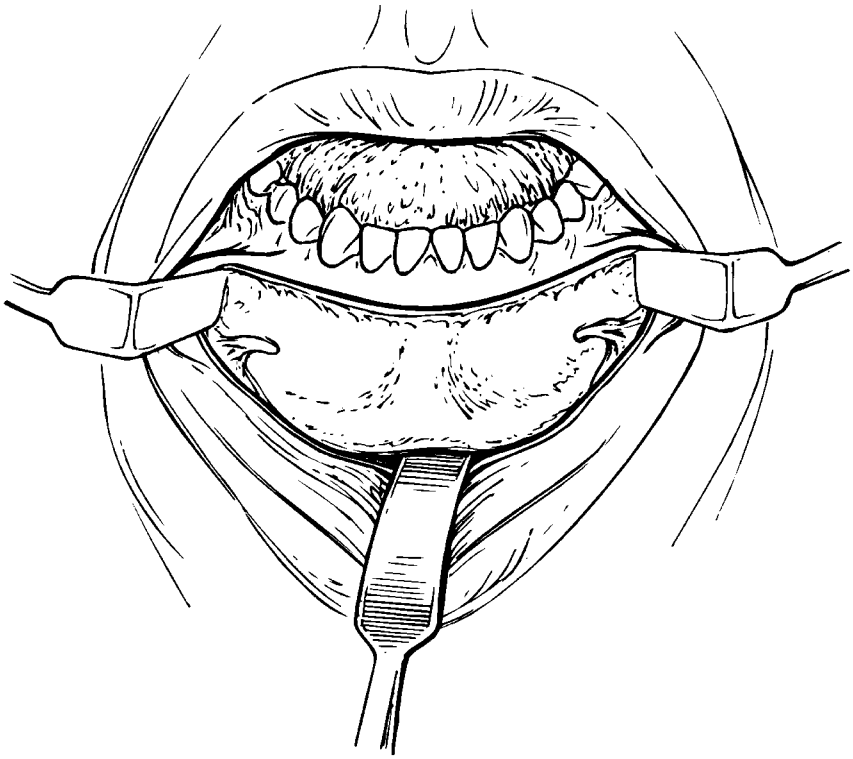

FIGURE 39–22. Schematic diagram of intraoral approach to symphyseal and parasymphyseal fractures. The dissection is subperiosteal and isolates and preserves the neurovascular pedicles from the mental foramina.

cant comminution of the fracture or bone loss. In each of these cases, a larger reconstruction plate may be required for repair. The external approach allows greater exposure for placement of large reconstruction plates.

As instrumentation and technology have progressed, treatment of mandibular fractures has evolved, but the goals have not changed. These goals include anatomic and functional stability of the mandible. Reduction and stabilization of any mandibular fracture should result in a pain-free function of the mandible without any eventual changes in the temporomandibular joint.

The strength of any bony fixation must be adequate to overcome any forces that will act on the repaired bone during function.[22] As previously mentioned, former techniques used wire fixation with interosseous wiring.[13,23] This method allows the bone to heal indirectly. Wire fixation is rarely used today. The only theoretical advantage of wire fixation for repair of mandibular fractures is the possibility of increased flexibility in cases with significant bone loss or comminution. In these situations, if rigid fixation is applied without proper restoration of premorbid occlusion, the result can be either poor occlusion or eventual change in the temporomandibular joint. If interosseous wiring is used, intermaxillary fixation should also be used for approximately 6 weeks for stable bone repair.

The rationale for the use of rigid internal fixation for repair of mandibular fractures is well documented.[13,24] With interosseous wire fixation, there is a clinically proven decrease in mouth opening seen 6 months after release of intermaxillary fixation.[15–18] Additionally, experimental and clinical evidence against wire fixation includes muscle atrophy[18] and histologic changes in the temporomandibular joint[19] after prolonged periods of intermaxillary fixation. Although an increased rate of infection has not been conclusively shown with intermaxillary fixation and interosseous wiring, the increased bone movement with nonrigid fixation makes this a theoretical consideration. As knowledge and technology have progressed, rigid internal fixation has become the standard in most centers for treatment of mandibular fractures. This allows the direct form of bone healing. Use of this type of bone repair requires surgical experience, advanced technology, and patient compliance. Direct bone healing can be achieved only with rigid fixation. If properly applied, stable rigid fixation of the mandible obviates the need for intermaxillary fixation.

Rigid fixation of the mandible can be performed by a variety of methods. The fracture is usu-

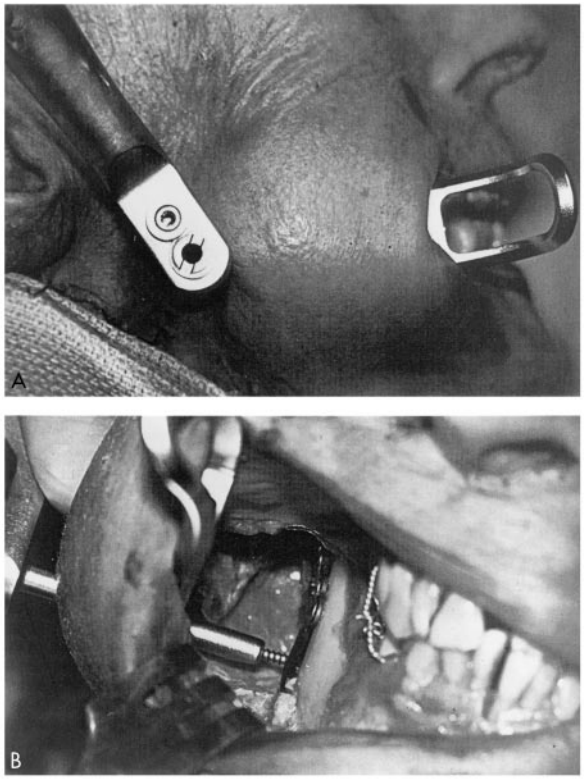

FIGURE 39–23. *A*, Lateral view of a cadaver showing use of the transcutaneous-transbuccal system approach for posterior fractures of the mandible. *A*, Stab wound incision has been used to insert the transbuccal system. *B*, Intraoral view showing use of the transbuccal system to place a plate and screws for fixation of a fracture of the angle of the mandible.

ally first reduced and the teeth put into premorbid occlusion by placing the patient in intermaxillary fixation. The fractures are then directly approached (with intermaxillary fixation in place), and anatomic fragment reduction is obtained. Rigid fixation is then performed. This can be accomplished with an inferior mandibular fracture plate (2.4 to 2.7 mm) and a superior monocortical two-hole tension band. The intraoral incision is retracted with a special intraoral retractor that is fitted to an extraoral device that will maintain a trochar passed through a stab incision in the cheek over the fracture site. Figure 39–24 illustrates the use of the device developed by Stryker-Leibinger (Kalamazoo, Michigan) for this purpose. The hollow trochar enables the passage of a plate-grasping device that itself is hollow and permits the passage of the drill bit. The plate is contoured to conform to the surface of the mandibular bone at the fracture site. With the plate in position, the screw holes are drilled, and the bicortical screws are passed. Two screws, as a minimum, are placed at each side of the fracture line.

In 1973, Michelet et al introduced the use of small monocortical plates for the fixation of mandibular fractures.[25] Champy et al popularized the use of these plates and emphasized the importance of lines of osteosynthesis (Figure 39–25).[26] The lines of natural compression forces at the angle and distal body of the mandible are exerted at the inferior border of the mandible, whereas the lines of tension or distraction occur at the superior border at

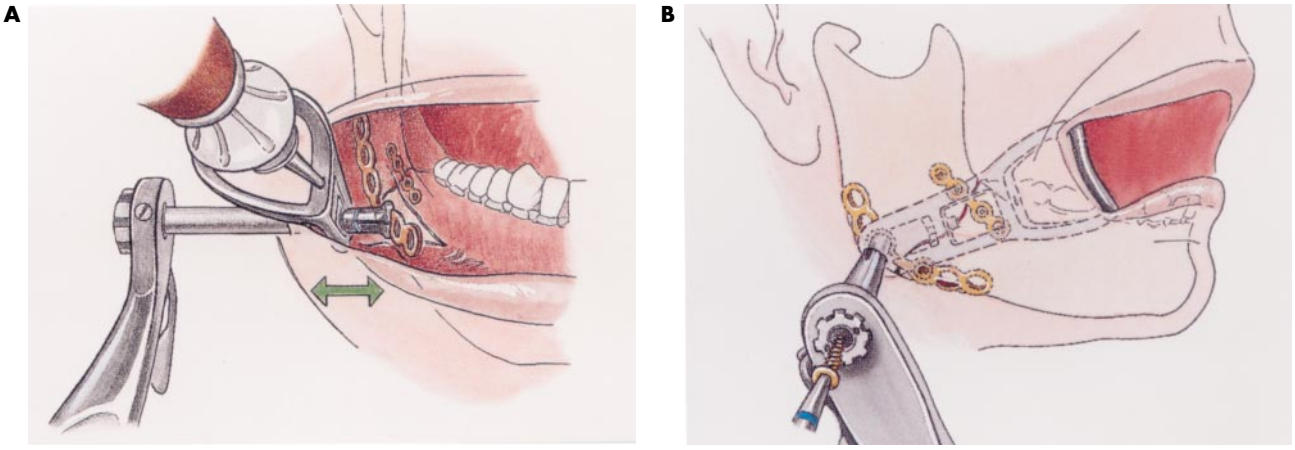

FIGURE 39–24. Transbuccal system for intraoral plating. *A*, Plate holder passed through a stab wound in the cheek. The buccal retractor is being secured to the plate holder. *B*, The drill hole has been made through the plate holder, and now the screw will be placed to fix the plate to the mandible.

the so-called lines of osteosynthesis (Figure 39–26). At the angle, only one plate is needed, but two plates are required at the parasymphyseal area because of the two lines of osteosynthesis. The plates are 0.9 mm thick and have either 4 to 6 holes or 8 to 16 holes. The diameter of the screw holes is 2.1 mm, and the holes are beveled at 30 degrees. Their rigidity and tensile strength are well within the forces of mastication and other forces normally encountered in mandibular activity. In angle fractures, the plate is placed at the external oblique line and in the symphyseal area, one at the inferior line and one in the superior line of osteosynthesis (Figure 39–27). The plates are placed in such a fashion to avoid contact with the tooth roots, although such contact is of no consequence in most instances. Care must be taken to avoid overtightening of the screws as this will produce microfractures and destabilize the fixation (Figure 39–28).[22,27]

Another means to achieve stable rigid fixation is the placement of lag screws.[20] This method employs a basic principle of woodworking and applies compression across the fracture line with minimal direct bone healing. This technique requires adequate exposure and subperiosteal undermining to allow placement of long screws that engage sufficient bone for fixation.

Lag-screw fixation requires that there will be sufficient obliquity to the fracture line to allow at least two, preferably three, lag screws to be placed at a significant distance from one another that will catch both mandibular cortices, thus stabilizing the reduction. The exception to this is the mandibular angle, where one screw is sufficient to achieve ade-

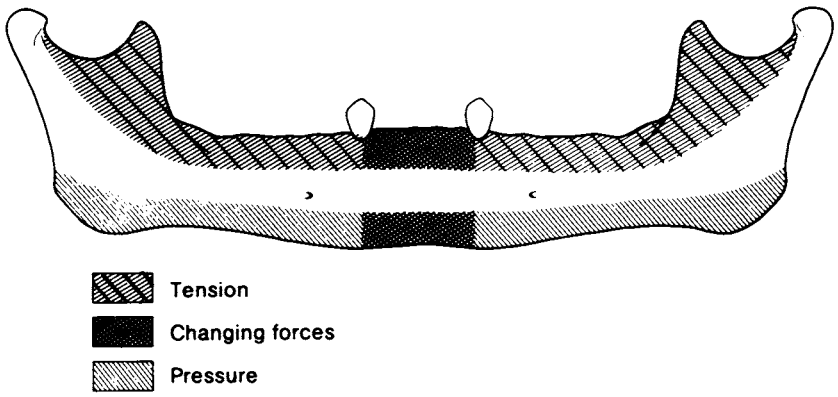

FIGURE 39–26. Forces of compression at the inferior border of the mandible and forces of tension at the superior border with a mandibular fracture.

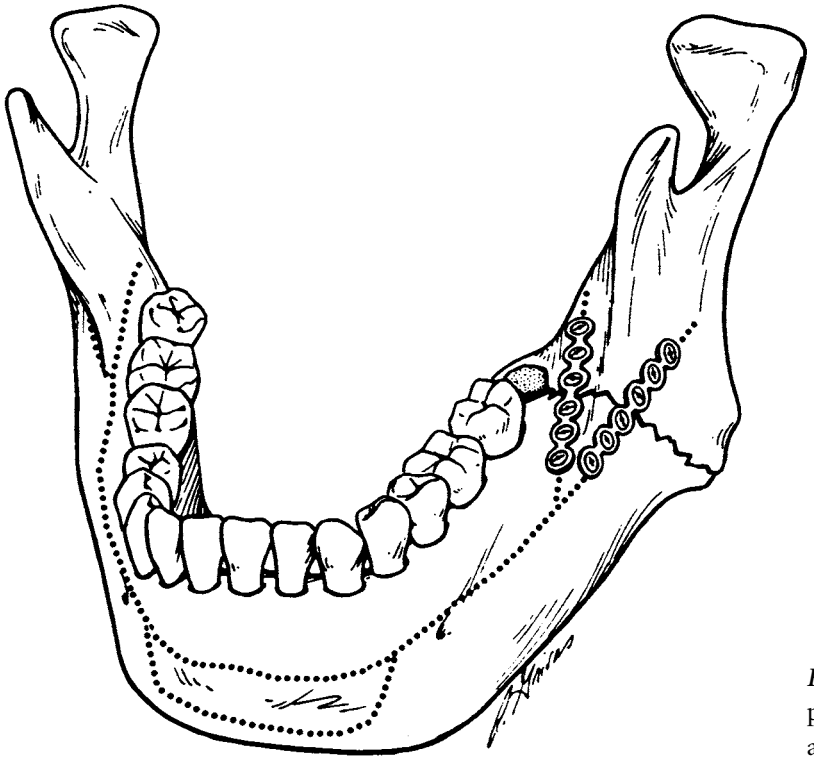

FIGURE 39–27. Champy miniplates placed on the mandible to secure an angle fracture of the mandible.

quate fixation. This technique is not applicable to all mandibular fractures and takes a degree of understanding of the dynamics of mandibular function and skill in inserting the screws appropriately. Through an intraoral approach, the fracture line is exposed, and the fracture is reduced and then maintained by arch bars or eyelet wires. For anteriorly located fractures in the parasymphyseal and mesial body, an intraoral approach can be done. For those fractures near the angle, the transbuccal approach is employed. A trochar is introduced through a stab incision in the cheek, and the penetrating point is removed prior to introducing the drill bit (Figure 39–29). A drill guide is placed

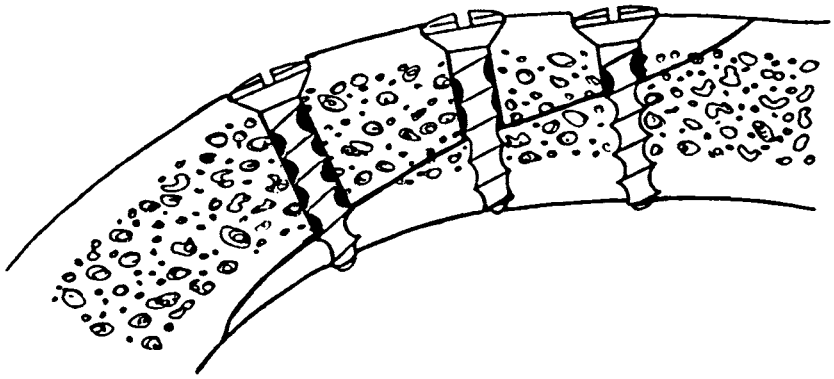
that will produce the "glide hole" for the portion of the screw that will pass through the buccal cortex. Once the fracture line is encountered, then a second guide is inserted through the hole just made to make the smaller guide hole in the lingual fragment. This screw hole must begin precisely in the center of the glide hole and be carried through the lingual cortex. A countersink is done at the start of the glide hole to accommodate the head of the screw. The screw is slid through the glide hole, and the threads then engage the thread hole. The fracture is compressed as the screw head enters the countersink.

In those fractures in the parasymphyseal area, the exposure can be done intraorally. The elevation of the mucoperiosteal flap must be done with an eye to avoid injuring the mental nerves. The gliding hole and the threading hole are placed in the same fashion as those in the area of the angle. The countersink is done, and the lag screw is placed to ensure stability. Two or three screws are placed (Figure 39–30). Screws are now available for which the screw flutes are wider than the diameter of the glide portion of the screw. This then requires that only one screw hole is drilled, and the passage of the thread portion of the screw pulls the gliding part through, giving tighter grip to the latter while achieving the necessary compression.

FIGURE 39–30. Illustration of the importance of placing two or three lag screws to ensure rigid fixation. Reproduced with permission from Kellman RM and Marentette LJ.[22]



If rigid fixation is stable, the patient may be taken out of intermaxillary fixation and allowed to function. Of course, this decision is based on the stability of the rigid fixation and on the individual patient's compliance. If either the fixation stability or patient compliance is in question, the patient may be left in intermaxillary fixation for up to 6 weeks.

Dental Injury Injury to the dentition is a common accompaniment to fractures of the mandible and maxilla. A chipping of a tooth that does not extend to the dentin can be managed by the dentist by grinding the occlusal surface smooth. Such injuries are usually unaccompanied by pain. Larger fractures of the tooth substance expose the dentin or pulp and are painful. It is important to dress the tooth immediately with a dental compound that not only protects the tooth but also alleviates discomfort. A mixture of zinc oxide and eugenol done with a metal spatula or a glass plate forms a sticky compound with the consistency of putty that hardens when wet by the saliva. Eugenol helps to soothe the pain. Other proprietary compounds such as Dycal may be used. Later, the dentist can restore the tooth with a crown. In the case of fracturing of a slab of tooth face in a vertical direction, especially from the incisors, the tooth can be repaired by bonding.

Avulsion of the crown at the gum line is managed either by the extraction of the root or by application of a dressing until the tooth can later be restored with a crown. If the dentition is neglected and carious, then extraction is the best solution.

Dental fractures that occur through the root present a special problem. Root fractures seriously jeopardize the viability of the tooth. If the soft tissue of the pulp is sufficiently traumatized, the tooth will die. Once the pulp undergoes necrosis, the stage is set for the development of a root abscess. This may occur a short time after the injury or may be delayed for years. If such an abscess were to occur during intermaxillary fixation, an osteomyelitis and even a nonunion could occur.

The management of a tooth in the line of fracture is controversial. Some guidelines do exist that may be of help. If the tooth is carious and the root is fractured, then the tooth should be removed. If a carious tooth has a fracture through the periodontal ligament, but the root is intact, extraction should be seriously entertained. If the tooth is healthy, the vital consideration is the importance of the tooth in the stability of the fracture. This is especially cogent in the circumstance of the erupted third molar tooth that lies in an unfavorably aligned fracture of the mandibular angle. In such a fracture, the line extends obliquely from anterior to posterior as it proceeds from the occlusal surface to the inferior border of the mandible. If the molar is in the distal fragment, its occlusion with the maxillary third molar above it will preclude its displacement. If this molar is extracted, the pull of the medial pterygoid and masseter muscles will displace the distal fragment upward. The wisdom tooth, being the most poorly calcified in the mouth, is the most susceptible of all to caries. One should probably remove a carious or impacted third molar in such a circumstance and achieve fixation by an open technique.

Any dental trauma can cause pulp necrosis, even without a root fracture. It is important to follow up patients after facial fractures with vitality testing of the teeth. Once viability is lost, then a root canal procedure should be done to prevent abscess and tooth loss.

The final consideration is that of avulsed teeth. Such teeth should be immediately replaced in the avulsion socket and fixed by wires to the adjacent teeth for splinting. Many such teeth later become nonvital and require root canal procedures. Most are retained, however, and their preservation helps greatly in the maintenance of dental arch integrity.

Postoperative Care Drains are usually placed in open reduction wounds of the body, angle, and ramus. These drains are usually removed on the first postoperative day. Local wound care to the suture line is best done with peroxide cleaning and antibiotic ointment to avoid infection. Intraoral care should begin as soon as possible and consist of a water pick to the dentition but not the suture line and/or gargle of a solution of mouthwash and peroxide. The lingual aspect of the dentition is inaccessible in the patient with closed reduction in intermaxillary fixation. The effervescence of the peroxide will help to débride the areas of the gum, gingiva, and teeth of the lingual surface.[14] These patients often complain of pain, especially in the first 2 postoperative weeks because of the spasm of the pterygoid and masseter muscles while the patient is in intermaxillary fixation. Codeine and acetaminophen with codeine syrup are useful analgesics during this immediate postoperative phase.

Persistence pain beyond 2 weeks requires nonsurgical examination of the operative site as well as a radiographic study to determine whether there has been a shift in the fracture site.

The increased metabolic demands of healing and the difficulty of eating while in intermaxillary fixation make adequate nutrition a common problem. Liquid diets must be supplemented with a protein powder as well as whole milk. It is not uncommon for patients to sustain severe weight loss during the ensuing 6 weeks of intermaxillary fixation. Dietary counseling is often helpful. If the patient remains in intermaxillary fixation, weekly checkups to tighten the intermaxillary wires are absolutely necessary. If the wire ligatures are used for intermaxillary fixation, the wire stretches, loosening the fixation. If there is not close contact with the maxillary and mandibular teeth, a lingual version may develop. This results in a severe malunion if not corrected before fibro-osseous union occurs. Tightening of the wires every week prevents this from happening. Dental checkups, when possible, are also necessary in the case of impending dental abscess.

Intermaxillary fixation may be removed 5 to 6 weeks postoperatively, providing that there is no evidence of a nonunion. Nonunion can best be assessed by palpation at the fracture site. If there is pain in the mandible and not the teeth at the operative site, a nonunion or fibrous union should be strongly suspected, especially when accompanied by mobility. Another technique is the "torque test," which involves placing a standard wooden tongue blade on the side of the fracture and having the patient bite down and break the tongue blade.[15] If there is no bone pain with this procedure, a good union has been achieved, and the arch bars may be removed. The patient is still cautioned to remain on a soft diet for 2 to 3 additional weeks.

When arch bars are removed, a dental consultation is needed to inspect the teeth for occlusal discrepancy. Orthodontia may provide the necessary correction. Major malunions may require osteotomy of the involved segment and repositioning with further intermaxillary fixation. With an accurate initial assessment, careful surgical technique, and good postoperative care, the need for further adjustments of occlusion should be infrequent.

Special Considerations: The Edentulous Mandible The fractured edentulous mandible presents specific management problems for the surgeon. With the absence of teeth, the alveolar cortical bone undergoes total resorption. The superior portion of the mandible is greatly attenuated. The overall height of the mandible, therefore, is much less than that of a tooth-bearing mandible. Maintaining correct mandibular height, however, especially in the case of angle, ramus, and condyle fractures, is essential to avoid possible temporomandibular joint problems.

Ideally, in a completely edentulous patient with mandible fractures, the dentures can simply be wired into place. In the maxilla, screws used in plating techniques or Kirschner wires are excellent means of fixing the upper denture to the palate. The lower denture is affixed using circum-mandibular wires. The patient should be kept in some form of intermaxillary fixation for at least 6 weeks.

Another form of fixation, although less acceptable, is a cap splint. This can be especially helpful in a fracture involving the body or symphyseal area. The cap splint is formed by placing acrylic over the ridge of the mandible with the fracture and affixing it to the mandible, using circum-mandibular wires. When dentures are not available or the fracture is in an area that cannot be splinted but intermaxillary fixation is necessary, dental impressions can be made as a template for Gunning splints. Gunning splints can be affixed to the edentulous upper and lower jaw by means of the same techniques used to affix dentures.

Open reduction is necessary in edentulous mandibles with unfavorable "fracture lines" and in severely comminuted fractures. Interosseous wiring can be accomplished in the same fashion as with tooth-bearing mandibles. Intermaxillary fixation, however, must be used in this situation. Compression plating is also convenient in these cases by way of either the external or intraoral approach. The advantage of using a compression plate is that rigid fixation is achieved that does not require intermaxillary fixation. In elderly patients, however, especially those with osteoporosis of the mandible, placement of a secure plate may be difficult and may loosen with time.

Pediatric Mandibular Fractures A mandibular fracture in a patient younger than 15 years requires a knowledge of the state of both permanent and deciduous dentition. The tooth buds of the permanent teeth are located below the roots of the deciduous teeth. Surgical trauma to the tooth buds may retard or completely negate the buds' ability to erupt later. Pri-

mary teeth are fully erupted usually by the second or third year of life. The central incisors are the first teeth to appear, followed by the lateral incisors, first molars, cuspids, and second molars. The shedding of these teeth occurs in the same order and is usually complete by 12 years of age. Therefore, in the first 12 years of life, there are tooth buds of permanent teeth or partially erupted permanent teeth that may be endangered by surgery. The presence of these tooth buds also makes the tooth-bearing areas of the mandible in a child more prone to fracture than in an adult. They, in effect, create a more porous bony surface with less structural support.

In the tooth-bearing areas of a mandibular fracture in a pediatric patient, an overlapping cap splint provides adequate, stable reduction to promote anatomic bone healing. Because of the ability of children to heal rapidly, the splint is required only for approximately 4 weeks. In the angle area, if the fracture is in an unfavorable line, open reduction may be attempted. Radiographic documentation of the proximity of the erupting of the third molar bud and second molar tooth bud should always be confirmed. If the fracture line is close to a tooth bud, closed reduction may be necessary. Arch bars can be used in a pediatric patient with wire ligatures; however, they may cause premature shedding of the deciduous teeth. Generally, intermaxillary fixation is not necessary in a child for safe healing of a fracture of the symphysis or body. Condylar fractures in the pediatric population have been seen to remodel completely without surgical intervention; therefore, no treatment is recommended.

Complications in Pediatric Fractures The tooth buds of an infant or young child are especially susceptible to damage that may cause deformities of the erupted mature tooth later.[28] A long-term follow-up study of 28 children with mandibular fractures was done by McGuirt and Salisbury.[29] The mean length of follow-up was 10½ years. The children were divided into condylar only, noncondylar, and condylar fractures with other facial fractures. Forty-six percent of the patients had temporomandibular joint compromise. Five patients were concerned about their external facial asymmetry. A medical/dental team reviewed abnormalities in 47% of the patients radiographically. Sixteen percent of the overall group were thought to be both clinically and radiographically abnormal enough to require interventional therapy. Therefore, one can expect nearly one of five children with a mandible fracture to have some sort of difficulty that may require later intervention. It is recommended that these patients be followed closely postoperatively by a dentist and/or orthodontist, and the use of braces and elastics may be necessary to promote growth and development of the fracture area.[29] The remodeling of untreated subcondylar fractures is well documented.[30,31]

Severe Mandibular Fractures If the trauma is from an explosion or a gunshot wound, or if the blunt trauma is excessively severe, there can be multiple missing pieces of mandible.[32,33] In these cases, open reduction and exploration are mandatory if the patient's condition permits. The bony fragments that do not have periosteal attachments should be removed and the area débrided and cleaned aggressively. Often in these fractures, there are portions of mandible that are pedicled on small pieces of periosteum. If less than 25% of the bone surface area is attached to periosteum, most surgeons would agree that débridement is necessary to prevent this from becoming a sequestrum.

Gunshot wounds require soft tissue débridement, especially high-velocity wounds in which there may be a large temporary cavity. A discussion of ballistics is beyond the scope of this chapter. Let it suffice to say that high-velocity weapons cause extensive soft tissue damage from both the impact of the weapon and the secondary missile effect of the mobilized bone through soft tissues. The use of external pin fixation and the application of the biphase appliance of the mandibular segments alleviate the possibility of infection that would otherwise be incurred by placement of a foreign body such as a plate in a potentially grossly infected wound.

If the wound can be cleaned adequately and soft tissue coverage achieved, a long mandibular plate can be used to approximate the (usually) multiple segments. Once healing has taken place and the infection is cleared, in 6 months to 1 year this area can be reconstructed using autogenous bone from a variety of sources or a free flap (Figure 39–31).[32]

ZYGOMATIC FRACTURES

The zygoma is the third most frequently fractured facial bone, with 85% of fractures occurring in men.

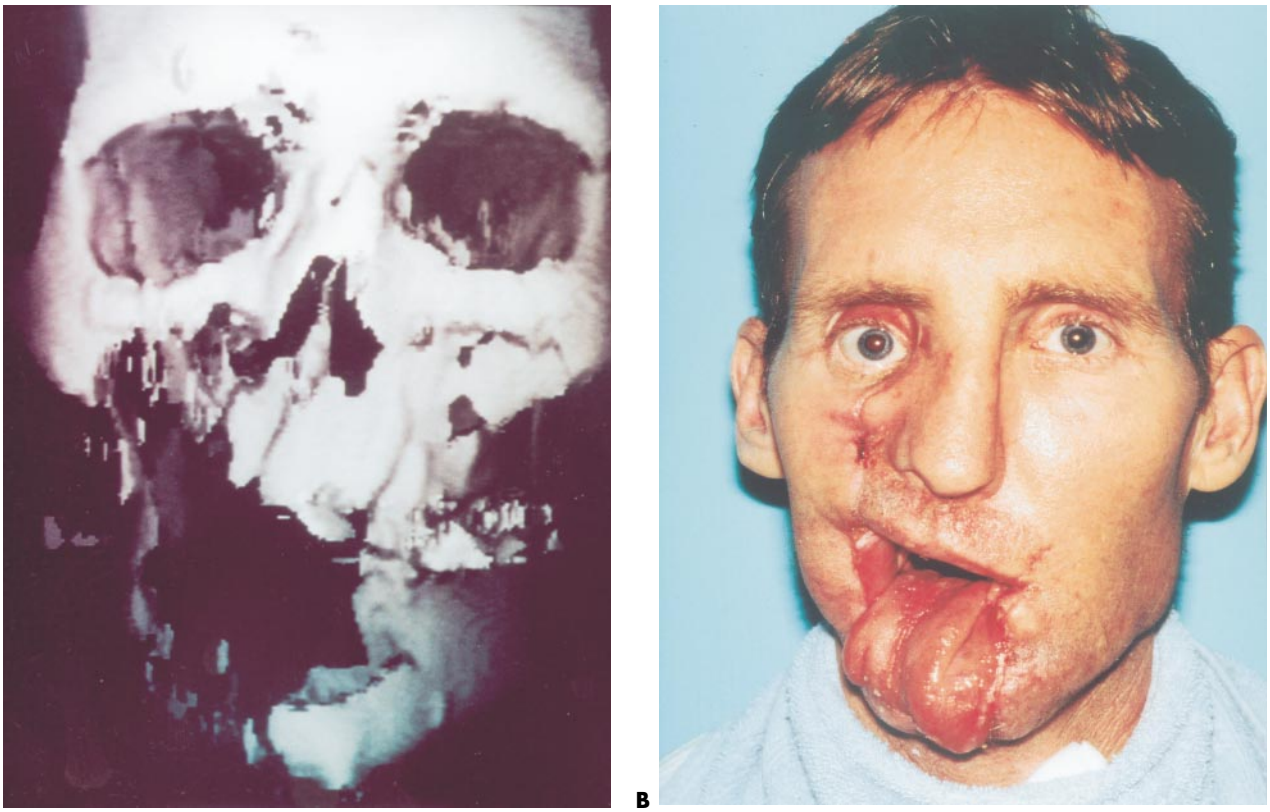


FIGURE 39–31. *A*, Three-dimensional computed tomogrpahic reconstruction of patient with a large defect secondary to a self-inflicted high-power rifle wound to the face. *B*, Preoperative patient has loss of mandible and soft tissue of the chin and neck. *C*, Reconstruction with fibular free flap.

Blunt trauma, owing to motor vehicle accidents or sports, makes up the great majority of zygomatic fractures. Fractures of this region are often called trimalar fractures, meaning fractures of the zygomatic frontal, zygomatic maxillary, and zygomatic temporal suture lines (Figure 39–32). Indeed, the fracture of the zygomatic sphenoid suture makes these fractures quadramalar.[6] The zygoma can withstand severe force, but as the most lateral extension of the facial skeleton, it is prone to injury in both the anteroposterior direction and the lateral and transverse directions. The attachments of the temporalis superiorly and the masseter muscle inferiorly tend to negate each other. However, the movement of the jaw with the masseter muscle does tend to distract the segments downward and medially.

The arch of the zygoma, which has contributions from both the zygomatic bone and the temporal bone, lies over the coronoid process. A depressed

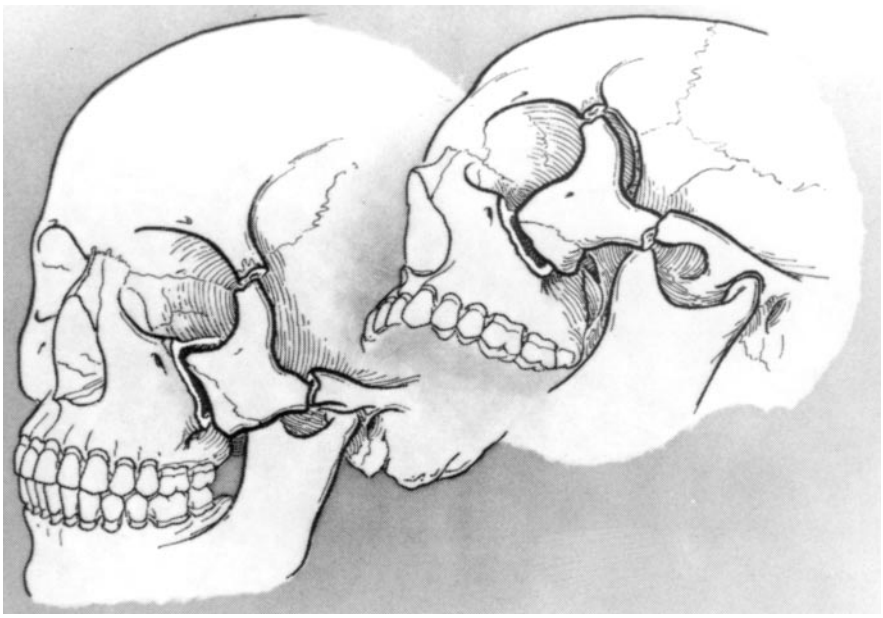

FIGURE 39–32. Classic tripod fracture of the zygoma. Reproduced with permission from Donald PJ. Zygomatic fractures. In: English GM, editor. Otolaryngology. Philadelphia: JB Lippincott; 1990.

fracture of the arch pushing into the temporal fossa often results in restriction in movement of the jaw because of impingement of the arch on the coronoid process. The fractures of the zygoma tend to occur at the articulations with the aforementioned bones. The body of the zygoma, which makes up the inferolateral orbital wall and is often the point of impact from trauma, is rarely fractured because it is the thickest part of the bone. Comminuted fractures of the zygomatic body are a difficult problem in surgical management.

Surgical Anatomy

The zygoma has four suture lines connecting it with the temporal, frontal, maxillary, and sphenoid bones. In addition to the temporalis and masseter muscles, the lesser and greater zygomatic muscles also insert on its surface. The orbital process of the zygoma makes up the anterolateral portion of the infraorbital foramen in the floor of the orbit. It is not uncommon, with a severe zygoma fracture, for there to be a herniation of orbital contents through the fracture of the maxillary zygomatic suture line. The infraorbital nerve exits from the infraorbital foramen at the articulation of the zygoma and maxilla. Damage to this nerve causes hypesthesia of the cheek on the affected side as well as the lateral aspect of the nose. From the body of the zygoma exit two sensory nerves, the zygomatic frontal and zygomatic temporal, which generally are clinically insignificant. When discussing a fracture of the zygoma, one must realize the importance of the intimate association to the lateral canthal tendon and the suspensory ligaments of the globe. There is some downward displacement in many fractures of the zygoma because of the previously mentioned traction of the masseter; therefore, the globe position can change. The entire globe can be pulled down because of downward displacement of the suspensory ligament of Lockwood, which attaches to Whitnall's tubercle, located on the lateral aspect of the orbital process of the zygoma. Also associated with the floor of the orbit are the inferior oblique and inferior rectus muscles, which are most often entrapped when the floor of the orbit is badly fractured (blowout fracture). Impalement of the muscles on a fracture fragment puts the muscle into spasm, which limits upward gaze. True entrapment of these muscles, which is rare, must be corrected surgically.

Diagnosis

History and physical examination are of primary importance in evaluating a zygomatic fracture. The patient gives a history of having received a blow from a fist, a ball, or other blunt object or has been involved in an automobile or motorcycle accident. He or she complains of localized pain and often has numbness over the ipsilateral cheek. If there is significant herniation of fat into the maxillary sinus,

diplopia ensues from herniation of orbital fat or entrapment of the inferior rectus and/or inferior oblique muscles. With no herniation of fat or evidence of an orbital floor dehiscence, inferior displacement of the zygomatic compound distracts Whitnall's tubercle and therefore the ligament of Lockwood, causing the same problem of diplopia.[6]

Trismus can result from impingement of the zygomatic arch on the coronoid process of the mandible. Often there is substantial masseter and temporalis spasm from contusion to that area, which may produce trismus even if the arch is intact.

The patient with a zygomatic fracture may also have epistaxis from bleeding into the maxillary sinus, the blood exiting by way of the ostium of the maxillary sinus and nose. On inspection, the patient has severe periorbital ecchymosis and swelling as well as a lateral subconjunctival hemorrhage secondary to tearing of vessels of the canthi. Blood in the anterior chamber (hyphema) indicates severe damage to the globe, and an emergency ophthalmologic consultation is mandatory.[34] Hemorrhage restricted to the subconjunctiva does not imply serious damage to the globe per se. Enophthalmos is common secondary to fat and muscle herniation into the maxillary sinus. Because concomitant intraocular injury is common, an ophthalmologic consultation should be obtained in all cases.

There is palpable facial skeletal asymmetry over the malar eminence and zygomatic arch if the swelling is not too severe. One may place a gloved finger into the oral cavity to feel the zygomatic buttress and appreciate crepitus and swelling. This movement is exquisitely tender to a patient with a fracture. There is trismus in some of these patients, defined as the inability to open the mouth more than 3 cm. In the absence of severe swelling, a fracture of the arch and the infraorbital rim can be palpated. The patient may be unable to raise the affected eye from the equator and experiences diplopia (Figure 39–33). A forced duction test should be done on all patients with diplopia. A positive test indicates entrapment of the inferior rectus or inferior oblique muscle. Table 39–3 provides a listing of signs and symptoms of zygomatic fractures.

Zygomatic fractures can be classified according to their severity. An isolated fracture of the zygomatic arch may occur with no orbital involvement. However, most fractures involve the four suture lines previously alluded to. Fracture of the zygomaticomaxillary suture line and orbital floor without involvement of the frontal zygomatic or frontal tem-

Epistaxis	Malar flattening
	Hypo-ophthalmus/enophthalmos
Trismus	Subconjunctival hemorrhage
Cosmetic deformity	

poral suture line constitutes an impure blowout fracture. A pure blowout fracture refers to a dehiscence of the orbital floor with an intact orbital rim.[35] A severely comminuted body fracture requires extensive exposure and is managed differently than a tripod fracture. The treatment of these various fractures differs, and diagnosis should be confirmed with radiographs.

Standard facial films including Waters', Caldwell's, Towne's, and submental vertex views are usually obtained on these patients. This battery of films helps rule out associated facial fractures. The Waters' and submental vertex views are of great help in diagnosis. The Waters' view can reveal an orbital floor dehiscence by the classic teardrop sign indicating herniation of orbital contents into the maxillary sinus. There is often blood in the maxillary sinus, however, which may obscure this sign. Also, the orbital rim, frontozygomatic suture line, and body of the zygoma are well visualized with the Waters' view. The submental vertex view is excellent for evaluating the zygomatic arch. Although most zygomatic fractures are readily diagnosed on plain radiographs, the CT scan affords a more accurate rendition of the fracture details. It is especially good at depicting the degree and severity of orbital floor fractures (Figure 39–34) and in detecting fractures of the orbital apex. Subtle unilateral associated fractures of the palate will be detected as well. Three-dimensional CT scanning provides a dramatic view of the fracture but adds little to the therapeutic decision-making process.

Treatment

The decision to repair a zygomatic fracture should be based on the goals one hopes to attain by such surgical intervention. The only strict indications for surgery are relief of trismus and correction of diplopia from an inferior displacement and entrapment of the inferior rectus and inferior oblique muscles. Most often, the patient desires repair for cosmetic reasons. If there is ipsilateral numbness after a fracture, this improves, in the large majority of cases, with no surgical intervention. Therefore, numbness of the cheek should not be the only indication for surgery. When obtaining the patient's consent for surgery, one must be careful to give counsel about the proximity of the globe to the surgical site and alert the patient to the real risk of retrobulbar hematoma and retinal tear from retraction of the globe.[34] These complications are extremely rare with careful surgical technique. More important in preoperative counseling, if an infraorbital rim approach is needed, is to inform the patient of the possibilities of prolonged lower lid edema and the possibility of ectropion. The onset of visual field changes,

FIGURE 39–34. Waters' view demonstrating orbital floor fracture and prolapse of orbital contents into the maxillary sinus.

diplopia, or a change in the patient's visual acuity requires an ophthalmologic consultation.

One of the possible occult injuries of a zygomatico-orbital fracture is a retinal tear. Traction of the globe during surgery to repair a zygoma may extend a small, insignificant retinal tear, creating a large visual field defect. This can be avoided by limiting retraction of the globe to short periods of time and using extreme caution.

Serious intraocular injury mandates delay of repair until the globe has stabilized. Otherwise, the timing of the repair of a zygomatic fracture depends on the degree of soft tissue swelling. If swelling is severe, waiting for 5 to 10 days is acceptable, and moving the zygoma will not be a significant problem during that time. After 10 to 14 days, the zygoma may form a fibrous union, making mobilization of the fracture difficult. A good rule of thumb is to reduce the fracture as soon as the swelling has subsided enough to compare both zygomas intraoperatively.

Surgical Technique Multiple techniques have been used to repair a zygoma fracture. The four fracture lines imply that there should be points of fixation to stabilize the fracture, both laterally and inferiorly. The "classic" technique of placing a plate or wire in the frontal zygomatic fracture line and the zygomaticomaxillary suture line at the infraorbital rim provides adequate stabilization for a large majority of fractures. Some fractures treated in this manner are not adequately stabilized and require antral packing or an intraoral approach to reduce the inferior aspect of the fracture. One-point fixation techniques have been described using either a Kirschner wire[36] or, more recently, a rigid miniplate.[37–39]

Fractures of the zygomatic arch (Figure 39–35) with a significant cosmetic defect or trismus can be elevated by means of a Gillies incision in the temporal hairline (Figure 39–36, A) and reduced directly. The temporal branch of the facial nerve is avoided by placing the elevator deep to the superficial fascia of the temporalis muscle. The Boies elevator is placed under the arch, and the fragments are levered into position (Figure 39–36, B). A plate is rarely ever required for fixation because of the splinting action of the underlying temporalis muscle.

For the open technique, a supraorbital brow incision is made within the brow line or as an

extended upper blepharoplasty incision (Figure 39–37), and the frontozygomatic suture line is exposed. The approach to the infraorbital incision varies depending on the surgeon's discretion. Choices include a transconjunctival approach (Figure 39–38) or an approach through the skin of the lower lid at various distances from the gray line of the lower lid. The placement of the subciliary incision should be along the crease and should be at least 3 to 4 mm below the ciliary line to avoid ectropion and prevent lid edema. The author advocates the step technique (Figure 39–39), in which a skin flap is elevated, leaving the orbicularis oculi muscle intact to prevent fat herniation from obstructing visualization of the fracture. Once the step incision of approximately 4 cm in length is made, it is carried down to the maxilla. The periosteum is entered below the infraorbital rim to avoid interruption of the septum orbitale that may cause later scarring and ectropion. The entire orbicularis oculi muscle and orbital septum are retracted superiorly.

These approaches provide good visualization of the rim and orbital floor while, at the same time, decreasing the chance of trauma to the infraorbital nerve. If there is a significant dehiscence of the orbital floor (greater than 1.5 cm) or entrapment of the inferior rectus or inferior oblique muscle, a graft of malar bone, nasal septum, Gelfilm, or irradiated cartilage should be used to repair the defect. The author recommends homografts to reconstruct the floor and feels that the danger of migration or extrusion with Silastic sheeting prohibits its use.[40–42] Titanium mesh has been added to the armamentarium of alloplasts to reconstruct the orbital floor. Initial results are encouraging, but the implant will need to stand the test of time.

A Boise elevator is then placed into the infratemporal fossa from the brow incision, beneath the arch, and the fracture is elevated to align the infraorbital rim and elevate the arch. Once the fracture has been put in proper position, a miniplate is bent to adapt to the reduced lateral orbital rim and is held in position to drill the screw holes. Holes to accommodate the screws for the miniplate that will be used to fix the frontozygomatic fracture are drilled on each side of the fracture line. Usually, two holes will be sufficient, but, on occasion, three holes are placed. Most plating systems now have self-taping screws so that tape is unnecessary. Some systems have self-drilling screws, however, and a small

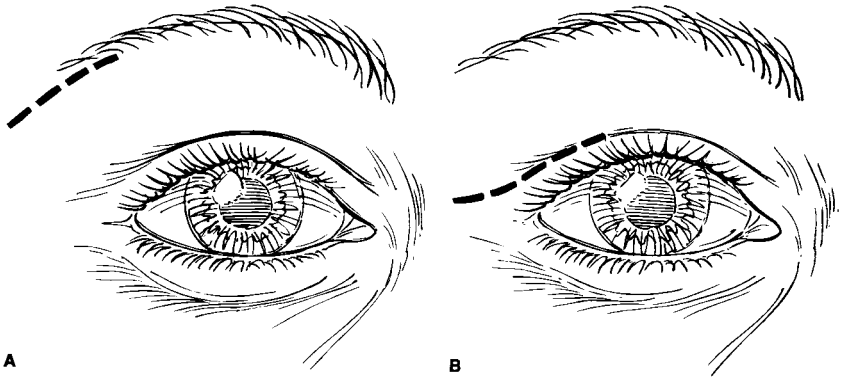

FIGURE 39–37. A, Schematic diagram of a lateral brow incision for approach to the frontozygomatic suture line. *B*, Schematic diagram of a right extended upper blepharoplasty incision for approach to the frontozygomatic suture line.

amount of pressure is initially required to get the screw started. This is not usually a problem in the lateral orbital wall but may be impossible in the infraorbital rim. A microplate is adapted to the infraorbital rim, and two drill holes are placed on either side of the fracture line (Figure 39–40). The screws are placed in the infraorbital and lateral orbital rims, providing the necessary two-point fixation. Some individuals add an additional plate at the inferior aspect of the zygomatic buttress. This will require an additional incision in the gingival buccal sulcus such as an extended Caldwell-Luc incision. A subperiosteal elevation will expose the underside of the zygomatic buttress. In most trimalar fractures, this step is entirely unnecessary.

Compound comminuted fractures of the body (Figure 39–41, A) require a direct approach by way of either a coronal scalp incision or extending the infraorbital incision superiorly and the upper brow incision laterally. Either a rigid miniplate or multiple interosseous wires can be used to fix multiple comminuted body fractures. When interosseous wiring is used for the compound body fracture, it is sometimes necessary to maintain elevation of the zygoma as it tends to prolapse. This can be done with an external pin fixation device such as a Morris biphase,

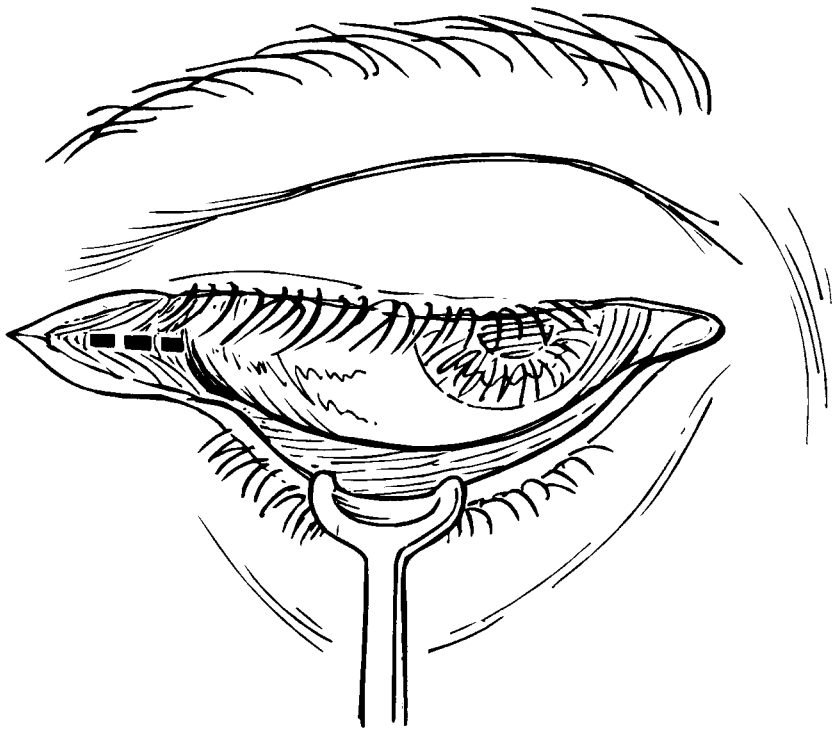

FIGURE 39–38. Schematic diagram of a transconjunctival approach to the infraorbital rim and orbital floor. It shows the transconjunctival incision and the lateral canthotomy already performed. The *dotted line* indicates the area for inferior cantholysis to improve exposure.

stabilizing it superiorly to the frontal bone. Properly placed rigid miniplate fixation eliminates the need for an external device and is the method of choice (Figure 39–41, B).

Postoperative Care After surgery, if the fracture is unstable, a head dressing should be applied to hold a zygoma guard in place (Figure 39–42). This will not necessarily protect the zygomatic arch from collapsing with some pressure but will remind the patient not to roll on that side of the face while sleeping. This protective device is best retained for at least 2 weeks but can be removed when the patient is not sleeping. The zygoma guard is necessary in patients who have had interosseus wiring of a trimalar fracture, a reduced but not rigidly fixed arch fracture, or an unstable fracture with multiple comminution. Most fractures fixed with a rigid plating system will not need the guard.

Routine wound care is administered in the postoperative period, and the sutures should be

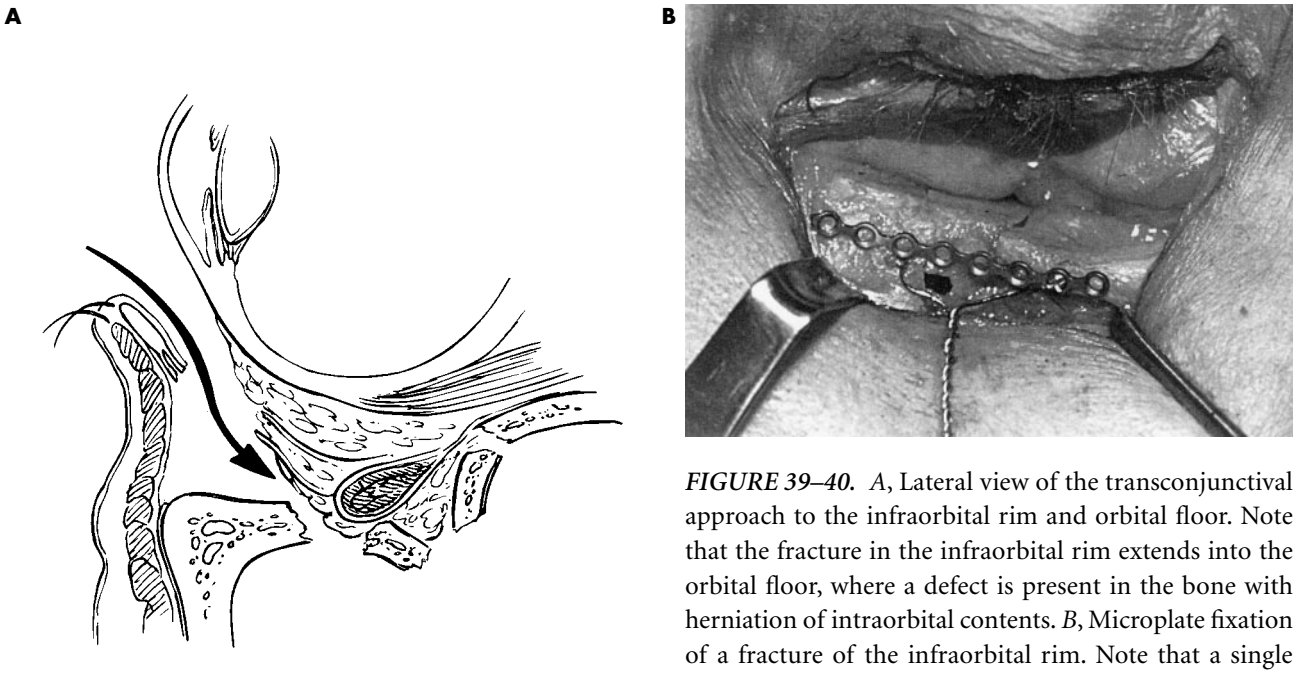

FIGURE 39–40. *A*, Lateral view of the transconjunctival approach to the infraorbital rim and orbital floor. FIGURE 39–41. *A*, Complex body fracture of zygoma. *B*, At least three-point stabilization is required for adequate fixation. Reproduced with permission from Donald PJ. Zygomatic fractures. In: English GM, editor. Otolaryngology. Philadelphia: JB Lippincott; in press.

removed within 3 to 5 days. Diplopia from surgery may not resolve for up to 2 months. If there is postoperative diplopia and a thorough exploration of the orbital floor revealed no significant blowout fracture, the patient may be managed expectantly, with a good prognosis. Unrepaired zygoma fractures often lead to cosmetic deformity. Because of the pull of the masseter muscle, the zygoma is distracted in a downward and medial direction. This type of deformity causes lack of cheekbone prominence and an increase in orbital volume.

Enophthalmos is the result of failure to reduce an orbital floor fracture properly, with subsequent atrophy of herniated orbital fat. The actual orbital volume is increased if the zygoma heals in a rotated position. If orbital volume is increased appreciably, the remaining orbital contents are insufficient to maintain normal anterior protrusion of the globe, resulting in the "sunken eye" appearance of enophthalmos.[43] In rare instances, posteromedial displacement creates a smaller orbital compartment and a concomitant exophthalmos.[44]

In the nonseeing eye, the problems of enophthalmos can be corrected with minimal risk. Allografts or autogenous material may be placed in the orbit to increase orbital volume. Bony deformities are treated with onlay grafts or osteotomies of the zygoma with interposed calvarial bone grafts.

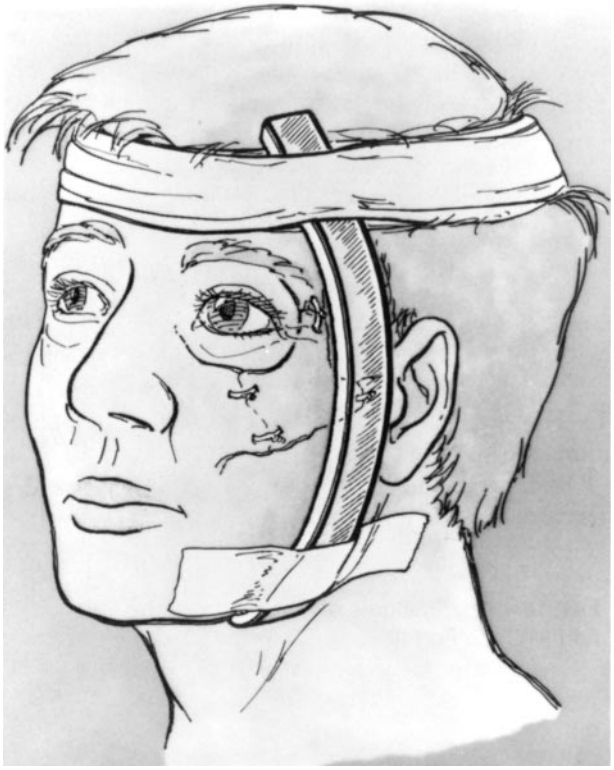

FIGURE 39–42. Guard placed to prevent displacement of the fracture reduction.

Enophthalmos in a person with vision can be safely corrected with calvarial bone grafts to the orbital floor. The use of other material such as titanium mesh or mesh covered in hydroxyapatite bone cement has also been advocated. Danger to the optic nerve and of extrusion or migration of alloplastic material[32] makes this procedure potentially hazardous.

An unreduced fracture of the zygomatic arch or one that is incompletely elevated into position may form a bony union with the coronoid process of the mandible. This is a very rare complication but will produce severe trismus that can be eliminated only by an open osteotomy and rigid fixation of the arch. Removal of the bony connection between the arch and the coronoid is essential, and placement of a Silastic sheet between the two bony structures may be necessary to prevent a relapse. The Silastic sheet may have to be removed at a future time, but if it is not problematic, it may remain indefinitely.

MAXILLARY (LE FORT) FRACTURES

Causes

Fractures of the midface, commonly referred to as Le Fort fractures, occur with much less frequency than fractures of the mandible, zygoma, or nose. Most often, they are the result of blunt trauma from accidents with automobiles, motorcycles, snowmobiles, or boats. The force required to fracture the maxilla and pterygoid plates of the sphenoid, which are the two fractured bones common to all Le Fort fractures, is considerable. Because of the alignment of the buttresses of the midface, which protect this area from vertical displacement, most of these fractures are caused by horizontal forces from the lateral, oblique, or anterior direction. The cranium and the orbit are intimately associated with these injuries and should be addressed with a high index of suspicion in all patients with midface injuries.

In the early 1900s, Rene Le Fort described the common lines of fractures associated with severe blunt trauma to cadaver heads.[45] Although his description is not characteristic of many compound midfacial fractures, it does serve to stage the degree of severity of the fracture and also alerts the physician to concomitant antecedent injuries that are peculiar to the three types of fractures. It is much more accurate to describe an injury in such terms as compound palatal zygomaticomaxillary or maxillonasal. Because of the number of bones in the face that can be associated with large compound midfacial injuries, however, and because many of them are not surgically accessible by any means, other than that associated with those injuries, the classic descriptions of Le Fort become useful indices for patient management and as tools for communication between physicians of different specialties.

Anatomy

The maxillae are the large paired bones of the midface that are approximately box shaped and almost fully pneumatized by their own sinuses. The lateral wall is part of the infratemporal fossa and articulates with the zygoma superiorly and the palatine bone posteriorly. The anterior wall has a lateral articulation with the nasal bones by way of the frontal process of the maxilla, which extends along the piriform aperture up toward the bony orbit to form the anterior crest of the lacrimal fossa. The medial wall is intimately associated superiorly with the ethmoid complex as well as the inferior turbinate. The posterior wall is relatively more substantial than the anterior wall "protecting" the pterygopalatine fossa and its nerves and vessels. Posteriorly, the maxilla also communicates with the sphenoid bone, both superiorly with the inferior aspect of the greater wing of the sphenoid and posterolaterally with the pterygoid plates. The vomer, ethmoid complex, palatine bones, zygoma, and nasal bones should also be considered part of the midface. One or all of these bones are often fractured in Le Fort fractures, although they may not all need direct treatment.

Le Fort's Classification Le Fort's classification refers to the lines of the three most common types of midface fractures (linae minores resistentiae). The Le Fort I fracture (Figure 39–43, A) is a lower palatal fracture that is also called Guérin's fracture. Le Fort II fractures (Figure 39–43, B) are also referred to as pyramidal fractures. Le Fort III fractures (Figure 39–43, C) are also known as craniofacial dysjunctions.

The Le Fort I fracture involves the floor of the nose, lower third of the maxilla, palate, and pterygoid plates, usually in one segment. Le Fort II fracture occurs across the nasal bony superstructure and the frontal process of the maxilla, down across

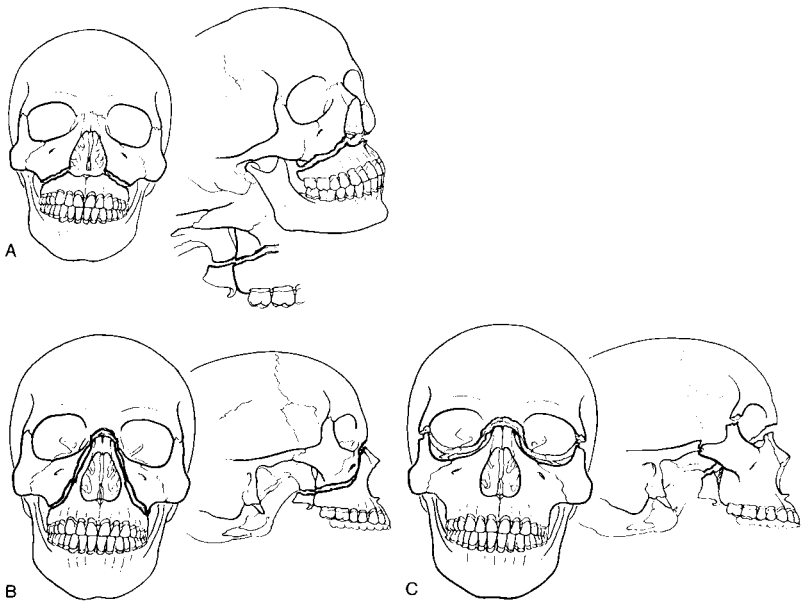

FIGURE 39–43. Le Fort fractures of the maxilla. *A*, Le Fort I. *B*, Le Fort II. *C*, Le Fort III.

the face of the anterior maxilla, and across the orbital floor, including the infraorbital foramen. The fracture line goes through the lateral wall of the maxilla extending to the pterygoid plates, usually higher than the Le Fort I. Le Fort III fractures are lateral fractures extending across the orbital floor into the lateral orbit through the zygoma. They can include the frontal zygomatic suture line. If the zygoma moves during palpation of the palate, a Le Fort III fracture is present.

Le Fort fractures are commonly found in combinations. A Le Fort I fracture may have an associated Le Fort II or III on the side of impact. A Le Fort II fracture may be a Le Fort III fracture on the side of the impact. The exact classification of the fractures on each side is important because of the differences of treatment associated with the different types. One should refer to the fractures based on the type of fracture on each side, for instance, left Le Fort III or right Le Fort I.

Further Considerations

Structural Pillars of the Midface Le Fort's classification was surprisingly complete in its description of the midfacial fractures, although there are certain limitations to his original descriptions. The classification of Le Fort fractures is based on the most superior fracture line involved in the fractures and does not take into account the fact that many of the fractures of the midface are comminuted and that within the confines of the midfacial skeleton, these multiple fractures may take on many configurations.[45–47] The concept of the structural pillars of the midface (Figure 39–44) helps to elucidate the key areas of fracture and therefore the subsequent stabilization of the midface as it relates to both potential cosmetic deformities and functional problems. An understanding of these structural pillars not only aids in assessment of the severity of the fracture but also provides an excellent strategic framework for surgical intervention.

There are three main buttresses of the midfacial cranial complex.[47] Going from anterior to posterior, the anteriormost buttress is the nasal maxillary buttress extending from the maxillary alveolus along the piriform aperture up to the medial side of the orbit through the anterior lacrimal crest, the frontal process of the maxilla to the superior orbital rim, and ending at the frontal bone of the cranium.

The zygomatic buttress extends from the maxillary alveolus above the anterior molar teeth to the zygomatic process of the frontal bone with a vertical component consisting of the zygomatic arch articulating with the zygomatic process of the temporal bone at the base of the skull.

The buttress of the pterygomaxillary alveolus articulates with the base of the skull through the orbital process of the palatine bone, articulating pos-

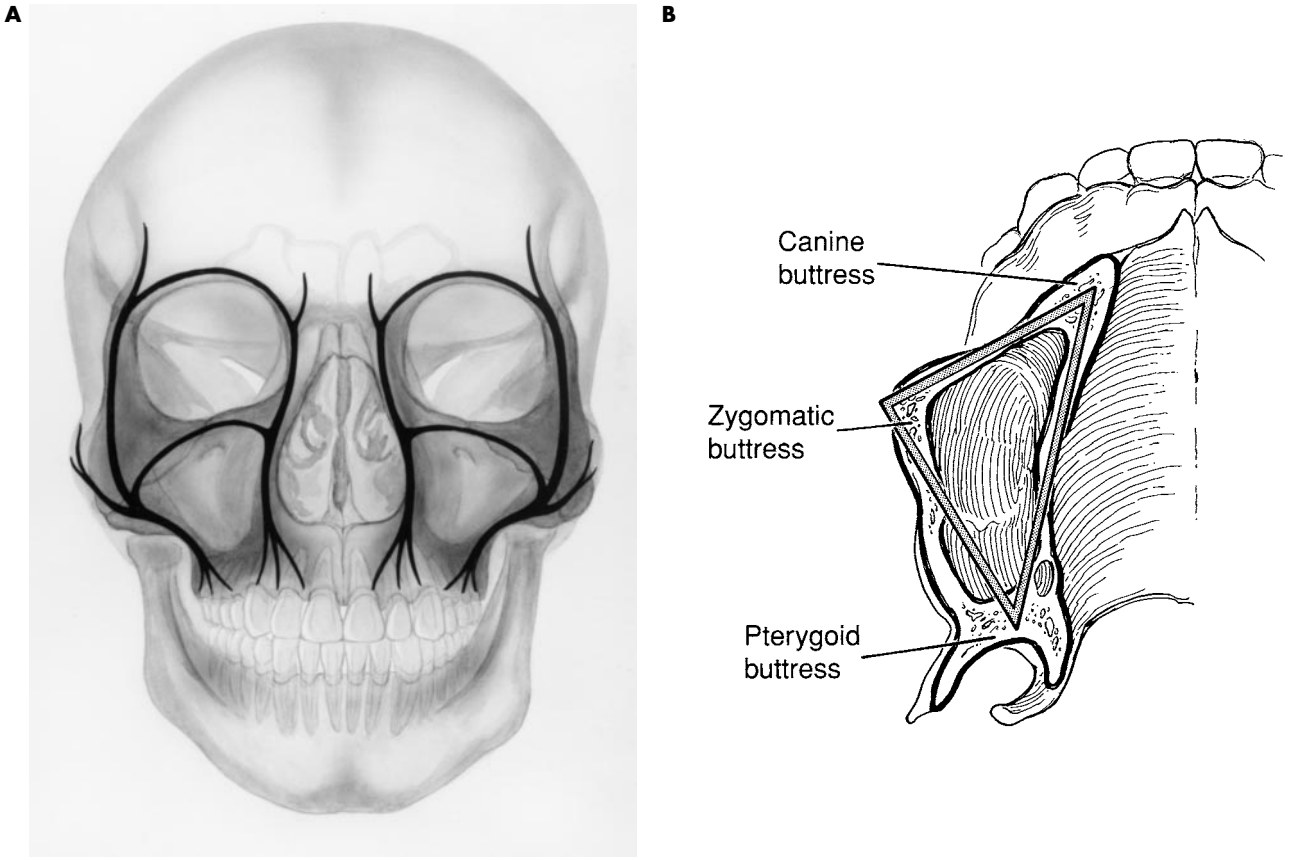

FIGURE 39–44. *A* and *B*, Biomechanical stress curves of the middle third of the face.

teriorly with the sphenoid bone. The pterygoid portion of this vertical buttress consists of the pterygoid plates extending inferiorly and anteriorly toward the maxilla. The horizontal system of buttresses divides the oral, nasal, and orbital regions of the face.

If one considered these pillars in midfacial fractures, therapy should be directed toward the stabilization of as many of these buttresses as possible. Probably the two most important areas of stabilization are the nasal maxillary buttress and the zygomatic buttress. The more posterior vertical pterygomaxillary buttress is more inaccessible surgically, although the most inferior portion of it can be stabilized if necessary. In severely comminuted Le Fort fractures, the surgeon must appreciate the advantage of open reduction and internal fixation of multiple fragments in their anatomic positions, especially those relating to this buttress complex. Without proper reduction of the midface fractures or proper stabilization of concomitant subcondylar mandibular fractures, there is always the possibility of midfacial telescoping, which results in a shortened midface.[46–48]

Diagnosis

Eliciting an accurate history on a patient with severe midfacial injury is often difficult or impossible because of associated intracranial, abdominal, or intrathoracic injuries. The motor vehicle accident victim may also be inebriated. If the patient is conscious, however, and does not have any life-threatening injuries requiring emergency surgical intervention, a thorough history is helpful in ascertaining the extent and severity of facial injury.

Because the maxilla forms the anterior floor of the orbit, there may be herniation of the orbital soft tissues into the maxillary sinus, similar to that seen in a blowout fracture. Diplopia may be a complaint in Le Fort II or III fractures. Complaints of blurred vision or a change in visual acuity mandate

an ophthalmologic evaluation. Epiphora may also be a component of compound fractures involving the lacrimal duct and/or the inferior medial orbital area. Difficulty in breathing is a common problem from congestion associated with edema from the fractures as well as physical derangement of the nasal bones and septal structures. Bleeding from the maxillary or ethmoid ostia or from lacerations within the nasal cavity may cause severe nasal obstruction. Patient complaints of a salty taste in the mouth should alert the physician of the possibility of a cerebrospinal fluid leak. Most commonly, these are found in the cribriform plate or the roof of the ethmoid sinuses.[5,6] Displacement of the maxilla causes the patient to complain of malocclusion. Although there may be either buccal or lingual version, the most common occlusal abnormality is an open-bite deformity. The open-bite deformity is caused by the powerful forces of the pterygoid muscles distracting the posterior part of the maxilla inferiorly.[6] A blow directed anteriorly causes displacement of the maxilla posteriorly, resulting in a so-called "dish face" deformity and a Class III malocclusion. A more detailed discussion of dental occlusion is given earlier in this chapter.

Airway compromise is often the presenting symptom. The posteroinferior displacement of the fractured maxilla by the pterygoid muscles tends to decrease the airway. This, coupled with attendant swelling and hemorrhage, may produce airway obstruction.

On physical examination, the patient may have periorbital ecchymosis, massive tissue swelling, or subconjunctival hemorrhage if the infraorbital rim is involved. Dental examination confirms the previously mentioned findings relating to open bite, lingual/buccal version, and Class III malocclusion. Bony crepitus of the midface, especially in severely comminuted injuries, is common. Also, extensive fractures in the presence of a large communication with the antrum and the nose cause subcutaneous emphysema.

Nasal or pharyngeal hemorrhage may be massive. This is important because most patients are evaluated in the supine position. Nasal and pharyngeal bleeding drains toward the posterior part of the pharynx and may go unnoticed. Palpation reveals a mobile palate. If the palate does not move even though there appear to be gross occlusal differences and/or obvious fractures, it is because the midface has impacted into an immobile position.[49] To move the palate in these cases may require considerable force.

Imaging

Radiologic diagnosis of Le Fort fractures is a very important adjunct to their treatment. Many midfacial fractures can be assessed with sinus radiographs, but the precision of the CT scan is a huge advantage in delineating the extent and severity of midfacial fractures. Central injuries can be ruled out by extending the scan through the head; any nasal-frontal or frontal sinus components can be delineated, and fractures of the sphenoid and orbital apex are excellently portrayed. Scans in both the axial and coronal planes are necessary for the most complete analysis. Magnetic resonance imaging is of little added assistance except in the case of cerebral trauma or compromise of the optic nerves. Three-dimensional reconstruction, although spectacular, offers little additional information that will guide therapy.

Treatment

As in all patients involved in trauma, the fundamental precepts of trauma care apply. The airway is of great importance in these patients. A displaced Le Fort fracture can compromise the airway, especially if it is associated with concomitant massive swelling of the tongue and oropharynx.[5,6] A cricothyroidotomy may be required urgently. Endotracheal intubation should be avoided because of the problems of poor visualization, the possibility of aggravating a cervical spine injury, and the possibility of causing injury to the central nervous system from the endotracheal tube. Nasotracheal intubation is even worse because of the danger of intracranial intubation through a fracture line in the skull base. Tracheostomy preferably should not be done in the emergency room but performed electively in the operating room. All other injuries should be ruled out, including intra-abdominal, intrathoracic, and intracranial injuries. The cervical spine should undergo radiographic evaluation.

If the patient is to undergo immediate general anesthesia for a related injury and is hemodynamically stable, immediate repair can be undertaken if good radiographic documentation of the injury has been obtained. Often, if a patient is rushed to the operating room because of a life-threatening injury,

proper radiographs may not have been obtained, and if a Le Fort fracture is suspected, the patient should be placed temporarily into intermaxillary fixation and undergo tracheostomy. In this emergency situation, the patient can be more fully evaluated radiographically at a later time to ascertain the extent of the midfacial fractures. Definitive repair of all fractures may be delayed for up to 10 days before bony union may make reduction difficult. Thorough preoperative planning to repair these fractures includes ophthalmologic examination, dental evaluation, and clearance by neurosurgeons if there are concomitant intracranial injuries. Repair should also be delayed until the status of the cervical spine is determined.

Surgical Approaches Incisions used to approach midfacial fractures vary according to the specific location of the fracture. Isolated Le Fort I fractures are usually approached by an extended sublabial incision (Figures 39–45 and 39–46). This incision allows exposure of the zygomaticomaxillary buttresses and piriform apertures bilaterally. If the fracture involves the infraorbital rim (Le Fort II), a transconjunctival-lateral canthotomy or subciliary incision is usually used to expose these fracture sites. If a Le Fort II fracture is more extensive and greater exposure to the nasoethmoid complex is required, an external Lynch incision or extended coronal incision may be used. The frontozygomatic suture line may be approached by a coronal, brow, or extended upper blepharoplasty (supratarsal) incision. The coronal incision has the advantage of providing exposure to the zygomatic arch and the nasoethmoid region. This obviates the need for a Lynch incision for nasoethmoid exposure.

The incisions used depend on the location and extent of the fractures. Most Le Fort fractures do not manifest as the original description but are combinations of complex fractures of the midface and require knowledge of multiple surgical approaches.

In patients with dentition, arch bars and intermaxillary fixation are initially applied to re-establish pretrauma occlusion. In edentulous patients, splint or denture containing an arch bar is fixed to the mandible or maxilla to re-establish appropriate skeletal relationships. This is performed with circum-mandibular wires or drop wires from the piriform rim or zygoma. The maxillary (palatal) splint may also be fixed to the palate with two transpalatal screws. In any case, splints or dentures are placed to re-establish the occlusal and skeletal relationship.

In patients in whom midfacial fractures are displaced, disimpaction of fractures may be required before placement of intermaxillary fixation. Disimpaction is best achieved by use of the Rowe-Killey disimpaction forceps (Figure 39–47). The straighter blade is placed in the nasal cavity along the nasal floor and the more curved blade over the alveolar ridge and along the palate. With the handles firmly grasped, a downward and anterior pull will disimpact the maxilla and restore it into its normal relationship with the mandible and skull base. After the occlusal relationship is re-established, all fracture

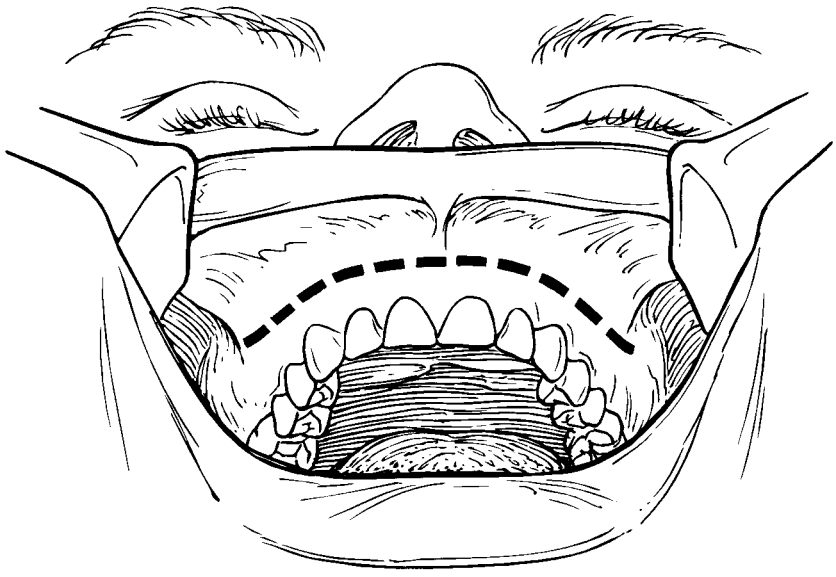

FIGURE 39–45. Schematic diagram of a sublabial incision for approach to midfacial fractures.

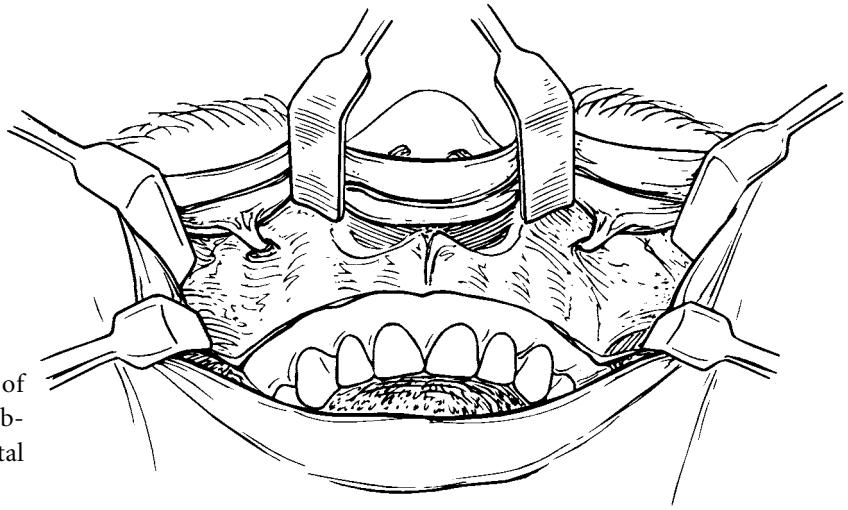

FIGURE 39–46. Schematic diagram of subperiosteal dissection through a sublabial incision exposing the infraorbital nerves.

sites are fully exposed. The facial skeleton should then be reconstituted in three dimensions: height, width, and depth.[46,47] Careful attention should be paid to re-establishing all important facial buttresses. In particular, the vertical zygomaticomaxillary and nasomaxillary buttresses should be carefully reduced and fixated to re-establish vertical facial height. All rigid fixation should be applied with sufficient stability to counteract any forces that could disrupt bone repair during healing.

For a Le Fort I fracture, a two-point stabilization at the nasomaxillary and zygomaticofacial buttresses is established on each side. Titanium low-profile miniplates in an "L," "X," or square configuration are placed on the anterior buttresses and usually an "L"-shaped plate on the undercurve of each zygoma onto the maxilla bilaterally (Figure 39–48). More recently, low-profile absorbable plates of polymers composed of polyglycolic or polylactic acid or a combination have been employed in place of titanium plates. These plates are reputed to retain sufficient strength to maintain fixation over the critical period of healing and are then absorbed. This is especially an advantage in children in whom the

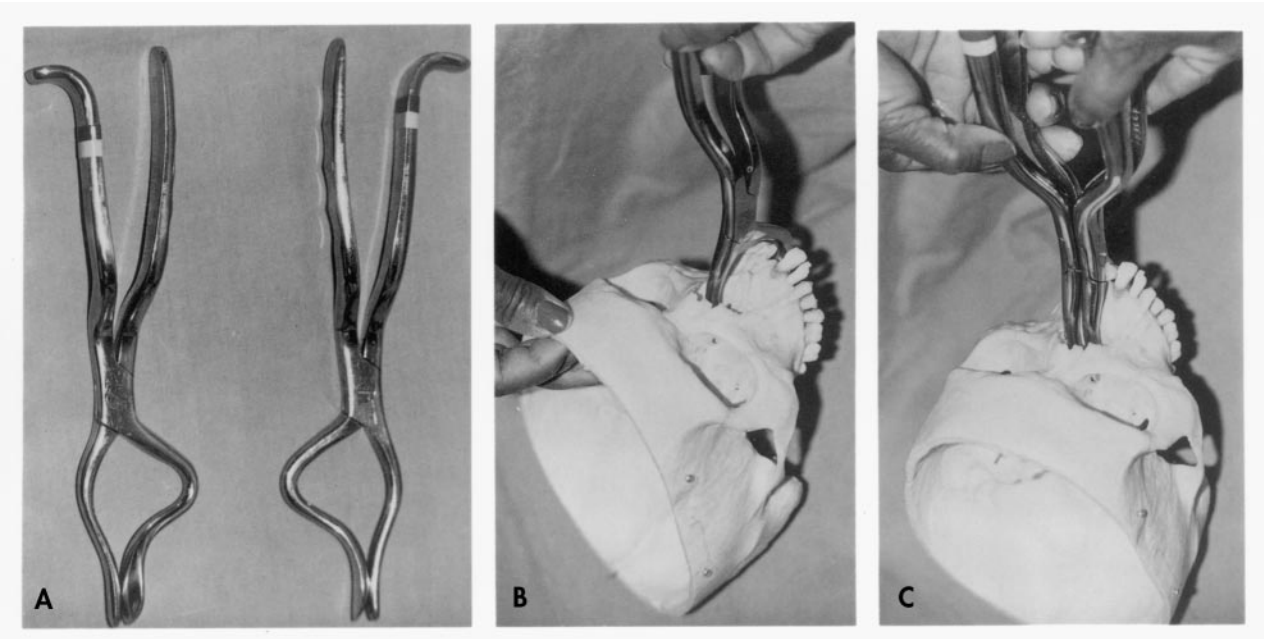

FIGURE 39–47. Maxillary disimpaction using Rowe-Killey forceps. *A*, Pair forceps. *B*, Forceps applied on one side. *C*, Forceps applied on both sides.

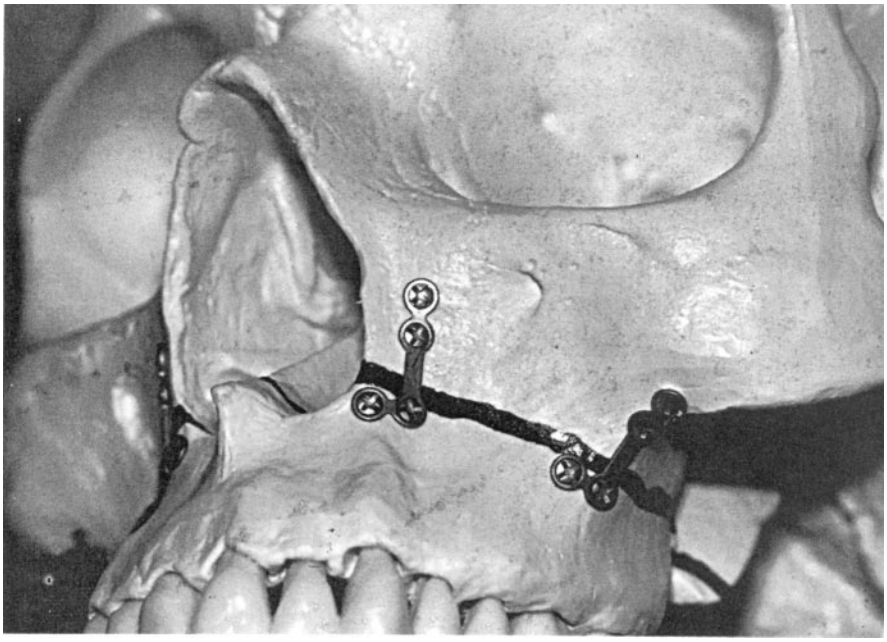

FIGURE 39–48. Miniplate fixation of a Le Fort I fracture. Note the stabilization of the nasomaxillary and zygomaticomaxillary buttresses.

metal plates may impede bony facial growth at suture lines. In adults, the principal advantages are in preventing pain that is occasionally seen with the metal plates and with time eliminating the palpable plate at the lateral and infraorbital rims. The durability and utility of absorbable plating systems have yet to stand the test of time.

Le Fort II fractures require fixation at the infraorbital rim and the zygomaticomaxillary buttresses. If the nasal bones are comminuted, microplates are used on the nasal bones. The infraorbital rims will be fixed with microplates as well. As in most instances, the miniplates have too high a profile and will be obvious through the skin.

The Le Fort III fracture is often a devastating injury usually accompanied by cerebral trauma. It is not uncommon to have a staged type of treatment in which the neurosurgeon controls the intracranial injury and the management of the facial component is limited to the performance of a tracheostomy and the application of arch bars and interdental elastic bands. The treatment of the maxillary fracture is delayed until the patient's neurologic status has stabilized. The shattered maxilla must be fixed between two stable platforms. The cranium provides the superior stabilization point and the mandible the inferior. All displaced fractures of the cranial vault must be restored to their normal anatomic position. Similarly, all fractures of the mandible must be rigidly fixed in correct position to establish the occlusal template for the maxillary dentition to approximate accurately. Rigid fixation of all mandibular fractures is vital to ensure this relationship. Displaced subcondylar fractures must be fixed to provide the stable platform even when only unilateral. Undisplaced subcondylar fractures are usually sufficiently stable to avoid rigid fixation. The goals of reduction and fixation of the Le Fort III fracture must be clearly borne in mind as fixation proceeds. First, the supporting buttresses of the face must be re-established. Second, the functional elements must be restored, such as the correct orbital volume, including an adequately restored orbital floor with orbital contents free of entrapment, a patent nasal airway bilaterally, and maxillary sinuses that will adequately drain. Third, all-important esthetic landmarks must be restored, such as the orbital rims, nasal dorsum, and malar eminences. It is not necessary and, in some instances, is indeed impossible to approximate every small maxillary fragment. The lateral orbital rims and the buttresses are fixed with miniplates and the nasal dorsum and infraorbital rims with microplates (Figure 39–49). Occasionally, small fragments in key positions may require fixation with fine wire or even suture material. The use of titanium wire will prevent interference in subsequent scans.

If rigid fixation is considered stable and if the patient is compliant, intermaxillary fixation may be

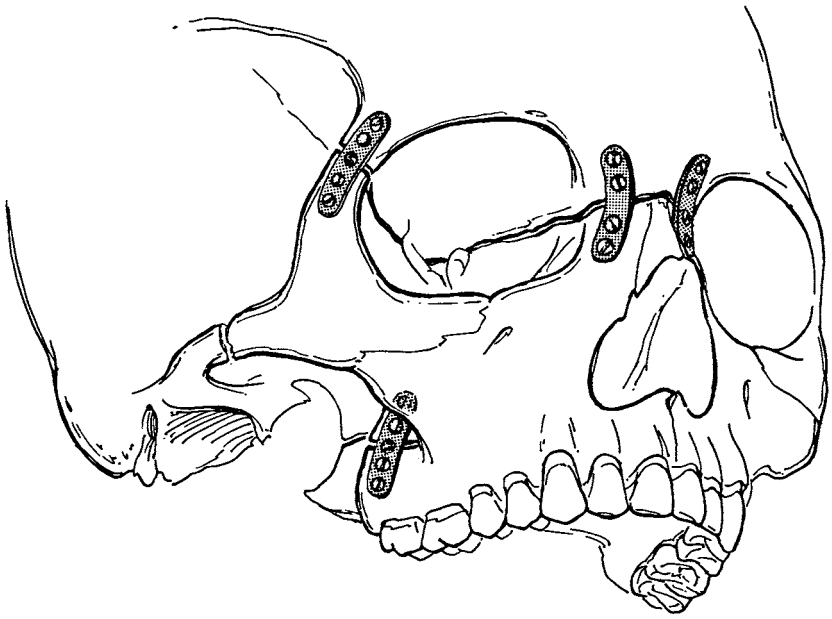

FIGURE 39–49. Three-point rigid fixation of a Le Fort III fracture.

removed at the conclusion of the operation or within the first 1 to 2 weeks after the operation. If the stability is in question (ie, with bone comminution or bone loss), intermaxillary fixation should be left in place for up to 6 to 8 weeks. This will help maintain the occlusion while bone healing occurs.

NASOFRONTAL-ETHMOIDAL FRACTURES AND TRAUMATIC TELECANTHUS

A central blow to the face created by a small-diameter object, such as the head of a hammer, may not produce a Le Fort type maxillary fracture but, if of sufficient force, may cause a severely comminuted nasal fracture that shatters the medial orbital walls and telescopes into the ethmoid block, lodging the fractured bones under the nasal process of the frontal bone (Figure 39–50). Not uncommonly, this nasofrontal-ethmoidal fracture will be accompanied by telecanthus that results from either the shearing away of the medial canthal tendons or a displacement of the lacrimal and maxillary bones into which the tendon or tendons insert. The nasal dorsum is essentially displaced into the fractured anterior ethmoid cells (Figure 39–51). This injury produces a typical clinical picture of a patient with a "pig snout" deformity consisting of a flattened nasal dorsum with an exaggerated excessively superiorly rotated tip (Figure 39–52).

The telecanthus may be unilateral or bilateral. The natural contraction of the orbicularis oculi, whose tendonous extension comprises the bulk of the medial canthal tendon, pulls the medial canthus away from the midline. This produces a blunting of

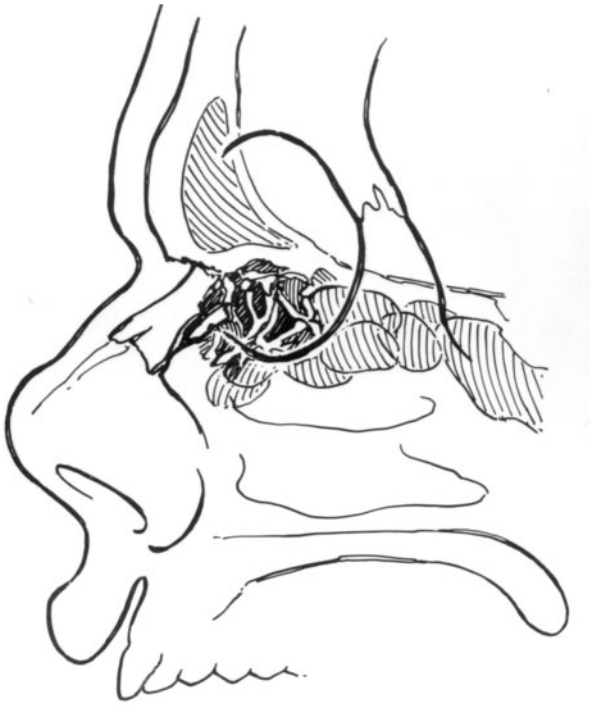

FIGURE 39–50. Nasofrontal complex fracture. Note nasal bones driven under the frontal bones. Reproduced with permission from Donald PJ et al.[51]

FIGURE 39–51. Computed tomographic scan showing a nasofrontoethmoidal fracture. *Arrows* show direction of displacement. Reproduced with permission from Donald PJ et al.[51]

the medial canthus, with a widening of the medial canthal angle, a shortening of the width of the palpebral fissure, a slight ectropion, and an inferior inclination of the medial canthus (Figure 39–53). The width of each palpebral fissure should normally be the width between both eyes, approximately 25.5 to 37.5 mm in adult women and 26.5 to 37.8 mm in men.[50] With this injury, there is usually the absence of the "bowstring" sign. If tension is created in the medial canthal tendon of the normal eye by pulling laterally on the lateral canthus of the eye, a taut bowstring-like sensation is felt by the palpating finger. If, instead, there is a soft, loose, boggy feeling at the inner canthus, then the presence of a ruptured tendon is highly likely. In addition, there may be injury to the lacrimal system with fracturing of the bony nasolacrimal duct. This will produce epiphora. Epiphora may also result from the loss of the effectiveness of the "lacrimal pump" mechanism. This is formed by the splitting of the medial canthal tendon into two slips of tendon, which insert onto the lacrimal bone both anteriorly and posteriorly to the lacrimal sac (Figure 39–54). With slackening of the tendon by displacement of the medial canthal tendon, the pump is unable to function effectively.

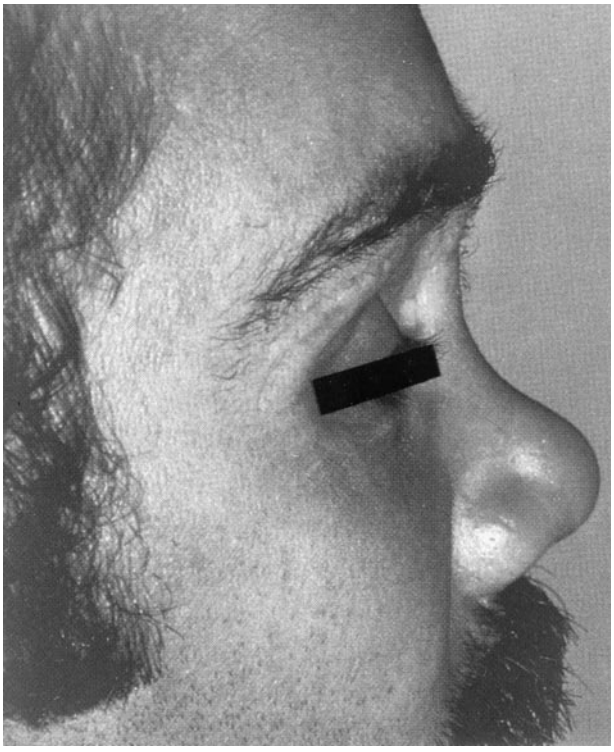

FIGURE 39–52. "Pig snout" deformity characteristic of a nasofrontoethmoidal complex fracture. Reproduced with permission from Donald PJ et al.[51]

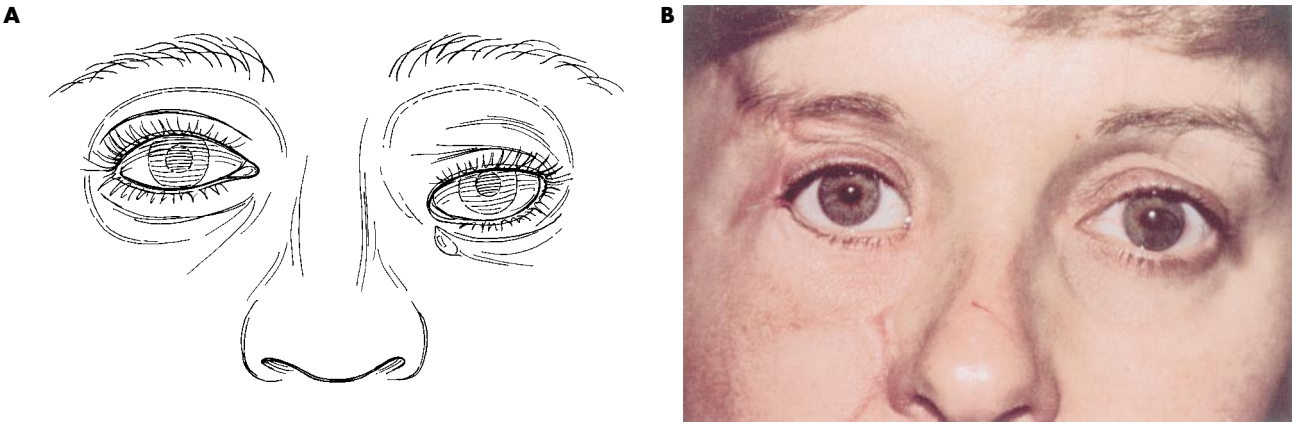

FIGURE 39–53. *A*, Diagram showing telecanthus. *B*, Patient with unilateral telecanthus.

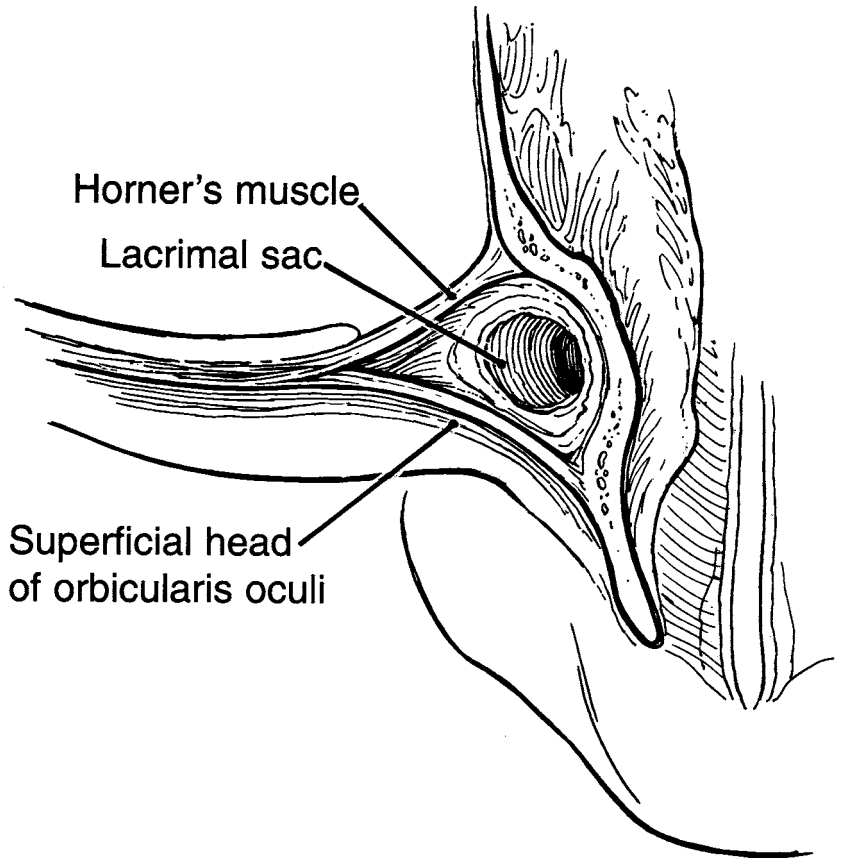
The repair of the nasoethmoidal fracture consists of disimpacting the nose from the collapsed ethmoid sinuses and, if there is telecanthus, repairing one or both canthal tendons. It is often a difficult task and should be undertaken as soon as possible after the accident. One method, using bilateral Lynch incisions, of disimpacting the fragments in the ethmoid is to dissect the periorbita away from the fractured lamina papyracea on both sides, insert two bone hooks into the ethmoid block, and turn the hooks nasally and then apply a down and forward traction (Figure 39–55). This will usually pull the fractured nasal bones into their normal anatomic position, where they can then be fixed to the frontal bone with a microplate. A badly comminuted nasal fracture may have insufficient bone

FIGURE 39–54. Horner's muscle. Reproduced with permission from Donald PJ et al.[51]



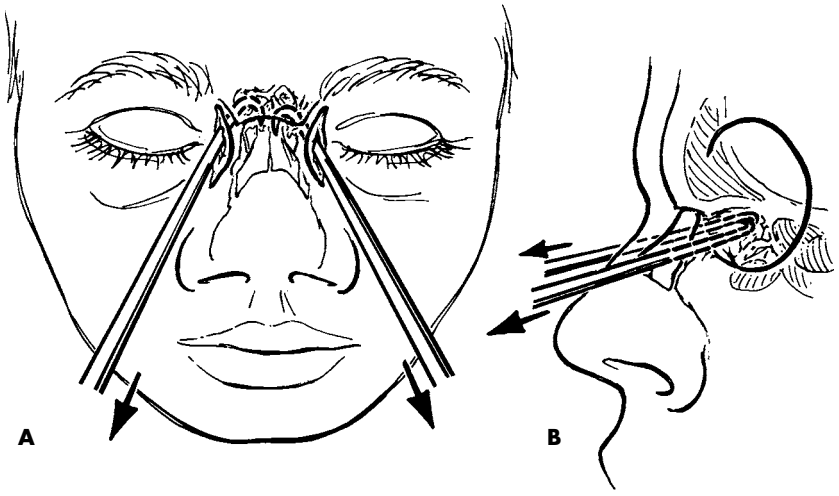


FIGURE 39–55. Reduction of frontoethmoidal fracture. *A*, Stout bone hooks are placed through the lamina papyracea into the ethmoid fracture. *B*, Forward and downward traction is exerted until fracture is reduced. Reproduced with permission from Donald PJ et al.[51]

to hold even the small 0.8 mm screws required for microplate fixation. A solution to this is the use of suspension wires and lead plates.[51] The wires are driven from one side of the nose to the other with the nasal skeleton in the reduced position. The wires penetrate skin, nasal bone, and ethmoid sinuses on one side and then pass through the septum and the same structures of the other side (Figure 39–56). It must be remembered that the plates act simply as anchoring sites for the wires and not as a means of narrowing the nose. Overtightening of the wires can lead to underlying skin necrosis. The wires are removed after 3 weeks.

Obtaining an excellent cosmetic result in the reduction of dislocated medial canthal tendons is one of the most demanding tasks in the surgery of facial trauma. The repair is best done as soon as possible after the accident. Late repairs are notoriously noted for their less than optimal results. Often the tendon comes away with a fragment of attached lacrimal bone. In those instances, two small holes are placed in the bone that will serve as anchor points for the wire used in fixation. If no anchoring bone exists, then some kind of stabilization must be created to prevent the wire from pulling through. The Kazanjian button may be created by twisting the two wires passed through the tendon into the configuration of a rosette.[35] Another method is the use of a Dacron bolster (Figure 39–57), which is usually used to stabilize hemostatic sutures placed in the aorta.[51] In a unilateral canthal repair, the wire can be secured to the bone of the medial wall of the opposite orbit. If enough bone of adequate strength is present on the ipsilateral side, then that would be preferable. A bone graft on the opposite side of the nose can be used or even two holes in a microplate that has been used to stabilize the nasal bones. It is vital to place the tendon high and posterior with some small overcorrection as some degree of relapse is almost inevitable.

The worse injury is the bilateral canthal tendon avulsion. The Converse-Hogan open sky technique is probably the most effective (Figure 39–58).[52] This method wires one canthal tendon to that of the opposite side and supports the skin of the nasal area with lead plates.

Two small holes are drilled in the lacrimal bone. *B*, Wire is passed through the tendon and the bone. Wire is passed through a small Dracon felt bolster to prevent wire tearing through the tendon. *C*, Wire is gently twisted for the ligature. Reproduced with permission from Donald PJ et al.[51]

Bone Grafting

In some patients with midfacial fractures, bone comminution or bone loss prevents proper re-establishment of facial buttresses. Loss of vertical height with midfacial shortening can result. When this condition is recognized, immediate bone grafting is indicated.[48] Grafting is usually performed by harvest of split calvarial bone grafts. These grafts have a good viability and stabilize fixation in cases with significant bone loss. In these patients, intermaxillary fixation usually should remain in place for at least 6 weeks.

In patients with severely comminuted nasal bones in whom an esthetically acceptable nose cannot be created, an onlay graft cantilevered from the forehead using a microplate can restore a more normal nasal dorsum. Small areas of avulsed or missing bone can also be replaced with hydroxyapatite bone cement.[53]

FRONTAL SINUS FRACTURES

Despite the use of the shoulder harness in automobiles, frontal sinus fractures still occur with regularity. The old-fashioned lap belt that restrained the passenger in the seat during the impact of a car crash unfortunately allowed the face to move forward, striking the dashboard with the frontal calvarium and often fracturing the frontal sinus. A considerable amount of force is required to fracture the anterior wall of the frontal sinus because of the arch configuration and its thickness. In Nahum's study, it was apparent that it took more foot-pounds of force to break the frontal sinus anterior wall than any other facial bone, including the symphyseal area of the mandible and the zygomatic body.[54]

The problems of the fracture of the frontal sinus center around the issues concerning the cavity, duct, and mucosa. The cavity on each side has a thick anterior wall but very thin posterior and inferior walls. It has only one point of egress: a funnel-shaped structure at the anteromedial part of the frontal sinus floor that empties into the middle meatus of the nose. According to Lang, 77.3% of individuals have a frontonasal duct and 22.7% have a foramen.[55] A fractured or even damaged duct has a marked propensity to undergo stenosis. The mucosa of the sinus cavity acts in a uniquely pathologic manner when traumatized. It has a tendency not to reconstitute itself with normal-appearing and normal-behaving mucosa as the other paranasal sinuses do when they are injured. In the frontal sinus, damaged mucosa has a propensity for subepithelial fibrosis, especially in the area of

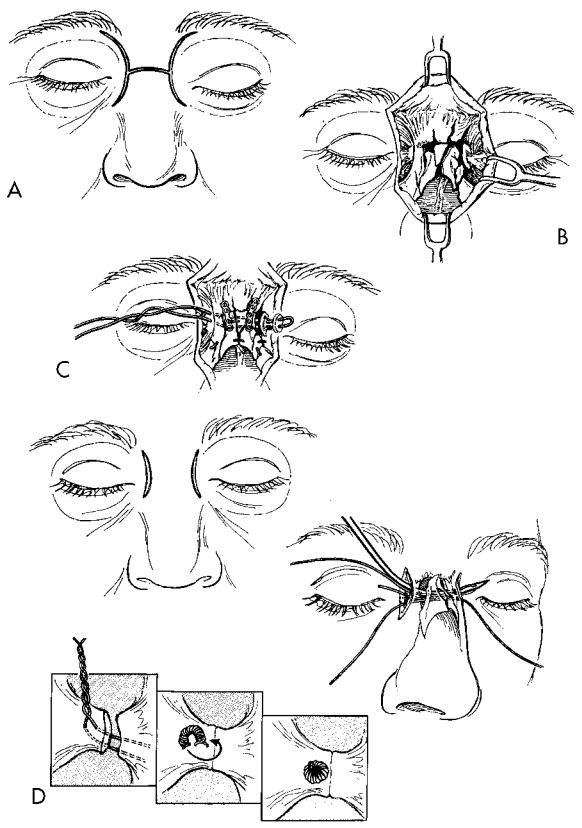

FIGURE 39–58. Bilateral medial canthal tendon avulsion repaired using the Converse-Hogan "open sky" technique. *A*, Incisions are opened. *B*, Fractures are reduced. *C*, Two pairs of wires are inserted—one through the medial canthal tendons (*above*), the second through adjacent nasal bones (*below*). *D*, Wires are tightened, bringing the canthal tendons into position. The wires are twisted together over each avulsed tendon, pulling the tendons together. Tendons are supported and soft tissue is splinted by Telfa pad-Silastic-lead plate assembly (see Figure 39–57).

the frontonasal ducts. Furthermore, it has a tendency to form cysts, some of which will enlarge and erode bone; the resulting mucocele may become infected and form a mucopyocele. Both have the notable characteristic of eroding bone.[56,57]

For the sake of treatment considerations, frontal sinus fractures can be classified as anterior wall, posterior wall, nasofrontal duct, and "through and through." They can be further classified as linear, displaced, compound, and compound with "missing bone." A treatment algorithm has been designed that specifically addresses each site and each type of fracture, bearing in mind that seldom do single fractures occur in isolation. However, with each site and each type, different therapeutic solutions need to be invoked. Therefore, in any given patient, some combination of procedures should be employed to repair the fracture adequately and safely.

Linear fractures of the anterior frontal sinus wall require no operative intervention. Depressed fractures must be opened, the fragments elevated, and all mucosa entrapped between the fragments excised. The fragments are restored to their normal anatomic position and fixed with miniplates. Exposure is through a coronal scalp flap or the so-called "butterfly incision" (Figure 39–59). If the patient has a compound fracture, the exposure can be gained by extending the laceration in a natural crease line in the forehead.[51]

Displaced posterior wall fractures are notoriously difficult to diagnose even with fine-cut CT scanning. In the authors' opinion, all posterior wall frontal sinus fractures should be opened. Even when a small amount of displacement occurs, mucosa can be entrapped and grow into the anterior cranial fossa or form a mucocele. Because the victims of trauma are often very hard to follow clinically, the first subsequent presentation of a patient that has been followed rather than operated on may be in the emergency department with meningitis or a brain

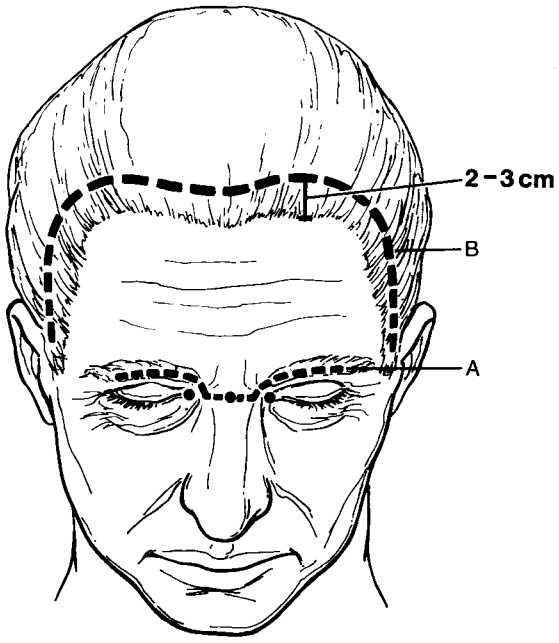

FIGURE 39–59. Incisions used for access for frontal sinus fracture repair. *A*, Butterfly incision. *B*, Coronal scalp incision.

abscess. The treatment of choice is the osteoplastic flap and fat obliteration procedure.

The area of the frontal sinus that is the most difficult to visualize radiographically is the region of the frontonasal duct. The most important radiographic sign is the presence of fluid in the sinus as demonstrated by sinus opacification. If this persists over a 3-week period, the index of suspicion regarding the possibility of a duct fracture is high. If the patient sustained an anterior wall fracture and early intervention for its repair is undergone, then, at the same time, a sinus endoscope can be placed through the site of the fracture and the duct visualized directly. If, however, there is a suspicion of an isolated duct fracture, then a trephine hole in the orbital roof will provide access to wash the sinus out with saline, install some cocaine, and then place a radiopaque dye within the sinus cavity. A subsequent radiograph will show presence of the dye within the nose if the duct is patent and absence of the contrast material if the duct is fractured. Surgical treatment of the fractured duct is somewhat controversial. The author prefers to do the osteoplastic flap and fat obliteration operation to eliminate the duct. Others prefer the Lynch procedure combined with a nasal septal or medially based lateral nasal wall flap, the so-called Sewall-Boyden flap.[58] Removal of the intersinus septum will allow egress of mucus from the fractured to the nonfractured side. More lately, the interest in functional endoscopic sinus surgery has prompted some to do a conservative removal of the duct through the nose. These procedures have yet to stand the test of time.

The most serious of all of the frontal sinus injuries is the "through-and-through fracture."[59] In this dramatic injury, the frontal skin is lacerated, both anterior and posterior walls of the sinus are fractured, often with extensive comminution, the dura is torn, and the brain is contused (Figure 39–60). The frontal sinus is often merely an inferior extension of a larger compound cranial fracture.

Approximately 50% of individuals afflicted by a through-and-through injury die at the scene of the

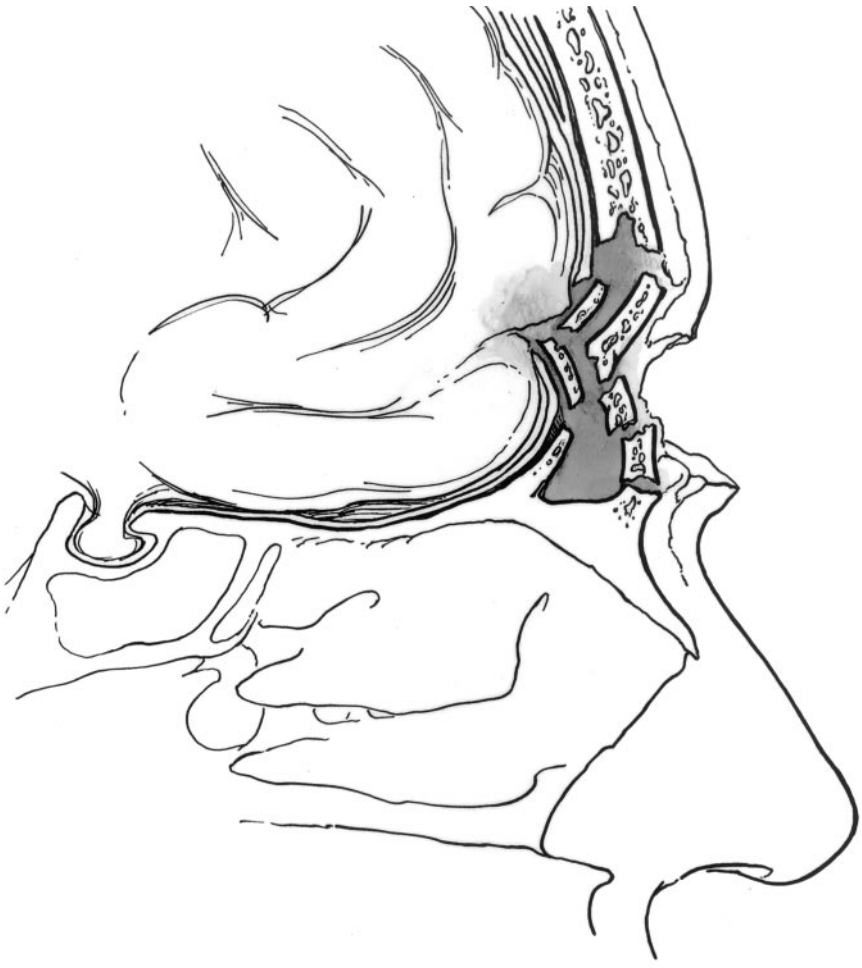

FIGURE 39–60. Through-and-through fracture of the frontal sinus. Reproduced with permission from Donald PJ et al.[51]

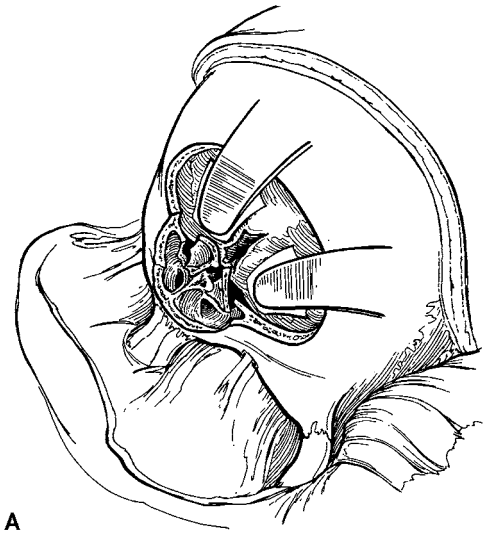

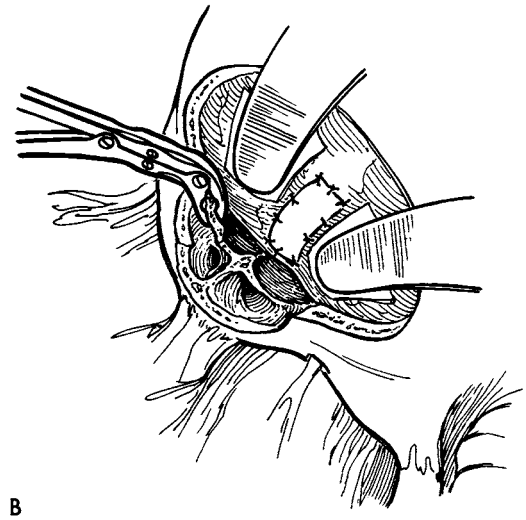

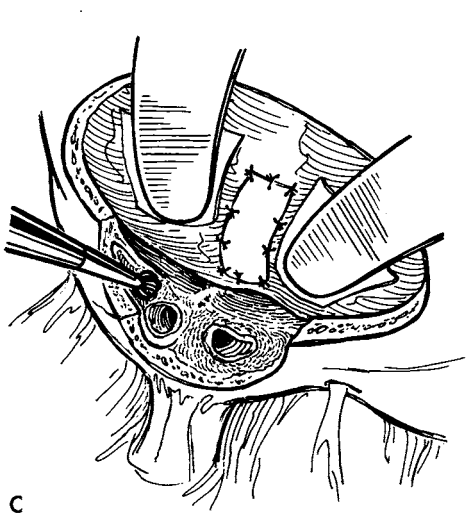

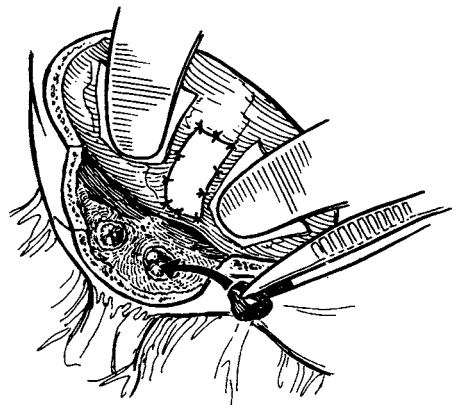

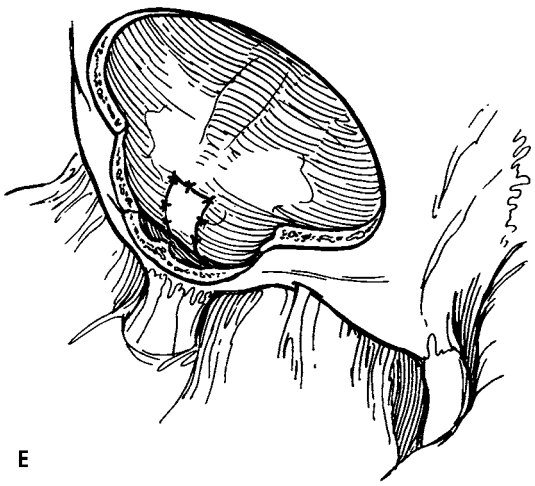

FIGURE 39–61. Repair of through-and-through fracture of the frontal sinus. *A*, Anterior craniotomy done. Anterior wall fragments are cleansed and stored. Fracture of both sinus walls, dural rent, and damaged brain exposed. *B*, Brain débrided, dura patched, and posterior wall remnants removed with double-actioned rongeur. *C*, Removal of the remaining posterior wall of the frontal sinus, producing cranialization. *D*, The mucosa of the sinus is removed from the sinus lumen, the nasofrontal duct mucosa is inverted on itself, and the frontonasal ducts are plugged with temporalis muscle. *E*, Brain migrates forward to fill the defect. Reproduced with permission from Donald PJ et al.[51]

accident. Often the first encounter with the patient by the otolaryngologist is during the craniotomy being done by the neurosurgeon to remedy the patient's intracranial injuries. Usually, a large anterior craniotomy has been done. Once the neurosurgeon has controlled the central hemorrhage, removed the devitalized brain, and repaired the dura, the otolaryngologist needs to manage the severely damaged frontal sinus. This is best done by the cranialization procedure[59] (Figure 39–61). The anterior wall fragments are removed, divested of mucosa, and thoroughly irrigated and débrided to ensure the removal of all of the contaminants acquired at the trauma scene. The bone fragments are stored in povidone-iodine until the end of the procedure. The posterior wall of the frontal sinus is completely removed with a rongeur and a cutting bur. The anterior cranial fossa is now entirely in continuity with the cavity of the frontal sinus. The cutting bur is used to thoroughly remove all vestiges of sinus mucosa including the small projections into the vascular pits in the frontal sinus anterior wall and floor. This is the most important step in the procedure. Any remaining mucosa provides the potential for its regrowth and subsequent infection. The mucosa of the nasofrontal duct is inverted on itself toward the anterior ethmoid sinuses. The duct is plugged with a block of temporalis muscle or bone dust. The anterior wall fragments are restored, and the dural graft will expand with time and fill the new space created in the anterior cranial fossa.

CONCLUSIONS

In summary, treatment of facial fractures requires a multisystem approach. All bony and soft tissue injuries should be diagnosed, and reconstitution of all tissue layers should be performed, if possible. The advancement of technology has enabled rigid fixation to become the standard of care for the fixation of most facial fractures. More precise stability and fixation of fractures have become possible, and intermaxillary fixation is used less frequently. Well-planned incisions minimize scarring. Adequate exposure, precise reduction, and stable fixation remain the hallmarks of treatment of facial fractures.

CHAPTER 40

Reconstruction of the Maxilla and Mandible

David Reiter, MD, DMD

The goals of head and neck reconstructive surgeons, namely, the restoration of function and esthetics in an expeditious manner with minimal surgical morbidity,[1] are tested as rigorously by defects of the jaws as by any other problem we face. We are in the midst of a revolution in reconstructive surgery. Advances in vascularized tissue transfer and custom fabrication of reconstructive flaps are occurring rapidly. Although research propels us toward a future in which we will no longer need to remove tumors and provide replacement tissues, we must maintain currency with such methods while we wait for what O'Leary et al aptly termed in 1994 "the molecular reconstructive 'cocktails' from the shelf of the next millennium."[2]

No more than 20 years ago, a chapter on reconstruction of the jaws would have focused on the mandible, for which there were many surgical options (no matter how unsatisfactory they might have been). Maxillary defects were almost exclusively a problem for the maxillofacial prosthodontist, and few surgical options existed. With the perfection and acceptance of vascularized free tissue transfer, mandibular repair and replacement have become routine. After a decade of clinical experience, the fibula has emerged as most facial plastic and reconstructive surgeons' donor site of choice for management of mandibular defects.

Conversely, surgical repair of most maxillary defects was limited to rudimentary adaptation of regional flaps until the 1990s. Whether because of pessimism over the potential to achieve successful surgical reconstruction or because of optimism that ongoing research in free tissue transfer would soon produce new methods far superior to the compromises then available, the literature of maxillary defect management focused largely on prosthetics until the end of the twentieth century. As free tissue transfer became routine, interest in surgical reconstruction of the maxilla accelerated. A MEDLINE search for articles on "maxilla and reconstruction" produced 11 works from 1960 to 1980, 51 from 1980 to 1990, and 96 from 1998 to 2000. There are currently multiple soft and hard tissue options in clinical use. Rapid refinement and ongoing research in methods and materials for maxillary reconstruction now recapitulate the evolution of mandibular reconstruction through the 1990s. It is an exciting time for head and neck and facial plastic surgeons interested in reconstruction of the jaws.

The jaws are the nucleus of many of the most sophisticated structural systems in the body. Although other bones in the body support more weight or more directly protect individual vital structures, only the jaws serve so many functions in so many ways. Masticatory forces approach 10,000 pounds per square inch between upper and lower molars, and load rates exceed 2,000 N/second.[3] Yet a grain of sand measuring only 0.06 mm between the same teeth causes the muscles of mastication to release their load within hundredths of a second. The jaws anchor and support the upper portals of the aerodigestive tract. They surround or otherwise protect important neurovascular conduits, including some of the major extracranial vasculature of the head and neck. They house and nurture developing tooth buds in the neonate and child. They facilitate respiration, speech, chewing, swallowing, communication, facial expression, and thus social interaction.

When part or all of the maxilla or mandible is lost to disease or injury, it would be ideal to provide exact restoration or reconstruction. Were it possible to provide a perfect replacement, function and appearance would not suffer, and the patient would have no post-treatment deficit. Although advances in modern reconstructive methodology have brought us closer to this goal, it remains elusive.

A damaged structure can be restored (returned to its normal state using original or identical materials and methods), reconstructed (brought to its normal state using new or additional materials), or replaced. All three alternatives exist for management of defects or loss of the jaws, although some of the most sophisticated restorative techniques are not yet available for routine clinical use. This chapter will address the management of each defect not only in terms of lost structure but also with consideration of functional deficits. As so many advances in head and neck reconstruction are being made every month, we will discuss some of the most promising methods on the cutting edge despite their current status as investigational. History suggests that many will have become routine between preparation and publication of this work.

Table 40–1 summarizes the spectrum of structural and functional deficits attendant on loss of part

TABLE 40–1. Defects, Deficits, and Options for Management of the Maxilla and Mandible

Defect	*	*Structural Deficit*	*Functional Deficit*	*Reconstructive Options*
			Maxilla	
Oroantral fistula	1–3	Lost integrity of antrum	Loss of air and water seal	Local flaps, buccal fat pad
Alveolar ridge loss	2–3	Tooth-bearing tissue	Dentition lost, possible oroantral fistula	Prosthesis, bone graft, distraction
Palatal shelf	1–3	Teeth plus antrum/ nasal cavity	Chewing, swallowing, nasal regurgitation, speech	Prosthesis, free flap (myocutaneous, osteomyocutaneous)
Hemimaxilla	2–4	All of above plus lip and check support	All of above	All of above
Hemimaxilla plus orbital floor	3–4	All of above plus orbital integrity and support	All of above plus diplopia	All of above
Hemimaxilla plus orbit	4–5	All of above plus contents of orbit	All of above plus sequelae of exenteration	All of above; megaflap
More than hemimaxilla	5	All of above plus midfacial structure	All of above plus nasal/ lip/midfacial support	All of above
			Mandible	
Body posterior to mental foramen	2	Lower facial support, part of dental arch	Chewing, swallowing, appearance	Plate, soft tissue, bone graft or flap (fibula, scapula, iliac; radius if small defect)
Ramus	3	Jaw stability and function	Chewing, swallowing, appearance	Plate, free flap (fibula)
Condyle	3	As above	As above	Plate with prosthesis, free fibula
Anterior arch	4–5	Tongue, lip, and facial support, teeth	Eating, speech, airway integrity, appearance	Free flap (fibula, scapula, iliac)

or all of the jaws, along with relative severity and current recommendations for management.

RESTORATION

Restoration is the building up of something to its original and complete form using original materials and methods.[4] Distraction osteogenesis (DO) is probably the only management method with any clinical utility at present that approaches true restoration of lost bone. It spans or augments bony defects by traction-induced neo-osteogenesis of the remaining original structure. Anecdotally accepted to have been introduced by Cordovilla in 1905 and first published by Putti in 1921,[5] this technique was brought to practical clinical utility with work by Ilizarov and others in the 1990s.[6] The methodology includes interruption of the cortical envelope (if intact) with maintenance of periosteal integrity to the mobilized end plate. Pins or other secure devices are anchored in the mobile segment of bone, and controlled force is applied to the anchors. Healing occurs within the periosteal envelope by neo-osteogenesis between the advancing end plate and the remaining bone. Segmental ends can be advanced toward each other to close gaps, and anchors in depressed or malaligned segments can be used to direct neo-osteogenesis for augmentation or realignment of the defect. There are now commercial appliances and systems available for DO, and the literature is replete with references to its clinical utility in management of defects of the jaws (Figure 40–1).[7–9]

FIGURE 40–1. External distraction osteogenesis device. Courtesy of W. Lorenz Surgical.

Constantino et al demonstrated the ability to fill 2.5 cm defects in dog mandibles using DO in 1993.[10] Regeneration was achieved at a rate of 1 mm per day, and function was normal at 1 year in all test animals. More recent studies verify this work and support its promise.[11,12] As mechanical limitations in appliance design are overcome, DO will become a routine clinical tool. Recent reports of clinical use in humans support the impression that DO will soon be a mainstay in reconstruction of bony defects of the jaws.[13,14]

The use of osteoinductive morphogens, although not yet a routine clinical tool, offers a second alternative for restoration of bony architecture. Bone morphogenetic proteins (BMPs) belong to the family of transforming growth factor-beta substances and play an important role in the growth and development of numerous tissues.[15] Work to date is promising, but clinical application of BMPs to stimulate replacement bone has not reached the stage of practical utility. Work is being done on application of BMPs in absorbable collagen sponge[16] and different forms of hydroxyapatite,[17] but such techniques have not yet reached practical application. It appears clear that BMPs will play a significant role in the true restoration of bony architecture in the head and neck as soon as the proper combination of morphogen, carrier, and methodology is found.

RECONSTRUCTION

To reconstruct is to rebuild.[3] There are many options for reconstruction of the jaws. Modern osseous autografting dates to 1867 and the pioneering work of Ollier.[18] Tibial bone was used prior to World War I, with the iliac crest rising in popularity as a donor soon after World War II.[19] Calvarial bone has been used for about 15 years but was boosted in popularity by the publication of a technique for temporal harvesting by Spear and Wiegering in 1987.[20] Rib has long been used for grafting in the head and neck. The safety and utility of autogenous bone grafting were documented by series such as Kline and Wolfe's 1,000 personal cases and 12,672 surveyed cases.[21] Thus, free autogenous bone grafting was a workhorse in the management of maxillary and mandibular defects until the era of practical free tissue transfer, despite the relatively high failure rate in recipient beds contaminated by oral secretions.[22] Osseous autografts remain useful in the management of small (< 4 cm) defects of the mandible and

in closure of many defects resulting from maxillectomy for which vascularized osteocutaneous free tissue transfer is neither required nor justified.[23] So, despite the wide acceptance of vascularized free tissue transfer and its use by the author since 1993, free nonvascularized bone grafts continue to have a limited but important role in head and neck reconstruction. There is even recent literature on improving the outcome of osseous autografts.[24]

Osseous allografts have been used in jaw reconstruction for many years. Freeze-dried irradiated fibula and other processed cadaver tissues were popular for a brief period in the 1980s, and autografting of explanted tumorous mandibles after chemical manipulation and irradiation to 120 cGy was advocated briefly.[25] However, more modern methods of management have largely relegated the above to historical significance.

The use of bone-like alloplastic substances as scaffolding for neo-osteogenesis is well documented and supported by histologic[26] and clinical[27] reports. One exception to this is the use of hydroxyapatite in mandibular defects secured with a reconstruction plate,[28] a technique not supported by any current literature or experience.

Functional and Cosmetic Reconstruction

Functional reconstruction is defined as creation of sufficient structure to return an organ or region to function, even though neither function nor structure exactly replicates the pretreatment or preinjury state. This describes the vast majority of flap and graft procedures as well as the use of hardware and/or soft tissue to replace bone. Appearance and/or function are often enhanced by substituting tissue of another kind for the resected specimen. Thus, for example, resected tongue tissue is routinely replaced with regional or free flaps despite the current impossibility of restoring volitional mobility to the reconstruction. Perioral soft tissues can be replaced with a variety of soft tissue flaps and grafts, but this will not restore the function of the oral sphincter. Similarly, ablation of a maxillectomy defect with soft tissue and/or bone may enhance oral function and/or appearance, but the region cannot be returned to its prepathologic state.

Soft tissue can also be used to augment a lateral mandibular defect, effacing the cosmetic deformity of mandibular loss and deviation but not restoring the native structure or its actual function. However, the reported success rate of this technique falls off rapidly beyond the first postoperative year, even in lateral mandibular defects posterior to the mental foramen (the most forgiving location in terms of reconstructive requirement and success). Reports of 40 to 50% failure after 1 year are common for techniques of mandibular reconstruction using a combination of soft tissue and plating, even when vascularized free tissue transfer is used for the soft tissue component.[29] Plate breakage is common, as is exposure, leading some authors to recommend plates and soft tissue only for temporary use in mandibular reconstruction.[30] Most authors have found this to be true regardless of the kind of plate chosen. One study suggests that modern plate technology and materials science have not lessened the incidence of plate exposure and have not eliminated the problem of plate breakage,[31] although another found the latest lower-profile mandibular reconstruction plates to have breakage and extrusion rates of about 4% each in a series of 27 cases,[32] which is certainly an acceptable rate of failure, given the problem and alternatives for management.

The wide variation in reported plate breakage rates demonstrates, at least in part, the sensitivity of this complex methodology to technical factors such as the mechanics of hardware placement. The use of a given plate-and-screw system must be taught rigorously and in detail if the method is to achieve clinical success. The use of non–self-tapping screws requires meticulous attention to the process of drilling and tapping holes in bone. If the drill and tap are not inserted and maintained perfectly straight along the desired axis or the threads are not cut perfectly perpendicular to the axis of the hole, the screw will be loose in the hole and stabilization will not be achieved. Even the use of self-tapping screws requires great care in the drilling of the holes and driving of the screws, for the same reasons.

On a temporary basis, the mandibular bone segments to either side of a defect can be stabilized and the defect spanned with a number of plating systems. Although far from a complete functionally restorative technique, proper selection and placement of a plate can provide a patient with satisfactory appearance, stabilization, and comfort for relatively normal social function, with the notable exception of chewing and swallowing. Liquids can be taken fairly

well by patients having such procedures, and the success rate is commonly reported as adequate for patients with poor prognoses or insufficient physiologic reserve to remain under anesthesia on the operating table for an additional few hours for a more formal reconstruction. However, Komisar reported no significant improvement in functional or social rehabilitation of mandibulectomy patients from simple restoration of mandibular continuity with a plate in an analysis of patients for whom vascularized tissue transfers were not provided.[33]

VASCULARIZED FREE TISSUE TRANSFER

Vascularized free tissue transfer has reached routine status in the United States in every academic and most major community medical centers for patients of all ages.[34] A decade ago, one could intelligently question the value of free flap transfers because long-term outcome studies had not been done, few surgeons and medical centers had the technical ability and physical plant required for optimum microsurgical management, and techniques had not been refined sufficiently to offer consistently high success rates. However, each of those questions has been answered well. Numerous studies support the statement that vascularized free flap reconstruction is both highly successful and cost effective for appropriately chosen head and neck surgery patients.[35,36] See Chapter 41 for the spectrum of available free flaps.

MANAGEMENT OF MAXILLARY DEFECTS

Goals of Management

The goals set forth by Hoopes and Edgerton in 1966 for surgical reconstruction of maxillectomy defects remain as valid today as when they were published, namely, obtain a healed wound, restore palatal competence and function, support the orbit or fill the orbital cavity in exenteration, obliterate the maxillectomy defect, and restore facial contour.[37]

Relevant Maxillary Anatomy

The maxilla has been described as a geometric structure with six walls[38] (Figure 40–2). The roof of the maxilla is the floor of the orbit above it. The medial wall delineates the lateral limit of the nasal cavity and contains the nasolacrimal duct. The maxillary floor consists of the hard palate and the alveolar ridge. The walls of the maxilla delineate the maxillary sinus, being contained within the central portion of the maxilla. In addition, many of the muscles of facial expression and mastication are anchored on the maxilla. The orbicularis oris and oculi, zygomaticus, buccinator, and various levators and depressors, together with the overlying skin and/or intraoral mucosa, constitute the units of the lower eyelid, cheek, upper lip, and oral commissure. The medial and lateral pterygoid muscles originate at the pterygoid plates along the posterior wall of the maxilla. Finally, the two horizontal and three vertical buttresses of the maxilla are responsible for midfacial projection and vertical facial height.

Muzaffar et al called the maxilla the "keystone of the midface."[39] They elegantly described it as uniting "… the key mid-facial elements—the orbits, the zygomaticomaxillary complex, the nasal unit, and the stomatognathic complex" into a functional and esthetic unit. Most maxillary defects are thus complex in nature, involving more than one surface or cavity and affecting more than one function of the midface. Quoting Muzaffar et al again, "In reconstructing maxillary defects secondary to trauma, ablative tumor surgery, or congenital deformities, the surgeon must obliterate the defect, provide adequate struc-

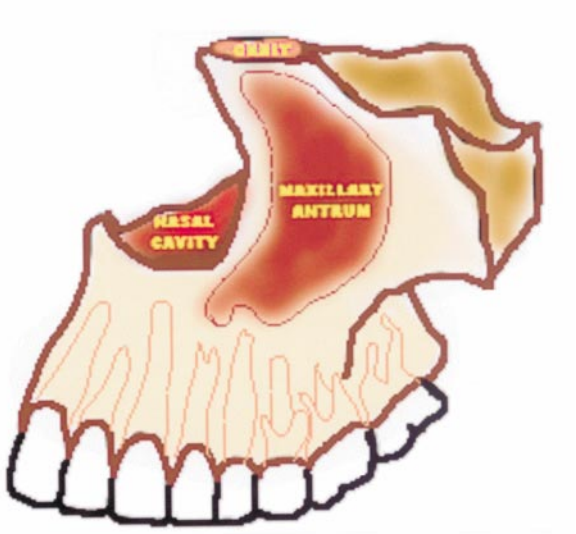

FIGURE 40–2. Maxillary anatomy.

tural support to each of the midfacial units, and address the essential functions of the midface."[39]

The maxilla is often described as being a trilevel structure, with unique functions attributed to each level. The floor of the maxilla houses the upper dental arch and separates the oral cavity from the antrum. The middle level contains the antrum and the path for its aeration. It serves as a vertical buttress for dissipation of masticatory forces and lends support and definition to the lips and the soft tissue vault of the nose. The upper level defines and supports the orbit and cheek and carries vasculature and sensory innervation to the midface.

The maxillae separate several cavities from one another. The alveolar ridges and hard palate separate the oral cavity from the antra, and the central portion of the hard palate separates the oral cavity from the nasal cavity. The medial maxillary walls separate the antra from the nasal cavities, and the orbital processes separate the orbital contents from the antra. The posterior walls of the maxillae separate the antra from the pterygopalatine fossae.

Spectrum of Maxillary Loss

The tissue deficit from maxillary surgery or injury may be as small as a single dental alveolus or as large as the entire party wall between the nasal and oral cavities. Even a tiny defect such as an oroantral fistula through the alveolus of an extracted tooth can cause major dysfunction and require repair. Further, surgical repair of even a tiny defect such as this has a significant failure rate, and much effort has been directed toward such reconstruction.[40] Management of an aggressive maxillary sinus tumor can create a defect that spans the distance from the oral cavity to the anterior part of the skull base. Repair may require re-creation of the roof of the mouth, the floor of the orbit, and support for the cheeks and lips. Aggressive ablation of such a tumor may also require resection of the orbital confines and contents, further complicating reconstruction.

Maxillofacial Prosthodontics

Prostheses have been the mainstays of management of maxillary defects for hundreds of years. Most maxillary defects resulting from oncologic surgery were managed with removable prosthetic obturation until the last decade of the twentieth century.[41] As long as there is a defect amenable to obturation, a prosthesis remains a viable option for many patients suffering loss of part or all of the maxilla, despite the compromises inherent in such management. Dental reconstruction and rehabilitation can be integral with palatal defect management by including prosthetic dentition in the prosthetic unit. Of course, retention of a prosthesis requires sufficient hard and/or soft tissue to anchor, support, and stabilize the device.

Removable palatal prostheses are more acceptable to patients comfortable with the concept of removable dental prostheses than to those with a full complement of natural teeth, and the edentulous proportion of most of the world's population is dropping. A recent British study found so predictable an improvement in the oral health of the general population that a lack of natural teeth will affect 25% of the British population between 65 and 74 years of age in 2008, down from 52% 20 years before.[42] In the United States, the rate is expected to decline from an observed 37% of all Americans in 1997 to 15% in 2020.[43] This suggests a decline in the number of future patients likely to accept and be satisfied with removable maxillary prosthetics. But it is important to note that education, economic status, and social function (the same socioeconomic factors that correlate strongly with facial trauma and with cancer of the head and neck) are independent predictors of low functional dental status.[44] As the population of the United States is growing at a rate close to that of reduction in tooth loss,[43] the absolute number of edentulous patients in a given age group is expected to remain constant. These are the patients who are both at greatest risk for head and neck cancer and least likely to expend the resources for state-of-the-art reconstruction. As a result, the role of removable maxillofacial prosthodontics in maxillary reconstruction will not likely dwindle below its current level of activity.

On the other hand, a progressive increase in oral health awareness and improvement in the oral health of civilized societies suggests an increasing demand for dental rehabilitation as an integral component of maxillofacial reconstruction. Advances in implantology have made osseointegrated implantation of posts, anchors, and other means of securing dental arch restorations and external maxillofacial prostheses readily available to those with the economic resources to obtain them. The spectrum of available management methods

now ranges from a removable obturator with rudimentary dentition and facial support to vascularized free osteocutaneous flap reconstruction with osseointegrated dental implants and fixed full-arch dental restorations. As a result, it is now more important than ever to identify the needs and desires of individual patients regarding maxillofacial reconstruction and rehabilitation.

One of the biggest problems facing the patient in need of a maxillary prosthesis is the availability of a maxillofacial prosthodontist. As Gotay and Yates pointed out, "… the majority work in private practice or a dental school, are primarily involved in clinical work or teaching, and see few cancer patients. Inadequate reimbursement and lack of collaboration with surgeons were cited as barriers to involvement in cancer patient care."[45] Cost-benefit analyses have been done comparing microsurgical reconstruction with traditional regional flap methods, but no such analysis appears in the literature comparing maxillofacial prosthodontic management with surgical reconstruction. As attention is directed toward the cost effectiveness of clinical methodology, removable prosthetic management of maxillary defects may emerge as a societal choice. However, it is far from ideal and necessitates many functional and esthetic compromises much better addressed by modern methods of tissue transfer.

Although head and neck surgeons traditionally express concern about the quality of prosthetic devices available to their patients, studies have shown that "Correlations between anatomic conditions and denture quality and patient satisfaction are weak."[46] Further, authors repeatedly suggest that psychological factors predominate in the acceptance of and adaptation to removable dentures. As a result, the lack of insurance coverage for maxillofacial prosthodontics is the biggest single factor controlling the availability of these important clinical services to head and neck cancer patients.

There are many patients for whom a removable prosthetic management plan is preferable to surgical reconstruction of maxillary defects. This group includes patients who have had multiple recurrences, patients with medical compromise affecting the likely success of surgical reconstruction, and patients whose personal philosophies favor seeking the quickest, simplest treatment that will allow them reasonable function despite some major compromises from ideality.

Surgical Considerations for Optimal Management with an Obturator

Because removable prosthodontic management of maxillectomy defects remains a valuable tool for the head and neck surgeon, it is appropriate to discuss the special surgical considerations necessary to optimize results. Davison et al included concise guidelines for maxillectomy to facilitate the best possible fit, retention, and function of an obturator in a recent work on reconstruction of maxillectomy defects.[47] These include the following:

- Leaving the largest amount of hard palate possible without compromising margins
- Preserving periodontal support for sound teeth adjacent to the defect (eg, making adjacent bony cuts through the center of the next alveolus, not between)
- Lining the soft tissue cavity with split-thickness skin
- Positioning the graft so that the resulting scar band at its junction with residual buccal mucosa aids retention of the obturator flange
- Removing turbinate if it might compromise seating of an adequate obturator
- Preserving nondiseased medial palatal mucosa for use as coverage of the medial bony margin
- Resecting all of the soft palate when more than half must be taken anteroposteriorly for tumor management

Surgical Management of Maxillary Defects

Oroantral Fistulae and Other Defects of the Posterior Part of the Maxilla Although maxillary reconstruction is most often associated with management of head and neck cancer, the most common causes of oroantral communications are dental.[40] Communication between the oral cavity and the maxillary antrum causes chronic sinusitis when it persists over time, compounding the problem of achieving closure of defects resulting from dental disease and its treatment.

Unfortunately, the historical mainstay of management for most maxillary defects, the palatal obturator, is of little help in managing oroantral fistulae in the edentulous patient. The most important factor in retention of an upper dental prosthesis is the integrity of the seal of the base of the appliance against the oral tissues. An oroantral communica-

tion allows air to get beneath the flange of the prosthesis, preventing the development of an adequate seal to retain the device.

This problem deserves specific mention both because of its commonality and the generally acknowledged difficulty in achieving closure.[48] Oroantral fistulae have perplexed the surgeon for centuries. Closure techniques reported in the latter half of the twentieth century include gold foil (a method in intermittent use for over a hundred years),[49] methylmethacrylate,[50] skin flaps, mucosal flaps,[40] and transposition of the buccal fat pad.[51] Although most otolaryngologist-head and neck surgeons have tried to facilitate antral drainage and aeration in the belief that this enhances the success of closure of palatal defects that communicate with the antrum, there is literature suggesting that this is not necessary.[52]

As summarized by Davison et al,[47] flaps of buccal, alveolar, and/or palatal mucosa or mucoperisoteum remain the most commonly used management methods for relatively small openings through the posterior part of the palate into the maxillary sinus. There is growing evidence, however, that the buccal fat pad produces reliable closure with fewer drawbacks than other methods in current use.[51]

Historical Approaches to Maxillary Reconstruction Early attempts at surgical reconstruction of maxillary defects used local or regional soft tissue flaps with limited success.[53,54] Perhaps the first staged maxillary reconstruction to use both bone and soft tissue was reported by Campbell in 1948.[55] He used temporalis muscle and palatal mucosa in the first stage, followed by placement of an iliac crest graft. This reconstruction was reportedly able to retain and support a traditional maxillary denture. Subsequent work by numerous surgeons saw methodologic progress through pedicled regional flaps[56] to pedicled regional flaps with free nonvascularized autogenous bone grafts[39] to free vascularized tissue transfers of all kinds. Prior to the advent of routine free tissue transfers, the mainstays of maxillary reconstruction were pedicled myocutaneous flaps with free nonvascularized cranial, iliac, or rib bone autografts.

Various combinations and permutations of vascularized and nonvascularized soft and hard tissue were then tried, including such innovative juxtapositions as free iliac bone with vascularized jejunal transfer.[57] Advances in microsurgery facilitated major advances in maxillary reconstruction, with reports of success using groin,[58] latissimus,[59] lateral arm,[60] scapula,[61] and radial forearm[62] flaps.

Current Management of Maxillary Defects

Functional wound closure, to prevent central nervous system infection and eliminate dead space, has a higher priority in reconstruction of midfacial defects than does cosmesis.[63] Further, despite major advances in midfacial reconstruction, a prosthesis remains an important part of rehabilitation for many maxillectomy defects in conjunction with vascularized free tissue transfer.[64] Thus, optimal current management of defects resulting from maxillectomy requires an armamentarium encompassing sophisticated surgical skills, prosthodontics, and a rehabilitative team for residual deficits in communicating and taking nutrition.

Optimal management of maxillary defects requires an understanding of the composite nature of the tissue loss. Reconstruction of communicating maxillary defects most often requires replacement of three separate tissue layers, those being the soft tissue linings of the two cavities whose party wall has been violated and the bone of the wall itself. If one considers the functions of these layers rather than their histology, one recognizes that the bone is primarily a barrier to penetration of the soft tissue on either side, with dissipation of forces a secondary but by no means insignificant contribution. Thus, if soft tissue of sufficient strength and puncture resistance could be provided, it might not be necessary to replace the bony component of every communicating maxillary defect. Alternatively, because the consequence of penetration of the party wall between the oral cavity and the antrum is transfer of air and contaminated substances into the antrum, simple obliteration of the antral cavity might suffice in lieu of restoration of bony integrity. Then there would be no open cavity into which penetration could allow spread of alien substances. Both approaches are in current use.

Local and Regional Flaps for Maxillary Reconstruction

Contemporary Use of Local Flaps Even composite defects involving skin and muscle and oroantral communication may be amenable to reconstruction

with local flaps alone. Creative use of cheek, buccal fat, and palatal mucosal flaps may produce excellent results in carefully selected patients.[65] Even the laterally based forehead flap, which was once quite popular for midfacial and intraoral reconstruction,[66,67] still has occasional use.

Temporalis Muscle Flaps. Flaps based on the temporalis muscle are successful and popular for management of intermediate-sized defects of the posterior part of the maxilla, especially when the orbital floor is included in the resection. Temporalis flaps can be muscular,[68] fascial,[69] myofascial,[70] myocutaneous,[71] or osteomyocutaneous.[72] Flaps based on the temporalis muscle are often mobile enough to use on contralateral defects,[73] especially if extended to include attached galea.

The placement of free nonvascularized bone within a temporalis flap has been described for maxillectomy defect reconstruction.[74] However, recent work has suggested that the vascular source for neoepithelialization of the flap's surface originates in the tissue surrounding the defect rather than the flap, possibly explaining less than universal success from use of a free nonvascularized bone graft within a vascularized flap in this application.[75]

Buccinator Musculomucosal Flap. Pribaz et al reported 18 reconstructions of midfacial defects of all kinds using a posteriorly based musculomucosal flap of buccinator that they believed was nourished by the facial vessels.[76] Although not widely known or used, this flap seems to offer a valuable alternative to regional flaps, especially when other local tissue is not available. Licameli and Dolan determined with cadaver dissections that the blood supply is from the buccal (buccinator) artery (a branch of the internal maxillary) and published a more recent series of reconstructions of the soft palate and retromolar trigone with this flap to support further its use.[77]

Chest Flaps The pectoralis major myocutaneous flap has been used for reconstruction of large maxillectomy defects.[78] Although it will fill the defect resulting from a total maxillectomy, with the bulk of muscle obliterating the antral cavity and the orbit if necessary, it does not readily reach high enough without resection of the medial third of the clavicle, and dental rehabilitation is difficult or impossible.

The deltopectoral flap has also been used for obliteration/reconstruction of maxillectomy defects, as typified by Konno et al's series of 46 patients reported 20 years ago.[79] However, this is primarily of use when free tissue transfer is not an option.

Microvascular Free Flaps for Maxillary Reconstruction Taylor et al's original report of successful transfer of vascularized fibula presaged the modern era of jaw reconstruction.[80] Subsequent investigators refined the principles and practice of vascularized fibular transfer, with Hidalgo et al's seminal work over the last decade of the twentieth century presenting and later confirming the reliability and versatility of free osteocutaneous tissue transfer for head and neck reconstruction.[81]

The scapula, fibula, and radius are the most frequently described osteocutaneous flaps for reconstruction of the maxillary region. Each donor site has its own advantages and disadvantages. To quote Schusterman et al,

> … no one flap can be used for all defects; certain flaps are better suited for specific situations. The radial forearm flap is the best choice for small defects around the orbit because it provides a small segment of bone and a thin, pliable paddle of soft tissue. The fibula, iliac crest, and scapula flaps are useful for larger defects involving the maxilla, where bulk and a strong bone buttress are required for prosthetic support and stabilization.[64]

The scapula can be used after an osteotomy to reconstruct the orbital floor and the maxillary buttress simultaneously. Separate skin islands can be used for reconstruction of the palate and the cheek, although parascapular skin and subcutaneous tissue are often quite bulky and not an ideal donor for reconstruction of the cheek and intraoral lining.

Scapular and Parascapular Flaps. The fasciocutaneous parascapular free flap has been in clinical use for about two decades (Figure 40–3). It was defined within the distribution of the circumflex scapular artery by Saijo in 1978.[82] Teot et al described the use of lateral scapular bone 3 years later with the first three reported cases,[83] and the addition of a skin paddle was presented by Nasif's group a year after that.[84] Subsequently, Coleman and Sultan demonstrated that the angular artery, a branch of the thoracodorsal artery, supplies the most inferior aspect of the lateral scapula.[85] The addition of this vascular

FIGURE 40–3. Parascapular flap donor site.

pedicle allows for two separate bony defects to be reconstructed from the same flap. The lateral border and the inferior tip of the scapula have been used together on their individual pedicles to fill a larger defect than the unaugmented lateral scapular border will span.

Coleman's group strongly advocated the use of the scapular osteocutaneous free flap (SOFF) over fibula and other donor sites, although their series included only four maxillary and midfacial reconstructions among 29 cases.[86] They cite the availability of significantly more skin surface area than can be obtained from fibular or iliac crest osteocutaneous harvests. However, they fail to point out that the latissimus dorsi muscle flap offers far more available skin on the same vascular trunk. Further, scapular bone is often but not always of adequate bulk and dimension to accommodate placement of osseointegrated dental implants.[87] It is useful for orbital floor reconstruction. Of the five patients from Coleman et al's study who remained available for long-term questioning, all complained of difficulty reaching above their heads and lifting objects, and two complained of moderate pain at the donor site.

Modern modifications of the SOFF have significantly increased its utility. However, the morbidity reported by Coleman et al, the unpredictability of bony bulk, and the availability of more bone and larger skin paddles from fibular harvest than that reported by others from scapula prevent the SOFF from being the flap of first choice. The interesting report of prefabricated scapular flaps from Holle's group adds new potential utility to the SOFF.[88] They placed osseointegrated dental implants into the dissected scapular segment and covered it with split-thickness skin grafts around which an expanded polytetrafluoroethylene sheet was placed. The flap was then left in situ for 3 months before harvesting and inserting it. Further improving the outcome was their ability to define preoperatively the anatomy and bulk of the scapula using a digital graphic workstation processing of high-resolution three-dimensional computed tomographic images. With refinement of techniques like that used by Holle's group, the SOFF is becoming a treatment of choice for maxillary reconstruction.

Management of Large Defects following Maxillectomy Large wounds, especially if they involve loss of more than one cutaneous and/or mucosal surface, usually require a rectus abdominis or a latissimus dorsi myocutaneous flap. These flaps can provide skull base coverage as well. Although the radial forearm flap satisfies midfacial soft tissue requirements, the fibular osteocutaneous free flap, now well established for mandibular reconstruction, is considered by many to be the flap of choice for maxillary defects of the hemipalate or greater since these defects require bony replacement to allow for osseointegrated implant use.

Rectus Abdominis Flaps. A large flap of rectus abdominis muscle can be harvested readily on a long pedicle of good caliber. Although usually based on the deep (inferior) epigastric artery, it can even be raised on its superior vasculature if the inferior pedicle is unusable or inadvertently damaged.[89] The rectus abdominis has several advantages over other soft tissue flaps. It can be harvested easily during the resection without repositioning the patient. The pedicle may be as long as 20 cm and is reliably 15 cm or more. A rectus abdominis myocutaneous free flap can be tailored into multiple skin paddles and/or myofascial components to reconstruct cheek, oral lining, and orbital lining. The muscle in this flap is thought by some authors to satisfactorily isolate a free nonvascularized bone graft placed within it to protect it from oral contamination.[74]

By using the rectus abdominis free flap in combination with nonvascularized bone grafts, a three-dimensional defect is reconstructed quite easily because bone, skin, and soft tissue may be inset in their proper positions without compromising the microvascular aspect of the reconstruction. However, most recent literature favors the use of a single donor source over multiple sites and discontinuous tissues.[23]

Latissimus Dorsi Flaps. Vascularized free latissimus dorsi flaps have been used for closure of extensive maxillectomy defects for almost two decades.[59] With so much collective experience, the facial plastic and reconstructive surgeon can rely on flaps supplied by the subscapular artery for reconstruction of moderate to very large maxillectomy defects. The spectrum of flaps supplied by the subscapular system is large,[90] including multicomponent "megaflaps" using various combinations of latissimus dorsi, scapula, parascapular skin, and serratus anterior muscle to reconstruct complex defects involving skin, bone, and mucosa (Figure 40–4). Ample literature exists supporting the utility and success rates of so-called "megaflaps" using skin, muscle, and/or bone supplied by branches of the subscapular-circumflex scapular-thoracodorsal system.[91]

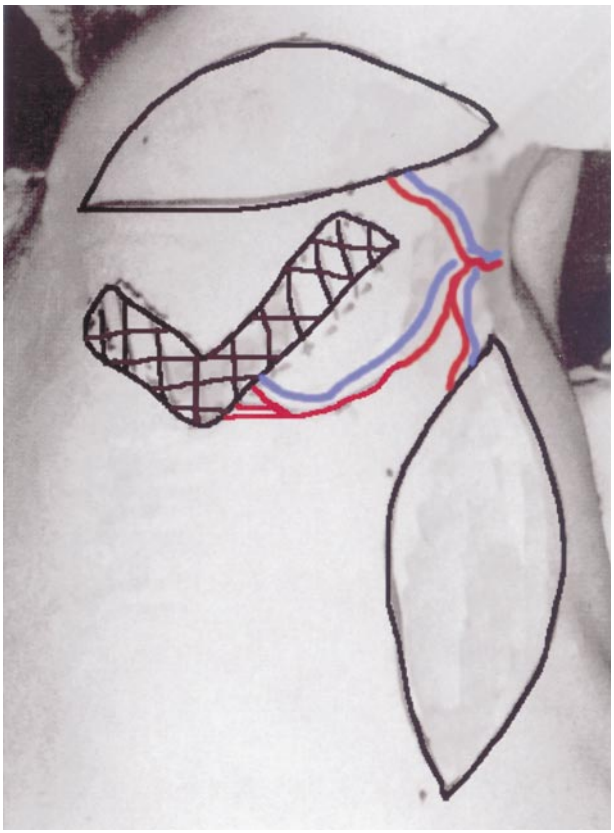

FIGURE 40–4. Megaflap donor site.

Radial Forearm Flaps for Maxillectomy Reconstruction

Microvascular free flaps based on the radial artery have been in clinical use for many years[92] and have achieved wide application in the management of maxillectomy defects.[93] Flaps can be tailored to include various combinations of skin, fat, fascia, tendon, and bone. The limiting factor in harvesting of osseous flaps in the radial artery distribution is the fragility of the remaining radius.

Complications at the donor site occur in about 15% of radial forearm flap harvests. In a large and well-studied series, 100 patients were followed for complications after radial forearm flap transfers.[94] Eighty-six patients were available for follow-up at 3 months and 74 at 1 year. Partial loss of the donor-site skin graft occurred in 14 patients (16%), with exposure of tendons in 11 patients (13%). Delay in healing of the split-thickness skin graft at the donor site occurred in 19 patients (22%). There were six fractures of the remaining radius in 35 patients having osteocutaneous flap harvests (17%). Superficial radial nerve sensation was reduced in 24 patients (32%), 10 reported cold intolerance, and 21 (28%) were unhappy with the appearance of the donor site. Function of the donor arm was restricted in 8 patients (16%) in the fasciocutaneous group, 7 patients (36%) in the composite group without fracture, and in all patients who sustained a postoperative donor site fracture. Detailed measurements of forearm circumference, grip strength, pinch strength, and wrist movements showed greater reduction in these parameters in patients reporting restricted function compared with those reporting normal function, confirming their subjective impressions. Fracture of the radius produced functional impairment in all cases.

Free vascularized radial osteocutaneous flaps have been used to reconstruct maxillectomy defects involving the infraorbital rim and midfacial skin,[95] as well as less extensive tissue loss. Preference for the radial osteocutaneous flap is expressed by sev-

eral authors for defects involving the orbital floor and inferior rim. Vascularized scapular blade is the alternative osteocutaneous flap of choice by some authors.[96]

MANDIBULAR RECONSTRUCTION

Mandibular Anatomy

The mandible is unique among the bones of the body. As part of the stomatognathic system, the mandible is suspended in space by muscles. It is free to move within an envelope of motion defined by its ligamentous attachments to other bones and by interdental contacts in patients with teeth. The ligaments of the temporomandibular joint combine with the stylomandibular ligament to place firm limits on mandibular excursion. Muscular attachments also limit mandibular movement, but these limitations are less well defined because of the distensibility and length tension phenomenon of muscle.

The muscles of mastication control mandibular movement, inserting on a significant portion of the overall surface of the mandible and exerting strong force on it during chewing. Suprahyoid muscles connect the mandible to the hyoid. The genioglossus and mylohyoid form the floor of the mouth, further defining mandibular orientation and movement.

The anatomic regions of the mandible include the condyle and condylar neck, sigmoid notch, coronoid process, ramus, angle, body, alveolar process, parasymphysis, and symphysis. Within the alveolar process are the teeth and supporting structures, including the periodontal ligament and the neurovascular bundles. The inferior alveolar artery, vein, and nerve course through the inferior alveolar canal within the body of the mandible to supply the teeth. The periodontium derives blood supply both from periapical vessels and from perforating vessels in the alveolar bone. The gingival blood supply is extraperiosteal and originates in the vessels of the face and neck.

When natural teeth are lost, the alveolar process resorbs, leaving the reduced height of basal bone of the maxilla and mandible. The relative bulk and anatomic contours of the jaws must be appreciated if appropriate reconstructive methods and materials are to be chosen.

Treatment Planning

It is necessary to consider the bone defect first when planning reconstruction of composite defects of the mandible and lip. Without adequate restoration of skeletal support in the region of the anterior mandibular arch, soft tissue reconstruction cannot achieve firm apposition of the upper and lower lips. Restoration of bony continuity is recommended for all patients with segmental mandibular defects since the rate of hardware failure and/or exposure is reported to be at least 25% by multiple authors.[97]

The mandible may be invaded by tumors of the oral cavity. In these cases, reconstruction must include the restoration of both the soft tissue and bony anatomy. Depending on the extent of tumor resection, the residual mandible may not have sufficient stock to withstand the forces of mastication. In considering reconstruction, important anatomic variables include the location and length of the defect and any associated soft tissue, skin, or neurovascular involvement.[98]

Although it is not clear that all mandibular defects require reconstruction, there is obvious benefit in many instances. For instance, resection of the anterior mandibular arch produces the "Andy Gump" deformity (Figure 40–5), which is a complete loss of anterior oromuscular support and oral competence. Because this is such a debilitating functional and esthetic problem, it is important to reconstruct this defect at the time of resection.[99] The use of an immediate microvascular bone-containing free flap is the optimal method to restore form and function to the lower third of the face and also allows the patient to wear a functional dental prosthesis. Other absolute indications for this type of reconstruction include through-and-through mandibular defects (which require reconstruction not only of bone but also of mucosa and external skin), severe mandibular osteoradionecrosis, and failure of previous attempts at mandibular reconstruction.

A variety of osseocutaneous free flaps have been described to reconstruct the mandible. The fibula is the most advantageous donor site, although the iliac crest may also be used.[100] The free fibula flap provides the greatest length of bone and a minimal donor-site defect. Multiple osteotomies can be made in the bone to properly contour it (Figure 40–6), and dental rehabilitation can be achieved with primary or secondary dental implants. The iliac crest free flap provides

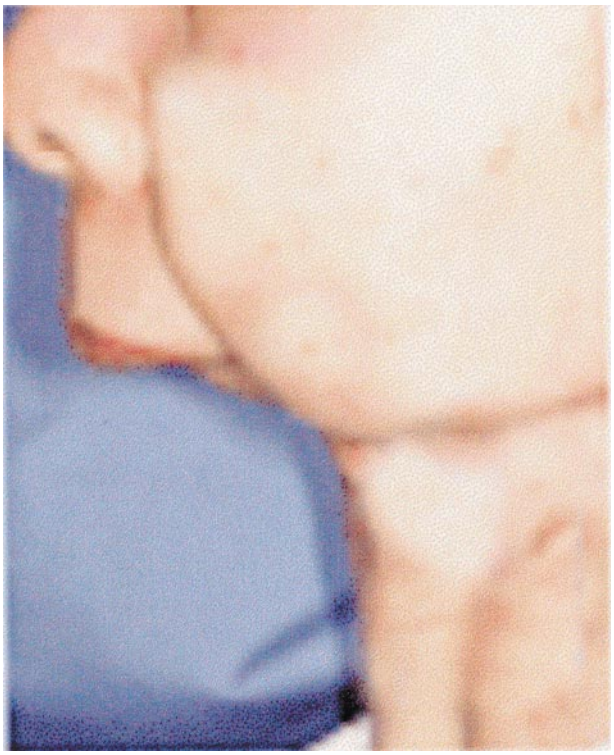

FIGURE 40–5. Unreconstructed mandibulectomy defect ("Andy Gump" deformity).

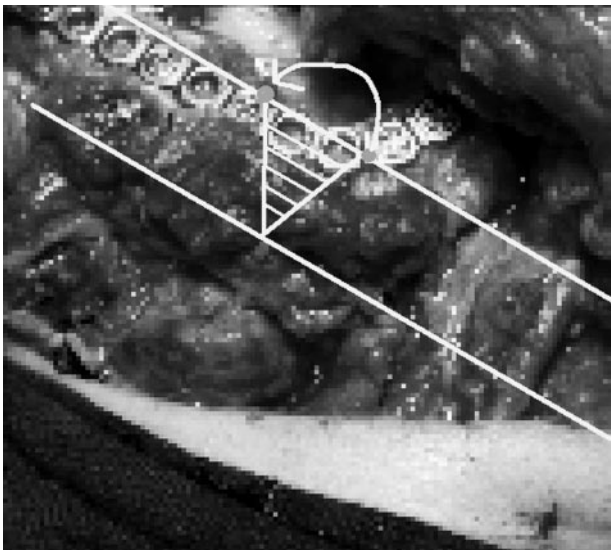

FIGURE 40–6. Fibular free flap with wedge ostectomy to create an angle.

thicker bone than the fibula in most cases, along with an abundance of soft tissue.[101] This combined osseomusculocutaneous flap has found favor with some authors for through-and-through mandibular defects because the muscle reconstructs the mucosal defect and the skin paddle fills the cutaneous defect.

In a comparative study of the suitability of implantable bone for osteointegration of dental implants,[102] the iliac crest was found to offer the best bone stock with the least variability in comparison with the scapula and fibula. Tempering this as a criterion for flap selection is the observation that few patients achieve optimal oral rehabilitation with implant-borne prostheses because of the cost of such management and the relative lack of insurance coverage for it.

Specific Considerations

There is little question that vascularized fibula is the donor site of choice for reconstruction of most mandibular defects.[103] The results of fibular free flap reconstruction of mandibular defects greater than 4 cm regardless of their location along the mandibular arch have been good. Defects anterior to the mental foramen require aggressive bony reconstruction to prevent the collapse of the mandibular arch (Figure 40–7). The fibular free flap provides about 25 cm of bone similar in cross-sectional shape and area to native mandibular body. The graft can be osteotomized without compromising segmental viability because the blood supply is both periosteal and endosteal. The vascular pedicle is long, of good cal-

FIGURE 40–7. Fibular free flap reconstruction of an anterior mandibular arch.

iber, and reliable. After initial reports of 30 to 40% failure of the skin paddle of fibular osteocutaneous flaps, published modifications in technique have increased the reliability of the skin paddle to that of the bone flap itself.[104] See Chapter 41 for a more detailed description of the spectrum of available flaps.

Although lateral defects of the mandibular body are better tolerated than are defects of other regions, the mandibular body is also easily reconstructed. The typical defect from unreconstructed lateral mandibular loss includes visible external collapse and deviation of the jaw to the contralateral side (Figure 40–8). This causes a functional impairment that can be improved but not corrected with dental prostheses. Improvements in denture design for mandibulectomy patients continue to be made,[105] but there is good literature support for primary reconstruction of pure lateral mandibular defects.[106] Primary reconstruction of lateral mandibular defects is routinely performed and strongly advocated because the cosmetic and functional residua of lateral resection are significant, even if they are relatively well tolerated. Reconstruction of a lateral mandibular defect with vascularized fibula produces a cosmetic and functional result approximating normalcy (Figure 40–9).

FIGURE 40–8. Unreconstructed lateral mandibular defect.

FIGURE 40–9. Normal occlusion after fibular replacement of body, angle, and ramus.

The cutaneous paddle of a fibular osteocutaneous flap can be rendered sensate by anastomosis of the lateral sural cutaneous nerve within the graft to the proximal end of a recipient sensory nerve such as the inferior alveolar, lingual, or great auricular.[107] Published results have been inconsistent, with some authors believing strongly that innervation of flaps and grafts must be restored surgically[108] and others finding return of sensory function in the absence of surgical reinnervation.[109] Further, some authors have suggested that sensation is not even necessary for function of the upper aerodigestive tract and that "Current beliefs about the utility of sensate free tissue transfer and the importance of sensation in swallowing in general may need refinement."[110]

Defects of the Anterior Mandibular Arch

Defects of the anterior mandibular arch cause severe problems that cannot be reversed without formal reconstruction. These problems combine to produce the classic "Andy Gump" deformity, named after the 1917 comic strip character whose appearance suggests loss of the anterior mandibular arch. The loss of anchorage of suprahyoid muscles to the genial tubercles causes collapse of the pharyngeal and hypopharyngeal airway. Detachment of the genioglossus from the mandible destabilizes the tongue and interferes with protrusive movements. Loss of labial support affects competence of the oral sphincter.

When the anterior mandibular arch is removed, there is usually an associated soft tissue

deficit too large to close primarily. A mandibular reconstruction plate can be used to secure the remaining mandibular bodies and restore continuity to the arch. The stabilizing function of the genial musculature can be approximated by suturing the hyoid and tongue base to the plate, but this provides only a crude and limited imitation. Soft tissue of varying character and from a variety of donor sites has been wrapped around such plates to fill the space left by the resected specimen, but this is also a crude management method. And, as cited earlier in this chapter, the rate of loosening and breakage of plates used in this fashion is very high, necessitating secondary reconstructive surgery in at least half of patients so treated over the next 3 years. The effects of shear and moment on security and stability of mandibular reconstruction plates have been demonstrated.[111] As the plate and screws used for reconstruction of the anterior mandibular arch are subject to multiplanar shear, torsion, bending, and loading, the high failure rate of plates not secured to a continuous bony arch is not surprising.

Insetting a vascularized bone graft and securing it firmly between the cut ends of the native mandibular remnants provides stability to the reconstruction. Regardless of the source of the bone graft, the success rate of the reconstruction is greatly enhanced over that of a plate with surrounding soft tissue. Fibula is preferred, as is the use of a skin paddle from the lateral lower leg whenever soft tissue coverage is also required. The inferior border of the fibular graft is aligned with that of the remaining mandible to achieve the best bone apposition as well as the best cosmetic result (Figure 40–10), despite the increased vertical dimension of removable or fixed dental prostheses that may be placed.[112]

In cases requiring replacement of skin of the lower face as well as oral lining, a fibular osteocutaneous flap is used for reconstruction of the mandible and facial skin with a second flap for replacement of oral lining (Figure 40–11). A radial forearm flap is ideal for this purpose. Some authors prefer a scapular-parascapular flap for this problem, resurfacing the face with a skin paddle on latissimus and closing the intraoral defect with the fascia-covered surface of the muscle. One could also accomplish this with two parascapular skin paddles, using the scapula itself for mandibular reconstruction and harvesting the entire flap on the circumflex scapular artery.

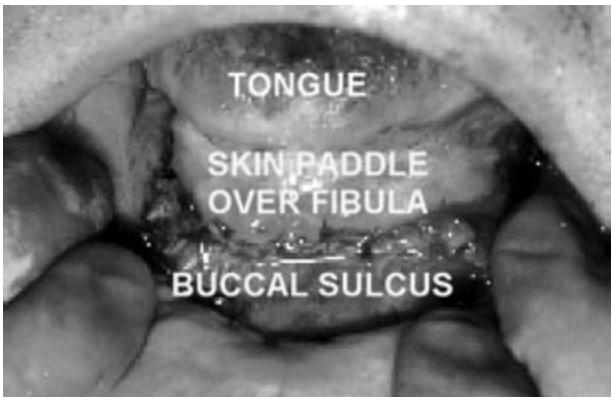

FIGURE 40–10. Insetting of a fibular osteocutaneous flap for anterior reconstruction.

Reconstruction of the Entire Mandible

As the average adult fibula yields at least 25 cm of transferable linear bone, it can be used to fabricate an entire mandible. Osteotomies and wedge ostectomies are routinely used to contour the graft. They do not compromise the viability and healing potential of the graft, even though they have been demonstrated to diminish distal blood flow in the graft.[113] However, care must be taken not to interrupt the periosteum because it carries the blood supply from segment to segment.

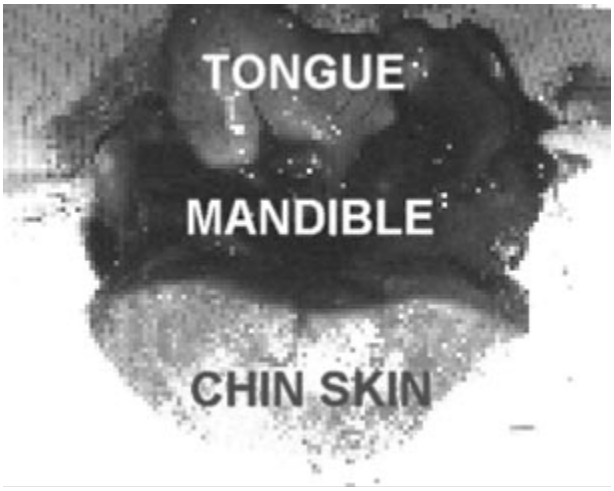

FIGURE 40–11. Through-and-through resection of the tongue, mandible, and chin.

Reconstruction of the Temporomandibular Joint

The spectrum of management methods for loss of the mandibular condyle have ranged from nonintervention, to extension of the smoothed end of a bone graft or flap into the glenoid fossa, to implantation of alloplastic joint prostheses. Explored along the way were methods as varied as securing the resected native condyle to a graft and reinserting it into the fossa, filling the fossa with temporalis muscle and/or fascia, and transplanting the head of the fifth metatarsal. Current work favors the placement of a smoothed fibular graft into the joint space, securing it with a 2-0 braided permanent suture through the articular disk (if it remains) or through an anchoring hole in the bony rim of the fossa (Figure 40–13).[114]

Maintenance of the articular disk is desirable, whenever possible, for improved stabilization of the neocondyle in the glenoid fossa. If the patient has adequate articulating upper and lower posterior teeth to define the vertical dimension of the occlusion, the exact method of managing temporomandibular joint loss is probably not so critical. However, many head and neck cancer patients are fully edentulous at the time of treatment and do not undergo oral rehabilitation. These patients will likely have sufficient difficulty with temporomandibular joint function to prevent them from chewing solid food in the absence of a functional temporomandibular joint reconstruction. Great care must be paid to shaping and placing a neocondyle during reconstruction of mandibular defects in these patients.

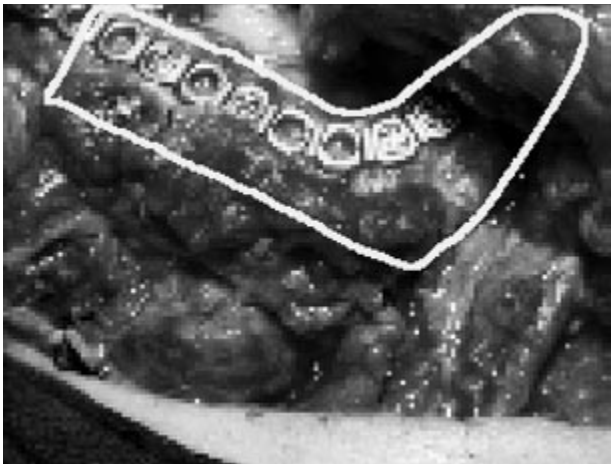

FIGURE 40–12. Shaped fibular end on temporalis muscle as a neocondyle.

Sensory Nerve Considerations in Mandibular Reconstruction

A word must be said about restoration of sensation during mandibular reconstruction. The inferior alveolar nerve will be sacrificed in all mandibular resections posterior to the mental foramen, rendering the ipsilateral lower lip numb. Grafting has been proposed at the time of resection and reconstruction.[115] This is a reasonable component of management, and the facial plastic and reconstructive surgeon should consider this during mandibular reconstruction. Grafting from the contralateral mental nerve has also been reported.[116]

Extensive and Unusual Defects

Extensive tumors of the lateral pharyngeal wall and retromolar trigone can necessitate resection of the mandible and maxilla (Figure 40–13). If the maxillary defect is confined to the lateral palate, alveolar ridge, and pterygoid hamulus, reconstruction of both the mandible and the maxilla can be accomplished with a single fibular osteocutaneous flap (Figure 40–14). Extensive defects of the maxilla and midface that require more skin than can be harvested with a fibular graft may necessitate a megaflap with scapular bone, parascapular skin, and latissimus dorsi muscle. Alternatives include the use of multiple free flaps, although this requires adequate donor vasculature to supply each flap.

Another innovation in reconstruction of the jaws and oral lining is the "bridging flap."[117] Because the peroneal artery and veni comitantes traverse the entire length of a fibular flap, the distal ends of the vessels can nourish a second flap. Thus, a radial forearm flap can be used to provide pliable oral lining over a fibular reconstruction of the mandible. This is especially useful when the oral defect is through and through the facial skin, requiring external as well as intraoral resurfacing (Figure 40–15).

FUTURE OF JAW RECONSTRUCTION

As can be seen, there are many reconstructive options for defects of the jaws. Distraction osteogenesis and physiologic osseous morphogens offer glimpses into

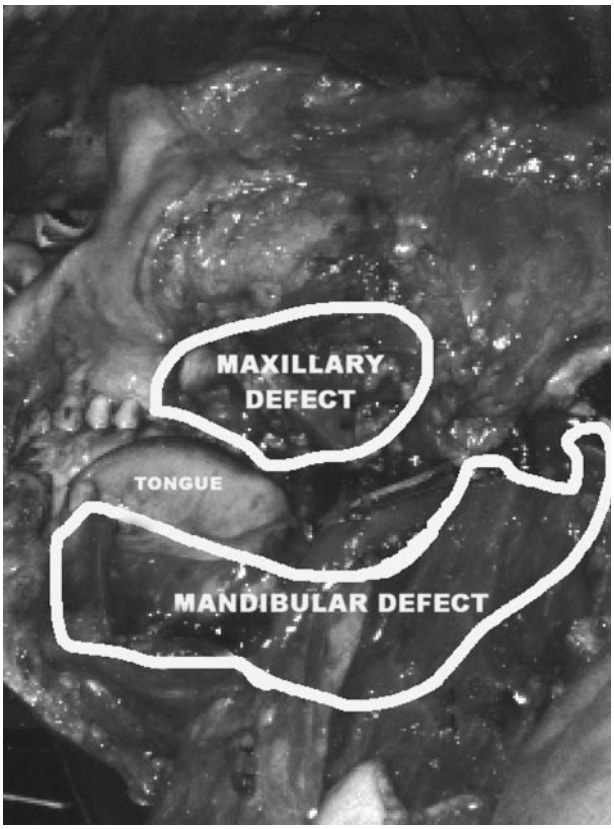

FIGURE 40–13. Composite defect including the maxilla and mandible.

the future of jaw reconstruction. Genetic engineering and flap prefabrication herald the day when tumors will be replaced with well-fitted autografts identical in composition and function to tissues sacrificed for tumor control. As we endure the wait for

FIGURE 40–14. Reconstruction of the defect in Figure 40–13 with a fibular osteocutaneous flap.

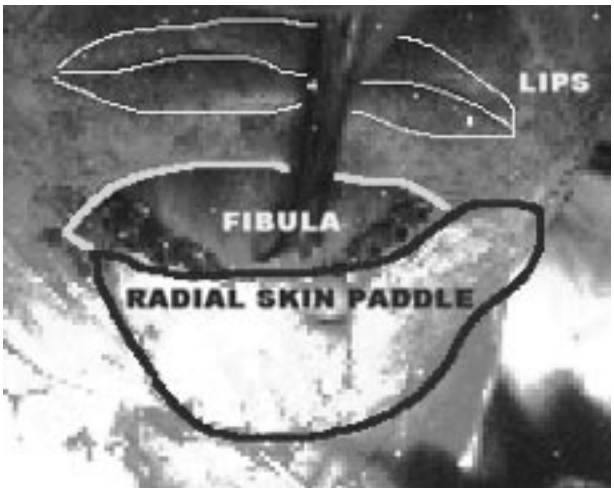

FIGURE 40–15. Reconstruction of the through-and-through defect from resection in Figure 40–11.

"molecular reconstructive 'cocktails' from the shelf of the next millennium," we have sufficient alternatives for reconstruction of the jaws to produce results that were unimaginable to surgeons only 25 years ago.

CHAPTER 41

Flaps and Grafts in the Head and Neck

Jane Y. Yang, MD, Marc R. Rosen, MD, William M. Keane, MD

The primary role of oncologic surgery is the curative resection of tumor. Equally important, however, is the subsequent reconstruction and rehabilitation, which should lead to an optimal functional and cosmetic result. The type of flap or graft employed in reconstruction is dictated by the location and size of the defect, and every attempt should be made to replace like tissue with like tissue. Simple mucosal defects may be allowed to heal secondarily or may require minor grafting procedures. Larger resections incorporating skin, mucosa, muscle, or bone demand more complex reconstruction, employing free flaps or compound myocutaneous flaps. The ideal reconstructive modality should be performed as a single-stage procedure while providing effective rehabilitation with minimum donor-site morbidity. A wide variety of reconstructive choices are available today. It is important to be familiar with these options while understanding their advantages and limitations.

GRAFTS

Smaller oral cavity and oropharyngeal defects may be allowed to heal by secondary intention. This is appropriate when subsequent wound contracture produces a minimal functional deficit. Defects of the hard palate, where underlying palatal bone has been preserved, are best allowed to heal by secondary intention. Similarly, defects of the tonsillar area, soft palate, buccal mucosa, and tongue heal effectively by secondary intention with minimal contracture. Conversely, only the smallest defects of the anterior floor of the mouth may be allowed to heal by secondary intention as scar contracture typically produces some degree of ankyloglossia.

Graft Physiology

Epithelial grafts are free tissue grafts that depend entirely on the recipient bed for their viability and so require a well-vascularized host bed. Revascularization of skin and mucosal grafts follows three phases: *serum imbibition* (plasmotic circulation), *revascularization*, and *organization*.[1]

Serum imbibition begins when the graft is placed on the recipient site and lasts about 48 hours. A thin layer of fibrin clot forms between the host bed and the skin graft, temporarily anchoring it in place. Nutrients from the plasma transudate, which come from the dilated capillaries of the host bed, diffuse into the graft.[2]

Revascularization of the graft begins with the ingrowth of the vascular buds from the host bed. The process of revascularization, although somewhat controversial, is believed to occur by two processes, *neovascularization* (ingrowth of vessels from the host into the graft) and *inosculation* (direct anastomoses of graft and host vessels).[1]

The *organization* phase begins with the infiltration of leukocytes soon after the graft is placed on the host. As the graft revascularizes, the leukocytes disappear. Fibroblasts begin to infiltrate the fibrin network by day 4, and as the fibroblasts proliferate, the fibrin resorbs. By day 9, the process is complete.

Types of Grafts

The location and size of the defect typically dictate the type of graft to be selected for reconstruction.

Split-Thickness Skin Graft Split-thickness skin grafts (STSGs) consist of the epidermis and a portion of the dermis. The thickness of the graft varies. Thin grafts are harvested at a thickness of 0.005 to 0.012 in, moderate grafts at 0.012 to 0.018 in, and thick grafts at 0.018 to 0.028 in. Thinner grafts are more readily nourished and have a high survival rate but are more liable to contract. Because adnexal structures (hair follicles, sebaceous and sweat glands) are located in the deeper portion of the der-

mis, thicker grafts may grow hair and reflect donor-site morphology (Figure 41–1).[2]

Split-thickness grafts are excellent choices for coverage of areas that require surveillance for tumor recurrence. Split-thickness skin grafts work well in the oral cavity and oropharynx when bulk is not required and when coverage is needed to prevent excessive wound contraction.

They are often meshed, allowing for expansion to cover more surface area. This is particularly appropriate for large superficial defects of the scalp. Powered dermatomes enable these grafts to be harvested with ease and precision. The anterior thigh, with its large surface area, is the favored donor site. Critical to the successful take of the skin graft is immobilization. This can be accomplished in some cases by simply suturing the central portion of the graft, but, in other cases, specifically contoured bolsters may be needed to ensure fixation.

Full-Thickness Skin Grafts Full-thickness skin grafts (FTSGs) contain the epidermis and the entire dermal layer. These grafts are most commonly used to cover defects of the nasal tip, lateral ear, or eyelids after the excision of cutaneous skin malignancies. The color and texture of the donor and recipient site should match as closely as possible. Preauricular, postauricular, and supraclavicular skin is ideal for most facial defects, whereas upper eyelid skin should be used to replace upper and lower lid defects. Because of their thickness, FTSGs do not contract. This quality, however, also leads to slower revascularization and a lower take rate. Unlike the STSG donor site, the FTSG donor site cannot re-epithelialize on its own and thus must be closed primarily or be covered with a STSG.

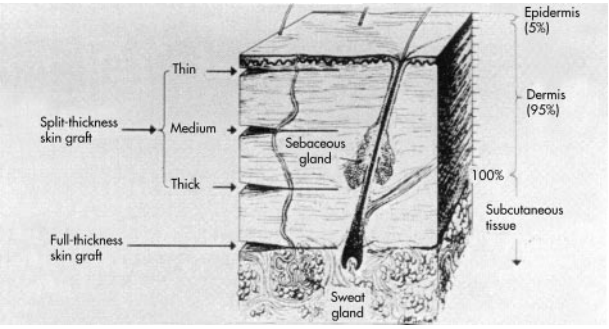

FIGURE 41–1. Diagrammatic representation of skin and subcutaneous tissue. The thickness of various types of skin grafts is illustrated. Reproduced with permission from Petruzzelli GJ and Johnson JT.[2]

Dermal Grafts Dermal grafts are mentioned primarily for historical interest. These grafts are harvested after the epidermal layer has been raised. They have been used in the past for oral and pharyngeal reconstruction and have been placed in the subcutaneous layer to improve facial contouring. These grafts have been used to protect the carotid artery when salivary leaks and skin breakdown might lead to carotid exposure and blowout. This technique has been largely abandoned because of complications of epithelialization of the graft on exposure to air or saliva and the growth of retained epithelium beneath the skin, resulting in cholesteatoma formation.

Mucosal Grafts Buccal mucosa is the usual donor site for mucosal grafts. The graft obtained should not exceed 2 × 3 cm to prevent excessive scarring with subsequent trismus. Buccal grafts are often used for airway reconstruction for which desquamating skin is not desirable.

FLAPS

Classification

A flap is a unit of tissue that may be advanced or rotated into a surgical defect while maintaining its original blood supply. Understanding its vascular supply is crucial to flap design and success. Flaps are defined as "random," "axial," or "free" depending on their pattern of blood supply. Random flaps derive nutrition from local, small, unnamed vessels of the dermal-subdermal plexus and are therefore severely restricted with respect to size. Axial pattern flaps are based on recognizable, usually named arteriovenous pedicles. An axial flap may include a "random" extension at the distal portion of the flap, increasing the amount of skin available. Free flaps are pedicled, axial pattern grafts detached from a distant site (Figure 41–2).

Flaps are classified as local, regional, and distant depending on their location. Tissues that are immediately adjacent to the defect are called local flaps. Local flaps usually have a random vascular pattern. Regional flaps possess an axial vascular pattern and are typically advanced and transferred from a more distal site while maintaining its vascular pedical attachment. Free or distant flaps are pedicled

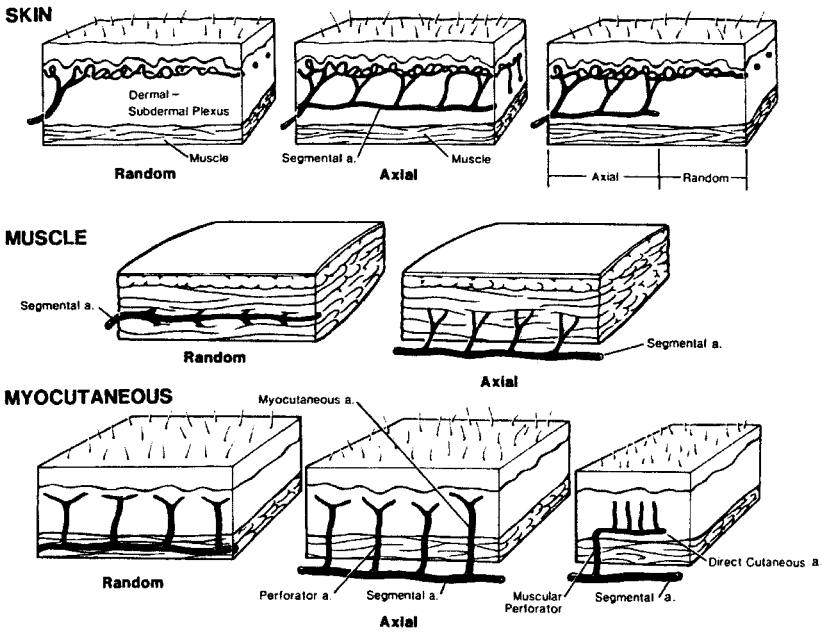

FIGURE 41–2. Diagrams illustrating the blood supply pattern to skin, muscle, and myocutaneous flaps. Reproduced with permission from Paparella MM, Shumrick DA, Gluckman JL, Otolaryngology. Vol IV. 3rd ed. Philadelphia: WB Saunders; 1991.

composite grafts that require separation of the vascular pedicle from the donor site with subsequent reanastomosis within the recipient bed.

Pedicled Regional Flaps

Prior to the development of pedicled regional flaps, head and neck reconstruction options consisted of primary closure, local flaps, or delayed procedures requiring prolonged hospitalization. These options were less than effective for large defects. Primary closure of the oral cavity often reduced the functional volume or tethered the tongue, causing ankyloglossia, dysarthria, or dysphagia. Such techniques also led to stenosis of the oropharynx and hypopharynx, with similar morbidity. The limitations of blood supply with random pattern flaps frequently created a relatively short flap, and attempts to reconstruct more distant sites were often associated with necrosis of the distal part of the flap. In addition, local flap rotation often resulted in stricture and tethering. Delayed flaps required multiple surgical procedures over a prolonged period of time.

Bakamjian introduced the two-stage deltopectoral flap for pharyngoesophageal reconstruction in 1965.[3] Other regional flaps were subsequently introduced, but it was only when Ariyan developed the pectoralis major myocutaneous flap in 1979 that the use of regional pedicled flaps became widespread.[4] Regional flaps dominated the reconstructive scene in the 1980s, with the pectoralis myocutaneous flap taking the lead while becoming the "workhorse" for head and neck reconstruction.

Many of these pedicled flaps can be modified to include a bone or cartilage graft. This modification has been largely replaced with free osseocutaneous flaps, which offer superior reconstructive options with a higher success rate.

A wide variety of pedicled regional flaps are available (Table 41–1) and are described in more detail.

Pectoralis Major Myocutaneous Flap Since the introduction of the pectoralis major myocutaneous flap in 1979, it has become the most commonly used pedicled regional flap for head and neck reconstruction while providing coverage for most defects of the head and neck from the scalp and skull base to the cervical region and hypopharynx.

The pectoralis major muscle is a large fan-shaped structure located over the anterior upper chest. This muscle is attached laterally to the medial surface of the humeral head, medially to the sternum, and inferiorly to the lower ribs. It adducts and medially rotates the humerus. The pectoral branch of the thoracoacromial artery is its primary blood supply, with a minor contribution by a small branch of the lateral thoracic artery. Its vascular pedicle is located in the clavipectoral fascia as it runs on the undersurface of the pectoralis major muscle along

TABLE 41–1. Flaps in Head and Neck Reconstruction

Flap	*Type*	*Vascular Supply*	*Sensory*
Pectoralis major	Pedicled	Thoracoacromial a.	Insensate
Trapezius	Pedicled	Transverse cervical, dorsal scapular, occipital a., perforating branches of the paraspinous vasculature	Insensate
Sternocleidomastoid	Pedicled	Occipital, suprascapular, external carotid/superior thyroid a.	Insensate
Deltopectoral	Pedicled	Internal mammary a.	Insensate
Temporalis	Pedicled	Deep temporal a.	Insensate
Platysma	Pedicled	Facial a.	Insensate
Latissimus dorsi	Pedicled or free	Thoracodorsal a.	Long thoracic n.
Gastric pull-up	Pedicled	Right gastric and gastroepiploic a.	Insensate
Radial forearm	Free	Radial a.	Lateral antibrachial cutaneous n.
Lateral arm	Free	Posterior branch of the radial collateral a.	Inferior lateral brachial cutaneous n.
Lateral thigh	Free	Perforators of the profunda femoris a.	Lateral femoral cutaneous n.
Rectus abdominis	Free	Deep inferior epigastric a.	Insensate
Fibula	Free	Peroneal a.	Lateral sural cutaneous n., sural communicating n.
Iliac crest	Free	Deep circumflex iliac a.	Insensate
Scapula/parascapula	Free	Circumflex scapular a.	Insensate
Jejunum	Free	Superior mesenteric a.	Insensate
Gastro-omental	Free	Right gastroepiploic a.	Insensate

a = artery; n = nerve.

an axis from the shoulder to the xiphoid (Figure 41–3).[5] The pectoralis major muscle receives a minor contribution from the lateral thoracic artery; however, this vessel is typically divided, allowing for a more effective arc of rotation.

This flap has many advantages for head and neck reconstruction. It is reliable, easy to raise, and in close proximity to the head and neck recipient site. It can be raised quickly with the patient in the supine position, and the donor-site defect can usually be closed, primarily when a relatively large skin paddle is harvested.

This flap may be fashioned as a myocutaneous or myofascial flap for the reconstruction of oral cavity or pharyngeal defects.[6] The myofascial flap eliminates several disadvantages of the myocutaneous flap, including excessive bulk, chest wall deformity, and transposition of hair to the aerodigestive tract. The incidence of partial flap loss ranges from 4 to 14% and total flap necrosis from 1 to 7%.[7]

The pectoralis major myocutaneous flap continues to play an important role in head and neck reconstruction, reflecting its versatility, reliability, and ease of harvest.

Trapezius Myocutaneous Flap The trapezius is a large, broad, flat, triangular muscle of the back and shoulder. It originates on the external occipital protuberance near the nuchal line and spinous processes of C7 to T12 and inserts onto the lateral

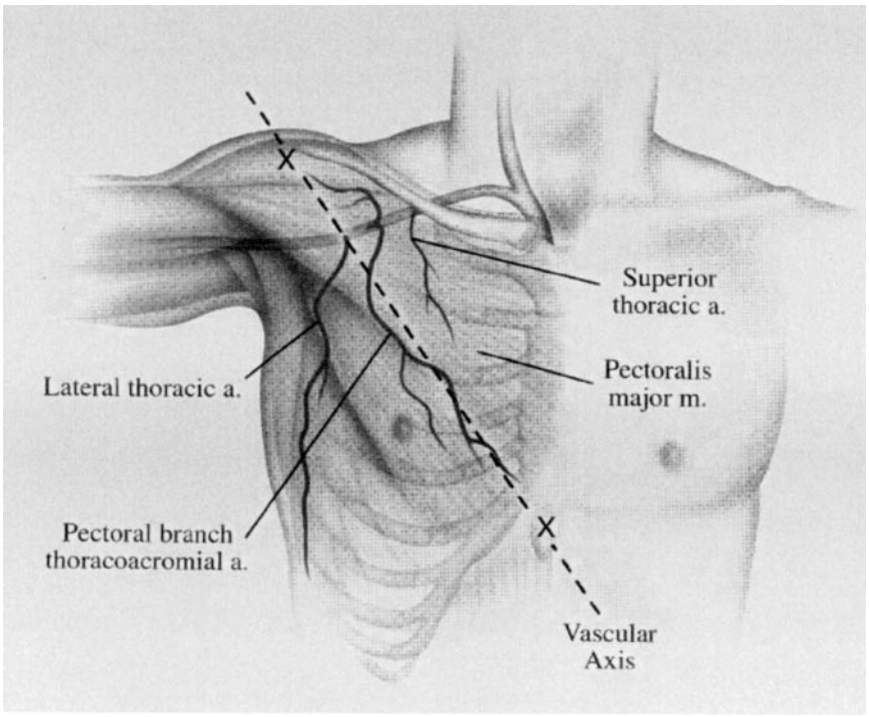

FIGURE 41–3. Illustration of the major blood supply to the pectoralis major myocutaneous flap. Reproduced with permission from Jacono AA, Moscatello AL. Pedicled myocutaneous flaps in head and neck surgery. Oper Tech Otolaryngol Head Neck Surg 2000;11(2).

third of the clavicle, the acromion, and the spine of the scapula. The trapezius acts to steady the scapula. Four arteries, the transverse cervical, dorsal scapular, occipital, and perforating branches of the paraspinous vasculature, supply this broad muscle. Although the transverse cervical is its primary blood supply, collateral circulation allows for the design of three musculocutaneous flaps through different pedicles, the superior flap, island (lateral) flap, and lower (posterior) flap.

The superior flap, first described by Conley in 1972, receives its primary vascular supply from the perforating branches of the posterior intercostal arteries with minor contribution by the occipital branches.[8] This flap requires a simple dissection without the need for identification of the feeding vessels and is useful for closure of ipsilateral regional skin or pharyngeal defects. It is a superiorly based flap and, as such, is not prone to wound separation secondary to gravitational pull (Figure 41–4).

The trapezius muscle is located outside the radiated field and its blood supply is not typically threatened during radical neck dissections.

A major disadvantage is its limited length, preventing the flap from extending across the midline. The most distal portion of the flap, lateral to the acromion, may not survive if the transverse cervical artery has been ligated during a radical neck dissection.[9] In these cases, a delayed procedure may be required to maintain the viability of the distal portion of the flap. The donor site usually requires a STSG.

The lateral island trapezius flap, first presented by Panje[10] and Demergasso[11] in 1978, is based on the transverse cervical vessels (Figure 41–5). This is the least reliable of the three flaps as mobilization is dependent on the course and length of the transverse cervical artery and vein. Both vessels must be patent for this flap to survive, so this flap is not recommended after radical neck dissection in which sacrifice of these vessels often takes place. This flap works well for soft tissue defects of the ipsilateral lateral and anterior neck, oral cavity, and pharynx. The flap itself is technically easy to develop, and the donor-site defect may be closed primarily.

The use of the lower trapezius myocutaneous island flap (LTMIF) was first introduced by Baek et al in 1980.[12] This flap provides the greatest length and arc of rotation and therefore is the most versatile. It is primarily supplied by the transverse cervical vessels, but the dorsal scapular artery feeds the distal portion of the flap. Both arteries usually arise from the thyrocervical trunk, with a great deal of variability in their origin and course. The LTMIF is often based solely on the transverse cervical vessels as the preservation of the dorsal scapular vascular

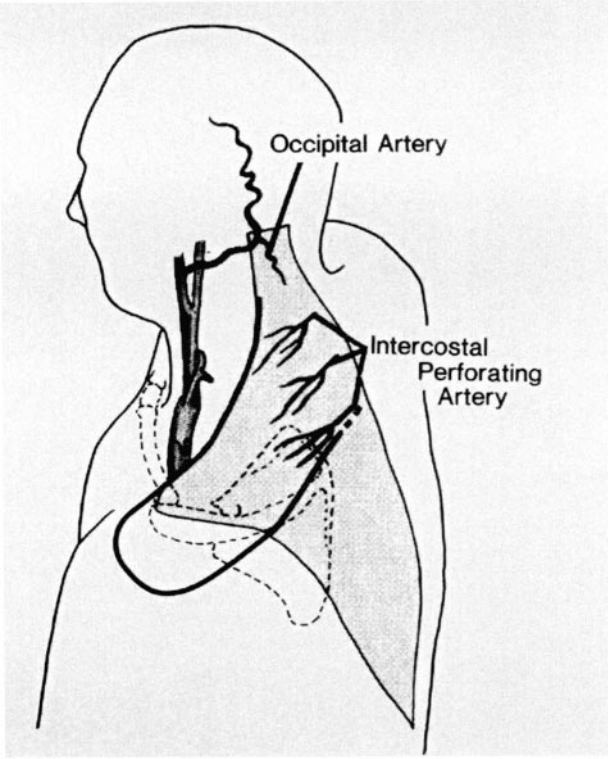

FIGURE 41–4. The superior trapezius myocutaneous flap received its primary blood supply from perforating branches of paraspinous arteries, with minor supplement from the occipital artery. Reproduced with permission from Panje WR, Schuller DE, Shagets FW. Musculocutaneous flap reconstruction of the head and neck. Philadelphia: Lippincott Williams and Wilkins; 1989.

bundle limits the flap's arc of rotation. This may place the distal portion of the flap at risk for partial necrosis, especially if the dorsal scapular artery is a dominant feeding vessel. The skin paddle is designed over the portion of the trapezius muscle bound by the vertebrae and the medial border of the scapula[13] (Figure 41–6).

The LTMIF provides effective coverage for lateral skull base and midface defects. It is a thin, pliable flap with an excellent arc of rotation. The function of the upper portion of the trapezius muscle is often preserved, and the donor defect may be closed primarily.

A significant disadvantage is the need to place the patient in a lateral decubitus position to harvest the flap. A history of prior radiation therapy alone did not affect the rate of flap necrosis, but a higher rate of flap necrosis in patients with a prior history of neck dissection has been noted.[14] Previous radical neck dissection is therefore considered a contraindication to its use.

Sternocleidomastoid Myocutaneous Flap Jianu first reported the sternocleidomastoid myocutaneous flap for facial reanimation in 1908.[15] This muscle originates with two heads and ascends obliquely to insert onto the lateral surface of the mastoid process and into the lateral half of the superior nuchal line. The sternocleidomastoid muscle receives its blood supply from the occipital, superior thyroid, external carotid, and suprascapular arteries.[16] The flap is harvested as a superiorly or inferiorly based flap and may incorporate a portion of the clavicle when used for mandibular reconstruction.

Since its initial description, it has not been overwhelmingly embraced. It is the least reliable of all pedicled flaps.[17] Its random pattern blood supply with the associated tenuous perfusion to its cutaneous portion results in a higher rate of failure.

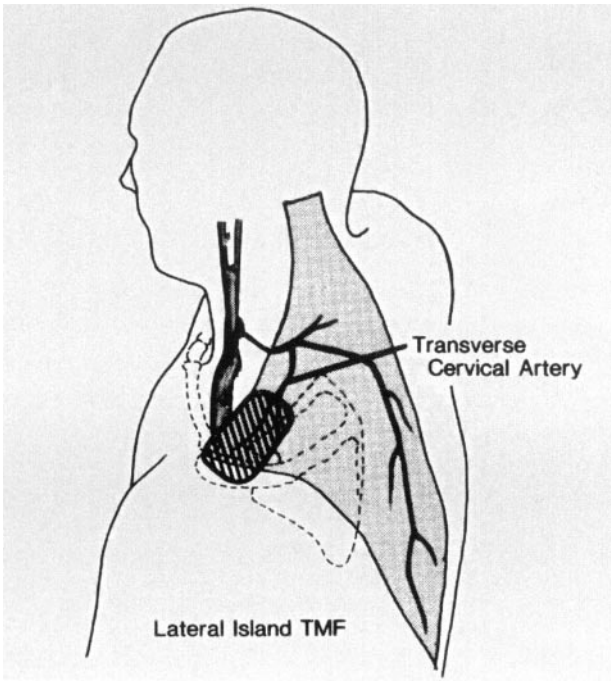

FIGURE 41–5. Transverse cervical artery through its superficial branch provides the primary blood supply to the island trapezius musculocutaneous flap. Reproduced with permission from Panje WR, Schuller DE, Shagets FW. Musculocutaneous flap reconstruction of the head and neck. Philadelphia: Lippincott Williams and Wilkins; 1989.

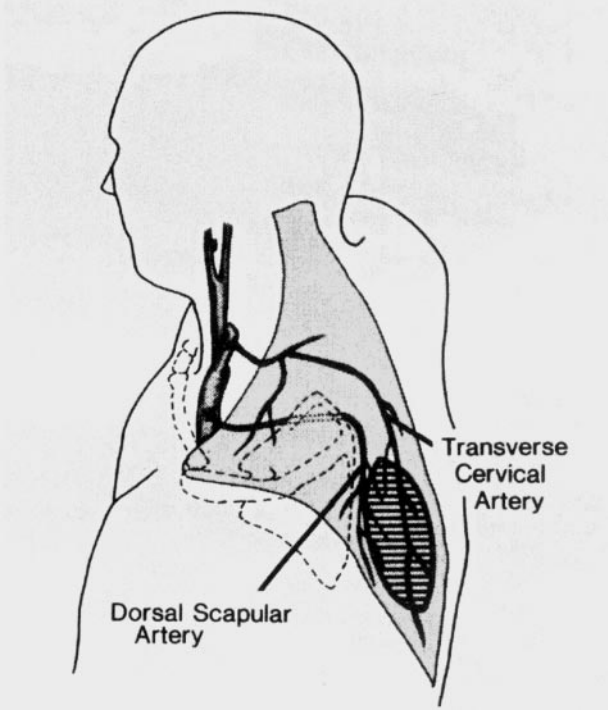

FIGURE 41–6. The lower trapezius myocutaneous island flap receives its primary blood supply from the descending branch of the transverse cervical artery with the dorsal scapular artery contributing to the distal portion of the flap. Adapted from Panje WR, Schuller DE, Shagets FW. Musculocutaneous flap reconstruction of the head and neck. Philadelphia: Lippincott Williams and Wilkins; 1989.

Sebastian et al reported an incidence of total flap loss of 7.5% and superficial skin loss of 22.7% in his large series.[18] This flap is not recommended in previously irradiated necks, and oncologic principles should not be compromised while preserving the sternocleidomastoid muscle for which nodal disease dictates a more radical procedure.[18] Therefore, the sternocleidomastoid myocutaneous flap has limited use but may be applicable for small oral and laryngopharyngeal defects.

Deltopectoral Flap Bakamjian popularized the use of the deltopectoral flap in 1965, and it remained the flap of choice for head and neck reconstruction until pedicled myocutaneous flaps and free flaps were introduced.[3] This thin flap is easy to harvest and leaves no functional deficit.

It is a fasciocutaneous flap based on the perforating branches of the internal mammary arteries. The vessels of the flap run in a plane superficial to the pectoralis major and deltopectoral muscle, requiring the flap to be elevated in a subfascial plane. Limiting elevation to within 2 cm of the sternal border prevents disruption of the feeding vessels. The deltoid branch of the thoracoacromial artery and the anterior circumflex humeral artery supplies the distal portion of the flap overlying the deltoid muscle.

The risk of flap necrosis increases as the flap is extended over the deltoid region, often requiring a delayed procedure. In some series, the rate of flap necrosis reached 25%.[19] To minimize this risk, Kingdom and Singer modified this dissection to include the first four perforators while limiting the medial dissection to the nipple line.[19] In addition, a retention suture is placed at the pivot point, counteracting the gravitational pull on the flap.[20] With these modifications, no major flap loss was reported, and only minor flap necrosis was noted in less than 20% of their cases.[19] Previous radiation or radical neck surgery does not impact the survival of the flap.[3,19] The donor-site defect requires coverage with a skin graft.

Pedicled myocutaneous flaps and free flaps are currently the method of choice over the deltopectoral flap for the reconstruction of oral cavity and pharyngeal defects; the deltopectoral flap continues to be an excellent method for cervical skin and soft tissue defects and remains a viable option for mucosal defects (Figure 41–7).

Temporalis Muscle Flap The temporalis muscle flap was first described by Verneuil in 1872 for interposition arthroplasty in temporomandibular joint ankylosis.[21] Since then, this flap has been used for augmentation of regional tissue defects, for the reconstruction of palatal defects, and to provide reanimation of unilateral facial paralysis.[22]

This fan-shaped muscle arises from the inferior temporal line, fills the entire temporal fossa, and inserts onto the coronoid process of the mandible. The deep temporal artery provides its vascular supply. The anterior third of the muscle is thicker, whereas the middle and posterior thirds are longer and thinner. These qualities make the central portion of the flap useful for facial reanimation. The muscle and periosteum are harvested down to the zygomatic arch and can be detached from the arch and coronoid process to increase the arc of rotation. The inferior rotation of the flap over the zygomatic arch will distort the facial contour. This problem is

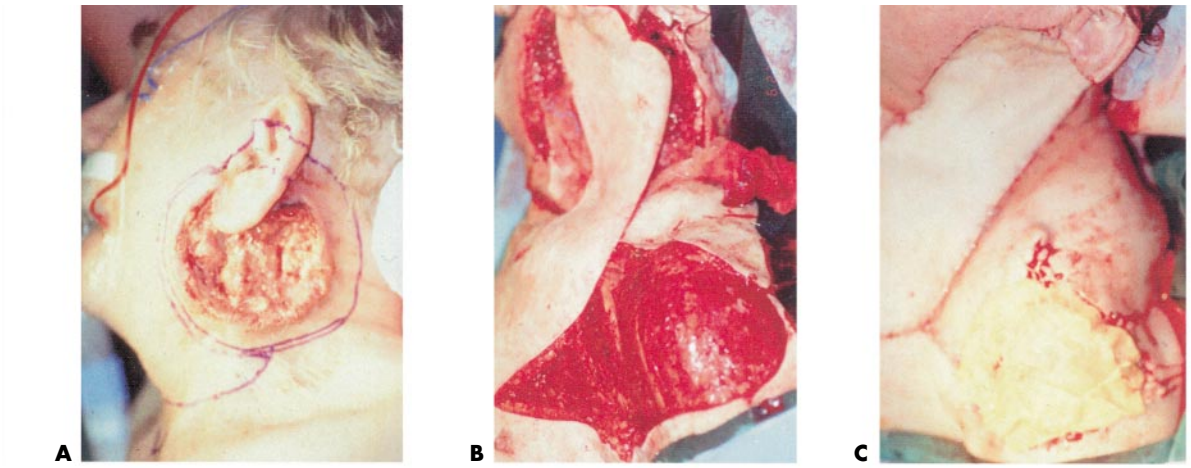

FIGURE 41–7. *A*, Squamous cell carcinoma of the parotid with skin exposure. *B*, Deltopectoral flap raised and rotated into the defect. *C*, The deltopectoral flap is inset into the cervical defect. Xeroform bolster placed over the split-thickness skin graft.

solved by detaching the zygomatic arch prior to rotation of the flap and then reattaching the arch with reconstruction plates.[23]

A major complication of the temporalis muscle flap is injury to the frontal branch of the facial nerve. Clauser et al noted an incidence of 19.2% transient paresis and 2.7% permanent paralysis.[22] Fibrosis of the retromolar trigone region has been experienced in oropharyngeal reconstruction and is best managed with postoperative jaw opening exercises.[22]

This flap is reliable but has a limited role beyond facial reanimation. Its primary use is to cover small to moderate-sized defects of the orbit, lateral aspect of the face, and lateral part of the skull base.

Temporoparietal Fascial Flap The temporoparietal fascia can be used as a pedicled or free flap. This thin, pliable flap may resurface a significant area without bulk.

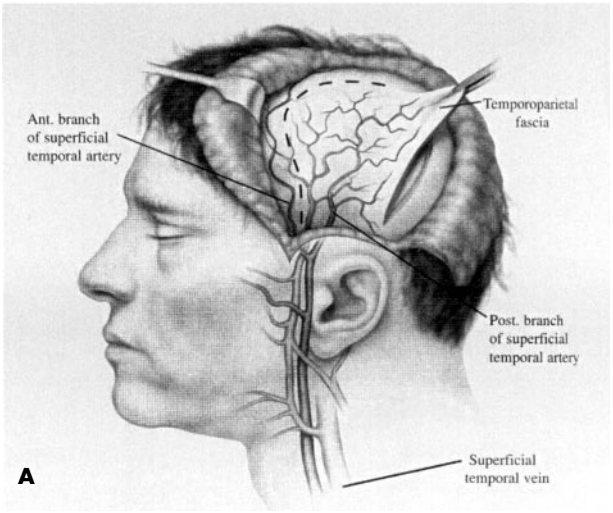
This fascia is the superficial covering that overlies the temporalis muscle and continues on as the superficial aponeurotic system inferiorly and the galea aponeurosis superiorly. Its vascular supply arises from the superficial temporal artery and vein and may be isolated 3 cm superior to the root of the helix prior to its division into an anterior and a posterior branch. The anterior branch, which extends into the frontal region, is often ligated 3 to 4 cm from its takeoff. Further peripheral dissection risks injury to the frontal branch of the facial nerve. The posterior branch, which extends into the parietal region, acts as the distal vascular pedicle (Figure 41–8). Dissection of the vascular pedicle is best monitored with intraoperative Doppler ultrasonography. The auriculotemporal nerve runs with the vascular pedicle and is usually sacrificed, leading to temporal numbness.

The donor site is well hidden within the hairline, creating minimal morbidity. Alopecia is occasionally produced.

This well-vascularized fascial flap is useful for resurfacing the orbit, midface, and lateral oral defects and is available for auricular reconstruction. The flap may include the overlying hair-bearing skin to reconstruct a brow and mustache.[24] The inclusion of a split calvarial bone graft with overlying galea aponeurosis creates a composite flap for the reconstruction of the orbit or zygoma.

Platysma Myocutaneous Flap The platysma myocutaneous flap has several advantages for use in oral cavity reconstruction.[25] It is located within the surgical field, easy to elevate, and pliable and has minimal donor-site morbidity.

This flap is created from the broad sheet of muscle that arises from the fascia covering the upper parts of the deltoid and pectoralis major muscles. It ascends across the clavicle and up the neck, reaching the lower border of the mandible and lateral half of the lower lip. The platysmal myocutaneous flap



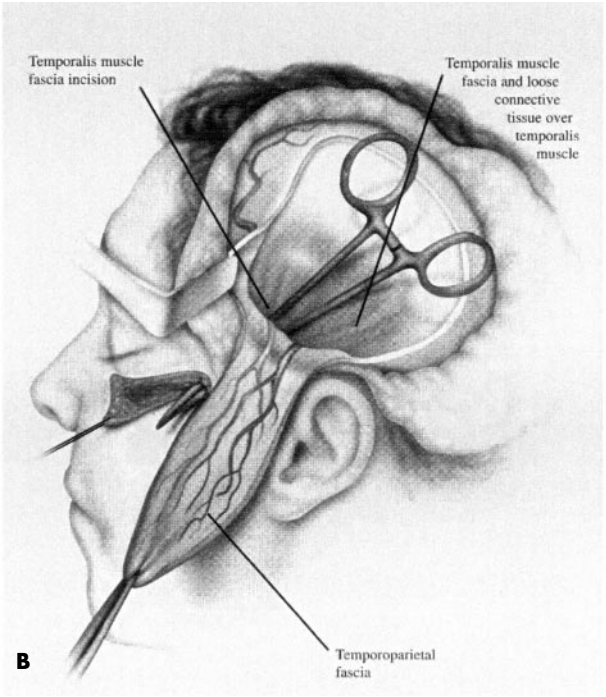


FIGURE 41–8. *A*, The posterior branch of the superficial temporal artery is usually the axial artery to the temporoparietal fascial flap. The superficial temporal vein usually accompanies it but can vary in relative position to the artery or even be completely absent. The incision sometimes requires a posterior T-extension of the vertical opening to maximize exposure. *B*, The temporoparietal flap has excellent range, as demonstrated here. The hemostat shows the safe tunnel made under the deep temporalis fascia over the muscle from the donor site to the subciliary incision. This maneuver allows protection of the facial nerve. Reproduced with permission from Friedman M. Operative techniques in otolaryngology-head and neck surgery—flaps for head and neck reconstruction. Part 1. Philadelphia: WB Saunders; 2000.

receives its blood supply from the submental branches of the facial artery. The platysmal myocutaneous flap can be used even if the ipsilateral facial artery is ligated as long as the submental branch distal to the submandibular gland is patent.[25,26]

This flap is not recommended in necks that have been irradiated or have undergone previous neck dissections.[26,27] A relative contraindication is the presence of ipsilateral facial paralysis because of atrophy of the muscle.[28] A high incidence of complication in patients who received neoadjuvant chemotherapy was noted by Verschuur et al.[25]

Indications for platysma myocutaneous flaps are in the reconstruction of a relatively small floor of mouth, gingival, and oropharyngeal defects not requiring bulk.

Latissimus Dorsi Myocutaneous Flap Quillen et al first described the latissimus dorsi myocutaneous pedicled flap for head and neck reconstruction in 1978.[29] This thin flap, with its large surface area, is extremely versatile for several reasons. Its size provides coverage of massive defects of the orbitomaxillary and lateral skull base region in a single-stage procedure without excessive bulk. The length of the pedicle enables it to reach nearly any area of the head and neck, and the pedicle may also be transferred as a free flap. Dynamic, sensate reconstruction after total glossectomy has been achieved by adding a hypoglossal-thoracodorsal nerve graft.[30]

The latissimus dorsi is a large, flat, triangular muscle that sweeps over the lumbar region and lower thorax. It arises from the posterior iliac crest, thoracolumbar fascia, external oblique fascia, and lower six vertebrae. It inserts into the intertubercular groove of the humerus. This muscle acts to adduct, extend, and medially rotate the humerus. Its blood supply is from the thoracodorsal artery. After the subscapular artery has branched to give off the circumflex scapular artery, it continues as the thoracodorsal artery. There it is joined by the vein and thoracodorsal nerve, which provides the muscle's

motor innervation. This neurovascular bundle enters the muscle at a single neurovascular hilum on its internal (costal) surface 6 to 12 cm from the subscapular artery and 1 to 4 cm medial to the lateral border of the muscle.[29] The artery gives off one to three large branches to the serratus anterior muscle before dividing at the hilum to supply the latissimus. The long thoracic nerve provides cutaneous sensory innervation. The vascular supply of the latissimus dorsi muscle is not affected by prior radiation. Reconstruction can be performed employing either a pedicled or free flap technique with equally high success rates[30] (Figure 41–9).

The flap does have some disadvantages. A lateral decubitus position is needed to harvest this flap, creating a need for intraoperative repositioning. In addition, when pedicled, the flap is passed through the axilla between the pectoralis major and minor muscles.

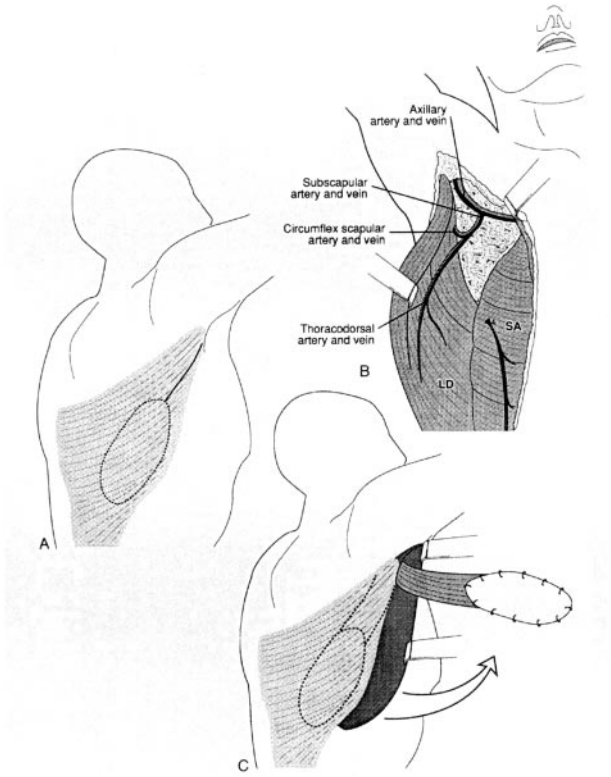

FIGURE 41–9. The latissimus dorsi myocutaneous flap: *A*, flap design; *B*, flap dissection; *C*, rotation of flap. Reproduced with permission from Shindo ML, Sullivan MJ. Muscular and myocutaneous pedicled flaps. Otolaryngol Clin North Am 1994;27:166.

Postoperatively, this puts the vascular pedicle at risk of compression in the region of the anterior axilla by the upper arm. The reconstructive surgeon needs to be familiar with the anatomy of the axilla, the axillary vessels, and their variations. Finally, owing to the shoulder dysfunction that may arise, this flap should be avoided if the trapezius muscle, pectoralis major muscle, or spinal accessory nerve has previously been compromised.[23,31]

In summary, this is a reliable and versatile flap that works well as a pedicled or free flap. It may provide coverage to distant areas, such as the scalp, lateral part of the skull base, and orbitomaxillary region, where a flap with a large surface area is required. It is also an excellent option for dynamic reconstruction after total glossectomy.

Gastric Pull-up The gastric pull-up plays an important role in reconstruction of total pharyngoesophageal defects when the tumor extends into the cervical esophagus. The gastric pull-up allows for single-stage reconstruction with good oral rehabilitation. The gastric tube is a well-vascularized flap that may be used in a previously irradiated or operated field. The technique requires a general surgical team to mobilize the stomach and to create the gastric tube. Posterior mediastinal dissection is performed through both the diaphragm and a cervical approach (Figures 41–10 and 41–11). With adequate mobilization, the distal portion of the flap may reach the soft palate. The flap is contraindicated in patients with severe pulmonary and hepatobiliary disease. Mortality rates as high as 18% and an incidence of severe complications reaching 50% have been reported.[32,33] The morbidity and mortality can be decreased to acceptable levels in carefully selected patients.

Free Flaps

Although microvascular free tissue transfer was introduced in the 1970s, it was not until the late 1980s that free flaps became popular. Pedicled regional flaps dominated the 1980s, reflective of their ease of use with shortened operative time while eliminating the skills required in microvascular surgery.

The use of microvascular free tissue transfer blossomed in the late 1980s and has become one of the primary reconstructive modalities in head and neck surgery. Flap survival rates ranging from 91 to

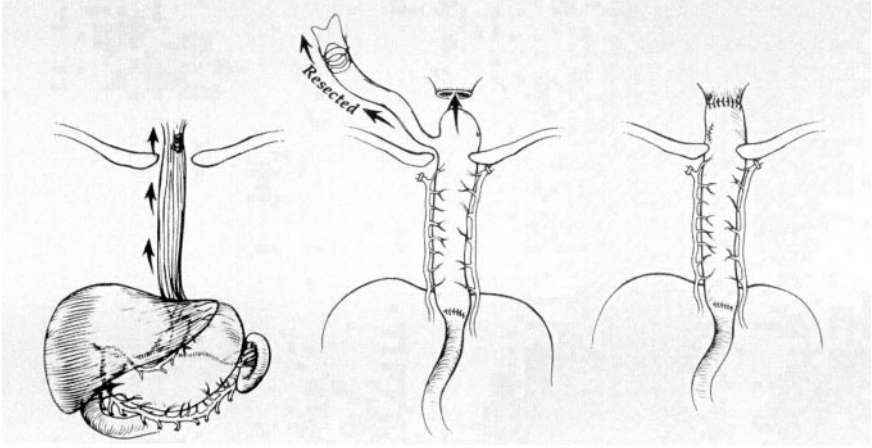

FIGURE 41–10. Technique of gastric pull-up. Reproduced with permission from Schusterman MA, Shestak K, deVries EJ, et al. Reconstruction of the cervical esophagus: free jejunal transfer versus gastric pull-up. Plast Reconstr Surg 1990;85:17.

99% are routinely achieved, reflecting a more predictable axial blood supply.[34,35] Free tissue transfer also allows for more donor-site options relating to size, thickness, and the need to include bone or innervation potential. Single-stage reconstruction was now possible in defects that had previously required a delayed procedure. Prior radiation did not affect flap survival.[36,37]

The success of free tissue transfer goes far beyond designing of flap dimensions. It requires

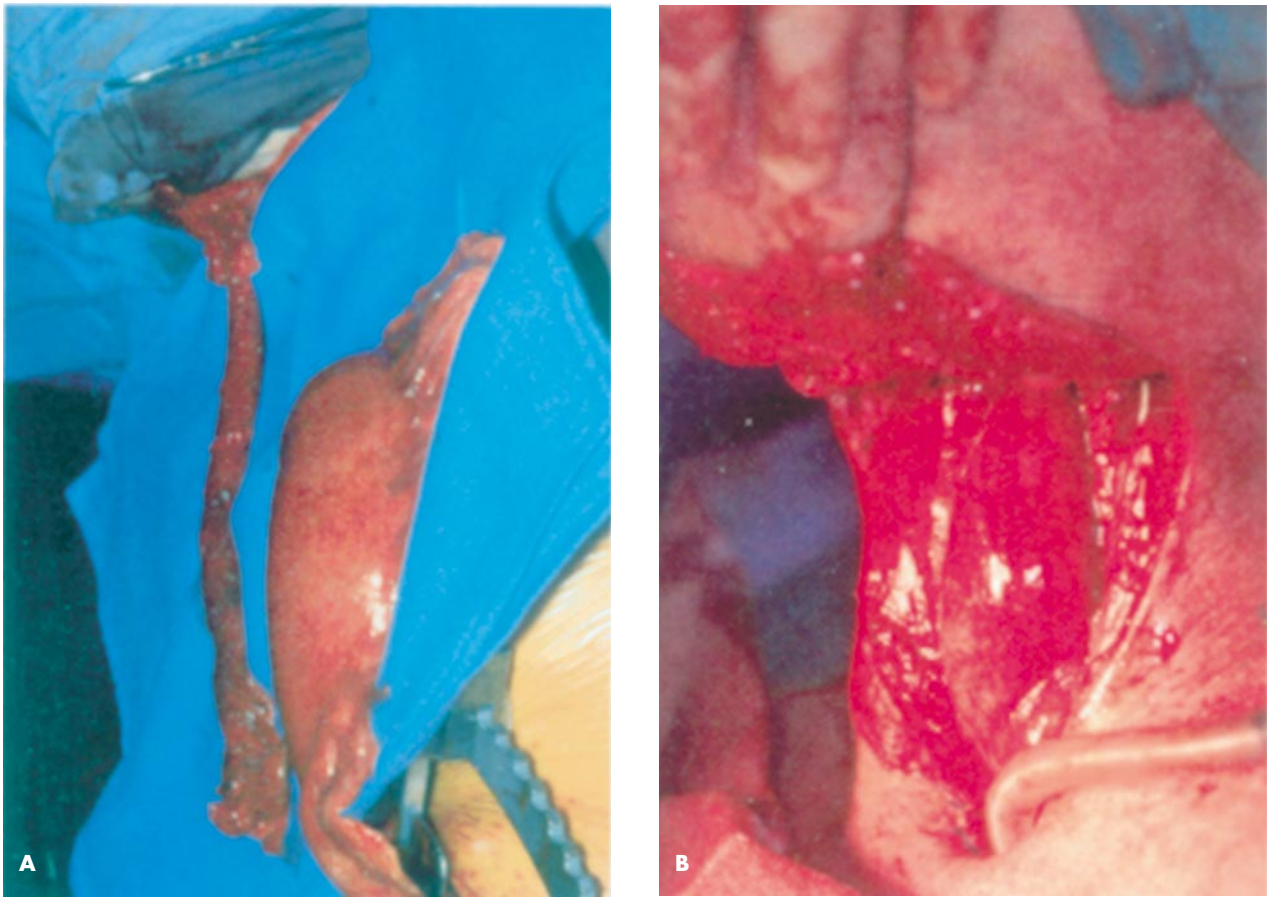

FIGURE 41–11. A, Proximal esophagus resected en bloc with hypopharynx. Note the mobilized gastric tube. *B*, Gastric tube in place. Note the pharyngogastric anastomosis.

careful planning and begins with an understanding of both the donor-site vascular pedicles and recipient-site vessel options. Careful harvest of the nutrient vascular pedicle is required, taking into account the length of pedicle needed to prevent tension on the vascular anastomosis while avoiding excessive length, which might result in twisting and kinking. The highly vascular nature of the head and neck region normally provides a plethora of recipient vessels to choose from. Previous or associated surgical resection required in a neck dissection may severely limit recipient vessel options. Prior radiation to the neck may lead to atherosclerosis of the recipient artery.[38] Determination of the length of the vascular pedicle and choice of recipient vessels are ultimately made at the time of resection and reconstruction.

The most critical aspect of microvascular reanastomosis is the accurate apposition of the cut edges of the vessels and maintenance of intimal continuity. The venous anastomosis is typically more demanding technically, given the thin and delicate walls of veins, and may lead to venous thrombosis, the most common cause of flap failure. The critical period for venous thrombosis is the first 3 to 5 days.

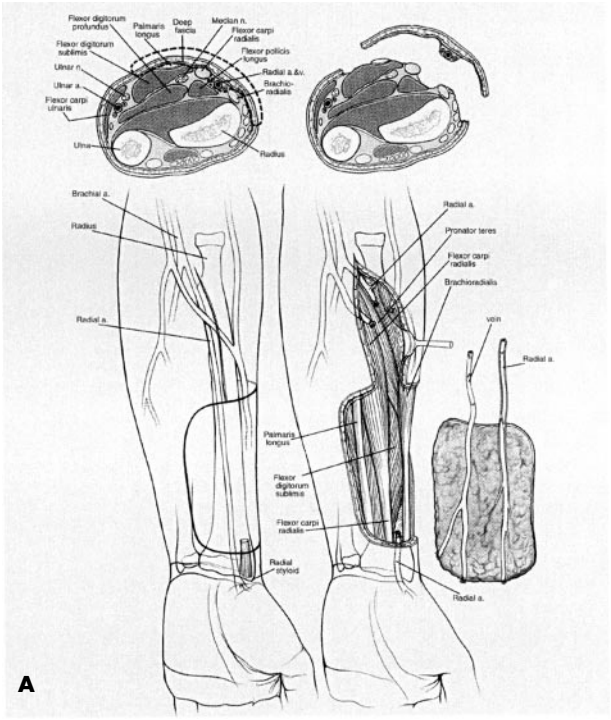
A variety of choices are generally available in the neck for recipient vessel selection, although it does partially depend on the region to be reconstructed. The most common choices for recipient arteries are the ipsilateral lower branches of the external carotid artery or branches of the thyrocervical trunk.[38] When ipsilateral recipient vessels are not available, contralateral neck vessels may be used as an alternative option. Interposition vein grafts may be necessary if the pedicle length is inadequate.[38] The primary recipient veins are the external and internal jugular veins and the transverse cervical vein. When these options are not available on the ipsilateral neck, the contralateral neck veins would be the next alternative.[38]

Some have raised the question of cost effectiveness in the use of microvascular free tissue transfer. Several studies have shown that the cost of free flaps is ultimately comparable to pedicled regional flaps. This slightly higher cost is more than offset by the superior functional results and lower complication rates.[39,40]

Radial Forearm Free Flap The radial forearm free flap is the most frequently chosen free flap for head and neck reconstruction. This pliable, robust flap has the ideal thinness for pharyngeal, palatal, and floor-of-mouth defects. With the addition of sensory reinnervation, it has become quite useful for tongue and hemilaryngopharyngeal reconstruction.

This flap is harvested from the volar surface of the forearm. The vascular supply is the radial artery and the cephalic vein or the venae comitantes (Figure 41–12).

Although a composite bone graft can be obtained by adding a portion of the radius, no more



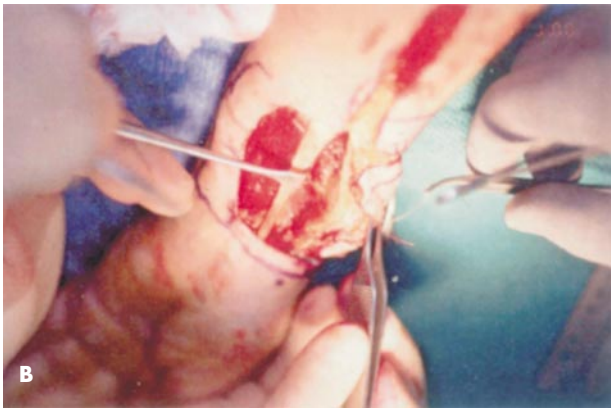


FIGURE 41–12. A, Pictorial representation of radial fasciocutaneous flap. Reproduced with permission from Silver CE, Rubin JS, editors. Atlas of head and neck surgery. Philadelphia: Churchill Livingstone; 1999. *B*, Intraoperative harvest of radial forearm free flap.

than 40% of the radius can be used without significantly increasing the risk of a radius fracture. Such fractures may adversely affect wrist mobility and hand strength. Because of the small size of this bone graft and the significant morbidity related to the fracture, other composite grafts, such as the fibular and the scapular flaps, are usually better choices when bone is required.

The ability to provide sensation to the flap has also made this flap particularly advantageous in oral cavity and pharyngeal reconstruction. The lateral antibrachial cutaneous nerve, which runs with the cephalic vein, is the nerve most commonly used for reinnervation. The medial antibrachial cutaneous nerve is also available.

The biggest concern with harvesting this flap is adequate perfusion of the hand by the ulnar artery via the palmar arch. It is crucial that the Allen test is properly performed preoperatively to assess the perfusion of the hand by the ulnar artery when the radial artery is occluded. Doppler ultrasonographic evaluation is also helpful in evaluating patency of the ulnar artery. Despite careful preoperative testing, if inadequate perfusion of the hand is discovered, a reverse vein graft can be placed to reconstitute flow through the radial artery.

Complications primarily arise at the donor site. In addition to the risk of radius fracture, failure to raise the flap in a suprafascial plane may lead to poor skin graft take and tendon exposure with subsequent wrist and hand dysfunction.[41]

Lateral Arm Fasciocutaneous Flap The lateral arm flap is a moderately thin and hairless flap. Its main advantage over the radial forearm flap is its minimal donor-site morbidity. The donor site can usually be closed primarily, no immobilization is required, and vascular compromise is not a concern.

This fasciocutaneous flap is centered on the intermuscular septum at the distal half of the lateral part of the upper arm. The flap is supplied by the posterior branch of the radial collateral artery, the terminal branch of the porfunda brachii artery. The vascular pedicle runs with the radial nerve along the anterolateral portion of the brachioradialis muscle and measures 10 to 12 cm. The posterior branch then enters the intermuscular septum. The venous drainage is via the cephalic vein and the venae comitantes. The inferior lateral brachial cutaneous nerve is harvested with the flap to provide sensation to the flap (Figure 41–13).

The primary limitation for this flap is the small caliber of the vascular pedicle with its associated decreased survival rate.[23]

Lateral Thigh Fasciocutaneous Flap The lateral thigh flap is a lower extremity version of the lateral arm flap while providing a much larger surface area. Hayden and Dreschler have described harvesting a graft measuring 27 × 14 cm; however, the exact limits of the graft size have not been established.[42] This flap has been used successfully in reconstructing total laryngopharyngectomy and total glossectomy defects and may effectively resurface large soft tissue defects in the cervical region. The donor site is usually closed primarily leaving an esthetically acceptable linear scar with minimal donor-site morbidity.

The skin paddle is centered over the intermuscular septum, which separates the vastus lateralis and the iliotibial tract anteriorly from the biceps

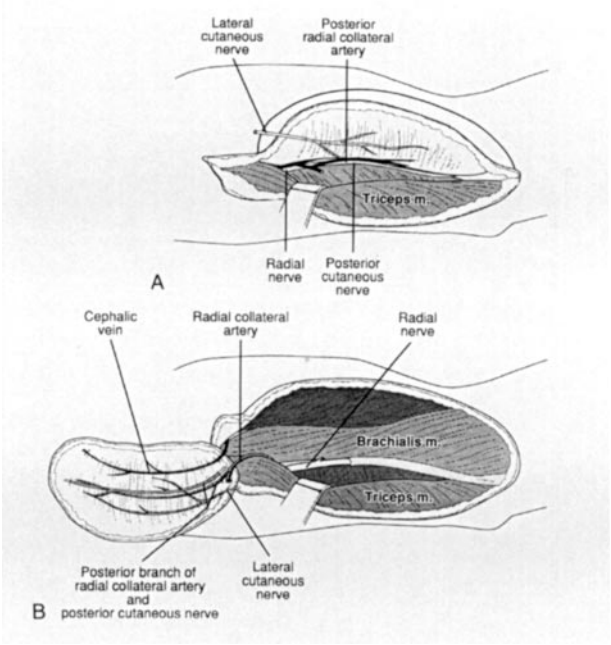

FIGURE 41–13. The lateral arm flap. *A*, Initial elevation of the posterior flap and identification of the vascular pedicle. *B*, The entire flap elevated and pedicled on the radial collateral artery. femoris posteriorly (Figure 41–14). It can be roughly located by drawing a line from the greater trochanter to the lateral epicondyle. The third perforator of the profunda femoris artery, which is usually the dominant vascular supply to the flap, can be found emerging from the septum at the midpoint of this line. Although the third perforator is usually the dominant blood supply, any one of the second to fourth perforators may prove to be the dominant vessel. A sensate flap can be obtained by harvesting the lateral femoral cutaneous nerve.

Preoperative evaluation is extremely important. If peripheral vascular disease exists, another donor site should be chosen. Because the thickness of the flap depends on the body habitus of the patient, the donor site must be carefully evaluated to match the needs of the recipient defect. This flap is rarely used in obese patients.

The complication rate compares favorably to other more commonly used free and pedicled flaps.[42] Donor-site morbidity includes seroma formation and compartment syndrome. The risk of compartment syndrome has been significantly minimized by wide undermining to avoid excessive tension and use of an active drain.

Latissimus Dorsi Free Flap The latissimus dorsi flap can be harvested as a pedicled or free flap. Although the pedicled flap can reach up to the orbitomaxillary and lateral skull base lesions, the free flap allows coverage of large scalp and cranial defects anywhere on the calvarium.

The anatomy of this flap was discussed earlier in the pedicled regional flaps section.

A vascular pedicle as long as 12 cm can be obtained by dissecting up to its takeoff from the axillary vessels.

As with the pedicled version, a lateral decubitus position is required in its harvesting. In addition, donor-site morbidity with shoulder dysfunction may develop.

Rectus Abdominis Free Flap The popularity of the rectus abdominis free flap relates to its ease to harvest, long vascular pedicle, and excellent reliability, with a success rate as high as 97.5%.[43] It provides a large surface area and bulk, making it particularly useful in extensive skull base defects. It is also effective in covering the orbitomaxillary regions and reconstructing total glossectomy defects. The bulk of the flap depends on body habitus. The flap can be harvested using the entire rectus as a small single island flap or as multiple skin islands. Attempts at a sensate flap have generally not been successful.

The flap is thicker inferiorly and then thins out superiorly above the costal margin.

The rectus abdominis muscle arises from the pubic crest and symphysis pubis and inserts into the fifth to seventh costal cartilages. The muscle is enveloped anteriorly and posteriorly by the rectus

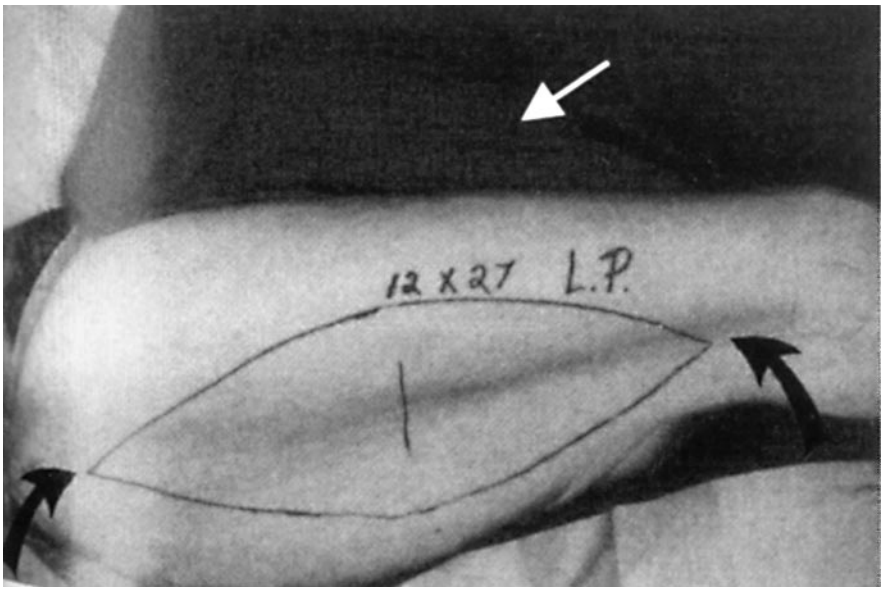

FIGURE 41–14. Preoperative planning of lateral thigh free flap harvest. The axis of the flap is based on the posterolateral intermuscular septum (*arrows*). Reproduced with permission from Hayden RE, Desch DG. Lateral thigh free flap for head and neck reconstruction. Laryngoscope 1999;109:1490.

sheath. It has two dominant vascular pedicles, the deep inferior epigastric and the superior epigastric vessels. The two vascular systems anastomose in the region above the umbilicus through a system of small caliber vessels called "choke vessels."[44] The deep inferior epigastric artery, with its large vessel diameter, is the preferred vascular pedicle for harvest. It gives rise to the major musculocutaneous perforators and thus supplies a larger area of skin (Figure 41–15, A). The largest concentration of cutaneous perforators is located in the paraumbilical region, with the cutaneous vessels radiating superiorly and laterally toward the costophrenic angle. The flap is designed to capture these perforators (Figure 41–15, B). The pedicle length can be extended up to 15 cm. The deep inferior epigastric artery and vein can be found entering the lateral border of the rectus muscle halfway between the pubis and umbilicus, about 3 to 4 cm below the arcuate line. Topographically, the arcuate line is located approximately at the level of the anterior superior iliac spine. The arcuate line is an important anatomic marker, not only to identify the vascular pedicle but also to identify the transition zone where the posterior sheath is composed of all three aponeuroses of the oblique muscles superiorly and only the transversalis fascia inferiorly. This creates a potential weak area below the arcuate line that puts it at risk for a ventral hernia if the anterior sheath is not carefully reapproximated in this region.

Donor-site morbidity is a major limitation, and this includes acute pain, ventral hernia, gait disturbance, and paresthesias with radiculopathy.

Contraindications for this flap are previous abdominal surgery, intrapelvic surgery, inguinal herniorrhaphy, and vascular surgery on the iliac system.[23]

Osteocutaneous Composite Free Flaps

Fibular Free Flap The fibula provides the longest bone graft, up to 25 cm, and thus allows reconstruction of the mandible from condyle to condyle. Because it is a non–weight-bearing bone, it can be harvested in its entirety, leaving only a 6 to 7 cm segment proximally and distally. This flap can be raised as a bone-only graft or as a composite graft by adding soft tissue and skin (Figure 41–16).

Several advantages of this flap make it particularly desirable for mandibular reconstruction. The cross-sectional area of the fibula is similar to that of the mandible. Osseointegrated dental implants can be placed primarily to provide masticator function. Finally, the cutaneous portion of the flap can be made sensate by the anastomosis of the lateral sural cutaneous nerve of the calf to the lingual nerve. The sural communicating nerve can also be anastomosed to the inferior alveolar nerve to provide sensation to the lower lip.[45]

The peroneal artery and vein provide the blood supply to the fibula via two routes. The endosteal blood supply is provided by the nutrient vessels that enter the fibula at the junction of the proximal and middle thirds of the bone. Several segmental perforators provide the periosteal blood supply. Thus,

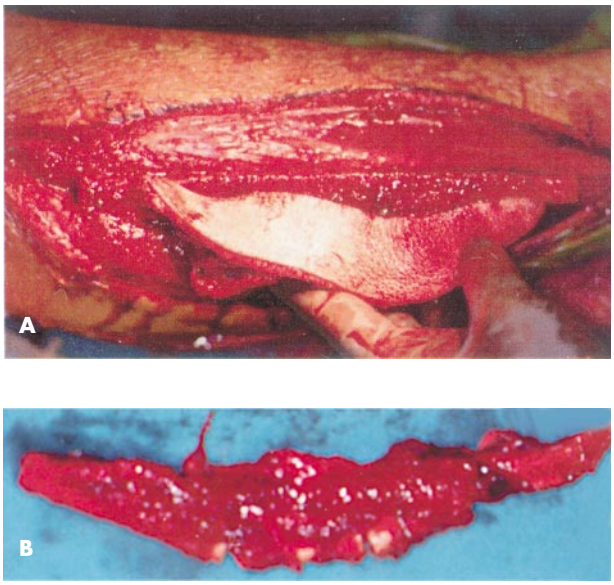

FIGURE 41–16. A, Composite fibula flap with skin, muscle, and bone. *B*, Bone-only fibula flap with osteotomies.

multiple osteotomies can be performed to contour the bone graft without threatening its viability. The septocutaneous perforators and the musculocutaneous perforators through the flexor hallucis longus and soleus muscles provide the vascular supply to the overlying lateral skin. Because of the importance of the musculocutaneous perforators in maintaining skin viability, it is important to harvest a cuff of soleus muscle and the flexor hallucis muscle when obtaining a composite graft (Figure 41–17).

Preoperative assessment of a lower extremity vascular pattern is accomplished with traditional or magnetic resonance angiography. These studies provide crucial information regarding peripheral vascular disease and an anomalous blood supply to the foot, which may be compromised with sacrifice of the peroneal artery.[46,47] A history of lower extremity fracture is a contraindication for this flap.

The most serious donor-site morbidity is the potential vascular compromise to the foot secondary to inadequate collateral flow after the peroneal artery is harvested.[46] This complication can be avoided through appropriate preoperative angiography. Vascular compromise may also occur as a result of an excessively tight closure. Distal pulses should be monitored in the postoperative period. Other donor-site complications include cold intolerance, edema, and weakness in dorsiflexion of the great toe owing to either injury to a branch of the peroneal nerve or scarring of the flexor hallucis longus. The common peroneal nerve should be identified early in the dissection to avoid traction injury, which may lead to an equinovarus deformity and anesthesia along the anterolateral surface of the lower leg and dorsum of the foot. A 6 to 7 cm segment of fibula should be preserved both proximally and distally to preserve the common peroneal nerve proximally and maintain stability of the ankle joint distally. In spite of these precautions, patients may experience pain and weakness on ambulation for several months.[46]

Iliac Crest Free Flap The iliac crest composite graft reflects the natural curve and length of the mandible (up to 16 cm), making it a good option for mandibular reconstruction. This graft provides adequate width and depth for placement of osseointegrated dental implants but does not offer the option of sensate rehabilitation.

The deep circumflex iliac artery supplies the iliac bone and arises from the lateral aspect of the external iliac artery approximately 1 to 2 cm above the inguinal ligament. It gives off the ascending branch to supply the internal oblique muscle. The vascular pedicle runs along the internal aspect of the iliac bone. Thus, osteotomies can be performed on the external cortex to contour the neomandible. The deep circumflex iliac artery gives off several perforators that traverse through the external oblique, internal oblique, and transversalis fascia to provide the blood supply to the overlying skin. The cutaneous perforators exit the external oblique in a zone 9 cm posterior to the anterior superior iliac spine and about 2.5 cm medial to the iliac crest. The skin paddle should be centered on a line drawn from the anterior superior iliac spine to the inferior angle of the ipsilateral scapula. The cutaneous portion makes this flap bulky and limits rotation of the soft tissue. The thin internal oblique can also be harvested to provide intraoral reconstruction by wrapping it around the iliac bone graft and allowing it to mucosalize secondarily. The skin paddle may then be used to reconstruct the external cutaneous defect or to act as an external monitor for flap viability (Figure 41–18).

Donor-site morbidity is the primary limitation. Prolonged donor-site pain and gait disturbances are common.[48]

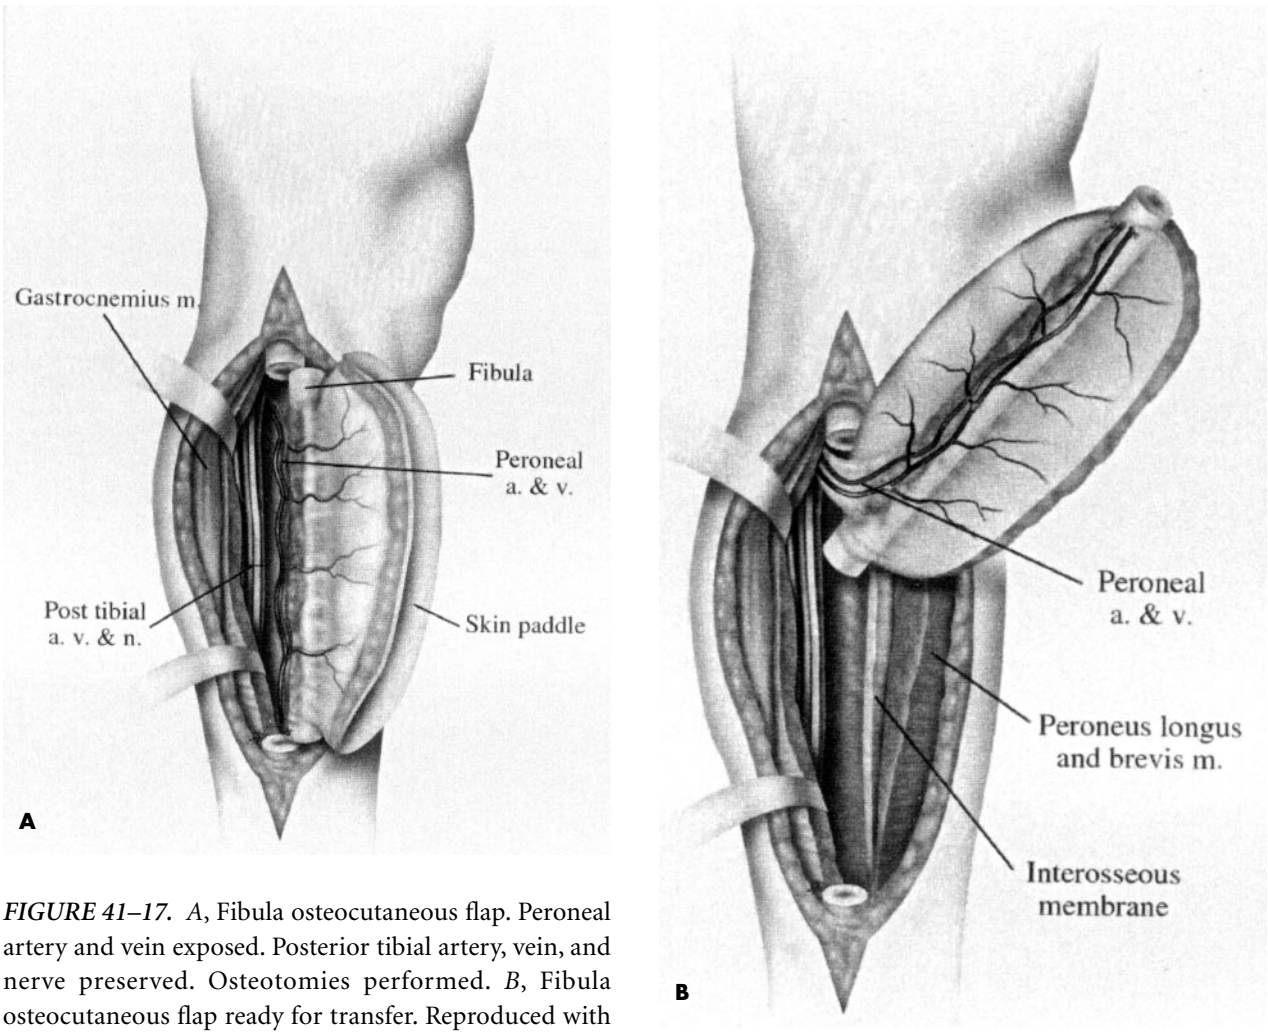

FIGURE 41–17. A, Fibula osteocutaneous flap. Peroneal artery and vein exposed. Posterior tibial artery, vein, and nerve preserved. Osteotomies performed. *B*, Fibula osteocutaneous flap ready for transfer. Reproduced with permission from Friedman M. Scapular and Parascapular Free Flaps This thin, pliable flap provides a tremendous amount of flexibility as a result of the ability to harvest the soft tissue separately from the bone graft and the capacity to rotate these separate flaps in different orientations.

The circumflex scapular artery supplies the majority of the osseous branches to the scapula. The angular artery, a branch of the thoracodorsal artery, supplies the most inferior aspect of the lateral part of the scapula. The scapula receives both an endosteal and periosteal blood supply, but the periosteal component dominates, so the periosteum should be carefully preserved during osteotomies. The terminal branches of the circumflex scapular artery exit through a triangular space bound by the teres major, teres minor, and long head of the triceps lateral to the scapula. One terminal branch divides in the subdermal fascia to send a horizontal branch on which the scapular skin flap is based and an oblique branch on which a parascapular skin flap is based. The vascular pedicle can be extended up to 14 cm by dissecting the pedicle up to its takeoff from the subscapular artery and vein. Previous axillary node dissection is a contraindication for this flap.

The scapular bone is harvested from the lateral border of the scapula 1 cm below the glenoid fossa to the tip of the scapula. The addition of the angular artery and vein allows for the harvest of two bony segments or a single longer segment, up to 12 cm in

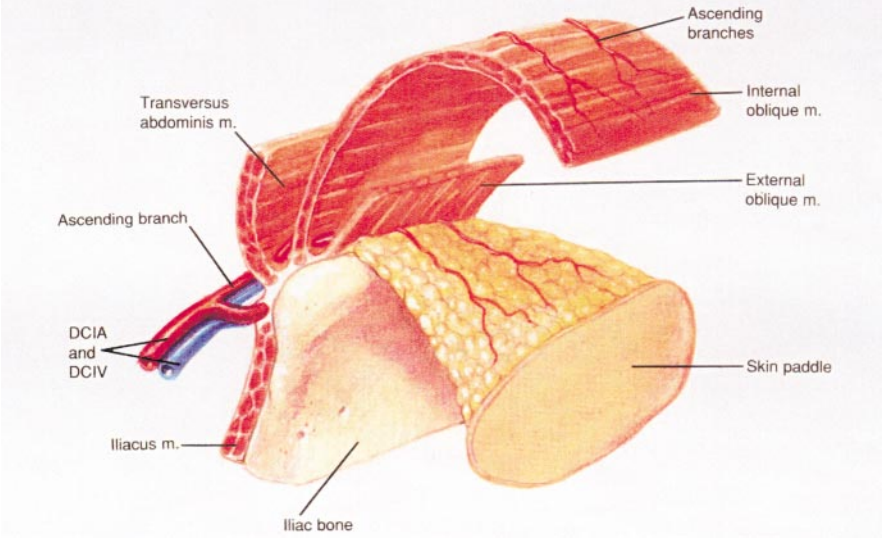

FIGURE 41–18. The tripartite iliac internal oblique osteomusculocutaneous flap. When this flap is inset into the oral cavity for oromandibular reconstruction, it is usually turned 180 degrees so that the crest forms the inferior border of the neomandible. Adapted from Urken ML, Cheney ML, Sullivan MJ, Biller HF, editors. Atlas of regional and free flaps for head and neck reconstruction. Philadelphia: Lippincott Williams and Wilkins; 1995.

length. Despite the fact that the bone is thinner and not as strong as the iliac crest or fibular bone graft, it is still a viable option for mandibular reconstruction and may permit the placement of osseointegrated dental implants. Harvesting this bone does require the detachment and reattachment of the teres major muscle to the remaining scapula to prevent donor-site morbidity. This flap provides a larger surface area of skin for reconstruction than the fibular or iliac crest composite flap. The two skin flaps can also be placed in different three-dimensional orientations since they have separate pedicles and may be used to resurface two contiguous sites (Figure 41–19).[49]

The donor-site defect, which is closed primarily, is located posteriorly, making it cosmetically advantageous. Donor-site morbidity is relatively infrequent and consists of shoulder weakness and diminished range of motion.[50]

Harvesting this flap requires special positioning and makes synchronous two-team surgery difficult.

This flap is well suited for composite defects that require a large amount of soft tissue. Its thinness and pliability also make it quite useful in palatal and orbital floor reconstruction. With de-epithelializing, this flap becomes useful for reconstruction of midface defects.[49]

Visceral Flaps

Visceral flaps provide certain advantages over cutaneous flaps. They provide a thin, pliable mucosal surface that is particularly beneficial in oral cavity

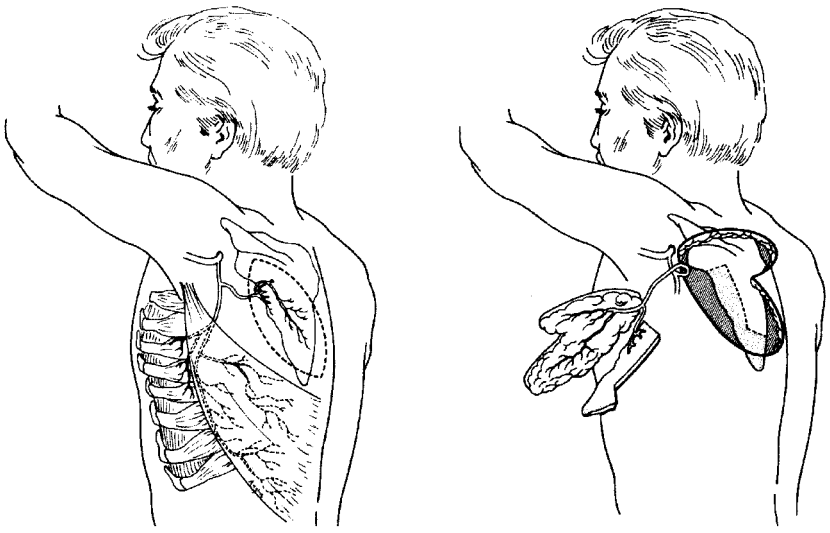

FIGURE 41–19. The lateral border of the scapula received a rich vascular supply from several vessels that leave the circumflex scapular artery near the bone. Since the vascular pedicle to the skin is separate from the pedicle to the bone, 360-degree rotation of the skin paddles around the axis of the one flap is possible. Adapted from Paparella MM, Shumrick DA, Gluckman JL, Meyerhoff WL, editors. Otolaryngology. Vol IV. 3rd ed. Philadelphia: WB Saunders; 1991.

and pharyngeal reconstruction. Because these visceral flaps also secrete mucus, the problems of xerostomia are diminished. In fact, in the early postoperative period, excess mucus production can be a problem. Despite these advantages, violation of the abdomen is required to obtain these flaps. The benefits of the visceral flaps must be balanced with potential intra-abdominal complications such as adhesions, peritonitis, and intra-abdominal abscess. The advent of laparoscopic surgery may provide an optimal method of harvesting these flaps with lessened morbidity.[51–54]

Jejunum Free jejunal transfer in head and neck reconstruction has been widely used for reconstruction of the pharyngoesophagus after total laryngopharyngectomy, and its use has been more recently expanded to encompass reconstruction of the oral cavity and oropharynx.

The jejunum is located just distal to the duodenum and constitutes 25 cm of proximal small bowel (Figure 41–20). The harvest is usually performed from the second loop of jejunum, which is perfused by the superior mesenteric artery. The superior mesenteric artery supplies the jejunum by forming a vascular arcade that divides the jejunum into segments that are based on a single mesenteric artery and vein. An appropriate-sized segment is harvested, along with the segmental vascular pedicle. If a pharyngoesophageal reconstruction is planned, the graft should be marked to differentiate the proximal from the distal end as the graft must be aligned with the jejunum in an isoperistaltic direction. The diameter of the jejunum is similar to the diameter of the proximal esophagus. Proximal anastomosis to the broader base of the tongue requires the jejunum to be bivalved, thereby increasing its circumference. Excessive length of the segment should be avoided to prevent redundancy with its associated stasis and dysphagia. To monitor flap viability during the early postoperative period, a small indicator segment of jejunum is exteriorized. Tracheoesophageal puncture can be performed but provides a wet voice (Figure 41–21).[55]

By opening the jejunum along its antimesenteric border, a patch graft is created.[56] This provides a thin, pliable flap that secretes mucus and resists contraction (Figure 41–22).

Primary contraindications for this procedure involve intra-abdominal pathology, particularly a history of ascites and chronic inflammatory bowel diseases.[55]

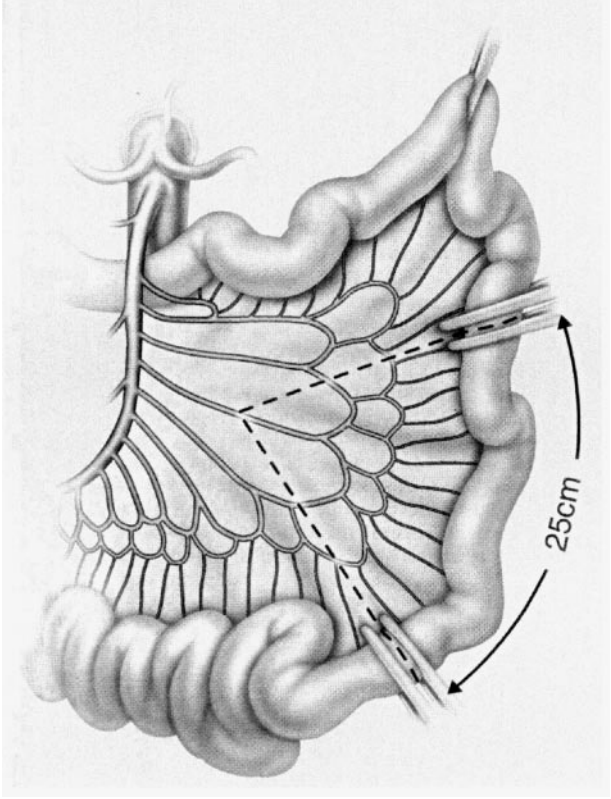

FIGURE 41–20. Jejunum is resected for use as a graft. Reproduced with permission from Friedman M. Operative techniques in Otolaryngology-head and neck surgery—flaps for head and neck reconstruction. Part 1. Philadelphia: WB Saunders; 2000.

Gastro-omental Free Flap A free omental or gastro-omental flap offers a great deal of versatility. This pliable flap may be readily tailored to provide an appropriate amount of bulk. Almost the entire omentum can be safely harvested. Conversely, the omentum can be trimmed away from the vascular system to thin the flap. The gastro-omental flap is ideal for intraoral and oropharyngeal defects. The addition of gastric mucosa provides a thin, pliable tissue with a smooth, mucus-secreting surface. The omental portion can be used to protect the carotid. The omental flap has been used for a variety of defects, taking advantage of these special properties. The omentum provides neovascularization to ischemic tissue through capillary ingrowth.[57,58] Because of this property, the omentum may be used to cover calvarial

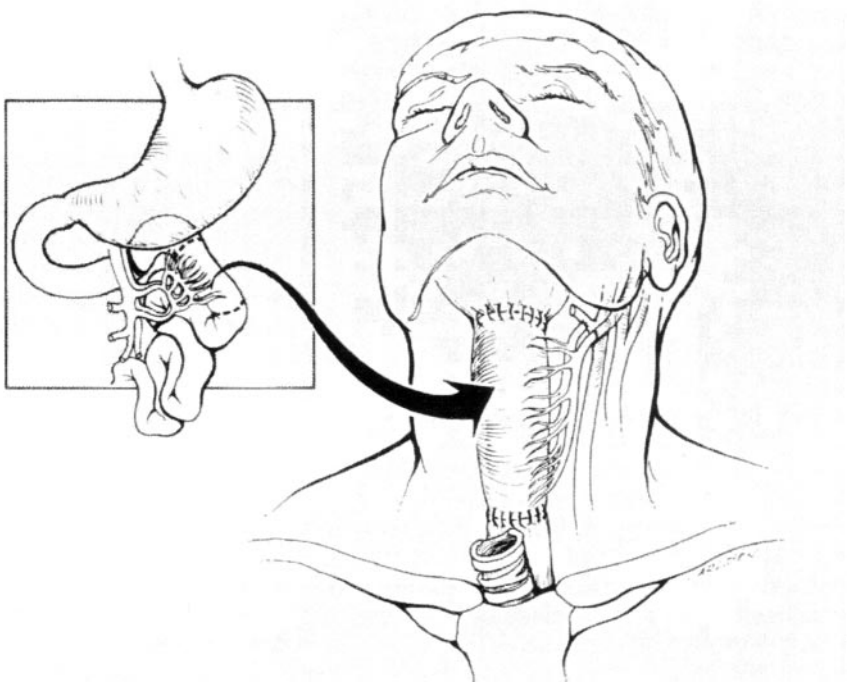

FIGURE 41–21. Technique of free jejunal transfer. Reproduced with permission from Schusterman MA, Shestak K, deVries EJ, et al. Reconstruction of the cervical esophagus: free jejunal transfer versus gastric pull-up. Plast Reconstr Surg 1990;85:17.

grafts or to revascularize areas of osteoradionecrosis and osteomyelitis. The omentum is also well suited for the augmentation of the midface, reflecting its ability to be subdivided into compartments.

The greater omentum is a large, double-layered peritoneum that hangs from its attachments to the greater curvature of the stomach and the transverse colon. The greater curvature of the stomach and the omentum are both supplied by the right and left gastroepiploic arteries. The right gastroepiploic is usually chosen as the pedicle because of its larger vessel diameter and longer pedicle length. This flap is rela-

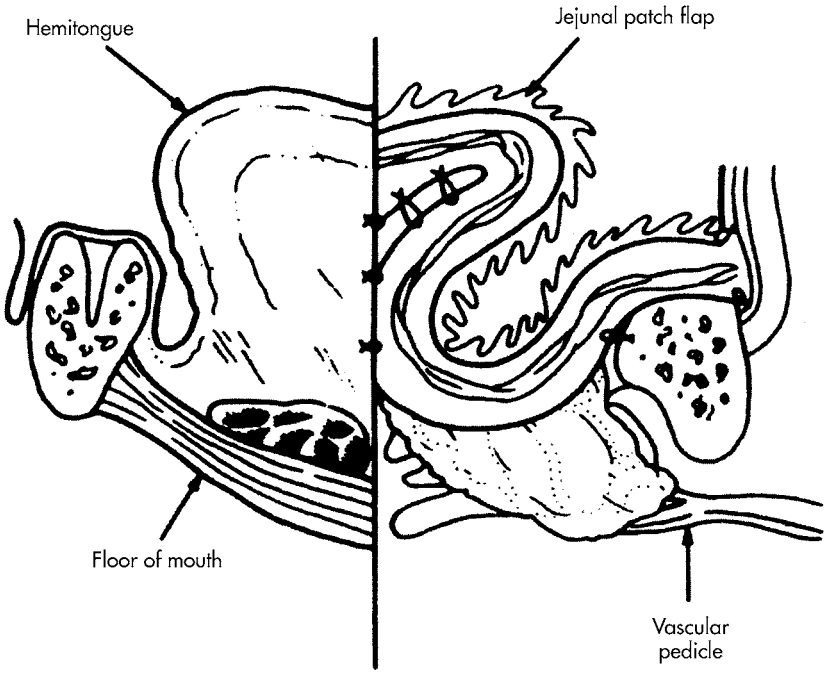

FIGURE 41–22. Schematic diagram showing free jejunal patch flap for reconstruction of hemitongue, floor of mouth, and hemi-mandibulectomy. tively easy to harvest but has the drawback of requiring a laparotomy (Figure 41–23).

This flap is contraindicated in patients with a history of gastric outlet obstruction and peptic ulcer disease.

RECONSTRUCTION OF REGIONAL DEFECTS

Oral Cavity and Pharynx

Reconstruction of the oral cavity and pharynx can be a challenging endeavor, and one must take into consideration the needs for normal deglutition and speech. Small intraoral defects may be allowed to heal by secondary intention. Mucous membrane grafts provide excellent coverage with minimal contracture. Local flaps are useful for the reconstruction of moderate-sized floor-of-mouth defects. Mucous membrane, platysma, and nasolabial flaps are readily available and provide dependable and adequate coverage in most patients. They are associated with few functional and cosmetic consequences and minimal donor-site morbidity.[59]

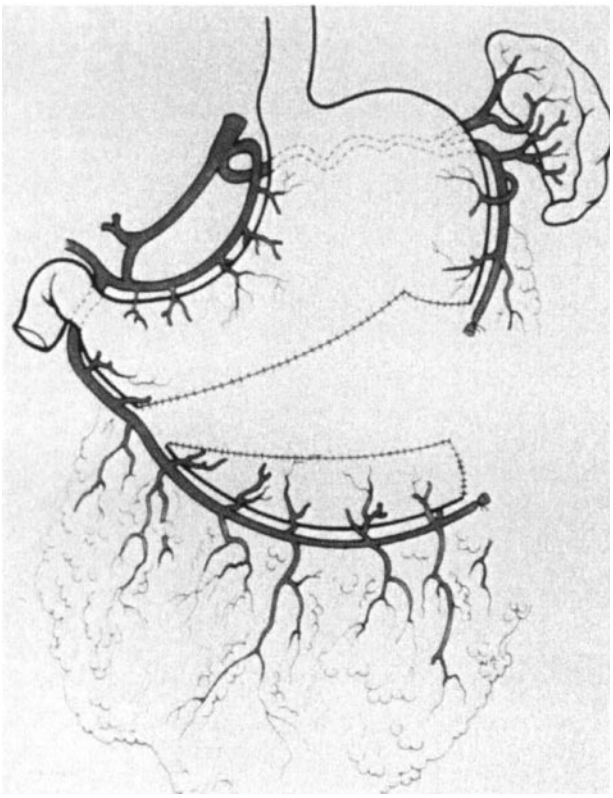

FIGURE 41–23. Schematic view of the free gastro-omental flap being harvested. The left gastroepiploic vessels have been sectioned. A stapling device has been employed to section a piece of the greater curvature from the rest of the stomach. The stomach flap with the omentum is pedicled on the right gastroepiploic vessels. Reproduced with permission from Hayden RE. Microvascular free flaps for soft-tissue defects. Otolaryngol Clin North Am 1991; 24:1343.

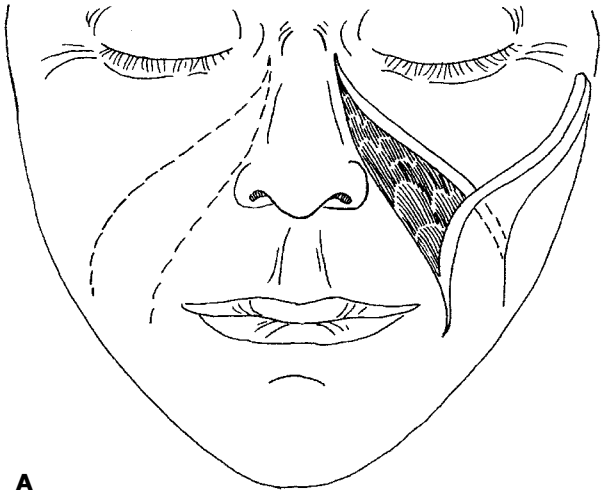
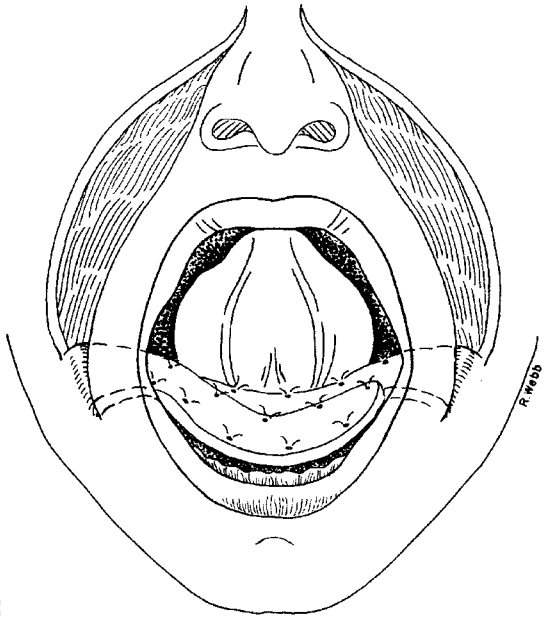
The tunneled, inferiorly based nasolabial flap is well suited for anterior intraoral defects. By using both cheeks as the donor site, up to 25 cm^2 of tissue may be provided for intraoral lining. The blood supply from the labial artery is excellent, making delay unnecessary. The flaps maintain a supple floor of the mouth, allowing for mobility of the remaining tongue. They provide excellent coverage for the exposed mandible after removal of the alveolus or lingual cortex with minimal bulk. Donor-site morbidity is minor, and cosmesis is excellent (Figure 41–24).[59]

Xerostomia is a significant problem with oral cavity cancers that require surgery and radiation therapy. The visceral flaps, including the jejunal patch and gastro-omental flap, have the advantage of providing tissue that continues to secrete mucus, making them appropriate for postradiation failures. These flaps work particularly well in areas for which a thin flap is preferred, such as the floor of the mouth, alveolar ridge, pharyngeal wall, and buccal mucosa. The jejunal flap can be folded in on itself to reconstruct a soft palate defect. Gastro-omental flaps are more appropriate when the oral cavity defect is associated with a large soft tissue neck defect. These visceral flaps may be the only flaps that are thin and pliable in an obese patient.

Large defects of the floor of mouth and oropharynx can be readily reconstructed with a pedicled regional flap. The pectoralis major myocutaneous flap is the flap of choice when a quick reliable flap is desired. A fasciocutaneous modification is appropriate when a large flap with less bulk is required.

Tongue mobility, adequate bulk, and sensation are key factors in planning oral cavity reconstruction. The radial forearm free flap meets these needs and represents the preferred choice for reconstruction after partial glossectomy. In addition, this flap can be bivalved to reconstruct both the tongue and the floor of the mouth. The lateral arm flap is an alternative if the radial forearm is not available.[60,61]





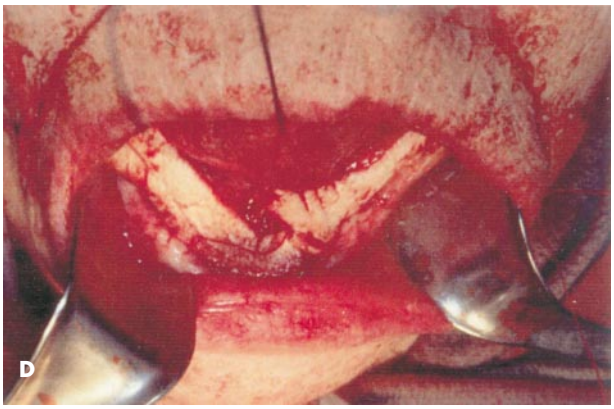


FIGURE 41–24. *A*, Nasolabial flaps outlined on the right and elevated on the left. Reproduced with permission from Atkins JP, Keane WM. Repair of the floor of the mouth with local flaps. Philadelphia: WB Saunders; 1980. *D*, Intraoperative photograph of the nasolabial flaps being placed onto the lingual surface of the mandible.

The ability to provide sensation to free flaps is a definite advantage over pedicled tissue.

In total glossectomy, adequate bulk is critical to allow contact of the flap with the hard palate. The latissimus dorsi and rectus abdominis free flaps are the best reconstructive alternatives for reconstruction of complete defects of the floor of the mouth and tongue. Depending on the patient's body habitus, a pectoralis major myocutaneous flap may also be appropriate.

Composite resections of the oral cavity, which include the mandible, may be reconstructed with the scapular, fibular, and iliac crest composite grafts. These problems are discussed in more detail in Chapter 40.

Free flap reconstruction of the mandible or oral cavity can be accomplished using the ipsilateral branches of the external carotid. If these are unavailable, the branches of the thyrocervical trunk, subclavian, or contralateral external carotid vessels are alternative options.[62]

Pharyngoesophagus

When more than 50% of the hypopharynx is resected, primary closure will lead to stenosis. Partial pharyngoesophageal defects are best reconstructed with either a pedicled pectoralis major myocutaneous flap or a radial forearm free flap.

Circumferential (total) defects require more options depending on the inferior and superior extent of the defect.

The simplest option is the tubed pectoralis major myocutaneous flap. This would be appropriate in patients with significant medical comorbidities. Difficulties with this choice include excessive bulk and multiple suture lines. A radial forearm free flap is the best choice for smaller circumferential defects.

When the resection extends into the cervical esophagus, the gastric pull-up is the procedure of choice. In these cases, skip lesions are a concern, and a total esophagectomy is oncologically more sound. The gastric pull-up allows primary closure with early deglutition. In some cases, this flap may not provide adequate length to reach the nasopharynx, resulting in excessive tension and subsequent wound dehiscence.

For defects that extend into the nasopharynx, free flaps such as the jejunal, radial forearm, and lateral thigh should be considered, and in obese patients, the jejunum is the flap of choice.[42,63,64] For hypopharyngeal and cervical esophageal reconstruction, the branches of the thyrocervical trunk, especially the transverse cervical vessels, are ideal for vascular reanastomosis.[38] Branches of the subclavian artery also are excellent options.[62]

Skull Base

Prior to the introduction of the microvascular free flaps, reconstructive options for skull base defects were particularly limited. These defects often required a large area of tissue that was not readily available. Pedicled flaps provided bulk, but their shorter pedicle length often failed to reach all limits of the defects and posed a high risk for partial flap necrosis. The rectus abdominis, with its bulk and long vascular pedicle, has been the flap of choice for large, laterally situated skull base defects. Although the rectus abdominis is considered the workhorse of skull base reconstruction, other flaps, such as the latissimus dorsi and omental free flaps, provide a thinner and more pliable option. The primary recipient vessels for scalp and skull base reconstruction are the superficial temporal vessels, with the posterior auricular, occipital, and transverse facial arteries as second choices.[62] Other vessels in the neck may also be used but may require an interposition vein graft.

CHAPTER 42

Microtia, Canal Atresia, and Middle Ear Anomalies

Simon C. Parisier, MD, Jose N. Fayad, MD, Charles P. Kimmelman, MD

The child born with a malformed ear faces a lifelong hearing and communication impairment along with the social stigma of a facial deformity. Associated disturbances of the vestibular system may add the developmental hurdle of a motor delay. Frequently, there are additional anomalies, such as mandibular hypoplasia, as well as other facial and skeletal deformities. There may be dysfunction of associated neural pathways, including cranial nerves and intracranial structures. Additionally, there are psychological factors to be considered, including parental guilt, peer ridicule, and the shame of "being different." Educationally and economically, these hearing-impaired children face the prospect of limited opportunities. The appropriate management involves recognizing the problems and limitations of therapy, which need to be thoroughly understood by the parents and, when appropriate, the patient.

EMBRYOLOGY OF ATRESIA AND MICROTIA

In the 3 to 4 mm embryo (3 to 4 weeks), the first indications of aural ontogenesis are the first and second branchiomeric structures and the otic placode, an ectodermal thickening on the lateral surface of the head opposite the fourth ventricle. The placode invaginates to first form a pit and then a vesicle detached from its surface origin. This otocyst forms the inner ear membranous structures, with the endolymphatic duct developing first at the 6 mm stage, followed by the appearance of the semicircular ducts and the cochlear diverticulum at the 15 mm stage (6 weeks). By the end of the third month, the cochlea is fully coiled.

The cranial nerves entering the otocyst exert an inductive influence to produce neuroepithelium, for which retinoic acid is a potent morphogen. Retinoic acid receptors are uniquely expressed in the developing organ of Corti; medications that affect retinoic acid metabolism, such as isotretinoin (Accutane, Roche, Nutley, New Jersey), can lead to embryopathies, including inner ear malformation.[1]

The cochleovestibular ganglia develop from the otic placode epithelium. The nerve fibers themselves not only influence sensory cell development but are also directed to the developing inner ear by the sensory cells.[2]

As the membranous structures of the inner ear form, they become enveloped in a cartilaginous capsule, which eventually gives rise to the petrous portion of the temporal bone. Concurrently, the structures that originate from the first pharyngeal pouch develop separately, but adjacent to, the otic capsule derivatives. The pouch begins to form in the 3 to 4 mm embryo and expands into a tubotympanic recess, which will eventually give rise to the eustachian tube, middle ear space, and mastoid air cell system. The third branchial arch migrates superiorly to the level of the recess, and its artery (the internal carotid) comes to lie dorsal to the eustachian tube. Variations in this relationship may result in a lateralized displacement of the internal carotid artery into the middle ear space. In adults, an ectopic carotid artery can be mistaken for a middle ear mass, such as a glomus tumor.

As the pharyngeal pouches form in the 3 to 4 mm embryo, corresponding grooves develop on the external surface of the nascent cervical region. The first of these branchial clefts deepens until it approaches the tubotympanic recess, being separated only by the thin layer of mesoderm destined to become the middle fibrous layer of the tympanic membrane. Subsequently, in the 30 mm embryo (8 weeks), the primordial external canal becomes occluded by an ectodermal plug. By the twenty-first

week, this begins to resorb to form the definitive external auditory canal, replete with its hair and glandular appendages. Aberrations in the canalization process can lead to stenosis, canal tortuosity, or fibrous/osseous obliteration. Since middle ear structures develop independently, the tympanic cavity and ossicles may be normal.

Defects in the canalization process may also be associated with faulty formation of the pinna, which arises in the 8 to 11 mm embryo from six mesodermal thickenings. These hillocks surround the entrance of the first branchial cleft. The first branchial arch cartilage (Meckel's) forms the tragus and superior helical crus; the remainder of the pinna derives from the second arch cartilage (Reichert's), although some authorities posit a hyoid arch derivation for all but the tragus. The developing auricular appendage migrates from its initial position in the lower face toward the temporal area. This movement occurs along the fusion plane of the first and second branchial arches. The auricle is initially located anteriorly in a horizontal axis; with development of the branchial structures it migrates from its original position in the lower face laterally, and as its axis rotates, it assumes a more vertical angulation. Branchial cleft dysmorphogenesis can impede this migration and leave the pinna in a low, transverse orientation (Figure 42–1).

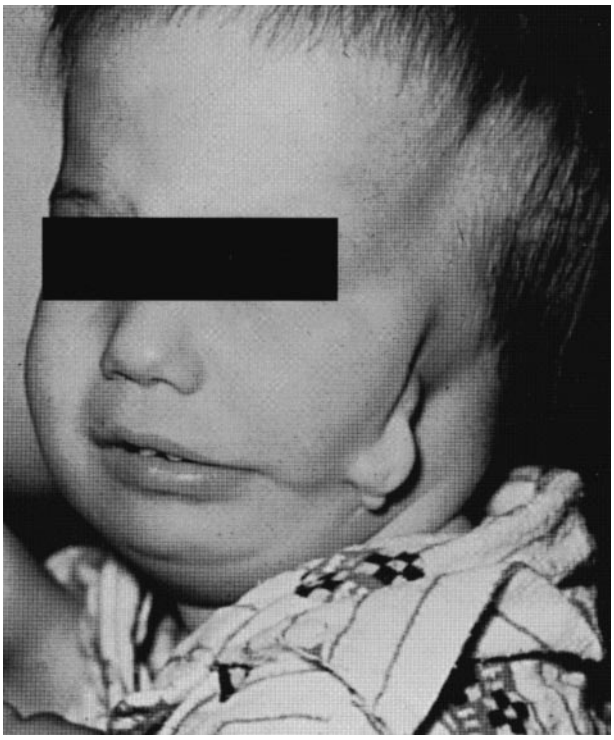

FIGURE 42–1. This child's auricle has not migrated from its embryonic low, transverse position.

As the middle ear forms, the separation between the first pharyngeal pouch and cleft is filled in by mesenchyme. In the 8 mm embryo (6 weeks), part of the connective tissue condenses to form the malleus handle; the subsequent expansion of the tympanic cavity superiorly is delayed until the cartilaginous otic capsule fully forms. The expansion of the first pharyngeal pouch results in the envelopment of the ossicles in an endodermal epithelium. The ossicles predominantly originate from mesenchymal visceral bars of the first and second arches. The first arch forms the head of the malleus and body of the incus, with the second arch giving rise to the manubrium, long process of the incus, stapes superstructure, and lateral portion of the footplate. The medial lamina of the footplate is derived from the otic capsule. The obturator foramen of the stapes forms around the stapedial artery, which usually remains diminutive while the stapes enlarges. If variations in vascular development cause enlargement of the artery, a conductive hearing loss may result from impairment of stapes motion. As the derivatives of the first pharyngeal pouch continue to extend into the developing temporal bone, the antrum, mastoid air cells, and petrous pyramid cells begin to form. Most mastoid development is postnatal; abnormalities that arrest middle ear formation result in a poorly pneumatized bone.

The facial nerve is intimately related to the development of the middle and inner ear structures outlined above. The blastema of the stapes is adjacent to the seventh nerve, which divides the second (hyoid) visceral mesenchymal bar into a laterohyale, stapes blastema, and interhyale. The interhyale forms the stapedius tendon, whereas the laterohyale forms part of the bony fallopian canal and pyramid. Thus, the development of the stapes is closely related to that of the facial nerve. Abnormalities in the development of the stapes are frequently associated with facial nerve anomalies. This relationship of facial nerve to developing middle ear structures increases the likelihood of an anomalous course of the nerve in the malformed middle ear.[3,4]

ETIOLOGY OF AURAL ATRESIA

Atresia and microtia are part of several known syndromes associated with inherited defects or acquired embryopathies owing to intrauterine infection (ru-

bella, syphilis), ischemic injury (hemifacial microsomia), or toxin exposure (thalidomide, isotretinoin).

Although inner ear abnormalities, such as Usher's syndrome, Waardenburg's syndrome, and the neurofibromatoses, are becoming understood on a molecular biologic basis, the genetic basis of external and middle ear anomalies generally remains poorly characterized.[5] Aural atresia occurs in approximately 1 in 20,000 live births. Although the inner and middle ears develop separately, inner ear abnormalities coexist in 12 to 50% of cases. Atresia is bilateral in 30% of cases, occurring more commonly in males and in the right ear.[6]

It is not surprising that an embryonic insult severe enough to cause aural atresia would also affect other organ systems. The following organs or systems may be anomalous in patients with atresia: neurocranium defects (Crouzon's disease or craniofacial dysostosis), central nervous system (mental retardation), oral cavity (first and second branchial arch syndromes), the eye (Goldenhar's syndrome), the neck (branchial fistulae), the CHARGE association (coloboma, heart defect, choanal atresia, retarded growth, genitourinary defects, and ear anomalies), Treacher Collins syndrome (mandibulofacial dysostosis), Duane's syndrome (abducens palsy with retracted globe), VATER complex (probable disorganization of the primitive streak with impairment of early mesodermal migration causing vertebral defects, anal atresia, tracheoesophageal fistula, renal defects, and genital anomalies), and Pierre Robin syndrome. Chromosomal anomalies affecting the external and middle ears include Turner's syndrome and trisomy 13 to 15, 18, 21, and 22 syndromes.[7]

Anomalies of the ear in the absence of syndromes are usually not familial. From the above information, it is obvious that other congenital anomalies should be assiduously sought; some, such as renal dysgenesis, may not be readily apparent. A chromosomal analysis may be indicated. As progress is made in the identification of genes and their products in the recently mapped human genome, the genetic basis for many of these disorders may provide a means of treatment or prevention.[8]

DIAGNOSIS AND EVALUATION

In the more severe cases of microtia, the diagnosis is apparent on inspection of the external ear. Depending on the degree of the abnormality, the microtic ear may be classified into three grades. In grade I, the auricle is developed and, though misshapen, has a readily recognizable, characteristic anatomy (Figure 42–2). In grade II, the helix is rudimentary and the lobule developed (Figure 42–3). In grade III, an amorphous skin tag is present[9] (Figure 42–4). In all stages, wide variations of morphology exist. The pinna may be fully formed with a transverse and low-set orientation. There may be accessory appendages of the pinna (pretragal tags with or without cartilage) and preauricular sinus tracts. The external canal may be stenotic or atretic to varying degrees[10] (Figure 42–5). In cases of stenosis, entrapped squamous epithelium may lead to a retention cholesteatoma with bone destruction.

FIGURE 42–2. This pinna exhibits a grade I microtia with canal atresia. The size of the auricle and the characteristic anatomic landmarks are fairly normal. A pretragal skin tag is present.

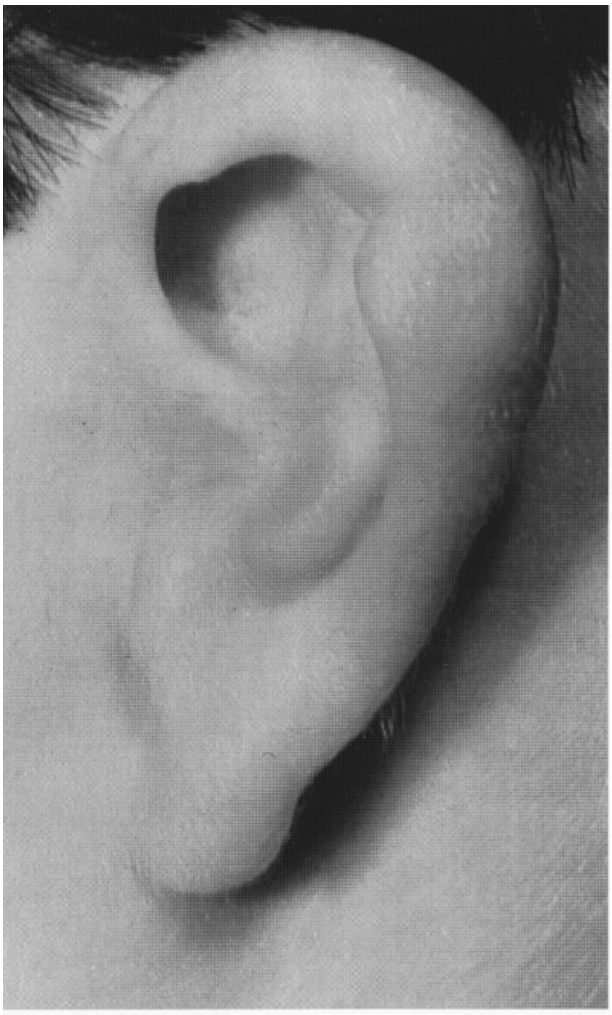

FIGURE 42–3. An example of a grade II microtia. The auricle is reduced in size and has a characteristic recognizable shape. The inferior and superior crura have not developed, although the helix is well preserved.

TABLE 42–1. Minor Congenital Middle Ear Abnormalities with Patent Ear Canal, Mobile Tympanic Membrane, and Conductive Loss

I. Ossicular Fixation
  A. Stapes Fixation
    1. Deficient annular ligament
    2. Elongated pyramidal process, ossified stapedial tendon
  B. Malleolar-Incudal Fixation
    1. Lateral epitympanic ankylosis
    2. Medial epitympanic ankylosis of body of incus, head of malleus
    3. Ossified anterior malleolar ligament
II. Ossicular Discontinuity
  A. Absent stapes arch
  B. Deficient lenticular process of incus
  C. Deficient long process of incus
III. Cochlear Capsule and Facial Nerve Anomalies
  A. Aplasia of oval or round window
  B. Facial nerve anomaly occluding oval window
  C. High jugular bulb occluding the round window niche

Schuknecht observed that in 7 ears with congenital meatal stenosis, all had cholesteatomas, whereas 3 of 11 ears with partial atresia and narrowed canals had cholesteatoma.[11] In 50 ears with complete atresia, only 2 had cholesteatomas.

Abnormalities of the tympanic cavity alone may occur with a normal tympanic membrane and external ear. In ears with conductive hearing losses and normal otoscopic examinations, isolated ossicular anomalies should be suspected (Table 42–1). Ossicular fixation can be produced by a variety of abnormalities and may involve the stapes, incus, or malleus. Alternatively, there may be a failure of bone development producing an ossicular discontinuity, which generally involves the incus and/or stapes arch. Ossicular malformations caused by abnormalities related to first or second branchial cartilaginous derivatives can frequently be surgically repaired (see Table 42–1, groups I and II). However, ossicular fixations owing to cochlear capsule abnormalities, especially when associated with an aberrant facial nerve, may not be surgically correctable (see Table 42–1, group III). Otic capsule abnormalities producing stapedial fixation are frequently associated with abnormal communication between the inner ear and the subarachnoid space. In these instances, manipulation of the stapes results in a persistent gusher of cerebrospinal fluid. Vascular malformations also occur in the middle ear, such as high jugular bulb, persistent stapedial artery, and anomalous course of the carotid artery.[12]

Further delineation of structural abnormalities requires computed tomography (CT).[13] Younger children may require sedation if they are unable to cooperate. The images are processed with a bone algorithm image enhancement using 1.5 mm slices at either 1.5 or 1 mm intervals. Optimally, both axial and coronal scans are obtained, although reformatted coronal or sagittal images may be adequate. Three-dimensional reconstruction[13,14] may be useful in visualizing the temporal bone topography in the

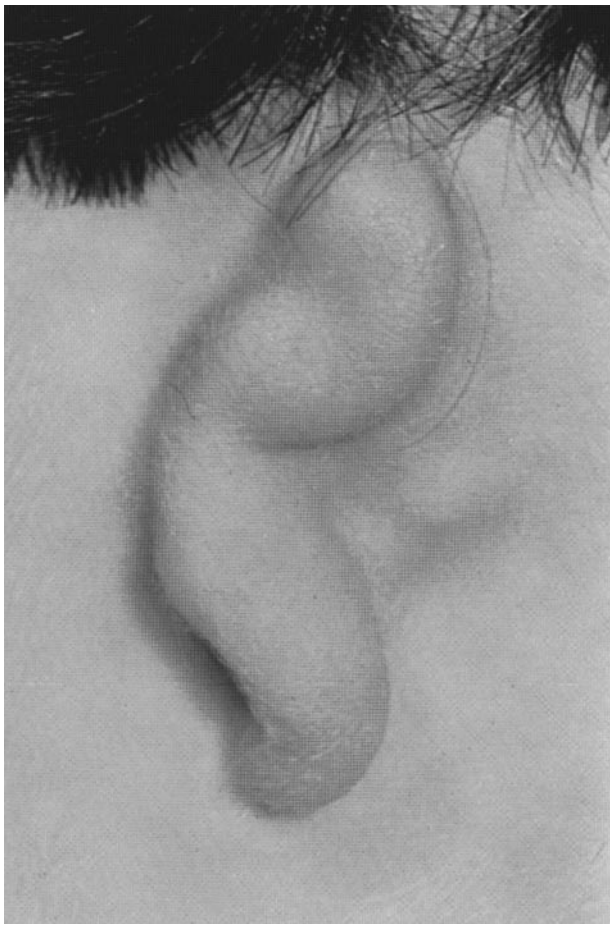

FIGURE 42–4. Auricle showing a grade III microtia. An amorphous ridge of skin and nubbins of cartilage are present in place of a recognizable, well-developed auricle.

more extensive malformations occurring in Treacher Collins syndrome and hemifacial microsomia. Computed tomography studies allow determination of the degree of the canal atresia, the thickness of the atresia plate (Figure 42–6, A), the extent of pneumatization of the middle ear and mastoid, the distance between the glenoid fossa and mastoid, the intratemporal course of the facial nerve, the status of the malleus and incus, and, in some instances, the presence or absence of the stapes and oval window (Figure 42–6, B). However, subtleties of oval and round window anatomy are often not revealed. An unsuspected cholesteatoma may also be apparent. The normalcy of the osseous inner ear structures is also revealed by CT.

Brainstem response audiometry should be performed neonatally in all children born with either microtia or atresia. In cases of microtia with fairly normal canals, an ossicular malformation producing a conductive hearing loss may be present. In patients with unilateral atresia, it is not unusual for the seemingly normal contralateral ear to have a hearing loss. Bilateral involvement may cause masking dilemmas; such is the case when one ear has a conductive loss and the other a sensorineural loss. These dilemmas may be minimized by using multichannel analysis of ipsilateral versus contralateral responses to determine the laterality of wave I.[15] As the infant matures, behavioral audiometric evaluations must be obtained to confirm the neurophysiologic tests of hearing. In children older than 1 year, conditioned free field play audiometry should help to quantify the overall hearing levels. Eventually, pure-tone and speech testing with masking should be obtained in children with fairly normal canals. Impedance and stapedial reflex measures in a seemingly normal ear can provide valuable information as well.

FIGURE 42–5. A grade II to III microtia with poor formation of the superior third of the auricle and a preauricular pit, possibly because of a first branchial arch dysmorphism. The lower portion of the ear, which is derived from the second branchial arch, has a relatively normal appearance. The canal is stenotic, leading to the subsequent development of a retention cholesteatoma.

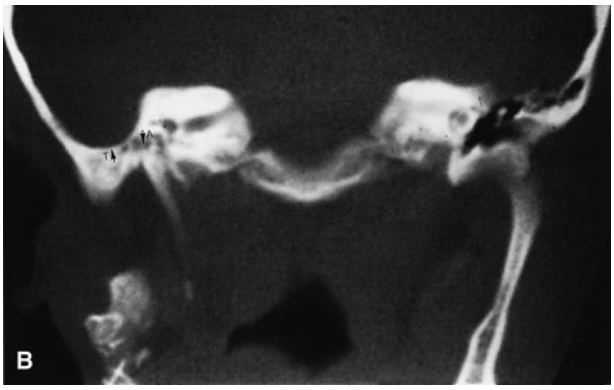

FIGURE 42–6. *A*, A coronal computed tomographic (CT) scan showing a bony atresia plate (*arrow*). The middle ear space is normally pneumatized. *B*, Coronal CT scan showing a low-lying tegmen (T), which precludes construction of an external canal. The middle ear cleft has not developed. A rudimentary antrum is unaerated (A). Atresia surgery is contraindicated in this case.

Evaluation of the function of other organ systems should be considered by the otologist. For example, some of the syndromal associations of atresia involve mandibular and laryngeal anomalies that can lead to airway obstruction; cardiac, renal, endocrine, and immune function should be ascertained in selected instances.

MANAGEMENT OF AURAL ATRESIA AND MICROTIA

Nonsurgical

The prime concern in the young child is the assessment and improvement of hearing. When ear deformities are present, the auditory brainstem response techniques outlined above are helpful in determining the type and severity of hearing loss and should be performed as early in life as possible. Early amplification, auditory training, and speech therapy can improve speech and language skills. In children with bilateral atresia, amplification with bone-conduction aids should be provided as soon as possible, preferably within the first few months of life.[16–18] In infants with a unilateral atresia and conductive hearing loss in the seemingly normal ear, an air-conduction aid should be fitted to the ear with a canal.

Surgical

In the unilateral case with normal contralateral hearing, repair of either the microtia or the atresia is considered elective, and there is less urgency to intervene during childhood. When the atresia is bilateral with acceptable-appearing auricles, reconstructive surgery can be performed at a fairly young age. However, in cases of microtia that require reconstruction, atresia repair should be deferred until the initial stages of the auricular repair are completed. Generally, microtia surgery requires a cartilage graft that is obtained from the lower costochondral region. An adequate graft requires sufficient growth and fusion at the donor site, which has usually occurred by 5 to 6 years of age. Additionally, in bilateral cases, many authorities recommend postponing surgery for the restoration of hearing until at least age 5 so that pneumatization can develop.[11] In children with frequent upper respiratory infections and suspected eustachian tube dysfunction, it may also be necessary to delay hearing reconstructive surgery.

Surgical Treatment of Congenital Conductive Hearing Loss The success of the surgical correction of congenital conductive hearing losses is related to the abnormality since a wide range of malformations is possible.[10] Surgery in an ear that has an isolated ossicular malformation with an otherwise

TABLE 42–2. Congenital Atresia Classification

Class I.	A. Aerated normal middle ear space
	B. Developed oval window with mobile stapes
	C. Oval window not obstructed by facial nerve
Class II.	A. Narrowed, but aerated, middle ear space
	B. Fixed stapes, oval window aplasia
	C. Oval window not obstructed by facial nerve
Class III.	A. Nonaerated, hypoplastic middle ear space
	B. Oval window obstructed by facial nerve
	C. Tegmen low hanging, obstructs access to middle ear space

patent canal, intact tympanic membrane, aerated middle ear cleft, normal facial nerve, and mobile stapes has the potential for excellent hearing (Table 42–2, class I). Conversely, an ear with canal atresia, a narrowed and poorly aerated middle ear space, and an anomalously positioned facial nerve occluding the oval window is destined to have poor postoperative hearing (see Table 42–2, class III). Between these two extremes is an array of anomalies with variable surgical outcomes. Even with sophisticated imaging techniques, the preoperative prediction of what awaits the otologist is not always accurate.[19]

Surgeons wishing to correct congenital conductive hearing losses are embarking on a procedure with significant potential complications. Generally, the initial attempt is the procedure most likely to improve the hearing. Unplanned revisions are often more complex and less successful. Additionally, if a significant sensorineural hearing loss occurs after surgery in a patient with bilateral malformations, the opposite ear is effectively excluded from surgical correction since it becomes the better hearing ear. Before assuming this responsibility, especially in children, the otologic surgeon must have sufficient experience to maximize the likelihood of a successful outcome.

The presence of a conductive hearing loss in an ear with a normal canal and mobile drumhead generally indicates that the ossicular chain is not transmitting sound energy to the cochlea. Isolated ossicular malformations involving the stapes arch and long process of the incus may not be appreciated on CT studies. In these cases, the middle ear can be explored by elevating a tympanomeatal flap and assessing the normalcy of the ossicular transduction mechanism. If the canal is small, a postauricular approach will improve operative exposure. Frequently, even the young child's ear canal has a sufficient diameter to admit an adequately sized ear speculum, even though the length of the canal is shorter.

Once the middle ear is entered, the surgeon needs to decide if the chain is fixed. If so, what is the cause of the fixation (see Table 42–1). First, the motility of the incus and malleus is ascertained. Is the fixation in the epitympanum and, if not, where (Figure 42–7)? Drilling away the bone over the malleus head and body of the incus provides the required exposure to explore this area. Is the stapedial tendon ossified? If the stapes is fixed, mobilization may produce a sustained improvement. Alternatively, a stapedectomy using a replacement prosthesis with an oval window tissue graft to prevent a perilymphatic leak may be performed. In some cases, the surgeon may elect to defer stapes surgery until the child is grown.

A gap interrupting the ossicular chain's continuity occurs most commonly at the incudostapedial joint, either owing to absence of the lenticular process and/or long process of the incus or the stapes arch. The presence of a mobile stapes facilitates the surgery and greatly improves the operative result. A variety of techniques have proven useful in the restoration of ossicular chain continuity by means of bridging an existing gap. If there is a small distance between the stapes capitulum and the long process of the incus, a tragal cartilage graft can successfully negotiate the gap. Deficiencies of the long process of the incus can be corrected by either interposing the reshaped incus between the mobile stapes and the malleus handle or using an alloplastic prosthesis designed for this purpose (type III tympanoplasty). When the stapes arch is absent, similar procedures can be performed to bridge the gap from either the malleus handle or the undersurface of the drumhead to the mobile footplate (type IV tympanoplasty). A coexisting fixation of the stapes or obstruction of the oval window by the facial nerve increases the technical difficulty, yields poorer hearing results, and increases the chance of complications, such as sensorineural hearing loss or facial nerve injury.[20]

Surgery for Microtia and Canal Stenosis or Atresia Congenital malformations of the auricle, external canal, and middle ear may occur as isolated abnormalities or in various combinations. Recon-

FIGURE 42–7. A coronal computed tomographic scan in a patient with a congenital conductive hearing loss caused by osseous fixation of the malleus head to the lateral epitympanic wall (*arrow*).

struction of the external ear is usually performed by a plastic surgeon, whereas external auditory canal and middle ear defects are corrected by the otologist; both work as a team to achieve the optimal result.

Microtia surgery is technically difficult, and not infrequently, the results are somewhat disappointing. The surgery should be performed by individuals with special expertise.[21] Auricular reconstruction is an elective procedure. The deformity can usually be masked by a longer hair style. Generally, the slight deformity of a grade I microtia may be cosmetically acceptable. Reconstruction of a moderately deformed grade II microtia must be individualized. Correction of a severe grade III microtia requires several staged procedures. During the first stage, a segment of cartilage is obtained from the lower costochondral skeleton. It is then carved to the appropriate shape to form a scaffold for the new auricle. This process requires an artistic appreciation of the external ear folds. The graft is implanted into a subcutaneous pocket at the appropriate position. A portion of the microtic skin tag is maintained to construct the lobule. The second stage is performed after several months. The auricle is freed from the scalp, and a split-thickness skin graft is applied to create a postauricular sulcus. At a third stage, several months later, the tragus is created. An alternative technique for the treatment of severe grade III microtia is to use a lifelike prosthetic ear, which is attached to surgically implanted titanium posts that securely hold the auricle in a normal anatomic position.

The timing of the microtia and atresia repairs requires close communication between the surgeons. Because scarring interferes with the auricular repair, reconstruction of the atresia is deferred until the auricular cartilaginous scaffolding is completed. However, it is important to position the reconstructed auricle correctly so that it aligns with the meatal opening and the middle ear. The meatal, canal, and middle ear reconstruction is frequently performed as part of the second or third stage of the auricular reconstruction.[13,22]

A postauricular approach is used, with great care being taken to avoid exposing the scaffold (Figure 42–8). Temporalis fascia is harvested for reconstruction of the tympanic membrane. The

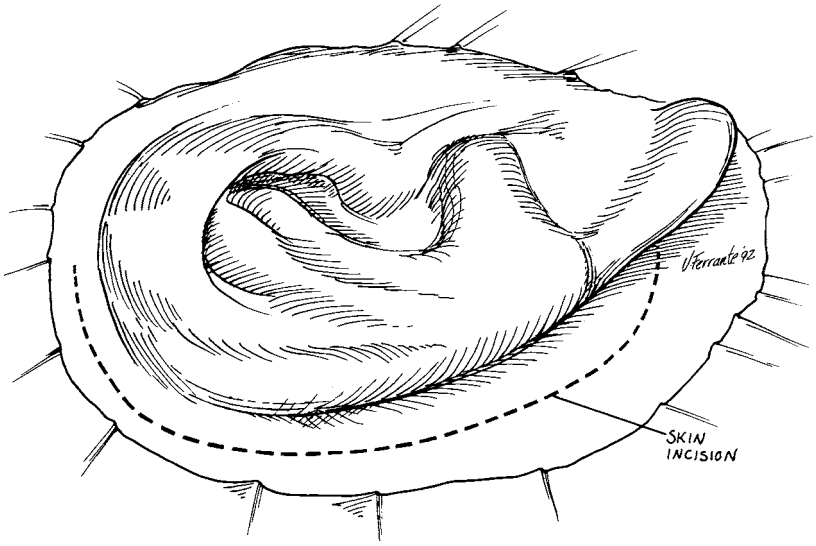

FIGURE 42–8. Surgery for canal atresia. A postauricular incision is made. While exposing the mastoid cortex and dysmorphic tympanic bone, the previously implanted cartilaginous auricular scaffold should be protected during retraction.

periosteum of the lateral surface of the temporal bone is elevated. A bony circular canal is created by drilling between the glenoid fossa anteriorly and the tegmen plate superiorly while trying to avoid entering mastoid air cells posteriorly (Figure 42–9). Continuous suction irrigation cools the bone and clears away blood and bone dust while the water enhances the translucency of the wet bone. This permits visualization of structures such as dura, facial nerve, and glenoid fossa through the intact thinned bone. The surgeon should anticipate that the facial nerve will be located more anteriorly and more laterally than in the normal temporal bone. The nerve frequently follows a C-shaped path in its course between the geniculate ganglion and its point of emergence from the temporal bone. The purposeful identification of the facial nerve will prevent inadvertent injury. A facial nerve monitor may facilitate identification of the nerve in atretic ears.

Visualization of the facial nerve as a landmark permits the opening of the atresia plate to approximate the size of a normal middle ear opening. While drilling on this plate, it must be remembered that the malleus handle may be fused to it. Precautions must be taken to avoid drilling on the mobilized atresia remnant since this may transmit traumatic vibratory energy through the ossicular chain to the inner ear and result in a permanent sensorineural hearing loss.

The status of the ossicular chain is assessed (Figure 42–10). If the stapes is mobile, an appropriate ossicular reconstruction is performed (Figure

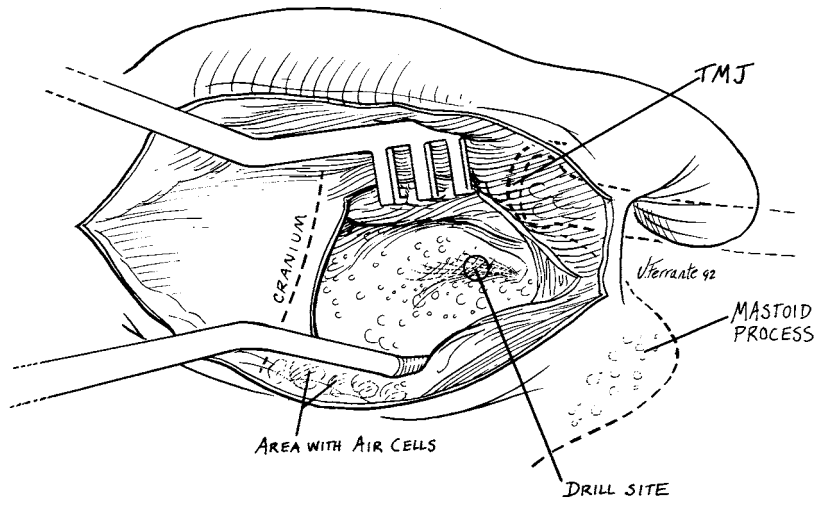

FIGURE 42–9. Construction of a canal is begun by drilling between the glenoid fossa anteriorly and the superior temporal line. The latter roughly corresponds to the tegmen (floor of the middle cranial fossa). When possible, entry into the mastoid air cells is avoided. TMJ = temporomandibular joint.

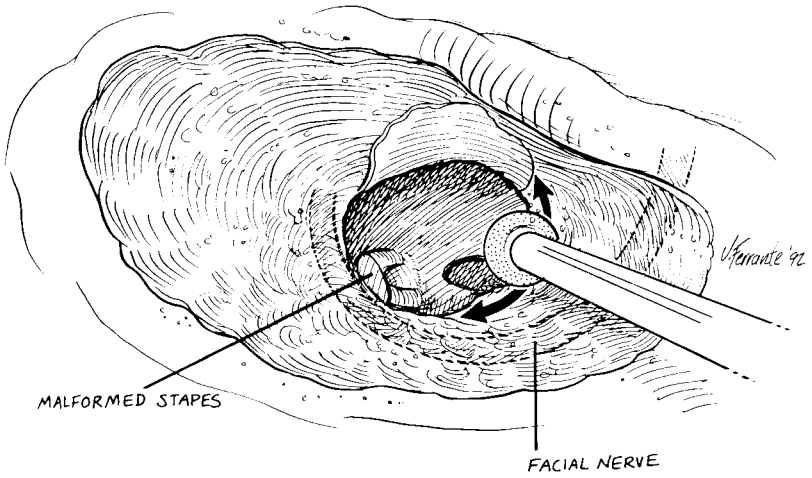

FIGURE 42–10. Drilling is continued until a normal-sized middle ear opening has been created. Great care is taken not to drill on a mobile, deformed, but intact ossicular chain. The anteriorly coursing facial nerve is identified.

42–11). If it is fixed or the oval window is obscured by the facial nerve, the ossicular reconstruction should be deferred. Temporalis fascia is used to fabricate a new tympanic membrane (Figure 42–12). A meatal opening is made in the area of the imperforate concha, incising the skin, to create a rectangularly shaped, anteriorly based conchal skin flap. The underlying cartilage and soft tissue are removed to debulk the flap and create an opening that communicates with the drilled out external canal (Figure 42–13). The conchal flap is rotated to resurface the anterior third of the external canal and is stabilized by suturing to the adjacent soft tissues (Figure 42–14). A thin split-thickness skin graft is harvested from the lower abdomen and is used to resurface the remaining ear canal. The canal is packed snugly with Gelfoam (Upjohn, Kalamazoo, Michigan) to compress the skin grafts against the underlying bone and soft tissue. The postauricular incision is reapproximated using absorbable sutures.

Risks and Benefits of Atresia Surgery Atresia surgery is technically demanding. The results achieved are directly related to the experience and skill of the operating surgeon. Generally, hearing improvement to a serviceable level can be achieved in approximately 65 to 75% of selected patients.[23,24] Complications of surgery include the small risk of facial paralysis, a severe to profound sensorineural hearing loss, stenosis requiring additional surgery, persistent otorrhea, and tympanic membrane graft failure with perforation.

In children with a unilateral atresia and a normal contralateral ear, surgery may not be routinely

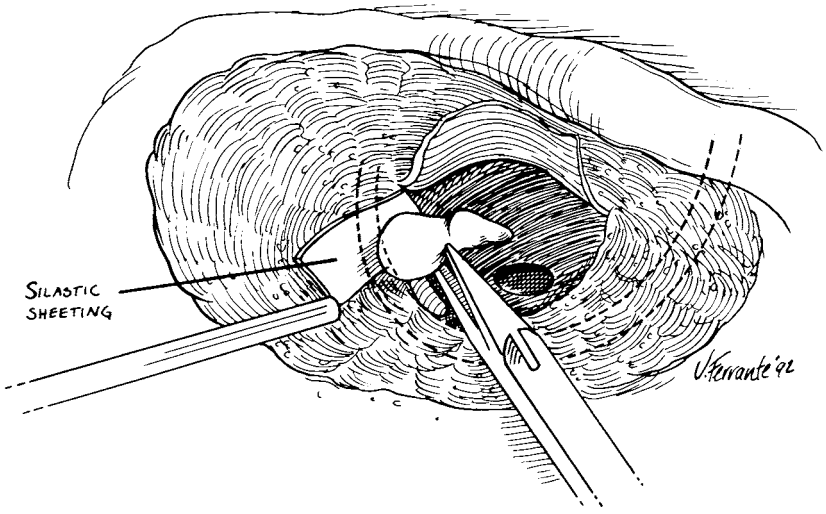

FIGURE 42–11. The ossicular chain is reconstructed by interposing the malformed, sculpted ossicle onto the stapes. Silastic sheeting, 0.005 inches thick, is positioned to prevent bony ankylosis.

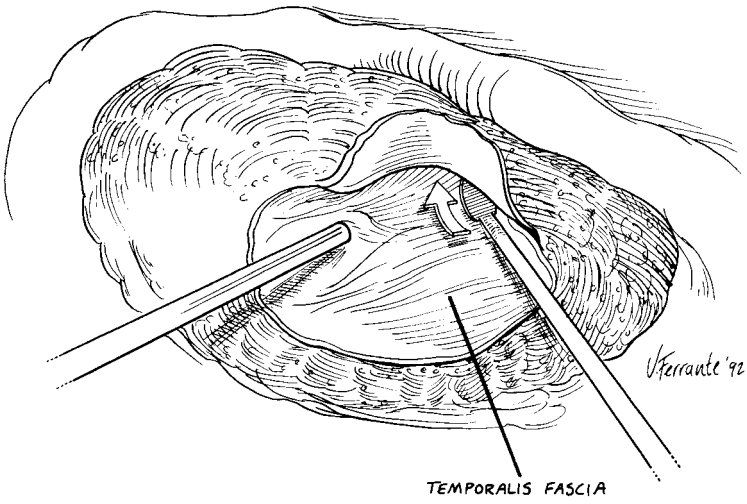

FIGURE 42–12. Temporalis fascia is used to construct a tympanic membrane.

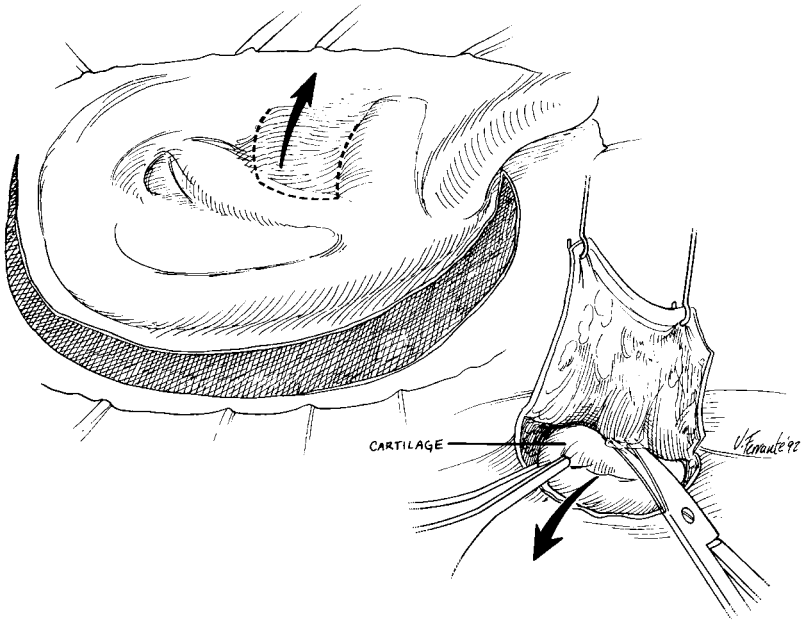

FIGURE 42–13. A meatal opening is made through the imperforate conchal skin. A rectangular, anteriorly based skin flap is debulked and rotated to line the anterior lateral third of the new canal.

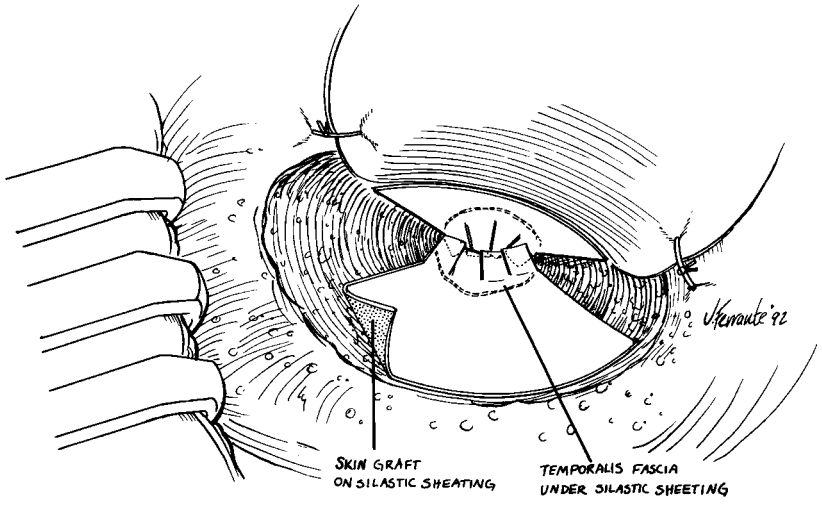

FIGURE 42–14. A thin, split-thickness skin graft harvested from the lower part of the abdomen is used to resurface the remainder of the canal. Handling and placement of the graft are facilitated by gluing the epidermal surface to thin (0.005 inch) Silastic sheeting. The raw surface of the graft is compressed against the bone by filing the canal lumen with Gelfoam.

indicated.[19] The potential benefit of this sophisticated surgery, that is, achieving binaural hearing, may not justify the risk of complications. In binaural cases, the successful creation of an external canal, even when hearing cannot be improved, will allow the use of an ear-level air-conduction hearing aid to restore hearing without using a cumbersome bone-conduction aid. Thus, in bilateral cases in which the facial nerve obstructs the oval window or when a hearing improvement cannot be achieved, providing the patient with a stable, skin-lined canal is a worthy goal in and of itself.

CHAPTER 43

Anatomy and Physiology of the Oral Cavity and Pharynx

Louis D. Lowry, MD, Selcuk Onart, MD

The mouth or oral cavity is divided into two compartments: the vestibule or external compartment (vestibulum oris) and the internal compartment (cavum oris). The vestibule is the space external to the maxillary and mandibular alveolar ridges and teeth and within the lips and buccal mucosa. Internal to the alveolar ridges and teeth, the oral cavity proper is the space bounded by the hard and soft parts of the palate superiorly (ie, the roof of the mouth) and the lingual mucosa inferiorly (ie, the floor of the mouth and covering over the genioglossus, geniohyoid, and mylohyoid, which lie under the tongue). The anterior two-thirds of the tongue, bound posteriorly by the line of circumvallate papillae, are also part of the oral cavity proper.

The anterior pillars of the palatine tonsils separate the oral cavity from the oropharynx.

The pharynx is a fibromuscular tube that serves as a conduit for both the respiratory and digestive tracts. It is divided regionally into three segments: Superiorly, the nasopharynx is a posterior extension of the nasal cavities and ends at the level of the soft palate. The oropharynx is the region between the soft palate and the base of the tongue, down to the superior tip of the epiglottis, bounded laterally by the palatoglossal and palatopharyngeal arches. The laryngopharynx is posterior to the larynx and extends from the superior border of the epiglottis to the inferior aspect of the cricoid cartilage.

TONGUE

The mobile anterior two-thirds of the tongue are divided into four parts: tip, lateral borders, dorsum, and ventral surface. The dorsal surface faces the hard palate and the ventral surface faces the floor of the mouth. The lingual muscles are extrinsic and intrinsic. The extrinsic muscles are attached to the mandibular, styloid, and hyoid bones. They are the genioglossus, styloglossus, and hyoglossus and are able to move the tongue in various directions. The intrinsic muscles are the superior and inferior longitudinal, transverse, and vertical and, because of their orientation, impart great diversity to the movements of the tongue. The tongue is attached to the floor of the mouth ventrally and anteriorly and centrally by the frenulum.

The posterior third of the tongue is divided from the anterior two-thirds by the sulcus terminalis, which is a V-shaped groove, with its apex being posterior (Figure 43–1). The foramen cecum is at the apex of the sulcus and marks the origin of the thyroglossal duct. The lingual tonsil constitutes most of the posterior one-third of the tongue and varies in size. Anteriorly, the tongue is covered by a thin mucous membrane closely attached to the underly-

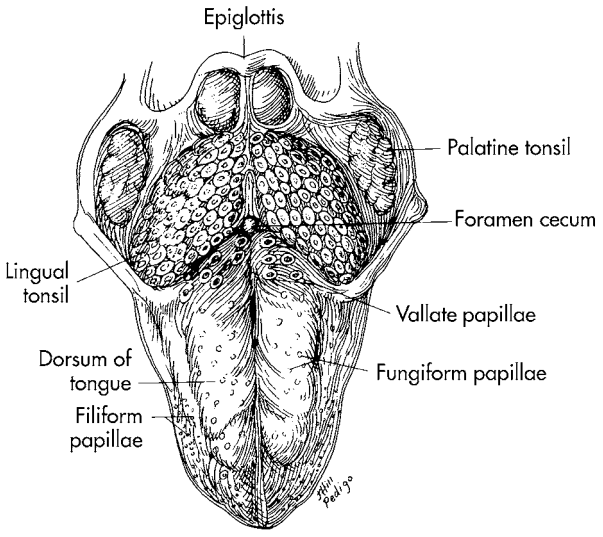

FIGURE 43–1. The dorsal surface of the tongue. Filiform papillae cover the dorsum. The lingual tonsil and palatine tonsils are part of Waldeyer's ring.

ing muscles. Posteriorly, the mucosa is thick and more freely moveable.

Innervation of the Tongue

The motor nerve to the tongue is the hypoglossal (cranial nerve [CN] XII), except for the palatoglossus muscle, which receives its innervation from the glossopharyngeal (CN IX) nerve. The hypoglossal nerve runs forward just above the greater cornu of the hyoid bone and has a course along the outer surface of the hyoglossus muscle, where it is accompanied by the lingual vein. The two major sensory nerves of the tongue are the lingual (CN V3) for the anterior two-thirds and the glossopharyngeal for the posterior one-third. The lingual nerve, a branch of mandibular division of the fifth cranial nerve the also receives the chorda tympani from the facial nerve (CN VII) (Table 43–1). The lingual nerve runs along the lateral border of the tongue above the submandibular gland and the hypoglossal nerve. The glossopharyngeal nerve passes around the posterior border and lateral surface of the stylopharyngeal muscle to reach the posterior part of the tongue deep to the hypoglossus muscle.

The trigeminal nerve (CN V) provides the general sensation to the anterior two-thirds of the tongue through the lingual nerve, whereas taste is subserved by CN VII (Figure 43–2). The glossopharyngeal nerve provides both taste and general sensation to the posterior third of the tongue and the circumvallate papillae.

Taste Buds

Taste buds in the human tongue, soft palate, pharynx, larynx, epiglottis, and esophagus are not distributed evenly. Most taste buds are found in the tongue, and in humans, there appear to be fewer extralingual taste buds than in laboratory animals.

TABLE 43–1. Relationship of the Branchial Arches and Their Nerves to the Sensation of the Tongue

Neural Branch	*Cranial Nerve*	*Branchial Arch*	*Sensory Modality Served*
Lingual nerve	V	First arch	Sensation to anterior two-thirds of tongue
Chorda tympani	VII	Second arch	Taste to anterior two-thirds of tongue
Glossopharyngeal	IX	Third arch	Taste and sensation to posterior one-third of tongue

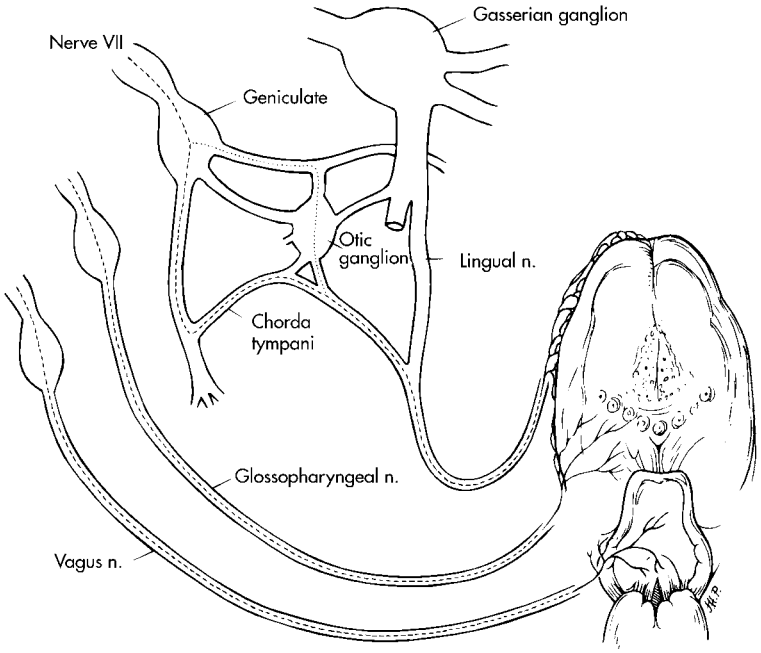

FIGURE 43–2. Diagram of the nerves serving the sense of taste on the tongue and surrounding regions.

In the tongue, taste buds are associated with three types of gustatory papillae, whereas extralingually, they are found on smooth epithelial surfaces. The number of taste buds varies among individuals, ranging between 500 and 20,000, with most in the 2,000 to 5,000 range.[1]

There are four types of lingual papillae: filiform, fungiform, foliate, and circumvallate. Filiform papillae are distributed throughout the dorsum of the tongue but do not have taste buds and function in the tactile aspects of feeding. Fungiform papillae are located on the anterior two-thirds of the tongue, number about 200, and usually contain one taste bud each.[2] They are shaped like mushrooms—hence their name, with the taste bud(s) found on their dorsal surface epithelium. The foliate papillae are found on the posterolateral sides of the tongue. There is only one foliate papilla on each side of the tongue, but each is a large structure arranged in a series of clefts that have grown beneath the tongue surface. The more rostral clefts, or the lateral rugae, contain no secretory ducts or taste buds. The more caudal clefts are called the foliate papillae folds and have ducts from lingual salivary glands (Ebner's glands) between the folds as well as a thinner epithelial lining that contains taste buds. Unlike taste buds on fungiform papillae, these taste buds are not found on the dorsal surface epithelium but instead face a cleft. In humans, there is an average of 600 taste buds in each foliate papilla, and each papilla is composed of between two and nine folds. The circumvallate papillae are found on the tongue just anterior to the sulcus terminalis. Humans have between 8 and 12 of them arranged in a V-shaped formation. Circumvallate papillae are large mushroom-shaped structures surrounded by a circular sulcus (vallum) and contain an average of 250 taste buds each. The taste buds are located along the walls of the sulcus, both on the papillae and on the adjacent epithelium. Secretions from Ebner's glands are released from ducts located at the base of the sulcus.[1]

The function of Ebner's glands has been under some debate recently. Traditionally, they were thought of as ancillary to taste buds and were mainly involved in simply washing the vallum, but some studies have suggested that they serve some additional purposes. One of these is the production of digestive enzymes, in particular lipase, which is important in the neonatal period when the pancreas is still immature. Also, it has been shown that Ebner's glands produce proteins that are involved in pheromone reception. For these functions to occur, it has been hypothesized that the glands must have access to detailed information about the chemical composition of the oral cavity. Supposedly, taste buds in the circumvallate papillae provide this information and help to control the activity of Ebner's glands.[3]

As stated above, extralingual taste buds are not found on papillae and are instead located within the epithelium. Extralingual taste buds tend not to be as well described as those on the tongue but still have some pattern of distribution that may be important functionally. Palatal taste buds are often located near the opening of ducts of mucus-secreting glands.[4]

Taste buds are made up of 50 to 150 neuroepithelial cells arranged in a compact gourd-shaped structure (Figure 43–3). Each receptor cell extends from the basement membrane of the epithelium to the epithelial surface, and the cells are arranged like sections of an orange. At the epithelial surface of each taste bud, there is a small opening called the taste pore, a channel that allows the microvilli of taste receptor cells access to gustatory stimuli. Tight junctions between taste receptor cells restrict the access of gustatory stimuli to the microvilli at the apices. There are generally four types of cells within each taste bud, and there is no firm agreement about the function or the origin of each type. The four types of cells are basal cells, type I (dark cells), type II (light cells), and type III (intermediate cells).[1]

Basal cells are small, undifferentiated, round cells near the basement membrane, from which most of the other taste bud cell types are thought to be derived. The other three types of cells are more elongated and bipolar, with microvilli at the apices and synapses with afferent fibers at the bases. These are thought to be the actual taste receptor cells. Over 50% of the taste receptor cells are type I, or dark cells. They have long microvilli and dense, membrane-bound granules near the cell apex. Type II, or light, cells have shorter microvilli, a lighter cytoplasm, and membranous vesicles near the apex. Type III, or intermediate, cells have characteristics of both type I and II cells.[1]

It is unclear whether the existence of four different cell types means that they have different functions or that they come from different cell lines. Some studies suggest that the different cell types are simply cells in different stages of development, with

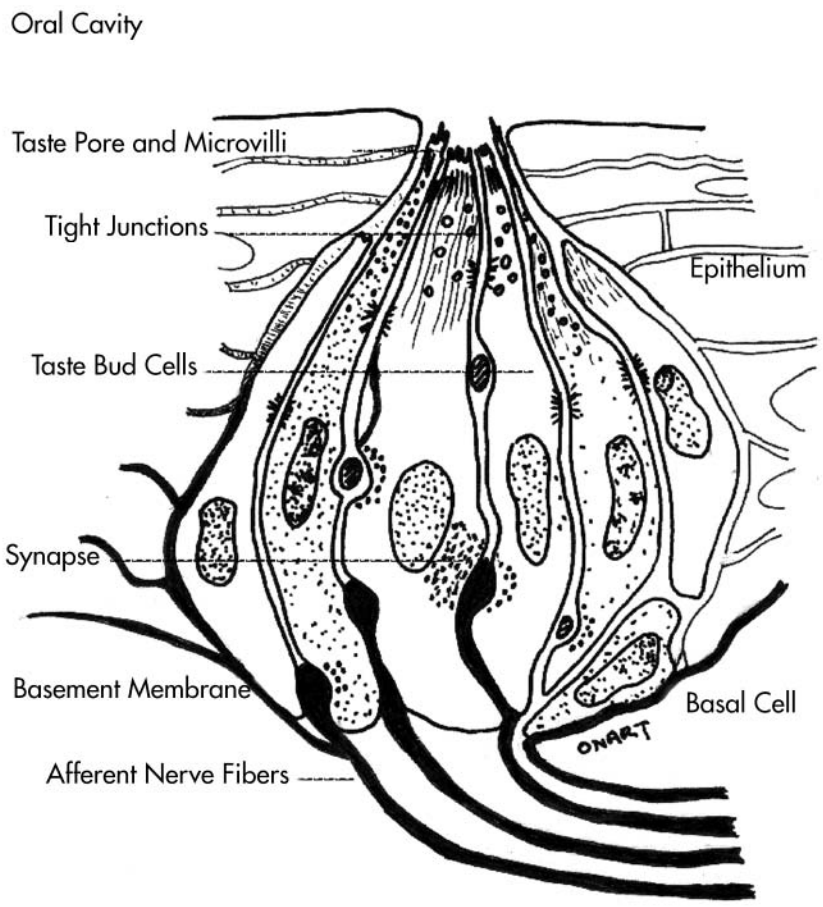

FIGURE 43–3. Taste bud demonstrating the relationship of the taste pore to the oral cavity. Afferent nerve fibers go to several different types of cells.

the basal cells turning into dark cells, which turn into intermediate cells, which turn into light cells. Other studies suggest that the light cells come from a separate cell line. Nevertheless, all three receptor cell types are known to synapse with afferent neurons, which make the arrangement complex when cells are turning over. The life span of an individual taste cell is only 10 to 14 days, and the cells are constantly being replaced, with the new cells constantly re-establishing connections with afferent nerve fibers to maintain taste sensation.[1]

Taste

The world of taste perception and the explanation of its mechanism of transduction is one convoluted at several different levels. Most importantly, taste should not be confused with flavor as the latter is actually a combined perception of gustation and olfaction. Additionally, one must understand that the study of taste relies on psychophysical perception and is thus prone to the error and complication of subjective experience. Therefore, it is often necessary to use the study of animal models, from which, for several reasons, the results are not always generalizable to humans. Further, it is necessary to qualify the concept of primary taste modalities. According to Brand, the criteria for the designation of a primary taste quality include

> 1) psychophysical and descriptive data that tend to isolate one primary taste from another on the basis of statistical criteria, 2) electrophysiologic evidence that reports unique neural transduction features of the putative taste modality, and 3) biochemical and molecular biological evidence that identifies and localizes unique receptors and cellular responses to the candidate primary modality.[5]

Generally, these criteria have been fulfilled for sweet, salty, sour, and bitter tastes, with evidence gradually proving for umami as well. Umami is the most recently discovered taste sensation that with continued research is slowly proving to be the fifth primary taste. Since the major prototypical stimulus for this taste has been shown to be the sodium salt of

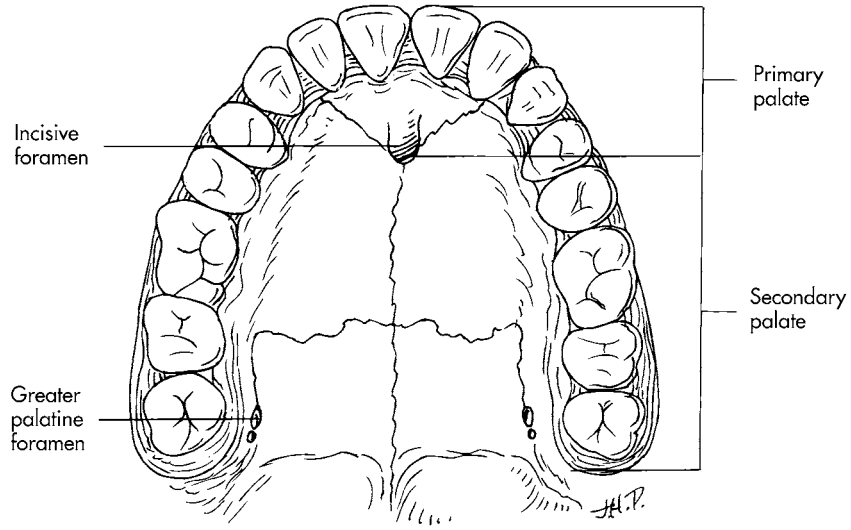

FIGURE 43–4. The hard palate and its divisions. Permanent teeth 1 through 16 are shown.

L-glutamic acid (monosodium glutamate), it is not surprising that umami means delicious in Japanese. It is a naturally occurring ingredient in many Asian foods. Given that the central nervous system harbors a multitude of receptors for glutamate, umami research has focused on the similarities and differences between receptors in the central nervous system and taste cells. For more information on the senses of smell and taste, see Chapter 27.

FLOOR OF THE MOUTH

The floor of the mouth contains the submandibular and sublingual salivary glands and the extrinsic musculature. It is supported by the paired mylohyoid muscles. The two muscles arise from the mandible and insert into a median raphe that extends posteriorly to the anterior surface of the hyoid bone. The muscles are so firm that swelling owing to infection above them can encroach on the airway.

BONES OF THE ORAL CAVITY

The *mandibles* form the skeleton of the lower jaw and the inferior part of the face They are the largest and strongest facial bones. Each mandible consists of two parts: the horizontal body and the vertical oblong ramus. The ramus ascends vertically from the posterior aspect of the body at the angle of the mandible. The superior part of the ramus has two processes: the posterior condylar process with a head, or condyle, and a neck and the anterior coronoid process. The condylar process is separated from the coronoid process by the mandibular notch, which forms the concave superior border of the mandible. On the internal aspect of the ramus is the large mandibular foramen, which is the entrance to the mandibular canal. The mandibular canal transmits the alveolar vessels and nerves. Branches of these vessels and the mental nerve emerge from the mental foramen, inferior to the second premolar tooth on the lateral side of each mandible. Inferiorly and slightly anteriorly from the mandibular foramen on the internal surface of the mandible runs the mylohyoid groove. This groove indicates the course taken by the mylohyoid nerve and vessels. Extending superiorly and posteriorly from the symphysis of the mandibular bodies is the mylohyoid line. Just superior to the anterior end of the mylohyoid line are two small sharp mental spines, which serve as attachments for the genioglossus muscle.

The palatine processes of the *maxillae* and the horizontal plates of the *palatine bones* form the anterior bony part of the palate (Figure 43–4). In hard palates of young people, a suture line, the palatine raphe, is visible between the premaxillary part of the maxilla and palatine processes of the maxillae. This represents the site of fusion of the median and lateral palatine processes during the twelfth week of prenatal development. In older people, this suture line is often absent. Contained within the hard palate are several canals. The incisive canal transmits the nasopalatine nerve and the terminal branch of the sphenopalatine artery. The incisive foramen is

located posterior to the maxillary central incisor teeth. Medial to the third molar tooth, the greater palatine foramen opens on the lateral border of the bony palate. It is the inferior orifice of the greater palatine canal. The greater palatine vessels and nerve emerge from this foramen and run anteriorly in two grooves on the palate. The lesser palatine foramina transmit the lesser palatine nerves and vessels to the soft palate and adjacent structures.

Fixed in the alveoli of the mandibular and maxillary bones are teeth. Although not bones, they will be described here for completeness. Deciduous teeth begin to develop before birth. The first tooth usually erupts at 6 to 8 months and the last by 24 months of age. The deciduous teeth are shed between 6 and 12 years of age and are replaced by permanent teeth. Eruption of permanent teeth is usually complete by 18 years of age, except for the third molars. If they are malposed or impacted, they may not erupt. There are 10 deciduous teeth in each jaw (2 medial incisors, 2 lateral incisors, 2 canines, 2 first molars, and 2 second molars). There are 16 permanent teeth in each jaw (2 medial incisors, 2 lateral incisors, 2 canines, 2 first premolars, 2 second premolars, 2 first molars, 2 second molars, and 2 third molars). The permanent teeth are numbered 1 to 32, starting with the right maxillary third molar as #1 and continuing to the mandible, with the left third molar as #17 and the right third mandibular molar as #32.

BLOOD SUPPLY TO THE ORAL CAVITY

The blood supply to the oral cavity is derived from branches of the external carotid artery (ECA). Most of the blood to this region comes from the ECA's first branches in the head, the lingual and external maxillary (facial) arteries, and their smaller branches. The ECA's two terminal branches, the internal maxillary and superficial temporal arteries, also contribute blood to the oral cavity. As in many regions of the head and neck, anastomoses between contributing arteries are important to the region's vascular integrity. Most of the blood drains to the jugular veins. The lingual artery, its branches, and veins of the same name provide circulation to the tongue and the floor of the mouth. Arising from the ECA opposite the greater horn of the hyoid bone, the lingual artery enters the tongue and supplies its muscles via its branching dorsal lingual artery. The lingual artery continues anteriorly and divides, sending the deep lingual artery superoanteriorly to supply the tip of the tongue and sending the sublingual branch to the sublingual gland and the floor of the mouth.

BLOOD SUPPLY OF THE PHARNYX AND TONSIL

The chief blood supply to the pharynx is derived from the ascending pharyngeal and tonsillar branches of the external maxillary artery and from the descending palatine branch of the internal maxillary artery (Figure 43–5). The tonsillar arteries, branches of the external maxillary artery, are the chief vessels to the tonsil, although the ascending palatine sometimes takes their place. The tonsillar arteries (or ascending pharyngeal artery) pass upward through the superior constrictor muscle, giving branches to the soft palate and tonsil. The dorsal lingual artery ascends to the base of the tongue and sends branches to the tonsil and tonsillar pillars. The descending palatine artery supplies the tonsil and soft palate from above, forming an anastomosis with the ascending palatine.

WALDEYER'S RING

Waldeyer's ring is a "ring" of lymphoid tissue, which provides the first contact of ingested or inhaled pathogens with the lymphoid system intimately related to epithelium. It is composed of the (1) ade-

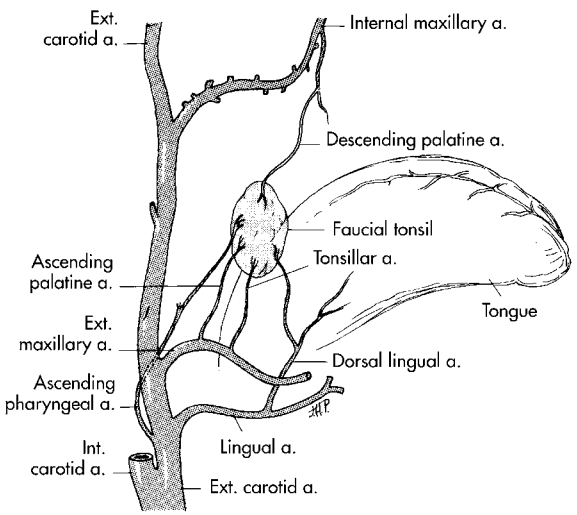

FIGURE 43–5. The blood supply of the palatine tonsil.

noid, (2) palatine tonsils, (3) lingual tonsil, (4) lateral pharyngeal bands, (5) scattered lymphoid follicles, and (6) nodules near the eustachian tube. This lymphoid tissue has only efferent lymphatics, much as Peyer's patches in the bowel, and is strategically located to sample everything that enters the aerodigestive tract. Waldeyer's ring is involved in the development of non–thymus-related lymphocytes or B cells, particularly in the first few years of life. Production of major classes of immunoglobulins and T lymphocytes with intact effector function of cell-mediated or "delayed" immunity can be attributed to elements of the ring.

Adenoid

The adenoid (also known as the pharyngeal or Luschka's tonsil) is a lobulated mass of lymphoid tissue found on the superior and posterior walls of the nasopharynx. The adenoid has no crypts but vertical folds lined by respiratory epithelium. It is composed of lymphoid tissue in a delicate reticulum of fibers and acts as a peripherally placed lymph node from which efferent lymph ducts pass to the cervical chain. The exposed surface of the adenoid is covered by stratified and pseudostratified epithelium. Groups of lymphoid cells are differentiated in the form of more or less rounded or oval areas with pale centers and darker margins. These lymphoid follicles or germ centers have the pseudonym germ centers of Goodsir. Unlike the palatine tonsil, the adenoid has no capsule. The incoming air from nasal breathing contacts the adenoid, and foreign substances initiate immune responses. The adenoids are capable of considerable hyperplasia and can obstruct the airway under adverse conditions (see Chapter 44).

In the midline of the nasopharynx, surrounded by the adenoid, is a depressed structure, the pharyngeal bursa, which represents the remnants of the notochord. Thornwaldt's disease is an infection of this bursa.

Palatine Tonsils

The palatine tonsils, also known as the faucial tonsils, are grape-like masses of lymphoid tissue lying between the palatoglossus muscle (anterior pillar) and the palatopharyngeus muscle (posterior pillar). The lateral surface of each tonsil is covered by pharyngeal fascia and attached to the superior pharyngeal constrictor muscle. Condensations of the fascia form a capsule. From the tonsillar capsule, trabeculae extend into the parenchyma of the tonsil and support blood vessels, nerves, and efferent lymphatic vessels. Contractions of the superior constrictor, palatoglossus, and palatopharyngeus (as in swallowing) cause compression of the tonsil. The free surface of the tonsil is covered by a closely adherent stratified squamous epithelium that extends into blind pouches or crypts. The epithelium lining the crypts is thin and, in fact, may be a semipermeable membrane that "lends" itself to sampling ingested material. The crypts, 8 to 10 in number, are usually compound, extend deep into the substance of the tonsil, and come into intimate contact with the lymphatic germinating follicles, suggesting permeability. With swelling of the tonsil, the bottom of the crypts remains relatively fixed; thus, the crypts become longer. The germinating follicles are centers in which mother cells of the leukocytic group form young lymphoid cells. The interfollicular tissue is made up of lymphoid cells in various stages of development. Above the tonsil and between the pillars is the supratonsillar fossa.

Lingual Tonsil

The lingual tonsil constitutes part of the base of the tongue and extends from the foramen cecum to the epiglottis. This sessile midline lymphoid accumulation is covered by stratified squamous epithelium. It is poorly separated from the tongue musculature by a layer of fibrous tissue. It consists of numerous rounded or crater-like elevations of lymphoid tissue in the center of which a duct of a mucous gland opens.

LYMPHATICS OF THE ORAL CAVITY

The lymphatic drainage of the oral cavity is composed of both superficial and deep vessels that ultimately drain into the submental, submandibular, upper jugular, and, occasionally, spinal accessory lymph nodes. Cancers arising in the buccal mucosa primarily drain into the preglandular lymph nodes of the submandibular triangle and secondarily drain into the upper jugular lymph nodes of the deep jugular chain. Contralateral metastases are infrequent.

The lymphatic network overlying the gingiva of maxillary and mandibular bones joins the lingual and buccal surfaces. The preglandular submandibu-

lar lymph nodes represent the primary drainage route for both systems.

The superficial lymphatic vessels of the floor of the mouth connect with the gingival system before draining to the preglandular submandibular lymph nodes (Figure 43–6). The superficial system located in the anterior part of the floor of the mouth crosses the midline and drains into either the ipsilateral or contralateral preglandular lymph nodes. The deep collecting system drains into the same preglandular lymph nodes before draining into the subdigastric lymph nodes of the internal jugular chain.

A second pathway bypasses the submandibular lymph nodes and drains into the jugular omohyoid lymph nodes. Additionally, an efferent upper jugular pathway crosses the midline and bypasses the submandibular lymph nodes (Figure 43–7).

The tongue possesses both a superficial and a deep lymphatic system. No midline separation exists, so crossover into contralateral lymphatics is not uncommon. Lymphatic capillaries in the anterior portion of the tongue tend to drain into the submental and midjugular lymph nodes, the lymphatics from the middle third to submandibular or digastric lymph nodes, and those from the base of the tongue to the upper jugular lymph nodes (Figure 43–8). The normal anatomic configuration of the lymph flow can be altered by obstruction caused by infection, neoplastic involvement, previous surgery, and irradiation.

Minor Salivary Glands

There are 600 to 1,000 minor salivary glands throughout the oral cavity and oropharynx, with the greatest concentration found in the palate. The hard palate has 250 minor salivary glands and the soft palate has 150, with their parasympathetic innervation coming from the sphenopalatine ganglion. The remaining minor salivary glands of the oral cavity and oropharynx receive their parasympathetic innervation from the lingual and glossopharyngeal nerves. Each gland has its own excretory duct emptying directly into the oral cavity or oropharynx. The vascular supply, venous outflow, and lymphatic drainage correspond to the region of the oral cavity and oropharynx where the glands are located.

PHYSIOLOGY

Saliva is the secretory product of the three paired major salivary glands and the 600 to 1,000 minor salivary glands. It has a myriad of functions, including aiding in digestion, gustation, protection against infection, dental caries and cancer, mastication, de-

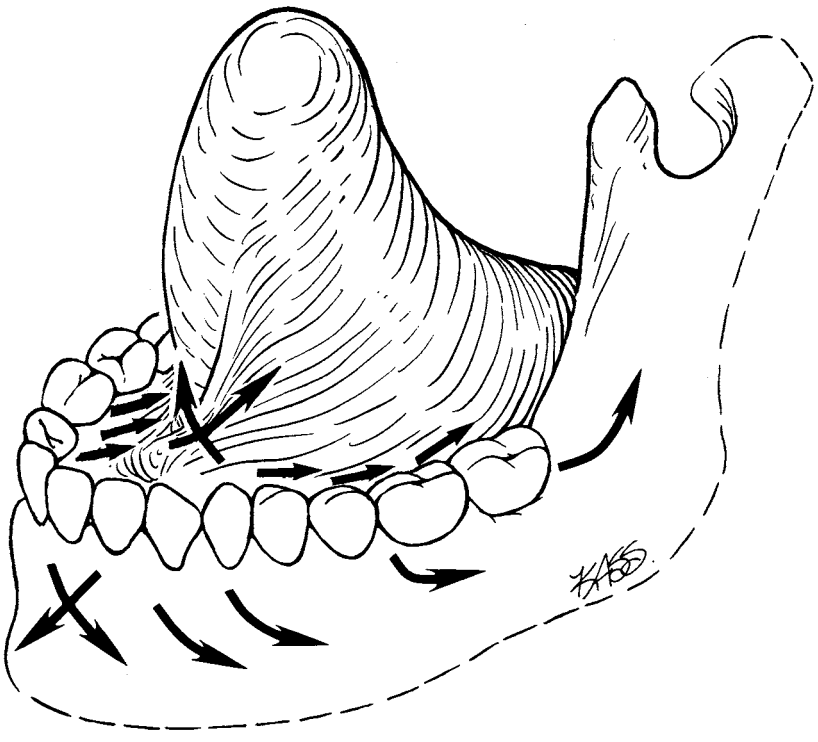

FIGURE 43–6. Drawing of the superficial lymphatic vessels of the floor of the mouth.

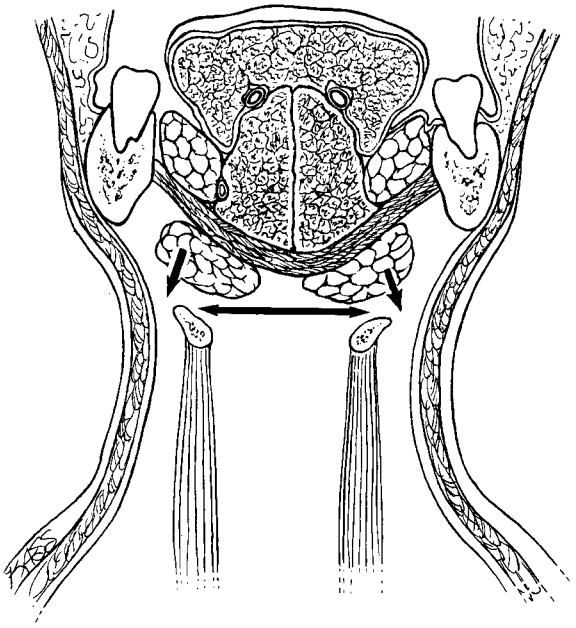

FIGURE 43–7. Drawing demonstrating the upper jugular efferent lymphatic communicating pathway when the submandibular group of lymph nodes has been bypassed.

glutition, lubrication, protective coating, and homeostasis, as well as hormonal interaction. Saliva has numerous components, including salts, gases, and organic substances, including immunoglobulin A, and its production is influenced by several factors, including psychological states, circadian rhythms, hydration, sleep, age, hormones, diet, and drugs. The actual production of saliva is a complex process involving both secretion and reabsorption. Saliva has many functions, many of which are intertwined. Saliva aids in digestion through lubrication that allows for the smooth passage of food. Saliva also allows for the dissolution of soluble food products and the active digestion of carbohydrates by amylase. The dissolution of soluble food products also enables their chemical interaction with taste receptors. The importance of salivary amylase has been debated since a lack of salivary amylase does not seem to precipitate nutritional deficits. Its activity, though, is not disputed, and it can be active in the stomach for several hours inside a food bolus.

Saliva serves an important protective role through numerous mechanisms. Saliva dilutes and dissolves retained food products, cellular debris, and bacteria. Glycoproteins in saliva coat the mucosal surface and serve as barriers to chemical irritants or desiccation. Lysozyme, peroxidase or thiocyanate-dependent factor, bacteriolysin, and immunoglobulin A all confer an antibacterial effect.

Saliva is composed of salts, namely sodium chloride, potassium chloride, sodium bicarbonate, bisodium and monosodium phosphates, calcium carbonate, calcium phosphate, and potassium sulfocyanate; gases, namely carbon dioxide, nitrogen, and oxygen; and organic substances, namely amylase, maltase, lysozyme, seralbumin, seroglobulin, urea, uric acid, creatine, amino acids, and mucin. The bicarbonates and phosphates serve to buffer the pH around 6.8. At alkaline pH levels, calcium salts precipitate and may form stones within the salivary ducts and cause the deposition of tartar (dental calculus).

Regulation of Saliva

One to 1½ L of saliva are produced daily. The rate of flow varies during the day but averages 1 mL/min. During sleep, practically no saliva is produced by the major salivary glands. Resting flow is estimated to be around 0.33 to 0.65 mL/min, which can increase to

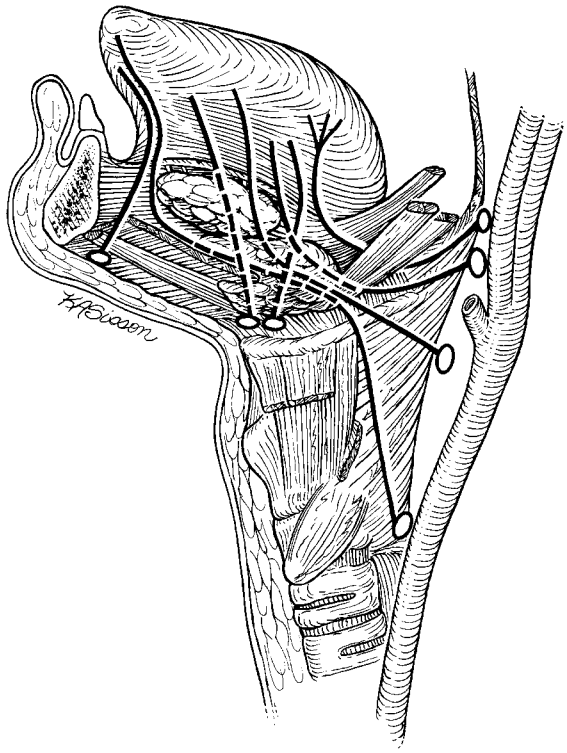

FIGURE 43–8. Lymphatic drainage routes from the tongue.

1.7 mL/min when stimulated. In the unstimulated state, saliva from the major salivary glands is produced predominantly by the submandibular glands (69%), followed by the parotid glands (26%) and the sublingual glands (5%). During stimulation, the parotid glands significantly increase saliva production and supplant the submandibular glands with 67% of saliva production. The minor salivary glands remain constant in their production of saliva at 7 to 8%.

Speech

The production of speech requires a source of air flow (lungs), a sound generator (vocal folds), and a resonator (pharynx and oral cavity; the nose is included in the resonating chamber when the palate is lowered). Articulators change the form of the vocal tract. The structures that affect articulation are the lips, tongue, mandible, teeth, palate, pharynx, and larynx; specifically, the gestures of these structures in articulation include opening, pursing, and tensing of the lips; position, configuration, and dynamics of the tip, margins, dorsum, and base of the tongue; opening and closure of the velopharyngeal valve by the palate and pharynx; movement of the side walls of the pharynx; and raising and lowering of the larynx. Articulators play the dominant role in producing speech sounds represented by consonants.

The dimensions of the vocal tract affect resonance. With resonance, formants or dominant frequencies emerge that can be altered or tuned by changing the shape of the vocal tract.[6–9] Formants are used to produce a voice quality unique to the individual. They determine vowel quality and provide a unique personal voice timbre. The two lowest formants determine most of the vowel color, and the third, fourth, and fifth determine the personal voice timbre (see Chapters 47 and 49).

Swallowing

Swallowing is a complex and complicated function and is divided into four overlapping phases: oral preparatory stage, oral stage, pharyngeal stage, and esophageal stage.[10] The first two are voluntary, and the third and fourth are involuntary. In the oral preparatory stage, the lips are sealed, and the cheeks tense to hold the muscles close to the teeth. The food is chewed while the tongue constantly repositions it to keep it between the teeth. The soft palate is in contact with the tongue, and the tongue holds the food in a ball ready to begin the oral stage of swallowing. In the oral stage of the swallow, the tongue and, to some extent, the buccal musculature move the food bolus from the front of the oral cavity to the anterior faucial arch, where the swallowing reflex is initiated.

The pharyngeal stage has four defined components: velopharyngeal closure; peristalsis of the superior, middle, and inferior pharyngeal constrictor muscles; airway protection; and cricopharyngeal relaxation. These are reflexive and are mediated in the brainstem in the reticular formation immediately adjacent to the respiratory center. There is coordination between the two centers. The larynx is elevated and closed (see Chapter 47), protecting the airway,[11] while the piriform sinuses contract and the cricopharyngeus muscle relaxes.[12] These reflex movements are in sequence and overlap one another.[13] This happens very rapidly as shown on videofluoroscopic analysis, where in a single frame (1/24 of a second), the barium from the piriform sinuses empties into the esophagus.

In the final esophageal stage, the bolus moves down the esophagus assisted by gravity, positive external pressure, peristalsis of the esophageal musculature, and negative intraesophageal pressure.

ACKNOWLEDGMENT

Dr. Lowry expresses appreciation to the following medical students who assisted in the development of this chapter: Esmael N. Amjad, Jennifer G. Andrus, Patrick C. Barth, Lisa Grunebaum, Brian Kung, Spencer Payne, and Joseph L. Smith.

CHAPTER 44

Diseases of the Oral Cavity, Oropharynx, and Nasopharynx

Lawrence W. C. Tom, MD, Ian N. Jacobs, MD

The oral cavity and oropharynx are contiguous anatomic regions, and diseases of these two areas should be considered together. A careful and systematic examination of the oral cavity will include the oropharynx. These regions are frequently exposed to the same external factors. Infectious, inflammatory, and traumatic conditions frequently affect both regions.

Although the nasopharynx is distinct from the oral cavity and oropharynx, the most common pediatric conditions affecting this area involve the adenoid tissue either through infection, hyperplasia, or both. In most cases, the tonsils are also involved, and it is only logical that the adenoids and tonsils be discussed together. Congenital anomalies and neoplasms of the nasopharynx are discussed in other chapters.

ORAL MANIFESTATIONS OF SYSTEMIC DISEASES

Lesions of the oral cavity and oropharynx may be presenting signs of an undetected systemic condition. These regions are readily accessible to the otolaryngologist, and with the proper equipment and a little patience, a thorough examination can usually be performed. Awareness and familiarity of the oral and oropharyngeal manifestations of systemic diseases are important for their early diagnosis. Some diseases can be diagnosed because of a characteristic presentation. Many other signs, however, are nonspecific, but their presence, especially when accompanied by symptoms and signs of disease in other regions of the body, should alert the otolaryngologist to the possibility of a systemic condition.

Infections

Several common viral childhood infections have oropharyngeal manifestations. Rubeola (measles) is characterized by cough, coryza, conjunctivitis, a generalized maculopapular rash, and Koplik's spots. Koplik's spots are red lesions with a pale blue center and are found on the buccal mucosa, most commonly opposite the lower molars. They appear 24 to 48 hours before the rash. With varicella (chickenpox), a generalized pruritic vesicular eruption usually begins on the trunk, spreading to the head and extremities, and is accompanied by mild systemic symptoms. Vesicles can affect any mucous membrane, including the oral cavity and pharynx. The vesicles rupture, progressing to shallow ulcers that resemble aphthous ulcers.

Inflammatory Disorders

Systemic inflammatory diseases frequently affect the oral cavity and oropharynx. Significant sequelae may develop if there is a delay in diagnosis and treatment.

Behçet's syndrome is rare in children. It is an inflammatory disorder of unknown etiology characterized by recurrent oral and genital ulcers and ocular inflammation such as uveitis and iridocyclitis. The initial complaint is usually that of a painful oral ulcer indistinguishable from an aphthous ulcer. The diagnosis should be suspected when the triad of findings is present but may be difficult because multifocal involvement may not occur simultaneously. The most common significant complication is scarring about the eye, leading to visual loss and even blindness. Corticosteroids, chlorambucil, and acyclovir have been used to treat this condition.

Reiter's syndrome is another condition of unknown cause that is uncommon in children. It occurs primarily in young men and classically presents with urethritis, uveitis, conjunctivitis, and arthritis. Oral lesions often occur and are characterized by superficial, erythematous ulcers, which are surrounded by white annular lines.[1] When the ulcers

occur on the tongue, the condition may be mistaken for geographic tongue. Although the ulcers usually present after the onset of the disease, their appearance helps to establish the diagnosis. Most children recover without complications. Treatment is supportive.

Wegener's granulomatosis may affect the oral cavity. Gingival hyperplasia is the most common early oral lesion.[2] Lingual, palatal, and buccal ulcers are also common. Characteristically, they are painful and surrounded by an erythematous rim.

Erythema multiforme is an acute inflammatory disorder of unknown etiology involving the skin and mucous membranes. Its onset has been associated with infections, autoimmune disease, emotional stress, and medications, including penicillins, cephalosporins, and sulfonamides. It affects males more than females and usually occurs in patients 10 to 30 years old.[3] There are two forms of the disease. Erythema multiforme minor causes minimal skin and mucosal damage and is self-limited, lasting 2 to 3 weeks. Erythema multiforme major (Stevens-Johnson syndrome) is associated with systemic manifestations, purulent conjunctivitis, and hemorrhagic, necrotic skin and mucosal lesions. It is common with drug ingestion and may result in death, primarily from pulmonary involvement.

The skin lesions usually begin on the palms and feet and are often accompanied by fever, malaise, and fatigue. The characteristic appearance is the "target" or "iris" lesion, a central bulla surrounded by an erythematous rim. These lesions may merge and typically spread symmetrically over the extremities. Oral lesions occur in 50% of cases, usually simultaneously with the skin lesion, but in 25% of patients, skin involvement is absent, making diagnosis difficult. The lips, tongue, and floor of the mouth are most often affected. The lesions begin as vesicles and bullae that rupture, producing superficial ulcers and hemorrhagic crusts, especially about the lips (Figure 44–1). The diagnosis is made clinically. Treatment of the minor form consists of local care and antihistamines. Treatment of Stevens-Johnson's syndrome requires systemic corticosteroids and, if possible, eliminating the causative agent.

Pemphigus vulgaris, pemphigoid, and cicatricial pemphigoid (benign mucous membrane pemphigoid) are autoimmune vesiculobullous disorders of the skin and mucous membranes. They occur primarily in patients between 40 and 60 years but may affect children. Differentiation among these conditions is based on clinical, histologic, and immunologic criteria. All conditions are characterized by a loss of cohesion among epidermal cells (acantholysis), with a resulting cleft and accumulation of intradermal fluid and blisters. In pemphigus vulgaris, the cleft is in the suprabasal layer and in pemphigoid at the basement membrane zone. Loss of epidermis by rubbing skin and mucous membranes (Nikolsky's sign) occurs in pemphigus vulgaris but not in pemphigoid.

FIGURE 44–1. Erythema multiforme with multiple erosions of the lips and tongue. Courtesy of George Lasarkis. Reproduced with permission of Lasarkis G.[9]

Pemphigus vulgaris is the most common form of pemphigus, representing over 90% of cases. It presents initially in the oral cavity in 60% of cases, and in over 90%, there will be oral cavity involvement. In children, almost all cases begin in the oral cavity.[4] Vesicles and bullae form and rupture, leaving painful, superficial ulcers. These lesions are nonspecific and are often indistinguishable from erythema multiforme. Cases limited to the oral cavity are difficult to diagnose. The presence of lesions on the skin and other mucosal surfaces should raise the suspicion for this disease. Patients are treated with corticosteroids and immunosuppressants. Although the prognosis is generally good, serious cases can be life threatening.

Cicatricial pemphigoid begins in the oral cavity in 95% of cases and eventually involves the oral mucosa in all cases. Desquamative gingivitis is the most common lesion. The mucosal lesions are characterized by recurrent vesicles or small bullae that rupture, causing erosions. The skin and other mucosal surfaces are less frequently involved. Bullous pemphigoid is primarily a cutaneous disease characterized by bullous lesions that rupture, leaving denuded areas. The oral mucosal lesions develop in 40% of cases. Cicatricial and bullous pemphigoid are treated with systemic corticosteroids.

Kawasaki's disease (mucocutaneous lymph node syndrome) is an acute multisystem vasculitis of unknown etiology. It is a disease occurring primarily in children under 5 years of age, with a peak incidence in children 1 to 2 years.[5] It is characterized by 4 to 5 days of high fever, bilateral conjunctivitis, polymorphous erythematous rash, erythema and edema of the extremities (Figure 44–2), cervical lymphadenopathy, and oropharyngeal changes, including strawberry tongue; dry, fissured lips; pharyngeal injection; and necrotic pharyngitis. Early diagnosis and treatment are paramount. Kawasaki disease is the most common cause of acquired cardiac disease in children under 5 years of age. Fifteen to 20% of untreated children will develop cardiac complications, with coronary artery aneurysm being the most serious. Patients are treated with intravenous gammaglobulin and aspirin.

Sjögren's syndrome is a collagen vascular disease characterized by the triad of keratoconjunctivitis, xerostomia, and arthritis. The xerostomia results from the lymphocytic infiltration of the salivary glands and causes dental caries and fissures and ulcers of the tongue, lips, and buccal mucosa. A labial biopsy will establish the diagnosis by demonstrating lymphocytic infiltration of the minor salivary glands.

Systemic lupus erythematosus is a generalized vasculitis affecting many organ systems. It primarily affects adolescents and young women. Twenty-five percent of patients with systemic lupus erythematosus have oral lesions. Xerostomia and its associated conditions are common. Other findings include petechiae, hemorrhagic bullae, and white keratotic plaques on the tongue and oral mucosa.[6]

FIGURE 44–2. Bilateral palmar erythema in a child with Kawasaki's disease.

Miscellaneous Disorders

Several vitamin and mineral disorders have oral manifestations. Iron deficiency anemia is common in children. Its oral manifestations include burning of the tongue, pallor of the mucous membranes and gingiva, atrophic smooth erythematous tongue, angular cheilitis, and, occasionally, hyperkeratotic lesions on the oral mucosa. Plummer-Vinson syndrome usually occurs in middle-aged women, with iron deficiency accompanied by dysphagia. The dysphagia is secondary to erosions and webs in the esophagus. This syndrome has been associated with development of oropharyngeal and esophageal malignancies.

Blue-black lines along the gingival margins and spots on the buccal mucosa, palate, and tongue may occur with lead, mercury, arsenic, and bismuth poisoning. Fluoride may cause staining of the teeth, whereas granulomas of the oral cavity have resulted from iodides and bromides.

Vitamin C deficiency, scurvy, is associated with swollen red gingiva, which frequently progresses to bleeding ulcerative gingivitis, oral petechiae and hemorrhages, and stomatitis. Glossitis occurs in the early stages of riboflavin (vitamin B_2) deficiency. As the condition continues, the tongue may appear smooth red. Gingival and labial pallor, angular cheliosis, and burning of the lips, mouth, and tongue may develop. Both vitamin B_{12} and folic acid deficiencies may cause a megaloblastic anemia and present with recurrent oral ulcers and painful atrophy of the oral mucosa and tongue. The signs and symptoms of niacin deficiency, pellegra, include pain, erythema, and edema of the oral mucosa and tongue, necrotizing ulcerative gingivitis, and angular cheilitis. Since multiple vitamin deficiencies are common, many of these findings may be noted together.

Lesions of the oral cavity often are among the initial signs of acute hematologic disorders. Petechiae, ecchymoses, and hemorrhages appear with thrombocytopenia, whereas pallor of the mucous membrane may occur with anemia. Patients with polycythemia may present with a purple-blue discoloration of the tongue and gums. In addition to being anemic and thrombocytopenic, patients with leukemia are often neutropenic, and secondary infections of the oral cavity and oropharynx commonly occur, resulting in necrosis and ulceration of the mucous membranes. Leukemic cells may also infiltrate the soft tissues of the oral cavity. Leukemic infiltration of the gums is common, causing gingival hypertrophy, edema, inflammation, and bleeding.

INFECTIONS

Infections of the oral cavity and oropharynx may be isolated local infections or manifestations of systemic infection. Acute viral pharyngitis constitutes one of the most common reasons for seeking outpatient medical care. The otolaryngologist must recognize the clinical pattern of infections, distinguish viral infections from other diseases, and institute proper treatment.

Viral Infections

Viral infections in the oral cavity may often be misdiagnosed as bacterial infections. At this time, there is no definitive therapy for most viral lesions. Fortunately, most are self-limited in duration. Many can be treated for symptomatic relief with mouthwashes. Occasionally, a superimposed bacterial infection may occur, and antibiotic coverage may be of additional benefit. With some viral infection, the agent may lie dormant for periods of time only to be reactivated, causing clinical exacerbations of the disease.

Herpangina Herpangina is a relatively common viral infection in young children and may mimic bacterial pharyngitis. It is usually caused by coxsackie A virus, but coxsackie B virus and other enteric pathogens may also cause herpangina. The peak incidence is during the summer and fall. Symptoms include rapid onset of severe sore throat, pyrexia, and malaise. Physical examination reveals severe erythema of the oral cavity and multiple small vesicles and superficial ulcers of the mucosa. The most common area of involvement is the posterior aspect of the oropharynx, including the soft palate, tonsils, uvula, and posterior pharyngeal wall. Usually, the gingiva is not affected. The disease is usually self-limited, and treatment is aimed at symptomatic relief.

Hand-Foot-and-Mouth Disease Hand-foot-and-mouth disease is a viral illness of the oral cavity mucosa caused by a coxsackie A virus. It usually affects young children. Its presentation is similar to herpangina, with the exception that it affects the anterior part of the oral cavity more frequently. The tongue, palate, and buccal mucosa are more likely to

be involved. In addition, vesiculopapular lesions are found on the palms and soles.[7] Associated pain and fever may occur. This disease is self-limited, and the treatment is supportive.

Herpes Simplex Herpes simplex virus (HSV) infection may present in two ways in the oropharynx: a primary infection, primary herpetic gingivostomatitis, and recurrent or secondary herpes. Primary herpetic gingivostomatitis is a common illness in the preschool child. Initially, it begins with a prodrome of nonspecific symptoms, including fever and malaise. Within a day or two, the oral mucosa becomes painful and erythematous. Vesicles form and rupture within 24 hours, and the ulcers heal in about 2 weeks. The ulcers form a gray pseudomembrane, may coalesce, and cover most of the oral cavity (Figure 44–3). Diffuse bilateral lymphadenopathy is common. In addition to the oral mucosa, lips, and tongue, the gingiva is almost always affected but often without the formation of vesicles. Diagnosis is made by viral studies and biopsy, which will reveal intranuclear inclusion bodies.

The HSV will remain dormant in the neuroganglion cells for life. Activation of the virus will result in recurrent herpes. Precipitating factors include sunlight, fever, bacterial infections, stress, immunodeficiency, and other systemic illness. Clinically, there may be an initial period of burning in the mouth. Multiple vesicles appear on the oral mucosa and near the vermilion borders, forming typical "cold sores," and rupture over a course of 10 to 14 days. Herpes labialis develops when the lips are involved. In most cases, treatment is symptomatic, but acyclovir may be beneficial.

Herpes Zoster Herpes zoster results from reactivation of the dormant varicella virus in the sensory ganglia. Oral and skin lesions develop along the distribution of the second and third branches of the trigeminal nerve. A classic trigeminal skin pattern establishes the diagnosis. Herpes zoster is uncommon in infants and children and usually occurs in elderly patients. Treatment is with topical antiviral agents such as acyclovir.

Cytomegalovirus Infection Cytomegalovirus (CMV) is a member of the herpes family, and CMV infections are becoming more prevalent, especially with the increasing number of immunosuppressed and immunodeficient patients. In the oral cavity, these infections are characterized by large ulcers of the mucosa and exudative pharyngotonsillitis, which is similar to that of infectious mononucleosis but less severe. Frequently, there is an associated cervical lymphadenopathy. Treatment is primarily symptomatic.

Infectious Mononucleosis Oropharyngeal signs are prominent in infectious mononucleosis. Children, adolescents, and young adults frequently present with a sore throat, grossly enlarged tonsils with a

FIGURE 44–3. Herpetic stomatitis with ulcers of the lips and tongue. Courtesy of Dr. Steven Handler.

gray membraneous exudate, and edema and petechiae of the soft palate (Figure 44–4). Other manifestations include cervical lymphadenopathy, which can be marked, hepatosplenomegaly, fever, malaise, and fatigue. Treatment is usually supportive, but when the tonsillar hypertrophy and pharyngeal edema cause respiratory distress, corticosteroids are used.

Human Immunodeficiency Virus Infection There are at least 40 oral manifestations of human immunodeficiency virus (HIV) infection, and the most common sites of involvement are the palate, tongue, lips, and buccal mucosa.[8,9] Signs that suggest the possibility of HIV infection include oral candidiasis; recurrent herpetic and aphthous ulcers; angular cheilitis; hairy leukoplakia, a white corrugated lesion found at the lateral borders of the tongue; periodontitis; gingivitis, especially bleeding ulcerative gingivitis; papillomas; and diffuse parotitis. Kaposi's sarcoma is highly suggestive of HIV infection. In the oral cavity, it may present early as a pigmented macule, papule, or patch or as a hemorrhagic lesion. These lesions may progress to necrosis and ulceration. Later, Kaposi's sarcoma may appear as a lobulated tumor with or without ulceration. In children, the most common signs of HIV infection are oral candidiasis, diffuse parotitis, and oral ulcers.[10]

Recurrent Respiratory Papillomatosis The human papillomavirus causes recurrent respiratory papillomatosis of the airway and may also involve the oral cavity and oropharynx. The virus causes the formation of exophytic, cauliflower-like lesions. Papillomas are found most commonly on the soft palate and tongue. Treatment involves surgical excision with a laser, electrocautery blade, or knife. Histologic analysis establishes the diagnosis and should always be performed because of the possibility of malignant transformation. Recurrences of papilloma in the oral cavity and oropharynx are relatively uncommon after complete excision.

Bacterial Infections

Streptococcal Infections Group A beta-hemolytic streptococcus may cause severe pharyngitis. Patients complain of fever, malaise, sore throat, odynophagia, dysphagia, otalgia, and halitosis. The oropharynx and, to a lesser extent, the oral cavity are swollen and red, and the tonsils are covered with exudates. Strawberry tongue, small red spots on the tongue, is a common finding. Examination of the neck may reveal swollen, tender lymph nodes. Since other bacterial pathogens may account for a similar presentation, cultures are required to make a definitive diagnosis. Scarlet fever produces a diffuse erythematous rash that is caused by an erythrogenic toxin produced by the group A beta-hemolytic streptococcus. Rheumatic fever and glomerulonephritis are potential complications of streptococcal pharyngitis. When streptococcus is suspected, antibiotics should be started before culture results have been reported. Penicillin and amoxicillin are initial choices.

FIGURE 44–4. Exudative tonsillitis in a patient with infectious mononucleosis. Courtesy of Dr. Steven Handler.

Diphtheria Diphtheria, which is caused by *Corynebacterium diphtheriae*, is rare in the United States but not uncommon in other parts of the world. The primary site of involvement is the oropharynx, where it presents as a necrotizing pharyngitis associated with severe erythema and a thick pseudomembrane. The disease may progress to involve the larynx and trachea, leading to airway obstruction. The bacteria produce exotoxins, which may cause systemtic symptoms, including cardiac and neurologic sequelae. *Corynebacterium diphtheriae* may be identified on stains from the pseudomembrane, but cultures are required for definitive diagnosis. Treatment for diphtheria consists of airway support, antitoxin, and antibiotics (see Chapter 52).

Syphilis and Gonorrhea Both syphilis and gonorrhea may involve the oral cavity and oropharynx. A classic feature of congenital syphilis is Hutchinson's teeth, hypoplastic teeth with notching of central incisors. Rhagades, atrophic glossitis, and a high arched palate are other common oral signs. In acquired syphilis, the primary lesion is a chancre, an enlarging ulcer surrounded by induration. If untreated, this resolves spontaneously, but secondary mucosal lesions, most commonly superficial ulcers covered by a grayish-white membrane, will develop. The oral lesions of tertiary syphilis include gummas of the palate, granulomatous lesions that may destroy and perforate the palate, and atrophic glossitis. Although it is uncommon, gonorrhea may affect this region, primarily the oropharynx. A gonococcal infection must be considered in any patient presenting with a membranous pharyngitis (see Chapter 30).

Fungal Infections

Candidiasis is the most common fungal infection of the oral cavity. *Candida albicans* is an opportunistic microorganism and part of the normal oral flora. When there is a reduction in the normal oral flora or a decrease in the host resistance, it becomes increasingly prevalent and causes an overt infection. Predisposing conditions include long-term antibiotic use, diabetes, corticosteroid therapy, and any condition causing immunosuppression. Three presentations are common in children.

Pseudomembranous candidiasis (thrush) is the most common candidal infection in the oral cavity. It occurs in all age groups but most often in infants. Patients complain of burning, dryness, and pain in the mouth. Thrush is characterized by the presence of fine white lacey plaques covering the mucosa of the oral cavity, usually the tongue, hard palate, and buccal mucosa. When the plaque is disrupted, a raw surface remains. In children with diabetes or immunodeficiency, severe invasive oropharyngeal and esophageal candidiasis may develop. The diagnosis is usually made on clinical grounds. Smears may demonstrate hyphae, but cultures are required for a definitive diagnosis.

Acute atrophic candidiasis occurs primarily as a result of long-term antibiotics, long-term corticosteroids, or immunosuppressive agents and is much less frequent than thrush. Patients complain of sore throat, burning of the mouth, and foul taste. Examination reveals red, ulcerated mucosa rather than a pseudomembrane.

Angular cheilitis is manifest by pain and erythema and microfissures at the oral commissure. As the condition continues, erosions of the skin and desquamation of epithelium surrounded by hyperkeratosis develop.

Before treating a candidal infection, a search for an underlying condition should be made. Most children can be treated with a topical, antifungal agent, and if this fails, a systemic agent such as ketoconazole, fluconazole, and even amphotericin can be used.

Other fungal agents may occasionally involve the oral cavity. Histoplasmosis may cause ulcers in the oral cavity. In immunosuppressed and chronically ill patients, mucormycosis may manifest as an ulcer or granuloma, usually on the hard palate.

Miscellaneous Conditions of the Oral Cavity

Leukoplakia Leukoplakia is characterized by the presence of a white plaque on the oral mucosa. It is primarily a condition of adults and has a prevalence of 0.1 to 5%. It is considered a precancerous lesion, with malignant transformation occurring in 2 to 6% of patients. If the plaque adheres to the mucosa and keratosis is present, the chance of malignancy increases. Although it is uncommon in children, it has been noted in children with candidiasis and some viral infections.

Hairy leukoplakia is characterized by slightly elevated, corrugated white plaque usually found on the lateral borders of the tongue. It suggests the

development of acquired immune deficiency syndrome (AIDS) in patients with HIV infection.

Aphthous Stomatitis Recurrent aphthous stomatitis is the most common condition affecting the oral mucosa. The exact etiology is unknown, but recent studies suggest that an altered cellular immune response is a predisposing factor. It occurs in all age groups but usually appears initially in older children and adolescents. The condition is more common in females. Twenty-four to 48 hours before the appearance of the ulcers, there is a prodrome of a tingling, burning feeling and erythema in the oral cavity. There are three forms of ulcers based on their size, number, and duration. Minor aphthous ulcers occur in 80% of the cases. They are painful, shallow, ovoid ulcers less than 0.6 cm in size. The ulcers are covered by a gray membrane and surrounded by a red halo. They may be found alone or in groups, most often on nonkeratinized oral mucosa, such as the buccal mucosa, lips, and tongue. They resolve within 2 weeks without scarring and usually recur in 1- to 5-month intervals. Major aphthous ulcers are a more severe form of the condition. They are characterized by one to five ulcers that are larger than 0.6 cm and more painful than minor ulcers (Figure 44–5). In addition to the sites of minor ulcers, major ulcers also occur on the soft palate, floor of the mouth, and peritonsillar area. They persist for 3 to 6 weeks, may leave a scar, and recur in 1- to 3-month intervals. Herpetiform ulcers, the least common form of the condition, are characterized by crops of painful, multiple, pinpoint ulcers. These ulcers may coalesce, leaving large, irregular ulcers. Herpetiform lesions are found in all locations in the oral cavity, persist for 1 to 2 weeks, and recur at 1- to 3-year intervals. Treatment for all forms of aphthous stomatitis is symptomatic. Topical corticosteroids, topical lidocaine, and mouthwashes may reduce the pain. In severe cases, intralesional or systemic corticosteroids and acyclovir may help.

Lichen Planus Lichen planus is a common inflammatory disorder of the skin and mucous membranes. It primarily affects middle-aged adults but may occur in older children and adolescents. Its cause is unknown, but the disease is a cell-mediated immune response that has been associated with several autoimmune diseases. Oral lichen planus is usually found on the tongue, buccal mucosa, and gingiva. It may follow a course of exacerbations and remissions. There are two variants. The reticular form, the most common type, is characterized by small white papules, which may be isolated or may coalesce to form interlacing white lines (Wickham's striae). They frequently occur with bilateral symmetry. The reticular form causes no symptoms. The erosive form is manifested by painful ulcers with papules or lines at the periphery. Malignant transformation may potentially occur with the erosive form. Diagnosis is established by a biopsy of the edges of the lesions. Asymptomatic lesions require no treatment, whereas painful ones may be treated with topical, injectable, or systemic corticosteroids.

Burning Mouth Syndrome Burning mouth syndrome is a disorder of peri- and postmenopausal women. Patients complain of burning on the tip and lateral border of the tongue, which appears normal. It is caused by a local neuropathy. Treatment includes amitriptyline and clonazepam.

Median Rhomboid Glossitis Median rhomboid glossitis is a congenital disorder caused by the persistence of the tuberculum impar. As a result, a rhomboid area free of papillae appears on the dorsal surface of the tongue. It may present as a smooth, red plaque or a firm, raised, smooth, red mass (Figure 44–6). Some cases have been associated with *Candida* infections. In most cases, no treatment is necessary.

Geographic Tongue Geographic tongue (benign migratory glossitis) occurs in all age groups, with a prevalence of 1 to 2%. Although the exact etiology is unknown, it may be an inherited condition. The condition results from a loss of filiform papillae. It is characterized by a white margin of desquamating epithelium of various sizes and shapes on the dorsum of the tongue surrounding a central, red, atrophic area (Figure 44–7). These lesions disappear and migrate to other areas of the tongue. Similar lesions may occur on the oral mucosa. The condition is chronic and may persist for years. Treatment is not necessary.

Fissured Tongue This condition is characterized by multiple fissures or grooves on the dorsum of the tongue. The fissured tongue is usually asymptomatic but may become irritated if food particles, bacteria, or fungi become trapped in the fissures. It is believed to be an inherited disorder and has been associated with the genetic disorders Melkersson-Rosenthal syndrome and Down syndrome. Melkersson-Rosenthal syndrome is characterized by recurrent facial nerve palsy and edema of the face and mouth. Fissuring of the tongue is not pathognomic of Melkersson-Rosenthal syndrome but occurs frequently in it. No treatment is required.

Hairy Tongue This is a common disorder that is characterized by the hypertrophy and growth of the filiform papillae on the dorsal surface of the tongue, giving the tongue a hairy appearance. The papillae may become colonized with pigmented bacteria, producing multiple colors. Black hairy tongue is a common presentation. The cause remains unknown, although certain predisposing factors have been identified, including tobacco abuse, oral antibiotics, poor oral hygiene, and radiation therapy. The disorder is benign and usually asymptomatic. Long papillae may cause discomfort and may be treated with brushing.

Macroglossia The tongue may appear enlarged in many conditions. Relative macroglossia occurs when

FIGURE 44–6. Median rhomboid glossitis. Courtesy of Dr. Steven Handler.

FIGURE 44–7. Geographic tongue.

the tongue is normal in size, but anomalies of the surrounding structures make it appear large. Pierre Robin syndrome and Down syndrome are two such examples. Primary macroglossia is hypertrophy of the tongue musculature, whereas secondary macroglossia is caused by infiltration of tongue tissue.[11] Causes of primary macroglossia include hypothyroidism, acromegaly, and Beckwith-Wiedemann syndrome. Beckwith-Wiedemann syndrome is an autosomal genetic disorder characterized by organomegaly, omphalocele, hypoglycemia, and macroglossia. Many children with this syndrome are at risk for developing airway obstruction. The causes of secondary macroglossia are varied and include lymphangioma, hemangioma, rhabdomyosarcoma, angioneurotic edema, amyloidosis, glycogen storage diseases, neurofibromatosis, actinomycosis, syphilis, and tuberculosis.

Ranulas There are two types of ranulas, and they occur in all age groups. The simple ranula is a cystic lesion of the floor of the mouth representing either a mucocele from obstruction of the sublingual gland or a mucus extravasation pseudocyst from the sublingual gland.[12] It appears as a blue, superficial, nontender, fluctuant mass and is usually found on one side of the floor of the mouth (Figure 44–8). Small ranulas are asymptomatic, whereas larger ones may cause speech and swallowing problems. The plunging ranula is less common. It arises from a mucus extravasation pseudocyst that has extended through the floor of the mouth and presents as a soft, painless, ballotable, submandibular mass. It may present with or without intraoral involvement, with the diagnosis being more difficult if there is no visible intraoral lesion. Simple ranulas may be treated with marsupialization or excision of the sublingual gland. Excision of the sublingual gland with evacuation of the ranula is the recommended treatment for plunging ranulas.

DENTAL INFECTIONS AND CYSTS

Dental infections arise from dental caries, trauma to the teeth, and periodontal disease. The pulp of the tooth becomes inflamed and then necroses, leading to low-grade chronic inflammation or abscess formation. The infected tooth will be painful, tender, sensitive to changes in pressure and temperature, and slightly mobile and will feel raised. The surrounding gingiva will be raised and inflamed, and a draining fistulous tract may develop, indicating pulpal necrosis and abscess in the root canal. A tract may even develop to the face. Electrical vitality testing may demonstrate diminished or absent responses. Dental infections may remain localized to the dentoalveolar process; spread along fascial planes to other regions of the face, head, and neck; or become disseminated. As the infection progresses, radiographic findings appear and include widening of the periodontal membrane space, radiolucency of the periapical bone, and osteitis and destruction of the alveolar

FIGURE 44–8. Ranula. Courtesy of Dr. Steven Handler.

bone. The extent and severity of the infection do not correlate with the radiographic findings.[13] Treatment of dental infections consists of antibiotics and root canal therapy or tooth extraction.

Inflammation of the tooth pulp, gingiva, and periodontal structures may cause epithelial proliferation, leading to the development of certain odontogenic cysts. The periapical cyst accounts for at least 65% of odontogenic cysts. Necrosis of the tooth pulp causes chronic inflammation, leading to granuloma formation. Further inflammation within the granuloma stimulates cyst formation. The most common symptom is discomfort with biting. Large cysts may present as compressible masses in the palate or vestibule. Radiographically, the periapical cyst appears as a well-defined periapical lucency. Dental cysts, which develop from the gingiva, and inflammatory follicular cysts, which develop from dental follicles of unerupted permanent teeth, occur infrequently.

The dentigerous cyst, the second most common odontogenic cyst, develops from expansion of an impacted tooth follicle. It occurs most often in the mandibular third molar. Most of these cysts are asymptomatic and are found on dental radiographs. Large cysts may expand, causing displacement of adjacent structures, infections, and pathologic jaw fractures. Radiographically, it appears as a unilocular, pericoronal radiolucency. The odontogenic keratocyst is associated with bone destruction and frequent recurrences, despite surgery. Other odontogenic cysts include the developmental lateral periodontal cyst and botryoid odontogenic cyst.

BENIGN LESIONS OF THE GINGIVA, MANDIBLE, AND MAXILLA

Many benign soft tissue lesions arise from the gingiva. The pyogenic granuloma is a smooth, red, soft, pedunculated lesion that bleeds easily. It develops as a response to trauma and is treated by local excision. The peripheral giant cell reparative granuloma also develops from trauma. It presents as a sessile reddish mass of vascular tissue that bleeds easily and is most often found on the gingiva anterior to the premolars. Treatment is with excision or curettage. Epstein's pearls are small keratin cysts found on the alveoli or palate of the newborn. They are transient, exfoliating within a few weeks. The congenital epulis is usually found on the anterior maxillary gingiva, presenting as a pink, round, lobulated, pedunculated, mucosa-covered mass. Excision is curative. The melanotic ectodermal tumor of infancy occurs in the first 6 months of life and usually on the anterior maxilla near the junction of the globular and maxillary processes. It presents as a firm, well-circumscribed mass that may be pigmented and may cause facial swelling and nasal obstruction. Treatment is complete excision.

A variety of benign tumors develop from the mandible and maxilla. Odontogenic tumors arise

from the precursors of tooth formation. The odontoma, the most common odontogenic tumor, is a hamartoma arising from a mixture of dentin, enamel, and cementum. It is often associated with dentigerous cysts. It grows by expansion but rarely becomes large enough to be symptomatic. Treatment is with enucleation. The ameloblastoma arises from tissue involved in enamel formation. Initially, it presents as a painless, hard mass, but cystic degeneration and softening develop. Ameloblastomas may be locally aggressive, infiltrating into adjacent tissue and causing significant deformity. Radiographs demonstrate a multicystic, osteolytic, and expansile lesion.[14] Treatment is complete excision. Myxomas occur most often in children over 10 years of age and young adults. They also present as painless masses, often associated with loose teeth. Myxomas are locally aggressive, infiltrating into neighboring bone. They require wide resection, but recurrence is not uncommon. Adenoameloblastoma, cementoma, and cementoblastoma are rare odontogenic tumors.

Nonodontogenic tumors of the jaws arise from tissues other than dental precursors. The most common lesion is the torus, an exophytic, mucosa-covered, bony overgrowth. It is usually noted after puberty. It occurs in the midline of the palate in 20% of the population. In 8% of the population, a torus occurs near the midline of the lingual surface of the mandible, and 80% of these mandibular tori are bilateral. Most are asymptomatic and require no treatment.

Fibrous dysplasia of the jaws is found more often in the maxilla and is usually monostotic. It frequently presents as painless swelling in the canine fossa or zygoma. These lesions grow rapidly from early childhood to early adolescence, causing facial swelling and even proptosis. With puberty, fibrous dysplasia tends to stabilize. Conservative subtotal resection is recommended for lesions causing cosmetic or functional problems.

The giant cell reparative granuloma occurs primarily in patients 10 to 20 years of age and more often involves the mandible. It presents as a nontender intraoral mass with an accompanying mandibular deformity. This lesion is treated with curettage or excision. Other causes of nonodontogenic tumors of the jaws include osteoma, eosinophilic granuloma, aneurysmal bone cysts, hemorrhagic bone cysts, and cherubism. Malignant neoplasmas of the oral cavity and oropharynx are discussed in Chapter 61.

TONSILS AND ADENOID

Diseases of the tonsils and adenoid are some of the most common problems seen in children. Adenotonsillar disease can be broadly classified as infectious, obstructive, and miscellaneous. The "miscellaneous" group includes unilateral tonsillar hypertrophy and tonsilloliths.

INFECTIONS

Tonsillitis Acute tonsillitis is defined as an acute infection of the tonsils with symptoms of sore throat, fever, odynophagia, and general malaise. Physical findings include tonsillar hypertrophy and erythema and exudates on the tonsillar surfaces. There may be associated cervical lymphadenopathy, skin rashes, and fever. The disease is usually self-limited, lasting from 7 to 14 days, but during this period there may be significant loss of time from school or work.

An episode of acute tonsillitis may progress to recurrent acute tonsillitis, repeated episodes of acute tonsillitis followed by periods in which the patient is asymptomatic. During each acute episode, the patient may develop symptoms of acute tonsillitis. In addition to the signs of acute tonsillitis, patients experiencing recurrent acute tonsillitis may develop enlarged tonsillar crypts that accumulate debris, persistent erythema of the tonsils, and dilated blood vessels on the surface of the tonsils.

Many pathogens may be cultured from the surface and the core of the tonsils and may cause acute tonsillitis. Of greatest concern is group A beta-hemolytic streptococcus because it may lead to the development of rheumatic cardiac disease and glomerulonephritis. Group A beta-hemolytic streptococcus may be isolated on the tonsil surface but in up to 60% of cases may be found deep within the tonsillar crypts.[15] Therefore, cultures of the tonsil surface may not detect group A beta-hemolytic streptococcus as the cause of acute tonsillitis.

Treatment of acute tonsillitis should be based on clinical judgment, taking into consideration the entire clinical picture rather than just cultures of the tonsil surface. Antimicrobial therapy may be started even in the absence of a positive culture for group A beta-hemolytic streptococcus. In most cases, penicillin and amoxicillin are the initial drugs of choice. If there is a history of treated recurrent acute tonsillitis, the responsible pathogens are likely to be β-lactamase-producing bacteria, and a β-lactamase-stable

antibiotic, such as amoxicillin-clavulanate, should be used.[16]

Some patients may be carriers of group A beta-hemolytic streptococcus. If the patient is asymptomatic, no treatment is necessary. Patients who experience frequent episodes of acute tonsillitis, infect other patients, or develop complications should be treated. An initial course of antibiotics may eradicate the bacteria and carrier state. Adenotonsillectomy is indicated for treatment failures.

Children who continue to experience recurrent acute tonsillitis, despite adequate antibiotic therapy, should be considered for tonsillectomy and adenoidectomy. In over 70% of cases, core tonsil and core adenoid tissue harbor the same pathogens, and both tonsillectomy and adenoidectomy lead to their eradication.[17] Patients with three or more episodes of acute tonsillitis within a year are candidates for tonsillectomy and adenoidectomy.[18] It is important to document the dates of the last two infections, degree of fever, severity of disease, results of any throat cultures, and response to antibiotics.

Chronic tonsillitis is defined as persistent tonsillar infection and usually occurs in older children and young adults. Patients complain of constant throat pain, halitosis, and fatigue. Examination of the tonsils reveals hypertrophy, erythema, and enlarged crypts filled with debris. Chronic tonsillitis is treated with tonsillectomy if the symptoms are severe or the persistent infection interferes with normal activities.

Peritonsillar Infections Peritonsillar infections occur in all age groups but more often in adolescents and young adults. It is the most frequent head and neck space infection in children and the most common complication of acute tonsillitis. Infections of the tonsillar crypts extend beyond the tonsillar capsule to involve the peritonsillar space. Most infections occur in the superior pole of the tonsil, but some involve the midtonsillar area and inferior pole. The infection begins as a cellulitis and progresses to an abscess.

Patients complain of fever, unilateral sore throat, odynophagia, and trismus. The examination may be difficult because of the inability to open the mouth. The classic signs include a muffled voice; drooling, unilateral swelling, and erythema of the superior tonsillar pole; deviation of the uvula to the opposite side; and bulging of the posterolateral part of the soft palate. The oral airway may be compromised. The diagnosis of a peritonsillar space infection is usually made clinically, but it may be difficult to distinguish between cellulitis and an early abscess.

Patients with a suspected peritonsillar infection should be hydrated and given intravenous antibiotics and analgesics. If there is no improvement after 48 hours, airway compromise, or definite abscess formation, drainage should be considered. There is no consensus regarding the best technique. Options include needle aspiration, incision and drainage, and immediate tonsillectomy. Needle aspiration and incision and drainage have success rates greater than 90%, but there is a 10 to 15% risk of abscess recurrence.[19] Immediate tonsillectomy is curative and prevents recurrence, but in many patients, tonsillectomy may not be necessary. Tonsillectomy should be performed in patients with a history of recurrent infections or previous abscess.

Adenoiditis The adenoid tissue may become infected during an upper respiratory tract infection, causing fever, nasal obstruction, purulent rhinorrhea, postnasal discharge, and cough. These signs and symptoms are nonspecific and can occur with respiratory tract infections and sinusitis. Examination with a mirror or telescope may demonstrate inflamed, swollen adenoid covered with exudates. Treatment is with antibiotics, and if the condition becomes recurrent, antibiotics with activity against β-lactamase-producing microorganisms are recommended. If the condition persists, adenoidectomy is performed.

The relationship between adenoid infections and sinusitis has not been clearly established. Since the presentation of these two conditions is similar, adenoiditis may be misdiagnosed as sinusitis, and adenoiditis may be a causal factor in pediatric sinusitis. In a child with chronic sinusitis, it has been suggested that an adenoidectomy be performed a minimum of 3 months prior to pediatric endoscopic sinus surgery.[20] If there is significant improvement of symptoms, sinus surgery may be avoided.

Obstruction

Upper airway obstruction is the second most common indication for tonsillectomy and adenoidectomy in children and may present in an acute or chronic fashion. Infections, such as mononucleosis or peri-

tonsillar abscess, may cause acute upper airway obstruction. With a history of sore throat and dysphagia, examination may reveal an acute infection with signs of airway obstruction. Some children may be managed as outpatients with antibiotics and corticosteroids. Others may require hospitalization, especially to monitor and secure the airway. If symptoms persist, an emergency tonsillectomy and adenoidectomy may be required. These patients may need to recover in a carefully monitored environment such as a pediatric intensive care unit. Sudden relief of upper airway obstruction may cause postobstructive pulmonary edema. Fluid may extravasate into the alveoli with a rapid change in intrathoracic pressure. Immediate recognition of this problem is essential. Treatment consists of intubation with the administration of positive end-expiratory pressure and diuretics.

Chronic upper airway obstruction most often occurs when both tonsils and adenoid are enlarged but may occur when either is enlarged. A thorough history is important to establish the diagnosis. Questions regarding mouth breathing, snoring, snorting, gasping, and apnea should be elicited. Parents should be asked about a child's sleep habits. Restless sleep, extension of the neck during sleep, enuresis, frequent waking, growth disturbances, and failure to thrive suggest airway obstruction. Dysphagia and choking on solid foods indicate obstructing tonsils, whereas hyponasal speech suggests enlarged adenoid tissue.

The obstruction is related to the relative size of the tonsils and adenoid. An oral examination will usually reveal enlarged, obstructing tonsils. Nasopharyngeal examination, which is usually performed with a nasopharyngoscope, may be performed in cooperative children and reveals the size of the adenoid and presence of obstruction. Collapse of the pharyngeal musculature and lymphoid structures into the airway during sleep increases the obstruction. Children with poor neuromuscular tone may be more susceptible to airway collapse during sleep, whereas children with craniofacial anomalies may be at greater risk for obstruction from lymphoid hypertrophy. In these children, the tonsils and adenoid may not appear enlarged but may contribute to the obstruction. Depending on the obstructing tissue, tonsillectomy and/or adenoidectomy can be performed.

Children with obstructing tonsils and adenoid may have obstructive sleep apnea (OSA). Sleep apnea is defined as the intermittent cessation of air flow at both the mouth and nose during sleep. There is a repetitive hypopnea (reduction in breathing) or apnea (cessation of breathing). Obstructive sleep apnea is caused by an obstruction in the upper airway, and there is a vigorous effort to overcome this obstruction. Obstructive sleep apnea must be distinguished from the less common central sleep apnea in which the cause is in the brainstem. With central sleep apnea (CSA), the neural drive to the respiratory muscles is temporarily abolished, and there is little effort to breathe.

If the diagnosis is equivocal, a lateral neck radiograph can be performed to assess the size of the tonsils, adenoid, and nasopharyngeal airway. Either polysomnography or sleep sonography will provide objective data regarding the presence and degree of obstruction. During polysomnography, the frequency of apneas per hour (apnea index), apneas and hypopneas per hour (hypopnea-apnea index), and arousals per hour (arousal index) is recorded. The severity of oxygen desaturation, degree of hypercapnia, and frequency and grade of any cardiac arrhythmia should also be recorded. Although polysomnography provides the best objective measurement for obstruction, it is expensive and inconvenient for most children and their families. For normal, nonsyndromic children, there is a close correlation between the results obtained from polysomnography and sleep sonography.[21]

Miscellaneous Conditions

Tonsilloliths Tonsilloliths are concretions of epithelial debris that develop within the depth of the tonsillar crypts. Prior tonsil infections have sealed the opening of the crypts, allowing the collection of the the debris. Tonsilloliths appear as gritty, caseous white or yellow calculi up to 1 cm in size and have a foul odor. They may be removed with a blunt instrument or water irrigation but frequently recur. If the patient is concerned about the condition, tonsillectomy will eliminate the condition.

Unilateral Tonsillar Enlargement The finding of a unilaterally enlarged tonsil often raises the concern of a neoplasm within the tonsil or tonsillar fossa. In most cases, the larger-appearing tonsil is situated more medially within the tonsillar fossa, giving the impression of enlargement. In some cases, the enlargement is caused by a unilateral infection. Only

rarely is the enlargement caused by a malignancy. In these cases, the tonsil is not only enlarged, but the surface appears abnormal, with areas of necrosis and ulceration. If a malignancy is suspected, the tonsil is removed and sent for appropriate studies.

Otitis Media with Effusion The adenoid affects eustachian tube function in some patients. Regardless of the size, removal of adenoid tissue may reduce the extrinsic mechanical obstruction of the eustachian tube, improving the ventilatory function of the eustachian tube and allowing for equalization of pressure.[22] In addition, adenoidectomy has been shown to decrease the recurrence rates of otitis media.[23] Adenoidectomy should be considered in any child with evidence of nasal obstruction or adenoiditis and who is undergoing tympanostomy tube placement. It should also be considered in any child in whom tympanostomy tubes are being replaced (see Chapter 9).

Technique of Tonsillectomy and Adenoidectomy

There are a variety of techniques for removal of the tonsils and adenoids. For a tonsillectomy, dissection in the subcapsular plane can be performed with a knife, protected electrocautery blade, harmonic scalpel, or laser. Hemostasis can be obtained with electrocautery, suture ligation, and topical thrombin. The adenoid can be removed with a curette, adenotome, or powered instrument.

Today, most procedures are performed under general anesthesia. The patient is intubated and placed supine in the Rose position with a roll under the shoulders. A mouth gag is placed to expose the oropharynx. The palate is palpated to detect the presence of a submucous or frank palatal cleft. A complete adenoidectomy should be considered with great caution if a cleft is detected because there is an increased likelihood of developing velopharyngeal insufficiency. If a cleft exists, superior adenoid tissue may be removed, leaving the base to participate in velopharyngeal closure.

Two urinary catheters are used to retract the soft palate, and the nasopharynx is visualized with a mirror. A curette is placed at the base of the vomer and advanced, removing the bulk of the adenoid. Any additional pieces of tissue can be removed in a similar fashion. When the adenoid has been removed, sponges are placed into the nasopharynx to help with hemostasis. The sponges are removed individually, and hemostasis is obtained with suction electrocautery. Cauterization should not be performed near the eustachian tube orifice to prevent development of scarring and subsequent eustachian tube dysfunction.

Tonsillectomy is performed next. The superior pole of the tonsil is grasped with an Allis clamp. The mucosa of the anterior tonsillar pillar is incised with an electrocautery blade (Figure 44–9). The plane of the tonsil capsule is identified. As the tonsil is retracted medially, dissection continues inferiorly in this plane (Figure 44–10). The inferior attachment of the tonsil is severed with cautery. Hemostasis is achieved using a suction cautery. A Hurd retractor may be used to expose areas of the tonsillar fossa to obtain better hemostasis. After hemostasis is achieved, the catheters and mouth gag are removed.

Complications Bleeding is the most serious complication of tonsillectomy and occurs in up to 3% of

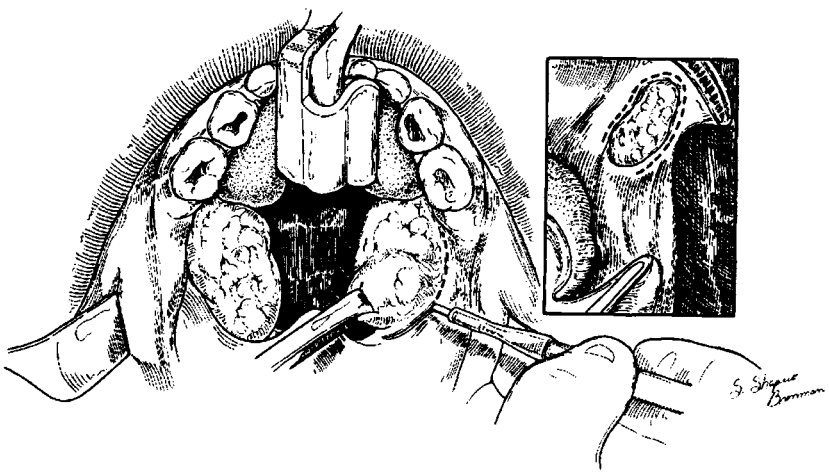

FIGURE 44–9. The tonsil is grasped with an Allis clamp, and the initial incision is made with an electrocautery blade. Courtesy of William P. Potsic, Robin T. Cotton, Steven Handler. Surgical pediatric otolaryngology. New York: Thieme Medical Publishers; 1997.

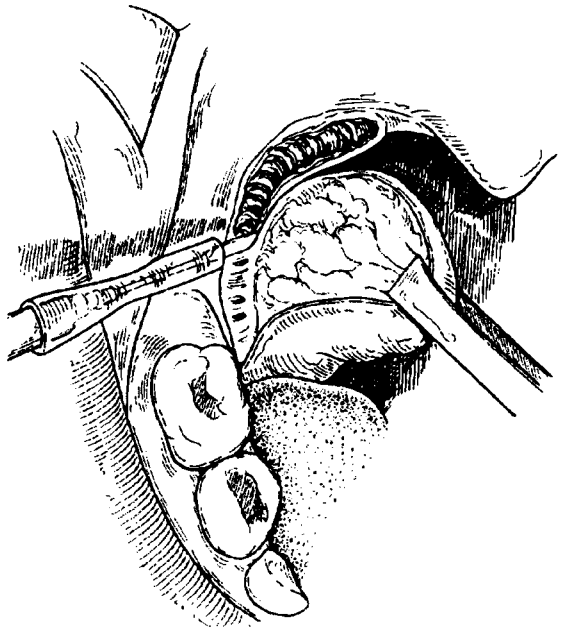

FIGURE 44–10. Dissection continues inferiorly in the plane of the tonsil. Courtesy of William P. Potsic, Robin T. Cotton, Steven Handler. Surgical pediatric otolaryngology. New York: Thieme Medical Publishers; 1997.

patients. Many of these patients must return to the operating room to control the bleeding, whereas others need only observation. Although it is rare, death from tonsillectomy still occurs and is usually a result of aspiration of blood into the airway rather than loss of blood volume.

Dehydration is a common complication in children. The children have severe sore throats and will not swallow because of the pain. These patients require intravenous hydration either on an inpatient or outpatient basis until they can maintain an adequate fluid intake.

Hypernasal speech is common immediately following the procedure because the pain causes limitation of the movement of the tonsillar pillars and soft palate. This usually resolves in several weeks. Permanent velopharyngeal insufficiency is usually caused by resection of the posterior pillars or an unrecognized palatal cleft. This may result in rhinolalia aperta and reflux of liquid through the nose. Treatment includes speech therapy and placement of a pharyngeal flap.

Torticollis is not uncommon and is usually caused by inflammation of the paraspinus muscles. This usually resolves spontaneously but may require a cervical collar or even cervical traction.

Nasopharyngeal and oropharyngeal stenosis, rare complications, are caused by resection of the posterior tonsillar pillars and cauterization of the base of the tongue, respectively. Nasopharyngeal stenosis is more common and is discussed in more detail later in this chapter. Oropharyngeal stenosis is usually caused by cauterization of the base of the tongue and posterior tonsillar pillar. Adhesions form between these structures, decreasing the size of the oropharynx.[24] Treatment includes injection with corticosteroids alone or combined with mucosal flaps.

HEAD AND NECK SPACE INFECTIONS

Antibiotics have reduced the incidence of infections of the fascial spaces of the head and neck, but these infections continue to occur. Atypical presentations are not uncommon in immunocompromised patients.

Fascia envelops the muscles, vessels, and viscera of the neck. Fascial planes form where adjacent fascia condenses. Fascial spaces are potential spaces between these planes.

The cervical fascia consists of two layers, the superficial or investing layer and deep fascia (Figure 44–11). The superficial layer lies just below the skin, completely encircles the neck, and is continuous with fascia of the face and the superficial fascia of the muscles of the back. Within this layer lie the platysma muscles, external jugular vein, and lymph nodes. The deep fascia comprises three layers. The anterior layer envelops the trapezius, sternocleidomastoid, omohyoid, and strap muscles and the parotid and submandibular glands. The middle or visceral layer surrounds the pharynx, esophagus, larynx, trachea, and thyroid gland. The prevertebral layer covers the vertebral bodies and paraspinus muscles. Contributions from all three layers form the carotid sheath, which contains the vagus nerve, carotid artery, and internal jugular vein.

Fascial spaces are potential avenues for the spread of infection. The spaces formed by fascia-enveloping muscle offer some resistance of the spread of infection, whereas the spaces formed by fascia-enveloping viscera and vessels are associated with the most serious infections because they offer little resistance to this spread.[25] Clinically, the most

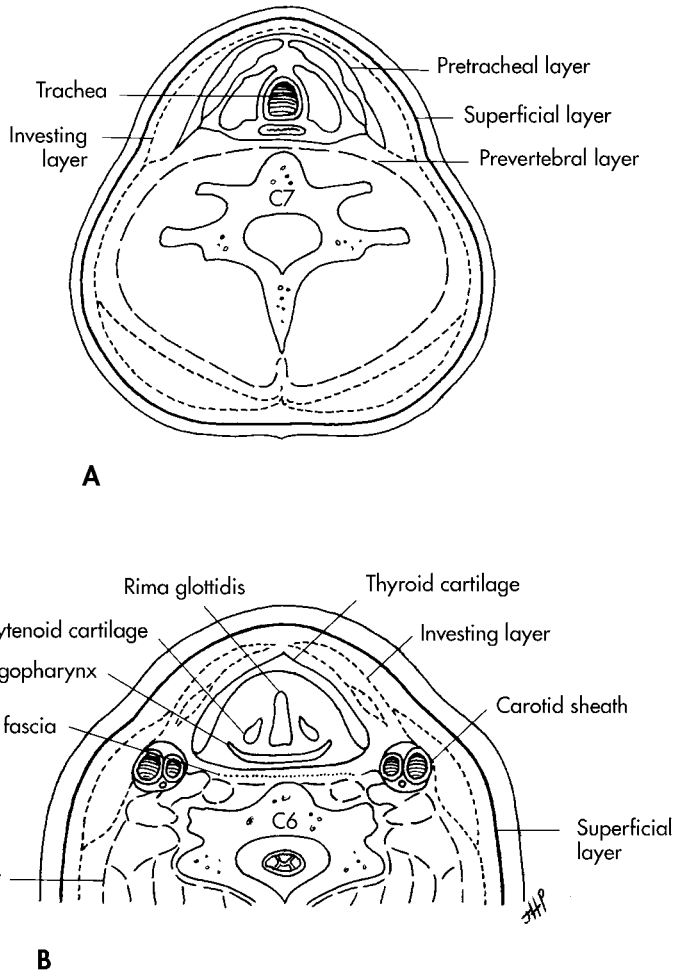

FIGURE 44–11. Fascial planes of the neck. *A*, Schematic representation of the fascial planes of the neck at the level of cervical vertebrae 7. *B*, Schematic representation of the fascial planes of the neck at the level of the thyroid cartilage.

important spaces are the prevertebral, retropharyngeal, lateral pharyngeal, and submandibular (Figure 44–12). The masticator, parotid, and peritonsillar spaces also have significance.

The prevertebral space lies between prevertebral fascia and the vertebral bodies and extends from the base of the skull to the coccyx.[26] Infections of this space may spread from the base of the skull to the psoas muscles.

The retropharyngeal space lies between the prevertebral fascia and the fascia covering the posterior pharyngeal wall and esophagus. It extends from the skull base to the tracheal bifurcation. It contains lymph nodes that receive afferent lymphatic vessels from the nose, nasopharynx, paranasal sinuses, oropharynx, and middle ear. These lymph nodes are prominent in children under 5 years of age and begin to atrophy after this age. This space is a major route for spread of infection into the mediastinum.

The lateral pharyngeal (parapharyngeal) space is cone shaped, with its base at the petrous portion of the temporal bone and its apex at the hyoid bone. Its contents include lymph nodes receiving afferents from the nasal cavity, paranasal sinuses, nasopharynx, oropharynx, and mastoid tip; the carotid artery; internal jugular vein; cranial nerves IX, X, XI, and XII; and the cervical sympathetic chain. The carotid sheath pierces this space at its apex. The lateral pharyngeal space communicates with the submandibular, retropharyngeal, and parotid spaces and is in close proximity to the masticator and peritonsillar spaces. The lateral pharyngeal space is the most frequently involved with serious infections and most frequent route of spread of infection from one region to another.

The submandibular space is divided by the mylohyoid muscle into two compartments, the sublingual space superiorly and submandibular space

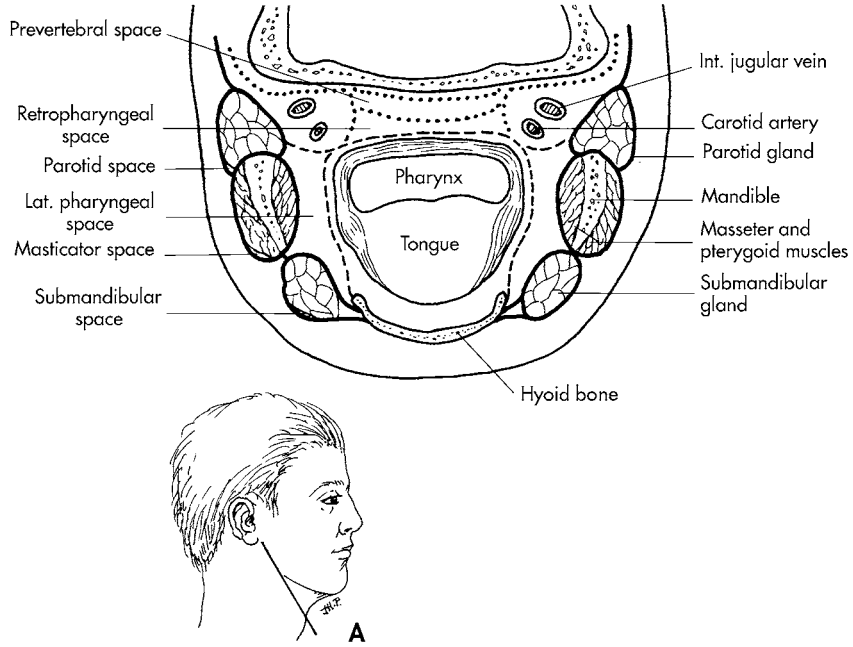

FIGURE 44–12. Fascial spaces of the neck at the plane indicated in *A*.

proper inferiorly. The two compartments are connected through an opening between the mylohyoid and geniohyoid muscles and communicate with their counterparts on the opposite side. The submandibular space is bound by the floor of the mouth, tongue, mandible, anterior layer of deep cervical fascia, and hyoid bone. It contains the sublingual and submandibular glands, lingual and hypoglossal nerves, facial artery, and lymph nodes.

The parotid space is formed when the anterior layer of deep cervical fascia splits and invests the parotid gland. The medial portion of the fascia is incomplete and communicates with the lateral pharyngeal space. Infections of the parotid may extend medially into the lateral pharyngeal space.

The masticator space surrounds the masseter, temporalis, and internal pterygoid muscles and ramus of the mandible and is adjacent to the lateral pharyngeal space. Since its fascia surrounds muscles, it offers some resistance to the spread of infections.

The peritonsillar space is bound by the capsule of the palatine tonsil, the anterior and posterior tonsillar pillars, and superior constrictor muscle. Peritonsillar abscesses may progress to involve the lateral pharyngeal space and carotid sheath.

Many microorganisms are responsible for head and neck space infections, reflecting the numerous possible sources. A mixed bacterial flora is frequently isolated from abscesses. The gram-positive aerobes, beta-hemolytic streptococcus and *Staphyloccocus aureus*, are the predominant pathogens. Gram-negative aerobes and anaerobes are also common. Anaerobes are especially prominent when an odontogenic infection is the primary source. Beta-lactamase-producing microorganisms have been found with increasing frequency in head and neck space infections.[27]

With the significant presence of gram-negative and β-lactamase-producing bacteria, penicillin is no longer the initial antibiotic of choice in the treatment of these infections. Before culture and sensitivity results have been obtained, the empirically chosen antibiotic should have activity against gram-positive and negative aerobes, anaerobes, and β-lactamase-producing microorganisms. Antibiotic combinations, such as clindamycin and cefuroxime and ampicillin and sulbactam, are excellent initial choices.

The diagnosis of a head and neck space infection can often be made after a history and physical examination. Most patients should have a complete blood count with differential, electrolytes, and coagulation studies. If a primary source is suspected, Gram stains and cultures of the infection should be taken, and if there is evidence of sepsis, blood cultures should be taken.

Radiologic studies help in determining the extent and severity of the infection, the primary source, and the presence of complications. The specific studies are determined in the individual case. Both the suspected source and affected space should be evaluated. Anteroposterior and lateral neck films may demonstrate airway compromise, tracheal deviation, and widening of the retropharyngeal space, indicating cellulitis or an abscess (Figure 44–13). An air-fluid level in the retropharyngeal space confirms an abscess. Chest radiographs are required to evaluate the airway and the mediastinum.

Contrast-enhanced computed tomography (CT) is the most valuable radiologic study. It is excellent for evaluation of all of the fascial spaces and may demonstrate findings of infection such as soft tissue edema, obliteration of fat planes, deviation of structures, and airway compromise. It is excellent for differentiating between an abscess and cellulitis. The finding of a rim-enhancing lesion or fluid within the lesion is diagnostic for an abscess. Contrast-enhanced CT will also demonstrate the size and location of an abscess and its position relative to the carotid artery and internal jugular vein (Figure 44–14). Contrast-enhanced magnetic resonance imaging (MRI) may be used, but it does not appear to offer any advantages over CT. Ultrasonography may help localize an abscess.

Although the cause and clinical presentation of these infections are dependent on the space involved, there are several important principles that apply to most of these infections. In children, infections of the upper aerodigestive tract are the most common cause of head and neck space infections, whereas odontogenic infections are the most common cause in adults. It is not uncommon to fail to identify a primary source of the infection. Oropharyngeal pain, fever, and limitation of jaw and/or neck movement are present in most of these infections. Initial treatment consists of intravenous antibiotics, hydration, and analgesics.

Peritonsillar abscess is the most frequent head and neck space infection in children and the most common complication of acute tonsillitis. Most infections occur in the superior pole, but some involve the midtonsillar area and inferior pole. The infection begins as a cellulitis and progresses to an abscess.

The submandibular space is the second most frequent location for head and neck space infections in children. Most infections are odontogenic in origin, usually from the second and third lower molars, which penetrate the mylohyoid muscle into the submandibular space.[28] Infections of the submandibular gland and nodes are other sources of infections. In children, it is not uncommon to find no primary

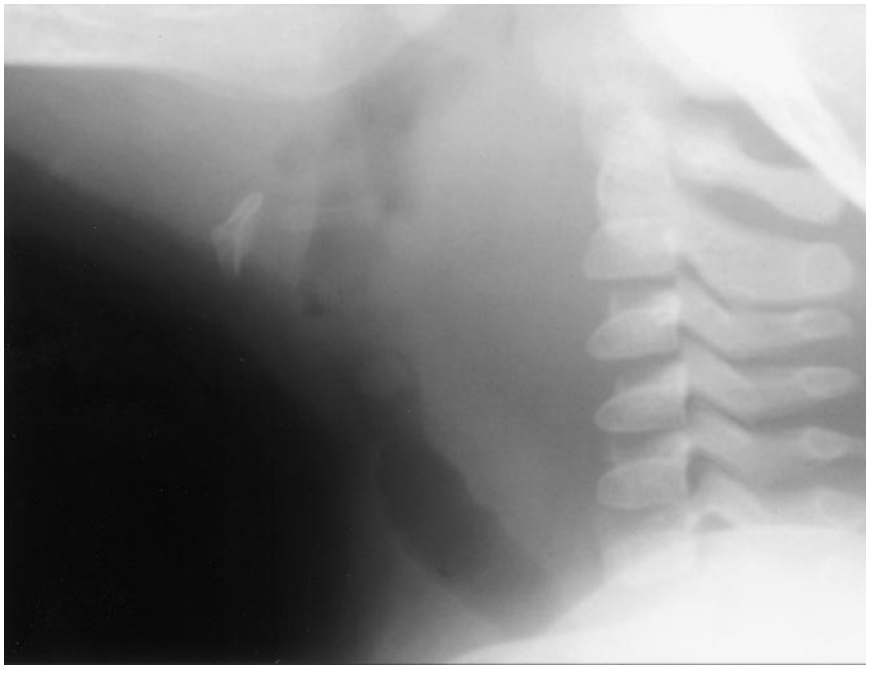

FIGURE 44–13. Lateral neck radiograph demonstrating widening of the retropharyngeal space.

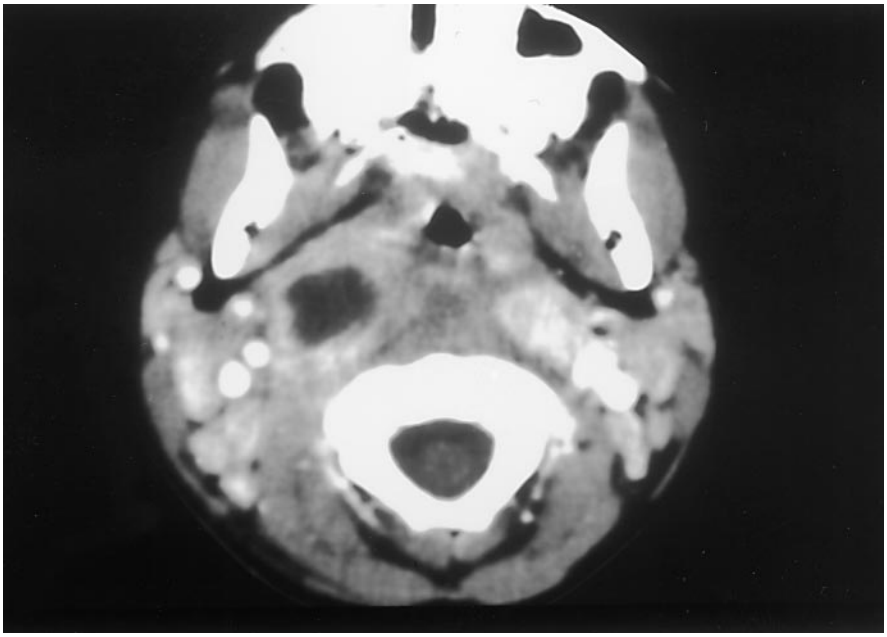

FIGURE 44–14. Contrast-enhanced computed tomographic scan of the neck showing a lateral pharyngeal space abscess medial to the great vessels.

source.[29] Ludwig's angina is a rapidly spreading cellulitis in the superior part of this space.

The initial presentation is dependent on the site of the infection. If the infection begins in the sublingual space superior to the mylohyoid muscle, pain, dysphagia, drooling, and muffled voice are prominent symptoms. Examination may reveal swelling and tenderness of the floor of the mouth, and the tongue may be displaced posteriorly, causing airway compromise. Infections beginning in the submandibular space inferior to the mylohyoid muscle present with cervical pain associated with tense, brawny suprahyoid and submental edema. An infection beginning in either space may spread both to its adjacent space and to the other side, producing a true Ludwig's angina. When the entire submandibular space is involved, the presentation is a combination of the sublingual space and submandibular space proper infections. Dysphagia and airway compromise are more severe because of the increased degree of tissue tension. Trismus is prominent because of involvement of the suprahyoid muscles.

The diagnosis of submandibular space infections can usually be made clinically. Plain lateral and anteroposterior neck radiographs may reveal airway compromise, whereas CT with contrast may demonstrate an abscess. Panoramic tomography may help to determine the primary source of infection.

Treatment must be aggressive. Intravenous antibiotics, management of the primary source, and supportive therapy may be sufficient to treat early cases. With Ludwig's angina, airway obstruction is a main concern. The airway must be secured with an endotracheal tube, often using fiber-optic intubation or a tracheostomy. After the airway is secured, the submandibular space is drained. In Ludwig's angina, colored, weeping exudate, not frank purulence, is usually found. Drains are placed deep to the mylohyoid muscle and into the sublingual space.

Retropharyngeal space infections usually occur primarily as a sequela of upper respiratory tract infections that drain into the retropharyngeal lymph nodes. The disease occurs primarily in young children. Retropharyngeal infections do occur in adults, and the incidence in adults may be greater than has been previously recognized.[30] Foreign bodies and trauma are other causes of these infections.

There is often a history of a recent upper respiratory tract infection. Symptoms include fever, sore throat, odynophagia, dysphagia, drooling, muffled voice, and difficulty breathing. Examination may reveal torticollis; limitation of neck movement; cervical tenderness; boggy, inflamed orpharyngeal mucosa; and bulging of the posterior pharyngeal wall to one side. The classic presentation occurs in less than 10% of children.[31]

With a retropharyngeal space infection, lateral neck radiograph findings include air in the soft tis-

sues, loss of the normal curvature of the cervical spine, and abnormal widening of the prevertebral soft tissue. Radiologic interpretation of this area in children is difficult because of difficulty in positioning, redundancy of normal soft tissue, and variation with inspiration and expiration. Computed tomography with contrast will confirm the presence of an abscess and determine its extent.

In young children, the airway may be obstructed and must be secured. If a retropharyngeal abscess is present, surgical drainage is indicated. Most abscesses can be drained intraorally. To avoid aspiration, the patient is placed in the Rose position (head down), and the neck is extended.

Lateral pharyngeal space infections occur later in childhood than retropharyngeal infections. In children, pharyngotonsillitis is the most common source, whereas odontogenic infections are the most common cause in adults. Infections may easily spread to and from this space.

Patients present with fever, sore throat, odynophagia, dysphagia, trismus, cervical pain, limitation of neck movement, and torticollis. Prominent signs include bulging of the lateral pharyngeal wall, anteromedial displacement of the tonsil, and cervical edema or lymphadenopathy. Respiratory compromise is a concern, especially in younger children. Deficits of cranial nerves IX, X, and XII and Horner's syndrome may occur.

Computed tomography with contrast should be performed in any patient with a suspected infection of the lateral pharyngeal space. It will demonstrate signs of infection and differentiate between cellulitis and abscess. The position, size, and extent of the abscess will be established, as well as its relationship to the great vessels.

If an abscess is identified, drainage is required. Traditionally, the external, cervical approach had been used exclusively to drain these abscesses because it provides excellent exposure, but with the development of CT, many abscesses can be drained transorally. If the CT demonstrates that the abscess is medial to the great vessels, drainage of the abscess can be performed safely and effectively through a transoral approach.[32] The transoral approach is technically easier to perform and is associated with less morbidity and shorter hospitalization. The external, cervical approach remains the approach of choice for abscesses that dissect along or are lateral to the great vessels.

DIFFERENTIAL DIAGNOSIS OF A NECK MASS

The differential diagnosis of a neck mass in adults and children is significantly different. In adults, the incidence of malignancy may be as high as 50%, and the protocol for the evaluation of a neck mass is well established.[33] Although malignancy is always a concern in a child, the incidence is low, and there are no established guidelines for the diagnosis of a pediatric neck mass.[34]

The age of the patient often suggests the type of lesion (Table 44–1). In children, the most common causes of neck masses are inflammatory lymph nodes from viral and bacterial infections. Congenital lesions are also common. Primary malignancies such as Hodgkin's and non-Hodgkin's lymphoma and leukemia occur, but their incidence is low.[35] In adolescents and adults to 40 years, congenital and developmental lesions and sialadenopathies are more common, whereas inflammatory lesions and malignancies are less frequent. In adults over 40 years, the first consideration must be a metastatic neoplasm.

A complete history often helps to narrow the diagnostic possibilities. A rapidly enlarging mass is suggestive of an inflammatory lesion or malignancy. The appearance of a mass after an upper respiratory tract infection or dental treatment indicates an inflammatory process. Constitutional symptoms of fever, weight loss, night sweats, and fatigue suggest a systemic condition such as a mycobacterial infection or lymphoma. A history of foreign travel or exposure to animals and insects makes infection likely.

A thorough head and neck examination is essential. Cervical lymphadenitis is usually the result of an infection elsewhere in the head and neck. Anterior cervical lymphadenitis is usually associated with oropharyngeal infections, whereas nasopharyngeal and paranasal sinus infections frequently cause posterior cervical lymphadenitis. In adults, all of the mucosal surfaces of the upper aerodigestive tract should be examined. Flexible fiber-optic endoscopes have greatly enhanced the ability to examine these mucosal surfaces in the office setting. If there are any questions regarding any lesions, the Storz-Hopkins telescopes can be used. Although flexible endoscopy is not necessary in all children, it should be attempted in children in whom the diagnosis is not apparent and in all adolescents presenting with pos-

terior cervical masses to evaluate for the presence of nasopharyngeal carcinoma (see Chapter 60).

All neck masses should be examined for size, multiplicity, laterality, tenderness, color, mobility, consistency, surrounding tissue changes, and the presence of bruits and thrills. Soft, compressible masses are characteristic of congenital cysts, hemangiomas, and lymphangioma. Lymphomas often present as firm, rubbery, nontender masses. Palpable cervical lymph nodes are unusual in adults but common in children. Localized unilateral cervical lymphadenopathy is usually associated with gram-positive bacterial infections, whereas viral infections usually cause bilateral or generalized lymphadenopathy. In a child, any lymph node larger than 2 cm, especially if it is enlarging, should be evaluated. The location of the mass is especially important. Specific lesions have a predilection for specific sites, and the location may point to a benign or malignant condition. Congenital lesions are usually found in the midline or anterior cervical triangle. Metastatic malignancies are distributed along the pathways of the cervical lymphatic channels. In children, a supraclavicular mass is suggestive of a lymphoma.[36]

After completing the history and physical examination, the diagnosis may be apparent, and no additional studies may be needed. If it is not established, diagnostic studies can be performed. These may include blood and urine studies, skin tests, plain radiographs, ultrasonography, CT, MRI, biopsy, and endoscopy.

In a child with a suspected malignancy, chest radiography should always be performed because many children with lymphoma of the neck have abnormal chest radiographs.[36] Both CT and MRI can identify the consistency of a neck mass and delineate its size and extent. Magnetic resonance imaging has several advantages and is preferred over CT for the evaluation of cervical masses.[37] Magnetic resonance imaging is more sensitive to changes in contrast between the mass and normal tissue, providing superior resolution. It demonstrates better anatomic detail, has multiplanar capability, and involves no radiation exposure. Computed tomography and MRI can be combined with contrast to demonstrate vascular lesions.

If no diagnosis can be established or a malignancy is suspected in a child, an excisional biopsy is preferred. With localized lesions, an excisional biopsy may be curative and provides for a sufficient amount of tissue for additional studies, such as permanent and frozen section, electron microscopy, and tumor

markers. Although needle aspiration biopsies are safe and accurate in adults, they often do not provide enough tissue to diagnose pediatric malignancies. These malignancies are rare and frequently consist of embryonal tissue. Most pathologists do not have sufficient experience with these tumors. In many cases, diagnosis requires special stains, electron microscopy, and tumor markers. Many biopsies are performed because of a suspicion of malignancy, but in most cases, no malignancy is found. If there is a high suspicion of malignancy even after a negative biopsy, a repeat biopsy should be performed.

A needle biopsy is preferred in adults if a biopsy is required for diagnosis. Open biopsy is not recommended because this interrupts both the tumor and lymphatic channels. A primary malignancy and metastatic neck lesion should be treated in a coordinated fashion. Coordinated treatment decreases the risk of wound necrosis, local recurrence, and distant metastasis.[38] If the diagnosis is a metastatic malignancy, endoscopy of the entire upper aerodigestive tract and biopsies of any suspicious mucosal areas and any likely primary sites should be performed.

NASOPHARYNX

Anatomy

The nasopharynx extends from the skull base to the soft palate. The nasopharynx is surrounded by bone. Its superior and posterior walls are continuous and formed by the body of the sphenoid bone, basilar process of the occipital bone, and first two cervical vertebrae. The adenoid tissue (pharyngeal tonsil) lies on the posterosuperior surface. The choanae form its anterior limit.

The eustachian tube passes laterally through the sinus of Morgagni, a defect just above the superior edge of the superior constrictor muscles, and its orifice is located along the lateral wall, just posterior to the choanae. The torus tubarius, which is a prominent cartilaginous elevation, marks the posterior boundary of the orifice. The salpingopharyngeal fold extends inferiorly from the torus tubarius (Figure 44–15). The fossa of Rosenmüller is a deep recess just posterior to the torus tubarius. Gerlach's tonsil, lymphoid tissue, is found around the orifice.

The anterior aspect of its inferior border is the soft palate. The isthmus, the narrowest portion of the nasopharynx, opens into the oropharynx (Figure 44–16).

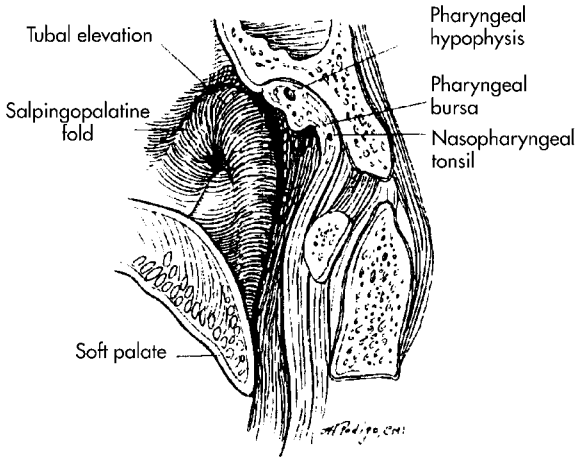

FIGURE 44–15. Sagittal view of the nasopharynx.

Physiology

The nasopharynx functions as a conduit for respired air and secretions from the eustachian tube and nose to pass to the oropharynx.

During swallowing and articulation of speech sounds represented by consonants, except m, n, and ng, the nasopharynx is separated from the oropharynx. During deglutition, there is circular closure of the isthmus by the coordinated actions of several muscles. The palatopharyngeus and salpingopha-

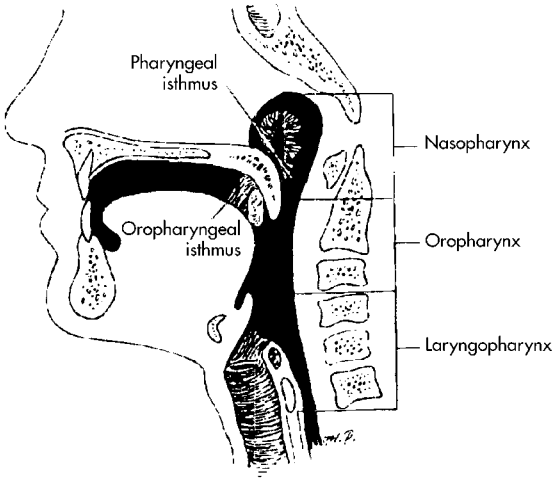

FIGURE 44–16. The regions of the pharynx are diagrammatically depicted.

ryngeus muscles contract to elevate the soft palate. The levator veli palatini lifts the muscular portion of the soft palate upward and backward. Contraction of the superior constrictor muscle narrows the nasopharynx laterally and forms Passavant's pad, a prominence of the posterior pharyngeal wall. The tensor veli palatini contributes to the closure of the isthmus during swallowing. Failure to separate the nasopharynx from the oropharynx results in velopharyngeal insufficiency. There may be reflux of fluid into the nasal airway or difficulty producing speech sounds such as "k."

Along with the nose, the nasopharynx is a resonating chamber that contributes to the quality of the voice. Loss of the resonating capacity produces a hyponasal voice or rhinolalia clausa. For certain vowels, proper velopharyngeal opening is necessary to avoid non-nasal speech. The nasopharynx acts as a resonating chamber for these phonemes.

The eustachian tube, which opens into the nasopharynx, is responsible for protection, ventilation, and clearance of fluid from the middle ear cleft. Proper function of the levator veli palatini and tensor veli palatini is essential for normal eustachian tube function. Children with anatomic abnormalities of the palate such as cleft palate and dysfunction of these muscles are likely to have problems with the middle ear cleft. Enlarged, nasopharyngeal lymphoid tissue may also affect eustachian tube function.

Examination

Evaluation of the nasopharynx can be done by indirect and direct examination. Indirect mirror examination is limited by patient cooperation and mirror distortion of the image. Nasopharyngoscopy, either with a flexible or rigid telescope, provides excellent visualization of most of the important structures, including the adenoid, eustachian tubes, and choanae. Direct examination in an operating room affords the best method of examination. The patient is in the same position as for an adenoidectomy. The nasopharynx may be visualized with mirrors and telescopes. Any suspicious areas may be palpated and even biopsied.

Benign Lesions of the Nasopharynx

These lesions are discussed in Chapter 46 and will be mentioned briefly.

Rathke's pouch develops when remnants of the buccal-mucosal invagination that forms the anterior lobe of the pituitary gland persist. A craniopharyngoma is a tumor that arises from these remnants. Symptoms take the form of pituitary-hypothalamic derangements.

The pharyngeal bursa of Thornwaldt is a midline nasopharyngeal structure located just inferior to Rathke's pouch and represents the proximal end of the notochord. It may form a cyst known as Thornwaldt's cyst. The cyst may become infected.

Teratomas, dermoid cysts, and gliomas are rare but may cause nasal obstruction and respiratory distress in newborns. Teratomas are often associated with other congenital abnormalities. Mucous retention cysts and hamartomas occur occasionally.

Choanal Atresia

Choanal atresia results from the failure of the buccopharyngeal membrane to regress so that the posterior part of the nasal cavity does not open into the nasopharynx. This developmental anomaly is discussed in Chapter 46.

Juvenile Angiofibroma

Juvenile angiofibroma of the nasopharynx is rare but is the most common benign neoplasm of the nasopharynx. It is discussed in Chapter 60.

Nasopharyngeal Stenosis

Nasopharyngeal stenosis occurs when scar tissue obstructs the nasopharynx.[39] The posterior tonsillar pillars and soft palate adhere to the posterior pharyngeal wall. The degree of scarring varies from a thin band to a complete cicatrix, and the obstruction may be partial or complete. Most cases result from tonsillectomy and adenoidectomy, but some cases are secondary to infection.

Nasopharyngeal stenosis may develop when inferolateral adenoid tissue is removed and there is simultaneous denuding or excision of the posterior tonsillar pillar.[24] Patients who undergo secondary adenoidectomy and have large lateral bands of lymphoid tissue are more likely to develop this stenosis. Treatment is dependent on the location and severity of the stenosis and includes corticosteroid injection, lysis of adhesions, and rotation and advancement flaps.

SLEEP APNEA

Sleep apnea is an increasingly recognized and important condition in adults. It has been estimated that 20 million Americans experience significant daytime somnolence because of sleep apnea.[40] Although it is more common in males, a significant number of women also suffer from this condition. A healthy adult may experience apneic periods of 10 seconds or less several times an hour during sleep, without significant clinical signs or symptoms. People with significant manifestations may have 15 or more events per hour, each lasting 20 to 30 seconds or longer.

Obstructive Sleep Apnea

It is estimated that 12 million Americans have OSA.[41] In OSA, the airway obstruction is caused by pharyngeal collapse, which is the end result of complex interactions between structural and neuromuscular factors. In healthy individuals, the patency of the pharynx is maintained by tonic activity of the pharyngeal dilatory muscles. Sleep results in a decrease in the behavioral responses, which maintain this tone, and relaxation narrows the airway.

The etiology of OSA is multifactorial and incompletely understood. Reduced neuromuscular control of the pharyngeal dilator muscles accentuates the physiologic pharyngeal narrowing, further reducing the lumen. Alcohol ingestion, which exaggerates the relaxation of the pharyngeal dilators, and neuromuscular diseases such as muscular dystrophy, myasthenia gravis, cerebrovascular accidents, and olivopontocerebellar degeneration are well known causes of OSA. Anatomic abnormalities cause obstruction, and with obstruction, greater inspiratory pressure is needed to generate airflow. The resulting increased negative pressure also contributes to pharyngeal collapse. Structural abnormalities often associated with OSA include nasal septal deviation, turbinate hypertrophy, elongated soft palate, adenoid and tonsil hypertrophy, macroglossia, retrognathia, and micrognathia. Cardiac disease, chronic obstructive pulmonary disease, obesity, hypothyroidism, acromegaly, gastroesophageal reflux, androgens, caffeine, and tobacco are other factors that may predispose or exacerbate OSA.

Common characteristics of individuals with OSA include male sex, advancing age, hypertension, truncal obesity, and neck circumference greater than 17 inches. The most common symptoms of OSA are snoring and excessive daytime somnolence. Other symptoms include frequent nocturnal arousal periods, restless sleep, memory loss, fatigue, irritability, morning headache, sexual dysfunction, and nocturia.

Although assessment of the upper airway is critical, examination of the patient with suspected OSA is not limited to this region. Predisposing and associated factors must be sought. Assessment of the patient's general medical condition, height, weight, blood pressure, neck size, and cardiopulmonary status is mandatory. The entire upper airway is thoroughly examined, and it is not uncommon to find more than one site of obstruction. Flexible fiberoptic endoscopy is essential. It provides for better inspection of the airway. Patients can be examined either erect or supine, and evaluation of the patient at rest with the mouth closed more closely simulates sleep. The Müller maneuver, fiber-optic examination during inspiration with the oral and nasal cavities closed, can be performed to help assess the pattern and degree of pharyngeal collapse.

Several imaging techniques are available to evaluate the structure and function of the upper airway. They include cephalometry, somnofluoroscopy, CT, and MRI. These imaging modalities are primarily considered investigational tools, and their clinical applications are evolving. Magnetic resonance imaging with three-dimensional reconstruction appears useful in the preoperative assessment of candidates for uvulopalatopharyngoplasty, whereas CT with three-dimensional reconstruction may be considered for candidates of maxillomandibular advancement.[42]

Polysomnography in a sleep laboratory is the definitive diagnostic study for OSA. Other studies have been developed either as screening devices or less expensive alternatives. Portable polysomnography, a convenient, inexpensive study, can be performed at home, but because it presently lacks universally accepted standards, it is not considered definitive. Nocturnal oximetry measures the oxygen levels during sleep. In children, sleep sonography provides objective data regarding the presence and degree of upper airway obstruction, but its ability to predict apnea is not established. The multiple sleep latency test does not diagnose OSA but measures daytime somnolence.

Treatment of OSA begins with management of any predisposing or associated factors. Although a

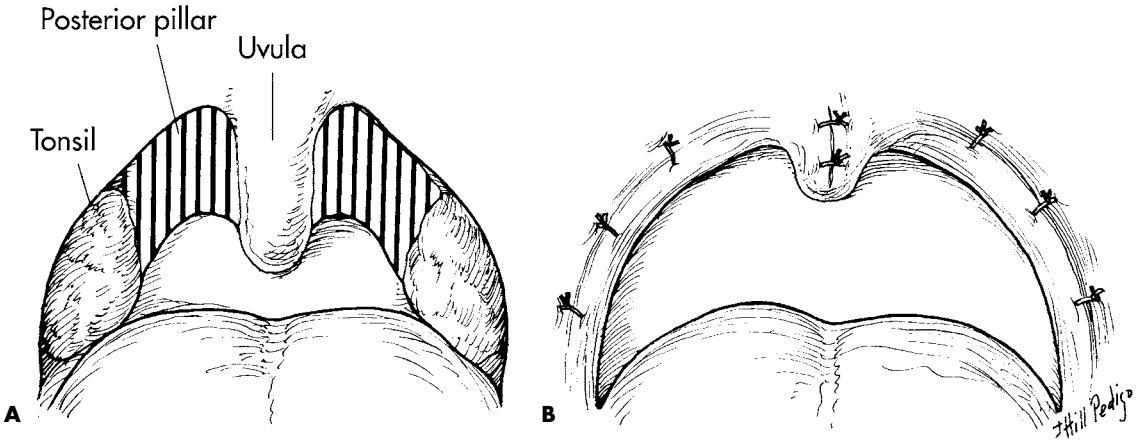

FIGURE 44–17. Diagram of uvulopalatopharyngoplasty. *A*, Obstruction to the oropharyngeal airway is caused by abnormally prominent posterior tonsillar pillars and the large, bulky uvula. *B*, An improved airway has been created by reduction in the size of these structures.

patient may not be obese, moderate weight reduction may improve the severity of the apnea. Alcohol, tobacco, and caffeine should be eliminated.

Nonsurgical treatment of OSA includes positioning, artificial airways, appliances, and positive airway pressure. The supine position often exacerbates OSA, and there are maneuvers and devices that can help one avoid this position. Nasopharyngeal and oral airways, tongue-retaining devices, and mandible advancement appliances may help improve snoring and OSA but are usually not well tolerated. Continuous positive airway pressure (CPAP) and biphasic positive airway pressure (BiPAP) provide pneumatic stenting of the pharyngeal airway. Their face mask delivery systems are cumbersome and discomforting.

The goal of surgery for OSA is relief of airway obstruction by increasing pharyngeal size, decreasing pharyngeal compliance, or both to maintain adequate airflow. The specific procedure depends on the site of obstruction, and consideration includes nasal surgery, tonsillectomy, adenoidectomy, palatal surgery, tongue base reduction, genioglossal advancement with hyoid myotomy, and maxillomandibular osteotomy and advancement. In severe, acute cases, tracheostomy may be considered.

The most common surgery performed for OSA is palatal surgery. Redundant tissue of the soft palate, uvula, tonsil pillars, and lateral pharyngeal walls causes obstruction, and reduction in the size of these structures enlarges the airway. Uvulopalatoplasty and uvulopalatopharyngoplasty (Figure 44–17) are the most widely performed procedures. Uvulopalatoplasty reduces the soft palatal and uvular tissue. It is an outpatient procedure that is often performed with a laser, and recently, radiofrequency energy ablation of these tissues has been used. Uvulopalatopharynoplasty, a more complex procedure, eliminates the palatal, tonsil pillar and pharyngeal redundancy by removing excess mucosal and submucosal tissue. Submucosal resection of the palatoglossus and palatopharyngeus muscles and removal of the posterior portion of the hard palate with advancement of the soft palate are other procedures that have been proposed.[43]

Central Sleep Apnea

Central sleep apnea is much less common than OSA and must be distinguished from it. Central sleep apnea occurs when the neural drive to the respiratory muscles is temporarily abolished, resulting in an absence of respiratory effort. There is little effort to breathe. During sleep, respiration is controlled by an automatic feedback system. Sensory signals from multiple receptors are relayed to the brainstem, where they are integrated, and the brainstem sends signals, which stimulate the muscles of respiration and lungs.

Any condition affecting this feedback system may cause CSA. Congenital central alveolar hypoventilation, which results from a very low sensitivity to increased PCO_2, is a cause of CSA. Chronic neuropathies may also impair the sensory component. Bilateral brainstem lesions from vascular con-

ditions, infections, and degenerative and metabolic diseases affect integrative function and cause CSA. Neuromuscular diseases, such as polio, amyotrophic lateral sclerosis, and muscular dystrophies, impair motor function and may cause CSA. In addition, chronic obstructive pulmonary disease and congestive heart failure are causes of CSA.

With polysomnography, CSA can be diagnosed, and its degree of severity and any associated physiologic changes can be determined. Central sleep apnea can also be confirmed by measuring esophageal pressure, an index of respiratory effort, during sleep.[44]

The primary treatment for CSA is nasal mask ventilation using CPAP, BIPAP, or intermittent positive pressure ventilation. Medications to stimulate respiration and to increase the tone of the genioglossus and geniohyoid muscles have had limited success. In the most severe cases, tracheostomy with ventilation may be required.

CHAPTER 45

Congenital Anomalies of the Larynx

Rodney P. Lusk, MD

Congenital lesions of the larynx are relatively rare; however, in their laryngeal laboratory, Chen and Holinger found congenital laryngeal lesions in 33 of 115 specimens.[1] Of all of the anomalies noted, the most common deformity is of the cricoid cartilage. The lesions develop during respiratory differentiation, which occurs during the fourth to tenth weeks of gestation. The clinical manifestations of laryngeal lesions fall into three broad categories:

1. *Respiratory distress*, which may range from complete obstruction with no air movement to minor types of stridor. The characteristics of the stridor are variable and depend on the site and degree of the obstruction. Most laryngeal lesions produce stridor during the inspiratory phase. The reason for this is found in Bernoulli's principle, which states that when a fluid or a gas is in motion, the pressure exerted on the wall of the airway decreases as the velocity of the gas increases. A well-known example is the wing of an airplane, shown in Figure 45–1. When the site of the obstruction is in an area not firmly fixed or supported, such as the supraglottis or larynx, as the air rushes into the airway, it produces a relatively negative pressure, which tends to close the airway (Figure 45–2). The harder the child breathes in, the faster the flow and the greater the created negative pressure, with the net effect of further decreasing the airway lumen. The negative pressure generated during inspiration may also cause supraclavicular and sternal retractions and be associated with nasal flare.
2. *Dysphonia*, which may be caused by laryngeal lesions that interfere with vocalization, with voice quality ranging from complete aphonia to hoarseness.
3. *Failure of the larynx to close the airway* during swallowing, which may cause feeding difficulties, with aspiration, cyanosis, or respiratory compromise.

Although this chapter deals only with laryngeal lesions and airway distress, any airway lesion may result in stridor, tachycardia, tachypnea, cyanosis, or restlessness. When evaluating patients with these signs, a history and examination of the entire airway should be performed. The history and physical examination are the most important diagnostic tools. Radiographic imaging (plain films, computed tomography [CT], and magnetic resonance imaging [MRI]) and laryngoscopy (direct and indirect) are important adjuncts and are discussed in each section.

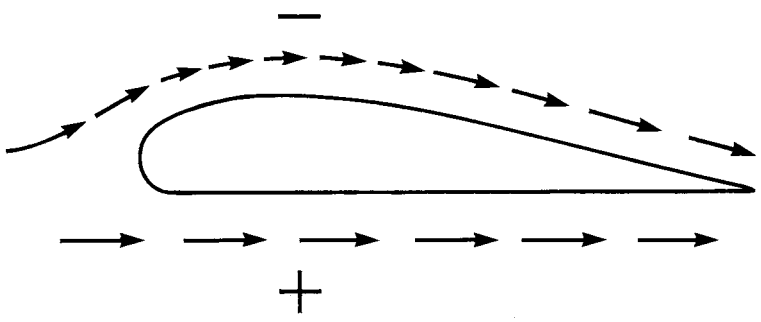

FIGURE 45–1. For a wing to produce lift, the air pressure on the top of the wing must be less than the pressure on the bottom. According to Bernoulli's principle, this can occur only when the velocity of the air is greater over the top of the wing, which is accomplished by increasing its upper curvature.

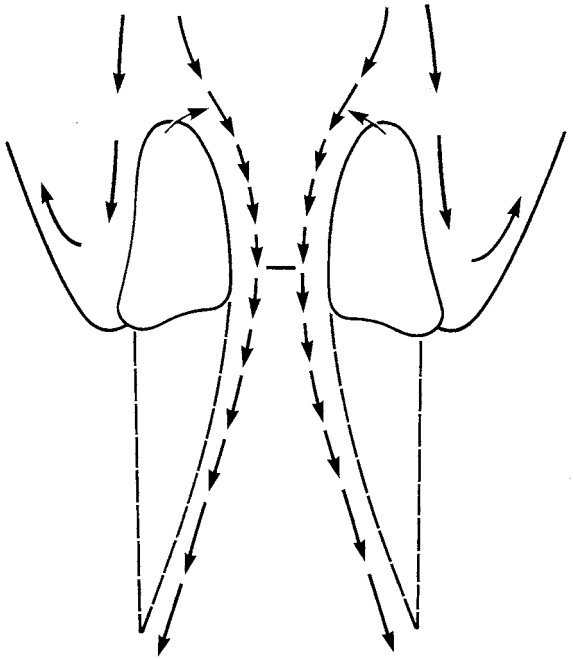

FIGURE 45–2. Demonstration of the arytenoids and the subglottis as compared to an air foil. Note that as the velocity of the air increases in the glottis, it creates negative pressure in the airway, pulling the cuneiform cartilages and aryepiglottic folds into the airway.

LARYNGOMALACIA

Laryngomalacia is a condition in which the laryngeal inlet collapses on inspiration, causing stridor. The terminology is confusing, with congenital laryngeal stridor,[2] congenital laryngeal obstruction,[3] congenital stridor of infants,[4] and inspiratory laryngeal collapse[5] all used synonymously. The term laryngomalacia, introduced by Jackson and Jackson in 1942,[6] is most frequently used. Some physicians confuse this entity with tracheomalacia, which is another disease altogether.

Incidence and Etiology

Laryngomalacia is the most common cause of stridor in the newborn. In some children, it may be an autosomal dominant lesion.[7] Hawkins and Clark evaluated 453 patients with the flexible fiberscope and found 84 with primary and 29 with secondary laryngomalacia.[8] Nussbaum and Maggi found that 68% of 297 children with laryngomalacia had other respiratory disorders, as noted with flexible bronchoscopy.[9]

Signs and Symptoms

The most common symptoms produced by laryngomalacia are inspiratory stridor, feeding problems, and gastric reflux. The inspiratory stridor worsens with increased respiratory effort, such as crying or feeding, and in the supine position. The symptoms begin shortly after birth in most patients,[10] increase in severity until 6 to 8 months of age, plateau at 9 months, and steadily improve thereafter.[5,11,12] No correlation exists between the duration of stridor and the severity or time of onset.[10]

Two theories have been proposed to account for the narrowing of the laryngeal inlet. The first is that a neuromuscular abnormality, by not allowing proper support of the supraglottis, causes increased flaccidity.[13] Kelemen suggested that the cause is ineffective dilators of the supraglottis,[14] but dissections by Belmont and Grundfast showed the dual insertion of the palatopharyngeus, lateral glossoepiglottic, and stylopharyngeal muscles, which could dilate the laryngeal inlet.[13] The incidence of neuromuscular disorders appears to be higher in children with laryngomalacia.[11] Reports of higher incidence of mental retardation in these patients[11] have not been substantiated.[10,13]

The other proposed mechanism is anatomic, with the narrowing resulting from (1) a flaccid epiglottis that folds against the posterior laryngeal wall or into the airway, (2) a long, tubular epiglottis that curls on itself, or (3) short and redundant aryepiglottic folds with varying sizes of cuneiform cartilage that rotate medially into the airway[15] (Figures 45–3 and 45–4). The W-shaped epiglottis is not thought to be a significant factor because it occurs in 30 to 50% of patients,[3,16–18] most of whom do not have stridor.

Feeding problems are frequent with laryngomalacia. Radiographic evidence of gastric reflux occurs in 80% and regurgitation in 40%[13] past 3 months of age. In the study by Zalzal and associates, 5 of 21 patients presented with feeding problems.[19] Some investigators believe that feeding problems are secondary to the high negative pressures generated during inspiration. Aspiration pneumonitis has been reported in 7% of children with laryngomalacia.[13] The mechanism for this is unclear but may be associated with the negative pressure and feeding problems.

Obstructive sleep apnea (23%) and central sleep apnea (10%) have also been noted.[13] Cor pulmonale can develop secondary to laryngomalacia.[19]

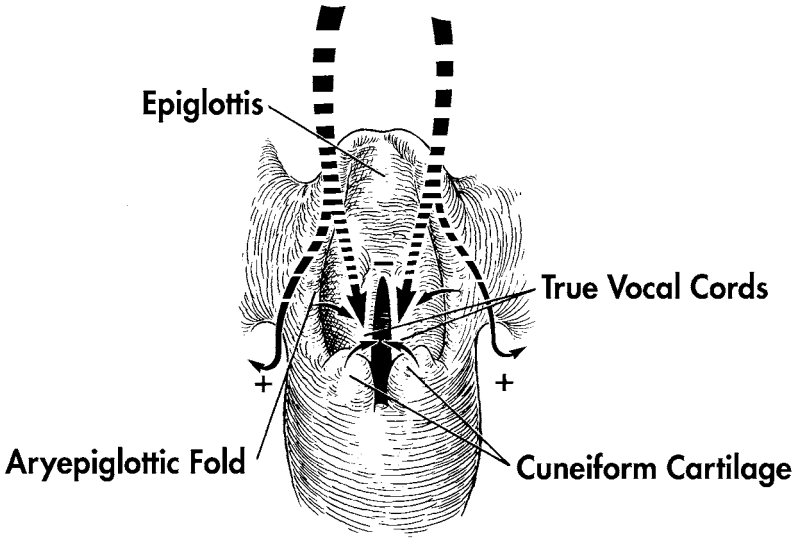

FIGURE 45–3. The airflow through the larynx creates a relative negative pressure and pulls the aryepiglottic folds and cuneiform cartilages into the airway.

Diagnosis

The diagnosis is most frequently based on the symptoms and signs, flexible laryngoscopy, and lateral radiographs of the neck and chest and rigid endoscopy to identify possible synchronous airway lesions such as subglottic stenosis. Hawkins and Clark have shown flexible laryngoscopy to be effective, even in neonates.[8] The advantage of using the flexible scope in an awake patient is that the dynamics of the supraglottis can readily be appreciated. The disadvantage is that the milder forms of laryngomalacia may be missed if the child is crying. The flexible scope can also be used to diagnose other synchronous glottic lesions such as vocal cord paralysis and glottic cysts. Mancuso et al retrospectively evaluated 233 patients with laryngomalacia to assess the necessity of performing a complete diagnostic workup in *all* patients.[20] Their conclusion was that rigid endoscopy in evaluation of an infant with laryngomalacia is rarely necessary because clinically significant synchronous airway lesions that require surgical intervention are rare. Historically, this has not been the case. Hawkins and Clark[8] and Nussbaum and Maggi[9] used flexible endoscopy to evaluate laryngomalacia, but their recommendation was that "all symptomatic" children be evaluated by bronchoscopy. Bluestone et al went "on record as recommending a complete evaluation of the tracheobronchial tree in all symptomatic infants."[21] The limitation of using a flexible scope is that it does not allow accurate assessment of the subglottis and trachea. The incidence of other lesions noted by additional authors has ranged from 18% in patients with congenital laryngeal lesions to 59.8% of all patients presenting with stridor.[22,23] The controversy lies in the likelihood of missing a clinically significant synchronous airway lesion that would otherwise have been treated if rigid endoscopy had been performed. Mancuso et al concluded that rigid endoscopy was not necessary in otherwise asymptomatic children.[20] Bluestone et al reached the opposite conclusion; based on "retrospective careers, [they] have encountered countless numbers of infants who have had clinically significant airway problems in whom the diagnosis of laryngomalacia was previously made by flexible fiberoptic laryngoscopy, but rigid endoscopy was omitted."[21] Deaths have been described in patients with severe disease.[24,25] This controversy is going to require additional data that are prospectively acquired. Currently, it would appear that if symptoms are not compatible with laryngomalacia alone or if the patient fails to thrive, direct laryngoscopy and rigid bronchoscopy should be performed to rule out secondary lesions. It is the surgeon's obligation to follow his or her patients closely until the symptoms resolve.

Treatment

Expectant observation is sufficient in most cases. The small percentage of patients (10 to 15%) with failure to thrive or more than one lesion may require surgical intervention. Iglauer, in 1922, was the first to

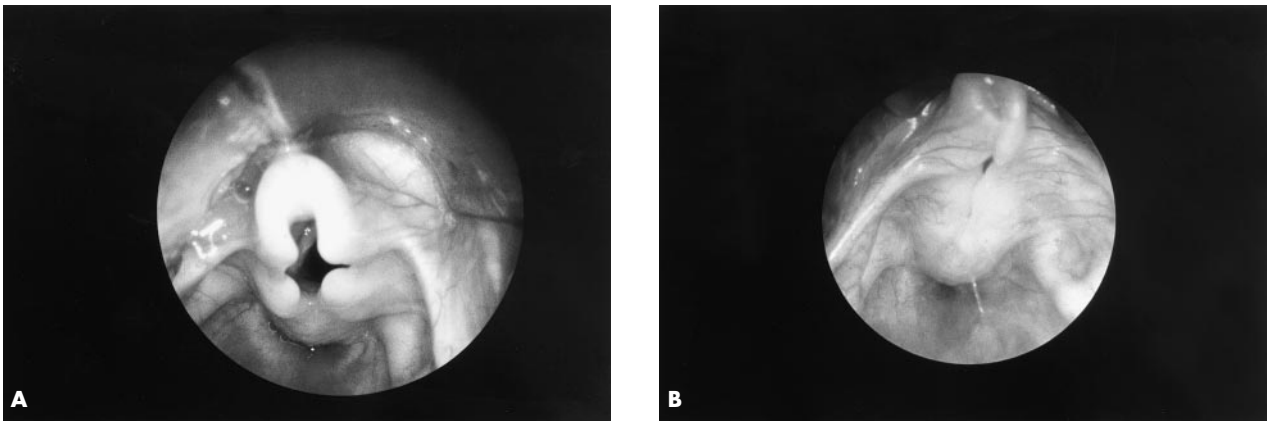

FIGURE 45–4. Example of laryngomalacia. *A*, Supraglottis at beginning of inspiration. *B*, Complete collapse of the supraglottis toward the end of inspiration. Courtesy of Dr. G. B. Healy, Boston's Children's Hospital, Boston, Massachusetts.

alter the supraglottis surgically in laryngomalacia.[26] Schwartz, in 1944, removed a V-shaped wedge from an epiglottis with good results.[5] Fearon and Ellis, in 1971, successfully treated a patient by suturing the epiglottis to the base of the tongue.[27] In that same year, hyomandibulopexy was advocated in France.[28,29] Templer and colleagues, in 1981, performed a supraglottectomy in an adult for longstanding stridor and obstructive sleep apnea secondary to laryngomalacia.[30] Lane and associates, in 1984, excised the tips of the arytenoids, edematous mucosa, a portion of the corniculate cartilages, and a portion of the aryepiglottic fold with microcupped forceps and Bellucci scissors.[31] Seid and colleagues successfully treated three patients with the laser in 1985.[32] Since then, numerous case reports have appeared in the literature.[33] Zalzal and associates trimmed the lateral edges of the epiglottis, aryepiglottic folds, and the corniculate cartilages with microlaryngeal scissors.[19] Solomons and Prescott recommended trimming the supraglottis and performing an anterior epiglottopexy.[16] The trimming of the aryepiglottic folds may involve both sides or only one side. Kelly and Gray recommended unilateral removal of redundant supraglottic tissue (supraglottoplasty) and to revise the other side if the patient is not asymptomatic.[34] We have recommended doing both sides at one setting. Either appears to give satisfactory results.

Holinger and Konior prefer the term supraglottoplasty to describe the surgical procedures for removing the flaccid supraglottic tissues.[15] These investigators used the laser to remove a portion of the cuneiform cartilage and the aryepiglottic folds (Figure 45–5). Care must be taken not to excise or traumatize the strip of mucosa between the arytenoids in the posterior part of the glottis. Holinger and Konior believe that prophylactic antibiotics should be used and that most patients may be extubated in the immediate postoperative period but should be observed overnight in the intensive care unit.[15]

ABSENT OR RUDIMENTARY EPIGLOTTIS

Incidence

The rare bifid epiglottis can be associated with stridor and aspiration. In the only thorough review of the world literature, Montreuil found only five clearly documented cases.[35] Since then, six additional cases have been reported.[36–38]

Signs and Symptoms

Patients have presented with respiratory distress secondary to rotation of the two halves of the epiglottis into the airway. The incidence of multiple congenital anomalies is high. A 44% incidence of polydactyly has been reported.[39] Graham and colleagues reported three cases of hypopituitarism.[37]

Diagnosis

The only means of diagnosing a bifid epiglottis is with flexible or direct laryngoscopy (Figure 45–6).

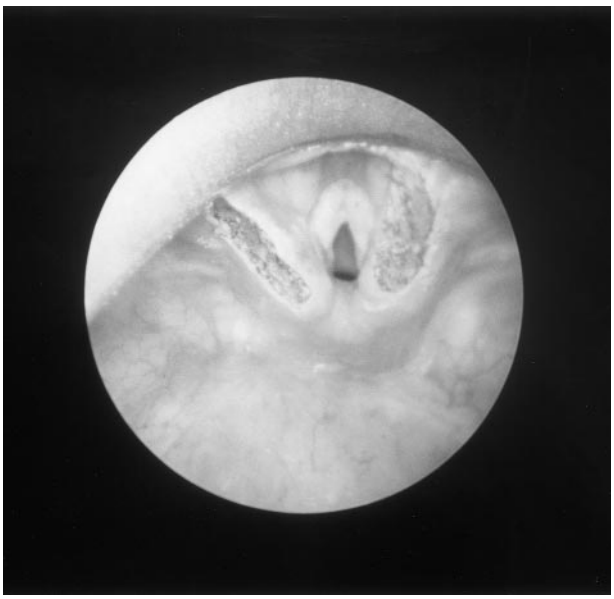

FIGURE 45–5. Example of supraglottoplasty with the laser. Note the sparing of the posterior commissure.

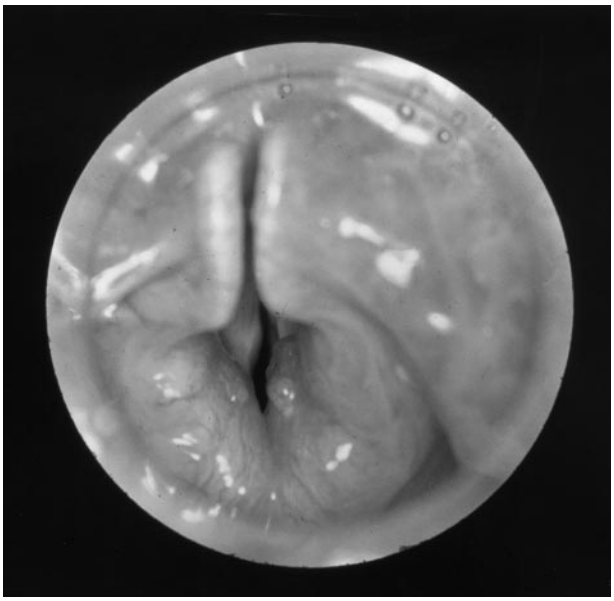

FIGURE 45–6. Bifid epiglottis. Courtesy of Dr. L. D. Holinger, Children's Memorial Hospital, Chicago, Illinois.

Because of the high incidence of associated airway lesions, direct laryngoscopy is suggested for all patients.

Treatment

If the airway distress is significant, a tracheostomy is warranted. Montreuil amputated the epiglottis with good results.[35] Healy and associates performed a tracheostomy in two patients, and in time the epiglottis matured, and both patients were decannulated without surgical intervention on the epiglottis.[39]

ATRESIA OF THE LARYNX

Atresia occurs when the laryngeal opening fails to develop and an obstruction is created at or near the glottis. Tracheal agenesis may also occur but is thought to be a rarer lesion.[40]

Incidence and Etiology

Congenital laryngeal atresia is a rare lesion, with only 51 cases reported in the world literature in 1987.[41] It is thought to be the rarest laryngeal lesion, accounting for only 1 of 846 congenital lesions evaluated by Holinger and colleagues[23,42] and none of 433 congenital lesions evaluated by Fearon and Ellis.[27] The lesion is thought to arise from the premature arrest of normal vigorous epithelial ingrowth into the larynx during the fourteenth to seventeenth stages of embryonic development.[43] In the embryonic larynx, a pharyngoglottic duct divides the larynx into an anterior (membranous) portion and a posterior (cartilaginous) portion.[44]

Signs and Symptoms

At delivery, the child makes strong respiratory efforts but does not move air, cry, or manifest any stridor. The child becomes markedly cyanotic when the umbilical cord is clamped. Most of these children die at birth unless an emergency tracheostomy is performed. Some children survive if they have a large tracheoesophageal fistula and if the esophagus is intubated. Not infrequently, a pharyngotracheal duct is present in the larynx. This should not be confused with a tracheoesophageal fistula, which is located much lower.

Diagnosis

The diagnosis is most frequently made at autopsy.[45] With the increased use of ultrasonography, the diagnosis of laryngeal atresia can be made before birth by noting enlarged edematous lungs, compressed fetal heart, severe ascites, and fetal hydrops.[46–50] Smith and Bain outlined three types of laryngeal

atresia deformities[51]; these investigators indicated that these types are not absolute but are gradations of a continuous spectrum. Type 1 involves the supraglottic and infraglottic larynx with fused arytenoids, an absent vestibule, and a deformed cricoid. Type 2 involves only the cricoid (subglottic area) with normal arytenoids, vestibule, and vocal cords. Type 3 involves a fused glottis with a normal vestibule and cricoid (Figure 45–7). The extent of the obstruction can be diagnosed with ultrasonography.[52] The subglottic lesions have been found to be cartilaginous or membranous.[44] When the lesion is diagnosed prenatally, it is called congenital high airway obstruction syndrome (CHAOS).[53] CHAOS results in a predictable constellation of findings: large echogenic lungs, flattened or inverted diaphragms, dilated airways distal to the obstruction, and fetal ascites and/or hydrops. Ultrasonography should be used to investigate the airway.[53]

Treatment

The patient will not survive unless an emergency tracheostomy is performed or the patient is ventilated through a tracheoesophageal fistula. Tracheoesophageal fistulae are frequently associated with this condition and usually arise at the tracheal bifurcation (Figure 45–8).[51,54,55] Most of the survivors have the membranous type 3 lesion or a type 2 lesion and a tracheoesophageal fistula, which allowed ventilation until a tracheostomy could be performed.

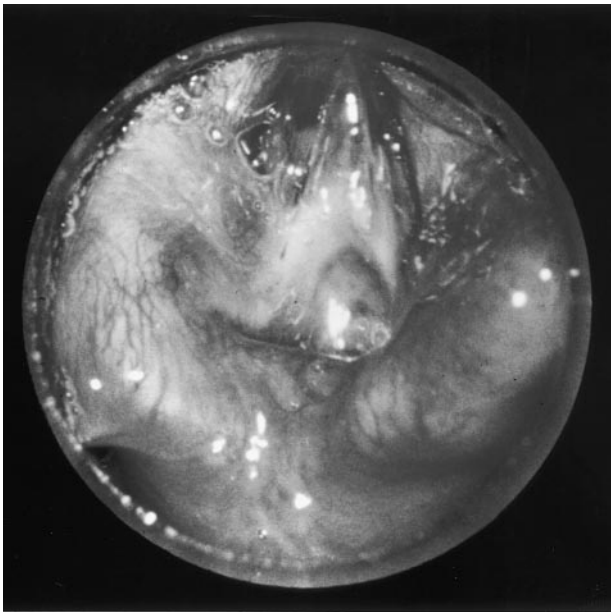

FIGURE 45–7. Type 3 laryngeal atresia. Courtesy of Dr. L. D. Holinger, Children's Memorial Hospital, Chicago, Illinois.

WEBS

Laryngeal webs occur in the glottis. Rarely, webs extend from the epiglottis to the lateral or posterior aspects of the hypopharynx and can result in significant airway compromise.[56] Holinger and associates described a patient with simultaneous supraglottic and laryngeal webs.[57] Most webs are located anteriorly and extend a varying length toward the arytenoids. The webs vary in thickness from a thin structure to one that is thicker and more difficult to eradicate. Benjamin and Mair described a rare type known as a congenital interarytenoid web, which limits the abduction of the arytenoids.[58]

Incidence

Congenital laryngeal webs are uncommon, constituting 5% of all congenital laryngeal lesions.[42,59] Acquired lesions are more common than congenital lesions, in a 60 to 40 ratio.[60] Associated anomalies are frequently seen, especially higher in the airway.[59,61,62] Posterior glottic webs occur in only 1 to 4% of patients.[60]

Signs and Symptoms

Symptoms of laryngeal webs are present at birth in 75% of patients and within 1 year in all patients.[62] The types of symptoms depend on the severity of

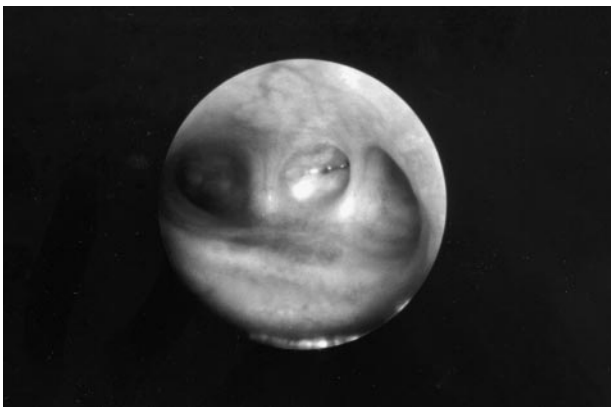

FIGURE 45–8. Tracheoesophageal fistula at the carina.

the web. Many children are asymptomatic until they are stressed, have an infection, or are intubated for a surgical procedure.

Vocal dysfunction is the most frequent symptom and was noted in 47 of 51 patients evaluated by Cohen.[61] The severity of the dysphonia is not necessarily indicative of the severity of the web. Cohen reported on 11 patients who complained of aphonia, 16 with weak or whispery voices, 7 with husky voices, and 4 with some hoarseness.

The second most common symptom is airway obstruction, and the severity is directly proportional to the degree of obstruction. The compromise may be so severe that stridor cannot be produced because of limited air movement through the larynx. If stridor is present, it will occur in both inspiratory and expiratory phases, and if the stridor is severe, the airway must be secured with intubation or a tracheostomy. Forty percent of Cohen's patients required a tracheostomy.[61]

Croup rarely occurs in children younger than 6 months. Cohen reported 15 of 51 children with a significant history of recurrent croup,[61] of whom 7 required tracheostomy, 9 presented with pneumonia, and 6 had tracheobronchitis.

Diagnosis

The only way to diagnose the extent of the web correctly is by direct laryngoscopy under general anesthesia.[63] The flexible scope may also have a role in the initial diagnosis, but experience in using it in patients with laryngeal webs is limited. Lateral radiographs of the neck may allow assessment of the width of the web.

Cohen divided laryngeal webs into four types, based on their appearance and an estimation of the degree of airway obstruction.[61] Type 1 is uniform in thickness, with no subglottic extension, with the true vocal cords clearly visible in the web, and compromises less than 35% of the airway (Figure 45–9). Hoarseness is usually only slight. Type 2 is slightly thicker, with a significantly thicker anterior component that may extend into the subglottis. The web restricts the airway by 35 to 50% and usually causes little airway distress, unless the patient has an acute infection or is traumatized during intubation (Figure 45–10). The voice is usually husky. Type 3 is a thick web that is solid anteriorly, with the true vocal cords not well delineated. The web restricts the airway by 50 to 75%, and one notes marked vocal dysfunction, with a weak and whispery voice. Type 4 is a uniformly thick, solid web occluding 75 to 90% of the airway (Figure 45–11). Respiratory obstruction is severe, and the patient is almost always aphonic.

Treatment

Approximately 60% of patients require surgical intervention.[62] Some webs are not repaired because

FIGURE 45–9. Type 1 laryngeal web.

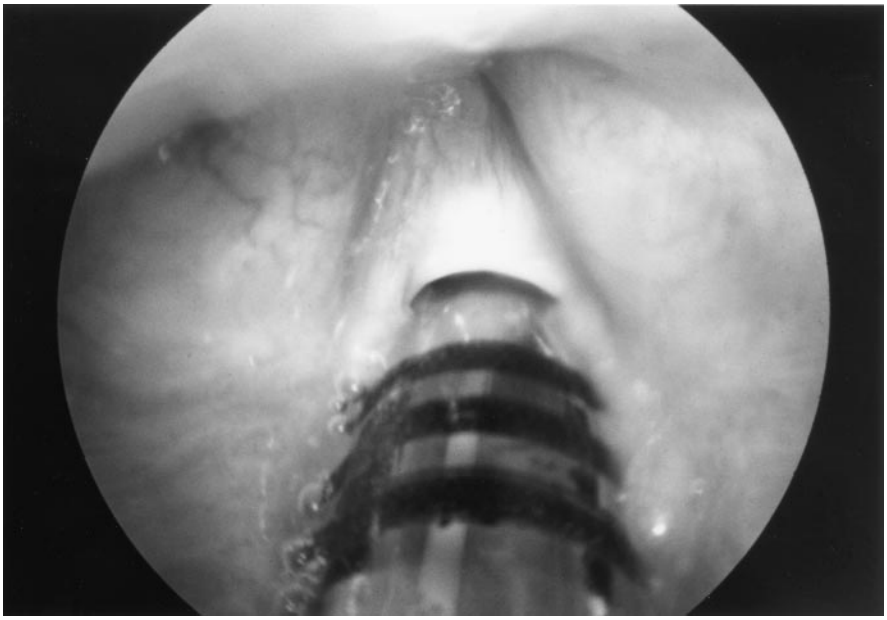

FIGURE 45–10. Type 2 laryngeal web that is intubated. This patient will likely be symptomatic after extubation.

the patients succumb to other systemic complications. Of all patients with laryngeal webs, 30 to 40% require a tracheostomy.[61,62] The type of lesion dictates the surgical approach. In general, the thinner webs are easier to treat; the more severe webs are resistant to surgical management. It is difficult to obtain a crisp anterior commissure, and even if one is obtained, this does not ensure a good voice.

Type I lesions are not life threatening. Many do not require surgery, but if surgery is performed, dilations or excisions with a knife, scissors, or laser are effective. Type 2 lesions require treatment, but not in childhood. Multiple procedures are necessary for excising small portions of the web in multiple steps. Corticosteroids and antibiotics decrease the amount of scarring, and speech therapy may be necessary to maximize phonation. Type 3 lesions frequently require tracheostomy to establish the airway. The child may develop progressive airway distress because of increased airway demands, trauma from intubation, or infection. These lesions may require multiple excisions and frequently necessitate the placement of a keel.[64,65] McGuirt and associates described a method using the laser to develop flaps of the web and reported near-normal results in all patients.[60] Type 4 lesions all require a tracheostomy and excision of the web with placement of a keel. Because they are tracheostomy dependent, these patients should be monitored with apnea monitors. Most surgeons would resect the web and place the keel through a laryngofissure. The airway results are good, but the voice is poor.[61]

SACCULAR CYSTS AND LARYNGOCELES

Laryngoceles and laryngeal saccular cysts are thought to arise from the laryngeal or saccular appendage[66–70] or from retention cysts resulting from obstruction of mucous gland ducts.[71] Morgagni incompletely described the saccule, and Galen also had mentioned it previously.[72] The appendage arises from the anterior part of the ventricle, extends superiorly, and curves slightly posteriorly deep to the false vocal cords and aryepiglottic folds. The orifice opens into the ventricle and measures only 0.5 to 1 mm. The ventriculosaccular fold probably serves to store mucus and direct it posteromedially to lubricate the vocal cords.[73] In the adult, the appendage extends as high as the superior border of the thyroid cartilage. Broyles found that 75% of the saccules measured 6 to 8 mm in length, 25% measured more than 10 mm, and 7% measured more than 15 mm.[74] In the fetus, 25% extend as high as the thyrohyoid membrane.[72] The type of lesion that develops is based on the size of the saccule, whether there is free communication with the laryngeal

FIGURE 45–11. Type 4 laryngeal web. Courtesy of Dr. L. D. Holinger, Children's Memorial Hospital, Chicago, Illinois.

lumen, and whether there is inflammation within the sac. DeSanto and colleagues believe that the differentiating factor between the development of a cyst or a laryngocele is the patency of the ventricle.[72,75]

Saccular Cysts

Incidence Laryngeal saccular cysts are most likely to become manifest in infancy.[72] Congenital laryngeal cysts are rare, but the awareness of their possibility is important because almost 50% of these cysts are diagnosed at autopsy after the infant has asphyxiated.[73] In 1967, Suehs and Powell found 27 reported cases of congenital laryngeal cysts.[76]

Signs and Symptoms Forty percent of congenital laryngeal cysts are discovered within a few hours of birth, and 95% of the children have symptoms before 6 months of age.[77] The most frequent symptom is stridor (90%), which is primarily inspiratory, although it may be biphasic.[73] The stridor improves in some infants during extension of the head. The cry has been reported as feeble, muffled, shrill, hoarse, or normal.[76,78] Dyspnea, apnea, and cyanosis have been noted in 55% of patients.[78] The associated feeding problems are similar to those in esophageal atresia or tracheoesophageal fistula without atresia and lead to failure to thrive in a large number of patients.[76,77]

Diagnosis Chest and lateral neck radiographs, barium swallow, and CT scan are useful preoperative evaluations of the stridor, but they are not diagnostic.[73,79] Hemangiomas, for example, can cause identical findings, although these lesions appear most frequently in the subglottis. The only way to make the diagnosis definitively is with direct laryngoscopy.[77] Cotton and Richardson suggested that at the time of endoscopy, one should have a large-bore needle, a tracheostomy tray, and an appropriate-size rigid bronchoscope available.[80] The cysts are typically divided into lateral wall saccular cysts and anterior saccular cysts. Lateral saccular cysts are most frequently located in the aryepiglottic fold, epiglottis, or lateral wall of the larynx[76,77] (Figure 45–12). Anterior saccular cysts extend medially and posteriorly between the true and false vocal cords and directly into the laryngeal lumen[77,79] (Figure 45–13). They are most frequently sessile but may be pedunculated. Mitchell and associates reported four subglottic cysts in patients who had previously been intubated and considered the cysts to be probably secondary to intubation.[77]

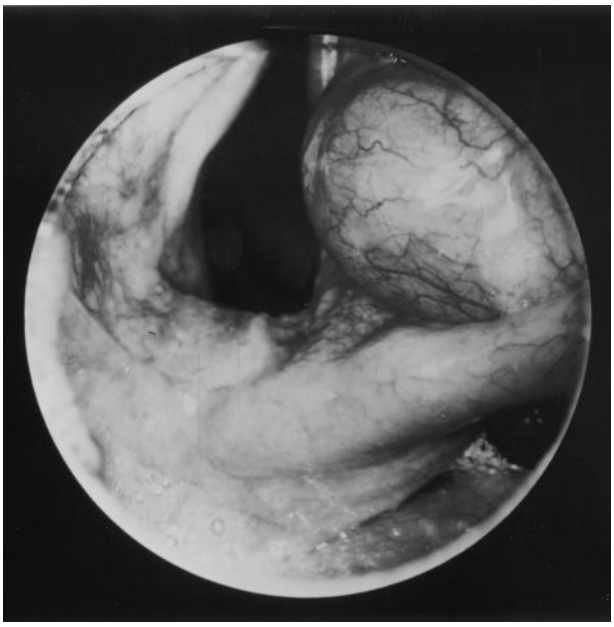

FIGURE 45–12. Lateral saccular cyst. Courtesy of Dr. L. D. Holinger, Children's Memorial Hospital, Chicago, Illinois.

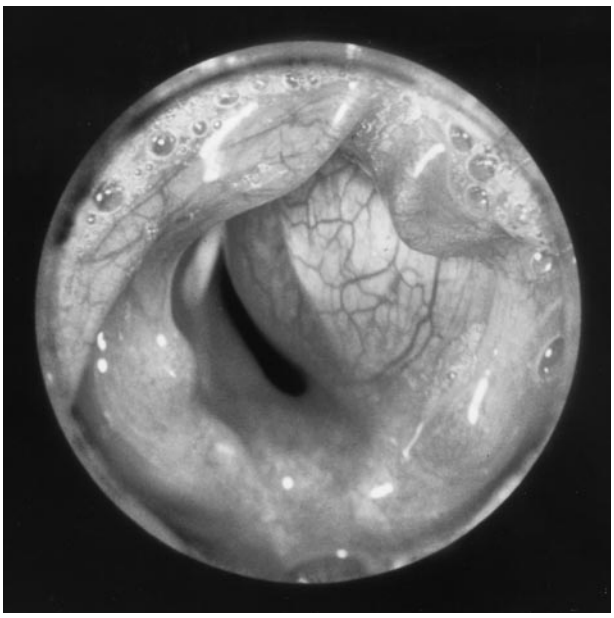

FIGURE 45–13. Anterior saccular cyst. Courtesy of Dr. L. D. Holinger, Children's Memorial Hospital, Chicago, Illinois.

Treatment Treatment of laryngeal cysts may require emergency tracheostomy.[73,81,82] Mitchell and associates noted that 20% of their patients required emergency intervention.[77] In the infant, the cysts should be treated primarily with endoscopic deroofing or aspiration. Suehs and Powell recommended endoscopic incision and drainage as needed.[76] Holinger and colleagues thought that smaller anterior saccular cysts could be effectively treated with cup forceps removal (excision biopsy) at the time of direct laryngoscopy.[73] These investigators would not attempt endoscopic dissection of the entire sac. Aspiration has also been recommended, but the incidence of recurrence is high.[67,83] Mitchell and associates reported successful treatment of 7 of 17 patients with deroofing or marsupialization.[77] A second deroofing was required in six of the seven recurrences. The remaining failure was treated with total excision through a laryngofissure.

Laryngoceles

Incidence As of 1977, 300 laryngoceles had been recorded in the world literature. They may occur in infants and children,[84] and they cause airway obstruction.[85] The presence of laryngoceles in this age group appears to be rare, however. Laryngoceles are much more common in adults and appear most commonly in the fifth decade.[84] Holinger and Brown reported on 12 patients with congenital laryngoceles in infancy.[78] Baker and associates found an increased incidence of laryngoceles in laryngeal cancer and suggested that obstruction of the saccule by the carcinoma was a factor in developing laryngoceles.[86]

Signs and Symptoms Laryngoceles are symptomatic only when they are filled with air or fluid, so the symptoms may be intermittent. Because the laryngocele may rapidly inflate and deflate, several radiographs may be necessary to document the lesion. A fluid-filled laryngocele may be difficult to differentiate from a cyst. If it becomes infected, it fills with mucopus and is called a laryngopyocele.

Diagnosis The definitive diagnosis is made with direct laryngoscopy, but because the symptoms are intermittent, more than one examination may be necessary. Laryngoceles originate from the ventricle and bulge out between the true and false vocal cords or dissect posteriorly into the arytenoid and aryepiglottic fold. In general, three types have been described: internal, external, and mixed[84]; however, this classification is artificial. The internal type is limited to the larynx, whereas the external type extends into the neck through the isthmus of the thyrohyoid membrane. The mixed type involves both internal and external portions and is the most common. Laryngoceles should be diagnosed with direct laryngoscopy when they are symptomatic, in addition to radiographic findings. Trapnell has emphasized that the radiographic appearance of a large saccule does not warrant the diagnosis of a laryngocele.[87]

Treatment Only symptomatic lesions require treatment. DeSanto preferred the external approach[72]; however, most of his experience was in adults. The procedure described by Yarington and Frazer provides adequate exposure for resection.[88] Holinger and associates emphasized that true laryngoceles are rare in children and should be treated endoscopically by deroofing with cup forceps.[73] On occasion, the laryngocele can be aspirated, and a more orderly resection can be performed at a later date.[89] The laser is also an alternative.

LARYNGEAL CLEFTS

Congenital laryngotracheoesophageal cleft is characterized by a deficiency in the separation between the esophagus and the larynx or trachea. Type I clefts are recognized more frequently[90,91]; however, the true incidence is not yet known. Larger clefts are associated with a high mortality.[92]

Incidence

Most clefts occur through the posterior part of the glottis; however, rare ventral or anterior clefts have been reported.[93–95] Clefts may be classified into three broad categories. Type I is called the laryngeal cleft and is found only in the posterior part of the glottis. Types II and III involve the trachea in addition to the larynx (Figure 45–14). Type II extends down to but not beyond the sixth tracheal ring, and type III can extend to the carina. As of 1983, 85 well-documented cases of clefts have been reported.[96] Finlay observed a family in which two of five children developed a cleft larynx.[97] Other investigators have reported similar examples.[85–87] The inheritance pattern is almost always autosomal dominant.[87] Posterior glottic clefts have been associated with tracheal agenesis, as well as many other congenital anomalies.[96]

Signs and Symptoms

In the world literature, of 85 patients, 35 had type I clefts, 36 had type Il clefts, and 14 had type III clefts.

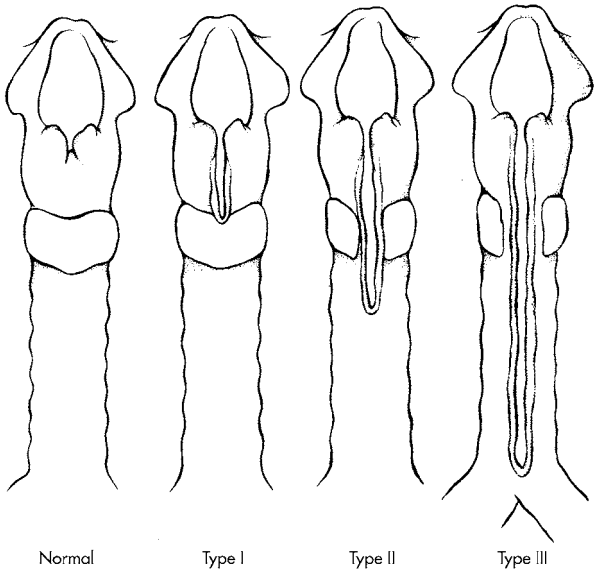

FIGURE 45–14. Classification of laryngeal and tracheoesophageal clefts as proposed by Evans.[98]

The following manifestations, in order of frequency, are associated with laryngotracheoesophageal clefts: aspiration and cyanosis (53%), postpartum asphyxia (33%), increased mucus production (23%), recurrent pneumonia (16%), voiceless crying (16%), stridor (10%), and impaired swallowing (5%).[96] The simultaneous occurrence of increased saliva production; low, soundless, or hurried crying; and stridor should lead to the suspicion of a cleft. The inspiratory stridor is produced by the collapse of redundant mucosa around the cleft and from the intrusion of the arytenoid into the airway.[98,99] Cohen reported that the stridor may be expiratory because of aspirated secretions.[100] One sees a frequent combination of posterior laryngeal clefts and tracheoesophageal fistulae.

Diagnosis

Occult posterior laryngeal clefts have been diagnosed with MRI.[101] A laryngeal cleft is frequently demonstrated by an esophagram with water-soluble contrast medium[102] or is suggested by aspiration pneumonia on a chest radiograph. The most important diagnostic test, however, is direct laryngoscopy. If one does not specifically look for the entity, it frequently escapes detection.[103] When the larynx is examined, redundant mucosa in the posterior cleft is usually the first clue to the defect (Figure 45–15). On inspiration, this redundant mucosa may rotate into the airway. The cleft can best be demonstrated by placing a laryngoscope, such as a Dedo or Jako, into the supraglottis and examining the posterior part of the glottis. If a posterior laryngeal cleft is present, this maneuver will clearly demonstrate the lesion and its extent (Figure 45–16). The posterior part of the glottis can also be palpated with a spatula or a similar thin instrument to demonstrate the defect. Some authors find microlaryngoscopy helpful.[98] Some clefts are submucous, and diagnosis is made only on laryngeal sections.[104,105] The clinical significance of submucous clefts is unknown. There is a high incidence of associated esophageal lesions and tracheoesophageal fistulae, for which careful examination must be made.[98,100,104,106,107]

Treatment

The prognosis for a patient with this lesion is not favorable. In the review presented by Roth and colleagues,[96] 24 patients died before surgical interven-

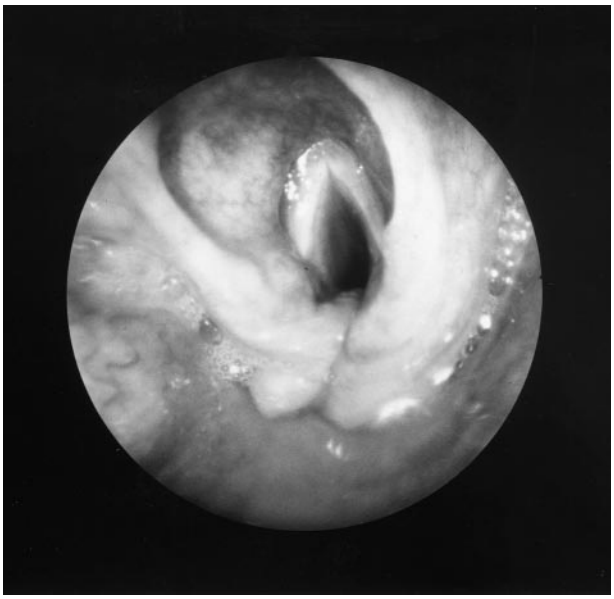

FIGURE 45–15. Laryngeal cleft demonstrating redundant mucosa prolapsing into the larynx on inspiration.

tion; of patients with type III clefts, 13 of 14 died; of those with type II clefts, 13 of 31 died; and of those with type I clefts, 13 of 30 died. Almost two-thirds of the deceased patients had other severe malformations. Clefts were repaired in 48 patients, 13 of whom died. A tracheostomy was performed in 50% of all patients. The first successful operative correction of the defect in the larynx was achieved by Petterson.[108]

Three surgical approaches to the posterior aspect of the larynx have been described: (1) minor type I clefts can be repaired endoscopically[109,110]; (2) lateral pharyngotomy has been used frequently, especially for the smaller laryngeal clefts,[96,98] the major disadvantage of which lies in the danger of injuring the recurrent nerve; the exposure is limited, and it is difficult to obtain a good layered closure; and (3) anterior laryngofissure does not risk the recurrent laryngeal nerve and has been used in neonates.[96,99,100,111–113] Evans reported better exposure and a better two-layer closure in type II and III clefts with a laryngofissure[98] (Figure 45–17). Prescott successfully repaired a cleft with a posterior rib graft through a laryngofissure.[114] A disturbance of the laryngeal growth appears unlikely. Intraoperative airway management has been a problem in repairing these lesions. Ahmad and associates solved the problem by using a bifurcated endotracheal tube.[115] Geiduschek and colleagues reported the use of extracorporeal membrane oxygenation for extensive cleft repair.[116] We have used bypass to repair long-segment tracheal stenosis.

Cotton and Schreiber have noted that, after repair of posterior clefts, the patient may have continued esophageal reflux and aspiration of gastric contents.[117] There appears to be a significant decrease in successful repair if a tracheoesophageal fistula is present.[107] When this occurs, these investigators recommend a high gastric section with a dou-

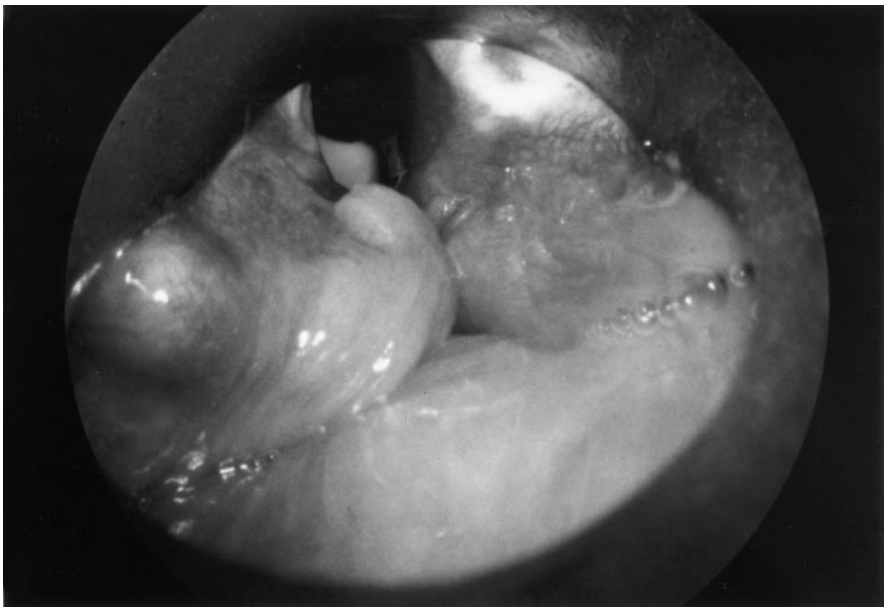

FIGURE 45–16. Jako laryngoscope inserted into the posterior commissure, demonstrating the laryngeal cleft.

FIGURE 45–17. Type I cleft repaired through a laryngofissure.

ble gastrostomy to minimize the chance of aspiration of gastric contents. Robie and associates reported that of 170 clefts repaired, 19 required revision surgery.[113]

VOCAL CORD PARALYSIS

Vocal cord paralysis can be categorized into congenital and acquired lesions. One or both of the true vocal cords may be involved, and bilateral vocal cord paralysis is more frequent.[118–120] Apnea is frequently seen in bilateral vocal cord paralysis.[121–123] Congenital lesions are frequently associated with central nervous system lesions, including hydrocephalus, meningomyelocele, Arnold-Chiari malformation, meningocele, encephalocele, cerebral agenesis, nucleus ambiguus dysgenesis, neuromuscular disorders, and myasthenia gravis.[124,125] Arnold-Chiari is the most frequent malformation and is likely a contributing factor in most cases.[126]

Incidence and Etiology

Estimates of the frequency of vocal cord paralysis range from 1.5 to 23%[120,127,128]; according to some authors, it ranks second in frequency among all congenital laryngeal lesions.[124] Holinger and associates found that congenital lesions were more frequent than acquired.[125] The acquired group can be further categorized into traumatic, infectious, or neoplastic. Traumatic lesions are most frequent secondary to stretching of the recurrent laryngeal nerve during vaginal delivery or surgical trauma in management of bronchogenic cysts, tracheoesophageal fistulae, or patent ductus arteriosus.[124] Infectious diseases such as whooping cough, encephalitis, poliomyelitis, diphtheria, rabies, tetanus, syphilis, and botulism are now rarely seen but can cause vocal cord paralysis.[123] Tumors of the brain and spinal column are also rare but can cause unilateral or bilateral vocal cord paralysis.

The pathophysiology of bilateral vocal cord paralysis is unclear, but the condition may result from (1) compression of the vagus nerves in their course through the foramen magnum, (2) traction of the cervical rootlets of the vagus nerves by the caudal displacement of the brainstem, or (3) brainstem dysgenesis.[129,130] Most authors favor the compression theory because, with timely decompression of hydrocephalus or the Arnold-Chiari malformation, the vocal cords regain function. Familial bilateral vocal cord paralysis[131–133] and persistent apnea after tracheostomy[121] appear to be most appropriately explained by the dysgenesis theory. Probably, more than one lesion can cause vocal cord paralysis.

Laryngeal lesions such as subglottis stenosis, laryngomalacia, and posterior laryngeal clefts have also been associated with, but do not cause, vocal cord paralysis.[134]

Signs and Symptoms

Any of the three laryngeal functions of respiration, voice production, and deglutition can be affected by vocal cord paralysis. With unilateral vocal cord paralysis, the voice is breathy and weak, but the patient has an adequate airway unless stressed. Stridor, weak cry, and some degree of respiratory distress can be seen in all patients with bilateral vocal cord paralysis.[130] Dedo noted that if *both* the recurrent and superior laryngeal nerves are paralyzed, the vocal cords will be in the intermediate position, and the airway then will frequently be sufficient to allow adequate ventilation.[124,135] If the recurrent nerves only are paralyzed, the vocal cords will be in the paramedian position, resulting in an inadequate airway.

Stridor is the most frequent presenting symptom of bilateral vocal cord paralysis,[125] and its onset may be sudden.[130] Older children suppress laughing and coughing because of the increased respiratory demand. The airway becomes narrower, and there will be an increase in stridor and the development of nasal flaring, restlessness, and the use of accessory respiratory muscles, with an indrawing of the sternum and epigastrium. The stridor may progress to cyanosis, apnea, and respiratory and cardiac arrest if not recognized and treated.

Aspiration and dysphagia are frequently noted in patients with bilateral vocal cord paralysis.[129,136] Pneumonia may first be apparent when signs of increasing cranial pressure appear.

Diagnosis

The diagnosis is made by flexible laryngoscopy or direct laryngoscopy. Vocal cord mobility may be difficult to examine in an infant, and the intermediate versus paramedian position may be impossible to assess.

Treatment

Once the diagnosis of vocal cord paralysis is made, the airway should be secured if the patient has significant airway distress. The airway is best established with intubation, followed by a full workup to ascertain the cause of the vocal cord paralysis. One must look specifically for associated findings of meningomyelocele, Arnold-Chiari malformation, and hydrocephalus.[125] If the compression of the nerve is relieved within 24 hours, the vocal cords will regain function within 2 weeks2[125,130]; otherwise, vocal cord function may not return for 1½ years, if at all. If intervention has been timely, the larynx should be examined periodically to assess vocal cord function. If the patient shows no evidence of function within 1 to 2 weeks, a tracheostomy should be performed to relieve the airway distress,[123] but central sleep apnea may continue even with appropriate early decompression.[121] Once the tracheostomy is in place, periodic examinations will be necessary to assess vocal cord function.

Approximately 50% of children with bilateral vocal cord paralysis require tracheostomy.[118,125,130] Bluestone and colleagues reported a 50% mortality rate secondary to shunt failure or infection in patients with Arnold-Chiari malformation.[130] Of those who survive, 25 to 48% can be decannulated.[119,129]

SUBGLOTTIC LESIONS

The principal subglottic lesions are stenoses and hemangiomas.

Stenosis

Stenoses of the subglottic area can be divided into cartilaginous stenoses, which are usually congenital, and acquired membranous or soft tissue stenoses.

Incidence and Etiology A stenosis is considered to be congenital when the patient has no history of endotracheal intubation or trauma. The normal subglottic lumen is 4.5 to 5.5 mm in a full-term neonate and 3.5 mm in a premature neonate. We do not know in how many infants' extubations fail because of congenitally small cricoid cartilages.

Congenital subglottic stenosis is the third most common congenital abnormality. Cricoid cartilage deformities are usually congenital and consist of abnormal shapes and sizes. The cricoid cartilage may have a normal shape but may be small or hypoplastic. It may also be elliptical, flattened, or otherwise distorted. The first tracheal ring can also be trapped under the cricoid cartilage, resulting in a narrowed subglottis. The primary causes of acquired or membranous subglottic stenosis (Figure 45–18) in children are (1) external injury from blunt trauma or a high tracheostomy and (2) internal injury from prolonged intubation and chemical or thermal burns. External injuries are rare in infants. Internal trauma, secondary to prolonged intubation, is thought to

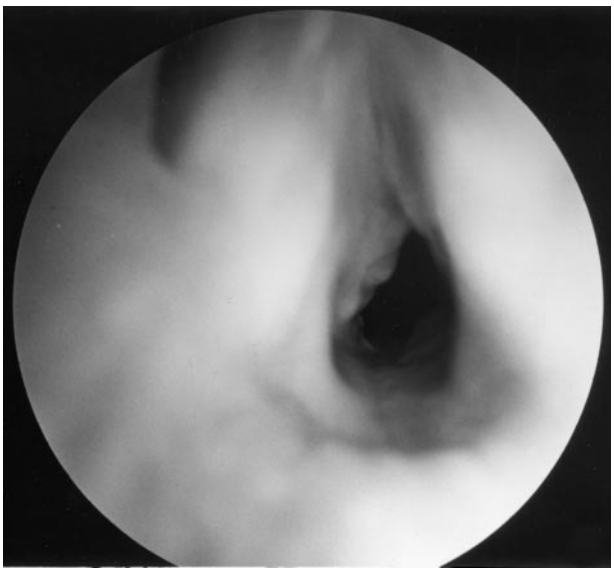

FIGURE 45–18. Membranous subglottic stenosis.

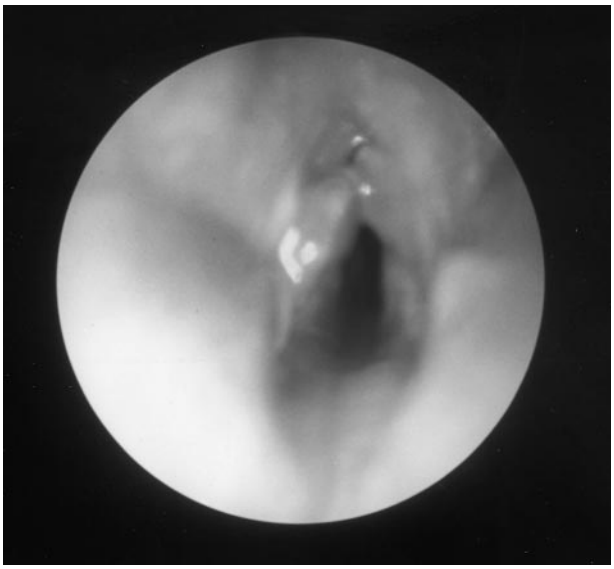

FIGURE 45–19. Ulcerated right vocal process.

account for approximately 90% of acquired subglottic stenosis.[137,138] The incidence of stenoses after intubation ranges from 0.9 to 8.3%.[139–142] The stenoses most frequently occur in the subglottis because (1) the cricoid cartilage is a complete circular ring, without any "give" for edema; (2) the edema can accumulate rapidly in the loose areolar tissue of the subglottis; (3) the pseudostratified, ciliated columnar respiratory epithelium is delicate and easily traumatized; and (4) the narrowest portion of the upper airway is in the subglottis and is therefore the most likely to be traumatized.[138]

The pathophysiology of acquired subglottic stenoses is well described. The endotracheal tube causes pressure necrosis of the respiratory epithelium. Edema and superficial ulceration begin, and the normal ciliary flow is interrupted. As the ulcer deepens, secondary infection of the areolar tissue and perichondrium begin. Chondritis may eventually occur, with necrosis and collapse of the cricoid cartilage. Benjamin characterized the traumatic lesions formed in the larynx with prolonged intubation.[143] He noted that, in the acute phase, one sees formation of posterolateral ulcerations at the vocal processes ("ulcerated troughs") (Figure 45–19), and usually one sees an "intact median strip" of mucosa and an "annular ulceration" of mucosa in the subglottis. "Tongues of granulation tissue" (Figure 45–20) form anterior and posterior in the ulceration, and frequently one sees generalized inflammation and edema of the ventricle that results in ventricular protrusions. The long-term complications of these lesions are characterized as posterior glottic synechiae, "healed furrows," posterior subglottic and glottic stenoses (Figure 45–21), "healed fibrous nodules," submucosal mucous gland hyperplasia with ductal cysts, and submucosal fibrosis and stenosis. The scar tissue forms in the subglottis and limits the airway.[144–148] Healing is inhibited in part by poor blood supply in the subglottis and constant motion of the larynx.

Neonates tolerate prolonged intubation better than adults. The reasons for this are unclear, but more pliable cartilage[144] and the higher position of the larynx in the neck[146] have been suggested as considerations.

Certain factors can increase the chances of developing subglottic stenosis. An oversized endotracheal tube or a tube of appropriate size in a patient with a small cricoid cartilage can increase the mucosal pressure and result in a deep ulceration. Primary intubation can traumatize the subglottis. In children, an endotracheal tube that allows a leak at pressure less than 20 cm H_2O should be chosen. Reintubation,[144,149] shearing motion of the tube on movement of the head,[150] and superimposed local or systemic bacterial infections[145] increase the risk. Gastroesophageal reflux can increase the inflammation

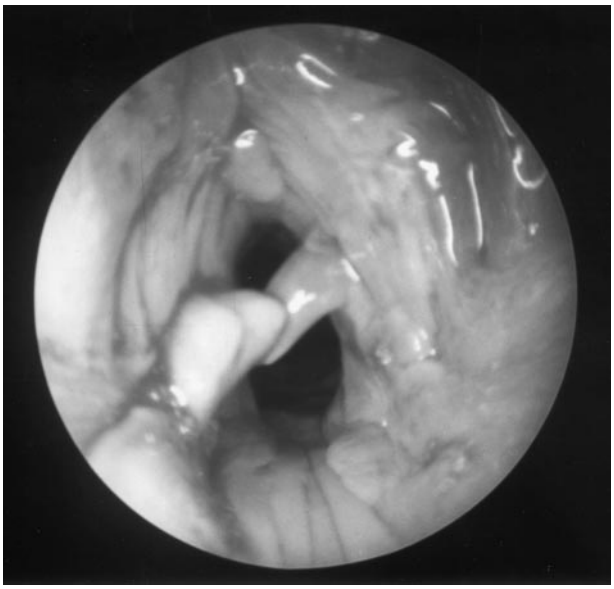

FIGURE 45–20. Tongues of granulation tissue.

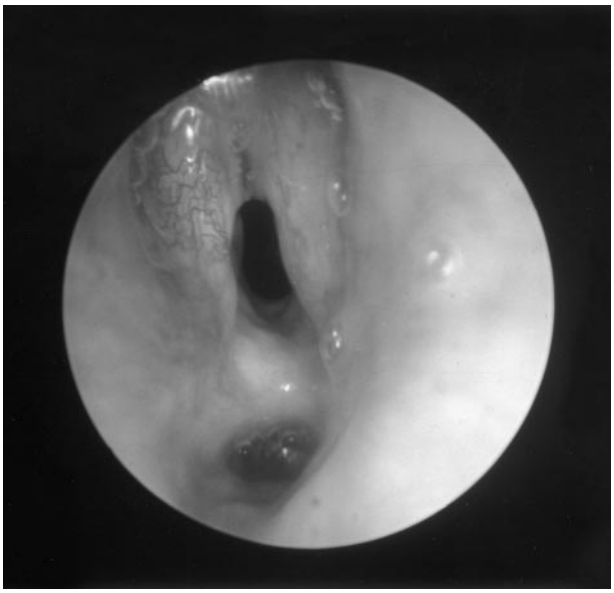

FIGURE 45–21. Posterior glottic web.

and tissue trauma. Nasogastric tubes and endotracheal tubes have been noted to cause pressure necrosis of the cricoid[145] and increase the risk of reflux.

Systemic factors such as immunodeficiency, anemia, neutropenia, toxicity, hypoxia, dehydration, and poor perfusion increase the risk of developing mucosal ulceration and subsequent scar formation.

Signs and Symptoms In the intubated neonate, evidence of subglottic stenosis may not manifest until the patient is ready for extubation. If a subglottic ulcer is present, the airway may be compromised immediately or edema may accumulate over a few hours. In some patients, symptoms do not develop until 2 to 4 weeks after intubation. If the patient has mild to moderate congenital subglottic stenosis, symptoms may not appear until an infection of the upper respiratory tract causes additional narrowing and respiratory distress.

If the stenosis is congenital, the only manifestation may be prolonged or recurrent croup. A common dictum is that "there is no such thing as croup under 1 year of age." As respiratory demands increase, the infant may become symptomatic.[80]

The main symptoms and signs relate to airway, voice, and feeding. Stridor is the primary sign and is biphasic, with the inspiratory phase always louder. With progressive narrowing of the airway, respiratory distress ensues. If the vocal cords are affected, hoarseness, abnormal cry, and aphonia will indicate that an anterior web is present. Dysphagia and aspiration pneumonia can occur.

Diagnosis Soft tissue radiographs of the lateral neck may demonstrate subglottic narrowing. Xeroradiography demonstrates the tissue–air interface better and is believed by many to be the best method for evaluating chronic airway problems.[151–153] Computed tomographic scans do not give adequate additional information.

Direct laryngoscopy is the most important diagnostic step in assessing the thickness and length of the stenosis and involvement of the larynx. Flexible fiber-optic laryngoscopy is most useful in assessing vocal cord function.[151] Because the flexible scope provides only a limited view of the posterior part of the glottis and subglottis, rigid endoscopy is necessary to assess the size and patency of the lumen. The airway may be sized with the bronchoscope or endotracheal tubes. Storz Hopkins rod lens telescopes are especially important in visualizing the extent of the stenosis in the subglottis. Because of the wide-angle view, estimating the actual dimensions of the lumen is difficult. Often the narrowing is so great that only the telescope can be used.

Treatment Congenital subglottic stenosis that is mild and causing mild symptoms and signs can be

treated expectantly. Some patients outgrow their lesions and are unlikely to need surgical correction.[154] Treatment must be individualized.

Tracheostomy is required in fewer than half of patients with congenital subglottic stenosis.[144] Normal growth and development may allow decannulation within 2 to 5 years.

The *anterior cricoid split operation* was initially devised to treat acquired subglottic stenosis,[155] and it was later applied to patients with the congenital form.[156,157] This procedure breaks the cartilaginous cricoid ring anteriorly to allow expansion of the subglottis. It is used in patients who have confirmed stenosis and failed extubation but do not require airway support and have mature lungs with oxygen requirements less than 35%. The procedure involves making a vertical incision through the lower third of the thyroid cartilage, the cricoid cartilage, and the first two tracheal rings. Many of the cricoid rings spring open, and the endotracheal tubes are readily seen through the incision. Others do not open to any significant degree. Some surgeons have recommended placement of auricular or rib grafts at the time of the decompression.[158–160] The patient is left intubated with an endotracheal tube one size bigger for 5 to 7 days and is re-examined at the time of extubation. Corticosteroids are usually administered 3 to 5 days before planned extubation.

In weighing the advantages of endoscopic and open procedures, the surgeon must take into account the extent of the scarring and the expertise required. The goal of any surgical procedure is to extubate or decannulate the patient by repairing the stenosis with minimal effect on the voice.

Dilatation is useful if the ulceration is still present and granulation tissue is forming. It is most appropriately used with immature scar or submucosal fibrosis. Gentle dilation is performed with a round, smooth instrument, usually in conjunction with corticosteroid injection.[161] Aggressive dilatation with corticosteroid injection can induce additional trauma and cause significant necrosis of the cartilage.

The use of *corticosteroids* is controversial. They tend to decrease scar formation through their anti-inflammatory action and by delay of collagen synthesis. They may be used systemically or injected locally. Corticosteroids have not been successfully used to treat mature scar in the subglottis.

A variety of methods for *endoscopic correction* of subglottic stenosis have been suggested, including microcauterization,[162] cryosurgery,[163,164] serial electrosurgical resection,[165] and carbon dioxide laser.[166] The carbon dioxide laser appears to be the current modality of choice.[146,166–171] The laser can only be used to resect membranous stenosis, and the procedure has to be performed in stages. The more aggressively the laser is used, the less the likelihood of a successful outcome and the greater the risk of inducing additional scarring. Cotton and Manoukian identified several factors associated with poor results: (1) circumferential scarring, (2) scar tissue greater than 1 cm in length, (3) scar in the posterior commissure, (4) severe bacterial infection of the trachea after a tracheostomy, (5) exposure of the perichondrium or cartilage with the laser, (6) combined laryngotracheal stenosis, (7) failure of previous endoscopic procedures, and (8) previous loss of cartilaginous framework.[172] Prophylactic systemic antibiotic therapy is recommended for endoscopic procedures. Adequate exposure of the subglottis is necessary. The subglottiscope designed by Healy is useful if the patient does not have a tracheostomy in place. Supraglottic jet ventilation provides the best exposure. Thin webs are most appropriately treated with the laser.

The *open procedures* have been traditionally used for the more severe lesions. Surgeons are increasingly using single-stage reconstruction.[159,173] This allows for more rapid correction of the problem and is perhaps more cost effective. The *hyoid interposition* was first reported by Looper.[174] Bennett also reported the use of a hyoid bone graft for the treatment of subglottic stenosis.[175] Bone resorption was a problem, which led to the development of pedicle hyoid-sternohyoid myo-osseous flaps.[176–178]

The anterior cricoid split with endotracheal tube stenting has been recommended for treatment of milder forms of stenosis. The standard reconstruction has been with autogenous costal cartilage.[179–181] Because of its abundance, costal cartilage is a better material to use than thyroid cartilage, hyoid bone, or muscle pedicle.

The *costal cartilage reconstruction* has been the standard method for subglottic reconstruction for the past several years. The fifth or sixth cartilaginous rib or costal margin cartilage is harvested. One incision can be used to harvest two ribs, but this is seldom necessary. The perichondrium is left on the lateral surface of the rib, with incisions through it along the superior and inferior borders and stripped

from the medial surface. Some surgeons use the rib stripper on small double-prong hooks and a freer elevator. The incision in the neck is usually a U-shaped flap through the tracheostoma or a horizontal incision over the cricoid if a tracheostomy is not in place. The larynx and trachea are exposed, and a midline incision is made through the length of the stenosis. If the stenosis is severe, the lumen can first be identified with a 25-gauge needle under endoscopic visualization. When only an anterior graft is used, the incision usually extends from the tracheal rings through the cricoid and the lower third of the larynx. If a posterior graft and stent are required, a full laryngofissure will be necessary. The intraluminal scar and mucosa are incised strictly in the midline. This is best performed by first marking the lumen transtracheally with a 25-gauge needle. Once the airway is open, the scar is not removed. The length of the trachea and larynx to be reconstructed is measured, and the rib graft is designed to fit the defect. The graft is elliptical, with the perichondrium toward the lumen. The rib is not thinned, and care is taken to shape the cartilage to be as wide as possible, with a lip or shelf to prevent the graft from falling into the airway (Figure 45–22).

In patients with greater subglottic stenosis, a posterior graft is needed, and the posterior cricoid lamina is divided in the midline to, but not through, the hypopharyngeal mucosa. In complete stenosis, a four-quadrant split has been recommended. The cricoid is separated to a distance of approximately 1 mm per year of age up to 10 mm between the two halves.[172] An appropriate wedge of rib with the perichondrium facing the lumen is sutured into the posterior cricoid cleft. If a posterior graft has been performed, a stent will be required to maintain the lumen postoperatively. The current stent of choice is the Aboulker-styled Teflon stent, which is round. Unfortunately, it can cause significant blunting, trauma, and granulation tissue formation at the anterior commissure.

Once the posterior cricoid graft is positioned, the stent is placed and the anterior tracheal wall is closed. Usually, posterior and anterior grafts are used concomitantly. When a stent is used, it must first be positioned in the airway with the tracheostomy in place. The best method of securing the tracheostomy to the stent is with wire, as described by Cotton and Manoukian.[172] Placement must be checked endoscopically. The stent should come to the level of the false vocal cords. If necessary, the stent length should be revised to hold the proper position. The rib is sutured into place with 4-0 Vicryl or polydioxanone suture, taking care to go through the cartilage and not allowing the suture to be exposed intraluminally. If suture is located in the lumen, granulation tissue and chronic infection will result. The neck wound is closed in layers. The stent is left in place for a variable length of time based on the surgeon's judgment and the severity of the stenosis.

Recently, auricular cartilage has been used as a graft material.[158,159] It is useful because it is malleable;

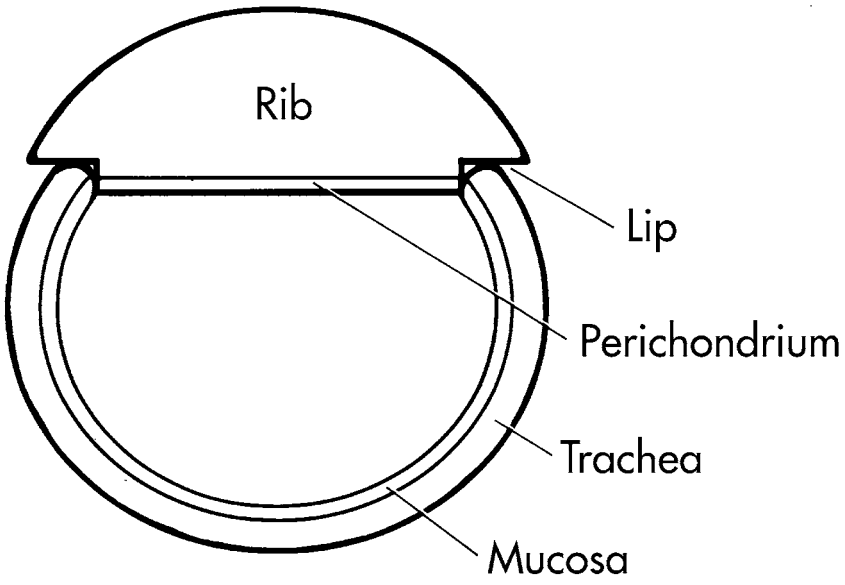

FIGURE 45–22. Drawing depicting the rib graft, which has not been thinned, and a lip to prevent collapse into the lumen.

its curved shape allows for greater anteroposterior dimensions than available with the rib graft (Figure 45–23). The auricular cartilage graft has not been used extensively with staged reconstructions.

The results of successful decannulation depend in part on the severity of the stenosis. Viral infections with respiratory syncytial virus and bacterial infections with *Pseudomonas* have been associated with an increased failure rate.[182] The ultimate outcome of grade 1 is 92% successful, that of grade 2 is 85% successful, that of grade 3 is 70% successful, and that of grade 4 is 36% successful.[183]

Subglottic Hemangioma

Incidence and Etiology Congenital subglottic hemangiomas are relatively rare lesions and develop primarily in the submucosa. Fifty percent are associated with cutaneous hemangiomas. No correlation exists between the size of the cutaneous lesion and the size of the laryngeal lesion.[184] A 2 to 1 female preponderance is recognized.

Signs and Symptoms The subglottic hemangioma develops in a typical growth pattern with increasing size, usually causing symptoms in the first 8 weeks of life. Almost all of these lesions will become manifest before 6 months of age. Some lesions extend into the perichondrium and tracheal rings and beyond the trachea. Variable and fluctuant respiratory distress usually progresses to persistent distress. The stridor is more prominent on inspiration but is present during expiration. The voice is altered to a varying degree, depending on the involvement of the larynx. Altered cry, hoarseness, barking cough, and failure to thrive are the other frequently noted manifestations. Recurrent croup is the most frequent erroneous diagnosis.

Diagnosis Lateral radiographic studies suggest a subglottic abnormality consistent with hemangioma. This is not diagnostic, however, and the diagnosis can only be made endoscopically (Figure 45–24). The appearance of these lesions is characteristic and can be made by the experienced endoscopist without a biopsy. The lesion is sessile, fairly firm, but compressible; pink, red, or bluish; and poorly defined. The vessels are rarely, if ever, cavernous. If a biopsy is performed, the bleeding is usually not profuse, but the airway must be maintained, most frequently with a tracheostomy. The lesion is usually unilateral or asymmetric. Multiple hemangiomas of the airway have been reported.[185] A thorough workup of the possible extent of the hemangioma in the mediastinum is recommended.

Treatment If the airway distress is significant at the time of diagnosis, immediate airway control will be necessary. Endoscopy may compromise the airway. If necessary, the airway may be secured with intubation or a tracheostomy. If the patient is intubated, tracheostomy is more likely to be required.

A wide range of treatments have been advocated. They include the following: tracheostomy with observation and awaiting spontaneous resolution; prolonged endotracheal intubation, with and without corticosteroid injection; injection of sclerosing agents; the use of systemic corticosteroids;

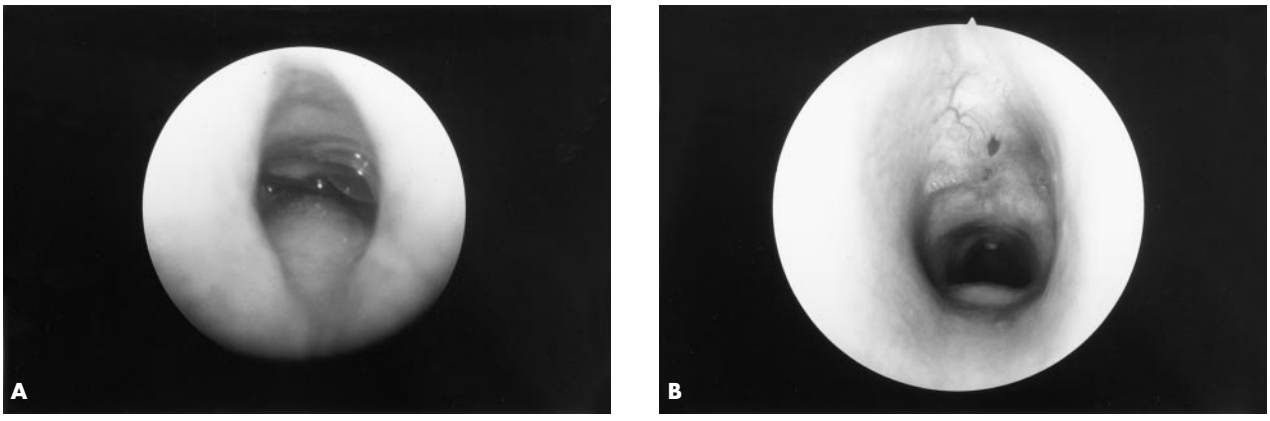

FIGURE 45–23. Preoperative (*A*) and postoperative (*B*) photographs after a laryngotracheoplasty with auricular cartilage.

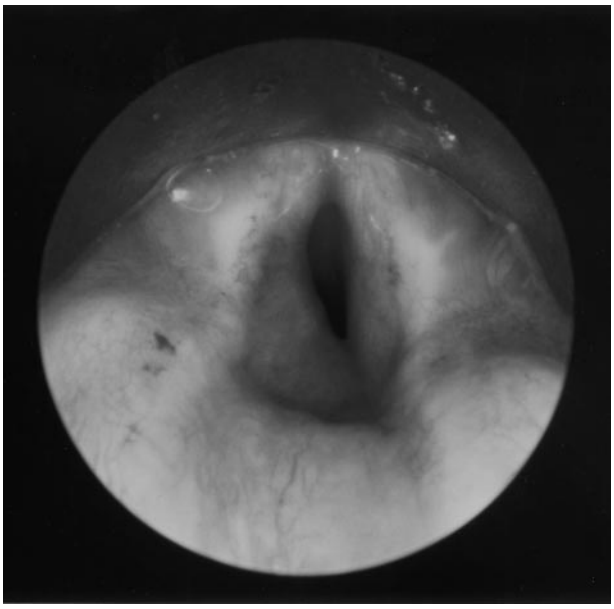

FIGURE 45–24. Subglottic hemangioma.

cryosurgery; external beam irradiation; gold seed irradiation; and laser excision. Prospective studies are not available. The judicious use of a laser to excise the lesion in stages, with the patient's airway protected by a tracheostomy when necessary, appears to be the treatment favored by most surgeons. External beam irradiation has been reported to have a cure rate of 93%, but the threat of radiation-induced malignant tumors of the thyroid gland strictly limits its use. Gold seeds are the treatment favored by Benjamin.[184] Unrecognized or mistreated subglottic hemangiomas have a high mortality rate.

CHAPTER 46

Congenital Anomalies of the Head and Neck

Lee D. Rowe, MD

Congenital head and neck anomalies represent a diverse group of clinical disorders. Frequently, these present as upper aerodigestive tract neoplasms and neck masses, with thyroglossal duct abnormalities most common, followed by branchial arch defects, lymphangiomas (cystic hygromas), and subcutaneous vascular anomalies (hemangiomas, arteriovenous malformations). Less common are teratomas, heterotopic neural tissue, and nasopharyngeal neoplasms. Additional disorders encountered include congenital disorders of the oral cavity including cleft lip and palate, Pierre Robin sequence (PRS), and other aberrations such as primary ciliary dyskinesia, Kartagener's syndrome, and craniofacial anomalies.

CONGENITAL DISORDERS OF THE NECK

Branchial Cleft Anomalies

Lateral cervical lesions, termed branchial cleft cysts, are congenital developmental defects that arise from the primitive branchial apparatus (branchial arch, cleft, and pouches). First branchial cleft anomalies are discussed elsewhere in this chapter.

Embryogenesis The branchial arches consist of five parallel mesodermal bars, each with its nerve supply and blood vessel (primitive aortic arches that develop during the third and fourth embryonic weeks). The branchial arches are separated externally by branchial clefts consisting of ectoderm and internally by endodermally lined branchial (pharyngeal) pouches. A branchial plate is located between each arch, separating pouch from cleft. The nerves are anterior to their respective arteries, except in the fifth arch, where the nerve is posterior to the artery. Caudal to all of the arches is the twelfth nerve, which arises from the epicardial ridge. The sternocleidomastoid muscle is derived from cervical somites posterior and inferior to the foregoing arches. In each arch, a central artery develops, connecting the two ventral and two dorsal aortas. The two ventral aortas fuse completely, whereas the two dorsal aortas only fuse caudally. With continued development, the ventral aortas become the external and common carotid arteries, whereas the arteries of the first and second arch degenerate. Segments of the dorsal aortas persist as the internal carotid arteries along with the artery of the third arch. The left fourth arch artery becomes the arch of the aorta, and the right fourth arch artery becomes the proximal portion of the subclavian artery. The primitive clefts pass between the corresponding arteries.[1] The most widely accepted theory of the genesis of branchial cleft anomalies is that fistulae, sinuses, and cysts result from incomplete closure of the connection between the cleft and the pouch, with rupture of the branchial plate. Recently, an induced first and second branchial arch syndrome in an animal model was shown to be secondary to disturbed migration of neural crest tissue during early embryogenesis.[2] Additionally, targeted mutations of two related basic helix-loop-helix transcription factors in the developing ventricles of the heart in mice have been associated with branchial arch hypoplasia, suggesting a molecular basis for branchial cleft anomalies.[3] These anomalies are generally lined with stratified squamous epithelium containing subepithelial lymphoid follicles, keratin, hair follicles, sweat glands, cartilage, and sebaceous glands.

Clinical Presentation Typically, branchial clefts present as smooth, round, fluctuant, nontender masses along the anterior border of the sternocleidomastoid muscle, anywhere from the external auditory canal to the clavicle. During upper respiratory tract infections, a painful increase in size is common and occasionally may be associated with external drainage through an unrecognized fistula. Small

cysts may not be recognized until the second decade in life. Male and female incidences are equal, and nearly all of these lesions are recognized by the time the patient reaches 30 years of age.

Second Branchial Cleft Anomalies Second branchial cleft lesions are the most common anomalies and are encountered most frequently in the anterior triangle of the neck along the anterior border of the sternocleidomastoid muscle inferior to the angle of the mandible. The fistula tract, if present, ascends along the carotid sheath, crosses over the hypoglossal and glossopharyngeal nerves, and courses between the internal and external carotid arteries. It ends in the tonsillar fossa, a second branchial pouch derivative.

Second pouch remnants may form blind sinuses in the pharyngeal tonsil and frequently cause recurrent unilateral tonsillitis. Treatment requires tonsillectomy and excision of the sinus tract.

Third Branchial Cleft Anomalies Third branchial cleft anomalies are unusual and constitute less than 1% of all branchial cleft anomalies.[4] The external ostium occurs at the same position as the second branchial cleft anomaly, and the cyst may be located anywhere along the fistula. The fistula tract ascends along the carotid sheath behind the internal carotid artery and over the hypoglossal nerve, and it enters the piriform sinus, piercing the middle constrictor muscle below the glossopharyngeal nerve. Clinically, the anomaly may mimic suppurative thyroiditis or symptoms of an external laryngocele and can cause recurrent infection, discharge, and, rarely, stridor.

Fourth Branchial Cleft Anomalies Fourth branchial cleft anomalies are extremely rare. Only 40 cases have been reported. The fistula tract descends along the carotid sheath, enters the chest, passing under either the aortic arch on the left or the subclavian artery on the right, and ascends in the neck to open at the apex of the piriform sinus. The sinus tract or cyst may become clinically manifested by recurrent episodes of neck abscess or acute suppurative thyroiditis (particularly in infants). A left predominance has been reported in one series.[5]

Treatment Complete surgical excision is the treatment of choice for branchial cleft anomalies and is indicated for recurrent infection, cosmetic deformity, and potential for malignant degeneration. Preoperative assessment with computed tomographic (CT) scanning or magnetic resonance imaging (MRI) is essential and may be combined with a fistulogram or pharyngoesophagram when indicated. A "stepladder" surgical approach is used to avoid long, cosmetically deforming incisions, paralleling the sternocleidomastoid muscle. To avoid recurrence, combined endoscopic examination for a pharyngeal pouch and sinus tract with meticulous dissection of a sinus tract, if present, will facilitate complete resection.

Branchiogenic Carcinoma The hypothesis that squamous cell carcinoma arises in a branchial cleft cyst (branchiogenic carcinoma) is controversial. Cystic squamous cell carcinoma presenting in the neck without an apparent primary is almost universally secondary to metastasis from a neoplasm arising in the faucial or lingual tonsillar crypt epithelium or nasopharyngeal tissue.[6] Malignant transformation in a branchial cleft cyst is therefore a rarity. Management is wide excision of the tumor and ipsilateral radical neck dissection followed by radiation therapy.[7]

Lymphangiomas, Hemangiomas, and Vascular Malformations

Congenital lymphangiomatous malformations of the head and neck represent a wide clinical spectrum. Lymphangiomas result from abnormal development of the lymphatic system at sites of lymphatic-venous connection, with obstruction of lymph drainage from the affected area causing multicystic endothelium-lined spaces. The neck is the most common site (25% of all cases). Over half of these lesions are present at birth, with 90% becoming apparent by 2 years of age. Those lymphangiomas arising above the mylohyoid tend to extend from skin to mucosa and are more infiltrative, whereas those below are more discreet and cystic.

Cystic Hygroma Cystic hygromas are large lymphangiomas most commonly found in the posterior triangle of the neck and axilla in children.[8] Cervical cystic hygromas commonly appear before 30 weeks gestation and are usually associated with karyotypic abnormalities, various malformation syndromes, and several teratogenic agents.[9] The prognosis is poor for these types of hygromas. By contrast, cys-

tic hygroma developing late in pregnancy has a more favorable outcome and is more likely to be encountered by the head and neck surgeon. Cystic hygromas are soft, painless, and compressible masses that may increase when the patient cries. Two-thirds are asymptomatic. After an upper respiratory tract infection, however, sudden enlargement with inflammation, infection, dysphagia, and stridor may develop. This is more commonly seen if the anterior triangle of the neck is involved or in patients with pharyngolaryngeal extension or intraoral involvement.

Vascular Lesions Other congenital vascular lesions of the head and neck include hemangiomas and arteriovenous malformations or lymphovenous lesions. Diagnostic imaging of these anomalies is based on the need for surgical treatment. Only those lesions that cause functional impairment or developmental disturbance are surgically addressed. Angiography, combined with MRI, allows separation into low-flow lesions (hemangiomas, venous, and lymphatic malformations) and high-flow lesions (arteriovenous malformations and invasive, combined lymphovascular malformations).

Treatment Treatment of small cystic hygromas that have not regressed but have enlarged is by surgical excision with staged debulking of larger cystic hygromas. Neural structures such as the facial nerve, vagus nerve, and phrenic nerves should not be sacrificed. Recurrence is uncommon when gross neoplasm is removed. Hemangiomas are frequently multiple with the parotid gland, a common site of occurrence. They grow rapidly for 1 to 2 years and then stabilize, and often regress spontaneously. Their growth may be slowed or inhibited with corticosteroids or interferon. Surgical excision is reserved for severe cosmetic deformity or life-threatening aerodigestive tract impairment.

For low-flow lesions, sclerosant therapy is effective, either alone in small lesions or combined with surgical resection or embolization. Preoperative embolization at the time of selective angiography and surgical excision are the treatment of choice in high-flow malformations.

Aberrant Thyroid Tissue

Ectopic thyroid tissue can occur anywhere from the foramen cecum to the lower neck (Figure 46–1). Most frequently, it occurs as a thyroglossal duct cyst associated with a normal thyroid gland. Less common is total ectopia, appearing as a lingual thyroid. True lateral neck thyroid ectopia lateral to the carotid artery and jugular vein cannot be confirmed based on embryogenesis.[10] Therefore, laterally situated thyroid tissue should direct attention to the ipsilateral thyroid lobe. If papillary carcinoma is found in an aberrant position, then either ipsilateral thyroid lobectomy with isthmusectomy or total thyroidectomy is performed.

Embryology In the 4-week-old embryo, the primitive thyroid gland begins as a ventral diverticulum of endodermal origin, arising in the floor of the pharynx between the tuberculum impar and the copula. Ultimately, the site of origin of the diverticulum becomes the foramen cecum, and the copula becomes the posterior third of the tongue. The thyroid descends caudally through or adjacent to the primitive hyoid bone. The developing thyroglossal duct reaches its final position in the midline of the

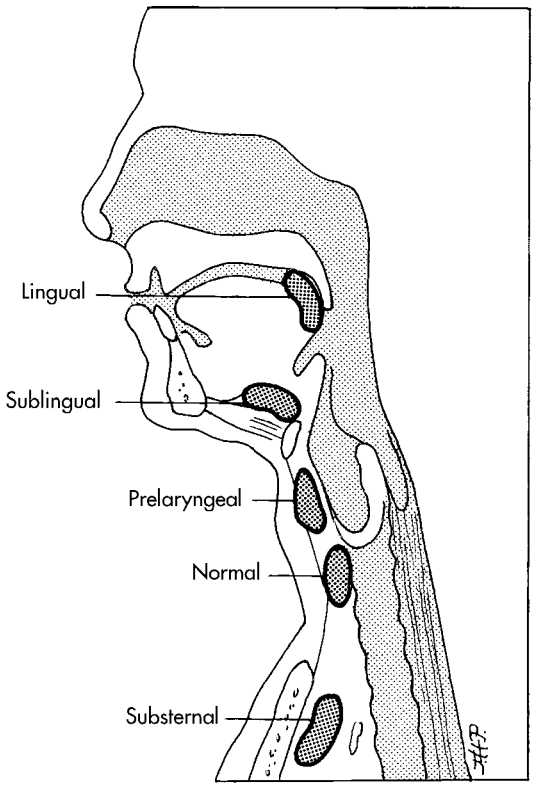

FIGURE 46–1. Most common locations of midline aberrant thyroid tissue schematically illustrated.

neck and develops into the median lobe of the thyroid. The duct normally persists as a hollow stalk for 6 weeks and then atrophies. Thyroglossal duct anomalies result from a failure of complete obliteration of the thyroglossal duct and are located anywhere along the descent of the gland.

Lingual Thyroid Lingual thyroid presents in the midline as a sessile, nontender reddish mass in the base of the tongue, anterior to the valleculae. It is the most frequent benign mass encountered in the oropharynx and, unlike other aberrant thyroid anomalies, has a 7 to 1 female preponderance. Symptoms may include dysphagia, cough, dysphonia, dyspnea, and hemorrhage. Lingual thyroid may become apparent during pregnancy because of increased thyroid function, and approximately 70% of these women have hypothyroidism.

Lingual thyroid is covered with stratified squamous epithelium and often exhibits an abundant aberrant vascular supply. The mass consists of normal or immature thyroid tissue, which may be either functional or dysfunctional. Indications for surgical removal include uncontrollable hyperthyroidism, hemorrhage, symptomatic enlargement, or a question of malignancy. Carcinoma arising in a lingual thyroid is rare, with only 26 cases reported.[11] Preoperatively, a thyroid uptake study and scan should be obtained to determine whether functioning thyroid tissue exists in its normal cervical location. Magnetic resonance imaging may also be of value because it allows multiplanar imaging and provides the best soft tissue definition. Excision is performed through the transhyoid route.

Thyroglossal Duct Anomalies *Signs and Symptons* A thyroglossal duct cyst is the most common congenital neck mass and the second most common of all childhood cervical neck masses. Cysts, sinuses, and fistulae of the thyroglossal duct manifest as anterior midline neck masses from the foramen cecum to the thyroid gland, typically before 20 years of age (most before 10 years). Thyroglossal ducts and fistulae are often asymptomatic. They may also become recurrently infected during upper respiratory tract infections, which can cause cyst enlargement, abscess development, and rupture with external sinus formation. Thyroglossal duct cysts are most commonly found below the hyoid bone and above the thyroid gland, displaying movement with anterior tongue protrusion and swallowing. Usually, the cysts are 1 to 3 cm in diameter and are smooth, round, and fluctuant.

A precise pathogenesis of thyroglossal duct cysts has not been determined. However, a hereditary etiology is suspected. Overall, for non-Americans, a predominantly autosomal dominant pattern of inheritance has been reported in older patients (mean age 13.9 years) versus an autosomal recessive pattern in younger patients (mean age 6.2 years).[12] In the United States, on the other hand, a female preponderance is observed with autosomal dominance and a younger mean age, which may be accounted for by genetic imprinting that is felt to be secondary to variations in DNA methylation.

Histopathologic Features. Thyroglossal duct cysts and fistulae are lined with squamous, ciliated columnar, or transitional cell epithelium. They may be surrounded by fibrous tissue with infiltrating inflammatory cells lacking organized lymphoid tissue. Islands of ectopic thyroid tissue and mucous glands are not uncommonly identified. The cyst or sinus tract is filled with mucoid or mucopurulent material.

Differential Diagnosis. The differential diagnosis includes dermoid cyst, pyramidal lobe hyperplasia or cyst, teratoma, hamartoma, lipoma, sebaceous cyst, cavernous hemangioma, hypertrophic lymph node, and malignant primary or metastatic neoplasm.

Treatment. As with lingual thyroid, a preoperative thyroid scan and uptake study are mandatory, even though concomitant agenesis of the thyroid gland is extremely rare. Malignant degeneration, recurrent infections, undesirable cosmetic appearance, and, rarely, intermittent upper airway obstruction are indications for surgical excision of thyroglossal duct cysts and fistulae. Incision and drainage may be necessary in the interim if an abscess has developed. Because of the high recurrence rate after excision, the Sistrunk procedure is recommended to prevent recurrence.[13] This involves a transverse incision over the cyst or a fusiform incision around an external fistula. All abnormal tissue, including the cyst, fistula, body of the hyoid bone (preferably more than 15 mm), and the fibrous cord extending to the foramen cecum, should be resected. Recurrence devel-

ops in up to 20% of cases as a result of failure to remove all abnormal tissue, including accessory ducts. Malignant degeneration of a thyroglossal duct cyst is rare (0.7%).[14]

Approximately 150 cases of thyroglossal duct carcinoma, predominantly of the papillary type, have been reported. Additional cases of Hürthle cell adenoma have also been described.[15] Most patients with papillary carcinoma are in their forties, although 20% are less than 20 years of age. Typically, the neoplasm is small and clinically unsuspected, and, in rare cases, it may be associated with regional or distant metastasis. Rarely, squamous cell carcinoma arising directly from the lining epithelium of a thyroglossal duct remnant has been reported and, as a rule, has a poor prognosis. Treatment consists of excision of the thyroglossal duct cyst, total or near-total thyroidectomy, ablative radioactive iodine therapy for residual metastatic thyroid neoplasm tissue, and careful interval follow-up with whole-body thyroid scanning.

THYMIC CYSTS

Cervical thymic cysts are extremely rare. Only 84 cases have been reported in the English language, with most occurring asymptomatically in children and adults. Only seven cases have involved patients younger than 1 year of age.[16] Cysts can arise from nests of thymic tissue anywhere along the descent of the thymic primordia from the angle of the mandible to the mediastinum and are primarily located anterior and deep to the middle one-third of the sternocleidomastoid muscle. In up to 50% of cervical thymic cysts, there is a mediastinal connection possibly requiring a sternotomy. Surgery is the definitive treatment (Figure 46–2).[16] Three additional cases of solid, ectopic, cervical thymus have been reported requiring complete excision.[17]

NEUROGENIC NEOPLASMS

Congenital neurogenic lesions involving the head and neck include all neoplasms or anomalies originating in the neural tissue or its covering. Two groups have been recognized: (1) heterotopic brain lesions with developmental defects and (2) neoplasms of neurogenic origin including neurinomas, neurofibromas, neuromas, ganglioneuromas, and meningiomas. Neurinomas originating from the connective tissue sheath of the nerve are termed schwannomas and may appear as multiple neurofibromas arising from cutaneous, visceral, and cranial nerves in neurofibromatosis (NF) 1 or 2. The incidence of head and neck manifestations in patients with NF (a genetic disease) varies between 14 and 37%. In NF1 (classic von Recklinghausen's disease), functional deficits include speech and voice abnormalities, airway obstruction, dysphagia, facial paresis, lip incompetence, and impaired mastication. Patients with NF2 (bilateral acoustic schwannomas) present with hearing loss.[18]

Typically, neuromas appear as solitary, encapsulated lesions with elongated, spindle-shaped cells with an oval or flattened nucleus. Ganglioneuromas, rarely seen in the head or neck, are characterized by ganglion and glial cells. Meningiomas are usually benign and arise from embryonic arachnoid rests. They may appear extracranially at the nasal root or in the sinuses. Whorl-like fibroblastic nuclei with hyaline formations producing a sand-like appearance may be present (psammoma body). Pharyngeal neuromas are rare and appear as a smooth, firm, rounded, and yellow mass. Symptoms depend on the size and location of the tumor. If multiple brown discolorations of the skin or café au lait spots are present, neurofibroma may be suggested. Treatment is surgical excision, and resection must be complete because recurrence is common.

CONGENITAL DISORDERS OF THE NOSE AND PARANASAL SINUSES

Heterotopic Neural Tissue

Heterotopic neural tissue or gliomas may manifest as isolated ectopic brain tissue with only a fibrous band connecting it to the endocranium. A glioma may be of the external or endonasal type. The external nasal glioma is typically found in the nasion as a red, relatively firm, mobile mass located subcutaneously that does not increase in size when the patient cries. The endonasal glioma is less common and arises from the middle turbinate or the lateral nasal vault, where it may be mistaken for a polyp. By contrast, a meningocele is a hernial protrusion of the meninges, and if it contains brain tissue, it is called an encephalocele.

An encephalocele is caused by a defect of the fetal skull and contains an ependyma-lined cavity

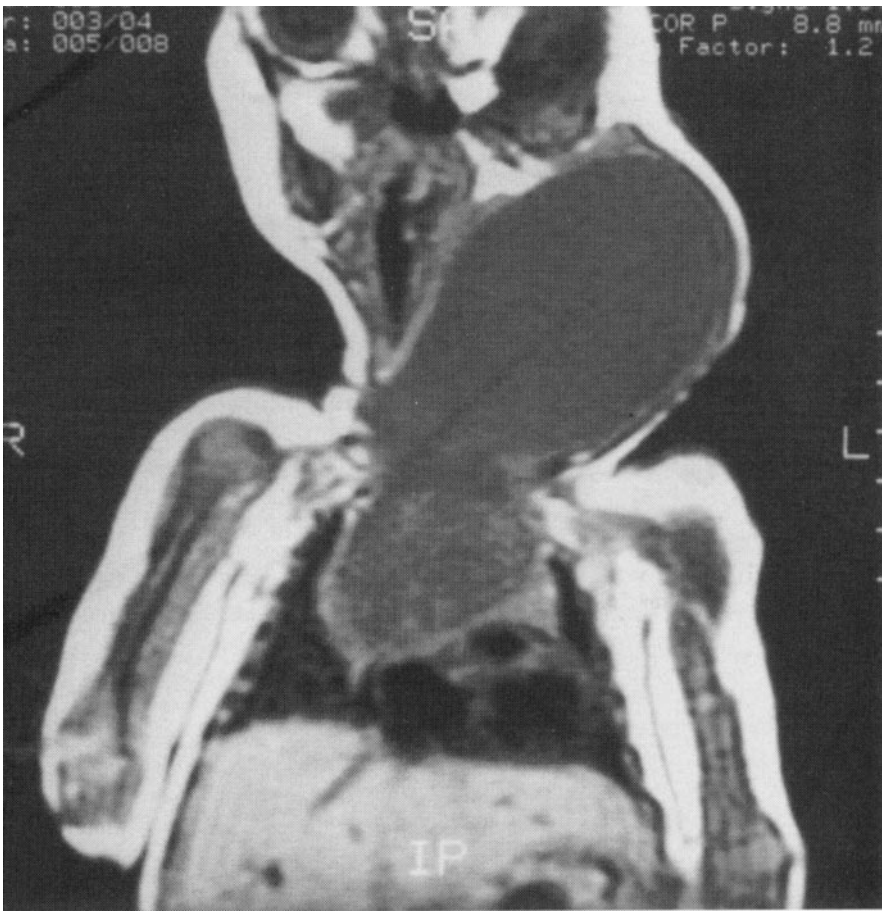

FIGURE 46–2. Coronal T_1-weighted magnetic resonance image of a neonate with a cervical thymic cyst with mediastinal involvement. Reproduced with permission from Nguyen Q et al.[16]

filled with cerebrospinal fluid. Two basic types of hernial protrusions are identified: the sincipital type and the basal type. The sincipital type is uncommon and is associated with termination of the meninges near the base of the nose. This type has three different forms: (1) nasofrontal, in which the encephalocele extends between the nasal and frontal bones, resulting in a midline swelling at the base of the nose; (2) nasoethmoidal, in which a defect among the nasal, frontal, and ethmoid bones allows the encephalocele to appear as a mass beneath the skin of the bony-cartilaginous junction; and (3) naso-orbital protrusion of the encephalocele through the suture lines among the lacrimal, frontal, and ethmoidal bones appearing as a conjunctival mass. The basal type, in which the hernia extends into the naso-orbital and pharyngeal region, is rarer than the sincipital. Three varieties have been identified: (1) sphenoid-pharyngeal, in which the encephalocele extends through the ethmoid or sphenoid bones or their sutures lines into the nasal or nasopharyngeal cavity; (2) sphenoid-orbital, in which the encephalocele extends through the spheno-orbital fissure into the posterior aspect of the orbit, resulting in pulsatile exophthalmos; and (3) sphenomaxillary, in which the encephalocele herniates through the spheno-orbital fissure into the orbit, with extension inferiorly through the inferior orbital fissure into the pterygomaxillary fissure.[19] This results in a mass bulging into the cheek or into the oropharynx, medial to the ramus of the mandible. In all cases, unlike with gliomas, pulsations and an increase in the size of the mass can be observed when the patient coughs or strains. Computed tomography and MRI are necessary to determine the appropriate combined transfacial and intracranial approach for surgical resection.[20]

Dermoid Cysts

Dermoid cysts occasionally occur in the neck, usually in the midline. Overall, fewer than 10% of all dermoid cysts occur in the head and neck. One-

fourth are found in the floor of the mouth, with the remainder in the periorbital region. These lesions are seen primarily in children and adolescents during the second decade of life, but they also may occur in infants. Cyst walls consist of squamous cell epithelium containing epidermal appendages. Periorbital dermoids are thought to originate from displacement of epidermal elements during the intramembranous growth phase of the nasal bones in the embryo. Because of the variability in clinical presentation and contiguous structure involvement, segregation of periorbital lesions into three distinct subgroups is helpful: (1) brow region dermoid cysts, (2) orbital region dermoid cysts, and (3) nasoglabellar dermoid cysts. Midline nasoglabellar cysts may have associated sinus tracts or fistulae (10 to 45%), which, in rare cases, may have intracranial extensions. In those patients with intracranial extension, the sinus tract traverses either the cribriform plate or foramen cecum and is attached to the dura, falx cerebri, or other intracranial structures.[21]

The treatment of choice is surgical excision after CT and MRI to evaluate intracranial extension.[22] All abnormal tissue must be removed to prevent recurrences. In patients with intracranial extension, a bicoronal flap is employed to facilitate removal and to prevent postoperative meningitis and abscess formation.

Other congenital midface cysts are those associated with the facial clefts, including the nasoethmoidal cleft cyst, nasolabial cyst, subalar cleft cyst, globulomaxillary cyst, cysts connected with cleft lip or palate, premaxillary cyst, nasopalatine cyst, foraminal incisor cyst, and Jacobson's organ cysts.

Choanal Atresia

Bilateral atresia of the choanae is the most frequently encountered congenital nasal anomaly (1 in 7,000 to 8,000 live births) and is a common cause of neonatal respiratory distress. Fifty to 60% of cases are unilateral. A recent analysis of 47 CT scans or histopathologic sections demonstrated 29% pure bony, 71% mixed bony and membranous, and no pure membranous atresia.[23] A female predisposition is seen in choanal atresia, and recent evidence points to an autosomal recessive mode of inheritance.

Failure of breakdown of the buccopharyngeal membrane on gestational day 45 is considered to be the cause of choanal atresia. Other theories include abnormalities in the migration of the cephalic neural crest following neural tube closure. Several craniofacial abnormalities, including skull base defects and systemic malformations, have been described in association with choanal atresia, including the CHARGE association (Table 46–1). The CHARGE association is a nonrandom pattern of congenital anomalies that has an estimated prevalence of 1 in 10,000 births. It occurs with choanal atresia (C = coloboma; H = congenital heart disease; A = atresia choanae; R = retarded growth and development; G = genital anomalies in males; E = ear abnormalities and deafness). Almost all patients have malformed pinnae and exhibit hypoplastic incudes, cochlear anomalies, and absent semicircular canals on CT scan (Figure 46–3). The majority demonstrate severe conductive or mixed hearing loss and vestibular dysfunction.[24] In addition, almost half exhibit facial nerve palsies. Laryngotracheal anomalies occur in one-third of cases. The combination of malformations in the CHARGE association suggests that this syndrome is a polytopic developmental field defect involving the neural tube and neural crest cells.[25]

Symptoms Respiratory distress at birth is the sine qua non of bilateral choanal atresia. In spite of vigorous attempts at respiration, effective air exchange does not occur until the neonate begins to cry, bypassing the nasal obstruction. Once the crying ceases, however, the neonate's mouth closes, and a pattern of cyclic obstruction gradually develops, resulting in increasing respiratory failure. Because neonates are obligatory nasal breathers, placement of an oral airway or McGovern nipple is lifesaving. By contrast, children with unilateral choanal atresia

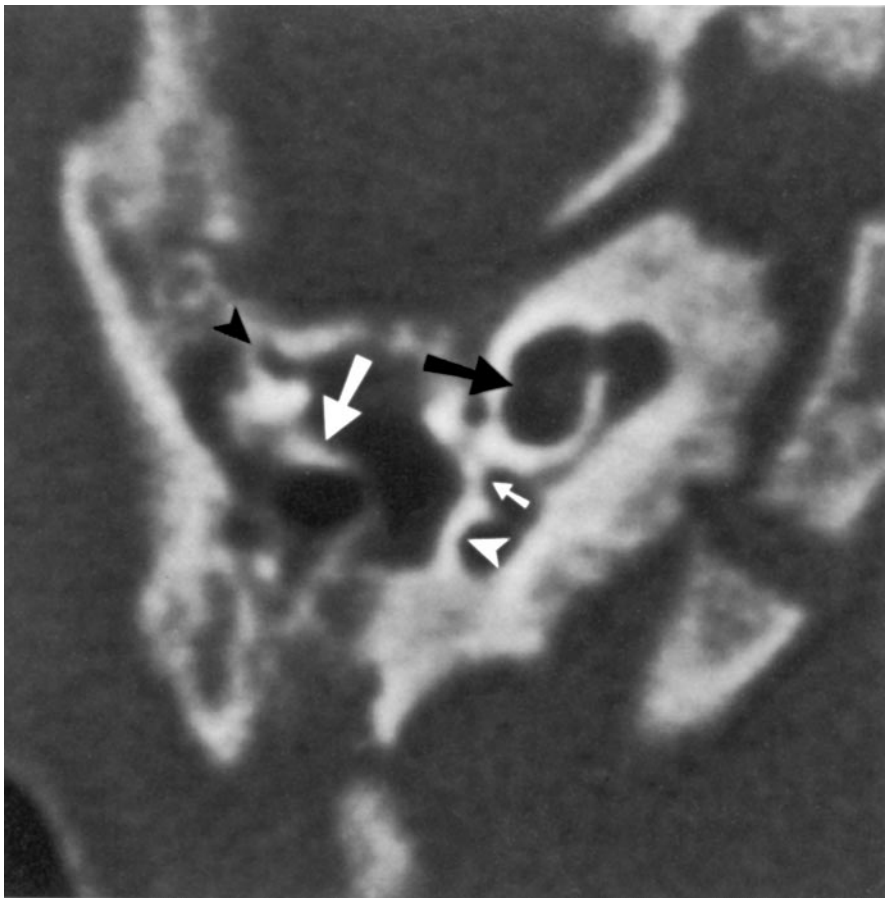

FIGURE 46–3. Axial 1 mm thick computed tomographic section through right mesotympanum in patient with CHARGE association. Note fixation of the malleus head to the anterior tympanic wall (*black arrowhead*), malformation and narrow rotation of the incus (*large white arrow*), and absence of stapes. Also note absence of the oval window (*small white arrow*) and presence of a round window niche with bony obliteration (*white arrowhead*). Tympanic sinus, pyramidal eminence, and stapedius muscle are absent. Interscalar septum between middle and apical turns of the cochlea is missing, as well as a normal cochlear modiolus (*black arrow*). Reproduced with permission from Dhooge I, Lemmerling M, Lagache M, et al. Otological manifestations of CHARGE association. Ann Otol Rhinol Laryngol 1998;107:935–41.

present later in life with unilateral rhinorrhea without respiratory distress.

Diagnosis The diagnosis of bilateral choanal atresia is confirmed by the inability to pass a No. 5 or 6 French feeding catheter at least 3 cm through the nose into the nasopharynx. In addition, direct observation with nasofiber-optic endoscopy and CT scan are essential to determine the type of obstruction. Specifically, the CT scan demonstrates the thickness of the atretic plate as well as its encroachment of the posterior aspect of the medial part of the maxilla.[26]

Treatment Multiple methods are available to repair choanal atresia. The appropriate method is determined by the age of the patient and whether the atresia is bilateral or unilateral. In all methods, the challenge is to provide adequate mucosal lining to the new choana and to prevent granulation tissue formation and subsequent stenosis. Treatment requires perforation of the atresia plate followed by stenting for 6 weeks with preservation of mucosal flaps.

Transnasal Approach. The most direct and simplest route for choanal atresia repair is transnasal, using a No. 2 Lempert or similar curette inserted 3 to 3.5 cm beyond the nares along the nasal floor and exerting firm pressure against the bony atresia plate until it is perforated. The anterior nasal mucous membrane is sacrificed after satisfactory enlargement of the choana to permit placement of a 3.5 mm Silastic endotracheal tube as a stent. Posterior membranous flaps are developed in a stellate fashion to cover the denuded bone (Figures 46–4 and 46–5). Care must be taken to prevent injury to the roof of the choana and the skull base because reported complications of this approach have included meningitis, cerebrospinal fluid leaks, brain injuries, Gradenigo's syndrome, and cervical vertebral subluxation. Studies indicate that

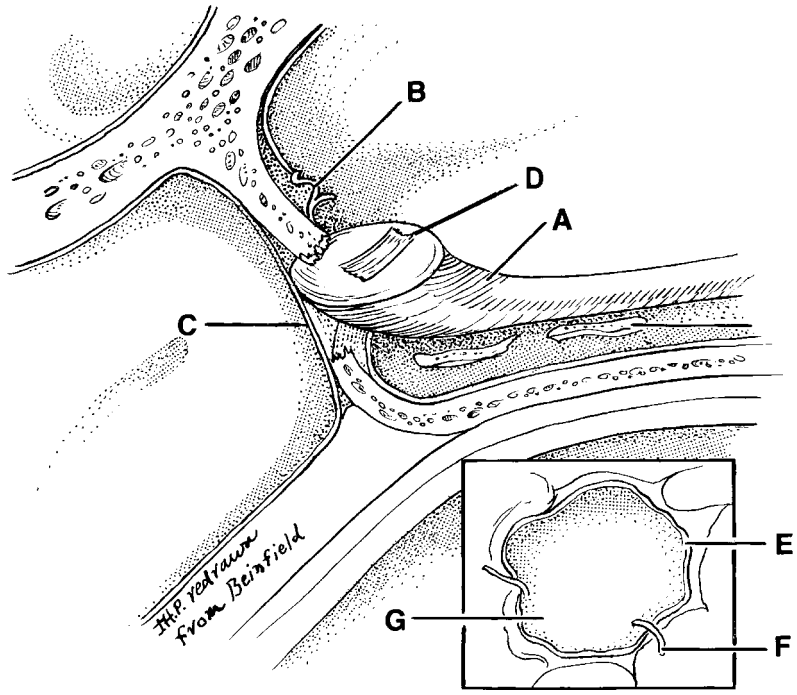

FIGURE 46–4. *A*, curette; *B*, shreds of nasal mucous membrane; *C*, intact nasopharyngeal mucous membrane; *D*, spicule of bone; *E*, bony atresia almost completely removed; *F*, shreds of mucous membrane; and *G*, intact pharyngeal mucous membrane.

transnasal curettage has a higher incidence of restenosis than newer techniques and requires additional revisions or dilatations. Other methods include the use of the carbon dioxide laser, endoscopic endonasal approach, and neodymium: yttrium-aluminum-garnet (Nd:YAG) laser technique. Currently, an endoscopic approach with a 2.5 or 4 mm telescope and powered instrumentation using attachable burs and blades with continuous suction is preferred, especially for neonates (Figure 46–6).[27] After effective removal and stenting and the use of topical corticosteroids to diminish granulation tissue formation, stenosis may still occur, and dilatation may be necessary. If this fails, a transpalatal approach will be required. A transseptal approach, which is reserved for older children with unilateral atresia, offers better exposure of the posterior part of the vomer without risk of palatal injury and impairment of growth. This approach can be modified either via sublabial extension or by an external rhinoplasty approach to improve visualization.

Transpalatal Approach. The transpalatal approach provides superior visualization of membranous or bony atresia and may be useful for both bilateral and unilateral atresia. Although impaired palatal growth is a potential problem in the neonate, the procedure can be safely used in patients older than 5 years who are treatment failures if one takes great care to avoid injury to the posterior palatine canals.

The procedure is carried out with the patient in the supine position and the neck extended. After infiltration of local anesthesia, a horseshoe-type incision is developed several millimeters posterior to the alveolar ridge, and a mucoperiosteal flap is then raised based on the greater palatine vessels. Once the posterior edge of the hard palate is reached, the mucosa is divided, providing access to the atretic plate. An attempt is made to maintain mucosal flaps on both sides of the atretic plate. The atretic plate, posterior part of the vomer, and medial aspect of the posterior part of the maxilla are removed with a diamond bur, otologic curette, or rongeur (Figure 46–7). After removal of bone, mucosal flaps are transposed to cover the superior and inner surfaces of the choana, with stents placed as previously described. The palatal flap is reapproximated anteriorly with absorbable sutures. If stenosis occurs after surgical repair, patients generally slowly develop progressive respiratory difficulties. Revision surgery and/or dilatation may be necessary.

CONGENITAL DISORDERS OF THE NASOPHARYNX AND OROPHARYNX

THORNWALDT'S CYST AND RATHKE'S POUCH CYST

If the pharyngeal segments of the primitive notochord remain connected to the endoderm in the nasopharynx, a bursa or embryonic pouch occurs. In approximately 3% of individuals, this invaginated connection persists, and the resulting sac and canal, located in the posterior midline of the nasopharynx, extends posteriorly and cephalad toward the occipital bone. If the bursa is occluded by inflammation, a cyst known as Thornwaldt's cyst will develop, and if the cyst becomes infected, an abscess will result. Anterior to the invagination and above the bursa is a small pharyngeal hypophysis developed from Rathke's pouch, which sometimes persists as the craniopharyngeal canal running from the sella turcica through the body of the sphenoid.

Most Thornwaldt's cysts appear clinically in the second and third decades of life, with males and females affected equally. Symptoms include intermittent or persistent postnasal discharge of tenacious mucus or purulent material, associated with odynophagia, halitosis, unpleasant taste, and, occasionally, a dull occipital headache exacerbated by head movement with associated stiffness of the posterior cervical muscles. Nasopharyngoscopy reveals a smooth, submucosal, 1 to 2 cm midline cystic mass, superior to the adenoidal pad. Frequently, a central dimple or fistula is identified. A CT scan demonstrates a soft tissue mass located high on the posterior nasopharyngeal wall with sharp borders. Magnetic resonance studies of the nasopharynx reveal high signal intensity on T_1-weighted, T_2-weighted, and fluid-attenuated inversion recovery images.[28] Microscopically, Thornwaldt's cyst is lined by respiratory epithelium with minimal amounts of lymphoid tissue in the wall. Treatment requires either excision to the periosteum or wide marsupialization.

Rathke's pouch cysts, on the other hand, are basically cysts lined by columnar or cuboidal, ciliated epithelium that may become secondarily infected or rupture intracranially and are most commonly associated with headache followed by galactorrhea, visual field loss, and hypopituitarism. Treatment is transsphenoidal drainage of the cyst with biopsy of the wall. If no demarcation between normal and involved tissue is evident at surgery, the cyst and residual pituitary are radically removed.[29] Radiation therapy is not indicated.

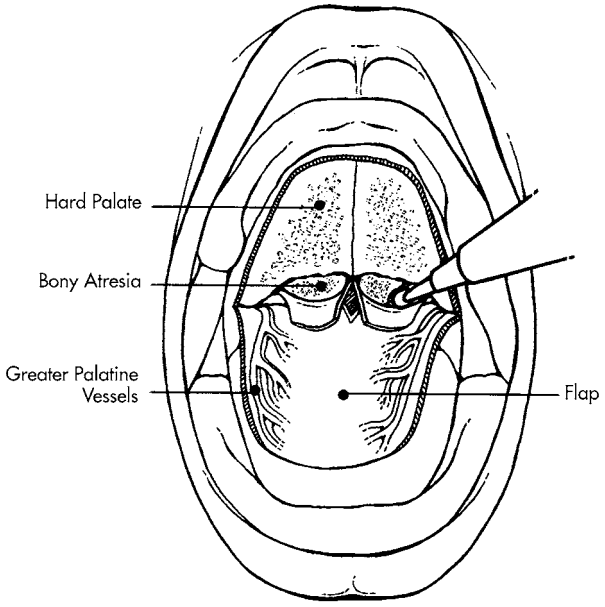

FIGURE 46–7. A transpalatal approach using a drill to remove the bony atretic plate; mucosa over the atretic plate has been preserved for reconstruction of the neochoana. Reproduced with permission from Park AH et al.[27]

Chordomas

Chordomas are rare malignant neoplasms arising from primitive notochordal remnants, primarily in the fifth or sixth decade of life. Fifty percent occur in the spheno-occipital area, with a mean patient age of 40 to 45 years. Males and females are approximately equally affected. Presenting signs and symptoms include an expanding nasopharyngeal mass, frontal headaches, cranial nerve palsies (sixth nerve involvement is seen in 60% of patients followed equally by ninth and tenth nerve involvement), and pituitary abnormalities.

Children under 5 years of age have a wider range of presenting symptoms, a greater prevalence of atypical histologic findings with aggressive behavior, and a higher incidence of metastasis to lung and lymph nodes. These tumors show no chondroid component compared to a 17.1% incidence in older patients.[30] Magnetic resonance imaging with gadolinium is essential to evaluate the extent of the tumor, and it may be helpful in distinguishing classic chordoma from the chondroid variant. Computed tomographic scanning frequently reveals extensive bone destruction at the skull base and is used to plan surgical resectability. Treatment is surgical resection via a skull base approach combined with postoperative radiation therapy or proton-photon therapy.[31] The prognosis in patients with chordomas is unfavorable, with median 5-year survival rates at 50% for patients with surgical resection only. The survival rates for combined surgery and radiation therapy are statistically significantly longer than for surgical treatment alone. The overall prognosis is directly related to the histologic pattern of the tumor: atypical chordomas carry a poor prognosis. There appears to be no significant difference for prognosis in patients older than 5 years of age with a classic or chondroid tumor.[30] For metastatic chordoma, multiagent systemic chemotherapy (ifosfamide and doxorubicin) has been efficacious, whereas systemic chemotherapy with intrathecal or intraventricular hydrocortisone, cytarabine, and methotrexate has been effective in controlling central nervous system involvement with chordoma.[32]

Craniopharyngiomas

Craniopharyngiomas arise from Rathke's pouch and are located in the sellar, parasellar, and third ventricular regions. They are composed of well-differentiated epithelial elements including cysts and ameloblasts as well as bone. Rarely, this lesion is first seen in the nasopharynx but most commonly occurs intracranially above the sella turcica. It accounts for approximately 10 to 15% of all childhood and adolescent intracranial neoplasms. Clinical manifestations include visual field defects, sudden blindness, extraocular motor paralysis, and hypopituitarism. The median age at presentation in children is 7.5 years, with an approximately equal female-to-male ratio. Magnetic resonance imaging with gadolinium or gadodiamide injection is mandatory for pretreatment assessment. Management of craniopharyngiomas has been controversial. Currently, surgical resection followed by radiation therapy achieves long-term control with low morbidity for tumors smaller than 5 cm. Ten-year actuarial overall survival rates are 90%. Despite major microsurgical advances, however, total removal of these tumors is associated with a high risk of death, endocrinologic complications, and behavioral dysfunction. Craniopharyngiomas located within an enlarged sella that are not adherent to parasella structures are removed

through a transsphenoidal approach with a lower incidence of recurrence.[33] Primary linear accelerated stereotactic radiation therapy has also proven valuable in the initial management of this tumor. A long-term (greater than 5 years) follow-up is essential to assess tumor control.[34,35]

Teratomas

Teratomas are true neoplasms that contain tissues foreign to the site in which they arise. The haphazard arrangement of tissue with asynchronous maturation is believed to be attributable to escape from the controlling influence of the primitive streak notochord or adjacent structures. Teratomas grow aggressively, and in the head and neck, they most commonly occur in the cervical area, followed by the nasopharynx. Nasopharyngeal teratomas occur with a female-to-male ratio of 6 to 1. Overall, teratomas of the head and neck comprise approximately 2 to 9% of all teratomas.

Teratomas of the nasopharynx typically arise on the lateral or superior wall. Four basic types are recognized: (1) dermoid cyst, the most common form, composed of ectoderm and mesoderm arising as an epithelium-lined cavity with variable numbers of skin appendages; (2) teratoid cyst, derived from all three germ layers but poorly differentiated; (3) true teratoma, composed of ectoderm, mesoderm, and endoderm, with specific tissue and organ differentiation; and (4) epignathus, in which well-developed fetal parts are recognizable; this type of teratoma arises from the soft or hard palate and is frequently incompatible with life.

Clinically, dermoids are more common than true teratomas, and in the nasopharynx, the dermoid cyst is the most common developmental anomaly found. Known as "hairy polyps," these lesions appear at birth as a pedunculated mass filling the nasopharynx, often with oropharyngeal extension. Patients with teratomas have nasal obstruction, dysphagia, and copious secretions. Infants with nasopharyngeal teratomas have a higher incidence of preterm birth, neonatal airway distress, and associated congenital anomalies along with polyhydramnios than do infants with dermoids.[36] Computed tomography and MRI are critical to define the extent of the neoplasm and to exclude either a nasoencephalomeningocele or intracranial extension of a sphenoid-based teratoma through the craniopharyngeal canal. Most cervical teratomas occurring in the neonate are benign. The tumor can surround or encroach on the airway, thereby causing progressive dysphagia and airway obstruction.

Surgical removal must be carefully planned to ensure a controlled airway throughout the intraoperative and postoperative periods. Tracheostomy is generally not necessary if orotracheal intubation is combined with a transoral removal of pedunculated nasopharyngeal teratomas or with early excision of cervical teratomas. Operative and postoperative bleeding in patients with nasopharyngeal teratomas is usually only slight because these tumors are poorly vascularized, and if removal is complete, recurrences are rare. More sessile tumors arising in the nasopharynx require a transpalatal approach. Malignant metastasizing cervical teratoma is extremely rare.

CONGENITAL DISORDERS OF THE ORAL CAVITY AND LIP

Numerous congenital defects of the oral cavity and related structures may occur. Common major anomalies, such as cleft lip and palate, are described in detail, whereas less common deformities are mentioned for completeness.

Congenital lesions of the tongue include aglossia, microglossia, and macroglossia (secondary to lymphangioma or hemangiomas or as commonly found in Down syndrome). Ankyloglossia owing to varying degrees of underdevelopment of the lingual frenulum is not uncommon. Indications for frenuloplasty with Z-plasty are notching of the protruding tongue tip, inability to contact the maxillary alveolar ridge, and/or restriction of protrusion beyond the mandibular alveolar ridge. Other glossal anomalies include dermoid cysts, hamartomas, lingual thyroid, fissured (scrotal) tongue, median rhomboid "glossitis," and enteric duplication cysts.

Nonodontogenic cysts derived from epithelial remnants trapped in embryonic fusion lines during the developmental stage include midline maxillary cysts (median alveolar, nasal palatal, median palatal) and lateral maxillary cysts (globomaxillary, nasolabial). Treatment varies from simple incision and drainage to removal of the cysts from the palatal side, with or without adjacent teeth. Noncleft lip congenital anomalies encountered include microstomia, congenital pits, and "double lip."

Finally, congenital epulis or gingival granular cell tumor arises exclusively from the alveolar ridge and is a rare lesion of unknown origin found in newborn female infants.

Cleft Lip and Palate

Cleft lip and palate are the most common congenital malformations of the head and neck, occurring approximately once in every 700 births. The risk of additional siblings having a defect increases when an older sibling is affected. Both cleft lip with or without cleft palate and isolated cleft palate may be further classified into those classes associated with (syndromic) or without (nonsyndromic) another recognized malformation. The cause of syndromic clefting may be single-gene transmission, chromosomal aberrations, teratogenicity, or environmental factors. Recent evidence points to multigenic inheritance with allelic variation at different loci. However, some pedigrees are monogenic, with either autosomal dominance or recessive inheritance. Exposure to teratogens such as ethanol, retinoids, or folate antagonists during the first trimester is associated with an increased risk of syndromic cleft lip or cleft palate.[37] In addition, a dose-response relationship between maternal smoking and an increased risk of having a child with cleft lip or cleft palate has been demonstrated.[38] Associated head and neck anomalies such as maxillary or malar hypoplasia, abnormal pinnae or atresia, facial nerve paresis or paralysis, and mandibular dysmorphism or abnormal excursion may be identified. Nonsyndromic clefting is associated with no obvious first or second arch anomalies or systemic organ malformation. Multifactorial inheritance is the cause of these clefts, and calculated risk rates are essential to provide genetic counseling to families.

Anatomy The lips are a movable muscular sphincter composed primarily of orbicularis oris muscle with motor supply from the seventh cranial nerve. The lips are covered by skin on the outer surface and mucosa on the inner. The vermillion or lip edge forms a junction with the skin (white line) that creates a gentle arching in the upper lip or "Cupid's bow." The cephalic extension from the handle of the Cupid's bow encloses a small depressed area at the base of the columella called the philtrum. These anatomic landmarks, plus the protrusion of the vermillion below the Cupid's bow or tubercle, are used for orientation in cleft lip repair.

The palate is composed of a hard anterior portion and a soft muscular posterior portion. The anterior primary palate is formed by the alveolar ridge and four incisor teeth plus the triangular premaxilla. The remaining hard palate is formed by the palatine processes of the maxillary and palatine bones, which, with the soft palate, comprise the secondary palate. The soft palate is a muscular curtain formed by the tensor veli palatini muscle innervated by the fifth cranial nerve and the levator veli palatini muscle, musculae uvulae, and glossopalatine and palatopharyngeus muscles innervated by the pharyngeal plexus.

Embryogenesis Clefts of the lip, alveolar ridge, or palate are midfacial soft tissue and skeletal fusion abnormalities. In the normally developing fetus, the median nasal process fuses with the maxillary processes to form the upper lip, premaxilla, and corresponding segments of the alveolar process. Together, the premaxilla and the alveolar ridge form the primary palate. The palatal processes fuse with each other to form the secondary palate, along with the nasal septum and premaxilla in the vicinity of the incisive foramen between gestational weeks 8 and 10. Palatal growth proceeds posteriorly toward the uvula. Failure of ingrowth of mesodermal tissue at this point results in a lack of cohesion of the palatal segments, causing a cleft palate, which may be seen in conjunction with clefts of the lip and/or alveolar process or alone. Interruption in the migration of mesodermal tissue during the first 2 months of embryonic life results in cleft lip deformities. Ultimately, a lack of fusion of the median nasal processes with the maxillary processes causes a cleft of the upper lip, premaxilla, and alveolar process. The incidence of cleft palate increases in the presence of a cleft lip, which occurs in an earlier stage than cleft palate. Moreover, the tongue is positioned higher in the oral cavity in cleft lip, further interfering with palatal fusion and leading to greater palatal clefting.

Management The head and neck surgeon is part of a cleft palate or craniofacial team that includes pediatrics, ophthalmology, general plastic surgery, neurosurgery, audiology, speech and language pathology, orthodontics, prosthodontics, oral surgery, genetics, dentistry, cytology, psychiatry, social

work, and nursing. The goals of this team are to restore normal anatomy and physiology, with an emphasis on muscular reconstruction of the lip and/or palate to allow normal facial development and to minimize growth disturbance.

The initial priority for infants with clefts is to establish adequate feeding and nutrition. Infants with a unilateral or bilateral cleft lip and alveolar ridge feed generally well by either breast or bottle. Infants with bilateral cleft lip, alveolar ridge, and palate have significant feeding problems and require modified nipples, with feeding in the upright position to minimize nasal regurgitation.

Although the timing of surgical repair is controversial, most experts perform cleft lip repair at 3 months of life and cleft palate repair at 12 months to establish a competent velopharyngeal sphincter. Two schools of thought have evolved: one advocating early closure of the lip and palate, a procedure imparting a high priority to early speech development, and the other recommending delayed closure of the hard palate, thus according a high priority to maxillary growth.[39] Surgical treatment is dictated by the anatomic defect, and a classification scheme is helpful in planning surgical repair: (1) cleft lip, unilateral or bilateral; (2) cleft palate, either with unilateral or bilateral cleft lip; and (3) isolated cleft palate.

Unilateral Cleft Lip. In the basic complete defect, the floor of the nose communicates with the oral cavity, and the alveolar defect passes through the developing dentition. One sees significant nasal deformity, including columellar displacement, nasal dome deformity, and alar flattening and retrodisplacement. The goals of surgical repair are restoration of orbicularis muscle function, alar base, and columellar height and creation of symmetry of philtral columns, tip height, Cupid's bow, and vermillion. This can be accomplished with a Millard rotation advancement procedure in concert with either preoperative orthodontic appliances or lip adhesion.

Bilateral Cleft Lip. The floor of the nose is absent bilaterally, and the nasal and oral cavities communicate freely. The central alveolar arch is displaced forward and superiorly, whereas the nasal tip is widened and the columella is short. The goals of bilateral cleft lip repair are the same as for unilateral defects. Bilateral lip adhesion, if indicated, is performed when the patient is 2 to 4 weeks old, with definitive lip repair followed at 4 to 6 months of age. If no lip adhesion is necessary to align the underlying maxillary segments before definitive lip repair, bilateral lip repair is performed at 3 months.

Cleft Palate. The basic defect, absence of the nasal floor, may be complete or incomplete, with or without associated cleft lip. The goals of cleft palate repair are to close the defect without inhibiting maxillary arch growth, to achieve adequate velopharyngeal function, and to normalize oronasal resonance and speech patterns.[40]

Although the exact timing of the repair is controversial, the procedure is performed when the patient is 10 to 18 months old and may require preoperative orthopedic devices to move the premaxilla posteriorly and to expand the lateral maxillary segments, facilitating surgical closure of the lip. Of the many techniques described for bilateral cleft palate repair, the two-flap palatoplasty by Bardach is commonly employed: (1) complete two-layer closure (oral and nasal sides) and (2) dissection, redirection, and suturing of the soft palatal musculature.

Secondary problems of cleft lip and palate that require subsequent treatment include correction of nasal airway impairment, cosmetic nasal defects, velopharyngeal insufficiency with associated hypernasality, and recurrent acute and chronic otitis media with effusion.

Pierre Robin Sequence. "Pierre Robin" is one of the most recognized diagnostic eponyms. It is a poorly understood, nonspecific grouping of malformations, however, which as yet have no prognostic significance. The classic PRS of glossoptosis, micrognathia, and cleft palate (all three findings in 50% of cases) may occur as an isolated, nonsyndromic congenital disorder or as part of a larger anomaly that may include facial dysmorphism, cardiac defects, mental retardation, and/or musculoskeletal anomalies.[41] Möbius' syndrome or nonprogressive congenital facial diplegia is such an example of PRS, with concomitant brachial and thoracic muscle aplasia along with cranial neuropathies (six and seven). Pierre Robin sequence has no sex predilection, and it may be secondary to an intrauterine insult during the fourth month of gestation or owing to hereditary causes. Syndromic PRS is often associated with ocular anomalies (detached

retina or glaucoma) or aural abnormalities (chronic otitis media and low-set pinna). Heredity appears to be a factor in isolated nonsyndromic PRS, and usually a complete U-shaped cleft palate is the primary determinator of the associated triad.[42]

Infants with PRS are at increased risk of airway obstruction and resulting hypoxemia, cor pulmonale, failure to thrive, and cerebral anoxia. Obstructive sleep apnea and snoring are common. Aspiration is a primary cause of death. Aerophagia associated with vomiting frequently results in aspiration. When compared with normal infants, infants with PRS exhibit a shorter tongue and mandibular length, with a narrow airway and a posteroinferior position of the hyoid bone resulting in airway compromise. Patients are initially given a trial of prone positional management with high-calorie gavage feeding. When continued respiratory distress and failure to thrive develop, a modified glossopexy, attaching the tongue at the mandibular alveolar ridge and the lower lip, is performed. The genioglossus is also released to lengthen the tongue. Bedside polysomnography may help to identify those infants without clinically severe airway obstruction who may benefit from a modified tongue lip adhesion. Tracheostomy is reserved for those patients following tongue lip adhesion who have continued failure to thrive and respiratory embarrassment. Patients with syndromic PRS have a higher rate of tracheostomy and gastrostomy tube placement and exhibit significantly lower Apgar scores and longer hospital stays.[43]

CONGENITAL DISORDERS OF THE SALIVARY GLANDS

Congenital anomalies of the salivary glands are uncommon. Rarely, the parotid gland may be absent in the first and second branchial arch syndromes. Congenital sialoadenitis with cystic dilatation of the salivary ducts can occur, resulting in single or multiple cystic spaces. Sialography in the infant under sedation may help to demonstrate ductal ectasia. If obstruction and stasis develop, recurrent infections may result, necessitating parotidectomy with seventh nerve preservation. Heterotopic salivary gland tissue may also appear in or adjacent to the salivary glands, developing from a defect in the growth of the ductal system or in relation to first branchial cleft anomalies. Usually, these congenital lesions present as a discharging sinus in the base of the neck.[44]

FIRST BRANCHIAL CLEFT ANOMALIES

First branchial cleft anomalies have been classified into two groups, types 1 and 2. Type 1 anomalies are first cleft ectodermal defects or duplication anomalies of the membranous external auditory canal. Type 1 cysts are found anterior and inferior to the pinnae in association with the parotid gland. The fistulous tract extends superiorly along the facial nerve and parallel to the external auditory canal, where it terminates. Type 2 branchial cysts are primarily first cleft and arch defects (ectodermal and mesoderm) with duplication of the external canal and pinnae. Type 2 cysts are found below the angle of the mandible along the sternocleidomastoid muscle. The fistulous tract, like in type 1 anomalies, is variable and may run lateral to, medial to, or between the main branches of the facial nerve, ultimately ending in the external auditory canal.

Clinically, first branchial cleft cysts are associated with repeated infection and may require incision and drainage of an apparent neck abscess, which is typically located above a horizontal plane passing through the hyoid bone. Occasionally, purulent otorrhea may occur in the absence of demonstrable middle ear disease. A third common clinical presentation is preauricular swelling in the parotid area. Microscopically, the cyst is lined with hair follicles, apocrine or sweat glands, and sebaceous glands. Treatment is surgical excision of the cyst, sinus tract, and skin surrounding the sinus tract orifice. Because of the intimate relationship between the seventh nerve and the sinus tract, it is critical to expose the seventh nerve as in a parotidectomy, using the bony landmarks (styloid process, mastoid tip, and tympanomastoid suture line) to help identify the nerve, instead of the tragal pointer.[45] A nerve integrity monitoring system may prove exceedingly beneficial in these difficult cases.

Hemangiomas and lymphangiomas are congenital lesions that may involve the salivary glands and are discussed earlier in this chapter.

PRIMARY CILIARY DYSKINESIA (KARTAGENER'S SYNDROME)

Primary ciliary dyskinesia syndrome is an inherited disorder characterized by recurrent upper and lower respiratory tract infections secondary to abnormal ciliary structure and function. Also termed immotile

cilia syndrome, its most recognizable form is in Kartagener's syndrome (bronchiectasis, chronic sinusitis, situs inversus, and sterility). It has also been recognized in Usher's syndrome type I, congenital heart disease, congenital esophageal dysfunction, and cutaneous abnormalities including folliculitis, nummular eczema, and pyoderma gangrenosum.

This disorder is characterized by defects in axonemal dynein complexes probably secondary to mutations in the genes encoding cytoplasmic heavy chains of the outer arms of the axonemes. Dyneins are large multisubunit adenosine triphosphatases that interact with microtubules in cilia to generate force. The resulting ultrastructural defect causes impaired mucociliary clearance throughout the pulmonary and sinonasal passages. Early recognition and treatment of individuals with these disorders could lead to reduction in irreversible sinus and pulmonary complications with improved survival.[46,47]

CHAPTER 47

Anatomy and Physiology of the Larynx

Clarence T. Sasaki, MD, Young-Ho Kim, MD, PhD

The human larynx is a complex organ that functions as a sphincter at the junction of the digestive tract and respiratory tract and participates in the diverse physiologic aspects of airway protection, respiration, and phonation. In his classic phylogenic observations, Negus allowed prioritization of the three functions of the larynx.[1] In order of their priority, these are (1) protection of the lower airway, (2) respiration, and (3) phonation. To perform these roles, the internal and external structures of the larynx interact under precise neural control, producing in humans the most complex of laryngeal functions. Thus, the anatomy of the larynx reflects the specialization required by these multiple roles and is best understood in relation to its diverse physiologic behaviors.

ANATOMY

Laryngeal Cartilages

Thyroid Cartilage The thyroid cartilage is a shield-shaped structure that serves to protect the internal anatomy of the larynx.[2–7] It is the largest cartilage of the larynx and is composed of two wings, the alae or laminae. The alae are fused in the midline and open posteriorly (Figure 47–1). In the male, the alae fuse at about 90 degrees, making a laryngeal prominence or Adam's apple. In the female, this prominence is absent owing to the more oblique fusion angle of 120 degrees. Superiorly, the fusion of the alae is deficient, accounting for the thyroid notch. Posteriorly, each ala has a superior and inferior horn or cornu. The inferior cornu articulates with a facet on the cricoid cartilage to form the cricothyroid joint. This is a synovial joint that allows rotation of the cricoid cartilage. This rotation varies the tension placed on the vocal folds. The superior cornu attaches to the greater cornu of the hyoid bone by way of the lateral thyrohyoid ligament. This ligament sometimes contains small triticeal cartilages. The two lateral thyrohyoid ligaments, along with the median thyrohyoid ligament, are condensations of the thyrohyoid membrane; these structures attach the hyoid bone to the thyroid cartilage. At the attachment of the superior cornu to the alae of the thyroid, a protuberance called the superior tubercle is found. About 1 cm anterior and superior to this tubercle, the superior laryngeal artery and the internal branch of the superior laryngeal nerve and associated lymphatics pierce the membrane to supply the supraglottic larynx. At this point, transcutaneous anesthesia of the internal branch can be performed. Running obliquely from the superior tubercle to the inferior tubercle (along the inferior margin of the thyroid cartilage) is a ridge called the oblique line, which serves as the attachment point for the thyrohyoid, sternothyroid, and inferior constrictor muscles.

The relationship of the surface anatomy to internal laryngeal anatomy merits consideration. Most important is the level of the true cords in relation to the thyroid cartilage. An understanding of this relationship is crucial to performing supraglottic laryngectomy and phonosurgery (thyroplasty type I). In this regard, the midline vertical distance from the thyroid notch to the inferior border of the thyroid cartilage ranges from 20 to 47 mm in men and 15.5 to 38 mm in women.[2,3] The anterior commissure is found at the midpoint between these landmarks. The posterior extent of the cords is anterior to the oblique line and is found in the middle third of this line.[3]

The thyroid cartilage is lined by a thick layer of perichondrium on all surfaces except the inner surface at the anterior commissure. At this point are attached five ligaments, which form the scaffolding for the corresponding laryngeal folds. From superior to inferior, they are the median thyroepiglottic ligament (median thyrohyoid fold), bilateral vestibular ligaments (vestibular folds or false cords), and bilateral vocal ligaments (vocal folds) (Figure 47–2, A).

The attachment of these ligaments penetrates the inner perichondrium, forming Broyle's ligament. This ligament contains blood vessels and lymphatics and constitutes an important barrier to the spread of laryngeal neoplasms.

Cricoid Cartilage The cricoid cartilage is a complete ring.[2–7] It is the only supporting structure that completely encircles the airway and serves as the major support for the functioning larynx. Its shape is classically described as that of a signet ring, with the anterior arch measuring 3 to 7 mm in height and the posterior lamina about 20 to 30 mm in height.[4–6] Its inferior border is nearly horizontal and is attached to the first tracheal cartilage by the cricotracheal ligament.

On the posterior surface of the cricoid, the posterior cricoarytenoid muscles are attached in depressions, which are separated by a midline vertical ridge. These muscles are the only abductors of the vocal folds. Attached to this midline vertical ridge are two fasciculi of longitudinal fibers of the esophagus. Housed on the superior surface of the posterior cricoid lamina are the paired arytenoid cartilages.

Posterior to anterior, the cricoid lamina slopes steeply downward to form the anterior cricoid arch. In the midline, between the superior portion of the arch and the inferior border of the thyroid cartilage, is the cricothyroid membrane. It is this structure that must be incised in performing an emergent cricothyrotomy.

Arytenoid Cartilages The arytenoids are paired cartilages that articulate with the posterosuperior portion of the cricoid cartilage.[2–7] Movement of these cartilages and their attached vocal folds allows the larynx its often diverse and complex functions. Each arytenoid is roughly pyramidal in shape, giving it a base, an apex, and three sides. The base of the arytenoid provides the articular facet as well as the muscular and vocal processes. The cricoarytenoid joint is a synovial joint with complex movements that are somewhat debated. It appears, however, that the most important movement of the joint is a rocking motion

of the cartilage around the long axis of its facet. Laterally, the base forms a broad muscular process, and anteriorly, it forms the thinner vocal process. The anterolateral surface receives the vestibular ligament as well as the thyroarytenoid and vocalis muscles. The posterior surface receives muscular attachments, and to the medial surface is attached the prominent posterior cricoarytenoid ligament. Sitting at the apex of the arytenoid is the corniculate cartilage.

Corniculate and Cuneiform Cartilages These are small, paired fibroelastic cartilages found in the larynx.[4] The corniculate, or cartilage of Santorini, is housed on the apex of the arytenoid cartilage. The cuneiform, or cartilage of Wrisberg, when present, is lateral to the corniculate cartilages and is embedded in the aryepiglottic fold. Although some feel that these cartilages are vestigial, they do appear to add rigidity to the aryepiglottic fold.[7] This rigidity augments the important rampart function of these folds, thus diverting swallowed matter laterally away from the larynx into the piriform sinuses.

Epiglottis The epiglottis is a leaf-shaped elastic fibrocartilage that functions mainly as a backstop against the entrance of swallowed matter into the laryngeal aditus.[2–7] During swallowing, the larynx is raised anterosuperiorly. This action pushes the epiglottis against the base of the tongue, posteriorly displacing it over the laryngeal aditus. The epiglottis has two anterior attachments. Superiorly, it is attached to the hyoid bone by the hyoepiglottic ligament. Inferiorly at the stem or petiole, it is attached to the inner surface of the thyroid cartilage just above the anterior commissure by the thyroepiglottic ligament. The surface of the epiglottic cartilage has multiple pits and is filled with mucous glands; these pits potentially allow the spread of cancer from one surface of the epiglottis to the other.

The epiglottis may arbitrarily be divided into a suprahyoid and an infrahyoid portion. The suprahyoid portion is free on both of its laryngeal and lingual surfaces, with the laryngeal mucosal surface being more adherent than the lingual. As the mucosa of the laryngeal surface is reflected back onto the base of the tongue, three folds result: two lateral glossoepiglottic folds and a median glossoepiglottic fold. The two depressions formed by these folds are known as the valleculae (little depression in Latin). The infrahyoid portion is free only on its laryngeal or posterior surface. This surface contains a small protuberance known as the tubercle. Between the anterior surface and the thyrohyoid membrane and the thyroid cartilage exists

a fat pad within the preepiglottic space. Attached laterally is the quadrangular membrane extending to the arytenoid and corniculate cartilages, constituting the aryepiglottic folds.

Ossification of Laryngeal Cartilages It has long been recognized that incomplete ossification of the laryngeal cartilages can be mistaken for a foreign body on plain roentgenograms of the neck.[8] This particularly applies to ossification of the superior and inferior cornua of the thyroid cartilage and linear ossification of the posterior portion of the cricoid. Thus, the need for understanding the normal ossification pattern of the larynx is self-evident. It is important to realize that only those structures composed of hyaline cartilage will undergo ossification (ie, thyroid, cricoid, and arytenoid cartilages).[8,9] It should be noted that the hyoid bone is completely ossified at 2 years of age and is generally not a point of radiographic confusion.

The thyroid cartilage undergoes ossification in the male about age 20 and in the female a few years later. Ossification begins posteroinferiorly on the lamina. It then extends anteriorly on the inferior border and superiorly at the posterior border. At this time, nuclei of ossification can be seen in the inferior and superior cornua. The cricoid and arytenoid cartilages undergo ossification somewhat later than the thyroid cartilage. Ossification of the cricoid cartilage generally begins at the inferior border, although the superior margin of the quadrate lamina may be an early site of ossification.

Neoplastic invasion of the laryngeal cartilages generally takes place in the ossified portion of the cartilage.[10] The incomplete ossification pattern may make it difficult to appreciate small areas of invasion.

Elastic Tissues

The elastic tissue of the larynx consists of two main parts: (1) the quadrangular membrane of the supraglottic larynx and (2) the thicker conus elasticus and vocal ligaments of the glottic and infraglottic larynx.
